To extract the desired information from the point cloud X_n , one builds a graph by connecting nearby points. More precisely, let $\eta : \mathbb{R}^d \rightarrow [0, \infty)$ be a radially symmetric kernel, radially decreasing, and decaying to zero sufficiently fast. We introduce a parameter ε which basically describes over which length scale the data points are connected. For $i, j \in \{1, \dots, n\}$, we consider the weight

$$w_{ij} = \eta\left(\frac{\mathbf{x}_i - \mathbf{x}_j}{\varepsilon}\right). \quad (1.12)$$

As more data points are available one takes smaller ε to obtain increased resolution. That is, one sets the length scale ε based on the number of available data points: $\varepsilon = \varepsilon_n$. We investigate under what scaling of ε_n on n the optimal balanced cuts (that is, minimizers of (1.1)) of the graph $\mathcal{G}_n = (X_n, W_n)$ converge towards optimal balanced cuts in the continuum setting (minimizers of (1.5)). On Figure 1, we illustrate the partitioning of a data cloud sampled from the uniform distribution on the given domain D .

Informal statement of (a part of) the main results. Consider $d \geq 2$ and assume the continuum balanced cut (1.5) has a unique minimizer $\{A, A^c\}$. Consider $\varepsilon_n > 0$ such that $\lim_{n \rightarrow \infty} \varepsilon_n = 0$ and

$$\lim_{n \rightarrow \infty} \frac{(\log n)^{pd}}{n^{1/d}} \frac{1}{\varepsilon_n} = 0, \quad (1.13)$$

where $p_d = 1/d$ for $d \geq 3$ and $p_2 = 3/4$. Then almost surely the minimizers, $\{Y_n, Y_n^c\}$, of the balanced cut (1.1) of the graph \mathcal{G}_n , converge to $\{A, A^c\}$. Moreover, after appropriate rescaling, almost surely the minimum of problem (1.1) converges to the minimum of (1.5). The result also holds for multiway cuts. That is, the minimizers of (1.4) converge towards minimizers of (1.11).

Let us make the notion of convergence of discrete partitions $\{Y_n, Y_n^c\}$ to continuum partitions $\{A, A^c\}$ precise.

To be able to easily account for the invariance $\{Y_n, Y_n^c\} = \{Y_n^c, Y_n\}$, let $Y_{n,1} = Y_n$ and $Y_{n,2} = Y_n^c$. Let $\mathbf{1}_{Y_{n,i}} : X_n \rightarrow \{0, 1\}$ for $i = 1, 2$ be the characteristic function of $Y_{n,i}$ (on the set X_n). We say that $\{Y_n, Y_n^c\}$ converge towards $\{A, A^c\}$ as $n \rightarrow \infty$ if there is a sequence of indices $I : \mathbb{N} \rightarrow \{1, 2\}$ such that

$$\frac{1}{n} \sum_{i=1}^n \mathbf{1}_{Y_{n,I(n)}}(\mathbf{x}_i) \delta_{\mathbf{x}_i} \xrightarrow{w} \mathbf{1}_A \nu \quad (1.14)$$

where \xrightarrow{w} denotes the weak convergence of measures (see Dudley (2002)). Since by assumption on the points \mathbf{x}_i it holds that $\frac{1}{n} \sum_{i=1}^n \delta_{\mathbf{x}_i} \xrightarrow{w} \nu$, the property (1.14) is equivalent

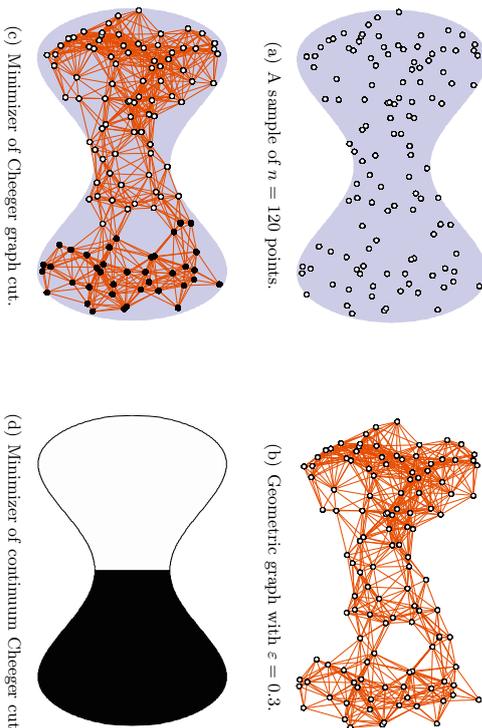

Figure 1: Given the sample of Figure (a), graph is constructed using $\eta(z) = \mathbf{1}_{\{|z| \leq 1\}}$ and $\varepsilon = 0.3$, as illustrated on Figure (b). On Figure (c) we present the solution to the Cheeger graph-cut problem obtained using algorithm of Bresson et al. (2012). A solution to the continuum Cheeger-cut problem is illustrated in Figure (d).

$$\text{to} \quad \frac{1}{n} \sum_{k=1}^n \mathbf{1}_{Y_{n,3-(\alpha)}(\mathbf{x}_k)} \delta_{\mathbf{x}_k} \stackrel{w}{\sim} \mathbf{1}_{A^c \nu}$$

In Section 2 we discuss this topology in more detail and present a conceptually clearer framework, which applies to general functions (not just characteristic functions of sets).

Let us also indicate briefly why the weight ρ^2 present in the weighted perimeter (1.6) can be expected to appear in the limit of balanced graph cuts (1.1). Let $\nu_n = \frac{1}{n} \sum_{i=1}^n \delta_{\mathbf{x}_i}$ be the empirical measure of the sample $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$. Let $A \subset D$ be a set with smooth boundary and let $A_n = A \cap X_n$. Then, using $\eta_\varepsilon(z) = \eta(z/\varepsilon)/\varepsilon^d$ we get

$$\begin{aligned} \frac{1}{n^2 \varepsilon^d} \text{Cut}(A_n, A_n^c) &= \frac{1}{n^2} \sum_{\mathbf{x}_i \in A_n} \sum_{\mathbf{x}_j \in A_n^c} \frac{1}{\varepsilon^d} \eta \left(\frac{\mathbf{x}_i - \mathbf{x}_j}{\varepsilon} \right) \\ &= \int_D \int_D \mathbf{1}_{A_n}(x) \mathbf{1}_{A_n^c}(y) \eta_\varepsilon(x-y) d\nu_n(x) d\nu_n(y) \\ &\sim \int_D \int_D \mathbf{1}_A(x) \mathbf{1}_{A^c}(y) \eta_\varepsilon(x-y) \rho(x) \rho(y) d\nu dx \\ &\sim C \int_{D \cap \partial A} \rho^2(x) dS(x). \end{aligned}$$

The factor $1/(n^2 \varepsilon^d)$ in front of the cut above is accounted for in the way we scale the cuts, see (5.6). We remark that the above just provides a rough heuristic idea as to what weight should be expected. It does not serve as a basis for our proof, since the optimal balanced graph cuts $\{Y_n^c, Y_n^c\}$ (minimizer of (1.1)) could be rather different from $\{A \cap X_n, A^c \cap X_n\}$ where $\{A, A^c\}$ is the optimal balanced domain cut (minimizer of (1.5)).

The reason for the presence of ρ in (1.8) is clear since the particles are drawn from the measure, ν , with density ρ , and thus the empirical measures of the sample, ν_n , converge to ν . Let us now indicate the reason for the presence of ρ^2 in (1.10). Namely for the graph weights given by (1.12) and A, X_n and A_n as above

$$\begin{aligned} \frac{1}{n^2 \varepsilon^d} \text{deg}(A_n) &= \frac{1}{n^2} \sum_{\mathbf{x}_i \in A_n} \sum_{\mathbf{x}_j \in X_n} \frac{1}{\varepsilon^d} \eta \left(\frac{\mathbf{x}_i - \mathbf{x}_j}{\varepsilon} \right) = \int_D \int_D \mathbf{1}_{A_n}(x) \eta_\varepsilon(x-y) d\nu_n(x) d\nu_n(y) \\ &\sim \int_D \int_D \mathbf{1}_A(x) \eta_\varepsilon(x-y) \rho(x) \rho(y) dy dx \\ &\sim C_\eta \int_D \mathbf{1}_A(x) \rho^2(x) dx. \end{aligned}$$

Therefore,

$$\frac{\text{deg}(A_n)}{\text{deg}(X_n)} \sim \frac{1}{\int_D \rho^2(x) dx} \int_D \mathbf{1}_A(x) \rho^2(x) dx = |A| \rho^2.$$

Since the proofs are analogous in most of the paper, we only consider the ratio and Cheeger cuts in detail and only comment briefly on sparsest and normalized cuts.

Remark 1 (Optimality of scaling of ε_n for $d \geq 3$) *If $d \geq 3$ then the rate presented in (1.13) is sharp in terms of scaling. Namely for $D = (0, 1)^d$, and ν the Lebesgue measure on D and η compactly supported, it is known from graph theory (see (Goel et al., 2004; Gupta and Kumar, 1999; Penrose, 1999)) that there exists a constant $c > 0$ such that if $\varepsilon_n < \frac{c \log(n)^{1/d}}{n^{1/d}}$ then the weighted graph associated to (X_n, W_n) is disconnected with high probability. The resulting optimal discrete cuts have zero energy, but may be very far from the optimal continuum cuts.*

While the above example demonstrates the optimality of our results, we remark that the convergence fails because the lack of connectedness of random geometric graphs (with connectivity radius below the before mentioned threshold) leads to undesirable partitions. Considering different objective functionals which are still based on perimeter, but more strongly penalize existence of small connected components, or considering different graph constructions (for example by restricting attention to the giant component) could lead to convergence even for some scaling ε_n below the connectivity threshold $\frac{1}{n^{1/d}} \ll \varepsilon_n < \frac{(\log n)^{1/d}}{n^{1/d}}$.

Remark 2 *In case $d = 2$ the connectivity threshold for a random geometric graph is $\varepsilon_n = \frac{\log(n)^{1/2}}{n^{1/2}}$, which is below the rate for which we can establish the consistency of balanced cuts. Thus, an interesting open problem is to determine if the consistency results we present in*

this paper are still valid when the parameter ε_n is taken below the rate $\frac{\log(n)^{3/4}}{n^{1/2}}$ we obtained the proof for, but above the connectivity rate. In particular we are interested in determining if connectivity is the determining factor in order to obtain consistency of balance graph cuts. We numerically explore this problem in Section 8.

1.4 Outline

In Section 2 we introduce the notion of convergence we use to bridge between discrete and continuum partitions. In particular this notion of convergence allows us to consider the discrete and continuum objective functionals in a common metric space, which we denote by TL^1 . This notion of convergence relies on some of the notions of the theory of optimal transportation which we recall. We also recall results on optimal min-max matching between the random sample and the underlying measure (Proposition 5), which are needed in the proof of the convergence. They represent the main estimates which account for randomness. The rest of the arguments in the paper are not probabilistic.

In Section 3 we study more carefully the notion of continuum partitioning (1.5). We introduce the notion of total variation of functions on D in Subsection 3.1 and recall some of its basic properties. This enables us to introduce, in Subsection 3.2, the general setting for problem (1.5) where desirable properties such as lower semicontinuity and existence of minimizers hold. In Section 4 we give the precise statement of the consistency result, both for the two-way cuts (Theorem 9) and the multi-way cuts (Theorem 12). Proving that minimizers of discrete balanced cuts converge to optimal continuum balanced cuts is reduced to proving that the discrete balanced-cut objective functionals converge (in the sense of the notion of variational convergence known as Γ -convergence) to continuum balanced-cut objective functionals. In Section 5 we recall the definition of Γ -convergence and its basic properties. In Subsection 5.1 we recall the results on Γ -convergence of graph total variation which provide the backbone for our results. Section 6 contains the proof of the Theorem 9 and Section 7 the proof of Theorem 12. Finally, in Section 8 we present numerical experiments which illustrate our results; we also investigate the issues related to Remark 2.

2. From Discrete to Continuum

Let $\mathbf{x}_1, \dots, \mathbf{x}_n, \dots$ be a sequence of i.i.d random points drawn from an underlying ground-truth measure ν . For the two-class case, our main result shows that a sequence of partitions $\{Y_n, Y_n^c\}$ of the point clouds $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\} \subset D$ converges toward a continuum partition $\{A, A^c\}$ of the domain D . In this section we expand on the notion of convergence introduced in Subsection 1.3 to compare the discrete and continuum partitions. We give an equivalent definition for such type of convergence which turns out to be more useful for the computations in the remainder.

Associated to the partitions $\{Y_n, Y_n^c\}$ are the characteristic functions of Y_n and Y_n^c , namely $\mathbf{1}_{Y_n} : X_n \rightarrow \{0, 1\}$ and $\mathbf{1}_{Y_n^c} : X_n \rightarrow \{0, 1\}$. Let $\nu_n = \frac{1}{n} \sum_{i=1}^n \delta_{\mathbf{x}_i}$ be the empirical measures associated to X_n . Note that $\mathbf{1}_{Y_n}, \mathbf{1}_{Y_n^c} \in L^1(\nu_n)$. Likewise a continuum partition of D by measurable sets A and $A^c = D \setminus A$ can be described via the characteristic functions $\mathbf{1}_A : D \rightarrow \{0, 1\}$ and $\mathbf{1}_{A^c} : D \rightarrow \{0, 1\}$. These too can be considered as L^1 functions, but with respect to the measure ν rather than ν_n .

We compare the partitions $\{Y_n, Y_n^c\}$ and $\{A, A^c\}$ by comparing the associated characteristic functions. To do so, we need a way of comparing L^1 functions with respect to different measures. We follow the approach of García Trillos and Slepčev (2016). We denote by $\mathcal{B}(D)$ the Borel σ -algebra on D and by $\mathcal{P}(D)$ the set of Borel probability measures on D . The set of objects of our interest is

$$TL^1(D) := \{(\mu, f) : \mu \in \mathcal{P}(D), f \in L^1(\mu)\}.$$

Note that $(\nu_n, \mathbf{1}_{Y_n})$ and $(\nu, \mathbf{1}_A)$ both belong to TL^1 . To compare functions defined with respect to different measures, say (μ, f) and (θ, g) in TL^1 , we need a way to say for which $(x, y) \in \text{supp}(\mu) \times \text{supp}(\theta)$ should we compare $f(x)$ and $g(y)$. The notion of *coupling* (or *transportation plan*) between μ and θ , provides a way to do that. A coupling between $\mu, \theta \in \mathcal{P}(D)$ is a probability measure π on the product space $D \times D$, such that the marginal on the first variable is μ and the marginal on the second variable is θ . The set of couplings $\Gamma(\mu, \theta)$ is thus

$$\Gamma(\mu, \theta) = \{\pi \in \mathcal{P}(D \times D) : (\forall U \in \mathcal{B}(D)) \pi(U \times D) = \mu(U) \text{ and } \pi(D \times U) = \theta(U)\}.$$

For (μ, f) and (θ, g) in $TL^1(D)$ we define the distance

$$d_{TL^1}((\mu, f), (\theta, g)) = \inf_{\pi \in \Gamma(\mu, \theta)} \iint_{D \times D} |x - y| + |f(x) - g(y)| d\pi(x, y). \quad (2.1)$$

This is the distance that we use to compare L^1 functions with respect to different measures.

It is motivated by optimal transportation distances (such as the Wasserstein distance and the earth-mover distance, see (García Trillos and Slepčev, 2016, 2015; Villani, 2003) and references therein). Indeed, the distance (2.1) can be seen as an optimal transportation distance between measures supported on the graphs of the functions f and g , as discussed in García Trillos and Slepčev (2016). To better understand it here, we focus on the case that one of the measures, say μ , is absolutely continuous with respect to the Lebesgue measure, as this case is relevant for us when passing from discrete to continuum. In this case, the convergence in TL^1 space can be formulated in simpler ways using transportation maps instead of couplings to match the measures. Given a Borel map $T : D \rightarrow D$ and $\mu \in \mathcal{P}(D)$, the *push-forward* of μ by T , denoted by $T\#\mu \in \mathcal{P}(D)$ is given by:

$$T\#\mu(A) := \mu(T^{-1}(A)), \quad A \in \mathfrak{B}(D).$$

A Borel map $T : D \rightarrow D$ is a *transportation map* between the measures $\mu \in \mathcal{P}(D)$ and $\theta \in \mathcal{P}(D)$ if $\theta = T\#\mu$. Associated to a transportation map T , there is a plan $\pi_T \in \Gamma(\mu, \theta)$ given by $\pi_T := (\text{Id} \times T)\#\mu$, where $(\text{Id} \times T)(x) = (x, T(x))$.

We note that if $\theta = T\#\mu$, then the following change of variables formula holds for any $f \in L^1(\theta)$

$$\int_D f(y) d\theta(y) = \int_D f(T(x)) d\mu(x). \quad (2.2)$$

In order to give the desired interpretation of convergence in TL^1 we also need the notion of a stagnating sequence of transportation maps. Given $\mu_n \in \mathcal{P}(D)$, for $n = 1, \dots$

and $\mu \in \mathcal{P}(D)$, a sequence $\{T_n\}_{n \in \mathbb{N}}$ of transportation maps between μ and μ_n (meaning that $T_n\#\mu = \mu_n$) is *stagnating* if

$$\int_D |x - T_n(x)| d\mu(x) \rightarrow 0 \quad \text{as } n \rightarrow \infty. \quad (2.3)$$

This notion is relevant to our considerations because for the measure ν and its empirical measures ν_n there exists (with probability one) a sequence of stagnating transportation maps $T_n\#\nu = \nu_n$. The idea is that as $n \rightarrow \infty$ the mass from ν needs to be moved only very little to be matched with the mass of ν_n . We make this precise in Proposition 5

We now provide the desired interpretation of the convergence in TL^1 , which is a part of Proposition 3.12 of García Trillos and Slepčev (2016).

Proposition 3 *Consider a measure $\mu \in \mathcal{P}(D)$ which is absolutely continuous with respect to the Lebesgue measure. Let $(\mu, f) \in TL^1(D)$ and let $\{(\mu_n, f_n)\}_{n \in \mathbb{N}}$ be a sequence in $TL^1(D)$. The following statements are equivalent:*

- (i) $(\mu_n, f_n) \xrightarrow{TL^1} (\mu, f)$ as $n \rightarrow \infty$.
- (ii) $\mu_n \xrightarrow{w} \mu$ and there exists a stagnating sequence of transportation maps $T_n\#\mu = \mu_n$ such that:

$$\int_D |f(x) - f_n(T_n(x))| d\mu(x) \rightarrow 0, \text{ as } n \rightarrow \infty. \quad (2.4)$$
- (iii) $\mu_n \xrightarrow{w} \mu$ and for any stagnating sequence of transportation maps $T_n\#\mu = \mu_n$ convergence (2.4) holds.

The previous proposition implies that in order to show that (μ_n, f_n) converges to (μ, f) in the TL^1 -sense, it is enough to find a sequence of stagnating transportation maps $T_n\#\mu = \mu_n$ and then show the L^1 convergence of $f_n \circ T_n$ to f in $L^1(\mu)$. An important feature of Proposition 3 is that there is complete freedom on what sequence of transportation maps $\{T_n\}_{n \in \mathbb{N}}$ to take, as long as it is stagnating. In particular this shows that if $\mu_n = \mu$ for all n then the convergence in TL^1 is equivalent to convergence in $L^1(\mu)$.

Remark 4 *Suppose that the sequence of probability measures $\{\mu_n\}_{n \in \mathbb{N}}$ is such that $\mu_n \xrightarrow{w} \mu$. Let $f_n \in L^1(\mu_n)$ and let $f \in L^1(\mu)$. With a slight abuse of notation we say that $f_n \xrightarrow{TL^1} f$ whenever $(\mu_n, f_n) \xrightarrow{TL^1} (\mu, f)$. In particular when we write $f_n \xrightarrow{TL^1} f$ it should be clear what the corresponding measures μ_n, μ are.*

To obtain the scaling of (1.13) we need a stagnating sequence of transportation maps between ν and $\{\nu_n\}_{n \in \mathbb{N}}$ with precise information on the rate at which convergence (2.3) occurs. More precisely for some of our considerations we need the control of $T_n(x) - x$ in the stronger $L^\infty(\nu)$ -norm, rather than in the $L^1(\nu)$ -norm. Since the typical distance between nearby points is of order $n^{-1/d}$ the typical transportation distance, $T_n(x) - x$, must be at least of that order. The optimal upper bound on the $L^\infty(\nu)$ -norm of $T_n - I$ however has an extra logarithmic correction. In particular in García Trillos and Slepčev (2015) it was shown that:

Proposition 5 *Let D be an open, connected and bounded subset of \mathbb{R}^d which has Lipschitz boundary. Let ν be a probability measure on D with density ρ which is bounded from below and from above by positive constants. Let $\mathbf{x}_1, \dots, \mathbf{x}_n, \dots$ be a sequence of independent random points distributed on D according to measure ν and let $\nu_n = \frac{1}{n} \sum_{i=1}^n \delta_{\mathbf{x}_i}$. Then there is a constant $C > 0$ (that depends on D and ρ) such that with probability one there exists a sequence of transportation maps $\{T_n\}_{n \in \mathbb{N}}$ from ν to ν_n ($T_n\#\nu = \nu_n$) and such that:*

$$\limsup_{n \rightarrow \infty} \frac{n^{1/d} \|\text{Id} - T_n\|_{L^\infty(\nu)}}{(\log n)^{p_d}} \leq C, \quad (2.5)$$

where the power p_d is equal to $1/d$ if $d \geq 3$ and equal to $3/4$ if $d = 2$.

The optimality of the upper bound is discussed in García Trillos and Slepčev (2015). If $d \geq 3$ it follows from the fact that for n large, with large probability there exists a ball of radius comparable to $((\ln n)/n)^{1/d}$ which contains none of the points $\mathbf{x}_1, \dots, \mathbf{x}_n$.

Having defined the TL^1 -convergence for functions, we turn to the TL^1 -convergence for partitions. When defining a notion of convergence for sequences of partitions $\{Y_1^n, \dots, Y_R^n\}$, we need to address the inherent ambiguity that arises from the fact that both $\{Y_1^n, \dots, Y_R^n\}$ and $\{Y_{(1)}^n, \dots, Y_{(R)}^n\}$ refer to the same partition for any permutation P of $\{1, \dots, R\}$. Having the previous observation in mind, the convergence of partitions is defined in a natural way.

Definition 6 *The sequence $\{Y_1^n, \dots, Y_R^n\}_{n \in \mathbb{N}}$ where $\{Y_1^n, \dots, Y_R^n\}$ is a partition of X_n , converges in the TL^1 -sense to the partition $\{A_1, \dots, A_R\}$ of D , if there exists a sequence of permutations $\{P_n\}_{n \in \mathbb{N}}$ of the set $\{1, \dots, R\}$, such that for every $r \in \{1, \dots, R\}$,*

$$\left(\nu_n, \mathbf{1}_{Y_{P_n(r)}^n} \right) \xrightarrow{TL^1} (\nu, \mathbf{1}_{A_r}) \quad \text{as } n \rightarrow \infty.$$

We note that the definition above is equivalent to

$$\frac{1}{n} \sum_{i=1}^n \mathbf{1}_{Y_{P_n(r)}^n}(x_i) \delta_{x_i} \xrightarrow{w} \mathbf{1}_{A_r} \nu \quad (2.6)$$

for all $r = 1, \dots, R$ which is analogous to the definition in (1.14) which we gave in Subsection (1.3) when discussing the main result. The equivalence follows from the fact that the TL^1 metric (2.1) can be seen as the distance between the graphs of functions, considered as measures. Namely given $(\mu, f), (\theta, g) \in TL^1(D)$, let $\Gamma_f = (\text{Id} \times f)\#\mu$ and $\Gamma_g = (\text{Id} \times g)\#\theta$ be the measures representing the graphs. Consider $d(\Gamma_f, \Gamma_g) := d_{\Gamma L}(\mu, f), (\theta, g)$. Proposition 3.3 in García Trillos and Slepčev (2016) (also see the paragraph right after Remark 3.1) implies that this distance metrizes the weak convergence of measures on the family of graph measures. Therefore the convergence of partitions of Definition 6 is equivalent to one given in (2.6).

We end this section by making some remarks about why the TL^1 -metric is a suitable metric for considering consistency problems. On one hand if one considers a sequence of minimizers $\{Y_n, Y_n^c\}$ of the graph balanced cut (1.1) the topology needs to be weak enough

for the sequence of minimizers to be guaranteed to converge (at least along a subsequence). Mathematically speaking the topology needs to be weak enough for the sequence to be pre-compact. On the other hand the topology has to be strong enough for one to be able to conclude that the limit of a sequence of minimizers is a minimizer of the continuum balanced cut energy. In Proposition 21 and Lemma 23 we establish that the TL -metric satisfies both of the desired properties.

Finally we point out that our approach from discrete to continuum can be interpreted as an extrapolation or extension approach, as opposed to restriction viewpoint. Namely when comparing (μ_n, f_n) and (μ, f) where μ_n is discrete and μ is absolutely continuous with respect to the Lebesgue measure we end up comparing two L^1 functions with respect to the Lebesgue measure, namely $f_n \circ T_n$ and f , in (2.4). Therefore $f_n \circ T_n$ used in Proposition 3 can be seen as a continuum representative (extrapolation) of the discrete f_n . We think that this approach is more flexible and suitable for the task than the, perhaps more common, approach of comparing the discrete and continuum by restricting the continuum object to the discrete setting (this would correspond to considering $f|_{\text{supp}(f_n)}$ and comparing it to f_n).

3. Continuum partitioning: rigorous setting

We first recall the general notion of (weighted) total variation and some notions of analysis and geometric measure theory.

3.1 Total Variation

Let D be an open and bounded domain in \mathbb{R}^d with Lipschitz boundary and let $\rho : D \rightarrow (0, \infty)$ be a continuous density function. We let ν be the measure with density ρ . We assume that ρ is bounded above and below by positive constants, that is, $\lambda \leq \rho \leq \Lambda$ on D for some $\Lambda \geq \lambda > 0$.

Given a function $u \in L^1(\nu)$, we define the weighted (by weight ρ^2) total variation of u by:

$$TV(u; \nu) := \sup \left\{ \int_D u(x) \text{div}(\Phi(x)) \, dx : \Phi(x) \in C_c^1(D; \mathbb{R}^d), \quad |\Phi(x)| \leq \rho^2(x) \right\}, \quad (3.1)$$

where in the above $C_c^1(D; \mathbb{R}^d)$ denotes the set of C^1 -functions from D to \mathbb{R}^d , whose support is compactly contained in D . If u is regular enough then the weighted total variation can be written as

$$TV(u; \nu) = \int_D |\nabla u| \rho^2(x) \, dx. \quad (3.2)$$

Also, given that $\rho : D \rightarrow \mathbb{R}$ is continuous, if $u \in \mathbf{1}_A$ is the characteristic function of a set $A \subseteq \mathbb{R}^d$ with C^1 boundary, then

$$TV(\mathbf{1}_A; \nu) = \int_{\partial A \cap D} \rho^2(x) \, d\mathcal{H}^{d-1}(x), \quad (3.3)$$

where \mathcal{H}^{d-1} represents the $(d-1)$ -dimensional Hausdorff measure in \mathbb{R}^d . In case ρ is a constant (ν is the uniform distribution), the functional $TV(\cdot; \nu)$ reduces to a multiple of

the classical total variation and in particular (3.3) reduces to a multiple of the surface area of the portion of ∂A contained in D .

Since ρ is bounded above and below by positive constants, a function $u \in L^1(\nu)$ has finite weighted total variation if and only if it has finite classical total variation. Therefore, if $u \in L^1(\nu)$ with $TV(u; \nu) < \infty$, then u is a BV function and hence it has a distributional derivative Du which is a Radon measure (see Chapter 13 of Leoni (2009)). We denote by $|Du|$ the total variation of the measure Du and denote by $|Du|_{\rho^2}$ the measure determined by

$$d|Du|_{\rho^2} = \rho^2(x) d|Du|. \quad (3.4)$$

By Theorem 4.1 of Baldi (2001)

$$TV(u; \nu) = |Du|_{\rho^2}(D) = \int_D \rho^2(x) \, d|Du|(x). \quad (3.5)$$

A simple consequence of the definition of the weighted TV is its lower semicontinuity with respect to L^1 -convergence. More precisely, if $u_k \xrightarrow{L^1(\nu)} u$ then

$$TV(u; \nu) \leq \liminf_{k \rightarrow \infty} TV(u_k; \nu). \quad (3.6)$$

Finally, for $u \in BV(D)$, the co-area formula

$$TV(u; \nu) = \int_{\mathbb{R}} TV(\mathbf{1}_{\{u>t\}}; \nu) \, dt,$$

relates the weighted total variation of u with the weighted total variation of its level sets. A proof of this formula can be found in Bellettini, Bouchitté, and Fragalà (1999). For a proof of the formula in the case that ρ is constant see Leoni (2009).

In the remainder of the paper, we write $TV(u)$ instead of $TV(u; \nu)$ when the context is clear.

3.2 Continuum partitioning

We use the total variation to rigorously formulate the continuum partitioning problem (1.5). The precise definition of the $\text{Cut}_{\rho}(A, A^c)$ functional in (1.5) is

$$\text{Cut}_{\rho}(A, A^c) = TV(\mathbf{1}_A; \nu),$$

where $TV(\mathbf{1}_A; \nu)$ is defined in (3.1). We note that $TV(\mathbf{1}_A; \nu)$ is equal to $TV(\mathbf{1}_{A^c}; \nu)$, and is the perimeter of the set A in D weighted by ρ^2 .

Recall that $|D| = \nu(D)$, as defined in (1.8). Given that ν is a probability measure supported on D we have $|D| = 1$. We now formulate the balance terms defined by (1.7) and (1.8) using characteristic functions. We start by extending the balance term to arbitrary functions $u \in L^1(\nu)$:

$$B_R(u) = \int_D |u(x) - \text{mean}_{\rho}(u)| \rho(x) \, dx \quad \text{and} \quad B_C(u) = \min_{c \in \mathbb{R}} \int_D |u(x) - c| \rho(x) \, dx, \quad (3.7)$$

where $\text{mean}_{\rho}(u)$ denotes the mean/expectation of $u(x)$ with respect to the measure $dv = \rho dx$.

Analogously, using the symbol $\int_D f(x)\rho^2(x)dx := \frac{1}{\int_D \rho^2(x)dx} \int_D f(x)\rho^2(x)dx$, we define

$$B_S(u) = \int_D |u(x) - \text{mean}_{\rho^2}(u)|\rho^2(x) dx \quad \text{and} \quad B_N(u) = \min_{c \in \mathbb{R}} \int_D |u(x) - c|\rho^2(x) dx, \quad (3.8)$$

where $\text{mean}_{\rho^2}(u) = \int_D u(x)\rho^2(x)dx$.

We have the desired relation with balance terms defined in (1.2) and (1.3)

$$B(\mathbf{1}_A) = \text{Bal}(A, A^c) \quad \text{for } I = R, C, S, \text{ and } N \quad (3.9)$$

for every measurable subset A of D . From here on, we use B to represent B_R, B_C, B_S , or B_N , depending on the context. We also consider *normalized indicator functions* $\tilde{\mathbf{1}}_A$ given by

$$\tilde{\mathbf{1}}_A := \frac{\mathbf{1}_A}{B(\mathbf{1}_A)}, \quad A \subseteq D,$$

and consider the set

$$\text{Ind}(D) := \{u \in L^1(\nu) : u = \tilde{\mathbf{1}}_A \text{ for some measurable set } A \subseteq D \text{ with } B(\mathbf{1}_A) \neq 0\}. \quad (3.10)$$

Then for $u = \tilde{\mathbf{1}}_A \in \text{Ind}(D)$

$$TV(u) = TV(\tilde{\mathbf{1}}_A) = TV\left(\frac{\mathbf{1}_A}{B(\mathbf{1}_A)}\right) = \frac{TV(\mathbf{1}_A)}{B(\mathbf{1}_A)} = \text{Cut}_{\rho}(A, A^c). \quad (3.11)$$

Consequently the problem (1.5) is equivalent to minimizing $E : TL^1(D) \rightarrow (-\infty, \infty]$, given by

$$E(\mu, u) := \begin{cases} TV(u) & \text{if } \mu = \nu \text{ and } u \in \text{Ind}(D) \\ +\infty & \text{otherwise.} \end{cases} \quad (3.12)$$

where μ is a probability measure on D , $u \in L^1(\mu)$, $TV(u) = TV(u; \nu)$, is given by (3.5) and $\text{Ind}(D)$ is defined by (3.10). Since the functional E is only non-trivial when $\mu = \nu$, from now on we write $E(u)$ instead of $E(u, u)$.

Before we show that both the continuum ratio cut and Cheeger cut indeed have a minimizer, we need the following lemma:

Lemma 7 (i) *The balance functions B_I are continuous on $L^1(\nu)$.*

(ii) *The set $\text{Ind}(D)$ is closed in $L^1(\nu)$.*

Proof Let us start by proving (i). We first consider the balance term $B_C(u)$ that corresponds to the Cheeger cut. Let $u_1, u_2 \in L^1(\nu)$. Let c_i be the median of u_i for $i = 1, 2$, that is let c_i be a minimizer of $c \mapsto \int_D |u_i(x) - c|\rho(x) dx$. Then, by (3.7),

$$\begin{aligned} B_C(u_1) - B_C(u_2) &\leq \int |u_1 - c_2|\rho(x) dx - \int |u_2 - c_2|\rho(x) dx \\ &\leq \int |u_1 - u_2|\rho(x) dx = \|u_1 - u_2\|_{L^1(\nu)}. \end{aligned}$$

Exchanging the role of u_1 and u_2 in this argument implies that $|B_C(u_1) - B_C(u_2)| \leq \|u_1 - u_2\|_{L^1(\nu)}$, which implies Lipschitz continuity of B_C .

Now consider the balance term $B_R(u)$ that corresponds to the ratio cut. Let $\{u_k\}_{k=1}^\infty$ be a sequence in $L^1(\nu)$ converging to u . The inequality $||a| - |b|| \leq |a - b|$ implies that

$$\begin{aligned} &\left| \int |u_k - \text{mean}_{\rho}(u_k)|\rho(x) dx - \int |u - \text{mean}_{\rho}(u)|\rho(x) dx \right| \\ &\leq \int |u_k - u|\rho(x) dx + \int |\text{mean}_{\rho}(u_k) - \text{mean}_{\rho}(u)|\rho(x) dx \\ &\leq \int |u_k - u|\rho(x) dx + |\text{mean}_{\rho}(u_k) - \text{mean}_{\rho}(u)|. \end{aligned}$$

Since $u_k \rightarrow u$ in $L^1(\nu)$ we have that $\text{mean}_{\rho}(u_k) \rightarrow \text{mean}_{\rho}(u)$ and therefore $|B_R(u_k) - B_R(u)| \leq \|u_k - u\|_{L^1(\nu)} + |\text{mean}_{\rho}(u_k) - \text{mean}_{\rho}(u)| \rightarrow 0$ as desired.

In order to prove (ii) suppose that $\{u_k\}_{k \in \mathbb{N}}$ is a sequence in $\text{Ind}(D)$ converging in $L^1(\nu)$ to some $u \in L^1(\nu)$; we need to show that $u \in \text{Ind}(D)$. By (i) we know that $B(u_k) \rightarrow B(u)$ as $k \rightarrow \infty$. Since $u_k \in \text{Ind}(D)$, in particular $B(u_k) = 1$. Thus, $B(u) = 1$. On the other hand, $u_k \in \text{Ind}(D)$ implies that u_k has the form $u_k = \alpha_k \mathbf{1}_{A_k}$. Since this is true for every k , in particular we must have that u has the form $u = \alpha \mathbf{1}_A$ for some real number α and some measurable subset A of D . Finally, the fact that B is 1-homogeneous implies that $1 = B(u) = \alpha B(\mathbf{1}_A)$. In particular $B(\mathbf{1}_A) \neq 0$ and $\alpha = \frac{1}{B(\mathbf{1}_A)}$. Thus $u = \tilde{\mathbf{1}}_A$ with $B(\mathbf{1}_A) \neq 0$ and hence $u \in \text{Ind}(D)$. ■

Lemma 8 *Let D and ν be as stated at the beginning of this section. There exists a measurable set $A \subseteq D$ with $0 < \nu(A) < 1$ such that $\tilde{\mathbf{1}}_A$ minimizes (3.12).*

Proof The statement follows by the direct method of the calculus of variations. Since the functional is bounded from below it suffices to show that it is lower semicontinuous with respect to the $L^1(\nu)$ norm and that a minimizing sequence is precompact in $L^1(\nu)$. To show lower semi-continuity it is enough to consider a sequence $u_n = \tilde{\mathbf{1}}_{A_n} \in \text{Ind}(D)$ converging in $L^1(\nu)$ to $u \in L^1(\nu)$. From Lemma 7 it follows that $u \in \text{Ind}(D)$ and hence $u = \tilde{\mathbf{1}}_A$ for some A with $B(\mathbf{1}_A) > 0$. Therefore $\mathbf{1}_{A_n} \rightarrow \mathbf{1}_A$ as $n \rightarrow \infty$ in $L^1(\nu)$. The lower semi-continuity then follows from the lower semi-continuity of the total variation (3.6), the continuity of B and the fact that since $B(\mathbf{1}_A) > 0$, $1/B(\mathbf{1}_{A_n}) \rightarrow 1/B(\mathbf{1}_A)$ as $n \rightarrow \infty$.

The pre-compactness of any minimizing sequence of (3.12) follows directly from Theorem 5.1 of Baldi (2001), which completes the proof. ■

4. Assumptions and statements of main results.

Here we present the precise hypotheses we use and state precisely the main results of this paper. Let D be an open, bounded, connected subset of \mathbb{R}^d with Lipschitz boundary, and let $\rho : D \rightarrow \mathbb{R}$ be a continuous density which is bounded below and above by positive constants, that is, for all $x \in D$

$$\lambda \leq \rho(x) \leq \Lambda \quad (4.1)$$

for some $\Lambda \geq \lambda > 0$. We let ν be the measure $d\nu = \rho dx$. Let $\boldsymbol{\eta} : [0, \infty) \rightarrow [0, \infty)$ be the radial profile of the similarity kernel, namely the function satisfying $\eta(x) = \boldsymbol{\eta}(|x|)$. We assume

(K1) $\boldsymbol{\eta}(0) > 0$ and $\boldsymbol{\eta}$ is continuous at 0.

(K2) $\boldsymbol{\eta}$ is non-increasing.

(K3) $\sigma_\boldsymbol{\eta} := \int_{\mathbb{R}^d} \boldsymbol{\eta}(|x|) | \langle x, e_1 \rangle | dx < \infty$.

We refer to the quantity $\sigma_\boldsymbol{\eta}$ as the *surface tension* associated to $\boldsymbol{\eta}$. In the above, $\langle x, e_1 \rangle$ denotes the inner product of the vector x with the vector whose first entry is 1 and whose other entries are equal to zero. We remark that due to radial symmetry, the vector e_1 can be replaced by any unit vector in \mathbb{R}^d without changing the value of $\sigma_\boldsymbol{\eta}$.

The kernel $\eta : \mathbb{R}^d \rightarrow [0, \infty)$ is now given by $\eta(x) = \boldsymbol{\eta}(|x|)$.

These hypotheses on $\boldsymbol{\eta}$ hold for the standard similarity functions used in clustering contexts, such as the Gaussian similarity function $\boldsymbol{\eta}(r) = \exp(-r^2)$ and the proximity similarity kernel $\boldsymbol{\eta}(r) = 1$ if $r \leq 1$ and $\boldsymbol{\eta}(r) = 0$ otherwise). For a sample $\mathbf{x}_1, \dots, \mathbf{x}_n$ from the measure ν , we denote by ν_n the empirical measure associated to the sample.

The main result of our paper is:

Theorem 9 (Consistency of cuts) *Let domain D , probability measure ν , with density ρ , and kernel η satisfy the conditions above. Let ε_n denote any sequence of positive numbers converging to zero that satisfy*

$$\lim_{n \rightarrow 0} \frac{(\log n)^{3/4}}{n^{1/2}} \frac{1}{\varepsilon_n} = 0 \quad (d = 2), \quad \lim_{n \rightarrow 0} \frac{(\log n)^{1/d}}{n^{1/d}} \frac{1}{\varepsilon_n} = 0 \quad (d \geq 3).$$

Let $\{\mathbf{x}_j\}_{j \in \mathbb{N}}$ be an i.i.d. sequence of random points in D drawn from the measure ν and let $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$. Let $\mathcal{G}_n = (X_n, W_n)$ denote the graph whose edge weights are

$$w_{ij}^n := \boldsymbol{\eta} \left(\frac{|\mathbf{x}_i - \mathbf{x}_j|}{\varepsilon_n} \right) \quad 1 \leq i, j \leq n$$

where $\boldsymbol{\eta}$ satisfies assumptions (K1)-(K3). Finally, let $\{Y_n^, Y_n^{*c}\}$ denote any optimal balanced cut of \mathcal{G}_n (solution of problem (1.1)). If problem (3.12) has a unique solution $\{A^*, A^{*c}\}$, then with probability one the sequence $\{Y_n^*, Y_n^{*c}\}$ converges to $\{A^*, A^{*c}\}$ in the TL^1 -sense. If there is more than one optimal continuum balanced cut (3.12) then with probability one, $\{Y_n^*, Y_n^{*c}\}$ converges along a subsequence to an optimal continuum balanced cut.*

Additionally, with probability one, \mathcal{C}_n the minimum balanced cut of the graph \mathcal{G}_n (the minimum of (1.1)), satisfies

$$\lim_{n \rightarrow \infty} \frac{2\mathcal{C}_n}{n^2 \varepsilon_n^{d+1}} = \sigma_\boldsymbol{\eta} \mathcal{C}, \tag{4.2}$$

where $\sigma_\boldsymbol{\eta}$ is the surface tension associated to the kernel η and \mathcal{C} is the minimum of (1.5).

As the proofs for sparsest and normalized cuts are analogous, in the remainder of the paper we only treat the ratio and Cheeger cuts in detail.

Remark 10 *For simplicity of notation, from now on we make the assumption that problem (3.12) has a unique solution $\{A^*, A^{*c}\}$. In the general case, Theorem 9 follows using the same approach; the only difference is that the convergence of minimizers happens along subsequences (see Proposition 17 below).*

As we discussed in Remark 1 for $d \geq 3$ the scaling of $\varepsilon = \varepsilon_n$ on n is essentially the best possible. The proof of Theorem 9 relies on establishing a variational convergence of discrete balanced cuts to continuum balanced cuts called the Γ -convergence which we recall in Subsection 5. The proof uses the results obtained of García Trillos and Slepčev (2016), where the notion of Γ -convergence was introduced in the context of objective functionals on random data samples, and in particular the Γ -convergence of the graph total variation is considered. The Γ -convergence, together with a compactness result, provides sufficient conditions for the convergence of minimizers of a given family of functionals to the minimizers of a limiting functional.

Remark 11 *A few remarks help clarify the hypotheses and conclusions of our main result. The scaling condition $\varepsilon_n \gg (\log n)^{p_n} n^{-1/d}$ comes directly from the existence of transportation maps from Proposition 5. This means that ε_n must decay more slowly than the maximal distance a point in D has to travel to match its corresponding data point in X_n . In other words, the similarity graph \mathcal{G}_n must contain information on a larger scale than that on which the intrinsic randomness operates. Lastly, the conclusion of the theorem still holds if the partitions $\{Y_n^*, Y_n^{*c}\}$ only approximate an optimal balanced cut, that is if the energies of $\{Y_n^*, Y_n^{*c}\}$ satisfy*

$$\lim_{n \rightarrow \infty} \left(\frac{\text{Cut}(Y_n^*, Y_n^{*c})}{\text{Bal}(Y_n^*, Y_n^{*c})} - \min_{Y \subseteq X_n} \frac{\text{Cut}(Y, Y^c)}{\text{Bal}(Y, Y^c)} \right) = 0.$$

This important property follows from a general result on Γ -convergence which we recall in Proposition 17.

We also establish the following multi-class equivalent to Theorem 9.

Theorem 12 *Let domain D , measure ν , kernel η , sequence $\{\varepsilon_n\}_{n \in \mathbb{N}}$, sample points $\{\mathbf{x}_i\}_{i \in \mathbb{N}}$, and graph \mathcal{G}_n satisfy the assumptions of Theorem 9. Let $(Y_{1,n}^*, \dots, Y_{R,n}^*)$ denote any optimal balanced cut of \mathcal{G}_n , that is a minimizer of (1.4). If (A_1^*, \dots, A_R^*) is the unique optimal balanced cut of D (that is minimizer of (1.11)) then with probability one the sequence $(Y_{1,n}^*, \dots, Y_{R,n}^*)$ converges to (A_1^*, \dots, A_R^*) in the TL^1 -sense. If the optimal continuum balanced cut is not unique then the convergence to a minimizer holds along subsequences. Additionally, \mathcal{C}_n , the minimum of (1.4), satisfies*

$$\lim_{n \rightarrow \infty} \frac{2\mathcal{C}_n}{n^2 \varepsilon_n^{d+1}} = \sigma_\boldsymbol{\eta} \mathcal{C},$$

where $\sigma_\boldsymbol{\eta}$ is the surface tension associated to the kernel η and \mathcal{C} is the minimum of (1.11).

The proof of Theorem 12 involves modifying the geometric measure theoretical results of García Trillos and Slepčev (2016). This leads to a substantially longer and more technical proof than the proof of Theorem 9, but the overall spirit of the proof remains the same in the sense that the Γ -convergence plays the leading role. Finally, we remark that analogous observations to the ones presented in Remark 11 apply to Theorem 12.

5. Background on Γ -convergence

We recall and discuss the notion of Γ -convergence. The usual Γ -convergence is defined for deterministic functionals. It extends to the random functionals that we consider in a natural way. Namely for almost every realization of the random event (in our case a sequence of random points in the domain) we require the Γ -convergence of resulting, deterministic, functionals. Such notion of Γ convergence has been used by Dirr and Ohtani (2009). We now define it precisely.

Let (X, d_X) be a metric space and let $(\Omega, \mathfrak{F}, \mathbb{P})$ be a probability space. Let $F_n : X \times \Omega \rightarrow [0, \infty]$ be a sequence of random functionals. For brevity, instead of writing $F_n(x, \omega)$ we simply write $F_n(x)$ with understanding that an element $\omega \in \Omega$ has been fixed.

Definition 13 *The sequence of random functionals $\{F_n\}_{n \in \mathbb{N}}$ Γ -converges with respect to metric d_X to the deterministic functional $F : X \rightarrow [0, \infty]$ as $n \rightarrow \infty$ if for \mathbb{P} -almost every ω , the following conditions hold simultaneously:*

1. *Liminf inequality:* For every $x \in X$ and every sequence $\{x_n\}_{n \in \mathbb{N}}$ converging to x ,

$$\liminf_{n \rightarrow \infty} F_n(x_n) \geq F(x).$$

2. *Limsup inequality:* For every $x \in X$ there exists a sequence $\{x_n\}_{n \in \mathbb{N}}$ converging to x satisfying

$$\limsup_{n \rightarrow \infty} F_n(x_n) \leq F(x).$$

We say that F is the Γ -limit of the sequence of functionals $\{F_n\}_{n \in \mathbb{N}}$ (with respect to the metric d_X).

Remark 14 *In most situations one does not prove the limsup inequality for all $x \in X$ directly. Instead, one proves the inequality for all x in a dense subset X' of X where it is somewhat easier to prove, and then deduce from this that the inequality holds for all $x \in X$. To be more precise, suppose that the limsup inequality is true for every x in a subset X' of X and the set X' is such that for every $x \in X$ there exists a sequence $\{x_k\}_{k \in \mathbb{N}}$ in X' converging to x and such that $F(x_k) \rightarrow F(x)$ as $k \rightarrow \infty$, then the limsup inequality is true for every $x \in X$. The proof of the claim is straightforward, using, for example Theorem 1.17(iii) of Braides (2002). This property is not related to the randomness of the functionals in any way.*

Definition 15 *We say that the sequence of nonnegative random functionals $\{F_n\}_{n \in \mathbb{N}}$ satisfies the compactness property if for \mathbb{P} -almost every ω , the following statement holds: any sequence $\{x_n\}_{n \in \mathbb{N}}$ bounded in X and for which*

$$\limsup_{n \rightarrow \infty} F_n(x_n) < +\infty,$$

is relatively compact in X .

Remark 16 *The boundedness assumption of $\{x_n\}_{n \in \mathbb{N}}$ in the previous definition is a necessary condition for relative compactness and so it is not restrictive.*

The notion of Γ -convergence is particularly useful when the functionals $\{F_n\}_{n \in \mathbb{N}}$ satisfy the compactness property. This is because it guarantees that with \mathbb{P} -probability one, minimizers (or approximate minimizers) of F_n converge to minimizers of F and it also guarantees convergence of the minimum energy of F_n to the minimum energy of F (this statement is made precise in the next proposition). This is the reason why Γ -convergence is said to be a variational type of convergence. The next proposition can be found in (Braides, 2002; Dal Maso, 1993) in the deterministic setting. We present its proof in this random setting for completeness and for the benefit of the reader. We also want to highlight the way this type of convergence works as ultimately this is one of the essential tools used to prove the main theorems of this paper.

Proposition 17 *Let $F_n : X \times \Omega \rightarrow [0, \infty]$ be a sequence of random nonnegative functionals which are not identically equal to $+\infty$, satisfying the compactness property and Γ -converging to the deterministic functional $F : X \rightarrow [0, \infty]$ which is not identically equal to $+\infty$. Suppose that for \mathbb{P} -almost every ω there is a bounded sequence $\{x_n\}_{n \in \mathbb{N}}$ (which may depend on ω) satisfying*

$$\lim_{n \rightarrow \infty} \left(F_n(x_n) - \inf_{x \in X} F_n(x) \right) = 0. \tag{5.1}$$

Then, with \mathbb{P} -probability one,

$$\lim_{n \rightarrow \infty} \inf_{x \in X} F_n(x) = \min_{x \in X} F(x), \tag{5.2}$$

every bounded sequence $\{x_n\}_{n \in \mathbb{N}}$ in X satisfying (5.1) is relatively compact, and each of its cluster points is a minimizer of F . In particular, if F has a unique minimizer, a bounded sequence $\{x_n\}_{n \in \mathbb{N}}$ satisfying (5.1) converges to the unique minimizer of F .

Proof Consider Ω' a set with \mathbb{P} -probability one for which all the statements in the definition of Γ -convergence together with the statement of the compactness property hold. We also assume that for every $\omega \in \Omega'$, there exists a bounded sequence $\{x_n\}_{n \in \mathbb{N}}$ satisfying (5.1). We fix such $\omega \in \Omega'$.

Let $\{x_n\}_{n \in \mathbb{N}}$ be a sequence as the one described above. Let $\tilde{x} \in X$ be arbitrary. By the limsup inequality we know that there exists a sequence $\{\tilde{x}_n\}_{n \in \mathbb{N}}$ with $\tilde{x}_n \rightarrow \tilde{x}$ and such that

$$\limsup_{n \rightarrow \infty} F_n(\tilde{x}_n) \leq F(\tilde{x}).$$

By 5.1 we deduce that

$$\limsup_{n \rightarrow \infty} F_n(x_n) = \limsup_{n \rightarrow \infty} \inf_{x \in X} F_n(x) \leq \limsup_{n \rightarrow \infty} F_n(\tilde{x}_n) \leq F(\tilde{x}), \tag{5.3}$$

and since \tilde{x} was arbitrary we conclude that

$$\limsup_{n \rightarrow \infty} F_n(x_n) \leq \inf_{x \in X} F(x). \tag{5.4}$$

The fact that F is not identically equal to $+\infty$ implies that the term on the right hand side of the previous expression is finite and thus $\limsup_{n \rightarrow \infty} F_n(x_n) < +\infty$. Since the

sequence $\{x_n\}_{n \in \mathbb{N}}$ was assumed bounded, we conclude from the compactness property for the sequence of functionals $\{F_n\}_{n \in \mathbb{N}}$ that $\{x_n\}_{n \in \mathbb{N}}$ is relatively compact.

Now let x^* be any accumulation point of the sequence $\{x_n\}_{n \in \mathbb{N}}$ (we know there exists at least one due to compactness), we want to show that x^* is a minimizer of F . Working along subsequences, we can assume without the loss of generality that $x_n \rightarrow x^*$. By the liminf inequality, we deduce that

$$\inf_{x \in X} F(x) \leq F(x^*) \leq \liminf_{n \rightarrow \infty} F(x_n). \quad (5.5)$$

The previous inequality and (5.3) imply that

$$F(x^*) \leq F(\tilde{x}),$$

where \tilde{x} is arbitrary. Thus, x^* is a minimizer of F and in particular $\inf_{x \in X} F(x) = \min_{x \in X} F(x)$. Finally, to establish (5.2) note that this follows from (5.4) and (5.5). ■

5.1 Γ -convergence of graph total variation

Of fundamental importance in obtaining our results is the Γ -convergence of the graph total variation proved in García Trillos and Slepčev (2016). Let us describe this functional and also let us state the results we use. Given a point cloud $X_n := \{\mathbf{x}_1, \dots, \mathbf{x}_n\} \subseteq D$ where D is a domain in \mathbb{R}^d , we denote by $GTV_{n,\varepsilon_n} : TL^1(D) \rightarrow [0, \infty]$ the functional defined as follows: $GTV_{n,\varepsilon_n}(\mu, u_n) = \infty$ if $\mu \neq \nu_n$ and

$$GTV_{n,\varepsilon_n}(\nu_n, u_n) := \frac{1}{n^2 \varepsilon_n^{d+1}} \sum_{i,j=1}^n \eta \left(\frac{|\mathbf{x}_i - \mathbf{x}_j|}{\varepsilon_n} \right) |u_n(\mathbf{x}_i) - u_n(\mathbf{x}_j)|, \quad (5.6)$$

where η is a kernel satisfying conditions **(K1)**-**(K3)**. Since we consider GTV_{n,ε_n} only for $\mu = \nu_n$, from now on we only write $GTV_{n,\varepsilon_n}(u_n)$, instead of $GTV_{n,\varepsilon_n}(\nu_n, u_n)$. Using the empirical measure ν_n , we may alternatively write $GTV_{n,\varepsilon_n}(u_n)$ as

$$GTV_{n,\varepsilon_n}(u_n) = \frac{1}{\varepsilon_n^d} \iint \eta \left(\frac{|x-y|}{\varepsilon_n} \right) |u_n(x) - u_n(y)| d\nu_n(x) d\nu_n(y).$$

The connection of the functional GTV_{n,ε_n} to problem (1.1) is the following: if Y_n is a subset of X_n , then the graph total variation of the indicator function $\mathbf{1}_{Y_n}$ is equal to a rescaled version of the graph cut of Y_n , that is,

$$GTV_{n,\varepsilon_n}(\mathbf{1}_{Y_n}) = \frac{2\text{Cut}(Y_n, Y_n^c)}{n^2 \varepsilon_n^{d+1}},$$

we recall that $w_{ij} = \eta \left(\frac{|\mathbf{x}_i - \mathbf{x}_j|}{\varepsilon_n} \right)$.

Now we recall the Theorems 1.1 and 1.2 of García Trillos and Slepčev (2016).

Theorem 18 (Γ - Convergence) *Let the domain D , measure ν , kernel η , sample points $\{\mathbf{x}_i\}_{i \in \mathbb{N}}$, sequence $\{\varepsilon_n\}_{n \in \mathbb{N}}$, and graph \mathcal{G}_n satisfy the assumptions of Theorem 9. Then,*

GTV_{n,ε_n} , defined by (5.6), Γ -converge to $\sigma_\eta TV_\nu$ as $n \rightarrow \infty$ in the TL^1 sense, where σ_η is the surface tension associated to the kernel η (see condition **(K3)**) and TV_ν is the extension to $TL^1(D)$ of weighted (by ρ^2) total variation functional introduced in (3.1), defined as follows:

$$TV_\nu((u, \mu)) = \begin{cases} \sigma_\eta TV(u) & \text{if } \mu = \nu \\ +\infty & \text{else.} \end{cases}$$

Moreover, we have the following compactness result.

Theorem 19 (Compactness) *Under the hypothesis of Theorem 18, the sequence of functionals $\{GTV_{n,\varepsilon_n}\}_{n \in \mathbb{N}}$ satisfies the compactness property. Namely, for \mathbb{P} -almost every ω the following holds: if a sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ satisfies*

$$\limsup_{n \in \mathbb{N}} \|u_n\|_{L^1(\nu_n)} < \infty,$$

and

$$\limsup_{n \in \mathbb{N}} GTV_{n,\varepsilon_n}(u_n) < \infty,$$

then $\{u_n\}_{n \in \mathbb{N}}$ is TL^1 -relatively compact.

To conclude this section, we present Corollary 1.3 in García Trillos and Slepčev (2016), which allows us to restrict the functionals GTV_{n,ε_n} and TV to characteristic functions of sets and still obtain Γ -convergence. Observe that the only subtle point is the limsup inequality as the liminf inequality and compactness statements are particular cases of Theorem 18 and Theorem 19.

Theorem 20 *Under the assumptions of Theorem 18, with probability one the following statement holds: for every $A \subseteq D$ measurable, there exists a sequence of sets $\{Y_n\}_{n \in \mathbb{N}}$ with $Y_n \subseteq X_n$ such that,*

$$\mathbf{1}_{Y_n} \xrightarrow{TL^1} \mathbf{1}_A$$

and

$$\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(\mathbf{1}_{Y_n}) \leq \sigma_\eta TV(\mathbf{1}_A).$$

The results stated above are the main tools in order to establish our main theorems. In the next section we use them together with a careful treatment of the balance term appearing in the denominator of the Cheeger/ratio cut functional.

6. Consistency of two-way balanced cuts

Here we prove Theorem 9.

6.1 Outline of the proof

Before proving that minimal balanced cuts $\{Y_n^*, Y_n^{*c}\}$ converge to minimal continuum partitions $\{A^*, A^{*c}\}$ in the sense of Definition 6, we first pause to outline the main ideas. Rather than work directly with the graph-cut-based functional defined on the sets of vertices we work with its relaxation defined on the set of functions from the graph to reals, $L^1(\nu_n)$. The relaxed discrete functionals E_n are defined in (6.6) and the relaxed continuum one, E is defined in (3.12).

We first show, by an explicit construction in Subsection 6.2, that the rescaled indicator functions of minimal balanced cuts, $\bar{\mathbf{1}}_{Y_n}(x) := \alpha_n \mathbf{1}_{Y_n}(x)$, (for explicit coefficient α_n that we will define later),

$$u_n^* := \bar{\mathbf{1}}_{Y_n^*}(x), \quad u_n^{**} := \bar{\mathbf{1}}_{Y_n^{*c}}(x) \quad \text{minimize} \quad E_n(u_n) \quad \text{over all} \quad u_n \in L^1(\nu_n). \quad (6.1)$$

Similarly, in Subsection 3.2 we showed that the normalized indicator functions

$$u^* := \bar{\mathbf{1}}_{A^*}(x), \quad u^{**} := \bar{\mathbf{1}}_{A^{*c}}(x) \quad \text{minimize} \quad E(u) \quad \text{over all} \quad u \in L^1(\nu). \quad (6.2)$$

In Subsection 6.3 we show that the approximating functionals E_n Γ -converge to $\sigma_\eta E$ in the TL^1 -sense. In Lemma 23 we establish that u_n^* and u_n^{**} exhibit the required compactness. Thus, they must converge toward the normalized indicator functions $\bar{\mathbf{1}}_{A^*}(x)$ and $\bar{\mathbf{1}}_{A^{*c}}(x)$ up to relabeling (see Proposition 17). If $\{A^*, A^{*c}\}$ is the unique minimizer, the convergence of the sequences (up to relabeling) $\{u_n^*\}, \{u_n^{**}\}$ follows. The convergence of the partition $\{Y_n^*, Y_n^{*c}\}$ toward the partition $\{A^*, A^{*c}\}$ in the sense of Definition 6 is a direct consequence. The convergence (4.2) follows from (5.2) in Proposition 17.

6.2 Functional description of discrete cuts

We introduce functionals that describe the discrete ratio and Cheeger cuts in terms of functions on X_n , rather than in terms of subsets of X_n . This mirrors the description of continuum partitions provided in Subsection 3.2. For $u_n \in L^1(\nu_n)$, we start by defining

$$B_n^R(u_n) := \frac{1}{n} \sum_{i=1}^n |u_n(\mathbf{x}_i) - \text{mean}_n(u_n)| \quad \text{and} \quad B_n^C(u_n) := \min_{c \in \mathbb{R}} \frac{1}{n} \sum_{i=1}^n |u_n(\mathbf{x}_i) - c|. \quad (6.3)$$

Here $\text{mean}_n(u_n) = \frac{1}{n} \sum_{i=1}^n u_n(\mathbf{x}_i)$. A straightforward computation shows that for $Y_n \subseteq X_n$

$$B_n^R(\mathbf{1}_{Y_n}) = \text{Bal}_R(Y_n, Y_n^c), \quad B_n^C(\mathbf{1}_{Y_n}) = \text{Bal}_C(Y_n, Y_n^c). \quad (6.4)$$

From here on we write B_n to represent either B_n^R or B_n^C depending on the context.

Instead of defining $E_n(u_n)$ simply as the ratio $GTY_{n,\varepsilon_n}(u_n)/B_n(u_n)$, which is the direct analogue of (1.1), it proves easier to work with suitably normalized indicator functions. Given $Y_n \subseteq X_n$ with $B_n(\mathbf{1}_{Y_n}) \neq 0$, the *normalized indicator function* $\mathbf{1}_{Y_n}(x)$ is defined by

$$\bar{\mathbf{1}}_{Y_n}(x) = \mathbf{1}_{Y_n}(x)/B_n^C(\mathbf{1}_{Y_n}) \quad \text{or} \quad \bar{\mathbf{1}}_{Y_n}(x) = \mathbf{1}_{Y_n}(x)/B_n^R(\mathbf{1}_{Y_n}).$$

Note that $B_n(\bar{\mathbf{1}}_A) = 1$. We also restrict the minimization of $E_n(u)$ to the set

$$\text{Ind}_n(D) := \{u_n \in L^1(\nu_n) : u_n = \bar{\mathbf{1}}_{Y_n} \text{ for some } Y_n \subseteq X_n \text{ with } B_n(\mathbf{1}_{Y_n}) \neq 0\}. \quad (6.5)$$

Now, suppose that $u_n \in \text{Ind}_n(D)$, in other words that $u_n = \bar{\mathbf{1}}_{Y_n}$, for some set Y_n with $B_n(\mathbf{1}_{Y_n}) > 0$. Using (3.9) together with the fact that GTY_{n,ε_n} (defined in (5.6)) is one-homogeneous implies, as in (3.11)

$$GTY_{n,\varepsilon_n}(u_n) = \frac{2}{n^{2-d+1}} \frac{\text{Cut}(Y_n, Y_n^c)}{\text{Bal}(Y_n, Y_n^c)}. \quad (6.6)$$

Thus, minimizing GTY_{n,ε_n} over all $u_n \in \text{Ind}_n(D)$ is equivalent to the balanced graph-cut problem (1.1) on the graph $\mathcal{G}_n = (X_n, W_n)$ constructed from the first n data points. We have therefore arrived at our destination, a proper reformulation of (1.1) defined over $TL^1(D)$ instead of subsets of X_n . The task is to

$$\text{Minimize} \quad E_n(\mu, u_n) := \begin{cases} GTY_{n,\varepsilon_n}(u_n) & \text{if } \mu = \nu_n \text{ and } u_n \in \text{Ind}_n(D) \\ +\infty & \text{otherwise.} \end{cases} \quad (6.7)$$

Since the measure is clear from context, from now on we write $E_n(u_n)$ for $E_n(\nu_n, u_n)$.

6.3 Γ -Convergence

Proposition 21 (Γ -Convergence) *Let domain D , measure ν , kernel η , sequence $\{\varepsilon_n\}_{n \in \mathbb{N}}$, sample points $\{\mathbf{x}_i\}_{i \in \mathbb{N}}$, and graph \mathcal{G}_n satisfy the assumptions of Theorem 9. Let E_n be as defined in (6.7) and E as in (3.12). Then*

$$E_n \xrightarrow{\Gamma} \sigma_\eta E \quad \text{with respect to } TL^1 \text{ metric as } n \rightarrow \infty$$

where σ_η is the surface tension defined in assumption (K3). This is implied by the following:

1. For any $u \in L^1(\nu)$ and any sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ that converges to u in TL^1 ,

$$\sigma_\eta E(u) \leq \liminf_{n \rightarrow \infty} E_n(u_n). \quad (6.8)$$
2. For any $u \in L^1(\nu)$ there exists at least one sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ which converges to u in TL^1 and also satisfies

$$\limsup_{n \rightarrow \infty} E_n(u_n) \leq \sigma_\eta E(u). \quad (6.9)$$

We leverage Theorem 18 to prove this claim. We first need a preliminary lemma which allows us to handle the presence of the additional balance terms in (6.7) and (3.12).

Lemma 22 *With probability one, the following hold:*

- (i) If $\{u_n\}_{n \in \mathbb{N}}$ is a sequence with $u_n \in L^1(\nu_n)$ and $u_n \xrightarrow{TL^1} u$ for some $u \in L^1(\nu)$, then $B_n(u_n) \rightarrow B(u)$.
- (ii) If $u_n = \bar{\mathbf{1}}_{Y_n}$, where $Y_n \subseteq X_n$, converges to $u = \bar{\mathbf{1}}_A$ in the TL^1 -sense, then $\mathbf{1}_{Y_n}$ converges to $\mathbf{1}_A$ in the TL^1 -sense.

Proof To prove (i), suppose that $u_n \in L^1(\nu_n)$ and that $u_n \xrightarrow{TL^1} u$. Let us consider $\{T_n\}_{n \in \mathbb{N}}$ a stagnating sequence of transportation maps between ν and $\{\nu_n\}_{n \in \mathbb{N}}$ (one such sequence exists with probability one by Proposition 5). Then, we have $u_n \circ T_n \xrightarrow{L^1(\nu)} u$ and thus by Lemma 7, we have that $B(u_n \circ T_n) \rightarrow B(u)$. To conclude the proof we notice that $B(u_n \circ T_n) = B_n(u_n)$ for every n . Indeed, by the change of variables (2.2) we have that for every $c \in \mathbb{R}$

$$\int_D |u_n(x) - c| d\nu_n(x) = \int_D |u_n \circ T_n(x) - c| d\nu(x). \quad (6.10)$$

In particular we have $B_C^n(u_n) = B_C(u_n \circ T_n)$. Applying the change of variables (2.2), we obtain $\text{mean}_n(u_n) = \text{mean}_\nu(u_n \circ T_n)$ and combining with (6.10) we deduce that $B_R^n(u_n) = B_R(u_n \circ T_n)$. ■

The proof of (ii) is straightforward.

Now we turn to the proof of Proposition 21.

Proof Liminf inequality. For arbitrary $u \in L^1(\nu)$ and arbitrary sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ and with $u_n \xrightarrow{TL^1} u$, we need to show that

$$\liminf_{n \rightarrow \infty} E_n(u_n) \geq \sigma_\eta E(u).$$

First assume that $u \in \text{Ind}(D)$. In particular $E(u) = TV(u)$. Now, note that working along a subsequence we can assume that the liminf is actually a limit and that this limit is finite (otherwise the inequality would be trivially satisfied). This implies that for all n large enough we have $E_n(u_n) < +\infty$, which in particular implies that $E_n(u_n) = GTV_{n,\varepsilon_n}(u_n)$. Theorem 18 then implies that

$$\liminf_{n \rightarrow \infty} E_n(u_n) = \liminf_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(u_n) \geq \sigma_\eta TV(u) = \sigma_\eta E(u).$$

Now let us assume that $u \notin \text{Ind}(D)$. Let us consider a stagnating sequence of transportation maps $\{T_n\}_{n \in \mathbb{N}}$ between $\{\nu_n\}_{n \in \mathbb{N}}$ and ν . Since $u_n \xrightarrow{TL^1} u$ then $u_n \circ T_n \xrightarrow{L^1(\nu)} u$. By Lemma 7, the set $\text{Ind}(D)$ is a closed subset of $L^1(\nu)$. We conclude that $u_n \circ T_n \notin \text{Ind}(D)$ for all large enough n . From the proof of Lemma 22 we know that $B_n(u_n) = B(u_n \circ T_n)$ and from this fact, it is straightforward to show that $u_n \circ T_n \notin \text{Ind}(D)$ if and only if $u_n \notin \text{Ind}_n(D)$. Hence, $u_n \notin \text{Ind}_n(D)$ for all large enough n and in particular $\liminf_{n \in \mathbb{N}} E_n(u_n) = +\infty$ which implies that the desired inequality holds in this case.

Limsup inequality. We now consider $u \in L^1(\nu)$. We want to show that there exists a sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ such that

$$\limsup_{n \rightarrow \infty} E_n(u_n) \leq \sigma_\eta E(u).$$

Let us start by assuming that $u \notin \text{Ind}(D)$. In this case $E(u) = +\infty$. From Theorem 18 we know there exists at least one sequence $\{u_n\}_{n \in \mathbb{N}}$ with $u_n \in L^1(\nu_n)$ such that $u_n \xrightarrow{TL^1} u$. Since $E(u) = +\infty$, the inequality is trivially satisfied in this case.

On the other hand, if $u \in \text{Ind}(D)$, we know that $u = \bar{\mathbf{1}}_A$ for some measurable subset A of D with $B(\mathbf{1}_A) \neq 0$. By Theorem 20, there exists a sequence $\{Y_n\}_{n \in \mathbb{N}}$ with $Y_n \subseteq X_n$, satisfying $\mathbf{1}_{Y_n} \xrightarrow{TL^1} \mathbf{1}_A$ and

$$\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(\mathbf{1}_{Y_n}) \leq \sigma_\eta TV(\mathbf{1}_A). \quad (6.11)$$

Since $\mathbf{1}_{Y_n} \xrightarrow{TL^1} \mathbf{1}_A$ Lemma 22 implies that

$$B_n(\mathbf{1}_{Y_n}) \rightarrow B(\mathbf{1}_A). \quad (6.12)$$

In particular $B_n(\mathbf{1}_{Y_n}) \neq 0$ for all n large enough, and thus we can consider the function $u_n := \bar{\mathbf{1}}_{Y_n} \in \text{Ind}_n(D)$. From (6.12) it follows that $u_n \xrightarrow{TL^1} u$ and together with (6.11) it follows that

$$\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(u_n) = \limsup_{n \rightarrow \infty} \frac{1}{B_n(Y_n)} GTV_{n,\varepsilon_n}(\mathbf{1}_{Y_n}) \leq \frac{1}{B(\mathbf{1}_A)} \sigma_\eta TV(\mathbf{1}_A) = \sigma_\eta TV(u)$$

Since, $u_n \in \text{Ind}_n(D)$ for all n large enough, in particular we have $GTV_{n,\varepsilon_n}(\mathbf{1}_{Y_n}) = E_n(\mathbf{1}_{Y_n})$ and also since $u \in \text{Ind}(D)$, we have $E(u) = TV(u)$. These facts together with the previous chain of inequalities imply the result. ■

6.4 Compactness

Lemma 23 (Compactness) *With probability one the following statement holds: Any sequence $\{u_n\}_{n \in \mathbb{N}}$ with*

$$\limsup_{n \rightarrow \infty} E_n(u_n) < +\infty$$

is precompact in TL^1 . In particular, any sequence $\{u_n^\}_{n \geq 1}$, of minimizers of E_n (defined in (6.1) and (6.2)) are precompact in the TL^1 -sense.*

Proof Let u_n denote a sequence satisfying

$$\limsup_{n \rightarrow \infty} E_n(u_n) < +\infty.$$

To show that any subsequence of u_n has a convergent subsequence it suffices to show that both

$$\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(u_n) < +\infty \quad (6.13)$$

$$\limsup_{n \rightarrow \infty} \|u_n\|_{L^1(\nu_n)} < +\infty \quad (6.14)$$

hold due to Theorem 19. Since the result is about asymptotic behavior, we can assume without loss of generality that $\sup_{n \in \mathbb{N}} E_n(u_n) < +\infty$. Inequality (6.13) follows from the fact that $E_n(u_n) = GTV_{n,\varepsilon_n}(u_n)$. Note that $E_n(u_n) < \infty$ in particular implies that u_n has the form $u_n = \frac{\mathbf{1}_{Y_n}}{B_n(Y_n)}$ for some $Y_n \subseteq X_n$.

To show (6.14), consider first the balance term that corresponds to the Cheeger cut. Define a sequence v_n as follows. Set $v_n := u_n$ if $|Y_n^c| \leq |Y_n^c|$ and $v_n = \frac{1_{Y_n^c}}{B_n(Y_n^c)}$ otherwise. It then follows that

$$\|v_n\|_{L^1(u_n)} = \frac{\min\{|Y_n|, |Y_n^c|\}}{\min\{|Y_n^c|, |Y_n^c|\}} = 1.$$

Also, note that $GT_{V_{n,\varepsilon_n}}(v_n) = GT_{V_{n,\varepsilon_n}}(u_n)$. Thus (6.13) and (6.14) hold for v_n , so that any subsequence of v_n has a convergent subsequence in the TL^1 -sense. Let $v_n \xrightarrow{TL^1} v$ denote a convergent subsequence. Thus, it follows from Proposition 21, that

$$\sigma_\eta E(v) \leq \liminf_{k \rightarrow \infty} E_{n_k}(v_{n_k}) < \infty,$$

and in particular v is a normalized characteristic function, that is, $v = \mathbf{1}_A/B(\mathbf{1}_A)$ for some $A \subseteq D$ with $B(\mathbf{1}_A) \neq 0$. Since $B_{n_k}(\mathbf{1}_{Y_{n_k}^c}) = B_{n_k}(\mathbf{1}_{Y_{n_k}^c})$, $v_{n_k} \xrightarrow{TL^1} v$ implies that

$$\frac{B_{n_k}(Y_{n_k})}{1} \rightarrow \frac{B(A)}{1}.$$

Therefore, for large enough k we have

$$\|u_{n_k}\|_{L^1(v_{n_k})} \leq \frac{1}{B_{n_k}(Y_{n_k})} \leq \frac{2}{B(A)}$$

We conclude that $\|u_{n_k}\|_{L^1(v_{n_k})}$ remains bounded in L^1 , so that it satisfies (6.14) and (6.13) simultaneously. This yields compactness in the Cheeger cut case.

Now consider the balance term $B(u) = B_n(u)$ that corresponds to the ratio cut. Define a sequence $v_n := u_n - \text{mean}_n(u_n)$, and note that $GT_{V_{n,\varepsilon_n}}(v_n) = GT_{V_{n,\varepsilon_n}}(u_n)$ since the total variation is invariant with respect to translation. It then follows that

$$\|v_n\|_{L^1(v)} = \int_D |u_n(x) - \text{mean}_n(u_n)| \rho(x) dx = B(u_n) = 1.$$

Thus the sequence $\{v_n\}_{n \in \mathbb{N}}$ is precompact in TL^1 . Let $v_n \xrightarrow{TL^1} v$ denote a convergent subsequence. Using a stagnating sequence of transportation maps $\{T_{n_k}\}_{k \in \mathbb{N}}$ between ν and the sequence of measures $\{\nu_{n_k}\}_{k \in \mathbb{N}}$, we have that $v_{n_k} \circ T_{n_k} \xrightarrow{L^1(\nu)} v$. By passing to a further subsequence if necessary, we may assume that $v_{n_k} \circ T_{n_k}(x) \rightarrow v(x)$ for ν -almost every x in D .

For any such x , we have that either $T_{n_k}(x) \in Y_{n_k}$ or $T_{n_k}(x) \in Y_{n_k}^c$ so that either

$$v_{n_k} \circ T_{n_k}(x) = \frac{1}{2|Y_{n_k}^c|} \quad \text{or} \quad v_{n_k} \circ T_{n_k}(x) = -\frac{1}{2|Y_{n_k}^c|}.$$

Now, by continuity of the balance term, we have

$$B(v) = \lim_{k \rightarrow \infty} B_{n_k}(v_{n_k}) = 1,$$

and also

$$\text{mean}_\rho(v) = \lim_{k \rightarrow \infty} \text{mean}_{n_k}(v_{n_k}) = 0.$$

In particular the ν -measure of the region in which v is positive is strictly greater than zero, and likewise the ν -measure of the region in which v is negative is strictly greater than zero. It follows that both $|Y_{n_k}^c|$ and $|Y_{n_k}^c|$ remain bounded away from zero for all k sufficiently large. As a consequence, the fact that

$$\|u_{n_k}\|_{L^1(v_{n_k})} = \frac{1}{2|Y_{n_k}^c|},$$

implies that both (6.13) and (6.14) hold along a subsequence, yielding the desired compactness. \blacksquare

6.5 Conclusion of the proof of Theorem 9

We may now turn to the final step of the proof. From Proposition 17, we know that any limit point of $\{u_n^*\}_{n \in \mathbb{N}}$ (in the TL^1 sense) must equal u^* or u^{**} . As a consequence, for any subsequence $u_{n_k}^*$ that converges to u^* we have that $\mathbf{1}_{Y_{n_k}^*} \xrightarrow{TL^1} \mathbf{1}_{A^*}$ by Lemma 22, while $\mathbf{1}_{Y_{n_k}^*} \xrightarrow{TL^1} \mathbf{1}_{A^{**}}$ if the subsequence converges to u^{**} instead. Moreover, in the first case we would also have $\mathbf{1}_{Y_{n_k}^{*c}} \xrightarrow{TL^1} \mathbf{1}_{A^{*c}}$ and in the second case $\mathbf{1}_{Y_{n_k}^{*c}} \xrightarrow{TL^1} \mathbf{1}_{A^{**}}$. Thus in either case we have

$$\{Y_{n_k}^{*c}, Y_{n_k}^{*c}\} \xrightarrow{TL^1} \{A^*, A^{*c}\}$$

Thus, for any subsequence of $\{Y_n^*, Y_n^{*c}\}_{n \in \mathbb{N}}$ it is possible to obtain a further subsequence converging to $\{A^*, A^{*c}\}$, and thus the full sequence converges to $\{A^*, A^{*c}\}$.

7. Consistency of multiway balanced cuts

Here we prove Theorem 12.

Just as what we did in the two-class case, the first step in the proof of Theorem 12 involves a reformulation of both the balanced graph-cut problem (1.4) and the analogous balanced domain-cut problem (1.11) as equivalent minimizations defined over spaces of functions and not just spaces of partitions or sets.

We let $B_n(u_n) := \text{mean}_n(u_n)$ for $u_n \in L^1(\nu_n)$ and $B(u) := \text{mean}_\rho(u)$ for $u \in L^1(\nu)$, to be the corresponding balance terms. Given this balance terms, we let $\text{Ind}_n(D)$ and $\text{Ind}(D)$ be defined as in (6.5) and (3.10) respectively.

We can then let the sets $\mathcal{M}_n(D)$ and $\mathcal{M}(D)$ consist of those collections $I = (u_1, \dots, u_R)$ comprised of exactly R disjoint, normalized indicator functions that cover D . The sets $\mathcal{M}_n(D)$ and $\mathcal{M}(D)$ are the multi-class analogues of $\text{Ind}_n(D)$ and $\text{Ind}(D)$ respectively.

Specifically, we let

$$\mathcal{M}_n(D) = \left\{ (u_1^n, \dots, u_R^n) : u_r^n \in \text{Ind}_n(D), \int_D u_r^n(x) u_s^n(x) d\nu_n(x) = 0 \text{ if } r \neq s, \sum_{r=1}^R u_r^n > 0 \right\} \quad (7.1)$$

$$\mathcal{M}(D) = \left\{ (u_1, \dots, u_R) : u_r \in \text{Ind}(D), \int_D u_r(x) u_s(x) d\nu(x) = 0 \text{ if } r \neq s, \sum_{r=1}^R u_r > 0 \right\}. \quad (7.2)$$

Note for example that if $\mathcal{U} = (u_1, \dots, u_R) \in \mathcal{M}(D)$, then the functions u_r are normalized indicator functions, $u_r = \mathbf{1}_{A_r}/|A_r|$ for $1 \leq r \leq R$, and the orthogonality constraints imply that $\{A_1, \dots, A_R\}$ is a collection of pairwise disjoint sets (up to Lebesgue-null sets). Additionally, the condition that $\sum_{r=1}^R u_r > 0$ holds almost everywhere implies that the sets $\{A_1, \dots, A_R\}$ cover D up to Lebesgue-null sets.

We proceed to define the functionals on the space of R -tuples of L^1 functions, namely

$$TL^1(D, R) := \{(\mu, \mathcal{U}) : \mu \in \mathcal{P}(D), \mathcal{U} = (u_1, \dots, u_R), u_i \in L^1(\mu) \text{ for } i = 1, \dots, R\}.$$

We note that convergence in $TL^1(D, R)$ is equivalent to convergence of the R components in $TL^1(D)$.

One may follow the same argument in the two-class case to conclude that the minimization

$$\text{Minimize } E_n(\mu, \mathcal{U}_n) := \begin{cases} \sum_{r=1}^R GTV_{n, \varepsilon_n}(u_r^n) & \text{if } \mu = \nu_n \text{ and } \mathcal{U}_n \in \mathcal{M}_n(D) \\ +\infty & \text{otherwise} \end{cases} \quad (7.3)$$

is equivalent to the balanced graph-cut problem (1.4), while the minimization

$$\text{Minimize } E(\mu, \mathcal{U}) := \begin{cases} \sum_{r=1}^R TV(u_r) & \text{if } \mu = \nu \text{ and } \mathcal{U} \in \mathcal{M}(D) \\ +\infty & \text{otherwise} \end{cases} \quad (7.4)$$

is equivalent to the balance domain-cut problem (1.11).

As in the two-class case we omit the first argument of E_n and E , when it is clear from context.

At this stage, the proof of Theorem 12, is completed by following the same steps as in the two-class case. In particular we want to show that E_n defined in (7.3) Γ -converges in the TL^1 -sense to $\sigma_n E$, where E is defined in (7.4).

Proposition 24 (Γ -Convergence) *Let domain D , measure ν , kernel η , sequence $\{\varepsilon_n\}_{n \in \mathbb{N}}$, sample points $\{\mathbf{x}_i\}_{i \in \mathbb{N}}$, and graph \mathcal{G}_n satisfy the assumptions of Theorem 9. Consider functionals E_n of (7.3) and E of (7.4). Then*

$$E_n \xrightarrow{\Gamma} \sigma_n E \quad \text{with respect to } TL^1(D, R) \text{ metric as } n \rightarrow \infty.$$

That is, with probability one, all of the following statements hold

1. For any $\mathcal{U} \in [L^1(\nu)]^R$ and any sequence $\mathcal{U}_n \in (L^1(\nu_n))^R$ that converges to \mathcal{U} in the TL^1 -sense,

$$E(\mathcal{U}) \leq \liminf_{n \rightarrow \infty} E_n(\mathcal{U}_n). \quad (7.5)$$

2. For any $\mathcal{U} \in [L^1(\nu)]^R$ there exists a sequence $\mathcal{U}_n \in (L^1(\nu_n))^R$ that both, converges to \mathcal{U} in the TL^1 -sense, and also satisfies

$$\limsup_{n \rightarrow \infty} E_n(\mathcal{U}_n) \leq E(\mathcal{U}). \quad (7.6)$$

The following lemma follows in a straightforward way. We omit its proof since it follows analogous arguments to the ones used in the proof of Lemma 23.

Lemma 25 (Compactness) *With probability one the following statement holds: Any sequence $\{\mathcal{U}_n\}_{n \in \mathbb{N}}$ with $\mathcal{U}_n \in [L^1(\nu_n)]^R$ satisfying*

$$\limsup_{n \rightarrow \infty} E_n(\mathcal{U}_n) < +\infty,$$

is precompact in the TL^1 -sense. In particular, any subsequence of $\{\mathcal{U}_n\}_{n \geq 1}$ of minimizers to (7.3) has a further subsequence that converges in the TL^1 -sense.

Finally, due to Proposition 24 and Lemma 25, the arguments presented in Subsections 6.1 and 6.5 can be adapted in a straightforward way to complete the proof of Theorem 12. So we focus on the proof of Proposition 24, where arguments not present in the two-class case are needed. On one hand, this is due to the presence of the orthogonality constraints in the definition of $\mathcal{M}_n(D)$ and $\mathcal{M}(D)$, and on the other hand, from a geometric measure theory perspective, due to the fact that an arbitrary partition of the domain D into more than two sets can not be approximated by smooth partitions as multiple junctions appear when more than two sets in the partition meet.

7.1 Proof of Proposition 24

The next lemma is the multiclass analogue of Lemmas 7 and 22 combined.

Lemma 26 (i) *If $\mathcal{U}_k \rightarrow \mathcal{U}$ in $(L^1(\nu))^R$ then $B(u_k^i) \rightarrow B(u_r)$ for all $1 \leq r \leq R$. (ii) The set $\mathcal{M}(D)$ is closed in $L^1(\nu)$. (iii) If $\{\mathcal{U}_n\}$ is a sequence with $\mathcal{U}_n \in (L^1(\nu_n))^R$ and $\mathcal{U}_n \xrightarrow{TL^1} \mathcal{U}$ for some $\mathcal{U} \in (L^1(\nu))^R$, then $B_n(u_n^i) \rightarrow B(u_r)$ for all $1 \leq r \leq R$. (iv) If $u_n = \mathbf{1}_{Y_n}$, where $Y_n \subset X_n$, converges to $u = \mathbf{1}_A$ in the TL^1 -sense, then $\mathbf{1}_{Y_n}$ converges to $\mathbf{1}_A$ in the TL^1 -sense.*

Proof Statements (i), (iii) follow directly from the proof of Proposition 22. Statement (iv) is exactly as in Proposition 22.

In order to prove the second statement, suppose that a sequence $\{\mathcal{U}_k\}_{k \in \mathbb{N}}$ in $\mathcal{M}(D)$ converges to some \mathcal{U} in $(L^1(\nu))^R$. We need to show that $\mathcal{U} \in \mathcal{M}(D)$. First of all note that for every $1 \leq r \leq R$, $u_k^r \xrightarrow{L^1(\nu)} u_r$. Since $u_k^i \in \text{Ind}(D)$ for every $k \in \mathbb{N}$, and since $\text{Ind}(D)$ is a closed subset of $L^1(\nu)$ (by Proposition 22), we deduce that $u_r \in \text{Ind}(D)$ for every r .

The orthogonality condition follows from Fatou's lemma. In fact, working along a subsequence we can without the loss of generality assume that for every r , $u_r^k \rightarrow u_r$ for almost every x in D . Hence, for $r \neq s$ we have

$$0 \leq \int_D u_r(x) u_s(x) dx(x) = \int_D \liminf_{k \rightarrow \infty} (u_r^k(x) u_s^k(x)) dx(x) \leq \liminf_{k \rightarrow \infty} \int_D u_r^k(x) u_s^k(x) dx(x) = 0$$

Now let us write $u_r^k = \mathbf{1}_{A_r^k}/B(\mathbf{1}_{A_r^k})$ and $u_r = \mathbf{1}_{A_r}/B(\mathbf{1}_{A_r})$. As in the proof of Proposition 22 we must have $B(\mathbf{1}_{A_r^k}) \rightarrow B(\mathbf{1}_{A_r})$, as $k \rightarrow \infty$. Thus, for almost every $x \in D$

$$\sum_{r=1}^R u_r(x) = \lim_{k \rightarrow \infty} \sum_{r=1}^R u_r^k(x) \geq \lim_{k \rightarrow \infty} \min_{r=1, \dots, R} \frac{1}{B(\mathbf{1}_{A_r^k})} = \min_{r=1, \dots, R} \frac{1}{B(\mathbf{1}_{A_r})} > 0.$$

■

Proof [of Proposition 24]

Liminf inequality. The proof of (7.5) follows the approach used in the two-class case. Let $\mathcal{U}_n \xrightarrow{TL} \mathcal{U}$ denote an arbitrary convergent sequence. As $\mathcal{M}(D)$ is closed, if $\mathcal{U} \notin \mathcal{M}(D)$ then as in the two-class case, it is easy to see that $\mathcal{U}_n \notin \mathcal{M}_n(D)$ for all n sufficiently large. The inequality (7.5) is then trivial in this case, as both sides of it are equal to infinity. Conversely, if $\mathcal{U} \in \mathcal{M}(D)$ then we may assume that $\mathcal{U}_n \in \mathcal{M}_n(D)$ for all n , since only those terms with $\mathcal{U}_n \in \mathcal{M}_n(D)$ can make the limit inferior less than infinity. In this case we easily have

$$\begin{aligned} \liminf_{n \rightarrow \infty} E_n(\mathcal{U}_n) &= \liminf_{n \rightarrow \infty} \sum_{r=1}^R GTV_{\eta_n, \varepsilon_n}(u_r^n) \geq \sum_{r=1}^R \liminf_{n \rightarrow \infty} GTV_{\eta_n, \varepsilon_n}(u_r^n) \\ &\geq \sigma_\eta \sum_{r=1}^R TV(u_r) = \sigma_\eta E(\mathcal{U}). \end{aligned}$$

The last inequality follows from Theorem 18. This establishes the first statement in Proposition 24.

Limsup inequality. We now turn to the proof of (7.6), which is significantly more involved than the two-class argument due to the presence of the orthogonality constraints. It proves useful to consider an extension of ρ to the whole \mathbb{R}^d by setting $\rho(x) = \lambda$ for $x \in \mathbb{R}^d \setminus D$. This extension is a lower semi-continuous function and has the same lower and upper bounds that the original ρ has.

Borrowing terminology from the Γ -convergence literature, we say that $\mathcal{U} \in (L^1(\rho))^R$ has a *recovery sequence* when there exists a sequence $\mathcal{U}_n \in (L^1(\rho_n))^R$ such that (7.6) holds. To show that each $\mathcal{U} \in (L^1(\rho))^R$ has a recovery sequence, we first remark that due to general properties of the Γ -convergence, it is enough to verify (7.6) for \mathcal{U} belonging to a dense subset of $\mathcal{M}(D)$ with respect to the energy E (see Remark 14). We furthermore remark that it is enough to consider $\mathcal{U} = (u_1, \dots, u_R) \in (L^1(D))^R$ for which $E(\mathcal{U}) < \infty$, as the other case is trivial. So we can consider $\mathcal{U} \in \mathcal{M}(D)$ that satisfy

$$\sum_{r=1}^R TV(u_r) < \infty.$$

Let $u_r = \mathbf{1}_{A_r}/B(\mathbf{1}_{A_r})$ and let $c_0 := \max\{B(\mathbf{1}_{A_1}), \dots, B(\mathbf{1}_{A_R})\}$ denote the size of the largest set in the collection. The fact that $E(\mathcal{U}) < \infty$ then implies that for every $s = 1, \dots, R$,

$$TV(\mathbf{1}_{A_s}) \leq c_0 TV(u_s) \leq c_0 \sum_{r=1}^R TV(u_r) < \infty,$$

so that all sets $\{A_1, \dots, A_R\}$ in the collection defining \mathcal{U} have finite perimeter. Additionally because $\mathcal{U} \in \mathcal{M}(D)$ implies that any two sets A_r, A_s with $r \neq s$ have empty intersection up to a Lebesgue-null set, we may freely assume without the loss of generality that the sets $\{A_1, \dots, A_R\}$ are mutually disjoint.

We say that a subset of \mathbb{R}^d has a *piecewise (PW) smooth boundary* if the boundary is a subset of the union of finitely many open $d-1$ -dimensional manifolds embedded in \mathbb{R}^d . We first construct a recovery sequence for \mathcal{U} , as above, whose defining sets $\{A_1, \dots, A_R\}$ are of the form $A_r = B_r \cap D$, where B_r has piecewise smooth boundary and satisfies $|D \setminus B_r|_{\rho^2}(\partial D) = 0$. We say that such \mathcal{U} is *induced by piecewise smooth sets*. We later prove that such partitions are dense among partitions of D by sets of finite perimeters. ²

Constructing a recovery sequence for \mathcal{U} induced by sets with piecewise smooth boundary. Let $Y_r^n = A_r \cap X_n$ denote the restriction of A_r to the first n data points. Now, let us consider the transportation maps $\{T_n\}_{n \in \mathbb{N}}$ from Proposition 5. We let A_n be the set for which $\mathbf{1}_{A_r^k} = \mathbf{1}_{Y_r^n} \circ T_n$.

We first notice that the fact that B_r has a piecewise smooth boundary in \mathbb{R}^d and the fact that $\mathbf{1}_{A_r^k} - \mathbf{1}_{A_r}$ is nontrivial only within the tubular neighborhood of ∂B_r of radius $\|\text{Id} - T_n\|_\infty$, imply that

$$\|\mathbf{1}_{A_r^k} - \mathbf{1}_{A_r}\|_{L^1(\rho)} \leq C_0(B_r) \|\text{Id} - T_n\|_\infty, \quad (7.7)$$

where $C_0(B_r)$ denotes some constant that depends on the set B_r . This inequality follows from the formulas for the volume of tubular neighborhoods (see Weyl (1939), page 461). In particular, note that by the change of variables (2.2) we have, $|Y_r^n| = |A_r^n| \rightarrow |A_r|$ as $n \rightarrow \infty$, so that in particular we can assume that $|Y_r^n| \neq 0$. We define $u_r^n := \mathbf{1}_{Y_r^n}/|Y_r^n|$ as the corresponding normalized indicator function. We claim that $\mathcal{U}_n := (u_1^n, \dots, u_R^n)$ furnishes the desired recovery sequence.

To see that $\mathcal{U}_n \in \mathcal{M}_n(D)$ we first note that each $u_r^n \in \text{Ind}_n(D)$ by construction. On the other hand, the fact that $\{A_1, \dots, A_R\}$ forms a partition of D implies that $\{Y_1^n, \dots, Y_R^n\}$ defines a partition of X_n . As a consequence,

$$E_n(\mathcal{U}_n) = \sum_{r=1}^R GTV_{\eta_n, \varepsilon_n}(u_r^n)$$

by definition of the E_n functionals.

Using (7.7), we can proceed as in remark 5.1 in García Trillos and Slepčev (2016). In particular, we can assume that η has the form $\eta(|z|) = a$ for $|z| < b$ and $\eta(z) = 0$ otherwise; the general case follows in a straightforward way by using an approximating procedure with

² Note that unlike in the two-class case, due to "multiple junctions" one cannot approximate a general partition by a partition with sets with smooth boundaries. This makes the construction more complicated.

kernels that are a finite sum of step functions like the one considered previously (see the proof of Theorem 1.1 in García Trillos and Slepčev (2016)).

We set $\tilde{\varepsilon}_n := \varepsilon_n + \frac{2}{n} \|\text{Id} - T_n\|_\infty$. Recall that by assumption $\|\text{Id} - T_n\|_\infty \ll \varepsilon_n$ (see the statement of Theorem 9 and Proposition 5), and thus $\tilde{\varepsilon}_n$ is a small perturbation of ε_n . Define the non-local total variation $TV_{\tilde{\varepsilon}_n}$ of an integrable function $u \in L^1(\nu)$ as

$$\widetilde{TV}_{\tilde{\varepsilon}_n}(u) := \frac{1}{\varepsilon_n^{d+1}} \int_{D \times D} \eta \left(\frac{|x-y|}{\tilde{\varepsilon}_n} \right) |u(x) - u(y)| \rho(x) \rho(y) \, dx dy.$$

Using the definition of $\tilde{\varepsilon}_n$, and the form of the kernel η , we deduce that for all $n \in \mathbb{N}$, and almost every $x, y \in D$ we have

$$\eta \left(\frac{|T_n(x) - T_n(y)|}{\varepsilon_n} \right) \leq \eta \left(\frac{|x-y|}{\tilde{\varepsilon}_n} \right).$$

This inequality an a change of variables (see 2.2) implies that

$$\frac{\varepsilon_n^{d+1}}{\tilde{\varepsilon}_n^{d+1}} GTV_{n,\varepsilon_n}(\mathbf{1}_{Y^n}) \leq \widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A^n}).$$

A straightforward computation shows that there exists a constant K_0 such that

$$|\widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A^n}) - \widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A_r})| \leq \frac{K_0}{\tilde{\varepsilon}_n} \|\mathbf{1}_{A^n} - \mathbf{1}_{A_r}\|_{L^1(\nu)} \leq K_0 C_0(B_r) \frac{\|\text{Id} - T_n\|_\infty}{\tilde{\varepsilon}_n}.$$

Since $\frac{\varepsilon_n}{\tilde{\varepsilon}_n} \rightarrow 1$, the previous inequalities imply that

$$\limsup_{n \in \mathbb{N}} GTV_{n,\varepsilon_n}(\mathbf{1}_{Y^n}) \leq \limsup_{n \in \mathbb{N}} \widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A^n}) = \limsup_{n \in \mathbb{N}} \widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A_r}).$$

Finally, from remark 4.3 in García Trillos and Slepčev (2016) we deduce that

$$\limsup_{n \rightarrow \infty} \widetilde{TV}_{\tilde{\varepsilon}_n}(\mathbf{1}_{A^n}) \leq \sigma_\eta TV(\mathbf{1}_{A_r}),$$

and thus we conclude that $\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(\mathbf{1}_{A^n}) \leq \sigma_\eta TV(\mathbf{1}_{A_r})$. As a consequence we have

$$\limsup_{n \rightarrow \infty} GTV_{n,\varepsilon_n}(u^n) = \limsup_{n \rightarrow \infty} \frac{GTV_{n,\varepsilon_n}(\mathbf{1}_{Y^n})}{B_n(\mathbf{1}_{Y^n})} \leq \sigma_\eta \frac{TV(\mathbf{1}_{A_r})}{B(\mathbf{1}_{A_r})}$$

for each r , by continuity of the balance term. From the previous computations we conclude that $E_n(\mathcal{U}_n) \rightarrow E(\mathcal{U})$, and from (7.7), we deduce that $\mathcal{U}_n \rightarrow \mathcal{U}$ in the TL^1 -sense, so that \mathcal{U}_n does furnish the desired recovery sequence.

Density. To prove Proposition 24, we show that for any $\mathcal{U} = (\tilde{\mathbf{1}}_{A_1}, \dots, \tilde{\mathbf{1}}_{A_R})$ where each of the sets A_r has finite perimeter, there exists a sequence $\{\mathcal{U}_m = (\tilde{\mathbf{1}}_{A_1^m}, \dots, \tilde{\mathbf{1}}_{A_R^m})\}_{m \in \mathbb{N}}$ where each of the \mathcal{U}_m is induced by piecewise smooth sets, and such that for every $r \in \{1, \dots, R\}$

$$\mathbf{1}_{A_r^m} \xrightarrow{L^1(\nu)} \mathbf{1}_{A_r},$$

and

$$\lim_{m \rightarrow \infty} TV(\mathbf{1}_{A_r^m}; \nu) = TV(\mathbf{1}_{A_r}; \nu).$$

Note that in fact, by establishing the existence of such approximating sequence, it immediately follows that $\mathcal{U}_m \rightarrow \mathcal{U}$ in $(L^1(\nu))^R$ and that $\lim_{m \rightarrow \infty} E(\mathcal{U}_m) = E(\mathcal{U})$ (by continuity of the balance terms). We provide the construction of the approximating sequence $\{\mathcal{U}_m\}_{m \in \mathbb{N}}$ through the sequence of three lemmas presented below.

Lemma 27 *Let $\{A_1, \dots, A_R\}$ denote a collection of open and bounded sets with smooth boundary in \mathbb{R}^d that satisfy*

$$\mathcal{H}^{d-1}(\partial A_r \cap \partial A_s) = 0, \quad \forall r \neq s. \quad (7.8)$$

Let D denote an open and bounded set. Then there exists a permutation $\pi : \{1, \dots, R\} \rightarrow \{1, \dots, R\}$ such that

$$TV(\mathbf{1}_{A_{\pi(r)}} \cup_{s=\pi(r)+1}^R \mathbf{1}_{A_{\pi(s)}}; \nu) \leq TV(\mathbf{1}_{A_{\pi(r)}}; \nu), \quad \forall r \in \{1, \dots, R\}.$$

Proof The proof is by induction on R . **Base case:** Note that if $R = 1$ there is nothing to prove. **Inductive Step:** Suppose that the result holds when considering any $R-1$ sets as described in the statement. Let A_1, \dots, A_R be a collection of open, bounded sets with smooth boundary satisfying (7.8). By the induction hypothesis it is enough to show that we can find $r \in \{1, \dots, R\}$ such that

$$TV(\mathbf{1}_{A_r \cup_{s \neq r} A_s}; \nu) \leq TV(\mathbf{1}_{A_r}; \nu). \quad (7.9)$$

To simplify notation, denote by Γ_i the set ∂A_i and define a_{ij} as the quantity

$$a_{ij} := \int_{\Gamma_i \cap (A_j \cup_{s \neq i, k \neq j} A_k) \cap D} \rho^2(x) \, d\mathcal{H}^{d-1}(x).$$

Hypothesis (7.8) and (3.3) imply that the equality

$$TV(\mathbf{1}_{A_r \cup_{s \neq r} A_s}; \nu) = \int_{\partial(A_r \cup_{s \neq r} A_s) \cap D} \rho^2 \, d\mathcal{H}^{d-1} = \int_{\Gamma_r \cap (\cup_{s \neq r} A_s) \cap D} \rho^2 \, d\mathcal{H}^{d-1} + \sum_{s: s \neq r} a_{sr} \quad (7.10)$$

holds for every $r \in \{1, \dots, R\}$, as does the inequality

$$TV(\mathbf{1}_{A_r}; \nu) \geq \int_{\Gamma_r \cap (\cup_{s \neq r} A_s) \cap D} \rho^2(x) \, d\mathcal{H}^{d-1} + \sum_{s: s \neq r} a_{rs}. \quad (7.11)$$

If $TV(\mathbf{1}_{A_r \cup_{s \neq r} A_s}; \nu) > TV(\mathbf{1}_{A_r}; \nu)$ for every r then (7.11) and (7.10) would imply that

$$\sum_{s: s \neq r} a_{sr} > \sum_{s: s \neq r} a_{rs}, \quad \forall r,$$

which after summing over r would imply

$$\sum_{r=1}^R \sum_{s: s \neq r} a_{sr} > \sum_{r=1}^R \sum_{s: s \neq r} a_{rs} = \sum_{r=1}^R \sum_{s: s \neq r} a_{sr}.$$

This would be a contradiction. Hence there exists at least one r for which (7.9) holds. \blacksquare

Lemma 28 *Let D denote an open, bounded domain in \mathbb{R}^d with Lipschitz boundary and let (B_1, \dots, B_R) denote a collection of R bounded and mutually disjoint subsets of \mathbb{R}^d that satisfy*

$$(i) \text{TV}(\mathbf{1}_{B_i}; \mathbb{R}^d) < +\infty, \quad (ii) |D\mathbf{1}_{B_i}|_{\rho^2}(\partial D) = 0 \quad \text{and} \quad (iii) D \subseteq \bigcup_{r=1}^R B_r.$$

Then there exists a sequence of mutually disjoint sets $\{A_1^m, \dots, A_R^m\}$ with piecewise smooth boundaries which cover D and satisfy

$$\mathbf{1}_{A_r^m} \xrightarrow{L^1(\mathbb{R}^d)} \mathbf{1}_{B_r} \quad \text{and} \quad \lim_{m \rightarrow \infty} \text{TV}(\mathbf{1}_{A_r^m}; \nu) = \text{TV}(\mathbf{1}_{B_r}; \nu) \quad (7.12)$$

for all $1 \leq r \leq R$.

Proof The proof of this lemma follows very similar ideas to those used when proving that sets with smooth boundary approximate sets with finite perimeter (see Theorem 13.46 in Leoni (2009)). Since our goal is to approximate partitions of more than two sets, we need to modify the arguments slightly. We highlight the important steps in the proof and refer to Leoni (2009) and Ambrosio et al. (2000) for details.

First of all note that $\text{TV}(\mathbf{1}_{B_r}; \mathbb{R}^d)$ and $|D\mathbf{1}_{B_r}|_{\rho^2}(\partial D)$ are defined considering ρ as a function from \mathbb{R}^d into \mathbb{R} . We are using the extension considered when we introduced the weighted total variation at the beginning of subsection 3.1. Given that $\rho^2 : \mathbb{R}^d \rightarrow (0, \infty)$ is lower semi-continuous and bounded below and above by positive constants then, it belongs to the class of weights considered in Baldi (2001) where the weighted total variation is studied.

For $r = 1, \dots, R$, we consider sequences of functions $u_r^k \in C^\infty(\mathbb{R}^d, [0, 1])$ satisfying

$$u_r^k \xrightarrow{L^1(\mathbb{R}^d)} \mathbf{1}_{B_r} \quad \text{and} \quad \text{TV}(u_r^k; \nu) \rightarrow \text{TV}(\mathbf{1}_{B_r}; \nu), \quad \text{as } k \rightarrow \infty. \quad (7.13)$$

This can be achieved by using standard, radially symmetric mollifiers J_k and setting $u_r^k = J_k * \mathbf{1}_{B_r}$, where $*$ stands for convolution. The functions J_k have the form $J_k(x) = k^d J(k|x|)$, where $J : [0, \infty) \rightarrow [0, \infty)$ is a smooth, decreasing function satisfying $\int_{\mathbb{R}^d} J(|x|) dx = 1$. See Theorem 13.46 in Leoni (2009) for more details.

The (u_1^k, \dots, u_R^k) also satisfy one additional property that will prove useful: there exists a constant $\alpha > 0$ so that

$$\Sigma^k(x) := \sum_{r=1}^R u_r^k(x) = \mathbf{1}_D * J_k(x) \geq \alpha > 0 \quad \text{for all } x \in D.$$

To see this, note that the fact that D is an open and bounded set with Lipschitz boundary implies that (see Grisvard (1985), Theorem 1.2.2.2) there exists a cone $C \subseteq \mathbb{R}^d$ with non-empty interior and vertex at the origin, a family of rotations $\{R_{x,r}\}_{x \in D}$ and a number $\zeta > 0$ such that for every $x \in D$,

$$x + R_{x,r}(C \cap B(0, \zeta)) \subseteq D.$$

The isotropy of J_k implies that

$$\begin{aligned} \int_D J_k(x-y) dy &\geq \int_{x+R_{x,r}(C \cap B(0, \zeta))} J_k(x-y) dy = \int_{C \cap B(0, \zeta)} J_k(y) dy = \int_{C \cap B(0, \zeta)} J(|y|) dy \\ &\geq \int_{C \cap B(0, \zeta)} J(|y|) dy =: \alpha > 0, \end{aligned}$$

for some positive constant α . The summation $\Sigma^k(x)$ of all u_r^k therefore satisfies the pointwise estimate

$$\Sigma^k(x) := \sum_{r=1}^R u_r^k(x) = \int_{\mathbb{R}^d} J_k(x-y) \sum_{r=1}^R \mathbf{1}_{B_r}(y) dy \geq \int_D J_k(x-y) dy \geq \alpha$$

for all $x \in D$ as claimed.

Now, for $k \in \mathbb{N}$, $t \in (0, 1)$ and $r = 1, \dots, R$, we let $B_r^k(t) := \{x : u_r^k(x) > t\}$. From (7.13), Sard's lemma (see Corollary 13.45 of Leoni (2009)), the lower semi-continuity of the total variation and the coarea formula for total variation, it follows that for almost every $t \in (0, 1)$,

$$\partial B_r^k(t) \text{ is smooth } \forall k, \quad \lim_{k \rightarrow \infty} \text{TV}(\mathbf{1}_{B_r^k(t)}; \nu) = \text{TV}(\mathbf{1}_{B_r}; \nu), \quad \mathbf{1}_{B_r^k(t)} \xrightarrow{L^1(\nu)} \mathbf{1}_{B_r}, \quad (7.14)$$

for all $r = 1, \dots, R$.

Combining (7.14) with Lemma 2.95 in Ambrosio et al. (2000), we can find positive numbers t_1, \dots, t_R strictly smaller than α/R , such that for every $r = 1, \dots, R$

$$\partial B_r^k(t_r) \text{ is smooth } \forall k, \quad \lim_{k \rightarrow \infty} \text{TV}(\mathbf{1}_{B_r^k(t_r)}; \nu) = \text{TV}(\mathbf{1}_{B_r}; \nu), \quad \mathbf{1}_{B_r^k(t_r)} \xrightarrow{L^1(\nu)} \mathbf{1}_{B_r}, \quad (7.15)$$

and such that for $r \neq s$,

$$\mathcal{H}^{d-1}(\partial B_r^k(t_r) \cap \partial B_s^k(t_s)) = 0, \quad \forall k \in \mathbb{N}.$$

We let $B_r^k := B_r^k(t_r)$ for $r = 1, \dots, R$ and $k \in \mathbb{N}$. We claim that for every $k \in \mathbb{N}$, the sets B_1^k, \dots, B_R^k cover D . To see this, suppose there exists $x \in D \setminus (\bigcup_{r=1}^R B_r^k)$. This would imply that $u_r^k(x) \leq t_r$ for all r . In turn, $\Sigma^k(x) \leq \sum_{r=1}^R t_r < \alpha$, which contradicts the estimate on Σ^k obtained earlier.

For every $k \in \mathbb{N}$, we can now use the sets (B_1^k, \dots, B_R^k) as input in Lemma (27) to obtain a partition (A_1^k, \dots, A_R^k) of D , defined by

$$A_r^k := B_r^k \setminus \bigcup_{s=\pi_k^{-1}(r)+1}^R B_{\pi_k(s)}^k$$

where π_k is a permutation of $\{1, \dots, R\}$ guaranteeing that for every $r = 1, \dots, R$

$$\text{TV}(\mathbf{1}_{A_r^k}; \nu) \leq \text{TV}(\mathbf{1}_{B_r^k}; \nu). \quad (7.16)$$

Each A_r^k has a piecewise smooth boundary due to the fact that each B_r^k has a smooth boundary. The disjointness of (B_1, \dots, B_R) combines with the L^1 -convergence of $\mathbf{1}_{B_r^k}$ to $\mathbf{1}_{B_r}$ to show that $\mathbf{1}_{A_r^k} \xrightarrow{L^1(\mathbb{R}^d)} \mathbf{1}_{B_r}$ as well. Finally, the lower semi-continuity of the total variation together with (7.16) and (7.15) imply (7.12). ■

To complete the construction, and therefore to conclude the proof of Lemma 24, we need to verify the hypotheses (i) – (ii) of the previous lemma. This is the content of our final lemma.

Lemma 29 *Let D be an open bounded domain with Lipschitz boundary and let $\{A_1, \dots, A_R\}$ denote a disjoint collection of sets that satisfy*

$$A_r \subset D \quad \text{and} \quad TV(\mathbf{1}_{A_r}; \nu) < \infty.$$

Then, there exists a disjoint collection of bounded sets (B_1, \dots, B_R) that satisfy $B_r \cap D = A_r$ together with the properties

$$(i) \quad TV(\mathbf{1}_{B_r}; \mathbb{R}^d) < +\infty \quad \text{and} \quad (ii) \quad |D\mathbf{1}_{B_r}|_{\rho^2}(\partial D) = 0.$$

The proof follows from Remark 3.43 in Ambrosio et al. (2000) (which with minimal modifications applies to total variation with weight ρ^2). ■

8. Numerical Experiments

We now present numerical experiments to provide a concrete demonstration and visualization of the theoretical results developed in this paper. We conduct all of our experiments using the Cheeger cut algorithm of Bresson et al. (2012); we omit the ratio cut for the sake of brevity and to avoid redundancy. These experiments focus on elucidating when and how minimizers of the graph-based Cheeger cut problem,

$$u_n^* \in \operatorname{argmin}_{u \in L^1(\nu_n)} E_n(u) \quad \text{with} \quad B_n(u) := \min_{c \in \mathbb{R}} \frac{1}{n} \sum_{i=1}^n |u(\mathbf{x}_i) - c|, \quad (8.1)$$

converge in the appropriate sense to a minimizer of the continuum Cheeger cut problem

$$u^* \in \operatorname{argmin}_{u \in L^1(\nu)} E(u) \quad \text{with} \quad B(u) := \min_{c \in \mathbb{R}} \int_D |u(x) - c| \, dx. \quad (8.2)$$

We always take $\rho(x) := 1/\operatorname{vol}(D)$ as the constant density. The data points $\tilde{X}_n := \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ therefore represent i.i.d. samples from the uniform distribution. We consider the following two rectangular domains

$$D_1 := (0, 1) \times (0, 4) \quad \text{and} \quad D_2 := (0, 1) \times (0, 1.5)$$

in our experiments. We may easily compute the optimal continuum Cheeger cut for these domains. The characteristic function

$$\mathbf{1}_{A_1}(x) \quad \text{for} \quad A_1 := \{(x, y) \in D_1 : y > 2\},$$

when appropriately normalized, provides a minimizer $u_1^* \in L^1(\nu)$ of the continuum Cheeger cut in the former case, while the characteristic function

$$\mathbf{1}_{A_2}(x) \quad \text{for} \quad A_2 := \{(x, y) \in D_2 : y > 0.75\}$$

analogously furnishes a minimizer $u_2^* \in L^1(\nu)$ in the latter case. Figure 2 provides an illustration of a sequence of discrete partitions, computed from the graph-based Cheeger cut problem, converging to the optimal continuum Cheeger cut.

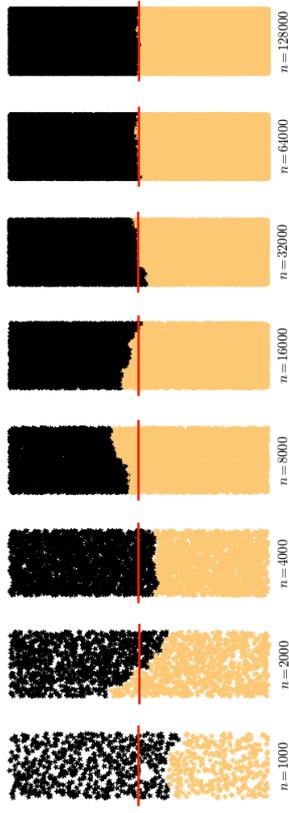

Figure 2: Visualization of the convergence process. Each figure depicts a computed optimal partition Y_n^* (in black) of one random realization of the random geometric graph $\mathcal{G}_n = (X_n, W_n)$ for each $k \in \{0, 1, \dots, 7\}$, where $n = 1000 \times 2^k$, $\varepsilon = n^{-0.3}$ and the domain considered is D_1 . Note that the scaling of ε with respect to n falls within the context of our theoretical results. The red line indicates the optimal cut, that is the boundary of the set $A_1 := \{(x, y) \in D_1 : y > 2\}$, at the continuum level.

Each of our experiments use the kernel $\eta(z) = \mathbf{1}_{\{|z| \leq 1\}}$ for the computation of the similarity weights,

$$w_{i,j} = \mathbf{1}_{\{\|\mathbf{x}_i - \mathbf{x}_j\| \leq \varepsilon_n\}},$$

so that the graphs $\mathcal{G}_n = (X_n, W_n)$ correspond to random geometric graphs (see Penrose (2003)). We use the domain D_1 only for the illustrations in Figure 2; all other experiments are conducted on the domain D_2 . We use the steepest descent algorithm of Bresson et al. (2012) to solve the graph-based Cheeger cut problem on these graphs. This algorithm relies upon a non-convex minimization, and its solutions depend upon the choice of initialization. We initialize it with the “ground-truth” partition $Y_n^i := A_i \cap X_n$ in an attempt to avoid sub-optimal solutions and to bias the algorithm towards the correct continuum cut. We terminate the algorithm once three consecutive iterates show 0% change in the corresponding partition of the graph. We let Y_n^* denote the partition of \mathcal{G}_n returned by the algorithm, which we view as the “optimal” solution of the graph-based Cheeger cut problem. Finally, we quantify the error between the optimal continuum partition $A_i \subseteq D_i$ and the n^{th} optimal graph-based partition Y_n^* of \mathcal{G}_n simply by using the percentage of misclassified data points,

$$\varepsilon_n = \min \left\{ \frac{1}{n} \sum_{i=1}^n |\mathbf{1}_{Y_n^i}(\mathbf{x}_i) - \mathbf{1}_{Y_n^*}(\mathbf{x}_i)|, \frac{1}{n} \sum_{i=1}^n |\mathbf{1}_{Y_n^i}(\mathbf{x}_i) - \mathbf{1}_{(Y_n^*)^c}(\mathbf{x}_i)| \right\}. \quad (8.3)$$

The rationale for this choice comes from the following observation. If $T_n(x)$ denotes a sequence of transportation maps between ν_n and ν that satisfy $\|\operatorname{Id} - T_n\|_\infty = o(1)$, then by

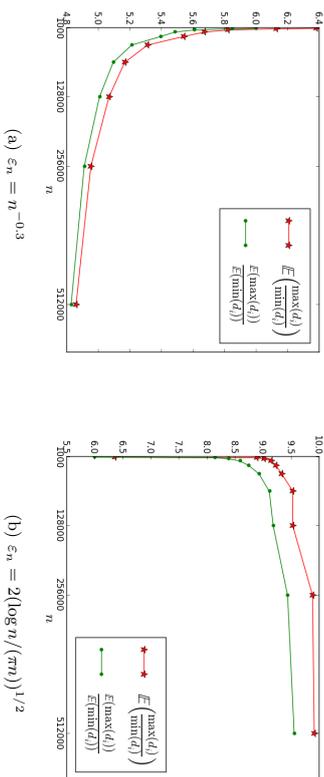

Figure 3: Graph regularity. We work with the domain D_2 . For each scaling of ε_n with n , the corresponding plot depicts two measures of regularity for the sequence of random geometric graphs. The first measure (in red) is the average $E[\max(d_i)/\min(d_i)]$, the average ratio of the maximal degree $\max(d_i)$ of G_n to the minimal degree. For each n , the average is computed over 1,440 independent graph realizations. The second measure (in green) corresponds to the ratio of the average maximal degree to the average minimal degree, computed over 1,440 independent trials as before. The graphs with $\varepsilon_n = n^{-0.3}$ become increasingly regular while the graphs with $\varepsilon_n = 2(\log n / (\pi n))^{1/2}$ become increasingly irregular.

the change of variables (2.2) (and ignoring the “min” for simplicity) we have

$$e_n = \int_D |\mathbf{1}_{A_i} \circ T_n(x) - \mathbf{1}_{Y_n^*} \circ T_n(x)| dx.$$

By the triangle inequality, we therefore obtain

$$\begin{aligned} \|\mathbf{1}_{A_i} - \mathbf{1}_{Y_n^*} \circ T_n\|_{L^1(\varphi)} &:= \int_D |\mathbf{1}_{A_i}(x) - \mathbf{1}_{Y_n^*} \circ T_n(x)| dx \\ &\leq e_n + \int_D |\mathbf{1}_{A_i}(x) - \mathbf{1}_{A_i} \circ T_n(x)| dx \leq e_n + O(\|\text{Id} - T_n\|_\infty). \end{aligned}$$

The last inequality follows since each A_i has a piecewise smooth boundary. In this way, if $\|\text{Id} - T_n\|_\infty = o(1)$ then verifying $e_n = o(1)$ suffices to show that TL^1 convergence of minimizers holds. Under the assumption that $\|\text{Id} - T_n\|_\infty = o(1)$, a similar argument shows that $e_n = o(1)$ is equivalent to TL^1 convergence. This equivalence motivates using e_n as a quantitative measure of TL^1 convergence in our experiments.

To check convergence, and to explore the issues related to Remark (2), we perform exhaustive numerical experiments for three distinct scalings of ε_n with respect to the total

number of sample points on the domain D_2 . Specifically, we consider the scalings

$$\varepsilon_n = n^{-0.3}, \quad \varepsilon_n = 2 \left(\frac{\log n}{\pi n} \right)^{1/2}, \quad \text{and} \quad \varepsilon_n = \left(\frac{\log n}{\pi n} \right)^{1/2}.$$

These scalings correspond to three distinct types of random geometric graphs. The first scaling falls well within the acceptable bounds for ε_n covered by our consistency theorems. Random graph theory shows that G_n is almost surely connected in this regime: the probability that G_n is disconnected vanishes in the $n \rightarrow \infty$ limit. The second scaling also gives rise to a sequence G_n of connected random geometric graphs for n sufficiently large (see Gupta and Kumar (1999), Penrose (2003)). However, the geometric graphs G_n exhibit rather different structural properties in this case: if $\varepsilon_n = n^{-0.3}$ then the graphs G_n become increasingly regular as $n \rightarrow \infty$, while if $\varepsilon_n = 2(\log n / (\pi n))^{1/2}$ then the graphs G_n become increasingly irregular. See Figure 3 for an illustration. The final scaling corresponds to a scaling below the connectivity threshold of random geometric graphs (see Gupta and Kumar (1999), Penrose (2003)). The graphs G_n are disconnected for large enough n under this scaling. However, in this regime each G_n has a “giant component” (a connected subgraph \mathcal{H}_n of G_n) that contains all but a small handful of vertices (see Figure 4 at right).

We designed our experiments to explore the extent to which a lack of graph-regularity or graph-connectivity might cause inconsistency of balanced cuts. The first scaling $\varepsilon_n = n^{-0.3}$ serves as a benchmark or control. It falls within the context of our consistency theorems, and so provides a means of determining the “typical” behavior of balanced cut algorithms when consistency holds. The second scaling, which falls outside the realm of our consistency results, tests whether connected graphs with different structural properties still lead to consistent results. The final scaling probes the realm where connectivity fails, but in a mild and easily correctable way. As the theory outlined above indicates, if we pose the balanced cut minimization over the full graph G_n then we can no longer expect consistency to hold. These graphs pose no practical difficulty, however, as we may simply extract the giant component \mathcal{H}_n of each G_n and then minimize the balanced cut over this connected subgraph. We simply assign each vertex in $G_n \setminus \mathcal{H}_n$ to one of the two classes uniformly at random. Our last experiment explores whether consistency might still hold using this modified approach.

Table 1 and Figure 4 report the results of these experiments. In all cases, we measure error by using the expected number of misclassified points (8.3) averaged over the number of trials indicated in Table 1. We used a smaller number of trials for large n simply due to the overwhelming computational burden. In general, we observe that sparser graphs lead to larger error (see Table 1). We caution that the corresponding rates reported in Figure 4 may not coincide with the true asymptotic rate of convergence, since we expect that as $n \rightarrow \infty$ the denser graph will still produce lower error. We furthermore remark that the measure of error we consider in Table 1 is also too weak to show convergence in the almost sure sense as provided by our consistency theorems. It does, however, indicate consistency in the weaker sense of convergence in probability (via Markov’s inequality). The algorithm we use to optimize the discrete Cheeger cut also relies upon a non-convex minimization (Bresson et al., 2012), so we cannot say with certainty that the corresponding computed optimizers are global. Instead, initializing the algorithm with the “ground truth” partition biases the

Table 1: Average error $\mathbb{E}(\varepsilon_n)$ between partitions. For each n and each scaling of ε_n , we obtained an estimate of the error $\mathbb{E}(\varepsilon_n)$ by computing the mean of (8.3) over the indicated number of independent trials. Figure 4 provides a corresponding error plot.

algorithm toward the correct cut. If the algorithm were to fail under these circumstances, it would provide strong numerical evidence *against* consistency.

The results appear rather similar regardless of whether ε_n lies in the strongly connected ($\varepsilon_n = n^{-0.3}$), weakly connected ($\varepsilon_n = 2(\log n/(\pi n))^{1/2}$) or weakly disconnected ($\varepsilon_n = (\log n/(\pi n))^{1/2}$) regimes. Indeed, in each case the error $\mathbb{E}(\varepsilon_n)$ decays to zero with a polynomial rate. The varying degree properties of the random geometric graphs in these regimes do not seem to play much of a role. A disconnected graph, while more problematic, is not an insurmountable obstacle provided \mathcal{G}_n contains a giant component. A naive handling of the disconnected vertices still leads to plausibly consistent results. While certainly not conclusive evidence, it seems reasonable to conjecture that consistency should hold, perhaps in the weaker probabilistic sense, for ε_n as small as the critical scaling for connectivity. We leave a further exploration of this for future research.

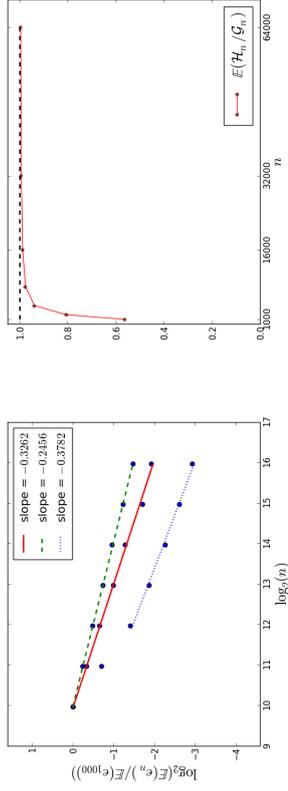

Figure 4: At left: a log-log plot of the relative expected errors $\mathbb{E}(\varepsilon_n)/\mathbb{E}(\varepsilon_{1000})$ computed in Table 1 together with a corresponding linear approximation for n large. The solid red line corresponds to the scaling $\varepsilon_n = n^{-0.3}$, the dashed green line corresponds to the scaling $\varepsilon_n = 2(\log n/(\pi n))^{1/2}$ and the dotted blue line corresponds to the scaling $\varepsilon_n = (\log n/(\pi n))^{1/2}$ of the disconnected regime. The linear approximation for the scaling $\varepsilon_n = (\log n/(\pi n))^{1/2}$ is given for those graphs \mathcal{G}_n that, in expectation, have more than 90% of vertices in the giant component. At right: the expected fraction of vertices that lie in the giant component \mathcal{H}_n of the disconnected random geometric graph \mathcal{G}_n .

Abstract

We address the problem of selecting groups of jointly informative, continuous, features in the context of classification and propose several novel criteria for performing this selection. The proposed class of methods is based on combining a Gaussian modeling of the feature responses with derived bounds on and approximations to their mutual information with the class label. Furthermore, specific algorithmic implementations of these criteria are presented which reduce the computational complexity of the proposed feature selection algorithms by up to two-orders of magnitude. Consequently we show that feature selection based on the joint mutual information of features and class label is in fact tractable; this runs contrary to prior works that largely depend on marginal quantities. An empirical evaluation using several types of classifiers on multiple data sets show that this class of methods outperforms state-of-the-art baselines, both in terms of speed and classification accuracy.

Keywords: feature selection, mutual information, entropy, mixture of Gaussians

1. Introduction

Given a collection of data in \mathbb{R}^D it is often advantageous to reduce its dimensionality by either extracting (Hinton and Salakhutdinov, 2006) or selecting (Guyon and Elisseeff, 2003) a subset of $d \ll D$ features, which carry “as much information as possible”. The motivation behind this dimensionality reduction can be either to control over-fitting by reducing the capacity of the classifier space or to improve the computational overhead by reducing the optimization domain. It can also be used as a tool to facilitate the understanding or the graphical representation of high-dimensional data.

In the present work we focus on the selection, rather than extraction, of features. In general feature selection methods can be divided into two large families: Techniques from the first group, *filters*, are predictor agnostic as they do not optimize the selection of features

for a specific prediction method. They are usually based on classical statistics or information theoretic tools; the novel methods we propose in this article belong to this category. Techniques from the second group, *wrappers*, choose features to optimize the performance of a certain predictor. They usually require the retraining of the predictor at each step of a greedy search. Consequently they are typically computationally more expensive than filters. Furthermore, as the selected features are tailored to a specific predictor, they often do not work well with other families of predictors.

In the following we present a filter approach to feature selection in the context of classification based on the maximization of the mutual information between the selected features and the class to predict. The use of mutual information as a criterion for feature selection has been extensively studied in the literature, and can be motivated in the context of classification by Fano’s inequality

$$H(Y|\hat{Y}) \leq 1 + P(e) \log(|\mathcal{Y}|-1)$$

where Y, \hat{Y} are the true and predicted labels respectively, while e is the event that $Y \neq \hat{Y}$. Combining the above with the data processing inequality (specifically the chain $Y \rightarrow X \rightarrow \hat{Y}$) results in the following lower bound on the probability of an incorrect classification P_E by

$$P(e) \geq \frac{H(Y) - I(X; Y) - 1}{(|\mathcal{Y}|-1)}$$

where $H(Y)$ is the entropy of the class prior and $I(X; Y)$ is the mutual information between the output (Y) and input (X) features.

An important issue that arises in this context, is that of the joint “informativeness” of the selected features. Though wrappers by their very nature tend to select features which are jointly informative, this issue is only partially addressed for filters due to the resulting computational complexity and need for very large training sets. Most existing methods (Peng et al., 2005; Fleuret, 2004; Hall and Smith, 1999; Liu and Yu, 2003) typically compromise by relying on the mutual information between individual features or very small groups of features (pairs, triplets) and the class. We argue however, that rather than compromising on the joint behavior of the selected features, it is preferable to accept a compromise on the density model, which will allow to analyze this joint behavior in an efficient manner.

In a classification task with continuous features context, if we aim at taking into account the joint behavior of features, a Gaussian model is a natural choice. This unfortunately leads to a technical difficulty: If such a model is used for the conditional distributions of the features given the class then the non-conditioned distribution is a mixture of Gaussians and its entropy has no simple analytical form. There is extensive prior work on the problem of approximating the entropy of a mixture of Gaussians (Hershey and Olsen, 2007), but most of the existing approximations are too computationally intensive to be used during an iterative optimization process which requires the estimation of the mutual information of a very large number of subsets of features with the class to predict.

We propose here an alternative approach wherein we derive both bounds on and approximations to the Mutual Information – and maximize these quantities *in lieu* of the true mutual information. We also propose specific algorithmic implementations that rely

* Part of this research was conducted while at the Computer Vision and Learning group of the Idiap Research Institute

on updating the inverses of covariance matrices iteratively instead of computing them from scratch drastically reducing the computational cost during the optimization of the selected feature set.

2. Related Works

When selecting d features from a pool of D candidates in the context of a classification task, it does not suffice to select features independently informative with respect to the class. When such greedy strategies are employed the risk of acquiring redundant, or even identical, features increases. Thus, it is also important that these features exhibit low redundancy between them: *joint* informativeness is at the core of feature selection.

As mentioned in the introduction, wrappers, due to their very nature, address this issue by creating subsets of features that perform well when combined with a specific predictor. Examples of such methods include iteratively training a *SVM*, removing at each iteration the features with the smallest weights (Guyon et al., 2002) or employing Adbost in connection with decision stumps to perform feature selection (Das, 2001). Other wrapper methods impose sparsity on the resulting predictor thus implicitly performing feature selection, for instance by using a Laplacian prior to perform sparse logistic regression (Cawley et al., 2006), casting a l_0 regularized *SVM* as a mixed integer programming problem (Tan et al., 2010), or imposing sparsity via a l_1 -norm regularizer (Argyriou et al., 2008) or l_1 -clipped norm (Xu et al., 2014). Such wrappers, that train predictors only once, tend to be much faster, however like other wrappers they tend not to generalize well across predictors. A wrapper approach that shares similarities with the algorithm proposed here, forward regression (Das and Kempe, 2011) iteratively augments a subset of features to build a linear regressor which is near-optimal in a least-squared error sense.

In the context of filters, the simplest methods are those that calculate statistics on individual features and then rank these features based on these values, keeping the d features of highest rank. Examples of such statistics are Fisher score, mutual information between the feature and the class (information gain), χ^2 etc. Though quick to compute, such approaches typically result in large feature redundancy and sub-optimal performance.

A slightly more computationally complex approach, the ReliefF algorithm (Robnik-Sikrija and Kononenko, 2003), looks at individual features assigning a score by randomly selecting samples and calculating for that feature and for each sample the difference in distance between the random sample and the nearest sample of the same class, dubbed “nearest hit”, and the random sample and the nearest sample of a different class, dubbed “nearest miss”. Despite looking at features in isolation, it has been shown to perform well in practice.

In the work on mRMR feature selection (Pang et al., 2005) the authors attempt to address the issue of redundancy by selecting feature of maximum relevance and minimum redundancy, that is features with high mutual information with the class and low mutual pairwise information with the remaining selected features, thus selecting features that are not pairwise redundant. Quadratic programming feature selection (Rodriguez-Lujan et al., 2010) casts the feature selection as an optimization task and can be used in conjunction with a number of similarity measure. When combined with mutual information it resembles

mRMR though it provides a ranking of features as opposed to the greedy selection process of mRMR.

Another approach (Vasconcelos, 2003) based on mutual information attempts to diversify the conditional distributions $p_{X|Y}$ by greedily choosing features that maximize the Kullback-Leibler divergence between the conditionals and the prior p_X . However only the marginal distributions pertaining to individual features are used and as such no joint informativeness of features is exploited.

The *FCBF* algorithm (Liu and Yu, 2003) uses symmetrical uncertainty $\frac{I(X;Y)}{I(X;Y)}$ as a quantitative criterion and adds features to a pool based on a novel concept of predominant correlation, namely that the feature is more highly correlated with the class than any of the features already in the pool. *CFS* (Hall and Smith, 1999) similarly combines symmetric uncertainty with Pearson’s correlation to add features exhibiting low correlation with the features already in the pool.

Redundancy may also be addressed via the concept of a Markov Blanket (Margaritis, 2009). The Markov blanket of a variable X is defined as the set of variables S such that X is independent of the remaining variables $D \setminus (S \cup X)$ given the values of the variables in S . Based on this concept, the authors in (Fleuret, 2004) select features that have high mutual information with the class when conditioned on one of the features already in the pool. The resulting algorithm is suitable only for binary data. Here however we explicitly address the problem of feature selection in a continuous domain.

Closely related, at least conceptually, to the work presented here is prior work (Torkkola, 2003) which similarly attempts to find features that are jointly informative by resorting to a Gaussian modeling. In that work however the aim is feature extraction and the mutual information is used as an objective to guide a gradient ascent algorithm.

Another promising line of work is that of (Song et al., 2012) which avoids density estimation necessary in mutual information based approaches by considering the Hilbert-Schmidt Independence Criterion. The authors show how to obtain unbiased estimates of the HSIC quantity. Furthermore the method can be kernelized thus allowing for the discovery of dependencies in high-(possibly infinite) dimensional feature space. The Hilbert-Schmidt Independence Criterion has also been used in conjunction with l_1 -norm regularization (Yamada et al., 2014).

Finally, we note a family of feature selection algorithms, which have become very popular in recent years, based on spectral clustering. In such approaches, features can be selected based on their influence on the affinity graph Laplacian (Jiang and Ren, 2011), or by analyzing the spectrum of the Laplacian matrix (Wolf and Shashua, 2005).

3. Feature Selection Criteria

We propose two novel criteria which characterize the informativeness of a set of features in a classification context using their mutual information with the class under a Gaussian model of the features given the class. While this approach is conceptually straight-forward, it requires the evaluation of the entropy of a mixture of Gaussians for which no closed-form expression is available.

Our first approach, dubbed “Gaussian compromise” and described in § 3.2.1, uses the entropy of a single Gaussian of same expectation and variance as the mixture to obtain an upper bound on, and subsequently an approximation to, the true entropy.

Table 1: Notation

$F = \{X_1, X_2, \dots, X_D\}$	the set of candidate features
X_j	a single feature
Y	the class label
S	a subset of F
S_{n-1}	the set of features selected up until iteration n
$\Sigma_{j,S}$	the covariance matrix of the features in S
$\Sigma_{j,S}^2$	the covariance vector of feature X_j and the features in S
$\sigma_{i,j}^2$	the covariance of features X_j and X_i
σ_i^2	the variance of feature i
Σ_y^S	the variance of the features in S conditioned on $Y = y$
$\sigma_{j S}^2$	the variance of feature X_j conditioned on the value of the features in S
$f_{j,S}$	the density of a normal approximation of the class conditional distributions
f^*	the Gaussian approximation of the joint law $\sum_y p_y f_y$
p_y	the prior on the class variable Y

Our second approach, described in § 3.2.2 is based on a decomposition of the mutual information, in the binary class case, as a sum of Kullback-Leibler divergence terms, which can be efficiently approximated. The n -class case is addressed by averaging the obtained quantity over the one-vs-all sub-problems.

3.1 Mutual Information and the Gaussian Model

Given a continuous variable X and a finite variable Y , their mutual information is defined as

$$I(X; Y) = H(X) - H(X|Y) \quad (1)$$

$$= H(X) - \sum_y H(X|Y = y)P(Y = y). \quad (2)$$

Using a Gaussian density model for continuous variables is a natural strategy, due in part to the simplicity of its parametrization, and to its ability to capture the joint behavior of its components. Moreover, the entropy of a n -dimensional multivariate Gaussian $X \sim \mathcal{N}(\mu, \Sigma)$ has a simple and direct expression, namely

$$H(X) = \frac{1}{2} \log(|\Sigma|) + \frac{n}{2} (\log 2\pi + 1).$$

3.2 Bounds on the Mutual Information and the Entropy

Estimating the mutual information as defined in equation (2) requires the estimation of the entropy of both the conditional distributions $X|Y = y$ for all y , and that of X itself. If we model the former with Gaussian distributions, the latter is a mixture of Gaussian distributions, the entropy of which has no simple analytic form.

We propose to mitigate this problem by deriving upper bounds and approximations with tractable forms. Let $f_y, y = 1, \dots, C$ denote Gaussian densities on \mathbb{R}^D , p_y a discrete distribution on $\{1, \dots, C\}$, and f^* the Gaussian approximation of the joint law

$$f = \sum_y f_y p_y,$$

that is the Gaussian density of same expectation and covariance matrix as the mixture. Let Y be a random variable of distribution p_y and X a continuous random variable with conditional distributions $\mu_{X|Y=y} = f_y$.

3.2.1 GAUSSIAN COMPROMISE CRITERION

As mentioned, we propose here to use an approximation of $H(f)$ based on the entropy of $H(f^*)$. While modeling f as a Gaussian is not consistent with the Gaussian models of the conditioned densities, estimating the mutual information with it still has all the important properties one desires for continuous feature selection:

- It captures the information content of individual features, since adding a non informative feature would change by the same amount all the terms of equation (2).
- It accounts for redundancy, since linearly dependent features would induce a small determinant of the covariance matrix and by extension small mutual information. This can be seen if we consider that the determinant of a matrix which has rows (or columns) which are linearly dependent is 0.
- It normalizes with respect to any affine transformation of the features, since such a transformation changes by the same amount all the densities in equation (2). This can be seen if we consider that translation has no effect on the covariance matrix and that a linear transformation A gives

$$H(AX) = \frac{1}{2} \log(|A\Sigma A^T|) + \frac{n}{2} (\log 2\pi + 1) = H(X) + \log(|A|).$$

However, this first-order approximation suffers from a core weakness, namely that the entropy of f^* can become arbitrarily larger than the entropy of $\sum_y p_y f_y$ (see figure 1). This leads to degenerated cases where families of features look “infinitely informative”. This effect can be mitigated by considering the following upper bound on the true entropy $H(\sum_y p_y f_y)$.

We have by definition

$$I(X; Y) = H\left(\sum_y f_y p_y\right) - \sum_y H(f_y) p_y.$$

Since f^* is a Gaussian density, it has the highest entropy for a given variance, and thus $H(f^*) \geq H(\sum_y f_y p_y)$, hence

$$I(X; Y) \leq H(f^*) - \sum_y H(f_y) p_y. \quad (3)$$

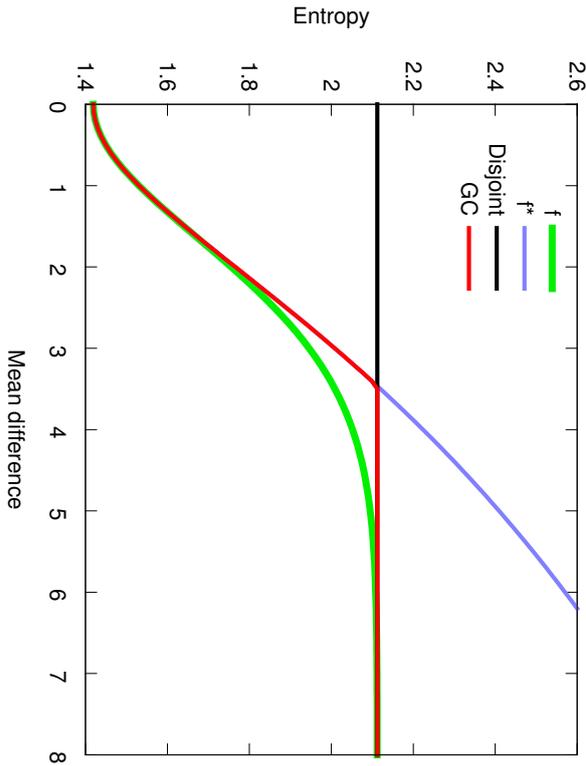

Figure 1: This graph shows several estimates of the entropy of a mixture of two IID Gaussian densities of variance 1, as a function of the difference between their means. The green curve is the true value of the entropy, estimated numerically. The blue curve is the entropy of a single Gaussian fitted on the mixture. The black line stands for the limit entropy when the two components are ‘far apart’. Finally, the red curve is the upper bound described in § 3.2.1.

The mutual information between X and Y is upper bounded by the entropy of Y as Y is discrete, hence

$$I(X; Y) \leq H(Y) = -\sum_y p_y \log p_y,$$

from which we get

$$I(X; Y) \leq \sum_y (H(f_y) - \log p_y) p_y - \sum_y H(f_y) p_y. \quad (4)$$

Taking the min of inequalities (3) and (4), we obtain the following upper bound

$$I(X; Y) \leq \min \left(H(f^*), \sum_y (H(f_y) - \log p_y) p_y \right) - \sum_y H(f_y) p_y. \quad (5)$$

Figure 1 illustrates the behavior of this bound in the case of two IID Gaussians. An upper bound on $H(X)$ follows directly:

From the concavity of the entropy function we obtain the following lower bound

$$H(X) \geq \sum_y p_y H(f_y). \quad (6)$$

Combining eq. (5), (6) gives

$$\min \left(H(f^*), \sum_y (H(f_y) - \log(p_{y_i})) p_{y_i} \right) \geq H(f) \geq \sum_y p_y H(f_y).$$

Note that the difference between upper and lower bound is itself bounded

$$-\sum_y p_y \log(p_{y_i}) \geq \min \left(H(f^*), \sum_y (H(f_y) - \log(p_{y_i})) p_{y_i} \right) - \sum_y p_y H(f_y).$$

The proposed GC criterion is based on an approximation to $H(X)$, namely

$$\tilde{H}(f) = \sum_y p_y \min(H(f^*), H(f_y) - \log(p_{y_i})).$$

We note that this approximation is also upper bounded by

$$\min \left(H(f^*), \sum_y (H(f_y) - \log(p_{y_i})) p_{y_i} \right) \geq \tilde{H}(f).$$

Furthermore, since $\forall y$

$$H(f_y) - \log(p_{y_i}) > H(f_y),$$

it follows that if $\forall y$

$$H(f^*) \geq H(f_y) \quad (7)$$

then

$$\tilde{H}(f) \geq \sum_y p_y H(f_y),$$

meaning the approximation $\tilde{H}(f)$ also lies between the two bounds and by extension

$$-\sum_y p_y \log(p_y) \geq |\tilde{H}(f) - H(f)|.$$

For (7) to hold it suffices that

$$\lambda_i^* \geq \lambda_i^y, \forall i, y \quad (8)$$

where λ_i^*, λ_i^y are the i th (sorted by magnitude) eigenvalues of Σ^* and Σ^y respectively, in which case

$$\prod_i \lambda_i^* \geq \prod_i \lambda_i^y.$$

That is to say a sufficient condition is that the variance of f^* when projected along any of the eigenvectors of the covariance matrix Σ^* is at least as large as the variance of f^y when projected along the corresponding eigenvector of $\Sigma^y, \forall y$. Alternatively, for (7) to hold it suffices that $\forall x, y$ (and in particular $\forall x$ which are eigenvectors of Σ^y)

$$x^T \Sigma^* x \geq x^T \Sigma^y x.$$

Given that

$$\Sigma^* = \sum_y p_y \Sigma^y + \sum_y p_y (\mu_y - \mu^*) (\mu_y - \mu^*)^T \quad (9)$$

this translates to

$$\sum_y p_y x^T \Sigma^y x + \sum_y p_y x^T (\mu_y - \mu^*) (\mu_y - \mu^*)^T x \geq x^T \Sigma^y x.$$

That is to say that it suffices that the variance of f_y along any direction can be accounted for either by the variances of the mixture components along this direction or by the variance of the mixture means in this direction. Note that in this case (8) also holds.

Based on the above, we use the following approximation to the mutual information to perform feature selection

$$\tilde{I}(X; Y) = \sum_y \min(H(f^*), H(f_y) - \log p_y) p_y - \sum_y H(f_y) p_y. \quad (10)$$

In figure 2 we show a comparison of the GC-approximation and the true mutual information. To compare the two we draw samples from a mixture of five Gaussians and use these samples to estimate the mutual information. Specifically, we create this mixture by sampling the expectations uniformly in $[-5, 5]$, sampling the standard deviations uniformly in $[0.001, 2.001]$ and the priors in $[0, 1]$ (which are then normalized). We observe that by taking the minimum over two sub-optimal estimators (the prior and the fitted Gaussian f^*) we obtain a very good estimator of the true mutual information.

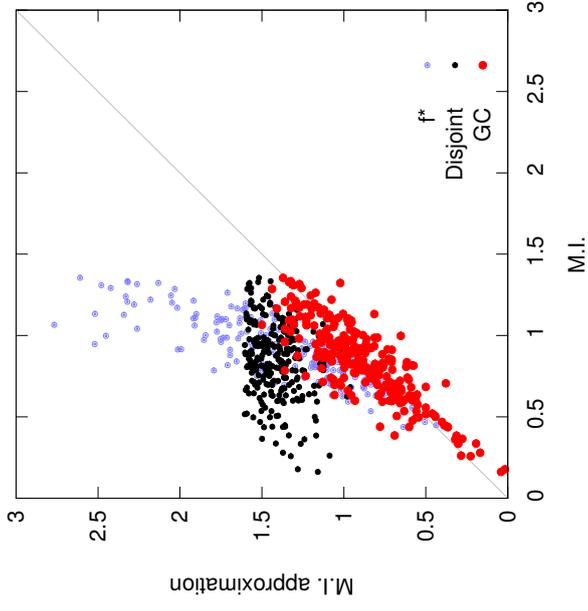

Figure 2: Comparison of the mutual information of a mixture of 5 Gaussians as estimated using the GC-approximation, using the fitted Gaussian f^* , and using the prior distribution (marked as *disjoint*), with the true mutual information calculated numerically.

3.2.2 KL-BASED BOUND

We derive here a more general bound in the case of a distribution f which is a mixture of two distributions $f = p_1 f_1 + p_2 f_2$. In this case we have:

$$H(f) = - \int_{-\infty}^{\infty} p_1 f_1(u) \log(p_1 f_1(u) + p_2 f_2(u)) \log(p_1 f_1(u) + p_2 f_2(u)) du.$$

Working with the first term in the above integral we have:

$$\begin{aligned} & - \int_{-\infty}^{\infty} p_1 f_1(u) \log(p_1 f_1(u) + p_2 f_2(u)) du \\ &= - \int_{-\infty}^{\infty} p_1 f_1(u) \log \left(1 + \frac{p_2 f_2(u)}{p_1 f_1(u)} \right) du \\ & \quad - \int_{-\infty}^{\infty} p_1 f_1(u) \log(p_1 f_1(u)) du \\ &= c - \int_{-\infty}^{\infty} p_1 f_1(u) \log \left(1 + \frac{p_2 f_2(u)}{p_1 f_1(u)} \right) du + p_1 H(f_1(u)) \\ &= p_1 D_{KL}(f_1(u) \| f_2(u)) + p_1 H(f_1(u)) + c', \end{aligned}$$

where c, c' are constants related to the mixture coefficients and the inequality comes from the fact that $\log(1+x) \geq \log(x)$. Similarly for the second term we have:

$$- \int_{-\infty}^{\infty} p_2 f_2(u) \log(p_1 f_1(u) + p_2 f_2(u)) du \leq p_2 D_{KL}(f_2(u) \| f_1(u)) + p_2 H(f_2(u)) + c''.$$

Based on this we have:

$$H(f) \leq p_2 D_{KL}(f_2(u) \| f_1(u)) + p_2 H(f_2(u)) + p_1 D_{KL}(f_1(u) \| f_2(u)) + p_1 H(f_1(u)) + c''',$$

and by extension we have the following bound on the mutual information:

$$I(X; Y) \leq p_2 D_{KL}(f_2(u) \| f_1(u)) + p_1 D_{KL}(f_1(u) \| f_2(u)) + c''''.$$

In the case where $f_1 = N(\mu_1, \Sigma_1)$ and $f_2 = N(\mu_2, \Sigma_2)$ are both multivariate Gaussian distributions of dimensionality D , we have that:

$$D_{KL}(f_1 \| f_2) = \frac{1}{2} \left(\text{tr}(\Sigma_2^{-1} \Sigma_1) - \ln \frac{|\Sigma_1|}{|\Sigma_2|} - D \right) + \frac{1}{2} (\mu_2 - \mu_1)^T \Sigma_2^{-1} (\mu_2 - \mu_1).$$

In the case of a binary classification problem, we can directly work with the above quantity for our mixture of two Gaussians. In the case where $|Y| > 2$, we consider the resulting $|Y|$ one-against-all binary classification problems and attempt to maximize the average of the upper bounds of the $|Y|$ mutual information values.

For each class y we consider the following mixture model:

$$f = p_y f_y + (1 - p_y) f_{Y \setminus y}$$

where the $f_{Y \setminus y}$ is the conditional distribution of $X|Y \neq y$. We then calculate the upper bound of the mutual information for all the possible mixtures f , one for each y .

3.3 Greedy Forward Selection

The derived bounds and approximations provide measures for assessing the optimal set of features S_N^* of size N . However as there are $\frac{F!}{N!(F-N)!}$ possible sets S_N of size N finding the optimal one by checking all the candidate sets is computationally intractable. Due to this intractability we employ a greedy optimization process in order to find a good approximation S_N .

In particular, we use greedy forward selection (see table 2) to iteratively build a sequence of sets S_n with $n = 1, \dots, N$ where each set S_n is built by adding one feature $X_{j(n)}$ to the previous set S_{n-1} , i.e. $S_n = S_{n-1} \cup X_{j(n)}$. At a given iteration n , the greedy forward selection algorithm calculates for every candidate feature $X_j \in F \setminus S_{n-1}$, the mutual information between the set $S_n^* = S_{n-1} \cup \{X_j\}$ and the label Y . It then creates the set S_n by adding that feature which leads to the largest value of the optimization criterion.

3.4 Complexity of the Gaussian Compromise Method

Though forward selection leads to a computationally tractable feature selection algorithm, it remains nonetheless very expensive. In the case of the Gaussian compromise approach, at each iteration n and for each feature X_j not in S_{n-1} , forward selection requires the estimation of an approximation of $I(S_{n-1} \cup \{X_j\}; Y)$, which in turn requires the estimation of $|Y| + 1$ determinants of the size $n \times n$ covariance matrices. A naive approach would be to calculate these determinants from scratch, incurring a cubic cost of $O(n^3)$ for the calculation of each determinant and a $O(|Y| F \setminus S_{n-1} |n|^3)$ cost per iteration with a $O(|Y| n^2)$ memory requirement for storing the covariance matrices and their inverses.

As shown in previous work (Lefakis and Fleuret, 2014) however it is possible to derive both an $O(|Y| F \setminus S_{n-1} |n|^2)$ algorithm with $O(|Y| n^2)$ memory requirements and an $O(|Y| F \setminus S_{n-1} |n|)$ algorithm with $O(|Y| n^2 + |Y| F \setminus S_{n-1} |n|)$ memory requirements. In the following we expand upon those methods, in particular the $O(|Y| F \setminus S_{n-1} |n|)$ one, and

present an approach that allows for a $O(|Y||F \setminus S_{n-1}|n)$ with $O(|Y|n^2 + |Y||F \setminus S_{n-1}|)$ memory requirements.

In order to speed up computations, we first note that for three random variables X , Y , Z

$$I(X, Z; Y) = I(Z; Y) + I(X; Y | Z)$$

which in the context of our forward selection algorithm, $\forall X_j \in F \setminus S_{n-1}$, and with $S'_n = S_{n-1} \cup \{X_j\}$, translates to

$$I(S'_n; Y) = I(S_{n-1}; Y) + I(X_j; Y | S_{n-1}).$$

The first term in the above expression is common for all candidate features X_j , meaning that finding the feature X_j that maximizes $I(S'_n; Y)$ is equivalent to finding the feature that maximizes $I(X_j; Y | S_{n-1})$. If $\sigma_{j|S_{n-1}}^2$ denotes the variance of feature j conditioned on the features in S_{n-1} and $\sigma_{j|Y, S_{n-1}}^2$ the variance conditioned on the features in S_{n-1} and the class $Y = y$, we have

$$\begin{aligned} \operatorname{argmax}_{X_j \in F \setminus S_{n-1}} I(X_j; Y | S_{n-1}) &= \operatorname{argmax}_{X_j \in F \setminus S_{n-1}} (H(X_j | S_{n-1}) - H(X_j | Y, S_{n-1})) \\ &= \operatorname{argmax}_{X_j \in F \setminus S_{n-1}} \left(\log \sigma_{j|S_{n-1}}^2 - \sum_y P(Y = y) \log \sigma_{j|Y, S_{n-1}}^2 \right) \end{aligned} \quad (11)$$

where here and in the following, we slightly abuse notation and use S_n to denote both the set and its contents, which of the two is meant will in any case be clear from context. To derive equation 12 we have exploited the fact that the conditional variance $\sigma_{j|S_{n-1}}$ is independent of the specific values of the features in S_{n-1} and thus the integrations of the entropies over the conditioned values are straightforward. That is

$$\begin{aligned} H(X_j | S_{n-1}) &= \int_{\mathbb{R}^{|S_{n-1}|}} H(X_j | S_{n-1} = s) \mu_{S_{n-1}}(s) ds \\ &= \frac{1}{2} \log \sigma_{j|S_{n-1}}^2 + \frac{1}{2} (\log 2\pi + 1). \end{aligned}$$

Under the Gaussian assumption, we have

$$\sigma_{j|S_{n-1}}^2 = \sigma_j^2 - \sum_{j', S_{n-1}} \Sigma_{j', S_{n-1}}^{-1} \Sigma_{j, S_{n-1}}.$$

From the above we can derive an $O(|Y||F \setminus S_{n-1}|n^2)$ with $O(|Y|n^2)$ memory requirements by noting that computing $\Sigma_{j', S_{n-1}}^{-1} \Sigma_{j, S_{n-1}}$ incurs a cost of $O(n^2)$ and that this must be done for every candidate feature j and every class y .

3.4.1 EFFICIENT COMPUTATION OF $\sigma_{j|S_{n-1}}^2$

As stated, we can further speed-up the proposed algorithm by a factor of n by considering more carefully the calculation of $\sigma_{j|S_{n-1}}^2$. If $S_{n-1} = S_{n-2} \cup X_i$, we have

$$\Sigma_{j', S_{n-1}}^{-1} \Sigma_{j, S_{n-1}} = \left[\Sigma_{j', S_{n-2}}^{-1} \sigma_{j_i}^2 \right] \Sigma_{S_{n-1}}^{-1} \left[\Sigma_{j, S_{n-2}} \right] \sigma_{j_i}^2 \quad (13)$$

We note that $\Sigma_{S_{n-1}}$ differs from $\Sigma_{S_{n-2}}$ by the addition of a row and a column

$$\Sigma_{S_{n-1}} = \begin{bmatrix} \Sigma_{S_{n-2}} & \Sigma_{i, S_{n-2}} \\ \Sigma_{i, S_{n-2}}^T & \sigma_i^2 \end{bmatrix}$$

Thus $\Sigma_{S_{n-1}}$ is the result of a rank-two update to the augmented matrix

$$\begin{bmatrix} \Sigma_{S_{n-2}} & 0_{n-2} \\ 0_{n-2}^T & \sigma_i^2 \end{bmatrix},$$

specifically a one rank-one update corresponding to changing the final row and a rank-one update corresponding to changing the final column. By applying the Sherman-Morrison formula twice to update $\Sigma_{S_{n-2}}^{-1}$ to $\Sigma_{S_{n-1}}^{-1}$, we can obtain¹ an update formula of the form

$$\Sigma_{S_{n-1}}^{-1} = \begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & -\frac{1}{\beta} \frac{u}{\sigma_i^2} \\ -\frac{1}{\beta} \frac{u^T}{\sigma_i^2} & \frac{1}{\beta} \left[\frac{u}{\sigma_i^2} \quad 0 \right] \end{bmatrix} \quad (14)$$

where

$$u = \Sigma_{S_{n-2}}^{-1} \Sigma_{i, S_{n-2}}$$

and

$$\beta = 1 - \frac{1}{\sigma_i^2} \Sigma_{i, S_{n-2}}^T \Sigma_{S_{n-2}}^{-1} \Sigma_{i, S_{n-2}}.$$

From equation (13) and (14) we have

$$\begin{aligned} \sigma_{j|S_{n-1}}^2 &= \sigma_j^2 - \Sigma_{j', S_{n-1}}^{-1} \left(\begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & -\frac{1}{\beta} \frac{u}{\sigma_i^2} \\ -\frac{1}{\beta} \frac{u^T}{\sigma_i^2} & \frac{1}{\beta} \left[\frac{u}{\sigma_i^2} \quad 0 \right] \end{bmatrix} \Sigma_{j, S_{n-1}} \right) \\ &= \sigma_j^2 - \Sigma_{j', S_{n-2}}^{-1} \Sigma_{j, S_{n-2}} + \beta \frac{\sigma_{j_i}^2}{\sigma_i^2} u^T \Sigma_{j, S_{n-2}} \\ &\quad - \Sigma_{j', S_{n-1}}^{-1} \left[\begin{bmatrix} -\frac{1}{\beta} \frac{u}{\sigma_i^2} \\ \frac{1}{\beta} \frac{u^T}{\sigma_i^2} \end{bmatrix} \sigma_{j_i}^2 \right] \\ &\quad - \frac{1}{\beta \sigma_i^2} \left(\Sigma_{j', S_{n-1}}^{-1} \begin{bmatrix} u \\ 0 \end{bmatrix} \right) \left(\begin{bmatrix} u^T & 0 \end{bmatrix} \Sigma_{j, S_{n-1}} \right) \end{aligned} \quad (15)$$

In eq (15) the main computational cost is incurred by the calculation of $\Sigma_{j', S_{n-1}}^{-1} \Sigma_{j, S_{n-1}}$ which costs $O(n^2)$. However this quantity has been already calculated $\forall j$ during the previous iteration of the algorithm since this involves calculating

$$\sigma_{j_i|S_{n-2}}^2 = \sigma_j^2 - \Sigma_{j', S_{n-2}}^{-1} \Sigma_{j, S_{n-2}} \Sigma_{j_i, S_{n-2}}.$$

Thus we only need carry this result over from the previous iteration incurring an additional memory load of $O(|Y||F \setminus S_{n-1}|)$.

The remaining terms in equation (15) can be calculated in $O(n)$ given β and u . As β and u depend only on the feature i selected in the previous iteration, remaining constant throughout iteration n , they can be pre-computed once at the beginning of each iteration. Thus the cost of calculating $\sigma_{j|S_{n-2}}^2$ can be reduced to $O(n)$ and the overall computational cost per iteration to $O(|Y||F \setminus S_{n-1}|n)$.

¹. The proof follows from simple verification.

3.5 Complexity of the KL-based Algorithms

In the case of the KL-based algorithms, similarly with the Gaussian compromise approach, a naive implementation would incur a cost of $O(|Y|F \setminus S_{n-1}|n^3)$. In previous work (Lefakis and Fleuret, 2014) an algorithm was sketched which had a $O(|Y|n^2)$ memory footprint. Here we expand on this analysis and furthermore present an alternative algorithm with a $O(|Y|F \setminus S_{n-1}|n)$ complexity, which however has an increased memory footprint (specifically $O(|Y|F \setminus S_{n-1}|n^2)$).

Working with the value:

$$P(Y = y)D_{KL}(p(S|Y = y) \| p(S|Y \neq y)) + P(Y = y)H(S | Y = y) \\ + P(Y \neq y)D_{KL}(p(S|Y \neq y) \| p(S|Y = y)) + P(Y \neq y)H(S | Y \neq y) + e^m$$

we note that the entropy values $H(S | Y = y)$ can be computed efficiently as in the previous subsection. What remains is to efficiently compute the Kullback-Leibler divergences for each of the $|Y|$ binary classification problems.

As both distributions are assumed to be Gaussians, $D_{KL}(p(S|Y \neq y) \| p(S|Y = y))$ is equal to

$$\frac{1}{2} \left(\text{tr} \left(\Sigma_{S_n}^{y} \Sigma_{S_n}^{-1} \Sigma_{S_n}^{y^c} \right) - \log \frac{|\Sigma_{S_n}^{y^c}|}{|\Sigma_{S_n}^y|} + \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)^T \Sigma_{S_n}^{y^c} \Sigma_{S_n}^{-1} \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right) - |S| \right).$$

In the following we show how each of these terms can be computed in time $O(n)$.

3.5.1 THE TERM $\log \frac{|\Sigma_{S_n}^{y^c}|}{|\Sigma_{S_n}^y|}$

From the chain rule,

$$H(S_{n-1} \cup X_j) = H(S_{n-1}) + H(X_j | S_{n-1})$$

we have

$$\log |\Sigma_{S_n}^y| + \frac{n}{2} (1 + \log 2\pi) = \log |\Sigma_{S_{n-1}}| + \frac{n-1}{2} (1 + \log 2\pi) + \log \sigma_{j|S_{n-1}}^2 + \frac{1}{2} (1 + \log 2\pi) \\ \log |\Sigma_{S_n}^{y^c}| = \log |\Sigma_{S_{n-1}}| + \log \sigma_{j|S_{n-1}}^2 \\ |\Sigma_{S_n}^y| = \sigma_{j|S_{n-1}}^2 |\Sigma_{S_{n-1}}|.$$

As shown in the previous section, the term $\sigma_{j|S_{n-1}}^2$ can be computed in $O(n)$ time. The term $|\Sigma_{S_{n-1}}|$ is independent of j and can be efficiently pre-computed from $|\Sigma_{S_{n-2}}|$ prior to iteration n using the matrix determinant lemma. By extension, the cost of calculating $\log \frac{|\Sigma_{S_n}^{y^c}|}{|\Sigma_{S_n}^y|}$ is itself $O(n)$.

3.5.2 CALCULATING $\Sigma_{S_n}^{y^c} u^{-1}$

Setting, here and in the rest of this section, $\Sigma_S = \Sigma_S^y$ for ease of exposition², we have similar to section 3.4 that

$$\Sigma_{S_n}^{y^c} u^{-1} = \begin{bmatrix} \Sigma_{S_{n-1}}^{-1} & -\frac{1}{\beta\sigma_j^2} u \\ -\frac{1}{\beta\sigma_j^2} u^T & \frac{1}{\beta\sigma_j^2} \end{bmatrix} + \frac{1}{\beta\sigma_j^2} \begin{bmatrix} u \\ 0 \end{bmatrix} \begin{bmatrix} u^T & 0 \end{bmatrix} \quad (16)$$

where

$$u = \Sigma_{S_{n-1}}^{-1} \Sigma_{j|S_{n-1}}$$

and

$$\beta = 1 - \frac{1}{\sigma_j^2} \Sigma_{j|S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{j|S_{n-1}}.$$

Here u and β cannot be pre-computed as they are different $\forall j$. They can either be calculated from scratch in $O(n^2)$ or, if we are willing to incur a memory overhead of $O(n)$, with $O(n)$ complexity from the product $\Sigma_{S_{n-2}}^{-1} \Sigma_{j|S_{n-2}}$ which has been computed during the previous iteration (as in section 3.4.1).

3.5.3 THE TERM $\left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)^T \Sigma_{S_n}^{y^c} \Sigma_{S_n}^{-1} \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)$

Having computed u and β as defined above, we can efficiently calculate the product

$$M = \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)^T \Sigma_{S_n}^{-1} \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)$$

given that $\mu_{S_n}^y = \begin{bmatrix} \mu_{S_{n-1}}^y \\ \mu_j^y \end{bmatrix}$ by decomposing it as follows

$$M = \begin{pmatrix} \mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \\ \mu_j^{y^c} - \mu_j^y \end{pmatrix}^T \Sigma_{S_{n-1}}^{-1} \begin{pmatrix} \mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \\ \mu_j^{y^c} - \mu_j^y \end{pmatrix} \\ - \frac{\left(\mu_j^{y^c} - \mu_j^y \right)^T u^T \left(\mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \right)}{\beta\sigma_j^2} \\ + \left(\mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \right)^T \begin{bmatrix} -\frac{1}{\beta\sigma_j^2} u \\ \frac{1}{\beta\sigma_j^2} \end{bmatrix} \begin{pmatrix} \mu_j^{y^c} - \mu_j^y \end{pmatrix} \\ + \frac{1}{\beta\sigma_j^2} \left(\left(\mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \right)^T \begin{bmatrix} u \\ 0 \end{bmatrix} \right) \left(\begin{bmatrix} u^T & 0 \end{bmatrix} \left(\mu_{S_{n-1}}^{y^c} - \mu_{S_{n-1}}^y \right) \right)$$

Of these four terms, the final three involving the vectors u and β can be calculated in $O(n)$ as they only involve inner products. The first term requires $O(n^2)$, however as the term is independent of j it can be calculated once at the beginning of each iteration. Consequently the complexity of calculating $\left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)^T \Sigma_{S_n}^{-1} \left(\mu_{S_n}^{y^c} - \mu_{S_n}^y \right)$ given u and β is $O(n)$.

² That is when a superscript is missing, u is implied.

3.5.4 THE TERM $\text{tr} \left(\Sigma_{S_n}^y -^{-1} \Sigma_{S_n'}^{y|y} \right)$

The term $\text{tr} \left(\Sigma_{S_n}^y -^{-1} \Sigma_{S_n'}^{y|y} \right)$ involves calculating, and summing, the main diagonal elements of the matrix product $\left(\Sigma_{S_n}^y -^{-1} \Sigma_{S_n'}^{y|y} \right)$. We have that

$$\Sigma_{S_n}^{y|y} = \begin{bmatrix} \Sigma_{S_{n-1}}^{y|y} & \Sigma_{j,S_{n-1}}^{y|y} \\ \Sigma_{j,S_{n-1}}^{y|y T} & \sigma_j^{y|y} \end{bmatrix}. \quad (17)$$

From equations (16) and (17) we see that the product can be decomposed into two parts. For the first

$$\begin{bmatrix} \Sigma_{S_{n-1}}^{-1} & -\frac{1}{\beta\sigma_j^2} u \\ -\frac{1}{\beta\sigma_j^2} u^T & \frac{1}{\beta\sigma_j^2} \end{bmatrix} \begin{bmatrix} \Sigma_{S_{n-1}}^{y|y} & \Sigma_{j,S_{n-1}}^{y|y} \\ \Sigma_{j,S_{n-1}}^{y|y T} & \sigma_j^{y|y} \end{bmatrix}$$

it is straightforward to show that the main diagonal elements can be calculated in $O(n)$ provided we have pre-computed the main diagonal elements of $\Sigma_{S_{n-1}}^{-1} \Sigma_{S_{n-1}}^{y|y}$. As this product does not depend on j this can be done prior to the beginning of the iteration. For the second we have

$$\frac{1}{\beta\sigma_j^2} \begin{bmatrix} \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}} \\ 0 \end{bmatrix} \begin{bmatrix} \Sigma_{j,S_{n-1}}^{-1} \Sigma_{S_{n-1}}^{-1} & 0 \\ \Sigma_{j,S_{n-1}}^{y|y T} & \sigma_j^{y|y} \end{bmatrix}$$

which, given that $\text{tr}(w^T w A) = \text{tr}(w A w^T)$, is equal to the product of $\frac{1}{\beta\sigma_j^2}$ and the trace of

$$\Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{S_{n-1}}^{y|y} \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}}.$$

As we have already calculated the vector $\Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}}$ when calculating $\Sigma_{S_{n-1}}^{-1}$ we concentrate here on calculating the vector $\Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{S_{n-1}}^{y|y}$.

As shown, the matrix $\Sigma_{S_{n-1}}^{-1}$ can be written in the form

$$\Sigma_{S_{n-1}}^{-1} = \begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & \gamma v \\ \gamma v^T & -\gamma \end{bmatrix} \begin{bmatrix} v \\ 0 \end{bmatrix} \begin{bmatrix} v^T & 0 \end{bmatrix}$$

where

$$v = \Sigma_{S_{n-2}}^{-1} \Sigma_{i,S_{n-2}}$$

and

$$\gamma = -\frac{1}{\beta\sigma_j^2}.$$

Thus the vector $\Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{S_{n-1}}^{y|y}$ can be decomposed into

$$\Sigma_{j,S_{n-1}}^T \begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & \gamma v \\ \gamma v^T & -\gamma \end{bmatrix} \Sigma_{S_{n-1}}^{y|y} - \gamma \Sigma_{j,S_{n-1}}^T \begin{bmatrix} v \\ 0 \end{bmatrix} \begin{bmatrix} v^T & 0 \end{bmatrix} \Sigma_{S_{n-1}}^{y|y}.$$

As v does not depend on j the product $\begin{bmatrix} v^T & 0 \end{bmatrix} \Sigma_{S_{n-1}}^{y|y}$ can be computed prior to the iteration and by extension the product $\gamma \Sigma_{j,S_{n-1}}^T \begin{bmatrix} v \\ 0 \end{bmatrix} \begin{bmatrix} v^T & 0 \end{bmatrix} \Sigma_{S_{n-1}}^{y|y}$ can be computed in $O(n)$. This leaves the final term

$$\Sigma_{j,S_{n-1}}^T \begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & \gamma v \\ \gamma v^T & -\gamma \end{bmatrix} \Sigma_{S_{n-1}}^{y|y}.$$

We note that the vector $\Sigma_{j,S_{n-1}}^T \begin{bmatrix} \Sigma_{S_{n-2}}^{-1} & \gamma v \\ \gamma v^T & -\gamma \end{bmatrix}$ has the form

$$\begin{bmatrix} \Sigma_{j,S_{n-2}} \Sigma_{S_{n-2}}^{-1} + \gamma \sigma_{j,i}^2 v^T \\ \gamma \Sigma_{j,S_{n-2}}^T v - \gamma \sigma_{j,i}^2 \end{bmatrix}^T.$$

Thus we have

$$\begin{bmatrix} \Sigma_{j,S_{n-2}} \Sigma_{S_{n-2}}^{-1} \Sigma_{S_{n-2}}^{y|y} & 0 \\ \gamma \Sigma_{j,S_{n-2}}^T \Sigma_{S_{n-2}}^{y|y} & 0 \end{bmatrix} + \gamma \sigma_{j,i}^2 \begin{bmatrix} v^T & 0 \\ 0 & 0 \end{bmatrix} \Sigma_{S_{n-1}}^{y|y} + \left(\gamma \Sigma_{j,S_{n-2}}^T v - \gamma \sigma_{j,i}^2 \right) \Sigma_{i,S_{n-1}}^{y|y}.$$

During the previous iteration we have already computed the vector $\Sigma_{j,S_{n-2}} \Sigma_{S_{n-2}}^{-1} \Sigma_{S_{n-2}}^{y|y}$ and thus if we use $O(n)$ memory to store it between iterations, we can also compute this final term in $O(n)$.

4. Using the Eigen-decomposition to Bound Computations

The fast implementation of the GC-approximation method presented in 3.4 requires at iteration n the calculation, for each feature $X_j \in F \setminus S_{n-1}$, of the conditioned variance

$$\sigma_{j|S_{n-1}}^2 = \sigma_j^2 - \Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}}.$$

As shown, each such computation can be done in $O(n)$. The main computational cost comes from the calculation of $\Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}}$. Thus it would be advantageous to acquire a ‘‘cheap’’ (independent of n) bound which will allow us to skip the calculation of this quantity for certain non-promising features.

We note that $\Sigma_{S_{n-1}}^{-1}$ is positive definite and symmetric and thus can be decomposed as

$$\Sigma_{S_{n-1}}^{-1} = U \Lambda U^T,$$

where U is orthonormal and Λ is a diagonal matrix with positive elements. Thus

$$\Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}} = \Sigma_{j,S_{n-1}}^T U \Lambda U^T \Sigma_{j,S_{n-1}}.$$

As U is orthonormal we have

$$\|\Sigma_{j,S_{n-1}}\|_2 = \|\Sigma_{j,S_{n-1}}^T U\|_2 = \|U^T \Sigma_{j,S_{n-1}}\|_2,$$

Symbolizing the eigenvalues as $\lambda_1, \lambda_2, \dots, \lambda_{n-1}$ and the elements of the vector $\Sigma_{j,S_{n-1}}^T U$ as x_1, x_2, \dots, x_{n-1} , we have that

$$\|\Sigma_{j,S_{n-1}}^T\|_2^2 \min_i \lambda_i \leq \Sigma_{j,S_{n-1}}^T \Sigma_{S_{n-1}}^{-1} \Sigma_{j,S_{n-1}} \leq \|\Sigma_{j,S_{n-1}}^T\|_2^2 \max_i \lambda_i. \quad (18)$$

Equation 18 gives us a bound, computable in $O(|Y|)$, which we can use to avoid unnecessary computations. Specifically, during iteration n of the algorithm, after having already calculated the scores of a subset of features, we have a candidate for best feature which has a score of s^* ; for each subsequent candidate feature X_j we can compute the following upper bound on the feature's score

$$ub_1(X_j) = \log \left(\sigma_j^2 - \|\Sigma_{j|S_{n-1}}^T\|_2^2 \max_i \lambda_i \right) - \sum_{y=0}^{|Y|-1} \left(\log \left(\sigma_j^{y^2} - \|\Sigma_{j|S_{n-1}}^{yT}\|_2^2 \min_i \lambda_i^y \right) \right), \quad (19)$$

where λ_i, λ_i^y are the eigenvalues of $\Sigma_{S_{n-1}}^{-1}$ and $\Sigma_{S_{n-1}}^{y^{-1}}$ respectively. Then if $ub(s) \leq s^*$, we can avoid the $O(|Y|n)$ computations required to estimate the feature's score s .

Furthermore should $ub_1(X_j) > s^*$ we can still proceed with the computations in a greedy manner. That is instead of calculating the exact score

$$\log \left(\sigma_j^2 |S_{n-1}| - \sum_{y=0}^{|Y|-1} \left(\log \left(\sigma_j^{y^2} |S_{n-1}| \right) \right) \right)$$

incurring $O(|Y|n)$ cost, we can compute the conditional variances one at a time and then reassess the upper bound. That is we first calculate $\sigma_{j|S_{n-1}}^2$ which costs us $O(n)$ and then re-estimate the upper bound as

$$ub_2(X_j) = \log \left(\sigma_{j|S_{n-1}}^2 \right) - \sum_{y=0}^{|Y|-1} \left(\log \left(\sigma_j^{y^2} - \|\Sigma_{j|S_{n-1}}^{yT}\|_2^2 \min_i \lambda_i^y \right) \right)$$

re-checking whether $ub(s) \leq s^*$. We can then continue, if necessary, by calculating

$$ub_3(X_j) = \log \left(\sigma_{j|S_{n-1}}^2 \right) - \log \left(\sigma_{j|S_{n-1}}^{y_0^2} \right) - \sum_{y=1}^{|Y|-1} \left(\log \left(\sigma_j^{y^2} - \|\Sigma_{j|S_{n-1}}^{yT}\|_2^2 \min_i \lambda_i^y \right) \right)$$

and so forth. Thus we can avoid estimating a number of conditional variances, incurring a smaller cost. This process can continue greedily by computing $ub_{1\dots|Y|+1}(X_j)$.

We note that the upper bound 19 involves $|Y|$ lower bounds

$$\log \left(\sigma_j^{y^2} - \|\Sigma_{j|S_{n-1}}^{yT}\|_2^2 \min_i \lambda_i^y \right)$$

on the conditional variances $\sigma_{j|S_{n-1}}^{y^2}$. As such the bound can become quite loose if the number of classes $|Y|$ is large. In order to empirically evaluate the usefulness of this bound in pruning computations, we considered 3 binary classification tasks: the binary task of the INRIA data set, and two tasks resulting from the CIFAR and STL data sets by a random partitioning of the classes (*i.e.* that is in each case 5 classes were randomly chosen to be labeled as positive and the rest as negative).

In figure 3 we can see for each of the three data sets, the number of features at each round for which we can skip a certain amount of computations. In the case $ub_1 \leq s^*$ we

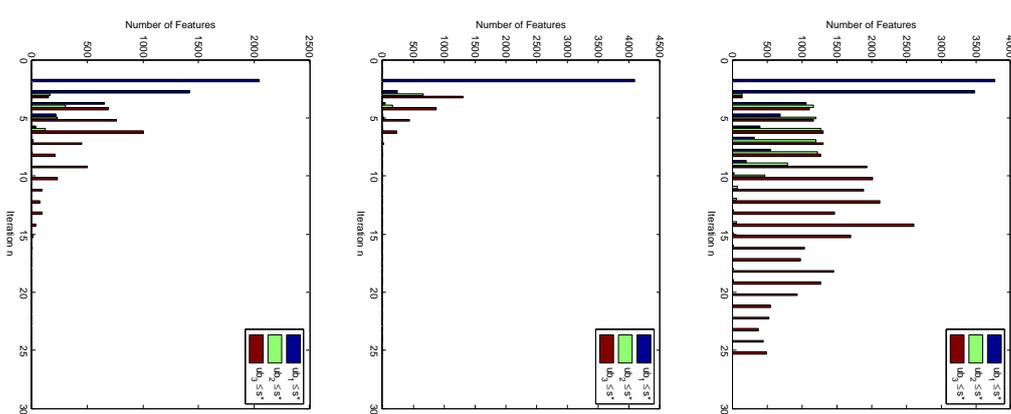

Figure 3: Number of features for which the upper bound ub_x allows us to skip computations for the top) INRIA, middle) STL, and bottom) CIFAR data sets.

can avoid all computations concerning the conditional variances. In the case $ub_2 \leq s^*$ only one conditional variance need be calculated, while in the case of $ub_3 \leq s^*$ two (out of a possible three). As can be seen, the bound can prove quite useful in pruning computations, as is the case in the INRIA data set. For the CIFAR data set, we see that the bound can still prove useful, especially early on. On the contrary in the case of the STL data set, the bound seems to provide little help in ways of avoiding computations.

Pruning computations using the above bounds requires access to the eigenvalues of the matrices $\Sigma_{S_{n-1}}^{y-1}$ which are the reciprocals of the eigenvalues of the matrices $\Sigma_{S_{n-1}}^y$. As computing the eigen-decomposition of a matrix, from scratch, can be expensive we present in the following a novel algorithm for efficiently calculating these eigenvalues, and the corresponding eigenvectors, of $\Sigma_{S_{n-1}}^{y-1}$ from the eigen-decomposition of $\Sigma_{S_{n-2}}^{y-1}$.

4.1 Eigen-system Update

The matrices $\Sigma_{S_{n-1}}^{y-1}$ results from the matrices $\Sigma_{S_{n-2}}^{y-1}$ by the addition of a row and a column. We are faced thus with the problem of updating the eigen-system of a symmetric and positive definite matrix Σ when a vector is inserted as an extra row and column.

More specifically, we shall present a method for *efficiently* computing the eigen-system U^{n+1}, Λ^{n+1} of a $(n+1) \times (n+1)$ matrix Σ^{n+1} when the eigen-system U^n, Λ^n of the $n \times n$ matrix Σ^n is known and Σ^{n+1} is related to Σ^n as follows:

$$\Sigma^{n+1} = \begin{bmatrix} \Sigma^n & \mathbf{v} \\ \mathbf{v}^T & c \end{bmatrix},$$

where \mathbf{v} and c are such that the matrix Σ^{n+1} is positive definite. Without loss of generality, we will consider in the following the special case $c = 1$.

If $\mathbf{u}_1, \dots, \mathbf{u}_n$, $\lambda_1^n, \dots, \lambda_n^n$ are the eigenvectors and respective eigenvalues of Σ^n , then $\begin{bmatrix} \mathbf{u}_i^n \\ 0 \end{bmatrix}$ is obviously an eigenvector of

$$\Sigma^y = \begin{bmatrix} \Sigma^n & \mathbf{0} \\ \mathbf{0}^T & 1 \end{bmatrix},$$

with associated eigenvalue λ_i^n . Also, if $\forall i \in \{1, \dots, n+1\}$, \mathbf{e}_i is the i th standard basis vector of \mathbb{R}^{n+1} , then $\Sigma^y \mathbf{e}_{n+1} = \mathbf{e}_{n+1}$ and \mathbf{e}_{n+1} is an eigenvector of Σ^y with a corresponding eigenvalue of $\lambda_{n+1}^y = 1$.

The matrix Σ^{n+1} can be expressed as the result of a rank-two update to Σ^y

$$\Sigma^{n+1} = \Sigma^y + \mathbf{e}_{n+1} \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix}^T + \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix} \mathbf{e}_{n+1}^T.$$

If U^y, Λ^y denote the eigen-system of Σ^y , by multiplying

$$\Sigma^{n+1} \mathbf{u}^{n+1} = \Lambda^{n+1} \mathbf{u}^{n+1},$$

on the left by U^{yT} , we have

$$U^{yT} \left(\Sigma^y + \mathbf{e}_{n+1} \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix}^T + \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix} \mathbf{e}_{n+1}^T \right) \mathbf{u}^{n+1} = \Lambda^{n+1} U^{yT} \mathbf{u}^{n+1}$$

Given that Σ^y is positive definite and symmetric it follows that $U^y U^{yT} = I$ and

$$U^{yT} \left(\Sigma^y + \mathbf{e}_{n+1} \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix}^T + \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix} \mathbf{e}_{n+1}^T \right) U^y U^{yT} \mathbf{u}^{n+1} = \Lambda^{n+1} U^{yT} \mathbf{u}^{n+1}$$

and since $U^{yT} \Sigma^y U^y = \Lambda^y$ we have

$$(\Lambda^y + \mathbf{e}_{n+1} \mathbf{q}^T + \mathbf{q} \mathbf{e}_{n+1}^T) U^y U^{yT} \mathbf{u}^{n+1} = \Lambda^{n+1} U^{yT} \mathbf{u}^{n+1}$$

where $\mathbf{q} = U^{yT} \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix}$, note $\mathbf{e}_{n+1}^T U^y = \mathbf{e}_{n+1}^T$.

Thus Σ^{n+1} and the matrix $\Sigma'' = (\Lambda^y + \mathbf{e}_{n+1} \mathbf{q}^T + \mathbf{q} \mathbf{e}_{n+1}^T)$ share eigenvalues. Furthermore the eigenvectors U^{n+1} are related to the eigenvectors U'' of Σ'' by $U^{n+1} = U^y U''$.

4.1.1 COMPUTING THE EIGENVALUES AND EIGENVECTORS OF Σ''

The matrix Σ'' has non-zero elements only on its main diagonal and on its last row and column. By developing the determinant $|\Sigma'' - \lambda I|$ along the final row we have

$$|\Sigma'' - \lambda I| = \prod_j (\lambda_j' - \lambda) + \sum_{i < n+1} \left(-q_i^2 \prod_{j \neq i, j < n+1} (\lambda_j' - \lambda) \right),$$

where q_i is the i th element of vector \mathbf{q} . The determinant thus has the same roots as the function

$$f(\lambda) = \frac{|\Sigma'' - \lambda I|}{\prod_{j < n+1} (\lambda_j' - \lambda)} \quad (20)$$

$$= \lambda'_{n+1} - \lambda + \sum_i \frac{-q_i^2}{(\lambda_i' - \lambda)}. \quad (21)$$

We have $\forall i, \lim_{\lambda \rightarrow \lambda_i'} f(\lambda) = +\infty$ and $\lim_{\lambda \rightarrow \lambda_i'} f(\lambda) = -\infty$. Furthermore we have

$$\frac{\partial f(\lambda)}{\partial \lambda} = -1 + \sum_i \frac{-q_i^2}{(\lambda_i' - \lambda)^2} \leq 0$$

meaning the function f is strictly decreasing between its poles. From this and from the positive definiteness of Σ'' we have that

$$0 < \lambda_1^{n+1} < \lambda_1' < \lambda_1^{n+1} < \dots < \lambda'_{n+1} < \lambda_{n+1}^{n+1}$$

i.e. the eigenvalues of Σ' and Σ'' are interlaced.

Though there is no analytical solution for finding the roots of $f(\lambda)$, given the above relationship they can be computed efficiently using a Householder method. We also note that $\text{tr}(\Lambda^y) = \text{tr}(\Sigma'')$ and consequently

$$\lambda_{n+1}^{n+1} = \sum_i \lambda_i' - \sum_{i < n+1} \lambda_i^{n+1}.$$

Once we have computed the eigenvalues λ'' , we can compute the eigenvectors U'' as follows: we first note that $\forall k$ the system of linear equations

$$\Sigma'' x = \lambda_k^{n+1} x$$

where

$$x = [x_1 \quad x_2 \quad \dots \quad x_{n+1}]^T$$

involves n equations of the form

$$\lambda_k' x_i + q_i x_{n+1} = \lambda_k^{n+1} x_i.$$

Given that $\lambda_k^{n+1} \neq \lambda_k'$, it follows that if $x_{n+1} = 0$ then $\forall i, x_i = 0$ and thus it must be that $x_{n+1} \neq 0$. As the system has one degree of freedom, we can set $x_{n+1} = 1$. We then have from the equations

$$\lambda_k' x_i + q_i x_{n+1} = \lambda_k^{n+1} x_i$$

that

$$x_i = \frac{q_i}{\lambda_k^{n+1} - \lambda_k'},$$

and by normalizing x we obtain the k th column of U'' . Finally we can obtain the eigen-decomposition of Σ^{n+1}

$$\Sigma^{n+1} = (U'' U''^T) \Lambda'' (U'' U''^T)^T.$$

4.1.2 COMPUTATIONAL EFFICIENCY

In order to empirically evaluate the derived eigen-decomposition update algorithm, we compare a C++ implementation against the LAPACK library's eigen-decomposition implementation. In figure 4.1.2 we see such a comparison of the CPU time required to compute Σ^{n+1} , from scratch, using the LAPACK library and using the proposed update algorithm, as a function of n .

4.1.3 NUMERICAL PRECISION

In order to test the numerical precision of the proposed update method, we consider two experimental setups. In the first setup, results on which are shown in figures 5.6, we iteratively augment a symmetric positive definite matrix by inserting a vector as an extra row and an extra column and at each iteration update its eigen-decomposition using the proposed method; that is to say at each iteration the eigen-decomposition is an updated version of previously updated decompositions. Figure 5 shows the maximum relative eigenvalue error as compared to the decomposition estimated by LAPACK which is assumed to be accurate. Similarly figure 6 shows the maximum angle between corresponding eigenvectors of the proposed method and the ones computed by the LAPACK library. As can be seen, after 2000 iterations the *maximum* relative eigenvalue error is of the order of magnitude of $\sim 1\%$, while the maximum angle between corresponding eigenvectors is less than 0.001 degrees.

In figure 7 we show the maximum relative eigenvalue when the eigen-decomposition is updated from the decomposition computed at the previous iteration using LAPACK.

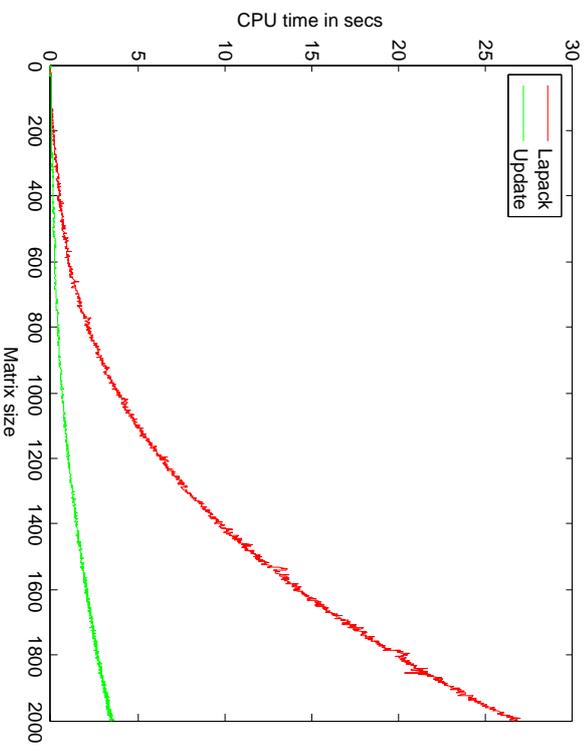

Figure 4: Comparison of computation time of the proposed update method and of computing the eigen-decomposition from scratch using the LAPACK library.

As can be seen the maximum relative error is of the order of magnitude of 10^{-10} . This value is related to the tolerance of the Newton method which was used to find the roots of equation 20 (which in these experiments we set to 10^{-10}). The maximum angle between corresponding eigenvectors was found to be 0, *i.e.* beneath double precision, in every case.

5. Experiments

In this section we present an empirical evaluation of the proposed algorithms. We first show on a synthetic controlled experiment that they behave as expected regarding groups of jointly informative features, and then provide results obtained on three popular real-world computer vision data sets.

5.1 Synthetic Examples

In order to show the importance of joint informativeness and the ability of the proposed algorithm to capture it we construct a simple synthetic experiment with a set of candidate features $F = \{X_1, X_2, X_3, X_4, X_5\}$ defined as follows:

$$\begin{aligned} X_1 &\sim N(0, 1) + 10^{-1}Y \\ X_2 &\sim (2Y - 1)X_1 + N(0, 1) \\ X_3 &\sim N(0, 1) \\ X_4 &\sim N(0, 1) + 10^{-1}Y \\ X_5 &\sim (2Y - 1)X_4 + N(0, 1) \end{aligned}$$

where Y is a classification label, $Y \sim B(0.5)$. Looking at the above marginals it can be seen that only X_1 and X_4 carry information regarding Y individually, X_2 and X_5 are very informative but only in conjunction with X_1 and X_4 respectively. X_3 is simply noise.

We generate 1,000 synthetic data sets of 25,000 data points each from the above distributions, and use the GC-approximation on the mutual information to select the features. In 49.2% of the experiments the algorithm ranks X_1 as the most informative feature. Even though X_4 would be the second most informative feature marginally, in every one of these experiments in the second iteration the algorithm chose the X_2 feature as it is jointly more informative when combined with X_1 . Similarly, in 47.1% of the experiments the algorithm ranked X_4 first and in each of these experiments selected X_5 second. In every one of the runs X_3 was ranked as the least informative of the 5 features.

5.2 Data Sets

We report results on three standard computer vision data-sets which we used for our experiments:

CIFAR-10 contains images of size 32×32 of 10 distinct classes depicting vehicles and animals. The training data consists of 5,000 images of each class. We pre-process the data as in (Coates and Ng, 2011) using the code provided by the authors. The original pool F of features consists of 2,048 candidates.

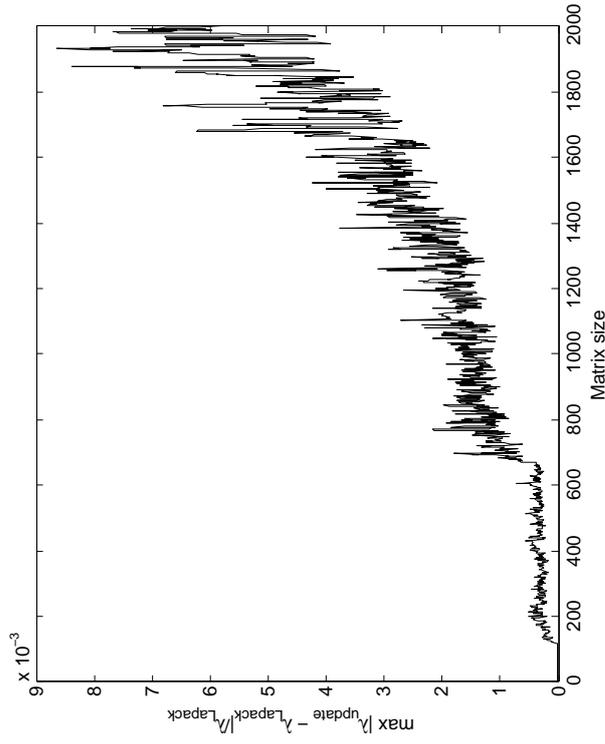

Figure 5: Numerical precision of the proposed update method when updating the decomposition iteratively. Maximum relative eigenvalue error.

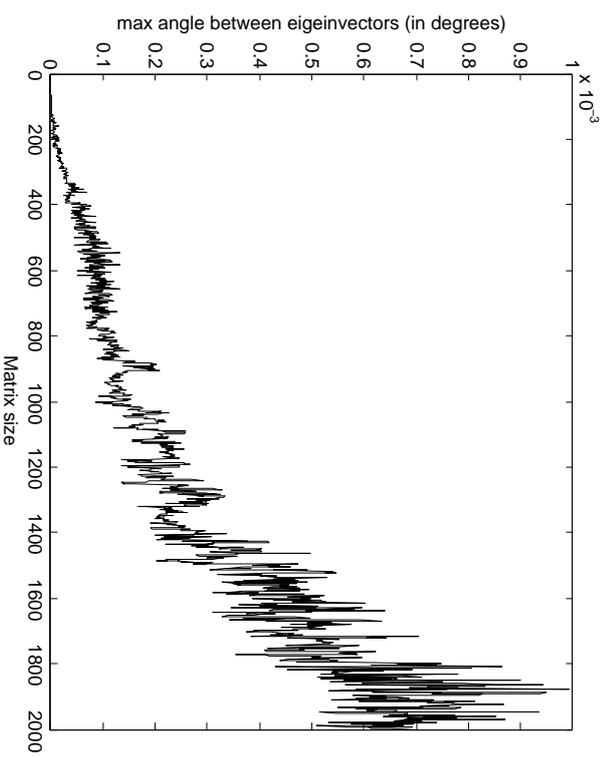

Figure 6: Numerical precision of the proposed update method when updating the decomposition iteratively. Maximum angle between corresponding eigenvectors.

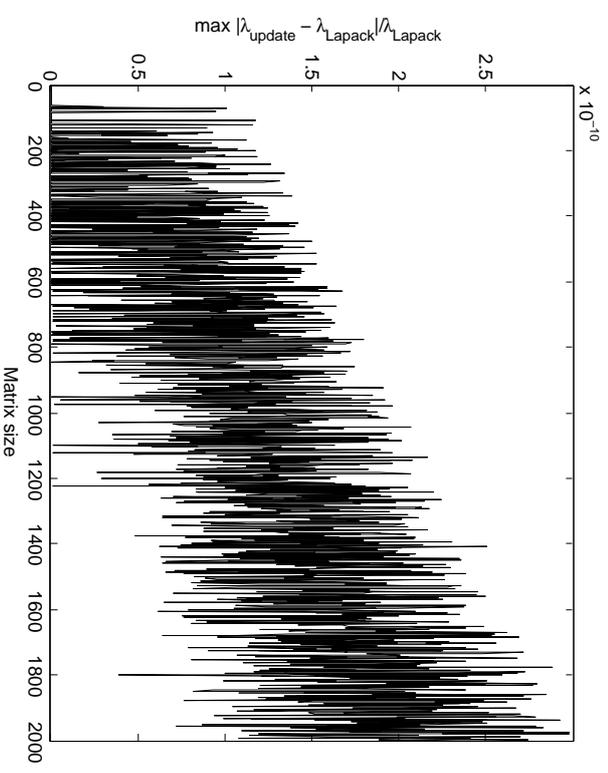

Figure 7: Maximum relative eigenvalue error when the eigen-decomposition is updated from the eigen-decomposition computed by LAPACK.

INRIA is a pedestrian detection data set. There are 12, 180 training images of size 64×128 of pedestrians and background images. We use 3, 780 HoG features that have been shown to perform well in practice (Dalal and Triggs, 2005).

STL-10 consists of images of size 96×96 belonging to 10 classes, each represented by 500 training images. As for CIFAR we pre-process the data as in (Coates and Ng, 2011), resulting in a pool F of 4, 096 features.

5.3 Baselines

We compare the proposed feature selection methods against a number of baselines. The **Fisher**, **T-test**, χ^2 , and **InfoGain** methods all compute statistics on individual features. In particular **InfoGain** calculates the mutual information of the individual features to the class, without taking into account their joint informativeness. As such, its comparison with our approaches is a very good indicator of the merit of joint informativeness and its effect on classification performance.

As noted in section 2, the **FCBF** (Liu and Yu, 2003) and **CFS** (Hall and Smith, 1999) baselines employ symmetric uncertainty criteria and check for pairwise redundancy of features. Similarly **MRRM** (Peng et al., 2005), uses mutual information to select features that have high relevance to the class while having low mutual information with the other selected features, thus checking for pairwise informativeness. Comparison with the proposed methods proves the importance of going beyond pairwise redundancy.

The **ReliefF** baseline (Robnik-Sikonja and Kononenko, 2003) looks at the nearest neighbors of random samples along the individual features. In order to compare with spectral clustering approaches we show results for (Wolf and Shashua, 2005), marked as **Spectral** in the tables, which we found to outperform (Zhao and Liu, 2007) in practice. Finally, we also show results for three wrapper methods, namely **SBMLR** (Cawley et al., 2006), which employs a logistic regression predictor, **CMTF** (Argyriou et al., 2008) which uses a sparsity inducing l_1 -norm, and **GBFS** (Xu et al., 2014) which uses gradient boosted trees.

We compare these baselines against the four methods proposed here, namely maximizing the entropy (**GC.E**) or the mutual information (**GC.MI**) under the Gaussian compromise approximation, and maximizing the KL-based entropy (**GKLE**) and mutual information (**GKL.MI**). In the case of the **GC** methods, when an iteration is reached where for all candidate features and for all classes the prior over the class variable is lower than the entropy of f^* , we halt the GC-approximation feature selection procedure and randomly select the remaining features.

5.4 Results

In tables 4, 5, 6, and 7, we show experimental results for the three data sets. In order to show the general applicability of the proposed methods, we combined the selected features with four different classifiers: AdaBoost with classification stumps, linear SVM, RBF-kernel SVM, and quadratic discriminant analysis (QDA). We show results for several numbers of selected features $\{10, 25, 50, 100\}$.

In each of these tables, for each data set and classifier we highlight the best three performing methods in bold, while underlining the best performing method. As can be seen

from these tables, **GC.MI** and **GKLE** consistently rank amongst the top three methods, with **GC.MI** ranking in the top three 24 out of 48 times and first 8 times, and **GKLE** being in the top three 27 out of 48 times and first 11 times. The only other comparable methods are **SBMLR**, which ranks in the top three 17 out of 48 times and first 10 times and **GBFS** which ranks in the top three 20 out of 48 times and first 5 times. We note that both of these methods are wrapper methods.

Furthermore as can be seen in table 3, the running time of the proposed methods³ is very competitive with respect to the more complex feature selection algorithms. The Gaussian Compromise algorithms are especially fast as they are two orders of magnitude faster than practically all other methods. We especially note that the **SBMLR** method which performs comparably in terms of accuracy is very slow when compared to **GC.MI**. Though the **MRRM** algorithm is faster than **GC.MI** on the INRIA data set, it performs considerably worse accuracy-wise on that data set; on the data sets where it does perform well (e.g. CIFAR) it is considerably slower than **GC.MI**. We also note that the **GBFS** method is quite slower than **GC.MI**.

The computation times provided were obtained with C++ implementations of the proposed methods. The **MRRM** algorithm is also implemented in C++, while the **Spectral** and **CMTF** baselines are implemented in MATLAB, as both these algorithms mainly use matrix algebra we believe these timings to be indicative. The remaining algorithms were implemented in Java. As noted in (Bouckaert et al., 2010) these implementations should be competitive in speed with C++ implementations.

	FCBF	MRRM	SBMLR	Spectral	GBFS	CFS	CMTF	ReliefF	GC.MI	GKLE
CIFAR	621	56	1449	1379	95	4262	394	1652	20	486

INRIA	247	32	88	1072	233	2516	459	2413	43	135

Table 3: (Approximate) Cost in CPU time of running the more sophisticated feature selection algorithms in order to select 100 features on the three data sets. We highlight in bold the fastest algorithm for each data set.

5.5 Finite Sample Analysis

The proposed methods all depend on the covariance matrices Σ, Σ^y . Of course, in practice, one rarely has access to the true covariance matrices of the underlying distributions but rather estimates based on using finite sets of samples. Given a $N \times D$ matrix P where each row is a sample from the underlying D -dimensional distribution, we symbolize

$$\hat{\Sigma}_N = \frac{1}{N} P^T P$$

the empirical estimation $\hat{\Sigma}_N$ of matrix Σ , computed from these N samples. The accuracy of this approximation is important to the success of the proposed methods. It can be shown

3. We note that for the **GKLE/MI** methods we used an $O(n^2)$ (per feature per iteration) implementation, in practice and assuming access to adequate memory the method should be even faster.

S															

(see theorem 5.39 in (Vershynin, 2012)) that in the case of a matrix with (sub)-Gaussian generated rows, we have $\forall t \geq 0$ with probability at least $1 - 2e^{-ct^2}$

$$\|\hat{\Sigma}_N - \Sigma\| \leq \max(\delta, \delta^2),$$

where

$$\delta = \frac{C\sqrt{D} + t}{\sqrt{N}}$$

and c, C are constants related to the sub-Gaussian norm of the rows of P . Replacing t with $C't\sqrt{D}$ in the above (see Corollary 5.50 in Vershynin (2012)), we have, for sufficiently large $C', \forall \epsilon \in (0, 1)$, and $\forall t \geq 1$ with probability at least $1 - 2e^{-ct^2}$

$$\text{If } N \geq C(t/\epsilon)^2 D \text{ then } \|\hat{\Sigma}_N - \Sigma\| \leq \epsilon.$$

Thus $N = O(D)$ samples are needed to sufficiently approximate the covariance matrix by the finite sample covariance matrix when the underlying distribution is sub-Gaussian, compared to $O(D \log D)$ for an arbitrary distribution (Corollary 5.52 (Vershynin, 2012)).

Based in this, in order to select d features, the proposed methods theoretically require $O(d)$ samples. This however assumes that the feature selection methods depend solely on the covariance matrices Σ . This holds true only for the GC-approximation in section 3.2.1, the KL-based bound depends both on Σ and Σ^{-1} . Furthermore, as shown in section 3.4, the more efficient implementation of the GC-approximation also depends on Σ^{-1} .

Unfortunately, estimating the precision matrix by taking the inverse of the sample covariance matrix is known to be unstable (Cai et al., 2016). Though a number of methods have been proposed to address this issue (Cai et al., 2011), their complexity makes them unsuitable in the present setting. To investigate whether this instability affects the performance of the proposed methods, we present in the following an empirical analysis of the effect of sample size on prediction performance.

5.5.1 EMPIRICAL EVALUATION

In order to assess the influence of sample set size on performance, we consider the accuracy on the test set of a linear SVM. Specifically we perform feature selection using a subset of the training data by selecting uniformly at random without replacement. Thus the relevant sample covariance matrices are estimated using these smaller sets. We then train a linear SVM using the selected subset of features but using the entire set of samples; this is done to avoid any influence of sample size on the training of the SVM and by extension on the final results.

In figure 8 we show the empirical results on the three data sets (STL, CIFAR, INRIA) in the case where feature selection is performed using the GC-approximation. As can be seen, in the case of the STL and CIFAR data sets the feature selection method proves to be very robust with regards to sample set size; performance degrades only slightly when the sample set size is very small (50 samples per class). On the contrary, in the case of the INRIA data set, we see that the method does not prove to be so robust and the performance suffers. We note that in the plot for the INRIA data set, the x-axis relates the number of samples in the positive class, the number of samples sampled from the negative class was chosen to preserve the class ratio ($\sim 6/1$).

Similarly in figure 9 we show results for the KL-bound case. Here we see that sample size is more influential. A possible explanation is that though the feature selection method arising from the GC-approximation involves the estimation of $|Y| + 1$ inverse covariance matrices, in the case of the KL-bound feature selection method involves $2|Y|$ inverses. Examining the plots in figure 9, we see that in the case of the STL and CIFAR data sets there is some degradation of performance for small sample set sizes, though the performance quickly reaches that of the full set as the subset size increases. In the case of the INRIA data set however we see that the method performs considerably worse when only a subset of the data set is used to perform feature selection.

6. Conclusion

The present work concentrates on developing tractable algorithms to exploit information theoretic criteria for feature selection. The proposed methods focus on feature selection in the context of classification and demonstrate that it is possible to choose features that are jointly informative by careful density modeling and algorithmic implementation. Thus the joint mutual information of variables can in fact be employed efficiently for feature selection as opposed to using only the mutual information of marginal or pairwise distributions as has typically been used in the literature.

The proposed methods rely on modeling the conditional joint distributions of the features given the class to predict and subsequently maximizing either upper bounds on the information theoretic measures or relevant approximations. To reduce the computational cost of a forward feature selection scheme incorporating these criteria, we have proposed efficient implementations for both approaches, so that they are competitive with other state-of-the-art methods in terms of speed. We have also presented a novel method for updating the eigen-decompositions of a specific family of matrices (and updates) which our GC-approximation feature selection algorithm exploits.

Empirical results show the methods to be competitive with current state-of-the-art with respect to prediction accuracy. Furthermore, an empirical analysis of the performance of these methods in connection with the number of samples in the data sets has shown them to be relatively robust in this respect.

Abstract

While machine learning has proven to be a powerful data-driven solution to many real-life problems, its use in sensitive domains has been limited due to privacy concerns. A popular approach known as *differential privacy* offers provable privacy guarantees, but it is often observed in practice that it could substantially hamper learning accuracy. In this paper we study the learnability (whether a problem can be learned by any algorithm) under Vapnik’s general learning setting with differential privacy constraint, and reveal some intricate relationships between privacy, stability and learnability. In particular, we show that a problem is privately learnable *if and only if* there is a private algorithm that asymptotically minimizes the empirical risk (AERM). In contrast, for non-private learning AERM alone is not sufficient for learnability. This result suggests that when searching for private learning algorithms, we can restrict the search to algorithms that are AERM. In light of this, we propose a conceptual procedure that always finds a universally consistent algorithm whenever the problem is learnable under privacy constraint. We also propose a generic and practical algorithm and show that under very general conditions it privately learns a wide class of learning problems. Lastly, we extend some of the results to the more practical (ϵ, δ) -differential privacy and establish the existence of a phase-transition on the class of problems that are approximately privately learnable with respect to how small δ needs to be.

Keywords: *differential privacy, learnability, characterization, stability, privacy-preserving machine learning*

1. Introduction

Increasing public concerns regarding data privacy have posed obstacles in the development and application of new machine learning methods as data collectors and curators may no longer be able to share data for research purposes. In addition to addressing the original goal of information extraction, privacy-preserving learning also requires the learning procedure to protect sensitive information of individual data entries. For example, the second Netflix Prize competition was canceled in response to a lawsuit and Federal Trade Commission privacy concerns, and the National Institute of Health decided in August 2008 to remove

aggregate Genome-Wide Association Studies (GWAS) data from the public web site, after learning about a potential privacy risk.

A major challenge in developing privacy-preserving learning methods is to quantify formally the amount of privacy leakage, given all possible and unknown auxiliary information the attacker may have, a challenge in part addressed by the notion of *differential privacy* (Dwork, 2006; Dwork et al., 2006b). Differential privacy has three main advantages over other approaches: (1) it rigorously quantifies the privacy property of any data analysis mechanism; (2) it controls the amount of privacy leakage regardless of the attacker’s resource or knowledge; (3) it has useful interpretations from the perspectives of Bayesian inference and statistical hypothesis testing, and hence fits naturally in the general framework of statistical machine learning, e.g., see (Dwork and Lei, 2009; Wasserman and Zhou, 2010; Smith, 2011; Lei, 2011; Wang et al., 2015), as well as applications involving regression (Chaudhuri et al., 2011; Thakurta and Smith, 2013) and GWAS data (Yu et al., 2014), etc.

In this paper we focus on the following fundamental question about differential privacy and machine learning: *What problems can we learn with differential privacy?* Most literature focuses on designing differentially private extensions of various learning algorithms, where the methods depend crucially on the specific context and differ vastly in nature. But with the privacy constraint, we have less choice in developing learning and data analysis algorithms. It remains unclear how such a constraint affects our ability to learn, and if it is possible to design a generic privacy-preserving analysis mechanism that is applicable to a wide class of learning problems.

Our Contributions We provide a general answer to the relationship between learnability and differential privacy under Vapnik’s General Learning Setting (Vapnik, 1995) in four aspects.

1. We characterize the subset of problems in the General Learning Setting that can be learned under differential privacy. Specifically, we show that a sufficient and necessary condition for a problem to be privately learnable is the existence of an algorithm that is differentially private and asymptotically minimizes the empirical risk. This characterization generalizes previous studies of the subject (Kasiviswanathan et al., 2011; Beimel et al., 2013a) that focus on binary classification in discrete domain under the PAC learning model. Technically, the result relies on the now well-known intuitive observation that “privacy implies algorithmic stability” and the argument in Shalev-Shwartz et al. (2010) that shows a variant of algorithmic stability is necessary for learnability.
2. We also introduce a weaker notion of learnability, which only requires consistency for a class of distributions \mathcal{D} . Problems that are not privately learnable (a surprisingly large class that includes simple problems such as 0-1 loss binary classification in continuous feature domain (Chaudhuri and Hsu, 2011)) are usually private \mathcal{D} -learnable for some “nice” distribution class \mathcal{D} . We characterize the subset of private \mathcal{D} -learnable problems that are also (non-privately) learnable using conditions analogous to those in distribution-free private learning.

3. Inspired by the equivalence between privacy learnability and private AERM, we propose a generic (but impractical) procedure that always finds a consistent and private algorithm for any privately learnable (or \mathcal{D} -learnable) problems. We also study a specific algorithm that aims at minimizing the empirical risk while preserving the privacy. We show that under a sufficient condition that relies on the geometry of the hypothesis space and the data distribution, this algorithm is able to privately learn (or \mathcal{D} -learn) a large range of learning problems including classification, regression, clustering, density estimation and etc, and it is computationally efficient when the problem is convex. In fact, this generic learning algorithm learns any privately learnable problems in the PAC learning setting (Beimel et al., 2013a). It remains an open problem whether the second algorithm also learns any privately learnable problem in the General Learning Setting.

4. Lastly, we provide a preliminary study of learnability under the more practical (ϵ, δ) -differential privacy. Our results reveal that whether there is separation between learnability and approximate private learnability depends on how fast δ is required to go to 0 with respect to the size of the data. Finding where the exact phase transition occurs is an open problem of future interest.

Our primary objective is to understand the conceptual impact of differential privacy and learnability under a general framework and the rates of convergence obtained in the analysis may be suboptimal. Although we do provide some discussion on polynomial time approximations to the proposed algorithm, learnability under computational constraints is beyond the scope of this paper.

Related work While a large amount of work has been devoted to finding consistent (and rate optimal) differentially private learning algorithms in various settings (e.g., Chaudhuri et al., 2011; Kifer et al., 2012; Jain and Thakurta, 2013; Bassily et al., 2014), the characterization of privately learnable problems were only studied in a few special cases.

Kasiviswanathan et al. (2011) showed that, for binary classification with a finite discrete hypothesis space, anything that is non-privately learnable is privately learnable under the agnostic Probably Approximately Correct (PAC) learning framework, therefore “finite VC-dimension” characterizes the set of private learnable problems in this setting. Beimel et al. (2013a) extends Kasiviswanathan et al. (2011) by characterizing the sample complexity of the same class of problems, but the result only applies to the realizable (non-agnostic) case. Chaudhuri and Hsu (2011) provided a counter-example showing that for continuous hypothesis space and data space, there is a gap between learnability and learnability under privacy constraint. They proposed to fix this issue by either weakening the privacy requirement to labels only or by restricting the class of potential distribution. While meaningful in some cases, these approaches do not resolve the learnability problem in general.

A key difference of our work from Kasiviswanathan et al. (2011); Chaudhuri and Hsu (2011); Beimel et al. (2013a) is that we consider a more general class of learning problems and provide a proper treatment in a statistical learning framework. This allows us to capture a wider collection of important learning problems (see Figure 1(a) and Table 1).

It is important to note that despite its generality, Yagnik’s general learning setting still does not nearly cover the full spectrum of private learning. In particular, our results do not apply to improper learning (learning using a different hypothesis class) as considered in Beimel et al. (2013a) or to structural loss minimization (the loss function jointly take all data points as input) considered in Beimel et al. (2013b). Also, our results do not address the sample complexity problem, which remains open in the general learning setting even for learning without privacy constraints.

Our characterization of private learnability (and private \mathcal{D} -learnability) in Section 3 uses a recent advance in the characterization of general learnability given by Shalev-Shwartz et al. (2010). Roughly speaking, they showed that a problem is learnable if and only if there exists an algorithm that (i) is stable under small perturbation of training data, and (ii) behaves like empirical risk minimization (ERM) asymptotically. We also makes use of a folklore observation that “Privacy \Rightarrow Stability \Rightarrow Generalization”. The connection of privacy and stability appeared as early as 2008 in a conference version of Kasiviswanathan et al. (2011). Further connection to “generalization” recently appeared in blog posts¹, stated as a theorem in Appendix F of Bassily et al. (2014), and was shown to hold with strong concentration in Dwork et al. (2015b).

Dwork et al. (2015b) is part of an independent line of work (Hardt and Ullman, 2014; Bassily et al., 2015; Dwork et al., 2015a; Blum and Hardt, 2015) on adaptive data analysis, which also stems from the observation that privacy implies stability and generalization. Comparing to adaptive data analysis works, our focus is quite different. Adaptive data analysis work focus on the impact of k on how fast the maximum absolute error of k -adaptively chosen queries goes to 0 as a function of n , while this paper is concerned with whether the error can go to 0 at all for each learning problem when we require the learning algorithm be differentially private with $\epsilon < \infty$. Nonetheless, we acknowledge that Theorem 7 in Dwork et al. (2015b) provides an interesting alternative proof for “differentially private learners have small generalization error”, when choosing the statistical query as evaluating a loss function at a privately learned hypothesis. The connection is not quite obvious and we provide a more detailed explanation in Appendix B.

The main tool used in the construction of our generic private learning algorithm in Section 4 is the Exponential Mechanism (McSherry and Talwar, 2007), which provides a simple and differentially-private approximation to the maximizer of a score function among a candidate set. In the general learning context, we use the negative empirical risk as the utility function, and apply the exponential mechanism to a possibly pre-discretized hypothesis space. This exponential mechanism approach was used in Bassily et al. (2014) for minimizing convex and Lipschitz functions. The sample discretization procedure has been considered in Chaudhuri and Hsu (2011) and Beimel et al. (2013a). Our scope and proof techniques are different. Our strategy is to show that, under some general regularity conditions, the exponential mechanism is stable and behaves like ERM. Our sublevel set condition has the same flavor

1. For instance, Frank McSherry described in a blog post an example of exploiting differential privacy for measure concentration <http://windsontheory.org/2014/02/04/differential-privacy-for-measure-concentration/>; Moritz Hardt discussed the connection of differential privacy to stability and generalization in his blog post <http://blog.mrtz.org/2014/01/13/false-discovery/>.

as that in the proof of Bassily et al. (2014, Theorem 3.2), although we do not need the loss function to be convex or Lipschitz.

Stability, privacy and generalization were also studied in Thakurta and Smith (2013) with different notions of stability. More importantly, their stability is used as an assumption rather than a consequence, so their result is not directly comparable to ours.

2. Background

2.1 Learnability under the General Learning Setting

In the General Learning Setting of Vapnik (1995), a learning problem is characterized by a triplet $(\mathcal{Z}, \mathcal{H}, \ell)$. Here \mathcal{Z} is the sample space (with a σ -algebra). The hypothesis space \mathcal{H} is a collection of models such that each $h \in \mathcal{H}$ describes some structures of the data. The loss function $\ell : \mathcal{H} \times \mathcal{Z} \rightarrow \mathbb{R}$ measures how well the hypothesis h explains the data instance $z \in \mathcal{Z}$. For example, in supervised learning problems $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$ where \mathcal{X} is the feature space and \mathcal{Y} is the label space; \mathcal{H} defines a collection of mapping $h : \mathcal{X} \rightarrow \mathcal{Y}$; and $\ell(h, z)$ measures how well h predicts the feature-label relationship $z = (x, y) \in \mathcal{Z}$. This setting includes problems with continuous input/output in potentially infinite dimensional spaces (e.g. RKHS methods), hence is much more general than PAC learning. In addition, the general learning setting also covers a variety of unsupervised learning problems, including clustering, density estimation, principal component analysis (PCA) and variants (e.g. Sparse PCA, Robust PCA), dictionary learning, matrix factorization and even Latent Dirichlet Allocation (LDA). Details of these examples are given in Table 1 (the first few are extracted from Shalev-Shwartz et al. (2010)).

To account for the randomness in the data, we are primarily interested in the case where the data $Z = \{z_1, \dots, z_n\} \in \mathcal{Z}^n$ are independent samples drawn from an unknown probability distribution \mathcal{D} on \mathcal{Z} . We denote such a random sample by $Z \sim \mathcal{D}^n$. For a given distribution \mathcal{D} , let $R(h)$ be the expected loss of hypothesis h and $\hat{R}(h, Z)$ the empirical risk from a sample $Z \in \mathcal{Z}^n$.

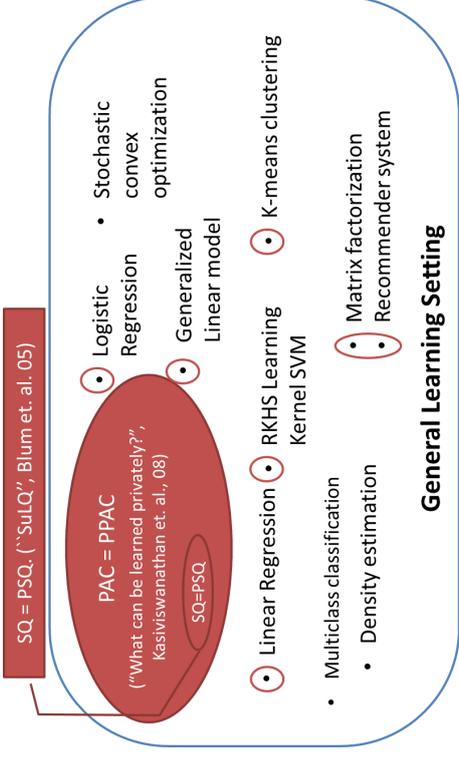

$$R(h) = \mathbb{E}_{z \sim \mathcal{D}} \ell(h, z), \quad \hat{R}(h, Z) = \frac{1}{n} \sum_{i=1}^n \ell(h, z_i).$$

The optimal risk $R^* = \inf_{h \in \mathcal{H}} R(h)$ and we assume that it is achieved by an optimal $h^* \in \mathcal{H}$. Similarly, the minimal empirical risk $\hat{R}^*(Z) = \inf_{h \in \mathcal{H}} \hat{R}(h, Z)$ is achieved by $\hat{h}^*(Z) \in \mathcal{H}$. For a possibly randomized algorithm $\mathcal{A} : \mathcal{Z}^n \rightarrow \mathcal{H}$ that learns some hypothesis $\mathcal{A}(Z) \in \mathcal{H}$ given data sample Z , we say \mathcal{A} is *consistent* if

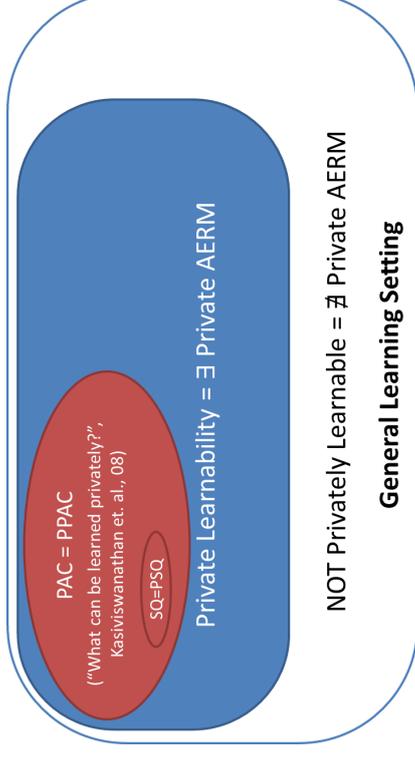

$$\lim_{n \rightarrow \infty} \mathbb{E}_{Z \sim \mathcal{D}^n} (\mathbb{E}_{h \sim \mathcal{A}(Z)} R(h) - R^*) = 0. \quad (1)$$

In addition, we say \mathcal{A} is consistent with rate $\xi(n)$ if

$$\mathbb{E}_{Z \sim \mathcal{D}^n} (\mathbb{E}_{h \sim \mathcal{A}(Z)} R(h) - R^*) \leq \xi(n), \quad \text{where } \lim_{n \rightarrow \infty} \xi(n) \rightarrow 0. \quad (2)$$

(a) Illustration of general learning setting. Examples of known DP extensions are circled in maroon.

(b) Our characterization of private learnable problems in the general learning setting (in blue).

Figure 1: The Big Picture: illustration of general learning setting and our contribution in understanding differentially private learnability.

Problem	Hypothesis class \mathcal{H}	\mathcal{Z} or $\mathcal{X} \times \mathcal{Y}$	Loss function ℓ
Binary classification	$\mathcal{H} \subset \{f : \{0, 1\}^d \rightarrow \{0, 1\}\}$	$\{0, 1\}^d \times \{0, 1\}$	$1(\ell(x) \neq y)$
Regression	$\mathcal{H} \subset \{f : [0, 1]^d \rightarrow \mathbb{R}\}$	$[0, 1]^d \times \mathbb{R}$	$ h(x) - y ^2$
Density Estimation	Bounded distributions on \mathcal{Z}	$\mathcal{Z} \subset \mathbb{R}^d$	$-\log(\ell(z))$
K-means Clustering	$\{S \subset \mathbb{R}^d : S = k\}$	$\mathcal{Z} \subset \mathbb{R}^d$	$\min_c \ c - z\ ^2$
RKHS classification	Bounded RKHS	$\text{RKHS} \times \{0, 1\}$	$\max_{\{0, 1\}} 1 - y \langle x, h \rangle $
RKHS regression	Bounded RKHS	\mathbb{R}^d	$ \langle x, h \rangle - y ^2$
Sparse PCA	Rank- r projection matrices	\mathbb{R}^d	$\ hz - z\ ^2 + \lambda \ h\ _1$
Robust PCA	All subspaces in \mathbb{R}^d	\mathbb{R}^d	$\ P_h(z) - z\ _1 + \lambda \text{rank}(h)$
Matrix Completion	All subspaces in \mathbb{R}^d	$\mathbb{R}^d \times \{1, 0\}^d$	$\min_{h \in \mathcal{H}} \ y \circ (\theta - x)\ ^2 + \lambda \text{rank}(h)$
Dictionary Learning	All dictionaries $\in \mathbb{R}^{d \times r}$	\mathbb{R}^d	$\min_{h \in \mathcal{H}} \ hb - z\ ^2 + \lambda \ h\ _1$
Non-negative MF	All dictionaries $\in \mathbb{R}^{d \times r}$	\mathbb{R}^d	$\min_{h \in \mathcal{H}} \ hb - z\ ^2$
Subspace Clustering	A set of k rank- r subspaces	\mathbb{R}^d	$\min_{h \in \mathcal{H}} \ P_h(z) - z\ ^2$
Topic models (LDA)	$\{\mathbb{P}(\text{word} \text{topic})\}$	Documents	$-\max_{h \in \{\text{Topic}\}} \sum_{w \in \mathcal{Z}} \log \mathbb{P}_{h,h}(w)$

Table 1: An illustration of problems in the General Learning setting.

Since the distribution \mathcal{D} is unknown, we cannot adapt the algorithm \mathcal{A} to \mathcal{D} , especially when privacy is a concern. Also, even if \mathcal{A} is pointwise consistent for any distribution \mathcal{D} , it may have different rates for different \mathcal{D} and potentially be arbitrarily slow for some \mathcal{D} . This makes it hard to evaluate whether \mathcal{A} indeed learns the learning problem and forbids the study of the learnability problem. In this study, we adopt the stronger notion of learnability considered in Shalev-Shwartz et al. (2010), which is a direct generalization of PAC-learnability (Valiant, 1984) and agnostic PAC-learnability (Kearns et al., 1992) to the General Learning Setting as studied by Haussler (1992).

Definition 1 (Learnability, Shalev-Shwartz et al., 2010) *A learning problem is learnable if there exists an algorithm \mathcal{A} and rate $\xi(n)$, such that \mathcal{A} is consistent with rate $\xi(n)$ for any distribution \mathcal{D} defined on \mathcal{Z} .*

This definition requires consistency to hold universally for any distribution \mathcal{D} with a uniform (distribution-independent) rate $\xi(n)$. This type of problem is often called *distribution-free learning* (Valiant, 1984), and an algorithm is said to be *universally consistent* with rate $\xi(n)$ if it realizes the criterion.

2.2 Differential privacy

Differential privacy requires that if we arbitrarily perturb a database by only one data point, the output should not differ much. Therefore, if one conducts a statistical test for whether any individual is in the database or not, the false positive and false negative probabilities cannot both be small (Wasserman and Zhou, 2010). Formally, define “Hamming distance”

$$d(Z, Z') := \#\{i = 1, \dots, n : z_i \neq z'_i\}. \quad (3)$$

Definition 2 (ϵ -Differential Privacy, Dwork, 2006) *An algorithm \mathcal{A} is ϵ -differentially private, if*

$$\mathbb{P}(\mathcal{A}(Z) \in H) \leq \exp(\epsilon) \mathbb{P}(\mathcal{A}(Z') \in H)$$

for $\forall Z, Z'$ obeying $d(Z, Z') = 1$ and any measurable subset $H \subseteq \mathcal{H}$.

There are weaker notions of differential privacy. For example (ϵ, δ) -differential privacy allows for a small probability δ where the privacy guarantee does not hold. In this paper, we will mainly work with the stronger ϵ -differential privacy. In Section 6 we discuss the problem of (ϵ, δ) -differential privacy and extend some of the results to this setting.

Our objective is to understand whether there is a gap between learnable problems and privately learnable problems in the general learning setting, and to quantify the tradeoff required to protect privacy. To achieve this objective, we need to show the existence of an algorithm that learns a class of problems while preserving differential privacy. More formally, we define

Definition 3 (Private learnability) *A learning problem is privately learnable with rate $\xi(n)$ if there exists an algorithm \mathcal{A} that satisfies both universal consistency (as in Definition 1) with rate $\xi(n)$ and ϵ -differential privacy with privacy parameter $\epsilon < \infty$.*

We can view the consistency requirement Definition 3 as a measure of utility. This utility is not a function of the observed data, however, but rather how the results generalize to unseen data.

The following lemma shows that the above definition of private learnability is actually equivalent to a seemingly much stronger condition with a vanishing privacy loss ϵ .

Lemma 4 *If there is an ϵ -DP algorithm that is consistent with rate $\xi(n)$ for some constant $0 < \epsilon < \infty$, then there is a $\frac{\epsilon}{\sqrt{n}}$ ($\epsilon - \epsilon^{-\gamma}$)-DP algorithm that is consistent with rate $\xi(\sqrt{n})$.*

The proof, given in Appendix A.1, uses a subsampling theorem adapted from Beimel et al. (2014, Lemma 4.4).

There are many approaches to design differentially private algorithms, such as noise perturbation using Laplace noise (Dwork, 2006; Dwork et al., 2006b) and the Exponential Mechanism (McSherry and Talwar, 2007). Our construction of generic differentially private learning algorithms applies the Exponential Mechanism to penalized empirical risk minimization. Our argument will make use of a general characterization of learnability described below.

2.3 Stability and Asymptotic ERM

An important breakthrough in learning theory is a full characterization of all learnable problems in the General Learning Setting in terms of stability and empirical risk minimization (Shalev-Shwartz et al., 2010). Without assuming uniform convergence of empirical risk, Shalev-Shwartz et al. showed that a problem is learnable if and only if there exists a “strongly uniform-RO stable” and “always asymptotically empirical risk minimization” (Always AERM) randomized algorithm that learns the problem. Here “RO” stands for “replace one”. Also,

any strongly uniform-RO stable and “universally” AERM (weaker than “always” AERM) learning rule learns the problem consistently. Here we give detailed definitions.

Definition 5 (Universally/Always AERM, Shalev-Shwartz et al., 2010) A (possibly randomized) learning rule \mathcal{A} is *Universally AERM* if for any distribution \mathcal{D} defined on domain \mathcal{Z}

$$\mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}^*(Z)] \rightarrow 0, \text{ as } n \rightarrow \infty$$

where $\hat{R}^*(Z)$ is the minimum empirical risk for data set Z . We say \mathcal{A} is *Always AERM*, if in addition,

$$\sup_{Z \in \mathcal{Z}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}^*(Z) \rightarrow 0, \text{ as } n \rightarrow \infty.$$

Definition 6 (Strongly Uniform RO-Stability, Shalev-Shwartz et al., 2010) An algorithm \mathcal{A} is *strongly uniform RO-stable* if

$$\sup_{z \in \mathcal{Z}} \sup_{\substack{z, z' \in \mathcal{Z}^n, \\ d(z, z') = 1}} |\mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z) - \mathbb{E}_{h \sim \mathcal{A}(Z')} \ell(h, z)| \rightarrow 0 \text{ as } n \rightarrow \infty.$$

where $d(Z, Z')$ is defined in (3), in other word, Z and Z' can differ by at most one data point.

Since we will not deal with other variants of algorithmic stability in this paper (e.g., hypothesis stability (Kearns and Ron, 1999), uniform stability (Bousquet and Elisseeff, 2002) and leave-one-out (LOO) stability in Mukherjee et al. (2006)), we simply call Definition 6 stability or uniform stability. Likewise, we will refer to ϵ -differential privacy as just “privacy” although there are several other notions of privacy in the literature.

3. Characterization of private learnability

We are now ready to state our main result. The only assumption we make is the uniform boundedness of the loss function. This is also assumed in Shalev-Shwartz et al. (2010) for the learnability problem without privacy constraints. Without loss of generality, we can assume $0 \leq \ell(h, z) \leq 1$.

Theorem 7 Given a learning problem $(\mathcal{Z}, \mathcal{H}, \ell)$, the following statements are equivalent.

1. The problem is *privately learnable*.
2. There exists a *differentially private universally AERM algorithm*.
3. There exists a *differentially private always AERM algorithm*.

The proof is simple yet revealing, we will present the arguments for $2 \Rightarrow 1$ (sufficiency of AERM) in Section 3.1 and $1 \Rightarrow 3$ (necessity of AERM) in Section 3.2. $3 \Rightarrow 2$ follows trivially from the definition of “always” and “universal” AERM.

The theorem says that we can stick to ERM-like algorithms for private learning, despite that ERM may fail for some problems in the (non-private) general learning setting (Shalev-Shwartz et al., 2010). Thus a standard procedure for finding universally consistent and

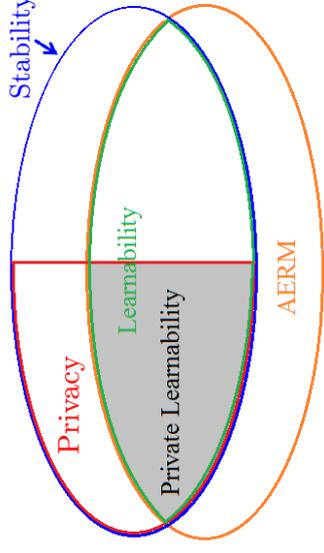

Figure 2: A summary of the relationships of various notions revealed by our analysis.

differentially private algorithms would be to approximately minimize the empirical risk using some differentially private procedures (Chaudhuri et al., 2011; Kifer et al., 2012; Bassily et al., 2014). If the utility analysis reveals that the method is AERM, we do not need to worry about generalization as it is guaranteed by privacy. This consistency analysis is considerably simpler than non-private learning problems where one typically needs to control generalization error either via uniform convergence (VC-dimension, Rademacher complexity, metric entropy, etc) or to adopt the stability argument (Shalev-Shwartz et al., 2010).

This result does not imply that privacy is helping the algorithm to learn in any sense, as the simplicity is achieved at the cost of having a smaller class of learnable problems. A concrete example of a problem being learnable but not privately learnable is given in (Chaudhuri and Hsu, 2011) and we will revisit it in Section 3.3. For some problems where ERM fails, it may not be possible to make it AERM while preserving privacy. In particular, we were not able to privatize the problem in Section 4.1 of Shalev-Shwartz et al. (2010).

To avoid any potential misunderstanding, we stress that Theorem 7 is a characterization of learnability, *not* learning algorithms. It does not prevent the existence of a universally consistent learning algorithm that is private but not AERM. Also, the characterization given in Theorem 7 is about consistency, and it does not claim anything on sample complexity. An algorithm that is AERM may be suboptimal in terms of convergence rate.

3.1 Sufficiency: Privacy implies stability

A key ingredient in the proof of sufficiency is a well-known heuristic observation that differential privacy by definition implies uniform stability, which is useful in its own right.

Lemma 8 (Privacy \Rightarrow Stability) Assume $0 \leq \ell(h, z) \leq 1$, any ϵ -differentially private algorithm satisfies $(\epsilon^\epsilon - 1)$ -stability. Moreover if $\epsilon \leq 1$ it satisfies 2ϵ -stability.

The proof of this lemma comes directly from the definition of differential privacy so it is algorithm independent. The converse, however, is not true in general (e.g., a non-trivial deterministic algorithm can be stable, but not differentially private.)

Corollary 9 (Privacy + Universal AERM \Rightarrow Consistency) *If a learning algorithm \mathcal{A} is $\epsilon(n)$ -differentially private and \mathcal{A} is universally AERM with rate $\xi(n)$, then \mathcal{A} is universally consistent with rate $\xi(n) + e^{\epsilon(n)} - 1 = O(\xi(n) + \epsilon(n))$.*

The proof of Corollary 9, provided in the Appendix, combines Lemma 8 and the fact that consistency is implied by stability and AERM (Theorem 28). Our Theorem 28 is based on minor modifications of Theorem 8 in Shalev-Shwartz et al. (2010). In fact, Corollary 9 can be stated in a stronger per distribution form, since universality is not used in the proof. We will revisit this point when we discuss a weaker notion of private learnability below.

Lemma 4 and Corollary 9 together establishes $2 \Rightarrow 1$ in Theorem 7.

If for a problem privacy and always AERM cannot coexist, then the problem is not privately learnable. This is what we will show next.

3.2 Necessity: Consistency implies Always AERM

To prove that the existence of an always AERM learning algorithm is necessary for any private learnable problems, it suffices to construct such a learning algorithm from or each learnable problem. any universally consistent learning algorithm.

Lemma 10 (Consistency + Privacy \Rightarrow Private Always AERM) *If \mathcal{A} is a universally consistent learning algorithm satisfying ϵ -DP with any $\epsilon > 0$ and consistent with rate $\xi(n)$, then there is another universally consistent learning algorithm \mathcal{A}' that is always AERM with rate $\xi(\sqrt{n})$ and satisfies $\frac{2}{\sqrt{n}}(\epsilon^e - e^{-\epsilon})$ -DP.*

Lemma 10 is proved in Appendix A.2. The proof idea is to run \mathcal{A} on a size $O(\sqrt{n})$ random subsample of Z , which will be universally consistent with a slower rate, differentially private with $\epsilon(n) \rightarrow 0$ (Lemma 27), and at the same time always AERM. The last part uses an argument in Lemma 24 of Shalev-Shwartz et al. (2010) which appeals to the universality of \mathcal{A} 's consistency on a specific discrete distribution supported on the given data set Z .

As pointed out by an anonymous reviewer, there is a simpler proof by invoking Theorem 10 of Shalev-Shwartz et al. (2010) that says any consistent and generalizing algorithm must be AERM and a result (e.g., Bassily et al., 2014, Appendix F) that says ‘‘privacy \Rightarrow generalization’’. This is a valid observation. But their Theorem 10 is proven using a detour through ‘‘generalization’’, which leads to a slower rate than what we are able to obtain in Lemma 10 using a more direct argument.

3.3 Private Learnability vs. Non-private Learnability

Now we have a characterization of all privately learnable problems, a natural question to ask is that whether any learnable problem is also privately learnable. The answer is ‘‘yes’’

for learning in Statistical Query (SQ)-model and PAC Learning model (binary classification) with finite hypothesis space, and is ‘‘no’’ for continuous hypothesis space (Chaudhuri and Hsu, 2011).

By definition, all privately learnable problems are learnable. But now that we know that privacy implies generalization, it is tempting to hope that privacy can help at least some problem to learn better than any non-private algorithm. In terms of learnability, the question becomes: Could there be a (learnable) problem that is *exclusively* learnable through private algorithms? We now show that such a problem does not exist.

Proposition 11 *If a learning problem is learnable by an ϵ -DP algorithm \mathcal{A} , then it is also learnable by a non-private algorithm.*

The proof is given in Appendix A.3. The idea is that $\mathcal{A}(Z)$ defines a distribution over \mathcal{H} . Pick an $z \in \mathcal{Z}$. If $z \notin Z$, algorithm $\mathcal{A}' = \mathcal{A}$. Otherwise, $\mathcal{A}'(Z)$ samples from a slightly different distribution than $\mathcal{A}(Z)$ that does not affect the expectation much.

On the other hand, not all learnable problems are privately learnable. This can already be seen from Chaudhuri and Hsu (2011), where the gap between learning and private learning is established. We revisit Chaudhuri and Hsu’s example in our notation under the general learning setting and produce an alternative proof by showing that differential privacy contradicts *always AERM*, then invoking Theorem 7 to show the problem is not privately learnable.

Proposition 12 (Chaudhuri and Hsu, 2011, Theorem 5) *There exists a problem that is learnable by a non-private algorithm, but not privately learnable. In particular, any private algorithm cannot be always AERM in this problem.*

We describe the counterexample and re-establish the impossibility of private learning for this problem using the contrapositive of Theorem 7, which suggests that if privacy and always AERM algorithm cannot coexist for some problem, then the problem is not privately learnable.

Consider the binary classification problem with $\mathcal{X} = [0, 1]$, $\mathcal{Y} = \{0, 1\}$ and 0-1 loss function. Let \mathcal{H} be the collection of threshold functions that output $h(x) = 1$ if $x > h$ and $h(x) = 0$ otherwise. This class has VC-dimension 1, and hence the problem is learnable.

Next we will construct $K = \lceil \exp(\epsilon_0 n) \rceil$ data sets such that if $K - 1$ of them obey AERM, the remaining one cannot be. Let $\eta = 1/\exp(\epsilon n)$, $K := \lceil 1/\eta \rceil$. Let h_1, h_2, \dots, h_K be a disjoint thresholds such that they are at least η apart and $[h_i - \eta/3, h_i + \eta/3]$ are disjoint intervals.

If we take $Z_i \subseteq [h_i - \eta/3, h_i + \eta/3]$ with half of the points in $[h_i - \eta/3, h_i)$ and the other half in $(h_i, h_i + \eta/3]$ and we label each data point in it with $\mathbf{1}(z > h_i)$, then empirical risk $\hat{R}(h_i, Z_i) = 0 \forall i = 1, \dots, K$. So for any AERM learning rule, $\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z_i) \rightarrow 0$ for all i . For some sufficiently large n , $\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z_i) < 0.1$.

Now consider Z_1 ,

$$\mathbb{P}(\mathcal{A}(Z_1) \notin [h_1 - \eta/3, h_1 + \eta/3]) \geq \sum_{i=2}^K \mathbb{P}(\mathcal{A}(Z_i) \in [h_i - \eta/3, h_i + \eta/3]), \quad (4)$$

since these intervals are disjoint. Then by the definition of ϵ -DP,

$$\mathbb{P}(\mathcal{A}(Z_1) \in [h_1 - \eta/3, h_1 + \eta/3]) \geq \exp(-\epsilon n) \mathbb{P}(\mathcal{A}(Z_i) \in [h_i - \eta/3, h_i + \eta/3]). \quad (5)$$

It follows that $\mathbb{P}(\mathcal{A}(Z_i) \in [h_i - \eta/3, h_i + \eta/3]) > 0.9$ otherwise $\mathbb{E}_{h \sim \mathcal{A}(Z_i)} \tilde{R}(h, Z_i) \geq 0.1$, therefore

$$\mathbb{P}(\mathcal{A}(Z_1) \notin [h_1 - \eta/3, h_1 + \eta/3]) \geq K \exp(-\epsilon n) 0.9 \geq 0.9, \quad (5)$$

and $\mathbb{E}_{h \sim \mathcal{A}(Z_i)} \tilde{R}(h, Z_i) \geq 0.9 \times 1 = 0.9$, which violates the “always AERM” condition that requires $\mathbb{E}_{h \sim \mathcal{A}(Z_1)} \tilde{R}(h, Z_1) < 0.1$. Therefore, the problem is not privately learnable.

As is pointed out by an anonymous reviewer, the same conclusion of this impossibility result of privately learning thresholds on $[0, 1]$ can be drawn numerically through the characterization of the sample complexity (Beimel et al., 2013a), via the bound that depends logarithmically on the $\log(|\mathcal{H}|)$ and on $[0, 1]$ this number is infinite. The above analysis provides different insights about the problem. We will be using it again for understanding the separation of learnability and learnability under (ϵ, δ) -Differential Privacy later in Section 6.

3.4 Private \mathfrak{D} -learnability

The above example implies that even very simple learning problems may not be privately learnable. To fix this caveat, note that most data sets of practical interest have nice distributions. Therefore, it makes sense to consider a smaller class of distributions, e.g., smooth distributions that have bounded k th order derivative, or those having bounded total variation. These are common assumptions in non-parametric statistics, such as kernel density estimation, smoothing spline regression and mode clustering. Similarly, in high dimensional statistics, there are often assumptions on the structures of the underlying distribution, such as sparsity, smoothness, and low-rank conditions.

Definition 13 ((Private) \mathfrak{D} -learnability) We say a learning problem $(\mathcal{Z}, \mathcal{H}, \ell)$ is \mathfrak{D} -learnable if there exists a learning algorithm \mathcal{A} that is consistent for every unknown distribution $\mathcal{D} \in \mathfrak{D}$. If in addition, the problem is \mathfrak{D} -learnable under ϵ -differential privacy for some $0 \leq \epsilon < \infty$, then we say the problem is privately \mathfrak{D} -learnable.

Almost all of our arguments hold in a per distribution fashion, therefore they also hold for any such subclass \mathfrak{D} . The only exception is the necessity of “always AERM” (Lemma 10), where we used the universal consistency on an arbitrary discrete uniform distribution in the proof. The characterization still holds if the class \mathfrak{D} contains all finite discrete uniform distributions. For general distribution classes, we characterize private \mathfrak{D} -learnability using a weaker “universally AERM” (instead of “always AERM”) under the assumption that the problem itself is learnable in a distribution-free setting without privacy constraints.

Lemma 14 (private \mathfrak{D} -learnability \Rightarrow private \mathfrak{D} -universal AERM) If an ϵ -DP algorithm \mathcal{A} is \mathfrak{D} -universally consistent with rate $\xi(n)$ and the problem itself is learnable in a distribution-free sense with rate $\xi'(n)$, then there exists a \mathfrak{D} -universally consistent learning algorithm \mathcal{A}' that is \mathfrak{D} -universally AERM with rate $12\xi'(n)^{1/4} + \frac{3\xi}{\sqrt{n}} + \xi(\sqrt{n})$ and satisfies $\frac{2}{\sqrt{n}}(\epsilon^\epsilon - \epsilon^{-\epsilon})$ -DP.

The proof, given in Appendix A.4, shows that the algorithm \mathcal{A}' that applies \mathcal{A} to a random subsample of size $\lfloor \sqrt{n} \rfloor$ is AERM for any distribution in the class \mathfrak{D} .

Theorem 15 (Characterization of private \mathfrak{D} -learnability) A problem is privately \mathfrak{D} -learnable if there exists an algorithm that is \mathfrak{D} -universally AERM and differentially private with privacy loss $\epsilon(n) \rightarrow 0$. If in addition, the problem is (distribution-free and non-privately) learnable, then the converse is also true.

Proof The “if” part is exactly the same as the argument in Section 3.1, since both Lemma 8 and Lemma 9 holds for each distribution independently. Under the additional assumption that the problem itself is learnable (distribution-free and non-privately), the “only if” part is given by Lemma 14. ■

This result may appear to be unsatisfactory due to the additional assumption of learnability. It is clearly a strong assumption because many problems that are \mathfrak{D} -learnable for a practically meaningful \mathfrak{D} are not actually learnable. We provide one such example here.

Example 1 Let the data space be $[0, 1]$, the hypothesis space be the class of all finite subset of $[0, 1]$ and the loss function $\ell(h, z) = 1_{z \notin h}$. This problem is not learnable, and not even \mathfrak{D} -learnable when \mathfrak{D} is the class of all discrete distributions with finite number of possible values. But it is \mathfrak{D} -learnable when \mathfrak{D} is further restricted with an upper bound on the total number of possible values.

Proof For any discrete distribution with a finite support set, there is an $h \in \mathcal{H}$ such that the optimal risk is 0. Assume the problem is learnable with rate $\xi(n)$, then for some n $\xi(n) < 0.5$. However, we can always construct a uniform distribution over $3n$ elements and it is information-theoretically impossible for any estimators based on n samples from the distribution to achieve a risk better than $2/3$. The problem is therefore not learnable. When we assume an upper bound N on the maximum number of bins of the underlying distribution, then the ERM which outputs just the support of all observed data will be universally consistent with rate $\xi(n) = N/n$. ■

It turns out that we cannot hope to completely remove the assumption from Theorem 15. The following example illustrates that some form of qualification (implied by the learnability assumption) is necessary for the converse statement to be true.

Example 2 Consider the learning problem in Example 1. Let \mathfrak{D} be the class of all continuous distributions. There is a learning problem that is s privately \mathfrak{D} -learnable but no private AERM algorithm exists.

Proof Let the learning problem be that in Example 1 and \mathcal{Q} be the class of all continuous distributions defined on $[0, 1]$. Consider the learning algorithm $\mathcal{A}(Z)$ always returns $h = \theta$. The optimal risk for any continuous distribution is 1 because any finite subset is of measure 0, output θ is 0-consistent and 0-generalizing, but not AERM, since the minimum empirical risk is 0. \mathcal{A} is also 0-differentially private, therefore the problem is privately \mathcal{Q} -learnable for \mathcal{Q} being the set of all continuous distributions.

However, it is not privately \mathcal{Q} -learnable via an AERM, i.e., no private AERM algorithm exists for this problem. We prove this by contradiction. Assume an ϵ -DP AERM algorithm exists, the subsampling lemma ensures the existence of an $\epsilon(n)$ -DP AERM algorithm \mathcal{A}' with $\epsilon(n) \rightarrow 0$. \mathcal{A}' is therefore generalizing by stability, and it follows that the \mathcal{A}' has risk $\mathbb{E}_{h \sim \mathcal{A}'(Z)} R(h)$ converging to 0. But there is no $h \in \mathcal{H}$ such that $R(h) < 1$, giving the contradiction. ■

Interestingly, this problem is \mathcal{Q} -learnable via a non-private AERM algorithm, which always outputs $h = Z$. This is 0-consistent, 0-AERM but not generalizing. This example suggests that \mathcal{Q} -learnability and learnability are quite different because for learnable problems, if an algorithm is consistent and AERM, then it must also be generalizing (Shalev-Shwartz et al., 2010, Theorem 10).

3.5 A generic learning algorithm

The characterization of private learnability suggests a generic (but impractical) procedure that learns all privately learnable problems (in the same flavor as the generic algorithm in Shalev-Shwartz et al. (2010)) that learns all learnable problems). This is to solve

$$\underset{\substack{(\mathcal{A}, \phi): \\ \mathcal{A}: \mathcal{Z}^n \rightarrow \mathcal{H}, \\ \mathcal{A} \text{ is } \epsilon\text{-DP}}}{\operatorname{argmin}} \left[\epsilon + \sup_{Z \in \mathcal{Z}^n} \left(\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \inf_{h \in \mathcal{H}} \hat{R}(h, Z) \right) \right], \quad (6)$$

or to privately \mathcal{Q} -learn the problem when (6) is not feasible

$$\underset{\substack{(\mathcal{A}, \phi): \\ \mathcal{A}: \mathcal{Z}^n \rightarrow \mathcal{H}, \\ \mathcal{A} \text{ is } \epsilon\text{-DP}}}{\operatorname{argmin}} \left[\epsilon + \sup_{D \in \mathcal{Q}} \mathbb{E}_{Z \sim \mathcal{D}^n} \left(\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \inf_{h \in \mathcal{H}} \hat{R}(h, Z) \right) \right]. \quad (7)$$

Theorem 16 *Assume the problem is learnable. If the problem is private learnable, (6) will always output a universally consistent private learning algorithm. If the problem is private \mathcal{Q} -learnable, (7) will always output a \mathcal{Q} -universally consistent private learning algorithm.*

Proof If the problem is private learnable, by Theorem 7 there exists an algorithm \mathcal{A} that is $\epsilon(n)$ -DP and always AERM with rate $\xi(n)$ and $\epsilon(n) + \xi(n) \rightarrow 0$. This \mathcal{A} is a witness in the optimization so we know that any minimizer of (6) will have a objective value that is no greater than $\epsilon(n) + \xi(n)$ for any n . Corollary 9 concludes its universal consistency. The second claim follows from the characterization of private \mathcal{Q} -learnability in Theorem 15. ■

Algorithm 1 Exponential Mechanism for regularized ERM

Input: Data points $Z = \{z_1, \dots, z_n\} \in \mathcal{Z}^n$, loss function ℓ , regularizer g_n , privacy parameter $\epsilon(n)$ and a hypothesis space \mathcal{H} .

1. Construct utility function $q(h, Z) := -\frac{1}{n} \sum_{i=1}^n \ell(h, z_i) - g_n(h)$, and its sensitivity $\Delta q := \sup_{h \in \mathcal{H}, d(Z, Z')=1} |q(h, Z) - q(h, Z')| \leq \frac{1}{n} \sup_{h \in \mathcal{H}, z \in \mathcal{Z}} \{\ell(h, z)\}$.

2. Sample $h \in \mathcal{H}$ with probability $\mathbb{P}(h) \propto \exp(\frac{\epsilon(n)}{2\Delta q} q(h, Z))$.

Output: h .

It is of course impossible to minimize the supremum over any data Z , nor is it possible to efficiently search over the space of all algorithms, let alone DP algorithms. But conceptually, this formulation may be of interest to theoretical questions related to the search of private learning algorithms and the fundamental limit of machine learning under privacy constraints.

4. Private learning for penalized ERM

Now we describe a generic and practical class of private learning algorithms, based on the idea of minimizing the empirical risk under privacy constraint:

$$\underset{h \in \mathcal{H}}{\operatorname{minimize}} F(Z, h) = \frac{1}{n} \sum_{i=1}^n \ell(h, z_i) + g_n(h). \quad (8)$$

The first term is empirical risk and the second term vanishes as n increases so that this estimator is asymptotically ERM. The same formulation has been studied before in the context of differentially private machine learning (Chandhuri et al., 2011; Kifer et al., 2012), but our focus is more generic and does not require the objective function to be convex, differentiable, continuous, or even have a finite dimensional Euclidean space embedding, hence covers a larger class of learning problems.

Our generic algorithm for differentially private learning is summarized in Algorithm 1. It applies the exponential mechanism (McSherry and Talwar, 2007) to penalized ERM. We note that this algorithm implicitly requires that $\int_{\mathcal{H}} \exp(\frac{\epsilon(n)}{2\Delta q} q(h, Z)) dh < \infty$, otherwise the distribution is not well-defined and it does not make sense to talk about differential privacy. In general, if \mathcal{H} is a compact set with a finite volume (with respect to a base measure, such as the Lebesgue measure or counting measure), then such a distribution always exists. We will revisit this point and discuss the practicality of this assumption in the Section 5.3.

Using the characterization results developed so far, we are able to give sufficient conditions for consistency of private learning algorithms without having to establish uniform convergence. Define the sublevel set as

$$S_{Z, t} = \{h \in \mathcal{H} \mid F(Z, h) \leq t + \inf_{h \in \mathcal{H}} F(Z, h)\}, \quad (9)$$

where $F(h, Z)$ is the regularized empirical risk function defined in (8). In particular, we assume the following conditions:

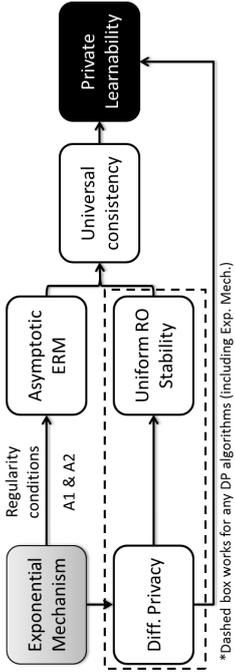

Figure 3: Illustration of Theorem 17: conditions for private learnability in general learning setting.

A1. Bounded loss function: $0 \leq \ell(h, z) \leq 1$ for any $h \in \mathcal{H}, z \in \mathcal{Z}$.

A2. Sublevel set condition: There exist constant positive integer n_0 , positive real number t_0 , and a sequence of regularizer g_n satisfying $\sup_{h \in \mathcal{H}} |g_n(h)| = o(n)$, such that for any $0 < t < t_0, n > n_0$

$$\mathbb{E}_{Z \sim \mathcal{D}^n} \left(\frac{\mu(\mathcal{H})}{\mu(\mathcal{S}_{Z,t})} \right) \leq K \left(\frac{1}{t} \right)^\rho, \tag{10}$$

where $K = K(n), \rho = \rho(n)$ satisfy $\log K + \rho \log n = o(n)$. Here the measure μ may depend on context, such as Lebesgue measure (\mathcal{H} is continuous) or counting measure (\mathcal{H} is discrete).

The first condition of boundedness is common. It is assumed in Vapnik’s characterization for ERM learnability and Shalev-Shwartz et al.’s general characterization of all learnable problems. In fact, we can always consider \mathcal{H} to be a sublevel set such that the boundedness condition holds. For the second condition, the intuition is that we require the sublevel set to be large enough such that the sampling procedure will return a good hypothesis with large probability. $\mu(\mathcal{S}_t)$ is a critical parameter in the utility guarantee for the exponential mechanism (McSherry and Talwar, 2007). Also, it is worth pointing out that A2 implies that the exponential distribution is well-defined.

Theorem 17 (General private learning) *Let $(\mathcal{Z}, \mathcal{H}, \ell)$ be any problem in the general learning setting. Suppose we can choose g_n such that A.1 and A.2 are satisfied with (ρ, K, g_n, n_0, t_0) for a distribution \mathcal{D} , then Algorithm 1 satisfies $\epsilon(n)$ -privacy and is consistent with rate*

$$\xi(n) = \frac{9 \lceil \log K + (\rho + 2) \log n \rceil}{n\epsilon(n)} + 2\epsilon(n) + \sup_{h \in \mathcal{H}} |g_n(h)|. \tag{11}$$

In particular, if $\epsilon(n) = o(1), \sup_{h \in \mathcal{H}} |g_n(h)| = o(1)$ and $\log K + \rho \log n = o(n\epsilon(n))$ for all \mathcal{D} (in \mathcal{D}) Algorithm 1 privately learns $(\mathcal{D}$ -learns) the problem.

We give an illustration of the proof in Figure 3. The detailed proof, based on the stability argument (Shalev-Shwartz et al., 2010), is deferred to Appendix A.5.

To see that Theorem 17 actually contains a large number of problems in the general learning setting. We provide concrete examples that satisfy A1 and A2 below for both privately learnable and privately \mathcal{D} -learnable problems that can be learned using Algorithm 1.

4.1 Examples of privately learnable problems

We start from a few cases where Algorithm 1 is universally consistent for all distributions.

Example 3 (Finite discrete \mathcal{H}) *Suppose \mathcal{H} can be fully encoded by M -bits, then*

$$\mu(\mathcal{S}_t) / \mu(\mathcal{H}) \geq |\mathcal{H}|^{-1} = 2^{-M},$$

since there are at least 1 optimal hypothesis for each function and now μ is the counting measure. In other word, we can take $K = 2^M$ and $\rho = 0$ in the (11). Plug this into the expression and take $g_n \equiv 0, \epsilon(n) = \sqrt{(M + \log n)/n}$, we get a rate of consistency $\xi(n) = O(\frac{M + \log n}{\sqrt{n}})$. In addition, if we can find a data-independent covering set for a continuous space, then we can discretize the space and the result same results follow. This observation will be used in the construction of many private learning algorithms below.

Example 4 (Lipschitz functions/Hölder class) *Let \mathcal{H} be a compact, β_p -regular subset of \mathbb{R}^d satisfying $\mu(B \cap \mathcal{H}) \geq \beta_p \mu(B)$ for any ℓ_p ball $B \subset \mathbb{R}^d$ that is small enough. Assume that $F(Z, \cdot)$ is L -Lipschitz on \mathcal{H} : for any $h, h' \in \mathcal{H}$,*

$$|F(Z, h) - F(Z, h')| \leq L \|h - h'\|_p.$$

Then for sufficiently small t , we have Lebesgue measure

$$\mu(\mathcal{S}_t) \geq \beta_p (t/L)^d$$

and Condition A.2 holds with $K = \mu(\mathcal{H})\beta_p^{-1}L^d, \rho = d$. Furthermore, if we take $\epsilon(n) = \sqrt{\frac{d(\log L + \log n) + \log(\mu(\mathcal{H})/\beta_p)}{n}}$, the algorithm is $O\left(\sqrt{\frac{d(\log L + \log n) + \log(\mu(\mathcal{H})/\beta_p)}{n}} + \sup_{h \in \mathcal{H}} |g_n(h)|\right)$ -consistent.

This shows that condition A2 holds for a large class of low-dimensional problems of interest in machine learning and one can learn the problem privately without actually needing to find a covering set algorithmically. Specifically, the example includes many practically used methods such as logistic regression, linear SVM, ridge regression, even multi-layer neural networks, since the loss functions in these methods are jointly bounded in (Z, h) and Lipschitz in h .

The example also raises an interesting observation that while differentially private classification is not possible in a distribution-free setting for 0-1 loss function (Chaudhuri and Hsu, 2011), it is learnable under smoother surrogate loss, e.g., logistic loss or hinge loss. In other words, private learnability and computational tractability both benefit from the same relaxation.

The Lipschitz condition still requires the dimension of the hypothesis space to be $o(n)$. Thus it does not cover high-dimensional machine learning problems where $d \gg n$, nor does it contain the example of Shalev-Shwartz et al. (2010) that ERM fails.

For high dimensional problems where d grows with n , typically some assumptions or restrictions need to be made either on the data or on the hypothesis space (so that it becomes essentially low-dimensional). We give one example here for the problem of sparse regression.

Example 5 (Best subset selection) Consider $\mathcal{H} = \{h \in \mathbb{R}^d : \|h\|_0 < s, \|h\|_2 \leq 1\}$ and let $\ell(l, z)$ be an L -Lipschitz loss function. The solution can only be chosen from $\binom{[d]}{s} < d^s$ different s -dimensional subspaces. We can apply Algorithm 1 twice to first sample a support set S with utility function being the $-\min_{h \in \mathcal{H}_S} F(Z, h)$, and then sample a solution in the chosen s -dimensional subspace. By the composition theorem this two-stage procedure is differentially private. Moreover, by the arguments in Example 3 and Example 4 respectively, we have $\mu(\mathcal{S}) \geq \left(\frac{1}{d}\right)^s$ for the subset selection and $\mu(\mathcal{S}) \geq \left(\frac{1}{T}\right)^s$ for the low-dimensional regression. Note that $p = 0$ in both cases and the dependency on the ambient dimension d is on the logarithm. The first stage ensures that for the chosen support set S , $\min_{h \in \mathcal{H}_S} F(Z, h)$ is close to $\min_{h \in \mathcal{H}} F(Z, h)$ by $O\left(\frac{s \log d + \log \frac{1}{\epsilon}}{n \epsilon(n)}\right)$ in expectation and (the second stage ensures that the sampled hypothesis from \mathcal{H}_S would have objective function close to $\min_{h \in \mathcal{H}_S} F(Z, h)$ by $O\left(\frac{s \log L + \log n + \log(\mu(\mathcal{H}_S)/\beta d)}{n \epsilon(n)}\right)$. This leads to an overall rate of consistency (they simply add up) of $O\left(\frac{s \log d + \log n + L + \log(\mu(\mathcal{H}_S)/\beta d)}{\sqrt{n}}\right)$ if we choose $\epsilon(n) = 1/\sqrt{n}$.

4.2 Examples of privately \mathfrak{D} -learnable problems.

For problems where private learnability is impossible to achieve, we may still apply Theorem 17 to prove the weaker private \mathfrak{D} -learnability for some specific class of distributions.

Example 6 (Finite Representation Dimension in the General Learning Setting) For binary classification problems with 0-1 loss (PAC learning), this has been well-studied. In particular, Beinel et al. (2013a) characterized the sample complexity of privately learnable problems using a combinatorial condition they call a ‘‘Probabilistic Representation’’, which basically involves finding a finite, data-independent set of hypotheses to approximate any hypothesis in the class. Their claim is that if the ‘‘representation dimension’’ is finite, then the problem is privately learnable, otherwise it is not. We can extend the notion of probabilistic representation beyond the finite discrete and countably infinite hypothesis class considered in Beinel et al. (2013a) to cases when the problem is not privately learnable (e.g. learning threshold functions on $[0, 1]$). The existence of probabilistic representation for all distributions in \mathfrak{D} would lead to a \mathfrak{D} -universally private learning algorithm.

Another way to define a class of distribution \mathfrak{D} is to assume the existence of a reference distribution that is close to any distribution of interest as in Chaudhuri and Hsu (2011).

Example 7 (Existence of a public reference distribution) To deal with the 0-1 loss classification problems on a continuous hypothesis domain, Chaudhuri and Hsu (2011) assume

that there exists a data-independent reference distribution \mathcal{D}^* , which by multiplying a fixed constant on its density, uniformly dominates any distribution of interest. This essentially produces a subset of distributions \mathfrak{D} . The consequence is that one can build an ϵ -net of \mathcal{H} with metric defined on the risk under \mathcal{D}^* and this will also be a (looser) covering set of any distribution $\mathcal{D} \in \mathfrak{D}$, thereby learning the problem for any distribution in the set.

The same idea can be applied to the general learning setting. For any fixed reference distribution \mathcal{D}^* defined on \mathcal{Z} and constant c ,

$$\mathfrak{D} = \{\mathcal{D} = (Z, \mathcal{F}, \mathbb{P}) \mid \mathbb{P}(\mathcal{D}(z \in A)) \leq c\mathbb{P}^*(z \in A) \text{ for } \forall A \in \mathcal{F}\}$$

is a valid set of distributions and we are able to \mathfrak{D} -privately learn this problem whenever we can construct a sufficiently small cover set with respect to \mathcal{D}^* and reduce the problem to Example 3. This class of problems includes high-dimensional and infinity dimensional problems such as density estimation, nonparametric regression, kernel methods and essentially any other problems that are strictly learnable (Vapnik, 1998), since they are characterized by one-sided uniform convergence (and the corresponding entropy condition).

4.3 Discussion on uniform convergence and private learnability

Uniform convergence requires that $\mathbb{E}_{Z \sim \mathcal{D}^n} \sup_{h \in \mathcal{H}} |\hat{R}(h, Z) - R(h)| \rightarrow 0$ for any distribution \mathcal{D} with a distribution independent rate. Most machine learning algorithms rely on uniform convergence to establish consistency result (e.g., through complexity measure such as VC-dimension, Rademacher Complexity, covering and bracketing numbers and so on). In fact, the learnability of ERM algorithm is characterized by the one-sided uniform convergence (Vapnik, 1998), which is only slightly weaker than requiring uniform convergence on both sides.

A key point in Shalev-Shwartz et al. (2010) is that the learnability (by any algorithm) in general learning setting is no longer characterized by variants of uniform convergence. However, the class of privately learnable problems is much smaller. Clearly, uniform convergence is not sufficient for a problem to be privately learnable (see Section 3.3), but is it necessary?

In binary classification with discrete domain (agnostic PAC Learning), since VC-dimension being finite characterizes the class of privately PAC learnable problems, the necessity of uniform convergence is clear. This could also be more explicitly seen from Beinel et al. (2013a) where the *probabilistic representation dimension* is a form of uniform convergence on its own.

In the general learning setting, the problem is still open. We were not able to prove that private learnability implies uniform convergence, but we could not construct a counter example either. All our examples in this section do implicitly or explicitly uses uniform convergence, which seems to hint at a positive answer.

5. Practical concerns

5.1 High confidence private learning via boosting

We have stated all results so far in expectation. We can easily convert these to the high-confidence learning paradigm by applying Markov's inequality, since convergence in expectation to the minimum risk implies convergence in probability to the minimum risk. While the $1/\delta$ dependence on the failure probability δ is not ideal, we can apply a similar meta-algorithm "boosting" (Schapire, 1990) as in Shalev-Shwartz et al. (2010, Section 7) to get a $\log(1/\delta)$ rate. The approach is similar to cross-validation. Given a pre-chosen positive integer a , the original boosting algorithm randomly partitions the data into $(a+1)$ subsamples of size $n/(a+1)$, and applies Algorithm 1 on the first a partitions, obtaining a candidate hypotheses. The method then returns the one hypothesis with smallest validation error, calculated using the remaining subsample. To ensure differential privacy, our method instead uses the exponential mechanism to sample the best candidate hypothesis, where the logarithm of sampling probability is proportional to the negative validation error.

Theorem 18 (High-confidence private learning) *If an algorithm \mathcal{A} privately learns a problem with rate $\xi(n)$ and privacy parameter $\epsilon(n)$, then the boosting algorithm \mathcal{A}' with $a = \log \frac{3}{\delta}$ is $\max \left\{ \epsilon \left(\frac{n}{\log(3/\delta)+1} \right), \frac{\log(3/\delta)+1}{\sqrt{n}} \right\}$ -differentially private, its output h obeys*

$$R(h) - R^* \leq \epsilon \xi \left(\frac{n}{\log(3/\delta)+1} \right) + C \sqrt{\frac{\log(3/\delta)}{n}}$$

for an absolute constant C with probability at least $1 - \delta$.

5.2 Efficient sampling algorithm for convex problems

Our proposed exponential sampling based algorithm is to establish a more explicit geometric condition upon which AERM holds, hence the algorithm may not be computationally tractable. Ignoring the difficulty of constructing the ϵ -covering set of an exponential number of elements, sampling from the set alone is not a polynomial time algorithm. But we can solve a subset of the continuous version of our Algorithm 1 described in Theorem 17 in polynomial time to arbitrary accuracy (see also Bassily et al. (2014, Theorem 3.4)).

Proposition 19 *If $n^{-1} \sum_{i=1}^n \ell(h, z_i) + g_n(h)$ is convex in h and \mathcal{H} is a convex set, then the sampling procedure in Algorithm 1 can be solved in polynomial time.*

Proof When $n^{-1} \sum_{i=1}^n \ell(h, z_i) + g_n(h)$ is convex, the utility function $q(h, Z)$ is concave in h . The density to be sampled from in Algorithm 1 is proportional to $\exp(\frac{aq(h, Z)}{B})$ and is log-concave. The Markov chain sampling algorithm in Applegate and Kannan (1991) is guaranteed to produce a sample from a distribution that is arbitrarily close to the target distribution (in the total variation sense) in polynomial time. ■

5.3 Exponential mechanism in infinite domain

As we mention earlier, the results in Section 4 based on the exponential mechanism implicitly assumes certain regularity conditions that ensures the existence of a probability distribution.

When \mathcal{H} is finite, the existence is trivial. On the other hand, an infinite set \mathcal{H} is tricky in that there may not exist a proper distribution that satisfies $\mathbb{P}(h) \propto e^{\frac{\epsilon}{2\Delta\gamma} q(Z;h)}$ for at least some $q(Z;h)$. For instance, if $\mathcal{H} = \mathbb{R}$ and $q(Z;h) \equiv 1$ then $\int_{\mathbb{R}} e^{\frac{\epsilon}{2\Delta\gamma} q(Z;h)} dh = \infty$. Such distributions that are only defined up to scale with no finite normalization constants are called improper distributions. In case of finite dimensional non-compact set, this translates into an additional assumption on the loss function and the regularization term.

Things get even trickier when \mathcal{H} is an infinite dimensional space, such as a subset of a Hilbert space. While probability measures can still be defined, no density function can be defined on such spaces. Therefore, we cannot use exponential mechanism to define a valid probability distribution.

The practical implication is that exponential mechanism is really only applicable to cases when the hypothesis space \mathcal{H} allows for definitions of densities in the usual sense, or then \mathcal{H} can be approximated by such a space. For example, a separable Hilbert space can be studied by finite-dimensional projections. Also, we can approximate RKHS induced by translation invariant kernels via random Fourier features (Rahimi and Recht, 2007).

6. Results for learnability under (ϵ, δ) -differential privacy

Another way to weaken the definition of private learnability is through (ϵ, δ) -approximate differential privacy.

Definition 20 (Dwork et al., 2006a) *An algorithm \mathcal{A} obeys (ϵ, δ) -differential privacy if for any Z, Z' such that $d(Z, Z') \leq 1$, and for any measurable set $S \subset \mathcal{H}$*

$$\mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in S) \leq e^\epsilon \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in S) + \delta.$$

We define a version of the problem to be

Definition 21 (Approximately Private Learnability) *We say a learning problem is $\Delta(n)$ -approximately privately learnable for some pre-specified family of rate $\Delta(n)$ if for some $\epsilon < \infty$, $\delta(n) \in \Delta(n)$, there exists a universally consistent algorithm that is $(\epsilon, \delta(n))$ -DP.*

This is a completely different subject to study and the class of approximately privately learnable problems could be substantially larger than the pure privately learnable problems. Moreover, the picture may vary with respect to how small $\delta(n)$ is required to be. In this section, we present our preliminary investigation on this problem.

Specifically, we will consider two questions:

1. Does the existence of an (ϵ, δ) -DP always AERM algorithm characterize the class of approximately private learnable problems?

2. Are all learnable problems approximately privately learnable for different choices of $\Delta(n)$?

The minimal requirement in the same flavor of Definition 3 would be to require $\Delta(n) = \{\delta(n) | \delta(n) \rightarrow 0\}$. The learnability problem turns out to be trivial under this definition due to the following observation.

Lemma 22 *For any algorithm \mathcal{A} that acts on Z , \mathcal{A}' that runs \mathcal{A} on a randomly chosen subset of Z of size \sqrt{n} is $(0, \frac{1}{\sqrt{n}})$ -DP.*

Proof Let Z and Z' be adjacent datasets that differs only in data point i . For any i and any $S \in \sigma(\mathcal{H})$,

$$\begin{aligned} \mathbb{P}_I(\mathcal{A}(Z) \in S) &= \mathbb{P}_I(\mathcal{A}(Z_I) \in S | i \in I) + \mathbb{P}_I(\mathcal{A}(Z_I) \in S | i \notin I) \mathbb{P}(i \notin I) \\ &= \mathbb{P}_I(\mathcal{A}(Z_I) \in S | i \in I) \mathbb{P}(i \in I) + \mathbb{P}_I(\mathcal{A}(Z_I) \in S | i \notin I) \mathbb{P}(i \notin I) \\ &= \mathbb{P}(\mathcal{A}'(Z') \in S) + \mathbb{P}_I(\mathcal{A}(Z_I) \in S | i \in I) - \mathbb{P}_I(\mathcal{A}'(Z_I) \in S | i \in I) \mathbb{P}(i \in I) \\ &\leq \mathbb{P}(\mathcal{A}'(Z') \in S) + \mathbb{P}(i \in I) \\ &= e^0 \mathbb{P}(\mathcal{A}'(Z') \in S) + \frac{1}{\sqrt{n}}. \end{aligned}$$

This verifies the $(0, 1/\sqrt{n})$ -DP of algorithm \mathcal{A}' . \blacksquare

The above lemma suggests that if $\delta(n) = o(1)$ is all we need for the *approximately private learnability*, then any consistent learning algorithm can be made approximately DP by simply subsampling. In other words, any learnable problem is also learnable under approximate differential privacy.

To get around this triviality, we need to specify a sufficiently fast rate of $\delta(n)$ going to 0. While it is common to require that $\delta(n) = o(1/\text{poly}(n))$ ² for cryptographically strong privacy protection, requiring $\delta(n) = o(1/n)$ is already enough to invalidate the above subsampling argument and makes the problem of learnability a non-trivial one.

Again, the question is whether AERM characterizes approximately private learnability and whether there is a gap between the class of learnable and approximately privately learnable problems.

Here we show that the “folklore” Lemma 8 and subsampling lemma (Lemma 27) can be extended to work with (ϵ, δ) -DP and then we provide a positive answer to the first question.

Lemma 23 (Stability of (ϵ, δ) -DP) *If \mathcal{A} is (ϵ, δ) -DP, and $0 \leq \ell(h, z) \leq 1$, then \mathcal{A} is $(\epsilon^e - 1 + \delta)$ -Strongly Uniform RO-stable.*

2. Here the notation “ $o(1/\text{poly}(n))$ ” means “decays faster than any polynomial of n ”. A sequence $a(n) = o(1/\text{poly}(n))$ if and only if $a(n) = o(n^{-\gamma})$ for any $\gamma > 0$.

Proof For any Z, Z' such that $d(Z, Z') \leq 1$ and for any $z \in \mathcal{Z}$. Let the event $E = \{h | p(h) \geq p'(h)\}$,

$$\begin{aligned} |\mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z) - \mathbb{E}_{h \sim \mathcal{A}(Z')} \ell(h, z)| &= \left| \int_E \ell(h, z) p(h) dh - \int_h \ell(h, z) p'(h) dh \right| \\ &\leq \sup_{h, z} \ell(h, z) \int_E p(h) - p'(h) dh \leq \int_E p(h) - p'(h) dh = \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in E) - \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) \\ &\leq (\epsilon^e - 1) \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) + \delta \leq \epsilon^e - 1 + \delta. \end{aligned}$$

The last line applies the definition of (ϵ, δ) -DP. \blacksquare

Lemma 24 (Subsampling Lemma of (ϵ, δ) -DP) *If \mathcal{A} is (ϵ, δ) -DP, then \mathcal{A}' that acts on a random subsample of Z of size γn obeys (ϵ', δ') -DP with $\epsilon' = \log(1 + \gamma e^{\epsilon} - 1)$ and $\delta' = \gamma \epsilon \delta$.*

Proof For any event $E \in \sigma(\mathcal{H})$, let i be the coordinate where Z and Z' differs

$$\begin{aligned} \mathbb{P}_{h \sim \mathcal{A}'(Z)}(h \in E) &= \gamma \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \sim E | i \in I) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \sim E | i \notin I) \\ &= \gamma \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \sim E | i \in I) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \notin I) \\ &= \gamma \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \sim E | i \in I) - \gamma \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \in I) + \gamma \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \in I) \\ &\quad + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \notin I) \\ &= \mathbb{P}_{h \sim \mathcal{A}'(Z)}(h \in E) + \gamma [\mathbb{P}_{h \sim \mathcal{A}(Z)}(h \sim E | i \in I) - \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \in I)] \\ &\leq \mathbb{P}_{h \sim \mathcal{A}'(Z)}(h \in E) + \gamma (\epsilon^e - 1) \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \in I) + \gamma \delta, \end{aligned} \tag{12}$$

where in last line, we apply (ϵ, δ) -DP of \mathcal{A} .

It remains to show that $\mathbb{P}_{h \sim \mathcal{A}(Z')} (h \sim E | i \in I)$ is similar to $\mathbb{P}_{h \sim \mathcal{A}'(Z')} (h \in E)$. First,

$$\mathbb{P}_{h \sim \mathcal{A}'(Z')} (h \in E) = \gamma \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E | i \in I) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E | i \notin I). \tag{13}$$

Denote $\mathcal{I}_1 = \{I | i \in I\}$, $\mathcal{I}_2 = \{I | i \notin I\}$. We know $|\mathcal{I}_1| = \binom{n-1}{\gamma n-1}$, and $|\mathcal{I}_2| = \binom{n-1}{\gamma n}$ and $|\mathcal{I}_1|/|\mathcal{I}_2| = \gamma n / (n - \gamma n)$. For every $I \in \mathcal{I}_2$ there are precisely γn elements $J \in \mathcal{I}_1$ such that $d(I, J) = 1$. Likewise, for every $J \in \mathcal{I}_1$, there are $n - \gamma n$ elements $I \in \mathcal{I}_2$ such that $d(I, J) = 1$. It follows by symmetry that if we apply (ϵ, δ) -DP to $1/\gamma n$ of each $I \in \mathcal{I}_2$ and change I to their corresponding $J \in \mathcal{I}_1$, then each $J \in \mathcal{I}_1$ will receive $(n - \gamma n) / \gamma n$ “contribution” in total from the sum over all $I \in \mathcal{I}_2$.

$$\begin{aligned} \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E | i \notin I) &= \frac{1}{|\mathcal{I}_2|} \sum_{I \in \mathcal{I}_2} \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) \\ &= \frac{1}{|\mathcal{I}_2|} \sum_{I \in \mathcal{I}_2} \sum_{j=1}^{\gamma n} \frac{1}{\gamma n} \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) \\ &\geq \frac{|\mathcal{I}_1|}{|\mathcal{I}_2|} \frac{1}{|\mathcal{I}_1|} \sum_{J \in \mathcal{I}_1} \frac{n - \gamma n}{\gamma n} e^{-\epsilon} \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) - \delta \\ &= \frac{1}{|\mathcal{I}_1|} \sum_{J \in \mathcal{I}_1} e^{-\epsilon} (\mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E) - \delta) = e^{-\epsilon} \mathbb{P}_{h \sim \mathcal{A}(Z')} (h \in E | i \in I) - e^{-\epsilon} \delta \end{aligned}$$

Substitute into (13), we get

$$\mathbb{P}_{h \sim \mathcal{A}(Z_I)}(h \in E) \leq \frac{1}{\gamma + (1-\gamma)e^{-\epsilon}} \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in E) + \frac{(1-\gamma)e^{-\epsilon}}{\gamma + (1-\gamma)e^{-\epsilon}} \delta.$$

We further relax the upper bound to a simple form $e^{\epsilon} \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in E) + \delta$ and substitute into (12), we have

$$\mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in E) \leq (1 + \gamma e^{\epsilon}(e^{\epsilon} - 1)) \mathbb{P}_{h \sim \mathcal{A}(Z)}(h \in E) + \gamma \delta + \gamma(e^{\epsilon} - 1)\delta,$$

which concludes the proof. \blacksquare

Using the above two lemmas, we are able to establish the same result which says that AERM characterizes the approximate private learnability for certain classes of $\Delta(n)$.

Theorem 25 *A problem is $\Delta(n)$ -approximately privately learnable implies that there exists an always AERM algorithm that is $(\epsilon(n), n^{-1/2}e^{\delta(\sqrt{n})})$ -DP for some $\epsilon(n) \rightarrow 0$ and $\delta(\sqrt{n}) \in \Delta(n)$. The converse is also true if $n^{-1/2}e^{\delta(\sqrt{n})} \in \Delta(n)$.*

Proof If we have an always AERM algorithm with $\xi_{erm}(n)$ that is $(\epsilon(n), \delta(n))$ -DP for $\delta(n) \in \Delta(n)$. Then by Lemma 23, this algorithm is strongly uniform RO-stable with rate $e^{\epsilon(n)} - 1 + \delta(n)$. By Theorem 28, the algorithm is universally consistent with rate $\xi_{erm}(n) + e^{\epsilon(n)} - 1 + \delta(n)$. This establishes the ‘‘if’’ part.

To see the ‘‘only if’’ part, by definition if a problem is $\Delta(n)$ -approximately privately learnable with ϵ and $\delta(n) \in \Delta(n)$. Then by Lemma 24 with $\gamma = 1/\sqrt{n}$, we get an algorithm that obeys the privacy condition. It remains to prove always AERM, which requires exactly the same arguments in the proof of Lemma 10. Details are omitted. \blacksquare

Note that the results above suggest that in the two canonical settings $\Delta(n) = o(1/n)$ or $\Delta(n) = o(1/\text{poly}(n))$, existence of a private AERM algorithm that satisfies the stronger constraint $\epsilon(n) = o(1)$ characterizes the learnability.

The next question that whether any learnable problems are also approximately privately learnable would depend on how fast $\delta(n)$ is required to decay. We know that when we only have $\Delta(n) = o(1)$, all learnable problems are approximately privately learnable, and when we have $\Delta(n) = \{0\}$, only a strict subset of these problems is privately learnable. The following result establishes that when $\delta(n)$ needs to go to 0 with a sufficiently fast rate, there is separation between learnability and approximately private learnability.

Proposition 26 *Let $\Delta(n) = \{\delta(n) \mid \delta(n) \leq \tilde{\delta}(n)\}$ for some sequence $\tilde{\delta}(n) \rightarrow 0$. The following statements are true.*

- All learnable problems are $\Delta(n)$ -approximately privately learnable, if $\tilde{\delta}(n) = \omega(1/n)$.
- There exists a problem that is learnable but not $\Delta(n)$ -approximately privately learnable, if $\tilde{\delta}(n) \leq \frac{\exp(-\epsilon(n^2)n^2)}{n}$.

Proof The first claim follows from the same argument in Lemma 22. If a problem is learnable, there exists a universally consistent learning algorithm \mathcal{A} . The algorithm that

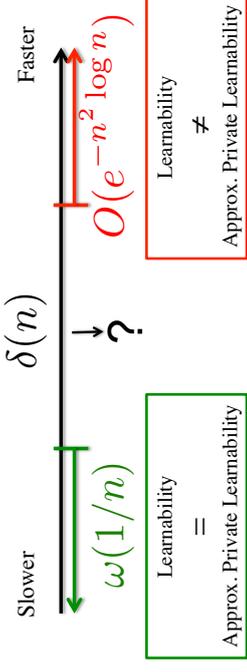

Figure 4: Illustration of Proposition 26 and the open problem.

applies \mathcal{A} on a $\tilde{\delta}(n)$ -fraction random subsample of the dataset is $(0, \tilde{\delta}(n))$ -DP and universally consistent with rate $\xi(n\tilde{\delta}(n))$. Since $\tilde{\delta}(n) = \omega(1/n)$, $n\tilde{\delta}(n) \rightarrow \infty$.

We now show that when we require a fast decaying $\delta(n)$, then suddenly the example in Section 3.3 due to Chaudhuri and Hsu (2011) becomes not approximately privately learnable even for (ϵ, δ) -DP. Let Z, Z' be two completely different data sets, by repeatedly applying the definition of (ϵ, δ) -DP, for any set $\mathcal{S} \subset \mathcal{H}$

$$\mathbb{P}(\mathcal{A}(Z) \in \mathcal{S}) \leq e^{\epsilon} \mathbb{P}(\mathcal{A}(Z) \in \mathcal{S}) + \sum_{i=1}^n e^{(i-1)\epsilon} \delta \leq e^{\epsilon} \mathbb{P}(\mathcal{A}(Z') \in \mathcal{S}) + ne^{(n-1)\epsilon} \delta.$$

When we shift the inequality around, we get

$$\mathbb{P}(\mathcal{A}(Z') \in \mathcal{S}) \leq e^{-\epsilon} \mathbb{P}(\mathcal{A}(Z') \in \mathcal{S}) - e^{-\epsilon} n \delta.$$

Consider the same example in Section 3.3 where we hope to learn a threshold on $[0, 1]$. Assuming there exists an algorithm \mathcal{A} that is universally AERM and $(\epsilon(n), \delta(n))$ -DP for $\epsilon(n) < \infty$ and $\delta(n) \leq 0.4ne^{-\epsilon n}$.

Everything up to (4) remains exactly the same. Now, apply the above implication of (ϵ, δ) -DP, we can replace (4) for each $i = 2, \dots, K$, by

$$\mathbb{P}(\mathcal{A}(Z_1) \in [h_i - \eta/3, h_i + \eta/3]) \geq \exp(-\epsilon n) \mathbb{P}(\mathcal{A}(Z_i) \in [h_i - \eta/3, h_i + \eta/3]) - n\delta(n).$$

Then (5) becomes

$$\mathbb{P}(\mathcal{A}(Z_1) \notin [h_1 - \eta/3, h_1 + \eta/3]) \geq K \exp(-\epsilon n) 0.9 - Ke^{-\epsilon} n \delta(n) \geq 0.9 \geq 0.5,$$

where the last inequality follows by $K > \exp(\epsilon n)$ and $\delta(n) \leq 0.4ne^{-\epsilon n}$. This yields the same contradiction to always AERM of \mathcal{A} on Z_1 , which requires $\mathbb{P}(\mathcal{A}(Z_1) \notin [h_1 - \eta/3, h_1 + \eta/3]) < 0.1$. Therefore, such AERM does not exist. By the contrapositive of Theorem 25, the problem is not approximately privately learnable for $\tilde{\delta}(n) \leq \frac{\exp(-\epsilon(n^2)n^2)}{n}$. \blacksquare

The bound can be further improved to $\exp(-\epsilon(n)/n)$ if we directly work with universal consistency on various distributions rather than through always AERM on specific data points. Even that is likely to be suboptimal as there might be more challenging problems and less favorable packings to consider.

The point of this exposition, however, is to illustrate that (ϵ, δ) -DP alone does not close the gap between learnability and private learnability. Additional relaxation on the specified rate of decay on δ does. We now know that the phase transition occurs when $\delta(n)$ is somewhere between $\Omega(\exp(-n^2 \log n))$ and $O(1/n)$; but there is still a substantial gap between the upper and lower bounds.³

7. Conclusion and future work

In this paper, we revisited the question “*What can we learned privately?*” and considered a broader class of statistical machine learning problems than those studied previously. Specifically, we characterized the learnability under privacy constraint by showing any privately learnable problems can be learned by a private algorithm that asymptotically minimizes the empirical risk for any data, and the problem is not privately learnable otherwise. This allows us to construct a conceptual procedure that privately learns any privately learnable problem. We also propose a relaxed notion of private learnability called private \mathfrak{D} -learnability, which requires the existence of an algorithm that is consistent for any the distribution within a class of distributions \mathfrak{D} . We characterized private \mathfrak{D} -learnability too with a weaker notion of AERM. For problems that can be formulated as penalized empirical risk minimization, we provide a sampling algorithm with a set of meaningful sufficient conditions on the geometry of the hypothesis space and demonstrate that it covers a large class of problems. In addition, we further extended the characterization to learnability under (ϵ, δ) -differential privacy and provided a preliminary analysis which establishes the existence of a phase transition from all learnable problems being approximately private learnable to some learnable problems being not approximately private learnable at some non-trivial rate of decay on $\delta(n)$.

Future work includes understanding the conditions under which privacy and AERM are contradictory (recall that we only have one example on learning thresholding functions due to Chandhuri and Hsu 2011), characterizing the rate of convergence, searching for practical algorithms that generically learns all privately learnable problems, and better understanding the gap between learnability and approximate private learnability.

3. After the paper was accepted for publication, we became aware that the phase transition occurs sharply at $O(1/n)$. The result follows from a sharp lower bound of sample complexity in learning threshold functions in Bun (2016, Theorem 4.5.2), which improves over a previously published result that requires $O(n^{-1-\epsilon})$ for any $\epsilon > 0$ in Bun et al. (2015). The consequence is that the general learning setting is hard for (ϵ, δ) -DP too unless δ becomes meaningfully large for privacy purposes.

Appendix A. Proofs of technical results

In this appendix, we provide detailed proofs to the technical results that in the main text.

A.1 Privacy in subsampling

Proof [Proof of Lemma 4] Let \mathcal{A} be the consistent ϵ -DP algorithm. Consider \mathcal{A}' that apply \mathcal{A} to a random subsample of $\lfloor \sqrt{n} \rfloor$ data points. By Lemma 27 with $\gamma = \frac{\lfloor \sqrt{n} \rfloor}{n} \leq \frac{1}{\sqrt{n}}$, we get the privacy claim. For the consistency claim, note that the given sample is an iid sample of size \sqrt{n} from the original distribution. ■

Lemma 27 (Subsampling theorem) *If Algorithm \mathcal{A} is ϵ -DP for $Z \in \mathcal{Z}^n$ for any $n = 1, 2, 3, \dots$, then the algorithm \mathcal{A}' that output the result of \mathcal{A} to a random subsample of size γn data points preserves $2\gamma(\epsilon^\epsilon - e^{-\gamma})$ -DP.*

Proof [Proof of Lemma 27 (Subsampling theorem)] This is a corollary of Lemma 4.4 in Beimel et al. (2014). To be self-contained, we reproduce the proof here in our notation.

Recall that \mathcal{A}' is the algorithm that first randomly subsample γn data points then apply \mathcal{A} . Let Z and Z' be any neighboring databases and assume they differ on the i th data point. Let $S \subset [n]$ be the indices of the random subset of the entries that are selected, and $\mathcal{R} \subset [n] \setminus \{i\}$ be a index size of size $\gamma n - 1$. We apply the law of total expectation twice and argue that for any adjacent Z, Z' , any event $E \subset \mathcal{H}$,

$$\begin{aligned} \mathbb{P}_{h \sim \mathcal{A}'(Z)}(h \in E) &= \gamma \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | i \in S) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | i \notin S) \\ \mathbb{P}_{h \sim \mathcal{A}'(Z')} &= \gamma \mathbb{P}_{h \sim \mathcal{A}(Z'_S)}(h \in E | i \in S) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z'_S)}(h \in E | i \notin S) \\ &= \sum_{\mathcal{R} \in [n] \setminus \{i\}} \mathbb{P}(\mathcal{R}) \left[\gamma \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{i\}) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{j\}, j \neq i) \right] \\ &= \sum_{\mathcal{R} \in [n] \setminus \{i\}} \mathbb{P}(\mathcal{R}) \left[\gamma \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{i\}) + (1 - \gamma) \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{j\}, j \neq i) \right] \end{aligned}$$

By the given condition that \mathcal{A} is ϵ -DP, we can replace $\mathcal{R} \cup \{i\}$ with $\mathcal{R} \cup \{j\}$ for an arbitrary j bounded changes in the probability and the above likelihood ratio can be upper bounded by

$$\frac{(\gamma e^\epsilon + 1 - \gamma) \mathbb{P}_{\mathcal{R} \in [n] \setminus \{i\}} \left[\gamma \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{j\}) \right]}{(\gamma e^{-\epsilon} + 1 - \gamma) \mathbb{P}_{\mathcal{R} \in [n] \setminus \{i\}} \left[\gamma \mathbb{P}_{h \sim \mathcal{A}(Z_S)}(h \in E | S = \mathcal{R} \cup \{j\}) \right]} = \frac{\gamma e^\epsilon + 1 - \gamma}{\gamma e^{-\epsilon} + 1 - \gamma} = \frac{1 + \gamma(e^\epsilon - 1)}{1 + \gamma(e^{-\epsilon} - 1)}.$$

By definition, the privacy loss of the algorithm \mathcal{A}' is therefore

$$\epsilon' \leq \log(1 + \gamma[e^\epsilon - 1]) - \log(1 + \gamma[e^{-\epsilon} - 1]).$$

Note that $\epsilon > 0$ implies that $-1 \leq e^{-\epsilon} - 1 < 0$ and $0 < e^\epsilon - 1 < \infty$. The result follows by applying the property of the natural logarithm:

$$\begin{aligned} \log(1+x) &\leq \frac{x}{2} + \frac{x}{1+x} && \text{for } 0 \leq x < \infty \\ \log(1+x) &\geq \frac{x}{2} + \frac{x}{1+x} \geq \frac{x}{1+x} && \text{for } -1 \leq x \leq 0 \end{aligned}$$

to upper bound the expression. \blacksquare

A.2 Characterization of private learnability

Privacy implies stability Lemma 8 says that an ϵ -differentially private algorithm is $(e^\epsilon - 1)$ -stable (and also $2e^\epsilon$ -stable if $\epsilon < 1$).

Proof [Proof of Lemma 8] Construct Z' by replacing an arbitrary data point in Z with z' and let the probability density/mass defined by $\mathcal{A}(Z)$ and $\mathcal{A}(Z')$ be $p(h)$ and $p'(h)$ respectively, then we can bound the stability as follows

$$\begin{aligned} & \left| \mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z) - \mathbb{E}_{h \sim \mathcal{A}(Z')} \ell(h, z) \right| \\ &= \left| \int_h \ell(h, z) p(h) dh - \int_h \ell(h, z) p'(h) dh \right| = \left| \int_h \ell(h, z) (p(h) - p'(h)) dh \right| \\ &\leq \sup_{h, z} |\ell(h, z)| \int_{p(h) \geq p'(h)} p(h) - p'(h) dh \leq 1 \cdot \int_{p(h) \geq p'(h)} p'(h) \left(\frac{p(h)}{p'(h)} - 1 \right) dh \\ &\leq (e^\epsilon - 1) \int_{p(h) \geq p'(h)} p'(h) dh \leq (e^\epsilon - 1). \end{aligned}$$

For $\epsilon < 1$ we have $\exp(\epsilon) - 1 < 2e$. \blacksquare

Stability + AERM \Rightarrow consistency

Theorem 28 (Randomized version of Shalev-Shwartz et al. 2010, Theorem 8) *If any algorithm is $\xi_1(n)$ -stable and $\xi_2(n)$ -AERM then it is consistent with rate $\xi(n) = \xi_1(n) + \xi_2(n)$.*

Proof

We will show the following the two steps as in Shalev-Shwartz et al. (2010)

1. Uniform RO stability \Rightarrow On average stability \Leftrightarrow On average generalization
2. AERM + On average generalization \Rightarrow consistency

The definition of these quantities is self-explanatory.

To show that ‘‘stability implies generalization’’, we have

$$\begin{aligned} & \left| \mathbb{E}_{Z \sim \mathcal{D}^n} \left(\mathbb{E}_{h \sim \mathcal{A}(Z)} R(h) - \mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) \right) \right| \\ &= \left| \mathbb{E}_{Z \sim \mathcal{D}^n} \left(\mathbb{E}_{z \sim \mathcal{D}} \mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z) - \frac{1}{n} \mathbb{E}_{h \sim \mathcal{A}(Z)} \sum_{i=1}^n \ell(h, z_i) \right) \right| \\ &= \left| \mathbb{E}_{Z \sim \mathcal{D}^n, \{z'_1, \dots, z'_n\} \sim \mathcal{D}^n} \left(\frac{1}{n} \sum_{i=1}^n \mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z'_i) - \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{h \sim \mathcal{A}(Z^{(i)})} \ell(h, z'_i) \right) \right| \\ &\leq \sup_{Z, Z^{(i)} \in \mathcal{Z}^n, d(Z, Z^{(i)})=1, z' \in \mathcal{Z}} \left| \mathbb{E}_{h \sim \mathcal{A}(Z)} \ell(h, z') - \mathbb{E}_{h \sim \mathcal{A}(Z^{(i)})} \ell(h, z') \right| \leq \xi_1(n), \end{aligned}$$

where $Z^{(i)}$ is obtained by replacing the i th entry of Z with z'_i . Next, we show that ‘‘generalization and AERM implies consistency’’. Let $h^* \in \arg \inf_{h \in \mathcal{H}} R(h)$. By definition, we have $\mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R}(h^*, Z) = R^*$. It follows that

$$\begin{aligned} & \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h) - R^*] = \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} R(h) - \hat{R}(h^*, Z)] \\ &= \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h, Z) - \mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h, Z)] + \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}(h^*, Z)] \\ &\leq \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h, Z) - \mathbb{E}_{h \in \mathcal{A}(Z)} R(h, Z)] + \mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \in \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}(h^*, Z)] \\ &\leq \xi_1(n) + \xi_2(n). \end{aligned}$$

Privacy + AERM \Rightarrow consistency **Proof** [Proof of Corollary 9] It follows by combining Lemma 8 and Theorem 28. \blacksquare

Necessity **Proof** [Proof of Lemma 10] We construct an algorithm \mathcal{A}' by subsampling the data points using a random subset of \sqrt{n} and then running \mathcal{A} . The privacy claim follows from Lemma 27 directly.

To prove the ‘‘always AERM’’ claim, we adapt the proof of Lemma 24 in Shalev-Shwartz et al. (2010). For any fixed data set $Z \in \mathcal{Z}^n$,

$$\begin{aligned} \hat{R}(\mathcal{A}'(Z), Z) - \hat{R}^*(Z) &= \mathbb{E}_{Z' \subset Z, |Z'| = \lfloor \sqrt{n} \rfloor} [\hat{R}(\mathcal{A}(Z'), Z) - \hat{R}^*(Z)] \\ &= \mathbb{E}_{Z' \sim \text{Unif}(Z), \lfloor \sqrt{n} \rfloor} [\hat{R}(\mathcal{A}(Z'), Z) - \hat{R}^*(Z)] \text{ no duplicates} \\ &\leq \frac{\mathbb{E}_{Z' \sim \text{Unif}(Z), \lfloor \sqrt{n} \rfloor} [\hat{R}(\mathcal{A}(Z'), Z) - \hat{R}^*(Z)]}{\mathbb{P}(\text{no duplicates})}, \end{aligned}$$

where $\text{Unif}(Z)$ is the uniform distribution defined on the n points in Z . We need to condition on the event that there are no duplicates for the second equality to hold because Z' is a subsample taken without replacements. The last inequality is by the law of total expectation and the non-negativity of the conditional expectation. But \mathbb{P} (no duplicates) = $\prod_{i=0}^{\lfloor \sqrt{n} \rfloor - 1} (1 - i/n) \geq 1 - \sum_{i=0}^{\lfloor \sqrt{n} \rfloor - 1} i/n \geq 1/2$. By universal consistency, \mathcal{A} is consistent on the discrete uniform distribution defined on Z , so

$$\hat{R}_{\mathcal{A}}(Z, Z) - \hat{R}^*(Z) \leq 2\mathbb{E}_{Z' \sim \text{Unif}(Z)^{[n]}} [\hat{R}(\mathcal{A}(Z'), Z) - \hat{R}^*(Z)] \leq 2\xi(\sqrt{n}).$$

It is obvious that \mathcal{A}' is consistent with rate \sqrt{n} as it applies \mathcal{A} on a random sample of size \sqrt{n} . By Lemma 4, \mathcal{A}' is $2n^{-1/2}(e^\epsilon - e^{-\epsilon})$ differentially private. By Corollary 9, the new algorithm \mathcal{A}' is universally consistent. ■

A.3 Proofs for Section 3.3

Proof [Proof of Proposition 11] If $\mathcal{A}(Z)$ is a continuous distribution, we can pick $h \in \mathcal{H}$ at any point where $\mathcal{A}(Z)$ has finite density and set $\mathcal{A}'(Z) | z \in Z$ to be h with probability $1/n$ and the same as $\mathcal{A}(Z)$ with probability $1 - 1/n$. This breaks privacy because conditioned on two databases with z or without z , \mathcal{A} , the probability ratio of outputting h is ∞ .

If $\mathcal{A}(Z)$ is a discrete distribution or a mixed distribution, it must have the same support of the point mass for all Z . Otherwise it violates DP because we need $\frac{\mathbb{P}_{h \in \mathcal{A}(Z)(h)}}{\mathbb{P}_{h \in \mathcal{A}(Z')(h)}} \leq \exp(\epsilon n)$ for any $Z, Z' \in \mathcal{Z}^n$. Specifically, let the discrete set of point mass be $\tilde{\mathcal{H}}$ if $\mathcal{H} \setminus \tilde{\mathcal{H}} \neq \emptyset$, then we can use the same technique as in the continuous case by adding a small probability $1/n$ on $\mathcal{H} \setminus \tilde{\mathcal{H}}$ when $z \in Z$.

If $\tilde{\mathcal{H}} = \mathcal{H}$, then \mathcal{H} is a discrete set, if $|\mathcal{H}| < n$, then by boundedness and Hoeffding, ERM is a deterministic algorithm that learns any learnable problem. On the other hand, if $|\mathcal{H}| > n$, then by pigeon hole principle, there always exists a hypothesis h that has probability smaller than $1/n$ in $\mathcal{A}(Z)$ for any $Z \in \mathcal{Z}^n$ and we can construct \mathcal{A}' by outputting a sample of $\mathcal{A}(Z)$ if z is not observed and outputting a sample $\mathcal{A}(Z) | \mathcal{A}(Z) \neq h$ whenever z is observed.

The consistency of \mathcal{A}' follows easily as its risk is at most $1/n$ larger than that of \mathcal{A} . ■

A.4 Proofs for characterization of private \mathfrak{D} -learnability

Proof [Proof of Lemma 14] Let \mathcal{A}' be the algorithm that applies \mathcal{A} to a random subsample of size $\lfloor \sqrt{n} \rfloor$. If we can show that, for any $\mathcal{D} \in \mathfrak{D}$,

- (a) the empirical risk of \mathcal{A}' converges to the optimal population risk R^* in expectation;
- (b) the empirical risk of the ERM learning rule also converges to R^* in expectation,

then by triangle inequality, the empirical risk of \mathcal{A}' must also converge to the empirical risk of ERM, i.e., \mathcal{A}' is \mathfrak{D} -universal AERM.

We will start with (a). For any distribution $\mathcal{D} \in \mathfrak{D}$, we have

$$\begin{aligned} \mathbb{E}_{Z' \sim \mathcal{D}^n} \hat{R}(\mathcal{A}'(Z), Z) &= \mathbb{E}_{Z' \sim \mathcal{D}^n} \left[\mathbb{E}_{Z' \subset Z, |Z'| = \lfloor \sqrt{n} \rfloor} \hat{R}(\mathcal{A}(Z'), Z) \right] \\ &= \mathbb{E}_{Z' \sim \mathcal{D}^n} \left[\frac{\lfloor \sqrt{n} \rfloor}{n} \hat{R}(\mathcal{A}(Z'), Z') + \mathbb{E}_{Z'' \sim \mathcal{D}^{n - \lfloor \sqrt{n} \rfloor}} \left(\frac{n - \lfloor \sqrt{n} \rfloor}{n} \hat{R}(\mathcal{A}(Z''), Z'') \right) \right] \\ &= \mathbb{E}_{Z' \sim \mathcal{D}^n} \left[\frac{\lfloor \sqrt{n} \rfloor}{n} \hat{R}(\mathcal{A}(Z'), Z') + \frac{n - \lfloor \sqrt{n} \rfloor}{n} R(\mathcal{A}(Z'')) \right] \leq \frac{1}{\sqrt{n}} + R^* + \xi(\sqrt{n}). \end{aligned} \quad (14)$$

The last inequality uses the boundedness of the loss function to get $\hat{R}(\mathcal{A}(Z'), Z') \leq 1$ and the \mathfrak{D} -consistency of \mathcal{A} to bound the excess risk of $\mathbb{E}_{Z''} R(\mathcal{A}(Z''))$.

To show (b), we need to exploit the assumption that the problem is (non-privately) learnable. By Shalev-Shwartz et al. (2010, Theorem 7), the problem being learnable implies that there exists a universally consistent algorithm \mathcal{B} (not restricted to \mathfrak{D}), that is universally AERM with rate $3\xi'(n^{\frac{1}{4}}) + \frac{2}{\sqrt{n}}$ and stable with rate $\frac{2}{\sqrt{n}}$. Moreover, by Shalev-Shwartz et al. (2010, Theorem 8), \mathcal{B} 's stability and AERM implies that \mathcal{B} is also generalizing, with rate $6\xi'(n^{\frac{1}{4}}) + \frac{18}{\sqrt{n}}$. Here the term “generalizing” means that the empirical risk is close to the population risk. Therefore, we can establish (b) via the following chain of approximations

$$\mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R}^*(Z) \stackrel{\text{Generalization of } \mathcal{B}}{\approx} \mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R}(\mathcal{B}(Z), Z) \stackrel{\text{Consistency of } \mathcal{B}}{\approx} R^* \stackrel{\text{AERM of } \mathcal{B}}{\approx} R^*.$$

More precisely,

$$\begin{aligned} & \left| \mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R}^*(Z) - R^* \right| \\ & \leq \left| \mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R}^*(Z) - \mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R} \right| + \left| \mathbb{E}_{Z \sim \mathcal{D}^n} \hat{R} - R(\mathcal{B}(Z), Z) \right| + |R(\mathcal{B}(Z), Z) - R^*| \\ & \leq [3\xi'(n^{\frac{1}{4}}) + \frac{8}{\sqrt{n}}] + [6\xi'(n^{\frac{1}{4}}) + \frac{18}{\sqrt{n}}] + [3\xi'(n^{\frac{1}{4}}) + \frac{10}{\sqrt{n}}] = 12\xi'(n^{\frac{1}{4}}) + \frac{36}{\sqrt{n}}. \end{aligned} \quad (15)$$

Combine (14) and (15), we obtain the AERM of \mathcal{A}' with rate $12\xi'(n^{1/4}) + \frac{37}{\sqrt{n}} + \xi(\sqrt{n})$ as required. The privacy of \mathcal{A}' follows from Lemma 27. ■

A.5 Proof for Theorem 17

We first present the proof for Theorem 17. Recall that the roadmap of the proof is summarized in Figure 3.

For readability, we denote $\epsilon(n)$ by simply ϵ .

Recall that the objective function is $F(h, Z) = \frac{1}{n} \sum_{i=1}^n \ell(h, z_i) + g_n(h)$ and the corresponding utility function $q(h, Z) = -F(h, Z)$. By the boundedness assumption, it is easy to show that if we replace one data point in any Z with something else, then sensitivity

$$\Delta q = \sup_{h \in \mathcal{H}, d(Z, Z')=1} |q(Z, h) - q(Z', h)| \leq \frac{2}{n}. \quad (16)$$

Then by McSherry and Talwar (2007, Theorem 6), Algorithm 1 that outputs $h \in \mathcal{H}$ with $\mathbb{P}(h) \propto \exp(\frac{\epsilon}{2\Delta q} q(h, Z))$ naturally ensures ϵ -differential privacy.

Denote shorthand $F^* := \inf_{h \in \mathcal{H}} F(Z, h)$ and $q^* := -F^*$, we can state an analog of the utility theorem of the exponential mechanism in (McSherry and Talwar, 2007).

Lemma 29 (Utility) *Assuming $\epsilon < \log n$ (otherwise the privacy protection is meaningless anyway), if assumption A1, A2 hold for distribution \mathcal{D} , then*

$$\mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} q(Z, h) \geq -\mathbb{E}_{Z \sim \mathcal{D}^n} F^* - \frac{9[(\rho+2)\log n + \log K]}{n\epsilon}. \quad (17)$$

Proof By the boundedness of ℓ and g

$$q(Z, h) = -\frac{1}{n} \sum_{i=1}^n \ell(h, z_i) - g_n(h) \geq -(1 + \zeta(n)).$$

By Lemma 7 in McSherry and Talwar (2007) (translated to our case),

$$\mathbb{P}_{h \sim \mathcal{A}(Z)} [q(Z, h) < -F^* - 2t] \leq \frac{\mu(\mathcal{H})}{\mu(\mathcal{S}_t)} e^{-\frac{2\epsilon t}{2\Delta q}}, \quad (18)$$

Apply (16), take expectation over the data distribution on both sides, and applying assumption A2, we get

$$\mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{P}_{h \sim \mathcal{A}(Z)} [q(Z, h) < -F^* - 2t] \leq Kt^{-\rho} e^{-\frac{\epsilon t}{4}} = e^{-\frac{\epsilon t}{4} + \log K - \rho \log t} := e^{-\gamma}. \quad (19)$$

Take $t = \frac{4[(\rho+2)\log n + \log(K)]}{\epsilon n}$, by the assumption that $\epsilon < \log n$, we get $\log(nt) > 0$. Substitute t into the expression of γ we obtain

$$\gamma = \frac{\epsilon n}{4} t - \log K + \rho \log t = 2 \log n + \rho \log(nt) \geq 2 \log n,$$

and therefore

$$\mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{P}_{h \sim \mathcal{A}(Z)} [q(Z, h) < -F^* - 2t] \leq n^{-2}.$$

Denote $\mathbb{P}_{h \sim \mathcal{A}(Z)} [q(Z, h) < -F^* - 2t] =: p$, we can then bound the expectation from below as follows:

$$\begin{aligned} \mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} q(Z, h) &\geq \mathbb{E}_{Z \sim \mathcal{D}^n} (-F^* - 2t)(1-p) + \min_{h \in \mathcal{H}, Z \in \mathcal{Z}^n} q(Z, h) \mathbb{E}_{Z \sim \mathcal{D}^n} p \\ &\geq \mathbb{E}_{Z \sim \mathcal{D}^n} (-F^* - 2t) + (-1 - \zeta(n)) n^{-2} \\ &\geq -\mathbb{E}_{Z \sim \mathcal{D}^n} F^* - \frac{8[(\rho+2)\log n + \log(K)]}{\epsilon n} - (1 + \zeta(n)) n^{-2} \\ &\geq -\mathbb{E}_{Z \sim \mathcal{D}^n} F^* - \frac{9[(\rho+2)\log n + \log(K)]}{\epsilon n}. \end{aligned}$$

Now we can say something about the learning problem. In particular, the AERM follows directly from the utility result and stability follows from the definition of differential privacy. \blacksquare

Lemma 30 (Universal AERM) *Assume A1 and A2, and $\epsilon \leq \log n$ (so Lemma 29 holds), then*

$$\mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}^*(Z)] \leq \frac{9[(\rho+2)\log n + \log(1/K)]}{n\epsilon} + \zeta(n).$$

Proof This is a simple consequence of boundedness and Lemma 29.

$$\begin{aligned} &\mathbb{E}_{Z \sim \mathcal{D}^n} [\mathbb{E}_{h \sim \mathcal{A}(Z)} \hat{R}(h, Z) - \hat{R}^*(Z)] \\ &= \mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} \frac{1}{n} \sum_{i=1}^n \ell(h, z_i) - \mathbb{E}_{Z \sim \mathcal{D}^n} \inf_h \frac{1}{n} \sum_{i=1}^n \ell(h, z_i) \\ &\leq \mathbb{E}_{Z \sim \mathcal{D}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} \left[\frac{1}{n} \sum_{i=1}^n \ell(h, z_i) + g_n(h) \right] - \mathbb{E}_{h \sim \mathcal{A}(Z)} g_n(h) \\ &\quad - \mathbb{E}_{Z \sim \mathcal{D}^n} \inf_h \left[\frac{1}{n} \sum_{i=1}^n \ell(h, z_i) + g_n(h) \right] + \sup_h (g_n(h)) \\ &= \mathbb{E}_{Z \sim \mathcal{D}^n} (-F^* - \mathbb{E}_{h \sim \mathcal{A}(Z)} q(Z, h)) + \sup_h g_n(h) - \mathbb{E}_{h \sim \mathcal{A}(Z)} g_n(h) \\ &\leq \frac{9[(\rho+2)\log n + \log(1/K)]}{n\epsilon} + 2\zeta(n). \end{aligned}$$

The last step applies Lemma 29 and $\sup_h |g_n(h)| \leq \zeta(n)$ as in Assumption A2 by using the fact that $\sup_h g_n(h) - \mathbb{E} g_n(h) \leq 2 \sup_h |g_n(h)|$ for any distribution of h the expectation is taken over. \blacksquare

The above theorem shows that Algorithm 1 is asymptotic ERM. By Theorem 8, the fact that this algorithm is ϵ -differential private implies that it is 2ϵ -stable. Now the proof follows by applying Theorem 28 which says that stability and AERM of an algorithm certify its consistency. Noting that this holds for any distribution \mathcal{D} completes our proof for learnability in Theorem 17.

A.6 Proofs of other technical results

High confidence private learning. **Proof** [Proof of Theorem 18] The algorithm \mathcal{A} privately learns the problem with rate $\xi(n)$ implies that

$$\mathbb{E}_{Z \in \mathcal{D}^n} \mathbb{E}_{h \sim \mathcal{A}(Z)} R(h) - R^* \leq \xi(n).$$

Let $h \sim \mathcal{A}(Z)$ and $Z \sim \mathcal{D}^n$, by Markov's inequality, with probability at least $1 - 1/e$,

$$R(h) - R^* \leq e\xi(n).$$

If we split the data randomly into $a + 1$ parts of size $n/(a + 1)$ and run \mathcal{A} on the first a partitions, then we get $h_j \sim \mathcal{A}(Z_j)$. Then with probability at least $1 - (1/e)^a$, at least one of them has risk

$$\min_{j \in [a]} R(h_j) - R^* \leq \epsilon \xi\left(\frac{n}{a+1}\right). \quad (20)$$

Since the $(a + 1)$ th partition are iid data, and ℓ is bounded, we can apply Hoeffding's inequality and union bound, so that with probability $1 - \delta_1$ for all $j = 1, \dots, a + 1$

$$\hat{R}(h_j, Z_{a+1}) - R(h_j) \leq \sqrt{\frac{\log(2a/\delta_1)}{2n}}. \quad (21)$$

This means that if exponential mechanism picked the one with the best validation risk it will be almost as good as the one with the best risk. Assume h_1 is the one that achieves the best validation risk.

Now it remains to bound the probability that exponential mechanism pick an $h \in \{h_1, \dots, h_a\}$ that is much worse than h_1 .

Recall that the utility function is the negative validation risk which depends only on the last partition I_{a+1} .

$$q(X, h) = \frac{1}{n/(a+1)} \sum_{i \in I_{a+1}} \ell_i(z_i, h).$$

This is in fact a random function of the data because we are picking the the validation set I_{a+1} randomly from the data. Suppose we arbitrarily replace one data point j from the dataset, the distribution of the output of function $q(Z, h)$ is a mixture of the two cases: $j \in I_{a+1}$ and $j \notin I_{a+1}$. Since in the first case, $q(Z, h) = q(Z', h)$ for all h , sensitivity for this case is 0. In the second case, by the boundedness assumption, the sensitivity is at most $2(a + 1)/n$. For the exponential mechanism guarantee ϵ differential privacy, it suffices to take the sensitivity parameter to be $2(a + 1)/n$.

By the utility theorem of the exponential mechanism,

$$\mathbb{P}\left[\hat{R}(h) > \hat{R}(h_1) + \frac{8(q)\log n + \log a}{\epsilon n/(a+1)}\right] \leq n^{-\eta}. \quad (22)$$

Combine (20)(21) and(22) we get

$$\mathbb{P}\left[R(h) - R^* > \epsilon \xi\left(\frac{n}{a+1}\right) + \sqrt{\frac{\log(2a/\delta_1)}{2n}} + \frac{8(q)\log n + \log a}{\epsilon n/(a+1)}\right] \leq n^{-\eta} + \delta_1 + e^{-a}.$$

Now by appropriately choosing $\eta = \log(3/\delta)/\log n$, $a = \log(3/\delta)$, $\delta_1 = \delta/3$, we get

$$\mathbb{P}\left[R(h) - R^* > \epsilon \xi\left(\frac{n}{\log(3/\delta)+1}\right) + \sqrt{\frac{\log(2\log(3/\delta)) + \log(3/\delta)}{2n}} + \frac{8(\log(3/\delta) + \log \log(3/\delta))}{\epsilon n/(\log(3/\delta)+1)}\right] \leq \delta$$

combine the terms and take $\epsilon = \frac{\log(3/\delta)+1}{\sqrt{n}}$, we get the bound of the excess risk in the theorem.

To get the privacy claim, note that we are applying \mathcal{A} on disjoint partitions of the data so the privacy parameter does not aggregate. Take the worst over all partitions, we get the overall privacy loss $\max\left\{\epsilon \left(\frac{n}{\log(3/\delta)+1}\right), \frac{\log(3/\delta)+1}{\sqrt{n}}\right\}$ as stated in the theorem. ■

The Lipschitz example. **Proof** [Proof of Example 4] Let $h^* \in \arg\min_{h \in \mathcal{H}} F(Z, h)$, the Lipschitz condition dictates that for any h ,

$$|F(h) - F(h^*)| \leq L\|h - h^*\|_p.$$

Choose a small enough $t < t_0$ such that h is in the small neighborhood of h^* , and we can construct a function \tilde{F} that within the sublevel set S_t , such that the above inequality (when we replace F with \tilde{F}) is equality, then for any $h \in S_{t_0}$, $F(h) \geq F(Z, h)$. Verify that the sublevel set of $\tilde{F}(h)$, denoted by \tilde{S}_t , always contains S_t . In addition, we can compute the measure $\mu(\tilde{S}_t)$ explicitly, since the function is a cone and

$$L\|h - h^*\|_p = |\tilde{F}(h) - \tilde{F}(h^*)| = \tilde{F}(h) - \tilde{F}(h^*) \leq t,$$

therefore

$$\tilde{S}_t = \{h \mid L\|h - h^*\|_p \leq t\}.$$

Since \mathcal{H} is β_p -regular, $\mu(B \cap \mathcal{H}) \geq \beta_p \mu(B)$ for any ℓ_p ball $B \subset \mathbb{R}^d$, the measure of the sublevel set can be lower bounded by β_p times the volume of the ℓ_p ball with radius t/L and since $\tilde{S}_t \subseteq S_t$, we have

$$\mu(\tilde{S}_t) \geq \mu(S_t) \geq \beta_p \mu(B(t/L)) = \beta_p (t/L)^d$$

as required. ■

Appendix B. Alternative proof of Corollary 9 via Dwork et al. (2015b), Theorem 7)

In this Appendix, we describe how the results in Dwork et al. (2015b) can be used to obtain the forward direction of our characterization without going through a stability argument. We first restate the result here in our notation:

Lemma 31 (Theorem 7 in Dwork et al. 2015b) *Let \mathcal{B} be an ϵ -DP algorithm such that given a dataset Z , \mathcal{B} outputs a function from \mathcal{Z} to $[0, 1]$. For any distribution \mathcal{D} over \mathcal{Z} and random variable $Z \sim \mathcal{D}^n$, we let $\phi \sim \mathcal{B}(Z)$. Then for any $\beta > 0$, $\tau > 0$ and $n \geq 12 \log(4/\beta)/\tau^2$, setting $\epsilon < \tau/2$ ensures*

$$\mathbb{P}_{\phi \sim \mathcal{B}(Z), Z \sim \mathcal{D}^n} \left[\left| \mathbb{E}_{z \sim \mathcal{D}} \phi(z) - \frac{1}{n} \sum_{z \in Z} \phi(z) \right| \geq \tau \right] \leq \beta.$$

This lemma was originally stated to prove the claim that privately generated mechanisms for answering statistical queries always generalize.

For statistical learning problems, we can simply take the statistical query ϕ to be the loss function $\ell(h, \cdot)$ parameterized by $h \in \mathcal{H}$. If an algorithm \mathcal{A} that samples from a distribution on \mathcal{H} upon observing data Z is ϵ -DP, then $\mathcal{B} : Z \rightarrow \ell(\mathcal{A}(Z), \cdot)$ is also ϵ -DP. The result therefore reduces to that the empirical risk and population risk are close with high probability. Due to the boundedness assumption, we can translate the high probability result to the expectation form, which verifies the definition of “generalization”.

However, “generalization” alone still does not imply “consistency”, as we also need

$$\mathbb{E}_{\phi \sim \mathcal{B}(Z)} \frac{1}{n} \sum_{z \in Z} \phi(z) \rightarrow R^* = \min_{\phi \in \Phi} \mathbb{E}_{z \sim \mathcal{D}} \phi(z)$$

as Z gets large, which does not hold for all DP-output ϕ . But when $\phi = \ell(h, \cdot)$, it can be obtained if we assume \mathcal{A} is AERM. This is shown via the following inequality

$$\mathbb{E}_{Z \in \mathcal{D}^n} \mathbb{E}_{\phi \sim \mathcal{B}(Z)} \frac{1}{n} \sum_{z \in Z} \phi(z) \rightarrow \mathbb{E}_{Z \in \mathcal{D}^n} \min_{\phi \in \Phi} \frac{1}{n} \sum_{z \in Z} \phi(z) \leq \mathbb{E}_{Z \in \mathcal{D}^n} \frac{1}{n} \sum_{z \in Z} \phi^*(z) = \mathbb{E} \phi^*(z) = R^*,$$

where $\phi^* = \ell(h^*, \cdot)$ and h^* is an optimal hypothesis function. This wraps up the proof of consistency.

The above proof of “consistency” via Lemma 31 and “AERM”, however, leads to a looser bound comparing to our result (Corollary 9) when the additional assumption on n and τ (equivalently ϵ) is active, i.e., when $\frac{\epsilon(n)}{\log(1/\epsilon(n))} < O\left(\frac{1}{\sqrt{n}}\right)$. In this case it only implies a $\xi(n) + \frac{\log n}{\sqrt{n}}$ bound due to that ϵ -DP implies ϵ' -DP for any $\epsilon' > \epsilon$. Our proof of Corollary 9 is considerably simpler and more general in that it does not require any assumption on the number of data points n .

This can easily lead to worse overall error bound for very simple learning problems with sufficiently fast rate. For example, in the problem of learning the mean of $X \in [0, 1]$, let the loss function be $|x - h|^{10}$. Consider the $\epsilon(n)$ -DP algorithm that outputs $\text{ERM} + \text{Laplace}\left(\frac{2}{\epsilon(n)n}\right)$ where $\epsilon(n)$ is chosen to be $n^{-9/10}$. This algorithm is AERM with rate $\xi(n) = \frac{10 \cdot 2!}{(\epsilon(n)n)^{10}} = O(n^{-1})$. By Corollary 9 we get an overall rate of $O(n^{-9/10})$ while through Lemma 31 and the argument that follows, we only get $O(n^{-1/2})$.

Abstract

Factorization Machines (FM) are currently only used in a narrow range of applications and are not yet part of the standard machine learning toolbox, despite their great success in collaborative filtering and click-through rate prediction. However, Factorization Machines are a general model to deal with sparse and high dimensional features. Our Factorization Machine implementation (*fastFM*) provides easy access to many solvers and supports regression, classification and ranking tasks. Such an implementation simplifies the use of FM for a wide range of applications. Therefore, our implementation has the potential to improve understanding of the FM model and drive new development.

Keywords: Python, MCMC, matrix factorization, context-aware recommendation

1. Introduction

This work aims to facilitate research for matrix factorization based machine learning (ML) models. Factorization Machines are able to express many different latent factor models and are widely used for collaborative filtering tasks (Rendle, 2012b). An important advantage of FM is that the model equation

$$w_0 \in \mathbb{R}, x, w \in \mathbb{R}^p, v_i \in \mathbb{R}^k$$

$$\hat{y}^{FM}(x) := w_0 + \sum_{i=1}^p u_i x_i + \sum_{i=1}^p \sum_{j>i}^p \langle v_i, v_j \rangle x_i x_j \quad (1)$$

conforms to the standard notation for vector based ML. FM learn a factorized coefficient $\langle v_i, v_j \rangle$ for each feature pair $x_i x_j$ (eq. 1). This makes it possible to model very sparse feature interactions, as for example, encoding a sample as $x = \{\dots, 0, \underbrace{1}_{x_1}, \dots, 0, \underbrace{1}_{x_2}, 0, \dots\}$ yields $\hat{y}^{FM}(x) = w_0 + u_i + w_j + v_i^T v_j$ which is equivalent to (biased) matrix factorization $R_{i,j} \approx b_0 + b_i + b_j + u_i^T v_j$ (Srebro et al., 2004). Please refer to Rendle (2012b) for more encoding examples. FM have been the top performing model in various machine learning competitions (Rendle and Schmidt-Thieme, 2009; Rendle, 2012a; Bayer and Rendle, 2013) with different objectives (e.g. What Do You Know? Challenge¹, EMI Music Hackathon²). *fastFM* includes solvers for regression, classification and ranking problems (see Table 1) and addresses the following needs of the research community: (i) easy interfacing for dynamic

1. <http://www.kaggle.com/c/WhatDoYouKnow>
2. <http://www.kaggle.com/c/MusicHackathon>

and interactive languages such as R, Python and Matlab; (ii) a Python interface allowing interactive work; (iii) a publicly available test suite strongly simplifying modifications or adding of new features; (iv) code is released under the **BSD-license** allowing the integration in (almost) any open source project.

2. Design Overview

The *fastFM* library has a multi layered software architecture (Figure 1) that separates the interface code from the performance critical parts (*fastFM-core*). The core contains the solvers, is written in C and can be used stand alone. Two user interfaces are available: a command line interface (CLI) and a Python interface. Cython (Behnel et al., 2011) is used to create a Python extension from the C library. Both, the Python and C interface, serve as reference implementation for bindings to additional languages.

2.1 fastFM-core

FM are usually applied to very sparse design matrices, often with a sparsity over 95 %, due to their ability to model interaction between very high dimensional categorical features. We use the standard compressed row storage (CRS) matrix format as underlying data structure and rely on the CXSparse³ library (Davis, 2006) for fast sparse matrix / vector operations. This simplifies the code and makes memory sharing between Python and C straight forward.

fastFM contains a test suite that is run on each commit to the GitHub repository via a continuous integration server⁴. Solvers are tested using state of the art techniques, such as Posterior Quantiles (Cook et al., 2006) for the MCMC sampler and Finite Differences for the SGD based solvers.

2.2 Solver and Loss Functions

fastFM provides a range of solvers for all supported tasks (Table 1). The MCMC solver implements the Bayesian Factorization Machine model (Freudenthaler et al., 2011) via Gibbs sampling. We use the pairwise Bayesian Personalized Ranking (BPR) loss (Rendle et al., 2009) for ranking. More details on the classification and regression solvers can be found in Rendle (2012b).

Task	Solver	Loss
Regression	ALS, MCMC, SGD	Square Loss
Classification	ALS, MCMC, SGD	Probit (MAP), Probit, Sigmoid
Ranking	SGD	BPR (Rendle et al., 2009)

Table 1: Supported solvers and tasks

3. CXSparse is LGPL licensed.
4. <https://travis-ci.org/ibayer/fastFM-core>

2.3 Python Interface

The Python interface is compatible with the API of the widely-used `scikit-learn` library (Pedregosa et al., 2011) which opens the library to a large user base. The following code snippet shows how to use MCMC sampling for an FM classifier and how to make predictions on new data.

```
fm = mcmc.FMClassification(init_std=0.01, rank=8)
y_pred = fm.fit_predict(X_train, y_train, X_test)
```

`fastFM` provides additional features such as warm starting a solver from a previous solution (see MCMC example).

```
fm = als.FMRegression(init_std=0.01, rank=8, l2_reg=2)
fm.fit(X_train, y_train)
```

3. Experiments

`libFM`⁵ is the reference implementation for FM and the only one that provides ALS and MCMC solver. Our experiments show, that the ALS and MCMC solver in `fastFM` compare favorable to `libFM` with respect to runtime (Figure 2) and are indistinguishable in terms of accuracy. The experiments have been conducted on the Movielens 10M data set using the original split with a fixed number of 200 iterations for all experiments. The x-axis indicates the number of latent factors (rank), and the y-axis the runtime in seconds. The plots show that the runtime scales linearly with the rank for both implementations. The code snippet

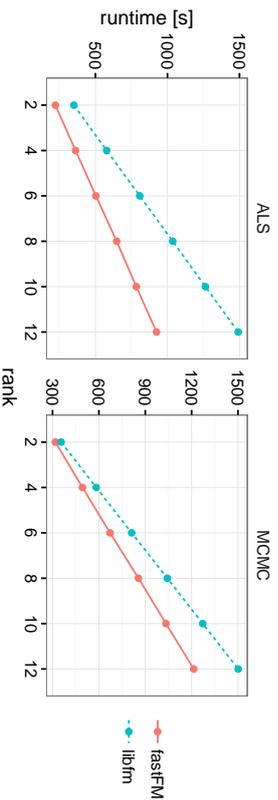

Figure 2: A runtime comparison between `fastFM` and `libFM` is shown. The evaluation is done on the Movielens 10M data set.

below shows how simple it is to write Python code that allows model inspection after every iteration. The induced Python function call overhead occurs only once per iteration and is therefore neglectable. This feature can be used for Bayesian Model Checking as demonstrated in Figure 3. The figure shows MCMC summary statistics for the first order hyper parameter σ_w . Please note that the MCMC solver uses Gaussian priors for the model parameter (Freudenthaler et al., 2011).

⁵ <http://libfm.org>

```
fm = mcmc.FMRegression(n_iter=0)
# initialize coefficients
fm.fit_predict(X_train, y_train, X_test)

for i in range(number_of_iterations):
    y_pred = fm.fit_predict(X_train, y_train, X_test, n_more_iter=1)
    # save, or modify (hyper) parameter
    print(fm.w_, fm.V_, fm.hyper_param_)
```

Many other analyses and experiments can be realized with a few lines of Python code without the need to read or recompile the performance critical C code.

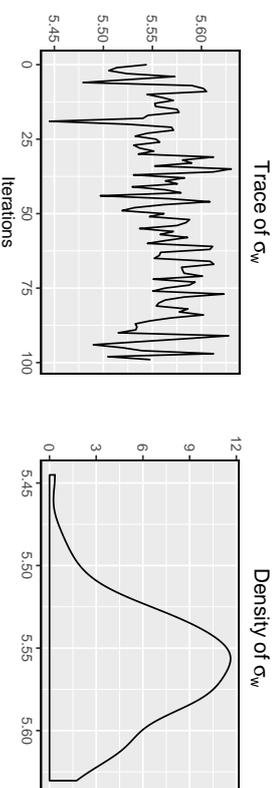

Figure 3: MCMC chain analysis and convergence diagnostics example for the hyperparameter σ_w evaluated on the Movielens 10M data set.

4. Related Work

Factorization Machines are available in the large scale machine learning libraries GraphLab (Low et al., 2014) and Bidmach (Canny and Zhao, 2013). The toolkit Svdfeatures by Chen et al. (2012) provides a general MF model that is similar to a FM. The implementations in GraphLab, Bidmach and Svdfeatures only support SGD solvers and don't provide a ranking loss. It's not our objective to replace these distributed machine learning frameworks: but to provide a FM implementation that is easy to use and easy to extend without sacrificing performance.

Abstract

We provide a hierarchical Bayesian model for estimating the effects of transient drug exposures on a collection of health outcomes, where the effects of all drugs on all outcomes are estimated simultaneously. The method possesses properties that allow it to handle important challenges of dealing with large-scale longitudinal observational databases. In particular, this model is a generalization of the self-controlled case series (SCCS) method, meaning that certain patient specific baseline rates never need to be estimated. Further, this model is formulated with layers of latent factors, which substantially reduces the number of parameters and helps with interpretability by illuminating latent classes of drugs and outcomes. We believe our work is the first to consider multivariate SCCS (in the sense of multiple outcomes) and is the first to couple latent factor analysis with SCCS. We demonstrate the approach by estimating the effects of various time-sensitive insulin treatments for diabetics.

1. Introduction

The medical community, the pharmaceutical industry, and health authorities are obligated to confirm that marketed medical products and prescription drugs have acceptable benefit-risk profiles; in fact, these entities have come under increasing scientific, regulatory, and public scrutiny to accurately estimate the effects of drugs. The increasing availability of large-scale longitudinal observational healthcare databases (LODs) opens up exciting new

opportunities to add to the evidence base concerning these issues, though the complexity and scale of some of the available databases presents interesting statistical and computational challenges. In what follows we focus on using longitudinal observational databases to make inferences about the effects of many drugs with respect to many outcomes simultaneously.

Many research studies have attempted to characterize the relationship between time-varying drug exposures and adverse events (AEs) related to health outcomes (e.g. in Madigan et al., 2011; Greene et al., 2011; Benchimol et al., 2013; Simpson et al., 2013; Chui et al., 2014) and the use of LODs to study *individual* drug-adverse effect combinations has become routine. The medical literature provides many examples and many different epidemiological and statistical approaches, often tailored to the specific drug and specific adverse effect. There is a major flaw in these approaches of estimating the effect of one drug on one outcome, which is that it is very clear that many drugs are closely related to each other (there are dozens of antibiotics for instance), and many health outcomes are closely related to each other (e.g., strokes, heart attacks, and other vascular diseases). In this work, we borrow strength across both drugs and outcomes in order to obtain better estimates for each individual drug and outcome. Since we are interested in the effects of drugs, and not in the patient-specific baseline rate of the outcome, we use the ideas of the self-controlled case series (SCCS) method of Farrington (1995), which is a conditional Poisson regression approach wherein each patient serves as his or her own control. The SCCS method has been widely applied, especially in vaccine studies (see the tutorial of Whitaker et al., 2006). SCCS controls for all fixed patient-level covariates but remains susceptible to time-varying confounding. The standard SCCS method focuses on one drug and one outcome. Simpson et al. (2013) introduced the high-dimensional multiple self-controlled case series (MSCCS) method that simultaneously provides effect estimates for multiple drugs and a single outcome. In fact, the MSCCS provides a self-controlled approach that can control for many time-varying covariates, drugs being a special case. Bayesian implementations of both SCCS and MSCCS provide significant advantages, especially in high-dimensional settings with thousands or even tens of thousands of drugs and outcomes and even larger numbers of interactions. Suchard et al. (2013a) and Madigan et al. (2014) describe large-scale empirical evaluations of SCCS and MSCCS in comparison with other standard methods for effect size estimation.

Neither SCCS nor MSCCS account for the fact that many drugs/treatments naturally form classes and therefore regression coefficients for drugs from within a single class might reasonably be modeled as arising exchangeably from a common prior distribution. Adverse events and health conditions can also be organized hierarchically, again affording an opportunity to “borrow strength” across related outcomes. For both drugs and outcomes, the hierarchy could extend to multiple levels. In what follows, we formalize these ideas within the framework of latent factor Bayesian hierarchical models.

Factor models, which have been traditionally used in behavioral sciences and bioinformatics, provide a flexible framework for modeling multivariate data via unobserved latent factors (e.g., Ghosh and Dumson, 2009; Carvalho et al., 2008). In this paper, we do not impose specific latent structure *a priori*. However, our approach can also be used for cases where classes of drugs and conditions are known *a priori*. We will show that the latent factor approach not only brings more interpretability to our model, but also can significantly contribute to reducing the computational complexity. To our knowledge, only a

few authors have previously considered matrix factorization-based data analysis techniques for drug safety and surveillance (for example, Ziftnik and Zupun 2014, for drug-induced liver injury prediction and Cobanoglu et al. 2013, for predicting drug-target interactions in neurobiological disorders, which are both very different from our study).

We introduce three models for predicting the effects of multiple drugs on multiple outcomes that use hierarchical Bayesian analysis. The first model (Model 0) does not use latent factors, and borrows strength across all drugs and outcomes. The second model (Model 1) uses one set of latent drugs and one set of latent outcomes, through a single matrix factorization. The third model (Model 2) uses two sets of latent factors, by factoring the matrix of coefficients into three matrices; one for converting drugs to latent drugs, another for converting outcomes to latent outcomes, and the third for modeling the effects of latent drugs on latent outcomes. By allowing for latent factors, the second and third models provide an increased level of interpretability; use fewer variables, and are thus more computationally efficient to estimate.

The rest of this paper is organized as follows: Section 2 provides an overview of the self-controlled case series (SCCS) method. In Sections 3, 4.1, 4.2, and 4.3 we describe the model and the Bayesian inference procedure. We then use a series of simulations in Section 5 to show that we can recover the true generating parameters from data. Finally, we demonstrate the approach in Section 6 for estimating the effects of various insulin treatments for diabetes. Our proposed methodology has broader applicability beyond estimating the effects of drugs considered in this paper.

2. Background: Overview of the Self-Controlled Case Series (SCCS)

The self-controlled case series method (Farrington, 1995) models the event rate during drug exposure in comparison to the baseline event rate while unexposed (see Whitaker et al., 2006; Madigan et al., 2010; Suchard et al., 2013a). In the self-controlled case series method, each individual also acts as their own control. Each treatment observation, which is a period of time that someone is drug-exposed, is considered with respect to other periods of time in which the same person is not exposed. This way of matching gracefully avoids patient-level selection bias; it controls for all fixed confounders, such as the individual's underlying frailty; the severity of their underlying disease, genetics, socioeconomic status, and so on. Further, because of the way the SCCS model is designed around this choice, the non-time dependent factors for each person cancel within the formula for the likelihood, and do not appear in the likelihood at all. This allows us to focus our modeling efforts on the time-dependent terms that involve the effects of the drugs.

To obtain SCCS's benefits, we also suffer its disadvantages and assumptions. First, SCCS is susceptible to bias due to potential unmeasured time-varying confounders. (However, SCCS does account for non-time-varying confounding.) This means we should include all features that affect the outcome and vary over time. Second, SCCS assumes that treatment effects are homogeneous across subjects. This avoids having to model patient-specific effects. However, it is possible that patients experience different effects from the various treatments. It is possible to create extensions of our approach that include patient specific random effects if desired. Third, the basic version of SCCS assumes that future outcomes are independent of past ones, but this can be changed, as discussed later. Conditional on

the model parameters, outcomes are assumed to be independent of each other, although because we are using latent factors, there can be marginal dependencies among the outcomes.

In the SCCS, events are modeled as arising from a non-homogeneous Poisson process. The event rate varies over time, based on exposure to drugs. Each patient $i = 1, \dots, N$ carries an unknown individual baseline event rate of e^{ϕ_i} . The exposure to drug $j = 1, \dots, J$ measured each day results in a multiplicative effect of e^{β_j} to this baseline rate e^{ϕ_i} . The historical data for patient i on day d ($d = 1, \dots, \tau_d$) includes a vector of drug exposure as $\mathbf{x}_{id} = [x_{id1}, x_{id2}, \dots, x_{idJ}]^T$, where $x_{idj} = 1$ if patient i is exposed to drug j on day d and 0 otherwise. The SCCS defines $\lambda_{id} = \exp(\phi_i + \mathbf{x}_{id}^T \boldsymbol{\beta})$ as the Poisson event rate for patient i on interval d , where $\boldsymbol{\beta} = [\beta_1, \beta_2, \dots, \beta_J]^T$ are regression coefficients. We denote y_{id} as the number of events that patient i experiences on day d . Conditioning on the total number of events for patient i , denoted by n_i , nuisance quantities ϕ_i cancel out of the SCCS likelihood, leaving log-likelihood as follows:

$$\mathcal{L}(\boldsymbol{\beta}) = \sum_i^N \left[\sum_d^{\tau_i} y_{id} \mathbf{x}_{id}^T \boldsymbol{\beta} - n_i \log \left(\sum_d^{\tau_i} e^{\mathbf{x}_{id}^T \boldsymbol{\beta}} \right) \right]. \quad (1)$$

Since larger LODs can contain millions of patients, avoiding estimation of the patient-specific baseline rates represents a significant computational and statistical advantage.

The most basic version of the SCCS deals with one drug and estimates a single unknown, β_1 , the effect estimate for the target drug of direct interest. However, most patients in longitudinal healthcare databases often take multiple drugs and treatments throughout the course of their observation and also experience multiple health outcomes. This motivates us to use a multiple-drug, multiple-outcome analysis.

3. Multi-drug, Multi-Outcome Self-Controlled Case Series - Notation and Inference

The methods proposed here generalize the self-controlled case series to handle multiple drugs/treatments and multiple outcomes/conditions. We describe the extended SCCS/MSCCS where there are J drugs and O health outcomes. The notation used throughout the paper is as follows:

- N : number of patients (i indexes individuals from 1 to N).
- x_{idj} : binary indicator reflecting whether patient i is exposed to drug j on interval d .
- $\mathbf{x}_{id} = [x_{id1}, x_{id2}, \dots, x_{idJ}]^T$: the vector of exposed drugs for patient i on interval d .
- J : number of drugs (treatments).
- O : number of health outcomes (adverse events).
- D_o^i : the set of observation intervals where patient i has outcome o .
- τ_o^i : the number of observation intervals where patient i has outcome o (the size of D_o^i).
- y_{id}^o : binary indicator reflecting whether patient i has outcome o on interval d .
- $\mathbf{y}_o^i = [y_{i1}^o, y_{i2}^o, \dots, y_{i\tau_o^i}^o]^T$: the vector of observed outcomes o for patient i .
- ϕ_o^i : baseline incidence of outcome o for patient i .

$$\boldsymbol{\Phi} = \begin{pmatrix} \phi_1^1 & \dots & \phi_1^O \\ \vdots & & \vdots \\ \phi_N^1 & \dots & \phi_N^O \end{pmatrix}: \text{baseline incidence matrix.}$$

β_j^o : regression coefficients associated with outcome o and drug j .
 $\beta^o = [\beta_1^o, \beta_2^o, \dots, \beta_J^o]^\top$: regression coefficients associated with outcome o .

$\mathbf{B} = \begin{pmatrix} \beta_1^O & \dots & \beta_1^O \\ \vdots & \ddots & \vdots \\ \beta_J^O & \dots & \beta_J^O \end{pmatrix}$: drug-outcome coefficient matrix.

$\lambda_{id}^0 = \exp(\phi_i^o + \mathbf{x}_{id}^\top \beta^o)$: the Poisson event rate of outcome o , for patient i , on interval d .

Similar to the SCCS, outcomes occur according to a nonhomogeneous Poisson process, where drug exposure can modulate the rate over time. Patient i has an individual baseline rate of $\exp(\phi_i^o)$ for outcome o that remains constant over time. Drug j has a multiplicative effect of $\exp(\beta_j^o)$ on the individual baseline rate $\exp(\phi_i^o)$ during its exposure period. The Poisson event rate for outcome o and patient i on interval d according to the SCCS is

$$\lambda_{id}^0 = \exp(\phi_i^o + \mathbf{x}_{id}^\top \beta^o).$$

The key benefit of the SCCS is that the ϕ_i^o terms do not need to be modeled, since we are interested in the ratio of Poisson intensities with and without the drug. For instance, considering only one drug j , comparing the intensity ratio for day d_1 to a different day d_2 with no exposure to the drug, we have

$$\frac{\lambda_{id_1}^0}{\lambda_{id_2}^0} = \frac{\exp(\phi_i^o + 1\beta_j^o)}{\exp(\phi_i^o + 0\beta_j^o)} = \exp(\beta_j^o).$$

As the Poisson rate is assumed to be constant within each interval, the number of outcomes o observed for patient i on interval d is distributed as a Poisson random variable (r.v.) denoted by Y_{id}^o as

$$\Pr(Y_{id}^o = y_{id}^o | \mathbf{x}_{id}) = \frac{e^{-\lambda_{id}^0} \lambda_{id}^0 y_{id}^o}{y_{id}^o!}.$$

Based on the above, the contribution to the likelihood for patient i and outcome o for the observed sequence of events $\mathbf{y}_i^o = [y_{i1}^o, y_{i2}^o, \dots, y_{iT^o}^o]^\top$, conditioned on the observed exposures $\mathbf{x}_i = [\mathbf{x}_{i1}, \dots, \mathbf{x}_{iT^o}]$ is

$$\begin{aligned} \mathcal{L}_i^o &= \Pr(\mathbf{y}_i^o | \mathbf{x}_i) = \prod_{d \in D_i^o} \Pr(y_{id}^o | \mathbf{x}_{id}) = \exp \left(- \sum_{d \in D_i^o} e^{\phi_i^o + \mathbf{x}_{id}^\top \beta^o} \right) \prod_{d \in D_i^o} \frac{(e^{\phi_i^o + \mathbf{x}_{id}^\top \beta^o})^{y_{id}^o}}{y_{id}^o!} \quad (2) \\ &= \exp \left(-e^{\phi_i^o} \sum_{d \in D_i^o} e^{\mathbf{x}_{id}^\top \beta^o} \right) \prod_{d \in D_i^o} e^{\phi_i^o y_{id}^o} \prod_{d \in D_i^o} \frac{(e^{\mathbf{x}_{id}^\top \beta^o})^{y_{id}^o}}{y_{id}^o!} \\ &= \exp \left(\phi_i^o n_i^o - e^{\phi_i^o} \sum_{d \in D_i^o} e^{\mathbf{x}_{id}^\top \beta^o} \right) \prod_{d \in D_i^o} \frac{(e^{\mathbf{x}_{id}^\top \beta^o})^{y_{id}^o}}{y_{id}^o!}, \end{aligned}$$

where $n_i^o = \sum_{d \in D_i^o} y_{id}^o$.

Two key assumptions underly the above likelihood. First, the model assumes that future outcomes are independent of past outcomes. For certain outcomes (e.g., myocardial infarction) this may not be reasonable. Simpson (2013), Schuemie et al. (2014), and Farrington et al. (2011) consider SCCS generalizations that allow for such dependence; in future work it is possible to consider similar generalizations of the method proposed here. The SCCS model also assumes that conditional on the parameters, outcomes are independent of each other. The latent structure, however, allows for arbitrary marginal dependence among outcomes.

One could form the full likelihood to estimate the unknown parameters (Φ, \mathbf{B}) . In order to avoid estimating the nuisance parameter set Φ , we can condition on its sufficient statistic, which removes the dependence on Φ . The cumulative intensity is a sum (rather than an integral) since we assume a constant intensity over each interval. Conditioning on n_i^o yields the following likelihood for person i :

$$\begin{aligned} \mathcal{L}_i^o &= \Pr(\mathbf{y}_i^o | \mathbf{x}_i, n_i^o) = \frac{\prod_{d \in D_i^o} \Pr(y_{id}^o | \mathbf{x}_{id})}{\Pr(n_i^o | \mathbf{x}_i)} = \frac{\prod_{d \in D_i^o} \Pr(y_{id}^o | \mathbf{x}_{id})}{\left[\frac{\exp \left(- \sum_{d \in D_i^o} \lambda_{id}^o \right) \left(\sum_{d \in D_i^o} \lambda_{id}^o \right)^{n_i^o}}{n_i^o!} \right]} \quad (3) \\ &\propto \exp \left(\prod_{d \in D_i^o} \left(\frac{e^{\mathbf{x}_{id}^\top \beta^o}}{\sum_{d'} e^{\mathbf{x}_{id'}^\top \beta^o}} \right)^{y_{id}^o} \right). \end{aligned}$$

Notice that because n_i^o is sufficient, the individual likelihood in the above expression no longer contains Φ . Assuming that patients are independent and outcomes are conditionally independent, the full conditional likelihood for event o is simply the product of the individual likelihoods (i.e. $\mathcal{L}^o = \prod_{i=1}^N \mathcal{L}_i^o$). Intuitively it follows that if i has no outcomes of type o , it cannot provide any information about the relative rate of outcome o .

Using the notation and the formula for the likelihood established in this section, we next present three hierarchical models called Factorized Self-Controlled Case Series methods, for multiple drug, multiple outcome analysis and discuss how to estimate the drug-outcome coefficient matrix \mathbf{B} . Two of the models have latent factors that allow \mathbf{B} to be expressed in a simpler and more interpretable way. In our experiments, the empirical performance of these methods is approximately the same.

4. Factorized Self-Controlled Case Series (FSCCS)

Building on the notation in the previous section, this section describes the proposed self-controlled case series methods within the three following subsections.

4.1 Model 0 - Hierarchical Model With No Latent Factors

Instead of estimating each coefficient independently, we borrow strength over both drugs and outcomes, which adds substantial regularization. This is particularly relevant when

considering a set of related outcomes and drugs, e.g., heart-disease related outcomes and the set of drugs one might prescribe for heart-related conditions. We take a hierarchical Bayesian approach. By analogy with ridge regression, we use normal priors for the regression parameters (sparsifying priors such as the double exponential could be used instead). We shrink the coefficients for drug j for all outcomes o to μ_j by placing an independent normal prior on each β_j^o as $\beta_j^o \sim \mathcal{N}(\mu_j, \sigma_j^2)$, $\forall (j, o)$, where $\mu_j \sim \mathcal{N}(0, \gamma^2)$, $\forall j$. This prior helps with numerical instability, overfitting, and makes the model more interpretable. We assume uniform priors for hyperparameters σ_j and γ as $\sigma_j \sim \mathbf{U}(0, a)$, $\forall j$ and $\gamma \sim \mathbf{U}(0, a)$, where hyperparameter a is a user-defined constant, which can also be determined through cross-validation. A natural extension of this model (not explored here) would be to have drugs belong to certain classes of drugs, so that priors can be defined based on each class of drugs; similarly with outcomes. The posterior density is as follows:

$$\begin{aligned} \Pr(\mathbf{B}, \boldsymbol{\mu}, \boldsymbol{\sigma}, \gamma | \mathbf{y}, a) &\propto \Pr(\mathbf{y} | \mathbf{B}) \times \Pr(\boldsymbol{\mu} | \boldsymbol{\sigma}) \times \Pr(\gamma | a) \times \Pr(\boldsymbol{\sigma} | a) \\ &\propto \prod_o \prod_i \prod_{d \in D_i} \prod \left(\frac{\exp(\mathbf{x}_{id}^\top \boldsymbol{\beta}^o)}{\sum_{d' \in D_i} \exp(\mathbf{x}_{id'}^\top \boldsymbol{\beta}^o)} \right)^{y_{id}^{(o)}} \\ &\times \prod_j \prod_o \mathcal{N}(\beta_j^o | \mu_j, \sigma_j^2) \times \prod_j \mathcal{N}(\mu_j | 0, \gamma^2) \times \prod_j \Pr(\sigma_j | a) \times \Pr(\gamma | a). \end{aligned} \quad (4)$$

The negative log-posterior (which can be used for finding the MAP solution if desired) is:

$$\mathcal{L}_1 = -\log(\Pr(\mathbf{B}, \boldsymbol{\mu}, \boldsymbol{\sigma}, \gamma | \mathbf{y}, a)).$$

The graphical representation of this model is shown in Figure 1.

4.2 Model 1 - One Level of Latent Factors

Two considerations motivate this model. First, modeling the full posterior distribution of Model 0 can be computationally expensive, particularly for large N , J , and O , where J and O determine the number of variables to be estimated within the \mathbf{B} matrix. Second, Model 0 overlooks the fact that drugs and outcomes might come from a smaller number of latent classes; for instance, there are commonly several drugs that are extremely similar to each other for treating a set of highly related illnesses. We consider F latent factors for drugs and outcomes. We model the $J \times O$ matrix \mathbf{B} as $\mathbf{B} = \mathbf{L}^{(D)} \times \mathbf{L}^{(O)}$, where

$$\mathbf{L}^{(D)} = \begin{pmatrix} L_{1,1}^{(D)} & \dots & L_{1,F}^{(D)} \\ \vdots & & \vdots \\ L_{J,1}^{(D)} & \dots & L_{J,F}^{(D)} \end{pmatrix}, \mathbf{L}^{(O)} = \begin{pmatrix} L_{1,1}^{(O)} & \dots & L_{1,O}^{(O)} \\ \vdots & & \vdots \\ L_{F,1}^{(O)} & \dots & L_{F,O}^{(O)} \end{pmatrix}.$$

This way, we do not assume we know in advance which drugs have similar effects on which outcomes, instead we estimate this from data. The number of latent factors F can be determined by cross-validation. The total number of latent factors is $J \times F + F \times O$, which can be substantially less than $J \times O$. The coefficient β_j^o associated with outcome o and drug j can be calculated as $\beta_j^o = \sum_{f=1}^F L_{j,f}^{(D)} \times L_{f,o}^{(O)}$.

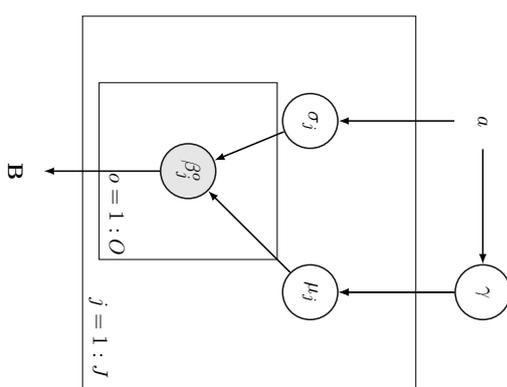

Figure 1: Graphical representation of Model 0

For drug latent factors, we place independent normal priors on the entries of $L^{(D)}$ as

$$L_{j,f}^{(D)} \sim \mathcal{N}(\mu_f^{(D)}, \sigma_f^{(D)2}), \forall (j, f), \text{ where } \mu_f^{(D)} \sim \mathcal{N}(0, \gamma^{(D)2}), \forall f.$$

Similarly, we define normal priors on the entries of $L^{(O)}$ as

$$L_{f,o}^{(O)} \sim \mathcal{N}(\mu_f^{(O)}, \sigma_f^{(O)2}), \forall (f, o), \text{ where } \mu_f^{(O)} \sim \mathcal{N}(0, \gamma^{(O)2}), \forall f.$$

We assume uniform priors for hyperparameters σ_j and γ as

$$\sigma_f^{(D)} \sim \mathbf{U}(0, a), \forall f, \sigma_f^{(O)} \sim \mathbf{U}(0, a), \forall f, \gamma^{(D)} \sim \mathbf{U}(0, b), \gamma^{(O)} \sim \mathbf{U}(0, b),$$

where (a, b) are known parameters. The posterior over the parameters is now defined as

$$\begin{aligned}
& \Pr(\mathbf{L}^{(D)}, \mathbf{L}^{(O)}, \boldsymbol{\mu}^{(D)}, \boldsymbol{\mu}^{(O)}, \boldsymbol{\sigma}^{(D)}, \boldsymbol{\sigma}^{(O)}, \gamma^{(D)}, \gamma^{(O)} | \mathbf{y}) \propto \Pr(\mathbf{y} | \mathbf{L}^{(D)}, \mathbf{L}^{(O)}) \\
& \times \Pr(\mathbf{L}^{(D)} | \boldsymbol{\mu}^{(D)}, \boldsymbol{\sigma}^{(D)}) \times \Pr(\mathbf{L}^{(O)} | \boldsymbol{\mu}^{(O)}, \boldsymbol{\sigma}^{(O)}) \times \Pr(\boldsymbol{\mu}^{(D)} | \gamma^{(D)}) \times \Pr(\boldsymbol{\mu}^{(O)} | \gamma^{(O)}) \\
& \times \Pr(\boldsymbol{\sigma}^{(D)} | a) \times \Pr(\boldsymbol{\sigma}^{(O)} | a) \times \Pr(\gamma^{(D)} | b) \times \Pr(\gamma^{(O)} | b) \\
& \propto \prod_{\sigma} \prod_i \prod_{d \in \mathcal{D}_i} \prod_{\sigma'} \left(\frac{\exp(\mathbf{x}_{id}^T \boldsymbol{\beta}^{\sigma'})}{\sum_{\sigma''} \exp(\mathbf{x}_{id}^T \boldsymbol{\beta}^{\sigma''})} \right)^{y_{id}^{\sigma'}} \\
& \times \prod_{j=1}^J \prod_{f=1}^F \mathcal{N}(L_{j,f}^{(D)} | \mu_{j,f}^{(D)}, \sigma_{j,f}^{(D)2}) \times \prod_{f=1}^F \prod_{o=1}^O \mathcal{N}(L_{f,o}^{(O)} | \mu_{f,o}^{(O)}, \sigma_{f,o}^{(O)2}) \\
& \times \prod_{f=1}^F \mathcal{N}(\mu_f^{(D)} | 0, \gamma^{(D)2}) \times \prod_{f=1}^F \mathcal{N}(\mu_f^{(O)} | 0, \gamma^{(O)2}) \\
& \times \Pr(\boldsymbol{\sigma}_f^{(D)} | b) \times \Pr(\boldsymbol{\sigma}_f^{(O)} | b) \times \Pr(\gamma^{(D)} | a) \times \Pr(\gamma^{(O)} | a).
\end{aligned} \tag{5}$$

The graphical representation of this hierarchical Bayesian model is given in Figure 2.

4.3 Model 2 - Two Levels of Latent Factors

Here we represent \mathbf{B} as

$$\mathbf{B} = \mathbf{L}^{(D)} \times \mathbf{L}^{(F)} \times \mathbf{L}^{(O)},$$

where

$$\mathbf{B} = \begin{pmatrix} L_{1,1}^{(D)} & \dots & L_{1,F_1}^{(D)} & \dots & L_{1,F_1}^{(D)} & \dots & L_{1,1}^{(F)} & \dots & L_{1,F_2}^{(F)} & \dots & L_{1,O}^{(O)} \\ \vdots & & \vdots \\ L_{F_1,1}^{(D)} & \dots & L_{F_1,F_1}^{(D)} & \dots & L_{F_1,F_1}^{(D)} & \dots & L_{F_1,1}^{(F)} & \dots & L_{F_1,F_2}^{(F)} & \dots & L_{F_2,O}^{(O)} \end{pmatrix}.$$

The number of latent factors is thus $J \times F_1 + F_1 \times F_2 + F_2 \times O$, which can be less than the number of variables of Model 1 in many cases. Its major benefit is interpretability, since now the number of latent drug factors and the number of latent outcome factors can be estimated differently. $\mathbf{L}^{(D)}$ represents the relationship between drugs and latent drug-related factors, $\mathbf{L}^{(F)}$ represents the relationship between latent drug-related factors and latent health-outcome-related factors, and $\mathbf{L}^{(O)}$ represents the relationship between latent health-outcome-related factors and health-outcome-related factors. $\mathbf{L}^{(F)}$ is really the core set of variables since they relate the latent treatments to the latent health outcomes.

The priors are $L_{j,f_1}^{(D)} \sim \mathcal{N}(\mu_{j,f_1}^{(D)}, \sigma_{f_1}^{(D)2})$, $L_{f_2,o}^{(O)} \sim \mathcal{N}(\mu_{f_2,o}^{(O)}, \sigma_{f_2,o}^{(O)2})$, $L_{f_1,f_2}^{(F)} \sim \mathcal{N}(\mu_{f_1,f_2}^{(F)}, \sigma_{f_1,f_2}^{(F)2})$, $\mu_{f_1}^{(D)} \sim \mathcal{N}(0, \gamma^{(D)2})$, $\mu_{f_2}^{(O)} \sim \mathcal{N}(0, \gamma^{(O)2})$, $\mu_{f_2}^{(F)} \sim \mathcal{N}(0, \gamma^{(F)2})$, $\mu_{f_1}^{(D)} \sim \mathcal{U}(0, a)$, $\sigma_{f_1}^{(D)} \sim \mathcal{U}(0, a)$, $\sigma_{f_2}^{(O)} \sim \mathcal{U}(0, a)$, $\gamma^{(D)} \sim \mathcal{U}(0, b)$, $\gamma^{(F)} \sim \mathcal{U}(0, b)$, and $\gamma^{(O)} \sim \mathcal{U}(0, b)$ for all (f_1, f_2, j, o) .

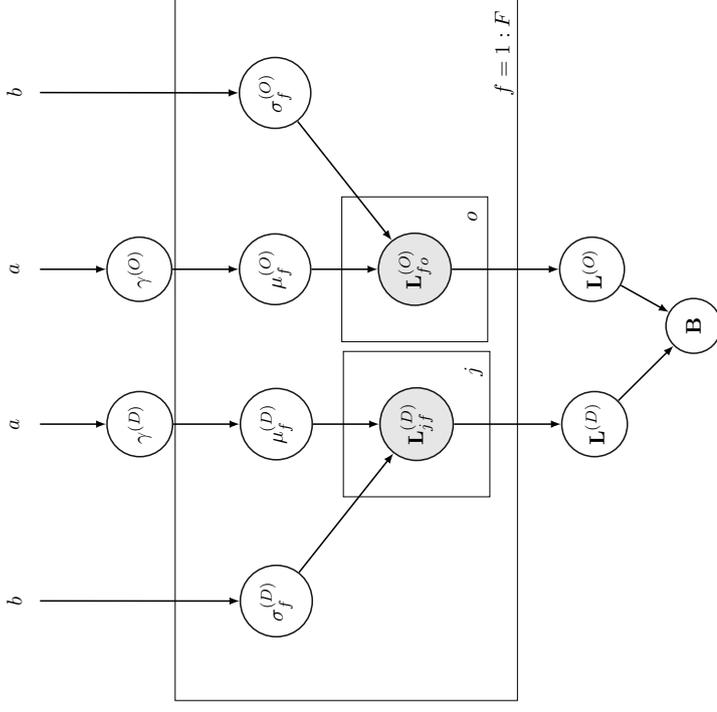

Figure 2: The Graphical Framework for Hierarchical Bayesian Model with one level of latent factors

The posterior density is

$$\begin{aligned}
& \Pr(\mathbf{L}^{(D)}, \mathbf{L}^{(F)}, \mathbf{L}^{(O)}, \boldsymbol{\mu}^{(D)}, \boldsymbol{\mu}^{(F)}, \boldsymbol{\mu}^{(O)}, \boldsymbol{\sigma}^{(D)}, \boldsymbol{\sigma}^{(F)}, \boldsymbol{\sigma}^{(O)}, \gamma^{(D)}, \gamma^{(F)}, \gamma^{(O)} | \mathbf{y}) \\
& \propto \Pr(\mathbf{y} | \mathbf{L}^{(D)}, \mathbf{L}^{(F)}, \mathbf{L}^{(O)}, \boldsymbol{\mu}^{(D)}, \boldsymbol{\mu}^{(F)}, \boldsymbol{\mu}^{(O)}, \boldsymbol{\sigma}^{(D)}, \boldsymbol{\sigma}^{(F)}, \boldsymbol{\sigma}^{(O)}) \times \Pr(\mathbf{L}^{(F)} | \boldsymbol{\mu}^{(F)}, \boldsymbol{\sigma}^{(F)}) \times \Pr(\mathbf{L}^{(O)} | \boldsymbol{\mu}^{(O)}, \boldsymbol{\sigma}^{(O)}) \\
& \times \Pr(\boldsymbol{\mu}^{(D)} | \gamma^{(D)}) \times \Pr(\boldsymbol{\mu}^{(F)} | \gamma^{(F)}) \times \Pr(\boldsymbol{\mu}^{(O)} | \gamma^{(O)}) \\
& \times \Pr(\boldsymbol{\sigma}^{(D)} | a) \times \Pr(\boldsymbol{\sigma}^{(F)} | a) \times \Pr(\boldsymbol{\sigma}^{(O)} | a) \times \Pr(\gamma^{(D)} | b) \times \Pr(\gamma^{(F)} | b) \times \Pr(\gamma^{(O)} | b).
\end{aligned} \tag{6}$$

Table 1 compares the number of parameters in each of the three models. Models 1 and 2 have much fewer parameters when F , F_1 , and F_2 are lower than J and O . We use Markov Chain Monte Carlo (MCMC) to approximate the entries of \mathbf{B} , specifically random walk Metropolis (RWM) Hasting. The algorithm employs a Gaussian proposal distribution

Model Name	# of Parameters	# of Hyperparameters	Total
Model 0	$J * O$	$2 * J + 1$	$J * O + 2 * J + 1$
Model 1	$J * F + F * O$	$4 * F + 2$	$J * F + F * O + 4 * F + 2$
Model 2	$J * F_1 + F_1 * F_2 + F_2 * O$	$2 * F_1 + 2 * F_2 + 5$	$J * F_1 + F_1 * F_2 + F_2 * O + 2 * F_1 + 2 * F_2 + 5$

Table 1: The number of parameters and hyperparameters in each model.

$J_i(x, x')$ which proposes a new parameter set x' given the current parameter set x . We denote Θ as the set of all parameters in the model excluding \mathbf{B} .

Step 1. Generate an initial state $\{\mathbf{B}^0, \Theta^0\}$ with positive probability $\Pr(\mathbf{B}^0, \Theta^0 | \mathbf{y})$ and set $t = 1$.

Repeat the following until stationary distribution and the desired number of samples are reached considering optional burn-in and/or thinning.

Step 2. Sample $\{\mathbf{B}^*, \Theta^*\}$ from the symmetric proposal distribution $J_i(\{\mathbf{B}^{t-1}, \Theta^{t-1}\}, \{\mathbf{B}^*, \Theta^*\})$.

Step 3. Calculate the acceptance probability

$$\alpha = \min \left(1, \frac{\Pr(\mathbf{B}^*, \Theta^* | \mathbf{y})}{\Pr(\mathbf{B}^{t-1}, \Theta^{t-1} | \mathbf{y})} \right).$$

Step 4. Draw a random number u from $\text{Unif}(0, 1)$. If $u \leq \alpha$, accept the proposal state $\{\mathbf{B}^*, \Theta^*\}$ and set $\mathbf{B}^t = \mathbf{B}^*$, $\Theta^t = \Theta^*$, else set $\mathbf{B}^t = \mathbf{B}^{t-1}$, $\Theta^t = \Theta^{t-1}$. Set $t: t + 1$.

Our implementation uses a component-wise sampling approach. For truly large-scale applications, blocked sampling approaches may be necessary.

5. Simulation Study

As a sanity check, we will show that for data generated from our model, the true data-generating parameters \mathbf{B} can be recovered. We simulated sample trajectories of drug exposure and health outcomes for 600 patients over 60 days. We set the number of drugs to $J = 4$, and the number of health conditions to $O = 4$. Each patient randomly took between 1 and J drugs over the past 60 days. The average exposure period was assumed to be 20% of the study interval for each patient (that is, on average, each patient was exposed to one or more drugs for at least 12 days). The exposure intervals are randomly selected, so these intervals could be multiple non-consecutive days, multiple consecutive days, or a combination of both. Drugs can have positive or negative contributions to the likelihood and intensity rate of each outcome. For each model (Model 0, Model 1, Model 2), we generated the elements of \mathbf{B} according to the model's hierarchy. Figure 3 and Figures 12-13 (which are given in the Appendix) show the posterior density for each parameter of \mathbf{B} , for Models 0, 1 and 2, as estimated by MCMC sampling. These figures show that the posterior samples were concentrated around the true values and the posterior mean of each variable was generally close to its true value. We summarize Figures 3, 12, and 13 in Figure 4, which provides a scatter plot of the posterior means and true values for each of the three models. It can be observed that each of the posterior means are very close to their true values.

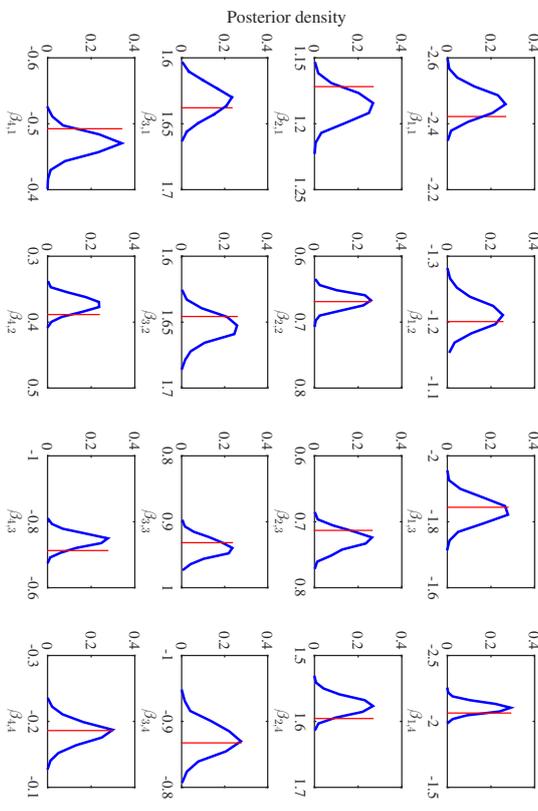

Figure 3: Normalized histograms of posterior samples for each element of \mathbf{B} in Model 0. The vertical line indicates the true value.

6. Application to Blood Glucose Analysis for Diabetes

We consider an application to Insulin-Dependent Diabetes Mellitus, where our goal is to predict blood glucose level outcomes under different circumstances of a patient's daily life, including their recent eating history, exercise, and insulin injections. Our data are longitudinal measurements taken multiple times per day from 70 patients (this is the AIM-94 data set provided by Michael Kahn, MD, PhD, Washington University, St. Louis, MO, Bache and Lichman, 2013). We aim mainly to illustrate (i) how the models we introduce can be used with complex longitudinal data to predict outcomes, (ii) the prediction power, and (iii) interpretability of the proposed models. It is well known that current therapies for regulating glucose level in diabetics are challenging and often frustrating, as they require patients to continuously regulate diet, exercise, and various medications – any deviations can be dangerous (Banchinnol et al., 2013). Blood glucose measurements, symptoms and insulin treatments were recorded with timestamps for each patient, over the course of several weeks to months. The two main classes of health outcomes considered here are hyperglycemia (high blood glucose) and hypoglycemia (low blood glucose). All other health outcomes we define later are related to these two classes. Figure 5 provides a schematic of the type of data we are considering for one patient over a course of day.

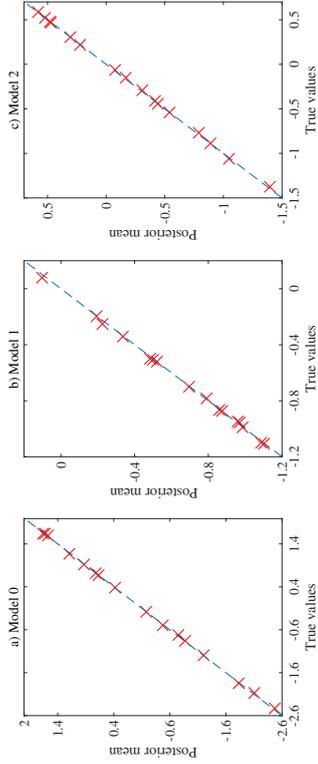

Figure 4: Scatter plot of posterior means vs. true parameter values of elements of **B** for Models 0, 1 and 2.

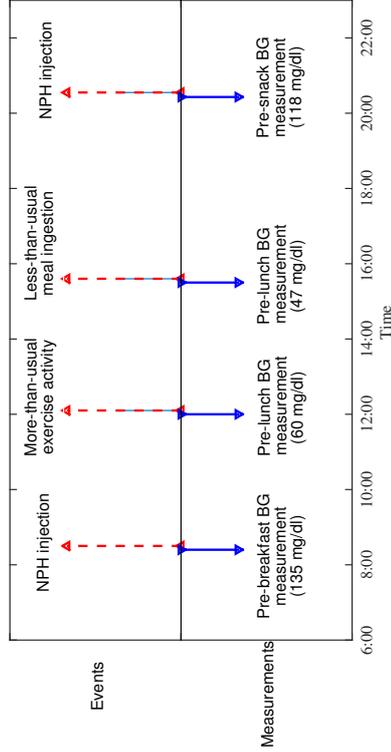

Figure 5: Sample longitudinal traces for a patient with multiple drug/treatments exposures and blood glucose measurements over a day. Downwards arrows indicate glucose measurements. Upwards arrows indicate treatments.

We will describe the setup in more detail:
Drugs/Treatments: Diet, exercise, and injected insulin were treated as three different classes of treatments. It is obvious that interactions among these treatments are important. Insulin doses are given one or more times a day, typically before meals and sometimes also at bedtime. Three types of insulin were considered: (1) regular, (2) Neutral Protamine Hagedorn (NPH), and (3) Ultralente. Each insulin type has its own characteristic time of

onset (O), time of peak action (P), and effective duration (D). The exposure time intervals for peak, and duration used in this paper, which were provided with the data set, are shown in Table 2 in the “Exposure Time” column in the bottom several rows of the table labeled “Insulin.”

	Treatment	Exposure Time	Health Outcome						
			Low Glucose Level			High Glucose Level			
			1. Too low	2. Low	3. D1	4. Hypo-Symptom	5. Too High	6. High	7. D10
Exercise	1. Normal	0-4 h	-	P	-	-	-	-	-
	2. Too High	0-4 h	-	P	-	-	-	-	-
	3. Low	0-4 h	-	P	-	-	-	-	-
Diet	4. Normal	0-4 h	-	-	-	-	-	-	-
	5. Too High	0-4 h	N	N	N	N	N	N	N
	6. Low	0-4 h	-	-	-	-	-	-	-
	7. After Meal	0-4 h	N	N	N	N	N	N	N
Insulin	8. Before Meal	0-4 h	P	P	P	P	P	P	P
	9. Peak	1-3 h	P	P	P	P	P	P	P
	10. Duration	0-6 h	P	P	P	P	P	P	P
	11. Peak	4-6 h	P	P	P	P	P	P	P
Ultralente	12. Duration	0-12 h	P	P	P	P	P	P	P
	13. Peak	14-24 h	P	P	P	P	P	P	P
	14. Duration	0-27 h	P	P	P	P	P	P	P

Table 2: The list of drugs/treatments and health outcomes and their known correlations. P means strong positive correlation, and N means strong negative correlation, D1 is lower decile and D10 means highest decile.

Based on the actual time of injection, we determined the intervals at which the patient is at peak and/or within the duration of an insulin injection. Based on this, six types of treatments were considered, (1) regular insulin on peak, (2) regular insulin on duration, (3) NPH insulin on peak, (4) NPH insulin on duration, (5) Ultralente insulin on peak, and (6) Ultralente insulin on duration. At each interval of time, the patient can be either insulin free or subject to one of the above six exposures.

The second class of treatment is exercise, which may have complex effects on the glucose level. For example, glucose levels can fall during exercise but also quite a few hours afterwards. Three types of exercise are reported, (1) normal exercise, (2) lower than normal exercise, and (3) higher than normal exercise. Each type of exercise was considered separately as a single treatment.

The third class of treatment is for diet, which also can have complex effects on the glucose level. For example, a larger meal may lead to a longer and possibly higher elevation of blood glucose. Missing a meal may put the patient at risk for low glucose levels in the hours that follow. Three types of diet are reported: (1) normal diet, (2) higher than normal diet, and (3) lower than normal diet. Each of these types of diet were taken as a single treatment. Since measurements were collected before a meal, after a meal, and at other times, we considered two other features in the model, (1) before meal measurement of blood glucose and (2) after meal measurement, and we treated them as binary features. These extra features allow us to distinguish whether the measurement was made before or after the meal (there is a big difference between glucose measurements taken before a meal and after a meal).

Based on all of the treatments described, the total number of variables associated with treatments in the model is 14 ($J = 14$). The variables are all listed on Table 2 in the “Treatment” column on the left.

Health Outcomes. The outcomes are divided into categories, based on glucose level. Given that normal pre-meal blood glucose ranges from approximately 80-120 mg, and post-meal blood glucose ranges from 80-140 mg/dl (Bache and Lichman, 2013), we considered seven health outcomes for glucose level: extremely low (below 40 mg/dl), low (between 40-80 mg/dl), high (over 140 mg/dl), extremely high (over 180 mg/dl), lower decile (lower 10% of glucose level for each patient), upper decile (upper 10% of glucose level for each patient), and hypoglycemic (low glucose) symptoms. Thus, the total number of outcomes considered for our analysis is $O = 7$. We can perform an evaluation only on intervals where we have glucose measurements, thus we only use those intervals. Note that more than one outcome can occur in each interval.

True Relationships Between Drugs and Outcomes. We wanted to determine whether our model reproduces known relationships between treatments and glucose levels from the data alone. The information about true relationships within Table 2 mainly come from material accompanying the data set and *www.diabetes.org*. We denoted known positive effects in Table 2 by \mathcal{P} , strong negative effects by \mathcal{N} , and relationships that were unknown were denoted by dashes “-”. For example, we expect NPH injection on peak to decrease the likelihood of having “Too High” glucose level, so the correlation between NPH on peak and “Too High” glucose level is known to be negative (\mathcal{N}).

Mixing. We performed cross-validation, dividing our data into five folds, training our models on four folds and testing on the fifth. We removed the first 5000 iterations (as burn-in) of Metropolis-Hastings sampling, and obtained 6000 additional samples to estimate the posterior. Figure 6 shows samples from the posterior of one of the variables, $\beta_{\text{NPH on peak}}^{\text{Too high GL}}$, for five separate model instantiations (Model 0, Model 1 with $F=2$, Model 1 with $F=3$, Model 2 with $F_1=2, F_2=2$, and Model 2 with $F_1=3, F_2=3$). Recall that in Models 1 and 2, we sample elements of the matrices of latent factors and then calculate \mathbf{B} . From this figure, we observe reasonable mixing for all models, and we observe that models with latent factors (Models 1 and 2) have better mixing and convergence, possibly due to the smaller number of variables.

Computation. The number of parameters differs substantially between models, which affects CPU time of the MCMC sampler. In Figure 7, the number of parameters for each model and the associated CPU time for running MCMC are shown. This figure shows a clear correlation between the number of variables and CPU time, that is CPU time increases with the number of parameters. In particular, Model 0 takes a long time to run, because it has substantially more variables than the other models. Interestingly, using latent factors has a purpose beyond interpretability and regularization, in that it helps with tractability.

Interpretation of coefficients in B and comparison with ground truth. We compare the estimated coefficients in \mathbf{B} to the ground truth signs of coefficients given in Table 2. It is not necessarily the case that the signs of the estimated coefficients need to agree with the ground truth signs in order for the model to perform well, but it is a reasonable aspect of the model to consider. To perform this comparison, we ranked the estimated coefficients in \mathbf{B} and used these rankings and the true signs of coefficients to generate an ROC curve. That is, the ROC curve was generated by placing thresholds at each point in

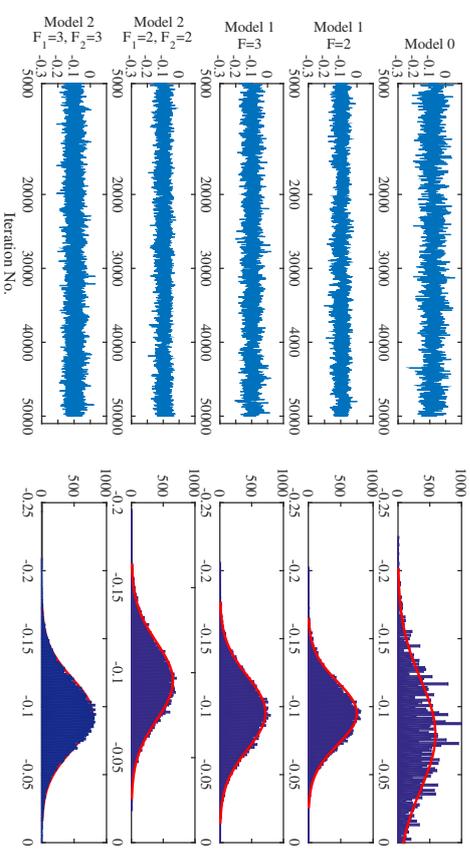

Figure 6: Samples from the posterior of $\beta_{\text{NPH on peak}}^{\text{Too high GL}}$ for five model instantiations (left), and their histograms (right). The first 5000 samples were discarded as burn-in. We observe better mixing and convergence in the models with latent factors (Model 1 and Model 2).

the ranking, and calculating the true positive rate and false positive rate with respect to the true coefficients. We computed these ROC curves for all five model instantiations to obtain Figure 8. These ROC curves indicate that all models performed well, in the sense of estimating reasonable signs for the coefficients. The curves also indicate that models with more latent factors performed slightly better than Model 0. The models with two latent treatment and outcome factors performed slightly better than the models with three latent treatment and outcome factors, though there was no significant difference in performance between Model 1 and Model 2 for the same number of latent treatment and outcome factors.

Drug Surveillance. We evaluated prediction performance of our model as follows: for each patient we calculated the Poisson rate of each condition at each hour considering all drug exposures. For each condition, we then checked whether or not the patient had the condition at that time. The Poisson rate acts as the score of each patient with regards to each condition. In Figure 9, we present the actual glucose level for a patient at 20 measurement points (upper figure) as well as the estimated intensity rate of the “Too-High glucose level for the same patient (lower figure). Each point in this figure represents the estimated $\mathbf{x}_{\text{int}}^T \hat{\beta}^e$, where $\hat{\beta}^e$ are the estimated regression coefficients associated with too-high glucose level and $\mathbf{x}_{\text{int}}^T$ is the known vector of drug exposures at interval d . The figure shows that the estimated intensity rate is reasonably close to the actual level of glucose, particularly when the glucose level is actually too high. In Figure 10, we repeated the

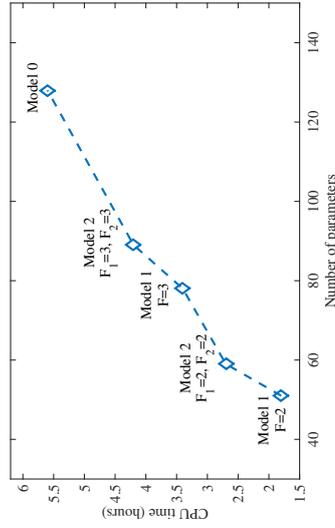

Figure 7: Comparison between the CPU time and number of variables in the five model instantiations. Model 0 has larger number of variables and significantly higher CPU time.

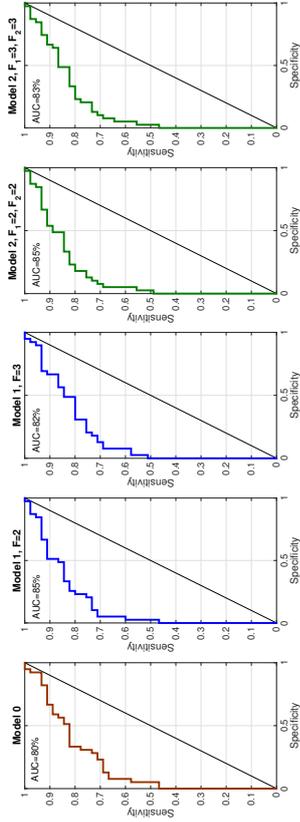

Figure 8: Receiver Operating Characteristic (curve) for evaluating the signs of coefficients against true signs for five model instantiations. See the text for details of how these curves were generated.

analysis for Too-Low glucose level. It can be observed from this figure that the times where this coefficient is particularly large are the same times where the glucose level drops substantially. This kind of dramatic agreement was not observed for all patients nor all conditions, so below we describe a more general evaluation procedure.

In Figure 11, we show the box plots for the estimated Poisson rates of the two conditions of “Too Low” glucose level and “Too High” glucose level on all seventy patients in the test sets. For comparison, we also plotted the box plots of the estimated Poisson rates for normal conditions, where patients did not have too-high or too-low glucose levels. For

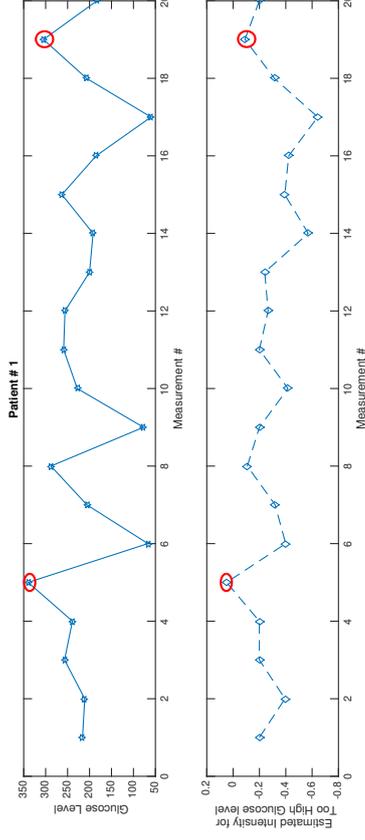

Figure 9: Monitoring Too-High glucose levels over 20 hours. The upper figure shows the true glucose levels obtained by measurement, and the lower figure shows the estimated $\alpha_{i,d}^T \beta^o$ for the Too-High glucose outcome over 20 consecutive measurements.

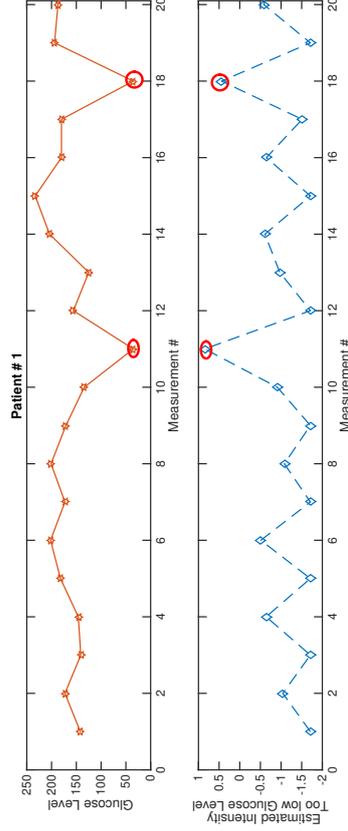

Figure 10: Monitoring too-low glucose levels over 20 hours. The upper figure shows the true glucose levels obtained by measurement, and the lower figure shows the estimated $\alpha_{i,d}^T \beta^o$ for the too-low glucose outcome over 20 hours.

clarity and fairness, we normalized the estimated Poisson rates for each patient. It can be observed from this figure that the estimated Poisson rate of these conditions are elevated when patients actually suffer from Too-Low (or Too-High, respectively) glucose. Thus, our model could be a useful approach for monitoring the likelihood of a condition, given the

timing of the drugs recently taken by the patient. The results were consistent across all five model instantiations.

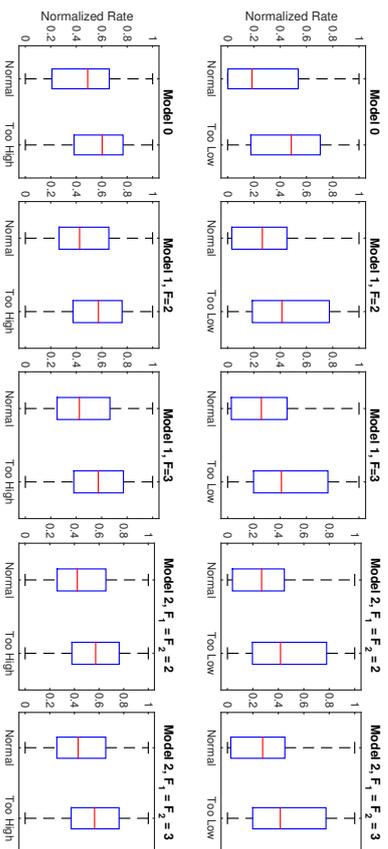

Figure 11: Comparison between the box-plots for Too-High and Too-Low glucose levels and the normal condition for all five model instantiations, where the Poisson rates were normalized for each person.

In Table 3, we report an AUC (area under the ROC curve) value that measures the probability that a method ranks a positive condition timepoint higher than a timepoint with no condition, for the same patient. In particular, we are testing whether the Poisson rate of a patient with a health condition is higher than the estimated rate of the same patient when no condition is present. For each model instantiation, we trained the model on four training folds and then calculated the AUC on the fifth fold, and we repeated this for each condition. We reported the average and standard deviation of AUC over all patients in the test sets. Again DI is the lower decile (lower 10% of glucose level for each patient), and D10 is the upper decile (upper 10% of glucose level for each patient).

Intuition of \mathbf{B} as compared with other methods. We compared the performance of the proposed models with that of the univariate self-controlled case series (SCCS), and multi-variate self-controlled case series (MSCCS) (Simpson et al., 2013) with and without an ℓ_2 regularization term on the coefficients. For each model instantiation and each method, the estimated entries of \mathbf{B} were compared to their known effects (positive or negative) from Table 2. For each method, we provide the area under the curve (AUC) for this comparison in Table 4. We also reported the mean, median, and standard deviation of all estimated coefficients in the group of Table 2’s positive group and Table 2’s negative group. Better models should have higher AUC, and the estimated coefficients of \mathbf{B} should agree in sign with those in Table 2. From Table 4, we observe that as expected, the MSCCS performed better than the SCCS, the regularized MSCCS worked slightly better than the normal

	Too low	Low	Too high	High	DI	D10	Hypo Symptom

	sd	9.52%	2.44%	3.16%	2.07%	3.31%	3.05%

Table 3: Average and standard deviation (sd) of AUC over 5 folds. The entries that were ranked for each AUC calculation are measurements for a patient including time points when the patient had a condition and time points when the patient did not have a condition. The AUC indicates whether our method ranks a randomly chosen time point where a patient had a condition higher than a randomly chosen time point where a patient did not have a condition.

MSCCS, and all FSCCS Bayesian model instantiations (Model 0-2) performed better than all of the traditional models, yielding higher AUC’s and better agreement in the mean signs of coefficients; further the standard deviations for the coefficient values were substantially lower. These performance benefits come in addition to the other benefits discussed earlier, including computational tractability and interpretability of the latent factors.

Measure	Method						
	Model 0	Model 1	Model 2	Model 2	SCCS	MSCCS	Regularized MSCCS
AUC	0.813	0.852	0.824	0.856	0.836	0.693	0.773
Mean	-0.190	-0.281	-0.276	-0.278	-0.282	-0.492	-0.663

	0.071	0.099	0.096	0.105	0.096	-0.552	-0.561
Median	0.030	0.103	0.111	0.106	0.106	0.065	0.126
	0.368	0.369	0.385	0.368	0.378	3.158	3.149

Table 4: Comparison with existing models.

7. Concluding Remarks

The novel elements of this work are as follows. (1) We estimate the effects of many drugs on many health outcomes simultaneously. Borrowing strength across similar drugs and outcomes allows us to create better estimates across both drugs and outcomes. (2) We use latent factors to encode latent classes of drugs and outcomes, to help with interpretability, and to provide a computational benefit. Another type of computational benefit is provided naturally by using the SCCS's framework, since we do not need to estimate the baseline rates of outcomes for each patient. This approach is scalable to large longitudinal observational databases, is applicable to problems beyond healthcare, and provides a level of interpretability to physicians and patients that was not previously possible. Fully Bayesian inference via MCMC may not be feasible for truly large-scale problems. Recent developments in cyclic coordinate descent algorithms (see, for example, in Suchard et al., 2013b) would apply in our context and represent one possible approach for very scale MAP estimation.

Abstract

Electronic Health Record (EHR) phenotyping utilizes patient data captured through normal medical practice, to identify features that may represent computational medical phenotypes. These features may be used to identify at-risk patients and improve prediction of patient morbidity and mortality. We present a novel deep multi-modality architecture for EHR analysis (applicable to joint analysis of *multiple* forms of EHR data), based on Poisson Factor Analysis (PFA) modules. Each modality, composed of observed counts, is represented as a Poisson distribution, parameterized in terms of hidden binary units. Information from different modalities is shared via a deep hierarchy of common hidden units. Activation of these binary units occurs with probability characterized as Bernoulli-Poisson link functions, instead of more traditional logistic link functions. In addition, we demonstrate that PFA modules can be adapted to discriminative modalities. To compute model parameters, we derive efficient Markov Chain Monte Carlo (MCMC) inference that scales efficiently, with significant computational gains when compared to related models based on logistic link functions. To explore the utility of these models, we apply them to a subset of patients from the Duke-Durham patient cohort. We identified a cohort of over 16,000 patients with Type 2 Diabetes Mellitus (T2DM) based on diagnosis codes and laboratory tests out of our patient population of over 240,000. Examining the common hidden units uniting the PFA modules, we identify patient features that represent medical concepts. Experiments indicate that our learned features are better able to predict mortality and morbidity than clinical features identified previously in a large-scale clinical trial.

Keywords: Deep learning, multi-modality learning, Poisson factor model, electronic health records, phenotyping.

1. Introduction

Electronic health records (EHR) are quickly becoming a primary depository of detailed patient health information. These data, if properly analyzed, have the potential to be a nidus for novel insights that may improve patient diagnosis, treatment and safety. In particular, there has been increasing focus on utilizing such data to rapidly identify disease cohorts or “phenotypes” that can be leveraged in clinical and epidemiological studies. However, EHR data, a by-product of the often messy day-to-day interactions of physicians and patients in primary care hospital and emergency room settings, are often challenging to manipulate and interpret without expert input.

Many of the initial EHR phenotyping methods in the literature (Hripsak and Alberts, 2013; Mareedu et al., 2009) relied and continue to rely explicitly on heuristics generated through the collaboration of physicians and informatics. These “computable” phenotypes identified clusters of patients that, for example, suffer from a particular ailment (Newton et al., 2013). Computable phenotypes are often structured similar to decision trees that utilize multiple modes of patients data captured by the EHR¹ to filter patient groups. These modes may include physician and nursing notes from prior encounters, procedure and diagnosis codes, laboratory results, medications, radiology and pathology. Alternatively, other methods have relied on physician-labeled case and control samples (Chen et al., 2013), to identify patient features that may represent a patient phenotype.

Computable phenotypes resemble an analysis that physicians intuitively perform while diagnosing patients. At a high level, physicians assign patients to a latent space of plausible disease phenotypes that inform diagnosis and treatment. This assignment is based on heterogeneous data from the patient interview and physical exam, in combination with other data such as radiology reports, laboratory results and prior medication and medical history. For example, a young child who presents with multiple respiratory infections at an early age increases the probability of a cystic fibrosis phenotype, and thus may be a candidate for associated genetic testing.

Despite their success in *(i)* advancing medical record data mining across large medical institutions and *(ii)* genotype/phenotypes studies, efforts to develop computable phenotypes are nonetheless iterative, manual and difficult to scale. Further, there appears to be widespread variability in disease definitions for even putatively “well-defined” diseases. In Richesson et al. (2013) it was shown that even for phenotypes where there is widespread agreement on the disease definition, such as Type 2 Diabetes Mellitus, definitions by different clinical groups captured different patient populations.

A complementary approach to modeling patient phenotypes from EHR data relies on utilizing unsupervised models. These computational phenotypes have the ability to identify not only feature sets that represent known medical concepts, but they may also discover feature sets that may represent novel phenotypes that are: *(i)* subtypes of and/or *(ii)* run counter to clinically intuited groups. Applied to health-system data and CMS (Centers for Medicare & Medicaid Services) claims data, it has been demonstrated that sparse tensor

1. See <https://phekb.org/>.

factorization of multimodal patient data, transformed into count data, generates concise sets of sparse factors that are recognizable by medical professionals (Ho et al., 2014a,b). Patients can then be treated as a weighted composites of such factors.

While these automated models are efficient at extracting phenotype data and reducing manual input, they have several limitations (Chen et al., 2013; Ho et al., 2014a). Current models are unable to capture correlation both between and within data modes. For example, tensor factorization requires the presence of all modes of patient data within a limited time window to capture the patient-physician interaction. As the number of modes increase, the probability of all modes of data being captured within a limited time window decreases. This prevents leveraging subsets of data modes from (often) limited patient interactions with care givers. Meanwhile, models that concatenate multiple data modes, or evaluate each mode separately, lose correlation between data types. Additionally, current models do not allow one to integrate classification in a straightforward manner. Rather, prediction is conducted in a step-wise manner relying on defining factors first and then entering them into a classification procedure. Current models also often only incorporate a single layer of information, depriving the model of potentially rich higher-level correlation structure within and between modes.

Deep models, understood as multilayer modular networks, have recently generated significant interest from the machine learning community, in part because of their ability to obtain state-of-the-art performance in a wide variety of modalities. Commonly used modules include, but are not limited to, Restricted Boltzmann Machines (RBMs) (Hinton, 2002), Sigmoid Belief Networks (SBNs) (Neal, 1992), convolutional networks (LeCun et al., 1998), feedforward neural networks, and Dirichlet Processes (DPs) (Blei et al., 2004). Deep models are often employed in topic modeling, modeling data characterized by vectors of word counts. As discussed below, EHR data may often be expressed in terms of counts of entities (*e.g.*, counts of types of medications, tests or procedure codes, generalizing the concept of words). Topic models are therefore of interest for EHR data. Examples of deep topic models, composed of DP modules, include the nested Chinese Restaurant Process (nCRP) (Blei et al., 2004), the hierarchical DP (HDP) (Teh et al., 2006), and the nested HDP (nHDP) (Paisley et al., 2015). Alternatively, topic models built using modules other than DPs have been proposed recently, for instance the Replicated Softmax Model (RSM) (Hinton and Salakhutdinov, 2009) based on RBMs, the Neural Autoregressive Density Estimator (NADE) (Larochelle and Laitly, 2012) based on neural networks, the Over-replicated Softmax Model (OSM) (Srivastava et al., 2013) based on DBMs, and Deep Poisson Factor Analysis (DPFA) (Gan et al., 2015a) based on SBNs.

DP-based models have attractive characteristics from the standpoint of interpretability, in the sense that their generative mechanism is parameterized in terms of *distributions over topics*, with each topic characterized by a *distribution over words*. Alternatively, non-DP-based models, in which modules are parameterized by a deep hierarchy of *binary units* (Hinton and Salakhutdinov, 2009; Larochelle and Laitly, 2012; Srivastava et al., 2013), do not have parameters that are as readily interpretable in terms of topics of this type, although model performance is often excellent. The DPFA model in Gan et al. (2015a) is one of the first representations that characterizes documents based on distributions over topics and words, while simultaneously employing a deep architecture based on binary units. Specifically, Gan et al. (2015a) integrates the capabilities of Poisson Factor Analysis (PFA)

(Zhou et al., 2012) with a deep architecture composed of SBNs (Gan et al., 2015b). PFA is a nonnegative matrix factorization framework closely related to DP-based models. Results in Gan et al. (2015a) show that DPFA outperforms other well-known deep topic models.

Building on the success of DPFA, this paper proposes a new deep multi-modality architecture for topic modeling, based entirely on PFA modules. Our model merges two key aspects of DP and non-DP-based architectures, namely: (i) its nonnegative formulation relies on Dirichlet distributions, and is thus readily interpretable throughout all its layers, not just at the base layer as in DPFA (Gan et al., 2015a); (ii) it adopts the rationale of traditional non-DP-based models such as DBNs and DBMs, by connecting different modalities and layers via binary units, to enable learning of high-order statistics and structured correlations within and across modalities. The probability of a binary unit being on is controlled by a Bernoulli-Poisson link (Zhou, 2015) (rather than a logistic link, as in the SBN), allowing repeated application of PFA modules at all layers of the deep architecture. An early version of our approach, for the special case of single-modality data, but mainly focused on topic models was previously described in Henao et al. (2015).

The main contributions of this paper are as follows. (i) We develop a novel deep architecture for topic models based entirely on PFA modules. (ii) The model has inherent shrinkage in all its layers, thanks to the DP-like formulation of PFA. This is unlike DPFA, which is based on SBNs. (iii) The proposed model yields greatly improved mixing, compared to DPFA which requires sequential updates for its binary units; in our formulation these are updated in block. (iv) The proposed approach provides the ability to build deep multi-modality architectures and discriminative topic models with PFA modules. (v) We develop an efficient MCMC inference procedure that scales as a function of the number of *non-zeros* in the data and binary units. In contrast, models based on RBMs and SBNs scale with the size of the data and binary units. Finally, (vi) we demonstrate the applicability of this framework to the analysis of EHR data, with an associated interpretation of the inferred data features (topics and meta-topics, as detailed below).

2. Model

2.1 Poisson factor analysis as a module

Assume \mathbf{x}_n is an M -dimensional vector containing counts of M different entities (*e.g.*, words in documents), for the n -th of N data vectors. We impose the model

$$\mathbf{x}_n \sim \text{Poisson}(\Psi(\theta_n \circ \mathbf{h}_n)), \quad (1)$$

where $\Psi \in \mathbb{R}_+^{M \times K}$ is the factor loadings matrix with K factors, $\theta_n \in \mathbb{R}_+^K$ are factor intensities, $\mathbf{h}_n \in \{0, 1\}^K$ is a vector of binary units indicating which factors are active for observation n , and \circ represents the element-wise (Hadamard) product. The representation in (1) may be expressed as

$$x_{mn} = \sum_{k=1}^K x_{mkn}, \quad x_{mkn} \sim \text{Poisson}(\lambda_{mkn}), \quad \lambda_{mkn} = \psi_{mk} \theta_{kn} h_{kn} \quad (2)$$

where ψ_k is column k of Ψ , ψ_{mk} is component m of ψ_k , x_{mn} is component m of \mathbf{x}_n , θ_{kn} is component k of θ_n , and h_{kn} is component k of \mathbf{h}_n . In (2) we have used the additive property

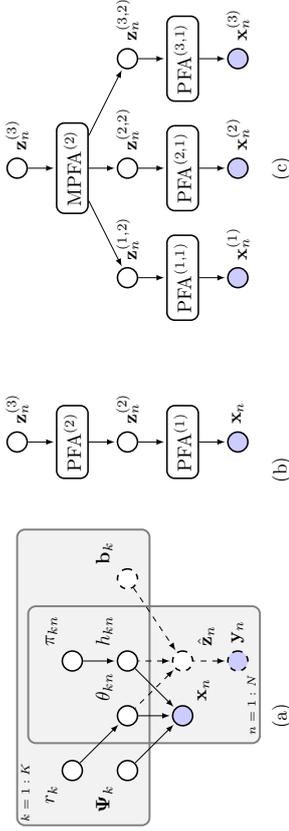

Figure 1: Graphical models. (a) Poisson Factor analysis module in (1)-(3). Nodes $(\mathbf{b}_k, \mathbf{z}_n)$ and \mathbf{y}_n and edges drawn with dashed lines correspond to the discriminative PFA described in Section 2.5. (b) Deep Poisson factor model in (5). (c) Deep Multi-task Poisson factor model in (6). Filled and empty nodes represent observed and latent variables, respectively.

of the Poisson distribution to decompose the m -th observed count of \mathbf{x}_n as K latent counts, $\{z_{mkn}\}_{k=1}^K$.

One possible prior specification for the model in (1), recently introduced by Zhou et al. (2012), is

$$\psi_k \sim \text{Dirichlet}(\eta \mathbf{1}_M), \quad \theta_{kn} \sim \text{Gamma}(r_k, (1-b)b^{-1}), \quad h_{kn} \sim \text{Bernoulli}(\pi_{kn}) \quad (3)$$

where $\mathbf{1}_M$ is an M -dimensional vector of all-ones. Furthermore, for simplicity we let $\eta = 1/K$, $b = 0.5$ and $r_k \sim \text{Gamma}(1, 1)$. Prior distributions for η and b that result in closed form conditionals exist, and can be used if desired; see for instance Escobar and West (1995) for η , and Zhou and Carin (2015) for b .

There is one parameter in (3) for which we have not specified a prior distribution, specifically $\mathbb{E}[\rho(h_{kn} = 1)] = \pi_{kn}$. In Zhou et al. (2012), h_{kn} is provided with a beta-Bernoulli process prior by letting $\pi_{kn} = \pi_k \sim \text{Beta}(c\epsilon, c(1-\epsilon))$, where usually $c = 1$ and $\epsilon = 1/K$, meaning that each of the N data vectors has on average the same probability of seeing a particular topic as active. It further assumes topics are independent of each other. These two assumptions are restrictive because: (i) in practice, the N data vectors often belong to a heterogeneous population (*e.g.*, patients); letting the data vectors have individual topic activation probabilities allows the model to better accommodate heterogeneity in the data. (ii) Some topics are likely to co-occur systematically, so being able to harness such correlation structures can improve the ability of the model for fitting the data.

The hierarchical model in (1)-(3) is denoted $\mathbf{x}_n \sim \text{PFA}(\Psi, \theta, \mathbf{h}_n; \eta, r_k, b)$, short for Poisson Factor Analysis (PFA), with graphical model representation shown in Figure 1(a). The model in (1)-(3) is closely related to other widely known topic model approaches, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), HDP (Teh et al., 2006) and Focused Topic Modeling (FTM) (Williamson et al., 2010). Connections between these models are discussed in Section 2.7.

2.2 Deep representations with PFA modules

Several models have been proposed recently to address the limitations described in the previous section (Blei et al., 2004; Blei and Lafferty, 2007; Gan et al., 2015a; Teh et al., 2006). In particular, Gan et al. (2015a) proposed using multilayer SBNs (Neal, 1992) to impose correlation structure across topics, while providing each data vector with the ability to control its topic activation probabilities, without the need of a beta-Bernoulli process (Zhou et al., 2012). Here we follow the same rationale as Gan et al. (2015a), but without SBNs. We start by noting that for a binary vector \mathbf{h}_n with elements h_{kn} , we can write

$$h_{kn} = \mathbf{1}(z_{kn} \geq 1), \quad z_{kn} \sim \text{Poisson}(\tilde{\lambda}_{kn}), \quad (4)$$

where z_{kn} is a latent count for variable h_{kn} , parameterized by a Poisson distribution with rate $\tilde{\lambda}_{kn}$. The function $\mathbf{1}(\cdot)$ is defined as $\mathbf{1}(\cdot) = 1$ if the argument is true, and $\mathbf{1}(\cdot) = 0$ otherwise. The model in (4), recently proposed in Zhou (2015), is known as the Bernoulli-Poisson Link (BPL) and is denoted $\mathbf{h}_n \sim \text{BPL}(\tilde{\lambda}_n)$, for $\tilde{\lambda}_n \in \mathbb{R}_+^K$. After marginalizing out the latent count z_{kn} (Zhou, 2015), the model in (4) has the interesting property that $p(h_{kn} = 1) = \text{Bernoulli}(\pi_{kn})$, where $\pi_{kn} = 1 - \exp(-\tilde{\lambda}_{kn})$. In order to sample h_{kn} we do not need to instantiate latent count z_{kn} but the rate of its underlying distribution $\tilde{\lambda}_{kn}$. Hence, rather than using the logistic function to represent binary unit probabilities as in SBNs, we employ $\pi_{kn} = 1 - \exp(-\tilde{\lambda}_{kn})$.

The binary distribution based on $p(h = 1) = \text{Bernoulli}(1 - \exp(-\tilde{\lambda}))$ is reminiscent of the complementary log-log link function (Piegorisch, 1992; Collett, 2002), where $\tilde{\lambda} = \exp(-u)$ and $u \in \mathbb{R}$. Unlike the logistic function, that is symmetric around the origin, $u = 0$ for $p(h = 1) = \text{Bernoulli}(1/(1 + \exp(-u)))$, the complementary log-log link is asymmetric, making it appropriate for imbalanced modalities, where the proportion of zeros is large. In our setting, this behavior is ideal because it encourages sparsity, in that it supports the assumption that a given data vector (patient) is explained by a small subset of topics selected via binary units, \mathbf{h}_n .

In (2) and (4) we have represented the Poisson rates as λ_{mkn} and $\tilde{\lambda}_{kn}$, respectively, to distinguish between the two. However, the fact that the count vector in (3) and the binary variable in (4) are both represented in terms of Poisson distributions suggests the following deep model, based on PFA modules

$$\begin{aligned} \mathbf{x}_n &\sim \text{PFA}(\Psi^{(1)}, \theta_n^{(1)}, \mathbf{h}_n^{(1)}; \eta^{(1)}, r_k^{(1)}, b^{(1)}), & \mathbf{h}_n^{(1)} &= \mathbf{1}(\mathbf{z}_n^{(2)}), \\ \mathbf{z}_n^{(2)} &\sim \text{PFA}(\Psi^{(2)}, \theta_n^{(2)}, \mathbf{h}_n^{(2)}; \eta^{(2)}, r_k^{(2)}, b^{(2)}), & & \vdots \\ & & & \vdots \\ & & & \mathbf{h}_n^{(L-1)} = \mathbf{1}(\mathbf{z}_n^{(L)}), \\ \mathbf{z}_n^{(L)} &\sim \text{PFA}(\Psi^{(L)}, \theta_n^{(L)}, \mathbf{h}_n^{(L)}; \eta^{(L)}, r_k^{(L)}, b^{(L)}), & \mathbf{h}_n^{(L)} &= \mathbf{1}(\mathbf{z}_n^{(L+1)}), \end{aligned} \quad (5)$$

where L is the number of layers in the model, and $\mathbf{1}(\cdot)$ is a vector operation in which each component imposes the left operation in (4). In this Deep Poisson Factor Model (DPFM), shown as a graphical model in Figure 1(b) and also previously described in Henao et al. (2015), the binary units at layer $\ell \in \{1, \dots, L\}$ are drawn $\mathbf{h}_n^{(\ell)} \sim \text{BPL}(\tilde{\lambda}_n^{(\ell+1)})$, for

$\lambda_n^{(l)} = \Psi^{(l)}(\theta_n^{(l)} \circ \mathbf{h}_n^{(l)})$. The form of the model in (5) introduces latent variables $\{\mathbf{z}_n^{(l)}\}_{l=2}^{L+1}$ and the element-wise function $\mathbf{1}(\cdot)$, rather than explicitly drawing $\{\mathbf{h}_n^{(l)}\}_{l=1}^L$ from the BPL distribution. Concerning the top layer, we let $\mathbf{z}_n^{(L+1)} \sim \text{Poisson}(\lambda_n^{(L+1)})$ and $\lambda_n^{(L+1)} \sim \text{Gamma}(a_0, b_0)$.

2.3 Deep multi-modality representation with PFA modules

In a multi-modality setting, each individual is characterized by D different count vectors, each of which is characterized by a different vocabulary (different types of entities being counted, *i.e.*, different modalities). Individual $n \in \{1, \dots, N\}$, data type $i \in \{1, \dots, D\}$ is denoted as $\mathbf{x}_n^{(i)}$, corresponding to an M_i -dimensional count vector. The dataset described in Section 3 is composed of $D = 3$ data types: medications, laboratory tests and codes. Since all D data types are composed of count vectors, we can in principle concatenate the D vectors for patient n into a long $\sum_i M_i$ -dimensional vector, $\left[\mathbf{x}_n^{(1)\top}, \dots, \mathbf{x}_n^{(D)\top}\right]^\top$, that we can model with the DPFM in (5). Such an approach will allow us to learn about the correlation structure of the variables in the concatenated modalities, but it ignores the fact that due to context, each data type in general has its own correlation structure. Another simple approach consists of modeling each data type individually, again using (5); however, this fails to acknowledge that different modality types can be correlated, as they represent different contexts or “views” of a larger representational space. In Henao et al. (2015), the authors employ this single-modality approach to model medications from the dataset described in Section 3, however they do not provide insights on how to combine multiple modalities. Motivated by the shortcomings of these two simplistic approaches, we modify the model in (5) to learn correlation structures of individual modalities, but at the same time to be able to share information across them to leverage their correlation structure. In particular, we propose a data-type-specific first layer and a deep architecture of shared PFA modules, formally written as

$$\begin{aligned} \mathbf{x}_n^{(i)} &\sim \text{PFA}^{(i+1)}, & \mathbf{h}_n^{(i+1)} &= \mathbf{1}\left(\mathbf{z}_n^{(i+2)}\right), & i &= 1, \dots, D, \\ \mathbf{z}_n^{(1+2)}, \dots, \mathbf{z}_n^{(D+2)} &\sim \text{MPPFA}^{(2)}, & & & \\ & \vdots & \mathbf{h}_n^{(L-1)} &= \mathbf{1}\left(\mathbf{z}_n^{(L)}\right), & \\ \mathbf{z}_n^{(L)} &\sim \text{PFA}^{(L)}, & \mathbf{h}_n^{(L)} &= \mathbf{1}\left(\mathbf{z}_n^{(L+1)}\right), & \end{aligned} \quad (6)$$

where

$$\text{PFA}^{(i+1)} \stackrel{\text{def}}{=} \text{PFA}\left(\Psi^{(i+1)}, \theta_n^{(i+1)}, \mathbf{h}_n^{(i+1)}, \eta_n^{(i+1)}, r_k^{(i+1)}, b^{(i+1)}\right), \quad (7)$$

$$\text{MPPFA}^{(2)} \stackrel{\text{def}}{=} \prod_i \text{PFA}\left(\Psi^{(i+2)}, \theta_n^{(i+2)}, \mathbf{h}_n^{(i+2)}, \eta_n^{(i+2)}, r_k^{(i+2)}, b^{(i+2)}\right), \quad (8)$$

$$\mathbf{z}_n^{(i+2)} \sim \text{PFA}\left(\Psi^{(i+2)}, \theta_n^{(i+2)}, \mathbf{h}_n^{(i+2)}, \eta_n^{(i+2)}, r_k^{(i+2)}, b^{(i+2)}\right). \quad (9)$$

The first layer in (6) is composed of D independent PFA modules as in (7), with explicit hierarchical model in (3). The multi-modality PFA model, denoted MPPFA in (8), is a PFA model

in which each modality has an associated factor loadings matrix, $\Psi^{(i+2)}$, but shared factor intensities, $\theta_n^{(i+2)}$, binary units, $\mathbf{h}_n^{(i+2)}$ and parameters $\{\eta_n^{(i+2)}, r_k^{(i+2)}, b^{(i+2)}\}$. This means that modality-specific latent counts, $\mathbf{z}_n^{(i+2)}$, can be drawn from a PFA module restricted to $\Psi^{(i+2)}$ as in (9). The MPPFA module in (8) is a novel specification, not previously considered by Henao et al. (2015), that extends the functionality of Poisson factor analysis beyond applications in electronic health records analysis. The architecture of the Deep Multi-modality Poisson Factor Model (DMPFM) in (6) is fully specified by $\{K_{(1,1)}, \dots, K_{(D,1)}, K_{(2)}, \dots, K_{(L)}\}$ and L , where $K_{(i,1)}$ are modality-specific loadings sizes (number of topics), $K_{(A)}$ are modality-shared loadings sizes and L is the number of layers. For example, Figure 1 shows a graphical model representation for a specification with $D = 3$ and $L = 2$. When the model is set for a single-modality, $D = 1$, the architecture in (6) is equivalent to DPFM, as shown in (5) and previously described by Henao et al. (2015).

2.4 Model interpretation

Consider modality i in layer 1 of (6), from which $\mathbf{x}_n^{(i)}$ is drawn. Assuming $\mathbf{h}_n^{(i+1)}$ is known, this corresponds to a focused topic model (Williamson et al., 2010). The columns of $\Psi^{(i+1)}$ correspond to modality- i topics, with the k -th column $\psi_k^{(i+1)}$ defining the probability with which entities (*e.g.*, medications) of modality i are manifested for topic k (each $\psi_k^{(i+1)}$ is drawn from a Dirichlet distribution, as in (3)). Generalizing the notation from (2), $\lambda_{kn}^{(i+1)} = \psi_k^{(i+1)} \theta_n^{(i+1)} h_{kn}^{(i+1)} \in \mathbb{R}^{M_i}$ is the rate vector associated with topic k , modality i and patient n , and it is active when $h_{kn}^{(i+1)} = 1$. The entity-count vector for patient n in modality i manifested from topic k is $\mathbf{x}_{kn}^{(i)} \sim \text{Poisson}\left(\lambda_{kn}^{(i+1)}\right)$, and $\mathbf{x}_n^{(i)} = \sum_{k=1}^{K_{(i,1)}} \mathbf{x}_{kn}^{(i)}$, where $K_{(i,1)}$ is the number of topics in the modality. The columns of $\Psi^{(i+1)}$ define correlation among the entities associated with the topics: for a given topic (column of $\Psi^{(i+1)}$), some entities co-occur with high probability, and other entities are likely jointly absent.

We now consider a two-layer model, with $\mathbf{h}_n^{(2)}$ assumed known. To generate $\mathbf{h}_n^{(i+1)}$, we first draw $\mathbf{z}_n^{(i+2)}$, which, analogous to above, may be expressed as $\mathbf{z}_n^{(i+2)} = \sum_{k=1}^{K_{(i+2)}} \mathbf{z}_{kn}^{(i+2)}$, with $\mathbf{z}_{kn}^{(i+2)} \sim \text{Poisson}\left(\lambda_{kn}^{(i+2)}\right)$ and $\lambda_{kn}^{(i+2)} = \psi_k^{(i+2)} \theta_n^{(i+2)} h_{kn}^{(i+2)}$. Note that factor intensities and binary units, respectively $\theta_n^{(i+2)}$ and $h_{kn}^{(i+2)}$, are shared across the $i = 1, \dots, D$ modalities. Column k of $\Psi^{(i+2)}$ corresponds to a *meta-topic* specific to modality i , with $\psi_k^{(i+2)}$ a $K_{(i,1)}$ -dimensional probability vector, denoting the probability with which each of the modality- i layer-1 topics are “on” when layer-2 “meta-topic” k is on (*i.e.*, when $h_{kn}^{(i+2)} = 1$). The columns of $\Psi^{(i+2)}$ define correlation among the modality- i layer-1 topics: for a given layer-2 meta-topic (column of $\Psi^{(i+2)}$), some layer-1 topics co-occur with high probability, and other layer-1 topics are likely jointly absent. Furthermore, columns of the concatenated meta-topic matrix, $\left[\Psi^{(1+2)}\right]^\top \dots \left[\Psi^{(D+2)}\right]^\top$, define correlation structure among all layer-1 topics at the same time.

As one moves up the hierarchy, to layers $\ell > 2$, the meta-topics become increasingly more abstract and sophisticated, manifested in terms of probabilistic combinations of topics and meta-topics at the layers below. Because of the properties of the Dirichlet distribution, each column of a particular $\Psi^{(l)}$ is encouraged to be sparse, implying that a column of $\Psi^{(l)}$

encourages use of a small subset of columns of $\Psi^{(\ell-1)}$, with this repeated all the way down to the data layer, and the topics reflected in the columns of $\Psi^{(1)}$. This deep architecture imposes correlation across the layer-1 topics in all modalities, and it does it through use of PFA modules at all layers of the deep architecture, unlike Gan et al. (2015a) which uses an SBN for layers 2 through L , and a PFA at the bottom layer. In addition to the elegance of using a single class of modules at each layer, the proposed deep model has important computational benefits, as discussed in Section 2.6.

We emphasize that $\{\theta_{kn}^{(2)}, h_{kn}^{(2)}\}$ are shared across all D data types, or modalities. The hierarchy that resides above them is meant to model underlying latent correlations in aspects of disease and health. The underlying state of the patient is independent of the modality with which he/she is viewed. When $h_{kn}^{(2)} = 1$, the k th meta-topic of health/disease is “on” for patient n ; $\psi_k^{(i,2)}$ characterizes how meta-topic k impacts the presence/absence of each topic associated with modality i . The modality-dependence is manifested at the bottom of the deep model, near the data, and the deep architecture above it imposes statistical relationships among the meta-topics, and is meant to characterize latent health/disease.

2.5 PFA modules for multi-label classification

Assume there is a C -dimensional vector of binary labels $\mathbf{y}_n \in \{0, 1\}^C$ associated with patient n (presence/absence of C maladies or illnesses). Provided that labels share the same covariates (patient n , \mathbf{x}_n) and are oftentimes correlated, it is reasonable to model all labels jointly as opposed to build individual models for each label. We seek to learn the model for mapping $\mathbf{x}_n \rightarrow \mathbf{y}_n$ simultaneously with learning the deep topic representation in Section (2.2). In fact, the mapping $\mathbf{x}_n \rightarrow \mathbf{y}_n$ is based on the deep generative process for \mathbf{x}_n in (5). This means that we can leverage the correlation structure of count data vectors and labels at the same time. We represent each element of \mathbf{y}_n , y_{cn} , using (4). We impose the model

$$y_{cn} = \mathbf{1}(\hat{z}_{cn} \geq 1), \quad \hat{z}_{cn} \sim \text{Poisson}(\hat{\lambda}_{cn}), \quad (10)$$

where $\hat{\lambda}_{cn}$ is element c of $\hat{\lambda}_n$. First considering the single-modality case, $\hat{\lambda}_n = \mathbf{B}(\boldsymbol{\theta}_n^{(1)} \circ \mathbf{h}_n^{(1)})$ and $\mathbf{B} \in \mathbb{R}_+^{C \times K}$ is a matrix of nonnegative classification weights, with prior distribution $\mathbf{b}_k \sim \text{Dirichlet}(\zeta \mathbf{1}_C)$, where \mathbf{b}_k is a column of \mathbf{B} . Here, we denote latent counts as $\hat{\mathbf{z}}_n = [\hat{z}_{1n} \dots \hat{z}_{Cn}]^T$ to differentiate them from those coming from the DPFM, denoted as \mathbf{z}_n in (5). The matrix of classification weights, \mathbf{B} , in (10) serves two purposes: (i) learns the correlation structure of labels, since large entries in \mathbf{b}_k , say $b_{c'k}$ and $b_{c''k}$ indicate their corresponding labels, c and c' are proportionally correlated; and (ii) provided that the prior for \mathbf{B} encourages sparsity, the resulting classifier is parsimonious and easier to interpret than that of a classifier with dense \mathbf{B} .

Figure 1(a) shows a graphical model representation of a PFA module connected to the multi-label classifier in (10), where solid nodes and edges represent PFA module components and dashed lines are specific to the classification model. Combining (5) with (10) allows us to learn the mapping $\mathbf{x}_n \rightarrow \mathbf{y}_n$ via the shared first-layer local representation, $\boldsymbol{\theta}_n^{(1)} \circ \mathbf{h}_n^{(1)}$, that encodes topic usage for document n . This sharing mechanism allows the model to learn

topics, $\Psi^{(1)}$, and meta-topics, $\{\Psi^{(\ell)}\}_{\ell=2}^L$, biased towards discrimination, as opposed to just explaining the data, \mathbf{x}_n .

For the deep *multi-modality* model in (6), we learn the mapping $\mathbf{x}_n^{(1)}, \dots, \mathbf{x}_n^{(D)} \rightarrow \mathbf{y}_n$ through the first-layer local representations from all modalities, hence $\hat{\lambda}_n = \sum_{i=1}^D \mathbf{B}_i(\boldsymbol{\theta}_n^{(i,1)} \circ \mathbf{h}_n^{(i,1)})$, where $\mathbf{B}_i \in \mathbb{R}_+^{C \times K(i,1)}$, for $i = 1, \dots, D$. In this case, the classifier uses information from all modalities but at the same time biases modality-specific topics, $\Psi^{(i,1)}$, towards discrimination. We call this construction *discriminative* deep multi-modality Poisson factor model. In cases where multi-class, not multi-label classification is required, we can use the formulation introduced by Henao et al. (2015), based on a multinomial likelihood function, instead of a Bernoulli-Poisson link as in (10). Although other DP-based discriminative topic models have been proposed (Lacoste-Julien et al., 2009; McAuliffe and Blei, 2008), they rely on approximations in order to combine the topic model, usually LDA, with softmax-based classification approaches.

2.6 Inference

A convenient feature of the model in (5) and (6) is that all its conditional posterior distributions can be written in closed form, due to local conjugacy. In this section, we focus on Markov chain Monte Carlo (MCMC) via Gibbs sampling for our implementation. In applications where the fully Bayesian treatment becomes prohibitive computationally, Stochastic Variational Inference (SVI) can be used (Henao et al., 2015). See Appendix A for details about SVI implementation for models based on PFA modules. Other alternatives for scaling up inference in Bayesian models such as the parameter server (Ho et al., 2013; Li et al., 2014), conditional density filtering (Guhaniyogi et al., 2014) and stochastic gradient-based approaches (Chen et al., 2014; Ding et al., 2014; Welling and Teh, 2011), are also possible but beyond the scope of this work.

Gibbs sampling for the model in (5) and (6) involves sampling in sequence from the conditional posterior of all the parameters of the model. For instance, for the DPFM in (5), we have $\{\Psi^{(\ell)}, \boldsymbol{\theta}_n^{(\ell)}, \mathbf{h}_n^{(\ell)}, r_k^{(\ell)}\}$, for $\ell = 1, \dots, L$, and $\boldsymbol{\lambda}^{(x+1)}$. For the multi-modality model in (6) we also have to account for modality-specific parameters in (7). The remaining parameters of the model are set to fixed values: $\eta = 1/K$, $b = 0.5$ and $a_0 = b_0 = 1$. We note that priors for η , b , a_0 and b_0 exist that result in Gibbs-style updates, and can be readily incorporated into the model if desired; however, we opted to keep the model as simple as possible, without compromising flexibility. The most unique conditional posteriors for a single PFA module are shown below, without layer index for clarity,

$$\begin{aligned} \psi_k &\sim \text{Dirichlet}(\eta + x_{1k}, \dots, \eta + x_{Mk}), \\ \theta_{kn} &\sim \text{Gamma}(r_k b_{kn} + x_{\cdot kn}, b^{-1}), \\ h_{kn} &\sim \delta(x_{\cdot kn} = 0) \text{Bernoulli}(\tilde{\pi}_{kn}(\tilde{\pi}_{kn} + 1 - \pi_{kn})^{-1}) + \delta(x_{\cdot kn} \geq 1), \end{aligned} \quad (11)$$

where

$$x_{mk} = \sum_{n=1}^N x_{mkn}, \quad x_{\cdot kn} = \sum_{m=1}^M x_{mkn}, \quad \tilde{\pi}_{kn} = \pi_{kn}(1-b)^{r_k}.$$

Complete details, including those for DMPEM and discriminative DMPEM in Sections 2.3 and 2.5, respectively, are provided in Appendix B.

Initialization is done at random from prior distributions, followed by modality-wise and layer-wise fitting (*pre-training*). In the experiments, when pre-training we run 150 Gibbs sampling cycles per layer. We have observed that 50 cycles are usually enough to obtain good initial values of the global parameters of the model, namely $\{\Psi^{(i,1)}, r_k^{(i,1)}, \Psi^{(i)}, r_k^{(i)}\}$, for $i = 1, \dots, D$, $\ell = 2, \dots, L$ and $\lambda^{(L+1)}$.

2.6.1 IMPORTANCE OF COMPUTATIONS SCALING WITH THE NUMBER OF NON-ZEROS

From a practical standpoint, the most important feature of the models in (5) and (6) is that inference does not scale as a function of the size of the total dataset, but as a function of its number of non-zero elements, which is advantageous in cases where the input data is sparse (often the case). For instance, $\sim 4\%$ of the entries in the dataset described in Section 3 are non-zero. Similar proportions are also observed in datasets traditionally used to benchmark topic models (word documents), such as 20 Newsgroups, Reuters and Wikipedia (details of which are discussed below). Furthermore, this feature also extends to all modalities and layers of the model, regardless of $\{\mathbf{h}_n^{(\ell)}\}$ being latent. Similarly, for the discriminative DMPEM in Section 2.5, inference scales with the number of positive cases in $\{\mathbf{y}_n\}_{n=1}^N$, not CN . This is particularly appealing in cases where C is large and the number of positive cases is small (a patient typically has a small subset of possible illnesses), $\sim 8\%$ in the dataset described in Section 3.

In order to show that this scaling behavior holds, it is enough to see that by construction, from (2), if $x_{mn} = \sum_{k=1}^K x_{mkn} = 0$ (or $z_{mn} = 0$ for $\ell > 1$), thus $x_{mkn} = 0$, $\forall k$ with probability 1. Besides, from (4) we see that if $h_{kn} = 0$ then $z_{kn} = 0$ with probability 1. As a result, update equations for all parameters of the model except for $\{\mathbf{h}_n^{(\ell)}\}$, depend only on non-zero elements of \mathbf{x}_n and $\{z_n^{(\ell)}\}$. Updates for the binary variables can be cheaply obtained in block from $h_{kn}^{(\ell)} \sim \text{Bernoulli}(\pi_{kn}^{(\ell)})$ via $\lambda_{kn}^{(\ell)}$ as previously described.

It is worth mentioning that models based on multinomial or Poisson likelihoods such as LDA (Blei et al., 2003), HDP (Teh et al., 2006), FTM (Williamson et al., 2010) and PFA (Zhou et al., 2012), also enjoy this property (scaling based on number of non-zero observations). However, the recently proposed deep PFA (Gan et al., 2015a) does not use PFA modules on layers other than the first one: it uses SBNs or RBMs that are known to scale with the number of binary variables as opposed to their non-zero elements.

2.7 Related work

2.7.1 CONNECTIONS TO OTHER DP-BASED TOPIC MODELS

PFA is a nonnegative matrix factorization model with Poisson link, that is closely related to other DP-based models. Specifically, Zhou et al. (2012) showed that by making $p(h_{kn} = 1) = 1$ and letting θ_{kn} have a Dirichlet, instead of a gamma distribution as in (3), we can recover LDA by using the equivalence between Poisson and multinomial distributions. By looking at (11), we see that PFA and LDA have the same blocked Gibbs updates (Blei et al., 2003), when Dirichlet distributions for θ_{kn} are used. An equivalent analogy for SVI updates (Hoffman et al., 2010) can be derived from the update equations in Appendix A.

In Zhou et al. (2012), the authors showed that using the Poisson-gamma representation of the negative binomial distribution and a beta-Bernoulli specification for $p(h_{kn})$ in (3), we can recover the FTM formulation and inference in Williamson et al. (2010). More recently, Zhou and Carin (2015) showed that PFA is comparable to HDP in that the former builds group-specific DPs with normalized gamma processes. A more direct relationship between a three-layer HDP (Teh et al., 2006) and a two-layer version of (5) can be established by grouping count data vectors by categories. In the HDP, three DPs are set for topics, data-dependent topic usage and category-wise topic usage. In our model, $\Psi^{(1)}$ represent K_1 topics, $\theta_n^{(1)} \circ \mathbf{h}_n^{(1)}$ encodes data-vector-wise topic usage and $\Psi^{(2)}$ encodes topic usage for K_2 categories. In HDP, data vectors are assigned to categories a *a priori*, but in our model data-vector-category *soft* assignments are estimated and encoded via $\theta_n^{(2)} \circ \mathbf{h}_n^{(2)}$. As a result, the model in (5) is a more flexible alternative to HDP in that it groups data vectors into categories in an unsupervised manner.

2.7.2 SIMILAR MODELS

Non-DP-based deep models for topic modeling employed in the deep learning literature typically utilize RBMs or SBNs as building blocks. For instance, Hinton and Salakhutdinov (2009) and Maaloe et al. (2015) extended RBMs via DBNs to topic modeling. In addition, Srivastava et al. (2013) proposed the over-replicated softmax model, a deep version of RSM that generalizes RBMs.

Recently, Ranganath et al. (2014) proposed a framework for generative deep models using exponential family modules. Although they consider Poisson-Poisson and gamma-gamma factorization modules akin to our PFA modules, their model lacks the explicit binary unit linking between layers commonly found in traditional deep models. Further, their inference approach, *black-box* variational inference, is not as conceptually simple, but it scales with the number of non-zeros of our model.

DPEA, proposed in Gan et al. (2015a), is the model closest to ours. Nevertheless, our proposed model has a number of key differentiating features. *(i)* Both models learn topic correlations by building a multilayer modular representation on top of PFA. Our model uses PFA modules throughout all layers in a conceptually simple and easy to interpret way. DPEA uses Gaussian distributed weight matrices within SBN modules; these are hard to interpret in the context of topic modeling. *(ii)* SBN architectures have the shortcoming of not having block closed-form conditional posteriors for their binary variables, making them difficult to estimate, especially as the number of variables increases. *(iii)* Factor loading matrices in PFA modules have natural shrinkage to counter overfitting, thanks to the Dirichlet prior used for their columns. In SBN-based models, shrinkage has to be added via variable augmentation at the cost of increasing inference complexity. *(iv)* Inference for SBN modules scales with the number of hidden variables in the model, not with the number of non-zero elements, as in our case.

In Henaq et al. (2015), we presented an early version of our approach, for the single-modality case in (5), but mainly focused on topic models. In this previous work, we introduced inference procedures based on Gibbs sampling and stochastic variational inference, and considered a discriminative model for multi-class classification. In the present work, we extend the DPEA architecture to multiple modalities (DMPEA) and introduce a discrimi-

native model specification for multi-label classification, of particular interest in electronic health records applications, as one patient may suffer from multiple illnesses at the same time. In the experiments, we will show the benefits of explicitly modeling multiple modalities using a DMPFM specification, as opposed to naive constructs based on the single-modality model of Henaio et al. (2015).

Several deep architectures have been recently proposed for multi-modality problems (Srivastava and Salakhutdinov, 2012, 2014; Sohn et al., 2014). These models use RBMs as building blocks and are traditionally geared towards applications with image (pixel intensities) and text (word counts) modalities. The main goals of these applications are classification based on image and text latent features, and information retrieval, that is, predicting values of one modality given observations of the others. Unlike our discriminative DMPFM and SupDocNADE (Supervised Document Neural Autoregressive Distribution Estimator Zheng et al., 2014) based on SBNs, most existing deep multi-modality models based on RBMs build classifiers as a two-step procedure, not jointly with the generative model as in our case. In its current form, our model does not allow for mixed data-types, however it is not too difficult to extend it to such case, as we can seamlessly use sparse Gaussian factor models (Carvalho et al., 2008; Henaio and Winther, 2011; Henaio et al., 2014) and rank-likelihood factor models (Yuan et al., 2015) as first-layer modules for real and ordinal-valued data, respectively. We leave these extensions as interesting future work.

3. Motivating Data

We utilize three modes of data: self-reported medication usage, laboratory tests, and diagnosis and procedure codes. Count matrices for each mode for each patient were extracted from a Duke University 5-year dataset. Specifically, we consider electronic health data generated from 2007 to 2011 in the care of Durham County residents within the Duke University Health System (DUHS), including three hospitals and an extensive network of outpatient clinics. This dataset includes over 240,000 patients with over 4.4 million patient visits.

3.1 Data Reconciliation

Patient data originated from the various hospitals and outpatient clinics of DUHS. As names for medications, laboratory tests and diagnosis and procedure codes are uniquely named at each facility, the data must first be reconciled to a common data dictionary.

Our dataset included 39,429 medication names. These names, which included both brand and generic names at various dosages and formulations, were mapped to their pharmaceutical active ingredients (AI) using a custom Python script that leveraged the RxNorm API². RxNorm is a depository of medication information maintained by the National Library of Medicine and includes trade names, brand names, dosage information and active ingredients (Nelson et al., 2011). Compound medications that include multiple active ingredients incremented counts for all AI in that medication. We discovered 1,694 unique AI in our dataset.

The data also include 4,391 types of laboratory tests, mapped to the Logical Observation Identifiers Names and Codes (LOINC) ontology (Vreeman et al., 2015). The LOINC

2. See <http://rxnav.nlm.nih.gov/RxNormAPIs.html>.

standard is common terminology for laboratory and clinical observations maintained by the Regenstrief Institute³. Mappings to the LOINC database were performed with the RELMA tool⁴. Each suggested mapping was reviewed by a physician to ensure that appropriate test and measurement units were aligned. Counts for patient laboratory tests reflect the number of times a test appears in a patients record. We discovered 1,869 unique LOINC tests in the data.

Lastly, the data include 21,305 diagnosis and procedure codes. These were mapped using their unique ICD-9 (International Statistical Classification of Diseases and Related Health Problem) and CPT (Current Procedural Terminology) identifiers. ICD codes are the international diagnostic coding system, and are maintained by the World Health Organization⁵. CPT procedure codes are maintained by the American Medical Association and are designed to ease uniform communication performed medical services⁶. We identified 21,013 unique ICD-9 and CPT codes in the dataset.

3.2 Cohort and Count Matrix Generation

To narrow our analysis, we focused on a cohort of Type-2 Diabetes Mellitus (T2DM) patients, using previous phenotype criteria for T2DM (Richesson et al., 2013). T2DM is a chronic disease with high disease and treatment costs. Patients with diabetes are at increased risk of complications such as Coronary Heart Disease (CHD), Acute Myocardial Infarction (AMI), Cerebral Vascular Disease (CVD), Chronic Renal Failure (CRF), and amputation (American Diabetes Association, 2014). Prediction of these outcomes is important for communicating prognosis and targeting treatment to the high-risk patients.

We identified 16,756 patients in the dataset, by filtering for the following criteria: (i) at least two counts of 250.xx ICD-9 codes, (ii) at least one laboratory measurement of hemoglobin A1c (HgbA1C) greater than 4.5%, and (iii) a medication record including at least one of the following T2DM medications: insulin, metformin, sulfonylurea, or sitagliptin. We generated counts for each data mode by mapping each patient's records to the common data elements as described above. We then counted the total number of occurrences for each data element over a defined time window. In our initial experiment exploring the mapping of medical concepts to discovered factors, this time window represented two years of data. In our classification experiment, this time window was six months prior to the classification date.

3.3 Classification

3.3.1 UK PROSPECTIVE DIABETES STUDY (UKPDS) OUTCOMES MODEL

Prediction equations to determine the risk of various complications in diabetes have been studied extensively (Wilson et al., 1998; Clarke et al., 2004; van Dieren et al., 2011). These risk estimates are helpful for identifying high-risk populations that may need closer clinical observation and higher intensity treatment (Simmons et al., 2009). Several equations are currently available to estimate CHD, AMI and CVD risk (Metcalf et al., 2008; Tao et al.,

Table 1: Definition of the 13 T2DM related outcomes for multi-label classification experiment in Section 2.5.

2013). UKPDS is a multicenter randomized trial involving 5,102 newly diagnosed patients with T2DM, recruited from 23 UK centers (King et al., 1999; Stevens et al., 2001); it has been utilized to generate outcome models for cardiovascular and cerebrovascular disease (Lu et al., 2012; Tao et al., 2013).

In the UKPDS model, the 1-year probability of CHD is:

$$\begin{aligned}
 p(\text{CHD}) \propto & b_0 + b_1 * (\text{Age} - 55) - b_2 \text{Female} - b_3 \text{AfroCaribbean} \\
 & + b_4 \text{Smoking} + b_5 (\text{HgbA1c} - 6.72) + b_6 (\text{SPB} - 135.7) / 10 \\
 & + b_7 (\log(\text{TC}/\text{HDL}) - 1.59),
 \end{aligned} \tag{12}$$

where mean Total Cholesterol (TC), mean High Density Lipoprotein (HDL), mean Systolic Blood Pressure (SPB), and mean Hemoglobin A1c (HgbA1c) are used, and $\{b_i\}_{i=0}^7$ are pre-specified classification weights (Stevens et al., 2001).

While patient care has changed rapidly since this study was performed (the original patients were recruited and followed prospectively from 1977-1997), numerous studies have since explored its application in more recent clinical cohorts. These differences as well as regional variation in health care access and disease burden compelled us to estimate the UKPDS parameters in our cohort to improve its classification results for our patients.

3.3.2 OUTCOMES IDENTIFICATION

We generated training and test cohorts for our classification experiment in Section 4.3 by defining well-known T2DM disease morbidities with diagnosis and procedure codes (American Diabetes Association, 2014). For each patient we capture the date of the 13 outcomes in Table 1.

3.3.3 GENERATING TEST AND TRAIN COHORTS

To generate training and test cohorts from our dataset, we selected a reference date that allowed us to (i) capture a large patient population with multiple patient encounters prior to the date, and (ii) evaluate encounters after the date for the existence of an outcome.

For the classification experiment we generated count matrices for each data mode by aggregating patient data for a six month period prior to the *patient visit*. We then determined if the patient had one or more of the above outcomes within 1 year of that visit. For the training cohort, the *patient visit* was defined as the encounter immediately prior to the date threshold of January 1, 2010. For our test set, we used a January 1, 2011 threshold date. We cleaned our data to remove any patients (i) that already had outcomes 6 months prior to the *patient visit* and (ii) removed any codes with less than 10 observations over the entire cohort. Lastly, we removed from the test set any patients that were in the original test set and did not have any additional visits since the training set threshold date. We also removed any individuals who did not have laboratory or vitals data in the prior 2 years, preventing us from computing a UKPDS risk score.

4. Experiments

In this section we start by presenting benchmark results using well-known corpora for topic models, the goal being to show how DPPM (single modality) compares to related deep models. Additional results for the single-modality case can be found in Henao et al. (2015). Next, we present extensive experiments using the motivating data described in Section 3. In particular, we evaluate DPPM and DMPPM in terms of model fit and classification performance. Finally, we analyze the topics estimated by DMPPM. All experiments were conducted on a 2.2GHz desktop machine with 8GB RAM. The code used, implemented in Matlab, will be made publicly available.

4.1 Benchmark corpora

We first evaluate the performance of the basic version of our model, specifically the deep single modality model in (5). For this purpose, we present experiments on three corpora: 20 Newsgroups (20 News), Reuters corpus volume 1 (RCV1) and Wikipedia (Wiki). 20 News is composed of 18,845 documents and 2,000 words, partitioned into a 11,315 document training set and a 7,531 document test set. RCV1 has 804,414 newswire articles containing 10,000 words. A random 10,000 subset of documents is used for testing. For Wiki, we obtained 10⁷ random documents, from which a subset of 1,000 is set aside for testing. Following Hoffman et al. (2010), we keep a vocabulary consisting of 7,702 words taken from the top 10,000 words in the Project Gutenberg Library.

As performance measure, we use held-out perplexity, a commonly used performance metric for topic models defined as the geometric mean of the inverse marginal likelihood of every word in the set. We cannot evaluate the intractable marginal for the model in (5), thus we compute the *predictive perplexity* on a 20% subset of the held-out set. The remaining 80% is used to learn document-specific variables of the model, $\{\theta_n^{(\ell)}, \mathbf{h}_n^{(\ell)}\}$, for $n = 1, \dots, N$ and $\ell = 1, \dots, L$. The training set is used to estimate the global parameters of the model, $\{\Psi^{(\ell)}, r_k^{(\ell)}\}$, for $\ell = 2, \dots, L$ and $\lambda^{(L+1)}$. For PFA-based models, the test perplexity for a

Model	Method	Size	20 News	RCV1	Wiki
DPFM	MCMC	128-64	780	908	783
DPEA-SBN	SGNHT	1024-512-256	—	942	770

LDA	Ghbbs	128	893	1179	1059
FTM	Ghbbs	128	887	1155	991
RSM	CD5	128	877	1171	1001

Table 2: Held-out perplexities for 20 News, RCV1 and Wiki. Size indicates number of topics and/or binary units, accordingly.

single modality can be calculated as (Zhou et al., 2012)

$$\text{perplexity} = \exp \left(-\frac{1}{x_{..}} \sum_{m=1}^M \sum_{n=1}^N x_{mn} \log \frac{\sum_{s=1}^S \sum_{k=1}^K \phi_{mk}^s \theta_{kn}^s h_{kn}^s}{\sum_{s=1}^S \sum_{m=1}^M \sum_{k=1}^K \phi_{mk}^s \theta_{kn}^s h_{kn}^s} \right),$$

where we have omitted modality and layer indices for clarity, S is the total number of collected samples, $x_{..} = \sum_{m=1}^M \sum_{n=1}^N x_{mn}$ and x_{mn} , ψ_{mk} , θ_{kn} and h_{kn} are elements of \mathbf{x}_n , Ψ , Θ , and \mathbf{h}_n , respectively.

We compare our single-modality deep model in (5) (denoted DPFM), against LDA (Blei et al., 2003), FTM (Williamson et al., 2010), RSM (Hinton and Salakhutdinov, 2009), nHDP (Paisley et al., 2015) and DPEA with SBNs (DPEA-SBN) and RBMs (DPEA-RBM) (Gan et al., 2015a). For all these models, we use the settings described in Gan et al. (2015a). Inference methods for RSM and DPEA are contrastive divergence with step size 5 (CD5) and stochastic gradient Nose-Hoover thermostats (SGNHT), respectively. For our model, (after the aforementioned pre-training) we run 3,000 samples, from which the first 2,000 are discarded (burnin). For the Wiki corpus, MCMC-based DPFM is run on a random subset of 10^6 documents.

Table 2 shows results for the corpora being considered. Figures for methods other than DPFM were taken from Gan et al. (2015a). We see that multilayer models (DPFM, DPFA and nHDP) consistently outperform single layer ones (LDA, FTM and RSM), and that DPFM has the best performance across all corpora for models of comparable size. We verified empirically (results not shown) that doubling the number of hidden units, adding a third layer or increasing the number of samples/iterations for DPFM does not significantly change the results in Table 2. As a note on computational complexity, one iteration of the two-layer model on the 20 News corpus takes approximately 2 seconds. For comparison, we also ran the DPEA-SBN model in Gan et al. (2015a) using a two-layer model of the same size; in their case it takes about 24, 4 and 5 seconds to run one iteration using MCMC, conditional density filtering (CDFE) and SGNHT, respectively. Runtimes for DPEA-RBM are similar to those of DPEA-SBN. Additional results for DPFM using stochastic variational inference can be found in Henao et al. (2015).

Size	Naive1		Naive2		DMPFM				
	Med	Lab	Med	Lab	Med	Lab

Table 3: Held-out perplexity for EHR data. Size indicates number of topics and/or binary units, accordingly. Naive1 uses one DPFM per modality and Naive2 one DPFM for stacked modalities (Meds, Labs and Codes). Naive2 and DMPFM use all modalities at once but perplexities are computed separately.

4.2 Model fitting

We evaluate the ability of the multi-modality model in (6) to fit the data introduced in Section 3. The data consist of 16,756 patients, and of these 7,892 were used for model fitting and 8,864 for testing. We considered the three modalities discussed above: 1,694 of the entities corresponded to medications (Meds), 1,869 corresponded to laboratory tests (Labs), and 21,013 corresponded to diagnosis and procedure codes (Codes). We filtered out variables with less than 10 occurrences over the entire cohort, reducing the data to 253, 606 and 4,222 entities for Meds, Labs and Codes, respectively. We consider three different models: (i) A single-modality approach, in which we treat each modality independently using (5) (denoted Naive1); (ii) another single-modality approach, in which all modalities are stacked into one data matrix, then modeled using (5) (denoted Naive2); and (iii) the multi-modality approach using (6) (denoted DMPFM). Note that Naive1 and Naive2 constitute direct applications of the DPFM model introduced by Henao et al. (2015). In all cases we collect 1,200 samples after running 1,200 burnin iterations. As the performance measure, we report held-out perplexities for each modality on a randomly selected 20% subset (the test set).

Table 3 shows predictive perplexities for different architectures. We consider two- and three-layer specifications (Size) in three different binary unit sizes each, for a total of 6 models. We see that Naive2 and DMPFM consistently outperform Naive1. These results demonstrate that sharing information across modalities produces a model with a richer correlation structure and improved model fit, compared to Naive1 and Naive2 that use the DPFM of Henao et al. (2015). We also see that DMPFM performs the best in all configurations, which highlights the importance of modeling correlation structure within and across modalities. In terms of number of layers, we see a modest perplexity improvement going from two to three layers in all cases. This is probably due to the size of the dataset; it is likely that more significant gains will be observed from cohorts with a larger number of variables and patients. It is worth noting that since our model is sparse, size K (on each layer) can be understood as an upper bound on the number of factors in the sense that the model has the ability of *turning off* entire factors by letting all its activations, h_{kn} , to be zero. In this experiment we present results for increasing values of K to show that the model is able to capture increasing amounts of detail (evidenced by decreasing perplexity)

Size	Med	Naive1 Lab	Code	Naive2 All	DMPFM All
64-32	0.592±0.05	0.594±0.05	0.745±0.06	0.751±0.06	0.771±0.07
96-48	0.596±0.04	0.583±0.05	0.727±0.06	0.750±0.06	0.781±0.06
128-64	0.590±0.04	0.590±0.05	0.725±0.06	0.751±0.06	0.779±0.06
64-32-16	0.601±0.05	0.594±0.05	0.726±0.05	0.742±0.06	0.771±0.06

128-64-32	0.590±0.04	0.588±0.05	0.732±0.05	0.757±0.06	0.784±0.07

Table 4: Mean test AUCs with standard deviations over 13 binary classification tasks. Size indicates number of topics and/or binary units, accordingly. Naive1 is one discriminative DPMFM per modality and Naive2 is one discriminative DPMFM for stacked modalities (Meds, Labs and Codes). Naive2 and DMPFM use all modalities to build classifiers.

as the model size grows, but also as a way to highlight that the model does not overfit, meaning that test performance (perplexity) does not deteriorate as the model size increases.

In terms of computational complexity, Naive1 and Naive2 take between 180 and 310 CPU depending on the size of the model: DMPFM takes between 190 and 480 minutes. Note that runtime include model fit, testing and perplexity calculations. In any case, runtimes are deemed reasonable considering the size of the dataset and the complexity of the models being evaluated.

4.3 Multi-label classification

We evaluate the discriminative DMPFM in Section 2.5 on the multi-label classification problem outlined in Section 3. We consider 13 well-known T2DM-related outcomes in Table 1, namely: Acute Myocardial Infarction (AMI), amputation, cardiac catheterization, coronary artery disease, depression, heart failure, chronic kidney disease, neurological disease, obesity, ophthalmic disease, stroke, unstable angina and death. We compare our discriminative DMPFM to discriminative versions of Naive1 and Naive2 based on DPMFMs. For a baseline comparison, we use the UKPDS model in (12) and sparse logistic regression (Friedman et al., 2001). For the UKPDS model we estimate model coefficients, $\{b_j\}_{j=0}^L$, for each outcome independently in a logistic regression setting. Note that UKPDS was originally intended for coronary heart disease, however we use its covariates (age, sex, race, smoking status, HgPA1c, SPB, TC and HDL) to build classifiers for all outcomes. We also use coronary heart disease interchangeably with coronary artery disease, which is the build up of plaque in the arteries of the heart and results in coronary heart disease. For PFA-based models, we collect 1,200 samples after running 1,200 burnin iterations. As a performance measure, we report area under the receiving operating characteristic (AUC) values on the test set (Fawcett, 2006). Provided that all classification tasks are very imbalanced, about 8% positive outcomes in average, we do not report test accuracies. Optimal thresholds can be obtained from ROC curves using outcome-specific prevalence information, if desired. Once threshold values have been selected, accuracies, true positive rates and true negative rates can be readily computed.

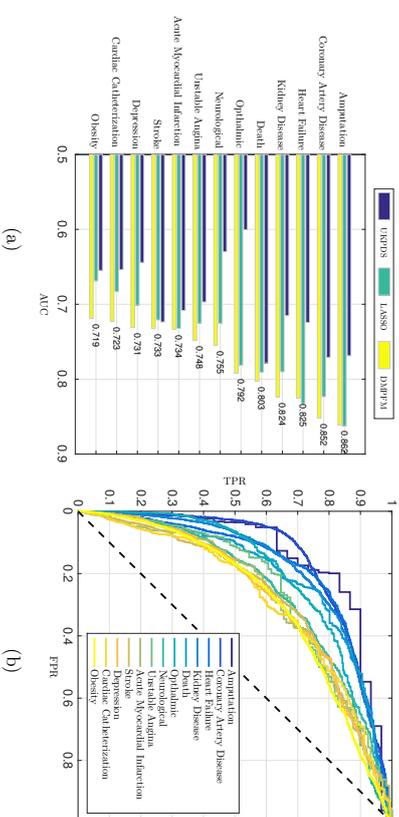

Figure 2: Test AUC and ROC curves from multi-label classification experiment. (a) AUC values for UKPDS, sparse logistic regression (LASSO) and DMPFM. Values beside each bar group correspond to AUC values obtained by DMPFM. (b) ROC curves from DMPFM. Each curve represents represents a classification task for an outcome. The dashed line is the AUC of a random classifier.

Table 4 shows average test AUCs for Naive1, Naive2 and DMPFM and different model architectures. Averages are computed over the 13 outcomes in Table 1. We see from the results for Naive1 that Codes carry significantly more classification power than Med and Lab modalities. Naive2, which combines all modalities into a single data matrix performs consistently better than Naive1, and DMPFM performs the best by a considerable margin, taking into account the size of the test set. In terms of model size, the largest three-layer model performs the best, closely followed by models of size 96-48-24 and 96-48.

Results in Figure 2a show test AUC values as bars for each outcome individually. We compare DMPFM against two baselines, UKPDS and sparse logistic regression. We see that DPMFM outperforms the others in nearly all classification tasks except for heart failure, in which sparse logistic regression (LASSO) performs best, and amputation, where DMPFM and LASSO perform about the same. Note that LASSO is considerably sparser than our model, because it tends to exclude heavily correlated variables, however we observed that our model tends to include the same variables deemed important by LASSO, as a subset. In Figure 2a we also show test AUC values obtained by DMPFM sorted in decreasing order, with corresponding ROC curves in Figure 2b.

The outcomes with the greatest predictive power was amputation and the lowest was obesity. Upon further examination these have potentially interesting clinical drivers. For example amputation of limbs in diabetic patients is often the result of longstanding neuropathy and microvascular damage hindering the ability of patients to not only identify injuries but also heal. We note that the second and fourth authors are medical doctors, and provided all medical analysis. A common clinical scenario involves patients with foot

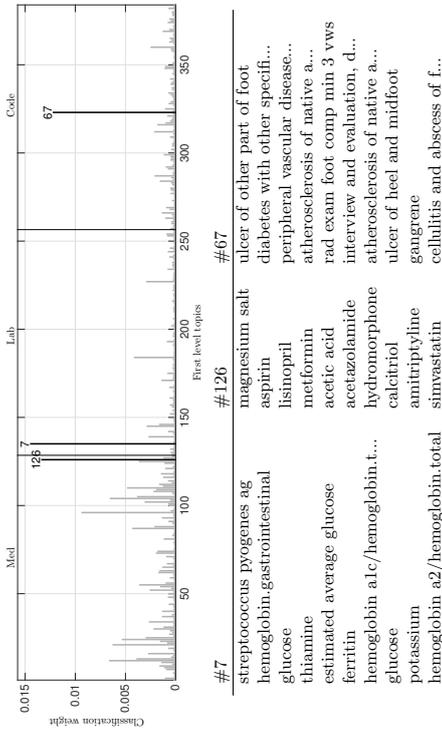

Figure 3: Top classification weights and topics associated with amputation. We show the top 10 words (bottom panel) from first-layer topics with the largest 3 classification weights (top panel), namely meds # 126, labs #7 and codes #67.

ulcerations that go undetected and result in gangrenous limbs and ultimately amputation. By plotting the classification coefficients for amputation (see Figure 3:top), we identify the top three contributors to this outcome (medications #126, labs #7, and codes #67) in Figure 3:bottom. In medications topic #126, we find the usage of standard diabetes, cholesterol and hypertension medications. Notably we also found Amitriptyline, which can be used to treat patients with diabetic neuropathy. In Labs #7, we identify laboratory tests that would be common in evaluating neuropathy (thiamine deficiency) and a test for a bacterial species common in skin infections, *Streptococcus Pyogenes* Antigen. This would be common antigen for a patient with skin infections including foot ulcerations. Lastly, the codes #67 refer to foot ulcers and peripheral vascular disease. Peripheral vascular disease can result from the accumulation of fatty deposits in the vasculature of the extremities and can be exacerbated by the microvascular damage of diabetes. While additional evaluation of topics with high classification coefficients may elicit unexpected predictors of amputation, this initial analysis revealed that the highest scoring topics correlated well with clinical intuition.

The poor predictive power for obesity likely rests with its prevalence in T2DM populations. Metabolic syndrome, a constellation of symptoms including hyperlipidemia, hypertension and obesity is a strong risk factor for obesity. An examination of contributing first-layer topics reveals medications that would be typical for a patient with symptoms of metabolic syndrome. The main lab first-layer topic shares the same topic #7 as in amputation. Interestingly, morbidly obese patients also share a high incidence of skin infections

#3	#13	#19
acid medication	digoxin	clididine

and pressure induced ulcerations due to their sedentary behaviors. Lastly, the code topics have codes related to abnormal weight gain.

4.4 Analysis of multi-modality model

We also examined the ability of the DPFA model to generate topics that represent intuitive medical concepts. For illustrative purposes, we discuss the intra-modality correlation of first and second level topics (meta-topics), starting with the medications mode and expand to other modalities. We plot the correlations between medication topics in Figure 4. We show first-layer topics (boxes) within a modality. Each box contains the first four words with the highest probability mass in that topic. The topics are connected into meta-topics (blue circles) representing both intra- and inter-modality correlations. As we see, the graph is considerably sparse taking into account that each meta-topic can have up to 128 edges. As a quantitative summary of graph sparsity, we note that the average node degree of the complete⁷ medication graph is 18 (edges in the graph are present if their weight is larger than 1e-2).

The center of the plot in Figure 4 includes topics (based on lowest layer in the model, touching the data) and meta-topics (based on the second layer in the model) with the highest level of correlation with other topics. Unsurprisingly, the central medicine topic (#3, see Table 5) includes the medication metformin, a first-line treatment for T2DM, and duloxetine, a treatment for peripheral neuropathy. Interestingly, this topic also includes several steroids including dexamethasone and budesonide, which can induce or worsen T2DM.

To better interpret the correlation structure, we started with meta-topics and explored both intra- and inter-modality correlation. To ease interpretability we focused on meta-topics with fewer connections. We found that many of the meta-topics represented coherent clinical narratives based on the discovered first-layer topics and meta-topics. For example the meta-topic #29 in Figure 5, includes first-layer medicine topics #19 #13 in Table 5. These two collections represent a wide variety of medications used to treat co-morbidities common to T2DM. However, this list also includes opioid pain killers and a chemotherapeutic agent, cyclosporine. While difficult to interpret with only intra-modality correlation,

7. The graph in Figure 4 only shows top four connections for clarity.

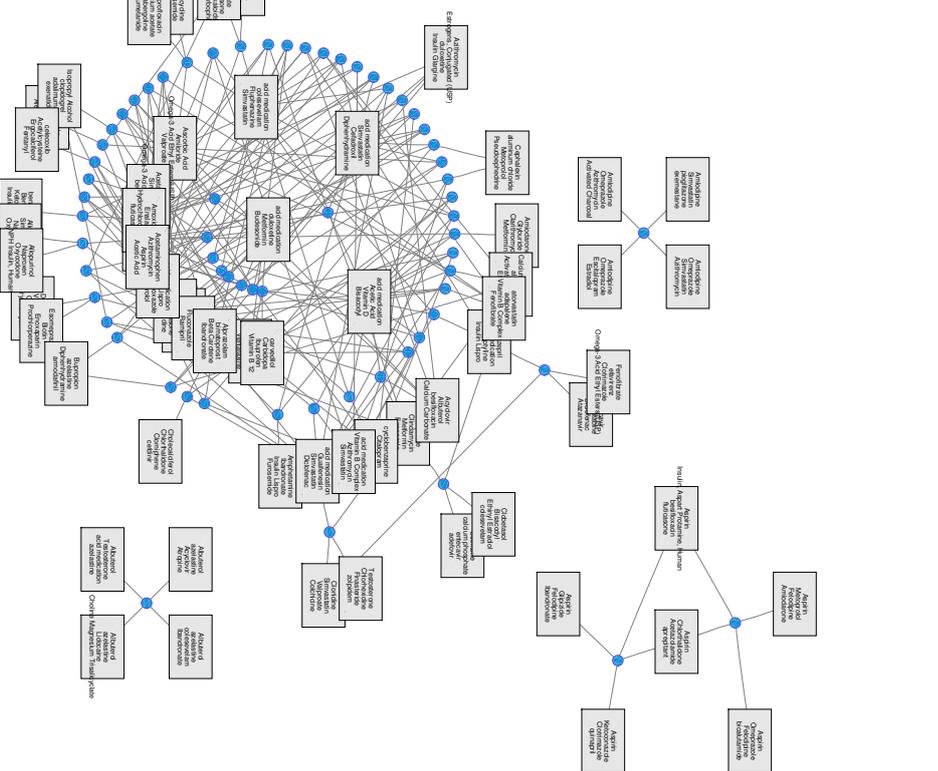

Figure 4: Graph representation obtained for medication interactions. Meta-topic are denoted by blue circles and first-layer topics as boxes, with word lists corresponding to the top four medications in first-layer topics, $\psi_k^{(1)}$. For clarity, we only show the top four connections between meta-topics and their associated topics.

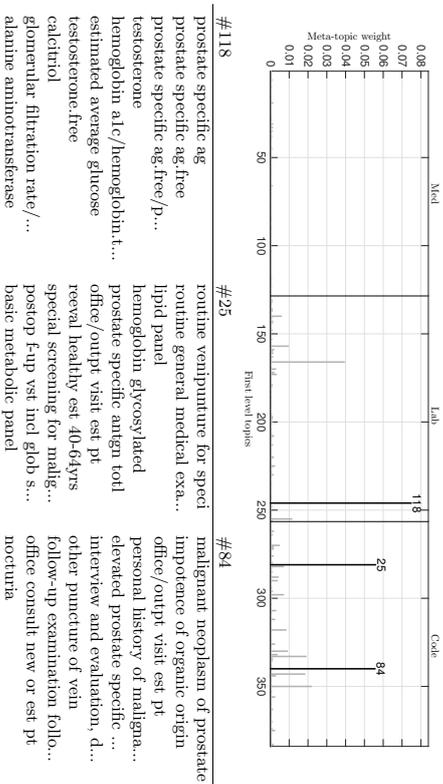

Figure 5: Top weights and topics associated with meta-topic #29. We show the top 10 words (bottom panel) from first-layer topics with the largest 3 meta-topic weights (top panel), namely labs #118 and codes #25 and #84.

further examination of first-layer topics across modalities that contribute disproportionately to this meta-topic identified laboratory and diagnostics codes which expand the narrative of this meta-topic. A patient weighted heavily with this meta-topic would have laboratory results characterized by hematuria (blood in urine) and prostate specific antigen testing. The combination of these medication and laboratory topics suggests a patient with metastatic prostate cancer causing pain and hematuria. This is confirmed when examining the first-layer code topic #84, which includes the code for malignant prostate cancer.

In another example, we explore meta-topic #3 in Figure 6, a topic that does not necessarily make intuitive sense, but could hint at the power of DPFA to identify novel correlations between different data. This meta-topic has two prominent first-layer medication topics. While the first medication topic, #33, contains a mix of hypertensive and antiviral medications, the second topic, #120, includes two notable drugs alprazolam (Xanax) and baclofen, a muscle relaxant. While these two medications may relate to the anxiety, myalgia and insomnia codes, we see in first-layer topic #19 for codes, it would be interesting to explore other first-layer topics contribute to this meta-topic and connect with other conditions identified such as major depressive disorder and chronic pain.

5. Discussion

In 2012, the American Diabetes Association estimated that the economic burden of diabetes in the United States exceeded 245 billion dollars⁸. High-throughput and widely available

8. See <http://diabetes.org/advocacy/news-events/cost-of-diabetes.html>.

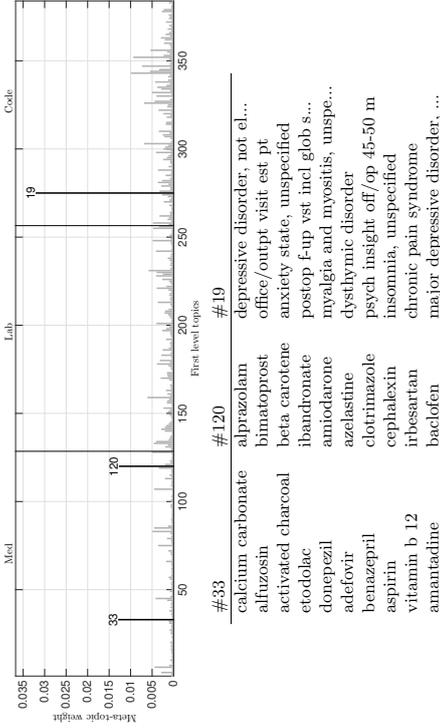

Figure 6: Top weights and topics associated with meta-topic #3. We show the top 10 words (bottom panel) from first-layer topics with the largest 3 meta-topic weights (top panel), namely labs #19 and codes #33 and #120.

methods to predict morbidity and mortality outcomes for patients would improve the deployment of medical resources, and may reduce costs through increased preventative care or reduced futile care.

Our initial evaluation of the proposed method illustrated that DMPFM can identify multiple candidate phenotypes from EHR data without expert or user supervision. Further, these candidate topics, when defined in the context of a classification task, can significantly outperform current benchmarks for risk prediction derived from large-scale clinical studies. This was perhaps unsurprising as we are able to utilize much richer datasets (in both number of clinical variables and patient numbers) than most clinical studies. We are also able to estimate the important factors directly from the data, thus minimizing bias on the behalf of the original study designers.

Despite these encouraging findings, many challenges remain before such high-throughput phenotyping efforts can be used in a clinical setting. First, the clinical evaluation of DMPFM for EHR relied on two clinical experts (second and fourth authors) to perform the data reconciliation and evaluate the topic groupings. This evaluation is subject to bias, and a more extensive study involving a panel of clinicians is necessary to validate this method's robustness. Second, as discussed above, some of the clinical phenotypes are not easily interpreted. Although our method encourages sparsity there remains a high level of correlation both within and between topics. These topics have many interconnections that remain to be fully explored. In addition, the appropriate metrics to evaluate words (entities), topics and meta-topics for clinical applications requires further research. Third, even in cases where we can generate a narrative around candidate phenotypes, many topics still contained

words/entities from each modality that appeared irrelevant to the larger meta-topic. Additional research is needed to establish the clinical relevance of these words/entities. Fourth, although we present a generative process for DMPFM, we did not perform experiments exploring the generation of topic weights for new patients. It would also be interesting to explore the number of patients that would be required to generate a fully comprehensive but sparse set of topics for any given patient population. Lastly, although it appears that we can generate meta-topics that represent patients, we did not perform case review of these patients that review those topics/meta-topics. It would be necessary to perform off-line review by physicians to establish clinical correlation between computational phenotypes and the true patient status.

The DMPFM is an extensible model applicable to any data modalities that can be represented with count data. This would naturally extend to free-text physician and nursing notes (in this case the counts are of actual words) as well as notes from specialty services, such as radiology and pathology. With the paucity of additional data that is contained with the medical record, we are confident that we can develop improved representations of patient traits that may lead to better diagnosis and treatment outcomes.

Appendix A. Stochastic variational inference

SVI is a scalable algorithm for approximating posterior distributions consisting of EM-style local-global updates, in which subsets of a dataset (*mini-batches*) are used to update in closed-form the variational parameters controlling both the local and global structure of the model in an iterative fashion Hoffman et al. (2013). This is done by using stochastic optimization with noisy natural gradients to optimize the variational objective function. Additional details and theoretical foundations of SVI can be found in Hoffman et al. (2013).

In practice the algorithm proceeds as follows, where again we have omitted the layer index for clarity: (i) let $\{\Psi^{(t)}, r_k^{(t)}, \lambda^{(t)}\}$ be the global variables at iteration t . (ii) Sample a mini-batch from the full dataset. (iii) Compute updates for the variational parameters of the local variables using (layer index omitted for clarity)

$$\begin{aligned} \theta_{mkn} &\propto \exp(\mathbb{E}[\log \psi_{mk}] + \mathbb{E}[\log \theta_{kn}]), \\ \theta_k &\sim \text{Gamma} \left(\mathbb{E}[r_k] \mathbb{E}[h_{kn}] + \sum_{m=1}^M \phi_{mkn}, b^{-1} \right), \\ h_{kn} &\sim \mathbb{E}[p(x_{:kn} = 0)] \text{Bernoulli}(\mathbb{E}[\tilde{\pi}_{kn}] \mathbb{E}[\tilde{\pi}_{kn}]^{-1}) + \mathbb{E}[p(x_{:kn} \geq 1)] \\ r_k &\sim \text{Gamma} \left(1 + \sum_n \mathbb{E}[u_{kn}], 1 - \sum_n \mathbb{E}[p(h_{kn} = 1)] \log(1 - b) \right), \\ z_{kn} &\sim \mathbb{E}[p(h_{kn} = 1)] \text{Poisson} + \left(\tilde{\lambda}_{kn} \right), \end{aligned}$$

where

$$\mathbb{E}[x_{mkn}] = \phi_{mkn}, \quad \mathbb{E}[\tilde{\pi}_{kn}] = \mathbb{E}[\pi_{kn}](1 - b_n)^{\mathbb{E}[r_k]}, \quad \mathbb{E}[u_{kn}] = \sum_{j=1}^{x_{kn}} \mathbb{E}[r_k] (\mathbb{E}[r_k] + j - 1)^{-1}.$$

In practice, expectations for θ_{kn} and h_{kn} are computed in log-domain. (iv) Compute a local update for the variational parameters of the global variables (only Ψ is shown) using

$$\hat{\psi}_{mk} = \eta + \frac{N}{NB} \sum_{n=1}^{N_B} x_{mn} \phi_{mkn}, \quad (13)$$

where N and N_B are sizes of the corpus and mini-batch, respectively. Finally, we update the global variables as $\psi_k^{(t+1)} = (1 - \rho_l) \psi_k^{(t)} + \rho_l \hat{\psi}_k$, where $\rho_l = (t + \tau)^{-\kappa}$. The forgetting rate, $\kappa \in (0.5, 1]$ controls how fast previous information is forgotten and the delay, $\tau \geq 0$, down-weights early iterations. These conditions for κ and τ guarantee that the iterative algorithm converges to a local optimum of the variational objective function. In the experiments, we set $\kappa = 0.7$ and $\tau = 128$.

Appendix B. Inference details

Conditional posteriors for Gibbs sampling (layer index omitted for clarity):

$$\begin{aligned} \psi_k &\sim \text{Dirichlet}(\eta + x_{1k}, \dots, \eta + x_{Mk}), \\ \theta_{kn} &\sim \text{Gamma}(r_k h_{kn} + x_{kn}, b^{-1}), \\ h_{kn} &\sim \delta(x_{kn} = 0) \text{Bernoulli}(\tilde{\pi}_{kn}(\tilde{\pi}_{kn} + 1 - \pi_{kn})^{-1}) + \delta(x_{kn} \geq 1), \\ r_k &\sim \text{Gamma}\left(1 + \sum_n u_{kn}, 1 - \sum_n h_{kn} \log(1 - b)\right), \\ z_{kn} &\sim \delta(h_{kn} = 1) \text{Poisson}_+(\tilde{\lambda}_{kn}), \end{aligned}$$

where $\text{Poisson}_+(\cdot)$ is the zero-truncated Poisson distribution and

$$\begin{aligned} x_{mk} &= \sum_{n=1}^N x_{mkn}, \\ x_{kn} &= \sum_{m=1}^M x_{mkn}, \\ \tilde{\pi}_{kn} &= \pi_{kn} (1 - b)^{r_k}, \\ u_{kn} &= \sum_{j=1}^{x_{kn}} u_{knj}, \quad u_{knj} \sim \text{Bernoulli}\left(\frac{r_k}{r_k + j - 1}\right). \end{aligned} \quad (14)$$

Note that for multilayer models, $\pi_{kn}^{(l)} = 1 - \exp(\lambda_{kn}^{(l+1)})$. The data augmentation scheme for r_k via u_{kn} is described in Zhou and Carin (2015).

For the discriminative DPFM, lets denote latent counts for \hat{y}_n as \hat{x}_{ckn} , with summaries analogous to (14), as \hat{x}_{ck} and \hat{x}_{kn} . Then,

$$\begin{aligned} \mathbf{b}_k &\sim \text{Dirichlet}(\zeta + \hat{x}_{1k}, \dots, \zeta + \hat{x}_{Ck}), \\ \theta_{kn} &\sim \text{Gamma}(r_k h_{kn} + x_{kn} + \hat{x}_{cnk}, b^{-1}), \\ h_{kn} &\sim \delta(x_{kn} = 0 \wedge \hat{x}_{cnk} = 0) \text{Bernoulli}(\tilde{\pi}_{kn}(\tilde{\pi}_{kn} + 1 - \pi_{kn})^{-1}) + \delta(x_{kn} \geq 1 \vee \hat{x}_{cnk} \geq 1). \end{aligned}$$

Provided that θ_n and \mathbf{b}_n are shared by two PFA modules, one for the count data, \mathbf{x}_n , and the other for the labels, \hat{y}_n , their conditional posteriors are functions of latent counts coming from both sources, x_{kn} and \hat{x}_{cnk} , respectively.

Abstract

Cluster analysis by nonnegative low-rank approximations has experienced a remarkable progress in the past decade. However, the majority of such approximation approaches are still restricted to nonnegative matrix factorization (NMF) and suffer from the following two drawbacks: 1) they are unable to produce balanced partitions for large-scale manifold data which are common in real-world clustering tasks; 2) most existing NMF-type clustering methods cannot automatically determine the number of clusters. We propose a new low-rank learning method to address these two problems, which is beyond matrix factorization. Our method approximately decomposes a sparse input similarity in a normalized way and its objective can be used to learn both cluster assignments and the number of clusters. For efficient optimization, we use a relaxed formulation based on Data-Cluster-Data random walk, which is also shown to be equivalent to low-rank factorization of the doubly-stochastically normalized cluster incidence matrix. The probabilistic cluster assignments can thus be learned with a multiplicative majorization-minimization algorithm. Experimental results show that the new method is more accurate both in terms of clustering large-scale manifold data sets and of selecting the number of clusters.

Keywords: cluster analysis, probabilistic relaxation, doubly stochastic matrix, manifold, multiplicative updates

1. Introduction

Cluster analysis is a main task of exploratory data mining, and a common technique for statistical data analysis used in many fields. Usually, optimization of the clustering objectives is NP-hard and relaxation to “soft” clustering is a widely used technique. In the past decade, various low-rank matrix approximation objectives, together with a nonnegativity constraint on the cluster indicator matrix, have widely been used for the relaxation purpose.

The most popular nonnegative low-rank approximation method is *Nonnegative Matrix Factorization* (NMF; Lee and Seung, 1999, 2001). It finds a matrix which approximates the pairwise similarities between the data items and can be factorized into two nonnegative low-rank matrices. NMF was originally applied to vector data, for which Ding et al. (2010) did later show that it is equivalent to the classical k -means method. NMF has also been applied to weighted graph defined by the pairwise similarities of the data items. For example, Ding et al. (2008) presented Nonnegative Spectral Cuts by using a multiplicative algorithm; and Arora et al. (2011, 2013) proposed Left Stochastic Decomposition that approximates a similarity matrix based on Euclidean distance and a left-stochastic matrix. Topic modeling represents another example of a related factorization problem. Hofmann (1999) introduced a generative model in *Probabilistic Latent Semantic Indexing* (PLSI) for counting data, which is essentially equivalent to NMF using Kullback-Leibler (KL) divergence and tri-factorizations. Bayesian treatment of PLSI by using Dirichlet priors was later introduced by Blei et al. (2001). Symmetric PLSI with the same Bayesian treatment is called *Interaction Component Model* (ICM; Sinkkonen et al., 2008).

Despite the remarkable progress, the above NMF-type clustering methods still suffer from one or more of the following problems: 1) they are not accurate for the data in curved manifolds; 2) they cannot guarantee balanced partitions; 3) their learning objectives cannot be used to choose the number of clusters. The first problem is common in many real-world clustering tasks, where data are represented by raw features and simple similarity metrics such as Euclidean or Hamming are only accurate in small neighborhoods. This induces sparse accurate similarity information (e.g. as with the K -Nearest-Neighbor for a relatively small K) as input for clustering algorithms. In the big data era, the sparsity is also necessary for computation efficiency for large amounts of data objects. Most existing clustering methods, however, do not handle well the sparse similarity. The second problem arises due to the lack of suitable normalization of partitions in the objective function. Consequently, the resulting cluster sizes can be drastically and spuriously variable, which hampers the general reliability of the methods for applications. The third problem forces users to manually specify the number of clusters or to rely on external clustering evaluation methods which are usually inconsistent with the used learning objective.

In this paper we propose a new clustering method that addresses all the above-mentioned problems. Our learning objective is to minimize the discrepancy between the similarity matrix and the doubly-stochastically normalized cluster incidence matrix, which ensures balanced clusterings. Different from conventional squared Euclidean distance, the discrepancy in our approach is measured by Kullback-Leibler divergence which is more suitable for sparse similarity inputs. Minimizing the objective over all possible partitions automatically returns the most appropriate number of clusters.

We also propose an efficient and convenient algorithm for optimizing the introduced objective function. First, by using a new nonnegative matrix decomposition form, we find an equivalent solution space of low-rank nonnegative doubly stochastic matrices. This provides us a probabilistic surrogate learning objective called Data-Cluster-Data (DCD in short). Next we develop a new multiplicative algorithm for this surrogate function by using the majorization-minimization principle.

The new method is compared against many other clustering methods on various real-world data sets. The results show that the DCD method can often produce more accurate

clusterings, especially for large-scale manifold data sets containing up to hundreds of thousands of samples. We also demonstrate that it can select the number of clusters much more precisely than other existing approaches.

Although a preliminary version of our method has been presented earlier (Yang and Oja, 2012a), the current paper introduces several significant improvements. First, we show that the proposed clustering objective can be used to learn not only the cluster assignments but also the number of clusters. Second, we show that the proposed structural decomposition is equivalent to the low-rank factorization of a doubly stochastic matrix. Previously it was known that the former is a subset of the latter and now we prove that the reverse also holds. Third, we have performed much more extensive experiments, where the results further consolidate our conclusions.

The remainder of the paper is organized as follows. We review the basic clustering objective in Section 2. Its relaxed surrogate, the DCD learning objective, as well as optimization algorithm, are presented in Section 3, and the experimental results in Section 4, respectively. We discuss related work in Section 5 and conclude the paper by presenting possible directions for future research in Section 6.

2. Normalized Output Similarity Approximation Clusterability

Given a set of data objects $\mathcal{K} = \{x_1, \dots, x_N\}$, cluster analysis assigns them into r groups, called clusters, so that the objects in the same cluster are more similar to each other than to those in the other clusters. The cluster assignments can be represented by a *cluster indicator matrix* $\bar{F} \in \{0, 1\}^{N \times r}$, where $\bar{F}_{ik} = 1$ if x_i is assigned to the cluster C_k , and $\bar{F}_{ik} = 0$ otherwise. The *cluster incidence matrix* is defined as $M = \bar{F}\bar{F}^T$. Then $M \in \{0, 1\}^{N \times N}$ and $\bar{M}_{ij} = 1$ iff x_i and x_j are in the same cluster.

Let $S_{ij} \geq 0$ be a suitably normalized similarity measure between x_i and x_j . For a good clustering, it is natural to assume that the matrix S should be close to the cluster incidence matrix \bar{M} . Visually, \bar{M} is a blockwise matrix if we sort the data by their cluster assignment, and S should be nearly blockwise. The discrepancy or approximation error between S and \bar{M} can be measured by a certain divergence $D(S||\bar{M})$, e.g. Euclidean distance or Kullback-Leibler divergence. For example, He et al. (2011); Arora et al. (2011, 2013) used $D(S||\bar{M})$ with Euclidean distance to derive their respective NMF clustering methods.

Directly minimizing $D(S||\bar{M})$ can yield imbalanced partitions (see e.g., Shi and Malik, 2000). That is, some clusters are automatically of much smaller size than others, which is undesirable in many real-world applications. To achieve a balanced clustering, one can normalize \bar{M} to M in the approximation such that $\sum_{i=1}^N \bar{M}_{ij} = 1$ and $\sum_{j=1}^N \bar{M}_{ij} = 1$, or equivalently by normalizing \bar{F} to F with $F_{ik} = \bar{F}_{ik} / \sqrt{\sum_{v=1}^N \bar{F}_{iv}}$. The matrix $M = FF^T$ then becomes *doubly stochastic*. Such normalization has appeared in different clustering approaches (e.g., Ding et al., 2005; Shi and Malik, 2000). In this way, each cluster in M has unitary normalized volume (the ratio between sum of within-cluster similarities and the cluster size; also called normalized association (Shi and Malik, 2000)).

In this work we define clusterability as the maximum proximity between the data and a clustering solution. In similarity-based cluster analysis, $C(S) \stackrel{\text{def}}{=} -\min_{\bar{M}} D(S||\bar{M})$ can be used as a measure of clusterability for the similarity S over all normalized clusterings. For

an easy reference within this paper, we call it *Normalized Output Similarity Approximation Clusterability* (NOSAC) and $D(S||M)$ the NOSAC residual for a specific clustering M . Note that the optimum is taken over partitions which possibly have different values of r . Therefore the *optimization can be used to learn not only cluster assignments but also the number of clusters*. Similarly, minimizing $D(S||M)$ can also be used to select an optimum among partitions produced by e.g. different hyper-parameters or different initializations.

Minimizing $D(S||M)$ or $D(S||\bar{M})$ is equivalent to a combinatorial optimization problem in discrete space which is typically a difficult task (see e.g. Aloise et al., 2009; Mahajan et al., 2009; Shi and Malik, 2000). In practice it is customary to first solve a relaxed surrogate problem in continuous space and then perform discretization to obtain \bar{F} or F . Different relaxations include, for example, nonnegative matrices (Ding et al., 2008; Yang and Oja, 2010) and stochastic matrices Arora et al. (2011, 2013) for the unnormalized indicator \bar{F} in $D(S||\bar{M})$, and orthogonal matrices (Shi and Malik, 2000), as well as nonnegative and orthogonal matrices (Ding et al., 2006; Yang and Oja, 2012b; Yang and Laaksonen, 2007; Yoo and Choi, 2008; Pompili et al., 2013) for the normalized indicator F in $D(S||M)$.

In this paper we emphasize that the doubly stochasticity constraint is essential for balanced clustering, which cannot be guaranteed by the above relaxations. Besides this constraint, we also keep the nonnegativity constraint to achieve sparser low-rank factorizing matrix. These conditions as a whole provide a tighter relaxed solution space \mathbb{A} for M :

$$\mathbb{A} = \left\{ A \mid \forall_i, \sum_{j=1}^N A_{ij} = 1; A = UU^T; U \in \mathbb{R}^{N \times r}; \forall_i, k, U_{ik} \geq 0 \right\}. \quad (1)$$

To our knowledge, however, there is no existing technique that can minimize a generic cost function over low-rank A or over U . The major difficulty arises because the doubly stochasticity constraint is indirectly coupled with the factorizing matrix U . Note that this optimization problem is different from normalizing the input similarity matrix to be doubly stochastic before clustering (Zass and Shashua, 2006; He et al., 2011; Wang et al., 2012).

3. Low-rank Doubly Stochastic Matrix Decomposition by Probabilistic Relaxation

In this section we show how to minimize $D(S||A)$ over $A \in \mathbb{A}$ with suitable choice of discrepancy measure and complexity control. First we identify an equivalent solution space of \mathbb{A} which is easier for optimization. Then we develop the multiplicative minimization algorithm for finding a stationary point of the objective function.

3.1 Probabilistic relaxation

We find an alternative solution space by relaxing M to another matrix B in the matrix set

$$\mathbb{B} = \left\{ B \mid B_{ij} = \sum_{k=1}^r \frac{W_{ik}W_{jk}}{\sum_{v=1}^N W_{iv}W_{kv}}; W \in \mathbb{R}^{N \times r}; \forall_i \sum_{k=1}^r W_{ik} = 1; \forall_i, k, W_{ik} \geq 0 \right\}. \quad (2)$$

Comparing the original low-rank doubly stochastic matrix decomposition space \mathbb{A} with the DCD space \mathbb{B} shows that the following equivalence holds:

Theorem 1 $\mathbb{A} = \mathbb{B}$.

The proof is given in Appendix A. Previously it was known that $\mathbb{A} \supseteq \mathbb{B}$ (Yang and Oja, 2012a). Now this theorem shows that $\mathbb{A} \subseteq \mathbb{B}$ also holds, which implies that we do not miss any solution in \mathbb{A} by using \mathbb{B} . We prefer \mathbb{B} because the minimization in \mathbb{B} is easier, as there is no explicit doubly stochasticity constraint and we can work with the right stochastic matrix W . Note that W appears in both the numerator and denominator within the sum over k . Therefore this structural decomposition goes beyond conventional nonnegative matrix factorization schemes.

A probabilistic interpretation of B is as follows. Let $W_{ik} = P(k|i)$, the probability of assigning the i th data object to the k th cluster.¹ In the following, i, j , and v stand for data sample indices (from 1 to N) while k and l stand for cluster indices (from 1 to r). Without preference to any particular sample, we impose a uniform prior $P(j) = 1/N$ over the data samples. With this prior, we can compute

$$P(j|k) = \frac{P(k|j)P(j)}{\sum_{v=1}^r P(k|v)P(v)} = \frac{P(k|j)}{\sum_{v=1}^r P(k|v)} \quad (3)$$

by the Bayes' formula. Then we can see that

$$B_{ij} = \sum_{k=1}^r \frac{W_{ik}W_{jk}}{\sum_{v=1}^r W_{vk}} \quad (4)$$

$$= \sum_{k=1}^r \frac{P(k|j)}{\sum_{v=1}^r P(k|v)} P(k|i) \quad (5)$$

$$= \sum_{k=1}^r P(j|k)P(k|i) \quad (6)$$

$$= P(j|i). \quad (7)$$

That is, if we define a bipartite graph with the data samples and clusters as graph nodes, B_{ij} is the probability that the i th data node reaches the j th data node via a cluster node (see Figure 1). We thus call this DCD random walk or DCD decomposition after the Data-Cluster-Data walking paths. Since B is nonnegative and symmetric (which follows easily from the definition), in non-trivial cases it can be seen as another similarity measure between data objects. Our learning target is to find a good approximation between the input similarity matrix S and the low-rank output similarity B .

3.2 Kullback-Leibler divergence

Euclidean distance or Frobenius norm is a conventional choice for the discrepancy measure D . However, it is improper for many real-world clustering tasks where the raw data features are weakly informative. Similarities calculated with most simple metrics such as Euclidean distance or Hamming distance are then only accurate in a small neighborhood, whereas data

1. We use the abbreviation to avoid excessive notation. In full, $P(k|i) \stackrel{\text{def}}{=} P(\beta = C_k | \xi = x_i)$, where β and ξ are random variables with possible outcomes in clusters $\{C_k\}_{k=1}^r$ and data samples $\{x_i\}_{i=1}^N$, respectively. Similarly $P(i) \stackrel{\text{def}}{=} P(\xi = x_i)$ and $P(i|k) \stackrel{\text{def}}{=} P(\xi = x_i | \beta = C_k)$.

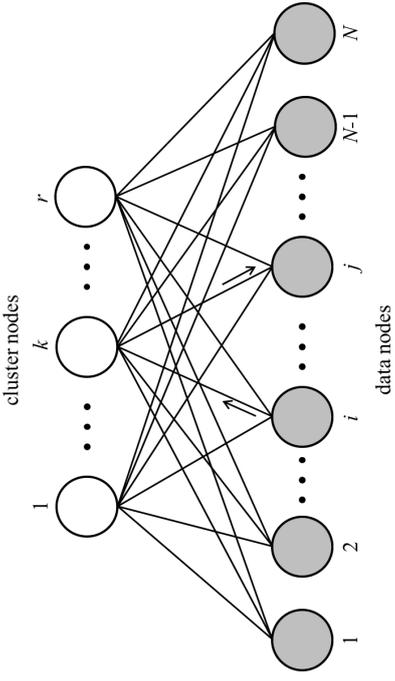

Figure 1: Data-cluster bipartite graph for N data samples and r clusters ($r < N$). The arrows show a Data-Cluster-Data (DCD) random walk path, which starts at the i th data node (sample) and ends at the j th data node via the k th cluster node.

points from different clusters often become mixed in wider neighborhoods. That is, only a small fraction of similarities, e.g. K -Nearest-Neighbor similarities with a relatively small value of K , are reliable and should be fed as a sparse input to clustering algorithms, while the similarities between the other, non-neighboring samples are set to zero. Least-square fitting with such a sparse similarity matrix is dominated by the approximation to the many zeros, which typically yields only poor or mediocre clustering results.

Here we propose to use (generalized) Kullback-Leibler divergence which is a more suitable approximation error measure between the sparse input similarity S and the dense output similarity B , because the approximation relies more heavily on the large values in S (see e.g. Févotte and Idier, 2011). The underlying Poisson likelihood models more appropriately the rare occurrences of reliable similarities. We thus formulate our learning objective in the relaxed DCD space as the following optimization problem:

$$\underset{W \geq 0}{\text{minimize}} \quad D_{\text{KL}}(S||B) = \sum_{i=1}^N \sum_{j=1}^N \left(S_{ij} \log \frac{S_{ij}}{B_{ij}} - S_{ij} + B_{ij} \right) \quad (8)$$

$$\text{subject to} \quad B_{ij} = \sum_{k=1}^r W_{ik}W_{jk} / \sum_{v=1}^r W_{vk}, \quad (9)$$

$$\sum_{k=1}^r W_{ik} = 1, \quad i = 1, \dots, N. \quad (10)$$

Dropping the constant terms in $D_{KL}(S||B)$, the objective function is equivalent to maximizing $\sum_{i=1}^N \sum_{j=1}^N S_{ij} \log B_{ij}$ because $\sum_{i=1}^N \sum_{j=1}^N B_{ij} = N$. Note that this form is similar to PLST (Hohmann, 1999) except for the decomposition form in B . Therefore we can enjoy the similar complexity control by using a Dirichlet prior (see Section 3.3).

Kullback-Leibler divergence also facilitates optimization, as we shall see in the algorithm development below. In objective and gradient calculation, it is straightforward to involve only the non-zero entries in S which brings an efficient implementation. Moreover, given properties of the logarithm function, we can break the comprehensive structure of B into several additive terms when majorizing the objective with the convex-concave procedure (Hunter and Lange, 2004). As a result, this yields relatively simple update rules in the algorithm. See Section 3.4 and Appendix B for details.

3.3 Regularization

The DCD learning objective function is parameterized by the matrix W whose rows sum to one. Assuming that these rows are observations from a common Dirichlet distribution, we can apply the log-Dirichlet prior to control the complexity in W . This gives the cost function of our DCD clustering method:

$$\mathcal{J}(W) = - \sum_{i=1}^N \sum_{j=1}^N S_{ij} \log B_{ij} - (\alpha - 1) \sum_{i=1}^N \sum_{k=1}^r \log W_{ik}. \quad (11)$$

This is also equivalent to regularization by using a total Shannon information term.

If S_{ij} are integers, the DCD objective is the log-likelihood of the following generative model: 1) draw the rows of W according to uniform Dirichlet distribution with parameter α ; 2) for $t = 1, \dots, T$, add one to entry $(i, j) \sim \text{Multinomial}(\frac{1}{N}B, 1)$. The Dirichlet prior vanishes when $\alpha = 1$. By using $\alpha > 1$, the prior gives further relaxation by smoothing the W entries, which is often desired in early stages of W learning.

Although it is possible to construct a multi-level graphical model similar to the Dirichlet process topic model (Blei et al., 2001; Sinkkonen et al., 2008), we emphasize that the smallest approximation error (i.e. with $\alpha = 1$) is the final DCD goal. The Dirichlet prior is used only in order to ease the optimization. Therefore we do not employ more complex generative models.

3.4 Optimization

Multiplicative updates are widely used in optimization for nonnegative matrix factorization problems. To minimize an objective \mathcal{J} over a nonnegative matrix W , we first calculate the gradient and separate it into two nonnegative parts ($\nabla_{ik}^+ \geq 0$ and $\nabla_{ik}^- \geq 0$):

$$\nabla_{ik} \stackrel{\text{def}}{=} \frac{\partial \mathcal{J}}{\partial W_{ik}} = \nabla_{ik}^+ - \nabla_{ik}^-. \quad (12)$$

Usually the separation can easily be identified from the gradient. Then the algorithm iteratively applies a multiplicative update rule $W_{ik} \leftarrow W_{ik} \frac{\nabla_{ik}^-}{\nabla_{ik}^+}$ until convergence. Such algorithms have several attractive properties, as they naturally maintain the positivity of

W and do not require extra effort to tune learning step size. For a variety of NMF problems, such multiplicative updates monotonically decrease \mathcal{J} after each iteration and therefore W can converge to a stationary point (Yang and Oja, 2011).

We cannot directly apply the above multiplicative fixed-point algorithm to DCD because there are probability constraints on the W rows. In practice, projecting the W rows to the probability simplex after each iteration would often lead to poor clustering result.

Instead, we employ a relaxing strategy (Zhu et al., 2013) to handle the probability constraint. We first introduce Lagrangian multipliers $\{\lambda_i\}_{i=1}^N$ for the constraints:

$$\mathcal{L}(W, \lambda) = \mathcal{J}(W) + \sum_i \lambda_i \left(\sum_{k=1}^r W_{ik} - 1 \right). \quad (13)$$

This suggests a preliminary multiplicative update rule for W :

$$W'_{ik} = W_{ik} \frac{\nabla_{ik}^- - \lambda_i}{\nabla_{ik}^+}, \quad (14)$$

where

$$\frac{\partial \mathcal{J}}{\partial W} = \underbrace{\left[(W^T Z W)_{kk} s_k^{-2} + W_{ik}^{-1} \right]}_{\nabla_{ik}^+} - \underbrace{\left[2 (Z W)_{kk} s_k^{-1} + \alpha W_{ik}^{-1} \right]}_{\nabla_{ik}^-}, \quad (15)$$

with $Z_{ij} = S_{ij}/B_{ij}$ and $s_k = \sum_{i=1}^N W_{ik}$. Imposing $\sum_k W'_{ik} = 1$ and isolating λ_i , we obtain

$$\lambda_i = \frac{b_i - 1}{a_i}, \quad (16)$$

where

$$a_i = \sum_{l=1}^r \frac{W_{il}}{\nabla_{il}^+}, \quad \text{and} \quad b_i = \sum_{l=1}^r \frac{W_{il}}{\nabla_{il}^-}. \quad (17)$$

Putting this λ back in Eq. 14, we obtain

$$W'_{ik} \leftarrow W_{ik} \frac{\nabla_{ik}^- a_i + 1 - b_i}{\nabla_{ik}^+ a_i}. \quad (18)$$

To maintain the positivity of W , we add b_i to both the numerator and denominator, which does not change the fixed point and gives the ultimate update rule:

$$W_{ik} \leftarrow W_{ik} \frac{\nabla_{ik}^- a_i + 1}{\nabla_{ik}^+ a_i + b_i}. \quad (19)$$

The above calculation steps are summarized in Algorithm 1. In implementation, one does not need to construct the whole matrix B . The ratio $Z_{ij} = S_{ij}/B_{ij}$ only requires calculation on the non-zero entries of S .

The above algorithm obeys a monotonicity guarantee provided by the following theorem.

Algorithm 1 Relaxed MM Algorithm for DCD

Input: similarity matrix S , number of clusters r , positive initial guess of W .

Output: cluster assigning probabilities W .

repeat

$$B_{ij} = \sum_{k=1}^r \frac{W_{ik}W_{jk}}{\sum_{v=1}^r W_{vk}}$$

$$Z_{ij} = S_{ij}/B_{ij}$$

$$s_k = \sum_{v=1}^N W_{vk}$$

$$\nabla_{ik}^- = 2(ZW)_{ik}s_k^{-1} + \alpha W_{ik}^{-1}$$

$$\nabla_{ik}^+ = (W^TZW)_{ik}s_k^{-2} + W_{ik}^{-1}$$

$$a_i = \sum_{l=1}^r \frac{W_{il}}{\nabla_{il}^+}, \quad b_i = \sum_{l=1}^r W_{il} \frac{\nabla_{il}^-}{\nabla_{il}^+}$$

$$W_{ik} \leftarrow \frac{\nabla_{ik}^- a_i + 1}{W_{ik} \frac{\nabla_{ik}^-}{\nabla_{ik}^+} a_i + b_i}$$

until W converges under the given tolerance

Theorem 2 Denote W^{new} the updated matrix after each iteration of Algorithm 1. It holds that $\mathcal{L}(W^{new}, \lambda) \leq \mathcal{L}(W, \lambda)$ with $\lambda_i = (b_i - 1)/a_i$.

The proof (given in Appendix B) mainly follows the Majorization-Minimization procedure (Hunter and Lange, 2004; Yang and Oja, 2011). The theorem shows that Algorithm 1 jointly minimizes the approximation error and drives the rows of W towards the probability simplex. The Lagrangian multipliers are adaptively and automatically selected by the algorithm, without extra human tuning effort. The quantities b_i are the row sums of the unconstrained multiplicative learning result, while the quantities a_i balance between the gradient learning force and the probability simplex attraction. Besides convenience, we find that this relaxation strategy works more robustly than the brute-force projection after each iteration.

DCD minimizes the relaxed NOSAC residual for a particular r . To select the best number of clusters, we can run Algorithm 1 over a range of r values, discretize W to obtain the hard cluster assignment \bar{F} , and return the one with smallest NOSAC residual. See Section 4.2 for examples.

3.5 Initialization

Proper initialization is needed to achieve satisfactory performance for practically any clustering method that involves non-convex optimization. DCD accepts any clustering results as its starting point. In our implementation, we add a small positive perturbation (e.g. 0.2) to all entries of the initial cluster indicator matrix. Next, the perturbed matrix is fed to our optimization algorithm (with $\alpha = 1$ in Algorithm 1). Among all runs of DCD, we return the clustering result with the smallest $D(S||M)$.

In particular, the regularized DCD (i.e. with various $\alpha \neq 1$) can also provide initialization for the non-regularized DCD (i.e. with $\alpha = 1$). That is, the parameter α only appears in the initialization and its best value is also determined by the smallest resulting $D(S||M)$.

4. Experiments

We have tested the DCD method and compared it with other existing cluster analysis approaches. The experiments were organized in two groups: 1) we ran the methods with a fixed number of clusters, mainly comparing their clustering accuracies; 2) we ran DCD across different r values, demonstrating how to use NOSAC residual to determine the optimal number of clusters as well as its advantage over several other clustering evaluation methods.

4.1 Clustering with known number of clusters

In the first group of experiments, the number of the ground truth classes in the data sets was known in advance, and we fixed r to that number. We compared DCD with a variety of state-of-the-art clustering methods, including Projective Nonnegative Matrix Factorization (PNMF; Yang et al., 2007; Yang and Oja, 2010), Nonnegative Spectral Clustering (NSC; Ding et al., 2008), Orthogonal Nonnegative Matrix Factorization (ONMF; Ding et al., 2006), Probabilistic Latent Semantic Indexing (PLSI; Hofmann, 1999), Left-Stochastic Decomposition (LSD; Arora et al., 2011, 2013), as well as two classical methods k-means (Lloyd, 1982) and Normalized Cut (Ncut; Shi and Malik, 2000). Besides NMF, we have also selected several recent clustering methods, including 1-Spectral (1-Spec; Hein and Bühler, 2010), Landmark-based Spectral Clustering (LSC; Chen and Cai, 2011; Cai and Chen, 2015), Sparse Subspace Clustering (SSC; Elhamifar and Vidal, 2009, 2013), and Multiclass Total Variation (MTV; Bresson et al., 2013). There are some other recent methods (e.g., Rodriguez and Laio, 2014; Liu and Tao, 2016), which is however not scalable to large numbers of samples and thus not included here.

We used default settings in the compared methods. The NMF-type methods were run with maximum 10,000 iterations of multiplicative updates and with convergence tolerance 10^{-6} . We used ratio Cheeger cut for 1-Spec. All methods except k-means, Ncut, 1-Spec, LSC, SSC, and MTV were initialized by Ncut. That is, their starting point was the Ncut cluster indicator matrix plus a small constant 0.2 to all entries.

We have compared the above methods on 43 data sets from various domains, including biology, image, video, text, remote sensing, etc. All data sets are publicly available on the Internet. The data sources and statistics are given in the supplemental document. For similarity-based clustering methods, we constructed K -Nearest-Neighbor graphs from the multivariate data with $K = 10$. The adjacency matrices of the graphs are then symmetrized and binarized to obtain S , i.e. $S_{ij} = 1$ if x_j is one of the K nearest neighbors of x_i or vice versa; otherwise $S_{ij} = 0$. This produces sparse similarity matrices.

We have used two performance measures for the clustering accuracies: the first is *cluster purity* which equals $\frac{1}{N} \sum_{k=1}^r \max_{1 \leq l \leq r} n_{kl}$, where n_{kl} is the number of data samples in the cluster k that belong to ground-truth class l ; the second performance measure is *Normalized Mutual Information* (NMI, Vinh et al., 2010) which equals $\sum_{k=1}^r \sum_{l=1}^r \frac{n_{kl}}{N} \log \frac{n_{kl}/N}{a_k b_l / N^2}$, with $a_k = \sum_{l=1}^r n_{kl}$ and $b_l = \sum_{k=1}^r n_{kl}$.

The resulting cluster purities and NMI's are shown in Tables 1 and 2, respectively. We can see that our method has much better performance than the other methods. DCD shows the optimal performance for 22 and 18 out of 43 data sets in purity and NMI, respectively, which is substantially more frequently than for any of the other methods. Even for some other data sets where DCD is not the winner, its cluster purities still remain close to the best method. Our method shows particularly superior performance when the number of samples grows. For the 19 data sets with $N > 4500$, DCD is the top performer in 17 and 11 cases in purity and NMI, respectively. Note that purity corresponds to classification accuracy up to a permutation between classes and clusters. In this sense, our method achieves accuracy very close to many modern supervised approaches for some large-scale data in a curved manifold such as MNIST², though our method does not use any class labels. For text document data set 20NG, DCD achieves comparable accuracy to those with comprehensive feature engineering and supervised classification (e.g. Srivastava et al., 2013), even though our method only uses simple bag-of-words TF-IDF features and no class labels at all.

4.2 Selecting the number of clusters

In the second group of experiments, we assume that the number of clusters is unknown and it must be automatically selected from a range around the number of ground truth classes. We ran DCD with different values of r and calculated the corresponding NOSAC residual after discretizing W to cluster indicator matrix: the best number of clusters was then selected by the r with the smallest NOSAC residual.

We have compared the above DCD selection method with several other clustering evaluation methods: Calinski-Harabasz (CH; Calinski and Harabasz, 1974), Davies-Bouldin (DB; Davies and Bouldin, 1979) and gap statistics (Tibshirani et al., 2001). We used their implementation in Matlab. Each cluster evaluation approach comes with a supported base clustering algorithm k-means (km) or linkage (lk). We thus have in total six methods for selecting the number of clusters to be compared against DCD. Some of these compared methods are very slow and required computation of more than five days for certain data sets. This drawback is especially severe for data sets with very high dimensionality such as CURLET and COLL100. In contrast, DCD required at most two hours for any tested data set.

The results are reported in Table 3, which shows that DCD performs the best also in terms of selecting the number of clusters. The corresponding curves of NOSAC residual vs. number of clusters by DCD are shown in Figure 2. In the selected number of clusters, the DCD results are closest to the ground truth for all data sets, much more accurately than for any of the other methods. DCD correctly selects the best for CURLET, OPTDIGITS, and MNIST, and almost correctly (only differing by 1) for BOTSWANA and PHONEME. For COLL20 and COLL100, the DCD results are also reasonably good because we did not deliberately tune the extent of the local neighborhoods. By simply replacing 10NN with 5NN as the input similarities, DCD respectively selects 21 for COLL20 and 99 for COLL100 as the best number of clusters.

Table 1: Clustering purities for the compared methods on various data sets. Boldface numbers indicate the best in each row. “-” means out-of-memory error.

5. Discussion

The results in the previous section demonstrate the solid performance of DCD on a wide variety of data sets. In this section, we discuss the connections and differences between DCD and other related work, and we also discuss other implementations of the input similarities than the symmetrized K-Nearest-Neighbors.

5.1 Comparison with related techniques

5.1.1 SPECTRAL CLUSTERING, K-MEANS, AND ORTHOGONALITY CONSTRAINT

Denote $X = [x_1, \dots, x_N]^T$ the data matrix (rows to be clustered). The classical k-means method seeks a clustering such that the sum of squared Euclidean distances between the samples and their assigned cluster means is minimized. This objective can be expressed by using the normalized cluster indicator matrix F defined in Section 2: $\min_F \|X - FF^T X\|_{F_0}^2 = \|X\|_{F_0}^2 - \text{Tr}(F^T X X^T F)$, where $\|\cdot\|_{F_0}$ is the Frobenius norm (Ding et al.,

Table 3: The automatically selected number of clusters. Boldface number indicates the closest (best) to the ground truth (number of classes, in the last column) in each row. The results marked with a star required computation of more than five days.

2005). The k-means method can be extended to a nonlinear case by replacing XX^T with another kernel matrix.

It is difficult to directly minimize over F in the combinatorial space (Aloise et al., 2009; Mahajan et al., 2009). A conventional way is to relax F to orthogonal matrix such that the optimization can be solved by eigendecomposition. This connects k-means or kernel k-means to spectral clustering (Ding et al., 2005). Despite the closed form solution, the obtained eigenvectors do not immediately reveal the cluster assignments. Extra effort such as k-means on the relaxed F rows (Ng et al., 2001) or iterative projection (Yu and Shi, 2003) is needed to convert the eigenvectors to the cluster indicator matrix. An alternative way is

to combine orthogonality and nonnegativity such that the relaxed F has only one non-zero entry in each row and thus indicates the cluster assignments (Ding et al., 2006; Yang and Oja, 2012b; Yang and Laaksonen, 2007; Yoo and Choi, 2008; Pomplii et al., 2013).

However, the orthogonality constraint does not necessarily guarantee balanced clustering because it does not restrict the magnitudes of the relaxed F rows. Moreover, the orthogonality favors Euclidean distance as the approximation error measure for simple update rules, which is against our requirement of the sparse similarity graph input.

In contrast, our relaxation employs doubly stochasticity of the relaxed FF^T (i.e. A or B), which ensures that each cluster has unitary (soft) normalized graph volume³ when combined with the nonnegativity constraint. Furthermore, although we do not explicitly use the orthogonality, in practice the resulting relaxed F (i.e. U) contains only one or a few significant non-zero entries in each row for clustered data. Therefore the best DCD objective is close to the discrete NOSAC residual by which we can select the number of clusters (see Section 4.2). This cannot be done in k -means or spectral clustering.

5.1.2 NONNEGATIVE MATRIX FACTORIZATION

Nonnegative Matrix Factorization (NMF) seeks nonnegative low-rank factorization of an input data matrix (Lee and Seung, 1999, 2001). Variants of NMF have been proposed for similarity-based clustering. For example, Ding et al. (2008) imposed nonnegativity to spectral clustering; Ding et al. (2006); Yang and Oja (2012b); Yang and Laaksonen (2007); Yoo and Choi (2008); Pomplii et al. (2013) proposed using both nonnegativity and orthogonality on the factorizing matrices; He et al. (2011) used the symmetric NMF for low-rank factors.

Probabilistic clustering is a natural way to relax the hard clustering problem. Recently Avora et al. (2011, 2013) introduced stochasticity for clustering, by using a left stochastic matrix in symmetric NMF. However, their method, called LSD, is restricted to the Euclidean distance. In addition, LSD does not prevent imbalanced clustering.

Our method has two major differences from LSD. First, our decomposition involves a normalizing factor which emphasizes balanced clusterings. Second, we use Kullback-Leibler divergence which is more suitable for sparse graph input or curved manifold data. This also enables us to make use of the Dirichlet and multinomial conjugacy pair to achieve more accurate clusterings.

5.1.3 PROBABILISTIC LATENT SEMANTIC ANALYSIS

Probabilistic Latent Semantic Analysis (PLSA, also known as PLSI especially in information retrieval) is a statistical technique for the analysis of two-mode and co-occurrence data. When PLSA applies to similarity-based clustering (Hofmann, 1999), it maximizes the log-likelihood $\sum_{i=1}^N \sum_{j=1}^N S_{ij} \log \sum_{k=1}^K P(i|k)P(j|k)$. Compared to the DCD objective, we can see that the major difference is in the decomposition form within the logarithm: PLSA learns the cluster prior $P(k)$ and the conditional likelihood of data points $P(i|k)$; while in DCD we assume uniform prior $P(i)$ and learn the conditional likelihood of clusters $P(k|i)$.

³ For the k th cluster, the soft cluster volume is $\sum_{i=1}^N \sum_{j=1}^N \frac{W_{i,j} W_{j,k}}{\sum_{i=1}^N \sum_{k=1}^K W_{i,j}}$ and soft cluster size is $\sum_{i=1}^N W_{i,k}$.

There are several reasons why the DCD decomposition is more beneficial than PLSA for cluster analysis. First, $P(k|i)$ in DCD is the direct answer to the probabilistic clustering problem, while the PLSA quantities are not. Second, in PLSA $\sum_{k=1}^K P(k)P(i|k)P(j|k) = P(i, j)$ is a joint probability matrix; it is not necessarily doubly stochastic and may not guarantee that each cluster has the same normalized graph volume, as DCD does. Third, DCD achieves a good balance in terms of the number of parameters, as it contains $N \times (r-1)$ free parameters while in PLSA there are $N \times r - 1$; this difference can be large when there are only few clusters (e.g. $r = 2$ or $r = 3$).

Both methods can be improved by using Dirichlet priors. In DCD the prior is only used in initialization and the prior parameter is chosen according to the smallest NOSAC residual. We find that this strategy is better than the conventional hyper-parameters tuning techniques in the topic model literature (e.g., Minka, 2000; Asuncion et al., 2009).

5.1.4 DOUBLY STOCHASTIC MATRIX PROJECTION

Normalizing a matrix to be doubly stochastic has been used to improve cluster analysis, but mainly on the input similarity matrix. The normalization dates back to the Sinkhorn-Knopp procedure (Sinkhorn and Knopp, 1967) or iterative proportional fitting procedure (Bishop et al., 1975). Zass and Shashua (2006) proposed to improve spectral clustering by replacing the original similarity matrix by its closest doubly stochastic similarities under L_1 or Frobenius norm. Wang et al. (2012) generalized the projection to the family of Bregman divergences. Note that the normalized matrix in general requires $O(N^2)$ memory if Frobenius norm projection is used.

In contrast, our method has three major differences: 1) it imposes the doubly stochastic constraint on the approximating matrix instead of the input similarity matrix; 2) the doubly stochastic matrix must be low-rank; in practice we need only $O(N \times r)$ memory; 3) our DCD decomposition equivalently fulfills the doubly stochastic requirement, and thus no extra normalization is needed.

5.1.5 CLUSTERABILITY

Clusterability or clustering tendency measures how “strong” or “conclusive” is the clustering structure of a given data set (Ackeman and Ben-David, 2009). The research dates back to Hopkins index for spatial randomness test (Hopkins and Skellam, 1954). Other notions include, for example, center perturbation clusterability (Ben-David et al., 2002), worst pair ratio clusterability (Eptel et al., 1999), separability clusterability (Ostrovsky et al., 2006), variance ratio clusterability (Ostrovsky et al., 2006), strict separation clusterability (Balcan et al., 2008), and target clusterability (Balcan et al., 2009). Ackeman and Ben-David (2009) gave a survey and comparison on the above clusterability notions.

These clusterability criteria, however, suffer from one or more of the following drawbacks: 1) they are defined over k -partitions with a fixed k and therefore cannot be used for clusterings with various k values; 2) they are restricted to center-based clustering methods and might not work for curved clusters; and 3) they employ minimum within-cluster distances and maximum between-cluster distances, which is sensitive to outlier data points.

In contrast, our NOSAC criterion does not have the above drawbacks. NOSAC is defined over all partitions, including those with a different number of clusters. The partitions can

Table 4: Clustering performance using approximated KNN: (top) purities and (bottom) NMI. Boldface numbers indicate the best in each row. “-” means out-of-memory error.

be obtained from any clustering methods, not necessarily center-based. Moreover, we use matrix divergences instead of only minimum or maximum of individual distances, which provides a more robust measure against outliers.

5.2 Input similarities

The inputs to DCD are the pairwise similarities between data items, for example the symmetrized and binarized KNN graph used in Section 4. Naive implementation of KNN requires $O(N^2)$ computational cost. There exist accelerated algorithms taking advantage of the fact that it is often not necessary to calculate all pairs but only those in local neighborhoods. We have used a simple implementation with a vantage-point index (Yianilos, 1993), where we slightly modified the code to admit sparse data and with interface to Matlab. For MNIST where $N = 70,000$, the accelerated KNN (with $K = 10$) algorithm requires in practice only about 7 minutes to completion.

Exact KNN by the above acceleration is still expensive for even larger data sets. In practice, we find that using highly accurate approximated KNN is enough for maintaining the DCD performance. Table 4 shows the comparison for large-scale data sets ($N > 10,000$) using the Fast Library of Approximated Nearest Neighbors (FLANN; Muja and Lowe, 2014). We can see that the resulting DCD purities and NMIs are close to those with exact KNN, and that the accuracy gains over the other compared methods mostly remain. By using FLANN, we can obtain the similarities for DCD much faster; for example, FLANN takes about 30 seconds for MNIST with $K = 10$.

KNN is not the only choice of input similarities. There are other more advanced neighborhood descriptors which could further improve DCD, for example, *Entropy Affinities*

which locally scales the spherical Gaussian kernels such that the neighborhoods around every data point have the same given entropy (Vladymyrov and Carreira-Perpinán, 2013), *Sparse Manifold Clustering and Embedding* that learns a sparse coding with respect to local manifold geometry and cluster distribution (Elhamifar and Vidal, 2011), and *AnchorGraph* which learns the low-rank sparse coding with a set of pre-clustered landmarks (Liu et al., 2010). Other approaches such as metric learning (e.g., Kulis, 2013) could also be applied to obtain better input similarities.

6. Conclusions

We have presented a new clustering method based on low-rank approximation with two major contributions: 1) a clusterability criterion which can be used for learning both cluster assignments and the number of clusters; 2) a relaxed formulation with novel low-rank doubly stochastic matrix decomposition which allows efficient optimization, as well as its multiplicative majorization-minimization algorithm. Experimental results showed that our method works robustly for various selected data sets and can substantially improve clustering accuracy for large manifold data sets.

There are also some other generic characteristics which affect clustering performance. In the learning objective, there is the possibility of using other information divergences as the approximation error measure, including the matrix-wise and non-separable divergences (e.g., Cichocki et al., 2009; Dhillon and Tropp, 2007; Dikmen et al., 2015). In optimization, currently the multiplicative algorithm runs in batch mode. In the future we aim to develop even more scalable implementations such as streaming mini-batches of similarities and distributed computing. In this way DCD can be applicable to even bigger data sets and further improve clustering accuracy. In implementation, our practice indicates that initialization could play an important role because most current algorithms are only local optimizers. Using Dirichlet prior is only one way to smooth the objective function space. It is an open question whether other priors or regularization techniques could in general achieve better initializations.

Appendix A. Proof of Theorem 1

Proof 1) Given a matrix $B \in \mathbb{B}$ and its corresponding W , let $U_{ik} = W_{ik}/\sqrt{\sum_{v=1}^N W_{vk}}$. Then $B = UU^T$ and

$$\sum_{j=1}^N B_{ij} = \sum_{j=1}^N \sum_{k=1}^N \frac{W_{ik}W_{jk}}{\sum_{v=1}^N W_{vk}} = \sum_{k=1}^N \frac{W_{ik} \sum_{j=1}^N W_{jk}}{\sum_{v=1}^N W_{vk}} = \sum_k W_{ik} = 1. \quad (20)$$

That is, $B \in \mathbb{A}$. Therefore $\mathbb{B} \subseteq \mathbb{A}$.

2) Given a matrix $A \in \mathbb{A}$ and its corresponding U , let $W = UE$, where E is diagonal and $E_{kk} = \sum_{v=1}^N U_{vk}$. Using $\sum_{j=1}^N A_{ji} = 1$, we have

$$1 = \sum_{j=1}^N A_{ji} \quad (21)$$

$$= \sum_{j=1}^N (UU^T)_{ji} \quad (22)$$

$$= \sum_{j=1}^N (UE^{-1}EU^T)_{ji} \quad (23)$$

$$= \sum_{j=1}^N \sum_{k=1}^r (UE^{-1})_{jk} (EU^T)_{ki} \quad (24)$$

$$= \sum_{j=1}^N \sum_{k=1}^r \frac{U_{jk}}{\sum_{v=1}^N U_{vk}} W_{jk} \quad (25)$$

$$= \sum_{k=1}^r \frac{\sum_{j=1}^N U_{jk}}{\sum_{v=1}^N U_{vk}} W_{jk} \quad (26)$$

$$= \sum_{k=1}^r W_{jk}. \quad (27)$$

Using $\sum_{i=1}^N W_{ik} = \sum_{i=1}^N U_{ik} \sum_{v=1}^N U_{vk}$, we have

$$A_{ij} = \sum_{k=1}^r U_{ik} U_{jk} = \sum_{k=1}^r \frac{W_{ik}}{\sum_{l=1}^N U_{lk}} \frac{W_{jk}}{\sum_{v=1}^N U_{vk}} = \sum_{k=1}^r \frac{W_{ik} W_{jk}}{\sum_{v=1}^N W_{vk}} \quad (28)$$

That is, $A \in \mathbb{B}$. Therefore $\mathbb{B} \supseteq \mathbb{A}$. \blacksquare

Appendix B. Proof of Theorem 2

Proof We use W and \widetilde{W} to distinguish the current estimate and the variable, respectively. (Majorization)

$$\text{Let } \phi_{ijk} = \frac{W_{ik} W_{jk}}{\sum_{v=1}^N W_{vk}} \left(\sum_{l=1}^r \frac{W_{il} W_{jl}}{\sum_{v=1}^N W_{vl}} \right)^{-1}.$$

$$\mathcal{L}(\widetilde{W}, \lambda) \leq - \sum_{i=1}^N \sum_{j=1}^r \sum_{k=1}^r S_{ij} \phi_{ijk} \left[\log \widetilde{W}_{ik} + \log \widetilde{W}_{jk} - \log \sum_v \widetilde{W}_{vk} \right] \quad (29)$$

$$- (\alpha - 1) \sum_{i=1}^N \sum_{k=1}^r \log \widetilde{W}_{ik} + \sum_{i=1}^N \sum_{k=1}^r \lambda_i \widetilde{W}_{ik} + C_1 \quad (30)$$

$$\leq - \sum_{i=1}^N \sum_{j=1}^r \sum_{k=1}^r S_{ij} \phi_{ijk} \left[\log \widetilde{W}_{ik} + \log \widetilde{W}_{jk} - \frac{\sum_{v=1}^N \widetilde{W}_{vk}}{\sum_{v=1}^N W_{vk}} \right] \quad (31)$$

$$- (\alpha - 1) \sum_{i=1}^N \sum_{k=1}^r \log \widetilde{W}_{ik} + \sum_{i=1}^N \sum_{k=1}^r \lambda_i \widetilde{W}_{ik} + C_2 \quad (32)$$

$$\leq - \sum_{i=1}^N \sum_{j=1}^r \sum_{k=1}^r S_{ij} \phi_{ijk} \left[\log \widetilde{W}_{ik} + \log \widetilde{W}_{jk} - \frac{\sum_{v=1}^N \widetilde{W}_{vk}}{\sum_{v=1}^N W_{vk}} \right] \quad (33)$$

$$- (\alpha - 1) \sum_{i=1}^N \sum_{k=1}^r \log \widetilde{W}_{ik} + \sum_{i=1}^N \sum_{k=1}^r \lambda_i \widetilde{W}_{ik} \quad (34)$$

$$+ \sum_{i=1}^N \sum_{k=1}^r \left(\frac{1}{a_i} + \frac{\alpha}{W_{ik}} \right) W_{ik} \left(\frac{\widetilde{W}_{ik}}{W_{ik}} - \log \frac{\widetilde{W}_{ik}}{W_{ik}} - 1 \right) + C_2 \quad (35)$$

$$\stackrel{\text{def}}{=} G(\widetilde{W}, W), \quad (36)$$

where

$$C_1 = \sum_{i=1}^N \sum_{j=1}^r \sum_{k=1}^r S_{ij} \phi_{ijk} \log \phi_{ijk}, \quad (37)$$

$$C_2 = C_1 + \sum_{i=1}^N \sum_{j=1}^r \sum_{k=1}^r S_{ij} \phi_{ijk} \left(\log \sum_{v=1}^N W_{vk} - 1 \right) \quad (38)$$

are constants irrelevant to the variable \widetilde{W} . The first two inequalities follow the CCCP majorization (Yang and Oja, 2011) using the convexity and concavity of $-\log(\cdot)$ and $\log(\cdot)$, respectively. The third inequality is called ‘‘moving term’’ technique used in multiplicative updates (Yang and Oja, 2010). It adds the same constant $\frac{1}{a_i} + \frac{\alpha}{W_{ik}}$ to both numerator and denominator in order to guarantee that the updated matrix entries are positive, which is implemented by using the inequality $x \geq 1 + \log x$ for $x > 0$. All the above upper bounds are tight at $\widetilde{W} = W$, i.e. $G(\widetilde{W}, W) = \mathcal{L}(\widetilde{W}, \lambda)$.

(Minimization)

$$\frac{\partial G}{\partial \widetilde{W}_{ik}} = \nabla_{ik}^+ - \frac{\alpha}{\widetilde{W}_{ik}} - \frac{W_{ik}}{\widetilde{W}_{ik}} \left(\nabla_{ik}^- - \frac{\alpha}{\widetilde{W}_{ik}} \right) \tag{39}$$

$$+ \lambda_i + \left(\frac{1}{a_i} + \frac{\alpha}{\widetilde{W}_{ik}} \right) W_{ik} \left(\frac{1}{\widetilde{W}_{ik}} - \frac{1}{\widetilde{W}_{ik}} \right) \tag{40}$$

$$= -\frac{W_{ik}}{\widetilde{W}_{ik}} \left(\nabla_{ik}^- + \frac{1}{a_i} \right) + \left(\nabla_{ik}^+ + \frac{b_i}{a_i} \right). \tag{41}$$

Setting the gradient to zero gives

$$W_{ik}^{\text{new}} = W_{ik} \frac{\nabla_{ik}^- + \frac{1}{a_i}}{\nabla_{ik}^+ + \frac{b_i}{a_i}} \tag{42}$$

Multiplying both numerator and denominator by a_i gives the last update rule in Algorithm 1. Therefore, $\mathcal{L}(W^{\text{new}}, \lambda) \leq G(W^{\text{new}}, W) \leq \mathcal{L}(W, \lambda)$. ■

Abstract

Clustering is unsupervised and exploratory in nature. Yet, it can be performed through penalized regression with grouping pursuit, as demonstrated in Pan et al. (2013). In this paper, we develop a more efficient algorithm for scalable computation and a new theory of clustering consistency for the method. This algorithm, called DC-ADMM, combines difference of convex (DC) programming with the alternating direction method of multipliers (ADMM). This algorithm is shown to be more computationally efficient than the quadratic penalty based algorithm of Pan et al. (2013) because of the former's closed-form updating formulas. Numerically, we compare the DC-ADMM algorithm with the quadratic penalty algorithm to demonstrate its utility and scalability. Theoretically, we establish a finite-sample mis-clustering error bound for penalized regression based clustering with the L_0 constrained regularization in a general setting. On this ground, we provide conditions for clustering consistency of the penalized clustering method. As an end product, we put R package *prclust* implementing PRclust with various loss and grouping penalty functions available on GitHub and CRAN.

Keywords: Alternating direction method of multipliers (ADMM), Difference of convex (DC) programming, Clustering consistency, Truncated L_1 -penalty (TLP).

1. Introduction

Clustering analysis separates a set of unlabeled data points into disparate groups, or clusters, based on some common properties of these points. It is a fundamental tool in machine learning, pattern recognition, and statistics, and has been widely applied in many fields, ranging from image processing to genetics. Clustering analysis has a long history, and, naturally, a large number of clustering methods have been developed; see Jain (2010) for an excellent overview.

Clustering analysis is regarded as unsupervised learning in absence of a class label, as opposed to supervised learning. Over the last few years, a new framework of clustering analysis has been introduced by treating it as a penalized regression problem (Pelckmans et al., 2005; Lindsten et al., 2011; Hocking et al., 2011; Pan et al., 2013; Chi and Lange, 2015) based on over-parameterization. Specifically, we parameterize p -dimensional observations, say x_i , $1 \leq i \leq n$, with its own centroid, say μ_i . Two observations are said to belong to the same cluster if their corresponding μ_i 's are equal. Then clustering analysis is formulated to identify a small subset of distinct values of these μ_i 's via solving the following optimization problem

$$\min_{\mu} \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 + \lambda \mathcal{J}(\mu),$$

where λ is a nonnegative tuning parameter controlling the trade-off between the model fit and the number of clusters, and $\mathcal{J}(\mu)$ is a penalty on $\mu = (\mu_1', \dots, \mu_n')$. Perhaps due to computational simplicity, a convex $\mathcal{J}(\mu)$ has been extensively studied. For example, sum-of-norms clustering (Lindsten et al., 2011) defines $\mathcal{J}(\mu) = \sum_{j=1}^n \sum_{i < j} \|\mu_i - \mu_j\|_q$, where $\|\cdot\|_q$ is the L_q -norm. However, a convex $\mathcal{J}(\mu)$ usually yields biased parameter estimates, leading to difficulties in separating the clusters. To overcome this disadvantage, Pan et al. (2013) proposed penalized regression-based clustering (PRclust), which uses the non-convex grouped truncated lasso penalty (gTLP) $\mathcal{J}(\mu) = \sum_{i < j} \text{TLP}(\|\mu_i - \mu_j\|_2; \tau)$. Specifically, TLP is defined as $\text{TLP}(\alpha; \tau) = \min(|\alpha|, \tau)$ for a scalar α and a tuning parameter τ . It can be thought of as the L_1 -penalty for a small $|\alpha| \leq \tau$, but no further penalization for a large $|\alpha| > \tau$. One benefit of PRclust is that it can treat some complex clustering situations, for example, in the presence of non-convex clusters, in which traditional methods such as K-means break down (Pan et al., 2013).

To deal with the nonseparable and non-convex grouping penalty in μ_i 's, a quadratic penalty based algorithm (Pan et al., 2013) was developed by introducing some new parameters $\theta_{ij} = \mu_i - \mu_j$. This algorithm is relatively slow, and due to use of the quadratic penalty, the estimated centroids from the same cluster can never be exactly the same. To overcome these difficulties, we develop a novel and efficient computational algorithm called DC-ADMM, which combines the benefit of the alternating direction method of multipliers (ADMM) (Boyd et al., 2011) with that of the difference of convex (DC) method (Le Thi Hoai and Tao, 1997). As a result, DC-ADMM is much faster than the quadratic penalty based algorithm, in addition to that some estimated centroids can be exactly equal to each other when their corresponding observations come from the same cluster. As a by-product of this new method, we make R package *prclust* implementing both the quadratic penalty based algorithm and DC-ADMM available in CRAN (<https://cran.r-project.org>) and GitHub (<https://github.com/ChongWu-Bioostat/prclust>).

Clustering consistency of PRclust remains unknown, though operating characteristics of PRclust have been studied via some simulations and real data analysis (Pan et al., 2013). In the penalized regression based clustering framework, clustering consistency of some related models has been studied (Radchenko and Mukherjee, 2014; Zhu et al., 2014). For example, Radchenko and Mukherjee (2014) studied clustering consistency of another method with univariate observations; Zhu et al. (2014) extended this result to multivariate observations by assuming only two clusters. In this paper, with some distributional assumptions, we

*. These authors contributed equally.

†. WP is the corresponding author.

establish a general clustering consistency theory for a wide range of models, including PRclust as a special case. Our theory is applicable to multiple clusters and provide a finite-sample mis-clustering error bound in the absence of overlapping clusters. On this ground, we give sufficient conditions for PRclust to correctly identifying clusters in terms of the expected Hellinger loss. As a result, PRclust not only reconstructs the true clusters, but also yields optimal parameter estimation through the L_0 grouping penalty.

The remaining of this paper is organized as follows. Section 2 introduces the new DC-ADMM algorithm and discusses a stability criterion to select the tuning parameters. A simulation study is then performed to demonstrate the numerical performance of the new algorithm as compared to other methods. This is followed by a theory for accuracy of clustering in Section 3. A discussion of the results is given in Section 4. The proofs of the main results are given in an Appendix.

2. New Algorithm

To treat non-convexity more efficiently, we introduce a DC algorithm based on the ADMM, called DC-ADMM. We prove DC-ADMM yields a Karush-Kuhn-Tucker (KKT) solution, and some extensions are discussed.

2.1 DC-ADMM

DC-ADMM contains three steps: first, it rewrites the original unconstrained cost function into a constrained one and introduces some new variables to simplify optimization with respect to the non-convex grouping penalty; second, DC programming is applied to convert the non-convex optimization problem into a sequence of convex relaxations; third, each relaxed convex problem is solved by a standard ADMM. First, rewrite the PRclust cost function

$$\min_{\mu} \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 + \lambda \sum_{i < j} \text{TLP}(\|\mu_i - \mu_j\|_2; \tau) \quad (1)$$

as the equivalent constrained problem

$$\min_{\mu, \theta} S(\mu, \theta) = \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 + \lambda \sum_{i < j} \text{TLP}(\|\theta_{ij}\|_2; \tau)$$

$$\text{subject to } \theta_{ij} = \mu_i - \mu_j, \quad 1 \leq i < j \leq n,$$

where $\|\cdot\|_2$ is the L_2 -norm. Here, we introduce new variables $\theta_{ij} = \mu_i - \mu_j$ for the differences between the centroids and thus simplify optimization with respect to the grouping penalty.

To treat the non-convex gTLP on θ_{ij} 's, we apply DC programming (Le Thi Hoai and Tao, 1997). In particular, the cost function $S(\mu, \theta)$ is decomposed into a difference of two convex functions $S(\mu, \theta) = S_1(\mu, \theta) - S_2(\theta)$:

$$\begin{aligned} S_1(\mu, \theta) &= \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 + \lambda \sum_{i < j} \|\theta_{ij}\|_2, \\ S_2(\theta) &= \lambda \sum_{i < j} (\|\theta_{ij}\|_2 - \tau)_+. \end{aligned}$$

where $(\alpha)_+$ denotes the positive part of α , which is α if $\alpha > 0$ and 0 otherwise.

Given the DC composition, we construct a sequence of upper approximations of $S(\mu, \theta)$ iteratively by replacing $S_2(\theta)$ at iteration $m + 1$ with its piecewise affine minorization

$$S_2^{(m)}(\theta) = S_2(\hat{\theta}^{(m)}) + \lambda \sum_{i < j} \left(\|\theta_{ij}\|_2 - \|\hat{\theta}_{ij}^{(m)}\|_2 \right) I\left(\|\hat{\theta}_{ij}^{(m)}\|_2 \geq \tau\right)$$

at the current estimate $\hat{\theta}^{(m)}$ from iteration m , leading to an upper convex approximating function at iteration $m + 1$:

$$\begin{aligned} S^{(m+1)}(\mu, \theta) &= \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 \\ &+ \lambda \sum_{i < j} (\|\theta_{ij}\|_2) I\left(\|\hat{\theta}_{ij}^{(m)}\|_2 < \tau\right) + \lambda \tau \sum_{i < j} I\left(\|\hat{\theta}_{ij}^{(m)}\|_2 \geq \tau\right), \end{aligned} \quad (2)$$

where $I(\cdot)$ is the indicator function.

Then apply ADMM to solve the corresponding constrained convex problem at iteration $m + 1$

$$\min_{\mu, \theta} S^{(m+1)}(\mu, \theta), \quad \text{subject to } \theta_{ij} = \mu_i - \mu_j, \quad 1 \leq i < j \leq n. \quad (3)$$

ADMM solves (3) by minimizing the corresponding scaled augmented Lagrangian

$$\begin{aligned} L_{\rho}(\mu, \theta) &= \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\|_2^2 + \lambda \sum_{i < j} (\|\theta_{ij}\|_2) I\left(\|\hat{\theta}_{ij}^{(m)}\|_2 < \tau\right) + \lambda \tau \sum_{i < j} I\left(\|\hat{\theta}_{ij}^{(m)}\|_2 \geq \tau\right) \\ &+ y' \sum_{i < j} (\theta_{ij} - (\mu_i - \mu_j)) + (\rho/2) \sum_{i < j} \|\theta_{ij} - (\mu_i - \mu_j)\|_2^2, \end{aligned} \quad (4)$$

where the dual variable y is a vector of Lagrange multipliers and ρ is a nonnegative penalty parameter. Using the scaled Lagrange multiplier $u = y/\rho$ (Boyd et al., 2011, §3.3.1), we can express ADMM as

$$\begin{aligned} \hat{\mu}_i^{k+1} &= \arg\min_{\mu_i} \frac{1}{2} \|x_i - \mu_i\|_2^2 + \frac{\rho}{2} \sum_{j>i} \|\hat{\theta}_{ij}^k - (\mu_i - \hat{\mu}_j^k) + \hat{u}_{ij}^k\|_2^2 \\ &+ \frac{\rho}{2} \sum_{j<i} \|\hat{\theta}_{ij}^k - (\mu_i - \hat{\mu}_j^{k+1}) + \hat{u}_{ij}^k\|_2^2, \\ \hat{\theta}_{ij}^{k+1} &= \arg\min_{\theta_{ij}} \begin{cases} \lambda \tau + \frac{\rho}{2} \|\theta_{ij} - (\hat{\mu}_i^{k+1} - \hat{\mu}_j^{k+1}) + \hat{u}_{ij}^k\|_2^2, & \text{if } \|\hat{\theta}_{ij}^{(m)}\|_2 \geq \tau; \\ \lambda \|\theta_{ij}\|_2 + \frac{\rho}{2} \|\theta_{ij} - (\hat{\mu}_i^{k+1} - \hat{\mu}_j^{k+1}) + \hat{u}_{ij}^k\|_2^2, & \text{if } \|\hat{\theta}_{ij}^{(m)}\|_2 < \tau; \end{cases} \\ \hat{u}_{ij}^{k+1} &= \hat{u}_{ij}^k + \hat{\theta}_{ij}^{k+1} - (\hat{\mu}_i^{k+1} - \hat{\mu}_j^{k+1}), \quad 1 \leq i < j \leq n, \end{aligned} \quad (5)$$

where k stands for step k in the standard ADMM. Using some simple algebra, we obtain the updating formula for μ as follows

$$\hat{\mu}_i^{k+1} = \frac{x_i + \rho \sum_{j>i} (\hat{\mu}_j^k + \hat{\theta}_{ij}^k + \hat{u}_{ij}^k) + \rho \sum_{j<i} (\hat{\mu}_j^{k+1} - \hat{\theta}_{ji}^k - \hat{u}_{ij}^k)}{1 + \rho(n-1)}.$$

Applying a block soft thresholding operator for the group lasso penalty (Yuan and Lin, 2006), we have

$$\hat{\theta}_{ij}^{k+1} = \begin{cases} \hat{\mu}_i^{k+1} - \hat{\mu}_j^{k+1} - \hat{u}_{ij}^k & \text{if } \|\hat{\theta}_{ij}^{(m)}\|_2 \geq \tau; \\ \text{ST}(\hat{\mu}_i^{k+1} - \hat{\mu}_j^{k+1} - \hat{u}_{ij}^k; \lambda/\rho) & \text{if } \|\hat{\theta}_{ij}^{(m)}\|_2 < \tau; \end{cases} \quad (6)$$

where $\text{ST}(\theta; \gamma) = (|\theta|_2 - \gamma)_+ \theta / \|\theta\|_2$. The convergence time of ADMM is highly related to the penalty parameter ρ . A poor selection of ρ can result in a slow convergence for the ADMM algorithm (Ghadimi et al., 2015) and thus DC-ADMM. In this paper, we fix $\rho = 0.4$ throughout for simplicity. For the subsequent relaxed convex problem (3), $\hat{\mu}^{(m+1)}$ and $\hat{\theta}^{(m+1)}$ are updated according to standard ADMM (5) until some stopping criteria, such as that both dual and primal residuals are small (Boyd et al., 2011), are met. We summarize the DC-ADMM algorithm in Algorithm 1.

Algorithm 1: DC-ADMM for penalized regression based clustering

Input : n observations $X = \{x_1, \dots, x_n\}$; tuning parameters λ, τ and ρ .

1 **Initialize:** Set $m = 0$, $\hat{u}_{ij}^{(0)} = 0$, $\hat{\mu}_i^{(0)} = x_i$ and $\hat{\theta}_{ij}^{(0)} = x_i - x_j$ for $1 \leq i < j \leq n$.

2 **while** $m = 0$ *or* $S(\hat{\mu}^{(m)}, \hat{\theta}^{(m)}) - S(\hat{\mu}^{(m-1)}, \hat{\theta}^{(m-1)}) < 0$ **do**

3 $m \leftarrow m + 1$

4 Update $\hat{\mu}^{(m)}$ and $\hat{\theta}^{(m)}$ based on (5) until convergence with a standard ADMM.

5 **end**

Output: Estimated centroids for the observations, $\hat{\mu}_1, \dots, \hat{\mu}_m$, from which a cluster label for each observation is assigned.

In Algorithm 1, for each iteration m , $\hat{\mu}_i^0 = x_i$ and $\hat{\theta}^0 = x_i - x_j$ for $1 \leq i < j \leq n$ are used as the starting values for (5); $(\hat{\mu}^{(m+1)}, \hat{\theta}^{(m+1)})$ is the limit point of the ADMM iterations in (5), or equivalently, is a minimizer of (3). $(\hat{\mu}^{(m+1)}, \hat{\theta}^{(m+1)})$ is then used to update the objective function $S^{(m+1)}(\mu, \theta)$ in (2) as a new approximation to $S(\mu, \theta)$. The process is iterated until the stopping criteria are met.

Since the cost function (3) is a sum of a differentiable and convex function and a convex penalty in θ (while $\theta^{(m)}$ is known), ADMM converges to its minimizer (Boyd et al., 2011). Then DC-ADMM's convergence in a finite number of steps follows by the facts that DC programming guarantees the decrease of the subsequent convex relaxations (2), and that $S^{(m+1)}(\mu, \theta)$ has only a finite set of possible forms across all m . Theorem 1 shows that the solution of the DC-ADMM converges to a KKT point.

Theorem 1 *In the DC-ADMM, $S(\hat{\mu}^{(m)}, \hat{\theta}^{(m)})$ converges in a finite number of steps; that is, there exists an $m^* < \infty$ with*

$$S(\hat{\mu}^{(m)}, \hat{\theta}^{(m)}) = S(\hat{\mu}^{(m^*)}, \hat{\theta}^{(m^*)}) \quad \text{for } m \geq m^*$$

Furthermore, $(\hat{\mu}^{(m^)}, \hat{\theta}^{(m^*)})$ is a KKT point.*

DC-ADMM only guarantees a local instead of a global minimizer. As shown in simulations, DC-ADMM performed well in terms of clustering accuracy. This suggests that DC-ADMM typically yields a good local solution, though not necessarily global. A variant of DC algorithms called outer approximation method of Breiman and Cutler (1993) gives a global minimizer, but may converge slowly. For a large-scale problem, we prefer the present version for its faster convergence at an expense of possibly missing global solutions.

With different random starting values, DC-ADMM could yield different KKT points for the same data and parameters. However, our limited numerical experience suggests that DC-ADMM gives good solutions with our proposed starting values.

Let $N_{\text{admm}}, N_{\text{quad}}$ be the numbers of iterations for running the standard ADMM and quadratic based algorithm, respectively. The computational complexity of updating θ and μ for one time is $O(pn^2)$. Note that the complexity of DC programming is $O(1)$ and N_{admm} typically scales as $O(1/\epsilon)$, where ϵ is the tolerance (He and Yuan, 2015). Then for the DC-ADMM algorithm, the computational complexity is $O(pn^2/\epsilon)$. In contrast, based on the empirical experience, N_{quad} relates to the number of observations n and quadratic based algorithm is much slower than DC-ADMM. In practice, especially in earlier iterations, one may not want to run the ADMM updates fully until convergence to save computing time. Another trick is that for the subsequent convex relaxations, we can initialize (warm start) $\hat{\mu}^0, \hat{\theta}^0$ and $\hat{\theta}^0$ at their optimal values from the previous relaxed convex problem, which significantly reduces the number of ADMM iterations.

In the DC-ADMM, the hard constraint guarantees that we can obtain exactly some $\hat{\mu}_i - \hat{\mu}_j - \hat{\theta}_{ij} = 0$; in contrast, in the quadratic penalty based algorithm (Pan et al., 2013), due to the use of soft constraint, we cannot obtain exactly $\hat{\mu}_i - \hat{\mu}_j - \hat{\theta}_{ij} = 0$ no matter how large the finite tuning parameter is chosen. Pan et al. (2013) provided an alternative algorithm (PRclust2) to force some $\hat{\mu}_i - \hat{\mu}_j - \hat{\theta}_{ij} = 0$ by running the quadratic based algorithm several times. Although PRclust2 leads to similar clustering results as DC-ADMM in our simulations, it is on average around 10 to 30 times slower than the quadratic based algorithm and is not feasible to large data sets.

2.2 Selection of the Number of Clusters

A generalized degrees of freedom (GDF) together with generalized cross validation (GCV) was proposed for selection of tuning parameters for clustering (Pan et al., 2013). This method, while yielding good performance, requires extensive computation and specification of a hyper-parameter, perturbation size. Here, we provide an alternative by modifying a stability-based criterion (Tibshirani and Walther, 2005; Liu et al., 2016) for determining the tuning parameters.

The main idea of the method is based on cross-validation. That is, (1) randomly partition the entire data set into a training set and a test set with an almost equal size; (2) cluster the training and test sets separately via PRclust with the same tuning parameters; (3) measure how well the training set clusters predict the test clusters. To be specific, first, randomly partition the entire data set into a training set X_{tr} and a test set X_{te} with a roughly equal size. Second, apply DC-ADMM (Algorithm 1) with the same tuning parameters to X_{tr} and X_{te} , leading to the corresponding clustering assignments l_{tr} and l_{te} , respectively. Third, assign X_{te} to clusters according to l_{tr} ; that is, assign each observation

in X_{ie} to the closest cluster of X_{ir} defined by l_{ir} in terms of the Euclidean distance, with $l_{e|ir}$ the corresponding clustering assignments. Note that the distance between an observation in X_{ie} and a cluster of X_{ir} is the minimum distance between the observation and each observations in the cluster. To measure how well the training set clusters predict the test clusters, we compute the adjusted Rand index (Hubert and Arabie, 1985) between $l_{e|ir}$ and l_{ie} as the prediction strength. Recall that the adjusted Rand index ranges between 0 and 1 with a higher value indicating a higher agreement. Repeat the above process T times and calculate the average prediction strength as the mean of T different prediction strengths. This process is repeated over various tuning parameter values, obtaining their corresponding average prediction strengths, then choose the set of the tuning parameters with the maximum average prediction strength. The intuition behind this idea is that if the tuning parameters lead to a stable clustering result, then the training set clusters will be similar to the test set clusters, and hence will predict them well, leading to a high average prediction strength.

2.3 Extensions

The K-means method uses squared L_2 -norm distances to generate cluster centroids, which may be inaccurate if outliers are present (Xu et al., 2005). In contrast, K-medians uses the L_1 -norm distance and is more robust to outliers. Corresponding to modifying the K-means to K-medians, we can extend PReclust by replacing the squared L_2 -norm with the L_1 -norm loss function and estimate the centroids μ through minimizing the following cost function

$$\min_{\mu} S_{L_1}(\mu) = \frac{1}{2} \sum_{i=1}^n \|x_i - \mu_i\| + \lambda \sum_{i < j} \text{TLIP}(\|\mu_i - \mu_j\|; \tau).$$

Due to the nature of the DC-ADMM algorithm, we just need to change the updating formula for $\hat{\mu}$ and leave the remaining updating formula (5), (6) unchanged. Note that

$$\begin{aligned} \hat{\mu}_i^{k+1} &= \operatorname{argmin}_{\mu_i} \frac{1}{2} \|x_i - \mu_i\| + \frac{\rho}{2} \sum_{j > i} \|\hat{\theta}_{ij}^k - (\mu_i - \mu_j^k) + \hat{u}_{ij}^k\|_2^2 \\ &\quad + \frac{\rho}{2} \sum_{j < i} \|\hat{\theta}_{ij}^k - (\mu_i - \mu_j^{k+1}) + \hat{u}_{ij}^k\|_2^2. \end{aligned}$$

To solve the above problem, we define $v_i = x_i - \mu_i$ and simplify the cost function with the L_1 -loss:

$$\begin{aligned} \hat{\mu}_i^{k+1} &= \operatorname{argmin}_{\mu_i} \frac{1}{2} \|v_i\|_1 + \frac{\rho}{2} \sum_{j > i} \|\hat{\theta}_{ij}^k - (x_i - v_i - \mu_j^k) + \hat{u}_{ij}^k\|_2^2 \\ &\quad + \frac{\rho}{2} \sum_{j < i} \|\hat{\theta}_{ij}^k - (x_i - v_i - \mu_j^{k+1}) + \hat{u}_{ij}^k\|_2^2. \end{aligned}$$

Using simple algebra and the soft thresholding operator for lasso (Tibshirani, 1996), we obtain an updating formula as:

$$\hat{\mu}_i^{k+1} = \text{STL} \left(\frac{\sum_{j > i} (\hat{\mu}_j^k + \hat{\theta}_{ij}^k + \hat{u}_{ij}^k - x_i) + \sum_{j < i} (\hat{\mu}_j^{k+1} - \hat{\theta}_{ij}^k - \hat{u}_{ij}^k - x_i)}{n-1}, \frac{1}{2\rho(n-1)} \right) + x_i,$$

where $\text{STL}(\alpha, \gamma) = \text{sign}(\alpha)(|\alpha| - \gamma)_+$. In this case, the scalar operation on a vector is element-wise.

In addition, we can also use other penalty functions. In an appendix, we provide details of the DC-ADMM algorithm for PReclust with lasso or TLP as grouping penalty.

2.4 Simulations

Consider two overlapped convex clusters with the same spherical shape in two dimensions. Specifically, a random sample of $n = 100$ observations was generated, with 50 from a bivariate Gaussian distribution $N((0, 0)', 0.3\mathbb{I})$, while the other 50 from $N((1, 1)', 0.3\mathbb{I})$, where \mathbb{I} is the identity matrix.

For PReclust, we searched $\tau \in \{0.1, 0.2, \dots, 1\}$ and $\lambda \in \{0.01, 0.05, 0.1, 0.2, 0.3, 0.5, 0.7, 1, 1.5, 2\}$. To evaluate the performance of selecting the tuning parameters, we used the Rand index (Rand, 1971) and adjusted Rand index (Hubert and Arabie, 1985), measuring the agreement between estimated cluster and the truth with a higher value indicating a higher agreement. PReclust with the stability based criterion selecting its tuning parameters performed well: the average number of clusters was 2.63, slightly larger than the truth, $K_0 = 2$; the correspond clustering results had high degrees of agreement with the truth, as evidenced by the high indices. Table 1 shows the frequencies of the number of clusters selected by the stability criterion: for the overwhelming majority (93%), either the correct number of cluster $K_0 = 2$ was selected, or a slightly larger $K = 3$ or 4 was selected. As expected, applying the quadratic penalty based algorithm with the stability criterion yielded a similar result. GCV with GDF yielded the similar results for clustering accuracy. However, to use GCV with GDF, the user has to specify the perturbation size, a hyper-parameter. In contrast, the stability based criterion is insensitive to the repeat times T . For the simulation, the average numbers of clusters selected with $T = 10, 50$ and 100 were 2.63, 2.68 and 2.76, respectively.

Now we illustrate differences between the two algorithms. First, we demonstrate how two algorithms operated differently with respect to various values of the tuning parameter λ while τ was fixed at 0.7 (Figure 1). Note that, due to the soft constraint of the quadratic penalty based algorithm, we cannot obtain exactly $\hat{\mu}_i - \mu_j - \hat{\theta}_{ij} = 0$. Even for a sufficiently large λ , there were still quite some unequal $\hat{\mu}_{i,1}$'s, which were all remarkably close to their true values 0 or 1. In contrast, due to using the hard constraint on $\hat{\theta}_{ij} = \mu_i - \mu_j$, DC-ADMM yielded some equal estimated centroids $\hat{\mu}_{i,1}$. In this simulation, the stability based criterion tended to select the most stable tuning parameters, confirming its selecting good tuning parameters and yielding good clustering results.

Figure 2 shows the run-time of two algorithms against the number of observations n and dimension p . As a matter of fact, the DC-ADMM is much faster than the quadratic penalty

Algorithm	Stability Based Criterion			GCV with GDF		
	Freq	\hat{K}	Rand	Freq	\hat{K}	Rand
DC-ADMM	All	2.63	0.950	All	3.29	0.956
	60	2.00	0.954	39	2.00	0.958
	26	3.00	0.949	22	3.00	0.965
	7	4.00	0.945	17	4.00	0.959
	5	5.00	0.924	8	5.00	0.940
	2	6.00	0.952	12	6.00	0.947
Quadratic	All	2.70	0.951	All	2.41	0.962
						9.925

Table 1: Comparison of the tuning parameter selection criteria based on 100 simulated data sets each with 2 clusters.

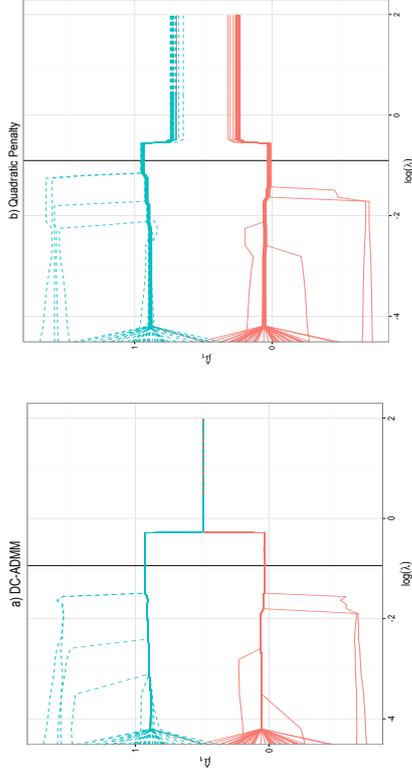

Figure 1: Solution paths of the first coordinate $\hat{\mu}_{i,1}$ for the first simulated data set. τ is fixed at 0.7. Vertical black line represents the tuning parameter selected by the stability based criterion.

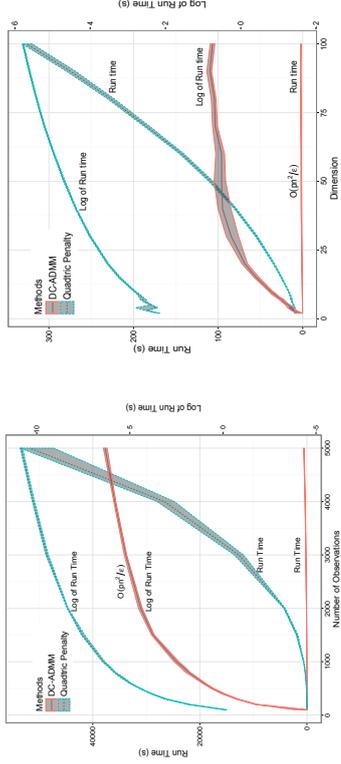

Figure 2: Comparison of run-times of DC-ADMM and quadratic penalty based algorithm based on the average of 100 simulations with different random seeds. Shaded regions represent the 25% and 75% quantiles of the run-times for corresponding algorithms. The complexity of DC-ADMM is $O(pn^2/\epsilon)$, whereas the quadratic penalty based algorithm is much slower.

based algorithm, particularly when either n or p is large. For DC-ADMM, the number of iteration was insensitive to the sample size and was around 100. In contrast, for the quadratic penalty based algorithm, it increased dramatically as the sample size increased; when the sample size was 200, the number of iteration was around 1,000; however, the number of iteration increased to around 85,000 when the sample size increased to 6,000. The complexity of DC-ADMM is quadratic in the sample size n (the ratio of run-time to n^2 was around 10^{-5}) and linear in the dimension p (the ratio of run-time to p was around 0.05), confirming that the computational complexity is $O(pn^2/\epsilon)$.

Figure 3 shows the solution paths for other methods. PRclust2 provided very similar results as DC-ADMM (Figure 3a). However, PRclust2 is extremely slow (around 10 to 30 times slower than the quadratic penalty based algorithm) and not feasible to large data sets. Convex penalties, such as the lasso and the L_2 -norm penalty, always shrink all the estimates towards zero and thus lead to severely biased parameter estimates. For example, if we used the L_2 -norm (Figure 3b) or the lasso (Figure 3c) as the grouping penalty, the estimated centroids were shrunk towards each other, leading to their convergence to the same point at the end and thus much worse performance in clustering. The TLP (Shen et al., 2012) performed much better than the lasso since it imposed no further penalty on large estimates (Figure 3d). Since the TLP does not borrow information from other variables, it performed slightly worse than its grouped version.

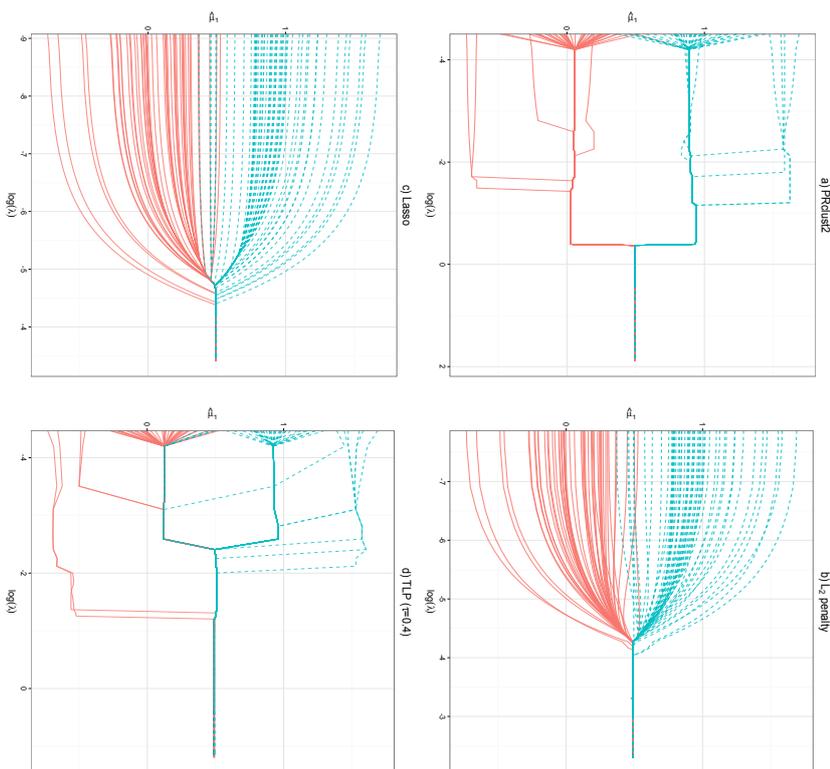

Figure 3: Solution paths of $\hat{\mu}_{i,1}$ for a) PRclust2, b) L_2 penalty, c) Lasso penalty and d) TTP for the first simulated data set.

3. Theory

Though operating characteristics of PRclust have been intensively studied, its clustering consistency properties remain unknown. In this section, based on the maximum likelihood estimation framework, we develop some theoretical properties for penalized regression based clustering method, which incorporates original PRclust (Pan et al., 2013) as a special case. Recall that PRclust does not put any distribution assumptions on the data, however, it can be treated as assuming a Gaussian distribution for the data implicitly as to be shown later. To avoid unaddressable complexity of over-parameterizing the underlying distribution, some mild technical assumptions are introduced. Then we develop a probability bound of clustering consistency which is slightly harder than clustering center consistency (Pollard, 1981).

3.1 PRclust in the Penalized Maximum Likelihood Framework

Assume $x_i \in \mathbb{R}^p \sim f_{\mu_i}(\cdot)$, $1 \leq i \leq n$ are n independent random samples, where f_{μ_i} is a probability density function of x_i with its centroid $\mu_i \in \mathbb{R}^p$. We obtain an estimate $\hat{\mu}^{L_0}$ of $\mu = (\mu_1, \dots, \mu_n)'$ $\in \mathbb{R}^{pn}$ via solving the following constrained L_0 -problem:

$$\min_{\mu} -\mathcal{L}(\mu) \quad \text{subject to} \quad \mathcal{J}(\mu) \leq J, \quad (7)$$

where J is a nonnegative tuning parameter controlling the trade-off between the model fit and the number of clusters, $\mathcal{L}(\mu) = \sum_{i=1}^n \log(f_{\mu_i}(x_i))$ is the log-likelihood that corresponds to the model fit, and $\mathcal{J}(\mu) = \sum_{i < j} I(d(\mu_i, \mu_j) \neq 0)$ is the grouping penalty that controls the number of clusters. $I(\cdot)$ is the indicator function and $d(\cdot, \cdot) : \mathbb{R}^p \times \mathbb{R}^p \rightarrow \mathbb{R}$ is a distance, which can be defined $d(\mu_i, \mu_j) = \|\mu_i - \mu_j\|_q = \{\sum_{m=1}^p |\mu_{im} - \mu_{jm}|^q\}^{1/q}$, $0 < q < \infty$. Then $\mathcal{J}(\mu)$ equals the number of distinct pairs of centroids $\mu_i \neq \mu_j$.

The regularization problem (7) is a constrained counterpart of the following penalized unconstrained L_0 -problem:

$$\min_{\mu} -\mathcal{L}(\mu) + \lambda \mathcal{J}(\mu), \quad (8)$$

where $\lambda \geq 0$ is a tuning parameter corresponding to J in (8). Note that (7) and (8) may not be equivalent in their global minimizers, which is unlike a convex problem.

In a high-dimensional situation, it is not computationally feasible to minimize a discontinuous cost function in (8) and (7). As a surrogate, we consider an estimator $\hat{\mu}^{TL_1}$ that minimizes the following truncated L_1 -problem:

$$\min_{\mu} -\mathcal{L}(\mu) + \lambda \mathcal{T}_{\tau}(\mu), \quad (9)$$

where $\mathcal{T}_{\tau}(\mu) = \sum_{i < j} \text{TTP}(d(\mu_i, \mu_j); \tau)$. Note that if assuming $x_i \sim MVN(\mu_i, \sigma^2 \mathbb{I})$, $1 \leq i \leq n$ and using L_2 -distance, we get $-\mathcal{L}(\mu) = \sum_{i=1}^n \log(f_{\mu_i}(x_i)) = \sum_{i=1}^n \log\left(\frac{1}{(2\pi)^p} \exp\left(-\frac{1}{2\sigma^2} \|x_i - \mu_i\|_2^2\right)\right)$ after ignoring some constants and $\mathcal{T}_{\tau}(\mu) = \sum_{i < j} \text{TTP}(\|\mu_i - \mu_j\|_2; \tau)$, which indicate that (9) reduces to the original PRclust (1) under multivariate Gaussian distribution assumption. When τ is sufficiently small, the truncated L_1 constraint has a good approximation to the L_0 loss (Shen et al., 2012).

3.2 A Fundamental Assumption for Over-parameterization

To reduce the unaddressable complexity to an addressable level, we propose a fundamental assumption. Let $C_k, 1 \leq k \leq K$ be K clusters that satisfy $\cup_{k=1}^K C_k = \{x_1, \dots, x_n\}$ and $C_i \cap C_j = \emptyset$ for $1 \leq i \neq j \leq K$. The number of partitions of n samples into K clusters is $(1/K!) \sum_{k=1}^K (-1)^{k-K} \binom{K}{k} k^n$, which in turn can be approximated by $K^n/K!$ (Steinley, 2006). Since PRclust is based on over-parameterization and assumes one parameter (centroid) for one corresponding sample, the complexity of PRclust is the same as all possible ways of constructing clusters based on all samples. Unfortunately, to the best of our knowledge, there is no possible probability bound that can cover this complexity that requires tail probability decreasing faster than $\exp(-n \log K)$. However, many of the clustering formulation lead to the overlapped clusters and there is no way to reconstruct the true clusters exactly. To recover non-overlapped true clusters, we put a mild technical restriction on the clustering formulation to reduce the complexity.

Assumption (A0): Partition samples x_1, x_2, \dots, x_n into K clusters. For any clusters C_1, C_2, \dots, C_K , there exists m points $y_1^{(k)}, \dots, y_m^{(k)} \in C_k$ such that $d(\bar{y}_m^{(k)}, x_k) \leq d(\bar{y}_m^{(k)}, x_c)$ for all $x_k \in C_k$ and $x_c \in C_c^c$, where $\bar{y}_m^{(k)} = \sum_{l=1}^m y_l^{(k)}/m$ and A^c denotes the complement of a set A . We define m as the *minimal disjoint centering number*.

Note that all the clusters are separated under (A0). Violating (A0) implies that there exist $x_k \in C_k$ and $x_c \in C_c^c$ such that $d(\bar{y}_m^{(k)}, x_k) > d(\bar{y}_m^{(k)}, x_c)$, indicating that there exists another cluster that overlaps with C_k . Interestingly, assumption of this kind seems necessary because clustering consistency is impossible when some clusters overlap, although it appears strong. Worth of note is that other papers, for instance Zhu et al. (2014), explicitly assume that different clusters are reasonably separable from each other for clustering consistency. Furthermore, (A0) excludes any irregular cluster structures, which are not constructed. Most importantly, Lemma 1 in the Appendix gives an upper bound of the number of ways of reconstructable clusters under (A0), reducing the overparameterization complexity from the super-exponential level in the sample size n , $\exp(-n \log K)$, to a polynomial level in n , $\exp(-mK \log n)$. Lastly, (A0) implies that all the clusters must include at least m samples, and guarantees cluster-center consistency asymptotically: for each $1 \leq k \leq K$, $\|\bar{y}_m^{(k)} - \mu_k\|_2 \rightarrow 0$ almost surely as $m \rightarrow \infty$, where μ_k is the centroid of the cluster C_k . Note that Pollard (1981) used a similar assumption for cluster-center consistency for the k -means method.

3.3 Clustering Consistency for L_0 -constrained Problem

Define $\mathcal{C} = \{\mathcal{C}(\mu) : \mu \in \mathbb{R}^{pn}\}$, where $\mathcal{C}(\mu) = \{C_1, \dots, C_K\}$ is a set of clusters based on μ such that for any cluster C_k , $d(\mu_i, \mu_j) = 0$, $\forall i, j \in C_k$ and $d(\mu_i, \mu_j) \neq 0$, $\forall i \in C_k, j \in C_k^c$. Let $\mu^* = (\mu_1^*, \dots, \mu_n^*) \in \mathbb{R}^{pn}$ with $\mu_i^* = (\mu_{i_1}^*, \dots, \mu_{i_p}^*) \in \mathbb{R}^p$ be the true centroid. We study asymptotic properties of $\hat{\mu}^{L_0}$ in (7) by giving a bound of the incorrect clustering probability: $P(\hat{\mu}^{L_0} \neq \mu^o)$, where $\mu^o = (\mu_{i_1}^o, \dots, \mu_{i_p}^o) = \text{argmin}_{\mathcal{C}(\mu) \in \mathcal{C}(\mu^*)} \mathcal{L}(\mu)$ is the oracle estimator that is usually unavailable unless the true clusters are known beforehand. Note that $\hat{\mu}^{L_0}$ is defined as a global minimizer of (7) and assume to be any global minimizer.

Before proceeding, we define a complexity measure for a given function space \mathcal{F} . For any $\epsilon > 0$, let $H(\epsilon, \mathcal{F})$ be the logarithm of the cardinality of the ϵ -bracketing of \mathcal{F} of the

smallest size. To be specific, let $S(\epsilon, \mathcal{F}, r) = \{f_1^r, f_1^r, \dots, f_r^r, f_r^r\}$ be the bracket covering of \mathcal{F} that satisfies $\max_{i \leq j \leq r} \|f_j^r - f_i^r\|_2 \leq \epsilon$, where $\|f\|_2 = (\int f^2 dv)^{1/2}$ and there exists a j such that $f_j^r \leq f \leq f_j^r$ for any $f \in \mathcal{F}$, then $H(\epsilon, \mathcal{F}) = \log(\min\{r : S(\epsilon, \mathcal{F}, r)\})$. For more discussions about metric entropy of this type, see Kolmogorov and Tikhomirov (1959). To construct the clustering consistency properties, we need the following two assumptions.

Assumption (A1): There exists some constant $d_0 > 0$ such that, for any $\epsilon > 0$,

$$\sup_{C \in \mathcal{C}; |C| \leq \mathcal{C}(\mu^*)} H(t, \mathcal{F}_C) \leq d_0 m \log(n) \log(\epsilon^2/2^8 t), \quad \epsilon^2/2^8 < t < 2^{1/2} \epsilon \leq 1,$$

where $\mathcal{F}_C = \{f_\mu : h_n^2(f_\mu, f_{\mu^*}) \leq \epsilon^2, \mu \in \mathcal{B}_C\}$, f_μ is the density of $x = (x_1', \dots, x_n')$, $\mathcal{B}_C = \{\mu : \mathcal{C}(\mu) = C\}$, $|A|$ is the cardinality of a set A and m is the *minimal disjoint centering number* defined in (A0).

Note that (A1) puts some constraints on the size of parameter space, which is similar as Assumption A in Shen et al. (2012) and is a direct modification of the assumption in Wong and Shen (1995).

Define

$$\mathcal{C}_{\min}(\mu^*) \equiv \inf_{\mu \in \mathcal{B}} \frac{h_n^2(f_\mu, f_{\mu^*})}{|\mathcal{C}(\mu)|}$$

to be the degree-of-separation or the level of difficulty of clustering, where $\mathcal{B} = \{\mu : \mathcal{C}(\mu) \neq \mathcal{C}(\mu^*), \mathcal{J}(\mu) \leq \mathcal{J}(\mu^*)\}$ is a parameter space of interest, $h_n(f_\mu, f_{\mu^*}) = \sum_{i=1}^n h(f_{\mu_i}, f_{\mu_i^*})/n^{1/2}$ is the averaged Hellinger metric with $h(f_{\mu_i}, f_{\mu_i^*}) = \left\{ \frac{1}{2} \int (f_{\mu_i}^{1/2} - f_{\mu_i^*}^{1/2})^2 dv \right\}^{1/2}$.

Assumption (A2): There exists some constant $d_1 > 0$ such that

$$\mathcal{C}_{\min}(\mu^*) > d_1 m \log(n)/n,$$

where m is the *minimal disjoint centering number* defined in (A0).

Assumption (A2) describes the least favorable situation through $\mathcal{C}_{\min}(\mu^*)$ under which we can identify the true cluster partition. In fact, $\mathcal{C}_{\min}(\mu^*)$ depends on the number of true clusters and the minimum distance among true cluster centers induced by the Hellinger loss. Since (A2) puts some regularity conditions on log-likelihood function via Hellinger loss, we do not make any regularity conditions for the log-likelihood function explicitly. Similar assumptions as (A2) can be found in the literature of feature selection. For example, Shen et al. (2012) assumed

$$\mathcal{C}_{\min}(\beta^*) \geq d_0 \log(p)/n, \quad (10)$$

where β^* is a true parameter vector of interest, d_0 is a positive constant, p is the dimension of β and n is the sample size. By assuming a probabilistic model such as the Gaussian distribution, (10) can be further specified as

$$\gamma_{\min}^2 = \min_{j: \beta_j^* \neq 0} |\beta_j^*| \geq d_0 \log(p)/n,$$

which implies the feature selection consistency can be constructed even when the minimal signal size is vanishing $\gamma_{\min} \rightarrow 0$ and the dimension of features is diverging $p \rightarrow \infty$. This assumption is much weaker than classical assumptions where γ_{\min} and p are usually fixed constants.

(A2) serves similar roles for clustering consistency as (10) for feature selection consistency. As to be shown later in Proposition 1, by assuming the Gaussian distribution, (A2) can be explicitly specified. More importantly, it allows the minimum distance among different cluster centroids decreases toward zero, $\alpha_{\min} = \min_{\mu_i^* \neq \mu_j^*} \|\mu_i^* - \mu_j^*\|^2 \rightarrow 0$, and the number of cluster diverge to infinity, $K \rightarrow \infty$, indicating that the assumption used here is weaker than many other studies where α_{\min} and K are usually fixed constants (Pollard, 1981; Pelckmans et al., 2005; Radchenko and Mukherjee, 2014; Zhu et al., 2014). Then we establish the main theory for clustering consistency as follows.

Theorem 2 Under Assumptions (A0) to (A2), if $J = \mathcal{J}(\mu^*)$, then, there exists some constant $c_3 > 0$, such that

$$P(\hat{\mu}^{l_0} \neq \hat{\mu}^0) \leq \exp(-c_2 n C_{\min}(\mu^*) + (n+1) \log(n) + 2),$$

provided that $d_1 > \max\{1/c_2, 2d_0(\log c_3)/c_1^2\}$. For example, we may use $c_2 = 4/(27 \times 1926)$, $c_3 = 10$ and $c_4 = (2/3)^{5/2}/512$. Further, $\hat{\mu}^{l_0}$ reconstructs the oracle estimator $\hat{\mu}^0$ with probability tending to one as $n \rightarrow \infty$. The following two asymptotic results hold as $n \rightarrow \infty$:

- (A) (Clustering consistency) $P(\hat{\mu}^{l_0} \neq \hat{\mu}^0) \rightarrow 0$ and hence $P(C(\hat{\mu}^{l_0}) \neq C(\hat{\mu}^*)) \rightarrow 0$.
(B) (Optimal parameter estimation) $E[h_n^2(f_{\hat{\mu}^{l_0}}, f_{\mu^*})] = (1+o(1))E[h_n^2(f_{\hat{\mu}^0}, f_{\mu^*})]$, provided that $c_2 n C_{\min}(\mu^*) + \log(E[h_n^2(f_{\hat{\mu}^0}, f_{\mu^*})]) \rightarrow \infty$.

Theorem 2 says that, under Assumptions (A0) to (A2), $\hat{\mu}^{l_0}$ consistently reconstructs the oracle estimator $\hat{\mu}^0$, and both an oracle clustering and an optimal parameter estimation with respect to expected Hellinger risk are asymptotically available by solving a constrained L_0 -problem. As pointed out by a reviewer, the number of clusters K is an important but unknown tuning parameter. Theorem 2 shows that if the tuning parameter J is chosen to be $J = |\mathcal{J}(\mu^*)|$ then optimal clustering can be constructed asymptotically. We believe that theory established here can be a starting point in developing some new tuning parameter selection criteria, though we have not fully explored in this aspect here. Theorem 2 provides an insight into or gives theoretical justification on when or under which condition the proposed method is expected to give correct clustering. For instance, the theory suggests that the optimal tuning parameters may depend on the underlying true parameters, which needs to be estimated for real data. This, together with the tuning parameter selection criterion lead to the estimated data-dependent tuning parameter for this real data set.

Although theoretical properties of penalized clustering have been intensively studied (Radchenko and Mukherjee, 2014; Zhu et al., 2014), our result is new and different from the proceeding ones. For example, Radchenko and Mukherjee (2014) proved clustering consistency with univariate samples, which are not practical and, in fact, relatively easy to prove in our context without assumption (A0) since the complexity of over-parametrization falls down to an addressable level. Zhu et al. (2014) extended the clustering consistency to multivariate samples by assuming there are only two clusters, say C_1 and C_2 with centroids μ_1 and μ_2 , respectively. To avoid some technical difficulties, Zhu et al. (2014) imposed an assumption that is not required in Theorem 2: two clusters C_1 and C_2 consist proportional number of samples in the sense that $|C_1|/|C_2| \rightarrow c$, where c is a positive constant. Theorem 2 established here extended clustering consistency to a more realistic situation: multivariate samples with many clusters.

3.4 Example: Truncated Multivariate Gaussian Distributions

In this example, we give a sufficient condition for (A2) to hold asymptotically, by constructing a lower bound of $C_{\min}(\mu^*)$ in terms of the minimum center distance $\alpha_{\min} = \min_{\mu_i^* \neq \mu_j^*} \|\mu_i^* - \mu_j^*\|^2$. Let ϕ_{μ_i} , $1 \leq i \leq n$ be the multivariate Gaussian density function with mean $\mu_i \in \mathbb{R}^p$ and identity covariance matrix $I_{p \times p}$; that is, $\phi_{\mu_i}(z) = (2\pi)^{-p/2} \exp(-\|z - \mu_i\|_2^2/2)$, $z \in \mathbb{R}^p$, $1 \leq i \leq n$. For notation simplicity, we denote $\phi_{\mu_i} = \phi$ when $\mu_i = 0$. Note that it is not generally anticipated for clustering consistency under the usual Gaussian distribution assumption since the Gaussian distribution leads to overlapped clusters and violates the assumption (A0). Hence we modify the underlying distributions for the results in Theorem 2 by considering non-overlapping situations.

Consider a class of the truncated densities $\phi_{\mu_i, \alpha}$, $1 \leq i \leq n$ with a truncation level $\alpha > 0$:

$$\phi_{\mu_i, \alpha}(z) = (1/c_\alpha) \phi_{\mu_i}(z) I(\|z - \mu_i\|_2 \leq \alpha/4), \quad (11)$$

where c_α is a normalizing constant. Note that $c_\alpha = \int_{A_{\mu_i, \alpha}} \phi_{\mu_i}(z) dz = \int_{A_\alpha} \phi(z) dz = \mathbf{X}_p(\alpha/4)$, where $A_{\mu_i, \alpha} = \{z : \|z - \mu_i\|_2 \leq \alpha/4\}$, $A_\alpha = \{z : \|z\|_2 \leq \alpha/4\}$ and \mathbf{X}_p is the chi-square distribution function with p degrees of freedom. Given two mean vectors $\mu_i \neq \mu_j$, $\phi_{\mu_i, \alpha}$ does not overlap with $\phi_{\mu_j, \alpha}$ if $\|\mu_i - \mu_j\|_2 > \alpha$. Since the truncated densities $\phi_{\mu_i, \alpha}$ for $1 \leq i \leq n$ in (11) are not overlapped to each other if we take $\alpha = \alpha_{\min} = \min_{\mu_i \neq \mu_j} \|\mu_i - \mu_j\|_2$, we assume that the samples are independently distributed with true truncated densities $\phi_{\mu_i^*, \alpha_{\min}}$, $1 \leq i \leq n$ with a truncation level α_{\min} .

Now, ignoring constraints, consider the problem in (7) for minimizing the minus log-likelihood $-\mathcal{L}(\hat{\mu}) = \sum_{i=1}^n \|x_i - \hat{\mu}\|_2^2/2$ under the constraint $\mathcal{J}(\hat{\mu}) \leq J$. To derive a sufficient condition for (A2), we construct a lower bound of $C_{\min}(\mu^*)$, the level of difficulty in recovering $C(\mu^*)$. Asymptotic properties cannot be established when cluster $C_j \in \mathcal{C}(\mu)$ only shares a finite number of samples with true clusters, and thus we make the following assumption.

Assumption (A3): For any $\mu \in \mathbb{R}^{np}$, there exists m_1 such that $\inf_{C \in \mathcal{C}(\mu)} C^* \text{e}^{\mathcal{C}(\mu^*)} C \cap C^* \neq \emptyset$ $|C \cap C^*| \geq m_1$.

Proposition 1 Let $r_{\alpha_{\min}} = \{\inf_{\mu \in \mathcal{B}} \inf_{\alpha_{\min} - \|\mu_i - \mu_i^*\|_2 \leq \phi_{\alpha_{\min}}} \mathbf{X}_p(t/4)\} / (4\mathbf{X}_p(\alpha_{\min}/4))$, where \mathbf{X}_p and \mathbf{X}_p are the chi-square density and distribution functions with p degrees of freedom, respectively. Under assumptions (A0), (A1) and (A3), if $J = \mathcal{J}(\mu^*)$ then the consistency results (A) and (B) in Theorem 2 hold, provided that

$$r_{\alpha_{\min}} \alpha_{\min} \geq d_1 m_1 K^* \log(n) / m_1, \quad (12)$$

for some constants $d_1 > \max\{1/c_2, 2d_0(\log c_3)/c_1^2\}$, where $K^* = \mathcal{C}(\mu^*)$.

Proposition 1 implies that (12) is a sufficient condition for (A2) for the truncated multivariate Gaussian distributions. In low dimensional situation, α_{\min} , p and K^* may be fixed, $r_{\alpha_{\min}}$ is bounded below, which implies the clustering consistency follows when $m \log(n) / m_1 \rightarrow \infty$ as $n \rightarrow \infty$. Moreover, clustering consistency holds when $\alpha_{\min} \rightarrow 0$ and $p \rightarrow \infty$. From L'Hopital's rule, $\lim_{\alpha_{\min} \rightarrow 0} r_{\alpha_{\min}} \leq \lim_{\alpha_{\min} \rightarrow 0} \mathbf{X}_p(\alpha_{\min}/4) / (4\mathbf{X}_p(\alpha_{\min}/4)) = \infty$ for any $p \geq 3$, which implies (12) is satisfied when $m_1 \alpha_{\min} / m_1 K^* \log(n) \rightarrow \infty$ as $n \rightarrow \infty$. For example, let $K^* \log(n) = n^k$, $m = n^p$ and $m_1 = n^{h_1}$ for some positive constants k, h and h_1 , then the theorem holds provided that $\alpha_{\min} n^{h_1 - (k+h)} \rightarrow \infty$ for any $k+h < h_1 < 1$,

implying that we can recover the true clusters even when $\alpha_{\min} \rightarrow 0$ and $K^* \rightarrow \infty$ as $n \rightarrow \infty$ for any $p \geq 3$.

At first sight, a truncated multivariate Gaussian distribution is an extreme example; however, after ignoring some constants the corresponding minus log-likelihood function $-\mathcal{L}(\mu) = \sum_{i=1}^n \|x_i - \mu\|_2^2$ is used in the original PRclust. Moreover, truncated multivariate Gaussian distributions guarantee that different clusters are separated from each other; non-truncated Gaussian distributions lead to overlapping clusters, and consistency of distance-based clustering methods, including ours, is not expected as a result. For example, suppose we have n observations, $n/2$ form a Gaussian distribution $N(-0.5, 1)$, while the other $n/2$ from $N(0.5, 1)$. According to the K-means cluster center consistency theory (Pollard, 1981), the cluster centers determined by the K-means with $K = 2$ converge to $a_1 = -0.9$ and $a_2 = 0.9$, not the original clusters centers at $\mu_1 = -0.5$ and $\mu_2 = 0.5$. The reason is that all the negative observations from the second distribution/cluster are mis-clustered into the first cluster, while all positive observations from the first clusters are incorrectly assigned to the second cluster by the K-means, leading to an under-estimated center for the first cluster; similarly the over-estimation of the second cluster center can be explained. This simple example suggests that clustering consistency cannot be established when non-truncated Gaussian distributions are used in K-means. Furthermore, previous works focused on establishing clustering consistency with the distance between clusters growing at a sufficiently fast rate. For example, Zhu et al. (2014) showed that if the distance between two clusters and sample size n grow at the same rate as $n \rightarrow \infty$, then the corresponding method can separate the two clusters perfectly. In contrast, clustering consistency established here still holds when minimum distance between the cluster centroids $\alpha_{\min} \rightarrow 0$, implying that the assumptions used here are weaker than the previous ones.

4. Discussion

The proposed new algorithm DC-ADMM bears some similarity to the quadratic penalty based algorithm in terms of the cost function and using difference convex programming. However, they differ significantly in their specific formulations. Instead of using the quadratic penalty technique, we use a hard constraint and an augmented Lagrangian in DC-ADMM. Consequently, the DC-ADMM is much faster than the quadratic penalty based algorithm and can be relatively easy to be extended to other cost functions that may have some advantages for certain problems.

The theory that states some sufficient conditions for clustering consistency and optimal parameter estimation in the PRclust framework covers a much wide range of loss functions and grouping penalties, which helps us study theoretical results uniformly for some specific PRclust implementations in the future. For example, when graph information is available, by adding a constraint on the two connected nodes in the graph, we can estimate a cluster partition and grouping structure of variables simultaneously. The mis-clustering error bound and asymptotic properties of this graph-based PRclust can be obtained via a slight modification to the theory established here.

The methods can be extended in several directions. First, the convergence of the DC-ADMM algorithm is related to the penalty parameter ρ . A poor choice of ρ may result in a slow convergence for the ADMM algorithm (Ghadimi et al., 2015). One may use an

over-relaxed ADMM algorithm to speed up. Other options exist; for example, we may use different values of ρ in each iteration (Wang and Liao, 2001). Second, since the algorithm is relatively fast, it is now feasible to deal with high dimensional data, for which variable selection is necessary. In principle, we may add a new penalty into the cost function for variable selection (Pan and Shen, 2007). Third, we may modify PRclust for noisy big data. Others have developed an iterative sub-sampling approach to improve the computational efficiency of a solution path clustering and to handle noisy big data (Marchetti and Zhou, 2014). A modification of PRclust along this direction may be useful.

An R package *prclust* implementing the DC-ADMM algorithm and the quadratic penalty algorithm with various loss and penalty functions is available at GitHub (<https://github.com/Chongwu-Biostat/prclust>) and CRAN (<http://cran.r-project.org/>).

Appendix A.

Proof of Theorem 1. The finite termination property of DC-ADMM follows from the following three facts. First, since (2) is closed, proper and convex and the augmented Lagrangian (4) has a saddle point, the standard ADMM converges (Boyd et al., 2011). Second, by construction of $S^{(m)}(\mu, \theta)$, for each $m \in \mathbb{N}$,

$$\begin{aligned} 0 &\leq S(\hat{\mu}^{(m)}, \hat{\theta}^{(m)}) = S^{(m+1)}(\hat{\mu}^{(m)}, \hat{\theta}^{(m)}) \leq S^{(m)}(\hat{\mu}^{(m)}, \hat{\theta}^{(m)}) \\ &\leq S^{(m)}(\hat{\mu}^{(m-1)}, \hat{\theta}^{(m-1)}) = S(\hat{\mu}^{(m-1)}, \hat{\theta}^{(m-1)}), \end{aligned}$$

implying that $S(\hat{\mu}^{(m)}, \hat{\theta}^{(m)})$ decreases in m ; otherwise the algorithm stops. Note that $(\hat{\mu}^{(m)}, \hat{\theta}^{(m)})$ is the limiting point of the ADMM iterations in (5). Third, since $S^{(m+1)}(\mu, \theta)$ depends on m only through that on the indicator functions $I(\|\hat{\theta}_{ij}^{(m)}\|_2 < \tau)$, which can be either 1 or 0, $S^{(m+1)}(\mu, \theta)$ has only a finite set of possible functional forms across all m , leading to a finite number of its possible and distinct minimal values. These facts imply that DC-ADMM terminates in a finite number of iterations.

To show that $(\hat{\mu}^{(m^*)}, \hat{\theta}^{(m^*)})$ is a KKT point of $S(\mu, \theta)$, we check if the solution satisfies a local optimality of $S(\mu, \theta)$. Since the subgradient of $S(\mu, \theta)$ and $S^m(\mu, \theta)$ are the same at the minimizer (Rockafellar, 2015), we verify the following requirement:

$$x_i + \rho \sum_{j>i} (\mu_j + \theta_{ij} + u_{ij}) + \rho \sum_{j<i} (\mu_j - \theta_{ji} - u_{ij}) - (1 + \rho(n-1))\mu_i = 0; \quad (13)$$

$$\begin{aligned} \lambda b_{ij} \theta_{ij} / \|\theta_{ij}\|_2 + \rho(\theta_{ij} - (\mu_i - \mu_j) + u_{ij}) &= 0; \\ \theta_{ij} - \mu_i - \mu_j &= 0, \end{aligned} \quad (14) \quad (15)$$

where b_{ij} is the regular subdifferential of $\min(\|\theta_{ij}\|_2, \tau)$ at $\|\theta_{ij}\|_2$. Easily, (15) is the hard constraint in the DC-ADMM and is met at convergence. Note that $(\hat{\mu}^{(m^*)}, \hat{\theta}^{(m^*)}, \hat{u}^{(m^*)}) = (\hat{\mu}^{(m^*-1)}, \hat{\theta}^{(m^*-1)}, \hat{u}^{(m^*-1)})$ at termination. Then (13) is satisfied with $(\mu, \theta, u) = (\hat{\mu}^{(m^*-1)}, \hat{\theta}^{(m^*-1)}, \hat{u}^{(m^*-1)})$. For (14), consider three cases.

- If $\|\hat{\theta}_{ij}^{(m^*-1)}\|_2 > \tau$, the $\hat{\theta}_{ij}^{(m^*-1)} = \hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - u_{ij}^{(m^*)}$, implying $\theta_{ij} = \hat{\theta}_{ij}^{(m^*)}$ since $b_{ij} = 0$.
- If $0 < \|\hat{\theta}_{ij}^{(m^*)}\|_2 < \tau$ and $\|\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}\|_2 > \lambda/\rho$, then

$$\hat{\theta}_{ij}^{(m^*)} = \left(\|\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}\|_2 - \frac{\lambda}{\rho} \right) \frac{\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}}{\|\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}\|_2},$$

hence that $\|\hat{\theta}_{ij}^{(m^*)}\|_2 = \|\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}\|_2 - \frac{\lambda}{\rho}$. Then (14) is met when $\theta_{ij} = \hat{\theta}_{ij}^{(m^*)}$ since $b_{ij} = 1$.

- If $0 < \|\hat{\theta}_{ij}^{(m^*)}\|_2 < \tau$ and $\|\hat{\mu}_i^{(m^*)} - \hat{\mu}_j^{(m^*)} - \hat{u}_{ij}^{(m^*)}\|_2 < \lambda/\rho$, then $\|\hat{\theta}_{ij}^{(m^*)}\|_2 = 0$, which contradicts to the fact that $0 < \|\hat{\theta}_{ij}^{(m^*)}\|_2 < \tau$.

This completes the proof. \blacksquare

Lemma 1. Given n observations $x_i \in \mathbb{R}^p$, $1 \leq i \leq n$, let the number of ways of constructing K clusters that satisfies disjoint condition (assumption A0) with the minimal disjoint centering number m be $c_{n,K,m}$. Then

$$c_{n,K,m} \leq (n-Km)^K \prod_{k=1}^K \binom{n-(k-1)m}{m}.$$

Proof of Lemma 1. Without loss of generality, we fix the first km points and form K disjoint subsets $S_k = \{x_{(k-1)m+1}, \dots, x_{km}\} \subset \{x_1, \dots, x_n\}$, $k \leq K$. Let $r_i^{(k)} = d(\bar{x}_m^{(k)}, x_i)$, $km+1 \leq i \leq n$ with $\bar{x}_m^{(k)} = \sum_{j=(k-1)m+1}^{km} x_j/m$ and $r_i^{(k)}$ be an ordered sequence of $r_i^{(k)}$ that satisfies $r_{km+1}^{(k)} \leq \dots \leq r_n^{(k)}$. Then a possible way of constructing a subset C_k based on S_k is including S_k and all the points within distance $r_i^{(k)}$. For a subset C_k , the number of constructing ways is $n - Km$ at most. Hence, the number of ways of constructing K subsets C_k , $k \leq K$ based on S_k is $(n - Km)^K$ at most.

Note that the number of ways of fixing possible K disjoint subsets S_k , $k \leq K$ is $\prod_{k=1}^K \binom{n-(k-1)m}{m}$. Hence the total number of ways of constructing K subsets along to the way described above is $(n - Km)^K \prod_{k=1}^K \binom{n-(k-1)m}{m}$ at most. Note that any cluster partition with K clusters that satisfies disjoint structure condition with the minimal disjoint centering number m can be constructed via the ways described above. Hence $c_{n,K,m} \leq (n - Km)^K \prod_{k=1}^K \binom{n-(k-1)m}{m}$. This completes the proof. \blacksquare

Proof of Theorem 2. On the set $\tilde{\mathcal{B}} = \{\mu : \mathcal{C}(\mu) = \mathcal{C}(\mu^*)\} \subset \{\mu : \mathcal{J}(\mu) \leq \mathcal{J}(\mu^*)\}$, we have $\hat{\mu}^{L_0} = \sup_{\mu \in \tilde{\mathcal{B}}} \mathcal{L}(\mu) = \hat{\mu}^0 = \sup_{\mathcal{C}(\mu) = \mathcal{C}(\mu^*)} \mathcal{L}(\mu)$. Let the parameter space of interest be $\mathcal{B} = \{\mu : \mathcal{C}(\mu) \neq \mathcal{C}(\mu^*), \mathcal{J}(\mu) \leq \mathcal{J}(\mu^*)\}$. Since $\mathcal{J}(\mu) \leq \mathcal{J}(\mu^*)$ implies $|\mathcal{C}(\mu)| \leq K^*$, we have $\mathcal{B} \subset \{\mu : \mathcal{C}(\mu) \neq \mathcal{C}(\mu^*), |\mathcal{C}(\mu)| \leq K^*\} \subset \cup_{k=1}^{K^*} \cup_{C \in \mathcal{C}_k} \mathcal{B}_C$, where $\mathcal{B}_C = \{\mu : \mathcal{C}(\mu) = C\}$ and $\mathcal{C}_k = \{C \in \mathcal{C} : C \neq \mathcal{C}(\mu^*), |C| = k\}$. Hence, using $\mathcal{L}(\hat{\mu}^0) \geq \mathcal{L}(\mu^*)$, we have

$$\begin{aligned} P(\hat{\mu}^{L_0} \neq \hat{\mu}^0) &\leq P^* \left(\sup_{\mu \in \tilde{\mathcal{B}}} \{\mathcal{L}(\mu) - \mathcal{L}(\hat{\mu}^0)\} > 0 \right) \\ &\leq P^* \left(\sup_{\mu \in \tilde{\mathcal{B}}} \{\mathcal{L}(\mu) - \mathcal{L}(\mu^*)\} > 0 \right) \\ &\leq \sum_{k=1}^{K^*} \sum_{C \in \mathcal{C}_k} P^* \left(\sup_{\mu \in \mathcal{B}_C} \{\mathcal{L}(\mu) - \mathcal{L}(\mu^*)\} > 0 \right), \end{aligned}$$

where P^* is the outer probability. Now we apply Theorem 1 of Wong and Shen (1995) to bound each term. For any $\mu \in \mathcal{B}_C$ and $C \in \mathcal{C}_k$, $h_2^2(f_\mu, f_{\mu^*}) \geq kC_{\min}(f_{\mu^*})$, there exists a constant $c_2 > 0$ such that

$$P^* \left(\sup_{\mu \in \mathcal{B}_C} \{\mathcal{L}(\mu) - \mathcal{L}(\mu^*)\} > 0 \right) \leq 4 \exp(-c_2 n k C_{\min}(f_{\mu^*})),$$

provided that the local entropy conditions are satisfied as follows: there exist constants $c_3 > 0$ and $c_4 > 0$ such that

$$\int_{\mathcal{E}^2/2^8}^{2^{1/2}\epsilon} H^{1/2}(t/c_3, \mathcal{F}_C) dt \leq c_4 n^{1/2} \epsilon^2 \quad (16)$$

for any $\epsilon^2 \geq k\mathcal{C}_{\min}(\mu^*)$. Let $\epsilon_n^2 = 2d_0 \log(c_3) m \log(n) / c_4^2 n$. Under (A1), ϵ_n solves the inequality

$$\max_{k \leq K^*} \sup_{C \in \mathcal{C}_0} \int_{\mathcal{E}^2/2^8}^{2^{1/2}\epsilon} H^{1/2}(t/c_3, \mathcal{F}_C) dt \leq (d_0 m \log(n))^{1/2} (2^{1/2}\epsilon_n \log(c_3))^{1/2} \leq c_4 n^{1/2} \epsilon_n^2$$

with respect to ϵ provided that $\epsilon_n < \epsilon$. Hence, (16) follows if $\mathcal{C}_{\min}(\mu^*) \geq \epsilon_n^2$, and from (A2), this holds when $d_1 \geq 2d_0 \log(c_3) m / c_4^2$. From Lemma 1, $|C_k| \leq (n - km)^k \prod_{j=1}^k \binom{n-j-1}{m} \leq n^{k+mk}$. Hence,

$$\begin{aligned} P(\hat{\mu}^{L_0} \neq \hat{\mu}^*) &\leq \sum_{k=1}^{K^*} 4 \exp(-c_2 n k \mathcal{C}_{\min}(\mu^*) + k(m+1) \log(n)) \\ &\leq 4R(\exp(-c_2 n \mathcal{C}_{\min}(\mu^*) + (m+1) \log(n)) \\ &\leq 5 \exp(-c_2 n \mathcal{C}_{\min}(\mu^*) + (m+1) \log(n)) \\ &\leq \exp(-c_2 n \mathcal{C}_{\min}(\mu^*) + (m+1) \log(n) + 2), \end{aligned}$$

where $R(x) = x/(1-x)$ is exponentiated logistic function.

Now (A) follows from $P(\mathcal{C}(\hat{\mu}^{L_0}) \neq \mathcal{C}(\mu^*)) \leq P(\hat{\mu}^{L_0} \neq \mu^*)$ and $d_1 > 1/c_2$. For the risk property, using $h_a^2(\hat{\mu}^{L_0}, \mu^*) \leq 1$,

$$\begin{aligned} E[h_a^2(\hat{\mu}^{L_0}, \mu^*)] &\leq E[h_a^2(\hat{\mu}^0, \mu^*)] + E[h_a^2(\hat{\mu}^{L_0}, \mu^*) I(\hat{\mu}^{L_0} \neq \hat{\mu}^0)] \\ &\leq E[h_a^2(\hat{\mu}^0, \mu^*)] + P(\hat{\mu}^{L_0} \neq \hat{\mu}^0) \\ &\leq (1 + o(1)) E[h_a^2(\hat{\mu}^0, \mu^*)] \end{aligned}$$

provided that $\exp(-c_2 n \mathcal{C}_{\min}(\mu^*)) / E[h_a^2(\hat{\mu}^0, \mu^*)] = o(1)$, and then (B) established. This completes the proof. \blacksquare

Proof of Proposition 1. It suffices to show that (12) is a sufficient condition for Assumption (A2). First, we give a lower bound of the Hellinger metric between $\phi_{\mu_i, \alpha_{\min}}$ and $\phi_{\mu_i^*, \alpha_{\min}}$ for a given $\mu \in \mathcal{B} = \{\mu : \mathcal{C}(\mu) \neq \mathcal{C}(\mu^*), \mathcal{J}(\mu) \leq \mathcal{J}(\mu^*)\}$. Let

$$A_{\alpha_{\min}} = \{z : \|z\|_2^2 \leq \alpha_{\min}/4\} \text{ and } A_{\mu_i, \alpha_{\min}} = \{z : \|z - \mu_i\|_2^2 < \alpha_{\min}/4\}, 1 \leq i \leq n.$$

Given $\mu_i \neq \mu_i^*$ with $\|\mu_i - \mu_i^*\|_2^2 \leq \alpha_{\min}$, let $\Delta_i^* = \mu_i - \mu_i^*$ then we have

$$\begin{aligned} &h^2(\phi_{\mu_i, \alpha_{\min}}, \phi_{\mu_i^*, \alpha_{\min}})^2 \\ &= h^2(\phi_{\alpha_{\min}}, \phi_{\Delta_i^*, \alpha_{\min}})^2 \\ &= \frac{1}{2} \int (\phi_{\alpha_{\min}}^{1/2}(z) - \phi_{\Delta_i^*, \alpha_{\min}}^{1/2}(z))^2 dz \\ &= \frac{1}{2\mathcal{X}_p^2(\alpha_{\min}/4)} \left(\int_{A_{\alpha_{\min}}} \phi(z) dz + \int_{A_{\Delta_i^*, \alpha_{\min}}} \phi_{\Delta_i^*}(z) dz - 2 \int_{A_{\alpha_{\min}} \cap A_{\Delta_i^*, \alpha_{\min}}} \phi(z)^{1/2} \phi_{\Delta_i^*}(z)^{1/2} dz \right) \\ &= \frac{1}{\mathcal{X}_p^2(\alpha_{\min}/4)} \left(\int_{A_{\alpha_{\min}}} \phi(z) dz - \int_{A_{\alpha_{\min}} \cap A_{\Delta_i^*, \alpha_{\min}}} \phi(z)^{1/2} \phi_{\Delta_i^*}(z)^{1/2} dz \right). \end{aligned}$$

Let $B_{\Delta_i^*, \alpha_{\min}} = \{z : \|z - \Delta_i^*\|_2^2 \leq \alpha/4 - \|\Delta_i^*\|_2^2/4\}$ then it is easy to see that

$$A_{\alpha_{\min}} \cap A_{\Delta_i^*, \alpha_{\min}} \subset B_{\Delta_i^*, \alpha_{\min}}.$$

By using the equality,

$$\phi(z)^{1/2} \phi_{\Delta_i^*}(z)^{1/2} = (2\pi)^{-p/2} \exp(-\|z - \Delta_i^*\|_2^2/2 - \|\Delta_i^*\|_2^2/8) = \exp(-\|\Delta_i^*\|_2^2/8) \phi_{\Delta_i^*/2}(z),$$

we have

$$\begin{aligned} &\int_{A_{\alpha_{\min}} \cap A_{\Delta_i^*, \alpha_{\min}}} \phi(z)^{1/2} \phi_{\Delta_i^*}(z)^{1/2} dz \leq \exp(-\|\Delta_i^*\|_2^2/8) \int_{B_{\Delta_i^*/2, \alpha_{\min}}} \phi_{\Delta_i^*/2}(z) dz \\ &= \exp(-\|\Delta_i^*\|_2^2/8) \mathcal{X}_p(\alpha_{\min}/4 - \|\Delta_i^*\|_2^2/4) \\ &\leq \mathcal{X}_p(\alpha_{\min}/4 - \|\Delta_i^*\|_2^2/4). \end{aligned}$$

According to the mean value theorem,

$$h^2(\phi_{\mu_i, \alpha_{\min}}, \phi_{\mu_i^*, \alpha_{\min}})^2 \geq \frac{\mathcal{X}_p(\alpha_{\min}/4) - \mathcal{X}_p(\alpha_{\min}/4 - \|\Delta_i^*\|_2^2/4)}{\mathcal{X}_p^2(\alpha_{\min}/4)} \geq r_{\alpha_{\min}} \|\mu_i - \mu_i^*\|_2^2, \quad (17)$$

where $r_{\alpha_{\min}} = \{\inf_{\mu \in \mathcal{B}} \inf_{\alpha_{\min} - \|\Delta_i^*\|_2^2 \leq \alpha_{\min}} \mathcal{X}_p(t/4)\} / 4\mathcal{X}_p(\alpha_{\min}/4)$. Next, we find a lower bound of $\mathcal{C}_{\min}(\mu^*)$. From (17), the inequality $h_a^2(f_\mu, f_{\mu^*}) \geq \sum_{i=1}^n h^2(f_{\mu_i}, f_{\mu_i^*})/n$ implies

$$n\mathcal{C}_{\min}(\mu^*) = n \inf_{\mu \in \mathcal{B}} h_a^2(f_\mu, f_{\mu^*}) / \mathcal{C}(\mu) \geq nr_{\alpha_{\min}} \inf_{\mu \in \mathcal{B}} \|\mu - \mu^*\|_2^2 / \mathcal{C}(\mu). \quad (18)$$

It is easy to see that $\inf_{\mu \in \{\mu : \mathcal{C}(\mu) < K^*\}} \|\mu - \mu^*\|_2^2 / \mathcal{C}(\mu) \geq \inf_{\mu \in \{\mu : \mathcal{C}(\mu) = K^*\}} \|\mu - \mu^*\|_2^2 / K^*$, since the sum of within cluster variances, $\|\mu - \mu^*\|_2^2 = \sum_{i=1}^n \|\mu_i - \mu_i^*\|_2^2$, is minimized when $|\mathcal{C}(\mu)| = K^*$. Hence, we have

$$\inf_{\mu \in \mathcal{B}} \|\mu - \mu^*\|_2^2 / \mathcal{C}(\mu) = \inf_{\mu \in \{\mu : \mathcal{C}(\mu) = K^*, \mathcal{C}(\mu) \neq \mathcal{C}(\mu^*)\}} \|\mu - \mu^*\|_2^2 / K^*. \quad (19)$$

Let $\mathcal{C}(\mu) = \{C_1, \dots, C_K\}$ and $\mathcal{C}(\mu^*) = \{C_1^*, \dots, C_{K^*}^*\}$. Since $\mathcal{C}(\mu) \neq \mathcal{C}(\mu^*)$, without loss of generality, we may assume that $C_s \cap C_t^* \neq \emptyset$ for $s, t = 1, 2$. Then the right-hand side of (19) achieves its minimum when $\mu \in \mathcal{B}_{12} = \{\mu : C_s \cap C_t^* \neq \emptyset \text{ for } s, t = 1, 2 \text{ and } \mu_i = \mu_i^* \text{ for } i \in$

$\cup_{3 \leq k \leq K^*} C_k^t$. Let $\mu_i = \nu_{s,i} \in C_s$ for $s = 1, 2$ and similarly let $\mu_i^t = \nu_i^*$, $i \in C_t^*$ for $t = 1, 2$. Then it follows that

$$\begin{aligned} \inf_{\mu \in \mathcal{B}} \|\mu - \mu^*\|_2^2 &= \inf_{\mu \in \mathcal{B}^{1,2}} \sum_{t=1,2} (n_{1t} \|\nu_1 - \nu_1^*\|_2^2 + n_{2t} \|\nu_2 - \nu_2^*\|_2^2) \\ &= \inf_{n_{s,t}; t=1,2} \sum_{t=1,2} (n_{1t} \|\nu_1^* - \nu_1^*\|_2^2 + n_{2t} \|\nu_2^* - \nu_2^*\|_2^2) \\ &= \inf_{n_{s,t}; t=1,2} \left(\frac{n_{11}n_{12}}{n_{11} + n_{12}} + \frac{n_{21}n_{22}}{n_{21} + n_{22}} \right) \|\nu_1^* - \nu_2^*\|_2^2, \end{aligned}$$

where $n_{st} = |C_s \cap C_t^*|$ for $s, t = 1, 2$ and $\nu_1^* = (n_{11}\nu_1^* + n_{12}\nu_2^*)/(n_{11} + n_{12})$ and $\nu_2^* = (n_{21}\nu_1^* + n_{22}\nu_2^*)/(n_{21} + n_{22})$ are the weighted means of ν_1^* 's and ν_2^* 's in C_1 and C_2 , respectively. From (A3), $n_{st} \geq m_1$ for $s, t = 1, 2$, which implies $n_{11}n_{12}/(n_{11} + n_{12}) = 1/(1/n_{11} + 1/n_{12}) \geq m_1/2$ and similarly, $n_{21}n_{22}/(n_{21} + n_{22}) \geq m_1/2$. Hence the lower bound becomes

$$\inf_{\mu \in \mathcal{B}} \|\mu - \mu^*\|_2^2 \geq m_1 \alpha_{\min}. \quad (20)$$

From (18), (19), (20) and definition of $C_{\min}(\mu^*)$, it is easy to see that (A2) is met if $C_{\min}(\mu^*) \geq r_{\alpha_{\min}} m_1 \alpha_{\min} / n K^* \geq d_1 m \log(n)/n$ which is equivalent to

$$r_{\alpha_{\min}} \alpha_{\min} \geq d_1 m K^* \log(n) / m_1.$$

This completes the proof. \blacksquare

Appendix B.

The cost function of PRclust with lasso grouping penalty will be convex and thus DC-ADMM is exactly same as ADMM and a global solution will be reached. Note that $\theta_{ij} = (\theta_{j1}, \dots, \theta_{jp})$, then the updating formulas can be summarized as follows:

$$\begin{aligned} \hat{\mu}_i^{(n+1)} &= \frac{x_i + \rho \sum_{j>i} \left(\hat{\mu}_j^{(n)} + \hat{\theta}_{ij}^{(n)} + \hat{u}_{ij}^{(n)} \right) + \rho \sum_{j<i} \left(\hat{\mu}_j^{(n+1)} - \hat{\theta}_{ji}^{(n)} - \hat{u}_{ij}^{(n)} \right)}{1 + \rho(n-1)}; \\ \hat{\theta}_{ij}^{(n+1)} &= \text{ST} \left(\hat{\mu}_{ij}^{(n+1)} - \hat{\mu}_{ji}^{(n+1)} - \hat{u}_{ij}^{(n)}, \lambda / \rho \right) \\ \hat{u}_{ij}^{(n+1)} &= \hat{u}_{ij}^{(n)} + \hat{\theta}_{ij}^{(n+1)} - (\hat{\mu}_{ij}^{(n+1)} - \hat{\mu}_{ji}^{(n+1)}), \quad 1 \leq i < j \leq n; i, l = 1, 2, \dots, p. \end{aligned}$$

The main difference between TLP and gTLP is that TLP is an element-wise penalty and the updating formulas (5) for PRclust with TLP can be summarized as follows, while the other part of DC-ADMM remains unchanged:

$$\begin{aligned} \hat{\mu}_i^{k+1} &= \frac{x_i + \rho \sum_{j>i} \left(\hat{\mu}_j^k + \hat{\theta}_{ij}^k + \hat{u}_{ij}^k \right) + \rho \sum_{j<i} \left(\hat{\mu}_j^{k+1} - \hat{\theta}_{ji}^k - \hat{u}_{ij}^k \right)}{1 + \rho(n-1)}; \\ \hat{\theta}_{ij}^{k+1} &= \begin{cases} \hat{\mu}_{ij}^{k+1} - \hat{\mu}_{ji}^{k+1} - \hat{u}_{ij}^k & \text{if } |\hat{\theta}_{ij}^{(m)}| \geq \tau; \\ \text{STL} \left(\hat{\mu}_{ij}^{k+1} - \hat{\mu}_{ji}^{k+1} - \hat{u}_{ij}^k; \lambda / \rho \right) & \text{if } |\hat{\theta}_{ij}^{(m)}| < \tau; \end{cases} \\ \hat{u}_{ij}^{k+1} &= \hat{u}_{ij}^k + \hat{\theta}_{ij}^{k+1} - (\hat{\mu}_{ij}^{k+1} - \hat{\mu}_{ji}^{k+1}), \quad 1 \leq i < j \leq n; i, l = 1, 2, \dots, p. \end{aligned}$$

Abstract

We use a geometric digraph family called class cover catch digraphs (CCCDs) to tackle the class imbalance problem in statistical classification. CCCDs provide graph theoretic solutions to the class cover problem and have been employed in classification. We assess the classification performance of CCCD classifiers by extensive Monte Carlo simulations, comparing them with other classifiers commonly used in the literature. In particular, we show that CCCD classifiers perform relatively well when one class is more frequent than the other in a two-class setting, an example of the *class imbalance problem*. We also point out the relationship between class imbalance and class overlapping problems, and their influence on the performance of CCCD classifiers and other classification methods as well as some state-of-the-art algorithms which are robust to class imbalance by construction. Experiments on both simulated and real data sets indicate that CCCD classifiers are robust to the class imbalance problem. CCCDs substantially undersample from the majority class while preserving the information on the discarded points during the undersampling process. Many state-of-the-art methods, however, keep this information by means of ensemble classifiers, but CCCDs yield only a single classifier with the same property, making it both appealing and fast.

Keywords: Class Cover Catch Digraphs, Class Cover Problem, Class Imbalance Problem, Class Overlapping Problem, Graph Domination, Prototype Selection, Support Estimation

1. Introduction

Class imbalance problem has recently become a topic of extensive research. In a two-class setting, imbalance in class(es) occurs when one class is represented by far more observations (points) than the other class in the data set (see, e.g., Chawla et al. (2004) and López et al. (2013)). Class imbalance problem is observed in many areas such as medicine, fraud detection and education. Some examples are clinical trials in which only 5% of patients in the data set have a certain disease, such as cancer (Mazurowski et al., 2008); detecting fraudulent customers where most individuals are law-abiding in insurance, credit card and telecommunications industries (Phua et al., 2004); and archives of college students where

mostly the ones who have fair results are kept (Thai-Nghe et al., 2009). In these and many other real life cases, majority class (i.e., the class with larger size) confounds the classifier performance by hindering the detection of subjects from the minority class (i.e., the class with fewer points).

The classification methods in machine learning usually suffer from the imbalance of class sizes in the data sets because most of these methods work on the assumption that class sizes are balanced (Japkowicz and Stephen, 2002). For example, the commonly used k -nearest neighbor (k -NN) classification algorithm is highly influenced by the class imbalance problem. In the k -NN approach, a new point is classified as the class of the most frequent one from its first k nearest neighbors (Fix and Hodges, 1989; Cover and Hart, 1967). As a result, in a two-class setting where one class substantially outnumbers the other, a point is more likely to be classified as the majority class by the k -NN classifier. In literature, sensitivity of k -NN classifier to the class imbalance problem and some solutions on choosing the appropriate k have been discussed in cases of imbalanced classes (see Mani and Zhang, 2003; Garcia et al., 2008; Hand and Vinciotti, 2003). Decision trees and support vector machines (SVM) are also some of the well known classifiers that are sensitive to the class imbalance in a data set (Japkowicz and Stephen, 2002; Tang et al., 2009). SVMs are among the most commonly used algorithms in the machine learning literature due to their well understood theory and high performance among popular algorithms (Wu et al., 2008; Fernández-Delgado et al., 2014), but these methods have been demonstrated to be inefficient against highly imbalanced data sets, although SVMs are still robust to moderately imbalanced data sets (Akbari et al., 2004; Raskutti and Kowalczyk, 2004).

We approach the classification of imbalanced data sets with methods that solve class cover problem (CCP), where the goal is to find a region that encapsulates all the members of the class of interest (i.e., target class). This particular region can be viewed as a *cover*; hence the name *class cover* (Cannon and Cowen, 2004). This problem is closely related to another problem in statistics, namely *support estimation*: estimating the support of a particular random variable defined in a measurable space (Schölkopf et al., 2001). Here, each cover can be realized as estimates of its associated class support. Priebe et al. (2001) introduced the class cover catch digraphs (CCCD) to find graph theoretic solutions to the CCP problem, and provided some results on the minimum dominating sets and the distribution of the domination number of such digraphs for one dimensional data. Priebe et al. (2003a) applied CCCDs on classification and showed that approximate minimum dominating sets of CCCDs (which were obtained by a greedy algorithm) and radii of the covering balls can be used to establish efficient classifiers. Moreover, DeVinney et al. (2002) defined random walk CCCDs (RW-CCCDs) where balls of class covers are more relaxed compared to previously introduced so called pure-CCCDs (P-CCCDs). In P-CCCDs, no member of the non-target class is covered, but RW-CCCDs allow some points of non-target class to be covered by the cover of the target class. Some target class points may also be uncovered in the process. Hence, RW-CCCDs may potentially avoid overfitting. CCCDs have been applied in face detection (Socolinsky et al., 2003) and latent class discovery in gene expression data (Priebe et al., 2003b). There are several other approaches in the literature to solve the class cover problem, including covering the classes with a set of boxes (Bereg et al., 2012) or set of convex hulls (Takigawa et al., 2009).

In this article, we study the effects of class imbalance on two CCCD classifiers, P-CCCD and RW-CCCD. Moreover, we report on the effects of class overlapping problem (which is defined as deterioration of classification performance when class supports overlap) along with the class imbalance problem to further investigate the performance of CCCD classifiers when imbalance and overlapping between classes co-exist. Thus, we show that when there is a considerable amount of class imbalance, whether class supports overlap or not, the CCCD classifiers perform better than the k -NN classifier. We show the robustness of CCCD classifiers to the class imbalance by simulating cases having increasing levels of class imbalance. We also compare CCCD classifiers with SVM classifiers which are potentially robust to moderate levels of class imbalance but not to high levels. With respect to class imbalance problem, the k -NN, SVM and decision tree classifiers may be referred to as “weak” classifiers; that is, these methods perform weakly when there is imbalance in the data set. However, such classifiers can be modified to address the unequal priors in a data set, and hence, can be converted to “strong” classifiers which are potentially robust to the class imbalance problem. We show that CCCD classifiers are also inherently robust (i.e., robust to class imbalance without any modification), and we compare the CCCD classifiers against the state-of-the-art strong classification methods which are constructed to perform well when class imbalance occurs. We consider ensemble learning, cost sensitive learning and resampling schemes in conjunction with k -NN, SVM and decision tree classifiers, and show that RW-CCCDs and P-CCCDs perform comparable to those strong classifiers.

Among the two variations of CCCD classifiers, we show that the RW-CCCD is more appealing in many aspects. For both simulated and real life examples, RW-CCCDs perform better than P-CCCDs and weak classifiers, and perform comparable to strong classifiers when the classes of data sets are imbalanced and/or overlapping. Moreover, we report on the complexity of the two CCCD classifiers and demonstrate that RW-CCCDs reduce the data sets substantially more than the other classifiers, thus increasing the testing speed. But most importantly, while reducing the majority class to mitigate the effects of class imbalances, CCCDs preserve the information on the discarded points of the majority class. CCCDs provide a novel potential solution to the class imbalance problem: that is, they capture the density around prototype points (i.e., members of the dominating sets) as radii of the covering balls. Hence, CCCDs preserve the information while reducing the data set. In the literature, only the strong classifiers based on hybrids of ensembles and resampling schemes achieve a similar task which requires multiple classifiers to be employed, and thus, result in lengthy training and testing time. However, CCCDs define single classifiers that undersample the data set with, possibly, a slight loss of information.

We provide a short review of the existing methods for classifying data sets with class imbalance in Section 2, introduce P-CCCD and RW-CCCD classifiers in Section 3, discuss the balancing effect of CCCD classifiers in Section 4. Finally, in Section 5, we compare the CCCD classifiers with the classifiers that are both sensitive (weak) and non-sensitive (strong) classifiers to class imbalance by simulated and real data sets, and report on the computational complexity of all weak classifiers.

2. Methods for Handling Class Imbalance Problem

Solving the class imbalance problem received considerable attention in the machine learning literature (see Chawla et al., 2004; Kotsiantis et al., 2006; Longadge and Dongre, 2013). Almost all algorithms designed to mitigate the effects of class imbalance incorporate a “weak” classifier which is modified to show some level of robustness to the class imbalance problem. The weak algorithm is modified either (i) in data level which involves a pre-processing of the data set being used in training, or (ii) in algorithmic level such that a “strong” classifier is constructed with a decision rule suited for the imbalances in the data set. Many modern algorithms are hybrids of both types; but in particular, there are mainly three of them: resampling methods, cost-sensitive methods, and ensemble methods (He and Garcia, 2009).

Resampling methods are commonly employed to remove the effects of class imbalance in the classification process. Resampling methods provide solutions to the class imbalance problem by (i) downsizing the majority class (undersampling) or (ii) generating new (synthetic) points for the minority class (oversampling). Hence, such methods modify the classifiers only at the data level. It might be useful to clean or erase some points in the majority class to balance the data (Drummond et al., 2003; Liu et al., 2009). However, in some cases, all points from both classes may be valuable/important, and hence, should be kept despite the differences in the class sizes. Oversampling methods generate synthetic points similar to the minority class to mitigate the class imbalance problem while preserving the information (Han et al., 2005). On the other hand, Batista et al. (2004) suggest that the combination of both over and undersampling methods can further improve the classification performance. One such method is the SMOTE+ENN method where the oversampling method SMOTE of Chawla et al. (2002) and edited nearest neighbors (ENN) method of Wilson (1972) are applied to an imbalanced data set, consecutively. While SMOTE balances the classes of the data set by generating artificial points between members of the minority class, ENN cleans the data set to further increase the classification performance of the weak classifier. Here, ENN method is an undersampling method that primarily aims to remove noisy points from the data set but not to balance the classes.

Another family of methods, namely cost-sensitive learning methods, has originated from real life: the cost of misclassifying a minority and a majority class member is usually not the same (Elkan, 2001). Frequently, the minority class has higher misclassification cost than the majority class. Classification methods such as decision trees (e.g., C4.5), can be modified to take these costs into account (see Ling et al., 2004; Zadrozny et al., 2003). C5.0 is an extended version of C4.5 incorporating the cost of each class (Kuhn and Johnson, 2013). Most weak classifiers can be easily modified so as to recognizing misclassification costs. The constrained violation cost C of SVM classifiers can be adjusted to individual class costs (Chang and Lin, 2011). As for k -NN, one solution is to appoint weights to all points of the data set with respect to their classes. Hence, such weights are the costs of classes giving precedence to minority class points (Barandela et al., 2003). On the other hand, for those algorithms that costs are not inherently recognizable or available, meta-learning schemes can be used along with weak classifiers without modifying the classifiers. Such learning methods are similar to ensemble learning methods (Domingos, 1999).

A fast developing field called ensemble learning also contributes to the family of methods handling the class imbalance problem (see Galar et al., 2012). The idea is to combine several classifiers to create a new classifier which has significantly better performance than its constituents (Rokach, 2010). AdaBoost is a popular algorithm among this family of learning methods (Freund and Schapire, 1997; Wu et al., 2008). AdaBoost assigns weights to each of the points in the data set and updates these weights in accordance with how well the points are estimated by each classifier. Galar et al. (2012) provide a survey of the most important ensemble learning methods that solve the class imbalance problem. However, it has been observed in some studies that ensemble learning methods work best when used together with resampling methods (López et al., 2013). In fact, ensemble and resampling schemes compensate the shortcomings of each other. The EasyEnsemble is a classifier with two levels of ensembles. First, a random undersampled majority class and the original minority class are used to train an ensemble classifier, then another random sample is drawn in the same way to train a second ensemble. This process is repeated several times to mitigate the effects of information loss as each ensemble would be applied on a different random subset of the majority class.

3. Classification with Class Cover Catch Digraphs

Class Cover Catch Digraphs (CCCDs) offer graph theoretic solutions to CCP (Priebe et al., 2001, 2003a). The objective of CCP is to find a region that covers the members of a specific class. More specifically, let (Ω, M) be a measurable space and let $\mathcal{X}_n = \{x_1, x_2, \dots, x_n\} \subset \Omega$ and $\mathcal{Y}_m = \{y_1, y_2, \dots, y_m\} \subset \Omega$ be observations from two classes \mathcal{X} and \mathcal{Y} with class conditional distributions F_X, F_Y and a joint cdf $F_{X,Y}$, respectively. Let $\Omega = \mathbb{R}^d$ and, without loss of generality, assume that the target class (i.e., the class of interest) is \mathcal{X} . In a CCCD, for $x_i, x_j \in \mathcal{X}_n \subset \mathbb{R}^d$ is the center of a ball with radius $r_i = r(x_i)$. Each ball is represented by $B_i = B(x_i, r_i)$ and if $x_j \in B_i$ then x_i is said to cover (or catch) x_j . Here, $d(\cdot, \cdot)$ can be any dissimilarity measure but we use the Euclidean distance henceforth. A CCCD is a digraph $D = D(V, A)$ with vertex set $V(D) = \mathcal{X}_n$ and the arc set $A(D)$ where $(x_i, x_j) \in A(D)$ if and only if $x_j \in B_i$. The term “catch” refers to arc (x_i, x_j) of the digraph D where x_i is said to catch x_j . The binary relation $x_i \sim x_j$, which is defined as $x_j \in B_i$, is asymmetric, thus the adjacency of x_i and x_j is represented with directed edges or arcs which yield a digraph instead of a graph.

In CCCDs, the goal is to find a subset of balls $C_X \subseteq B_X = \{B_1, B_2, \dots, B_n\}$ such that $Q_X \subseteq \cup_{B \in C_X} B$ for $Q_X \subseteq \mathcal{X}_n$ where the set Q_X is some desirable subset of the target class training set \mathcal{X}_n which we want to cover. Preferably, the goal is to find a set C_X such that $Q_X = \mathcal{X}_n$, however it might be desirable that the class cover may ignore some target class points to avoid overfitting. If a class cover of a CCCD fails to cover some target class points, it is called an *improper* cover, otherwise it is a *proper* cover. For covering \mathcal{Y}_m , we reverse the roles of classes \mathcal{X} and \mathcal{Y} . The class \mathcal{Y} becomes the target class and \mathcal{X} becomes the non-target class. Finding an appropriate cover C_X is equivalent to finding the dominating set of the CCCD with $V(D) = \mathcal{X}_n$. Let $N(s) = \{t \in V(D) : (s, t) \in A(D)\}$ be the *open neighborhood* of a vertex $s \in V(D)$: the set of vertices that have an arc from the vertex s , or the neighbors of s . A dominating set of a digraph D is defined as a subset of vertices $S \subseteq V(D)$ such that union of the closed neighborhoods, defined by $\bar{N}(s) = N(s) \cup \{s\}$, of elements of S

is the vertex set of the digraph: $\cup_{s \in \bar{N}(s)} = V(D)$. Among all dominating sets, usually the ones with minimum cardinality, called the minimum dominating sets, are preferable. The cardinality of the minimum dominating set(s) is referred to as the *domination number*, denoted as $\gamma(D)$. However, minimum dominating sets are often computationally intractable and finding them is, in general, an NP-hard optimization problem. Hence, greedy algorithms are often employed to find sets with approximately minimum cardinality (Chvatal, 1979; DeVinney, 2003).

CCCDs can easily be generalized to the multi-class case with k classes. To establish the set of covers $\mathcal{C} = \{C_1, C_2, \dots, C_k\}$ associated with a set of classes $\mathfrak{X} = \{\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k\}$, we merge the classes into two classes as $\mathcal{X}_T = \mathcal{X}_i$ and $\mathcal{X}_{YT} = \cup_{j \neq i} \mathcal{X}_j$ for $i, j = 1, \dots, k$. We refer to classes \mathcal{X}_T and \mathcal{X}_{YT} as target class and non-target class, respectively. More specifically, target class is the class we want to find the cover of, and the non-target class is the union of the remaining classes. We transform the multi-class case into a two-class setting and find the cover of i -th class, C_i , for each $i = 1, \dots, k$.

We employ two families of CCCDs, pure-CCCDs (P-CCCDs) and random walk CCCDs (RW-CCCDs) that differ in the definition of the radius $r(x)$. In these two digraphs, the (approximate) minimum dominating set S and the classifier are defined in slightly different ways; with the main distinction between the two being the way the covers are defined. The covering balls of P-CCCDs do not contain any non-target class point (hence the name “pure”) whereas RW-CCCDs possibly allow some non-target class points inside of the class cover of the target class so as to avoid overfitting. Moreover, some target class points may also be excluded from the covers of RW-CCCDs. Therefore, P-CCCDs construct pure and proper covers but RW-CCCD covers are not necessarily pure or proper.

3.1 Classification with P-CCCDs

In P-CCCDs, the covering balls $B_x = B(x, r(x))$ exclude all non-target class points. Thus, for a target class point $x \in \mathcal{X}_n$, which is the center of a ball B_x , the radius $r(x)$ should be smaller than the distance between x and the closest non-target point $y \in \mathcal{Y}_m$: $r(x) < \min_{y \in \mathcal{Y}_m} d(x, y)$. Given $\tau \in (0, 1]$, the radius $r(x)$ is defined as follows (Marchette, 2010):

$$r(x) := (1 - \tau)d(x, l(x)) + \tau d(x, u(x)), \quad (1)$$

where

$$u(x) := \operatorname{argmin}_{y \in \mathcal{Y}_m} d(x, y)$$

and

$$l(x) := \operatorname{argmax}_{z \in \mathcal{X}_n} \{d(x, z) : d(x, z) < d(x, u(x))\}.$$

The effect of parameter τ on the radius $r(x)$ is illustrated in Figure 1 (DeVinney, 2003). The ball with radius $r(x)$ catches the neighboring target class points, and for any $\tau \in (0, 1]$, the ball B_x catches the same points as well. Hence, the choice of τ does not effect the structure of digraph but might affect the classification performance which will be shown later in Section 5. On the other hand, for all $x \in \mathcal{X}_n$, the definition of $r(x)$ in Equation (1) keeps any non-target point $y \in \mathcal{Y}_m$ out of the ball B_x , that is $\mathcal{Y}_m \cup B_x = \emptyset$ for all $B_x \in C_X$. Here, B_x is an open ball: $B_x = \{z \in \mathbb{R}^d : d(x, z) < r(x)\}$. The digraph D is “pure” since

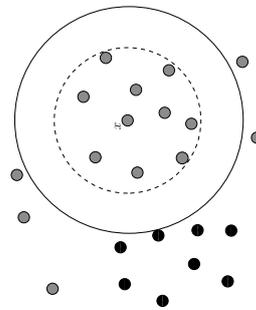

Figure 1: The effect of τ on the radius $r(x)$ of the target class point x in a two-class setting. Grey and black points represent the target and non-target classes, respectively. The solid circle centered at x is constructed with the radius associated with $\tau = 1$ and the dashed one with $\tau = 0.0001$ (DeVinney, 2003).

the balls contain only the target class points; hence, the name pure-CCCD. Once all balls are constructed, so is the digraph D . Therefore, we have to find a covering set C_X which is equivalent to finding a minimum dominating set $S \subseteq V(D)$. The greedy algorithm of finding an approximate minimum dominating set of a P-CCCD is given in Algorithm 1. At each iteration, the vertex which has the largest neighborhood (i.e., highest number of arcs) is removed from the graph together with its neighbors. Then, the process is repeated until all vertices of D are removed. The algorithm adds elements to the dominating set until all points are either dominated or dominate some other points. Hence, the covers established by P-CCCDs are proper covers: $Q_X = \mathcal{X}_n$ and $Q_Y = \mathcal{Y}_m$. The P-CCCD of one class, its associated class cover (constructed by the elements of the dominating set), and covers of both classes are illustrated in Figure 2.

Algorithm 1 The greedy algorithm for finding an approximate minimum dominating set of a digraph D . Here, $D[H]$ is the graph induced by the set of vertices $H \subseteq V(D)$ (see West, 2000).

Input: A digraph $D = D(V, A)$
Output: An approximate minimum dominating set, S

- 1: set $H = V(D)$ and $S = \emptyset$
- 2: **while** $H \neq \emptyset$ **do**
- 3: $\sigma^* = \text{argmax}_{v \in V(D)} |\bar{N}(v)|$
- 4: $S = S \cup \{\sigma^*\}$
- 5: $H = V(D) \setminus \bar{N}(\sigma^*)$
- 6: $D = D[H]$
- 7: **end while**

Before Algorithm 1 finds an approximate solution, we should first construct the digraph D . The P-CCCD cover C_X and the P-CCCD D depend on the distances between points of the target class \mathcal{X}_n , denoted by the matrix \mathcal{M}_X , and the distances from all points of \mathcal{X}_n to all points of \mathcal{Y}_m , denoted by matrix $\mathcal{M}_{X,Y}$. Later, we construct the set of balls

$B_X = \{B_1, B_2, \dots, B_n\}$, and get the set of arcs $A(D)$ where $V(D) = \mathcal{X}_n$. Hence, the minimum cardinality ball cover problem is reduced to a minimum dominating set problem. We find such a cover with Algorithm 2 which runs in quadratic time and, in addition, depends on the dimensionality of the training set $\mathcal{X}_n \cup \mathcal{Y}_m$.

Algorithm 2 The greedy algorithm for finding an approximate minimum cardinality ball cover C_X of the target class points \mathcal{X}_n given a set of non-target class points \mathcal{Y}_m .

Input: Points of the target class \mathcal{X}_n , the non-target class \mathcal{Y}_m , and the P-CCCD parameter $\tau \in (0, 1]$
Output: An approximate minimum cardinality ball cover C_X

- 1: $r(x) := (1 - \tau)d(x, l(x)) + \tau d(x, u(x))$ for all $x \in \mathcal{X}_n$
- 2: Construct the digraph D with the set B_X .
- 3: Find the approximate minimum dominating set S of digraph D by Algorithm 1.
- 4: $C_X := \cup_{x \in S} B(x, r(x))$

Theorem 1 Algorithm 2 is an $\mathcal{O}(\log n)$ -approximation algorithm and finds an approximate minimum cardinality ball cover C_X of the target class \mathcal{X} in $\mathcal{O}(n(n + m)d)$ time.

Proof. The algorithm is polynomial time reducible to a greedy minimum set cover algorithm which finds an approximate solution with size at most $\mathcal{O}(\log n)$ times of the optimum solution (Chvatal, 1979; Canny and Cowen, 2004). We first calculate the distance matrices \mathcal{M}_X and $\mathcal{M}_{X,Y}$ which take $\mathcal{O}(n^2d)$ and $\mathcal{O}(nm d)$ time, respectively. Constructing the digraph D requires computing $l(x)$ and $u(x)$ in Equation (1) for all $x \in \mathcal{X}_n$, taking $\mathcal{O}(n^2 + nm)$ time in total. Then, we set the arc set $A(D)$ in $\mathcal{O}(n^2)$ time. Finally, the algorithm finds a solution for the digraph D in $\mathcal{O}(n^2)$ time, hence the total running time of the algorithm is $\mathcal{O}(n(n + m)d)$. ■

When \mathcal{Y} is the target class, observe that the time complexity is $\mathcal{O}(n(n + m)d)$, and an approximate solution is of size at most $\mathcal{O}(\log m)$ times the optimal solution by Theorem 1, since $m = |\mathcal{Y}_m|$. A P-CCCD classifier consists of the covers of all classes, hence the total training time of finding CCCDs of a data set with two-class setting is $\mathcal{O}((n + m)^2d)$.

After establishing both class covers C_X and C_Y , any new data point can be classified in \mathbb{R}^d according to where it resides. Here, there are three cases according to the location of the given point, z , to be classified: z is (i) only in C_X or C_Y , (ii) in both C_X and C_Y or (iii) in neither of C_X and C_Y . The case (i) is straightforward: z belongs to class \mathcal{X} if $z \in C_X \setminus C_Y$ or to class \mathcal{Y} if $z \in C_Y \setminus C_X$. For cases (ii) and (iii), we need to find a way to decide the class of the point in a reasonable way. In fact, for all the cases, the estimated class of a given point z is determined by

$$\underset{C \in \{C_X, C_Y\}}{\text{argmin}} \left[\min_{x \in B(x, r)} \rho(z, x) \right] \quad (2)$$

where $\rho(z, x) = d(z, x)/r(x)$ (Marchette, 2010). The dissimilarity measure $\rho(x, z)$ indicates whether or not the point z is in the ball of radius $r(x)$ with center x , since $\rho(x, z) \leq 1$ if z is inside the (closure of the) ball and > 1 otherwise. The measure $\rho : \Omega \times \Omega \rightarrow \mathbb{R}_+$ is simply a scaled dissimilarity measure, since Euclidean distance between two points, $d(x, y)$, is divided (or scaled) with the radius, $r(x)$ or $r(y)$. This measure violates the symmetry axiom among metric axioms since $\rho(x, y) \neq \rho(y, x)$ whenever $r(x) \neq r(y)$. However, Priebe et al. (2003a) showed that the dissimilarity measure ρ satisfies the continuity condition,

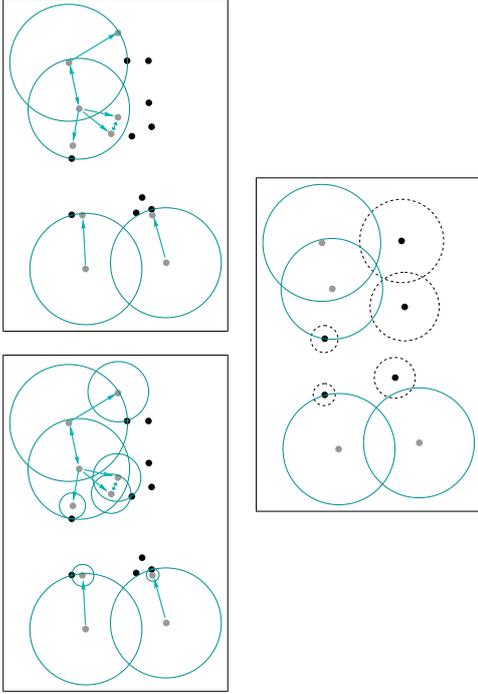

Figure 2: An illustration of the CCCDs (with the grey points representing the points from the target class) in a two-class setting. Presented in top left are all covering balls and the digraph $D = (V, A)$ and in top right are the balls that constitute a class cover for the target class and are centered at points which are the elements of the dominating set $S \subseteq V(D)$. In the bottom panel, we present the dominating sets of both classes and their associated balls which establish the class covers. The class cover of grey points is the union of solid circles, and that of black points is the union of dashed circles.

i.e., under the assumptions that both F_X and F_Y are continuous and strictly separable ($\inf_{x \in \mathcal{X}_n, y \in \mathcal{Y}_m} d(x, y) = \delta > 0$), P-CCCD classifiers are consistent; that is, their misclassification error approaches to the Bayes optimal classification error as $m, n \rightarrow \infty$. The measure ρ favors points with bigger radii; that is, for example, for a new point z equidistant to two points, the point with bigger radius is closer in terms of this scaled dissimilarity measure; for example, $\rho(x, z) < \rho(y, z)$ when $d(x, z) = d(y, z)$ and $r(x) > r(y)$. The radius $r(x)$ can be viewed as an indicator of the density around the point x . Thus, a point x with bigger radius might suggest that the point z is more likely be drawn from the same distribution (or class) where x is drawn (i.e., from the denser class).

3.2 Classification with Random Walk CCCDs

For P-CCCDs, the class covers defined by CCCDs were “pure” of non-target class points; that is, no member of the non-target class was allowed inside the cover of the target class. As in Figure 1, the ball centered at the point x cannot expand any further since its radius is restricted by the distance to the closest non-target class point. This strategy may cause the

cover to overfit or be sensitive to noise or outliers in the non-target class. By allowing some neighboring non-target class points inside the cover and some target class points outside the cover, the random walk CCCDs (RW-CCCDs) catch as much target class points as possible with an adaptive strategy of choosing the radii (DeVinney et al., 2002). For $x \in \mathcal{X}_n$, $|\mathcal{X}_n| = n$ and $|\mathcal{Y}_m| = m$, RW-CCCDs define a function on radius of a ball given by

$$R_x(r) = R_x(r; \mathcal{X}_n, \mathcal{Y}_m) \quad (3)$$

$$:= \frac{m}{n} |\{z \in \mathcal{X}_n : d(x, z) \leq r\}| - |\{z \in \mathcal{Y}_m : d(x, z) \leq r\}|.$$

where second and third arguments in $R_x(r; \mathcal{X}_n, \mathcal{Y}_m)$ are suppressed when there is no ambiguity. The function $R_x(r)$ can be viewed as a one-dimensional random walk. When the ball centered at $x \in \mathbb{R}^d$ expands, it hits either a target class point or a non-target class point which increases or decreases the random walk by one unit, respectively. The ratio m/n is included in the first term as to avoid the bias resulted by unequal sample sizes (i.e., class imbalance). An illustration is given in Figure 3 for the case $m = n$. The function $R_x(r)$ aims to find such radii that it contains a few non-target class points and sufficiently many target class points. In addition, we also want to avoid balls with large radii. Hence, the radius of x is the value maximizing $R_x(r)$ with an additional penalty function $P_x(r)$ which biases toward small radii:

$$r_x := \operatorname{argmax}_{r \in \{d(x, z) : z \in \mathcal{X}_n \cup \mathcal{Y}_m\}} R_x(r) - P_x(r). \quad (4)$$

Although a penalty function seems fit, DeVinney (2003) pointed out that the choice of $P_x(r) = 0$ usually works sufficiently well in practice. As in P-CCCDs, the radius of a ball represents the density of its center’s neighborhood. Maximizing $R_x(r)$ determines the best possible radius. Moreover, unlike P-CCCDs, the balls of RW-CCCDs are closed balls: $B_x = \{z \in \mathbb{R}^d : d(x, z) \leq r(x)\}$.

Similar to P-CCCDs, finding a cover, or a dominating set, of a RW-CCCD is an NP-hard problem. However, RW-CCCDs find the minimum dominating sets in a slightly different fashion. Instead of finding a set S such that $\cup_{s \in S} \bar{N}(s) = V(D)$ as in Algorithm 1, we first locate the vertex x^* (a target class point) which has maximum of some score, T_{x^*} , and remove all target and non-target class points covered with the ball of this vertex, B_{x^*} . In the next iteration, we recalculate the radii of remaining target class points, find the next point with the maximum score and continue until all target class points are covered. This greedy method of finding dominating set(s) S of RW-CCCDs is given in Algorithm 3. The resulting dominating set S has approximate minimum cardinality. For each target class point $x \in \mathcal{X}_n$, the score T_x is associated with $R_x(r_x)$ and is given by

$$T_x = R_x(r_x) - \frac{r_x^{n_u}}{2d_m(x)} \quad (5)$$

where n_u is the number of uncovered target class points in the current iteration, and $d_m(x) = \max_{z \in \mathcal{X}_n} d(x, z)$. The term which is linear in r_x of the right hand side of Equation (5) is similar to $P(r)$ in Equation (4): it biases the scores toward choosing dominating points with smaller radii. On the other hand, Algorithm 3 is likely to choose dominating points with radius $r = 0$. These points only dominate themselves but they are thought of being

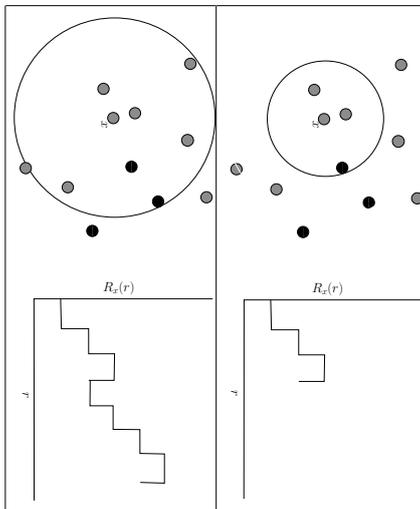

Figure 3: Two snapshots of $R_x(r)$ associated with the ball B_x centered at x for $m = n$.

Algorithm 3 The greedy algorithm for finding an approximate minimum dominating set for RW-CCCDs of points \mathcal{X}_n from the target class given non-target class points \mathcal{Y}_m .

Input: Target class points \mathcal{X}_n and non-target class points \mathcal{Y}_m
Output: Approximate dominating set S of \mathcal{X}_n

- 1: $H_0 = \mathcal{X}_n, H_1 = \mathcal{Y}_m$ and $S = \emptyset$
- 2: $\forall x \in \mathcal{X}_n, d_m(x) = \max_{z \in \mathcal{X}_n} d(x, z)$
- 3: **while** $H_0 \neq \emptyset$ **do**
- 4: $n_u = |H_0|$
- 5: **for all** $x \in \mathcal{X}_n$ **do**
- 6: $r(x) = \operatorname{argmax}_r, R_x(r; H_0, H_1)$ for $r \in \{d(x, z) : z \in H_0 \cup H_1\}$
- 7: **end for**
- 8: $x^* = \operatorname{argmax}_{x \in H_0} R_x(r(x); H_0, H_1) - \frac{r(x)n_u}{2d_m(x)}$
- 9: $S = S \cup \{x^*\}$
- 10: $H_0 = H_0 \setminus (\bar{N}(x^*) \cap \mathcal{X}_n)$ and $H_1 = H_1 \setminus (\bar{N}(x^*) \cap \mathcal{Y}_m)$
- 11: **end while**
- 12: $C_X := \cup_{s \in S} B(s, r(s))$

not covered since their balls have radii $r = 0$. Hence, RW-CCCDs may establish improper covers.

Algorithm 3 is similar to Algorithm 2, however after each iteration, a point is added to the set S and the random walk $R_x(r)$ is recalculated for all uncovered $x \in \mathcal{A}_0$. Hence, we need an additional sweep on the training set which makes Algorithm 3 run in cubic time.

Theorem 2 Algorithm 3 finds covers C_X of the target class \mathcal{X} and \mathcal{Y} in $\mathcal{O}((n + d + \log(n + m))(n + m)^2)$ time.

Proof. In Algorithm 3, the matrix of distances between points of training set $\mathcal{X}_n \cup \mathcal{Y}_m$ should be computed since, for all $x \in \mathcal{X}_n \cup \mathcal{Y}_m$, the entire data set is swept to maximize $R_x(r)$. This takes $\mathcal{O}((n + m)^2d)$ time. The algorithm runs until all target class points

are covered, but for each iteration, the random walk $R_x(r)$ is recalculated. The maximum $R_x(r_x)$ could be found by sorting the distances for all $x \in \mathcal{A}_0$ which could be done prior to the while loop. This sorting takes $\mathcal{O}((n + m)^2 \log(n + m))$ time. Since \mathcal{A}_0 and \mathcal{A}_1 are updated at each iteration, we can just erase the distances corresponding to points covered by $N(x^*)$ which does not change the order of sorted list provided before the while loop. Hence, $\operatorname{argmax} R_x(r_x)$ is found and the covered points erased in $\mathcal{O}((n + m)^2)$ time. The while loop iterates n times in the worst case, and hence the algorithm runs in a total of $\mathcal{O}((n + d + \log(n + m))(n + m)^2)$ time. ■

Note that Algorithm 3 finds a cover of \mathcal{Y}_m in $\mathcal{O}((m + d + \log(n + m))(n + m)^2)$ time which makes a RW-CCCD classifier trained in $\mathcal{O}((n + m)^3)$ time for $d < n$ and $\log(n + m) < n$. RW-CCCD classifiers are much better classifiers that potentially avoid overfitting, but with a cost of being much slower compared to the P-CCCD classifiers.

Since P-CCCD covers are pure and proper covers, P-CCCD classifiers tend to overfit (DeVinney, 2003). In RW-CCCDs, covering balls allow some points of \mathcal{Y}_m inside C_X to increase average classification performance. In that case, Algorithm 3 cannot be reduced to a minimum set cover problem since the definition of sets change after adding a single point to the dominating set. Hence, the upper bound $\mathcal{O}(\log n)$ does not apply to RW-CCCDs. However, we expect to get bigger balls in RW-CCCDs compared to the ones in P-CCCDs which intuitively suggests that the covers of RW-CCCDs are lower in cardinality. We conduct empirical studies to show that RW-CCCDs, in fact, produce dominating sets with lower size compared to P-CCCDs in some cases.

In RW-CCCD, once the class covers (or dominating sets) are determined, the scaled dissimilarity measure in Equation (2) is a good choice for estimating the class of a new point z . However, DeVinney (2003) incorporates the scores of each ball to produce better performing class covers in classification. Hence, the class of a new point z is determined by

$$\operatorname{argmin}_{C \in \{C_X, C_Y\}} \left[\min_{x \in B(x, r)} \rho(z, x) T_x^e \right]$$

where $\rho(z, x)$ is defined as in Equation (2). Here, $e \in [0, 1]$ controls at what level the score T_x is incorporated. We observe that for $d(z, x) < r(x)$, $\rho(z, x) = d(z, x)/r(x)$ decreases as T_x increases. Hence, if a new point z is in both covers, $z \in C_X \cap C_Y$, the score T_x is a good indicator to which class the new point z belongs since the bigger the T_x , the more likely the ball contains more target class points. For $e = 1$, we fully incorporate each score T_x of covering balls and with $e = 0$, we ignore the scores. By introducing a value for the parameter e in $(0, 1)$, it is possible to further improve the performance of RW-CCCD classifiers.

4. Balancing the Class Sizes with CCCDs

The CCCD classifiers substantially reduce the number of majority class observations in a data set. The reason is that balls of majority class members are more likely to catch neighboring points of the same class. The greedy algorithm given in Algorithm 1 selects vertices with the largest closed neighborhood. Similarly, Algorithm 3 selects vertices so that their balls are as dense as possible (i.e., target class points are abundant in the balls) with some contaminating non-target class points. Both algorithms choose balls with a large

number of target class points, and hence substantially reduce the data set (in particular, majority class points). Points of the minimum dominating set correspond to the centers of balls that establish the class covers. Hence CCCD classifiers can also be viewed as *prototype selection* methods where the objective is finding a set of points, or *prototypes*, S ; from the training set to preserve or increase the classification performance while substantially reducing the sample size. However, the radii of dominating set(s) are also stored and used in the classification process.

In Figure 4, we illustrate the behavior of balls associated with P-CCCDs and RW-CCCDs. Note that in both families of digraphs, balls of the majority class tend to be larger and hence are more likely to catch more majority class points. Since the majority class has much more members than the minority class, balls of the majority points are more likely to catch the neighboring majority points. CCCD classifiers keep the information of ball centers and their associated radii. Larger cardinality of the majority class allows the construction of bigger balls and hence, larger values of radii are more likely to correspond to larger number of caught class members. As a result, CCCDs balance the data set and, at the same time, preserve the information of the local density by retaining the radii. The data set becomes balanced since the center of balls are the points of the new training data set which will be employed later in classification.

The loss of information in undersampling schemes are of course inevitable, however it is possible to preserve a portion of that discarded information by other means. EasyEnsemble is an ensemble classifier used for that very purpose; however, it needs multiple classifiers to be employed. Each classifier is trained on a different balanced subset of the original training data set, and hence the ensemble classifier preserves the information on the entire data set given by a collection of unbiased classifiers. On the other hand, CCCDs achieve the same goal by transforming the density around points into the radii. CCCDs resemble cluster based resampling methods in that regard. Instead of randomly sampling the data set, cluster based sampling schemes divide each class into clusters, and then, oversample the minority class or undersample the majority class proportional to each subclass. Covering balls of CCCDs have a similar purpose which has also been discussed in Pritebe et al. (2003b). They use the covering balls of the minimum dominating sets to explore the latent subclasses of each class of gene expression data sets. In fact, the balls of CCCDs may correspond to clusters. Hence, sets of points associated with each cluster is undersampled to a single point (i.e., a prototype or a dominating point), and the information on the cluster is provided by the radius which represents the density of that cluster. The bigger the radius, the more influence a prototype has over the domain. In P-CCCDs, the radii may be sensitive to noise, but RW-CCCDs ignore noisy points to avoid overfitting. Moreover, in RW-CCCDs, we have an additional statistic provided by each cluster, the score given in Equation (5) based on the random walk. We use both the radii and these scores to define the RW-CCCD classifiers, and thus achieve better performing classifiers with more reduction and less information loss.

We approach the problem of class imbalance from the perspective of class overlapping problem as well. Several researchers on class imbalance revealed that overlap between the class supports degrade the classification performance of imbalanced data sets even more (see Prati et al., 2004; Batista et al., 2004, 2005; Galar et al., 2012). Let $E \subset \mathbb{R}^d$, and let $s(F_X)$ and $s(F_Y)$ be the supports of the classes \mathcal{X} and \mathcal{Y} , respectively. We define E as the overlapping region of these two class supports, $E := s(F_X) \cap s(F_Y)$. Moreover, let

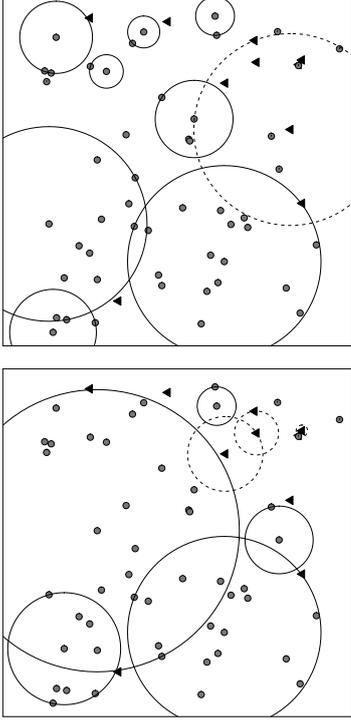

Figure 4: An illustration of the covering balls associated with majority and minority P-CCCD (left) and the corresponding RW-CCCDs ($\tau = 0.0001$) (right) of an imbalanced data set in a two-class setting where majority and minority class points are represented by grey dots and black triangles, respectively.

$q(E) := |\mathcal{Y}_m \cap E|/|\mathcal{X}_n \cap E|$ be ratio of class sizes restricted to the region $E \subset \mathbb{R}^d$. We say $q(E)$ is the “local” imbalance ratio with respect to E . Also, let the “global” imbalance ratio be $q = q(\mathbb{R}^d) = m/n$. Throughout this work, in both simulated and real data examples, we study and discuss the local imbalance ratio $q(E)$ restricted to the overlapping region E and the global imbalance ratio q . We specifically illustrate the performance of several classifiers for various levels of class imbalance (local or global) and class overlapping, and assess the performance of CCCD classifiers compared to weak and strong versions of k -NN, SVM and C4.5 classifiers.

5. Comparing CCCDs with Other Classifiers

We study the performance of CCCD classifiers in comparison with weak and strong classifiers in two separate sections. Recall that we call a classifier as “weak” when the method is inherently sensitive to class imbalance, and as “strong” when it is non-sensitive (or less sensitive). We use the area under curve (AUC) measure to evaluate the performance of the classifiers on the imbalanced data sets (López et al., 2013). AUC measure is often used on imbalanced real data classes. This measure has been shown to be better than the correct classification rate in general (Huang and Ling, 2005). We discuss the computational complexity of weak classifiers to emphasize the testing speed of CCCD classifiers when trained by imbalanced data sets. Finally, we compare both weak and strong classifiers with CCCDs on real data sets by considering the overlapping and imbalance ratios of all data sets.

5.1 Monte Carlo Simulation Study with Weak Classifiers

In this section, we compare the CCCD-based classifiers, namely P-CCCD and RW-CCCD, with k -NN, support vector machines (SVM) and C4.5, on simulated data sets. These classifiers are listed in Table 1. We employ the `cccd`, `e0171` and `Rkcka` packages in R to classify test data sets with the P-CCCD, SVM (with Gaussian kernel) and C4.5 classifiers, respectively (Marchette, 2013; Meyer et al., 2014; R Core Team, 2015).

For each of four classification methods other than C4.5, we assign the optimum parameter values which are the best performing values among all considered parameters. For example, an optimum the P-CCCD parameter τ is found in a preliminary (pilot) Monte Carlo simulation study associated with the main simulation setting (i.e., the same setting of the main simulation). In the pilot study, we perform a Monte Carlo simulation with 200 replications and count how many times a τ value has the maximum AUC among $\tau = 0.0, 0.1, \dots, 1.0$ in 200 trials. Note that, since $\tau \in (0, 1]$, we denote $\tau = \epsilon$ (machine epsilon) as $\tau = 0$ for the sake of simplicity. For each replication of the pilot simulation, we (i) classify the test data set with all τ values, (ii) record the τ values with maximum AUC and (iii) update the count of the recorded τ values. Finally, we appoint the one that has the maximum count (the best performing τ) as the τ^* , the optimum τ . Then, we use τ^* as the parameter of P-CCCD classifier in our main simulation. The parameters of optimal k -NN, SVM and RW-CCCD classifiers are defined similarly. SVM methods often incorporate both a kernel parameter γ and a constrained violation cost C . We only optimize γ since the selection of an optimum C parameter will be more crucial for cost-sensitive SVM methods. Moreover, we consider two versions of the C4.5 classifier where both incorporate Laplace smoothing. The first tree classifier, C45-LP, prunes the decision tree with %25 confidence level but the second classifier, C45-LNP, does not use pruning at all.

We first consider a simulation setting similar to the one in DeVinney et al. (2002) where CCCD classifiers showed relatively good performance compared to the k -NN classifier. Here, we simulate a two-class setting where observations from both classes are drawn from separate multivariate uniform distributions: $F_X = U(0, 1)^d$ and $F_Y = U(0.3, 0.7)^d$ for $d = 2, 3, 5, 10$. Notice that $s(F_Y) \subset s(F_X)$; i.e., $E = s(F_Y)$. We perform Monte Carlo replications where on each replication, we train the data with equal sizes of observations ($m = n$) from each class for $n = 50, 100, 200, 500$. On each replication, we record the AUC measures of the classifiers on the test data set with 100 observations from each class, resulting a test data set of size 200. We simulate test data sets until AUCs of all classifiers achieve a standard error below 0.0005. Average of AUCs of all classifiers in Table 1 are given in Figure 5 for all (n, d) combinations. Additionally, in Figure 6, we report the τ values of best performing P-CCCD classifiers in our pilot simulation study for all (n, d) combinations. In Figure 6, there are separate histograms for each combination. Each histogram represents the number of times a τ value has the maximum AUC. Also in Figure 7, we report the e values of the best performing RW-CCCD classifiers of the same pilot simulation study for $e = 0, 0.1, \dots, 1.0$.

We start by investigating the effect of τ and e on CCCD classifiers. The relationship between τ , n and d can also be observed in Figure 6. The higher the τ value, the better the performance of P-CCCD classifier with increasing d and decreasing n . This may indicate that balls with $\tau = 0$ (i.e., $\tau = \epsilon$) represent the density around their centers better for low dimensional data sets. However, with increasing dimensionality and lower class sizes, the

Method	Description
P-CCCD	P-CCCD with the optimum τ (in the pilot study) among $\tau = 0.0, 0.1, \dots, 1.0$
RW-CCCD	RW-CCCD with the optimum e (in the pilot study) among $e = 0.0, 0.1, \dots, 1.0$
k -NN	k -NN with optimum k (in the pilot study) among $k = 1, 2, \dots, 30$
SVM	SVM with the radial basis function (Gaussian) kernel with the optimum γ (in the pilot study) among $\gamma = 0.1, 0.2, \dots, 3.9, 4.0$ (Joachims, 1999)
C45-LP	C4.5 with Laplace smoothing and reduced error pruning (%25 confidence)
C45-LNP	C4.5 with Laplace smoothing and no pruning

Table 1: The description of classifiers employed in the article.

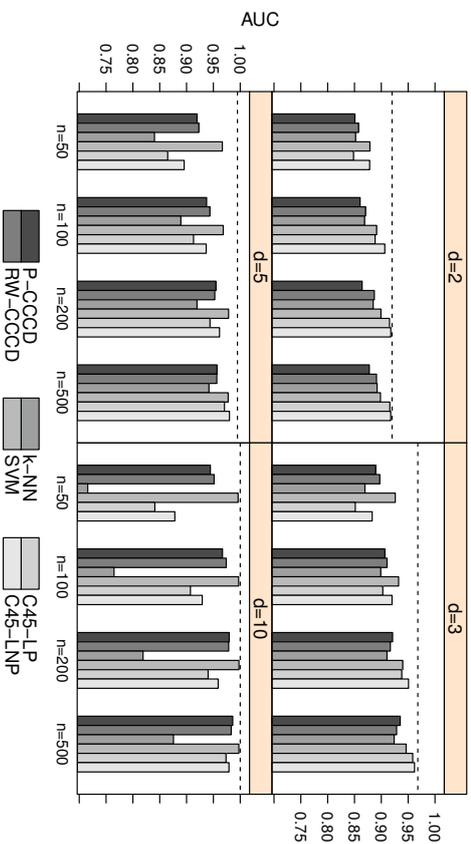

Figure 5: CCRs in the two-class setting, $F_X = U(0, 1)^d$ and $F_Y = U(0.3, 0.7)^d$ under various simulation settings, with $d = 2, 3, 5, 10$ and equal class sizes $m = n = 50, 100, 200, 500$.

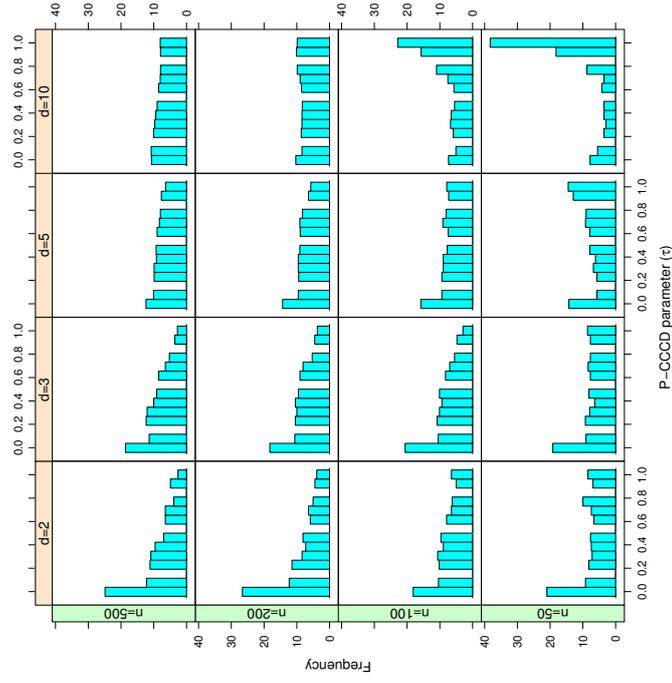

Figure 6: Frequencies of the best performing τ values among $\tau = 0.0, 0.1, \dots, 1.0$ in our pilot study (this is used to determine the optimal τ used in P-CCCD). The simulation setting is same as to the one presented in Figure 5.

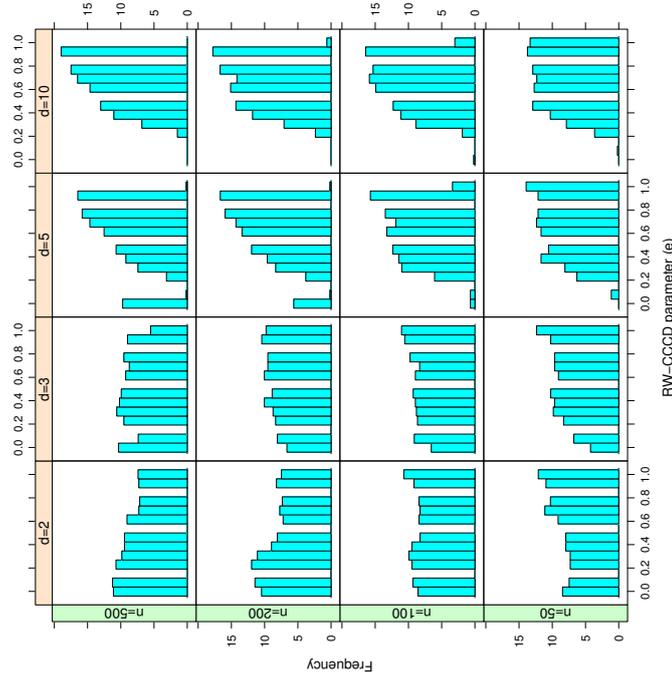

Figure 7: Frequencies of the best performing ϵ values among $\epsilon = 0.0, 0.1, \dots, 1.0$ in our pilot study (this is used to determine the optimal ϵ used in RW-CCCD). The simulation setting is same as to the one presented in Figure 5.

set of points gets sparser in \mathbb{R}^d . In the case of RW-CCCD, classifiers with high e values are either better or comparable to those with lower e values. The scores \mathcal{I}_x of covering balls are definitely beneficial to the performance of the RW-CCCD classifiers, however with increasing n and decreasing d (especially for $n = 500$ and $d = 2$) RW-CCCD with lower e is better since the radii successfully represent the density around the prototype points due to the high number of observations in the data set.

Figure 5 illustrates the AUCs of all classifiers along with the Bayes optimal performance given with the dashed line. Comparing the performance of CCCD classifiers with other classification methods, we observe that RW-CCCD and P-CCCD classifiers outperform the k -NN classifier when the support of one class is entirely embedded inside that of the other class. These results are similar to the conclusions of DeViney et al. (2002): with increasing dimensionality, the difference between k -NN and CCCD classifiers becomes more apparent, i.e., CCCD classifiers have nearly 0.20 AUC more than k -NN. On the other hand, the SVM classifier has about 0.05 more AUC than P-CCCD and RW-CCCD classifiers, especially for lower class sizes. Although, both versions of CCCD classifiers outperform the k -NN and C4.5 classifiers with increasing dimensionality, the gap between these two classifiers and CCCD classifier is getting narrower with increasing class sizes. The RW-CCCD classifier is slightly better than the P-CCCD classifier for lower n . In addition, C45-LNP achieves slightly better results than C45-LP.

In the setting presented in Figure 5, apparently, two classes overlap on the region $E = s(F_X) = [0.3, 0.7]^d$ which is the entire support of the class \mathcal{Y} . For equal class sizes, $q = m/n = 1$ but $q(E) \approx (1/0.4)^d = \text{Vol}(s(F_X))/\text{Vol}(s(F_X))$, where $\text{Vol}(\cdot)$ is the volume functional. The classes are clearly imbalanced in E , although $m = n$. Hence, class \mathcal{X} becomes the minority and class \mathcal{Y} becomes the majority class with respect to E . However, readjusting the class sizes m and n might change the performance of P-CCCD and RW-CCCD classifiers compared to the k -NN and C4.5 classifiers. Therefore, we conduct another simulation study with classes from the same uniform distributions, but we set $m = 50$ and $n = 200$ for $d = 2, 3$, and $m = 50$ and $n = 1000$ for $d = 5, 10$. In this experiment, we simulated 4 times more \mathcal{X} class members than \mathcal{Y} for $d = 2, 3$, and 20 times more for $d = 5, 10$. Results of this second experiment is given in Figure 8. k -NN and C4.5 classifiers outperform P-CCCD classifier in all d cases and has comparable AUC with SVM. However, only for $d = 2, 5$, RW-CCCD classifier achieves considerably more or comparable AUC compared to other classifiers. In this example, k -NN classifiers have nearly 0.05 more AUC than P-CCCD, and also RW-CCCD have, in general, 0.05 more AUC than k -NN classifiers.

Results from Figures 5 and 8 seem conflicting to each other, even though $E = s(F_X)$. In the simulation setting of Figure 8, we draw more samples from the class \mathcal{X} to balance the class sizes with respect to E . In fact, the effect on the difference of AUCs between CCCD, k -NN and C4.5 classifiers depends heavily on the local class imbalance restricted to the overlapping region E . The classes in region E are less imbalanced in setting of Figure 8 than in the setting of Figure 5. Observe that $q(E) \approx (1/0.4)^d/4$ when $(m, n) = (50, 200)$, $q(E) \approx (1/0.4)^d/20$ when $(m, n) = (50, 1000)$, and $q(E) \approx (1/0.4)^d$ in $(m, n) = (50, 50)$. Hence, d does also affect the balance between classes. With increasing d , the region E gets smaller in volume compared to $s(F_X)$ and, as a result, fewer points of the class \mathcal{X} falls in E . Thus, we need to draw more samples from \mathcal{X} as dimensionality increases, in order to balance the classes with respect to E . These results suggest that, the more imbalanced the data set

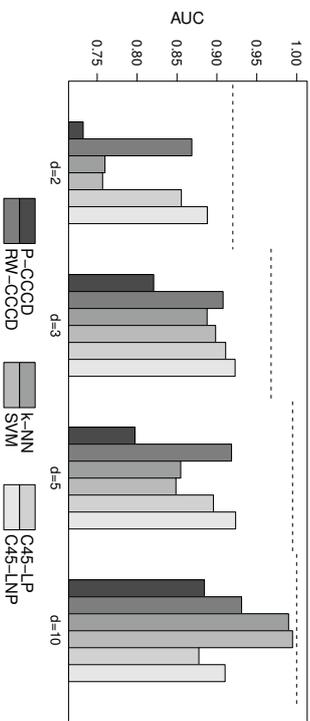

Figure 8: CCRs in a two-class setting, $F_X = U(0, 1)^d$ and $F_Y = U(0.3, 0.7)^d$ with fixed $n = 200$ and $m = 50$ in $d = 2, 3$, and with fixed $n = 1000$ and $m = 50$ in $d = 5, 10$.

in overlapping region E , the worse the performance of k -NN and C4.5 classifiers while CCCD classifiers preserve their classification performance. So, CCCD classifiers exhibit robustness (to the class imbalance problem). On the other hand, in Figure 5, we observe that the AUC of k -NN classifier approaches to the AUC of CCCD classifiers with increasing class sizes. Because, when q and $q(E)$ are fixed, the classification performance still depends on individual values of n or m . This result is in line with the results of Japkowicz and Stephen (2002) who reported that the effect of class imbalance on the classification performance diminishes if both class sizes are sufficiently large. Furthermore, SVM classifier performs better than all classifiers in Figure 5, and performs worse than RW-CCCD classifiers only for $d = 2, 5$ in Figure 8. This might be an indication that SVM classifier is also not affected by the local class imbalance with respect to E , and performs usually better than both P-CCCD and RW-CCCD classifiers if the support of one class is inside the other. For the C4.5 classifier, on the other hand, it is known for quite some time that the pruning is detrimental for classifying imbalanced data sets (Cieslak and Chawla, 2008). In any case, C45-LNP has more AUC than C45-LP in all simulation settings.

In a two-class setting with an overlapping region E , we should expect CCCD classifiers to outperform k -NN classifiers in cases of (global or local) class imbalance. Let $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ for $\delta, q = 0.05, 0.10, \dots, 0.95, 1.00$; $d = 2, 3, 5, 10$; $n = 400$ and $m = qn$. Here, the shifting parameter δ controls the level of overlap. The class supports get more overlapped with decreasing δ . Since $E = (\delta, 1)^d$ and the supports of both classes are unit boxes, observe that $q(E) \approx q$. The closer the value of q to 1, more balanced the classes are. We aim to address the relationship between the classifiers for various combinations of overlapping and global class imbalance ratios.

Figure 9 illustrates the difference between AUCs of CCCD and other classifiers (k -NN, SVM and C4.5) in separate heat maps for $d = 2, 3, 5, 10$. We use the unpurged C4.5 classifier

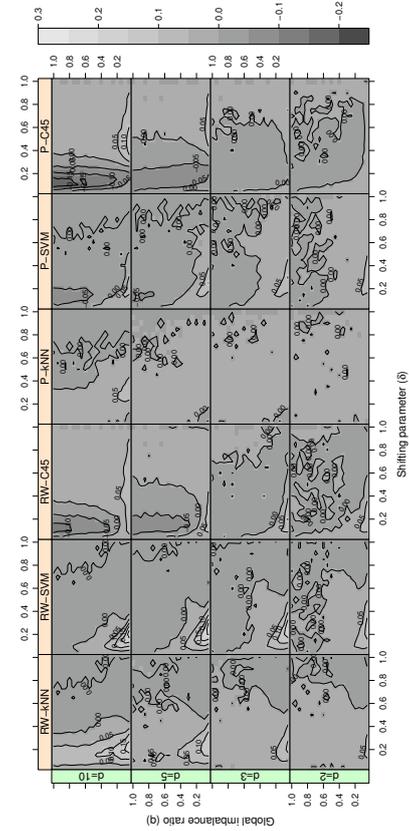

Figure 9: Differences between the AUCs of CCCD and other classifiers. For example, the panel titled with "RW-kNN" presents $AUC(RW\text{-}CCCD) - AUC(k\text{NN})$. In this two-class setting, classes are drawn from $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ with $d = 2, 3, 5, 10$. Each cell of the grey scale heat map corresponds to a single combination of simulation parameters $\delta, q = 0.05, 0.1, \dots, 0.95, 1.00$ with $n = 400$ and $m = qn$.

C4.5-LNP, since it tends to perform better for imbalanced data sets, and we refer to C4.5-LNP as C4.5 for simplicity. Each cell of a single heat map is associated with a combination of δ and q values. Lighter tone cells indicate that CCCD classifiers are better than the other classifiers in terms of AUC, and vice versa for the darker tones. When the classes are imbalanced and moderately overlapping, RW-CCCD classifier has at least 0.05 more AUC than all other non-CCCD classifiers but P-CCCD classifier is only better than all others provided that $d = 10$. If the classes are balanced or their supports are not considerably overlapping, there seem to be no visible difference between CCCD and the other classifiers. Thus, the other classifiers suffer from the imbalance of the data while CCCD classifiers show robustness to the class imbalance. But more importantly, this difference is getting more apparent with increasing dimensionality. When d is high, fewer points of the minority class fall in E although $q(E)$ is fixed. Even though the classes are imbalanced, if the minority class have substantially small size, the class imbalance problem becomes more detrimental (Japkowicz and Stephen, 2002). Under the conditions that the data set has substantial imbalance and overlapping, AUC of RW-CCCD classifier is followed, in order by, the AUC of C4.5, SVM and k -NN classifiers.

Unlike the comparison of CCCD and SVM classifiers in Figures 5 and 8, SVM classifier has less AUC than CCCD classifiers with low δ and low q values in Figure 9. In this setting, n is fixed to 400 and the lowest value of m is 20. Compared to our experiments in Figures 5 and 8, this setting produces highly imbalanced data sets (one class has far

more observations than the other, $m \ll n$). Akbani et al. (2004) conducted a detailed investigation and listed some reasons of SVM classifier being sensitive to highly imbalanced UCI data sets (Bache and Lichman, 2013). They did not, however, address the problem of overlapping class supports but offered a modification to SMOTE algorithm in order to improve the robustness of SVM. On the other hand, especially for $d = 5$ and $d = 10$, SVM, k -NN and C4.5 classifiers have more AUC than CCCD classifiers with increasing q and decreasing δ . This may indicate that other weak classifiers are better than CCCD classifiers for balanced classes.

The effects of class imbalance might also be observed when the class supports are well separated. If the class supports are disjoint, that is $s(F_X) \cap s(F_Y) = \emptyset$, the AUC is fairly high. However, it might still be affected by the global imbalance level, q . Therefore, we simulate a data set with two classes where $F_X = U(0, 1)^d$ and $F_Y = U(1 + \delta, 2 + \delta) \times U(0, 1)^{d-1}$. Figure 10 illustrates the results of this simulation study. Both class supports are d dimensional unit boxes as in the previous simulation setting, however they are now disjoint (separated along the first dimension). In addition, the parameter δ controls the smallest distance between the class supports where $\delta = 0.05, 0.10, \dots, 0.45, 0.50$. With increasing δ , the points of class \mathcal{Y} move further away from the points of \mathcal{X} . Figure 10 illustrates the difference between AUCs of CCCD and other classifiers under this simulation setting.

In Figure 10, unlike the performance of CCCD classifiers in Figure 9, P-CCCD classifiers have more AUC than RW-CCCD classifiers. When classes are imbalanced and supports are close, P-CCCD classifiers outperform both SVM and k -NN classifiers for all d values, but RW-CCCD classifiers have nearly 0.03 more AUC than these classifiers only in $d = 10$. However, this is not the case with C4.5 classifier since none of the classifiers outperform C4.5; that is, C4.5 yields over 0.04 more AUC than CCCD classifiers. A well separated data set is more likely to be classified better with C4.5 tree classifier because a single separating line exists between the two class supports. Hence, C4.5 locates such a line and efficiently classifies points regardless of the distance between class supports as long as the distance is positive. On the other hand, the balls of P-CCCD classifiers establish appealing covers for the class supports because the supports do not overlap. P-CCCD classifiers establish covering balls, big enough to catch substantial amount of points from the same class. Similarly, RW-CCCD classifiers establish pure covers, and this is the result of the separation between class supports. However, P-CCCD classifiers achieve better classification performance than RW-CCCD classifiers. When the classes are well separated, the radii of a ball in random walk, say from class \mathcal{X} , is likely $\max_{z \in \mathcal{X}_n} d(z, x)$ but in P-CCCD classifiers, it is $\min_{z \in \mathcal{Y}_n} d(z, x)$. In fact, the RW-CCCD classifiers are nearly equivalent to P-CCCD classifiers. Thus, when $\tau > 0$, P-CCCD classifiers are more likely to produce bigger balls than RW-CCCD classifiers, and potentially avoid overfitting.

In Figure 10, RW-CCCD classifiers have slightly or considerably less AUC than other classifiers when data sets are imbalanced and the supports are slightly far away from each other. The random walk contaminates the class cover with some non-target class points to improve the classification performance. However, since the classes are well separated and one class has substantially fewer points than the other, random walks are likely to yield balls to cover some points from the support of the non-target class, resulting in a degradation in the performance of RW-CCCD classifiers. On the other hand, P-CCCD classifiers outperform both k -NN and SVM classifiers for lower q and lower δ . The closer and more imbalanced the

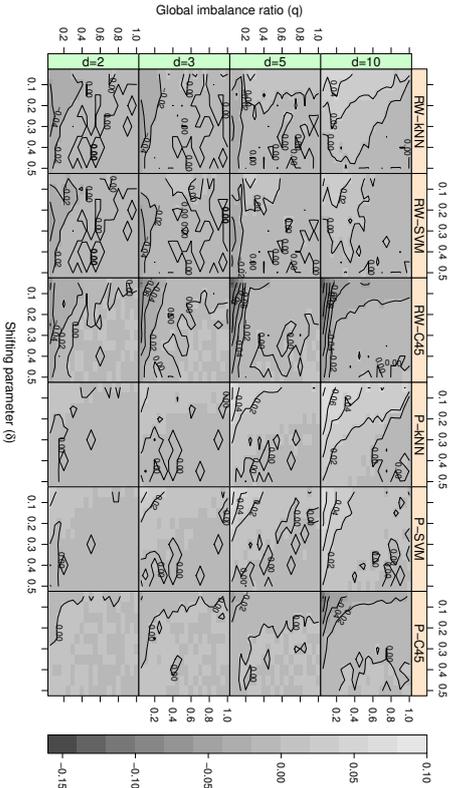

Figure 10: Differences between the AUCCs of CCCD and other classifiers (see Figure 9 for details). In this two-class setting, classes are drawn from $F_X = U(0, 1)^d$ and $F_Y = U(1 + \delta, 2 + \delta) \times U(0, 1)^{d-1}$ where $d = 2, 3, 5, 10$, $\delta = 0.05, 0.1, \dots, 0.45, 0.50$ and $q = 0.05, 0.1, \dots, 0.95, 1.00$ with $n = 400$ and $m = qn$. AUCCs of all classifiers are over 88% since the class supports are well separated.

data, the better the performance of P-COCEDs than other classifiers. Although the classes do not overlap, the effect of class imbalance is still observed when the supports are close. When there is mild imbalance between classes, COCCD classifiers have either comparable or less AUC. In addition, note that the performances of SVM and k -NN classifiers deteriorate but P-COCED classifiers preserve their AUC with increasing d . Let $E \subset \mathbb{R}^d$ be some region that contains points of both classes which are sufficiently close to the decision boundary. With increasing d , fewer minority class points are in this region, and hence fewer members of this class fall in E . As a result, the performance of both SVM and k -NN classifiers suffer from local class imbalance with respect to E .

Finally, we investigate the effect of dimensionality when classes are balanced (i.e., $q = 1$) and their supports are overlapping. In this setting, $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$. Here, let $q(E) \approx q = 1$, hence the classes are also locally balanced with respect to E as well as being globally balanced. Also, δ controls the level of overlap between two classes. However, we define δ in such a way that the overlapping ratio $\alpha \in [0, 1]$ is fixed for all dimensions. When α is 0, the supports are well separated, and when α is 1, the supports of classes are the same, i.e., $s(F_X) = s(F_Y)$. The closer α to 1, the more the supports overlap. Observe that $\delta \in [0, 1]$ can be expressed in terms of the overlapping ratio α and

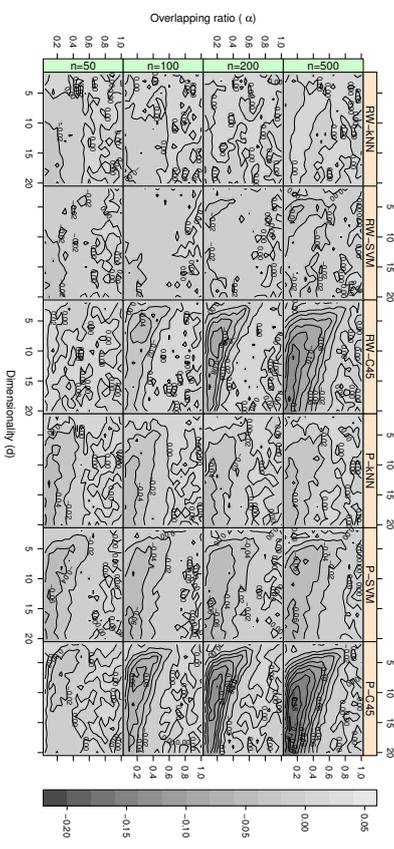

Figure 11: Differences between the AUCCs of CCCD and other classifiers (see Figure 9 for details). In this two-class setting, classes are drawn from $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ where $n = 50, 100, 200, 500$, $\alpha = 0.05, 0.1, \dots, 0.45, 1.00$ and $d = 2, 3, 4, \dots, 20$.

dimensionality d :

$$\alpha = \frac{\text{Vol}(s(F_X) \cap s(F_Y))}{\text{Vol}(s(F_X) \cup s(F_Y))} = \frac{(1 - \delta)^d}{2 - (1 - \delta)^d} \iff \delta = 1 - \left(\frac{2\alpha}{1 + \alpha} \right)^{1/d}. \quad (6)$$

Hence, we calculate δ for each (d, α) combination by the Equation (6). In Figure 11, each cell of the grey scale heat map corresponds to a single combination of simulation parameters $\alpha = 0.05, 0.1, \dots, 0.95, 1.00$ and $d = 2, 3, 4, \dots, 20$. In Figure 11, the differences between the AUCCs of COCCD classifiers and other classifiers are up to 0.20. The k -NN and SVM classifiers have comparable performance with COCCD classifiers, or outperform both COCCD classifiers. However, C4.5 has more AUC with increasing d . Employing COCCD classifiers do not considerably increase the classification performance over other classifiers when classes are balanced.

5.2 Empirical Comparison of COCCD-based and Strong Classifiers

In this section, we compare the COCCD-based classifiers with strong versions of k -NN, SVM and C4.5 classifiers on simulated data sets. Each classifier is modified in three different schemes, namely, resampling, ensemble and cost-sensitive schemes. We use SMOTE+ENN algorithm as the resampling scheme and EasyEnsemble algorithm as the ensemble scheme. As for the cost sensitive versions on weak classifier, we adjust the classifiers into recognizing class weights. For k -NN, we employ an algorithm giving more weight on neighboring minority class members; for SVM, we use two separate constrained violation costs for each

Method	Description
SMOTE+ENN	A combination of SMOTE ($t = 2$ and $k = 5$) and ENN ($k = 3$) (Batista et al., 2004).
EasyEnsemble	A combination of undersampling ($T = 4$) and Adaboost ($s_i = 10$) for $i = 1, 2, \dots, T$ (Liu et al., 2006).
C5.0	The cost sensitive version of C4.5 (Kuhn and Johnson, 2013).
CKNN	A cost sensitive version of k -NN (Barandela et al., 2003).
CSVM	A cost sensitive version of SVM (Chang and Lin, 2011).

Table 2: The description of classifiers employed in the article.

corresponding class; and for C4.5, we employ the C5.0. With three schemes and three weak classifiers, we get nine strong classifiers to study. We list and describe all these schemes in Table 2.

SMOTE+ENN algorithm, first, oversamples the entire training data set by generating artificial points in between a point and its neighbors. Specifically, for each point in the data set, t points among k neighbors are selected, and until the data set is balanced, new artificial points are generated in between these points and their selected neighbors. Later, ENN algorithm cleans the data set of noisy points by checking all points if the majority of their k neighbors are labeled as the class of the point. If not, the point is erased from the data set. Simply, SMOTE+ENN is a hybrid of over and undersampling methods. EasyEnsemble algorithm is a hybrid of undersampling and ensemble methods. An ensemble of weak classifiers is established by generating T many undersampled balanced data sets from the training data set. Then, each data set is used to train individual Adaboost classifiers with s_i many weak classifiers for $i = 1, 2, \dots, T$. Hence, EasyEnsemble is an ensemble of $\sum_{i=1}^T s_i$ many weak classifiers.

We choose one of the simulation settings conducted in Section 5.1. Since CCCD classifiers are observed to be better than other classifiers when both class imbalance and overlapping occurred, we only compare CCCD classifiers with strong classifiers on a single simulation setting. Hence we choose the setting presented in Figure 9, i.e., we let $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ for $\text{bura } \delta, q = 0.05, 0.10, \dots, 0.95, 1.00, n = 400$ and $m = qn$. We aim to highlight the differences between the strong classifiers and CCCD classifiers for various combinations of overlapping and class imbalance ratios. The results on average AUCs of each strong classifier is given in Figure 12. In general, RW-CCCDs seem to perform better than P-CCCDs. For $d > 2$, P-CCCDs have nearly 0.10 less AUC than RW-CCCDs when the classes are substantially overlapping and imbalanced, and it is observed that P-CCCDs are usually worse compared to the strong classifiers considered. However, the AUCs of RW-CCCD classifiers are either comparable or slightly less compared to others with the most difference being seen in the case of $d = 10$ when RW-CCCDs compared to EC4.5 and C5.0, ensemble and cost sensitive versions of the C4.5 classifier, respectively. However, with decreasing δ and q , the RW-CCCDs have only 0.05 less AUC than others. Also, RW-CCCDs seem to have 0.05 more AUC than C5.0 for moderately overlapping and imbalanced data sets, and seem to have 0.05 more AUC than EC4.5, ensemble based SVMs, when the data set is both overlapping and imbalanced. This suggests that RW-CCCDs yield comparable results in comparison to the state-of-the-art robust methods when class imbalance and class overlapping co-exist. Additionally, we show in Section 5.3 that RW-CCCDs generate prototype sets that considerably reduce the training data set.

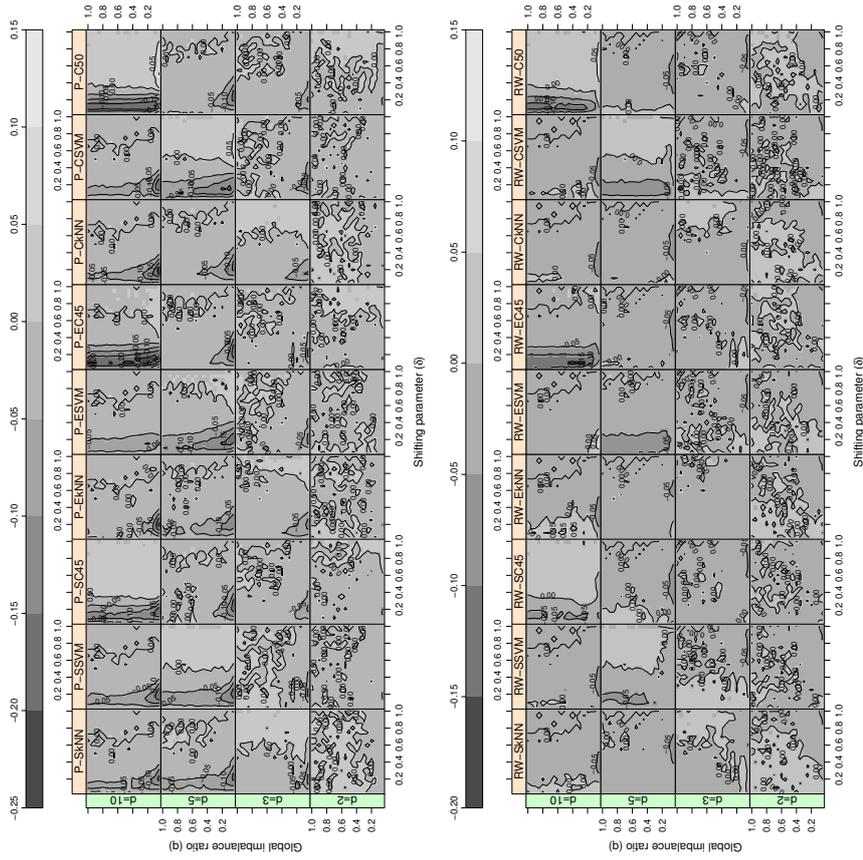

Figure 12: Differences between the AUCs of CCCD and other classifiers (see Figure 9 for details). P-CCCD in (top) and RW-CCCD in (bottom). Here, resampling scheme strong classifiers are coded with “S”, ensemble schemes with “E”, and cost sensitive schemes with “C”. For example, “SKNN” refers to the resampling scheme k -NN classifier. In this two-class setting, classes are drawn from $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ where $d = 2, 3, 5, 10, q, \delta = 0.05, 0.1, \dots, 0.95, 1.00$ with $n = 400$ and $m = qn$.

	Training		Testing	
	Time	Space	Time	Space

Table 3: Training and testing space and time complexities of the weak classifiers.

5.3 Complexity Analysis of the Classifiers

In Table 3, we compare training and testing time and space complexities of P-CCCDs, RW-CCCDs, k -NN, SVM and C4.5 classifiers. Let $N = n + m$ be the size of training data set. C4.5 is the fastest among all classifiers and requires the least space. However, unpruned C4.5 constitute a tree with its space complexity increasing exponentially on d since the data set is divided into at most two for all dimensions. The remaining classifiers are all instance based learning methods which depend on a matrix of distances between the points of training data set. Hence, their space complexity is at least $\mathcal{O}(N^2)$ and they run in at least $\mathcal{O}(N^2d)$ time. Both SVM and RW-CCCD classifiers run in $\mathcal{O}(N^3)$ time for $d < N$, and P-CCCD runs in $\mathcal{O}(N^2d)$ time. Minimum dominating set problem of P-CCCDs are polynomial time reducible to minimum set cover problems, and hence they run in $\mathcal{O}(N^2)$ time in the worst case but they require the computation of the distance matrix which takes the most time. However, in RW-CCCDs, covering balls are re-defined each time a new point is added to the prototype set. As a result, this operation requires an additional sweep on the training set on each iteration which makes RW-CCCD run in $\mathcal{O}(N^3)$ time, for $d < n$. For SVM, the training time of usual optimization algorithms is $\mathcal{O}(N^3)$ for $d < n$. However, it is possible to reduce the complexity to $\mathcal{O}(N^{2.3})$ with sequential minimal optimization (SMO) method (Chang and Lin, 2011).

Note that, k -NN does not require any training time or space, and should use the entire training data set to classify the test data set. However, CCCD and SVM classifiers reduce the training data set by means of prototype sets (minimum dominating sets in CCCD and support vectors in SVMs) even though their worst case testing space complexity is $\mathcal{O}(Nd)$. The entire training data set could be chosen as the prototype set for some cases, but we show that the data set is substantially reduced when the classes are imbalanced. In Figure 13, we compare the sizes of the set of prototypes in RW-CCCDs and the set of support vectors in SVM and GSYM classifiers. We consider the simulation settings with two classes for $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$, $\delta = 0.1, 0.4, 0.7, 1.0$, $d = 2, 3, 5, 10$, $n = 400$ and $m = qn$.

In Figure 13, the number of both support vectors and prototypes decrease with increasing δ . The prototype set heavily depends on the overlapping ratio between class supports. Undoubtedly, when points of either class are further away from each other, covering balls get bigger for CCCDs, and the separating hyperplane requires less support vectors. On the other hand, observe that the number of support vectors are much higher than the number of prototypes of RW-CCCDs. The number of support vectors decreases with decreasing q .

The more imbalanced the data set, the fewer support vectors are generated. But in any case, RW-CCCDs still reduce the training data set more than SVMs. In Figure 14, we compare the number of prototypes in both CCCD classifier and the size of the C4.5 and C5.0 classifier trees for the same simulation setting.

The number of prototypes in P-CCCDs are, in general, much higher than that of other classifiers. Also, notice that the less imbalanced the classes are, the less the data reduction in P-CCCDs. However, there is not much change in the number in RW-CCCDs, C4.5 and C5.0, and since the size of trees grows exponentially on d , the size of trees get bigger than the size of CCCDs for some substantially high δ and d . Moreover, the size of trees in C5.0 is considerably less than that in C4.5 (Kuhn and Johnson, 2013). Although the number of prototypes are much higher than the size of trees in highly overlapped and imbalanced cases, RW-CCCDs reduce the training set substantially more than C4.5 and C5.0 in moderately imbalanced and moderately overlapped higher dimensional settings.

5.4 Real Data Examples

In this section, we compare the performance of CCCD classifiers and all other weak and strong classifiers on several data sets from UC Irvine (UCI) Machine Learning and KEEL repositories (Bache and Lichman, 2013; Alcalá-Fdez et al., 2011). To test the difference between the AUC of classifiers, we employ the 5x2 cross validation (CV) paired t -test (see Dietterich, 1998) and the combined 5x2 CV F -test (see Alpaydm, 1999). The 5x2 CV test has been devised by Dietterich (1998) and found to be the most powerful test among those with acceptable type-I error. However, the test statistics of 5x2 t -tests depend on which one of the ten folds is used. Hence, Alpaydm (1999) offered a combined 5x2 CV F -test which works as an omnibus test for all ten possible 5x2 t -tests (for each five repetitions there are two folds, hence ten folds in total). Basically, if a majority of ten 5x2 t -tests suggests that two classifiers are significantly different in terms of performance, the F -test also suggests a significant difference. Hence, an F -test with high p -value suggests that some of the ten t -tests fail to have low p -values.

We also provide the overlapping ratios and imbalance levels of these data sets. In a simulation study such as the one in Section 5.1, we have control on the overlapping region of two classes since we can choose the supports of the classes, hence their overlapping region is exactly known. However, in real data sets where the support of classes are neither defined nor available, we need methods to estimate the supports and hence estimate the overlapping ratios for the two classes. We employ the support vector data description (SVDD) method of Tax and Dunn (2004) for this purpose. The method finds a description (or a region) of a data set, which covers a desired percentage of the points. SVDDs are also used in novelty or outlier detection. It has been inspired by the SVM classifiers and is based on defining a sphere around the data set. Similar to SVM, kernel functions can be employed to define more relaxed regions. SVDD is also a one-class learning method where the goal is to decide if a new point belongs to this particular class or not (Juszczak et al., 2002). By using SVDD approach, Xiong et al. (2010) found the SVDD regions of each class and its overlapping region. We also use SVDD to find the overlapping region E of each pair and report on the imbalance ratio with respect to E . The overlapping ratio is the percentage of points from both classes that reside in A . We use the Dtools toolbox (Tax, 2014) of

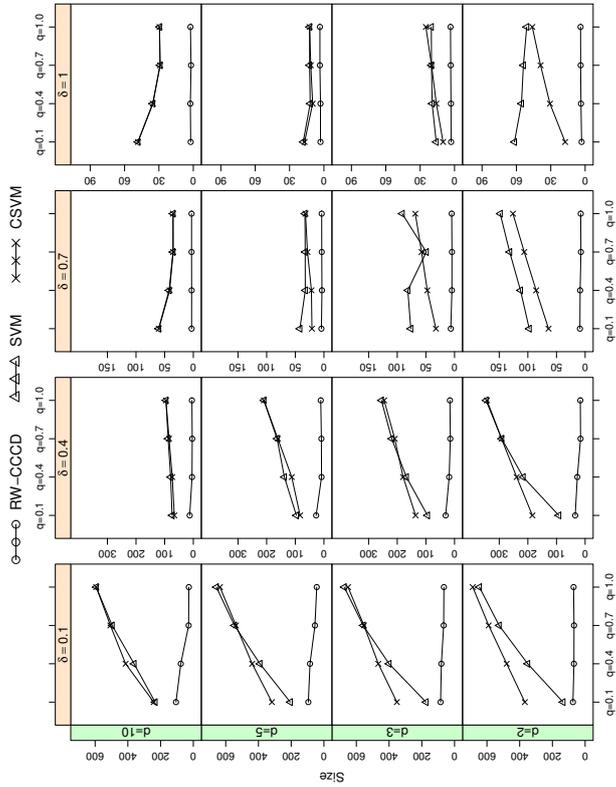

Figure 13: Comparison of the sizes of reduced data sets in RW-CCCDs, SVM and CSMV classifiers. Here “size” refers to the number of covering balls in RW-CCCD or the number of support vectors in SVM classifiers. In this two-class setting, classes are drawn from $F_X = U(0, 1)^d$ and $F_Y = U(\delta, 1 + \delta)^d$ where $\delta, q = 0.1, 0.4, 0.7, 1.0$ with $n = 400$ and $m = qn$.

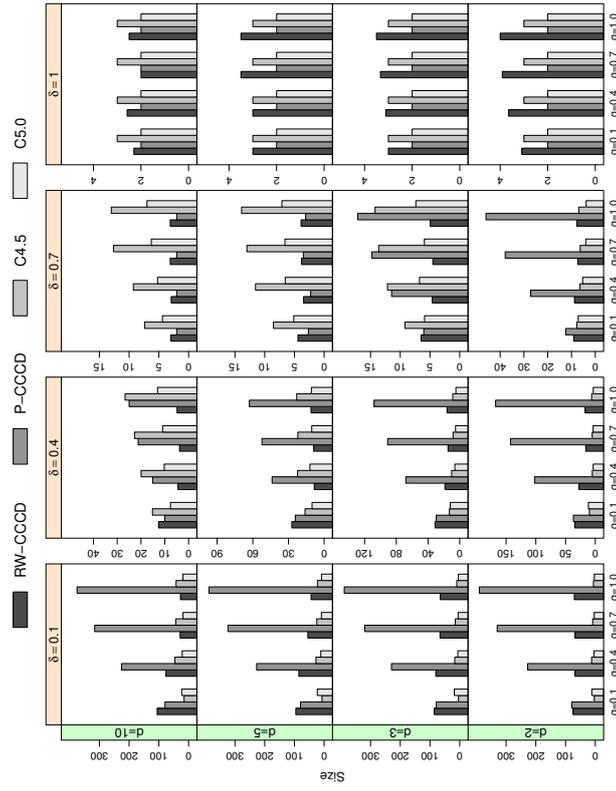

Figure 14: Comparison of the sizes of reduced data sets in CCCDs and C4.5. Here “size” refers to the number of covering balls in CCCDs or the number of nodes in the decision tree of C4.5 classifiers. The simulation setting is same as in Figure 13.

Table 4: Overlapping ratios and (local) imbalance ratios in the overlapping region of data sets. ‘‘IR’’ stands for the imbalance ratio in the overlapping region and ‘‘OR’’ stands for the overlapping ratio which is the percentage of points from both classes residing in the overlapping region. IR=‘‘NA’’ indicates that one of the classes has no members in the intersections of SVDD regions of classes.

MATLAB environment to produce the SVDDs of classes. Our choice of the kernel is the same as we have used with SVM classifiers in this study, the radial basis (i.e., Gaussian) kernel, for consistency. However, the selection of σ in the kernel is crucial for the SVDD region.

In Table 4, we present the overlapping ratios and the imbalance in the overlapping areas of all data sets for $\sigma = 2, 3, \dots, 10$. Although the value of σ produces different overlapping ratios, it is apparent that classes of data sets Ionosphere, Abalone19, Yeast4, Yeast6 and Yeast1289vs7 have more overlap than others, and these overlapping data sets have substantial local class imbalance in their respective overlapping regions. Other data sets have almost no overlapping nor imbalance in the overlapping regions even though their classes are globally imbalanced. One of these data sets is Yeast5 which has a imbalance ratio of $q = 32.70$ but has no imbalance in the small overlapping region.

In Table 5, we give the average AUC measures and their standard deviations of all CCCD-based and other classifiers according to the 5x2 CV scheme for the data sets. All other classifiers, weak or strong, have been two-way tested with 5x2 CV F -test against both RW-CCCD and P-CCCD classifiers. Their p -values are also provided in Table 5. For each of five repetitions, we divide the data into two folds. The AUC of fold 1 is given by using fold 1 as a training set and fold 2 as the test set. For fold 2, the process is similar. We repeated these experiments five times for all three classifiers. Looking at results from 11 data sets, RW-CCCD usually performs better than P-CCCD classifiers, and in addition,

ensemble based classifiers perform the best in general. Moreover, ensemble classifiers seem to perform better than RW-CCCDs but this difference is usually not significant, meaning RW-CCCDs perform comparable to ensemble classifiers in more than few folds of all ten folds. For example, compared to ensemble methods, RW-CCCD has nearly 0.07 less AUC in Yeast5, 0.02 less AUC in Yeast6, and 0.1 less AUC in Yeast1289vs7 data set. The difference is significant, however, with the data set Abalone19 with a level of < 0.03 . Although RW-CCCD achieves an average AUC value 0.6, ensemble classifiers achieve over 0.7. On the other hand, there is no significant difference between AUCs of RW-CCCD and ensembles in other highly overlapped and locally imbalanced data sets. On these data sets, RW-CCCD have significantly more AUC than weak classifiers and have AUC comparable to strong classifiers. Thus, these results from real data sets seem to resonate with the results from our simulations and further support the robustness of CCCD classifiers to the class imbalance problem.

6. Summary and Discussion

We assess the classification performance of various classifiers such as RW-CCCD, pure-CCCD, k -NN, SVM and C4.5 classifiers and their variants when class imbalance occurs, and we illustrate the robustness of CCCD classifiers to the class imbalance in data sets. This imbalance often occurs in real life data sets where, in two-class settings, minority class (the class with fewer number of observations) is usually dwarfed by the majority class. Class imbalances hinder the performance of many classification algorithms. We studied the performance of CCCD classifiers under class imbalance problem by first simulating a two-class setting similar to the one used in DeVinney (2003). In this setting, the support of one class is entirely embedded in the support of the other. Drawing equal number of observations from both class supports results in an imbalance between two classes with respect to their overlapping region, called *local (or restricted) class imbalance*. This difference in the class sizes was also the case in the example of DeVinney (2003), and it is the reason that CCCD classifiers show better results than the k -NN classifier. We show that P-CCCD classifiers with lower τ values tend to perform better than the ones with higher τ values. This is merely a result of balls with $\tau = 0$ representing the local density of the target class points better. Similarly, the RW-CCCD classifiers with lower e values are better when the dimensionality is low and the class sizes are high. This might indicate that the denser the data set in \mathbb{R}^d , the less useful the scores T_x . However, fully utilizing the scores usually increases the classification performance.

Analysis of both simulated and real data sets indicate that both CCCD classifiers show robustness to the class imbalance problem. We demonstrated this by studying the effects of the class overlapping problem together with the class imbalance problem. In fact, there are studies in the literature focusing on the performance of classification methods when class overlapping and class imbalance problems occur simultaneously (Prati et al., 2004; Demir and Trautenberg, 2010). Overlapping of classes is an important factor in the classification of imbalanced data sets; that is, it drastically affects the classification performance of most algorithms. When classes are both imbalanced and overlapping, performance of k -NN, SVM and C4.5 classifiers deteriorate whereas CCCD classifiers are not affected as severely as these methods. We use two alternatives of C4.5 classifiers where we prune the decision

Table 5: Average of AUC values of ten folds, and standard deviations, of CCCD, weak and strong classifiers for data sets. The p -values of 5x2 CV F -tests show the results of two-way tests comparing both CCCDs with other classifiers. Some of best performers are given in bold.

tree in one and do not in the other. It is known for some time that pruning deteriorates the performance of tree classifiers under class imbalance. Moreover, SVM is robust to moderately imbalanced class sizes but demonstrates no robustness in highly imbalanced cases. However, whether the data set is highly or moderately imbalanced, CCCD classifiers seem to preserve their AUC compared to k -NN, SVM and C4.5 classifiers. Hence, our study suggests that CCCD classifiers are appealing alternatives when data have class imbalance. In addition, we mention the effect of the individual class sizes on the class imbalance problem (Japkowicz and Stephen, 2002). Whatever the ratio between class sizes is, if the minority class has a substantially high number of points, the effect of imbalances between classes tend to diminish.

The classifiers k -NN, SVM and C4.5 are referred to as weak classifiers since, by construction, they are sensitive to imbalances between classes in data sets. In addition, we consider three distinct families of methods to establish strong classifiers based on weak classifiers, and compare them with CCCD classifiers. We conduct simulation studies to determine how the classification performance jointly depends on both (global) class imbalance and class overlapping, parameterized as q and δ , respectively. Finally, we apply all these classifiers on several UCI and KEEL data sets. By using the SVDD method of Tax and Duin (2004), we estimated the overlapping ratios of all these data sets. We show that CCCD classifiers outperform or perform comparable to k -NN, SVM and C4.5 classifiers for some overlapping and imbalance ratios in both simulated and real data sets. In particular, CCCDs are better than SVM classifiers in highly imbalanced cases. The effect of high class imbalance on SVM classifier is also studied in Akbani et al. (2004) and Raskutti and Kowalczyk (2004). However, when no imbalance occurs between classes, CCCD classifiers usually show either comparable or slightly worse performance than the other classifiers. As for strong classifiers, we employ the most successful methods from three families of schemes where EasyEnsemble and SMOT-ENN methods are among them. In our simulation studies, we demonstrated that CCCD classifiers, especially RW-CCCDs, work well compared to these strong classifiers when there are considerable overlap and the high (local) imbalance between classes. However, these methods are slightly better than RW-CCCDs as these strong classifiers are the best performing ones among their respective families (Batista et al., 2004; López et al., 2013). Nevertheless, RW-CCCDs have still high performance compared to these classifiers with additional increase in testing speed.

We also investigate the performance of CCCD classifiers under different conditions. Specifically, in two different experiments, we simulate two classes where (i) classes are imbalanced but supports are not overlapping (well separated) and (ii) classes are balanced and supports are overlapping with increasing dimensionality. P-CCCD classifiers are better than RW-CCCD classifiers in experiment (i). Both CCCD classifiers mostly outperform k -NN and SVM classifiers when classes are imbalanced and not overlapping, however RW-CCCD classifiers outperform these classifiers only when dimensionality is sufficiently high. In experiment (ii), the classification performance of CCCD classifiers slightly degrade compared to k -NN and SVM classifiers, especially with increasing d . Among CCCD classifiers, random walk covers appear to be better when classes are both overlapping and imbalanced, however our results suggest the use of pure covers when classes are imbalanced and well separated (i.e., not overlapping). In fact, class supports are often overlapping in real life data sets, hence RW-CCCD classifiers seem to be more appealing in practice.

In practice, classifiers based on CCCD classifiers resemble prototype selection methods. CCCDs balance the class sizes by defining balls that catch surrounding points of the same class, and discard these points from the training set. The resulting data set is composed of the centers of these balls and associated radii which are used in scaled dissimilarity measures. Although, CCCD classifiers remove substantial amount of observations from the majority class, they preserve (most of) the information with the radii. The bigger the radius, the more likely that the balls of CCCD classifiers contain more points. The radii could be considered as an indicator of the local density of the target class. The real advantage of CCCD classifiers are these prototype sets which are of (approximately) minimum cardinality, although training time and space of P-CCCDs and RW-CCCDs may be considerably high. However, the number of points in the prototype set is substantially low, and hence testing speed is increased. In some cases, RW-CCCDs provide classifiers with the least testing space complexity. Only the decision tree based classifiers, C4.5 and C5.0, achieve comparable or slightly more reduction to RW-CCCDs. However, with increasing dimensionality, sizes of these trees grow exponentially, making them less appealing than RW-CCCDs in the sense of classification space complexity. Hence, CCCDs preserve important information regarding the data sets while substantially increasing the testing speed. In literature, many classifiers have been devised to preserve the information on the deleted majority class points, however they are all ensemble based classifiers which substantially increase both training and testing time complexities. In that regard, CCCDs offer a novel approach to this particular problem.

Eveland et al. (2005) modified RW-CCCD classifiers as to increase the speed of the face detection in which imbalances between classes occur naturally. They did only refer to the real life applications which consist of class imbalances. They did not, however, investigate the relationship between class imbalance and overlapping problems as thoroughly as our study does. On the other hand, establishing class covers with Euclidean balls raise the possibility of using different regions (the regions are Euclidean hyperballs around target class points in CCCD) to balance the data and, thus, construct non-parametric classifiers with more classification performance. Along this line, CCCDs can be generalized using *proximity maps* (Jaromczyk and Toussaint, 1992). For example, Ceyhan (2005) defined *proximity catch digraphs* (PCDs) that are generalized versions of CCCDs. Ceyhan (2005) has introduced three families of PCDs and used them to test spatial data patterns of segregation and association (see Ceyhan and Priebe, 2005; Ceyhan et al., 2006, 2007). PCDs can also be used to derive new graph-based classifiers which are potentially robust to the class imbalance problem. The study of their properties and performance is a topic of ongoing research by the authors.

Editor: Manfred Opper

Abstract

We consider a hidden Markov model, where the signal process, given by a diffusion, is only indirectly observed through some noisy measurements. The article develops a variational method for approximating the hidden states of the signal process given the full set of observations. This, in particular, leads to systematic approximations of the smoothing densities of the signal process. The paper then demonstrates how an efficient inference scheme, based on this variational approach to the approximation of the hidden states, can be designed to estimate the unknown parameters of stochastic differential equations. Two examples at the end illustrate the efficacy and the accuracy of the presented method.

Keywords: Variational inference, stochastic differential equations, diffusion processes, hidden Markov model, optimal control

1. Introduction

Diffusion processes modeled by stochastic differential equations (SDEs) appear in several disciplines varying from mathematical finance to systems biology. For example, in systems biology stochastic differential equations are used for efficient modeling of the states of the chemical species in a reaction system when they are present in high abundance Wilkinson (2006). Oftentimes, the state of the system or the signal process is not directly observed, and inference of the state trajectories and parameter of the system has to be achieved based on noisy partial observations. Typically, in such a scenario, the observation data is conveniently modeled as a function of the hidden state corrupted with independent additive noise. However, generalizations of this basic setup, which, for example, could include stronger coupling between the hidden signal and the observation processes, are often used for modeling more complex phenomena.

In such a model optimal filtering theory concerns itself with recurrent estimation of the current state of the hidden signal process given the observation data until the present time. This is particularly useful in tracking problems where the estimation of the current location

of an object needs to be constantly updated as new noisy information flows in. On the other hand, optimal smoothing involves the class of methods which can be used in reconstruction of any past state of the signal process given a set of measurements up to the present time. More specifically, given the signal process X and the observation process Y , filtering theory entails computation of the conditional expectations of the form $\mathbb{E}[\phi(X_t)|\mathcal{F}_t^Y]$, where $\{\mathcal{F}_t^Y\}$ denotes the filtration generated by the process Y . The σ -algebra \mathcal{F}_t^Y contains all the information about the observation process Y up to the present time t . Smoothing, however, involves evaluation of the conditional expectations of the form $\mathbb{E}[\phi(X_s)|\mathcal{F}_t^Y]$, where $s < t$. The smoothing techniques can also be viewed as tools of estimation of the current state given a data set which includes future observations. This interpretation is particularly relevant in statistics, where such techniques are essentially the means of computing certain posterior conditional densities given the observation set. The present article focuses on a variational approach to this smoothing problem and later employs the method for estimation of parameters of diffusion processes.

Evaluation of such conditional expectations or densities are quite difficult, since they are often solutions of suitable (stochastic) partial differential equations. These are usually infinite-dimensional problems and analytical solutions are generally impossible. Hence, effort has been directed toward developing of a variety of numerical schemes for efficient approximation of these conditional densities. While Markov chain Monte Carlo methods for inference use discretization of the given SDE for writing down an approximate likelihood Kushner and Dupuis (2001); Pagès and Pham (2005); Andrieu et al. (2010), particle methods approximate the (posterior) conditional densities by suitably weighted point masses Crisan and Lyons (1999); Del Moral et al. (2001); Bain and Crisan (2009). However, these methods often rely on a suitable discretization of the problem which is mostly done in an ad-hoc way. Since a theoretical framework for obtaining approximations is not present, the approximation error might be difficult to quantify.

In contrast, the present paper focuses on a variational approach to this estimation problem. The main idea in such a method is to approximate the (posterior) conditional probability distribution of the system's state (given the observed data) by an appropriate Gaussian distribution, where the optimal parameters for the Gaussian distribution are obtained by minimizing the relative entropy (or Kullback-Leibler distance) between the posterior process and a suitable approximating SDE. Earlier works like Archambeau et al. (2007, 2008); Archambeau and Opper (2011); Cseke et al. (2013); Vrettas et al. (2015) considered the case when the signal process is modeled by an SDE with a constant diffusion term. The advantage of working with a constant diffusion term is that it implies that the approximating SDE will simply have a linear drift so that marginals are distributed as Gaussian. This simple expression of the SDE with a linear drift makes the subsequent optimization problem for finding the suitable parameters for this approximating SDE easier. However, since most physical phenomena cannot be realistically modeled by SDEs with constant diffusion term, there is a pressing need of extending the approach to general SDEs. One natural but naive approach in this regard could be to freeze the diffusion term at an appropriate value, that is, to take the zeroth order expansion of the diffusion coefficient. Although simple to implement, the efficacy of the method is not guaranteed by theoretical results and will vary from case to case, and a reasonable error analysis might require unreasonably restrictive conditions on the model.

Instead, the present article delves much deeper in to the problem and develops methods for finding the optimal approximating SDE such that the relative entropy between it and the true posterior process is minimized subject to the condition that the marginals of the former follow Gaussian distributions. The main obstacle that needs to be overcome in this approach stems from the fact that unlike the previous case, the approximating SDE here cannot be taken to be the one with a linear drift, and a suitable expression of it needs to be found so that the marginals are still Gaussian. This has been achieved in Theorem 9. In fact, our work outlines the most general techniques for approximating the posterior density by any density from the exponential family or mixture of exponential families. In this connection we would like to note that the reason for requiring that the marginals follow a Gaussian distribution or more generally, a distribution from the exponential family because this results in a finite-dimensional smoother which can be used for approximating a wide range of distributions.

It should be noted that the variational method considered here is different from the so-called extended Kalman filter (EKF) in two ways: first, EKF is employed for filtering problems; but more importantly, EKF starts by linearizing the signal (prior) SDE and then freezing its diffusion term, while the variational approach is concerned with approximation of the posterior SDE. Therefore even though in the constant diffusion term case, the approximating SDE happens to have linear drift and thus resulting in a Gaussian smoother, it is not based on the same philosophy behind the EKF. And as mentioned before, in the non-constant diffusion term case although our method can be used to obtain a finite-dimensional smoother, in particular, a Gaussian smoother, it completely avoids any form of linearization of the given SDE or subsequent freezing of the diffusion term.

In our paper this variational approximation method has been formulated as an optimal control problem. The advantage of this theoretical framework is that necessary conditions for global optimality are then obtained by employing the Pontryagin maximum principle. This leads to considerable computational advantages of the variational method compared to numerically solving the underlying (stochastic) PDEs, that is highlighted by two examples.

The later part of the paper focusses on the important topic of parameter inference of SDEs. The above scheme of estimating the hidden states and the smoothing densities is cleverly used in designing an efficient method for estimating parameters of SDEs. In particular, the paper proposes an iterative EM-type algorithm which aims to compute approximate maximum likelihood estimates of the parameters in a tractable way. Two illustrative examples, which are important in mathematical finance, demonstrate the accuracy and efficiency of the proposed algorithms. Future projects will address more complicated models.

The layout of this article is as follows: In Section 2 we formally introduce the problem setting. We consider as a running example throughout the manuscript a geometric Brownian motion. The variational approximation idea is motivated in Section 3 leading to a specific class of optimization problems that is addressed in Section 4. It is then reformulated in Section 5 as an optimal control problem and necessary conditions for optimality are derived. Section 6 explains how the variational approximation can be used to infer unknown parameters of the model. Section 7 discusses the presented variational approximation in the context of a discrete time measurement model. The theoretical results are applied in Section 8 to two examples: a geometric Brownian motion and to the Cox-Ingersoll-Ross

process. We finally conclude with some remarks and directions for future work in Section 9. Certain technical proofs are relegated to the appendix.

Notation. Hereafter, I_n is the n -dimensional identity matrix and E_t is the $n \times n$ matrix where the i -th entry is one and zero elsewhere. We let $\text{Sym}(n, \mathbb{R})$ and $\text{GL}(n, \mathbb{R})$ be respectively the set of symmetric and invertible $n \times n$ matrices with real entries. For matrices $A, B \in \mathbb{R}^{n \times n}$ let $\langle A, B \rangle := \text{tr}(A^T B)$ denote the Frobenius inner product. For a vector $b \in \mathbb{R}^n$ and a positive definite matrix A , we employ the norm $\|b\|_A := \sqrt{b^T A^{-1} b}$. We define the standard n -simplex as $\Delta_n := \{x \in \mathbb{R}^n : x \geq 0, \sum_{i=1}^n x_i = 1\}$. Let $\mathcal{C} := \mathcal{C}([0, T], \mathbb{R}^n)$ denote the space of continuous functions on $[0, T]$ taking values in \mathbb{R}^n . Let S be a metric space, equipped with its Borel σ -field $\mathcal{B}(S)$. The space of all probability measures on $(S, \mathcal{B}(S))$ is denoted by $\mathcal{P}(S)$. The relative entropy (or Kullback-Leibler divergence) between any two probability measures $\mu, \nu \in \mathcal{P}(S)$ is defined as

$$D(\mu \parallel \nu) := \begin{cases} \int \log \left(\frac{d\mu}{d\nu} \right) d\mu, & \text{if } \mu \ll \nu \\ +\infty, & \text{otherwise,} \end{cases}$$

where \ll denotes absolute continuity of measures and $\frac{d\mu}{d\nu}$ is the Radon-Nikodym derivative. By convention *measurable* means *Borel-measurable* in the sequel. Given an S -valued random variable X with Law $(X) = \mu \in \mathcal{P}(S)$, let $\mathbb{E}_\mu[X]$ denote the expectation of X .

2. Model setup

As usual, we will work on a complete probability space $(\Omega, \mathcal{F}, \mathbb{P})$ equipped with a filtration $\{\mathcal{F}_t\}$ satisfying the usual conditions, that is, $\{\mathcal{F}_t\}$ is complete, right continuous and contains all the \mathbb{P} -null sets. The basic objects in our study consist of a signal process X and an observation process Y , both of which are assumed to be $\{\mathcal{F}_t\}$ -adapted. The unobserved signal process X is modeled by the following stochastic differential equation describing the state evolution of a dynamical system:

$$dX_t = f(X_t)dt + \sigma(X_t)dW_t, \quad X_0 = x_0, \quad 0 \leq t \leq T, \tag{1}$$

where $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$, $\sigma : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$, and W is an n -dimensional Brownian motion independent of x_0 . The observation process Y is modeled as noisy measurements of some function of the signal process X . Mathematically, Y is defined as

$$Y_t = \int_0^t h(X_s)ds + B_t, \tag{2}$$

where $h : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is called the observation function and B is an m -dimensional Brownian motion independent of x_0 and W .

Assumption 1 We stipulate that

- (i) f and σ are globally Lipschitz;
- (ii) and h is twice continuously differentiable.

It is known Kallenberg (2002) that under Assumption 1 there exists a unique strong solution to the SDE (1). Given the observed data up to some time T , $\{Y_s : s \leq T\}$, the goal of the paper is to outline an approximation method for the smoothing density, $\mathcal{P}_S(x, t)$, which is the conditional probability density of X_t given $\{Y_s : s \leq T\}$. In other words, the smoothing density is defined by the equation:

$$\mathbb{E}[\phi(X_t) | \mathcal{F}_T^X] = \int \phi(x) \mathcal{P}_S(x, t) dx, \quad (3)$$

up to a.s. equivalence, where ϕ is any bounded measurable function from \mathbb{R}^n to \mathbb{R} and $\{\mathcal{F}_t^Y\}$ denotes the filtration generated by the process Y .

More generally, we will be interested in approximating the full conditional probability measure on the path space, $C \equiv C([0, T], \mathbb{R}^n)$. To describe this mathematically, assume that a regular conditional probability measure $\mathbb{P}[\cdot | \mathcal{F}_T^X]$ is chosen. Then there exists a measurable probability kernel $y \in C \rightarrow \Pi_{\text{post}}(\cdot, y) \in \mathcal{P}(C)$ such that for any measurable set $A \subset C$,

$$\mathbb{P}[X_{[0, T]} \in A | \mathcal{F}_T^X] = \Pi_{\text{post}}(A, Y_{[0, T]}).$$

Given the observation process up to time T , $Y_{[0, T]}$, we now describe a characterization of the probability measure $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$, which will play a pivotal role for our purposes. The probability measure $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$ is actually the distribution of a diffusion process \bar{X}^T on C , and the latter is obtained by a modification of the original signal process X :

$$d\bar{X}_t^T = g(\bar{X}_t^T, t)dt + \sigma(\bar{X}_t^T)d\bar{W}_t, \quad \bar{X}_0^T = x_0, \quad (4)$$

where \bar{W} is an $\{\mathcal{F}_t\}$ -adapted Brownian motion that is independent of Y . Notice that the diffusion coefficient of the above SDE (which we will henceforth call the posterior SDE or posterior diffusion) is same as that of the original SDE, and the drift of this posterior SDE is time-dependent and is obtained as

$$g(x, t) := f(x) + a(x)\nabla \log w(x, t), \quad (5)$$

where $a(x) := \sigma(x)\sigma(x)^\top$. We give details about the (random) function w a little later, but the important point to note here is that the new drift function is the old drift function with an extra additive term, and the observation process $Y_{[0, T]}$ enters into the characterization of $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$ only through w .

To see this characterization of $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$, we first look at the usual filtering density $\mathcal{P}_F(x, t)$, which is naturally defined by

$$\mathbb{E}[\phi(X_t) | \mathcal{F}_t^Y] = \int \phi(x) \mathcal{P}_F(x, t) dx. \quad (6)$$

Under suitable technical conditions, the filter density \mathcal{P}_F satisfies the Kushner-Stratonovich equation (for example, see Stratonovich (1960); Kushner (1967); Bain and Crisan (2009)). For our purposes, however, it is convenient to work with the unnormalized filter density $p(x, t)$, that is, $\mathcal{P}_F(x, t) = p(x, t) (\int_{\mathbb{R}^n} p(x, t) dx)^{-1}$, which satisfies the so-called Zakai equation Zakai (1969)

$$\begin{cases} dp(x, t) = \mathcal{A}^* p(x, t) dt + p(x, t) h(x)^\top dY_t \\ p(x, 0) = p_0(x). \end{cases} \quad (7)$$

Here p_0 denotes the density of x_0 and \mathcal{A}^* is the adjoint of the infinitesimal generator of the process X given by $\mathcal{A}\psi(x) = \sum_i f_i(x) \frac{\partial \psi}{\partial x_i} + \frac{1}{2} \sum_{i,j} a_{i,j}(x) \frac{\partial^2 \psi}{\partial x_i \partial x_j}$ for $\psi \in \mathcal{C}_0^2(\mathbb{R}^n, \mathbb{R})$. We next consider the backward stochastic partial differential equation (SPDE)

$$\begin{cases} dw(x, t) = -\mathcal{A}w(x, t)dt - w(x, t)h(x)^\top dY_t \\ w(x, T) = 1. \end{cases} \quad (8)$$

Conditions about existence of solutions to (7) and (8) can be found in Pardoux (1981/82). It is well known (Pardoux, 1981/82, Corollary 3.8) that the smoothing density can be expressed as

$$\mathcal{P}_S(x, t) = \frac{p(x, t)w(x, t)}{\int_{\mathbb{R}^n} p(x, t)w(x, t)dx}. \quad (9)$$

Now by using (7), (8) and (9), it can be shown¹ that the smoothing density solves the following Kolmogorov forward equation

$$\left(\frac{\partial}{\partial t} + \sum_i \frac{\partial}{\partial x_i} g(x, t) - \frac{1}{2} \sum_{i,j} \frac{\partial^2}{\partial x_i \partial x_j} a_{i,j}(x) \right) \mathcal{P}_S(x, t) = 0, \quad (10)$$

with the drift term g defined by (5). In other words, the conditional probability measure $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$ on C is induced by the diffusion process \bar{X}^T as defined in (4).

Evaluating $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$ is what is known as the path estimation problem. Except for a few simple cases, the SPDEs, that are involved in this estimation of the hidden path, are analytically intractable. The variational approach that we undertake in this paper actually has the goal of approximating $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$. Toward this end, a natural objective is to approximate $\Pi_{\text{post}}(\cdot, Y_{[0, T]})$ by a probability measure such that the corresponding marginals of the latter come from a known family of distributions (e.g. exponential family). As a result, the marginal of this approximating probability measure at time t approximates the smoothing density $\mathcal{P}_S(x, t)$. The procedure adopted in this article involves finding the optimal parameters of this approximating distribution by minimizing the relative entropy between the posterior distribution and the approximating one.

2.1 Example: Geometric Brownian Motion

We present as a running example throughout the article the geometric Brownian motion that is used to model stock prices in the Black-Scholes model, see Shiryaev (1999). The system dynamics (1) is given by a one-dimensional geometric Brownian motion

$$dX_t = \kappa X_t dt + \lambda X_t dW_t, \quad X_0 = x_0 \sim \log \mathcal{N}(\mu, \sigma), \quad (11)$$

for $0 \leq t \leq T$, $\lambda, \kappa > 0$ and an observation process (2) defined by

$$Y_t = \int_0^t X_s ds + B_t. \quad (12)$$

It is straightforward to see that Assumption 1 holds in this setting.

1. See Appendix A for a detailed derivation.

3. Variational approximation: Motivation

Let Π_{prior} denote the distribution of the original signal process X on \mathcal{C} , that is, for a measurable $\mathcal{A} \subset \mathcal{C}$, $\Pi_{\text{prior}}(\mathcal{A}) = \mathbb{P}[X_{[0,T]} \in \mathcal{A}]$. Define the two terms

$$H_T(X_{[0,T]}, y) := -h(X_T)_{yT} + \int_0^T y_s dh(X_s) + \frac{1}{2} \int_0^T \|h(X_s)\|^2 ds \quad (13)$$

$$I(H_T(\cdot, y)) := -\log \left(\int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}} \right). \quad (14)$$

Let y be a sample path of the observation process Y on the interval $[0, T]$. Then notice that by the pathwise Kallianpur-Striebel formula (or the Bayes formula), we have

$$\frac{d\Pi_{\text{post}}(\cdot, y)}{d\Pi_{\text{prior}}} = \frac{\exp(-H_T(\cdot, y))}{\int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}}} = \frac{\exp(-H_T(\cdot, y))}{L(y)},$$

where $L(y) = \int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}}$. Consequently, $L(y)$ can be interpreted naturally as the likelihood of the path y , or equivalently, $I(H_T(\cdot, y))$ is viewed as the negative log-likelihood of the sample path y . The term $H_T(X_{[0,T]}, y)$ can be interpreted as the X -conditional information and the information in the observation that $Y = y$, see Mitter and Newton (2003) for more details. Now for any probability measure Q^2 on $C([0, T], \mathbb{R})$, the relative entropy between Q and $\Pi_{\text{post}}(\cdot, y)$ can be expressed by the following lemma.

Lemma 2 $D(Q||\Pi_{\text{post}}(\cdot, y)) = -I(H_T(\cdot, y)) + D(Q||\Pi_{\text{prior}}) + \mathbb{E}_Q[H_T(\cdot, y)]$.

Proof. The proof essentially follows the one in (van Handel, 2007, Lemma 2.2.1). Splitting the relative entropy and using the pathwise Kallianpur-Striebel formula yields

$$\begin{aligned} D(Q||\Pi_{\text{prior}}) &= \int \left[\log \left(\frac{dQ}{d\Pi_{\text{post}}(\cdot, y)} \right) + \log \left(\frac{d\Pi_{\text{post}}(\cdot, y)}{d\Pi_{\text{prior}}} \right) \right] dQ \\ &= D(Q||\Pi_{\text{post}}(\cdot, y)) + \int \log \left(\frac{d\Pi_{\text{post}}(\cdot, y)}{d\Pi_{\text{prior}}} \right) dQ \\ &= D(Q||\Pi_{\text{post}}(\cdot, y)) + \int \log \left(\frac{\exp(-H_T(\cdot, y))}{\int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}}} \right) dQ \\ &= D(Q||\Pi_{\text{post}}(\cdot, y)) - \mathbb{E}_Q[H_T(\cdot, y)] - \log \left(\int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}} \right). \quad \blacksquare \end{aligned}$$

Mitter and Newton Mitter and Newton (2003) provide an information-theoretic interpretation to this result. They interpret the term (14) as the *total information* available to the estimator Q through the sample path y . On the other hand, they call the quantity $\mathcal{F}(Q, y) := D(Q||\Pi_{\text{prior}}) + \mathbb{E}_Q[H_T(\cdot, y)]$ the *apparent information* of the estimator. By non-negativity of the relative entropy $\mathcal{F}(Q, y) \geq I(H_T(\cdot, y))$ with equality if and only if $Q = \Pi_{\text{post}}(\cdot, y)$. In this sense, a suboptimal estimator appears to have access to more information than is actually available.

² Q will be called the approximating probability measure in the sequel.

Since the total information $I(H_T(\cdot, y))$ does not depend on Q , minimizing the relative entropy between Q and $\Pi_{\text{post}}(\cdot, y)$ over a class of probability measures \mathcal{Q} is equivalent to minimizing the apparent information $\mathcal{F}(Q, y)$. This motivates to consider an approximating distribution Q on \mathcal{C} that is characterized as the solution to the following optimization problem:

Problem 3 Minimize $D(Q||\Pi_{\text{prior}}) + \mathbb{E}_Q[H_T(\cdot, y)]$ subject to

(i) Q is a probability distribution induced by an SDE of the form

$$dZ_t = u(Z_t, t)dt + \sigma(Z_t)dW_t, \quad Z_0 = x_0, \quad 0 \leq t \leq T; \quad (15)$$

(ii) The marginals of Q at time t , i.e., the distribution of Z_t , belong to a chosen family of distributions.

We will show in the remainder of this article how Problem 3 can be restated as an optimal control problem, which leads to a standard formulation of necessary optimality conditions in terms of Pontryagin's maximum principle.

Note that the objective function of Problem 3 is known to be strictly convex with respect to Q , see Giszszár (1975). The constraint (ii) restricts the feasible set approximating distributions Q to a nonconvex set. Note that such problems (i.e., absence of constraint (i)) have been studied in the literature Pinski et al. (2015)). In our setting, the set of feasible solutions is also coupled with the first constraint (i), that parametrizes the feasible set of distributions in terms of the drift function u . This coupling is investigated in Section 4, in particular Theorem 9 characterizes the set of all drift terms u such that the distribution induced by (15) has finite dimensional marginals that belong to a given family of distributions. Hence, Problem 3 can alternatively be interpreted as minimizing the objective function over a class of drift functions u that induce Q via (15) and such that Q satisfies constraint (ii). For example, if the goal is to approximate the posterior distribution Π_{post} by a distribution Q whose marginals are normal distributions, then one aims to find a drift term u such that the objective function is minimized and such that the solution Z_t to (15) admits a normal distribution.

Remark 4 Notice that the unconstrained optimization of the objective function in Problem 3 with respect to Q will simply yield the minimizer Q to be Π_{post} . Since, as discussed in the beginning of Section 2, Π_{post} is induced by the SDE, (4), the constraint (i) in Problem 3 is essentially inbuilt. In other words, it is the constraint (ii) which plays the crucial role in the methods outlined in this paper.

The objective function in Problem 3, in particular the relative entropy between the approximating distribution Q and the prior distribution Π_{prior} can be simplified, since due to the constraint (i) the underlying SDEs (15) and (1) share the same diffusion coefficient. In view of (15) and (1), consider two SDEs for $0 \leq t \leq T$

$$dX_t = f(X_t)dt + \sigma(X_t)dW_t, \quad dZ_t = u(Z_t, t)dt + \sigma(Z_t)dW_t, \quad X_0 = Z_0 = x_0,$$

with $u: \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$, $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$, $\sigma: \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$, W an n -dimensional Brownian motion independent of x_0 and both SDEs satisfying Assumption 1. Let $(\Omega, \mathcal{F}_T, P)$ be a probability

space, where \mathcal{F}_T is the sigma algebra $\sigma(W_s : s \leq T)$ and let Π_{prior} and Q denote the the laws of X_t and Z_t with respect to P . It follows by Girsanov's Theorem Øksendal (2003), that

$$\mathbb{E}_Q \left[\log \left(\frac{dQ}{d\Pi_{\text{prior}}} \right) \right] = \frac{1}{2} \mathbb{E}_Q \left[\int_0^T \varphi(s, \omega)^\top \varphi(s, \omega) ds \right],$$

where $\varphi(s, \omega) := \sigma(Z_s(\omega))^{-1} (u(X_s(\omega)) - f(X_s(\omega)))$. Therefore, the relative entropy between Q and Π_{prior} is

$$D(Q \| \Pi_{\text{prior}}) = \frac{1}{2} \mathbb{E}_Q \left[\int_0^T \|u(X_s, s) - f(X_s)\|_{\sigma(X_s)}^2 ds \right],$$

where $\|u(x, s) - f(x)\|_{\sigma(x)}^2 := (u(x, s) - f(x))^\top a(x)^{-1} (u(x, s) - f(x))$. Hence, the objective function in Problem 3 can be expressed as

$$\begin{aligned} D(Q \| \Pi_{\text{prior}}) + \mathbb{E}_Q[H_T(\cdot, y)] \\ = \int_0^T \mathbb{E}_Q \left[\frac{1}{2} \|u(X_t, t) - f(X_t)\|_{\sigma(X_t)}^2 + y_t \left(u(X_t, t)^\top \nabla h(X_t) \right. \right. \\ \left. \left. + \frac{1}{2} \sigma(X_t)^\top \nabla^2 h(X_t) \sigma(X_t) \right) + \frac{1}{2} \|h(X_t)\|^2 \right] dt - y_T \mathbb{E}_Q[h(X_T)], \end{aligned} \quad (16)$$

where the last equality is due to Fubini's Theorem and Itô's Lemma. The two coupling constraints (i) and (ii) in Problem 3 are studied in the next section and will finally allow us to reformulated Problem 3 as an optimal control problem.

4. Multi-dimensional SDE with prescribed marginal law

This section establishes conditions on the drift function in the approximate SDE (15) such that the induced marginal distributions evolve in a given exponential family.

Definition 5 (Exponential family) Let $\mathcal{H}_1, \dots, \mathcal{H}_m$ be Hilbert spaces and let $\mathcal{H} = \prod_{i=1}^m \mathcal{H}_i$ be endowed with the inner product $\langle \cdot, \cdot \rangle$. Let the functions $c_i : \mathbb{R}^n \rightarrow \mathcal{H}_i$ for $i = 1, \dots, m$ be linearly independent, have at most polynomial growth, be twice continuously differentiable and denote $c(x) = (c_1(x), \dots, c_m(x))$. Assume that the convex set

$$\Gamma := \{\Theta \in \mathcal{H} : \psi(\Theta) = \log \int \exp(\langle \Theta, c(x) \rangle) dx < \infty\}$$
 has non-empty interior. Then

$$EM(c) = \{p(\Theta), \Theta \in \Lambda\}, \quad p(x, \Theta) := \exp(\langle \Theta, c(x) \rangle) - \psi(\Theta),$$

where $\Lambda \subseteq \Gamma$ is open, is called an exponential family of probability densities.

Definition 6 (Mixture of exponential families) Let $EM(c^{(i)})$ for $i = 1, \dots, k$ be exponential families according to Definition 5. Then

$$EM(c^{(1)}, \dots, c^{(k)}) = \left\{ \sum_{\ell=1}^k \nu_\ell p_\ell(\cdot, \Theta^{(\ell)}) : p_\ell(\cdot, \Theta^{(\ell)}) \in EM(c^{(\ell)}), \nu \in \Delta_k \right\}$$

is called a mixture of k exponential families of probability densities.

Consider the stochastic differential equation (15), where $u : \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$, $\sigma : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times d}$ and W is a d -dimensional Brownian motion independent of x_0 .

Assumption 7

1. The SDE (15) satisfies Assumption 1.
2. The initial condition x_0 has a density p_0 that is absolutely continuous with respect to the Lebesgue measure and has finite moments of any order.
3. The unique solution X_t to (15) admits a density $p(x, t)$ that is absolutely continuous with respect to the Lebesgue measure and that satisfies the Kolmogorov forward equation.

Problem 8 Let $EM(c^{(1)}, \dots, c^{(k)})$ be a mixture of exponential families, let p_0 be a density contained in $EM(c^{(1)}, \dots, c^{(k)})$, let σ be a diffusion term and let $a(\cdot) := \sigma(\cdot)\sigma(\cdot)^\top$. Let $\mathcal{U}(x_0, \sigma)$ denote the set of all drifts u such that x_0, u, σ and its related SDE (15) satisfy Assumption 7. Assume $\mathcal{U}(x_0, \sigma)$ to be non-empty. Then given a curve $t \mapsto p(\cdot, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$ in $EM(c^{(1)}, \dots, c^{(k)})$, find a drift in $\mathcal{U}(x_0, \sigma)$ whose related SDE has a solution with marginal density $p(\cdot, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$.

A solution to Problem 8 is given by the following theorem.

Theorem 9 Given the assumptions and notation of Problem 8. Consider the SDE (15) with drift term

$$u_t(x, t) = \frac{1}{2} \sum_{j=1}^n \frac{\partial}{\partial x_j} a_{ij}(x) + \frac{1}{2} \sum_{j=1}^n a_{ij}(x) \frac{\partial}{\partial x_j} p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)}) - \frac{1}{p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})} \sum_{\ell=1}^k \nu_\ell p_\ell(x, \Theta_t^{(\ell)}) \left\langle \dot{\Theta}_t^{(\ell)}, \mathcal{I}_t^{(\ell)}(x) \right\rangle,$$

for $i = 1, \dots, n$, where

$$\mathcal{I}_i^{(\ell)}(x) := \int_{-\infty}^{x_i} \varphi_i^{(\ell)}((x_{-i}, \xi_i), \Theta_t^{(\ell)}) \exp \left(\left\langle \Theta_t^{(\ell)}, c^{(\ell)}(x_{-i}, \xi_i) - c^{(\ell)}(x) \right\rangle \right) d\xi_i, \quad (17)$$

$(x_{i-}, \xi_i) := (x_1, \dots, x_{i-1}, \xi_i, x_{i+1}, \dots, x_n)^\top$ and the functions $\varphi_i^{(\ell)} : \mathbb{R}^n \times \mathcal{H} \rightarrow \mathcal{H}$ for all $\ell = 1, \dots, k$ satisfy

$$\sum_{i=1}^n \left\langle \dot{\Theta}_t^{(\ell)}, \varphi_i^{(\ell)} \left((x_{-i}, \xi_i), \Theta_t^{(\ell)} \right) \right\rangle_{\xi_i=x_i} = \left\langle \dot{\Theta}_t^{(\ell)}, c^{(\ell)}(x) - \nabla \psi_\ell(\Theta_t^{(\ell)}) \right\rangle. \quad (18)$$

If $u \in \mathcal{U}(x_0, \sigma)$, then the SDE (15) solves Problem 8, i.e., X_t has a density

$$p_{X_t}(x) = \sum_{\ell=1}^k \nu_\ell \exp \left(\left\langle \Theta_t^{(\ell)}, c^{(\ell)}(x) \right\rangle - \psi_\ell(\Theta_t^{(\ell)}) \right), \quad \text{for all } t \leq T.$$

The proof is provided in Appendix B.

Remark 10 1. For the non-mixture and one-dimensional case ($k = n = 1$), the result is known Brigo (2000) and coincides with Theorem 9. Furthermore, it can be seen by the proof in Brigo (2000) and by invoking the existence and uniqueness theorem for ODEs, that the drift function u is uniquely determined.

2. For the multi-dimensional case ($n > 1$), the drift function is not unique anymore, as there exist multiple choices for $\varphi_i^{(\theta)}$. This gives rise to a natural question, if there exist a particular choice of $\varphi_i^{(\theta)}$ such that the integral terms $\mathcal{I}_i^{(\theta)}$ in (17) admit closed-form expressions. In Section 4.1 (Proposition 11), we derive such functions $\varphi_i^{(\theta)}$ for the mixture of multivariate normal densities.

3. In a non-mixture setting ($k = 1$), the drift function simplifies to

$$u_i(x; t) = \frac{1}{2} \sum_{j=1}^n \frac{\partial}{\partial x_j} a_{i,j}(x) + \frac{1}{2} \sum_{j=1}^n a_{i,j}(x) \left\langle \Theta_i, \frac{\partial c(x)}{\partial x_j} \right\rangle - \left\langle \Theta_i, \int_{-\infty}^{x_i} \varphi_i((x_{-i}, \xi), \Theta_i) \exp \left[\langle \Theta_i, c(x_{-i}, \xi) - c(x) \rangle \right] d\xi \right\rangle,$$

where the functions φ_i have to satisfy (18).

As remarked, the drift term proposed in Theorem 9 consists of the integral terms (17), that depend on the particular exponential families considered. In the following, we restrict ourselves to the mixture of multivariate normal densities and show that these integral terms, and hence the drift function, admit a closed-form expression.

4.1 Mixture of multivariate normal densities

Consider the family of multivariate Gaussian distributions with mean $m \in \mathbb{R}^n$ and covariance matrix $S \in \text{Sym}(n, \mathbb{R})$, that can be expressed in terms of Definition 5 as follows. Let the Hilbert space $\mathcal{H} = \mathbb{R}^n \times \mathbb{R}^{m \times n}$ be endowed with the inner product $\langle (a, A), (b, B) \rangle = a^\top b + \text{tr}(A^\top B)$ and define

$$\begin{aligned} \Theta &= (\eta, \theta) := \left(S^{-1}m, -\frac{1}{2}S^{-1} \right) \in \mathcal{H}, \quad c : \mathbb{R}^n \rightarrow \mathcal{H}, \quad c(x) = (x, xx^\top) \\ \psi : \mathcal{H} &\rightarrow \mathbb{R}, \quad \psi(\Theta) &= -\frac{1}{4} \text{tr}(\eta \eta^\top \theta^{-1}) + \frac{1}{2} \log \det \left(-\frac{1}{2} \theta^{-1} \right) + \frac{n}{2} \log(2\pi). \end{aligned} \quad (19)$$

A direct computation, using $\text{tr}(\eta \eta^\top \theta^{-1}) = \eta^\top \theta^{-1} \eta$, leads to

$$p(x, \Theta) = \exp \left(\langle c(x), \Theta \rangle - \psi(\Theta) \right) = \frac{1}{(2\pi)^{\frac{n}{2}} (\det S)^{\frac{1}{2}}} \exp \left(-\frac{1}{2} (x - m)^\top S^{-1} (x - m) \right).$$

3. For example, $\varphi_i^{(\theta)}(x, \Theta_i^{(\theta)}) := \delta_{\eta_j} c^{(\theta)}(x) - \nabla_{\Theta} \psi(\Theta_i^{(\theta)})$ for all $j \in \{1, \dots, n\}$ are feasible choices for $\varphi_i^{(\theta)}$, as they satisfy (18).

We point out again that for the proposed variational method, it is favourable if the approximating SDE (15) has a drift function that admits a closed-form expression. Furthermore, since the drift function is not unique (cf. Remark 10), among all feasible solutions characterized by the $\varphi_i^{(\theta)}$ functions, we want to find one that can be computed analytically. The latter turns out to be a difficult task and depending heavily on the specific exponential family chosen. From now on, we consider the exponential family of the multivariate normal probability densities that is given by (19). In this setting, it is possible to find functions $\varphi_i^{(\theta)}$ such that the integral terms (17), and therefore the drift function, can be computed in closed form.

Proposition 11 For the mixture of multivariate normal densities, one possible choice for the drift function proposed by Theorem 9 is

$$u(x; t) = \frac{1}{2} \text{div}(a(x)) + \frac{\sum_{\ell=1}^k \nu_\ell p_\ell(x, \Theta_\ell^{(\theta)})}{p(x, \Theta^{(1)}, \dots, \Theta_\ell^{(k)})} \left(\frac{1}{4} \theta_\ell^{(\theta)-1} \theta_\ell^{(\theta)} \theta_\ell^{(\theta)-1} \theta_\ell^{(\theta)} - \frac{1}{2} \theta_\ell^{(\theta)-1} \dot{\eta}_\ell^{(\theta)} - \frac{1}{2} \theta_\ell^{(\theta)-1} \dot{\theta}_\ell^{(\theta)} x + a(x) \left(\frac{1}{2} \eta_\ell + \theta_\ell x \right) \right).$$

The proof is provided in Appendix C.

Remark 12 For the non-mixture setting the drift term simplifies to

$$u(x; t) = \frac{1}{2} \text{div}(a(x)) + \frac{1}{4} \theta_r^{-1} \dot{\theta}_r \theta_r^{-1} \eta_r - \frac{1}{2} \theta_r^{-1} \dot{\eta}_r - \frac{1}{2} \theta_r^{-1} \dot{\theta}_r x + a(x) \left(\frac{1}{2} \eta_r + \theta_r x \right),$$

that in the special case of a constant diffusion term is a linear function, as one would expect.

We introduce the following ansatz for the drift function

$$u(x; t) = \frac{1}{2} \text{div}(a(x)) + \frac{\sum_{\ell=1}^k \nu_\ell p_\ell(x, \Theta_\ell^{(\theta)}) \left(A_\ell^{(\theta)} + B_\ell^{(\theta)} x + a(x) \left(C_\ell^{(\theta)} + D_\ell^{(\theta)} x \right) \right)}{p(x, \Theta^{(1)}, \dots, \Theta_\ell^{(k)})}, \quad (20)$$

where $B_\ell^{(\theta)}, D_\ell^{(\theta)} \in \mathbb{R}^{n \times n}$ and $A_\ell^{(\theta)}, C_\ell^{(\theta)} \in \mathbb{R}^n$ for all $\ell = 1, \dots, k$. The coefficients $A_\ell^{(\theta)}, B_\ell^{(\theta)}, C_\ell^{(\theta)}$ and $D_\ell^{(\theta)}$ cannot be chosen arbitrarily. They are coupled according to Proposition 11. By comparing the coefficients of Proposition 11 and (20) one gets

$$A_\ell^{(\theta)} = \frac{1}{4} \theta_\ell^{(\theta)-1} \dot{\theta}_\ell^{(\theta)} \theta_\ell^{(\theta)-1} \theta_\ell^{(\theta)} - \frac{1}{2} \theta_\ell^{(\theta)-1} \dot{\eta}_\ell^{(\theta)}, \quad B_\ell^{(\theta)} = -\frac{1}{2} \theta_\ell^{(\theta)-1} \dot{\theta}_\ell^{(\theta)}, \quad C_\ell^{(\theta)} = \frac{1}{2} \eta_\ell^{(\theta)}, \quad D_\ell^{(\theta)} = \theta_\ell^{(\theta)}.$$

Hence, one directly sees that the four parameters $A_\ell^{(\theta)}, B_\ell^{(\theta)}, C_\ell^{(\theta)}$ and $D_\ell^{(\theta)}$ for all $\ell = 1, \dots, k$ are coupled via the two ODEs

$$\frac{dC_\ell^{(\theta)}}{dt} = -D_\ell^{(\theta)} A_\ell^{(\theta)} - B_\ell^{(\theta)\top} C_\ell^{(\theta)}, \quad \frac{dD_\ell^{(\theta)}}{dt} = -2D_\ell^{(\theta)} B_\ell^{(\theta)}. \quad (21)$$

Note that the parametrization introduced in (20) provides relatively simple expressions for the mean and variance of the variational approximation derived in the next section (Section 4.2). In the authors' opinion this parametrization therefore helps to keep the notation simple.

4.2 Equations for mean and variance

Theorem 9 provides an explicit formula for the drift term in the approximating SDE (15), that simplifies to (20) in the case of multi-normal marginal densities. Therefore, the mean and variance of the approximating SDE (15) are characterized via the following two ODEs.

Theorem 13 *Consider the SDE (15) with drift term u given by (20), such that the solution X_t has a marginal density $p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)}) \in EM(c_1, \dots, c_k)$ that is an arbitrary convex combination of densities $p_\ell(x, \Theta_t^{(\ell)}) \in EM(c_\ell)$ for $\ell = 1, \dots, k$. Let $m_t^{(\ell)}$ and $S_t^{(\ell)}$ denote the mean and variance of X_t with respect to $p_t(x, \Theta_t^{(\ell)})$. Then,*

$$-\frac{dm_t^{(\ell)}}{dt} = \frac{1}{2} \mathbb{E}_{p_t^{(\ell)}}[\operatorname{div}(a(X))] + A_t^{(\ell)} + B_t^{(\ell)} m_t^{(\ell)} + \mathbb{E}_{p_t^{(\ell)}}[a(X)] C_t^{(\ell)} + \mathbb{E}_{p_t^{(\ell)}}[a(X) D_t^{(\ell)} X] \quad (22)$$

and

$$\begin{aligned} \frac{dS_t^{(\ell)}}{dt} &= \frac{1}{2} \mathbb{E}_{p_t^{(\ell)}}[X \operatorname{div}(a(X))] + \frac{1}{2} \mathbb{E}_{p_t^{(\ell)}}[\operatorname{div}(a(X)) X^\top] - \frac{1}{2} m_t^{(\ell)} \mathbb{E}_{p_t^{(\ell)}}[\operatorname{div}(a(X))]^\top \\ &\quad - \frac{1}{2} \mathbb{E}_{p_t^{(\ell)}}[\operatorname{div}(a(X))] m_t^{(\ell)\top} + \mathbb{E}_{p_t^{(\ell)}}[a(X)] + S_t^{(\ell)} B_t^{(\ell)\top} + B_t^{(\ell)} S_t^{(\ell)} \\ &\quad + \mathbb{E}_{p_t^{(\ell)}}[X C_t^{(\ell)\top} a(X)] + \mathbb{E}_{p_t^{(\ell)}}[a(X) C_t^{(\ell)} X^\top] - m_t^{(\ell)} C_t^{(\ell)\top} \mathbb{E}_{p_t^{(\ell)}}[a(X)] \\ &\quad - \mathbb{E}_{p_t^{(\ell)}}[a(X)] C_t^{(\ell)} m_t^{(\ell)\top} + \mathbb{E}_{p_t^{(\ell)}}[X X^\top D_t^{(\ell)} a(X)] + \mathbb{E}_{p_t^{(\ell)}}[a(X) D_t^{(\ell)} X X^\top] \\ &\quad - m_t^{(\ell)} \mathbb{E}_{p_t^{(\ell)}}[X^\top D_t^{(\ell)} a(X)] - \mathbb{E}_{p_t^{(\ell)}}[a(X) D_t^{(\ell)} X] m_t^{(\ell)\top}. \end{aligned} \quad (23)$$

The proof is provided in Appendix D. Note that given $m_t^{(\ell)}$ and $S_t^{(\ell)}$ the mean and variance of X_t can be expressed as $m_t = \sum_{\ell=1}^k \nu_\ell m_t^{(\ell)}$ and $S_t = \sum_{\ell=1}^k \nu_\ell S_t^{(\ell)} + \sum_{\ell=1}^k \nu_\ell m_t^{(\ell)} m_t^{(\ell)\top} - (\sum_{\ell=1}^k \nu_\ell m_t^{(\ell)}) (\sum_{\ell=1}^k \nu_\ell m_t^{(\ell)})^\top$, respectively.

Remark 14 If the coefficients ν_ℓ in the convex combination of the marginal density $p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$ in Theorem 13 are fixed a priori, the ODEs (22) and (23) are only sufficient for describing $m_t^{(\ell)}$ and $S_t^{(\ell)}$. Oftentimes, however, one is interested in choosing those coefficients a posteriori, for example by solving an auxiliary optimization problem. In such a setting the ODEs given by Theorem 13 are necessary and sufficient.

We have studied how to reformulate the constraints (i) and (ii) of Problem 3 by deriving an expression for the drift term to the approximating SDE (15). In the case that the marginals in (ii) are restricted to a mixture of multivariate normal densities this reformulation reduces to the ODEs (21), (22) and (23).

4.3 Example: Geometric Brownian Motion

We continue the geometric Brownian motion example started in Section 2.1. The goal is to approximate the smoothing density by a normal density. Therefore, according to Proposition 11, the drift function for the approximating SDE (15) has to be chosen as

$$u(x, t) = A_t + (\lambda^2 + B_t)x + \lambda^2 x^2 (C_t + D_t x), \quad (24)$$

where the coefficients A_t, B_t, C_t, D_t are coupled via the two ODEs (21). This choice of drift function leads to ODEs for the mean and the variance of the posterior process, according to Theorem 13

$$\frac{dm_t}{dt} = \lambda^2 m_t + A_t + B_t m_t + \lambda^2 C_t (m_t^2 + S_t) + \lambda^2 D_t (m_t^3 + 3m_t S_t) \quad (25)$$

$$\frac{dS_t}{dt} = \lambda^2 (m_t^2 + 3S_t) + 2B_t S_t + 4\lambda^2 C_t m_t S_t + 6\lambda^2 D_t (m_t^2 S_t + S_t^2). \quad (26)$$

5. Optimal control problem formulation

In this section, we show that the optimization problem 3, using the results derived from Theorem 9, can be reformulated as a standard optimal control problem (OCP), which conceptually is similar to Mitter and Newton (2003)⁴. Therefore, the presented variational approximation method to the path estimation problem for SDEs can be expressed as an OCP and as such leads to a standard formulation of necessary global optimality conditions in terms of Pontryagin's maximum principle. Consider the vector spaces $\mathcal{V} := \mathbb{R}^n \times \mathbb{R}^{\alpha \times n}$, $\hat{\mathcal{Z}} := \mathbb{R}^n \times \operatorname{Sym}(n, \mathbb{R}) \times \mathbb{R}^n \times \operatorname{Sym}(n, \mathbb{R})$ and define the trajectories

$$\begin{aligned} [0, T] \ni t \mapsto v^{(\ell)}(t) &:= (A_t^{(\ell)}, B_t^{(\ell)}) \in \hat{\mathcal{V}} \\ [0, T] \ni t \mapsto z^{(\ell)}(t) &:= (m_t^{(\ell)}, S_t^{(\ell)}, C_t^{(\ell)}, D_t^{(\ell)}) \in \hat{\mathcal{Z}}, \end{aligned}$$

for $\ell = 1, \dots, k$. We introduce the state variable $z(t) := (z^{(1)}(t), \dots, z^{(k)}(t)) \in \prod_{\ell=1}^k \hat{\mathcal{Z}} :=: \mathcal{Z}$ and the control variable $v(t) := (v^{(1)}(t), \dots, v^{(k)}(t)) \in \prod_{\ell=1}^k \hat{\mathcal{V}} =: \mathcal{V}$ for $t \in [0, T]$. As a first step, in view of the cost functional (16) of Problem 3, the so-called Lagrangian

$$\begin{aligned} \mathbb{E}_Q \left[\frac{1}{2} \|u(X_t, t) - f(X_t)\|_{\alpha(X_t)}^2 \right. \\ \left. + y_t \left(u(X_t, t)^\top \nabla h(X_t) + \frac{1}{2} \sigma(X_t)^\top \nabla^2 h(X_t) \sigma(X_t) \right) + \frac{1}{2} \|h(X_t)\|^2 \right] \end{aligned} \quad (27)$$

is expressed as a function of only $z(t), v(t)$ and t . This step, while being exact in some cases, may require an approximation. In the case that the marginals of Q are mixtures of normal densities, the expectation of any polynomial in X_t can be expressed as a function of its mean and variance. If the diffusion term σ is a polynomial, and no mixture is considered ($k = 1$), the drift function u , according to (20), is a polynomial. We refer to Section 8 to see how the Lagrangian can be derived for two concrete examples. Consider a Lagrangian

$$L : [0, T] \times \mathcal{Z} \times \mathcal{V} \rightarrow \mathbb{R}, \quad L(t, z(t), v(t)) \approx (27),$$

where \approx indicates that in order to express the term (27) by the state and control variables only, an approximation might be needed, as explained above. Similarly to the Lagrangian, in view of the cost functional (16), we introduce a terminal cost $F : \mathcal{Z} \rightarrow \mathbb{R}$ by

$$F(z(T)) \approx -y_T \mathbb{E}_Q[h(X_T)].$$

⁴. Note that Mitter and Newton (2003) addresses a related problem, whose main difference, when compared to the presented method, is that the variational characterization considered there is exact.

Under the assumption that the drift term σ is a polynomial, the ODEs derived in the previous section can be expressed in standard form. We define the function $H : \mathcal{Z} \times \mathcal{V} \rightarrow \mathcal{Z}$ by

$$H(z(t), v(t)) = \left(H_1^{(1)}(z(t), v(t)), \dots, H_4^{(1)}(z(t), v(t)), \dots, H_1^{(k)}(z(t), v(t)), \dots, H_4^{(k)}(z(t), v(t)) \right),$$

where

$$\begin{aligned} \frac{dm_t^{(\ell)}}{dt} &= \frac{dz_1^{(\ell)}}{dt}(t) = H_1^{(\ell)}(z(t), v(t)), & \frac{dC_t^{(\ell)}}{dt} &= \frac{dz_3^{(\ell)}}{dt}(t) = H_3^{(\ell)}(z(t), v(t)), \\ \frac{dS_t^{(\ell)}}{dt} &= \frac{dz_2^{(\ell)}}{dt}(t) = H_2^{(\ell)}(z(t), v(t)), & \frac{dD_t^{(\ell)}}{dt} &= \frac{dz_4^{(\ell)}}{dt}(t) = H_4^{(\ell)}(z(t), v(t)), \end{aligned}$$

for $\ell = 1, \dots, k$ are given by (22), (23) and (21). Thus, we have shown so far in this article that Problem 3 can be reformulated as the following optimal control problem

$$\begin{cases} \text{minimize} & J(v) = \int_0^T L(t, z(t), v(t)) dt + F(z(T)) \\ \text{subject to} & \dot{z}(t) = H(z(t), v(t)), \quad t \in [0, T] \text{ a.e.} \\ & z(0) = z_0, \end{cases} \quad (28)$$

where $\mathcal{M}([0, T], \mathcal{V})$ denotes the space of measurable functions from $[0, T]$ to \mathcal{V} . It remains to discuss how to find the initial condition z_0 in the OCP (28). A straightforward, however, clearly not efficient, method for that is solving the Pardoux equation (8), which according to (9) provides the smoothing density at initial time as $\mathcal{P}_S(x, 0) = \frac{\rho_0(x) \nu(x, 0)}{\int_{\mathbb{R}^n} \rho_0(x) \nu(x, 0) dx}$, from where z_0 can be derived.

5.1 Maximum principle

We derive necessary conditions for global optimality of the optimization problem (28) that are provided by the Pontryagin maximum principle (PMP). Since the control set \mathcal{V} is unbounded, we need an extended setting of the standard PMP, see (Clarke, 2013, Section 22.4) for a comprehensive survey. It requires some further assumptions.

Assumption 15 Let the process $(z^*(t), v^*(t))_{t \in [0, T]}$ be a local minimizer for the OCP (28), that satisfies

- (i) The function F is continuously differentiable;
- (ii) The functions H and L are continuous and admit derivatives relative to z which are themselves continuous in all variables (t, z, v) ;
- (iii) There exist $\varepsilon > 0$, a constant c , and a summable function d such that for almost every $t \in [0, T]$, we have

$$|z - z^*(t)| \leq \varepsilon \Rightarrow |\nabla_z(H, L)(t, z, v^*(t))| \leq c(|(H, L)(t, z, v^*(t))| + d(t).$$

Note that Assumption 15(iii) is implied if

$$|\nabla_z H(t, z, v)| + |\nabla_z L(t, z, v)| \leq c(|H(t, z, v)| + |L(t, z, v)|) + d(t)$$

holds for all $v \in \mathcal{V}$ when z is restricted to a bounded set, which is satisfied by many systems. Moreover, the condition automatically holds if v^* happens to be bounded.

Lemma 16 (PMP (Clarke, 2013, Theorem 22.2)) *Given Assumption 15, let the process $(z^*(t), v^*(t))_{t \in [0, T]}$ be a local minimizer for the problem (28). Then there exists an absolutely continuous function $p : [0, T] \rightarrow \mathcal{Z}$ satisfying*

1. *the adjoint equation $\dot{p}(t) = -\nabla_z \langle p(t), H(z^*(t), v^*(t)) \rangle - \nabla_z L(t, z^*(t), v^*(t))$ for almost every $t \in [0, T]$;*
2. *the transversality condition $p(T) = \nabla_z F(z(T))$;*
3. *the maximum condition*

$$\langle p(t), H(z^*(t), v^*(t)) \rangle + L(t, z^*(t), v^*(t)) = \inf_{v \in \mathcal{V}} \langle p(t), H(z^*(t), v) \rangle + L(t, z^*(t), v)$$
almost every $t \in [0, T]$.

Remark 17 1. Given that an optimal process (z^*, v^*) exists⁵, the maximum condition 3 can be used to derive a feedback law

$$v^*(t) \in \arg \min_{v \in \mathcal{V}} \langle p(t), H(z^*(t), v) \rangle + L(t, z^*(t), v).$$

2. Lemma 16, basically leads to a boundary value problem with initial conditions for the states and terminal conditions for the adjoint states, that provides necessary conditions for global optimality of Problem 3.

We summarize the described method to approximate the smoothing density introduced so far. It basically consists of the following three steps, that provide a solution to Problem 3:

- Step 1** Fix a mixture of exponential families of probability densities, e.g., the mixture of multivariate normal densities. Theorem 9, that simplifies to Proposition 11 for the multivariate normal densities, characterizes the approximate posterior SDE (15) whose solution admits marginal densities evolving in the chosen mixture of exponential families.

- Step 2** Given the approximate posterior SDE (15), we derive an optimal control formulation of Problem 3. For the mixture of multivariate normal densities, this derivation is presented in Sections 4 and 5 and finally leads to the OCP (28).

- Step 3** Necessary conditions for optimality of the OCP (28), and hence for Problem 3, can be derived from Pontryagin's maximum principle and result in a structured boundary value problem.

5. Existence of an optimal process can be assured by standard existence results, see for example (Clarke, 2013, Theorem 23.11).

Remark 18 It is important to note that the presented method chooses the best approximating SDE in a desired class using an objective distance measure between the corresponding probability distributions. One crucial advantage of this approach is that this distance could be quantified and numerically calculated (note that the first term in Lemma 2 can be directly computed and the remaining two terms form the objective function of the optimal control problem considered), and hence the user gets an excellent estimate on the necessary approximating error. For instance, Figure 1d and Figure 2d demonstrated the accuracy of corresponding approximating SDEs by plotting the relative entropies between the approximate models and the exact ones for the two examples considered in the paper.

5.2 Computational complexity

If the initial condition to the OCP (28) is known, the PMP, Lemma 16, reduces to a boundary value problem, that can usually be solved numerically more efficiently than (S)PDEs by using numerical methods specifically tailored to these problems, such as the shooting method, see Stoer and Bulirsch (2002). Therefore, the major computational difficulty of the presented variational approach lies in estimating the initial condition to the OCP (28), for example via estimating the smoothing density at initial time. A straightforward, however clearly not efficient, method for that is solving the Pardoux equation (8), as explained in Section 2, which we used in the numerical examples in Section 8. As such, whereas the standard PDE approach for computing a smoothing density requires solving a Zakai equation and the Pardoux equation (8), the presented variational approach relies on only a Pardoux equation and the mentioned boundary value problem. This can usually be seen as a reduction in terms of computational effort required and is demonstrated by two numerical examples in Section 8, Table 1. Moreover, for future work, we aim to study the derivation of an estimator for the marginal smoothing density at terminal time without solving a Pardoux equation, that would then allow us to apply the proposed variational approximation method to high-dimensional problems, see Section 9 for more details. Another idea to circumvent the estimation of this mentioned terminal condition is to use an alternative approach to the PMP, for characterizing a solution to the OCP (28) that is briefly described in the following remark.

Remark 19 (Semidefinite programming) Solutions to the OCP (28) can be characterized via the so-called weak formulation which consists of an infinite-dimensional linear program, see (Lasserre, 2010, Chapter 10) for details. Therefore, numerical approximation schemes to such infinite-dimensional linear programs, that have been studied in the literature, can be employed to solve Problem 3. This approach seems particularly promising when the data of the OCP (dynamics and costs) are described by polynomials, as then the seminal Lasserre hierarchy based on solving a sequence of semidefinite programs, is applicable Lasserre (2001, 2010).

5.3 Example: Geometric Brownian Motion

We continue the geometric Brownian motion example started in Sections 2.1 and 4.3 and formulate the corresponding optimal control problem (28). Recall that the state variable is defined as $z(t) := (m_t, S_t, C_t, D_t)$ and the control variable as $v(t) := (A_t, B_t)$. The ODEs for

the state variables are given by (21), (25) and (26). The objective function of the optimal control problem (28) can be expressed as $F(x(T)) = -\gamma m_T$ and

$$\begin{aligned} L(t, z(t), v(t)) = & \frac{A_t^2}{2\lambda^2(m_t^2 + S_t)} + \frac{A_t(\lambda^2 + B_t - \kappa)}{\lambda^2 m_t} + \frac{(\lambda^2 + B_t - \kappa)^2}{2\lambda^2} + A_t C_t + \gamma_t A_t \\ & + m_t (C_t(\lambda^2 + B_t - \kappa) + A_t D_t + \gamma_t(\lambda^2 + B_t)) \\ & + (m_t^2 + S_t) \left(\frac{1}{2} \lambda^2 C_t^2 + D_t(\lambda^2 + B_t - \kappa) + \frac{1}{2} + \lambda^2 \gamma_t C_t \right) \\ & + (m_t^3 + 3m_t S_t) (\lambda^2 C_t D_t + \lambda^2 \gamma_t D_t) + (m_t^4 + 6m_t^2 S_t + 3S_t^2) \frac{\lambda^2}{2} D_t^2, \end{aligned}$$

where, in order to derive the cost function above, the first two inverse moments of X_t with respect to Q have been approximated. Due to the non-negativity of the GBM, we use the approximation $\mathbb{E}_Q[X_t^{-1}] \approx \mathbb{E}_Q[X_t^{-2}]^{-1} = m_t^{-1}$ and $\mathbb{E}_Q[X_t^{-2}] \approx \mathbb{E}_Q[X_t]^{-2} = (S_t + m_t^2)^{-1}$, whose accuracy has been investigated in Garcia and Palacios (2001).

6. Parameter inference

The goal of this section is to outline the use of the techniques, developed so far for path estimation, for inference of parameters in a hidden Markov model. We consider a class of dynamical systems

$$dX_t^\kappa = f(X_t^\kappa, \kappa)dt + \sigma(X_t^\kappa, \kappa)dW_t, \quad X_0^\kappa = x_0, \quad 0 \leq t \leq T, \quad (29)$$

parameterized by κ . The observation process can be modeled by (2), but as discussed in the next section, the approach discussed below can also be used with necessary modifications for a discrete observation process.

As a natural notation, for each parameter κ , the probability distribution of $X_{[0,T]}^\kappa$ on \mathcal{C} will be denoted by $\Pi_{\text{prior}}^\kappa$. Given a sample path $\{y_t : 0 \leq t \leq T\}$ of the observation process $Y_{[0,T]}$, the objective is to select an optimal $\kappa^* \in \mathbb{R}^d$ such that the observation process $(Y_t)_{t \in [0,T]}$ in (2) has a high probability of reproducing the given data y . This is basically the inference scheme based on classical maximum likelihood estimation, and we propose an algorithm similar to the lines of *expectation maximization (EM) algorithm* (see Cappé et al. (2005) for a comprehensive survey), which aims to obtain the optimal κ^* through multiple iterations. Recalling (14), for each κ , we define $I^\kappa(H_T(\cdot, y)) := -\log \left(\int \exp(-H_T(\cdot, y)) d\Pi_{\text{prior}}^\kappa \right)$. As already noted in Section 3, for each parameter κ , the term $I^\kappa(H_T(\cdot, y))$ provides the total information available through the sample path y , and can be interpreted as the negative log-likelihood of y given the parameter κ . However, minimizing this negative log-likelihood function, even if numerical evaluation of it can be done, usually is a hard problem. But, as mentioned in Section 3, Lemma 2 and non-negativity of the relative entropy together imply that an upper bound to this negative log-likelihood term is given by the apparent information, $\mathcal{F}(Q, \kappa) := D(Q || \Pi_{\text{prior}}^\kappa) + \mathbb{E}_Q[H_T(\cdot, y)]$. The advantage of this observation is that this upper bound to the negative log-likelihood function is also the objective function in Problem 3, for which the program for finding the minimizer Q is by now well-established. Therefore instead of minimizing the actual negative

log-likelihood, we minimize an upper bound of it. The path to find the *right* parameter κ corresponding to the sample path y is now quite standard in statistics. After initialization of the parameter κ , we find the optimal Q by solving the Problem 3, and then in the subsequent step, for this Q we obtain the optimal parameter κ by minimizing $\mathcal{F}(Q, \kappa)$. This yields an iterative EM-type algorithm whose details are given below.

EM-type algorithm

initialize $i = 0, \kappa_i := \hat{\kappa}_0$
while $i \leq M$
Step 1: compute Q_i by solving Problem 3 with parameter κ_i
Step 2: update parameter as $\kappa_{i+1} \in \arg \min_{\kappa} \mathcal{F}(Q_i, \kappa)$
Step 3: set $i \rightarrow i + 1$

Remark 20 Analyzing convergence of the above algorithm and consistency of the above corresponding estimator is the next important step and will be addressed in our future projects.

We refer to Section 8 for a numerical visualization of this variational parameter inference method applied to two examples and to Section 9 for a discussion about convergence and consistency of the estimator as a topic of further research.

7. Discrete time measurement model

In most practical examples, the measurements of physical quantities are processed by computers, and as such the data available are obtained only at discrete times, potentially restricted to a low number. The goal of this section is to outline how the discussed variational approximation scheme adapts naturally to such cases with obvious modifications.

In this case the signal process (1) is observed through noisy measured data $y := \{y_k\}_{k=1}^N$ at discrete times $t_1 \leq t_2 \leq \dots \leq t_N \leq T$. The canonical model for the observation process is thus given by

$$Y_k = h(X_k, t_k) + \rho_k, \quad \text{for } k = 1, \dots, N, \quad (30)$$

where $X_k := X_{t_k}$, $h: \mathbb{R}^n \times \mathbb{R} \rightarrow \mathbb{R}^n$ is a measurable function, the ρ_k are \mathbb{R}^n -valued i.i.d. Gaussian random variables with zero mean and covariance R_k , and they are independent of x_0 and $\sigma(W_s : s \leq T)$. We consider m such that $t_m \leq t < t_{m+1}$ and similarly to Section 2 define the filter density p and smoothing density \mathcal{P}_S by

$$\mathbb{E}[\phi(X(t)) | Y_1, \dots, Y_m, x_0] = \int \phi(x) p(x, t) dx \quad (31)$$

$$\mathbb{E}[\phi(X(t)) | Y_1, \dots, Y_N, x_0] = \int \phi(x) \mathcal{P}_S(x, t) dx, \quad (32)$$

where ϕ is any measurable function from \mathbb{R}^n to \mathbb{R} . It is well known (see (Eynik, 2000, Appendix)) for a derivation) that the smoothing can be expressed as

$$\mathcal{P}_S(x, t) = \frac{p(x, t) w(x, t)}{\int_{\mathbb{R}^n} p(x, t) w(x, t) dx}, \quad (33)$$

where $p(x, t)$ and $w(x, t)$ in between the observation times are the solutions to the

$$\begin{cases} dp(x, t) = \mathcal{A}^* p(x, t) dt \\ p(x, 0) = p_0(x), \end{cases} \quad \text{Kolmogorov forward equation:} \quad (34)$$

$$\begin{cases} dw(x, t) = -\mathcal{A} w(x, t) dt \\ w(x, T) = 1, \end{cases} \quad \text{Kolmogorov backward equation:} \quad (35)$$

punctuated by jumps at the data points t_k for $k = 1, \dots, N$

$$p(x, t_k^+) \propto p(x, t_k) \exp\left(y_k^\top R_k^{-1} h(x, t_k) - \frac{1}{2} h(x, t_k)^\top R_k^{-1} h(x, t_k)\right) \quad (36)$$

$$w(x, t_k) \propto w(x, t_k^+) \exp\left(y_k^\top R_k^{-1} h(x, t_k) - \frac{1}{2} h(x, t_k)^\top R_k^{-1} h(x, t_k)\right). \quad (37)$$

Similar to the continuous time measurement model, it can be shown that the smoothing density solves the Kolmogorov forward equation given by (10), with drift function $g(x, t) := f(x) + a(x) \nabla \log w(x, t)$, where w is the solution to (35). As before, we denote the prior probability measure by $\Pi_{\text{prior}}(\mathcal{A}) = \mathbb{P}[X_{[0, T]} \in \mathcal{A}]$ and the posterior probability measure, induced by the solution to (10), by $\Pi_{\text{post}}(\mathcal{A}, Y) = \mathbb{P}[X_{[0, T]} \in \mathcal{A} | \mathcal{F}_T^Y]$, where $\mathcal{F}_T^Y = \sigma(x_0, Y_1, \dots, Y_N)$. Let y_k denote a realization of the observation process at the time t_k . The variational approximation derived in Section 3, and, in particular, Problem 3 carries over to the discrete time observation setting considered here. As before, the path to the objective function starts from Lemma 2, which holds in this case with

$$H_T(X, y) := \sum_{i=1}^N \left(\frac{1}{2} \|R_k^{-1} h(X_i, t_i)\|^2 - y_i^\top R_k^{-1} h(X_i, t_i) \right). \quad (38)$$

One way to see this is to recast the discrete model in the traditional setup of Section 2, and then use the Kallianpur-Striebel theorem. To do this, first assume that without loss of generality $R_k = I$. Define the function $\bar{h}: C \times [0, T] \rightarrow \mathbb{R}^n$ by

$$\bar{h}(x, t) = \sum_{k=t}^N (t_{k+1} - t_k)^{-1/2} h(x \circ \eta(t), \eta(t)) \mathbb{1}_{\{t_k \leq t < t_{k+1}\}},$$

where $\eta: [0, T] \rightarrow [0, T]$ is defined as

$$\eta(t) = t_k, \quad \text{if } t_k \leq t < t_{k+1}.$$

Define the observation model $\bar{Y}_t = \int_0^t \bar{h}(X_s, s) ds + B_t$. Notice that for each k ,

$$\bar{Y}_{k+1} - \bar{Y}_k = (t_{k+1} - t_k)^{1/2} h(X_k, t_k) + (B(t_{k+1}) - B(t_k)),$$

and hence

$$(t_{k+1} - t_k)^{-1/2}(\tilde{Y}_{k+1} - \tilde{Y}_k) = h(X_k, t_k) + \tilde{\rho}_k,$$

where $\tilde{\rho}_k \stackrel{Law}{=} \rho_k \sim \mathcal{N}(0, I)$. In other words, $(t_{k+1} - t_k)^{-1/2}(\tilde{Y}_{k+1} - \tilde{Y}_k) \stackrel{Law}{=} \tilde{Y}_k$, and in this sense the discrete measurement model can be subsumed in the observation model given by $\tilde{Y}_t = \int_0^t h(X_s, s) ds + \tilde{B}_t$.

Notice that by the definitions of \tilde{Y} and \bar{h} , the exponent in Kallianpur-Striebel formula is given by

$$\int_0^T \frac{1}{2} \|\bar{h}(X, s)\|^2 ds - \int_0^T \bar{h}(X, s) d\tilde{Y}(s) = \sum_{k=1}^N \left(\frac{1}{2} \|h(X_k, t_k)\|^2 - \frac{(\tilde{Y}_{k+1} - \tilde{Y}_k)^\top h(X_k, t_k)}{(t_{k+1} - t_k)^{1/2}} \right) - L_{\tilde{Y}}^w \sum_{k=1}^N \left(\frac{1}{2} \|h(X_k, t_k)\|^2 - Y_t^\top h(X_k, t_k) \right),$$

which leads to (38). Therefore, in this case the objective function in Problem 3 can be expressed as

$$D(Q \| \Pi)_{\text{prior}} + \mathbb{E}_Q[H_T(\cdot, y)] = \int_0^T \mathbb{E}_Q \left[\frac{1}{2} \|u(X_t, t) - f(X_t)\|_{\sigma(X_t)}^2 + \iota(X_t, t) \right] dt, \quad (39)$$

where

$$\iota(X_t, t) = \sum_{i=1}^N \left(y_i^\top R_k^{-1} h(X_t, t_i) - \frac{1}{2} \|R_k^{-1} h(X_t, t_i)\|^2 \right) \delta(t - t_i). \quad (40)$$

Section 4 is independent of the considered measurement model, and by following Section 5 we arrive at an optimal control problem (28), where the cost functional is replaced by (39). The derivation of necessary conditions for global optimality of the optimization problem (28), compared to the continuous time measurement model, here is somewhat nonstandard, due to the Dirac delta terms (40) involved in the Lagrangian. However, the problem can be seen as an OCP with so-called *intermediate constraints*, for which an extension of the PMP is available Dmitruk and Kaganovich (2008).

Assumption 21 Let the process $(z^*(t), v^*(t))_{t \in [0, T]}$ be a local minimizer for the optimal control problem (28), that satisfies

- (i) Assumptions 15(i) and (ii);
- (ii) v^* is measurable and essentially bounded.

Lemma 22 (Extended PMP) Let the process $(z^*(t), v^*(t))_{t \in [0, T]}$ be a local minimizer for the problem (28). Given Assumption 21, then there exists an absolutely continuous function $p: [0, T] \rightarrow \mathcal{Z}$ satisfying

1. the adjoint equation $\dot{p}(t) = -\nabla_z \langle p(t), H(z^*(t), v^*(t)) \rangle - \nabla_z L(t, z^*(t), v^*(t))$ for almost all $t \in [0, T]$;
2. the transversality conditions $p(t_i) = p(t_i^-) - \nabla_z \mathbb{E}_Q[\iota(X, t_i)]$ for $i = 1, \dots, N$ and $p(T) = 0$;

3. the maximum condition

$$\begin{aligned} & \langle p(t), H(z^*(t), v^*(t)) \rangle + L(t, z^*(t), v^*(t)) \\ &= \sup_{v \in \mathcal{M}([0, T], \mathcal{V})} \langle p(t), H(z^*(t), v(t)) \rangle + L(t, z^*(t), v(t)) \text{ for almost all } t \in [0, T]. \end{aligned}$$

Proof Follows directly from Dmitruk and Kaganovich (2008), when transforming problem (28) into an OCP with intermediate constraints. \blacksquare

Remark 23 1. Note that the data (measurements) enter the expression through the cost function, namely the term (40), which is nonzero only at measurement times $\{t_i\}_{i=1}^N$ and leads to jumps in the adjoint state.

2. Lemma 22, basically leads to a boundary value problem, that provides necessary conditions for optimality of Problem 3. See Section 5.2 for a discussion about how to numerically solve it. We refer to the numerical examples in Section 8 for the performance of such a solution.

8. Simulation results

In this section, we present two examples to illustrate the performance of the variational approximation method introduced. Both examples have important applications in mathematical finance. As a first example, we consider the geometric Brownian motion that we introduced as a running example in Sections 2.1, 4.3 and 5.3. The second example is concerned with the Cox-Ingersoll-Ross process, that is often used for describing the evolution of interest rates Cox et al. (1985).

8.1 Geometric Brownian motion

As presented in Sections 2.1, 4.3 and 5.3 we consider a one-dimensional geometric Brownian motion (GBM) (11) and assume that the available data are noisy observations $\{y_k\}_{k=1}^N$ at time t_k , modeled by the observation process

$$Y_k = X_{t_k} + \rho_k,$$

where $\{\rho_k\}_{k=1}^N$ are i.i.d. normal random variables with zero mean, standard deviation R and $t_N = T$.

PDE approach. As explained in Section 7, the smoothing density can be characterized by (33) that is the (normalized) product of two densities w and p . The first density satisfies equation (35) with jump conditions (37) at the measurement times and terminal condition $w(x, T) = \frac{1}{\sqrt{2\pi}R} \exp\left(-\frac{(x-y)^2}{2R^2}\right)$. Its marginals are shown in Figure 1a. The second density, called the filter density, is given by equation (34) with jump conditions (36) and initial condition $p(x, 0) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(\log x - \mu)^2}{2\sigma^2}\right)$ that is given by (11). Its marginals are shown in Figure 1b. The smoothing density is depicted in Figure 1c as the solid line.

Variational approximation. Following Section 4.3, the drift function for the approximating SDE (15) has to be chosen as (24). The optimal control problem can be formulated along the lines of Section 5.3, choosing the discrete-time measurement setting presented in Section 7. Note that Assumption 21 can be easily verified to hold, if we restrict the optimizers in (28) to bounded controls. We solve the boundary value problem obtained from Lemma 22 under the assumption that the smoothing density at initial time is available, see Section 5.5.2 for a discussion about this assumption. The solution is depicted in Figure 1c as the dashed line. Finally, Figure 1d shows the relative entropy between the marginals of the smoothing density obtained by the PDE approach and the variational method, and hence reflects the accuracy of the variational approximation.

Parameter inference. We consider the case where the drift parameter κ in (11) is assumed to be unknown. Figure 1e shows the performance of the EM-Algorithm introduced in Section 6 for an initial guess $\hat{\kappa}_0 = 4$ of the unknown parameter. It can be seen that the estimator $\hat{\kappa}$ is close to the true value of $\kappa = 1$ indicating the efficacy of our algorithm. Also, the algorithm converges quite rapidly.

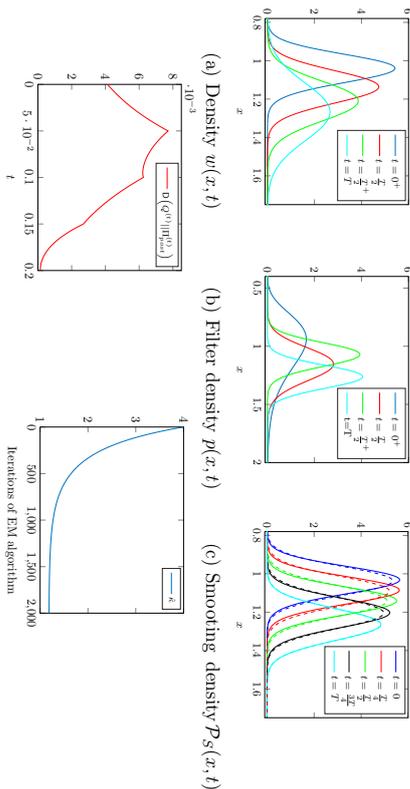

Figure 1: Geometric Brownian motion: Comparison of the PDE solution (solid) versus the variational approach (dashed). The considered numerical values are: $\kappa = 1$, $\lambda = 0.1$, $R = 0.15$, $T = 0.2s$, $\mu = 0$, $\sigma = 0.25$, $N = 4$, $t_1 = T/4$, $t_2 = T/2$, $t_3 = 3T/4$ and $t_4 = T$.

8.2 Cox-Ingersoll-Ross

Consider as underlying system a Cox-Ingersoll-Ross (CIR) process

$$dX_t = \kappa(b - X_t)dt + \lambda\sqrt{X_t}dW_t, \quad X_0 = x_0 \sim \mathcal{N}(\mu, \sigma), \quad (41)$$

for $0 \leq t \leq T$ and assume that the available data are noisy observations $\{y_k\}_{k=1}^N$ at time t_k , modeled by an observation process

$$Y_k = X_{t_k} + \rho_k,$$

where ρ_k are i.i.d. normal random variables with zero mean, standard deviation R and $t_N = T$.

PDE approach. As in the GBM example 8.1, we solve the underlying PDEs introduced in Section 7, to characterize the smoothing density as the (normalized) product of two densities v and p . Figure 2a shows the marginals of the first density w , the filter density p is depicted in Figure 2b and the smoothing density in Figure 2c as the solid line.

Variational approximation. The variational approximation is derived similarly to the GBM example 8.1, where we chose a drift function for the approximating SDE (15), according to Theorem 9, as

$$u(x, t) = \frac{1}{2}\lambda^2 x^2 + A(t) + B(t)x + \lambda^2 x(C(t) + D(t)x). \quad (42)$$

The variational approximation to the smoothing density is depicted in Figure 2c as the dashed line. Finally, Figure 2d shows the relative entropy between the marginals of the smoothing density obtained by the PDE solution and the variational approximation.

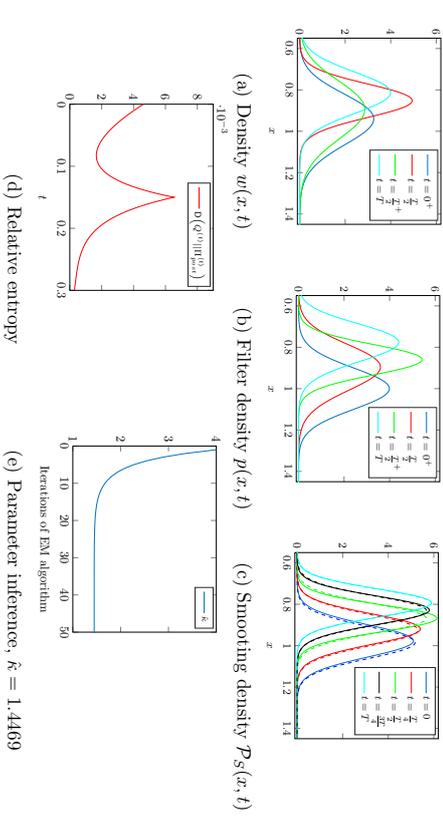

Figure 2: Cox-Ingersoll-Ross: Comparison of the PDE solution (solid) versus the variational approach (dashed). The considered numerical values are: $\lambda = 0.2$, $\kappa = 1$, $b = 0.3$, $\mu = 1$, $\sigma = 0.1$, $R = 0.1$, $T = 0.3s$, $N = 2$, $t_1 = T/2$ and $t_2 = T$.

Parameter inference. We consider the case where the parameter κ in the drift term of (41) is unknown. Figure 2e shows the EM-Algorithm introduced in Section 6 for an initial guess $\hat{\kappa}_0 = 4$ of the unknown parameter. It can be seen that the estimator $\hat{\kappa}$ is close to the true

Table 1: **Runtime comparison.** The presented variational approach for approximating the smoothing density is compared with the standard PDE approach for the two examples in Sections 8.1 and 8.2. All simulations are performed on a 2.3 GHz Intel Core i7 processor with 8 GB RAM using Matlab.

	Geometric Brownian motion	Cox-Ingersoll-Ross
Forward PDE (34)	2.02 s	1.33 s
Backward PDE (35)	2.87 s	2.38 s
Boundary value problem	0.10 s	0.23 s
PDE approach ⁶	4.89 s	3.70 s
Variational approach ⁷	2.97 s	2.61 s

value of $\kappa = 1$ indicating the efficacy of our algorithm. Also, the algorithm converges very fast.

Table 1 summarizes the runtimes of the two numerical examples above. It can be seen that the boundary value problems provided by the maximum principle can be solved by roughly one magnitude faster than the backward PDE (35), that is the reason for the speedup of the variational approach compared to the PDE approach. Moreover, it is highlighted that the main computational effort in the variational approach is needed to estimate the marginal smoothing density at initial time, which is done by solving the backward PDE (35). If, however, the backward density at initial time could be estimated in a more efficient way, e.g., by using an MCMC method, the proposed variational approximation method could be applicable to high-dimensional problems.

9. Conclusion

The paper is devoted to a variational method for estimating paths of a signal process in a hidden Markov model. In particular, this leads to approximations of smoothing density which can be used to reconstruct any past state of the signal process given a full set of observations. A crucial fact that plays an important role in our method is that the smoothing distribution is induced by a posterior SDE which itself is a modification of the original signal process. The presented variational approach proposes an approximate SDE which minimizes the relative entropy between the posterior SDE and a class of SDEs whose marginals belong to a chosen mixture of exponential families. In the simplest case of normal marginals and a posterior SDE with constant diffusion term, the approximating SDE consists of a linear drift and constant diffusion term, which is well known. It is shown that the prescribed approximation scheme can be formulated as an optimal control problem, and necessary conditions for global optimality are obtained by the Pontryagin maximum principle. The resulting numerical methods have considerable computational advantages over numerically solving the underlying (S)PDEs, that is highlighted by two examples. The developed approximation scheme is then used for designing an efficient method for parameter inference for SDEs.

6. consists of solving the two PDEs (34) and (35)

7. consists of the PDE (35) and the boundary value problem in order to solve Problem 3

For future work, as mentioned in Section 5.2, we aim to study how to efficiently estimate the backward density at initial time. Then, the presented variational approximation method reduces to solving a PMP-shooting-type boundary value problem that is tractable even in relatively large dimensions, compared to PDEs. Additionally, it would be interesting to study numerical methods specifically tailored to the boundary value problems resulting from the maximum principle, such as the shooting method, see Stoer and Bulirsch (2002) for a comprehensive summary, as well as the approach of solving the optimal control problem via its weak formulation as pointed out in Remark 19.

Our future projects will also delve into analyzing the convergence of the EM-type algorithm used for parameter inference as well as the properties of the obtained estimators. We will also focus on refining the basic inference algorithm to get better efficiency and speed. One promising path to take in this direction would be designing of suitable adaptive EM-type algorithms. It is also conceivable that the ideas mentioned in the paper can be combined with suitable MCMC schemes or techniques known as Assumed Density Filtering, see Harel et al. (2015), to get better accuracy and efficiency in high-dimensional models.

Appendix A. Derivation of Equation (10)

We consider the one-dimensional case; an extension to the multi-dimensional case is straightforward. According to (9) the smoothing density is given by $\mathcal{P}_S(x, t) = K(t)p(x, t)w(x, t)$, where $K(t) := (\int_{\mathbb{R}^n} p(x, t)w(x, t)dx)^{-1}$. The main idea is to recall that the process $(K(t))_{t \in [0, T]}$ is known to be almost surely constant (Pardoux, 1981/82, Theorem 3.2). Therefore

$$\begin{aligned} \frac{\partial}{\partial t} \mathcal{P}_S(x, t) &= K(t)p(x, t) \frac{\partial}{\partial t} w(x, t) + K(t)w(x, t) \frac{\partial}{\partial t} p(x, t) \\ &= \frac{\mathcal{P}_S(x, t)}{w(x, t)} \left(-f(x)w'(x, t) - \frac{1}{2}a(x)w''(x, t) - w(x, t)h(x)^\top dY_t' \right) \\ &\quad + w(x, t) \left(- \left(\frac{f(x)\mathcal{P}_S(x, t)}{w(x, t)} \right)' + \frac{1}{2} \left(\frac{a(x)\mathcal{P}_S(x)}{w(x, t)} \right)'' + \frac{\mathcal{P}_S(x, t)}{w(x, t)} h(x)^\top dY_t' \right). \end{aligned}$$

The proof follows by a straightforward computation. We compute in a preliminary step

$$\left(\frac{f(x)\mathcal{P}_S(x, t)}{w(x, t)} \right)' = \frac{1}{w^2(x, t)} \left((f'(x)\mathcal{P}_S(x, t) + f(x)\mathcal{P}_S'(x, t))w(x, t) - f(x)\mathcal{P}_S(x, t)w'(x, t) \right),$$

and

$$\begin{aligned} \left(\frac{a(x)\mathcal{P}_S(x, t)}{w(x, t)} \right)'' &= \frac{1}{w(x, t)} \left(a''(x)\mathcal{P}_S(x, t) + 2a'(x)\mathcal{P}_S'(x, t) + a(x)\mathcal{P}_S''(x, t) \right) \\ &\quad - \frac{1}{w^2(x, t)} \left(2w'(x, t)a'(x)\mathcal{P}_S(x, t) + 2w'(x, t)a(x)\mathcal{P}_S'(x, t) + a(x)\mathcal{P}_S(x, t)w''(x, t) \right) \\ &\quad + \frac{1}{w^3(x, t)} \left(2a(x)w'(x, t)^2\mathcal{P}_S(x, t) \right). \end{aligned}$$

Using this two preliminaries, we get

$$\begin{aligned} \frac{\partial}{\partial t} \mathcal{P}_S(x, t) &= -f'(x)\mathcal{P}_S(x, t) - f(x)\mathcal{P}_S'(x, t) + a'(x)\mathcal{P}_S'(x, t) + \frac{1}{2}(a''(x)\mathcal{P}_S(x, t) + a(x)\mathcal{P}_S''(x, t)) \\ &\quad - \frac{1}{w(x, t)} \left(a'(x)w'(x, t)\mathcal{P}_S(x, t) + a(x)w''(x, t)\mathcal{P}_S(x, t) + a(x)w'(x, t)\mathcal{P}_S'(x, t) \right) \\ &\quad + \frac{1}{w^2(x, t)} a(x)w'(x, t)^2\mathcal{P}_S(x, t) \\ &= - \left(f'(x)\mathcal{P}_S(x, t) + f(x)\mathcal{P}_S'(x, t) + \frac{1}{w(x, t)} \left(a'(x)w'(x, t)\mathcal{P}_S(x, t) \right. \right. \\ &\quad \left. \left. + a(x)w''(x, t)\mathcal{P}_S(x, t) + a(x)w'(x, t)\mathcal{P}_S'(x, t) - \frac{1}{w^2(x, t)} \left(a(x)w'(x, t)^2\mathcal{P}_S(x, t) \right) \right) \right. \\ &\quad \left. + \frac{1}{2} \left(a'(x)\mathcal{P}_S(x, t) + a(x)\mathcal{P}_S''(x, t) \right)' \right. \\ &= - \left(\left(f(x) + a(x) \frac{w'(x, t)}{w(x, t)} \right) \mathcal{P}_S(x, t) \right)' + \frac{1}{2} \left(a(x)\mathcal{P}_S(x, t) \right)'' \\ &= - \left(\left(f(x) + a(x) (\log w(x, t))' \right) \mathcal{P}_S(x, t) \right)' + \frac{1}{2} \left(a(x)\mathcal{P}_S(x, t) \right)'' , \end{aligned}$$

and as such (10) holds.

Appendix B. Proof of Theorem 9

Consider an arbitrary curve $t \mapsto p(\cdot, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$ evolving in $\text{EM}(c^{(1)}, \dots, c^{(k)})$. Define a diffusion

$$dZ_t = u(Z_t, t)dt + \sigma(Z_t)dB_t, \quad Z_0 = x_0,$$

with the given diffusion coefficient $a(\cdot) = \sigma(\cdot)\sigma(\cdot)^\top$. Clearly the density of Z_t coincides with $p(\cdot, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$ if and only if $p(\cdot, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$ satisfies the Kolmogorov forward equation for Z_t , i.e.,

$$\begin{aligned} \frac{\partial p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})}{\partial t} &= - \sum_{i=1}^n \frac{\partial}{\partial x_i} \left(u_i(x, t)p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)}) \right) \\ &\quad + \frac{1}{2} \sum_{j=1}^n \sum_{j=1}^n \frac{\partial^2}{\partial x_j \partial x_j} \left(a_{ij}(x)p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)}) \right). \end{aligned} \quad (43)$$

We will show this in two steps that (43) holds for the proposed drift term. Consider the decomposition $u_i(x, t) = g_i(x, t) + \gamma_i(x, t)$ for all $i = 1, \dots, n$, where

$$g_i(x, t) := \frac{1}{2} \sum_{j=1}^n \frac{\partial}{\partial x_j} a_{ij}(x) + \frac{1}{2} \sum_{j=1}^n a_{ij}(x) \frac{\partial}{\partial x_j} p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)}) \quad (44)$$

and

$$\gamma_i(x, t) := \frac{-1}{p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})} \sum_{\ell=1}^k \nu_{q\ell}(x, \Theta_t^{(\ell)}) \left\langle \dot{\Theta}_t^{(0)}, \mathcal{I}_\ell^{(0)}(x) \right\rangle. \quad (45)$$

We use the shorthand notation $p(x, \Theta_t^{(1k)}) := p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})$.

Claim 24 *The functions g_i defined in (44) for all $i = 1, \dots, n$ satisfy*

$$\sum_{i=1}^n \frac{\partial}{\partial x_i} \left(g_i(x, t)p(x, \Theta_t^{(1k)}) \right) = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \frac{\partial^2}{\partial x_i \partial x_j} \left(a_{ij}(x)p(x, \Theta_t^{(1k)}) \right).$$

Claim 24 follows from a straightforward computation, see Appendix B in the extended version Sutter et al. (2015) for a detailed derivation.

Claim 25 *The functions γ_i defined in (45) for all $i = 1, \dots, n$ satisfy*

$$\frac{\partial}{\partial t} p(x, \Theta_t^{(1k)}) = - \sum_{i=1}^n \frac{\partial}{\partial x_i} \left(\gamma_i(x, t)p(x, \Theta_t^{(1k)}) \right).$$

Proof.

$$\frac{\partial}{\partial t} p(x, \Theta_t^{(1k)}) = \sum_{\ell=1}^k \nu_\ell \frac{\partial}{\partial t} p(x, \Theta_t^{(\ell)}) = \sum_{\ell=1}^k \nu_\ell \left\langle \dot{\Theta}_t^{(\ell)}, c^{(\ell)}(x) - \nabla \theta \psi_\ell(\Theta_t^{(\ell)}) \right\rangle p(x, \Theta_t^{(\ell)}).$$

Moreover,

$$\frac{\partial}{\partial x_i} \gamma_i(x, t) = \frac{1}{p(x, \Theta_t^{(1k)})^2} \left(\frac{\partial}{\partial x_i} p(x, \Theta_t^{(1k)}) \right) \sum_{\ell=1}^k \nu_\ell q\ell(x, \Theta_t^{(\ell)}) \left\langle \dot{\Theta}_t^{(\ell)}, \mathcal{I}_\ell^{(0)}(x) \right\rangle$$

$$- \frac{1}{p(x, \Theta_t^{(\ell)})} \sum_{\ell=1}^k \nu_\ell \left\langle \dot{\Theta}_t^{(\ell)}, \varphi_i^{(\ell)}(x, \Theta_t^{(\ell)}) \exp \left(\langle \Theta_t^{(\ell)}, c^{(\ell)}(x) \rangle - \psi_t(\Theta_t^{(\ell)}) \right) \right\rangle,$$

where we used

$$\begin{aligned} p_t(x, \Theta_t^{(\ell)}) \left\langle \dot{\Theta}_t^{(\ell)}, \mathcal{I}_t^{(\ell)} \right\rangle \\ = \left\langle \dot{\Theta}_t^{(\ell)}, \int_{-\infty}^{x_i} \varphi_i^{(\ell)}(x-i, \xi_i), \Theta_t^{(\ell)} \exp \left(\langle \Theta_t^{(\ell)}, c^{(\ell)}(x-i, \xi_i) \rangle - \psi_t(\Theta_t^{(\ell)}) \right) d\xi_i \right\rangle. \end{aligned}$$

Therefore,

$$\begin{aligned} \frac{\partial}{\partial x_i} \left(\gamma_i(x, t) p(x, \Theta_t^{(1:k)}) \right) &= \left(\frac{\partial}{\partial x_i} \gamma_i(x, t) \right) p(x, \Theta_t^{(1:k)}) + \gamma_i(x, t) \left(\frac{\partial}{\partial x_i} p(x, \Theta_t^{(1:k)}) \right) \\ &= - \sum_{\ell=1}^k \nu_\ell \left\langle \dot{\Theta}_t^{(\ell)}, \varphi_i^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle p_t(x, \Theta_t^{(\ell)}), \end{aligned}$$

and

$$\begin{aligned} - \sum_{i=1}^n \frac{\partial}{\partial x_i} \left(\gamma_i(x, t) p(x, \Theta_t^{(1:k)}) \right) &= \sum_{\ell=1}^k \nu_\ell p_t(x, \Theta_t^{(\ell)}) \left(\sum_{i=1}^n \left\langle \dot{\Theta}_t^{(\ell)}, \varphi_i^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle \right) \\ &= \sum_{\ell=1}^k \nu_\ell p_t(x, \Theta_t^{(\ell)}) \left\langle \dot{\Theta}_t^{(\ell)}, c^{(\ell)}(x) - \nabla_{\theta} \psi_t(\Theta_t^{(\ell)}) \right\rangle = \frac{\partial}{\partial t} p(x, \Theta_t^{(1:k)}), \end{aligned}$$

where we used (18). ■

The two claims imply (43) and hence complete the proof. ■

Appendix C. Proof of Proposition 11

The proof basically requires Theorem 9 and two additional lemmas. We first propose in Lemma 26 a choice of functions $\varphi_i^{(\ell)}$ that satisfy (18) in Theorem 9. Then we show in a second step, in Lemma 27, that for this choice the integral terms (17) admit a closed form expression. We start with a few preparatory results that are needed to prove Proposition 11. Note that $\nabla_{\Theta} \psi(\Theta) = (\nabla_{\eta} \psi(\Theta), \nabla_{\theta} \psi(\Theta)) \in \mathcal{H}$ and recall that according to (Bernstein, 2009, p.631) for $A \in \mathbb{R}^{n \times m}$, $B \in \mathbb{R}^{m \times n}$ and $X \in \text{GL}(n, \mathbb{R})$ $\frac{d}{dX} \text{tr}(AX^{-1}B) = -X^{-1}BAX^{-1}$ and $\frac{d}{dX} \log \det(AX^{-1}B) = -X^{-1}B(AX^{-1}B)^{-1}AX^{-1}$ and therefore

$$\nabla_{\eta} \psi(\Theta) = -\frac{1}{2} \theta^{-1} \eta, \quad \nabla_{\theta} \psi(\Theta) = \theta^{-1} \left(\frac{1}{4} \eta \eta^{\top} \theta^{-1} - \frac{1}{2} \mathbf{I}_n \right). \quad (46)$$

Lemma 26 Consider the functions $\varphi_i^{(\ell)} : \mathbb{R}^n \times \mathcal{H} \rightarrow \mathcal{H}$, where $\varphi_i^{(\ell)} = \left(\varphi_{1,i}^{(\ell)}, \varphi_{2,i}^{(\ell)} \right)$ with $\varphi_{1,i}^{(\ell)} : \mathbb{R}^n \times \mathcal{H} \rightarrow \mathbb{R}^n$ and $\varphi_{2,i}^{(\ell)} : \mathbb{R}^n \times \mathcal{H} \rightarrow \mathbb{R}^{n \times n}$ for $\ell = 1, \dots, k$. Let $\varphi_{1,i}^{(\ell)}$ and $\varphi_{2,i}^{(\ell)}$ be defined as

$$\varphi_{1,i}^{(\ell)}(x-i, \xi_i), \Theta_t^{(\ell)} := \theta_t^{(\ell)-1} E_i \theta_t^{(\ell)}(c_1^{(\ell)}(x-i, \xi_i) - \nabla_{\eta} \psi_t(\Theta_t^{(\ell)}))$$

$$\begin{aligned} \varphi_{2,i}^{(\ell)}(x-i, \xi_i), \Theta_t^{(\ell)} &:= \theta_t^{(\ell)-1} E_i \left(\theta_t^{(\ell)}(c_2^{(\ell)}(x-i, \xi_i) - \nabla_{\theta} \psi_t(\Theta_t^{(\ell)})) \Theta_t^{(\ell)} \right. \\ &\quad \left. - \frac{1}{2} \theta_t^{(\ell)}(x-i, \xi_i) \eta_t^{(\ell)\top} + \frac{1}{2} \eta_t^{(\ell)}(x-i, \xi_i)^{\top} \theta_t^{(\ell)} \right) \theta_t^{(\ell)-1}. \end{aligned}$$

Then, (18) holds for all $\ell = 1, \dots, k$.

Proof of Lemma 26. According to (19) we have

$$\sum_{i=1}^n \left\langle \dot{\Theta}_t^{(\ell)}, \varphi_i^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle = \sum_{i=1}^n \left(\left\langle \dot{\eta}_t^{(\ell)}, \varphi_{1,i}^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle + \left\langle \dot{\theta}_t^{(\ell)}, \varphi_{2,i}^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle \right),$$

consisting of the two components

$$\begin{aligned} \sum_{i=1}^n \left\langle \dot{\eta}_t^{(\ell)}, \varphi_{1,i}^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle &= \sum_{i=1}^n \left\langle \dot{\eta}_t^{(\ell)}, \theta_t^{(\ell)-1} E_i \theta_t^{(\ell)}(c_1^{(\ell)}(x) - \nabla_{\eta} \psi_t(\Theta_t^{(\ell)})) \right\rangle \\ &= \left\langle \dot{\eta}_t^{(\ell)}, \sum_{i=1}^n \theta_t^{(\ell)-1} E_i \theta_t^{(\ell)}(c_1^{(\ell)}(x) - \nabla_{\eta} \psi_t(\Theta_t^{(\ell)})) \right\rangle = \left\langle \dot{\eta}_t^{(\ell)}, c_1^{(\ell)}(x) - \nabla_{\eta} \psi_t(\Theta_t^{(\ell)}) \right\rangle \end{aligned}$$

and

$$\begin{aligned} \sum_{i=1}^n \left\langle \dot{\theta}_t^{(\ell)}, \varphi_{2,i}^{(\ell)}(x, \Theta_t^{(\ell)}) \right\rangle &= \left\langle \dot{\theta}_t^{(\ell)}, \sum_{i=1}^n \left(\theta_t^{(\ell)-1} E_i \theta_t^{(\ell)}(c_2^{(\ell)}(x) - \nabla_{\theta} \psi_t(\Theta_t^{(\ell)})) \right. \right. \\ &\quad \left. \left. - \frac{1}{2} \theta_t^{(\ell)-1} E_i \theta_t^{(\ell)} x \eta_t^{(\ell)\top} \theta_t^{(\ell)-1} + \frac{1}{2} \theta_t^{(\ell)-1} E_i \eta_t^{(\ell)} x^{\top} \right) \right\rangle \\ &= \left\langle \dot{\theta}_t^{(\ell)}, c_2^{(\ell)}(x) - \nabla_{\theta} \psi_t(\Theta_t^{(\ell)}) \right\rangle - \frac{1}{2} \left\langle \dot{\theta}_t^{(\ell)}, x \eta_t^{(\ell)\top} \theta_t^{(\ell)-1} \right\rangle + \frac{1}{2} \left\langle \dot{\theta}_t^{(\ell)}, \theta_t^{(\ell)-1} \eta_t^{(\ell)} x^{\top} \right\rangle \\ &= \left\langle \dot{\theta}_t^{(\ell)}, c_2^{(\ell)}(x) - \nabla_{\theta} \psi_t(\Theta_t^{(\ell)}) \right\rangle, \end{aligned}$$

where we have used in the last step that $\left\langle \dot{\theta}_t^{(\ell)}, x \eta_t^{(\ell)\top} \theta_t^{(\ell)-1} \right\rangle = \left\langle \dot{\theta}_t^{(\ell)}, \theta_t^{(\ell)-1} \eta_t^{(\ell)} x^{\top} \right\rangle$, since for $A \in \text{Sym}(n, \mathbb{R})$ and $B \in \mathbb{R}^{n \times n}$ $\text{tr}(AB^{\top}) = \text{tr}(AB)$. ■

Lemma 27 For $i = 1, \dots, n$, $j = 1, 2$ and $\ell = 1, \dots, k$ consider

$$\mathcal{I}_{j,i}^{(\ell)}(s_i, x) := \int_{-\infty}^{s_i} \varphi_{j,i}^{(\ell)}((x-i, \xi_i), \Theta_t^{(\ell)}) \exp \left(\left\langle \dot{\Theta}_t^{(\ell)}, c^{(\ell)}(x-i, \xi_i) - c^{(\ell)}(x) \right\rangle \right) d\xi_i,$$

where the functions $\varphi_{j,i}^{(\ell)}$ are chosen according to Lemma 26. Then,

$$\begin{aligned} \mathcal{I}_{1,i}^{(\ell)}(s_i, x) &= \frac{1}{2} \theta_t^{(\ell)-1} e_i \exp \left(\left\langle \dot{\Theta}_t^{(\ell)}, c^{(\ell)}(x-i, s_i) - c^{(\ell)}(x) \right\rangle \right) \\ \mathcal{I}_{2,i}^{(\ell)}(x_i, x) &= \frac{1}{4} \theta_t^{(\ell)-1} e_i (2\theta_t^{(\ell)} x - \eta_t^{(\ell)})^{\top} \theta_t^{(\ell)-1}. \end{aligned}$$

Note that $\mathcal{I}_i^{(\theta)}(x) = (\mathcal{I}_{1,i}^{(\theta)}(x_i, x), \mathcal{I}_{2,i}^{(\theta)}(x_i, x))$, where $\mathcal{I}_i^{(\theta)}(x)$ is the function defined in (17) and e_i denote the canonical basis vectors of \mathbb{R}^n .

Proof of Lemma 27.

$$\begin{aligned} \mathcal{I}_{1,i}^{(\theta)}(s_i, x) &= \int_{-\infty}^{s_i} \varphi_{1,i}^{(\theta)}(x-i, \xi_i) \Theta_i^{(\theta)} \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{2} \theta_i^{(\theta)-1} \int_{-\infty}^{s_i} E_i 2\theta_i^{(\theta)} (c_1^{(\theta)}(x-i, \xi_i) - \nabla_{\eta} \psi_i(\Theta_i^{(\theta)})) \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{2} \theta_i^{(\theta)-1} \int_{-\infty}^{s_i} E_i 2\theta_i^{(\theta)} \left((x-i, \xi_i) + \frac{1}{2} \theta_i^{(\theta)-1} \eta_i^{(\theta)} \right) \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{2} \theta_i^{(\theta)-1} \int_{-\infty}^{s_i} E_i \left(2\theta_i^{(\theta)}(x-i, \xi_i) + \eta_i^{(\theta)} \right) \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i, \end{aligned}$$

where (46) was used. Consider the substitution $z := \left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle$ that leads to

$$\mathcal{I}_{1,i}^{(\theta)}(s_i, x) = \frac{1}{2} \theta_i^{(\theta)-1} e_i \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, s_i) - c^{(\theta)}(x) \right\rangle \right),$$

where we used that $\theta_i^{(\theta)} < 0$, since $\theta_i^{(\theta)} = -\frac{1}{2} S_i^{(\theta)-1}$ and the inverse of a negative definite matrix is negative definite. For the second integral term

$$\begin{aligned} \mathcal{I}_{2,i}^{(\theta)}(x) &= \int_{-\infty}^{x_i} \varphi_{2,i}^{(\theta)}((x-i, \xi_i), \Theta_i^{(\theta)}) \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{4} \theta_i^{(\theta)-1} \int_{-\infty}^{x_i} E_i \left(4\theta_i^{(\theta)} (c_2^{(\theta)}(x-i, \xi_i) - \nabla_{\theta} \psi_i(\Theta_i^{(\theta)})) \theta_i^{(\theta)} - 2\theta_i^{(\theta)} (x-i, \xi_i) \eta_i^{(\theta)\top} \right. \\ &\quad \left. + 2\eta_i^{(\theta)}(x-i, \xi_i)^\top \theta_i^{(\theta)} \right) \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{4} \theta_i^{(\theta)-1} \int_{-\infty}^{x_i} E_i \left(2\theta_i^{(\theta)}(x-i, \xi_i)^\top 2\theta_i^{(\theta)} - \eta_i^{(\theta)\top} \eta_i^{(\theta)} + 2\theta_i^{(\theta)} \right. \\ &\quad \left. - 2\theta_i^{(\theta)}(x-i, \xi_i) \eta_i^{(\theta)\top} + 2\eta_i^{(\theta)}(x-i, \xi_i)^\top \theta_i^{(\theta)} \right) \theta_i^{(\theta)-1} \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i, \end{aligned}$$

where we have used (46). By expanding terms and using integration by parts together with the first assertion of this lemma

$$\begin{aligned} \mathcal{I}_{2,i}^{(\theta)}(x) &= \frac{1}{2} \int_{-\infty}^{x_i} \frac{1}{2} \theta_i^{(\theta)-1} E_i (2\theta_i^{(\theta)}(x-i, \xi_i) + \eta_i^{(\theta)}) (2\theta_i^{(\theta)}(x-i, \xi_i) - \eta_i^{(\theta)\top} \theta_i^{(\theta)-1} \\ &\quad \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &\quad + \frac{1}{2} \int_{-\infty}^{x_i} \theta_i^{(\theta)-1} E_i \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{2} \mathcal{I}_{1,i}^{(\theta)}(x_i, x) (2\theta_i^{(\theta)} x - \eta_i^{(\theta)})^\top \theta_i^{(\theta)-1} - \frac{1}{2} \int_{-\infty}^{x_i} \mathcal{I}_{1,i}^{(\theta)}(\xi_i, x) (2\theta_i^{(\theta)} e_i)^\top \theta_i^{(\theta)-1} d\xi_i \\ &\quad + \frac{1}{2} \int_{-\infty}^{x_i} \theta_i^{(\theta)-1} E_i \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \end{aligned}$$

$$\begin{aligned} &= \frac{1}{4} \theta_i^{(\theta)-1} e_i (2\theta_i^{(\theta)} x - \eta_i^{(\theta)})^\top \theta_i^{(\theta)-1} \\ &\quad - \frac{1}{2} \int_{-\infty}^{x_i} \frac{1}{2} \theta_i^{(\theta)-1} e_i \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) e_i^\top 2\theta_i^{(\theta)} \theta_i^{(\theta)-1} d\xi_i \\ &\quad + \frac{1}{2} \int_{-\infty}^{x_i} \theta_i^{(\theta)-1} E_i \exp \left(\left\langle \Theta_i^{(\theta)}, c^{(\theta)}(x-i, \xi_i) - c^{(\theta)}(x) \right\rangle \right) d\xi_i \\ &= \frac{1}{4} \theta_i^{(\theta)-1} e_i (2\theta_i^{(\theta)} x - \eta_i^{(\theta)})^\top \theta_i^{(\theta)-1}. \quad \blacksquare \end{aligned}$$

Proof of Proposition 11 We decompose the function $u_i(x, t)$, given by Theorem 9 into $u_i(x, t) = g_i(x, t) + \gamma_i(x, t)$ for all $i = 1, \dots, n$, where

$$\begin{aligned} g_i(x, t) &:= \frac{1}{2} \sum_{j=1}^n \frac{\partial}{\partial x_j} a_{ij}(x) + \frac{1}{2} \sum_{j=1}^n a_{ij}(x) \frac{\partial}{\partial x_j} p(x, \Theta_i^{(1)}, \dots, \Theta_i^{(k)}) \\ &\quad p(x, \Theta_i^{(1)}, \dots, \Theta_i^{(k)}) \\ \gamma_i(x, t) &:= -\frac{1}{2} \sum_{\ell=1}^k \nu_\ell p_\ell(x, \Theta_i^{(\ell)}) \left\langle \Theta_i^{(\ell)}, \mathcal{I}_i^{(\ell)}(x) \right\rangle. \end{aligned}$$

As a preliminary step by invoking Lemma 27

$$\begin{aligned} \left\langle \Theta_i^{(\ell)}, \mathcal{I}_i^{(\ell)}(x) \right\rangle &= \left\langle \eta_i^{(\ell)}, \mathcal{I}_{1,i}^{(\ell)}(x) \right\rangle + \left\langle \theta_i^{(\ell)}, \mathcal{I}_{2,i}^{(\ell)}(x) \right\rangle \\ &= \left\langle \eta_i^{(\ell)}, \frac{1}{2} \theta_i^{(\ell)-1} e_i \right\rangle + \left\langle \theta_i^{(\ell)}, \frac{1}{2} \theta_i^{(\ell)-1} e_i x^\top - \frac{1}{4} \theta_i^{(\ell)-1} e_i \eta_i^{(\ell)\top} \theta_i^{(\ell)-1} \right\rangle \\ &= \frac{1}{2} \eta_i^{(\ell)\top} (\theta_i^{(\ell)-1} e_i) + \frac{1}{2} \text{tr} \left(\theta_i^{(\ell)} (\theta_i^{(\ell)-1} e_i x^\top)^\top \right) - \frac{1}{4} \text{tr} \left(\theta_i^{(\ell)} (\theta_i^{(\ell)-1} e_i \eta_i^{(\ell)\top} \theta_i^{(\ell)-1})^\top \right) \\ &= \frac{1}{2} \eta_i^{(\ell)\top} \theta_i^{(\ell)-1} e_i + \frac{1}{2} e_i^\top \theta_i^{(\ell)-1} \dot{\theta}_i^{(\ell)} x - \frac{1}{4} e_i^\top \theta_i^{(\ell)-1} \dot{\theta}_i^{(\ell)} \theta_i^{(\ell)-1} \eta_i^{(\ell)}. \end{aligned}$$

Therefore,

$$\begin{aligned} \gamma_i(x, t) &= -\frac{1}{2} \frac{1}{p(x, \Theta_i^{(1)}, \dots, \Theta_i^{(k)})} \sum_{\ell=1}^k \nu_\ell p_\ell(x, \Theta_i^{(\ell)}) \\ &\quad \left(\frac{1}{2} \theta_i^{(\ell)-1} \eta_i^{(\ell)} + \frac{1}{2} \theta_i^{(\ell)-1} \dot{\theta}_i^{(\ell)} x - \frac{1}{4} \theta_i^{(\ell)-1} \dot{\theta}_i^{(\ell)} \theta_i^{(\ell)-1} \eta_i^{(\ell)} \right). \end{aligned}$$

Furthermore,

$$\begin{aligned} \frac{\partial}{\partial x_j} p(x, \Theta_i^{(1)}, \dots, \Theta_i^{(k)}) &= \sum_{\ell=1}^k \nu_\ell \left\langle \Theta_i^{(\ell)}, \frac{\partial c^{(\ell)}(x)}{\partial x_j} \right\rangle \exp \left(\left\langle \Theta_i^{(\ell)}, c^{(\ell)}(x) \right\rangle - \psi_\ell(\Theta_i^{(\ell)}) \right) \\ &= \sum_{\ell=1}^k \nu_\ell \left\langle \Theta_i^{(\ell)}, (e_j, e_j x^\top + x e_j^\top) \right\rangle \exp \left(\left\langle \Theta_i^{(\ell)}, c^{(\ell)}(x) \right\rangle - \psi_\ell(\Theta_i^{(\ell)}) \right) \\ &= \sum_{\ell=1}^k \nu_\ell \left(\eta_i^{(\ell)\top} e_j + 2e_j^\top \theta_i^{(\ell)} x \right) \exp \left(\left\langle \Theta_i^{(\ell)}, c^{(\ell)}(x) \right\rangle - \psi_\ell(\Theta_i^{(\ell)}) \right), \end{aligned}$$

and therefore

$$g(x, t) = \frac{1}{2} \operatorname{div}(a(x)) + \frac{1}{2} \frac{\sum_{\ell=1}^k \nu_{\ell} p_{\ell}(x, \Theta_t^{(\ell)}) a(x) \left(\eta_t^{(\ell)} + 2\theta_t^{(\ell)} x \right)}{p(x, \Theta_t^{(1)}, \dots, \Theta_t^{(k)})}.$$

Note that our choice of $\varphi_t^{(\ell)}$ satisfy (18) as shown in Lemma 26, which then completes the proof. ■

Appendix D. Proof of Theorem 13

Lemma 28 For an SDE of the form (15) the mean m_t and covariance matrix S_t of X_t satisfy

$$\begin{aligned} dm_t &= \mathbb{E}[u(X_t, t)] dt, \\ dS_t &= \left(\mathbb{E}[X_t u(X_t, t)^\top] + \mathbb{E}[u(X_t, t) X_t^\top] + \mathbb{E}[\sigma(X_t) \sigma(X_t)^\top] \right. \\ &\quad \left. - m_t \mathbb{E}[u(X_t, t)]^\top - \mathbb{E}[u(X_t, t)] m_t^\top \right) dt. \end{aligned} \quad (47)$$

Proof. The equation for the mean is trivial. For the variance let $Y_t := X_t X_t^\top$. According to Itô's Lemma Øksendal (2003) $dY_t = X_t(u(X_t, t) dt + \sigma(X_t) dB_t)^\top + (u(X_t, t) dt + \sigma(X_t) dB_t) X_t^\top + \sigma(X_t) \sigma(X_t)^\top dt$, and similarly $dm_t^2 = (m_t \mathbb{E}[u(X_t, t)]^\top + \mathbb{E}[u(X_t, t)] m_t^\top) dt$. Hence,

$$dS(t) = \mathbb{E}[dY(t)] - dm_t^2 = \left(\mathbb{E}[X_t u(X_t, t)^\top] + \mathbb{E}[u(X_t, t) X_t^\top] + \mathbb{E}[\sigma(X_t) \sigma(X_t)^\top] \right. \\ \left. - m_t \mathbb{E}[u(X_t, t)]^\top - \mathbb{E}[u(X_t, t)] m_t^\top \right) dt. \quad \blacksquare$$

Lemma 29 Mean m_t and variance S_t satisfy

$$m_u = \sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)}, \quad S_t = \sum_{\ell=1}^k \nu_{\ell} S_t^{(\ell)} + \sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} m_t^{(\ell)\top} - \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right) \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right)^\top.$$

Proof. The statement for the mean is straightforward. For the variance,

$$\begin{aligned} S_t &= \sum_{\ell=1}^k \nu_{\ell} \mathbb{E}_{p_{\ell}}[X X^\top] - \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right) \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right)^\top \\ &= \sum_{\ell=1}^k \nu_{\ell} \left(\mathbb{E}_{p_{\ell}}[X X^\top] - m_t^{(\ell)} m_t^{(\ell)\top} \right) + \sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} m_t^{(\ell)\top} - \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right) \left(\sum_{\ell=1}^k \nu_{\ell} m_t^{(\ell)} \right)^\top. \quad \blacksquare \end{aligned}$$

Proof of Theorem 13 Consider a drift function $u(x, t)$ given by (20). In view of Lemma

28

$$\frac{dm_t}{dt} = \sum_{\ell=1}^k \nu_{\ell} \left(\mathbb{E}_{p_{\ell}} \left[\frac{1}{2} \operatorname{div}(a(X)) \right] + A_t^{(\ell)} + B_t^{(\ell)} m_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X)] C_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X) D_t^{(\ell)} X^\top] \right),$$

which can be simplified according to Lemma 29, such that

$$\begin{aligned} \sum_{\ell=1}^k \nu_{\ell} \frac{dm_t^{(\ell)}}{dt} &= \sum_{\ell=1}^k \nu_{\ell} \left(\mathbb{E}_{p_{\ell}} \left[\frac{1}{2} \operatorname{div}(a(X)) \right] + A_t^{(\ell)} \right. \\ &\quad \left. + B_t^{(\ell)} m_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X)] C_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X) D_t^{(\ell)} X^\top] \right). \end{aligned} \quad (48)$$

Note that (48) has to hold for all $\nu_{\ell} \geq 0$ such that $\sum_{\ell=1}^k \nu_{\ell} = 1$. Therefore

$$\frac{dm_t^{(\ell)}}{dt} = \mathbb{E}_{p_{\ell}} \left[\frac{1}{2} \operatorname{div}(a(X)) \right] + A_t^{(\ell)} + B_t^{(\ell)} m_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X)] C_t^{(\ell)} + \mathbb{E}_{p_{\ell}}[a(X) D_t^{(\ell)} X^\top]. \quad (49)$$

For the variance, we have according to Lemma 29

$$\frac{dS_t}{dt} = \sum_{\ell=1}^k \nu_{\ell} \left(\frac{dS_t^{(\ell)}}{dt} + \frac{dm_t^{(\ell)}}{dt} m_t^{(\ell)\top} + m_t^{(\ell)} \left(\frac{dm_t^{(\ell)}}{dt} \right)^\top - \frac{dm_t^{(\ell)}}{dt} m_t^\top - m_t \left(\frac{dm_t^{(\ell)}}{dt} \right)^\top \right).$$

This implies

$$\sum_{\ell=1}^k \nu_{\ell} \frac{dS_t^{(\ell)}}{dt} = \frac{dS}{dt} + \sum_{\ell=1}^k \nu_{\ell} \left(\frac{dm_t^{(\ell)}}{dt} (m_t^\top - m_t^{(\ell)\top}) + (m_t - m_t^{(\ell)}) \left(\frac{dm_t^{(\ell)}}{dt} \right)^\top \right),$$

where $\frac{dS_t}{dt}$ is given according to Lemma 28, by

$$\frac{dS_t}{dt} = \mathbb{E}[X_t u(X_t, t)^\top] + \mathbb{E}[u(X_t, t) X_t^\top] + \mathbb{E}[\sigma(X_t) \sigma(X_t)^\top] - m_t \left(\frac{dm_t}{dt} \right)^\top - \frac{dm_t}{dt} m_t^\top.$$

Therefore,

$$\begin{aligned} \sum_{\ell=1}^k \nu_{\ell} \frac{dS_t^{(\ell)}}{dt} &= \mathbb{E}[X_t u(X_t, t)^\top] + \mathbb{E}[u(X_t, t) X_t^\top] + \mathbb{E}[\sigma(X_t) \sigma(X_t)^\top] \\ &\quad - \sum_{\ell=1}^k \nu_{\ell} \left(\frac{dm_t^{(\ell)}}{dt} m_t^{(\ell)\top} + m_t^{(\ell)} \left(\frac{dm_t^{(\ell)}}{dt} \right)^\top \right). \end{aligned} \quad (50)$$

Recall that $\frac{dm_t^{(\ell)}}{dt}$ is given by (49). Next, we compute

$$\begin{aligned} \mathbb{E}[X u(X, t)^\top] &= \sum_{\ell=1}^k \nu_{\ell} \left(\mathbb{E}_{p_{\ell}} \left[\frac{1}{2} X \operatorname{div}(a(X))^\top \right] + m_t^{(\ell)} A_t^{(\ell)\top} + (m_t^{(\ell)} m_t^{(\ell)\top} + S_t^{(\ell)}) B_t^{(\ell)\top} \right. \\ &\quad \left. + \mathbb{E}_{p_{\ell}}[X C_t^{(\ell)\top} a(X)] + \mathbb{E}_{p_{\ell}}[X X^\top D_t^{(\ell)} a(X)] \right), \\ \mathbb{E}[u(X, t) X^\top] &= \sum_{\ell=1}^k \nu_{\ell} \left(\mathbb{E}_{p_{\ell}} \left[\frac{1}{2} \operatorname{div}(a(X)) X^\top \right] + A_t^{(\ell)} m_t^{(\ell)-1} + B_t^{(\ell)} (m_t^{(\ell)} m_t^{(\ell)\top} + S_t^{(\ell)}) \right. \\ &\quad \left. + \mathbb{E}_{p_{\ell}}[a(X) C_t^{(\ell)} X^\top] + \mathbb{E}_{p_{\ell}}[a(X) D_t^{(\ell)} X X^\top] \right), \end{aligned}$$

$$\mathbb{E}_p[\sigma(X)\sigma(X)^\top] = \mathbb{E}_p[a(X)] = \sum_{\ell=1}^k \nu_\ell \mathbb{E}_{p_\ell}[a(X)],$$

such that by evaluating (50) and by recalling that it has to hold for all convex combinations, we get the assertion (23). ■

Abstract

Novelty detection or one-class classification starts from a model describing some type of ‘normal behaviour’ and aims to classify deviations from this model as being either novelties or anomalies.

In this paper the problem of novelty detection for point patterns $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\} \subset \mathbb{R}^d$ is treated where examples of anomalies are very sparse, or even absent. The latter complicates the tuning of hyperparameters in models commonly used for novelty detection, such as one-class support vector machines and hidden Markov models.

To this end, the use of extreme value statistics is introduced to estimate explicitly a model for the abnormal class by means of extrapolation from a statistical model X for the normal class. We show how multiple types of information obtained from any available extreme instances of S can be combined to reduce the high false-alarm rate that is typically encountered when classes are strongly imbalanced, as often occurs in the one-class setting (whereby ‘abnormal’ data are often scarce).

The approach is illustrated using simulated data and then a real-life application is used as an exemplar, whereby accelerometry data from epileptic seizures are analysed - these are known to be extreme and rare with respect to normal accelerometer data.

Keywords: Sequence classification; novelty detection; extreme value theory; class imbalance; asymptotic theory

1. Introduction

Novelty detection is a particular example of pattern recognition that addresses the problem of identifying new patterns in data that are previously unseen. It shares many similarities with anomaly detection where one also wishes to detect abnormalities, but where in the latter these may not necessarily be entirely novel; i.e. a small amount of the training data

may contain outliers or anomalies. Novelty detection has a broad range of applications ranging from intrusion detection in computer related systems; industrial damage detection; to healthcare (Pimentel et al., 2014). All these applications have in common the fact that data describing failure conditions (or other abnormal behaviour) are rare or even absent, such that traditional classification methods may perform suboptimally. Novelty detection provides an alternative approach that starts from a model of normal behaviour and then detects deviations from this model (Bishop, 1994). It is for this reason that novelty detection is also termed one-class classification where there is no explicit model for ‘abnormal behaviour’. It may also be described in terms of a hypothesis test, in which the null-hypothesis is described by the model of normality.

This article considers one-class classification of ‘point patterns’, defined as sets of vectors $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$, $k \in \mathbb{N}_0$ located in data space \mathbb{R}^d where each \mathbf{x}_i is a realization of a random variable X^1 . We propose a statistical approach that starts from a probability density function (PDF) $y = p(\mathbf{x})$ associated with X that models the normal behaviour described by a dataset $D \subset \mathbb{R}^d$. Novelty detection then addresses the question of whether a set S of vectors is drawn from the distribution X or not.

In this article the use of the use of extreme value theory (EVT) is introduced to tackle classification of sets S (Embrechts et al., 1997). The Poisson point process (PPP) characterization of EVT is used to extract count data describing the number of times measurements in S fall in low-density regions defined by X . Furthermore, asymptotic results are provided in this article that allow us to unify this count information with the mean and maximal excess in $p(S)$ with respect to a low threshold e^{-u} . The method is evaluated using synthetic as well as real-world data, and is compared with commonly used algorithms for outlier detection such as one-class support vector machines (OCSVMs) and hidden Markov models (HMMs).

In contrast to existing novelty detection methods, EVT enables us to define a model for the abnormal class, where data are sparse or even unobserved. This enables us to circumvent the optimization of hyperparameters that is typically encountered in using one-class classifiers and which often requires data from the abnormal class. In essence, the use of EVT relies on extrapolation from the normal class, providing a class of models for low-density regions; the latter are particularly beneficial for novelty detection, because the decision boundary is expected to be situated in regions where data are sparse.

The remainder of this paper is organized as follows. Section 2 is devoted to related work on sequence classifications and provides an introduction to EVT. Subsequently, Section 3 introduces the EVT-based one-class classifier. In Section 4, the method is evaluated and its limitations are discussed.

2. Related work and EVT

This section starts with a short review of related work on sequence classification. The necessary background of EVT is then reviewed.

1. The common convention in statistics is used that applies capital letters to refer to population attributes and lower-case letters to refer to sample attributes.

2.1 Related work

The problem setting in this article is an example of a collective novelty detection problem where the individual instances within a set S are not classified with respect to the distribution X . Instead, the entire set S of vectors is considered to be one single instance that is assigned a single label. This contrasts with conventional one-class classification, in which every element of S is classified independently. Closely related to this problem is that of sequential learning. However in the latter each instance of the set S is given a different label. Widely-used machine learning techniques for sequential learning, such as HMMs and conditional random fields (CRFs), are not able to learn from one class only (Bishop, 2006; Sutton and McCallum, 2011). A commonly-used technique to tackle sequence classification is to concatenate the separate labels that are obtained by applying a one-class classifier (e.g., an OCSVM) to each instance \mathbf{x}_i separately. The mean novelty score of all instances, for example, can be used to decide whether or not S is novel (Dettendorf, 2002). This latter approach, however, is more naturally expressed by taking a point-wise approach where, from a statistical point of view, a number (k) of hypothesis tests are considered:

$$\begin{aligned} H_0 : \mathbf{x}_i \text{ is a realization of } X \\ H_1 : \mathbf{x}_i \text{ is novel with respect to } X, \end{aligned}$$

where H_0 denotes the so-called null-hypothesis and H_1 the alternative hypothesis. Due to the multiple hypothesis-testing problem, the number of false alarms can increase considerably for $k > 1$. Indeed, while each hypothesis test is chosen to have a small type-I error α (i.e., the probability of wrongly classifying \mathbf{x}_i as being novel, which is a false positive), the error of making at least one type-I error among the k hypothesis tests corresponds to $\bar{\alpha} = 1 - (1 - \alpha)^k$, e.g., when $\alpha = 5\%$ and $k = 6$, $\bar{\alpha} = 26\%$.

To obtain the correct decision boundary corresponding to the significance level α , Clifton et al. (2011) considered the univariate distribution over the probability density values $p(\mathbf{x})$ on the image $\text{Im}(p) = \{p(\mathbf{x}) \mid \mathbf{x} \in \mathcal{D}\}$ by reducing the multivariate analysis of the multidimensional data set \mathcal{D} to an univariate analysis on $\text{Im}(p)$. The PDF $y = p(\mathbf{x})$ can be obtained, for example, using a kernel density estimator (Scott, 1992). The distribution Y of these densities is strongly related to that of X , with a density defined by:

$$q(y) = \frac{dQ}{dy}(y) \quad \text{and} \quad Q(y) = \int_{p^{-1}(0,y)} p(\mathbf{x}) d\mathbf{x}. \quad (1)$$

As will be made clear in the following section, univariate EVT can then be used to describe sets $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$, which have a typical minimal density with respect to $y = p(\mathbf{x})$. In this way, a distribution is obtained for the most ‘extreme’ vectors that possibly occur in (truly ‘normal’) samples S drawn from X . A new set S is then evaluated by comparing its most extreme vector w.r.t. this model of extremes. Although this approach enables one to obtain a correct statistical type I-error α in testing S , its main drawback is that it captures limited information concerning the set S (Luca et al., 2014b). Indeed, only the single most extreme element in S is used to obtain a decision, while (non-extreme) information contained in the remaining part of the set is discarded. In this article we show how EVT can be used to include information contained in the remaining part of the pattern S while maintaining the correct statistical type I-error when testing S .

2.2 An introduction to EVT

EVT is a statistical discipline where the objective is to model the stochastic behavior of a univariate process at unusually large (or small) levels. It has already been used for many applications ranging from biomedical engineering, structural health monitoring, meteorology, and risk assessment in financial domains (Embrechts et al., 1997).

The central result in EVT is the Fisher-Tippett theorem concerning the limiting distribution of maxima of a sequence of independent and identically distributed (i.i.d.) random variables X_1, \dots, X_k according to a common distribution X :

$$M_k = \max\{X_1, \dots, X_k\},$$

as $k \rightarrow +\infty$. It states that when the following convergence in distribution appears:

$$P\left(\frac{M_k - c_k}{d_k} \leq x\right) \rightarrow G_\xi(x), \quad \text{as } k \rightarrow +\infty \quad (2)$$

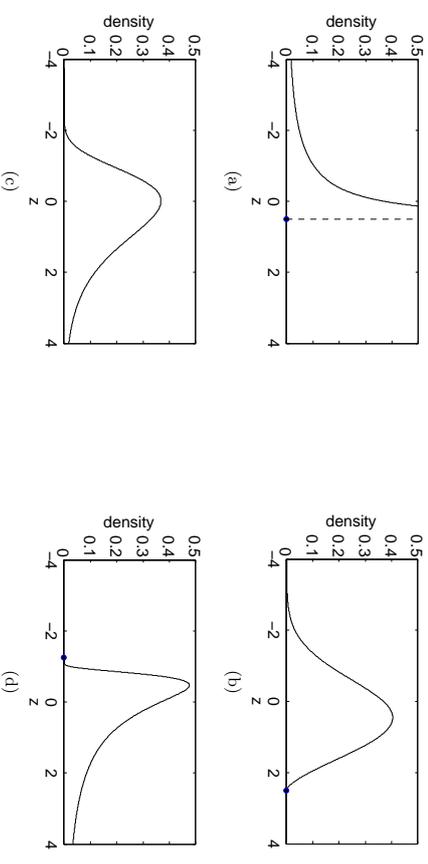

Figure 1: Different members of the GEV family in Eq. (3), with different values of the shape parameter ξ . The dot in the figures indicates the abscissa $z = -\frac{1}{\xi}$, where the density is zero, (a) $\xi = -2$ where we see that when $\xi \leq -1$ a short tail with an upper bound is described (b) $\xi = -0.4$ where we see that when $-1 < \xi < 0$ maxima have an upper bound (c) $\xi = 0$ where the maxima have no upper- or lower bound. Finally, (d) $\xi = 0.8$ where we see that for $\xi > 0$ the maxima have a lower bound.

for some normalizing constants c_k, d_k , the limiting distribution $G_\xi(x)$ is a member of the so-called family of *generalized extreme value (GEV) distributions*:

$$G_\xi(x) = \begin{cases} \exp\left\{-[1 + \xi x]^{-\frac{1}{\xi}}\right\}, & \xi \neq 0 \\ \exp\{-\exp(-x)\}, & \xi = 0. \end{cases} \quad (3)$$

For $\xi \neq 0$ the domain of the distribution is restricted to the set $\{x \mid 1 + \xi x > 0\}$. When the shape parameter ξ is negative, zero, or positive, the subset of members of the family correspond to the *Weibull*, *Gumbel* and *Fréchet* families respectively. The shape parameter thus determines the behaviour in the tail of the distribution of X , as shown in Figure 1.

The normalizing constants in (2) prevent a degenerate limit of the distribution of M_k , because clearly:

$$\lim_{k \rightarrow +\infty} P(M_k \leq x) = \lim_{k \rightarrow +\infty} \prod_{i=1}^k P(X_i \leq x)$$

which approaches zero for each $x < x_+$, where x_+ (possible $+\infty$) denotes the rightmost endpoint of the support of X .

The GEV family provides a model for block maxima, obtained by blocking (or windowing) the training data into blocks of equal length, and then fitting the GEV to the obtained

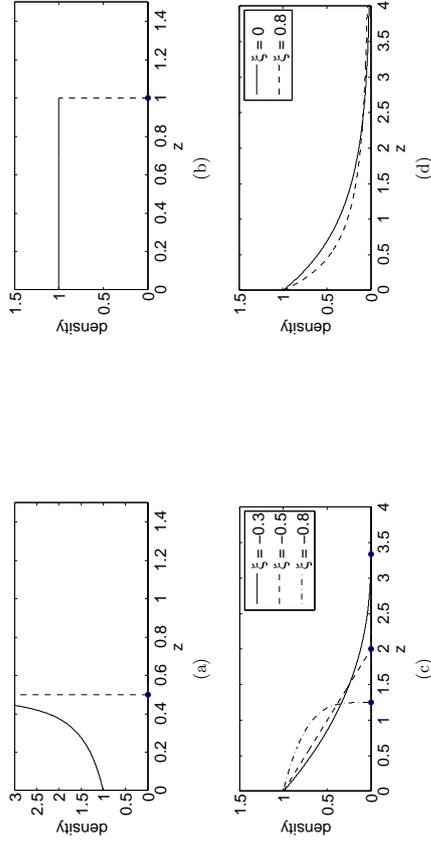

Figure 2: Different members of the GPD family in Eq. (3). The dot in the figures indicates the abscissa $z = -\frac{1}{\xi}$, where the density is zero, (a) $\xi = -2$, where $\xi < -1$, an asymptote occurs at $z = -\frac{1}{\xi}$. (b) $\xi = -1$ corresponds to an uniform distribution of excesses. (c) Different types of behaviour for $-1 < \xi < 0$ corresponding to excesses with an upper-bound. (d) For $\xi > 0$ the density has an intercept at $(0, 1)$.

set of block maxima. However, when these block are relatively large, this leads to using only a few block maxima, which can bias the estimation process. An alternative approach to overcome this problem is the so-called peaks over threshold (POT) method. In this approach, complete tails of a distribution X are modelled, defined as those measurements X_i of a sequence X_1, X_2, \dots that fall above some threshold u . A basic result of EVT states that when (2) holds for some member $G_\xi(x)$ of the GEV-family, the distribution of the exceedances $X - u$, conditional on $X > u$, satisfies the limiting property:

$$\lim_{u \uparrow x_+} P\left(\frac{X - u}{a(u)} < x \mid X > u\right) = H_\xi(x) \quad (4)$$

for some appropriate scaling factor $a(u)$ and

$$H_\xi = \begin{cases} 1 - (1 + \xi x)^{-1/\xi} & \text{if } \xi \neq 0 \\ 1 - e^{-x} & \text{if } \xi = 0 \end{cases} \quad (5)$$

denotes the family of generalized Pareto distributions (GPDs) where $x \geq 0$ for $\xi \geq 0$ and $0 \leq x \leq -\frac{1}{\xi}$ for $\xi \leq 0$, as shown Figure 2. For the Gumbel case $\xi = 0$, the scaling factor $a(u)$ is given by $E(X - u \mid X > u)$.

2.3 Poisson point processes and EVT

An elegant way to describe extremes, and one that unifies the block and POT approaches is based on Poisson point processes (PPPs). Any inference made using one of both above approaches could equally be made using the PPP model because it can be parametrized in terms of the GEV- and GPD- parameters. In this way, no extra computational effort is needed when using the PPP model.

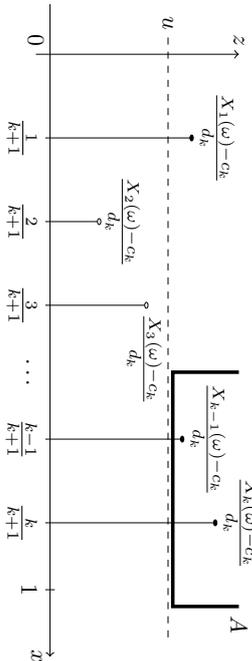

Generally a point process \mathcal{P} on a subset $U \subset \mathbb{R}^d$ is a stochastic model for which any one realization consists of a set of points $\{x_1, x_2, \dots, x_N\}$ that are randomly located in U and of which the number N is a random variable. The point processes closely related to EVT are the point processes of exceedances and consider those observations from sequences of random variables X_1, \dots, X_k which exceed a threshold u .

In particular, for a fixed choice of $k \in \mathbb{N}$, the point process of exceedances \mathcal{P}_k is defined on regions of the form $U =]0, 1[\times]u, +\infty[$ and considers those points that are situated in the intersection:

$$\mathcal{P}_k(\omega) = \left\{ \left(\frac{i}{k+1}, \frac{X_i(\omega) - c_k}{d_k} \mid 1 \leq i \leq k \right) \cap]0, 1[\times]u, +\infty[, \right. \quad (6)$$

where c_k and d_k are normalizing constants and ω denotes the stochastic event corresponding to a realization $\mathcal{P}_k(\omega)$ of the point process of exceedances. The indices are divided by the factor $k+1$ to rescale the process to the interval $]0, 1[$, as illustrated in Figure 3. The point processes \mathcal{P}_k can be characterised by *random counting measures*, which assign to each subset of the form $A =]t_1, t_2[\times]u + x, +\infty[\subset]0, 1[\times]u, +\infty[$ a random variable N_A describing the number of points of a realization that fall in region A :

$$N_A^k : \omega \mapsto \text{“number of points of } \mathcal{P}_k(\omega) \text{ in } A \text{”}$$

Figure 3: A realization $\mathcal{P}_k(\omega)$ of a point process of exceedances with $N_A^k(\omega) = 2$.

Indeed the values of these counting measures N_A^k for all subsets A give sufficient information to reconstruct completely those X_i that fall above a threshold of value $c_k + d_k u$. In fact, setting $A = \{\frac{k}{k+1}\} \times]z, +\infty[$, $N_A^k(\omega) > 0$ only applies when $X_i(\omega) > c_k + d_k z$.

The point process characterization of EVT is obtained by letting $k \rightarrow +\infty$. It is known (Embrechts et al., 1997) that when (2) holds for some normalization constants c_k and d_k , then the corresponding point processes of exceedances \mathcal{P}_k will converge to a PPP \mathcal{P} for $u > x_-$ where x_- denotes the leftmost endpoint of the support of the GEV-distribution in (2). This means that the following convergence of distributions holds:

$$N_A^k \xrightarrow{d} \text{Poi}[\Lambda(A)] \text{ as } k \rightarrow +\infty \quad (7)$$

on sets $A =]t_1, t_2[\times]u+x, +\infty[\subset U$ and where the distributions of N_A^k on non-overlapping sets A are mutually independent; i.e., the occurrence of a point at a location should not influence the probability of the occurrence of other points at other locations. In the limiting case, the rate parameter of the Poisson distribution $\Lambda(A)$ depends on the set A and is called the *intensity measure* $\Lambda(A)$ of the PPP. The fact that the PPP-characterization of extremes unifies the block and POT approach is due to the fact that the values of $\Lambda(A)$ in (7) can be written as a function of ξ (Embrechts et al., 1997):

$$\Lambda(A) = (t_2 - t_1) (1 + \xi(u+x))^{-1/\xi} = (t_2 - t_1) \lambda (1 + \xi \lambda^\xi x)^{-1/\xi} \quad (8)$$

with $\lambda = (1 + \xi u)^{-1/\xi}$. Therefore any inference made using the PPP limit of extremes yields immediately the shape parameter ξ in (2) and (21). In this way EVT describes three equivalent limiting properties (2), (4), and (7).

3. Learning from sparse data regions

In this article, a learning algorithm is proposed that explores the link between the three representations of extremes as introduced in the previous section. For this purpose so-called EVT-based features will be introduced in section 3.1 that describe characterizing measures of a set $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$ of vectors independently drawn from a distribution X . In Section 3.2, a joint asymptotic distribution of these features is calculated as $k \rightarrow +\infty$. Subsequently,

analytical expressions of cumulative scores with respect to this distribution are obtained that will be used as novelty scores to evaluate the novelty of S with respect to X for large k .

3.1 EVT-based features

Consider a d -dimensional random variable X with PDF $g = p(\mathbf{x})$. The transformation $Z = -\log p(X)$ allows us to study multivariate low-density regions $\{\mathbf{x} \mid p(\mathbf{x}) < e^{-u}\}$ with u some large real number, as a convex univariate region $\{z \mid z > u\}$. Associated with a sequence of i.i.d. random variables X_1, \dots, X_k , we define the following associated features based on the log-transformed sequence Z_1, \dots, Z_k , $Z_i = -\log p(X_i)$:

1. The number of exceedances among Z_1, \dots, Z_k above some threshold u_k :

$$N_k = \sum_{i=1}^k \mathbb{I}_{\{Z_i > u_k\}},$$

where $\mathbb{I}_{\{Z_i > u_k\}}$ denotes an indicator function taking the value 1 when $Z_i > u_k$ and zero otherwise. This feature describes the number of multivariate points from a sequence $\{X_1, \dots, X_k\}$ that are situated in a low density region $\mathcal{R}_k = \{\mathbf{x} \mid p(\mathbf{x}) < e^{-u_k}\}$.

2. The mean exceedance among Z_1, \dots, Z_k above some threshold u_k :

$$V_k = \frac{1}{N_k} \sum_{i=1}^k (Z_i - u_k) \mathbb{I}_{\{Z_i > u_k\}}$$

A high value of V_k indicates that, on average, the points of the sequence X_1, \dots, X_k are outlying with respect to the locus of the training data while a low value indicates that the sequence is situated near the locus of the training data.

3. The maximal exceedance among Z_1, \dots, Z_k above some threshold u_k :

$$M_k = \max_{1 \leq i \leq k} \{Z_i - u_k \mid Z_i > u_k\}$$

corresponding to the most outlying point of X_1, \dots, X_k with respect to the training data.

Note that the mean exceedance V_k and the maximal exceedance M_k are only well-defined when $N_k \geq 1$. The features above provide a natural way to summarize the extent to which densities of observations falling in low-density regions exceed some low threshold e^{-u_k} . Therefore when a set $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$ of k observations is novel with respect to the distribution X , it is expected that the corresponding features v_k , m_k , and ms_k of the sample S have a higher cumulative score given their respective distributions V_k , M_k , and N_k . Hence these features allow us to summarize the information contained in the tail of a d -dimensional distribution X (that can be of arbitrarily high dimension) in a 3-dimensional distribution. To determine the joint distribution of these EVT-based features, the PPP characterization (7) is applied to the univariate random variable Z whose tail describes the

multivariate points X that are lying in low-density regions. In the next section we will determine the joint distribution of these 3 features to fuse the information from each.

To apply the PPP characterization to Z , we consider the sequence of point processes \mathcal{P}_k on \mathbb{R}^2 associated with $Z = -\log p(X)$:

$$\mathcal{P}_k = \left\{ \left(\frac{i}{k+1}, Z_i \right) \mid 1 \leq i \leq k \right\}.$$

From the limiting property (7), the point processes \mathcal{P}_k will converge to a PPP as $k \rightarrow +\infty$ on regions of the form $[0, 1[\times]u_k, +\infty)$, with $u_k = c_k + ud_k$, $u \in \mathbb{R}$, and with c_k, d_k being the normalizing constants as in (6). Block maxima of Z_i are not bounded from above or below, and so the Gumbel distribution is the only possible limiting EVT distribution for this one-class formulation; i.e., $\xi = 0$ in the limiting property (7). For the Gumbel case it is known that the normalizing constants can be chosen as (Embrechts et al., 1997)²:

$$c_k = \inf \left\{ z \mid P(Z \leq z) \geq 1 - \frac{1}{k} \right\} \quad \text{and} \quad d_k = E(Z - c_k \mid X > c_k). \quad (9)$$

The intensity measure of the limiting PPP can be obtained by letting $\xi \rightarrow 0$ in (8):

$$\Lambda(A) = (t_2 - t_1)e^{-(x+u)} = (t_2 - t_1)\lambda e^{-x}, \quad \text{with } \lambda = e^{-u} \quad (10)$$

and where the parameter λ is given by the expected number of exceedances of Z above $u_k(x) = c_k + (u+x)d_k$. We can now state the following theorem that is proved in Appendix A.1 and that characterizes the distribution of the EVT features defined above.

Theorem 1 Consider the random variables N_k, V_k and M_k associated with sets S of k observations $\{X_1, \dots, X_k\}$ drawn from a d -dimensional random variable X . Denote $y = p(\mathbf{x})$ the PDF of X and suppose $Z = -\log p(X)$ satisfies the following limiting property:

$$\lim_{w \rightarrow +\infty} P \left(\frac{Z-w}{a(w)} > x \mid Z > w \right) = e^{-x}, \quad \forall x \in \mathbb{R}^+ \quad (11)$$

where $a(w) = E(X-w \mid X > w)$. Denoting, for $u \geq 0$, the following sequence of thresholds:

$$u_k = c_k + ud_k, \quad \text{with } c_k = \inf \left\{ z \mid P(Z \leq z) \geq 1 - \frac{1}{k} \right\}, \quad d_k = a(c_k),$$

the following limiting properties hold as $k \rightarrow +\infty$:

- (i) The distribution N_k of the number of observations among k of X that fall in regions $\{\mathbf{x} \mid p(\mathbf{x}) \leq e^{-u_k}\}$ converges to a Poisson distribution with a rate $\lambda = e^{-u}$:

$$\lim_{k \rightarrow +\infty} P(N_k = n) = \frac{\lambda^n e^{-\lambda}}{n!} \quad (12)$$

2. The operator \inf in (9) refers to the infimum or greatest lower bound.

- (ii) After normalization, the distribution of the maximal exceedance M_k above threshold u_k converge in distribution to a Gumbel member of the GEV family with $\mu = \log \lambda$ that is conditioned on the positive real line; i.e.,

$$\lim_{k \rightarrow +\infty} P \left(\frac{M_k - \mu}{d_k} \leq m \mid N_k \geq 1 \right) = \frac{\exp \left\{ -\exp \left[-(m - \log \lambda) \right] \right\}}{1 - e^{-\lambda}} \quad (13)$$

- (iii) After normalization, the mean exceedance V_k above u_k converges in distribution to a random variable distributed according to a cumulative distribution function:

$$\lim_{k \rightarrow +\infty} P \left(\frac{V_k - \mu}{d_k} \leq v \mid N_k \geq 1 \right) = 1 - \frac{1}{e^{\lambda v - 1}} \left(\sum_{j=0}^{+\infty} \frac{\lambda^j}{j!} (v)^j e^{-lv} \right) \quad (14)$$

Figure 4 illustrates the limiting properties obtained in Theorem 1 based on a two-dimensional distribution X given by a Gaussian mixture model (GMM) of two standard normal distributions centred at the origin and (1, 1) respectively. The constants c_k and d_k were estimated by an empirical estimation of (9) based on a simulated sample of length 5×10^6 from the mixture. Setting $u = 0$, the empirical distributions of N_k, M_k and V_k were estimated based on 5×10^3 sets of lengths $k \in \{5, 20, 50\}$ and compared with the analytical expression obtained in Theorem 1. The figure shows that the distributions are approximating the limiting case more closely as k increases, while for $k \geq 20$ this approximation may already be seen to be satisfactory.

3.2 EVT-based one-class classifier

A joint distribution is here calculated to fuse the information from the EVT-based features M_k, N_k , and V_k , as introduced in Section 3.1. For this purpose, we suppose that at least one exceedance of $-\log p(X_i)$ above u_k is observed in a sequence $S = \{X_1, \dots, X_k\}$ of length $|S| = k$. The proof of the following theorem can be found in Appendix A.2.

Theorem 2 Consider the random variables N_k, V_k , and M_k associated with sets S of k observations $\{X_1, \dots, X_k\}$ drawn from a d -dimensional random variable X . Denote $y = p(\mathbf{x})$ the density function of X and suppose $Z = -\log p(X)$ satisfies the following limiting property:

$$\lim_{w \rightarrow +\infty} P \left(\frac{Z-w}{a(w)} > x \mid Z > w \right) = e^{-x}, \quad \forall x \in \mathbb{R}^+ \quad (15)$$

where $a(w) = E(Z-w \mid Z > w)$. After normalization, the joint cumulative distribution function of (N_k, V_k, M_k) conditioned on $N_k \geq 1$ and related to the sequence of thresholds u_k as in Theorem 1:

$$F_k(v, m, n) = P \left(\frac{V_k - \mu}{d_k} \leq v, \frac{M_k - \mu}{d_k} \leq m, N_k \leq n \mid N_k \geq 1 \right), \quad (16)$$

converges on $D = \{(v, m, n) \mid \frac{m}{n} \leq v \leq m\}$ to a mixture of translated chi-squared distribution as k tends to infinity:

$$F(v, m, n) = \lim_{k \rightarrow +\infty} F_k(v, m, n) = \sum_{i=1}^n \frac{\lambda^i e^{-\lambda}}{i!(1 - e^{-\lambda})} \sum_{l=0}^r (-1)^l \binom{r}{l} e^{-im} \chi_{2l} (2(lv - im)) \quad (17)$$

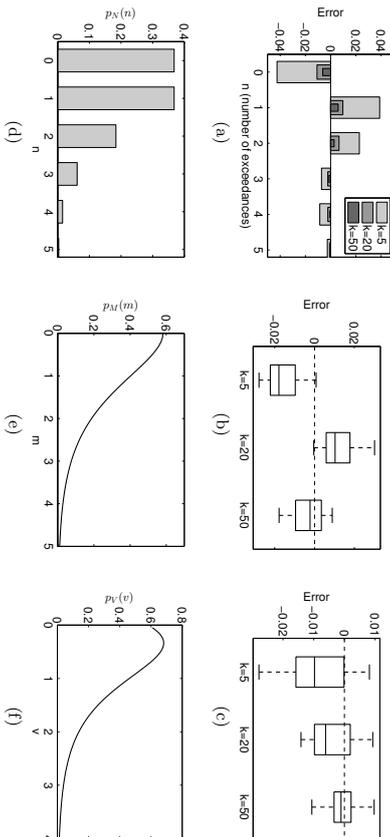

Figure 4: Comparison between limiting distribution as $k \rightarrow +\infty$ and empirical distribution functions for $k \in \{5, 20, 50\}$ using simulated data from a GMM when $u = 0$. (a) - (c) Differences between empirical distribution and asymptotic distribution for N_k , M_k , and V_k respectively; (d) - (f) Limiting PDFs p_N , p_M , and p_V from Eqs. (12) - (14) as $k \rightarrow +\infty$ for N_k , M_k , and V_k respectively.

where $r = \lfloor \frac{ln}{m} \rfloor$ (i.e. $\frac{ln}{m} \in [r, r+1[$, for $0 \leq r \leq l-1$), χ_p denotes the cumulative chi-squared distribution function with p degrees of freedom and $\lambda = e^{-u}$ is the exceedance rate of the limiting Poisson distribution of N_k as in Theorem 1-(i).

Note that the term in (17) for $l = 1$ has the identity line $m = v$ as its domain and the expression reduces to $\frac{\lambda e^{-\lambda}}{1 - e^{-\lambda}}(1 - e^{-m})$. The corresponding limiting joint density function of (N_k, V_k, M_k) on D can be found by partial derivation of formula (17):

$$f(v, m, n \mid n \geq 1) = \begin{cases} e^{-nv} \sum_{i=1}^{\lfloor \frac{mn}{m} \rfloor} c_{in} (nv - im)^{n-2}, & n \geq 2 \\ \frac{\lambda}{e^{-\lambda} - 1} e^{-m} \mathbb{I}_{i=m}, & n = 1 \end{cases} \quad (18)$$

where c_{in} are constants defined for $1 \leq i \leq n$ as:

$$c_{in} = -\frac{n\lambda^n}{(e^\lambda - 1)\Gamma(n)\Gamma(n-1)} (-1)^i \binom{n-1}{i-1}.$$

and where $\mathbb{I}_{i=m}(v, m)$ is an indicator function taking the value 1 when $v = m$, and which is zero elsewhere.

To apply Theorem 2, note that (15) implies that an exponential approximation of the exceedances is valid from some high threshold u_0 :

$$P(Z - u_0 > x \mid Z > u_0) \approx e^{-\frac{x}{\sigma}} \quad (19)$$

with $\sigma = \alpha(u_0) = E(Z - u_0 \mid Z > u_0)$ and $\sigma \approx d_k$. Then, based on Theorems 1 and 2, a novelty score of a sequence S with corresponding EVT features (v_S, m_S, n_S) can be defined:

$$XS = \begin{cases} P(N_k < n_S) + P(V_k \leq v_S, M_k \leq m_S, N_k = n) & \text{when } n_S > 0 \\ P(N_k = 0) & \text{when } n_S = 0 \end{cases}$$

and for large k this is approximated by:

$$XS \approx \begin{cases} \left(\sum_{i=0}^{n_S-1} \lambda^i e^{-\lambda} \right) + F\left(\frac{v_S}{\sigma}, \frac{m_S}{\sigma}, n_S\right) - F\left(\frac{v_S}{\sigma}, \frac{m_S}{\sigma}, n_S - 1\right) & \text{when } n_S > 0 \\ e^{-\lambda} & \text{when } n_S = 0 \end{cases} \quad (20)$$

These novelty scores quantify the ‘extremity’ of a sequence S by cumulatively summing the probability of having fewer than n_S exceedances, while the mean and maximal exceedances with respect to the threshold u_0 do not exceed v_S and m_S respectively. There is a valid probabilistic interpretation to XS making it a risk metric that quantifies the risk that S is novel; i.e., that S has some distribution other than X .

The choice of u_0 in the approximation (19) can be assessed by means of a *mean excess plot* which is a graphic diagnostic in which the sample means of the excesses $(Z - u)$ are plotted against a range of thresholds along with the confidence intervals (Embrechts et al., 1997). The threshold is chosen to be the lowest level where all the higher threshold-based sample mean excesses are consistent with a horizontal line. Alternatively an empirically driven rule-of-thumb can be chosen that specifies the tail fraction which satisfies the approximation in (19) and where u_0 is estimated as the quantile at $1 - \frac{n}{n \log \log(n)}$ of a sample of length n of the distribution (Scarrot and MacDonald, 2012). The parameters σ and λ can then be estimated by means of maximum likelihood estimation (Falk et al., 2011).

Figure 5(a)-(b) illustrates the limiting joint PDF (18) on the domain D conditioned on the number of exceedances for $n = 3$ and $n = 5$ for a GMM X of two standard normal distribution centred at $(0, 0)$ and $(1, 1)$. As the number of exceedances increases, the mode of the distributions moves diagonally upwards. Figure 5(c) shows a probability-probability (P-P) plot assessing the limiting property (17) for $k = 20$. For this purpose a sample of 5×10^3 sets of length $k = 20$ were simulated from X to estimate the cumulative probabilities $F_k(v, m, n)$ empirically, on a grid of $(v, m, n) \in [0, 10] \times [0, 10] \times \{2, 3, 5\}$ consisting of 300 vertices and compare these estimations with $F(v, m, n)$.

4. Experiments

In this section, the validity of our proposed method is illustrated using both artificial and real-world data sets. The novel EVT algorithm is compared with the conventional sequence classifiers HMMs and OCSVMs. To this end, 5-fold cross-validation is performed where in each run a random subset of the data from the normal class is used for training and the remainder of the data is split evenly between validation and test data. The randomized runs are kept the same across the different classifiers to allow a consistent comparison. The novelty score of a sequence with respect to a HMM or OCSVM is calculated as being the mean of the likelihoods assigned by the model to each individual instance of the sequence.

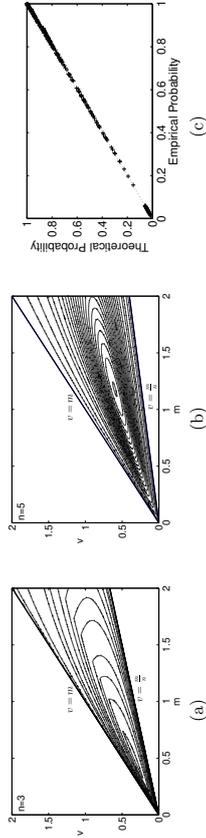

Figure 5: (a) - (b) Limiting joint PDF (18) on the domain D conditioned on $n = 3$ and $n = 5$ respectively, for a GMM X consisting of two standard normal distribution centred at $(0, 0)$ and $(1, 1)$. (b) A probability-probability (P-P)-plot comparing the joint empirical cumulative distribution of (V_k, M_k, N_k) for $k = 20$ with the limiting joint distribution.

Both HMMs and OCSVMs depend on hyperparameters, the value of which are estimated using the validation sets by maximizing a cost-function. For the HMM, the number of states varies from 1 – 4 (Rabiner and Murray, 1989), while for the OCSVM the standard hyperparameters (σ, ν) are optimized that respectively denote the kernel width of the Gaussian kernel that is used and an upper bound on the fraction of outliers (Schölkopf et al., 2001). The threshold on the novelty scores is optimized using the validation data.

For the EVT model, no validation step is performed and no data from the abnormal class are considered during training. A threshold of 95% is chosen on the novelty score (motivated from a probabilistic viewpoint). The density of the distribution X describing the normal class is estimated using a kernel density estimation with Gaussian kernels, and where the kernel width is estimated by minimization of the mean integrated squared error (Scott, 1992).

4.1 Synthetic data set

In order to validate the use of our EVT-based method a simulated dataset is constructed where data from the abnormal class are situated in the tail regions of a planar Gaussian mixture X consisting of two components located at $(-2, -2)$ and $(0, 0)$ respectively with covariance matrix $\frac{1}{2}I_2$, with I_2 the identity matrix in $\mathbb{R}^{2 \times 2}$. The training data of the normal class consisted of 100 sets of length $k = 20$ points drawn from X . Several experiments were performed where the proportion of abnormal instances in the validation and test sets varied in the range $p_a \in \{0.01, 0.05, 0.1, 0.5\}$. The abnormal class of patterns contained a mixture of normal instances from X and abnormal instances coming from the tail region where the density $p(\mathbf{x}) \leq 5 \times 10^{-4}$. In a 5-fold cross-validation experiment, the ability of the detection of these patterns between an OCSVM, a HMM, and our EVT model is compared.

Figure 6(a) shows the contours of the tail region obtained from applying the Gumbel model of M_k on the densities that are estimated using a kernel density estimation of X . The dark contour surrounding the central region indicates the tail region estimated by the Gumbel model. In this region, the dark contour corresponds to an empirical estimation of

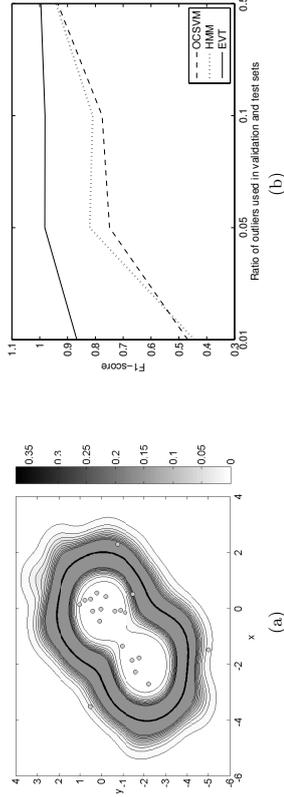

Figure 6: (a) The estimation of the tails of a Gaussian mixture X using a Gumbel model on the distribution of densities (1). The bold contour indicates the estimation of the EVT threshold e^{-u_k} for $k = 20$ on the likelihoods as defined in Theorem 1. (b) F1-scores averaged over the runs of a 5-fold-validation experiment across different ratios of available abnormalities.

the threshold $u_k = c_k + \nu d_k$ where u is set to zero (see Theorem 1). It is with respect to this threshold that the number of exceedances N_k and the maximal and mean exceedance M_k and V_k are calculated. Using our EVT-based method, an abnormal sequence can be evaluated as a cumulative probability score (20) with respect to the joint distribution of the EVT-based features. For example, the sequence of gray points shown in Figure 6 contains three exceedances with respect to the threshold u_k and has a score $X_S = 98.97\%$ such that it is classified as being novel with respect to X . Figure 6(b) shows the F1-scores of the classifiers, averaged over the 5 folds in our cross-validation experiment. When the ratio of abnormal patterns in the training phase is 50% the classifiers perform equally well. EVT, however, is able to outperform the classifiers when data from the abnormal class become sparse, as is typically the case for novelty detection problems. When there is a lack of examples from the abnormal class, the optimization of the hyperparameters and the novelty threshold in a HMM and an OCSVM is suboptimal. EVT, on the other hand, provides a class of models for the tail region where training data are sparse and is able to estimate the threshold exactly by using a statistical distribution that is obtained by extrapolation from the normal class (where data are usually abundant).

4.2 Accelerometer data for the detection of epileptic seizures

In this section, a case study in the healthcare domain is considered using a set of acceleration data collected from movements of patients suffering from epilepsy (Cuppens et al., 2013). The acceleration data were recorded during several nights using four 3D acceleration sensors attached to the extremities of 7 children with hypermotor seizures, all between the age of 5 and 16 years. Hypermotor seizures are epileptic convulsions that are marked by a strong and uncontrolled movement of the arms and legs that can last from a couple of seconds to a number of minutes. Due to the exaggerated movement involved, the patient can injure

themselves during the seizure, which increases the need for an alarm system with high sensitivity to abnormality.

In a pre-processing phase, movement events E_s are extracted from the data set using an energy-based threshold. We denote the acceleration vectors in these events as

$$E_s = \{a_{t,l} | 1 \leq t \leq T, 1 \leq l \leq 4\}$$

where the indices refer to the time index and the limb respectively (1 = left arm, 2 = right arm, 3 = left leg, 4 = right leg). Cuppens et al. (2013) performed a feature analysis where 3 features were identified as being relevant to this application:

- i) Movement length, $f_1 = |E_s| = T$
- ii) Average energy in a movement:

$$f_2 = \frac{1}{T} \sum_{t,l} \|a_{t,l}\|^2$$

- iii) The maximal energy in an arm movement:

$$f_3 = \max_{1 \leq l \leq T} \left\{ \|a_{t,1}\|^2, \|a_{t,2}\|^2 \right\}$$

The features are calculated within sliding windows containing 125 samples (Luca et al., 2014a) which are randomly subsampled to obtain sets $S = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$ of fixed length $k = 20$ containing data instances $\mathbf{x}_i = (f_1, f_2, f_3) \in \mathbb{R}^3$ on which the EVT algorithm for sequence classification can be applied.

The data are highly unbalanced as may be seen in Table 1. Only three patient recordings contain more than 3 examples of seizures. For these patients, an OCSVM and HMM were trained in a 5-fold cross-validation experiment where in each fold the seizures are randomly split between validation and test sets to optimize the following cost-function (Cuppens et al., 2013):

$$C(\boldsymbol{\lambda}) = 2 \cdot SS(\boldsymbol{\lambda}) + PPV(\boldsymbol{\lambda})$$

with respect to the hyper-parameters $\boldsymbol{\lambda}$ of the model. Here, the weight of the sensitivity (SS) is higher than the weight of the positive predictive value (PPV), because missing a

seizure is more costly than generating a false-positive classification for this type of seizure. Tables 2(a) and 2(b) show the mean performance scores calculated over the different test sets in the runs for three patients of which more than 3 examples of seizures were available for the training of these models. As there are at most 3 seizures present for the remaining patients, at most two seizures could be used in the validation set when training the HMMs and OCSVMs. In this way at most one of the seizures could be held out and detected by the algorithms during the different cross-validation experiments.

Table 2(c) shows performance scores related to the EVT approach. In contrast to the OCSVM and HMM, performance scores could easily be obtained for all patients without the need for optimization using validation data. As hypermotor seizures are marked by strong and uncontrolled movements, the use of EVT is very suitable in this application to recognize this type of ‘extremity’ from the class of normal movement events. In contrast to an OCSVM our EVT-based method was able to improve PPV values in patients 2 and 6 (averaged over the folds, a decrease of 3 false alarms while testing 50 normal movements was obtained) while the SS scores remained 100%. The OCSVM was able to outperform the EVT method for patient 5. This is mainly due to (i) the seizures for this patient are less extreme than in the rest of the data (Cuppens et al., 2013); (ii) a sufficient amount of seizures is present giving the OCSVM the ability to perform a thorough optimization of the hyperparameters during the training phase. A HMM was not able to detect all seizures and obtained better PPV values compared to our EVT-based method.

5. Conclusion

This article focuses on the problem of novelty detection, where data instances from the normal class are abundant but where examples from the abnormal class are sparse. In particular a new approach is introduced that is based on the use of EVT and which is particularly well-suited to detecting outliers that present ‘extreme’ behaviour with respect to a statistical model X . It is shown how EVT can be adapted to define a model over

regions where data are sparse (or even unavailable) circumventing the need for optimization of hyperparameters as otherwise occurs when using conventional OCSVMs or HMMs. This leads to a more robust and exact estimation of the support of X when abnormal data are limited in availability.

One of the main challenges in novelty detection is to improve the PPV. Indeed, when classes are highly unbalanced, an unusually high accuracy is required to overcome a high false-alarm rate. Therefore rich models that combine several types of information in a natural way are needed to increase the PPV of a novelty detector. An estimation procedure from EVT is proposed that encodes the three different types of EVT-based information for a sequence S . Given a threshold u and an estimation $y = \hat{p}(\mathbf{x})$ of the density of X , the following types of information were fused: (i) the maximal exceedance of $-\log p(S)$ above u ; (ii) the mean exceedance of $-\log p(S)$ above u ; and (iii) the number of exceedances of $-\log p(S)$ above u .

We have demonstrated the use of this method on both artificial data and a real-world set of acceleration data collected from movements of patients that suffer from epilepsy. By applying the proposed method, it was shown that SS scores and PPV scores could be improved compared to the use of conventional HMMs and OCSVMs, especially when examples from the abnormal class are sparse.

Acknowledgments

Special thanks go to Peter Karsmakers for the fruitful discussions concerning the validation steps and preprocessing study of the epileptic seizure data. This data set is collected in collaboration with the Pulderbos rehabilitation Center for Children and Youth in Zandhoven (Pulderbos), Belgium and the assistance of Bertien Ceulemans, Lieven Lagae, Anouk Van de Vel and Sabine Van Huffel in the framework of an IWT TBM project 100404. The authors would also like to acknowledge networking support by the ICT COST action IC1303 (AAPLE). David A. Clifton is funded by the Royal Academy of Engineering and an EPSRC Healthcare Technologies Challenge Award.

Appendix A. Proofs

In this appendix we prove the results obtained in Section 3.

A.1 Proof of Theorem 1

Proof In terms of the normalized sequence of random variables $\frac{Z-c_i}{d_i}$, it can be shown that (11) is equivalent to:

$$\lim_{i \rightarrow +\infty} P \left(\frac{Z - c_i}{d_i} < u + x \mid \frac{Z - c_i}{d_i} > u \right) = 1 - e^{-x} \quad (21)$$

with $u \in \mathbb{R}$ and $x \geq 0$ (Falk et al., 2011, p.21). The statements (i)-(iii) can now be proven as follows.

(i) This result follows by applying the link between the limiting properties (2), (4) and (7)

on the transformed variable $Z = -\log(p(X))$ as discussed in Sections 2.2 and 2.3. The exceedance rate of the PPP can be found by calculating the limit:

$$\begin{aligned} \lim_{k \rightarrow +\infty} kP(Z \geq c_k + d_k u) &= \lim_{k \rightarrow +\infty} \frac{P(Z \geq c_k + d_k u)}{P(Z > c_k)}, \quad \text{as } P(Z \leq c_k) = 1 - \frac{1}{k} \\ &= \lim_{k \rightarrow +\infty} P(Z \geq c_k + d_k u | Z > c_k) \\ &= \lim_{k \rightarrow +\infty} P \left(\frac{Z - c_k}{a(c_k)} \geq u | Z > c_k \right), \quad \text{as } d_k = a(c_k) \\ &= \lim_{w \rightarrow +\infty} P \left(\frac{Z - w}{a(w)} \geq u | Z > w \right), \quad \text{as } \lim_{k \rightarrow +\infty} c_k = +\infty \\ &= e^{-u} \end{aligned}$$

(ii) The limiting distribution of the maximal exceedance M_k conditioned on the number of exceedances $N_k \geq 1$ is obtained as:

$$\begin{aligned} \lim_{k \rightarrow +\infty} P \left(\frac{M_k}{d_k} \leq m | N_k = l \right) &= \lim_{k \rightarrow +\infty} P \left(\frac{Z - u_k}{d_k} \leq m \mid Z > u_k \right)^l \\ &= \lim_{k \rightarrow +\infty} P \left(\frac{Z - c_k}{d_k} - u \leq m \mid \frac{Z - c_k}{d_k} > u \right)^l \\ &= (1 - e^{-m})^l. \end{aligned} \quad (22)$$

where we used (21). The distribution of M_k is found by marginalization over the number of excesses $1 \leq l \leq k$ conditioned on $N_k \geq 1$. From (i) one finds:

$$\begin{aligned} \lim_{k \rightarrow +\infty} P \left(\frac{M_k}{d_k} \leq m | N_k \geq 1 \right) &= \lim_{k \rightarrow +\infty} \sum_{l=1}^k P \left(\frac{M_k}{d_k} \leq m | N_k = l \right) P(N_k = l | N_k \geq 1) \\ &= \frac{1}{1 - e^{-\lambda}} \sum_{l=1}^{+\infty} (1 - e^{-m})^l \left(\frac{\lambda^l}{l!} e^{-\lambda} \right) \end{aligned}$$

Further simplification leads to:

$$\begin{aligned} \lim_{k \rightarrow +\infty} P \left(\frac{M_k}{d_k} \leq m | N_k \geq 1 \right) &= \frac{e^{-\lambda}}{1 - e^{-\lambda}} \sum_{l=1}^{+\infty} \frac{(\lambda(1 - e^{-m}))^l}{l!} \\ &= \frac{e^{-\lambda}}{1 - e^{-\lambda}} \left[\exp \left\{ \lambda - \lambda e^{-m} \right\} - 1 \right] \\ &= \frac{\exp \left\{ -\exp \left[-(m - \ln \lambda) \right] \right\} - e^{-\lambda}}{1 - e^{-\lambda}} \end{aligned}$$

which is the cumulative distribution function of a Gumbel member of the family (3) located at $\mu = \ln \lambda$ and conditioned on the positive real line.

(iii) From (21) it follows that the excesses $\frac{Z - c_i}{d_i} - u$ converge in distribution to an exponential distribution as $i \rightarrow +\infty$. Therefore, from the continuous mapping theorem (stating that

convergence is preserved by continuous transformation (Embrechts et al., 1997, p. 561), the mean of n such independent excesses converges to the distribution of a mean of n independent variables that are distributed according to an exponential distribution. Thus the limiting distribution conditioned on $N_k = l \geq 1$ is given by an Erlang distribution with shape-parameter l and rate parameter l (Feller, 1971, p. 11) with a cumulative distribution function:

$$\lim_{k \rightarrow +\infty} P\left(\frac{V_k}{d_k} \leq v \mid N_k = l\right) = 1 - \sum_{j=0}^{l-1} \frac{1}{j!} (lv)^j e^{-lv}$$

Marginalisation over the number of exceedances leads to:

$$\begin{aligned} \lim_{k \rightarrow +\infty} P\left(\frac{V_k}{d_k} \leq v \mid N_k \geq 1\right) &= \lim_{k \rightarrow +\infty} \sum_{l=1}^k P\left(\frac{V_k}{d_k} \leq v \mid N_k = l\right) P(N_k = l \mid N_k \geq 1) \\ &= \sum_{l=1}^{+\infty} \left(1 - \sum_{j=0}^{l-1} \frac{1}{j!} (lv)^j e^{-lv}\right) \left(\frac{\lambda^l e^{-\lambda}}{l! 1 - e^{-\lambda}}\right) \\ &= \frac{1}{e^{\lambda} - 1} \left((e^{\lambda} - 1) - \sum_{l=1}^{+\infty} \sum_{j=0}^{l-1} \frac{\lambda^l}{l! j!} (lv)^j e^{-lv} \right) \\ &= 1 - \frac{1}{e^{\lambda} - 1} \left(\sum_{l=1}^{+\infty} \sum_{j=0}^{l-1} \frac{\lambda^l}{l! j!} (lv)^j e^{-lv} \right) \end{aligned}$$

■

A.2 Proof of Theorem 2

Proof Convergence in distribution is expressed in terms of the joint (cumulative) distribution of the features V_k, M_k and N_k conditioned on $N_k \geq 1$:

$$F_k(v, m, n) = P\left(\frac{V_k}{d_k} \leq v, \frac{M_k}{d_k} \leq m, N_k \leq n \mid N_k \geq 1\right). \quad (23)$$

Clearly, the mean v of a sequence of n positive numbers is situated between $\frac{m}{n}$ and m such that the support of F_k is situated in $D = \{(v, m, n) \mid \frac{m}{n} \leq v \leq m\}$. The conditioned joint distribution (23) can be written as:

$$\begin{aligned} F_k(v, m, n) &= \sum_{l=1}^n \frac{P\left(\frac{V_k}{d_k} \leq v, \frac{M_k}{d_k} \leq m, N_k = l\right)}{1 - P(N_k = 0)} \\ &= \sum_{l=1}^n \frac{P\left(\frac{V_k}{d_k} \leq v \mid \frac{M_k}{d_k} \leq m, N_k = l\right) P\left(\frac{M_k}{d_k} \leq m \mid N_k = l\right) P(N_k = l)}{1 - P(N_k = 0)} \end{aligned} \quad (24)$$

The limiting distribution of (23) can be obtained by considering the limit of each factor in the nominators of the terms in (24) as $k \rightarrow +\infty$. Firstly, from Theorem 1-(i), it follows

$$\text{that:} \quad \lim_{k \rightarrow +\infty} P(N_k = l) = \frac{\lambda e^{-\lambda}}{l!}, \quad \lambda = e^{-u}. \quad (25)$$

Secondly, the limiting distribution of $P\left(\frac{M_k}{d_k} \leq m \mid N_k = l\right)$ is given by (22). Thirdly, the distribution $P\left(\frac{V_k}{d_k} \leq v \mid \frac{M_k}{d_k} \leq m, N_k = l\right)$ corresponds to the distribution of the mean of l independent exceedances that each converge in distribution to an exponential distribution truncated at m :

$$\begin{aligned} \lim_{k \rightarrow +\infty} P\left(\frac{Z - u_k}{d_k} \leq v \mid \frac{Z - u_k}{d_k} \leq m\right) &= \lim_{k \rightarrow +\infty} P\left(\frac{Z - c_k}{d_k} - u \leq v \mid \frac{Z - c_k}{d_k} - u \leq m\right) \\ &= \frac{1 - e^{-v}}{1 - e^{-m}}. \end{aligned}$$

Therefore, according to the continuous mapping theorem (Embrechts et al., 1997), the distribution of V_k converge in distribution to the sum of l truncated exponential distributions such that (Bain and Weeks, 1964):

$$\lim_{k \rightarrow +\infty} P\left(\frac{V_k}{d_k} \leq v \mid \frac{M_k}{d_k} \leq m, N_k = l\right) = \frac{1}{(1 - e^{-m})^l} \sum_{i=0}^r (-1)^i \binom{l}{i} e^{-im} \chi_{2i} (2(lv - im))$$

for $r = \lfloor \frac{lv}{m} \rfloor$. Substituting the latter expression together with (22) and (25) in the factorisation (24) gives the desired result. ■

Abstract

The article examines in some detail the convergence rate and mean-square-error performance of momentum stochastic gradient methods in the constant step-size and slow adaptation regime. The results establish that momentum methods are equivalent to the standard stochastic gradient method with a re-scaled (larger) step-size value. The size of the re-scaling is determined by the value of the momentum parameter. The equivalence result is established for all time instants and not only in steady-state. The analysis is carried out for general strongly convex and smooth risk functions, and is not limited to quadratic risks. One notable conclusion is that the well-known benefits of momentum constructions for deterministic optimization problems do not necessarily carry over to the adaptive online setting when small constant step-sizes are used to enable continuous adaptation and learning in the presence of persistent gradient noise. From simulations, the equivalence between momentum and standard stochastic gradient methods is also observed for non-differentiable and non-convex problems.

1. Introduction

Stochastic optimization focuses on the problem of optimizing the expectation of a loss function, written as

$$\min_{w \in \mathbb{R}^M} J(w) \triangleq \mathbb{E}_{\theta} [Q(w; \theta)], \quad (1)$$

where θ is a random variable whose distribution is generally unknown and $J(w)$ is a convex function (usually strongly-convex due to regularization). If the probability distribution of the data, θ , is known beforehand, then one can evaluate $J(w)$ and seek its minimizer by means of a variety of gradient-descent or Newton-type methods (Polyak, 1987; Bertsekas, 1999; Nesterov, 2004). We refer to these types of problems, where $J(w)$ is known, as *deterministic* optimization problems. On the other hand, when the probability distribution of the data is unknown, then the risk function $J(w)$ is unknown as well; only instances

of the loss function, $Q(w; \theta)$, may be available at various observations θ_i , where i refers to the sample index. We refer to these types of problems, where $J(w)$ is unknown but defined implicitly as the expectation of some known loss form, as *stochastic* optimization problems. This article deals with this second type of problems, which are prevalent in online adaptation and learning contexts (Widrow and Stearns, 1985; Haykin, 2008; Sayed, 2008; Theodoridis, 2015).

When $J(w)$ is differentiable, one of the most popular techniques to seek minimizers for (1) is to employ the *stochastic* gradient method. This algorithm is based on employing instantaneous approximations for the true (unavailable) gradient vectors, $\nabla_w J(w)$, by using the gradients of the loss function, $\nabla_w Q(w; \theta_i)$, evaluated at successive samples of the streaming data θ_i over the iteration index i , say, as:

$$w_i = w_{i-1} - \mu \nabla_w Q(w_{i-1}; \theta_i), \quad i \geq 0. \quad (2)$$

where $\mu > 0$ is a step-size parameter. Note that we are denoting the successive iterates by w_i and using the boldface notation to refer to the fact that they are random quantities in view of the randomness in the measurements $\{\theta_i\}$. Due to their simplicity, robustness to noise and uncertainty, and scalability to big data, such stochastic gradient methods have become popular in large-scale optimization, machine learning, and data mining applications (Zhang, 2004; Bottou, 2010; Gemulla et al., 2011; Sutskever et al., 2013; Kahou et al., 2013; Cevher et al., 2014; Szegedy et al., 2015; Zareba et al., 2015).

1.1 Convergence Rate

Stochastic-gradient algorithms can be implemented with decaying step-sizes, such as $\mu(i) = \tau/i$ for some constant τ , or with constant step-sizes, $\mu > 0$. The former generally ensure asymptotic convergence to the true minimizer of (1), denoted by w^o , at a convergence rate that is on the order of $O(1/i)$ for strongly-convex risk functions. This guarantee, however, comes at the expense of turning off adaptation and learning as time progresses since the step-size value approaches zero in the limit, as $i \rightarrow \infty$. As a result, the algorithm loses the ability to track concept drifts. In comparison, constant step-sizes keep adaptation and learning alive and infuse a desirable tracking mechanism into the operation of the algorithm: even if the minimizers drift with time, the algorithm will generally be able to adjust and track their locations. Moreover, convergence can now occur at the considerably faster exponential rate, $O(\alpha^i)$, for some $\alpha \in (0, 1)$. These favorable properties come at the expense of a small deterioration in the limiting accuracy of the iterates since almost-sure convergence is not guaranteed any longer. Instead, the algorithm converges in the mean-square-error sense towards a small neighborhood around the true minimizer, w^o , whose radius is on the order of $O(\mu)$. This is still a desirable conclusion because the value of μ is controlled by the designer and can be chosen sufficiently small.

A well-known tradeoff therefore develops between convergence rate and mean-square-error (MSE) performance. The asymptotic MSE performance level approaches $O(\mu)$ while the convergence rate is given by $\alpha = 1 - O(\mu)$ (Polyak, 1987; Sayed, 2014a). It is nowadays well-recognized that the small $O(\mu)$ degradation in performance is acceptable in most large-scale learning and adaptation problems (Bousquet and Bottou, 2008; Bottou, 2010; Sayed, 2014b). This is because, in general, there are always modeling errors in formulating

optimization problems of the form (1): the cost function may not reflect perfectly the scenario and data under study. As such, insisting on attaining asymptotic convergence to the true minimizer may not be necessarily the best course of action or may not be worth the effort. It is often more advantageous to tolerate a small steady-state error that is negligible in most cases, but is nevertheless attained at a faster exponential rate of convergence than the slower rate of $O(1/n)$. Furthermore, the data models in many applications are more complex than assumed, with possibly local minima. In these cases, constant step-size implementations can help reduce the risk of being trapped at local solutions.

For these various reasons, and since our emphasis is on algorithms that are able to learn continuously, we shall focus on small *constant* step-size implementations. In these cases, gradient noise is always present, as opposed to decaying step-size implementations where the gradient noise terms get annihilated with time. The analysis in the paper will establish analytically, and illustrate by simulations, that, for sufficiently small step-sizes, any benefit from a momentum stochastic-construction can be attained by adjusting the step-size parameter for the original stochastic-gradient implementation. We emphasize here the qualification “small” for the step-size. The reason we focus on small step-sizes (which correspond to the slow adaptation regime) is because, in the stochastic context, mean-square-error stability and convergence require small step-sizes.

1.2 Acceleration Methods

In the *deterministic* optimization case, when the true gradient vectors of the smooth risk function $J(w)$ are available, the iterative algorithm for seeking the minimizer of $J(w)$ becomes the following gradient-descent recursion

$$w_i = w_{i-1} - \mu \nabla_w J(w_{i-1}), \quad i \geq 0, \quad (3)$$

There have been many ingenious methods proposed in the literature to enhance the convergence of these methods for both cases of convex and strongly-convex risks, $J(w)$. Two of the most notable and successful techniques are the heavy-ball method (Polyak, 1964, 1987; Qian, 1999) and Nesterov’s acceleration method (Nesterov, 1983, 2004, 2005) (the recursions for these algorithms are described in Section 3.1). The two methods are different but they both rely on the concept of adding a momentum term to the recursion. When the risk function $J(w)$ is ν -strongly convex and has δ -Lipschitz continuous gradients, both methods succeed in accelerating the gradient descent algorithm to attain a faster exponential convergence rate (Polyak, 1987) (Nesterov, 2004), and this rate is proven to be optimal for problems with smooth $J(w)$ and cannot be attained by standard gradient descent methods. Specifically, it is shown in (Polyak, 1987) (Nesterov, 2004) that for heavy-ball and Nesterov’s acceleration methods, the convergence of the iterates w_i towards w^o occurs at the rate:

$$\|w_i - w^o\|^2 \leq \left(\frac{\sqrt{\delta} - \sqrt{\nu}}{\sqrt{\delta} + \sqrt{\nu}} \right)^2 \|w_{i-1} - w^o\|^2, \quad (4)$$

In comparison, in Theorem 2.1.15 of (Nesterov, 2005) and Theorem 4 in Section 1.4 of (Polyak, 1987), the fastest rate for gradient descent method is shown to be

$$\|w_i - w^o\|^2 \leq \left(\frac{\delta - \nu}{\delta + \nu} \right)^2 \|w_{i-1} - w^o\|^2. \quad (5)$$

It can be verified that

$$\frac{\sqrt{\delta} - \sqrt{\nu}}{\sqrt{\delta} + \sqrt{\nu}} < \frac{\delta - \nu}{\delta + \nu} \quad (6)$$

when $\delta > \nu$. This inequality confirms that the momentum algorithm can achieve a faster rate in deterministic optimization and, moreover, this faster rate cannot be attained by standard gradient descent.

Motivated by these useful acceleration properties in the *deterministic* context, momentum terms have been subsequently introduced into *stochastic* optimization algorithms as well (Polyak, 1987; Proakis, 1974; Sharma et al., 1998; Shynk and Roy, June 1988; Roy and Shynk, 1990; Tugay and Tank, 1989; Bellanger, 2001; Wiegand et al., 1994; Hu et al., 2009; Xiao, 2010; Lan, 2012; Ghadimi and Lan, 2012; Zhong and Kwok, 2014) and applied, for example, to problems involving the tracking of chirped sinusoidal signals (Ting et al., 2000) or deep learning (Sutskever et al., 2013; Kahou et al., 2013; Szegedy et al., 2015; Zareba et al., 2015). However, the analysis in this paper will show that the advantages of the momentum technique for deterministic optimization do not necessarily carry over to the *adaptive* online setting due to the presence of stochastic gradient noise (which is the difference between the actual gradient vector and its approximation). Specifically, for sufficiently small step-sizes and for a momentum parameter not too close to one, we will show that any advantage brought forth by the momentum term can be achieved by staying with the original stochastic-gradient algorithm and adjusting its step-size to a larger value. For instance, for optimization problem (1), we will show that if the step-sizes, μ_m for the momentum (heavy-ball or Nesterov) methods and μ for the standard stochastic gradient algorithms, are sufficiently small and satisfy the relation

$$\mu = \frac{\mu_m}{1 - \beta} \quad (7)$$

where β , a positive constant that is not too close to 1, is the momentum parameter, then it will hold that

$$\mathbb{E}\|w_{m,i} - w_i\|^2 = O(\mu^{3/2}), \quad i = 0, 1, 2, \dots \quad (8)$$

where $w_{m,i}$ and w_i denote the iterates generated at time i by the momentum and standard implementations, respectively. In the special case when $J(w)$ is quadratic in w , as happens in mean-square-error design problems, we can tighten (8) to

$$\mathbb{E}\|w_{m,i} - w_i\|^2 = O(\mu^2), \quad i = 0, 1, 2, \dots \quad (9)$$

What is important to note is that, we will show that these results hold *for every i* , and not only asymptotically. Therefore, when μ is sufficiently small, property (8) establishes that the stochastic gradient method and the momentum versions are fundamentally equivalent

since their iterates evolve close to each other at all times. We establish this equivalence result under the situation where the risk function is convex and differentiable. However, as our numerical simulations over a multi-layer fully connected neural network and a second convolutional neural network (see Section 7.4) show, the equivalence between standard and momentum stochastic gradient methods are also observed in non-convex and non-differentiable scenarios.

1.3 Related Works in the Literature

There are useful results in the literature that deal with special instances of the general framework developed in this work. These earlier results focus mainly on the mean-square-error case when $J(w)$ is quadratic in w , in which case the stochastic gradient algorithm reduces to the famed least-mean-squares (LMS) algorithm. We will not be limiting our analysis to this case so that our results will be applicable to a broader class of learning problems beyond mean-square-error estimation (e.g., logistic regression would be covered by our results as well). As the analysis and derivations will reveal, the treatment of the general $J(w)$ case is demanding because the Hessian matrix of $J(w)$ is now w -dependent, whereas it is a constant matrix in the quadratic case.

Some of the earlier investigations in the literature led to the following observations. It was noted in (Polyak, 1987) that, for quadratic costs, stochastic gradient implementations with a momentum term do not necessarily perform well. This work remarks that although the heavy-ball method can lead to faster convergence in the early stages of learning, it nevertheless converges to a region with worse mean-square-error in comparison to standard stochastic-gradient (or LMS) iteration. A similar phenomenon is also observed in (Proakis, 1974; Sharma et al., 1998). However, in the works (Proakis, 1974; Polyak, 1987; Sharma et al., 1998), no claim is made or established about the equivalence between momentum and standard methods.

Heavy-ball LMS was further studied in the useful works (Roy and Shynk, 1990) and (Tugay and Tanik, 1989). The reference (Roy and Shynk, 1990) claimed that no significant gain is achieved in convergence speed if both the heavy-ball and standard LMS algorithms approach the same *steady-state* MSE performance. Reference (Tugay and Tanik, 1989) observed that when the step-sizes satisfy relation (7), then heavy-ball LMS is “equivalent” to standard LMS. However, they assumed Gaussian measurement noise in their data model, and the notion of “equivalence” in this work is only referring to the fact that the algorithms have similar starting convergence rates and similar steady-state MSE levels. There was no analysis in (Tugay and Tanik, 1989) of the behavior of the algorithms during all stages of learning – see also (Bellanger, 2001). Another useful work is (Wiegierneck et al., 1994), which considered the heavy-ball stochastic gradient method for general risk, $J(w)$. By assuming a sufficiently small step-size, and by transforming the error difference recursion into a differential equation, the work concluded that heavy-ball can be equivalent to the standard stochastic gradient method asymptotically (i.e., for i large enough). No results were provided for the earlier stages of learning.

All of these previous works were limited to examining the heavy-ball momentum technique; none of them considered other forms of acceleration such as Nesterov’s technique although this latter technique is nowadays widely applied to stochastic gradient learning,

including deep learning (Sutskever et al., 2013; Kahou et al., 2013; Szegedy et al., 2015; Zareba et al., 2015). The performance of Nesterov’s acceleration with *deterministic* and *bounded* gradient error was examined in (d’Aspremont, 2008; Devolder et al., 2014; Lessard et al., 2016). The source of the inaccuracy in the gradient vector in these works is either because the gradient was assessed by solving an auxiliary “simpler” optimization problem or because of numerical approximations. Compared to the standard gradient descent implementation, the works by (d’Aspremont, 2008; Lessard et al., 2016) claimed that Nesterov’s acceleration is not robust to the errors in gradient. The work by (Devolder et al., 2014) also observed that the superiority of Nesterov’s acceleration is no longer absolute when inexact gradients are used, and they further proved that the performance of Nesterov’s acceleration may be even worse than gradient descent due to error accumulation. These works assumed bounded errors in the gradient vectors and focused on the context of deterministic optimization. None of the works examined the stochastic setting where the gradient error is random in nature and where the assumption of bounded errors are generally unsuitable. We may add that there have also been analyses of Nesterov’s acceleration for *stochastic* optimization problems albeit for *decaying* step-sizes in more recent literature (Hu et al., 2009; Xiao, 2010; Lan, 2012; Ghadimi and Lan, 2012; Zhong and Kwok, 2014). These works proved that Nesterov’s acceleration can improve the convergence rate of stochastic gradient descent at the initial stages when deterministic risk components dominate; while at the asymptotic stages when the stochastic gradient noise dominates, the momentum correction cannot accelerate convergence any more. Another useful study is (Flammarion and Bach, 2015), in which the authors showed that momentum and averaging methods for stochastic optimization are equivalent to the same second-order difference equations but with different step-sizes. However, (Flammarion and Bach, 2015) does not study the equivalence between standard and momentum stochastic gradient methods, and they focus on quadratic problems and also employ decaying step-sizes.

Finally, we note that there are other forms of stochastic gradient algorithms for empirical risk minimization problems where momentum acceleration has been shown to be useful. Among them, we list recent algorithms like SAG (Roux et al., 2012), SVRG (Johnson and Zhang, 2013) and SAGA (Defazio et al., 2014). In these algorithms, the variance of the stochastic gradient noise diminishes to zero and the deterministic component of the risk becomes dominant in the asymptotic regime. In these situations, momentum acceleration helps improve the convergence rate, as noted by (Nitanda, 2014) and (Zhu, 2016). Another family of algorithms to solve empirical risk minimization problems are stochastic dual coordinate ascent (SDCA) algorithms. It is proved in (Shalev-Shwartz, 2015; Johnson and Zhang, 2013) that SDCA can be viewed as a variance-reduced stochastic algorithm, and hence momentum acceleration can also improve its convergence for the same reason noted by (Shalev-Shwartz and Zhang, 2014).

In this paper, we are studying online training algorithms where data can stream in continuously as opposed to running multiple passes over a finite amount of data. In this case, the analysis will help clarify the limitations of momentum acceleration in the slow adaptation regime. We are particularly interested in the constant step-size case, which enables continuous adaptation and learning and is regularly used, e.g., in deep learning implementations. There is a non-trivial difference between the decaying and constant step-size situations. This is because gradient noise is always present in the constant step-size

case, while it is annihilated in the decaying step-size case. The presence of the gradient noise interferes with the dynamics of the algorithms in a non-trivial way, which is what our analysis discovers. There are limited analyses for the constant step-sizes scenario.

1.4 Outline of Paper

The outline of the paper is as follows. In Section 2, we introduce some basic assumptions and review the stochastic gradient method and its convergence properties. In Section 3 we embed the heavy-ball and Nesterov’s acceleration methods into a unified momentum algorithm, and subsequently establish the mean-square stability and fourth-order stability of the error moments. Next, we analyze the equivalence between momentum and standard LMS algorithms in Section 4 and then extend the results to general risk functions in Section 5. In Section 6 we extend the equivalence results into a more general setting with diagonal step-size matrices. We illustrate our results in Section 7, and in Section 8 we comment on the stability ranges of standard and momentum stochastic gradient methods.

2. Stochastic Gradient Algorithms

In this section we review the stochastic gradient method and its convergence properties. We denote the minimizer for problem (1) by w^o , i.e.,

$$w^o \triangleq \arg \min_w J(w). \quad (10)$$

We introduce the following assumption on $J(w)$, which essentially amounts to assuming that $J(w)$ is strongly-convex with Lipschitz gradient. These conditions are satisfied by many problems of interest, especially when regularization is employed (e.g., mean-square-error risks, logistic risks, etc.). Under the strong-convexity condition, the minimizer w^o is unique.

Assumption 1 (Conditions on risk function) *The cost function $J(w)$ is twice differentiable and its Hessian matrix satisfies*

$$0 < \nu I_M \leq \nabla^2 J(w) \leq \delta I_M, \quad (11)$$

for some positive parameters $\nu \leq \delta$. Condition (11) is equivalent to requiring $J(w)$ to be ν -strongly convex and for its gradient vector to be δ -Lipschitz, respectively (Boyd and Vandenberghe, 2004; Sayed, 2014a). ■

The stochastic-gradient algorithm for seeking w^o takes the form (2), with initial condition w_{-1} . The difference between the true gradient vector and its approximation is designated *gradient noise* and is denoted by:

$$s_i(w_{i-1}) \triangleq \nabla_w Q(w_{i-1}; \theta_i) - \nabla_w \mathbb{E}[Q(w_{i-1}; \theta_i)]. \quad (12)$$

In order to examine the convergence of the standard and momentum stochastic gradient methods, it is necessary to introduce some assumptions on the stochastic gradient noise.

Assumptions (13) and (14) below are satisfied by important cases of interest, as shown in (Sayed, 2014a) and (Sayed, 2014b), such as logistic regression and mean-square-error risks. Let the symbol \mathcal{F}_{i-1} represent the filtration generated by the random process w_j for $j \leq i-1$ (basically, the collection of past history until time $i-1$):

$$\mathcal{F}_{i-1} \triangleq \text{filtration}\{w_{-1}, w_0, w_1, \dots, w_{i-1}\}.$$

Assumption 2 (Conditions on gradient noise) *It is assumed that the first and second-order conditional moments of the gradient noise process satisfy the following conditions for any $w \in \mathcal{F}_{i-1}$:*

$$\mathbb{E}[s_i(w) | \mathcal{F}_{i-1}] = 0 \quad (13)$$

$$\mathbb{E}[\|s_i(w)\|^2 | \mathcal{F}_{i-1}] \leq \gamma^2 \|w^o - w\|^2 + \sigma_s^2 \quad (14)$$

almost surely, for some nonnegative constants γ^2 and σ_s^2 . ■

Condition (13) essentially requires the gradient noise process to have zero mean, which amounts to requiring the approximate gradient to correspond to an unbiased construction for the true gradient. This is a reasonable requirement. Condition (14) requires the size of the gradient noise (i.e., its mean-square value) to diminish as the iterate w gets closer to the solution w^o . This is again a reasonable requirement since it amounts to expecting the gradient noise to get reduced as the algorithm approaches the minimizer. Under Assumptions 1 and 2, the following conclusion is proven in Lemma 3.1 of (Sayed, 2014a).

Lemma 1 (Second-order stability) *Let Assumptions 1 and 2 hold, and consider the stochastic gradient recursion (2). Introduce the error vector $\tilde{w}_i = w^o - w_i$. Then, for any step-sizes μ satisfying*

$$\mu < \frac{2\nu}{\delta^2 + \gamma^2}, \quad (15)$$

it holds for each iteration $i = 0, 1, 2, \dots$ that

$$\mathbb{E}\|\tilde{w}_i\|^2 \leq (1 - \mu\nu)\mathbb{E}\|\tilde{w}_{i-1}\|^2 + \mu^2\sigma_s^2, \quad (16)$$

and, furthermore,

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{w}_i\|^2 \leq \frac{\sigma_s^2 \mu}{\nu} = O(\mu). \quad (17)$$

■

We can also examine the stability of the fourth-order error moment, $\mathbb{E}\|\tilde{w}_i\|^4$, which will be used later in Section 5 to establish the equivalence between the standard and momentum stochastic implementations. For this case, we tighten the assumption on the gradient noise by replacing the bound in (14) on its second-order moment by a similar bound involving its fourth-order moment. Again, this assumption is satisfied by problems of interest, such as mean-square-error and logistic risks (Sayed, 2014a,b).

Assumption 3 (Conditions on gradient noise) *It is assumed that the first and fourth-order conditional moments of the gradient noise process satisfy the following conditions for any $\mathbf{w} \in \mathcal{F}_{i-1}$:*

$$\mathbb{E}[\mathbf{s}_i(\mathbf{w}) | \mathcal{F}_{i-1}] = 0 \quad (18)$$

$$\mathbb{E}[\|\mathbf{s}_i(\mathbf{w})\|^4 | \mathcal{F}_{i-1}] \leq \gamma_4^4 \|\mathbf{w}^o - \mathbf{w}\|^4 + \sigma_{s,4}^4 \quad (19)$$

■ *almost surely, for some nonnegative constants γ_4^4 and $\sigma_{s,4}^4$.*

It is straightforward to check that if Assumption 3 holds, then Assumption 2 will also hold. The following conclusion is a modified version of Lemma 3.2 of (Sayed, 2014a).

Lemma 2 (Fourth-order stability) *Let the conditions under Assumptions 1 and 3 hold, and consider the stochastic gradient iteration (2). For sufficiently small step-size μ , it holds that*

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 \leq \rho^{i+1} \mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 + A\sigma_s^2(i+1)\rho^{i+1}\mu^2 + \frac{B\sigma_s^4\mu^2}{\nu^2} \quad (20)$$

where $\rho \triangleq 1 - \mu\nu$, and A and B are some constants. Furthermore,

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 \leq \frac{B\sigma_s^4\mu^2}{\nu^2} = O(\mu^2) \quad (21)$$

■ **Proof** See Appendix A.

3. Momentum Acceleration

In this section, we present a generalized momentum stochastic gradient method, which captures both the heavy-ball and Nesterov's acceleration methods as special cases. Subsequently, we derive results for its convergence property.

3.1 Momentum Stochastic Gradient Method

Consider the following general form of a stochastic-gradient implementation, with two momentum parameters $\beta_1, \beta_2 \in [0, 1)$:

$$\psi_{i-1} = \mathbf{w}_{i-1} + \beta_1(\mathbf{w}_{i-1} - \mathbf{w}_{i-2}), \quad (22)$$

$$\mathbf{w}_i = \psi_{i-1} - \mu_m \nabla_w Q(\psi_{i-1}; \boldsymbol{\theta}_i) + \beta_2(\psi_{i-1} - \psi_{i-2}), \quad (23)$$

with initial conditions

$$\mathbf{w}_{-2} = \psi_{-2} = \text{initial states}, \quad (24)$$

$$\mathbf{w}_{-1} = \mathbf{w}_{-2} - \mu_m \nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1}), \quad (25)$$

where μ_m is some constant step-size. We refer to this formulation as the momentum stochastic gradient method.¹

When $\beta_1 = 0$ and $\beta_2 = \beta$ we recover the heavy-ball algorithm (Polyak, 1964, 1987), and when $\beta_2 = 0$ and $\beta_1 = \beta$, we recover Nesterov's algorithm (Nesterov, 2004). We note that Nesterov's method has several useful variations that fit different scenarios, such as situations involving smooth but not strongly-convex risks (Nesterov, 1983, 2004) or non-smooth risks (Nesterov, 2005; Beck and Teboulle, 2009). However, for the case when $J(w)$ is strongly convex and has Lipschitz continuous gradients, the Nesterov construction reduces to what is presented above, with a constant momentum parameter. This type of construction has also been studied in (Lessard et al., 2016; Dieuleveut et al., 2016) and applied in deep learning implementations (Sutskever et al., 2013; Kahou et al., 2013; Szegedy et al., 2015; Zareba et al., 2015).

In order to capture both the heavy-ball and Nesterov's acceleration methods in a unified treatment, we will assume that

$$\beta_1 + \beta_2 = \beta, \quad \beta_1, \beta_2 = 0, \quad (26)$$

for some fixed constant $\beta \in [0, 1)$. Next we introduce a condition on the momentum parameter.

Assumption 4 *The momentum parameter β is a constant that is not too close to 1, i.e., there exists a small fixed constant $\epsilon > 0$ such that $\beta \leq 1 - \epsilon$.* ■

Assumption 4 is quite common in studies on adaptive signal processing and neural networks — see, e.g., (Tugay and Tanik, 1989; Roy and Slynn, 1990; Bellanger, 2001; Wiegierinck et al., 1994; Attoh-Okine, 1999). Also, in recent deep learning applications it is common to set $\beta = 0.9$, which satisfies Assumption 4 (Krizhevsky et al., 2012; Szegedy et al., 2015; Zhang and LeCun, 2015). Under (26), the work (Flammario and Bach, 2015) also considers recursions related to (22)–(23) for the special case of quadratic risks.

3.2 Mean-Square Error Stability

In preparation for studying the performance of the momentum stochastic gradient method, we first show in the next result how recursions (22)–(23) can be transformed into a first-order recursion by defining extended state vectors. We introduce the transformation matrices:

$$V = \begin{bmatrix} I_M & -\beta I_M \\ I_M & -I_M \end{bmatrix}, \quad V^{-1} = \frac{1}{1-\beta} \begin{bmatrix} I_M & -\beta I_M \\ I_M & -I_M \end{bmatrix}. \quad (27)$$

Recall $\tilde{\mathbf{w}}_i = \mathbf{w}^o - \mathbf{w}_i$ and define the transformed error vectors, each of size $2M \times 1$:

$$\begin{bmatrix} \hat{\tilde{\mathbf{w}}}_i \\ \check{\tilde{\mathbf{w}}}_i \end{bmatrix} \triangleq V^{-1} \begin{bmatrix} \tilde{\mathbf{w}}_i \\ \tilde{\mathbf{w}}_{i-1} \end{bmatrix} = \frac{1}{1-\beta} \begin{bmatrix} \tilde{\mathbf{w}}_i - \beta \tilde{\mathbf{w}}_{i-1} \\ \tilde{\mathbf{w}}_i - \tilde{\mathbf{w}}_{i-1} \end{bmatrix}. \quad (28)$$

¹ Traditionally, the terminology of a ‘‘momentum method’’ has been used more frequently for the heavy-ball method, which corresponds to the special case $\beta_1 = 0$ and $\beta_2 = \beta$. Given the unified description (22)–(23), we will use this same terminology to refer to both the heavy-ball and Nesterov's acceleration methods.

Lemma 3 (Extended recursion) Under Assumption 1 and condition (26), the momentum stochastic gradient recursion (22)–(23) can be transformed into the following extended recursion:

$$\begin{bmatrix} \widehat{\mathbf{w}}_i \\ \widetilde{\mathbf{w}}_i \end{bmatrix} = \begin{bmatrix} I_M - \frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} & \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \\ -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} & \beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \end{bmatrix} \begin{bmatrix} \widehat{\mathbf{w}}_{i-1} \\ \widetilde{\mathbf{w}}_{i-1} \end{bmatrix} + \frac{\mu_m}{1-\beta} \begin{bmatrix} \mathbf{s}_i(\psi_{i-1}) \\ \mathbf{s}_i(\psi_{i-1}) \end{bmatrix}, \quad (29)$$

where $\mathbf{s}_i(\psi_{i-1})$ is defined according to (12) and

$$\beta' \triangleq \beta \beta_1 + \beta_2, \quad (30)$$

$$\mathbf{H}_{i-1} \triangleq \int_0^1 \nabla_w^2 J(w^\circ - t\widetilde{\psi}_{i-1}) dt, \quad (31)$$

where $\widetilde{\psi}_{i-1} = w^\circ - \psi_{i-1}$.

Proof See Appendix B. \blacksquare

The transformed recursion (29) is important for at least two reasons. First, it is a first-order recursion, which facilitates the convergence analysis of $\widehat{\mathbf{w}}_i$ and $\widetilde{\mathbf{w}}_i$ and, subsequently, of the error vector $\widehat{\mathbf{w}}_i$ in view of (28) — see next theorem. Second, as we will explain later, the first row of (29) turns out to be closely related to the standard stochastic gradient iteration; this relation will play a critical role in establishing the claimed equivalence between momentum and standard stochastic gradient methods.

The following statement establishes the convergence property of the momentum stochastic gradient algorithm. It shows that recursions (22)–(23) converge exponentially fast to a small neighborhood around w° with a steady-state error variance that is on the order of $O(\mu_m)$. Note that in the following theorem the notation $a \preceq b$, for two vectors a and b , signifies element-wise comparisons.

Theorem 4 (Mean-square stability) Let Assumptions 1, 2 and 4 hold and recall conditions (26). Consider the momentum stochastic gradient method (22)–(23) and the extended recursion (29). Then, when step-sizes μ_m satisfies

$$\mu_m \leq \frac{(1-\beta)^2 \nu}{32\gamma^2 \nu^2 + 4\delta^2}, \quad (32)$$

it holds that the mean-square values of the transformed error vectors evolve according to the following recursive inequality:

$$\begin{bmatrix} \mathbb{E}\|\widehat{\mathbf{w}}_i\|^2 \\ \mathbb{E}\|\widetilde{\mathbf{w}}_i\|^2 \end{bmatrix} \preceq \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} \mathbb{E}\|\widehat{\mathbf{w}}_{i-1}\|^2 \\ \mathbb{E}\|\widetilde{\mathbf{w}}_{i-1}\|^2 \end{bmatrix} + \begin{bmatrix} e \\ f \end{bmatrix}, \quad (33)$$

where

$$\begin{aligned} a &= 1 - \frac{\mu_m \nu}{1-\beta} + O(\mu_m^2), & b &= \frac{\mu_m \beta^2 \delta^2}{\nu(1-\beta)} + O(\mu_m^2), & c &= \frac{2\mu_m^2 \delta^2}{(1-\beta)^3} + \frac{2\mu_m^2 \gamma^2 (1+\beta_1)^2 \nu^2}{(1-\beta)^2}, \\ d &= \beta + O(\mu_m^2), & e &= \frac{\mu_m^2 \sigma_s^2}{(1-\beta)^2}, & f &= \frac{\mu_m^2 \sigma_s^2}{(1-\beta)^2}. \end{aligned} \quad (34)$$

and the coefficient matrix appearing in (33) is stable, namely,

$$\rho \left(\begin{bmatrix} a & b \\ c & d \end{bmatrix} \right) < 1. \quad (35)$$

Furthermore, if μ_m is sufficiently small it follows from (33) that

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\widehat{\mathbf{w}}_i\|^2 = O\left(\frac{\mu_m \sigma_s^2}{(1-\beta)^\nu}\right), \quad \limsup_{i \rightarrow \infty} \mathbb{E}\|\widetilde{\mathbf{w}}_i\|^2 = O\left(\frac{\mu_m^2 \sigma_s^2}{(1-\beta)^3}\right), \quad (36)$$

and, consequently,

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\widetilde{\mathbf{w}}_i\|^2 = O\left(\frac{\mu_m \sigma_s^2}{(1-\beta)^\nu}\right). \quad (37)$$

Proof See Appendix C. \blacksquare

Although $\mathbb{E}\|\mathbf{w}_i\|^2 = O(\mu_m^2)$ in result (36) is shown to hold asymptotically in the statement of the theorem, it can actually be strengthened and shown to hold for *all* time instants. This fact is crucial for our later proof of the equivalence between standard and momentum stochastic gradient methods.

Corollary 5 (Uniform mean-square bound) Under the same conditions as Theorem 4, it holds for sufficiently small step-sizes that

$$\mathbb{E}\|\mathbf{w}_i\|^2 = O\left(\frac{(\delta^2 + \gamma^2)\rho^{i+1}\mu_m^2}{(1-\beta)^4} + \frac{\sigma_s^2 \mu_m^2}{(1-\beta)^3}\right), \quad \forall i = 0, 1, 2, \dots \quad (38)$$

where $\rho_1 \triangleq 1 - \frac{\mu_m \nu}{2(1-\beta)}$, and $\widetilde{\mathbf{w}}_i$ is defined in (29).

Proof See Appendix D. \blacksquare

Corollary 5 has two implications. First, since $\beta, \delta, \gamma, \sigma_s^2$ are all constants, and $\rho_1 < 1, \alpha < 1$, we conclude that

$$\mathbb{E}\|\widetilde{\mathbf{w}}_i\|^2 = O(\mu_m^2), \quad \forall i = 0, 1, 2, \dots \quad (39)$$

Besides, since $\rho_1^i \rightarrow 0$ as $i \rightarrow \infty$, according to (38) we also achieve

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\mathbf{w}_i\|^2 = O\left(\frac{\sigma_s^2 \mu_m^2}{(1-\beta)^3}\right), \quad (40)$$

which is consistent with (36).

3.3 Stability of Fourth-Order Error Moment

In a manner similar to the treatment in Section 2, we can also establish the convergence of the fourth-order moments of the error vectors, $\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4$ and $\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4$.

Theorem 6 (Fourth-order stability) *Let Assumptions 1, 3 and 4 hold and recall conditions (26). Then, for sufficiently small step-sizes μ_m , it holds that*

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O(\mu_m^2), \quad (41)$$

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O(\mu_m^4), \quad (42)$$

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O(\mu_m^2). \quad (43)$$

■ **Proof** See Appendix E.

Again, result (42) is only shown to hold asymptotically in the statement of the theorem. In fact, $\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4$ can also be shown to be bounded for all time instants, as the following corollary states.

Corollary 7 (Uniform forth-moment bound) *Under the same conditions as Theorem 6, it holds for sufficiently small step-sizes that*

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O\left(\frac{\gamma^2 \rho_2^{i+1}}{(1-\beta)^3 \mu_m} + \left[\frac{\sigma_s^2(\delta^2 + \gamma^2)(i+1)\rho_2^{i+1}}{(1-\beta)^7} + \frac{(\gamma^2 + \nu^2)\sigma_s^4 + \nu^2\sigma_{s,4}^4}{(1-\beta)^6 \nu^2} \mu_m^4\right]\right) \quad (44)$$

where $\rho_2 \triangleq 1 - \frac{\mu_m \nu}{4(1-\beta)} \in (0, 1)$.

■ **Proof** See Appendix F.

Corollary 7 also has two implications. First, since β , δ , γ , σ_s and $\sigma_{s,4}$ are constants, we conclude that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O(\mu_m^2), \quad \forall i = 0, 1, 2, \dots \quad (45)$$

Besides, since $\rho_2^i \rightarrow 0$ and $i\rho_2^i \rightarrow 0$ as $i \rightarrow \infty$, we will achieve the following fact according to (44)

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O\left(\frac{(\gamma^2 + \nu^2)\sigma_s^4 + \nu^2\sigma_{s,4}^4}{(1-\beta)^6 \nu^2} \mu_m^4\right) = O(\mu_m^4), \quad (46)$$

which is consistent with (42).

4. Equivalence in the Quadratic Case

In Section 3 we showed the momentum stochastic gradient algorithm (22)–(23) converges exponentially for sufficiently small step-sizes. But some important questions remain. Does the

momentum implementation converge faster than the standard stochastic gradient method (2)? Does the momentum implementation lead to superior steady-state mean-square-deviation (MSD) performance, measured in terms of the limiting value of $\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2$? Is the momentum method generally superior to the standard method when considering both the convergence rate and MSD performance? In this and the next sections, we answer these questions in some detail. Before treating the case of general risk functions, $J(w)$, we examine first the special case when $J(w)$ is quadratic in w to illustrate the main conclusions that will follow.

4.1 Quadratic Risks

We consider mean-square-error risks of the form

$$J(w) = \frac{1}{2} \mathbb{E} \left(\mathbf{d}(i) - \mathbf{u}_i^\top w \right)^2, \quad (47)$$

where $\mathbf{d}(i)$ denotes a streaming sequence of zero-mean random variables with variance $\sigma_d^2 = \mathbb{E} \mathbf{d}^2(i)$, and $\mathbf{u}_i \in \mathbb{R}^M$ denotes a streaming sequence of independent zero-mean random vectors with covariance matrix $R_{u_i} = \mathbb{E} \mathbf{u}_i \mathbf{u}_i^\top > 0$. The cross covariance vector between $\mathbf{d}(i)$ and \mathbf{u}_i is denoted by $r_{du} = \mathbb{E} \mathbf{d}(i) \mathbf{u}_i$. The data $\{\mathbf{d}(i), \mathbf{u}_i\}$ are assumed to be wide-sense stationary and related via a linear regression model of the form:

$$\mathbf{d}(i) = \mathbf{u}_i^\top w^o + \mathbf{v}(i), \quad (48)$$

for some unknown w^o , and where $\mathbf{v}(i)$ is a zero-mean white noise process with power $\sigma_v^2 = \mathbb{E} \mathbf{v}^2(i)$ and assumed independent of \mathbf{u}_j for all i, j . If we multiply (48) by \mathbf{u}_i from the left and take expectations, we find that the model parameter w^o satisfies the normal equations $R_u w^o = r_{du}$. The unique solution that minimizes (47) also satisfies these same equations. Therefore, minimizing the quadratic risk (47) enables us to recover the desired w^o . This observation explains why mean-square-error costs are popular in the context of regression models.

4.2 Adaptation Methods

For the least-mean-squares problem (47), the true gradient vector at any location \mathbf{w} is

$$\nabla_w J(\mathbf{w}) = R_u \mathbf{w} - r_{du} = -R_u(w^o - \mathbf{w}), \quad (49)$$

while the approximate gradient vector constructed from an instantaneous sample realization is:

$$\nabla_w Q(\mathbf{w}; \mathbf{d}(i), \mathbf{u}_i) = -\mathbf{u}_i (\mathbf{d}(i) - \mathbf{u}_i^\top \mathbf{w}). \quad (50)$$

Here the loss function is defined by

$$Q(\mathbf{w}; \mathbf{d}(i), \mathbf{u}_i) \triangleq \frac{1}{2} \mathbb{E} \left(\mathbf{d}(i) - \mathbf{u}_i^\top \mathbf{w} \right)^2 \quad (51)$$

The resulting LMS (stochastic-gradient) recursion is given by

$$\mathbf{w}_i = \mathbf{w}_{i-1} + \mu \mathbf{u}_i (\mathbf{d}(i) - \mathbf{u}_i^\top \mathbf{w}_{i-1}) \quad (52)$$

and the corresponding gradient noise process is

$$\mathbf{s}_i(\mathbf{w}) = (R_u - \mathbf{u}_i \mathbf{u}_i^\top)(w^\circ - \mathbf{w}) - \mathbf{u}_i v(i). \quad (53)$$

It can be verified that this noise process satisfies Assumption 2 — see Example 3.3 in (Sayed, 2014a). Subtracting w° from both sides of (52), and recalling that $\tilde{\mathbf{w}}_i = w^\circ - \mathbf{w}_i$, we obtain the error recursion that corresponds to the LMS implementation:

$$\tilde{\mathbf{w}}_i = (I_M - \mu R_u) \tilde{\mathbf{w}}_{i-1} + \mu \mathbf{s}_i(\mathbf{w}_{i-1}), \quad (54)$$

where μ is some constant step-size. In order to distinguish the variables for LMS from the variables for the momentum LMS version described below, we replace the notation $\{\mathbf{w}_i, \tilde{\mathbf{w}}_i\}$ for LMS by $\{\mathbf{x}_i, \tilde{\mathbf{x}}_i\}$ and keep the notation $\{\mathbf{w}_i, \tilde{\mathbf{w}}_i\}$ for momentum LMS, i.e., for the LMS implementation (54) we shall write instead

$$\tilde{\mathbf{x}}_i = (I_M - \mu R_u) \tilde{\mathbf{x}}_{i-1} + \mu \mathbf{s}_i(\mathbf{x}_{i-1}). \quad (55)$$

On the other hand, we conclude from (22)–(23) that the momentum LMS recursion will be given by:

$$\psi_{i-1} = \mathbf{w}_{i-1} + \beta_1(\mathbf{w}_{i-1} - \mathbf{w}_{i-2}), \quad (56)$$

$$\mathbf{w}_i = \psi_{i-1} + \mu_m \mathbf{u}_i (\mathbf{d}(i) - \mathbf{u}_i^\top \psi_{i-1}) + \beta_2(\psi_{i-1} - \psi_{i-2}), \quad (57)$$

Using the transformed recursion (29), we can transform the resulting relation for $\tilde{\mathbf{w}}_i$ into:

$$\begin{bmatrix} \tilde{\mathbf{w}}_i \\ \tilde{\mathbf{w}}_i \end{bmatrix} = \begin{bmatrix} I_M - \frac{\mu_m}{1-\beta} R_u & \frac{\mu_m \beta'}{1-\beta} R_u \\ -\frac{\mu_m}{1-\beta} R_u & \beta I_M + \frac{\mu_m \beta'}{1-\beta} R_u \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{w}}_{i-1} \\ \tilde{\mathbf{w}}_{i-1} \end{bmatrix} + \frac{\mu_m}{1-\beta} \begin{bmatrix} \mathbf{s}_i(\psi_{i-1}) \\ \mathbf{s}_i(\psi_{i-1}) \end{bmatrix}, \quad (58)$$

where the Hessian matrix, \mathbf{H}_{i-1} , is independent of the weight iterates and given by R_u for quadratic risks. It follows from the first row that

$$\hat{\mathbf{w}}_i = \left(I_M - \frac{\mu_m}{1-\beta} R_u \right) \hat{\mathbf{w}}_{i-1} + \frac{\mu_m \beta'}{1-\beta} R_u \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m}{1-\beta} \mathbf{s}_i(\psi_{i-1}). \quad (59)$$

Next, we assume the step-sizes $\{\mu, \mu_m\}$ and the momentum parameter are selected to satisfy

$$\mu = \frac{\mu_m}{1-\beta}. \quad (60)$$

Since $\beta \in [0, 1)$, this means that $\mu_m < \mu$. Then, recursion (59) becomes

$$\hat{\mathbf{w}}_i = (I_M - \mu R_u) \hat{\mathbf{w}}_{i-1} + \mu \beta' R_u \tilde{\mathbf{w}}_{i-1} + \mu \mathbf{s}_i(\psi_{i-1}). \quad (61)$$

Comparing (61) with the LMS recursion (55), we find that both relations are quite similar, except that the momentum recursion has an extra driving term dependent on $\tilde{\mathbf{w}}_{i-1}$. However, recall from (28) that $\tilde{\mathbf{w}}_{i-1} = (\tilde{\mathbf{w}}_{i-2} - \tilde{\mathbf{w}}_{i-1})/(1-\beta)$, which is the difference between two consecutive points generated by momentum LMS. Intuitively, it is not hard to see that $\tilde{\mathbf{w}}_{i-1}$ is in the order of $O(\mu)$, which makes $\mu \beta' R_u \tilde{\mathbf{w}}_{i-1}$ in the order of $O(\mu^2)$. When the step-size μ is very small, this $O(\mu^2)$ term can be ignored. Consequently, the above recursions for $\hat{\mathbf{w}}_i$ and $\tilde{\mathbf{x}}_i$ should evolve close to each other, which would help to prove that \mathbf{w}_i and \mathbf{x}_i will also evolve close to each other as well. This conclusion can be established formally as follows, which proves the equivalence between the momentum and standard LMS methods.

Theorem 8 (Equivalence for LMS) *Consider the LMS and momentum LMS recursions (52) and (56)–(57). Let Assumptions 1, 2 and 4 hold. Assume both algorithms start from the same initial states, namely, $\psi_{-2} = \mathbf{w}_{-2} = \mathbf{x}_{-1}$. Suppose conditions (26) holds, and that the step-sizes $\{\mu, \mu_m\}$ satisfy (60). Then, it holds for sufficiently small μ that for $\forall i = 0, 1, 2, 3, \dots$*

$$\|\mathbf{w}_i - \mathbf{x}_i\|^2 = O\left(\left[\frac{\delta^2 + \gamma^2}{(1-\beta)^2} \rho_1^{i+1} + \frac{\delta^2 \sigma_s^2}{\nu^2(1-\beta)}\right] \mu^2 + \frac{\delta^2(\delta^2 + \gamma^2)(i+1)\rho_1^{i+1}}{\nu(1-\beta)^2} \mu^3\right). \quad (62)$$

where $\rho_1 = 1 - \frac{\mu^2}{2} \in (0, 1)$.

Proof See Appendix G. ■

Similar to Corollary 5 and 7, Theorem 8 also has two implications. First, it holds that

$$\|\mathbf{w}_i - \mathbf{x}_i\|^2 = O(\mu^2), \quad \forall i = 0, 1, 2, \dots \quad (63)$$

Besides, since $\rho_1^i \rightarrow 0$ and $i\rho_1^i$ as $i \rightarrow \infty$, we also conclude

$$\limsup_{i \rightarrow \infty} \|\mathbf{w}_i - \mathbf{x}_i\|^2 = O\left(\frac{\delta^2 \sigma_s^2 \mu^2}{\nu^2(1-\beta)}\right). \quad (64)$$

Theorem 8 establishes that the standard and momentum LMS algorithms are fundamentally equivalent since their iterates evolve close to each other at all times for sufficiently small step-sizes. More interpretation of this result is discussed in Section 5.2.

5. Equivalence in the General Case

We now extend the analysis from quadratic risks to more general risks (such as logistic risks). The analysis in this case is more demanding because the Hessian matrix of $J(\mathbf{w})$ is now w -dependent, but the same equivalence conclusion will continue to hold as we proceed to show.

5.1 Equivalence in the General Case

Note from the momentum recursion (29) that

$$\hat{\mathbf{w}}_i = \left(I_M - \frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \right) \hat{\mathbf{w}}_{i-1} + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m}{1-\beta} \mathbf{s}_i(\psi_{i-1}), \quad (65)$$

where \mathbf{H}_{i-1} is defined by (31). In the quadratic case, this matrix was constant and equal to the covariance matrix, R_u . Here, however, it is time-variant and depends on the error vector, $\tilde{\psi}_{i-1}$, as well. Likewise, for the standard stochastic gradient iteration (2), we obtain that the error recursion in the general case is given by:

$$\tilde{\mathbf{x}}_i = (I_M - \mu \mathbf{R}_{i-1}) \tilde{\mathbf{x}}_{i-1} + \mu \mathbf{s}_i(\mathbf{x}_{i-1}), \quad (66)$$

where we are introducing the matrix

$$\mathbf{R}_{i-1} = \int_0^1 \nabla_w^2 J(w^\circ - \tau \tilde{\mathbf{x}}_{i-1}) d\tau \quad (67)$$

and $\tilde{\mathbf{x}}_i = w^o - \mathbf{x}_i$. Note that \mathbf{H}_{i-1} and \mathbf{R}_{i-1} are different matrices. In contrast, in the quadratic case, they are both equal to R_w .

Under the assumed condition (60) relating $\{\mu, \mu_m\}$, if we subtract (66) from (65) we obtain:

$$\begin{aligned} \hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i &= (I_M - \mu \mathbf{H}_{i-1})(\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1} \\ &\quad + \mu^\beta \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \mu \mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1}). \end{aligned} \quad (68)$$

In the quadratic case, the second term on the right-hand side is zero since $\mathbf{R}_{i-1} = \mathbf{H}_{i-1} = R_w$. It is the presence of this term that makes the analysis more demanding in the general case.

To examine how close $\hat{\mathbf{w}}_i$ gets to $\tilde{\mathbf{x}}_i$ for each iteration, we start by noting that

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &= \mathbb{E}\|(I_M - \mu \mathbf{H}_{i-1})(\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1} + \mu^\beta \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} \\ &\quad + \mu^\beta \mathbb{E}\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^2. \end{aligned} \quad (69)$$

Now, applying a similar derivation to the one used to arrive at (137) in Appendix C, and the inequality $\|a + b\|^2 \leq 2\|a\|^2 + 2\|b\|^2$, we can conclude from (69) that

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq (1 - \mu\nu)\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \frac{2\mu\beta^2\delta^2}{\nu}\mathbb{E}\|\hat{\mathbf{w}}_{i-1}\|^2 \\ &\quad + \frac{2\mu\mathbb{E}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1}\|^2 + \mu^2\mathbb{E}\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^2}{\nu}. \end{aligned} \quad (70)$$

Using the Cauchy-Schwartz inequality we can bound the cross term as

$$\mathbb{E}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1}\|^2 \leq \mathbb{E}(\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^2 \|\tilde{\mathbf{x}}_{i-1}\|^2) \leq \sqrt{\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 \mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4}. \quad (71)$$

In the above inequality, the term $\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4$ can be bounded by using the result of Lemma 2. Therefore, we focus on bounding $\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4$ next. To do so, we need to introduce the following smoothness assumptions on the second and fourth-order moments of the gradient noise process and on the Hessian matrix of the risk function. These assumptions hold automatically for important cases of interest, such as least-mean-squares and logistic regression problems — see Appendix H for the verification.

Assumption 5 Consider the iterates ψ_{i-1} and \mathbf{x}_{i-1} that are generated by the momentum recursion (22) and the stochastic gradient recursion (2). It is assumed that the gradient noise process satisfies:

$$\mathbb{E}\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^2 | \mathcal{F}_{i-1} \leq \xi_1 \|\psi_{i-1} - \mathbf{x}_{i-1}\|^2, \quad (72)$$

$$\mathbb{E}\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^4 | \mathcal{F}_{i-1} \leq \xi_2 \|\psi_{i-1} - \mathbf{x}_{i-1}\|^4. \quad (73)$$

for some constants ξ_1 and ξ_2 .

Assumption 6 The Hessian of the risk function $J(w)$ in (1) is Lipschitz continuous, i.e., for any two variables $w_1, w_2 \in \text{dom } J(w)$, it holds that

$$\|\nabla_w^2 J(w_1) - \nabla_w^2 J(w_2)\| \leq \kappa \|w_1 - w_2\|. \quad (74)$$

for some constant $\kappa \geq 0$.

Using these assumptions, we can now establish two auxiliary results in preparation for the main equivalence theorem in the general case.

Lemma 9 (Uniform bound) Consider the standard and momentum stochastic gradient recursions (2) and (22)-(23) and assume they start from the same initial states, namely, $\psi_{-2} = \mathbf{w}_{-2} = \mathbf{x}_{-1}$. We continue to assume conditions (26), and (60). Under Assumptions 1, 3, 4, 5 and for sufficiently small step-sizes μ , the following result holds:

$$\mathbb{E}\|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4 = O\left(\frac{\delta^4(i+1)^{\delta+1}\mu}{\nu^3} + \frac{\delta^4\sigma_s^4}{\nu^6}\mu^2\right), \quad (75)$$

where $\rho_2 = 1 - \mu\nu/4$.

Proof See Appendix I. ■

Although sufficient for our purposes, we remark that the bound (75) for $\mathbb{E}\|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4$ is not tight. The reason is that in the derivation in Appendix I we employed a looser bound for the term $\mathbb{E}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1}\|^4$ in order to avoid the appearance of higher-order powers, such as $\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^8$ and $\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^8$. To avoid this possibility, we employed the following bound (using (11) to bound $\|\mathbf{R}_{i-1}\|^4$ and $\|\mathbf{H}_{i-1}\|^4$ and the inequality $\|a + b\|^4 \leq 8\|a\|^4 + 8\|b\|^4$):

$$\begin{aligned} \mathbb{E}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1}\|^4 &\leq \mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 \|\tilde{\mathbf{x}}_{i-1}\|^4 \\ &\leq 8\mathbb{E}\{(\|\mathbf{R}_{i-1}\|^4 + \|\mathbf{H}_{i-1}\|^4)\|\tilde{\mathbf{x}}_{i-1}\|^4\} \leq 16\delta^4\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4. \end{aligned} \quad (76)$$

Based on Lemma 9, we can now bound $\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4$, which is what the following lemma states.

Lemma 10 (Bound on Hessian difference) Consider the same setting of Lemma 9. Under Assumptions 1, 3, 4, 6 and for sufficiently small step-sizes μ , the following two result holds:

$$\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 = O\left(\frac{\delta^4 i \rho_2^5 \mu}{\nu^3} + \frac{\delta^4 \sigma_s^4}{\nu^6} \mu^2\right), \quad (77)$$

where $\rho_2 = 1 - \mu\nu/4$.

Proof See Appendix J. ■

With the upper bounds of $\mathbb{E}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4$ and $\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4$ established in Lemma 10 and Lemma 2 respectively, we are able to bound $\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{\mathbf{x}}_{i-1}\|$ in (71), which in turn helps to establish the main equivalence result.

Theorem 11 (Equivalence for general risks) Consider the standard and momentum stochastic gradient recursions (2) and (22)-(23) and assume they start from the same initial states, namely, $\psi_{-2} = \mathbf{w}_{-2} = \mathbf{x}_{-1}$. Suppose conditions (26) and (60) hold. Under

Assumptions 1, 3, 4, 5, and 6, and for sufficiently small step-size μ , it holds that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O\left(\frac{\delta^2 \sigma_s^2 \tau_2^{i+1} \mu^{3/2}}{(1-\beta)^{\nu^2/2}} + \left[\frac{\delta^2 + \gamma^2}{(1-\beta)^2} \beta_1^{i+1} + \frac{\delta^2 \sigma_s^4}{(1-\beta)^2 \nu^2}\right] \mu^2\right), \quad \forall i = 0, 1, 2, 3, \dots \quad (78)$$

where $\rho_1 = 1 - \frac{\mu^2}{2} \in (0, 1)$ and $\tau_2 \triangleq \sqrt{1 - \mu\nu/4} \in (0, 1)$.

Proof See Appendix K. ■

Similar to Corollary 5, 7 and Theorem 8, Theorem 11 implies that

$$\mathbb{E}\|\mathbf{w}_i - \mathbf{x}_i\|^2 = O(\mu^{3/2}), \quad \forall i = 0, 1, 2, \dots \quad (79)$$

Besides, since $\rho_1^i \rightarrow 0$ and $i^2 \tau_2^i \rightarrow 0$ as $i \rightarrow \infty$, we will also conclude

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O\left(\frac{\delta^2 \sigma_s^4 \mu^2}{(1-\beta)^{\nu^2}}\right) = O(\mu^2). \quad (80)$$

Remark When we refer to ‘‘sufficiently small step-sizes’’ in Theorems 8 and 11, we mean that step-sizes are smaller than the stability bound, and are also small enough to ensure a desirable level of mean-square-error based on the performance expressions.

5.2 Interpretation of Equivalence Result

The result of Theorem 11 shows that, for sufficiently small step-sizes, the trajectories of momentum and standard stochastic gradient methods remain within $O(\mu^{3/2})$ from each other for *every* i (for quadratic cases the trajectories will remain within $O(\mu^2)$ as stated in Theorem 8). This means that these trajectories evolve together for all practical purposes and, hence, we shall say that the two implementations are ‘‘equivalent’’ (meaning that their trajectories remain close to each other in the mean-square-error sense).

A second useful insight from Theorem 8 is that the momentum method is essentially equivalent to running a standard stochastic gradient method with a larger step-size (since $\mu > \mu_{\text{opt}}$). This interpretation explains why the momentum method is observed to converge faster during the transient phase albeit towards a worse MSD level in steady-state than the standard method. This is because, as is well-known in the adaptive filtering literature (Sayed, 2008, 2014a) that larger step-sizes for stochastic gradient method do indeed lead to faster convergence but worse limiting performance.

In addition, Theorem 11 enables us to compute the steady-state MSD performance of the momentum stochastic gradient method. It is guaranteed by Theorem 11 that momentum method is equivalent to standard stochastic gradient method with larger step-size, $\mu = \mu_{\text{opt}}/(1-\beta)$. Therefore, once we compute the MSD performance of the standard stochastic gradient, according to (Haykin, 2008; Sayed, 2008, 2014a), we will also know the MSD performance for the momentum method.

Another consequence of the equivalence result is that any benefits that would be expected from a momentum stochastic gradient descent can be attained by simply using a

standard stochastic gradient implementation with a larger step-size; this is achieved without the additional computational or memory burden that the momentum method entails.

Besides the theoretical analysis given above, there is an intuitive explanation as to why the momentum variant leads to worse steady-state performance. While the momentum terms $\mathbf{w}_i - \mathbf{w}_{i-1}$ and $\psi_i - \psi_{i-1}$ can smooth the convergence trajectories, and hence accelerate the convergence rate, they nevertheless introduce additional noise into the evolution of the algorithm because all iterates \mathbf{w}_i and ψ_i are distorted by perturbations. This fact illustrates the essential difference between stochastic methods with constant step-sizes, and stochastic or deterministic methods with decaying step-sizes: in the former case, the presence of gradient noise essentially eliminates the benefits of the momentum term.

5.3 Stochastic Gradient Method with Diminishing Momentum

(Tygert, 2016; Yuan et al., 2016) suggest one useful technique to retain the advantages of the momentum implementation by employing a *diminishing* momentum parameter, $\beta(i)$, and by ensuring $\beta(i) \rightarrow 0$ in order not to degrade the limiting performance of the implementation. By doing so, the momentum term will help accelerate the convergence rate during the transient phase because it will smooth the trajectory (Nedjic and Bertsekas, 2001; Xiao, 2010; Lan, 2012). On the other hand, momentum will not cause degradation in MSD performance because the momentum effect would have died before the algorithm reaches state-state.

According to (Tygert, 2016; Yuan et al., 2016), we adapt the momentum stochastic method into the following algorithm

$$\begin{aligned} \psi_{i-1} &= \mathbf{w}_{i-1} + \beta_1(i)(\mathbf{w}_{i-1} - \mathbf{w}_{i-2}), \\ \mathbf{w}_i &= \psi_{i-1} - \mu \nabla_w Q(\psi_{i-1}; \boldsymbol{\theta}_i) + \beta_2(i)(\psi_{i-1} - \psi_{i-2}), \end{aligned} \quad (81)$$

$$(82)$$

with the same initial conditions as in (24)–(25). Similar to condition (26), $\beta_1(i)$ and $\beta_2(i)$ also need to satisfy

$$\beta_1(i) + \beta_2(i) = \beta(i), \quad \beta_1(i)\beta_2(i) = 0, \quad (83)$$

The efficacy of (81)–(82) will depend on how the momentum decay, $\beta(i)$, is selected. A satisfactory sequence $\{\beta(i)\}$ should decay slowly during the initial stages of adaptation so that the momentum term can induce an acceleration effect. However, the sequence $\{\beta(i)\}$ should also decrease drastically prior to steady-state so that the vanishing momentum term will not introduce additional gradient noise and degrade performance. One strategy, which is also employed in the numerical experiments in Section 7, is to design $\beta(i)$ to decrease in a stair-wise fashion, namely,

$$\beta(i) = \begin{cases} \beta_0 & \text{if } i \in [1, T], \\ \beta_0/T^\alpha & \text{if } i \in [T+1, 2T], \\ \beta_0/(2T)^\alpha & \text{if } i \in [2T+1, 3T], \\ \beta_0/(3T)^\alpha & \text{if } i \in [3T+1, 4T], \\ \dots & \dots \end{cases} \quad (84)$$

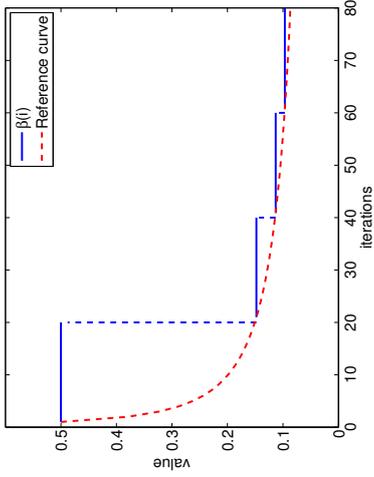

Figure 1: $\beta(i)$ changes with iteration i according to (84), where $\beta_0 = 0.5$, $T = 20$ and $\alpha = 0.4$. The reference curve is $f(i) = 0.5/t^{0.4}$.

where the constants $\beta_0 \in [0, 1]$, $\alpha \in (0, 1)$ and $T > 0$ determines the width of the stair steps. Fig. 1 illustrates how $\beta(i)$ varies when $T = 20$, $\beta_0 = 0.5$ and $\alpha = 0.4$.

Algorithm (81)–(82) works well when $\beta(i)$ decreases according to (84) (see Section 7). However, with Theorems 8 and 11, we find that this algorithm is essentially equivalent to the standard stochastic gradient method with decaying step-size, i.e.,

$$\mathbf{x}_i = \mathbf{x}_{i-1} - \mu_s(i) \nabla_w Q(\mathbf{x}_{i-1}; \boldsymbol{\theta}_i), \quad (85)$$

where

$$\mu_s(i) = \frac{\mu}{1 - \beta(i)} \quad (86)$$

will decrease from $\mu/[1 - \beta(0)]$ to μ . In another words, the stochastic algorithm with decaying momentum is still not helpful.

6. Diagonal Step-size Matrices

Sometimes it is advantageous to employ separate step-size for the individual entries of the weight vectors, see (Duchi et al., 2011). In this section we comment on how the results from the previous sections extend to this scenario. First, we note that recursion (2) can be generalized to the following form, with a diagonal matrix serving as the step-size parameter:

$$\mathbf{x}_i = \mathbf{x}_{i-1} - D \nabla_w Q(\mathbf{x}_{i-1}; \boldsymbol{\theta}_i), \quad i \geq 0, \quad (87)$$

where $D = \text{diag}\{\mu_1, \mu_2, \dots, \mu_M\}$. Here, we continue to use the letter “ \mathbf{x} ” to refer to the variable iterates for the standard stochastic gradient descent iteration, while we reserve

the letter “ \mathbf{w} ” for the momentum recursion. We let $\mu_{\max} = \max\{\mu_1, \dots, \mu_M\}$. Similarly, recursions (22) and (23) can be extended in the following manner:

$$\psi_{i-1} = \mathbf{w}_{i-1} + B_1(\mathbf{w}_{i-1} - \mathbf{w}_{i-2}), \quad (88)$$

$$\mathbf{w}_i = \psi_{i-1} - D_m \nabla_w Q(\psi_{i-1}; \boldsymbol{\theta}_i) + B_2(\psi_{i-1} - \psi_{i-2}), \quad (89)$$

with initial conditions

$$\mathbf{w}_{-2} = \psi_{-2} = \text{initial states}, \quad (90)$$

$$\mathbf{w}_{-1} = \mathbf{w}_{-2} - D_m \nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1}), \quad (91)$$

where $B_1 = \text{diag}\{\beta_1^1, \dots, \beta_M^1\}$ and $B_2 = \text{diag}\{\beta_1^2, \dots, \beta_M^2\}$ are momentum coefficient matrices, while D_m is a diagonal step-size matrix for momentum stochastic gradient method. In a manner similar to (26), we also assume that

$$0 \leq B_k < I_M, \quad k = 1, 2, \quad B_1 + B_2 = B, \quad B_1 B_2 = 0. \quad (92)$$

where $B = \text{diag}\{\beta_1, \dots, \beta_M\}$ and $0 < B < I_M$. In addition, we further assume that B is not too close to I_M , i.e.

$$B \leq (1 - \epsilon)I_M, \quad \text{for some constant } \epsilon > 0. \quad (93)$$

The following results extend Theorems 1, 3, and 4 and they can be established following similar derivations.

Theorem 1B (Mean-square stability). *Let Assumptions 1 and 2 hold and recall conditions (92) and (93). Then, for the momentum stochastic gradient method (88)–(89), it holds under sufficiently small step-size μ_{\max} that*

$$\limsup_{i \rightarrow \infty} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^2 = O(\mu_{\max}). \quad (94)$$

■ **Theorem 3B (Equivalence for quadratic costs).** *Consider recursions (52) and (56)–(57) with $\{\mu, \mu_m, \beta_1, \beta_2\}$ replaced by $\{D, D_m, B_1, B_2\}$. Assume they start from the same initial states, namely, $\psi_{-2} = \mathbf{w}_{-2} = \mathbf{x}_{-1}$. Suppose further that conditions (92) and (93) hold, and that the step-sizes matrices $\{D, D_m\}$ satisfy a relation similar to (60), namely,*

$$D = (I - B)^{-1} D_m. \quad (95)$$

Then, it holds under sufficiently small μ_{\max} , that

$$\mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O(\mu_{\max}^2), \quad \forall i = 0, 1, 2, 3, \dots \quad (96)$$

■ **Theorem 4B (Equivalence for general costs).** *Consider the stochastic gradient recursion (87) and the momentum stochastic gradient recursions (88)–(89) to solve the general problem (1). Assume they start from the same initial states, namely, $\psi_{-2} = \mathbf{w}_{-2} = \mathbf{x}_{-1}$.*

Suppose conditions (92), (93), and (95) hold. Under Assumptions 1, 3, 5, and 6, and for sufficiently small step-sizes, it holds that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O(\mu_{\max}^{3/2}), \quad \forall i = 0, 1, 2, 3, \dots \quad (97)$$

Furthermore, in the limit,

$$\limsup_{i \rightarrow \infty} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O(\mu_{\max}^2). \quad (98)$$

7. Experimental Results

In this section we illustrate the main conclusions by means of computer simulations for both cases of mean-square-error designs and logistic designs. We also run simulations for algorithm (81)–(82) and verify its advantages in the stochastic context.

7.1 Least Mean-Squares Error Designs

We apply the standard LMS algorithm to (47). To do so, we generate data according to the linear regression model (48), where $\mathbf{w}^o \in \mathbb{R}^{10}$ is chosen randomly, and $\mathbf{u}_i \in \mathbb{R}^{10}$ is i.i.d and follows $\mathbf{u}_i \sim \mathcal{N}(0, \Lambda)$ where $\Lambda \in \mathbb{R}^{10 \times 10}$ is randomly-generated diagonal matrix with positive diagonal entries. Besides, $\mathbf{v}(i)$ is also i.i.d and follows $\mathbf{v}(i) \sim \mathcal{N}(0, \sigma_v^2 \mathbf{I}_{10})$, where $\sigma_v^2 = 0.01$. All results are averaged over 300 random trials. For each trial we generated 800 samples of \mathbf{u}_i , $\mathbf{v}(i)$ and $\mathbf{d}(i)$.

We first compare the standard and momentum LMS algorithms using $\mu = \mu_m = 0.003$. The momentum parameter β is set as 0.9. Furthermore, we employ the heavy-ball option for the momentum LMS, i.e., $\beta_1 = 0, \beta_2 = \beta$. Both the standard and momentum LMS methods are illustrated in the left plot in Fig. 2 with blue and red curves, respectively. It is seen that the momentum LMS converges faster, but the MSD performance is much worse. Next we set $\mu_m = \mu(1 - \beta) = 0.0003$ and illustrate this case with the magenta curve. It is observed that the magenta and blue curves are almost indistinguishable, which confirms the equivalence predicted by Theorem 8 for all time instants. We also illustrate an implementation with a decaying momentum parameter $\beta(i)$ by the green curve. In this simulation, we set $\mu_m = 0.003$ and make $\beta(i)$ decrease in a stair-wise fashion: when $i \in [1, 100]$, $\beta(i) = 0.9$; when $i \in [101, 200]$, $\beta(i) = 0.9/(100^{0.3})$; \dots ; when $i \in [2401, 2500]$, $\beta(i) = 0.9/(2400^{0.3})$. With this decaying $\beta(i)$, it is seen that the momentum LMS method recovers its faster convergence rate and attains the same steady-state MSD performance as the LMS implementation. Finally, we also implemented the standard LMS with initial step-size $\mu = 0.003$ and then decrease it gradually according to $\mu_s(i) = \mu/[1 - \beta(i)]$. As implied by Theorem 8, it is observed that the green and black curves are also almost indistinguishable, which confirms that the LMS algorithm with decaying momentum is still equivalent to the standard LMS with appropriately chosen decaying step-sizes. We also compared the standard and momentum LMS algorithms when $\mu = \mu_m = 0.003$ and β is set as 0.5, 0.6, 0.7, 0.8, and the same performance as the left plot in Fig. 2 is observed. To save space, we show the right plot in Fig. 2 in which $\beta = 0.5$ and omit the figures when β is set as 0.6, 0.7, 0.8.

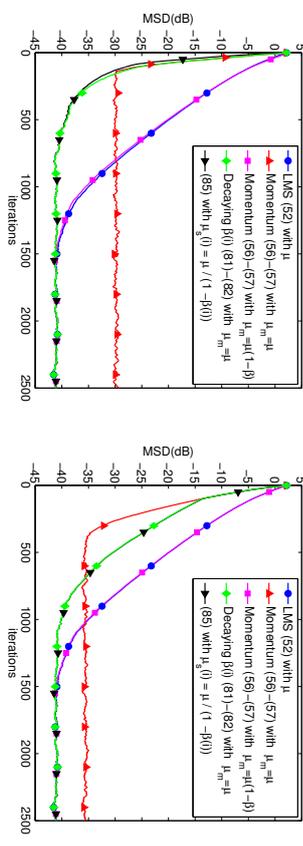

Figure 2: Convergence behavior of standard and momentum LMS (heavy-ball LMS) algorithms applied to the mean-square-error design problem (47) with $\beta = 0.9$ in the left plot and $\beta = 0.5$ in the right plot. Mean-square-deviation (MSD) means $\mathbb{E}\|\mathbf{w}^o - \mathbf{w}_i\|^2$.

Next we employ the Nesterov's acceleration option for the momentum LMS method, and compare it with standard LMS. The experimental settings are exactly the same as the above except that $\beta_1 = \beta$ and $\beta_2 = 0$. Both the standard and momentum LMS methods are illustrated in Fig. 3. As implied by Theorem 8, it is observed that Nesterov's acceleration applied to LMS is equivalent to standard LMS with rescaled step-size. Besides, by comparing Figs. 2 and 3, it is also observed that both momentum options, the heavy-ball and the Nesterov's acceleration, have the same performance. To save space, in the following experiments in Section 7.2–7.4 we just show the performance of momentum method with the option of heavy-ball.

7.2 Regularized Logistic Regression

We next consider a regularized logistic regression risk of the form:

$$J(\mathbf{w}) \triangleq \frac{\rho}{2} \|\mathbf{w}\|^2 + \mathbb{E} \left\{ \ln [1 + \exp(-\gamma(i) \mathbf{h}_i^T \mathbf{w})] \right\} \quad (99)$$

where the approximate gradient vector is chosen as

$$\nabla_{\mathbf{w}} Q(\mathbf{w}; \mathbf{h}_i, \gamma(i)) = \rho \mathbf{w} - \frac{\exp(-\gamma(i) \mathbf{h}_i^T \mathbf{w})}{1 + \exp(-\gamma(i) \mathbf{h}_i^T \mathbf{w})} \gamma(i) \mathbf{h}_i \quad (100)$$

In the simulation, we generate 20000 samples $(\mathbf{h}_i, \gamma(i))$. Among these training points, 10000 feature vectors \mathbf{h}_i correspond to label $\gamma(i) = 1$ and each $\mathbf{h}_i \sim \mathcal{N}(1.5 \times \mathbf{I}_{10}, R_h)$ for some diagonal covariance R_h . The remaining 10000 feature vectors \mathbf{h}_i correspond to label $\gamma(i) = -1$ and each $\mathbf{h}_i \sim \mathcal{N}(-1.5 \times \mathbf{I}_{10}, R_h)$. We set $\rho = 0.1$. The optimal solution \mathbf{w}^o is computed via the classic gradient descent method. All simulation results shown below are averaged over 300 trials.

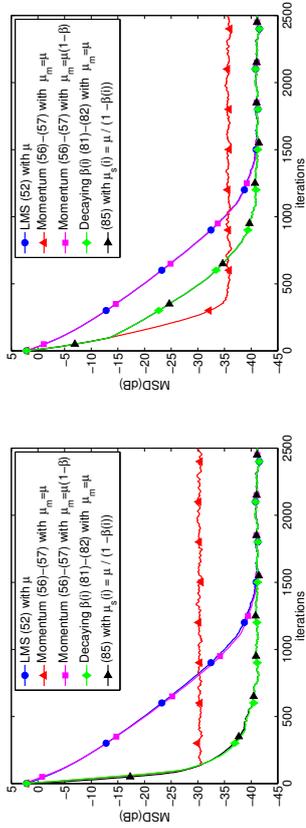

Figure 3: Convergence behavior of standard and momentum LMS (Nesterov’s acceleration LMS) algorithms applied to the mean-square-error design problem (47) with $\beta = 0.9$ in the left plot and $\beta = 0.5$ in the right plot.

Similar to the least-mean-squares error problem, we first compare the standard and momentum stochastic methods using $\mu = \mu_m = 0.005$. The momentum parameter β is set to 0.9. These two methods are illustrated in Fig. 4 with blue and red curves, respectively. It is seen that the momentum method converges faster, but the MSD performance is much worse. Next we set $\mu_m = \mu(1 - \beta) = 0.0005$ and illustrate this case with the magenta curve. It is observed that the magenta and blue curves are indistinguishable, which confirms the equivalence predicted by Theorem 11 for all time instants. Again we illustrate an implementation with a decaying momentum parameter $\beta(i)$ by the green curve. In this simulation, we set $\mu_m = 0.005$ and make $\beta(i)$ decrease in a stair-wise manner: when $i \in [1, 200]$, $\beta(i) = 0.9$; when $i \in [201, 400]$, $\beta(i) = 0.9/(200^{0.3})$; when $i \in [401, 600]$, $\beta(i) = 0.9/(400^{0.3})$; ...; when $i \in [1801, 2000]$, $\beta(i) = 0.9/(1800^{0.3})$. With this decaying $\beta(i)$, it is seen that the momentum method recovers its faster convergence rate and attains the same steady-state MSD performance as the stochastic-gradient implementation. Finally, we implemented the standard stochastic gradient descent with initial step-size $\mu_m = \mu = 0.005$ and then decrease it gradually according to $\mu_s(i) = \mu/[1 - \beta(i)]$. As implied by Theorem 11, it is observed that the green and black curves are almost indistinguishable, which confirms that the algorithm with decaying momentum is still equivalent to the standard stochastic gradient descent with appropriately chosen decaying step-sizes.

Next, we test the standard and momentum stochastic methods for regularized logistic regression problem over a benchmark data set — the Adult Data Set². The aim of this dataset is to predict whether a person earns over \$50K a year based on census data such as age, workclass, education, race, etc. The set is divided into 6414 training data and 26147 test data, and each feature vector has 123 entries. In the simulation, we set $\mu = 0.1$, $\rho = 0.1$, and $\beta = 0.9$. To check the equivalence of the algorithms, we set $\mu_m = (1 - \beta)\mu = 0.01$. In Fig. 5,

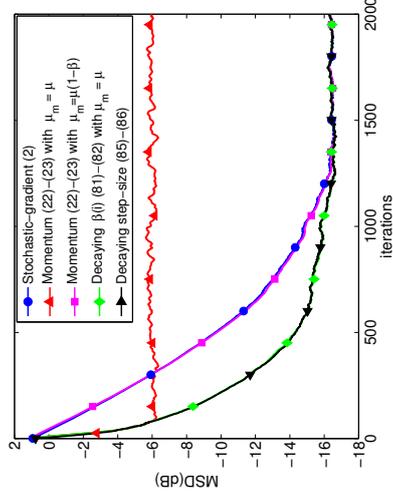

Figure 4: Convergence behaviors of standard and momentum stochastic gradient methods applied to the logistic regression problem (99).

the curve shows how the accuracy performance, i.e., the percentage of correct prediction, over the test dataset evolved as the algorithm received more training data³. The horizontal x-axis indicates the number of training data used. It is observed that the momentum and standard stochastic gradient methods cannot be distinguished, which confirms their equivalence when training the Adult Data Set.

For the experiments shown in this section, Section 7.3 and 7.4, we also tested the cases when β is set as 0.5, 0.6, 0.7, 0.8. Since the experimental results with different β are similar, we just plot the situation when $\beta = 0.9$, a setting which is usually employed in practice (Szegedy et al., 2015; Krizhevsky et al., 2012; Zhang and LeCun, 2015).

7.3 Further Verification of Theorems 8 and 11

In this section we further illustrate the conclusions of Theorems 8 and 11 by checking the behavior of the iterate difference, i.e., $\mathbb{E}\|\mathbf{w}_i - \mathbf{x}_i\|^2$, between the standard and momentum stochastic gradient methods.

For the least-mean-squares error problem, the selection of \mathbf{u}_i , $\mathbf{v}(i)$, $\mathbf{d}(i)$ and β is the same as in the simulation generated earlier in Subsection 7.1. For some specific step-size μ , \mathbf{x}_i is the iterate generated through LMS recursion (52) with step-size μ , and \mathbf{w}_i is the iterate generated momentum LMS recursion (56)–(57) with step-size $\mu_m = \mu(1 - \beta)$. Now we introduce the maximum difference:

$$d_{\max}(\mu) = \max_i \mathbb{E}\|\mathbf{w}_i - \mathbf{x}_i\|^2 \quad (101)$$

3. To smooth the performance curve, we applied the weighted average technique from equation (74) of (Ying and Sayed, 2015, 2016).

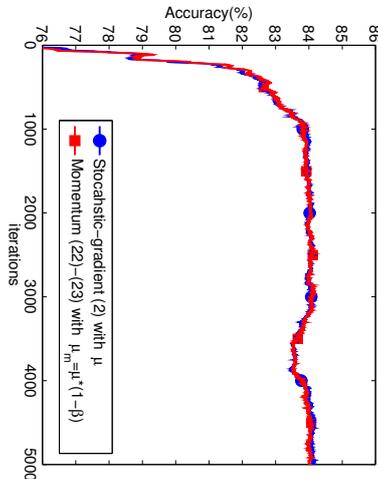

Figure 5: Performance accuracy of the standard and momentum stochastic gradient methods applied to logistic regression classification on the adult data test set.

and the difference at steady state

$$d_{ss}(\mu) = \limsup_{t \rightarrow \infty} \mathbb{E} \|\mathbf{w}_t - \mathbf{x}_2\|^2. \quad (102)$$

Note that both $d_{\max}(\mu)$ and $d_{ss}(\mu)$ are related with μ and we will examine how they vary according to different step-sizes. Obviously, since $\mathbb{E} \|\mathbf{w}_t - \mathbf{x}_2\|^2 \leq d_{\max}(\mu)$, if $d_{\max}(\mu)$ is illustrated to be on the order of $O(\mu^2)$, then it follows that $\mathbb{E} \|\mathbf{w}_t - \mathbf{x}_2\|^2 = O(\mu^2)$ for $t \geq 0$. Similarly, if we can illustrate $d_{ss}(\mu) = O(\mu^2)$, then it follows that $\limsup_{t \rightarrow \infty} \mathbb{E} \|\mathbf{w}_t - \mathbf{x}_2\|^2 = O(\mu^2)$.

Note that the fact $d_{\max}(\mu) = c\mu^2$ for some constant c holds if and only if

$$d_{\max}(\mu)(\text{dB}) = 20 \log \mu + 10 \log c, \quad (103)$$

where $d_{\max}(\mu)(\text{dB}) = 10 \log d_{\max}(\mu)$. Relation (103) can be confirmed with red circle line in Fig. 6. In this simulation, we choose 8 different step-size values $\{\mu_k\}_{k=1}^8$, and it can be verified that each data pair $(\log \mu_k, d_{\max}(\mu_k)(\text{dB}))$ satisfies relation (103). For example, in the red circle solid line, at $\mu_1 = 10^{-2}$ we read $d_{\max}(\mu_1)(\text{dB}) = -32\text{dB}$; while at $\mu_2 = 10^{-4}$ we read $d_{\max}(\mu_2)(\text{dB}) = -72\text{dB}$. It can be verified that

$$d_{\max}(\mu_1)(\text{dB}) - d_{\max}(\mu_2)(\text{dB}) = 20(\log \mu_1 - \log \mu_2) = 40. \quad (104)$$

Using a similar argument, the blue square solid line can also implies that $d_{ss} = O(\mu^2)$.

Figure 6 also reveals the order of d_{\max} and d_{ss} , with magenta and green dash lines respectively; for the regularized logistic regression problem from Subsection 7.2. With the same argument as above, $d_{ss}(\mu)$ can be confirmed on the order of $O(\mu^2)$. Now we check the order of $d_{\max}(\mu)$. The fact that $d_{\max}(\mu) = c\mu^{3/2}$ holds if and only if

$$d_{\max}(\mu)(\text{dB}) = 15 \log \mu + 10 \log c. \quad (105)$$

According to the above relation, at $\mu_1 = 10^{-2}$ and $\mu_2 = 10^{-4}$ we should have

$$d_{\max}(\mu_1)(\text{dB}) - d_{\max}(\mu_2)(\text{dB}) = 15(\log \mu_1 - \log \mu_2) = 30. \quad (106)$$

However, in the triangle magenta dash line we read $d_{\max}(\mu_1) = -30\text{dB}$ while $d_{\max}(\mu_2) = -66\text{dB}$ and hence

$$30\text{dB} < d_{\max}(\mu_1)(\text{dB}) - d_{\max}(\mu_2)(\text{dB}) < 40\text{dB}$$

Therefore, the order of d_{\max} should be between $O(\mu^{3/2})$ and $O(\mu^2)$, which still confirms Theorem 11.

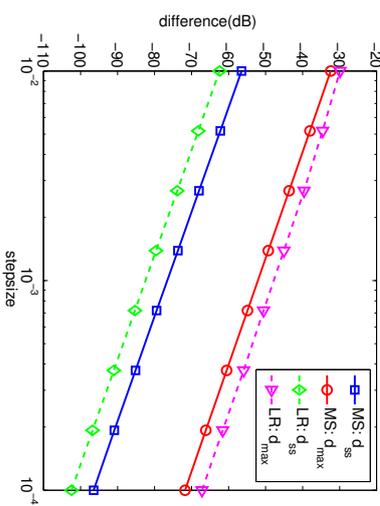

Figure 6: d_{\max} and d_{ss} as a function of the step-size μ . *MS* stands for mean-square-error and *LR* stands for logistic regression.

7.4 Visual Recognition

In this subsection we illustrate the conclusions of this work by re-examining the problem of training a neural network to recognize objects from images. We employ the CIFAR-10 database⁴, which is a classical benchmark dataset of images for visual recognition. The CIFAR-10 dataset consists of 60000 color images in 10 classes, each with 32×32 pixels. There are 50000 training images and 10000 test images. Similar to (Sutskever et al., 2013), and since the focus of this paper is on optimization, we only report training errors in our experiment.

To help illustrate that the conclusions also hold for non-differentiable and non-convex problems, in this experiment we train the data with two different neural network structures: (a) a 6-layer fully connected neural network and (b) a 4-layer convolutional neural network, both with ReLU activation functions. For each neural network, we will compare the performance of the momentum and standard stochastic gradient methods.

4. <https://www.cs.toronto.edu/~kriz/cifar.html>

6-Layer Fully Connected Neural Network. For this neural network structure, we employ the softmax measure with ℓ_2 regularization as a cost objective, and the ReLU as an activation function. Each hidden layer has 100 units, the coefficient of the ℓ_2 regularization term is set to 0.001, and the initial value w_{-1} is generated by a Gaussian distribution with 0.05 standard deviation. We employ mini-batch stochastic-gradient learning with batch size equal to 100. First, we apply a momentum backpropagation (i.e., momentum stochastic gradient) algorithm to train the 6-layer neural network. The momentum parameter is set to $\beta = 0.9$, and the initial step-size μ_m is set to 0.01. To achieve better accuracy, we follow a common technique (e.g., (Szegedy et al., 2015)) and reduce μ_m to $0.95\mu_m$ after every epoch. With the above settings, we attain an accuracy of about 90% in 80 epochs.

However, what is interesting, and somewhat surprising, is that the same 90% accuracy can also be achieved with the standard backpropagation (i.e., stochastic gradient descent) algorithm in 80 epochs. According to the step-size relation $\mu = \mu_m / (1 - \beta)$, we set the initial step-size μ of SGD to 0.1. Similar to the momentum method, we also reduce μ to 0.95μ after every epoch for SGD, and hence the relation $\mu = \mu_m / (1 - \beta)$ still holds for each iteration. From Figure 7, we observe that the accuracy performance curves for both scenarios, with and without momentum, are overlapping even when the overall risk is not necessarily convex or differentiable.

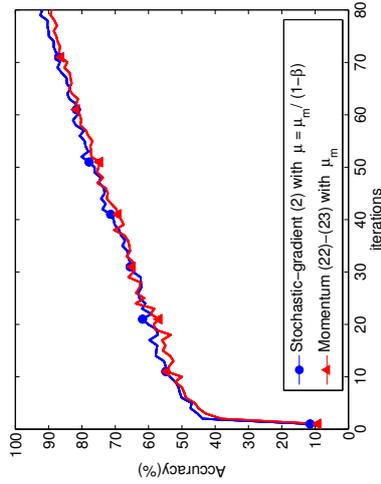

Figure 7: Classification accuracy of the standard and momentum stochastic gradient methods applied to a 6-layer fully-connected neural network on the CIFAR-10 test data set.

4-Layer Convolutional Neural Network. In a second experiment, we consider a 4-layer convolutional neural network. We employ the same objective and activation functions. This network has the structure:

$$(\text{conv} - \text{ReLU} - \text{pool}) \times 2 - (\text{affine} - \text{ReLU}) - \text{affine}$$

In the first convolutional layer, we use filters of size $7 \times 7 \times 3$, stride value 1, zero padding 3, and the number of these filters is 32. In the second convolutional layer, we use filters of size

$7 \times 7 \times 32$, stride value 1, zero padding 3, and the number of filters is still 32. We implement MAX operation in all pooling layers, and the pooling filters are of size 2×2 , stride value 2 and zero padding 0. The hidden layer has 500 units. The coefficient of the ℓ_2 regularization term is set to 0.001, and the initial value w_{-1} is generated by a Gaussian distribution with 0.001 standard deviation. We employ mini-batch stochastic-gradient learning with batch size equal to 50, and the step-size decreases by 5% after each epoch.

First, we apply the momentum backpropagation algorithm to train the neural network. The momentum parameter is set at $\beta = 0.9$, and we performed experiments with step-sizes $\mu_m \in \{0.01, 0.005, 0.001, 0.0005, 0.0001\}$ and find that $\mu_m = 0.001$ gives the highest training accuracy after 10 epochs. In Fig. 8 we draw the momentum stochastic gradient method with red curve when $\mu_m = 0.001$ and $\beta = 0.9$. The curve reaches an accuracy of 94%. Next we set the step-size of the standard backpropagation $\mu = \mu_m / (1 - \beta) = 0.01$, and illustrate its convergence performance with the blue curve. It is also observed that the two curves are indistinguishable. The numerical results shown in Figs. 7 and 8 imply that the performance of momentum SGD can still be achieved by standard SGD by properly adjusting the step-size according to $\mu = \mu_m / (1 - \beta)$.

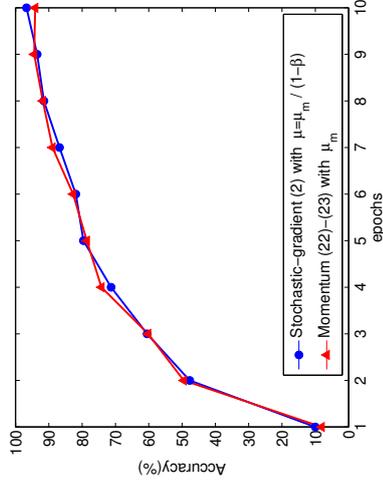

Figure 8: Classification accuracy of the standard and momentum stochastic gradient methods applied to a 4-layer convolutional neural network on the CIFAR-10 training data set.

8. Comparison for Larger Step-sizes

According to Theorem 11, the equivalence results between the standard and momentum stochastic gradient methods hold for sufficiently small step-sizes μ . When larger values for μ are used, the $O(\mu^{3/2})$ term is not negligible any longer so that the momentum and gradient-descent implementations are not equivalent anymore under these conditions. While in practical implementations small step-sizes are widely employed in order to ensure satisfactory steady-state MSD performance, one may still wonder how both algorithms would

compare to each other under larger step-sizes. For example, it is known that the larger the step-size value is, the more likely it is that the stochastic-gradient algorithm will become unstable. Does the addition of momentum help enlarge the stability range and allow for proper adaptation and learning over a wider range of step-sizes?

Unfortunately, the answer to the above question is generally negative. In fact, we can construct a simple numerical example in which the momentum can hurt the stability range. This example considers the case of quadratic risks, namely problems of the form (47). We suppose $M = 5$, $\mathbf{u}_i \sim \mathcal{N}(0, 0.5I_5)$ and $\mathbf{d}(i) = \mathbf{u}_i^T \mathbf{w}^o + \mathbf{v}(i)$ where $\mathbf{v}(i) \sim \mathcal{N}(0, 0.01)$. We compare the convergence of standard LMS and Nesterov's acceleration method with fixed parameter $\beta_2 = 0$ and $\beta = 0.5$. Both algorithms are set with the same step-size $\mu = \mu_m = 0.4$, which is a relatively large step-size. All results are averaged over 1000 random trials. For each trial we generated 200 samples of \mathbf{u}_i , $\mathbf{v}(i)$ and $\mathbf{d}(i)$. In Fig. 9, it shows that standard LMS converges at $\mu = 0.4$ while momentum LMS diverges, which indicates that momentum LMS has narrower stability range than standard LMS.

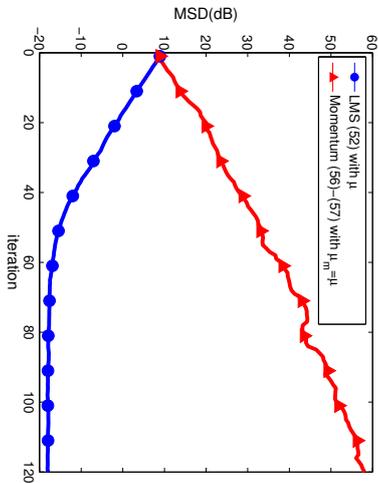

Figure 9: Convergence comparison between standard and momentum LMS algorithms when $\mu = \mu_m = 0.4$ and $\beta = 0.5$.

9. Conclusion

In this paper we analyzed the convergence and performance behavior of momentum stochastic gradient methods in the constant step-size and slow adaptation regime. The results establish that the momentum method is equivalent to employing the standard stochastic gradient method with a re-scaled (larger) step-size value. The size of the re-scaling is determined by the momentum parameter, β . The analysis was carried out under general conditions and was not limited to quadratic risks, but is also applicable to broader choices of the risk function. Overall, the conclusions indicate that the well-known benefits of momentum constructions in the deterministic optimization scenario do not necessarily carry over

to the stochastic setting when adaptation becomes necessary and gradient noise is present. The analysis also comments on a way to retain some of the advantages of the momentum construction by employing a decaying momentum parameter: one that starts at a constant level and decays to zero over time. adaptation is retained without the often-observed degradation in MSD performance.

The authors would like to thank PhD student Chung-Kai Yu for contributing to Section 5.3, and undergraduate student Gabrielle Robertson for contributing to the simulation in Section 7.4.

Appendix A. Proof of Lemma 2

It is shown in Eq. (3.76) of (Sayed, 2014a) that $\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4$ evolves as follows:

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 \leq (1 - \mu\nu)\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_1\mu^2\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 + a_2\mu^4, \quad (107)$$

where the constants a_1 and a_2 are defined as

$$a_1 \triangleq 16\sigma_s^2, \quad a_2 \triangleq 3\sigma_s^4. \quad (108)$$

If we iterate (16) we find that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq (1 - \mu\nu)^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2 + a_3\mu, \quad (109)$$

where a_3 is defined as

$$a_3 \triangleq \frac{\sigma_s^2}{\nu}. \quad (110)$$

Substituting inequality (109) into (107), we find that it holds for each iteration $i = 0, 1, 2, \dots$

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 &\leq (1 - \mu\nu)\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_2\mu^4 + a_1a_3\mu^3 + a_4\mu^2(1 - \mu\nu)^i, \\ &= \rho\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_2\mu^4 + a_1a_3\mu^3 + a_4\mu^2\rho^i \end{aligned} \quad (111)$$

where

$$\rho \triangleq 1 - \mu\nu, \quad a_4 \triangleq a_1\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2. \quad (112)$$

Iterating the inequality (111) we get

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 &\leq \rho^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 + a_2\mu^4 \sum_{s=0}^i \rho^s + a_1a_3\mu^3 \sum_{s=0}^i \rho^s + a_4\mu^2(i+1)\rho^i \\ &\leq \rho^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 + \frac{a_2\mu^4}{1-\rho} + \frac{a_1a_3\mu^3}{1-\rho} + a_4\mu^2(i+1)\rho^i \end{aligned}$$

$$\begin{aligned} &\leq \rho^{i+1} \mathbb{E} \|\tilde{\mathbf{w}}_{-1}\|^4 + a_5 \mu^3 + a_6 \mu^2 + a_4 \mu^2 (i+1) \rho^i \\ &\stackrel{(a)}{\leq} \rho^{i+1} \mathbb{E} \|\tilde{\mathbf{w}}_{-1}\|^4 + 2a_6 \mu^2 + a_4 \mu^2 (i+1) \rho^i, \end{aligned} \quad (113)$$

where

$$a_5 \triangleq \frac{a_2}{\nu}, \quad a_6 \triangleq \frac{a_1 a_3}{\nu}, \quad (114)$$

and (a) holds because for sufficiently small μ such that $a_6 \mu^2 > a_5 \mu^3$, we have

$$a_5 \mu^3 + a_6 \mu^2 = 2a_6 \mu^2 - (a_6 \mu^2 - a_5 \mu^3) \leq 2a_6 \mu^2. \quad (115)$$

Substituting (108), (110), (112) and (114) into (113), we get

$$\begin{aligned} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 &\leq \rho^{i+1} \mathbb{E} \|\tilde{\mathbf{w}}_{-1}\|^4 + A_1 \sigma_s^2 (i+1) \rho^i \mu^2 + \frac{A_2 \sigma_s^4 \mu^2}{\nu^2} \\ &= \rho^{i+1} \mathbb{E} \|\tilde{\mathbf{w}}_{-1}\|^4 + \frac{A_1}{\rho} \sigma_s^2 (i+1) \rho^{i+1} \mu^2 + \frac{A_2 \sigma_s^4 \mu^2}{\nu^2} \end{aligned} \quad (116)$$

for some constants A_1 and A_2 . When μ is sufficiently small, there must exist some constant A_3 such that

$$\frac{A_1}{\rho} = \frac{A_1}{1 - \mu\nu} \leq A_3. \quad (117)$$

Therefore, (116) becomes

$$\mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 \leq \rho^{i+1} \mathbb{E} \|\tilde{\mathbf{w}}_{-1}\|^4 + A_3 \sigma_s^2 (i+1) \rho^{i+1} \mu^2 + \frac{A_2 \sigma_s^4 \mu^2}{\nu^2}. \quad (118)$$

Appendix B. Proof of Lemma 3

We substitute the expression for the gradient noise from (12), evaluated at ψ_{i-1} , into (23) to get:

$$\mathbf{w}_i = \psi_{i-1} - \mu_m \nabla_w J(\psi_{i-1}) + \beta_2 (\psi_{i-1} - \psi_{i-2}) - \mu_m \mathbf{s}_i(\psi_{i-1}). \quad (119)$$

Let again $\tilde{\mathbf{w}}_i = \mathbf{w}^o - \mathbf{w}_i$ and $\tilde{\psi}_i = \mathbf{w}^o - \psi_i$. Subtracting both sides of (119) from \mathbf{w}^o gives:

$$\tilde{\mathbf{w}}_i = \tilde{\psi}_{i-1} + \mu_m \nabla_w J(\psi_{i-1}) - \beta_2 (\psi_{i-1} - \psi_{i-2}) + \mu_m \mathbf{s}_i(\psi_{i-1}). \quad (120)$$

We now appeal to the mean-value theorem (relation (D.9) in (Sayed, 2014a)) to write

$$\nabla J_w(\psi_{i-1}) = - \left(\int_0^1 \nabla_w^2 J_w(\mathbf{w}^o - t\tilde{\psi}_{i-1}) dt \right) \tilde{\psi}_{i-1} \triangleq -\mathbf{H}_{i-1} \tilde{\psi}_{i-1}. \quad (121)$$

and express the momentum term in the form

$$\psi_{i-1} - \psi_{i-2} = \psi_{i-1} - \mathbf{w}^o + \mathbf{w}^o - \psi_{i-2} = -\tilde{\psi}_{i-1} + \tilde{\psi}_{i-2}. \quad (122)$$

Then, expression (120) can be rewritten as

$$\tilde{\mathbf{w}}_i = (I_M + \beta_2 I_M - \mu_m \mathbf{H}_{i-1}) \tilde{\psi}_{i-1} - \beta_2 \tilde{\psi}_{i-2} + \mu_m \mathbf{s}_i(\psi_{i-1}). \quad (123)$$

On the other hand, expression (22) gives

$$\tilde{\psi}_{i-1} = \tilde{\mathbf{w}}_{i-1} + \beta_1 (\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{w}}_{i-2}). \quad (124)$$

Substituting (124) into (123), we have

$$\tilde{\mathbf{w}}_i = \mathbf{J}_{i-1} \tilde{\mathbf{w}}_{i-1} + \mathbf{K}_{i-1} \tilde{\mathbf{w}}_{i-2} + L \tilde{\mathbf{w}}_{i-3} + \mu_m \mathbf{s}_i(\psi_{i-1}), \quad (125)$$

where boldface quantities denote random variables:

$$\mathbf{J}_{i-1} = (1 + \beta_1)(1 + \beta_2) I_M - \mu_m (1 + \beta_1) \mathbf{H}_{i-1} \stackrel{(26)}{=} (1 + \beta) I_M - \mu_m (1 + \beta_1) \mathbf{H}_{i-1} \quad (126)$$

$$\mathbf{K}_{i-1} = -(\beta_1 + \beta_2 + 2\beta_1 \beta_2) I_M + \mu_m \beta_1 \mathbf{H}_{i-1} = -\beta I_M + \mu_m \beta_1 \mathbf{H}_{i-1} \quad (127)$$

$$L = \beta_1 \beta_2 = 0 \quad (128)$$

It follows that we can write the extended relation:

$$\begin{bmatrix} \tilde{\mathbf{w}}_i \\ \tilde{\mathbf{w}}_{i-1} \end{bmatrix} = \begin{bmatrix} \mathbf{J}_{i-1} & \mathbf{K}_{i-1} \\ I_M & 0 \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{w}}_{i-1} \\ \tilde{\mathbf{w}}_{i-2} \end{bmatrix} + \mu_m \begin{bmatrix} \mathbf{s}_i(\psi_{i-1}) \\ 0 \end{bmatrix}. \quad (129)$$

$$\stackrel{\triangleq}{\mathbf{B}_{i-1}}$$

where we are denoting the coefficient matrix by \mathbf{B}_{i-1} , which can be written as the difference

$$\mathbf{B}_{i-1} \triangleq P - \mathbf{M}_{i-1}, \quad (130)$$

with

$$P = \begin{bmatrix} (1 + \beta) I_M & -\beta I_M \\ I_M & 0 \end{bmatrix}, \quad \mathbf{M}_{i-1} = \begin{bmatrix} \mu_m (1 + \beta_1) \mathbf{H}_{i-1} & -\mu_m \beta_1 \mathbf{H}_{i-1} \\ 0 & 0 \end{bmatrix}. \quad (131)$$

The eigenvalue decomposition of P can be easily seen to be given by $P = V D V^{-1}$, where

$$V = \begin{bmatrix} I_M & -\beta I_M \\ I_M & -I_M \end{bmatrix}, \quad V^{-1} = \frac{1}{1 - \beta} \begin{bmatrix} I_M & -\beta I_M \\ I_M & -I_M \end{bmatrix}, \quad D = \begin{bmatrix} I_M & 0 \\ 0 & \beta I_M \end{bmatrix}. \quad (132)$$

Therefore, we have

$$\mathbf{B}_{i-1} = V (D - V^{-1} \mathbf{M}_{i-1} V) V^{-1} = V \begin{bmatrix} I_M - \frac{\mu_m}{1 - \beta} \mathbf{H}_{i-1} & \frac{\mu_m \beta'}{1 - \beta} \mathbf{H}_{i-1} \\ -\frac{\mu_m}{1 - \beta} \mathbf{H}_{i-1} & \beta I_M + \frac{\mu_m \beta'}{1 - \beta} \mathbf{H}_{i-1} \end{bmatrix} V^{-1}, \quad (133)$$

where

$$\beta' \triangleq \beta \beta_1 + \beta - \beta_1 = \beta \beta_1 + \beta_2. \quad (134)$$

Multiplying both sides of (129) by V^{-1} from the left and recalling definition (28), we obtain

$$\begin{bmatrix} \hat{\mathbf{w}}_i \\ \hat{\mathbf{w}}_i \end{bmatrix} = \begin{bmatrix} I_M - \frac{\mu_m}{1 - \beta} \mathbf{H}_{i-1} & \frac{\mu_m \beta'}{1 - \beta} \mathbf{H}_{i-1} \\ -\frac{\mu_m}{1 - \beta} \mathbf{H}_{i-1} & \beta I_M + \frac{\mu_m \beta'}{1 - \beta} \mathbf{H}_{i-1} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{w}}_{i-1} \\ \hat{\mathbf{w}}_{i-1} \end{bmatrix} + \frac{\mu_m}{1 - \beta} \begin{bmatrix} \mathbf{s}_i(\psi_{i-1}) \\ \mathbf{s}_i(\psi_{i-1}) \end{bmatrix}. \quad (135)$$

Appendix C. Proof of Theorem 4

From the first row of recursion (29) we have

$$\hat{\mathbf{w}}_t = \left(I_M - \frac{\mu_m \mathbf{H}_{t-1}}{1-\beta} \right) \hat{\mathbf{w}}_{t-1} + \frac{\mu_m \beta' \mathbf{H}_{t-1}}{1-\beta} \hat{\mathbf{w}}_{t-1} + \frac{\mu_m}{1-\beta} \mathbf{s}_t(\psi_{t-1}). \quad (136)$$

Let $t \in (0, 1)$. Squaring both sides and taking expectations conditioned on \mathcal{F}_{t-1} , and using Jensen's inequality, we obtain under Assumptions 1 and 2:

$$\begin{aligned} & \mathbb{E} \|\hat{\mathbf{w}}_t\|^2 | \mathcal{F}_{t-1}] \\ &= \left\| \left(I_M - \frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \right) \hat{\mathbf{w}}_{t-1} + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} \right\|^2 + \frac{\mu_m^2}{(1-\beta)^2} \mathbb{E} \|\mathbf{s}_t(\psi_{t-1})\|^2 | \mathcal{F}_{t-1}] \\ &\stackrel{(a)}{\leq} \left\| (1-t) \frac{1}{1-t} \left(I_M - \frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \right) \hat{\mathbf{w}}_{t-1} + t \frac{1}{t} \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} \right\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &\leq \frac{1}{1-t} \left\| \left(I_M - \frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \right) \hat{\mathbf{w}}_{t-1} \right\|^2 + \frac{1}{t} \left\| \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} \right\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &\stackrel{(b)}{\leq} \frac{1}{1-t} \left(1 - \frac{\mu_m \nu}{1-\beta} \right)^2 \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{1}{t} \frac{\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^2} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &\stackrel{(c)}{=} \left(1 - \frac{\mu_m \nu}{1-\beta} \right) \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m \beta'^2 \delta^2}{\nu(1-\beta)} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2). \end{aligned} \quad (137)$$

where (a) holds because of equation (14) in Assumption (2), (b) holds because $\nu I \leq \mathbf{H}_{t-1} \leq \delta I$ under Assumption (1), and (c) holds because we selected $t = \frac{\mu_m \nu}{1-\beta}$. Taking expectation again, we remove the conditioning to find:

$$\mathbb{E} \|\hat{\mathbf{w}}_t\|^2 \leq \left(1 - \frac{\mu_m \nu}{1-\beta} \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2}{\nu(1-\beta)^2} (\gamma^2 \mathbb{E} \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2). \quad (138)$$

Furthermore, squaring (124) and using the inequality $\|a + b\|^2 \leq 2\|a\|^2 + 2\|b\|^2$ we get

$$\begin{aligned} \|\tilde{\mathbf{w}}_{t-1}\|^2 &\leq 2(1 + \beta_1)^2 \|\tilde{\mathbf{w}}_{t-1}\|^2 + 2\beta_1^2 \|\tilde{\mathbf{w}}_{t-2}\|^2 \leq 2(1 + \beta_1)^2 (\|\tilde{\mathbf{w}}_{t-1}\|^2 + \|\tilde{\mathbf{w}}_{t-2}\|^2) \\ &= 2(1 + \beta_1)^2 \left\| \begin{bmatrix} \tilde{\mathbf{w}}_{t-1} \\ \tilde{\mathbf{w}}_{t-2} \end{bmatrix} \right\|^2 = 2(1 + \beta_1)^2 \|V V^{-1} \begin{bmatrix} \tilde{\mathbf{w}}_{t-1} \\ \tilde{\mathbf{w}}_{t-2} \end{bmatrix}\|^2 \\ &\leq 2(1 + \beta_1)^2 \|V\|^2 \left\| \begin{bmatrix} \tilde{\mathbf{w}}_{t-1} \\ \tilde{\mathbf{w}}_{t-2} \end{bmatrix} \right\|^2. \end{aligned} \quad (139)$$

It is known that there exists some constant $d > 0$ such that $\|V\|^2 \leq d \|V\|_F^2$. From expression (27) for V we have

$$\|V\|_F^2 = 3\|I_M\|_F^2 + \beta^2 \|I_M\|_F^2 \leq 4\|I_M\|_F^2 = 4M.$$

Let $v^2 \triangleq 4dM$, so that $\|V\|^2 \leq v^2$. Therefore, under expectation, we conclude that it also holds:

$$\mathbb{E} \|\tilde{\psi}_{t-1}\|^2 \leq 2(1 + \beta_1)^2 v^2 (\mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2). \quad (140)$$

Substituting (140) into (138), we get

$$\begin{aligned} \mathbb{E} \|\hat{\mathbf{w}}_t\|^2 &\leq \left(1 - \frac{\mu_m \nu}{1-\beta} + \frac{2(1 + \beta_1)^2 \gamma^2 v^2}{(1-\beta)^2} \mu_m^2 \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2 \sigma_s^2}{(1-\beta)^2} \\ &\quad + \left(\frac{\mu_m \beta'^2 \delta^2}{\nu(1-\beta)} + \frac{2(1 + \beta_1)^2 \gamma^2 v^2}{(1-\beta)^2} \mu_m^2 \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2. \end{aligned} \quad (141)$$

Now, let us consider the second row of (29), namely,

$$\hat{\mathbf{w}}_t = -\frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \right) \hat{\mathbf{w}}_{t-1} + \frac{\mu_m}{1-\beta} \mathbf{s}_t(\psi_{t-1}). \quad (142)$$

As before, squaring and taking expectations of both sides, and using Jensen's inequality, we obtain under Assumptions 1 and 2:

$$\begin{aligned} & \mathbb{E} \|\hat{\mathbf{w}}_t\|^2 \\ &\leq \mathbb{E} \left\| \beta \hat{\mathbf{w}}_{t-1} + \left(\frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} - \frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} \right) \right\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \mathbb{E} \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &\stackrel{(a)}{\leq} \beta \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{1}{1-\beta} \mathbb{E} \left\| \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} - \frac{\mu_m}{1-\beta} \mathbf{H}_{t-1} \hat{\mathbf{w}}_{t-1} \right\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \mathbb{E} \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &\leq \beta \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{2\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^3} \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{2\mu_m^2 \delta^2}{(1-\beta)^3} \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \mathbb{E} \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2) \\ &= \left(\beta + \frac{2\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^3} \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{2\mu_m^2 \delta^2}{(1-\beta)^3} \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2}{(1-\beta)^2} (\gamma^2 \mathbb{E} \|\tilde{\psi}_{t-1}\|^2 + \sigma_s^2), \end{aligned} \quad (143)$$

where (a) holds since $\mathbb{E} \|\beta \mathbf{x} + \mathbf{y}\|^2 = \mathbb{E} \|\beta \mathbf{x} + (1-\beta) \frac{1}{1-\beta} \mathbf{y}\|^2 \leq \beta \mathbb{E} \|\mathbf{x}\|^2 + \frac{1}{1-\beta} \mathbb{E} \|\mathbf{y}\|^2$. Substituting (139) into (143), it follows that:

$$\begin{aligned} \mathbb{E} \|\hat{\mathbf{w}}_t\|^2 &\leq \left(\beta + \frac{2\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 v^2}{(1-\beta)^2} \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 + \frac{\mu_m^2 \sigma_s^2}{(1-\beta)^2} \\ &\quad + \left(\frac{2\mu_m^2 \delta^2}{(1-\beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 v^2}{(1-\beta)^2} \right) \mathbb{E} \|\hat{\mathbf{w}}_{t-1}\|^2 \end{aligned} \quad (144)$$

Combining relations (141) and (144) leads to the desired result (33)–(34). Let us now examine the stability of the 2×2 coefficient matrix:

$$\Gamma \triangleq \begin{bmatrix} a & b \\ c & d \end{bmatrix}, \quad (145)$$

where

$$\begin{aligned} a &= 1 - \frac{\mu_m \nu}{1-\beta} + \frac{2(1 + \beta_1)^2 \gamma^2 v^2}{(1-\beta)^2} \mu_m^2, & b &= \frac{\mu_m \beta'^2 \delta^2}{\nu(1-\beta)} + \frac{2(1 + \beta_1)^2 \gamma^2 v^2}{(1-\beta)^2} \mu_m^2, \\ c &= \frac{2\mu_m^2 \delta^2}{(1-\beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 v^2}{(1-\beta)^2}, & d &= \beta + \frac{2\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 v^2}{(1-\beta)^2}. \end{aligned} \quad (146)$$

When μ_m is sufficiently small, a, b, c, d are all positive. Since the spectral radius of a matrix is upper bounded by its 1-norm, we have that

$$\rho(\Gamma) \leq \max\{a + c, b + d\}. \quad (147)$$

From (146), we further have

$$\begin{aligned} a + c &\leq 1 - \frac{\mu_m \nu}{1 - \beta} + \frac{2(1 + \beta_1)^2 \gamma^2 \nu^2}{(1 - \beta)^2} \mu_m^2 + \frac{2\mu_m^2 \delta^2}{(1 - \beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 \nu^2}{(1 - \beta)^2} \\ &= 1 - \frac{\mu_m \nu}{1 - \beta} + \frac{4(1 + \beta_1)^2 \gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2 \\ &\leq 1 - \frac{\mu_m \nu}{1 - \beta} + \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2, \end{aligned} \quad (148)$$

where the last inequality holds because $1 - \beta < 1$ and $1 + \beta_1 < 2$. Similarly, we also have

$$b + d \leq \beta + \frac{\delta^2 \mu_m}{\nu(1 - \beta)} + \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2. \quad (149)$$

Combining (147)–(149), we reach

$$\rho(\Gamma) \leq \max \left\{ 1 - \frac{\mu_m \nu}{1 - \beta} + \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2, \beta + \frac{\delta^2 \mu_m}{\nu(1 - \beta)} + \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2 \right\}. \quad (150)$$

If the step-size μ_m is small enough to satisfy the following conditions

$$\begin{cases} \frac{\mu_m \nu}{1 - \beta} > \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2, \\ \frac{\delta^2 \mu_m}{\nu(1 - \beta)} > \frac{16\gamma^2 \nu^2 + 2\delta^2}{(1 - \beta)^3} \mu_m^2, \\ 1 - \beta > \frac{2\delta^2 \mu_m}{\nu(1 - \beta)}, \end{cases} \quad (151)$$

which is also equivalent to

$$\mu_m < \min \left\{ \frac{(1 - \beta)^2 \nu}{32\gamma^2 \nu^2 + 4\delta^2}, \frac{(1 - \beta)^2 \delta^2}{16\gamma^2 \nu^3 + 2\delta^2 \nu}, \frac{\nu(1 - \beta)^2}{2\delta^2} \right\} = \frac{(1 - \beta)^2 \nu}{32\gamma^2 \nu^2 + 4\delta^2}, \quad (152)$$

then it holds that

$$\rho(\Gamma) < \max \left\{ 1 - \frac{\mu_m \nu}{2(1 - \beta)}, \beta + \frac{2\delta^2 \mu_m}{\nu(1 - \beta)} \right\} \leq 1, \quad (153)$$

in which case Γ will be a stable matrix.

When Γ is stable, it then follows from (33) that

$$\limsup_{i \rightarrow \infty} \frac{\mathbb{E} \|\tilde{\mathbf{w}}_i\|^2}{\mathbb{E} \|\mathbf{w}_i\|^2} \leq (I_2 - \Gamma)^{-1} \begin{bmatrix} e \\ f \end{bmatrix}. \quad (154)$$

Notice that

$$(I_2 - \Gamma)^{-1} = \begin{bmatrix} 1 - a & -b \\ -c & 1 - d \end{bmatrix}^{-1} = \frac{1}{(1 - a)(1 - d) - bc} \begin{bmatrix} 1 - d & b \\ c & 1 - a \end{bmatrix} \quad (155)$$

$$\begin{aligned} &\stackrel{(146)}{=} \frac{1}{\mu_m \nu + p_1 \mu_m^2 + p_2 \mu_m^3 + p_3 \mu_m^4} \begin{bmatrix} 1 - \beta + p_4 \mu_m^2 & \frac{\mu_m \beta^2 \delta^2}{\nu(1 - \beta)} + p_5 \mu_m^2 \\ \frac{2\mu_m^2 \delta^2}{(1 - \beta)^3} + \frac{2\mu_m^2 \gamma^2 (1 + \beta_1)^2 \nu^2}{(1 - \beta)^2} & \frac{\mu_m \nu}{1 - \beta} + p_6 \mu_m^2 \end{bmatrix} \end{aligned} \quad (155)$$

where

$$\begin{aligned} p_1 &\triangleq -\frac{2(1 + \beta_1)^2 \gamma^2 \nu^2}{1 - \beta} < 0, \quad p_4 \triangleq -\frac{2\beta^2 \delta^2}{(1 - \beta)^3} - \frac{2\gamma^2 (1 + \beta_1)^2 \nu^2}{(1 - \beta)^2} < 0, \\ p_5 &\triangleq \frac{2(1 + \beta_1)^2 \gamma^2 \nu^2}{(1 - \beta)^2} > 0, \quad p_6 \triangleq -\frac{2(1 + \beta_1)^2 \gamma^2 \nu^2}{(1 - \beta)^2} < 0. \end{aligned} \quad (156)$$

For simplicity, we omit the expression of p_2 and p_3 here. Notice that

$$\mu_m \nu + p_1 \mu_m^2 + p_2 \mu_m^3 + p_3 \mu_m^4 = \frac{\mu_m \nu}{2} + \left(\frac{\mu_m \nu}{2} + p_1 \mu_m^2 + p_2 \mu_m^3 + p_3 \mu_m^4 \right). \quad (157)$$

Although $p_1 < 0$, it still holds that $\frac{\mu_m \nu}{2} + p_1 \mu_m^2 + p_2 \mu_m^3 + p_3 \mu_m^4 > 0$ when μ_m is sufficiently small, which implies that

$$\mu_m \nu + p_1 \mu_m^2 + p_2 \mu_m^3 + p_3 \mu_m^4 > \frac{\mu_m \nu}{2}. \quad (158)$$

Similarly, it holds that

$$\frac{\mu_m \beta^2 \delta^2}{\nu(1 - \beta)} + p_5 \mu_m^2 = \frac{2\mu_m \beta^2 \delta^2}{\nu(1 - \beta)} - \left(\frac{\mu_m \beta^2 \delta^2}{\nu(1 - \beta)} - p_5 \mu_m^2 \right) \leq \frac{2\mu_m \beta^2 \delta^2}{\nu(1 - \beta)}, \quad (159)$$

where the last inequality holds because $\frac{2\mu_m \beta^2 \delta^2}{\nu(1 - \beta)} - p_5 \mu_m^2 > 0$ for sufficiently small step-size. Furthermore, since $p_4 < 0$ and $p_6 < 0$, we also have

$$1 - \beta + p_4 \mu_m^2 < 1 - \beta, \quad \frac{\mu_m \nu}{1 - \beta} + p_6 \mu_m^2 < \frac{\mu_m \nu}{1 - \beta}. \quad (160)$$

Substitute (158), (159) and (160) into (155), we have

$$(I_2 - \Gamma)^{-1} \leq \begin{bmatrix} \frac{4\mu_m \delta^2}{(1 - \beta)^3 \nu} + \frac{\mu_m \nu}{4\mu_m \gamma^2 (1 + \beta_1)^2 \nu^2} & \frac{4\beta^2 \delta^2}{\nu^2 (1 - \beta)} \\ \frac{2(1 - \beta)}{4\mu_m \delta^2} + \frac{4\beta^2 \delta^2 \nu}{(1 - \beta)^2 \nu} & \frac{4\beta^2 \delta^2}{\nu^2 (1 - \beta)} \end{bmatrix} \quad (161)$$

Combining (154) and (161), we have

$$\begin{aligned} \limsup_{i \rightarrow \infty} \frac{\mathbb{E} \|\tilde{\mathbf{w}}_i\|^2}{\mathbb{E} \|\mathbf{w}_i\|^2} &\leq (I_2 - \Gamma)^{-1} \begin{bmatrix} e \\ f \end{bmatrix} \\ &\leq \begin{bmatrix} \frac{2(1 - \beta)}{4\mu_m \delta^2} + \frac{\mu_m \nu}{4\mu_m \gamma^2 (1 + \beta_1)^2 \nu^2} & \frac{4\beta^2 \delta^2}{\nu^2 (1 - \beta)} \\ \frac{2(1 - \beta)}{4\mu_m \delta^2} + \frac{4\beta^2 \delta^2 \nu}{(1 - \beta)^2 \nu} & \frac{4\beta^2 \delta^2}{\nu^2 (1 - \beta)} \end{bmatrix} \begin{bmatrix} \frac{\mu_m^2 \delta^2}{(1 - \beta)^2} \\ \frac{\mu_m \nu}{1 - \beta} \end{bmatrix} \\ &= \begin{bmatrix} \frac{2\mu_m^2 \delta^2}{(1 - \beta)^3} + \frac{4\mu_m^3 \delta^2 \nu}{(1 - \beta)^2 \nu} & \frac{2\mu_m \delta^2}{(1 - \beta) \nu} + \frac{4\beta^2 \delta^2 \nu \mu_m^2}{4\mu_m \gamma^2 (1 + \beta_1)^2 \nu^2} \\ \frac{2\mu_m^2 \delta^2}{(1 - \beta)^3} + \frac{4\mu_m^3 \delta^2 \nu}{(1 - \beta)^2 \nu} & \frac{2\mu_m \delta^2}{(1 - \beta) \nu} + \frac{4\beta^2 \delta^2 \nu \mu_m^2}{4\mu_m \gamma^2 (1 + \beta_1)^2 \nu^2} \end{bmatrix} \leq \begin{bmatrix} \frac{3\mu_m \delta^2}{(1 - \beta)^2} \\ \frac{3\mu_m \nu}{(1 - \beta)^2} \end{bmatrix} \end{aligned} \quad (162)$$

where in the last inequality we choose sufficiently small μ_m such that

$$\frac{4\beta^2\delta^2\sigma_s^2\mu_m^2}{(1-\beta)^3\nu^2} < \frac{\mu_m\sigma_s^2}{(1-\beta)\nu} + \frac{4\mu_m^3\delta^2\sigma_s^2}{(1-\beta)^5\nu} + \frac{4\mu_m^3\gamma^2(1+\beta)^2\nu^2\sigma_s^2}{(1-\beta)^4\nu} < \frac{\mu_m^2\sigma_s^2}{(1-\beta)^3} \quad (163)$$

Therefore, we have the following result

$$\limsup_{t \rightarrow \infty} \mathbb{E} \|\hat{w}_t\|^2 = O\left(\frac{\mu_m\sigma_s^2}{(1-\beta)\nu}\right), \quad \limsup_{t \rightarrow \infty} \mathbb{E} \|w_t\|^2 = O\left(\frac{\mu_m^2\sigma_s^2}{(1-\beta)^3}\right). \quad (164)$$

and

$$\begin{aligned} \limsup_{t \rightarrow \infty} \mathbb{E} \left\| \begin{bmatrix} \hat{w}_t \\ \hat{w}_{t-1} \end{bmatrix} \right\|^2 &= \limsup_{t \rightarrow \infty} \mathbb{E} \left\| V \begin{bmatrix} \hat{w}_t \\ \hat{w}_{t-1} \end{bmatrix} \right\|^2 \\ &\leq \nu^2 \left(\limsup_{t \rightarrow \infty} \mathbb{E} \left\| \begin{bmatrix} \hat{w}_t \\ \hat{w}_{t-1} \end{bmatrix} \right\|^2 \right) \\ &= \nu^2 \left(\limsup_{t \rightarrow \infty} (\mathbb{E} \|\hat{w}_t\|^2 + \mathbb{E} \|\hat{w}_{t-1}\|^2) \right) = O\left(\frac{\mu_m\sigma_s^2}{(1-\beta)\nu}\right), \end{aligned} \quad (165)$$

from which we conclude that (37) holds.

Appendix D. Proof of Corollary 5

To simplify the notation, we refer to (33) and introduce the quantities:

$$z_t = \begin{bmatrix} \mathbb{E} \|\hat{w}_t\|^2 \\ \mathbb{E} \|\hat{w}_{t-1}\|^2 \end{bmatrix}, \quad \Gamma = \begin{bmatrix} a & b \\ c & d \end{bmatrix}, \quad r = \begin{bmatrix} e \\ f \end{bmatrix}. \quad (166)$$

Then, relation (33) can be rewritten as

$$z_t \preceq \Gamma z_{t-1} + r. \quad (167)$$

It follows that, in terms of the 1-norm,

$$\|z_t\|_1 \leq \|\Gamma\|_1 \|z_{t-1}\|_1 + \|r\|_1, \quad (168)$$

where

$$\|\Gamma\|_1 = \max \left\{ 1 - \frac{\mu_m\nu}{1-\beta} + B_1\mu_m^2, \beta + B_3\mu_m \right\} \quad (169)$$

for some constant B_1 and B_2 . Now we can choose μ_m sufficiently small to satisfy

$$B_1\mu_m^2 < \frac{\nu\mu_m}{2(1-\beta)}, \quad \left(B_2 + \frac{\nu}{2(1-\beta)} \right) \mu_m < 1 - \beta, \quad (170)$$

which implies that

$$\|\Gamma\|_1 \leq 1 - \frac{\mu_m\nu}{1-\beta} + B_1\mu_m^2 \leq 1 - \frac{\mu_m\nu}{2(1-\beta)} \triangleq \rho_1 < 1 \quad (171)$$

Then, from (168) we have

$$\|z_t\|_1 \leq \rho_1 \|z_{t-1}\|_1 + \|r\|_1. \quad (172)$$

Iterating (172) gives

$$\|z_t\|_1 \leq \rho_1^{t+1} \|z_{-1}\|_1 + \frac{\|r\|_1}{1-\rho_1}. \quad (173)$$

Recall the expressions of e and f from (34), we have $\|r\|_1 \leq \frac{B_3\mu_m^2\sigma_s^2}{(1-\beta)^3}$ for some constant B_3 .

Since $1 - \rho_1 = \frac{\mu_m\nu}{2(1-\beta)}$, we get $\|r\|_1 / (1 - \rho_1) \leq \frac{2B_3\mu_m\sigma_s^2}{(1-\beta)\nu}$. From (173), we have

$$\|z_t\|_1 \leq \rho_1^{t+1} \|z_{-1}\|_1 + \frac{2B_3\mu_m\sigma_s^2}{(1-\beta)\nu}. \quad (174)$$

Accordingly, using

$$\|z_t\|_1 = \mathbb{E} \|\hat{w}_t\|^2 + \mathbb{E} \|\hat{w}_{t-1}\|^2 \quad (175)$$

we also find that

$$\mathbb{E} \|\hat{w}_t\|^2 \leq \rho_1^{t+1} \|z_{-1}\|_1 + \frac{2B_3\mu_m\sigma_s^2}{(1-\beta)\nu}. \quad (176)$$

On the other hand, we know from the second row of (33) that

$$\mathbb{E} \|\hat{w}_t\|^2 \leq (\beta + c_1\mu_m^2) \mathbb{E} \|\hat{w}_{t-1}\|^2 + c_2\mu_m^2 \mathbb{E} \|\hat{w}_{t-1}\|^2 + c_3\mu_m^2 \quad (177)$$

for constants

$$c_1 \triangleq \frac{2\beta^2\delta^2}{(1-\beta)^3} + \frac{2\gamma^2(1+\beta_1)^2\nu^2}{(1-\beta)^2}, \quad c_2 \triangleq \frac{2\delta^2}{(1-\beta)^3} + \frac{2\gamma^2(1+\beta)^2\nu^2}{(1-\beta)^2}, \quad c_3 \triangleq \frac{\sigma_s^2}{(1-\beta)^2}. \quad (178)$$

To simplify the notation, with the facts that $\beta' < 1$, $\beta < 1$ and $\beta_1 < 1$, we have

$$c_1 \leq \frac{B_4(\delta^2 + \gamma^2)}{(1-\beta)^3} \triangleq c_4, \quad c_2 \leq \frac{B_4(\delta^2 + \gamma^2)}{(1-\beta)^3} = c_4 \quad (179)$$

for some constant B_4 . Substituting (179) into (177) we get

$$\mathbb{E} \|\hat{w}_t\|^2 \leq (\beta + c_4\mu_m^2) \mathbb{E} \|\hat{w}_{t-1}\|^2 + c_4\mu_m^2 \mathbb{E} \|\hat{w}_{t-1}\|^2 + c_3\mu_m^2. \quad (180)$$

Now we substitute (176) into (180), and reach

$$\mathbb{E} \|w_t\|^2 \leq (\beta + c_4\mu_m^2) \mathbb{E} \|\hat{w}_{t-1}\|^2 + c_4\mu_m^2 \|z_{-1}\|_1 + \frac{2B_3c_4\sigma_s^2}{(1-\beta)\nu} \mu_m^3 + c_3\mu_m^2. \quad (181)$$

When μ_m is sufficiently small such that

$$\frac{2B_3c_4\sigma_s^2}{(1-\beta)\nu} \mu_m^3 \leq c_3\mu_m^2, \quad (182)$$

(181) becomes

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq (\beta + c_4\mu_m^2)\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 + c_4\rho_1^i\|z_{-1}\|_1\mu_m^2 + 2c_3\mu_m^2. \quad (183)$$

Notice that

$$\beta + c_4\mu_m^2 = 1 - (1 - \beta) + c_4\mu_m^2 = 1 - \frac{1 - \beta}{2} + \left(c_4\mu_m^2 - \frac{1 - \beta}{2}\right). \quad (184)$$

It is clear that we can choose a sufficiently small μ_m for the last term between brackets to become negative, in which case

$$\beta + c_4\mu_m^2 \leq 1 - \frac{1 - \beta}{2} = \frac{1 + \beta}{2} \triangleq \alpha < 1 \quad (185)$$

It follows that

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 &\leq \alpha\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 + (c_4\|z_{-1}\|_1\rho_1^i)\mu_m^2 + 2c_3\mu_m^2 \\ &\leq \alpha^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2 + c_4\|z_{-1}\|_1\mu_m^i\rho_1^i \sum_{s=0}^i \left(\frac{\alpha}{\rho_1}\right)^s + \frac{2c_3\mu_m^2}{1 - \alpha}. \end{aligned} \quad (186)$$

Recall that $\rho_1 = 1 - \frac{\mu_m\nu}{2(1-\beta)}$ and $\alpha = 1 - (1 - \beta)/2$. Therefore, it holds that $\alpha/\rho_1 < 1$ for sufficiently small μ_m . As a result, we have

$$\sum_{s=0}^i \left(\frac{\alpha}{\rho_1}\right)^s \leq \frac{1}{1 - \frac{\alpha}{\rho_1}} = \frac{\rho_1}{\rho_1 - \alpha} = \frac{2(1 - \beta) - \mu_m\nu}{(1 - \beta)^2 - \mu_m\nu} \leq \frac{B_5}{1 - \beta} \quad (187)$$

for some constant B_5 when μ_m is sufficiently small. Substituting (187) into (186), we get

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq \alpha^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2 + \frac{B_5c_4\|z_{-1}\|_1\rho_1^i}{1 - \beta}\mu_m^2 + \frac{4c_3\mu_m^2}{1 - \beta}. \quad (188)$$

To assess the term that depends on the initial state, $\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2$, let us consider the boundary conditions (24)–(25). Then, from (28) it holds that

$$\tilde{\mathbf{w}}_{-1} = \frac{\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{w}}_{-2}}{1 - \beta} = \frac{\mathbf{w}_{-2} - \mathbf{w}_{-1}}{1 - \beta} = \frac{\mu_m\nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1})}{1 - \beta} \quad (189)$$

so that $\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^2 = c_5\mu_m^2$, where

$$c_5 \triangleq \mathbb{E}\|\nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1})\|^2 / (1 - \beta)^2. \quad (190)$$

Substituting this conclusion into (188), and recalling the expression of c_3 , c_4 and c_5 , we arrive at

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 &\leq \frac{B_6\alpha^{i+1}\mu_m^2}{(1 - \beta)^2} + \frac{B_7(\delta^2 + \gamma^2)\rho_1^i}{(1 - \beta)^4}\mu_m^2 + \frac{B_8\mu_m^2\sigma_s^2}{(1 - \beta)^3} \\ &\stackrel{(a)}{\leq} \frac{B_9\rho_1^{i+1}\mu_m^2}{(1 - \beta)^2} + \frac{B_9(\delta^2 + \gamma^2)\rho_1^{i+1}}{(1 - \beta)^4}\mu_m^2 + \frac{B_8\mu_m^2\sigma_s^2}{(1 - \beta)^3} \end{aligned}$$

$$\stackrel{(b)}{\leq} \frac{B_{10}(\delta^2 + \gamma^2)\rho_1^{i+1}}{(1 - \beta)^4}\mu_m^2 + \frac{B_8\mu_m^2\sigma_s^2}{(1 - \beta)^3}, \quad (191)$$

where (a) holds because $\alpha \leq \rho_1$ when μ_m is sufficiently small, and there must exist some constant B_9 such that $B_7/\rho_1 < B_9$; (b) holds because there must exist some constant B_{10} such that

$$B_6(1 - \beta)^2 + B_9(\delta^2 + \gamma^2) \leq B_{10}(\delta^2 + \gamma^2). \quad (192)$$

Appendix E. Proof of Theorem 6

The argument below is motivated by the derivation of Theorem 9.2 in (Sayed, 2014a). Here, however, we extend the arguments and expand the details in order to clearly identify the constants inside the $O(\mu)$ notation, which was not necessary in (Sayed, 2014a). The derivation becomes more demanding, as the arguments show.

From the first row of recursion (29) we have

$$\tilde{\mathbf{w}}_i = \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m}{1 - \beta} \mathbf{s}_i(\psi_{i-1}). \quad (193)$$

Now applying the following inequality, for any two vectors $\{a, b\}$:

$$\|a + b\|^4 \leq \|a\|^4 + 3\|b\|^4 + 8\|a\|^2\|b\|^2 + 4\|a\|^2(a^\top b) \quad (194)$$

we get

$$\begin{aligned} &\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 \mathcal{F}_{i-1} \\ &= \mathbb{E}\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} + \frac{3\mu_m}{(1 - \beta)^4} \mathbb{E}\|\mathbf{s}_i(\psi_{i-1})\|^4 \mathcal{F}_{i-1} \right\|^4 \\ &\quad + \frac{8\mu_m^2}{(1 - \beta)^2} \mathbb{E}\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} \right\|^2 \mathbb{E}\|\mathbf{s}_i(\psi_{i-1})\|^2 \mathcal{F}_{i-1} \\ &\leq \mathbb{E}\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} \right\|^4 + \frac{3\mu_m^4 (\gamma_4^4 \|\tilde{\psi}_{i-1}\|^4 + \sigma_{s,4})}{(1 - \beta)^4} \\ &\quad + \frac{8\mu_m^2}{(1 - \beta)^2} \mathbb{E}\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} \right\|^2 (\gamma^2 \|\tilde{\psi}_{i-1}\|^2 + \sigma_s^2). \end{aligned} \quad (195)$$

We next bound each of the terms that appear on the right-hand side. Using Jensen's inequality, the lower and upper bounds on the Hessian matrix from (11), we have

$$\begin{aligned} &\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} \right\|^4 \\ &= \left\| (1-t) \frac{1}{1-t} \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1 - \beta}\right) \tilde{\mathbf{w}}_{i-1} + t \frac{1}{t} \frac{\mu_m \beta' \mathbf{H}_{i-1}}{1 - \beta} \tilde{\mathbf{w}}_{i-1} \right\|^4 \end{aligned}$$

$$\begin{aligned}
&\leq \frac{1}{(1-t)^3} \left(1 - \frac{\mu_m \nu}{1-\beta}\right)^4 \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{1}{t^3} \frac{\mu_m^4 \beta^4 \delta^4}{(1-\beta)^4} \|\hat{\mathbf{w}}_{i-1}\|^4 \\
&\stackrel{(a)}{=} \left(1 - \frac{\mu_m \nu}{1-\beta}\right) \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{\mu_m \beta^4 \delta^4}{(1-\beta) \nu^3} \|\hat{\mathbf{w}}_{i-1}\|^4 \\
&= (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^4 + q_2 \mu_m \|\hat{\mathbf{w}}_{i-1}\|^4,
\end{aligned} \tag{196}$$

where (a) holds because we set $t = \mu_m \nu / (1 - \beta)$, and q_1, q_2 are defined as

$$q_1 \triangleq \frac{\nu}{1-\beta}, \quad q_2 \triangleq \frac{\beta^4 \delta^4}{(1-\beta) \nu^3}. \tag{197}$$

Next we check the terms $\mathbb{E}[\|\mathbf{s}_i(\psi_{i-1})\|^2 | \mathcal{F}_{i-1}]$ and $\mathbb{E}[\|\mathbf{s}_i(\psi_{i-1})\|^4 | \mathcal{F}_{i-1}]$. From (139) we have

$$\|\tilde{\psi}_{i-1}\|^2 \leq B_1 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\mathbf{w}_{i-1}\|^2), \tag{198}$$

where $B_1 = 2(1 + \beta_1)^2 \nu^2$, which also implies that

$$\begin{aligned}
\|\tilde{\psi}_{i-1}\|^4 &\leq B_1^2 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\mathbf{w}_{i-1}\|^2)^2 \\
&\leq 2B_1^2 (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\mathbf{w}_{i-1}\|^4) = B_2 (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\mathbf{w}_{i-1}\|^4),
\end{aligned} \tag{199}$$

where $B_2 = 2B_1^2$. Furthermore, recall in (137) that

$$\begin{aligned}
&\left\| \left(I_M - \frac{\mu_m \mathbf{H}_{i-1}}{1-\beta} \right) \hat{\mathbf{w}}_{i-1} + \frac{\mu_m \beta \mathbf{H}_{i-1}}{1-\beta} \tilde{\mathbf{w}}_{i-1} \right\|^2 \\
&\leq \left(1 - \frac{\mu_m \nu}{1-\beta}\right) \|\hat{\mathbf{w}}_{i-1}\|^2 + \frac{\mu_m \beta^2 \delta^2}{\nu(1-\beta)} \|\tilde{\mathbf{w}}_{i-1}\|^2 \\
&= (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 + q_3 \mu_m \|\tilde{\mathbf{w}}_{i-1}\|^2,
\end{aligned} \tag{200}$$

where we define

$$q_3 \triangleq \frac{\beta^2 \delta^2}{\nu(1-\beta)}. \tag{201}$$

Now substituting (196), (198), (199) and (200) into (195), we get

$$\begin{aligned}
&\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}] \\
&\leq (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^4 + q_2 \mu_m \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{3B_2^4 \mu_m^4}{(1-\beta)^4} (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\tilde{\mathbf{w}}_{i-1}\|^4) + \frac{3\sigma_s^4 \mu_m^4}{(1-\beta)^4} \\
&\quad + \frac{8\mu_m^2}{(1-\beta)^2} [(1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 + q_3 \mu_m \|\tilde{\mathbf{w}}_{i-1}\|^2] [\gamma^2 B_1 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\tilde{\mathbf{w}}_{i-1}\|^2) + \sigma_s^2] \\
&= (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^4 + q_2 \mu_m \|\hat{\mathbf{w}}_{i-1}\|^4 + q_4 \mu_m^4 (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\tilde{\mathbf{w}}_{i-1}\|^4) + q_5 \mu_m^4 \\
&\quad + q_6 \mu_m^2 [(1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 + q_3 \mu_m \|\tilde{\mathbf{w}}_{i-1}\|^2] [\gamma^2 B_1 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\tilde{\mathbf{w}}_{i-1}\|^2) + \sigma_s^2], \\
&= (1 - q_1 \mu_m + q_4 \mu_m^4) \|\hat{\mathbf{w}}_{i-1}\|^4 + (q_2 \mu_m + q_4 \mu_m^4) \|\tilde{\mathbf{w}}_{i-1}\|^4 + q_5 \mu_m^4 \\
&\quad + q_6 \gamma^2 B_1 (1 - q_1 \mu_m) \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^4 + q_6 q_3 \gamma^2 B_1 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^4
\end{aligned}$$

$$\begin{aligned}
&+ q_6 \gamma^2 B_1 \mu_m^2 (1 - q_1 \mu_m + q_3 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 \|\tilde{\mathbf{w}}_{i-1}\|^2 \\
&+ q_6 \sigma_s^2 \mu_m^2 (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 + q_6 q_3 \sigma_s^2 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^2 \\
&\stackrel{(a)}{\leq} (1 - q_1 \mu_m + q_4 \mu_m^4) \|\hat{\mathbf{w}}_{i-1}\|^4 + (q_2 \mu_m + q_4 \mu_m^4) \|\tilde{\mathbf{w}}_{i-1}\|^4 + q_5 \mu_m^4 \\
&+ q_6 \gamma^2 B_1 (1 - q_1 \mu_m) \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2 + q_6 q_3 \gamma^2 B_1 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^2 \\
&+ q_6 \gamma^2 B_1 \mu_m^2 (1 - q_1 \mu_m + q_3 \mu_m) (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\tilde{\mathbf{w}}_{i-1}\|^4) \\
&+ q_6 \sigma_s^2 \mu_m^2 (1 - q_1 \mu_m) \|\hat{\mathbf{w}}_{i-1}\|^2 + q_6 q_3 \sigma_s^2 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^2,
\end{aligned} \tag{202}$$

where we define

$$q_4 \triangleq \frac{3B_2^4 \gamma^4}{(1-\beta)^4}, \quad q_5 \triangleq \frac{3\sigma_s^4}{(1-\beta)^4}, \quad q_6 \triangleq \frac{8}{(1-\beta)^2}, \tag{203}$$

and (a) holds because for any two variables $a, b > 0$ we have

$$ab < 2ab \leq a^2 + b^2. \tag{204}$$

When μ_m is chosen sufficiently small, from (202) we reach

$$\begin{aligned}
&\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}] \\
&\leq \left(1 - \frac{q_1 \mu_m}{2}\right) \|\hat{\mathbf{w}}_{i-1}\|^4 + 2q_2 \mu_m \|\hat{\mathbf{w}}_{i-1}\|^4 + q_6 \sigma_s^2 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2 + q_6 q_3 \sigma_s^2 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^2 + q_5 \mu_m^4 \\
&= \left(1 - \frac{q_1 \mu_m}{2}\right) \|\hat{\mathbf{w}}_{i-1}\|^4 + 2q_2 \mu_m \|\hat{\mathbf{w}}_{i-1}\|^4 + q_7 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2 + q_8 \mu_m^3 \|\tilde{\mathbf{w}}_{i-1}\|^2 + q_5 \mu_m^4,
\end{aligned} \tag{205}$$

where we define

$$q_7 \triangleq q_6 \sigma_s^2, \quad q_8 \triangleq q_6 q_3 \sigma_s^2. \tag{206}$$

On the other hand, recall from (142) that

$$\hat{\mathbf{w}}_i = -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \tilde{\mathbf{w}}_{i-1} + \frac{\mu_m}{1-\beta} \mathbf{s}_i(\psi_{i-1}). \tag{207}$$

Now we also apply inequality (194) to the above equation and get

$$\begin{aligned}
&\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}] \\
&= \left\| -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \tilde{\mathbf{w}}_{i-1} \right\|^4 + \frac{3\mu_m^4}{(1-\beta)^4} \mathbb{E}[\|\mathbf{s}_i(\psi_{i-1})\|^4 | \mathcal{F}_{i-1}] \\
&\quad + \frac{8\mu_m^2}{(1-\beta)^2} \left\| -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \tilde{\mathbf{w}}_{i-1} \right\|^2 \mathbb{E}[\|\mathbf{s}_i(\psi_{i-1})\|^2 | \mathcal{F}_{i-1}] \\
&\leq \left\| -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \tilde{\mathbf{w}}_{i-1} \right\|^4 + \frac{3\mu_m^4}{(1-\beta)^4} \frac{\gamma^4 (\|\hat{\psi}_{i-1}\|^4 + \sigma_s^4)}{(1-\beta)^4} \\
&\quad + \frac{8\mu_m^2}{(1-\beta)^2} \left\| -\frac{\mu_m}{1-\beta} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} + \left(\beta I_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \tilde{\mathbf{w}}_{i-1} \right\|^2 (\gamma^2 \|\tilde{\psi}_{i-1}\|^2 + \sigma_s^2).
\end{aligned} \tag{208}$$

We next bound each of the terms that appear on the right-hand side. Using Jensen's inequality, the lower and upper bounds on the Hessian matrix from (11), and the inequality $\|a + b\|^4 \leq 8\|a\|^4 + 8\|b\|^4$, we have

$$\begin{aligned} & \left\| \frac{\mu_m \mathbf{H}_{i-1}}{1-\beta} \hat{\mathbf{w}}_{i-1} + \left(\beta \mathbf{I}_M + \frac{\mu_m \beta'}{1-\beta} \mathbf{H}_{i-1} \right) \hat{\mathbf{w}}_{i-1} \right\|^4 \\ &= \left\| \beta \hat{\mathbf{w}}_{i-1} + (1-\beta) \left(\frac{\mu_m \beta'}{(1-\beta)^2} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} - \frac{\mu_m}{(1-\beta)^2} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} \right) \right\|^4 \\ &\leq \beta \|\hat{\mathbf{w}}_{i-1}\|^4 + (1-\beta) \left\| \frac{\mu_m \beta'}{(1-\beta)^2} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} - \frac{\mu_m}{(1-\beta)^2} \mathbf{H}_{i-1} \hat{\mathbf{w}}_{i-1} \right\|^4 \\ &\leq \beta \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{8\mu_m^4 \beta'^4 \delta^4}{(1-\beta)^7} \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{8\mu_m^4 \delta^4}{(1-\beta)^7} \|\hat{\mathbf{w}}_{i-1}\|^4 \\ &= (\beta + p_1 \mu_m^4) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4, \end{aligned} \quad (209)$$

where we define

$$p_1 \triangleq \frac{8\beta^4 \delta^4}{(1-\beta)^7}, \quad p_2 \triangleq \frac{8\delta^4}{(1-\beta)^7}.$$

Moreover, recall in (143) that

$$\begin{aligned} & \left\| \beta \hat{\mathbf{w}}_{i-1} + \left(\frac{\mu_m \beta'}{1-\beta} \hat{\mathbf{w}}_{i-1} - \frac{\mu_m \mathbf{H}_{i-1}}{1-\beta} \hat{\mathbf{w}}_{i-1} \right) \right\|^2 \\ &\leq \left(\beta + \frac{2\mu_m^2 \beta'^2 \delta^2}{(1-\beta)^3} \right) \|\hat{\mathbf{w}}_{i-1}\|^2 + \frac{2\mu_m^2 \delta^2}{(1-\beta)^3} \|\hat{\mathbf{w}}_{i-1}\|^2 \\ &= (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 + p_4 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2, \end{aligned} \quad (210)$$

where we define

$$p_3 \triangleq \frac{2\beta'^2 \delta^2}{(1-\beta)^3}, \quad p_4 \triangleq \frac{2\delta^2}{(1-\beta)^3}. \quad (212)$$

Now substituting (209), (211), (198) and (199) into (208), we have

$$\begin{aligned} & \mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}] \\ &\leq (\beta + p_1 \mu_m^4) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 + \frac{3B_2 \gamma^4 \mu_m^4}{(1-\beta)^4} (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\hat{\mathbf{w}}_{i-1}\|^4) + \frac{3\sigma_s^4 \mu_m^4}{(1-\beta)^4} \\ &\quad + \frac{8\mu_m^2}{(1-\beta)^2} [(\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 + p_4 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2] [\gamma^2 B_1 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\hat{\mathbf{w}}_{i-1}\|^2) + \sigma_s^2] \\ &= (\beta + p_1 \mu_m^4) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 + p_5 \mu_m^4 (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\hat{\mathbf{w}}_{i-1}\|^4) + p_6 \mu_m^4 \\ &\quad + p_7 \mu_m^2 [(\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 + p_4 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2] [\gamma^2 B_1 (\|\hat{\mathbf{w}}_{i-1}\|^2 + \|\hat{\mathbf{w}}_{i-1}\|^2) + \sigma_s^2] \\ &= [\beta + (p_1 + p_5) \mu_m^4] \|\hat{\mathbf{w}}_{i-1}\|^4 + (p_2 + p_5) \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 + p_6 \mu_m^4 \\ &\quad + p_7 \gamma^2 B_1 \mu_m^2 (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_4 p_7 \gamma^2 B_1 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 \\ &\quad + p_7 \gamma^2 B_1 \mu_m^2 (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 \|\hat{\mathbf{w}}_{i-1}\|^2. \end{aligned}$$

$$\begin{aligned} & + p_7 \sigma_s^2 \mu_m^2 (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 + p_4 p_7 \sigma_s^2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^2 \\ &\leq [\beta + (p_1 + p_5) \mu_m^4] \|\hat{\mathbf{w}}_{i-1}\|^4 + (p_2 + p_5) \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 + p_6 \mu_m^4 \\ &\quad + p_7 \gamma^2 B_1 \mu_m^2 (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_4 p_7 \gamma^2 B_1 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^4 \\ &\quad + p_7 \gamma^2 B_1 \mu_m^2 (\beta + p_3 \mu_m^2) (\|\hat{\mathbf{w}}_{i-1}\|^4 + \|\hat{\mathbf{w}}_{i-1}\|^4) \\ &\quad + p_7 \sigma_s^2 \mu_m^2 (\beta + p_3 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^2 + p_4 p_7 \sigma_s^2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^2, \end{aligned} \quad (213)$$

where we define

$$p_5 \triangleq \frac{3B_2 \gamma^4}{(1-\beta)^4}, \quad p_6 \triangleq \frac{3\sigma_s^4}{(1-\beta)^4}, \quad p_7 \triangleq \frac{8}{(1-\beta)^2}. \quad (214)$$

When μ_m is sufficiently small, we obtain from (213):

$$\begin{aligned} & \mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}] \\ &\leq (\beta + 2p_7 \gamma^2 B_1 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^4 + 2p_7 \gamma^2 B_1 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^4 + p_4 p_7 \sigma_s^2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^2 \\ &\quad + 2p_7 \beta \sigma_s^2 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^2 + p_6 \mu_m^4 \\ &= (\beta + p_8 \mu_m^2) \|\hat{\mathbf{w}}_{i-1}\|^4 + p_8 \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^4 + p_9 \mu_m^4 \|\hat{\mathbf{w}}_{i-1}\|^2 + p_{10} \mu_m^2 \|\hat{\mathbf{w}}_{i-1}\|^2 + p_6 \mu_m^4 \end{aligned} \quad (215)$$

where we define

$$p_8 \triangleq 2p_7 \gamma^2 B_1, \quad p_9 \triangleq p_4 p_7 \sigma_s^2, \quad p_{10} \triangleq 2p_7 \beta \sigma_s^2. \quad (216)$$

Combining (205) and (215), we have

$$\left[\frac{\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}]}{\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4 | \mathcal{F}_{i-1}]} \right] \leq \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} \|\hat{\mathbf{w}}_{i-1}\|^4 \\ \|\hat{\mathbf{w}}_{i-1}\|^2 \end{bmatrix} + \begin{bmatrix} a' & b' \\ c' & d' \end{bmatrix} \begin{bmatrix} e \\ f \end{bmatrix}, \quad (217)$$

where the constants are

$$\begin{aligned} a &\triangleq 1 - \frac{q_1}{2} \mu_m, & b &\triangleq 2q_2 \mu_m, & d &\triangleq q_6 \sigma_s^2 \mu_m^2, & d' &\triangleq q_3 q_6 \sigma_s^2 \mu_m^3, \\ c &\triangleq p_8 \mu_m^2, & d &\triangleq \beta + p_8 \mu_m^2, & c' &\triangleq p_9 \mu_m^4, & d' &\triangleq p_{10} \mu_m^2, \\ e &\triangleq q_5 \mu_m^4, & f &\triangleq p_6 \mu_m^4. \end{aligned} \quad (218)$$

Taking expectations again over \mathcal{F}_{i-1} for both sides of the inequality (217), we have

$$\left[\frac{\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4]}{\mathbb{E}[\|\hat{\mathbf{w}}_i\|^4]} \right] \leq \underbrace{\begin{bmatrix} a & b \\ c & d \end{bmatrix}}_{\mathbf{r}} \begin{bmatrix} \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^4] \\ \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^2] \end{bmatrix} + \begin{bmatrix} a' & b' \\ c' & d' \end{bmatrix} \begin{bmatrix} e \\ f \end{bmatrix}, \quad (219)$$

Recall from Theorem 4 that

$$\limsup_{t \rightarrow \infty} \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^2] = O(\mu_m), \quad \limsup_{t \rightarrow \infty} \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^4] = O(\mu_m^2), \quad (220)$$

then it holds that

$$\limsup_{t \rightarrow \infty} \begin{bmatrix} a' & b' \\ c' & d' \end{bmatrix} \begin{bmatrix} \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^2] \\ \mathbb{E}[\|\hat{\mathbf{w}}_{i-1}\|^4] \end{bmatrix} + \begin{bmatrix} e \\ f \end{bmatrix} = \begin{bmatrix} O(\mu_m^3) \\ O(\mu_m^3) \end{bmatrix}. \quad (221)$$

When μ_m is sufficiently small, it can be verified that Γ is stable. Therefore, it holds that

$$\begin{aligned} \left[\limsup_{i \rightarrow \infty} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 \right] &= (I - \Gamma)^{-1} \left(\limsup_{i \rightarrow \infty} \begin{bmatrix} a' & b' \\ c' & d' \end{bmatrix} \begin{bmatrix} \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 \\ \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^4 \end{bmatrix} + \begin{bmatrix} e \\ f \end{bmatrix} \right) \\ &= \begin{bmatrix} O(\mu_m^2) \\ O(\mu_m^4) \end{bmatrix}. \end{aligned} \quad (222)$$

Furthermore,

$$\limsup_{i \rightarrow \infty} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 \leq 2\nu^4 \limsup_{i \rightarrow \infty} [\mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 + \mathbb{E} \|\mathbf{w}_i\|^4] = O(\mu_m^2). \quad (223)$$

Appendix F. Proof of Corollary 7

Recall from (219) that

$$\underbrace{\begin{bmatrix} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 \\ \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 \end{bmatrix}}_{y_i} \leq \underbrace{\begin{bmatrix} a & b \\ c & d \end{bmatrix}}_{\Gamma_1} \underbrace{\begin{bmatrix} \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^4 \\ \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^4 \end{bmatrix}}_{y_{i-1}} + \underbrace{\begin{bmatrix} a' & b' \\ c' & d' \end{bmatrix}}_{\Gamma_2} \underbrace{\begin{bmatrix} \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 \\ \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 \end{bmatrix}}_{z_{i-1}} + \underbrace{\begin{bmatrix} e \\ f \end{bmatrix}}_{\tau}. \quad (224)$$

We then have

$$\|y_i\|_1 \leq \|\Gamma_1\|_1 \|y_{i-1}\|_1 + \|\Gamma_2\|_1 \|z_{i-1}\|_1 + \|\tau\|_1. \quad (225)$$

Notice that

$$\|\Gamma_1\|_1 = \max \left\{ 1 - \frac{q_1 \mu_m}{2} + p_8 \mu_m^2, \beta + 2q_2 \mu_m + p_8 \mu_m^2 \right\}, \quad (226)$$

we can always choose μ_m small enough such that

$$\|\Gamma_1\|_1 \leq 1 - \frac{q_1 \mu_m}{4} = 1 - \frac{\mu_m \nu}{4(1-\beta)} \triangleq \rho_2. \quad (227)$$

Similarly, we can also choose μ_m small enough such that

$$\|\Gamma_2\|_1 = \max \{ q_6 \sigma_s^2 \mu_m^2 + p_9 \mu_m^4, q_3 q_6 \sigma_s^2 \mu_m^3 + p_{10} \mu_m^2 \} \leq (q_6 \sigma_s^2 + p_{10}) \mu_m^2. \quad (228)$$

Also recall (174) that

$$\|z_i\|_1 \leq \rho_1^{i+1} \|z_{-1}\|_1 + s_1 \mu_m \stackrel{(a)}{\leq} \rho_2^{i+1} \|z_{-1}\|_1 + s_1 \mu_m \quad (229)$$

where we define

$$s_1 \triangleq \frac{2E_1 \sigma_s^2}{(1-\beta) \nu^4}, \quad (230)$$

for some constant E_1 , and (a) holds because $\rho_1 = 1 - \frac{\mu_m \nu}{2(1-\beta)} \leq \rho_2$. Substituting (227), (228) and (229) into (225), we have

$$\|y_i\|_1 \leq \rho_2 \|y_{i-1}\|_1 + (q_6 \sigma_s^2 + p_{10}) (\rho_2^i \|z_{-1}\|_1 + s_1 \mu_m) \mu_m^2 + 2p_8 \mu_m^4$$

$$\begin{aligned} &= \rho_2 \|y_{i-1}\|_1 + s_2 \rho_2^i \mu_m^2 + s_3 \mu_m^3 + 2p_8 \mu_m^4 \\ &\stackrel{(a)}{\leq} \rho_2 \|y_{i-1}\|_1 + s_2 \rho_2^i \mu_m^2 + 2s_3 \mu_m^3, \end{aligned} \quad (231)$$

where (a) holds when μ_m is sufficiently small, and the constants s_2 and s_3 are defined as

$$s_2 \triangleq (q_6 \sigma_s^2 + p_{10}) \|z_{-1}\|_1, \quad s_3 \triangleq (q_6 \sigma_s^2 + p_{10}) s_1. \quad (232)$$

Iterating (231), we reach

$$\|y_i\|_1 \leq \rho_2^{i+1} \|y_{-1}\|_1 + s_2 (\dot{i} + 1) \rho_2^i \mu_m^2 + \frac{2s_3 \mu_m^3}{1-\rho_2}. \quad (233)$$

Since $\|y_i\|_1 = \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 + \mathbb{E} \|\mathbf{w}_i\|^4$, we have

$$\begin{aligned} \mathbb{E} \|\tilde{\mathbf{w}}_i\|^4 &\leq \rho_2^{i+1} \|y_{-1}\|_1 + s_2 (\dot{i} + 1) \rho_2^i \mu_m^2 + \frac{2s_3 \mu_m^3}{1-\rho_2} \\ &= \rho_2^{i+1} \|y_{-1}\|_1 + s_2 (\dot{i} + 1) \rho_2^i \mu_m^2 + \frac{8(1-\beta) s_3 \mu_m^2}{\nu} \\ &= \rho_2^{i+1} \|y_{-1}\|_1 + s_2 (\dot{i} + 1) \rho_2^i \mu_m^2 + s_4 \mu_m^2, \end{aligned} \quad (234)$$

where s_4 is defined as

$$s_4 \triangleq \frac{8(1-\beta) s_3}{\nu} \quad (235)$$

Now we substitute (234) and (176) into the second row of (219) and reach

$$\begin{aligned} \mathbb{E} \|\mathbf{w}_i\|^4 &\leq (\beta + p_8 \mu_m^2) \mathbb{E} \|\mathbf{w}_{i-1}\|^4 + p_8 \mu_m^2 [\rho_2^i \|y_{-1}\|_1 + s_2 i \rho_2^{i-1} \mu_m^2 + s_4 \mu_m^2] \\ &\quad + p_{10} \rho_2^i \mu_m^2 \|\mathbf{w}_{i-1}\|^2 + p_9 \mu_m^4 [\rho_2^i \|z_{-1}\|_1 + s_1 \mu_m] + p_8 \mu_m^4. \end{aligned} \quad (236)$$

Using the bounds for $\mathbb{E} \|\mathbf{w}_i\|^2$ from Corollary 5, the above inequality becomes

$$\begin{aligned} \mathbb{E} \|\mathbf{w}_i\|^4 &\leq (\beta + p_8 \mu_m^2) \mathbb{E} \|\mathbf{w}_{i-1}\|^4 + p_8 \mu_m^2 [\rho_2^i \|y_{-1}\|_1 + s_2 i \rho_2^{i-1} \mu_m^2 + s_4 \mu_m^2] \\ &\quad + p_{10} E_2 \mu_m^2 \left(\frac{(\rho_2^2 + \gamma^2) \rho_1^i \mu_m^2}{(1-\beta)^4} + \frac{\sigma_s^2 \mu_m^2}{(1-\beta)^3} \right) \\ &\stackrel{(a)}{\leq} (1 - \frac{1-\beta}{2}) \mathbb{E} \|\mathbf{w}_{i-1}\|^4 + s_5 \rho_2^i \mu_m^2 + s_6 i \rho_2^{i-1} \mu_m^4 + s_7 \mu_m^4 \\ &\quad + s_8 \rho_1^i \mu_m^4 + s_9 \mu_m^4 + s_{10} \rho_2^i \mu_m^4 + p_9 \mu_m^4 + s_{11} p_9 \mu_m^5 \\ &\stackrel{(b)}{\leq} \alpha \mathbb{E} \|\mathbf{w}_{i-1}\|^4 + s_5 \rho_2^i \mu_m^2 + s_6 i \rho_2^{i-1} \mu_m^4 + s_8 \rho_1^i \mu_m^4 + s_{10} \rho_2^i \mu_m^4 \\ &\quad + (s_7 + s_9 + 2p_9) \mu_m^4 \\ &\stackrel{(c)}{\leq} \alpha \mathbb{E} \|\mathbf{w}_{i-1}\|^4 + s_5 \rho_2^i \mu_m^2 + s_6 i \rho_2^{i-1} \mu_m^4 + s_8 \rho_1^i \mu_m^4 + s_{10} \rho_2^i \mu_m^4 \\ &\quad + (s_7 + s_9 + 2p_9) \mu_m^4 \end{aligned} \quad (237)$$

where E_2 is some constant. The inequality (a) holds because step-size μ_m is chosen small enough such that $(1-\beta)/2 > p_8\mu_m^2$, (b) holds because $\alpha = 1 - (1-\beta)/2$ and μ_m is chosen such that $p_6\mu_m^4 > s_1p_9\mu_m^5$, and (c) holds because $\rho_1 < \rho_2$. Moreover, the other constants are defined as

$$\begin{aligned} s_5 &\triangleq p_8\|y_{-1}\|_1, & s_6 &\triangleq p_8s_2, & s_7 &\triangleq p_8s_4 \\ s_8 &\triangleq \frac{p_{10}E_2(\delta^2 + \gamma^2)}{(1-\beta)^4}, & s_9 &\triangleq \frac{p_{10}E_2\sigma_s^2}{(1-\beta)^3}, & s_{10} &\triangleq p_9\|z_{-1}\|_1. \end{aligned} \quad (238)$$

Now we continue iterating (237) and reach

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 &\leq \alpha^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 + s_5\mu_m^2 \sum_{k=0}^i \left(\frac{\alpha}{\rho_2}\right)^k + s_6\mu_m^4 \sum_{k=0}^{i-1} (i-k) \left(\frac{\alpha}{\rho_2}\right)^k \\ &\quad + s_8\mu_m^4 \rho_2^i \sum_{k=0}^i \left(\frac{\alpha}{\rho_2}\right)^k + s_{10}\mu_m^4 \rho_2^i \sum_{k=0}^i \left(\frac{\alpha}{\rho_2}\right)^k + \frac{2(s_7 + s_9 + 2p_6)\mu_m^4}{1-\beta}. \end{aligned} \quad (239)$$

Recall $\rho_2 = 1 - \frac{\mu_m\nu}{4(1-\beta)}$, and we can choose μ_m small enough such that $\rho_2 > \alpha = 1 - \frac{1-\beta}{2}$. In this situation, we have

$$\frac{\alpha}{\rho_2} < 1, \quad \text{and} \quad \sum_{k=0}^i \left(\frac{\alpha}{\rho_2}\right)^k < \sum_{k=0}^{\infty} \left(\frac{\alpha}{\rho_2}\right)^k = \frac{\rho_2}{\rho_2 - \alpha} \leq \frac{E_3}{1-\beta}, \quad (240)$$

where E_3 is some constant. Meanwhile, we also have

$$\sum_{k=0}^i (i-k) \left(\frac{\alpha}{\rho_2}\right)^k \leq i \sum_{k=0}^i \left(\frac{\alpha}{\rho_2}\right)^k \leq i \sum_{k=0}^{\infty} \left(\frac{\alpha}{\rho_2}\right)^k \leq \frac{iE_3}{1-\beta}. \quad (241)$$

We substitute (240) and (241) into (239), and reach

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 &\leq \rho_2^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 + \frac{E_3s_5\mu_m^2\rho_2^i}{1-\beta} + \frac{iE_3s_6\mu_m^4\rho_2^{i-1}}{1-\beta} \\ &\quad + \frac{E_3s_8\mu_m^4\rho_2^i}{1-\beta} + \frac{E_3s_{10}\mu_m^4\rho_2^i}{1-\beta} + \frac{2(s_7 + s_9 + 2p_6)\mu_m^4}{1-\beta}. \end{aligned} \quad (242)$$

Recall from (189) that $\mathbb{E}\|\tilde{\mathbf{w}}_{-1}\|^4 = E_4\mu_m^4$, where $E_4 = \mathbb{E}\|\nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1})\|^4$. Substituting into (242) we reach that

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 &\leq E_4\mu_m^{i+1} + \frac{E_3s_5\mu_m^2\rho_2^i}{1-\beta} + \frac{iE_3s_6\mu_m^4\rho_2^{i-1}}{1-\beta} \\ &\quad + \frac{E_3s_8\mu_m^4\rho_2^i}{1-\beta} + \frac{E_3s_{10}\mu_m^4\rho_2^i}{1-\beta} + \frac{2(s_7 + s_9 + 2p_6)\mu_m^4}{1-\beta}. \end{aligned} \quad (243)$$

Substituting (238) into (243) and recall $\alpha < \rho_2$, we finally reach

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 = O\left(\frac{\gamma^2\rho_2^i}{(1-\beta)^3}\mu_m^2 + \rho_2^{i+1}\mu_m^4 + \frac{\gamma^2\sigma_s^2 i \rho_2^{i-1}}{(1-\beta)^5}\mu_m^4 + \frac{\sigma_s^2(\delta^2 + \gamma^2)\rho_2^i}{(1-\beta)^7}\mu_m^4 + \frac{\delta^2\sigma_s^2\rho_2^i}{(1-\beta)^6}\mu_m^4\right)$$

$$+ \frac{\gamma^2\sigma_s^4}{(1-\beta)^5\nu^2}\mu_m^4 + \frac{\sigma_{s,4}^4}{(1-\beta)^6}\mu_m^4 + \frac{\sigma_{s,4}^4}{(1-\beta)^5}\mu_m^4 \Big). \quad (244)$$

Since there must exist some constants E_5, E_6 and E_7 such that

$$\begin{aligned} \frac{\gamma^2\rho_2^i}{(1-\beta)^3}\mu_m^2 &\leq \frac{E_5\gamma^2\rho_2^{i+1}}{(1-\beta)^3}\mu_m^2, \\ \rho_2^{i+1}\mu_m^4 + \frac{\gamma^2\sigma_s^2 i \rho_2^{i-1}}{(1-\beta)^5}\mu_m^4 + \frac{\sigma_s^2(\delta^2 + \gamma^2)\rho_2^i}{(1-\beta)^7}\mu_m^4 + \frac{\delta^2\sigma_s^2\rho_2^i}{(1-\beta)^6}\mu_m^4 &\leq \frac{E_6\sigma_s^2(\delta^2 + \gamma^2)(i+1)\rho_2^{i+1}}{(1-\beta)^7}\mu_m^4, \\ \frac{\gamma^2\sigma_{s,4}^4}{(1-\beta)^5\nu^2}\mu_m^4 + \frac{\sigma_{s,4}^4}{(1-\beta)^6}\mu_m^4 + \frac{\sigma_{s,4}^4}{(1-\beta)^5}\mu_m^4 &\leq \frac{E_7[(\gamma^2 + \nu^2)\sigma_{s,4}^4 + \sigma_{s,4}^4\nu^2]}{(1-\beta)^6\nu^2}\mu_m^4, \end{aligned} \quad (245)$$

we finally reach the conclusion in (44).

Appendix G. Proof of Theorem 8

Subtracting (55) and (61) we get

$$\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i = (I_M - \mu R_u)(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu(\mathbf{s}_i(\boldsymbol{\psi}_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})) + \mu\beta R_u \tilde{\mathbf{w}}_{i-1}, \quad (246)$$

where

$$\mathbf{s}_i(\boldsymbol{\psi}_{i-1}) = (R_u - \mathbf{u}_i \mathbf{u}_i^\top) \tilde{\boldsymbol{\psi}}_{i-1} - \mathbf{u}_i \mathbf{v}(i), \quad \mathbf{s}_i(\mathbf{x}_{i-1}) = (R_u - \mathbf{u}_i \mathbf{u}_i^\top) \tilde{\mathbf{x}}_{i-1} - \mathbf{u}_i \mathbf{v}(i). \quad (247)$$

Substituting into (246) gives

$$\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i = (I_M - \mu R_u)(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu(R_u - \mathbf{u}_i \mathbf{u}_i^\top)(\tilde{\boldsymbol{\psi}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu\beta R_u \tilde{\mathbf{w}}_{i-1}. \quad (248)$$

Now note that in the quadratic case, the Hessian matrix of $J(w)$ is equal to R_u . It follows that condition (11) is satisfied with the identifications $\nu = \lambda_{\min}(R_u)$, $\delta = \lambda_{\max}(R_u)$. Let $t \in (0, 1)$. By squaring (248) and taking expectations, and applying Jensen's inequality, we obtain

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq \mathbb{E}\|(I_M - \mu R_u)(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}) + \mu\beta R_u \tilde{\mathbf{w}}_{i-1}\|^2 + \mu^2 \mathbb{E}\|R_u - \mathbf{u}_i \mathbf{u}_i^\top\|^2 \mathbb{E}\|\tilde{\boldsymbol{\psi}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 \\ &\stackrel{(a)}{\leq} \frac{1}{1-t} (1-\mu\nu)^2 \mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \frac{1}{t} \mu^2 \beta^2 \delta^2 \mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 + B_1 \mu^2 \mathbb{E}\|\tilde{\boldsymbol{\psi}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 \\ &\stackrel{(b)}{\leq} (1-\mu\nu) \mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \frac{\mu\beta^2\delta^2}{\nu} \mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 + B_1 \mu^2 \mathbb{E}\|\tilde{\boldsymbol{\psi}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2, \end{aligned} \quad (249)$$

where (a) holds because of Jensen's inequality and we let $B_1 = \mathbb{E}\|R_u - \mathbf{u}_i \mathbf{u}_i^\top\|^2$, and (b) holds by choosing $t = \mu\nu$. To bound the last term in the above relation, we use (124) to note that

$$\tilde{\boldsymbol{\psi}}_i - \tilde{\mathbf{x}}_i = \tilde{\mathbf{w}}_i + \beta_1(\tilde{\mathbf{w}}_i - \tilde{\mathbf{w}}_{i-1}) - \tilde{\mathbf{x}}_i = (\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i) - \beta_1(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{w}}_i) \quad (250)$$

On the other hand, from (28) we have

$$\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i = \frac{1}{1-\beta}(\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i) - \frac{\beta}{1-\beta}(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_i) = (\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i) - \frac{\beta}{1-\beta}(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{w}}_i). \quad (251)$$

so that

$$\tilde{\psi}_i - \tilde{\mathbf{x}}_i = \hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i + \frac{\beta - \beta_1 + \beta\beta_1}{1-\beta}(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{w}}_i) = \hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i + \frac{\beta'}{1-\beta}(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{w}}_i) = \hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i - \beta' \tilde{\mathbf{w}}_i. \quad (252)$$

where we used the definition for β' from (30) and the definition for $\tilde{\mathbf{w}}_i$ from (28). Therefore, from Jensen's inequality again, we get

$$\mathbb{E}\|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^2 \leq 2\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\beta'^2\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2. \quad (253)$$

Substituting into (249) gives

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq (1 - \mu\nu + 2B_1\mu^2)\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \left(\frac{\mu\beta^2\delta^2}{\nu} + 2B_1\beta^2\mu^2\right)\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 \\ &\stackrel{(a)}{\leq} \left(1 - \frac{\mu\nu}{2}\right)\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \frac{2\mu\beta^2\delta^2}{\nu}\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2 \\ &\leq \left(1 - \frac{\mu\nu}{2}\right)\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \frac{B_2\mu\delta^2}{\nu}\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^2, \end{aligned} \quad (254)$$

where $B_2 = 2\beta^2$ and the inequality (a) holds when μ is chosen small enough such that

$$\frac{\mu\nu}{2} > 2B_1\mu^2 \quad \text{and} \quad \frac{\mu\beta^2\delta^2}{\nu} > 2B_1\beta^2\mu^2. \quad (255)$$

Recall from Corollary 5 that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq C_1 \left(\frac{(\delta^2 + \gamma^2)\rho_1^{i+1}\mu_m^2}{(1-\beta)^4} + \frac{\sigma_s^2\mu_s^2}{(1-\beta)^3} \right) \quad (256)$$

for each iteration $i = 0, 1, 2, 3, \dots$, where C_1 is some constant. Recall $\mu = \mu_m/(1-\beta)$, we then have

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq C_1 \left(\frac{(\delta^2 + \gamma^2)\rho_1^{i+1}\mu^2}{(1-\beta)^2} + \frac{\sigma_s^2\mu^2}{1-\beta} \right) \quad (257)$$

This fact, together with inequality (254), leads to

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq \left(1 - \frac{\mu\nu}{2}\right)\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + B_2C_1 \left(\frac{\delta^2(\delta^2 + \gamma^2)\rho_1^i\mu^3}{\nu(1-\beta)^2} + \frac{\delta^2\sigma_s^2\mu^3}{\nu(1-\beta)} \right). \quad (258)$$

Recall from Corollary 5 that $\rho_1 = 1 - \frac{\mu\nu}{2(1-\beta)} = 1 - \frac{\mu\nu}{2}$, then (258) becomes

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq \rho_1\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + B_2C_1 \left(\frac{\delta^2(\delta^2 + \gamma^2)\rho_1^i\mu^3}{\nu(1-\beta)^2} + \frac{\delta^2\sigma_s^2\mu^3}{\nu(1-\beta)} \right). \quad (259)$$

For brevity, we denote

$$e_1 \triangleq \frac{B_2C_1(\delta^2 + \gamma^2)\delta^2}{\nu(1-\beta)^2}, \quad e_2 \triangleq \frac{B_2C_1\delta^2\sigma_s^2}{\nu(1-\beta)}. \quad (260)$$

Inequality (259) will become

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq \rho_1\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + e_1\rho_1^i\mu^3 + e_2\mu^3 \\ &\leq \rho_1^{i+1}\mathbb{E}\|\hat{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}\|^2 + e_1(i+1)\rho_1^i\mu^3 + \frac{e_2\mu^3}{1-\rho_1}. \end{aligned} \quad (261)$$

Recall from the first equation in (251) that for $i = -1$:

$$\hat{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1} = \frac{1}{1-\beta}(\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}) - \frac{\beta}{1-\beta}(\tilde{\mathbf{w}}_{-2} - \tilde{\mathbf{x}}_{-1}). \quad (262)$$

Now, using the assumption that the momentum and standard recursions started from the same initial states, $\mathbf{w}_{-2} = \mathbf{x}_{-1}$ and $\mathbf{w}_{-1} = \mathbf{w}_{-2} - \mu_m\nabla_w Q(\mathbf{w}_{-2}; \mathbf{d}(-1), \mathbf{u}_{-1})$, and recall $\mu = \mu_m/(1-\beta)$, then we have

$$\hat{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1} = \frac{1}{1-\beta}(\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{w}}_{-2}) = \mu\nabla_w Q(\mathbf{w}_{-2}; \mathbf{d}(-1), \mathbf{u}_{-1}). \quad (263)$$

Therefore, it holds that

$$\mathbb{E}\|\hat{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}\|^2 = B_4\mu^2, \quad (264)$$

where $B_4 = \mathbb{E}\|\nabla_w Q(\mathbf{w}_{-2}; \mathbf{d}(-1), \mathbf{u}_{-1})\|^2$. Substituting (264) and (260) into (261), we reach

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq B_4\rho_1^{i+1}\mu^2 + \frac{B_2C_1(\delta^2 + \gamma^2)\delta^2(i+1)\rho_1^i}{\nu(1-\beta)^2}\mu^3 + \frac{4B_2C_1\delta^2\sigma_s^2}{\nu^2(1-\beta)}\mu^2. \quad (265)$$

Furthermore, using (251) and $\tilde{\mathbf{w}}_i = \frac{\tilde{\mathbf{w}}_i - \tilde{\mathbf{w}}_{i-1}}{1-\beta}$ from (28) we have

$$\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i = (\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i) + \beta\tilde{\mathbf{w}}_i, \quad (266)$$

which implies that

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq 2\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\beta^2\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2 \leq 2\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\mathbb{E}\|\tilde{\mathbf{w}}_i\|^2. \quad (267)$$

Substituting (257) and (265) into (267), we have

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq B_4\rho_1^{i+1}\mu^2 + \frac{B_2C_1(\delta^2 + \gamma^2)\delta^2(i+1)\rho_1^i}{\nu(1-\beta)^2}\mu^3 + \frac{4B_2C_1\delta^2\sigma_s^2}{\nu^2(1-\beta)}\mu^2 \\ &\quad + 2C_1 \left(\frac{(\delta^2 + \gamma^2)\rho_1^{i+1}\mu^2}{(1-\beta)^2} + \frac{\sigma_s^2\mu^2}{1-\beta} \right) \\ &= O \left(\frac{\delta^2 + \gamma^2}{(1-\beta)^2}\rho_1^{i+1}\mu^2 + \frac{\delta^2(\delta^2 + \gamma^2)(i+1)\rho_1^{i+1}}{\nu(1-\beta)^2}\mu^3 + \frac{\delta^2\sigma_s^2\mu^2}{\nu^2(1-\beta)} \right). \end{aligned} \quad (268)$$

Appendix H. Verifying Assumptions 5 and 6

Least-mean-squares problem. Consider first the mean-squares cost (47). Since in this case $\mathbf{H}_{i-1} = \mathbf{R}_{i-1} = \mathbf{R}_u$, we find that Assumption 6 holds automatically. With regards to Assumption 5, at any iteration i , we have

$$\mathbf{s}_i(\mathbf{w}_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1}) = (\mathbf{R}_u - \mathbf{u}_i \mathbf{u}_i^\top)(\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}). \quad (269)$$

so that, under the assumption of independent and stationary regression vectors,

$$\mathbb{E}[\|\mathbf{s}_i(\mathbf{w}_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^2 | \mathcal{F}_{i-1}] \leq \xi_1 \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2, \quad (270)$$

where $\xi_1 = \mathbb{E}\|\mathbf{R}_u - \mathbf{u}_i \mathbf{u}_i^\top\|^2$. Similarly,

$$\mathbb{E}[\|\mathbf{s}_i(\mathbf{w}_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^4 | \mathcal{F}_{i-1}] \leq \xi_2 \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4, \quad (271)$$

where $\xi_2 = \mathbb{E}\|\mathbf{R}_u - \mathbf{u}_i \mathbf{u}_i^\top\|^4$. Therefore, Assumption 5 holds.

Regularized logistic regression. Consider next the regularized logistic regression risk

$$J(w) \triangleq \frac{\rho}{2} \|w\|^2 + \mathbb{E} \left\{ \ln [1 + \exp(-\gamma(i) \mathbf{h}_i^\top w)] \right\}, \quad (272)$$

where $\mathbf{h}_i \in \mathbb{R}^M$ is a streaming sequence of independent feature vectors with $R_h = \mathbb{E} \mathbf{h}_i \mathbf{h}_i^\top > 0$, and $\gamma(i) \in \{-1, +1\}$ is a streaming sequence of class labels. We assume the random processes $\{\gamma(i), \mathbf{h}_i\}$ are wide-sense stationary. Moreover, $\rho > 0$ is a regularization parameter. We first verify the feasibility of Assumption 5. Note that the approximate gradient vector is given by:

$$\widehat{\nabla_w J}(w) = \rho w - \frac{\exp(-\gamma(i) \mathbf{h}_i^\top w)}{1 + \exp(-\gamma(i) \mathbf{h}_i^\top w)} \gamma(i) \mathbf{h}_i \quad (273)$$

and, hence,

$$\begin{aligned} & \widehat{\nabla_w J}(\psi_{i-1}) - \widehat{\nabla_w J}(\mathbf{x}_{i-1}) \\ & \leq \rho \|\psi_{i-1} - \mathbf{x}_{i-1}\| + \|\mathbf{h}_i\| \left\| \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1})}{1 + \exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1})} - \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})}{1 + \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})} \right\| \end{aligned} \quad (274)$$

Note that

$$\begin{aligned} & \left\| \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1})}{1 + \exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1})} - \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})}{1 + \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})} \right\| \\ & = \left\| \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1}) - \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})}{[1 + \exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1})][1 + \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})]} \right\| \\ & \leq \left\| \frac{\exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1}) - \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})}{\exp(-\gamma(i) \mathbf{h}_i^\top \psi_{i-1}) + \exp(-\gamma(i) \mathbf{h}_i^\top \mathbf{x}_{i-1})} \right\| \\ & = \left\| \frac{\exp(\gamma(i) \mathbf{h}_i^\top \frac{\mathbf{x}_{i-1} - \psi_{i-1}}{2}) - \exp(-\gamma(i) \mathbf{h}_i^\top \frac{\mathbf{x}_{i-1} - \psi_{i-1}}{2})}{\exp(\gamma(i) \mathbf{h}_i^\top \frac{\mathbf{x}_{i-1} - \psi_{i-1}}{2}) + \exp(-\gamma(i) \mathbf{h}_i^\top \frac{\mathbf{x}_{i-1} - \psi_{i-1}}{2})} \right\| \end{aligned}$$

$$= \left| \tanh \left(\gamma(i) \mathbf{h}_i^\top (\mathbf{x}_{i-1} - \psi_{i-1}) / 2 \right) \right| \leq \frac{1}{2} \|\mathbf{h}_i\| \|\psi_{i-1} - \mathbf{x}_{i-1}\|. \quad (275)$$

where in the last inequality we used the property $|\tanh(y)| \leq |y|$, $\forall y \in \mathbb{R}$. Substituting (275) into (274), we get

$$\left\| \widehat{\nabla_w J}(\psi_{i-1}) - \widehat{\nabla_w J}(\mathbf{x}_{i-1}) \right\| \leq \eta_{i,i} \|\psi_{i-1} - \mathbf{x}_{i-1}\|, \quad (276)$$

where $\eta_{i,i} = \rho + \|\mathbf{h}_i\|^2 / 2$ is a random variable.

On the other hand, it is shown in Eq. (2.20) of (Sayed, 2014a) that the Hessian matrix $\nabla_w^2 J(w)$ is upper bounded by δJ_M , where $\delta = (\rho + \lambda_{\max}(R_h))$. We conclude from Lemma E.3 in the same reference that $\nabla_w J(w)$ is Lipschitz continuous with modulus δ , i.e.,

$$\left\| \nabla_w J(\psi_{i-1}) - \nabla_w J(\mathbf{x}_{i-1}) \right\| \leq \delta \|\psi_{i-1} - \mathbf{x}_{i-1}\|. \quad (277)$$

Combining these results we get

$$\begin{aligned} \|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\| &= \left\| \widehat{\nabla_w J}(\psi_{i-1}) - \widehat{\nabla_w J}(\mathbf{x}_{i-1}) - [\nabla_w J(\psi_{i-1}) - \nabla_w J(\mathbf{x}_{i-1})] \right\| \\ &\leq \eta_i \|\psi_{i-1} - \mathbf{x}_{i-1}\|. \end{aligned} \quad (278)$$

where $\eta_i = \eta_{1,i} + \delta$ is a random variable. Since the $\{\mathbf{h}_i\}$ are independent feature vectors and η_i is only related to \mathbf{h}_i , it follows that

$$\mathbb{E}[\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^2 | \mathcal{F}_{i-1}] \leq \xi_1 \|\psi_{i-1} - \mathbf{x}_{i-1}\|^2, \quad (279)$$

$$\mathbb{E}[\|\mathbf{s}_i(\psi_{i-1}) - \mathbf{s}_i(\mathbf{x}_{i-1})\|^4 | \mathcal{F}_{i-1}] \leq \xi_2 \|\psi_{i-1} - \mathbf{x}_{i-1}\|^4, \quad (280)$$

where $\xi_1 = \mathbb{E} \eta_i^2$ and $\xi_2 = \mathbb{E} \eta_i^4$.

Next we check the feasibility of Assumption 6. For simplicity, we write γ instead of $\gamma(i)$. It can be verified that for the cost function $J(w)$ in (272):

$$\nabla_w^2 J(w) = \rho J_M + \mathbb{E} \left\{ \mathbf{h}_i \mathbf{h}_i^\top \left(\frac{\exp(-\gamma \mathbf{h}_i^\top w)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w)]^2} \right) \right\}. \quad (281)$$

Now, for any two variables w_1 and w_2 we have

$$\begin{aligned} & \left\| \nabla_w^2 J(w_1) - \nabla_w^2 J(w_2) \right\| \\ &= \left\| \mathbb{E} \left\{ \mathbf{h}_i \mathbf{h}_i^\top \left(\frac{\exp(-\gamma \mathbf{h}_i^\top w_1)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_1)]^2} - \frac{\exp(-\gamma \mathbf{h}_i^\top w_2)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_2)]^2} \right) \right\} \right\| \\ &\leq \mathbb{E} \left\| \mathbf{h}_i \mathbf{h}_i^\top \left(\frac{\exp(-\gamma \mathbf{h}_i^\top w_1)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_1)]^2} - \frac{\exp(-\gamma \mathbf{h}_i^\top w_2)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_2)]^2} \right) \right\| \\ &\leq \mathbb{E} \left\{ \left\| \mathbf{h}_i \mathbf{h}_i^\top \right\| \left\| \frac{\exp(-\gamma \mathbf{h}_i^\top w_1)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_1)]^2} - \frac{\exp(-\gamma \mathbf{h}_i^\top w_2)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_2)]^2} \right\| \right\} \end{aligned} \quad (282)$$

Let $\mathbf{x}_1 = -\gamma \mathbf{h}_i^\top w_1$ and $\mathbf{x}_2 = -\gamma \mathbf{h}_i^\top w_2$. Then,

$$\left\| \frac{\exp(-\gamma \mathbf{h}_i^\top w_1)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_1)]^2} - \frac{\exp(-\gamma \mathbf{h}_i^\top w_2)}{[1 + \exp(-\gamma \mathbf{h}_i^\top w_2)]^2} \right\|$$

$$\begin{aligned}
&= \left\| \frac{\exp(\mathbf{x}_1)}{[1 + \exp(\mathbf{x}_1)]^2} - \frac{\exp(\mathbf{x}_2)}{[1 + \exp(\mathbf{x}_2)]^2} \right\| \\
&= \left\| \frac{\exp(\mathbf{x}_1)[1 + \exp(\mathbf{x}_2)]^2 - \exp(\mathbf{x}_2)[1 + \exp(\mathbf{x}_1)]^2}{[1 + \exp(\mathbf{x}_1)]^2[1 + \exp(\mathbf{x}_2)]^2} \right\| \\
&\stackrel{(a)}{\leq} \left\| \frac{\exp(-\mathbf{x}_2) - \exp(-\mathbf{x}_1) + \exp(\mathbf{x}_2) - \exp(\mathbf{x}_1)}{2(\exp(-\mathbf{x}_2) + \exp(-\mathbf{x}_1) + \exp(\mathbf{x}_2) + \exp(\mathbf{x}_1))} \right\| \\
&\leq \left\| \frac{\exp(-\mathbf{x}_2) - \exp(-\mathbf{x}_1)}{2(\exp(-\mathbf{x}_2) + \exp(-\mathbf{x}_1))} \right\| + \left\| \frac{\exp(\mathbf{x}_2) - \exp(\mathbf{x}_1)}{2(\exp(-\mathbf{x}_2) + \exp(-\mathbf{x}_1) + \exp(\mathbf{x}_2) + \exp(\mathbf{x}_1))} \right\| \\
&\leq \left\| \frac{\exp(-\mathbf{x}_2) - \exp(-\mathbf{x}_1)}{2(\exp(-\mathbf{x}_2) + \exp(-\mathbf{x}_1))} \right\| + \left\| \frac{\exp(\mathbf{x}_2) - \exp(\mathbf{x}_1)}{2(\exp(\mathbf{x}_2) + \exp(\mathbf{x}_1))} \right\| \\
&\stackrel{(b)}{=} \frac{1}{2} \left\| \frac{\exp(-\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) - \exp(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2})}{\exp(-\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) + \exp(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2})} \right\| + \frac{1}{2} \left\| \frac{\exp(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) - \exp(-\frac{\mathbf{x}_2 - \mathbf{x}_1}{2})}{\exp(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) + \exp(-\frac{\mathbf{x}_2 - \mathbf{x}_1}{2})} \right\| \\
&= \left\| \tanh(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) \right\|,
\end{aligned} \tag{283}$$

where (a) holds because of the following two facts:

$$\begin{aligned}
&\exp(\mathbf{x}_1)[1 + \exp(\mathbf{x}_2)]^2 - \exp(\mathbf{x}_2)[1 + \exp(\mathbf{x}_1)]^2 \\
&= \exp(\mathbf{x}_1) + \exp(\mathbf{x}_1 + 2\mathbf{x}_2) - \exp(\mathbf{x}_2) - \exp(\mathbf{x}_2 + 2\mathbf{x}_1) \\
&= \exp(\mathbf{x}_1 + \mathbf{x}_2)[\exp(-\mathbf{x}_2) + \exp(\mathbf{x}_2) - \exp(-\mathbf{x}_1) - \exp(\mathbf{x}_1)],
\end{aligned} \tag{284}$$

and

$$\begin{aligned}
&[1 + \exp(\mathbf{x}_1)]^2[1 + \exp(\mathbf{x}_2)]^2 \\
&= (1 + 2\exp(\mathbf{x}_1) + \exp(2\mathbf{x}_1))(1 + 2\exp(\mathbf{x}_2) + \exp(2\mathbf{x}_2)) \\
&\geq 2\exp(\mathbf{x}_1) + 2\exp(\mathbf{x}_2) + 2\exp(\mathbf{x}_1 + 2\mathbf{x}_2) + 2\exp(\mathbf{x}_2 + 2\mathbf{x}_1) \\
&= 2\exp(\mathbf{x}_1 + \mathbf{x}_2)[\exp(-\mathbf{x}_2) + \exp(\mathbf{x}_2) + \exp(-\mathbf{x}_1) + \exp(\mathbf{x}_1)].
\end{aligned} \tag{285}$$

In addition, (b) holds if we extract $\exp(-\frac{\mathbf{x}_1 \pm \mathbf{x}_2}{2})$ and $\exp(\frac{\mathbf{x}_1 \pm \mathbf{x}_2}{2})$ from both the denominator and numerator of the first and second terms respectively.

Using the definitions for \mathbf{x}_1 and \mathbf{x}_2 , this last expression gives

$$\left\| \tanh(\frac{\mathbf{x}_2 - \mathbf{x}_1}{2}) \right\| = \left\| \tanh\left(\frac{1}{2}\gamma\mathbf{h}_i^\top(w_2 - w_1)\right) \right\| \leq \frac{1}{2}\|\mathbf{h}_i\|\|w_2 - w_1\|. \tag{286}$$

Substituting (286) into (282), we obtain $\|\nabla_w^2 J(w_1) - \nabla_w^2 J(w_2)\| \leq \kappa\|w_1 - w_2\|$, where $\kappa = \mathbb{E}\|\mathbf{h}_i\mathbf{h}_i^\top\| \|\mathbf{h}_i\|/2$. Therefore, Assumption 6 holds.

Appendix I. Proof of Lemma 9

Referring to relation (68) and apply the inequality (194), we reach

$$\begin{aligned}
&\mathbb{E}\|\hat{w}_i - \tilde{w}_i\|^4 \|\mathcal{F}_{i-1}\| \\
&= \|\mathbf{I}_M - \mu\mathbf{H}_{i-1}\|(\hat{w}_{i-1} - \tilde{w}_{i-1}) + \mu(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{w}_{i-1} + \mu\beta^3\mathbf{H}_{i-1}\tilde{w}_{i-1}\|^4
\end{aligned}$$

$$\begin{aligned}
&+ 3\mu^4\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^4 \|\mathcal{F}_{i-1}\| + 8\mu^2\|(I_M - \mu\mathbf{H}_{i-1})(\hat{w}_{i-1} - \tilde{w}_{i-1}) \\
&+ \mu(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{w}_{i-1} + \mu\beta^3\mathbf{H}_{i-1}\tilde{w}_{i-1}\|^2\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2 \|\mathcal{F}_{i-1}\| \\
&\leq \frac{1}{(1-t)^3}\|(I_M - \mu\mathbf{H}_{i-1})(\hat{w}_{i-1} - \tilde{w}_{i-1})\|^4 + \frac{8\mu^4}{t^3}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|\|\tilde{w}_{i-1}\|^4 + \frac{8\mu^4\beta^4}{t^3}\|\mathbf{H}_{i-1}w_{i-1}\|^4 \\
&+ 3\mu^4\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^4 \|\mathcal{F}_{i-1}\| + 8\mu^2\left(\frac{1}{1-t}\|(I_M - \mu\mathbf{H}_{i-1})(\hat{w}_{i-1} - \tilde{w}_{i-1})\|^2\right. \\
&\left. + \frac{2\mu^2}{t}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|\|\tilde{w}_{i-1}\|^2 + \frac{2\mu^2\beta^2}{t}\|\mathbf{H}_{i-1}w_{i-1}\|^2\right)\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2 \|\mathcal{F}_{i-1}\| \\
&\stackrel{(b)}{\leq} (1 - \mu\nu)\|\hat{w}_{i-1} - \tilde{w}_{i-1}\|^4 + \frac{8\mu}{\nu^3}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|\|\tilde{w}_{i-1}\|^4 + \frac{8\mu\beta^4\delta^4}{\nu^3}\|\tilde{w}_{i-1}\|^4 \\
&+ 3\mu^4\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^4 \|\mathcal{F}_{i-1}\| + 8\mu^2\left((1 - \mu\nu)\|\hat{w}_{i-1} - \tilde{w}_{i-1}\|^2\right. \\
&\left. + \frac{2\mu}{\nu}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{w}_{i-1}\|^2 + \frac{2\mu\beta^2\delta^2}{\nu}\|w_{i-1}\|^2\right)\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2 \|\mathcal{F}_{i-1}\|,
\end{aligned} \tag{287}$$

where (a) holds because the facts that for any $a, b, c \in \mathbb{R}^m$,

$$\begin{aligned}
\|a + b + c\|^4 &= \|(1-t)\frac{1}{1-t}a + t\frac{1}{t}(b + c)\|^4 \\
&\leq (1-t)\|\frac{1}{1-t}a\|^4 + t\|\frac{1}{t}(b + c)\|^4 = \frac{1}{(1-t)^3}\|a\|^4 + \frac{1}{t^3}\|b + c\|^4 \\
&\leq \frac{1}{(1-t)^3}\|a\|^4 + \frac{8}{t^3}\|b\|^4 + \frac{8}{t^3}\|c\|^4,
\end{aligned} \tag{288}$$

and

$$\begin{aligned}
\|a + b + c\|^2 &= \|(1-t)\frac{1}{1-t}a + t\frac{1}{t}(b + c)\|^2 \\
&\leq (1-t)\|\frac{1}{1-t}a\|^2 + t\|\frac{1}{t}(b + c)\|^2 = \frac{1}{1-t}\|a\|^2 + \frac{1}{t}\|b + c\|^2 \\
&\leq \frac{1}{1-t}\|a\|^2 + \frac{2}{t}\|b\|^2 + \frac{2}{t}\|c\|^2,
\end{aligned} \tag{289}$$

In addition, (b) holds by choosing $t = \mu\nu$.

To further simplify inequality (287), we first note that

$$\begin{aligned}
\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^2 &\leq 2(\|\mathbf{R}_{i-1}\|^2 + \|\mathbf{H}_{i-1}\|^2) \leq 4\delta^2, \\
\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 &\leq 8(\|\mathbf{R}_{i-1}\|^4 + \|\mathbf{H}_{i-1}\|^4) \leq 16\delta^4.
\end{aligned} \tag{290}$$

As a result, we have

$$\begin{aligned}
\frac{8\mu}{\nu^3}\|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|\|\tilde{w}_{i-1}\|^4 &\leq \alpha_1\mu\|\tilde{w}_{i-1}\|^4, \\
\frac{2\mu}{\nu}\|(\mathbf{R}_{i-1} - \mathbf{H}_{i-1})\tilde{w}_{i-1}\|^2 &\leq \alpha_2\mu\|\tilde{w}_{i-1}\|^2,
\end{aligned} \tag{291}$$

where we define

$$\alpha_1 \triangleq 128\delta^4/\nu^3, \quad \alpha_2 \triangleq 8\delta^2/\nu. \tag{293}$$

On the other hand, from conditions (72)–(73), we have

$$3\mu^4\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^4\|\mathcal{F}_{i-1}\| \leq 3\xi_2\mu^4\|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4, \quad (294)$$

$$8\mu^2\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2\|\mathcal{F}_{i-1}\| \leq 8\xi_1\mu^2\|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2, \quad (295)$$

In addition, from (252) we get

$$\|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^2 \leq 2\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\beta^2\|\tilde{\mathbf{w}}_i\|^2, \quad \|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4 \leq 8\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 + 8\beta^4\|\tilde{\mathbf{w}}_i\|^4. \quad (296)$$

Combining (294)–(296), we have

$$3\mu^4\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^4\|\mathcal{F}_{i-1}\| \leq 24\xi_2\mu^4\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + 24\xi_2\mu^4\|\tilde{\mathbf{w}}_{i-1}\|^4, \quad (297)$$

$$8\mu^2\mathbb{E}\|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2\|\mathcal{F}_{i-1}\| \leq 16\xi_1\mu^2\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + 16\xi_1\mu^2\|\tilde{\mathbf{w}}_{i-1}\|^2, \quad (298)$$

In this way, relation (287) becomes

$$\begin{aligned} & \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4\|\mathcal{F}_{i-1}\| \\ & \leq (1 - \mu\nu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_1\mu\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_3\mu\|\tilde{\mathbf{w}}_{i-1}\|^4 + [(1 - \mu\nu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 \\ & \quad + a_4\mu\|\tilde{\mathbf{w}}_{i-1}\|^2 + a_2\mu\|\tilde{\mathbf{x}}_{i-1}\|^2][a_5\mu^2\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + a_5\mu^2\|\tilde{\mathbf{w}}_{i-1}\|^2] \\ & \quad + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \leq (1 - \mu\nu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_1\mu\|\tilde{\mathbf{x}}_{i-1}\|^4 + a_3\mu\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_5(1 - \mu\nu)\mu^2\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 \\ & \quad + a_5\mu^2(1 - \mu\nu + a_4\mu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2\|\tilde{\mathbf{w}}_{i-1}\|^2 + a_4a_5\mu^3\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \quad + a_2a_5\mu^3\|\tilde{\mathbf{x}}_{i-1}\|^2\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + a_2a_5\mu^3\|\tilde{\mathbf{x}}_{i-1}\|^2\|\tilde{\mathbf{w}}_{i-1}\|^2 \\ & \quad + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \stackrel{(a)}{\leq} (1 - \mu\nu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_1\mu\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_3\mu\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_5(1 - \mu\nu)\mu^2\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 \\ & \quad + a_5\mu^2(1 - \mu\nu + a_4\mu)\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_5\mu^2(1 - \mu\nu + a_4\mu)\|\tilde{\mathbf{w}}_{i-1}\|^4 + a_4a_5\mu^3\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \quad + a_2a_5\mu^3\|\tilde{\mathbf{x}}_{i-1}\|^4 + a_2a_5\mu^3\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_2a_5\mu^3\|\tilde{\mathbf{x}}_{i-1}\|^4 + a_2a_5\mu^3\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \quad + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_6\mu^4\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & \leq (1 - \frac{\mu\nu}{2})\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + 2a_1\mu\|\tilde{\mathbf{x}}_{i-1}\|^4 + 2a_3\mu\|\tilde{\mathbf{w}}_{i-1}\|^4. \end{aligned} \quad (299)$$

where we define

$$a_3 \triangleq \frac{8\beta^4\delta^4}{\nu^4}, \quad a_4 \triangleq \frac{2\beta^2\delta^2}{\nu}, \quad a_5 \triangleq 16\xi_1, \quad a_6 \triangleq 24\xi_2. \quad (300)$$

Taking expectations over \mathcal{F}_{i-1} for both sides of (299), we have

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 & \leq (1 - \frac{\mu\nu}{2})\mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + 2a_1\mu\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4 + 2a_3\mu\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4 + 2a_3\mu\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4 \\ & = \rho_1\mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + 2a_1\mu\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4 + 2a_3\mu\mathbb{E}\|\tilde{\mathbf{w}}_{i-1}\|^4. \end{aligned} \quad (301)$$

Now recall from (20) that

$$\mathbb{E}\|\tilde{\mathbf{x}}_i\|^4 \leq \rho^{i+1}\mathbb{E}\|\tilde{\mathbf{x}}_{-1}\|^4 + A_1\sigma_s^2(i+1)\rho^{i+1}\mu^2 + \frac{A_2\sigma_s^4\mu^2}{\nu^2}, \quad (302)$$

where $\rho = 1 - \mu\nu$ and A_1 and A_2 are some constants. On the other hand, recall from (44) that

$$\mathbb{E}\|\tilde{\mathbf{w}}_i\|^4 \leq \frac{B_1\gamma^2\rho_2^{i+1}}{1-\beta}\mu^2 + \frac{B_1\sigma_s^2(\delta^2 + \gamma^2)(i+1)\rho_2^{i+1}}{(1-\beta)^3}\mu^4 + \frac{B_1[(\gamma^2 + \nu^2)\sigma_s^4 + \sigma_{s,4}\nu^2]}{(1-\beta)^2\nu^2}\mu^4, \quad (303)$$

where $\rho_2 = 1 - \mu\nu/4$. Besides, we denote $\rho_1 = 1 - \mu\nu/2$ and clearly $\rho < \rho_1 < \rho_2$. Substituting (302) and (303) into (301) we reach

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 & \leq \rho_1\mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_7\rho_1^i\mu + a_8i^i\rho_1^i\mu^3 + a_9\mu^3 + a_{10}i^i\mu^3 + a_{11}i^i\rho_2^i\mu^5 + a_{12}\mu^5 \\ & \stackrel{(a)}{\leq} \rho_1\mathbb{E}\|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4 + a_7\rho_1^i\mu + a_8i^i\rho_2^i\mu^3 + a_{10}i^i\mu^3 + a_{11}i^i\rho_2^i\mu^5 + 2a_9\mu^3, \end{aligned} \quad (304)$$

where the constants are defined as

$$\begin{aligned} a_7 & \triangleq 2a_1\mathbb{E}\|\tilde{\mathbf{x}}_{-1}\|^4, \quad a_8 \triangleq 2A_1a_1\sigma_s^2, \quad a_9 \triangleq \frac{2A_2a_1\sigma_s^4}{\nu^2}, \quad a_{10} \triangleq \frac{2B_1a_3\gamma^2}{1-\beta} \\ a_{11} & \triangleq \frac{2B_1a_3\sigma_s^2(\delta^2 + \gamma^2)}{(1-\beta)^3}, \quad a_{12} \triangleq \frac{2B_1a_3[(\gamma^2 + \nu^2)\sigma_s^4 + \sigma_{s,4}\nu^2]}{(1-\beta)^2\nu^2}. \end{aligned} \quad (305)$$

The inequality (a) holds because μ is chosen small enough such that $a_9\mu^3 > a_{12}\mu^5$. Now we continue iterating (304) and get

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 & \leq \rho_1^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}\|^4 + a_7(i+1)\rho_1^i\mu + a_8i^i\mu^3 \sum_{k=0}^i (i-k) \left(\frac{\rho_1}{\rho_2}\right)^k \\ & \quad + a_{10}\rho_2^i\mu^3 \sum_{k=0}^i \left(\frac{\rho_1}{\rho_2}\right)^k + a_{11}\rho_2^i\mu^5 \sum_{k=0}^i (i-k) \left(\frac{\rho_1}{\rho_2}\right)^k + \frac{2a_9\mu^3}{1-\rho_2}. \end{aligned} \quad (306)$$

Note that $\rho_1 < \rho_2$, we then have

$$\sum_{k=0}^i \left(\frac{\rho_1}{\rho_2}\right)^k \leq \sum_{k=0}^{\infty} \left(\frac{\rho_1}{\rho_2}\right)^k \leq \frac{\rho_2}{\rho_2 - \rho_1} = \frac{4 - \mu\nu}{\mu\nu} \leq \frac{B_2}{\mu\nu}, \quad (307)$$

where B_2 is some constant. Meanwhile, it also holds that

$$\sum_{k=0}^i (i-k) \left(\frac{\rho_1}{\rho_2}\right)^k \leq i \sum_{k=0}^i \left(\frac{\rho_1}{\rho_2}\right)^k \leq \frac{iB_2}{\mu\nu}. \quad (308)$$

Substituting (307) and (308) into (306), we get

$$\begin{aligned} \mathbb{E}\|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 & \leq \rho^{i+1}\mathbb{E}\|\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}\|^4 + a_7(i+1)\rho_1^i\mu + \frac{a_8B_2i^i\mu^2}{\nu} \\ & \quad + \frac{a_{10}B_2\rho_2^i\mu^2}{\nu} + \frac{a_{11}i^i\rho_2^i\mu^4}{\nu} + \frac{4a_9\mu^2}{\nu}. \end{aligned} \quad (309)$$

Recall from (263) that $\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1} = \mu \nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1})$. Then it holds that

$$\mathbb{E} \|\tilde{\mathbf{w}}_{-1} - \tilde{\mathbf{x}}_{-1}\|^4 = B_3 \mu^4, \quad (310)$$

where $B_3 = \mathbb{E} \|\nabla_w Q(\mathbf{w}_{-2}; \boldsymbol{\theta}_{-1})\|^4$. With this fact, expressions (309) becomes

$$\begin{aligned} & \mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 \\ & \leq B_3 \rho_2^{i+1} \mu^4 + \alpha \tau (i+1) \rho_1^i \mu + \frac{\alpha_8 B_2 i \rho_2^i \mu^2}{\nu} + \frac{\alpha_{10} B_2 \rho_2^i \mu^2}{\nu} + \frac{\alpha_{11} i \rho_2^i \mu^4}{\nu} + \frac{4\alpha_9 \mu^2}{\nu} \\ & \leq B_3 \rho_2^{i+1} \mu^4 + \alpha \tau (i+1) \rho_2^i \mu + \frac{\alpha_8 B_2 i \rho_2^i \mu^2}{\nu} + \frac{\alpha_{10} B_2 \rho_2^i \mu^2}{\nu} + \frac{\alpha_{11} i \rho_2^i \mu^4}{\nu} + \frac{4\alpha_9 \mu^2}{\nu}. \end{aligned} \quad (311)$$

Furthermore, recall from (296) that

$$\mathbb{E} \|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4 \leq 8\mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^4 + 8\mathbb{E} \|\tilde{\mathbf{w}}_i\|^4. \quad (312)$$

and recall the upper bound of $\mathbb{E} \|\tilde{\mathbf{w}}_i\|^4$ in (303). With the definition of all constants we finally reach

$$\mathbb{E} \|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4 = O\left(\frac{\delta^4 i \rho_2^i \mu}{\nu^3} + \frac{\delta^4 (\sigma_s^2 + \gamma^2) i \rho_2^i \mu^2}{(1-\beta)\nu^5} + \frac{\delta^4 (\delta^2 + \gamma^2) \sigma_s^2 i \rho_2^i \mu^4}{(1-\beta)^3 \nu} + \frac{\delta^4 \sigma_s^4}{\nu^6} \mu^2\right). \quad (313)$$

To further simplify the notation, we notice that when μ is sufficiently small it holds that

$$\begin{aligned} & \frac{\delta^4 i \rho_2^i \mu}{\nu^3} + \frac{\delta^4 (\sigma_s^2 + \gamma^2) i \rho_2^i \mu^2}{(1-\beta)\nu^5} + \frac{\delta^4 (\delta^2 + \gamma^2) \sigma_s^2 i \rho_2^i \mu^4}{(1-\beta)^3 \nu} \\ & = i \rho_2^i \mu \left(\frac{\delta^4}{\nu^3} + \frac{\delta^4 (\sigma_s^2 + \gamma^2) \mu}{(1-\beta)\nu^5} + \frac{\delta^4 (\delta^2 + \gamma^2) \sigma_s^2 \mu^3}{(1-\beta)^3 \nu} \right) \\ & \leq \frac{2\delta^4 i \rho_2^i \mu}{\nu^3} \leq \frac{B_4 \delta^4 (i+1) \rho_2^{i+1} \mu}{\nu^3} \end{aligned} \quad (314)$$

for some constant B_4 . As a result, we obtain

$$\mathbb{E} \|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^4 = O\left(\frac{\delta^4 (i+1) \rho_2^{i+1} \mu}{\nu^3} + \frac{\delta^4 \sigma_s^4}{\nu^6} \mu^2\right). \quad (315)$$

Appendix J. Proof of Lemma 10

Under Assumption 6, we have

$$\begin{aligned} & \|\mathbf{H}_{i-1} - \mathbf{R}_{i-1}\| \\ & = \left\| \int_0^1 \nabla_w^2 J(w^0 - r\tilde{\psi}_{i-1}) dr - \int_0^1 \nabla_w^2 J(w^0 - r\tilde{\mathbf{x}}_{i-1}) dr \right\| \\ & \leq \int_0^1 \|\nabla_w^2 J(w^0 - r\tilde{\psi}_{i-1}) - \nabla_w^2 J(w^0 - r\tilde{\mathbf{x}}_{i-1})\| dr \\ & \leq \int_0^1 \kappa r \|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\| dr = \frac{\kappa}{2} \|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|. \end{aligned} \quad (316)$$

As a result, it holds that

$$\mathbb{E} \|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 \leq \bar{\kappa} \mathbb{E} \|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^4, \quad (317)$$

where $\bar{\kappa} = \kappa^4/16$. Using (75), we reach the desired bounds shown in (77).

Appendix K. Proof of Theorem 11

For (72) in Assumption 5, if we take expectation over \mathcal{F}_{i-1} of both sides, it holds that

$$\mathbb{E} \|s_i(\psi_{i-1}) - s_i(\mathbf{x}_{i-1})\|^2 \leq \xi_1 \mathbb{E} \|\psi_{i-1} - \mathbf{x}_{i-1}\|^2. \quad (318)$$

Combining the above fact and inequalities (70)–(71), we get

$$\begin{aligned} & \mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \\ & \leq (1 - \mu\nu) \mathbb{E} \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + \tau_1 \mu \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 \\ & \quad + \tau_2 \mu \sqrt{\mathbb{E} \|\mathbf{R}_{i-1} - \mathbf{H}_{i-1}\|^4 \mathbb{E} \|\tilde{\mathbf{x}}_{i-1}\|^4} + \xi_1 \mu^2 \mathbb{E} \|\tilde{\psi}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2, \end{aligned} \quad (319)$$

where the constants are defined as

$$\tau_1 \triangleq \frac{2\beta^2 \sigma^2}{\nu}, \quad \tau_2 \triangleq \frac{2}{\nu}. \quad (320)$$

Likewise, from (253) we have

$$\mathbb{E} \|\tilde{\psi}_i - \tilde{\mathbf{x}}_i\|^2 \leq 2\mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\mathbb{E} \|\tilde{\mathbf{w}}_i\|^2. \quad (321)$$

Substituting the above inequality along with (77) into (319) gives

$$\begin{aligned} & \mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \\ & \leq (1 - \mu\nu + 2\xi_1 \mu^2) \mathbb{E} \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + (\tau_1 \mu + 2\xi_1 \mu^2) \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 + \left[\sqrt{\tau_3} \rho_2^{i/2} \mu^{3/2} + r_4 \mu^2 \right] \sqrt{\mathbb{E} \|\tilde{\mathbf{x}}_{i-1}\|^4} \\ & \leq \left(1 - \frac{\mu\nu}{2}\right) \mathbb{E} \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + 2\tau_1 \mu \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 + \left[r_3 \sqrt{\tau_3} \rho_2^{i/2} \mu^{3/2} + r_4 \mu^2 \right] \sqrt{\mathbb{E} \|\tilde{\mathbf{x}}_{i-1}\|^4} \\ & = \rho_1 \mathbb{E} \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + 2\tau_1 \mu \mathbb{E} \|\tilde{\mathbf{w}}_{i-1}\|^2 + \left[r_3 \sqrt{\tau_3} \rho_2^{i/2} \mu^{3/2} + r_4 \mu^2 \right] \sqrt{\mathbb{E} \|\tilde{\mathbf{x}}_{i-1}\|^4} \end{aligned} \quad (322)$$

where the constants are defined as

$$r_3 \triangleq \frac{r_2 \delta^2}{\nu^{3/2}}, \quad r_4 \triangleq \frac{r_2 \delta^2 \sigma_s^2}{\nu^3}. \quad (323)$$

Recall the upper bound of $\mathbb{E} \|\tilde{\mathbf{w}}_i\|^2$ in (38) that

$$\mathbb{E} \|\tilde{\mathbf{w}}_i\|^2 \leq \frac{C_2 (\delta^2 + \gamma^2) \rho_1^i \mu^2}{(1-\beta)^2} + \frac{C_1 \sigma_s^2 \mu^2}{1-\beta} \quad (324)$$

where $\alpha = 1 - \epsilon/2 < \rho_1$, and C_1 and C_2 are some constants. Substituting (324) into (322), we have

$$\begin{aligned} & \mathbb{E} \|\tilde{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \\ & \leq \rho_1 \mathbb{E} \|\tilde{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + (\tau_5 \rho_1^i \mu^3 + r_6 \mu^3) + \left[2r_3 \sqrt{\tau_3} \rho_2^{i/2} \mu^{3/2} + r_6 \mu^2 \right] \sqrt{\mathbb{E} \|\tilde{\mathbf{x}}_{i-1}\|^4}, \end{aligned} \quad (325)$$

where the constants are defined as

$$r_5 \triangleq \frac{2C_2 \tau_1 (\delta^2 + \gamma^2)}{(1-\beta)^2}, \quad r_6 \triangleq \frac{2C_1 \tau_1 \sigma_s^2}{1-\beta}. \quad (326)$$

Next, using (20) we have

$$\begin{aligned} \sqrt{\mathbb{E}\|\tilde{\mathbf{x}}_i\|^4} &\leq \sqrt{\rho^{i+1}\mathbb{E}\|\tilde{\mathbf{x}}_{i-1}\|^4 + A_3\sigma_s^2(i+1)\rho^{i+1}\mu^2 + \frac{A_2\sigma_s^4\mu^2}{\nu^2}} \\ &\leq C_3\rho^{(i+1)/2} + C_4\sigma_s\sqrt{i+1}\rho^{(i+1)/2}\mu + C_5\frac{\sigma_s^2\mu}{\nu} \\ &\leq C_3\rho_2^{(i+1)/2} + C_4\sigma_s\sqrt{i+1}\rho_2^{(i+1)/2}\mu + C_5\frac{\sigma_s^2\mu}{\nu}. \end{aligned} \quad (327)$$

Substituting (327) into (325), we reach

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq \rho_1\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + (r_5\rho_1^i\mu^3 + r_6\mu^3) + r_7\sqrt{i}\rho_2^i\mu^{3/2} + r_8i\rho_2^i\mu^{5/2} + r_9\sqrt{i}\rho_2^i\mu^{5/2} \\ &\quad + r_{10}\mu^2\rho_2^{i/2} + r_{11}\sqrt{i}\rho_2^{i/2}\mu^3 + r_{12}\mu^3, \end{aligned} \quad (328)$$

where the constants are defined as

$$\begin{aligned} r_7 &\triangleq 2C_3r_3, \quad r_8 \triangleq 2C_4r_3\sigma_s, \quad r_9 \triangleq \frac{2C_5r_3\sigma_s^2}{\nu} \\ r_{10} &\triangleq C_3r_6, \quad r_{11} \triangleq C_4r_6\sigma_s, \quad r_{12} \triangleq \frac{C_5r_6\sigma_s^2}{\nu}. \end{aligned} \quad (329)$$

Now we denote

$$\tau_1 \triangleq \rho_1^{1/2}, \quad \tau_2 \triangleq \rho_2^{1/2}. \quad (330)$$

Clearly, we have

$$\rho_1 < \tau_1, \quad \rho_2 < \tau_2, \quad \tau_1 < \tau_2. \quad (331)$$

With the above relation, expressions (328) becomes

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq \tau_2\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + (r_5\tau_1^i\mu^3 + r_6\mu^3) + r_7\sqrt{i}\tau_2^i\mu^{3/2} + r_8i\tau_2^i\mu^{5/2} + r_9\sqrt{i}\tau_2^i\mu^{5/2} \\ &\quad + r_{10}\mu^2\tau_2^{i/2} + r_{11}\sqrt{i}\tau_2^{i/2}\mu^3 + r_{12}\mu^3 \\ &\leq \tau_2\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + 2r_{10}\tau_2^i\mu^2 + 2r_7\sqrt{i}\tau_2^i\mu^{3/2} + r_8i\tau_2^i\mu^{5/2} + (r_6 + r_{12})\mu^3 \\ &\leq \tau_2^{i+1}\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 + 2r_{10}(i+1)\tau_2^i\mu^2 + 2r_7\tau_2^i\mu^{3/2} \left(\sum_{k=0}^i \sqrt{i-k} \right) \\ &\quad + r_8\tau_2^i\mu^{5/2}(i+1) + \frac{(r_6 + r_{12})\mu^3}{1 - \tau_2}. \end{aligned} \quad (332)$$

Note that $\tau_2 = \sqrt{\rho_2} = \sqrt{1 - \mu\nu/4}$. When μ is sufficiently small, we have $\tau_2 = 1 - \mu\nu/8$ and hence $1 - \tau_2 = \mu\nu/2$. With this fact and recall that $\mathbb{E}\|\hat{\mathbf{w}}_{i-1} - \tilde{\mathbf{x}}_{i-1}\|^2 = C_6\mu^2$, finally we can show that

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq C_6\tau_2^{i+1}\mu^2 + 2r_{10}(i+1)\tau_2^i\mu^2 + 2r_7\tau_2^i\mu^{3/2} \left(\sum_{k=0}^i \sqrt{i-k} \right)$$

$$+ r_8\tau_2^i\mu^{5/2}(i+1) + \frac{8(r_6 + r_{12})\mu^2}{\nu}. \quad (333)$$

Substituting the definitions of all constants, we get

$$\begin{aligned} \mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 &\leq C_7 \left(\frac{\delta^2 s_1(i)\tau_2^i\mu^{3/2}}{\nu^{5/2}} + \tau_2^{i+1}\mu^2 + \frac{\sigma_s^2\delta^2(i+1)\tau_2^i\mu^{5/2}}{(1-\beta)\nu} + \frac{\sigma_s\delta^2s_2(i)\tau_2^i\mu^{5/2}}{\nu^{5/2}} + \frac{\delta^2\sigma_s^4\mu^2}{(1-\beta)\nu^2} \right) \\ &\leq C_8 \left(\frac{\delta^2\sigma_s^2s_2(i)\tau_2^{i+1}\mu^{3/2}}{(1-\beta)\nu^{5/2}} + \frac{\delta^2\sigma_s^4\mu^2}{(1-\beta)\nu^2} \right). \end{aligned} \quad (334)$$

where

$$s_1(i) \triangleq \sum_{k=0}^i \sqrt{i-k}, \quad s_2(i) \triangleq i(i+1) \quad (335)$$

Furthermore, it holds that

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 \leq 2\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 + 2\beta^2\mathbb{E}\|\hat{\mathbf{w}}_i\|^2. \quad (336)$$

Using the upper bound for $\mathbb{E}\|\hat{\mathbf{w}}_i\|^2$ in (324), we then have

$$\mathbb{E}\|\hat{\mathbf{w}}_i - \tilde{\mathbf{x}}_i\|^2 = O\left(\frac{\delta^2\sigma_s^2s_2(i)\tau_2^{i+1}\mu^{3/2}}{(1-\beta)\nu^{5/2}} + \frac{(\delta^2 + \gamma^2)\rho_1^{i+1}\mu^2}{(1-\beta)^2} + \frac{\delta^2\sigma_s^4\mu^2}{(1-\beta)\nu^2} \right). \quad (337)$$

Abstract

Rank aggregation systems collect ordinal preferences from individuals to produce a global ranking that represents the social preference. Rank-breaking is a common practice to reduce the computational complexity of learning the global ranking. The individual preferences are broken into pairwise comparisons and applied to efficient algorithms tailored for independent paired comparisons. However, due to the ignored dependencies in the data, naive rank-breaking approaches can result in inconsistent estimates. The key idea to produce accurate and consistent estimates is to treat the pairwise comparisons unequally, depending on the topology of the collected data. In this paper, we provide the optimal rank-breaking estimator, which not only achieves consistency but also achieves the best error bound. This allows us to characterize the fundamental tradeoff between accuracy and complexity. Further, the analysis identifies how the accuracy depends on the spectral gap of a corresponding comparison graph.

Keywords: Rank aggregation, Plackett-Luce model, Sample complexity

1. Introduction

In several applications such as electing officials, choosing policies, or making recommendations, we are given partial preferences from individuals over a set of alternatives, with the goal of producing a global ranking that represents the collective preference of the population or the society. This process is referred to as *rank aggregation*. One popular approach is *learning to rank*. Economists have modeled each individual as a rational being maximizing his/her perceived utility. Parametric probabilistic models, known collectively as Random Utility Models (RUMs), have been proposed to model such individual choices and preferences (McFadden, 1980). This allows one to infer the global ranking by learning the inherent utility from individuals' revealed preferences, which are noisy manifestations of the underlying true utility of the alternatives.

Traditionally, learning to rank has been studied under the following data collection scenarios: pairwise comparisons, best-out-of- k comparisons, and k -way comparisons. *Pairwise comparisons* are commonly studied in the classical context of sports matches as well as more recent applications in crowdsourcing, where each worker is presented with a pair of choices and asked to choose the more favorable one. *Best-out-of- k comparisons* data sets are commonly available from purchase history of customers. Typically, a set of k alternatives are offered among which one is chosen or purchased by each customer. This has been widely studied in operations research in the context of modeling customer choices for revenue management and assortment optimization. The *k-way comparisons* are assumed in traditional rank aggregation scenarios, where each person reveals his/her preference as

a ranked list over a set of k items. In some real-world elections, voters provide ranked preferences over the whole set of candidates (Lundell, 2007). We refer to these three types of ordinal data collection scenarios as 'traditional' throughout this paper.

For such traditional data sets, there are several computationally efficient inference algorithms for finding the Maximum Likelihood (ML) estimates that provably achieve the minimax optimal performance (Negahban et al., 2012; Shah et al., 2015a; Hajek et al., 2014). However, modern data sets can be unstructured. Individual's revealed ordinal preferences can be implicit, such as movie ratings, time spent on the news articles, and whether the user finished watching the movie or not. In crowdsourcing, it has also been observed that humans are more efficient at performing batch comparisons (Gomes et al., 2011), as opposed to providing the full ranking or choosing the top item. This calls for more flexible approaches for rank aggregation that can take such diverse forms of ordinal data into account. For such non-traditional data sets, finding the ML estimate can become significantly more challenging, requiring run-time exponential in the problem parameters.

To avoid such a computational bottleneck, a common heuristic is to resort to *rank-breaking*. The collected ordinal data is first transformed into a bag of pairwise comparisons, ignoring the dependencies that were present in the original data. This is then processed via existing inference algorithms tailored for *independent* pairwise comparisons, hoping that the dependency present in the input data does not lead to inconsistency in estimation. This idea is one of the main motivations for numerous approaches specializing in learning to rank from pairwise comparisons, e.g., (Ford Jr., 1957; Negahban et al., 2014; Azari Soufiani et al., 2013). However, such a heuristic of full rank-breaking defined explicitly in (1), where all pairwise comparisons are weighted and treated equally ignoring their dependencies, has been recently shown to introduce inconsistency (Azari Soufiani et al., 2014).

The key idea to produce accurate and consistent estimates is to treat the pairwise comparisons unequally, depending on the topology of the collected data. A fundamental question of interest to practitioners is how to choose the weight of each pairwise comparison in order to achieve not only consistency but also the best accuracy, among those consistent estimators using rank-breaking. We study how the accuracy of resulting estimate depends on the topology of the data and the weights on the pairwise comparisons. This provides a guideline for the optimal choice of the weights, driven by the topology of the data, that leads to accurate estimates.

Problem formulation. The premise in the current race to collect more data on user activities is that, a hidden true preference manifests in the user's activities and choices. Such data can be explicit, as in ratings, ranked lists, pairwise comparisons, and like/dislike buttons. Others are more implicit, such as purchase history and viewing times. While more data in general allows for a more accurate inference, the heterogeneity of user activities makes it difficult to infer the underlying preferences directly. Further, each user reveals her preference on only a few contents.

Traditional collaborative filtering fails to capture the diversity of modern data sets. The sparsity and heterogeneity of the data renders typical similarity measures ineffective in the nearest-neighbor methods. Consequently, simple measures of similarity prevail in practice, as in Amazon's "people who bought ... also bought ..." scheme. Score-based methods require translating heterogeneous data into numeric scores, which is a priori a difficult task. Even if explicit ratings are observed, those are often unreliable and the scale of such ratings vary from user to user.

We propose aggregating ordinal data based on users' revealed preferences that are expressed in the form of *partial orderings* (notice that our use of the term is slightly different from its original

use in revealed preference theory). We interpret user activities as manifestation of the hidden preferences according to discrete choice models (in particular the Plackett-Luce model defined in (1)). This provides a more reliable, scale-free, and widely applicable representation of the heterogeneous data as partial orderings, as well as a probabilistic interpretation of how preferences manifest. In full generality, the data collected from each individual can be represented by a *partially ordered set (poset)*. Assuming consistency in a user's revealed preferences, any ordered relations can be seamlessly translated into a poset, represented as a Hasse diagram by a directed acyclic graph (DAG). The DAG below represents ordered relations $a > \{b, d\}$, $b > c$, $\{c, d\} > e$, and $e > f$. For example, this could have been translated from two sources: a five star rating on a and a three star ratings on b, c, d , a two star rating on e , and a one star rating on f ; and the item b being purchased after reviewing c as well.

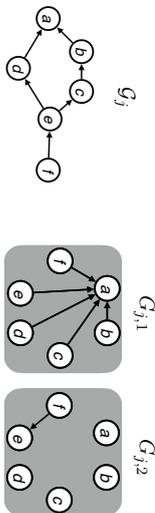

Figure 1: A DAG representation of consistent partial ordering of a user j , also called a Hasse diagram (left). A set of rank-breaking graphs extracted from the Hasse diagram for the separator item a and e , respectively (right).

There are n users or agents, and each agent j provides his/her ordinal evaluation on a subset S_j of d items or alternatives. We refer to $S_j \subset \{1, 2, \dots, d\}$ as *offerings* provided to j , and use $k_j = |S_j|$ to denote the size of the offerings. We assume that the partial ordering over the offerings is a manifestation of her preferences as per a popular choice model known as Plackett-Luce (PL) model. As we explain in detail below, the PL model produces total orderings (rather than partial ones). The data collector queries each user for a partial ranking in the form of a poset over S_j . For example, the data collector can ask for the top item, unordered subset of three next preferred items, the fifth item, and the least preferred item. In this case, an example of such poset could be $a < \{b, c, d\} < e < f$, which could have been generated from a total ordering produced by the PL model and taking the corresponding partial ordering from the total ordering. Notice that we fix the topology of the DAG first and ask the user to fill in the node identities corresponding to her total ordering as (randomly) generated by the PL model. Hence, the structure of the poset is considered deterministic, and only the identity of the nodes in the poset is considered random. Alternatively, one could consider a different scenario where the topology of the poset is also random and depends on the outcome of the preference, which is out-side the scope of this paper and provides an interesting future research direction.

The PL model is a special case of *random utility models*, defined as follows (Walker and Ben-Akiva, 2002; Azari Soufiani et al., 2012). Each item i has a real-valued latent utility θ_i . When presented with a set of items, a user's revealed preference is a partial ordering according to noisy manifestation of the utilities, i.e. i.i.d. noise added to the true utility θ_i 's. The PL model is a special case where the noise follows the standard Gumbel distribution, and is one of the most popular model in social choice theory (McFadden, 1973; McFadden and Train, 2000). PL has several important

properties, making this model realistic in various domains, including marketing (Guadagni and Little, 1983), transportation (McFadden, 1980; Ben-Akiva and Lerman, 1985), biology (Shan and Curtis, 1995), and natural language processing (Mikolov et al., 2013). Precisely, each user j , when presented with a set S_j of items, draws a noisy utility of each item i according to

$$u_i = \theta_i + Z_i,$$

where Z_i 's follow the independent standard Gumbel distribution. Then we observe the ranking resulting from sorting the items as per noisy observed utilities u_j 's. Alternatively, the PL model is also equivalent to the following random process. For a set of alternatives S_j , a ranking $\sigma_j : [|S_j|] \rightarrow S_j$ is generated in two steps: (1) independently assign each item $i \in S_j$ an unobserved value X_i , exponentially distributed with mean $e^{-\theta_i}$; (2) select a ranking σ_j so that $X_{\sigma_j(1)} \leq X_{\sigma_j(2)} \leq \dots \leq X_{\sigma_j(|S_j|)}$.

The PL model (i) satisfies Luce's 'independence of irrelevant alternatives' in social choice theory (Ray, 1973), and has a simple characterization as sequential (random) choices as explained below; and (ii) has a maximum likelihood estimator (MLE) which is a convex program in θ in the traditional scenarios of pairwise, best-out-of- k and k -way comparisons. Let $\mathbb{P}(a > \{b, c, d\})$ denote the probability a was chosen as the best alternative among the set $\{a, b, c, d\}$. Then, the probability that a user reveals a linear order ($a > b > c > d$) is equivalent as making sequential choice from the top to bottom:

$$\begin{aligned} \mathbb{P}(a > b > c > d) &= \mathbb{P}(a > \{b, c, d\}) \mathbb{P}(b > \{c, d\}) \mathbb{P}(c > d) \\ &= \frac{e^{\theta_a}}{(e^{\theta_a} + e^{\theta_b} + e^{\theta_c} + e^{\theta_d})} \frac{e^{\theta_b}}{(e^{\theta_b} + e^{\theta_c} + e^{\theta_d})} \frac{e^{\theta_c}}{(e^{\theta_c} + e^{\theta_d})} \frac{e^{\theta_d}}{(e^{\theta_c} + e^{\theta_d})}. \end{aligned}$$

We use the notation ($a > b$) to denote the event that a is preferred over b . In general, for user j presented with offerings S_j , the probability that the revealed preference is a total ordering σ_j is $\mathbb{P}(\sigma_j) = \prod_{i \in \{1, \dots, k_j - 1\}} (e^{\theta_{\sigma_j^{-1}(i)}}) / (\sum_{i' \in S_j} e^{\theta_{\sigma_j^{-1}(i')}})$. We consider the true utility $\theta^* \in \Omega_b$, where we define Ω_b as

$$\Omega_b \equiv \left\{ \theta \in \mathbb{R}^d \mid \sum_{i \in [d]} \theta_i = 0, |\theta_i| \leq b \text{ for all } i \in [d] \right\}.$$

Note that by definition, the PL model is invariant under shifting the utility θ_i 's. Hence, the centering ensures uniqueness of the parameters for each PL model. The bound b on the dynamic range is not a restriction, but is written explicitly to capture the dependence of the accuracy in our main results.

We have n users each providing a partial ordering of a set of offerings S_j according to the PL model. Let G_j denote both the DAG representing the partial ordering from user j 's preferences. With a slight abuse of notations, we also let G_j denote the set of rankings that are consistent with this DAG. For general partial orderings, the probability of observing G_j is the sum of all total orderings that is consistent with the observation, i.e. $\mathbb{P}(G_j) = \sum_{\sigma \in G_j} \mathbb{P}(\sigma)$. The goal is to efficiently learn the true utility $\theta^* \in \Omega_b$ from the n sampled partial orderings. One popular approach is to compute the maximum likelihood estimate (MLE) by solving the following optimization:

$$\underset{\theta \in \Omega_b}{\text{maximize}} \quad \sum_{j=1}^n \log \mathbb{P}(G_j).$$

This optimization is a simple convex optimization, in particular a logit regression, when the structure of the data $\{\mathcal{G}_j\}_{j \in [n]}$ is traditional. This is one of the reasons the PL model is attractive. However, for general posets, this can be computationally challenging. Consider an example of position- p ranking, where each user provides which item is at p -th position in his/her ranking. Each term in the log-likelihood for this data involves summation over $O((p-1)!) rankings, which takes $O(n(p-1)!) operations to evaluate the objective function. Since p can be as large as d , such a computational blow-up renders MLE approach impractical. A common remedy is to resort to rank-breaking, which might result in inconsistent estimates.$$

Rank-breaking. Rank-breaking refers to the idea of extracting a set of pairwise comparisons from the observed partial orderings and applying estimators tailored for paired comparisons treating each piece of comparisons as independent. Both the choice of which paired comparisons to extract and the choice of parameters in the estimator, which we call *weights*, turns out to be crucial as we will show. Inappropriate selection of the paired comparisons can lead to inconsistent estimators as proved in Azari Soufiani et al. (2014), and the standard choice of the parameters can lead to a significantly suboptimal performance.

A naive rank-breaking that is widely used in practice is to apply rank-breaking to all possible pairwise relations that one can read from the partial ordering and weighing them equally. We refer to this practice as *full rank-breaking*. In the example in Figure 1, full rank-breaking first extracts the bag of comparisons $\mathcal{C} = \{(a > b), (a > c), (a > d), (a > e), (a > f), \dots, (e > f)\}$ with 13 paired comparison outcomes, and apply the maximum likelihood estimator treating each paired outcome as independent. Precisely, the *full rank-breaking estimator* solves the convex optimization of

$$\hat{\theta} \in \arg \max_{\theta \in \Omega_{\theta}} \sum_{(i, i') \in \mathcal{C}} (\theta_i - \log(e^{\theta_i} + e^{\theta_{i'}})) \quad (1)$$

There are several efficient implementation tailored for this problem (Ford Jr., 1957; Hunter, 2004; Negahban et al., 2012; Maystre and Grossglauser, 2015a), and under the traditional scenarios, these approaches provably achieve the minimax optimal rate (Hajek et al., 2014; Shah et al., 2015a). For general non-traditional data sets, there is a significant gain in computational complexity. In the case of position- p ranking, where each of the n users report his/her p -th ranking item among κ items, the computational complexity reduces from $O(n(p-1)!) for the MLE in (1) to $O(np(\kappa-p)) for the full rank-breaking estimator in (1). However, this gain comes at the cost of accuracy. It is known that the full-rank breaking estimator is inconsistent (Azari Soufiani et al., 2014); the error is strictly bounded away from zero even with infinite samples.$$

Perhaps surprisingly, Azari Soufiani et al. (2014) recently characterized the entire set of consistent rank-breaking estimators. Instead of using the bag of paired comparisons, the sufficient information for consistent rank-breaking is a set of rank-breaking graphs defined as follows.

Recall that a user j provides his/her preference as a poset represented by a DAG \mathcal{G}_j . Consistent rank-breaking first identifies all *separators* in the DAG. A node in the DAG is a separator if one can partition the rest of the nodes into two parts. A partition A_{top} which is the set of items that are preferred over the separator item, and a partition A_{bottom} which is the set of items that are less preferred than the separator item. One caveat is that we allow A_{top} to be empty, but A_{bottom} must have at least one item. In the example in Figure 1, there are two separators: the item a and the item e . Using these separators, one can extract the following partial ordering from the original poset: $(a > \{b, c, d\} > e > f)$. The items a and e separate the set of offerings into partitions, hence

the name separator. We use ℓ_j to denote the number of separators in the poset \mathcal{G}_j from user j . Let $p_{j,a}$ denote the ranked position of the a -th separator in the poset \mathcal{G}_j , and we sort the positions such that $p_{j,1} < p_{j,2} < \dots < p_{j,\ell_j}$. The set of separators is denoted by $\mathcal{P}_j = \{p_{j,1}, p_{j,2}, \dots, p_{j,\ell_j}\}$. For example, since the separator a is ranked at position 1 and e is at the 5-th position, $\ell_j = 2$, $p_{j,1} = 1$, and $p_{j,2} = 5$. Note that f is not a separator (whereas a is) since corresponding A_{bottom} is empty.

Conveniently, we represent this extracted partial ordering using a set of DAGs, which are called *rank-breaking graphs*. We generate one rank-breaking graph per separator. A rank breaking graph $G_{j,a} = (S_j, E_{j,a})$ for user j and the a -th separator is defined as a directed graph over the set of offerings S_j , where we add an edge from a node that is less preferred than the a -th separator to the separator, i.e. $E_{j,a} = \{(i, i') \mid i' \text{ is the } a\text{-th separator, and } \sigma_j^{-1}(i) > p_{j,a}\}$. Note that by the definition of the separator, $E_{j,a}$ is a non-empty set. An example of rank-breaking graphs are shown in Figure 1.

This rank-breaking graphs were introduced in Azari Soufiani et al. (2013), where it was shown that the pairwise ordinal relations that is represented by edges in the rank-breaking graphs are sufficient information for using any estimation based on the idea of rank-breaking. Precisely, on the converse side, it was proved in Azari Soufiani et al. (2014) that any pairwise outcomes that is not present in the rank-breaking graphs $G_{j,a}$'s lead to inconsistency for a general θ^* . On the achievability side, it was proved that all pairwise outcomes that are present in the rank-breaking graphs give a consistent estimator, as long as all the paired comparisons in each $G_{j,a}$ are weighted equally.

It should be noted that rank-breaking graphs are defined slightly differently in Azari Soufiani et al. (2013). Specifically, Azari Soufiani et al. (2013) introduced a different notion of rank-breaking graph, where the vertices represent positions in total ordering. An edge between two vertices i_1 and i_2 denotes that the pairwise comparison between items ranked at position i_1 and i_2 is included in the estimator. Given such observation from the PL model, Azari Soufiani et al. (2013) and Azari Soufiani et al. (2014) prove that a rank-breaking graph is consistent if and only if it satisfies the following property. If a vertex i_1 is connected to any vertex i_2 , where $i_2 > i_1$, then i_1 must be connected to all the vertices i_3 such that $i_3 > i_1$. Although the specific definitions of rank-breaking graphs are different from our setting, the mathematical analysis of Azari Soufiani et al. (2013) still holds when interpreted appropriately. Specifically, we consider only those rank-breaking that are consistent under the conditions given in Azari Soufiani et al. (2013). In our rank-breaking graph $G_{j,a}$, a separator node is connected to all the other item nodes that are ranked below it (numerically higher positions).

In the algorithm described in (33), we satisfy this sufficient condition for consistency by restricting to a class of convex optimizations that use the same weight $\lambda_{j,a}$ for all $(\kappa - p_{j,a})$ paired comparisons in the objective function, as opposed to allowing more general weights that defer from a pair to another pair in a rank-breaking graph $G_{j,a}$.

Algorithm. Consistent rank-breaking first identifies separators in the collected posets $\{\mathcal{G}_j\}_{j \in [n]}$ and transform them into rank-breaking graphs $\{G_{j,a}\}_{j \in [n], a \in [\ell_j]}$ as explained above. These rank-breaking graphs are input to the MLE for paired comparisons, assuming all directed edges in the rank-breaking graphs are independent outcome of pairwise comparisons. Precisely, the *consistent*

rank-breaking estimator solves the convex optimization of maximizing the paired log likelihoods

$$\mathcal{L}_{\text{RB}}(\theta) = \sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a} \left\{ \sum_{(i,i') \in E_{j,a}} \left(\theta_{i'} - \log \left(e^{\theta_i} + e^{\theta_{i'}} \right) \right) \right\}, \quad (2)$$

where $E_{j,a}$'s are defined as above via separators and different choices of the non-negative weights $\lambda_{j,a}$'s are possible and the performance depends on such choices. Each weight $\lambda_{j,a}$ determine how much we want to weigh the contribution of a corresponding rank-breaking graph $G_{j,a}$. We define the consistent rank-breaking estimate $\hat{\theta}$ as the optimal solution of the convex program:

$$\hat{\theta} \in \arg \max_{\theta \in \Omega_b} \mathcal{L}_{\text{RB}}(\theta). \quad (3)$$

By changing how we weigh each rank-breaking graph (by choosing the $\lambda_{j,a}$'s), the convex program (3) spans the entire set of consistent rank-breaking estimators, as characterized in Azari Soufiani et al. (2014). However, only asymptotic consistency was known, which holds independent of the choice of the weights $\lambda_{j,a}$'s. Naturally, a uniform choice of $\lambda_{j,a} = \lambda$ was proposed in (Azari Soufiani et al., 2014).

Note that this can be efficiently solved, since this is a simple convex optimization, in particular a logit regression, with only $O(\sum_{j=1}^n \ell_j \kappa_j)$ terms. For a special case of position- p breaking, the $O(n(p-1))$ complexity of evaluating the objective function for the MLE is now significantly reduced to $O(n(k-p))$ by rank-breaking. Given this potential exponential gain in efficiency, a natural question of interest is "what is the price we pay in the accuracy?". We provide a sharp analysis of the performance of rank-breaking estimators in the finite sample regime, that quantifies the price of rank-breaking. Similarly, for a practitioner, a core problem of interest is how to choose the weights in the optimization in order to achieve the best accuracy. Our analysis provides a data-driven guideline for choosing the optimal weights.

Contributions. In this paper, we provide an upper bound on the error achieved by the rank-breaking estimator of (3) for any choice of the weights in Theorem 8. This explicitly shows how the error depends on the choice of the weights, and provides a guideline for choosing the optimal weights $\lambda_{j,a}$'s in a data-driven manner. We provide the explicit formula for the optimal choice of the weights and provide the error bound in Theorem 2. The analysis shows the explicit dependence of the error in the problem dimension d and the number of users n that matches the numerical experiments.

If we are designing surveys and can choose which subset of items to offer to each user and also can decide which type of ordinal data we can collect, then we want to design such surveys in a way to maximize the accuracy for a given number of questions asked. Our analysis provides how the accuracy depends on the topology of the collected data, and provides a guidance when we do have some control over which questions to ask and which data to collect. One should maximize the spectral gap of corresponding comparison graph. Further, for some canonical scenarios, we quantify the price of rank-breaking by comparing the error bound of the proposed data-driven rank-breaking with the lower bound on the MLE, which can have a significantly larger computational cost (Theorem 4).

Notations. Following is a summary of all the notations defined above. We use d to denote the total number of items and index each item by $i \in \{1, 2, \dots, d\}$. $\theta \in \Omega_b$ denotes vector of utilities

associated with each item. θ^* represents true utility and $\hat{\theta}$ denotes the estimated utility. We use n to denote the number of users/agents and index each user by $j \in \{1, 2, \dots, n\}$. $S_j \subseteq \{1, \dots, d\}$ refer to the offerings provided to the j -th user and we use $\kappa_j = |S_j|$ to denote the size of the offerings. G_j denote the DAG (Hasse diagram) representing the partial ordering from user j 's preferences. $P_j = \{p_{j,1}, p_{j,2}, \dots, p_{j,\ell_j}\}$ denotes the set of separators in the DAG G_j , where $p_{j,1}, \dots, p_{j,\ell_j}$ are the positions of the separators, and ℓ_j is the number of separators. $G_{j,a} = (S_j, E_{j,a})$ denote the rank-breaking graph for the a -th separator extracted from the partial ordering G_j of user j .

For any positive integer N , let $[N] = \{1, \dots, N\}$. For a ranking σ over S , i.e., σ is a mapping from $|S|$ to S , let σ^{-1} denote the inverse mapping. For a vector x , let $\|x\|_2$ denote the standard ℓ_2 norm. Let $\mathbf{1}$ denote the all-ones vector and $\mathbf{0}$ denote the all-zeros vector with the appropriate dimension. Let S^d denote the set of $d \times d$ symmetric matrices with real-valued entries. For $X \in S^d$, let $\lambda_1(X) \leq \lambda_2(X) \leq \dots \leq \lambda_d(X)$ denote its eigenvalues sorted in increasing order. Let $\text{Tr}(X) = \sum_{i=1}^d \lambda_i(X)$ denote its trace and $\|X\| = \max\{|\lambda_1(X)|, |\lambda_d(X)|\}$ denote its spectral norm. For two matrices $X, Y \in S^d$, we write $X \succeq Y$ if $X - Y$ is positive semi-definite, i.e., $\lambda_1(X - Y) \geq 0$. Let e_i denote a unit vector in \mathbb{R}^d along the i -th direction.

2. Comparisons Graph and the Graph Laplacian

In the analysis of the convex program (3), we show that, with high probability, the objective function is strictly concave with $\lambda_2(H(\theta)) \leq -C_b \gamma \lambda_2(L) < 0$ (Lemma 11) for all $\theta \in \Omega_b$ and the gradient is bounded by $\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2 \leq C_b' \sqrt{\log d \sum_{j \in [n]} \ell_j}$ (Lemma 10). Shortly, we will define γ and $\lambda_2(L)$, which captures the dependence on the topology of the data, and C_b' and C_b are constants that only depend on b . Putting these together, we will show that there exists a $\theta \in \Omega_b$ such that

$$\|\hat{\theta} - \theta^*\|_2 \leq \frac{2\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2}{-\lambda_2(H(\theta))} \leq C_b'' \frac{\sqrt{\log d \sum_{j \in [n]} \ell_j}}{\gamma \lambda_2(L)}.$$

Here $\lambda_2(H(\theta))$ denotes the second largest eigenvalue of a negative semi-definite Hessian matrix $H(\theta)$ of the objective function. The reason the second largest eigenvalue shows up is because the top eigenvector is always the all-ones vector which by the definition of Ω_b is infeasible. The accuracy depends on the topology of the collected data via the comparison graph of given data.

Definition 1. (Comparison graph \mathcal{H}). We define a graph $\mathcal{H}([d], E)$ where each alternative corresponds to a node, and we put an edge (i, i') if there exists an agent j whose offerings is a set S_j such that $i, i' \in S_j$. Each edge $(i, i') \in E$ has a weight $A_{ii'}$ defined as

$$A_{ii'} = \sum_{j \in [n]: i, i' \in S_j} \frac{\ell_j}{\kappa_j(\kappa_j - 1)},$$

where $\kappa_j = |S_j|$ is the size of each sampled set and ℓ_j is the number of separators in S_j defined by rank-breaking in Section 1.

Define a diagonal matrix $D = \text{diag}(A\mathbf{1})$, and the corresponding graph Laplacian $L = D - A$, such that

$$L = \sum_{j=1}^n \frac{\ell_j}{\kappa_j(\kappa_j - 1)} \sum_{i < i' \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top. \quad (4)$$

Let $0 = \lambda_1(L) \leq \lambda_2(L) \leq \dots \leq \lambda_d(L)$ denote the (sorted) eigenvalues of L . Of special interest is $\lambda_2(L)$, also called the spectral gap, which measured how well-connected the graph is. Intuitively, one can expect better accuracy when the spectral gap is larger, as evidenced in previous learning to rank results in simpler settings (Negahban et al., 2014; Shah et al., 2015a; Hajek et al., 2014). This is made precise in (4), and in the main result of Theorem 2, we appropriately rescale the spectral gap and use $\alpha \in [0, 1]$ defined as

$$\alpha \equiv \frac{\lambda_2(L)(d-1)}{\text{Tr}(L)} = \frac{\lambda_2(L)(d-1)}{\sum_{j=1}^n \ell_j}. \quad (5)$$

The accuracy also depends on the topology via the maximum weighted degree defined as $D_{\max} \equiv \max_{i \in [d]} D_{ii} = \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \ell_j / \kappa_j \right\}$. Note that the average weighted degree is $\sum_i D_{ii} / d = \text{Tr}(L) / d$, and we rescale it by D_{\max} such that

$$\beta \equiv \frac{\text{Tr}(L)}{dD_{\max}} = \frac{\sum_{j=1}^n \ell_j}{dD_{\max}}. \quad (6)$$

We will show that the performance of rank breaking estimator depends on the topology of the graph through these two parameters. The larger the spectral gap α the smaller error we get with the same effective sample size. The degree imbalance $\beta \in [0, 1]$ determines how many samples are required for the analysis to hold. We need smaller number of samples if the weighted degrees are balanced, which happens if β is large (close to one).

The following quantity also determines the convexity of the objective function.

$$\gamma \equiv \min_{j \in [n]} \left\{ \left(1 - \frac{p_{i\ell_j}}{\kappa_j} \right)^{\lfloor 2e^{2b} \rfloor - 2} \right\}. \quad (7)$$

Note that γ is between zero and one, and a larger value is desired as the objective function becomes more concave and a better accuracy follows. When we are collecting data where the size of the offerings κ_j 's are increasing with d but the position of the separators are close to the top, such that $\kappa_j = \omega(d)$ and $p_{i\ell_j} = O(1)$, then for $b = O(1)$ the above quantity γ can be made arbitrarily close to one, for large enough problem size d . On the other hand, when $p_{i\ell_j}$ is close to κ_j , the accuracy can degrade significantly as stronger alternatives might have small chance of showing up in the rank breaking. The value of γ is quite sensitive to b . The reason we have such a inferior dependence on b is because we wanted to give a universal bound on the Hessian that is simple. It is not difficult to get a tighter bound with a larger value of γ , but will inevitably depend on the structure of the data in a complicated fashion.

To ensure that the (second) largest eigenvalue of the Hessian is small enough, we need enough samples. This is captured by η defined as

$$\eta \equiv \max_{j \in [n]} \{\eta_j\}, \quad \text{where} \quad \eta_j = \frac{\kappa_j}{\max\{\ell_j, \kappa_j - p_{i\ell_j}\}}. \quad (8)$$

Note that $1 < \eta_j \leq \kappa_j / \ell_j$. A smaller value of η is desired as we require smaller number of samples, as shown in Theorem 2. This happens, for instance, when all separators are at the top, such that $p_{i\ell_j} = \ell_j$ and $\eta_j = \kappa_j / (\kappa_j - \ell_j)$, which is close to one for large κ_j . On the other hand, when all separators are at the bottom of the list, then η can be as large as κ_j .

We discuss the role of the topology of data captures by these parameters in Section 4.

3. Main Results

We present the main theoretical results accompanied by corresponding numerical simulations in this section.

3.1 Upper Bound on the Achievable Error

We present the main result that provides an upper bound on the resulting error and explicitly shows the dependence on the topology of the data. As explained in Section 1, we assume that each user provides a partial ranking according to his/her position of the separators. Precisely, we assume the set of offerings S_j , the number of separators ℓ_j , and their respective positions $\mathcal{P}_j = \{p_{j,1}, \dots, p_{j,\ell_j}\}$ are predetermined. Each user draws the ranking of items from the PL model, and provides the partial ranking according to the separators of the form of $\{a > \{b, c, d\} > e > f\}$ in the example in the Figure 1.

Theorem 2. *Suppose there are n users, d items parametrized by $\theta^* \in \Omega_b$, each user j is presented with a set of offerings $S_j \subseteq [d]$, and provides a partial ordering under the PL model. When the effective sample size $\sum_{j=1}^n \ell_j$ is large enough such that*

$$\sum_{j=1}^n \ell_j \geq \frac{2^{11} e^{18b} \eta \log(\ell_{\max} + 2)^2}{\alpha^2 \gamma^2 \beta} d \log d, \quad (9)$$

where $b \equiv \max_i \{\theta_i^*\}$ is the dynamic range, $\ell_{\max} \equiv \max_{j \in [n]} \ell_j$, α is the (rescaled) spectral gap defined in (5), β is the (rescaled) maximum degree defined in (6), γ and η are defined in Eqs. (7) and (8), then the rank-breaking estimator in (3) with the choice of

$$\lambda_{j,a} = \frac{1}{\kappa_j - p_{j,a}}, \quad (10)$$

for all $a \in [\ell_j]$ and $j \in [n]$ achieves

$$\frac{1}{\sqrt{d}} \|\hat{\theta} - \theta^*\|_2 \leq \frac{4\sqrt{2}e^{4b}(1+e^{2b})^2}{\alpha\gamma} \sqrt{\frac{d \log d}{\sum_{j=1}^n \ell_j}}, \quad (11)$$

with probability at least $1 - 3e^3 d^{-3}$.

Consider an ideal case where the spectral gap is large such that α is a strictly positive constant and the dynamic range b is finite and $\max_{j \in [n]} p_{j,\ell_j} / \kappa_j = C$ for some constant $C < 1$ such that γ is also a constant independent of the problem size d . Then the upper bound in (11) implies that we need the effective sample size to scale as $O(d \log d)$, which is only a logarithmic factor larger than the number of parameters to be estimated. Such a logarithmic gap is also unavoidable and due to the fact that we require high probability bounds, where we want the tail probability to decrease at least polynomially in d . We discuss the role of the topology of the data in Section 4.

The upper bound follows from an analysis of the convex program similar to those in (Negahban et al., 2012; Hajek et al., 2014; Shah et al., 2015a). However, unlike the traditional data collection scenarios, the main technical challenge is in analyzing the probability that a particular pair of items appear in the rank-breaking. We provide a proof in Section 8.1.

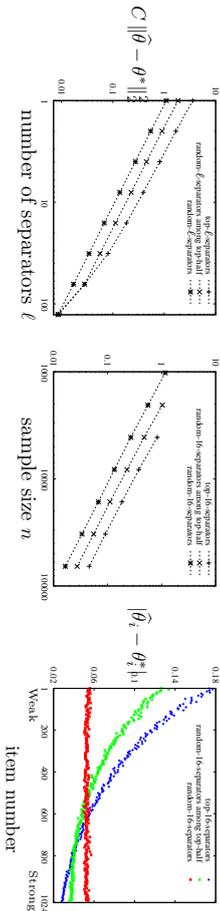

Figure 2: Simulation confirms $\|\hat{\theta}^* - \hat{\theta}\|_2^2 \propto 1/(\ell n)$, and smaller error is achieved for separators that are well spread out.

In Figure 2, we verify the scaling of the resulting error via numerical simulations. We fix $d = 1024$ and $\kappa_j = \kappa = 128$, and vary the number of separators $\ell_j = \ell$ for fixed $n = 128000$ (left), and vary the number of samples n for fixed $\ell_j = \ell = 16$ (middle). Each point is average over 100 instances. The plot confirms that the mean squared error scales as $1/(\ell n)$. Each sample is a partial ranking from a set of κ alternatives chosen uniformly at random, where the partial ranking is from a PL model with weights θ^* chosen i.i.d. uniformly over $[-b, b]$ with $b = 2$. To investigate the role of the position of the separators, we compare three scenarios. The *top- ℓ -separators* choose the top ℓ positions for separators, the *random- ℓ -separators among top-half* choose ℓ positions uniformly random from the top half, and the *random- ℓ -separators* choose the positions uniformly at random. We observe that when the positions of the separators are well spread out among the κ offerings, which happens for *random- ℓ -separators*, we get better accuracy.

The figure on the right provides an insight into this trend for $\ell = 16$ and $n = 16000$. The absolute error $|\hat{\theta}_i^* - \hat{\theta}_i|$ is roughly same for each item $i \in [d]$ when breaking positions are chosen uniformly at random between 1 to $\kappa - 1$ whereas it is significantly higher for weak preference score items when breaking positions are restricted between 1 to $\kappa/2$ or are top- ℓ . This is due to the fact that the probability of each item being ranked at different positions is different, and in particular probability of the low preference score items being ranked in top- ℓ is very small. The third figure is averaged over 1000 instances. Normalization constant C is n/d^2 and $10^3\ell/d^2$ for the first and second figures respectively. For the first figure n is chosen relatively large such that $n\ell$ is large enough even for $\ell = 1$.

3.2 The Price of Rank Breaking for the Special Case of Position- p Ranking

Rank-breaking achieves computational efficiency at the cost of estimation accuracy. In this section, we quantify this tradeoff for a canonical example of position- p ranking, where each sample provides the following information: an unordered set of $p - 1$ items that are ranked high, one item that is ranked at the p -th position, and the rest of $\kappa_j - p$ items that are ranked on the bottom. An example of a sample with position-4 ranking six items $\{a, b, c, d, e, f\}$ might be a partial ranking of $\{(a, b, d) > \{c, f\}\}$. Since each sample has only one separator for $2 < p$, Theorem 2 simplifies to the following Corollary.

Corollary 3. *Under the hypotheses of Theorem 2, there exist positive constants C and c that only depend on b such that if $n \geq C(\eta d \log d)/(\alpha^2 \gamma^2 \beta)$ then*

$$\frac{1}{\sqrt{d}} \|\hat{\theta} - \theta^*\|_2 \leq \frac{c}{\alpha \gamma} \sqrt{\frac{d \log d}{n}}. \quad (12)$$

Note that the error only depends on the position p through γ and η , and is not sensitive. To quantify the price of rank-breaking, we compare this result to a fundamental lower bound on the minimax rate in Theorem 4. We can compute a sharp lower bound on the minimax rate, using the Cramér-Rao bound, and a proof is provided in Section 8.3.

Theorem 4. *Let \mathcal{U} denote the set of all unbiased estimators of θ^* and suppose $b > 0$, then*

$$\inf_{\hat{\theta}} \sup_{\theta^* \in \Omega_b} \mathbb{E} \|\hat{\theta} - \theta^*\|_2^2 \geq \frac{1}{2p \log(\kappa_{\max})^2} \sum_{i=2}^d \frac{1}{\lambda_i(L)} \geq \frac{1}{2p \log(\kappa_{\max})^2} \frac{(d-1)^2}{n},$$

where $\kappa_{\max} = \max_{j \in [n]} |S_j|$ and the second inequality follows from the Jensen's inequality.

Note that the second inequality is tight up to a constant factor, when the graph is an expander with a large spectral gap. For expanders, α in the bound (12) is also a strictly positive constant. This suggests that rank-breaking gains in computational efficiency by a super-exponential factor of $(p-1)!$, at the price of increased error by a factor of p , ignoring poly-logarithmic factors.

3.3 Tighter Analysis for the Special Case of Top- ℓ Separators Scenario

The main result in Theorem 2 is general in the sense that it applies to any partial ranking data that is represented by positions of the separators. However, the bound can be quite loose, especially when γ is small, i.e. $p_j \ell_j$ is close to κ_j . For some special cases, we can tighten the analysis to get a sharper bound. One caveat is that we use a slightly sub-optimal choice of parameters $\lambda_{j,a} = 1/\kappa_j$ instead of $1/(\kappa_j - a)$, to simplify the analysis and still get the order optimal error bound we want. Concretely, we consider a special case of top- ℓ separators scenario, where each agent gives a ranked list of her most preferred ℓ_j alternatives among κ_j offered set of items. Precisely, the locations of the separators are $(p_{j,1}, p_{j,2}, \dots, p_{j,\ell_j}) = (1, 2, \dots, \ell_j)$.

Theorem 5. *Under the PL model, n partial orderings are sampled over d items parametrized by $\theta^* \in \Omega_b$, where the j -th sample is a ranked list of the top- ℓ_j items among the κ_j items offered to the agent. If*

$$\sum_{j=1}^n \ell_j \geq \frac{2^{12} e^{6b}}{\beta \alpha^2} d \log d, \quad (13)$$

where $b \equiv \max_{i,x} |\theta_i^* - \theta_x^*|$ and α, β are defined in (5) and (6), then the rank-breaking estimator in (3) with the choice of $\lambda_{j,a} = 1/\kappa_j$ for all $a \in [k_j]$ and $j \in [n]$ achieves

$$\frac{1}{\sqrt{d}} \|\hat{\theta} - \theta^*\|_2 \leq \frac{16(1 + e^{2b})^2}{\alpha} \sqrt{\frac{d \log d}{\sum_{j=1}^n \ell_j}}, \quad (14)$$

with probability at least $1 - 3e^{-3d}$.

A proof is provided in Section 8.4. In comparison to the general bound in Theorem 2, this is tighter since there is no dependence in γ or η . This gain is significant when, for example, p_{j,ℓ_j} is close to κ_j . As an extreme example, if all agents are offered the entire set of alternatives and are asked to rank all of them, such that $\kappa_j = d$ and $\ell_j = d - 1$ for all $j \in [n]$, then the generic bound in (11) is loose by a factor of $(e^{db}/2\sqrt{2})d^{(2e^{2b})-2}$, compared to the above bound.

In the top- ℓ separators scenario, the data set consists of the ranking among top- ℓ_j items of the set S_j , i.e., $[\sigma_j(1), \sigma_j(2), \dots, \sigma_j(\ell_j)]$. The corresponding log-likelihood of the PL model is

$$\mathcal{L}(\theta) = \sum_{j=1}^n \sum_{m=1}^{\ell_j} \left[\theta_{\sigma_j(m)} - \log \left(\exp(\theta_{\sigma_j(m)}) + \exp(\theta_{\sigma_j(m+1)}) + \dots + \exp(\theta_{\sigma_j(\kappa_j)}) \right) \right], \quad (15)$$

where $\sigma_j(a)$ is the alternative ranked at the a -th position by agent j . The Maximum Likelihood Estimator (MLE) for this *traditional* data set is efficient. Hence, there is no computational gain in rank-breaking. Consequently, there is no loss in accuracy either, when we use the optimal weights proposed in the above theorem. Figure 3 illustrates that the MLE and the data-driven rank-breaking estimator achieve performance that is identical, and improve over naive rank-breaking that uses uniform weights. We also compare performance of Generalized Method-of-Moments (GMM) proposed by Azari Soufiani et al. (2013) with our algorithm. In addition, we show that performance of GMM can be improved by optimally weighing pairwise comparisons with $\lambda_{j,a}$. MSE of GMM in both the cases, uniform weights and optimal weights, is larger than our rank-breaking estimator. However, GMM is on average about four times faster than our algorithm. We choose $\lambda_{j,a} = 1/(\kappa_j - a)$ in the simulations, as opposed to the $1/\kappa_j$ assumed in the above theorem. This settles the question raised in Hajek et al. (2014) on whether it is possible to achieve optimal accuracy using rank-breaking under the top- ℓ separators scenario. Analytically, it was proved in (Hajek et al., 2014) that under the top- ℓ separators scenario, naive rank-breaking with uniform weights achieves the same error bound as the MLE, up to a constant factor. However, we show that this constant factor gap is not a weakness of the analyses, but the choice of the weights. Theorem 5 provides a guideline for choosing the optimal weights, and the numerical simulation results in Figure 3 show that there is in fact no gap in practice, if we use the optimal weights. We use the same settings as that of the first figure of Figure 2 for the figure below.

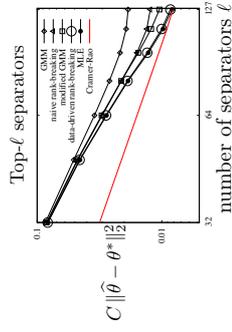

Figure 3: The proposed data-driven rank-breaking achieves performance identical to the MLE, and improves over naive rank-breaking with uniform weights.

To prove the order-optimality of the rank-breaking approach up to a constant factor, we can compare the upper bound to a Cramér-Rao lower bound on any unbiased estimators, in the following theorem. A proof is provided in Section 8.5.

Theorem 6. Consider ranking $\{\sigma_j(i)\}_{i \in [\ell_j]}$ revealed for the set of items S_j , for $j \in [n]$. Let \mathcal{U} denote the set of all unbiased estimators of $\theta^* \in \Omega_b$. If $b > 0$, then

$$\inf_{\hat{\theta} \in \mathcal{U}} \sup_{\theta^* \in \Omega_b} \mathbb{E}[\|\hat{\theta} - \theta^*\|^2] \geq \left(1 - \frac{1}{\ell_{\max}} \sum_{i=1}^{\ell_{\max}} \frac{1}{\kappa_{\max} - i + 1} \right)^{-1} \sum_{i=2}^d \frac{1}{\lambda_i(L)} \geq \frac{(d-1)^2}{\sum_{j=1}^n \ell_j}, \quad (16)$$

where $\ell_{\max} = \max_{j \in [n]} \ell_j$ and $\kappa_{\max} = \max_{j \in [n]} \kappa_j$. The second inequality follows from the Jensen's inequality.

Consider a case when the comparison graph is an expander such that α is a strictly positive constant, and $b = O(1)$ is also finite. Then, the Cramér-Rao lower bound show that the upper bound in (14) is optimal up to a logarithmic factor.

3.4 Optimality of the Choice of the Weights

We propose the optimal choice of the weights $\lambda_{j,a}$'s in Theorem 2. In this section, we show numerical simulations results comparing the proposed approach to other naive choices of the weights under various scenarios. We fix $d = 1024$ items and the underlying preference vector θ^* is uniformly distributed over $[-b, b]$ for $b = 2$. We generate n rankings over sets S_j of size κ for $j \in [n]$ according to the PL model with parameter θ^* . The comparison sets S_j 's are chosen independently and uniformly at random from $[d]$.

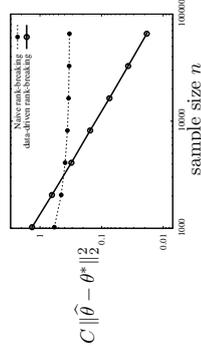

Figure 4: Data-driven rank-breaking is consistent, while a random rank-breaking results in inconsistency.

Figure 4 illustrates that a naive choice of rank-breakings can result in inconsistency. We create partial orderings data set by fixing $\kappa = 128$ and select $\ell = 8$ random positions in $\{1, \dots, 127\}$. Each data set consists of partial orderings with separators at those 8 random positions, over 128 randomly chosen subset of items. We vary the sample size n and plot the resulting mean squared error for the two approaches. The data-driven rank-breaking, which uses the optimal choice of the weights, achieves error scaling as $1/n$ as predicted by Theorem 2, which implies consistency. For fair comparisons, we feed the same number of pairwise orderings to a naive rank-breaking estimator. This estimator uses randomly chosen pairwise orderings with uniform weights, and is

generally inconsistent. However, when sample size is small, inconsistent estimators can achieve smaller variance leading to smaller error. Normalization constant C is $10^3\ell/d^2$, and each point is averaged over 100 trials. We use the minorization-maximization algorithm from Hunter (2004) for computing the estimates from the rank-breakings.

Even if we use the consistent rank-breakings first proposed in Azari Soufiani et al. (2014), there is ambiguity in the choice of the weights. We next study how much we gain by using the proposed optimal choice of the weights. The optimal choice, $\lambda_{j,a} = 1/(\kappa_j - p_{j,a})$, depends on two parameters: the size of the offerings κ_j and the position of the separators $p_{j,a}$. To distinguish the effect of these two parameters, we first experiment with fixed $\kappa_j = \kappa$ and illustrate the gain of the optimal choice of $\lambda_{j,a}$'s.

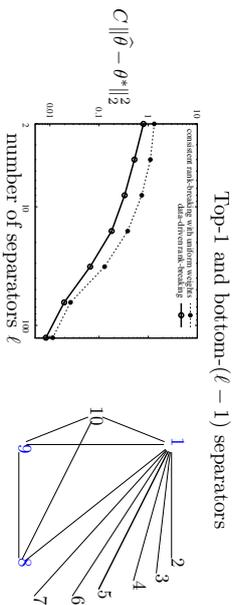

Figure 5: There is a constant factor gain of choosing optimal $\lambda_{j,a}$'s when the size of offerings are fixed, i.e. $\kappa_j = \kappa$ (left). We choose a particular set of separators where one separator is at position one and the rest are at the bottom. An example for $\ell = 3$ and $\kappa = 10$ is shown, where the separators are indicated by blue (right).

Figure 5 illustrates that the optimal choice of the weights improves over consistent rank-breaking with uniform weights by a constant factor. We fix $\kappa = 128$ and $n = 128000$. As illustrated by a figure on the right, the position of the separators are chosen such that there is one separator at position one, and the rest of $\ell - 1$ separators are at the bottom. Precisely, $(p_{j,1}, p_{j,2}, p_{j,3}, \dots, p_{j,\ell}) = (1, 128 - \ell + 1, 128 - \ell + 2, \dots, 127)$. We consider this scenario to emphasize the gain of optimal weights. Observe that the MSE does not decrease at a rate of $1/\ell$ in this case. The parameter γ which appears in the bound of Theorem 2 is very small when the breaking positions $p_{j,a}$ are of the order κ_j as is the case here, when ℓ is small. Normalization constant C is n/d^2 .

The gain of optimal weights is significant when the size of S_j 's are highly heterogeneous. Figure 6 compares performance of the proposed algorithm, for the optimal choice and uniform choice of weights $\lambda_{j,a}$ when the comparison sets S_j 's are of different sizes. We consider the case when n_1 agents provide their top- ℓ_1 choices over the sets of size κ_1 , and n_2 agents provide their top-1 choice over the sets of size κ_2 . We take $n_1 = 1024$, $\ell_1 = 8$, and $n_2 = 10n_1\ell_1$. Figure 6 shows MSE for the two choice of weights, when we fix $\kappa_1 = 128$, and vary κ_2 from 2 to 128. As predicted from our bounds, when optimal choice of $\lambda_{j,a}$ is used MSE is not sensitive to sample set sizes κ_2 . The error decays at the rate proportional to the inverse of the effective sample size, which is $n_1\ell_1 + n_2\ell_2 = 11n_1\ell_1$. However, with $\lambda_{j,a} = 1$ when $\kappa_2 = 2$, the MSE is roughly 10 times worse. Which reflects that the effective sample size is approximately $n_1\ell_1$, i.e. pairwise comparisons counting

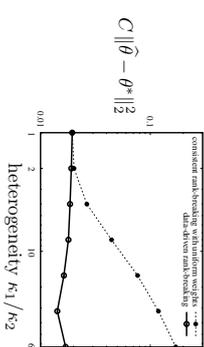

Figure 6: The gain of choosing optimal $\lambda_{j,a}$'s is significant when κ_j 's are highly heterogeneous.

from small set size do not contribute without proper normalization. This gap in MSE corroborates bounds of Theorem 8. Normalization constant C is $10^3/d^2$.

4. The Role of the Topology of the Data

We study the role of topology of the data that provides a guideline for designing the collection of data when we do have some control, as in recommendation systems, designing surveys, and crowdsourcing. The core optimization problem of interest to the designer of such a system is to achieve the best accuracy while minimizing the number of questions.

4.1 The Role of the Graph Laplacian

Using the same number of samples, comparison graphs with larger spectral gap achieve better accuracy, compared to those with smaller spectral gaps. To illustrate how graph topology effects the performance, we reproduce known spectral properties of canonical graphs, and numerically compare the performance of data-driven rank-breaking for several graph topologies. We follow the examples and experimental setup from Shah et al. (2015a) for a similar result with pairwise comparisons. Spectral properties of graphs have been a topic of wide interest for decades. We consider a scenario where we fix the size of offerings as $\kappa_j = \kappa = O(1)$ and each agent provides partial ranking with ℓ separators, positions of which are chosen uniformly at random. The resulting spectral gap α of different choices of the set S_j 's are provided below. The total number edges in the comparisons graph (counting hyper-edges as multiple edges) is defined as $|E| \equiv \binom{\kappa}{\ell} n$.

- Complete graph: when $|E|$ is larger than $\binom{d}{\ell}$, we can design the comparison graph to be a complete graph over d nodes. The weight A_{ij} on each edge is $n\ell/(d(d-1))$, which is the effective number of samples divided by twice the number of edges. Resulting spectral gap is one, which is the maximum possible value. Hence, complete graph is optimal for rank aggregation.
- Sparse random graph: when we have limited resources we might not be able to afford a dense graph. When $|E|$ is of order d^2 , we have a sparse graph. Consider a scenario where each set S_j is chosen uniformly at random. To ensure connectivity, we need $n = \Omega(\log d)$. Following standard spectral analysis of random graphs, we have $\alpha = \Theta(1)$. Hence, sparse random graphs are near-optimal for rank-aggregation.

- Chain graph: we consider a chain of sets of size κ overlapping only by one item. For example, $S_1 = \{1, \dots, \kappa\}$ and $S_2 = \{\kappa, \kappa + 1, \dots, 2\kappa - 1\}$, etc. We choose n to be a multiple of $\tau \equiv (d - 1)/(\kappa - 1)$ and offer each set n/τ times. The resulting graph is a chain of size κ cliques, and standard spectral analysis shows that $\alpha = \Theta(1/d^2)$. Hence, a chain graph is strictly sub-optimal for rank aggregation.
- Star-like graph: We choose one item to be the center, and every offer set consists of this center node and a set of $\kappa - 1$ other nodes chosen uniformly at random without replacement. For example, center node = $\{1\}$, $S_1 = \{1, 2, \dots, \kappa\}$ and $S_2 = \{1, \kappa + 1, \kappa + 2, \dots, 2\kappa - 1\}$, etc. n is chosen in the way similar to that of the Chain graph. Standard spectral analysis shows that $\alpha = \Theta(1)$ and star-like graphs are near-optimal for rank-aggregation.
- Barbell-like graph: We select an offering $S = \{S', i, j\}$, $|S'| = \kappa - 2$ uniformly at random and divide rest of the items into two groups V_1 and V_2 . We offer set S $n\kappa/d$ times. For each offering of set S , we offer $d/\kappa - 1$ sets chosen uniformly at random from the two groups $\{V_1, i\}$ and $\{V_2, j\}$. The resulting graph is a barbell-like graph, and standard spectral analysis shows that $\alpha = \Theta(1/d^2)$. Hence, a chain graph is strictly sub-optimal for rank aggregation.

Figure 7 illustrates how graph topology effects the accuracy. When θ^* is chosen uniformly at random, the accuracy does not change with d (left), and the accuracy is better for those graphs with larger spectral gap. However, for a certain worst-case θ^* , the error increases with d for the chain graph and the barbell-like graph, as predicted by the above analysis of the spectral gap. We use $\ell = 4$, $\kappa = 17$ and vary d from 129 to 2049. κ is kept small to make the resulting graphs more like the above discussed graphs. Figure on left shows accuracy when θ^* is chosen i.i.d. uniformly over $[-b, b]$ with $b = 2$. Error in this case is roughly same for each of the graph topologies with chain graph being the worst. However, when θ^* is chosen carefully for chain graph and barbell-like graph increases with d as shown in the figure right. We chose θ^* such that all the items of a set have same weight, either $\theta_i = 0$ or $\theta_i = b$ for chain graph and barbell-like graph. We divide all the sets equally between the two types for chain graph. For barbell-like graph, we keep the two types of sets on the two different sides of the connector set and equally divide items of the connector set into two types. Number of samples n is $100(d - 1)/(\kappa - 1)$ and each point is averaged over 100 instances. Normalization constant C is $n\ell/d^2$.

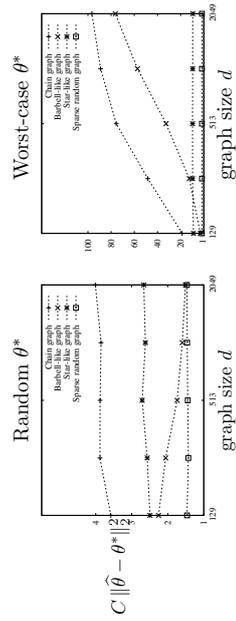

Figure 7: For randomly chosen θ^* the error does not change with d (left). However, for particular worst-case θ^* the error increases with d for the Chain graph and the Barbell-like graph as predicted by the analysis of the spectral gap (right).

4.2 The Role of the Position of the Separators

As predicted by theorem 2, rank-breaking fails when γ is small, i.e. the position of the separators are very close to the bottom. An extreme example is the bottom- ℓ separators scenario, where each person is offered κ randomly chosen alternatives, and is asked to give a ranked list of bottom ℓ alternatives. In other words, the ℓ separators are placed at $(p_{j,1}, \dots, p_{j,\ell}) = (\kappa_j - \ell, \dots, \kappa_j - 1)$. In this case, $\gamma \simeq 0$ and the error bound is large. This is not a weakness of the analysis. In fact we observe large errors under this scenario. The reason is that many alternatives that have large weights θ_i 's will rarely be even compared once, making any reasonable estimation infeasible.

Figure 8 illustrates this scenario. We choose $\ell = 8$, $\kappa = 128$, and $d = 1024$. The other settings are same as that of the first figure of Figure 2. The left figure plots the magnitude of the estimation error for each item. For about 200 strong items among 1024, we do not even get a single comparison, hence we omit any estimation error. It clearly shows the trend: we get good estimates for about 400 items in the bottom, and we get large errors for the rest. Consequently, even if we only take those items that have at least one comparison into account, we still get large errors. This is shown in the figure right. The error barely decays with the sample size. However, if we focus on the error for the bottom 400 items, we get good error rate decaying inversely with the sample size. Normalization constant C in the second figure is $10^2 \cdot x \cdot d/\ell$ and $10^2(400)d/\ell$ for the first and second lines respectively, where x is the number of items that appeared in rank-breaking at least once. We solve convex program (3) for θ restricted to the items that appear in rank-breaking at least once. The second figure of Figure 8 is averaged over 1000 instances.

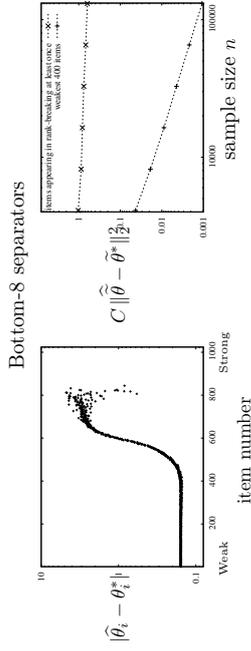

Figure 8: Under the bottom- ℓ separators scenario, accuracy is good only for the bottom 400 items (left). As predicted by Theorem 7, the mean squared error on the bottom 400 items scale as $1/n$, where as the overall mean squared error does not decay (right).

We make this observation precise in the following theorem. Applying rank-breaking to only to those weakest \tilde{d} items, we prove an upper bound on the achieved error rate that depends on the choice of the \tilde{d} . Without loss of generality, we suppose the items are sorted such that $\theta_1^* \leq \theta_2^* \leq \dots \leq \theta_d^*$. For a choice of $\tilde{d} = \ell d / (2\kappa)$, we denote the weakest \tilde{d} items by $\theta^* \in \mathbb{R}^{\tilde{d}}$ such that $\theta_i^* = \theta_{\ell i}^* - (1/\tilde{d}) \sum_{j=i}^{\tilde{d}} \theta_j^*$, for $i \in [\tilde{d}]$. Since $\theta^* \in \Omega_b$, $\theta^* \in [-2b, 2b]^{\tilde{d}}$. The space of all possible preference vectors for $[\tilde{d}]$ items is given by $\tilde{\Omega} = \{\theta \in \mathbb{R}^{\tilde{d}} : \sum_{i=1}^{\tilde{d}} \theta_i = 0\}$ and $\tilde{\Omega}_{2b} = \tilde{\Omega} \cap [-2b, 2b]^{\tilde{d}}$.

Although the analysis can be easily generalized, to simplify notations, we fix $\kappa_j = \kappa$ and $\ell_j = \ell$ and assume that the comparison sets S_j , $|S_j| = \kappa$, are chosen uniformly at random from the set of

d items for all $j \in [n]$. The rank-breaking log likelihood function $\mathcal{L}_{\text{RB}}(\tilde{\theta})$ for the set of items $[d]$ is given by

$$\mathcal{L}_{\text{RB}}(\tilde{\theta}) = \sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a} \left\{ \sum_{(i,i') \in E_{j,a}} \mathbb{I}_{\{i,i' \in [d]\}} \left(\theta_{i'} - \log \left(e^{\theta_i} + e^{\theta_{i'}} \right) \right) \right\}. \quad (17)$$

We analyze the rank-breaking estimator

$$\hat{\tilde{\theta}} \equiv \max_{\tilde{\theta} \in \Omega_{2b}} \mathcal{L}_{\text{RB}}(\tilde{\theta}). \quad (18)$$

We further simplify notations by fixing $\lambda_{j,a} = 1$, since from Equation (24), we know that the error increases by at most a factor of 4 due to this sub-optimal choice of the weights, under the special scenario studied in this theorem.

Theorem 7. *Under the bottom- ℓ separators scenario and the PL model, S_j 's are chosen uniformly at random of size κ and n partial orderings are sampled over d items parametrized by $\theta^* \in \Omega_b$. For $d = \ell d / (2\kappa)$ and any $\ell \geq 4$, if the effective sample size is large enough such that*

$$n\ell \geq \left(\frac{2^{14} e^{8b} \kappa^3}{\chi^2 \ell^3} \right) d \log d, \quad (19)$$

where

$$\chi \equiv \frac{1}{4} \left(1 - \exp \left(- \frac{2}{9(\kappa - 2)} \right) \right), \quad (20)$$

then the rank-breaking estimator \hat{m} (18) achieves

$$\frac{1}{\sqrt{d}} \|\hat{\tilde{\theta}} - \tilde{\theta}^*\|_2 \leq \frac{128(1 + e^{4b})^2 \kappa^3 \ell^2}{\chi \ell^{3/2}} \sqrt{\frac{d \log d}{n\ell}}, \quad (21)$$

with probability at least $1 - 3e^3 d^{-3}$.

Consider a scenario where $\kappa = O(1)$ and $\ell = \Theta(\kappa)$. Then, χ is a strictly positive constant, and also κ/ℓ is a finite constant. It follows that rank-breaking requires the effective sample size $n\ell = O(d \log d / \varepsilon^2)$ in order to achieve arbitrarily small error of $\varepsilon > 0$, on the weakest $\tilde{d} = \ell d / (2\kappa)$ items.

5. Real-World Data Sets

On real-world data sets on sushi preferences (Kamishima, 2003), we show that the data-driven rank-breaking improves over Generalized Method-of-Moments (GMM) proposed by Azari Soufiani et al. (2013). This is a widely used data set for rank aggregation, for instance in Azari Soufiani et al. (2013, 2012); Maystre and Grossglauser (2015b); Le Van et al. (2015); Lu and Boutlier (2011a, b). The data set consists of complete rankings over 10 types of sushi from $n = 5000$ individuals. Below, we follow the experimental scenarios of the GMM approach in Azari Soufiani et al. (2013) for fair comparisons.

To validate our approach, we first take the estimated PL weights of the 10 types of sushi, using Hunter (2004) implementation of the ML estimator, over the entire input data of 5000 complete rankings. We take thus created output as the ground truth θ^* . To create partial rankings and compare the performance of the data-driven rank-breaking to the state-of-the-art GMM approach in Figure 9, we first fix $\ell = 6$ and vary n to simulate top- ℓ separators scenario by removing the known ordering among bottom $10 - \ell$ alternatives for each sample in the data set (left). We next fix $n = 1000$ and vary ℓ and simulate top- ℓ separators scenarios (right). Each point is averaged over 1000 instances. The mean squared error is plotted for both algorithms.

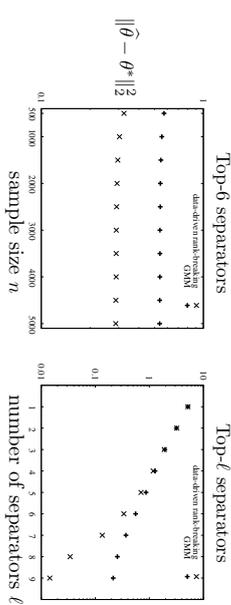

Figure 9: The data-driven rank-breaking achieves smaller error compared to the state-of-the-art GMM approach.

Figure 10 illustrates the Kendall rank correlation of the rankings estimated by the two algorithms and the ground truth. Larger value indicates that the estimate is closer to the ground truth, and the data-driven rank-breaking outperforms the state-of-the-art GMM approach.

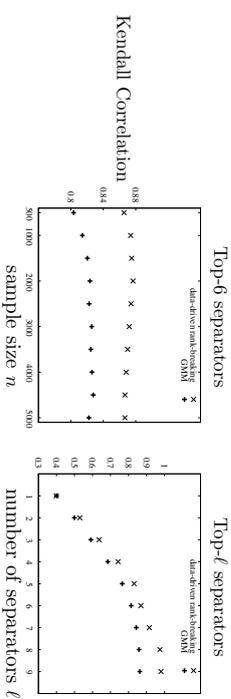

Figure 10: The data-driven rank-breaking achieves larger Kendall rank correlation compared to the state-of-the-art GMM approach.

To validate whether PL model is the right model to explain the sushi data set, we compare the data-driven rank-breaking, MLE for the PL model, GMM for the PL model, Borda count and Spearman's footrule optimal aggregation. We measure the Kendall rank correlation between the estimates and the samples and show the result in Table 1. In particular, if $\sigma_1, \sigma_2, \dots, \sigma_n$ denote sample rankings and $\hat{\sigma}$ denote the aggregated ranking then the correlation value is $(1/n) \sum_{i=1}^n (1 - \frac{4K(\hat{\sigma}, \sigma_i)}{K(\hat{\sigma}, \hat{\sigma})})$, where $K(\sigma_1, \sigma_2) = \sum_{i < j \in [k]} \mathbb{I}_{(\sigma_1^{-1}(i) - \sigma_1^{-1}(j))(\sigma_2^{-1}(i) - \sigma_2^{-1}(j)) < 0}$. The results are reported

for different number of samples n and different values of ℓ under the top- ℓ separators scenarios. When $\ell = 9$, we are using all the complete rankings, and all algorithms are efficient. When $\ell < 9$, we have partial orderings, and Spearman’s footrule optimal aggregation is NP-hard. We instead use scaled footrule aggregation (SFO) given in Dwork et al. (2001). Most approaches achieve similar performance, except for the Spearman’s footrule. The proposed data-driven rank-breaking achieves a slightly worse correlation compared to other approaches. However, note that none of the algorithms are necessarily maximizing the Kendall correlation, and are not expected to be particularly good in this metric.

	MLE under PL	data-driven RB	GMM	Borda count	Spearman’s footrule
$n = 500, \ell = 9$	0.306	0.291	0.315	0.315	0.159
$n = 5000, \ell = 9$	0.309	0.309	0.315	0.315	0.079
$n = 5000, \ell = 2$	0.199	0.199	0.201	0.200	0.113
$n = 5000, \ell = 5$	0.217	0.200	0.217	0.295	0.152

Table 1: Kendall rank correlation on sushi data set.

We compare our algorithm with the GMM algorithm on two other real-world data-sets as well. We use jester data set (Goldberg et al., 2001) that consists of over 4.1 million continuous ratings between -10 to $+10$ of 100 jokes from 48,483 users. The average number of jokes rated by an user is 72.6 with minimum and maximum being 36 and 100 respectively. We convert continuous ratings into ordinal rankings. This data-set has been used by Miyahara and Pazzani (2000); Polat and Du (2005); Cortes et al. (2007); Lebanon and Mao (2007) for rank aggregation and collaborative filtering.

Similar to the settings of sushi data experiments, we take the estimated PL weights of the 100 jokes over all the rankings as ground truth. Figure 11 shows comparative performance of the data-driven rank-breaking and the GMM for the two scenarios. We first fix $\ell = 10$ and vary n to simulate random-10 separators scenario (left). We next take all the rankings $n = 73421$ and vary ℓ to simulate random- ℓ separators scenario (rights). Since sets have different sizes, while varying ℓ we use full breaking if the setsize is smaller than ℓ . Each point is averaged over 100 instances. The mean squared error is plotted for both algorithms.

We perform similar experiments on American Psychological Association (APA) data-set (Diaconis, 1989). The APA elects a president each year by asking each member to rank order a slate of five candidates. The data-set represents full rankings given by 5738 members of the association in 1980’s election. The mean squared error is plotted for both algorithms under the settings similar to that of jester data-set.

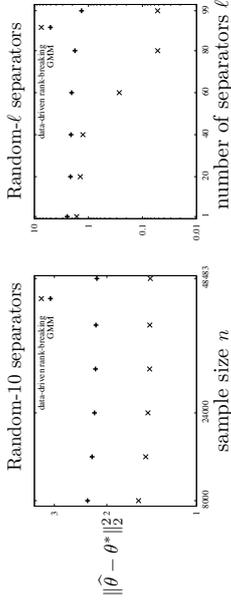

Figure 11: jester data set: The data-driven rank-breaking achieves smaller error compared to the state-of-the-art GMM approach.

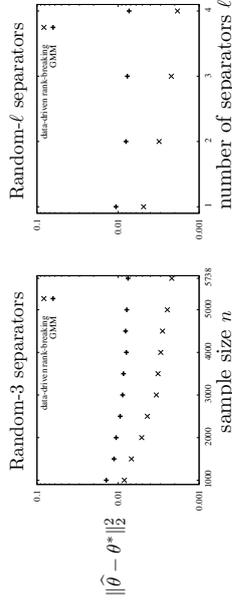

Figure 12: APA data set: The data-driven rank-breaking achieves smaller error compared to the state-of-the-art GMM approach.

6. Related Work

Initially motivated by elections and voting, rank aggregation has been a topic of mathematical interest dating back to Condorcet and Borda (De Condorcet, 1785; de Borda, 1781). Using probabilistic models to infer preferences has been popularized in operations research community for applications such as assortment optimization and revenue management. The PL model studied in this paper is a special case of MultiNomial Logit (MNL) models commonly used in discrete choice modeling, which has a long history in operations research (McFadden, 1980). Efficient inference algorithms has been proposed to either find the MLE efficiently or approximately, such as the iterative approaches in Ford Jr. (1957); Dykstra (1960), minorization-maximization approach in Hunter (2004), and Markov chain approaches in Negahban et al. (2012); Maystre and Grossglauser (2015a). These approaches are shown to achieve minimax optimal error rate in the traditional comparisons scenarios. Under the pairwise comparisons scenario, Negahban et al. (2012) provided Rank Centrality that provably achieves minimax optimal error rate for randomly chosen pairs, which was later generalized to arbitrary pairwise comparisons in Negahban et al. (2014). The analysis shows the explicit dependence on the topology of data shows that the spectral gap of comparisons graph similar to the one presented in this paper. This analysis was generalized to k -way comparisons in Hajek et al. (2014) and generalized to best-of- k comparisons with sharper bounds in Shah et al. (2015a). In an effort to give a guarantee for exact recovery of the top- ℓ items in the ranking, Chen

and Suh (2015) proposed a new algorithm based on Rank Centrality that provides a tighter error bound for L_∞ norm, as opposed to the existing L_2 error bounds. Another interesting direction in learning to rank is non-parametric learning from paired comparisons, initiated in several recent papers such as Duchi et al. (2010); Rajkumar and Agarwal (2014); Shah et al. (2015b); Shah and Wainwright (2015).

More recently, a more general problem of learning *personal* preferences from ordinal data has been studied (Yi et al., 2013; Lu and Boutilier, 2011b; Ding et al., 2015). The MNL model provides a natural generalization of the PL model to this problem. When users are classified into a small number of groups with same preferences, mixed MNL model can be learned from data as studied in Ammar et al. (2014); Oh and Shah (2014); Wu et al. (2015). A more general scenario is when each user has his/her individual preferences, but inherently represented by a lower dimensional feature. This problem was first posed as an inference problem in Lu and Negahban (2014) where convex relaxation of nuclear norm minimization was proposed with provably optimal guarantees. This was later generalized to k -way comparisons in Oh et al. (2015). A similar approach was studied with a different guarantees and assumptions in Park et al. (2015). Our algorithm and ideas of rank-breaking can be directly applied to this collaborative ranking under MNL, with the same guarantees for consistency in the asymptotic regime where sample size grows to infinity. However, the analysis techniques for MNL rely on stronger assumptions on how the data is collected, and especially on the independence of the samples. It is not immediate how the analysis techniques developed in this paper can be applied to learn MNL.

In an orthogonal direction, new discrete choice models with sparse structures has been proposed recently in Farias et al. (2009) and optimization algorithms for revenue management has been proposed Farias et al. (2013). In a similar direction, new discrete choice models based on Markov chains has been introduced in Blanchet et al. (2013), and corresponding revenue management algorithms has been studied in Feldman and Topaloglu (2014). However, typically these models are analyzed in the asymptotic regime with infinite samples, with the exception of Ammar and Shah (2011). A non-parametric choice models for pairwise comparisons also have been studied in Rajkumar and Agarwal (2014); Shah et al. (2015b). This provides an interesting opportunities to studying learning to rank for these new choice models.

We consider a fixed design setting, where inference is separate from data collection. There is a parallel line of research which focuses on adaptive ranking, mainly based on pairwise comparisons. When performing sorting from noisy pairwise comparisons, Braverman and Mossel (2009) proposed efficient approaches and provided performance guarantees. Following this work, there has been recent advances in adaptive ranking Alon (2011); Jannison and Nowak (2011); Maystre and Grossglauser (2015b).

7. Discussion

We study the problem of learning the PL model from ordinal data. Under the traditional data collection scenarios, several efficient algorithms find the maximum likelihood estimates and at the same time provably achieve minimax optimal performance. However, for some non-traditional scenarios, computational complexity of finding the maximum likelihood estimate can scale super-exponentially in the problem size. We provide the first finite-sample analysis of computationally efficient estimators known as rank-breaking estimators. This provides guidelines for choosing the

weights in the estimator to achieve optimal performance, and also explicitly shows how the accuracy depends on the topology of the data.

This paper provides the first analytical result in the sample complexity of rank-breaking estimators, and quantifies the price we pay in accuracy for the computational gain. In general, more complex higher-order rank-breaking can also be considered, where instead of breaking a partial ordering into a collection of paired comparisons, we break it into a collection of higher-order comparisons. The resulting higher-order rank-breakings will enable us to traverse the whole spectrum of computational complexity between the pairwise rank-breaking and the MLE. We believe this paper opens an interesting new direction towards understanding the whole spectrum of such approaches. However, analyzing the Hessian of the corresponding objective function is significantly more involved and requires new technical innovations.

8. Proofs

8.1 Proof of Theorem 2

We prove a more general result for an arbitrary choice of the parameter $\lambda_{j,a} > 0$ for all $j \in [n]$ and $a \in [f_j]$. The following theorem proves the (near)-optimality of the choice of $\lambda_{j,a}$'s proposed in (10), and implies the corresponding error bound as a corollary.

Theorem 8. *Under the hypotheses of Theorem 2 and any $\lambda_{j,a}$'s, the rank-breaking estimator achieves*

$$\frac{1}{\sqrt{d}} \|\hat{\theta} - \theta^*\|_2 \leq \frac{4\sqrt{2}e^{4\theta} (1 + e^{2\theta})^2 \sqrt{d \log d} \sqrt{\sum_{j=1}^n \sum_{a=1}^{f_j} (\lambda_{j,a})^2 (\kappa_j - p_{j,a} + 1)}}{\alpha^\gamma \sum_{j=1}^n \sum_{a=1}^{f_j} \lambda_{j,a} (\kappa_j - p_{j,a})}, \quad (22)$$

with probability at least $1 - 3e^3 d^{-3}$, if

$$\sum_{j=1}^n \sum_{a=1}^{f_j} \lambda_{j,a} (\kappa_j - p_{j,a}) \geq 2^6 e^{18\theta} \frac{\eta \delta}{\alpha^2 \beta \gamma^2 \tau} d \log d, \quad (23)$$

where γ , η , τ , δ , α , β , are now functions of $\lambda_{j,a}$'s and defined in (7), (8), (25), (27) and (30).

We first claim that $\lambda_{j,a} = 1/(\kappa_j - p_{j,a} + 1)$ is the optimal choice for minimizing the above upper bound on the error. From Cauchy-Schwarz inequality and the fact that all terms are non-negative, we have that

$$\frac{\sqrt{\sum_{j=1}^n \sum_{a=1}^{f_j} (\lambda_{j,a})^2 (\kappa_j - p_{j,a}) (\kappa_j - p_{j,a} + 1)}}{\sum_{j=1}^n \sum_{a=1}^{f_j} \lambda_{j,a} (\kappa_j - p_{j,a})} \geq \frac{1}{\sqrt{\sum_{j=1}^n \sum_{a=1}^{f_j} \frac{(\kappa_j - p_{j,a})}{(\kappa_j - p_{j,a} + 1)}}}, \quad (24)$$

where $\lambda_{j,a} = 1/(\kappa_j - p_{j,a} + 1)$ achieves the universal lower bound on the right-hand side with an equality. Since $\sum_{j=1}^n \sum_{a=1}^{f_j} \frac{(\kappa_j - p_{j,a})}{(\kappa_j - p_{j,a} + 1)} \geq \sum_{j=1}^n f_j$, substituting this into (22) gives the desired error bound in (11). Although we have identified the optimal choice of $\lambda_{j,a}$'s, we choose a slightly different value of $\lambda = 1/(\kappa_j - p_{j,a})$ for the analysis. This achieves the same desired error bound in (11), and significantly simplifies the notations of the sufficient conditions.

We first define all the parameters in the above theorem for general $\lambda_{j,a}$. With a slight abuse of notations, we use the same notations for \mathcal{H} , L , α and β for both the general $\lambda_{j,a}$'s and also the specific choice of $\lambda_{j,a} = 1/(\kappa_j - p_{j,a})$. It should be clear from the context what we mean in each case. Define

$$\tau \equiv \min_{j \in [n]} \tau_j, \quad \text{where } \tau_j \equiv \frac{\sum_{a=1}^{\ell_j} \lambda_{j,a} (\kappa_j - p_{j,a})}{\ell_j} \quad (25)$$

$$\delta_{j,1} \equiv \left\{ \max_{a \in [\ell_j]} \left\{ \lambda_{j,a} (\kappa_j - p_{j,a}) \right\} + \sum_{a=1}^{\ell_j} \lambda_{j,a} \right\}, \quad \text{and } \delta_{j,2} \equiv \sum_{a=1}^{\ell_j} \lambda_{j,a} \quad (26)$$

$$\delta \equiv \max_{j \in [n]} \left\{ 4\delta_{j,1}^2 + \frac{2(\delta_{j,1}\delta_{j,2} + \delta_{j,2}^2)\kappa_j}{\eta_j \ell_j} \right\}. \quad (27)$$

Note that $\delta \geq \delta_{j,1}^2 \geq \max_a \lambda_{j,a}^2 (\kappa_j - p_{j,a})^2 \geq \tau^2$, and for the choice of $\lambda_{j,a} = 1/(\kappa_j - p_{j,a})$ it simplifies as $\tau = \tau_j = 1$. We next define a comparison graph \mathcal{H} for general $\lambda_{j,a}$, which recovers the proposed comparison graph for the optimal choice of $\lambda_{j,a}$'s

Definition 9. (Comparison graph \mathcal{H}). Each item $i \in [d]$ corresponds to a vertex i . For any pair of vertices i, i' , there is a weighted edge between them if there exists a set S_j such that $i, i' \in S_j$; the weight equals $\sum_{j:i, i' \in S_j} \frac{\tau_j \ell_j}{\kappa_j (\kappa_j - 1)}$.

Let A denote the weighted adjacency matrix, and let $D = \text{diag}(A1)$. Define,

$$D_{\max} \equiv \max_{i \in [d]} \left\{ \sum_{j:i \in S_j} \frac{\tau_j \ell_j}{\kappa_j} \right\} \geq \tau \min_{i \in [d]} \left\{ \sum_{j:i \in S_j} \frac{\ell_j}{\kappa_j} \right\}. \quad (28)$$

Define graph Laplacian L as $L = D - A$, i.e.,

$$L = \sum_{j=1}^n \frac{\tau_j \ell_j}{\kappa_j (\kappa_j - 1)} \sum_{i < i' \in S_j} (e_i - e_{i'}) (e_i - e_{i'})^\top. \quad (29)$$

Let $0 = \lambda_1(L) \leq \lambda_2(L) \leq \dots \leq \lambda_d(L)$ denote the sorted eigenvalues of L . Note that $\text{Tr}(L) = \sum_{i=1}^d \sum_{j:i \in S_j} \tau_j \ell_j / \kappa_j = \sum_{j=1}^n \tau_j \ell_j$. Define α and β such that

$$\alpha \equiv \frac{\lambda_2(L)(d-1)}{\text{Tr}(L)} = \frac{\lambda_2(L)(d-1)}{\sum_{j=1}^n \tau_j \ell_j} \quad \text{and} \quad \beta \equiv \frac{\text{Tr}(L)}{dD_{\max}} = \frac{\sum_{j=1}^n \tau_j \ell_j}{dD_{\max}}. \quad (30)$$

For the proposed choice of $\lambda_{j,a} = 1/(\kappa_j - p_{j,a})$, we have $\tau_j = 1$ and the definitions of \mathcal{H} , L , α , and β reduce to those defined in Definition 1. We are left to prove an upper bound, $\delta \leq 32(\log(\ell_{\max} + 2))^2$, which implies the sufficient condition in (9) and finishes the proof of Theorem 2. We have,

$$\begin{aligned} \delta_{j,1} &\equiv \max_{a \in [\ell_j]} \left\{ \lambda_{j,a} (\kappa_j - p_{j,a}) \right\} + \sum_{a=1}^{\ell_j} \lambda_{j,a} = 1 + \sum_{a=1}^{\ell_j} \frac{1}{\kappa_j - p_{j,a}} \\ &\leq 1 + \sum_{a=1}^{\ell_j} \frac{1}{a} \\ &\leq 2 \log(\ell_j + 2), \end{aligned} \quad (31)$$

where in the first inequality follows from taking the worst case for the positions, i.e. $p_{j,a} = \kappa_j - \ell_j + a - 1$. Using the fact that for any integer x , $\sum_{a=0}^{x-1} 1/(x+a) \leq \log((x+\ell-1)/(x-1))$, we also have

$$\begin{aligned} \frac{\delta_{j,2}\kappa_j}{\eta_j \ell_j} &\leq \sum_{a=1}^{\ell_j} \frac{1}{\kappa_j - p_{j,a}} \frac{\max\{\ell_j, \kappa_j - p_{j,\ell_j}\}}{\ell_j} \\ &\leq \min \left\{ \log(\ell_j + 2), \log \left(\frac{\kappa_j - p_{j,\ell_j} + \ell_j - 1}{\kappa_j - p_{j,\ell_j} - 1} \right) \right\} \frac{\max\{\ell_j, \kappa_j - p_{j,\ell_j}\}}{\ell_j} \\ &\leq \frac{\log(\ell_j + 2)\ell_j}{\max\{\ell_j, \kappa_j - p_{j,\ell_j}\}} \frac{\ell_j}{\ell_j} \\ &\leq 2 \log(\ell_j + 2), \end{aligned} \quad (32)$$

where the first inequality follows from the definition of η_j , Equation (8). From (31), (32), and the fact that $\delta_{j,2} \leq \log(\ell_j + 2)$, we have

$$\delta = \max_{j \in [n]} \left\{ 4\delta_{j,1}^2 + \frac{2(\delta_{j,1}\delta_{j,2} + \delta_{j,2}^2)\kappa_j}{\eta_j \ell_j} \right\} \leq 28(\log(\ell_{\max} + 2))^2.$$

8.2 Proof of Theorem 8

We first introduce two key technical lemmas. In the following lemma we show that $\mathbb{E}_{\theta^*}[\nabla \mathcal{L}_{\text{RB}}(\theta^*)] = 0$ and provide a bound on the deviation of $\nabla \mathcal{L}_{\text{RB}}(\theta^*)$ from its mean. The expectation $\mathbb{E}_{\theta^*}[\cdot]$ is with respect to the randomness in the samples drawn according to θ^* . The log likelihood Equation (2) can be rewritten as

$$\mathcal{L}_{\text{RB}}(\theta) = \sum_{j=1}^n \sum_{a=1}^{\ell_j} \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,a}\}} \lambda_{j,a} \left(\theta_{i,i'} \mathbb{I}_{\{\sigma_j^{-1}(i) < \sigma_j^{-1}(i')\}} + \theta_{i',i} \mathbb{I}_{\{\sigma_j^{-1}(i) > \sigma_j^{-1}(i')\}} - \log(e^{\theta_i} + e^{\theta_{i'}}) \right). \quad (33)$$

We use $(i, i') \in G_{j,a}$ to mean either (i, i') or (i', i) belong to $E_{j,a}$. Taking the first-order partial derivative of $\mathcal{L}_{\text{RB}}(\theta)$, we get

$$\nabla_{i'} \mathcal{L}_{\text{RB}}(\theta^*) = \sum_{j:i \in S_j} \sum_{a=1}^{\ell_j} \sum_{i' \in S_j, i' \neq i} \lambda_{j,a} \mathbb{I}_{\{(i, i') \in G_{j,a}\}} \left(\mathbb{I}_{\{\sigma_j^{-1}(i) < \sigma_j^{-1}(i')\}} - \frac{\exp(\theta_{i'}^*)}{\exp(\theta_i^*) + \exp(\theta_{i'}^*)} \right). \quad (34)$$

Lemma 10. Under the hypotheses of Theorem 2, with probability at least $1 - 2e^3 d^{-3}$,

$$\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2 \leq \sqrt{\frac{6 \log d \sum_{j=1}^n \sum_{a=1}^{\ell_j} (\lambda_{j,a})^2 (\kappa_j - p_{j,a}) (\kappa_j - p_{j,a} + 1)}{\theta_{i,i'}^2 d^3}}.$$

The Hessian matrix $H(\theta) \in \mathcal{S}^d$ with $H_{i,i'}(\theta) = \frac{\partial^2 \mathcal{L}_{\text{RB}}(\theta)}{\partial \theta_i \partial \theta_{i'}}$ is given by

$$H(\theta) = - \sum_{j=1}^n \sum_{a=1}^{\ell_j} \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,a}\}} \lambda_{j,a} \left((e_i - e_{i'}) (e_i - e_{i'})^\top \frac{\exp(\theta_i + \theta_{i'})}{[\exp(\theta_i) + \exp(\theta_{i'})]^2} \right). \quad (35)$$

It follows from the definition that $-H(\theta)$ is positive semi-definite for any $\theta \in \mathbb{R}^d$. The smallest eigenvalue of $-H(\theta)$ is equal to zero and the corresponding eigenvector is all-ones vector. The following lemma lower bounds its second smallest eigenvalue $\lambda_2(-H(\theta))$.

Lemma 11. *Under the hypotheses of Theorem 2, if*

$$\sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a}(\kappa_j - p_{j,a}) \geq 2^6 e^{18b} \frac{\eta\delta}{\alpha^2 \beta^2 \tau} d \log d \quad (36)$$

then with probability at least $1 - d^{-3}$, the following holds for any $\theta \in \Omega_b$:

$$\lambda_2(-H(\theta)) \geq \frac{e^{-4b}}{(1 + e^{2b})^2} \frac{\alpha\gamma}{d-1} \sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a}(\kappa_j - p_{j,a}). \quad (37)$$

Define $\Delta = \hat{\theta} - \theta^*$. It follows from the definition that Δ is orthogonal to the all-ones vector. By the definition of $\hat{\theta}$ as the optimal solution of the optimization (3), we know that $\mathcal{L}_{\text{RB}}(\hat{\theta}) \geq \mathcal{L}_{\text{RB}}(\theta^*)$ and thus

$$\mathcal{L}_{\text{RB}}(\hat{\theta}) - \mathcal{L}_{\text{RB}}(\theta^*) - \langle \nabla \mathcal{L}_{\text{RB}}(\theta^*), \Delta \rangle \geq -\langle \nabla \mathcal{L}_{\text{RB}}(\theta^*), \Delta \rangle \geq -\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2 \|\Delta\|_2, \quad (38)$$

where the last inequality follows from the Cauchy-Schwartz inequality. By the mean value theorem, there exists a $\theta = a\hat{\theta} + (1-a)\theta^*$ for some $a \in [0, 1]$ such that $\theta \in \Omega_b$ and

$$\mathcal{L}_{\text{RB}}(\hat{\theta}) - \mathcal{L}_{\text{RB}}(\theta^*) - \langle \nabla \mathcal{L}_{\text{RB}}(\theta^*), \Delta \rangle = \frac{1}{2} \Delta^\top H(\theta) \Delta \leq -\frac{1}{2} \lambda_2(-H(\theta)) \|\Delta\|_2^2, \quad (39)$$

where the last inequality holds because the Hessian matrix $-H(\theta)$ is positive semi-definite with $H(\theta)\mathbf{1} = \mathbf{0}$ and $\Delta^\top \mathbf{1} = 0$. Combining (38) and (39),

$$\|\Delta\|_2 \leq \frac{2\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2}{\lambda_2(-H(\theta))}. \quad (40)$$

Note that $\theta \in \Omega_b$ by definition. Theorem 8 follows by combining Equation (40) with Lemma 10 and Lemma 11.

8.2.1 PROOF OF LEMMA 10

The idea of the proof is to view $\nabla \mathcal{L}_{\text{RB}}(\theta^*)$ as the final value of a discrete time vector-valued martingale with values in \mathbb{R}^d . Define $\nabla \mathcal{L}_{G_{j,a}}(\theta^*)$ as the gradient vector arising out of each rank-breaking graph $\{G_{j,a}\}_{j \in [n], a \in [\ell_j]}$ that is

$$\nabla_i \mathcal{L}_{G_{j,a}}(\theta^*) \equiv \sum_{\substack{i \in S_j \\ i' \neq i}} \lambda_{j,a} \mathbb{I}_{\{(i,i') \in G_{j,a}\}} \left(\mathbb{I}_{\{\sigma_j^{-1}(i) < \sigma_j^{-1}(i')\}} - \frac{\exp(\theta_i^*)}{\exp(\theta_i^*) + \exp(\theta_{i'}^*)} \right). \quad (41)$$

Consider $\nabla \mathcal{L}_{G_{j,a}}(\theta^*)$ as the incremental random vector in a martingale of $\sum_{j=1}^n \ell_j$ time steps. Lemma 12 shows that the expectation of each incremental vector is zero. Observe that the conditioning event $\{i' < i : \sigma^{-1}(i') < p_{j,a}\}$ given in (43) is equivalent to conditioning on the history

$\{G_{j,a'}\}_{a' < a}$. Therefore, using the assumption that the rankings $\{\sigma_j\}_{j \in [n]}$ are mutually independent, we have that the conditional expectation of $\nabla \mathcal{L}_{G_{j,a}}(\theta^*)$ conditioned on $\{G_{j',a'}\}_{j' < j, a' \in [\ell_{j'}]}$ is zero. Further, the conditional expectation of $\nabla \mathcal{L}_{G_{j,a}}(\theta^*)$ is zero even when conditioned on the rank breaking due to previous separators $\{G_{j',a'}\}_{a' < a}$ that are ranked higher (i.e. $a' < a$), which follows from the next lemma.

Lemma 12. *For a position- p rank breaking graph G_p , defined over a set of items S , where $p \in [|S| - 1]$,*

$$\mathbb{P}[\sigma^{-1}(i) < \sigma^{-1}(i') \mid (i, i') \in G_p] = \frac{\exp(\theta_i^*)}{\exp(\theta_i^*) + \exp(\theta_{i'}^*)}, \quad (42)$$

for all $i, i' \in S$ and also

$$\mathbb{P}[\sigma^{-1}(i) < \sigma^{-1}(i') \mid (i, i') \in G_p \text{ and } \{i'' \in S : \sigma^{-1}(i'') < p\}] = \frac{\exp(\theta_i^*)}{\exp(\theta_i^*) + \exp(\theta_{i'}^*)}. \quad (43)$$

This is one of the key technical lemmas since it implies that the proposed rank-breaking is consistent, i.e. $\mathbb{E}_{\theta^*}[\nabla \mathcal{L}_{\text{RB}}(\theta^*)] = 0$. Throughout the proof of Theorem 2, this is the only place where the assumption on the proposed (consistent) rank-breaking is used. According to a companion theorem in Azari Souhaimi et al. (2014, Theorem 2), it also follows that any rank-breaking that is not union of position- p rank-breakings results in inconsistency, i.e. $\mathbb{E}_{\theta^*}[\nabla \mathcal{L}_{\text{RB}}(\theta^*)] \neq 0$. We claim that for each rank-breaking graph $G_{j,a}$, $\|\nabla \mathcal{L}_{G_{j,a}}(\theta^*)\|_2^2 \leq (\lambda_{j,a})^2 (\kappa_j - p_{j,a}) (\kappa_j - p_{j,a} + 1)$. By Lemma 13 which is a generalization of the Azuma-Hoeffding inequality found in (Hayes, 2005, Theorem 1.8), we have

$$\mathbb{P}[\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2 \geq \delta] \leq 2e^3 \exp\left(-\frac{\delta^2}{2 \sum_{j=1}^n \sum_{a=1}^{\ell_j} (\lambda_{j,a})^2 (\kappa_j - p_{j,a}) (\kappa_j - p_{j,a} + 1)}\right),$$

which implies the result.

Lemma 13. *Let (X_1, X_2, \dots, X_n) be real-valued martingale taking values in \mathbb{R}^d such that $X_0 = 0$ and for every $1 \leq i \leq n$, $\|X_i - X_{i-1}\|_2 \leq c_i$, for some non-negative constant c_i . Then for every $\delta > 0$,*

$$\mathbb{P}[\|X_n\|_2 \geq \delta] \leq 2e^3 e^{-\frac{\delta^2}{2 \sum_{i=1}^n c_i^2}}. \quad (44)$$

It follows from the upper bound on $\|\nabla \mathcal{L}_{G_{j,a}}(\theta^*)\|_2^2 \leq c_i^2$ with $c_i^2 = \lambda^2 (\kappa_j - p_{j,a})^2 + (\kappa_j - p_{j,a})$. In the expression (41), $\nabla \mathcal{L}_{G_{j,a}}(\theta^*)$ has one entry at $p_{j,a}$ -th position that is compared to $(\kappa_j - p_{j,a})$ other items and $(\kappa_j - p_{j,a})$ entries that is compared only once, giving the bound

$$\|\nabla \mathcal{L}_{G_{j,a}}(\theta^*)\|_2^2 \leq \lambda_{j,a}^2 (\kappa_j - p_{j,a})^2 + \lambda_{j,a}^2 (\kappa_j - p_{j,a}).$$

8.2.2 PROOF OF LEMMA 12

Define event $E \equiv \{(i, i') \in G_p\}$. Observe that

$$E = \left\{ \left(\mathbb{I}_{\{\sigma^{-1}(i)=p\}} + \mathbb{I}_{\{\sigma^{-1}(i')=p\}} = 1 \right) \wedge \left(\sigma^{-1}(i), \sigma^{-1}(i') \geq p \right) \right\}.$$

Consider any set $\Omega \subset S \setminus \{i, i'\}$ such that $|\Omega| = p - 1$. Let M denote an event that items of the set Ω are ranked in top- $(p - 1)$ positions in a particular order. It is easy to verify the following:

$$\begin{aligned} \mathbb{P}\left[\sigma^{-1}(i) < \sigma^{-1}(i') \mid E, M\right] &= \frac{\mathbb{P}\left[\left(\sigma^{-1}(i) < \sigma^{-1}(i')\right), E, M\right]}{\mathbb{P}\left[E, M\right]} \\ &= \frac{\mathbb{P}\left[\left(\sigma^{-1}(i) = p\right), M\right]}{\mathbb{P}\left[\left(\sigma^{-1}(i) = p\right), M\right] + \mathbb{P}\left[\left(\sigma^{-1}(i') = p\right), M\right]} \\ &= \frac{\exp(\theta_i^*)}{\exp(\theta_i^*) + \exp(\theta_{i'}^*)} = \mathbb{P}\left[\sigma^{-1}(i) < \sigma^{-1}(i')\right]. \end{aligned}$$

Since M is any particular ordering of the set Ω and Ω is any subset of $S \setminus \{i, i'\}$ such that $|\Omega| = p - 1$, conditioned on event E probabilities of all the possible events M over all the possible choices of set Ω sum to 1.

8.2.3 PROOF OF LEMMA 13

It follows exactly along the lines of proof of Theorem 1.8 in (Hayes, 2005).

8.2.4 PROOF OF LEMMA 11

The Hessian $H(\theta)$ is given in (35). For all $j \in [n]$, define $M^{(j)} \in \mathcal{S}^d$ as

$$M^{(j)} \equiv \sum_{a=1}^{\ell_j} \lambda_{j,a} \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,a}\}} (e_i - e_{i'})(e_i - e_{i'})^\top, \quad (45)$$

and let $M \equiv \sum_{j=1}^n M^{(j)}$. Observe that M is positive semi-definite and the smallest eigenvalue of M is zero with the corresponding eigenvector given by the all-ones vector. If $|\theta_i| \leq b$, for all $i \in [d]$, $\frac{\exp(\theta_i + \theta_{i'})}{\exp(\theta_i) + \exp(\theta_{i'})} \geq \frac{e^{2b}}{(1 + e^{2b})^2}$. Recall the definition of $H(\theta)$ from Equation (35). It follows that $-H(\theta) \succeq \frac{e^{2b}}{(1 + e^{2b})^2} M$ for $\theta \in \Omega_b$. Since, $-H(\theta)$ and M are symmetric matrices, from Weyl's inequality we have, $\lambda_2(-H(\theta)) \geq \frac{e^{2b}}{(1 + e^{2b})^2} \lambda_2(M)$. Again from Weyl's inequality, it follows that

$$\lambda_2(M) \geq \lambda_2(\mathbb{E}[M]) - \|M - \mathbb{E}[M]\|, \quad (46)$$

where $\|\cdot\|$ denotes the spectral norm. We will show in (51) that $\lambda_2(\mathbb{E}[M]) \geq 2\gamma e^{-6b} (\alpha/(d - 1)) \sum_{j=1}^n \tau_j \ell_j$, and in (63) that $\|M - \mathbb{E}[M]\| \leq 8e^{3b} \sqrt{\frac{\eta^b \log d}{\beta \pi d}} \sum_{j=1}^n \tau_j \ell_j$.

$$\lambda_2(M) \geq \frac{2e^{-6b} \alpha \gamma}{d - 1} \sum_{j=1}^n \tau_j \ell_j - 8e^{3b} \sqrt{\frac{\eta^b \log d}{\beta \pi d}} \sum_{j=1}^n \tau_j \ell_j \geq \frac{e^{-6b} \alpha \gamma}{d - 1} \sum_{j=1}^n \tau_j \ell_j, \quad (47)$$

where the last inequality follows from the assumption that $\sum_{j=1}^n \tau_j \ell_j \geq 2^6 e^{18b} \frac{\eta^b}{\alpha^2 \beta \gamma \pi} d \log d$. This proves the desired claim.

To prove the lower bound on $\lambda_2(\mathbb{E}[M])$, notice that

$$\mathbb{E}[M] = \sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a} \sum_{i < i' \in S_j} \mathbb{P}\left[(i, i') \in G_{j,a} \mid (i, i') \in S_j\right] (e_i - e_{i'})(e_i - e_{i'})^\top. \quad (48)$$

The following lemma provides a lower bound on $\mathbb{P}[(i, i') \in G_{j,a} \mid (i, i') \in S_j]$.

Lemma 14. Consider a ranking σ over a set $S \subseteq [d]$ such that $|S| = \kappa$. For any two items $i, i' \in S$, $\theta \in \Omega_b$, and $1 \leq \ell \leq \kappa - 1$,

$$\mathbb{P}_\theta \left[\sigma^{-1}(i) = \ell, \sigma^{-1}(i') > \ell \right] \geq \frac{e^{-6b} (\kappa - \ell)}{\kappa (\kappa - 1)} \left(1 - \frac{\ell}{\kappa} \right)^{\alpha_{i, i', \ell, \theta} - 2}, \quad (49)$$

where the probability \mathbb{P}_θ is with respect to the sampled ranking resulting from PL weights $\theta \in \Omega_b$, and $\alpha_{i, i', \ell, \theta}$ is defined as $1 \leq \alpha_{i, i', \ell, \theta} = \lceil \tilde{\alpha}_{i, i', \ell, \theta} \rceil$, and $\tilde{\alpha}_{i, i', \ell, \theta}$ is,

$$\tilde{\alpha}_{i, i', \ell, \theta} \equiv \max_{\ell' \in [d] \setminus \Omega \setminus \{i, i'\}} \max_{\substack{|\Omega| = \kappa - \ell' \\ \left\{ \frac{\exp(\theta_i) + \exp(\theta_{i'})}{\sum_{j \in \Omega} \exp(\theta_j)} \right\} / |\Omega|}}. \quad (50)$$

Note that we do not need $\max_{\ell' \in [d]}$ in the above equation as the expression achieves its maxima at $\ell' = \ell$, but we keep the definition to avoid any confusion. In the worst case, $2e^{-2b} \leq \tilde{\alpha}_{i, i', \ell, \theta} \leq 2e^{2b}$. Therefore, using definition of rank breaking graph $G_{j,a}$, and Equations (48) and (49) we have,

$$\begin{aligned} \mathbb{E}[M] &\succeq \gamma e^{-6b} \sum_{j=1}^n \sum_{a=1}^{\ell_j} \lambda_{j,a} \frac{2(\kappa_j - p_{j,a})}{\kappa_j (\kappa_j - 1)} \sum_{i < i' \in S_j} (e_i - e_{i'}) (e_i - e_{i'})^\top \\ &\succeq 2\gamma e^{-6b} \sum_{j=1}^n \sum_{a=1}^{\ell_j} \frac{1}{\kappa_j (\kappa_j - 1)} \lambda_{j,a} (\kappa_j - p_{j,a}) \sum_{i < i' \in S_j} (e_i - e_{i'}) (e_i - e_{i'})^\top \\ &= 2\gamma e^{-6b} L, \end{aligned} \quad (51)$$

where we used $\gamma \leq (1 - p_{i, \ell_j} / \kappa_j)^{\alpha_{i, i', \ell, \theta} - 2}$ which follows for the definition in (7). (51) follows from the definition of Laplacian L , defined for the comparison graph \mathcal{H} in Definition 9. Using $\lambda_2(L) = (\alpha/(d - 1)) \sum_{j=1}^n \tau_j \ell_j$ from (30), we get the desired bound $\lambda_2(\mathbb{E}[M]) \geq 2\gamma e^{-6b} (\alpha/(d - 1)) \sum_{j=1}^n \tau_j \ell_j$.

Next we need to upper bound $\|\sum_{j=1}^n \mathbb{E}[M^{(j)}]\|$ to bound the deviation of M from its expectation. To this end, we prove an upper bound on $\mathbb{P}[\sigma_j^{-1}(i) = p_{j,a} \mid i \in S_j]$ in the following lemma.

Lemma 15. Under the hypotheses of Lemma 14,

$$\mathbb{P}_\theta \left[\sigma^{-1}(i) = \ell \right] \leq \frac{e^{6b}}{\kappa} \left(1 - \frac{\ell}{\kappa + \alpha_{i, \ell, \theta}} \right)^{\alpha_{i, \ell, \theta} - 1} \leq \frac{e^{6b}}{\kappa - \ell}, \quad (52)$$

where $0 \leq \alpha_{i, \ell, \theta} = \lceil \tilde{\alpha}_{i, \ell, \theta} \rceil$, and $\tilde{\alpha}_{i, \ell, \theta}$ is,

$$\tilde{\alpha}_{i, \ell, \theta} \equiv \min_{\ell' \in [d] \setminus \Omega \setminus \{i\}} \min_{\substack{|\Omega| = \kappa - \ell' + 1 \\ \left\{ \frac{\exp(\theta_i)}{\sum_{j \in \Omega} \exp(\theta_j)} \right\} / |\Omega|}}. \quad (53)$$

In the worst case, $e^{-2b} \leq \tilde{\alpha}_{i, \ell, \theta} \leq e^{2b}$. Note that $\alpha_{i, \ell, \theta} = 0$ gives the worst upper bound.

Therefore using Equation (52), for all $i \in [d]$, we have,

$$\mathbb{P}[\sigma_j^{-1}(i) \in \mathcal{P}_j] \leq \min \left\{ 1, \frac{e^{6b}\ell_j}{\kappa_j - p_{j,\ell_j}} \right\} \leq \frac{e^{6b}\ell_j}{\max\{\ell_j, \kappa_j - p_{j,\ell_j}\}} \leq \frac{e^{6b}\eta\ell_j}{\kappa_j}, \quad (54)$$

where we used η defined in Equation (8). Define a diagonal matrix $D^{(i)} \in \mathcal{S}^d$ and a matrix $A^{(i)} \in \mathcal{S}^d$,

$$A_{i\ell_j}^{(i)} \equiv \mathbb{I}_{\{i, i' \in \mathcal{S}_j\}} \sum_{a=1}^{\ell_j} \lambda_{j,a} \mathbb{I}_{\{(i, i') \in G_{j,a}\}}, \quad \text{for all } i, i' \in [d], \quad (55)$$

and $D_{i\ell_j}^{(i)} = \sum_{i' \neq i} A_{i\ell_j}^{(i')}$. Observe that $M^{(i)} = D^{(i)} - A^{(i)}$. For all $i \in [d]$, we have,

$$\begin{aligned} D_{i\ell_j}^{(i)} &= \mathbb{I}_{\{i \in \mathcal{S}_j\}} \sum_{i'=1}^{\kappa_j} \mathbb{I}_{\{\sigma_j^{-1}(i) = i'\}} \sum_{a=1}^{\ell_j} \lambda_{j,a} \deg_{G_{j,a}}(\sigma_j^{-1}(i')) \\ &\leq \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \mathbb{I}_{\{\sigma_j^{-1}(i) \in \mathcal{P}_j\}} \left(\max_{a \in [k_j]} \left\{ \lambda_{j,a} (\kappa_j - p_{j,a}) \right\} + \sum_{a=1}^{\ell_j} \lambda_{j,a} \right) + \mathbb{I}_{\{\sigma_j^{-1}(i) \notin \mathcal{P}_j\}} \left(\sum_{a=1}^{\ell_j} \lambda_{j,a} \right) \right\} \\ &= \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \mathbb{I}_{\{\sigma_j^{-1}(i) \in \mathcal{P}_j\}} \delta_{j,1} + \mathbb{I}_{\{\sigma_j^{-1}(i) \notin \mathcal{P}_j\}} \delta_{j,2} \right\}, \end{aligned} \quad (56)$$

where the last equality follows from the definition of $\delta_{j,1}$ and $\delta_{j,2}$ in Equation (26). Note that $\max_{i \in [d]} |D_{i\ell_j}| = \delta_{j,1}$. Using (54) and (56), we have,

$$\mathbb{E} \left[D_{i\ell_j}^{(i)} \right] \leq \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \frac{e^{6b}\eta\ell_j}{\kappa_j} \left(\delta_{j,1} + \frac{\delta_{j,2}\kappa_j}{\eta\ell_j} \right) \right\}. \quad (57)$$

Similarly we have,

$$\mathbb{E} \left[(D_{i\ell_j}^{(i)})^2 \right] \leq \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \frac{e^{6b}\eta\ell_j}{\kappa_j} \left(\delta_{j,1}^2 + \frac{\delta_{j,2}^2\kappa_j}{\eta\ell_j} \right) \right\} \quad (58)$$

For all $i \in [d]$, we have,

$$\begin{aligned} \mathbb{E} \left[\sum_{i'=1}^d ((A^{(i)})^2)_{i\ell_j} \right] &\leq \mathbb{E} \left[\left(\sum_{i'=1}^d A_{i\ell_j}^{(i')} \right) \max_{i \in [d]} \left\{ \sum_{i'=1}^d A_{i\ell_j}^{(i')} \right\} \right] \\ &\leq \mathbb{E} \left[D_{i\ell_j}^{(i)} \delta_{j,1} \right] \\ &\leq \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \frac{e^{6b}\eta\ell_j}{\kappa_j} \left(\delta_{j,1}^2 + \frac{\delta_{j,1}\delta_{j,2}\kappa_j}{\eta\ell_j} \right) \right\}. \end{aligned} \quad (59)$$

Using (58) and (59), we have, for all $i \in [d]$,

$$\begin{aligned} &\sum_{i'=1}^d \left| \mathbb{E} \left[(M^{(i)})^2 \right]_{i\ell_j} \right| \\ &= \sum_{i'=1}^d \left| \mathbb{E} \left[(D^{(i)})^2 \right]_{i\ell_j} - \mathbb{E} \left[D^{(i)} A^{(i)} \right]_{i\ell_j} - \mathbb{E} \left[(A^{(i)} D^{(i)}) \right]_{i\ell_j} + \mathbb{E} \left[(A^{(i)})^2 \right]_{i\ell_j} \right| \\ &\leq 2\mathbb{E} \left[(D_{i\ell_j}^{(i)})^2 \right] + \sum_{i'=1}^d \left(\mathbb{E} \left[\delta_{j,1} (A^{(i)}) \right]_{i\ell_j} + \mathbb{E} \left[(A^{(i)})^2 \right]_{i\ell_j} \right) \\ &\leq \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \frac{e^{6b}\eta\ell_j}{\kappa_j} \left(4\delta_{j,1}^2 + \frac{2(\delta_{j,1}\delta_{j,2} + \delta_{j,2}^2)\kappa_j}{\eta\ell_j} \right) \right\} \\ &= \mathbb{I}_{\{i \in \mathcal{S}_j\}} \left\{ \frac{e^{6b}\delta\eta\ell_j}{\kappa_j} \right\}, \end{aligned} \quad (60)$$

where the last equality follows from the definition of δ , Equation (27).

To bound $\|\sum_{j=1}^n \mathbb{E}[(M^{(j)})^2]\|$, we use the fact that for $J \in \mathbb{R}^{\delta \times d}$, $\|J\| \leq \max_{i \in [d]} \sum_{i'=1}^d |J_{i\ell_j}^i|$. Therefore, we have

$$\begin{aligned} \left\| \sum_{j=1}^n \mathbb{E} \left[(M^{(j)})^2 \right] \right\| &\leq e^{6b}\delta\eta \max_{i \in [d]} \left\{ \sum_{j: i \in \mathcal{S}_j} \frac{\ell_j}{\kappa_j} \right\} \\ &= \frac{e^{6b}\eta\delta}{\tau} D_{\max} \\ &= \frac{e^{6b}\eta\delta}{\beta\tau d} \sum_{j=1}^n \tau_j \ell_j, \end{aligned} \quad (61)$$

$$= \frac{e^{6b}\eta\delta}{\beta\tau d} \sum_{j=1}^n \tau_j \ell_j, \quad (62)$$

where (61) follows from the definition of D_{\max} in Equation(28) and (62) follows from the definition of β in (30). Observe that from Equation (56), $\|M^{(i)}\| \leq 2\delta_{j,1} \leq 2\sqrt{\delta}$. Applying matrix Bernstein inequality, we have,

$$\mathbb{P} \left[\|M - \mathbb{E}[M]\| \geq t \right] \leq d \exp \left(\frac{-t^2/2}{\frac{e^{6b}\eta\delta}{\beta\tau d} \sum_{j=1}^n \tau_j \ell_j + 4\sqrt{\delta t}/3} \right).$$

Therefore, with probability at least $1 - d^{-3}$, we have,

$$\|M - \mathbb{E}[M]\| \leq 4e^{3b} \sqrt{\frac{\eta\delta \log d}{\beta\tau d} \sum_{j=1}^n \tau_j \ell_j} + \frac{64\sqrt{\delta} \log d}{3} \leq 8e^{3b} \sqrt{\frac{\eta\delta \log d}{\beta\tau d} \sum_{j=1}^n \tau_j \ell_j}, \quad (63)$$

where the second inequality uses $\sum_{j=1}^n \tau_j \ell_j \geq 2^6(\beta\tau/\eta)d \log d$ which follows from the assumption that $\sum_{j=1}^n \tau_j \ell_j \geq 2^6 e^{18b} \frac{\eta\delta}{\beta\tau\alpha\beta} d \log d$ and the fact that $\alpha, \beta \leq 1, \gamma \leq 1, \eta \geq 1$, and $\delta > \tau^2$.

8.2.5 PROOF OF LEMMA 14

Since providing a lower bound on $\mathbb{P}_\theta[\sigma^{-1}(i) = \ell, \sigma^{-1}(i') > \ell]$ for arbitrary θ is challenging, we construct a new set of parameters $\{\tilde{\theta}_j\}_{j \in [d]}$ from the original θ . These new parameters are constructed such that it is both easy to compute the probability and also provides a lower bound on the original distribution. We denote the sum of the weights by $W \equiv \sum_{j \in S} \exp(\theta_j)$. We define a new set of parameters $\{\tilde{\theta}_j\}_{j \in S}$:

$$\tilde{\theta}_j = \begin{cases} \log(\tilde{\alpha}_{i,i',\ell,\theta}/2) & \text{for } j = i \text{ or } i', \\ 0 & \text{otherwise.} \end{cases} \quad (64)$$

Similarly define $\tilde{W} \equiv \sum_{j \in S} \exp(\tilde{\theta}_j) = \kappa - 2 + \tilde{\alpha}_{i,i',\ell,\theta}$. We have,

$$\begin{aligned} & \mathbb{P}_\theta[\sigma^{-1}(i) = \ell, \sigma^{-1}(i') > \ell] \\ &= \sum_{\substack{j_1 \in S \\ j_1 \neq i, i'}} \left(\frac{\exp(\theta_{j_1})}{W} \sum_{\substack{j_2 \in S \\ j_2 \neq i, i', j_1}} \left(\frac{\exp(\theta_{j_2})}{W - \exp(\theta_{j_1})} \dots \right. \right. \\ & \quad \left. \left. \left(\sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, i', \\ j_1, \dots, j_{l-2}}} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=j_1}^{j_{l-2}} \exp(\theta_k)} \frac{\exp(\theta_{j_l})}{W - \sum_{k=j_1}^{j_{l-1}} \exp(\theta_k)} \dots \right) \right) \right) \\ &= \frac{\exp(\theta_i)}{W} \sum_{\substack{j_1 \in S \\ j_1 \neq i, i'}} \left(\frac{\exp(\theta_{j_1})}{W - \exp(\theta_{j_1})} \sum_{\substack{j_2 \in S \\ j_2 \neq i, i', j_1}} \left(\frac{\exp(\theta_{j_2})}{W - \exp(\theta_{j_1}) - \exp(\theta_{j_2})} \dots \right. \right. \\ & \quad \left. \left. \sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, i', \\ j_1, \dots, j_{l-2}}} \left(\frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=j_1}^{j_{l-1}} \exp(\theta_k)} \dots \right) \right) \right) \end{aligned} \quad (65)$$

Consider the last summation term in the above equation and let $\Omega_\ell = S \setminus \{i, i', j_1, \dots, j_{l-2}\}$. Observe that, $|\Omega_\ell| = \kappa - \ell$ and from equation (50), $\frac{\exp(\theta_i) + \exp(\theta_{i'})}{\sum_{j \in \Omega_\ell} \exp(\theta_j)} \leq \frac{\tilde{\alpha}_{i,i',\ell,\theta}}{\kappa - \ell}$. We have,

$$\begin{aligned} & \sum_{j_{l-1} \in \Omega_\ell} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=j_1}^{j_{l-1}} \exp(\theta_k)} \\ &= \sum_{j_{l-1} \in \Omega_\ell} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=j_1}^{j_{l-2}} \exp(\theta_k) - \exp(\theta_{j_{l-1}})} \\ &\geq \frac{\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})}{W - \sum_{k=j_1}^{j_{l-2}} \exp(\theta_k) - (\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})) / |\Omega_\ell|} \end{aligned} \quad (66)$$

$$\begin{aligned} &= \frac{\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})}{\exp(\theta_i) + \exp(\theta_{i'}) + \sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}}) - (\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})) / |\Omega_\ell|} \\ &= \left(\frac{\exp(\theta_i) + \exp(\theta_{i'})}{\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})} + 1 - \frac{1}{\kappa - \ell} \right)^{-1} \\ &\geq \left(\frac{\tilde{\alpha}_1}{\kappa - \ell} + 1 - \frac{1}{\kappa - \ell} \right)^{-1} \end{aligned} \quad (67)$$

$$\begin{aligned} &= \frac{\kappa - \ell}{\tilde{\alpha}_1 + \kappa - \ell - 1} \\ &= \sum_{j_{l-1} \in \Omega_\ell} \frac{\exp(\tilde{\theta}_{j_{l-1}})}{\tilde{W} - \sum_{k=j_1}^{j_{l-2}} \exp(\tilde{\theta}_k) - \exp(\tilde{\theta}_{j_{l-1}})}, \end{aligned} \quad (68)$$

where (66) follows from the Jensen's inequality and the fact that for any $c > 0, 0 < x < c, \frac{x}{c-x}$ is convex in x . Equation (67) follows from the definition of $\tilde{\alpha}_{i,i',\ell,\theta}$, (50), and the fact that $|\Omega_\ell| = \kappa - \ell$. Equation (68) uses the definition of $\{\tilde{\theta}_j\}_{j \in S}$.

Consider $\{\Omega_\ell\}_{2 \leq \ell \leq l-1}$, $|\Omega_\ell| = \kappa - \ell$, corresponding to the subsequent summation terms in (65). Observe that $\frac{\exp(\theta_i) + \exp(\theta_{i'})}{\sum_{j \in \Omega_\ell} \exp(\theta_j)} \leq \tilde{\alpha}_{i,i',\ell,\theta} / |\Omega_\ell|$. Therefore, each summation term in equation (65) can

be lower bounded by the corresponding term where $\{\theta_j\}_{j \in S}$ is replaced by $\{\tilde{\theta}_j\}_{j \in S}$. Hence, we have

$$\begin{aligned}
& \mathbb{P}_\theta \left[\sigma^{-1}(i) = \ell_i, \sigma^{-1}(i') > \ell \right] \\
& \geq \frac{\exp(\theta_i)}{W} \sum_{\substack{j_1 \in S \\ j_1 \neq i, i'}} \left(\frac{\exp(\tilde{\theta}_{j_1})}{W - \exp(\tilde{\theta}_{j_1})} \sum_{\substack{j_2 \in S \\ j_2 \neq i, i', j_1}} \left(\frac{\exp(\tilde{\theta}_{j_2})}{W - \exp(\tilde{\theta}_{j_1}) - \exp(\tilde{\theta}_{j_2})} \dots \right. \right. \\
& \quad \left. \left. \sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, i', \\ j_1, \dots, j_{l-2}}} \left(\frac{\exp(\tilde{\theta}_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-1}} \exp(\tilde{\theta}_k)} \right) \right) \right) \\
& \geq \frac{e^{-4b} \exp(\tilde{\theta}_i)}{\tilde{W}} \sum_{\substack{j_1 \in S \\ j_1 \neq i, i'}} \left(\frac{\exp(\tilde{\theta}_{j_1})}{W - \exp(\tilde{\theta}_{j_1})} \sum_{\substack{j_2 \in S \\ j_2 \neq i, i', j_1}} \left(\frac{\exp(\tilde{\theta}_{j_2})}{W - \exp(\tilde{\theta}_{j_1}) - \exp(\tilde{\theta}_{j_2})} \dots \right. \right. \\
& \quad \left. \left. \sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, i', \\ j_1, \dots, j_{l-2}}} \left(\frac{\exp(\tilde{\theta}_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-1}} \exp(\tilde{\theta}_k)} \right) \right) \right) \\
& = (e^{-4b}) \mathbb{P}_{\tilde{\theta}} \left[\sigma^{-1}(i) = \ell_i, \sigma^{-1}(i') > \ell \right]. \tag{69}
\end{aligned}$$

The second inequality uses $\frac{\exp(\tilde{\theta}_i)}{W} \geq e^{-2b}/\kappa$ and $\frac{\exp(\tilde{\theta}_i)}{W} \leq e^{2b}/\kappa$. Observe that $\exp(\tilde{\theta}_j) = 1$ for all $j \neq i, i'$ and $\exp(\tilde{\theta}_i) + \exp(\tilde{\theta}_{i'}) = \tilde{\alpha}_{i, i', \ell, \theta} \leq [\tilde{\alpha}_{i, i', \ell, \theta}] = \alpha_{i, i', \ell, \theta} \geq 1$. Therefore, we have

$$\begin{aligned}
& \mathbb{P}_\theta \left[\sigma^{-1}(i) = \ell_i, \sigma^{-1}(i') > \ell \right] \\
& = \frac{\binom{\kappa-2}{\ell-1}}{(\kappa-2)!} \frac{(\tilde{\alpha}_{i, i', \ell, \theta}/2)(\ell-1)!}{(\kappa-2 + \tilde{\alpha}_{i, i', \ell, \theta})(\kappa-2 + \alpha_{i, i', \ell, \theta} - 1) \dots (\kappa-2 + \tilde{\alpha}_{i, i', \ell, \theta} - (\ell-1))} \\
& \geq \frac{(\kappa-2)!}{(\kappa-2)!} \frac{(\tilde{\alpha}_{i, i', \ell, \theta}/2)(\ell-1)!}{e^{-2b}} \\
& = \frac{(\kappa-\ell-1)! (\kappa + \alpha_{i, i', \ell, \theta} - 2)(\kappa + \alpha_{i, i', \ell, \theta} - 3) \dots (\kappa + \alpha_{i, i', \ell, \theta} - (\ell+1))}{e^{-2b} (\kappa - \ell + \alpha_{i, i', \ell, \theta} - 2)(\kappa - \ell + \alpha_{i, i', \ell, \theta} - 3) \dots (\kappa - \ell)} \\
& = \frac{(\kappa + \alpha_{i, i', \ell, \theta} - 2)(\kappa + \alpha_{i, i', \ell, \theta} - 3) \dots (\kappa - 1)}{(\kappa - 1) (\kappa - \ell + \alpha_{i, i', \ell, \theta} - 2)(\kappa - \ell + \alpha_{i, i', \ell, \theta} - 3) \dots (\kappa - \ell)} \\
& \geq \frac{e^{-2b}}{\binom{\kappa-1}{\ell-1}} \left(\frac{1 - \frac{\ell}{\kappa}}{\alpha_{i, i', \ell, \theta} - 1} \right) \\
& = \frac{e^{-2b} (\kappa - \ell) \binom{\ell}{\kappa}}{\kappa (\kappa - 1) \binom{\ell}{\kappa}} \alpha_{i, i', \ell, \theta}^{-2}, \tag{71}
\end{aligned}$$

where (70) follows from the fact that $\tilde{\alpha}_{i, i', \ell, \theta} \geq 2e^{-2b}$. Claim (49) follows by combining Equations (69) and (71).

8.2.6 PROOF OF LEMMA 15

Analogous to the proof of Lemma 14, we construct a new set of parameters $\{\tilde{\theta}_j\}_{j \in [d]}$ from the original θ . We denote the sum of the weights by $W \equiv \sum_{j \in S} \exp(\theta_j)$. We define a new set of parameters $\{\tilde{\theta}_j\}_{j \in S}$:

$$\tilde{\theta}_j = \begin{cases} \log(\tilde{\alpha}_{i, \ell, \theta}) & \text{for } j = i, \\ 0 & \text{otherwise.} \end{cases} \tag{72}$$

Similarly define $\tilde{W} \equiv \sum_{j \in S} \exp(\tilde{\theta}_j) = \kappa - 1 + \tilde{\alpha}_{i, \ell, \theta}$. We have,

$$\begin{aligned}
& \mathbb{P}_\theta \left[\sigma^{-1}(i) = \ell \right] \\
& = \sum_{\substack{j_1 \in S \\ j_1 \neq i}} \left(\frac{\exp(\theta_{j_1})}{W} \sum_{\substack{j_2 \in S \\ j_2 \neq i, j_1}} \left(\frac{\exp(\theta_{j_2})}{W - \exp(\theta_{j_1})} \dots \left(\sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, \\ j_1, \dots, j_{l-2}}} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-1}} \exp(\theta_k)} \right) \right) \right) \\
& \leq \sum_{\substack{j_1 \in S \\ j_1 \neq i}} \left(\frac{\exp(\theta_{j_1})}{W} \sum_{\substack{j_2 \in S \\ j_2 \neq i, j_1}} \left(\frac{\exp(\theta_{j_2})}{W - \exp(\theta_{j_1})} \dots \left(\sum_{\substack{j_{l-1} \in S \\ j_{l-1} \neq i, \\ j_1, \dots, j_{l-2}}} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-1}} \exp(\theta_k)} \right) \right) \right) \frac{e^{2b}}{\kappa - \ell + 1} \tag{73}
\end{aligned}$$

Consider the last summation term in the equation (73), and let $\Omega_\ell = S \setminus \{i, j_1, \dots, j_{l-2}\}$, such that $|\Omega_\ell| = \kappa - \ell + 1$. Observe that from equation (53), $\sum_{j \in \Omega_\ell} \frac{\exp(\theta_j)}{\exp(\theta_j)} \geq \kappa - \ell + 1$. We have,

$$\begin{aligned}
& \sum_{j_{l-1} \in \Omega_\ell} \frac{\exp(\theta_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-2}} \exp(\theta_k)} = \frac{\sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})}{\exp(\theta_i) + \sum_{j_{l-1} \in \Omega_\ell} \exp(\theta_{j_{l-1}})} \\
& \leq \left(\frac{\tilde{\alpha}_{i, \ell, \theta}}{\kappa - \ell + 1} + 1 \right)^{-1} \\
& = \frac{\tilde{\alpha}_{i, \ell, \theta} + \kappa - \ell + 1}{\kappa - \ell + 1} \\
& = \sum_{j_{l-1} \in \Omega_\ell} \frac{\exp(\tilde{\theta}_{j_{l-1}})}{W - \sum_{k=1}^{j_{l-2}} \exp(\tilde{\theta}_k)}, \tag{74}
\end{aligned}$$

where (74) follows from the definition of $\{\tilde{\theta}_j\}_{j \in S}$.

Consider $\{\Omega_j\}_{2 \leq j \leq l-1}$, $|\Omega_j| = \kappa - \tilde{\ell} + 1$, corresponding to the subsequent summation terms in (73). Observe that $\frac{\exp(\theta_j)}{\sum_{j \in \Omega_j} \exp(\theta_j)} \geq \tilde{\alpha}_{i, \ell, \theta} / |\Omega_j|$. Therefore, each summation term in equation (65) can be lower bounded by the corresponding term where $\{\theta_j\}_{j \in S}$ is replaced by $\{\tilde{\theta}_j\}_{j \in S}$. Hence, we

have

$$\begin{aligned}
& \mathbb{P}_\theta[\sigma^{-1}(i) = \ell] \\
& \leq \sum_{\substack{j_1 \in S \\ j_1 \neq i}} \left(\frac{\exp(\tilde{\theta}_{j_1})}{\tilde{W}} \sum_{\substack{j_2 \in S \\ j_2 \neq i, j_1}} \left(\frac{\exp(\tilde{\theta}_{j_2})}{\tilde{W} - \exp(\tilde{\theta}_{j_1})} \cdots \left(\sum_{\substack{j_{\ell-1} \in S \\ j_{\ell-1} \neq i, \\ j_1, \dots, j_{\ell-2}}} \frac{\exp(\tilde{\theta}_{j_{\ell-1}})}{\tilde{W} - \sum_{k=j_1}^{j_{\ell-2}} \exp(\tilde{\theta}_k)}} \right) \right) \frac{e^{2b}}{\kappa - \ell + 1} \right) \\
& \leq e^{4b} \sum_{\substack{j_1 \in S \\ j_1 \neq i}} \left(\frac{\exp(\tilde{\theta}_{j_1})}{\tilde{W}} \sum_{\substack{j_2 \in S \\ j_2 \neq i, j_1}} \left(\frac{\exp(\tilde{\theta}_{j_2})}{\tilde{W} - \exp(\tilde{\theta}_{j_1})} \cdots \right. \right. \\
& \quad \left. \left. \left(\sum_{\substack{j_{\ell-1} \in S \\ j_{\ell-1} \neq i, \\ j_1, \dots, j_{\ell-2}}} \frac{\exp(\tilde{\theta}_{j_{\ell-1}})}{\tilde{W} - \sum_{k=j_1}^{j_{\ell-2}} \exp(\tilde{\theta}_k)} \frac{\exp(\tilde{\theta}_{j_{\ell-1}})}{\tilde{W} - \sum_{k=j_1}^{j_{\ell-2}} \exp(\tilde{\theta}_k)}} \right) \right) \right) \\
& \leq e^{4b} \mathbb{P}_\theta[\sigma^{-1}(i) = \ell]
\end{aligned} \tag{75}$$

The second inequality uses $\tilde{\alpha}_2/(\kappa - \ell + \tilde{\alpha}_{i,\ell,\theta}) \geq e^{-2b}/(\kappa - \ell + 1)$. Observe that $\exp(\tilde{\theta}_j) = 1$ for all $j \neq i$ and $\exp(\tilde{\theta}_i) = \tilde{\alpha}_{i,\ell,\theta} \geq [\tilde{\alpha}_{i,\ell,\theta}] = \alpha_{i,\ell,\theta} \geq 0$. Therefore, we have

$$\begin{aligned}
\mathbb{P}_\theta[\sigma^{-1}(i) = \ell] & = \frac{(\kappa-1)}{(\ell-1)!} \frac{\tilde{\alpha}_{i,\ell,\theta}(\ell-1)!}{(\kappa-1 + \tilde{\alpha}_{i,\ell,\theta})(\kappa-2 + \tilde{\alpha}_{i,\ell,\theta}) \cdots (\kappa-\ell + \tilde{\alpha}_{i,\ell,\theta})} \\
& \leq \frac{(\kappa-\ell)!}{(\kappa-\ell)!} \frac{e^{2b}}{(\kappa-1 + \alpha_{i,\ell,\theta})(\kappa-2 + \alpha_{i,\ell,\theta}) \cdots (\kappa-\ell + \alpha_{i,\ell,\theta})} \\
& \leq \frac{e^{2b}}{\kappa} \left(1 - \frac{\ell}{\kappa + \alpha_{i,\ell,\theta}} \right)^{\alpha_{i,\ell,\theta} - 1},
\end{aligned} \tag{76}$$

Note that equation (76) holds for all values of $\alpha_{i,\ell,\theta} \geq 0$. Claim 52 follows by combining Equations (75) and (76).

8.3 Proof of Theorem 4

Let $H(\theta) \in \mathcal{S}^d$ be Hessian matrix such that $H_{i'i'}(\theta) = \frac{\partial^2 \mathcal{L}(\theta)}{\partial \theta_i \partial \theta_{i'}}$. The Fisher information matrix is defined as $I(\theta) = -\mathbb{E}_\theta[H(\theta)]$. Fix any unbiased estimator $\hat{\theta}$ of $\theta \in \Omega_b$. Since, $\hat{\theta} \in \mathcal{U}$, $\hat{\theta} - \theta$ is orthogonal to $\mathbf{1}$. The Cramér-Rao lower bound then implies that $\mathbb{E}[\|\hat{\theta} - \theta\|^2] \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\theta))}$. Taking the supremum over both sides gives

$$\sup_{\theta} \mathbb{E}[\|\hat{\theta} - \theta\|^2] \geq \sup_{\theta} \sum_{i=2}^d \frac{1}{\lambda_i(I(\theta))} \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\mathbf{0}))}.$$

The following lemma provides a lower bound on $\mathbb{E}_\theta[H(\mathbf{0})]$, where $\mathbf{0}$ indicates the all-zeros vector.

Lemma 16. *Under the hypotheses of Theorem 4,*

$$\mathbb{E}_\theta[H(\mathbf{0})] \succeq - \sum_{j=1}^n \frac{2p \log(\kappa_j)^2}{\kappa_j(\kappa_j - 1)} \sum_{i' < i \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top. \tag{77}$$

Observe that $I(\mathbf{0})$ is positive semi-definite. Moreover, $\lambda_1(I(\mathbf{0}))$ is zero and the corresponding eigenvector is the all-ones vector. It follows that

$$\begin{aligned}
I(\mathbf{0}) & \preceq \sum_{j=1}^n \frac{2p \log(\kappa_j)^2}{\kappa_j(\kappa_j - 1)} \sum_{i' < i \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top \\
& \preceq \underbrace{2p \log(\kappa_{\max})^2 \sum_{j=1}^n \frac{1}{\kappa_j(\kappa_j - 1)} \sum_{i' < i \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top}_{=L},
\end{aligned}$$

where L is the Laplacian defined for the comparison graph \mathcal{H} , Definition 1, as $\ell_j = 1$ for all $j \in [n]$ in this setting. By Jensen's inequality, we have

$$\sum_{i=2}^d \frac{1}{\lambda_i(L)} \geq \frac{(d-1)^2}{\sum_{i=2}^d \lambda_i(L)} = \frac{(d-1)^2}{\text{Tr}(L)} = \frac{(d-1)^2}{n}.$$

8.3.1 PROOF OF LEMMA 16

Define $\mathcal{L}_j(\theta)$ for $j \in [n]$ such that $\mathcal{L}(\theta) = \sum_{j=1}^n \mathcal{L}_j(\theta)$. Let $H^{(j)}(\theta) \in \mathcal{S}^d$ be the Hessian matrix such that $H_{i'i'}^{(j)}(\theta) = \frac{\partial^2 \mathcal{L}_j(\theta)}{\partial \theta_i \partial \theta_{i'}}$ for $i, i' \in S_j$. We prove that for all $j \in [n]$,

$$\mathbb{E}_\theta[H^{(j)}(\mathbf{0})] \succeq - \frac{2p \log(\kappa_j)^2}{\kappa_j(\kappa_j - 1)} \sum_{i' < i \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top. \tag{78}$$

In the following, we omit superscript/subscript j for brevity. With a slight abuse of notation, we use $\mathbb{1}_{\{\Omega^{-1}(i)=a\}} = 1$ if item i is ranked at the a -th position in all the orderings $\sigma \in \Omega$. Let $\mathbb{P}[\theta]$ be the likelihood of observing $\Omega^{-1}(p) = i^{(p)}$ and the set Λ (the set of the items that are ranked before the p -th position). We have,

$$\mathbb{P}(\theta) = \sum_{\sigma \in \Omega} \left(\frac{\exp(\sum_{m=1}^p \theta_{\sigma(m)})}{\prod_{\sigma=1}^p \left(\sum_{m'=a}^{\kappa} \exp(\theta_{\sigma(m')}) \right)} \right). \tag{79}$$

For $i, i' \in S_j$, we have

$$H_{i'i'}(\theta) = \frac{1}{\mathbb{P}(\theta)} \frac{\partial^2 \mathbb{P}(\theta)}{\partial \theta_i \partial \theta_{i'}} - \frac{\nabla_i \mathbb{P}(\theta) \nabla_{i'} \mathbb{P}(\theta)}{(\mathbb{P}(\theta))^2} \tag{80}$$

We claim that at $\theta = \mathbf{0}$,

$$-H_{i'i'}(\mathbf{0}) = \begin{cases} C_1 & \text{if } i = i', \{\Omega^{-1}(i) \geq p\} \\ C_2 + A_3^2 - C_3 & \text{if } i = i', \{\Omega^{-1}(i) < p\} \\ -B_1 & \text{if } i \neq i', \{\Omega^{-1}(i) \geq p, \Omega^{-1}(i') \geq p\} \\ -B_2 & \text{if } i \neq i', \{\Omega^{-1}(i) \geq p, \Omega^{-1}(i') < p\} \\ -B_2 & \text{if } i \neq i', \{\Omega^{-1}(i) < p, \Omega^{-1}(i') \geq p\} \\ -(B_3 + B_4 - A_3^2) & \text{if } i \neq i', \{\Omega^{-1}(i) < p, \Omega^{-1}(i') < p\}. \end{cases} \tag{81}$$

where constants $A_3, B_1, B_2, B_3, B_4, C_1, C_2$ and C_3 are defined in Equations (88), (90), (91), (92), (93), (95), (96) and (97) respectively. From this computation of the Hessian, note that we have

$$H(\mathbf{0}) = \sum_{i' < i \in S} (e_i - e_{i'}) (e_i - e_{i'})^\top (H_{i'i'}(\mathbf{0})). \quad (82)$$

which follows directly from the fact that the diagonal entries are summations of the off-diagonals, i.e. $C_1 = B_1(\kappa - p) + B_2(p - 1)$ and $C_2 + A_3^2 - C_3 = B_2(\kappa - p + 1) + (B_3 + B_4 - A_3^2)(p - 2)$. The second equality follows from the fact that $C_2 = B_2(\kappa - p + 1) + B_3(p - 2)$ and $A_3^2(p - 1) = B_4(p - 2) + C_3$. Note that since $\theta = \mathbf{0}$, all items are exchangeable. Hence, $\mathbb{E}[H_{i'i'}(\mathbf{0})] = \mathbb{E}[H_{i'i'}(\mathbf{0})]/(\kappa - 1)$, and substituting this into (82) and using Equations (81), we get

$$\begin{aligned} & \mathbb{E}[H(\mathbf{0})] \\ &= -\frac{1}{\kappa - 1} \left(\mathbb{P}[\Omega^{-1}(i) \geq p] C_1 + \mathbb{P}[\Omega^{-1}(i) < p] (C_2 + A_3^2 - C_3) \right) \sum_{i' < i \in S} (e_i - e_{i'}) (e_i - e_{i'})^\top \\ &\succeq -\frac{1}{\kappa(\kappa - 1)} \sum_{i' < i \in S} (e_i - e_{i'}) (e_i - e_{i'})^\top \\ &\quad \left((\kappa - p + 1) \log \left(\frac{\kappa}{\kappa - p} \right) + (p - 1) \left(\log \left(\frac{\kappa}{\kappa - p + 1} \right) + \log \left(\frac{\kappa}{\kappa - p + 1} \right)^2 \right) \right) \\ &\succeq -\frac{2p \log(\kappa)^2}{\kappa(\kappa - 1)} \sum_{i' < i \in S} (e_i - e_{i'}) (e_i - e_{i'})^\top, \end{aligned} \quad (83)$$

where (83) uses $\sum_{a=1}^p \frac{1}{\kappa - a + 1} \leq \log \left(\frac{\kappa}{\kappa - p} \right)$ and $C_3 \geq 0$. Equation (84) follows from the fact that for any $x > 0$, $\log(1 + x) \leq x$. To prove (81), we have the first order partial derivative of $\mathbb{P}(\theta)$ given by

$$\nabla_{\theta_i} \mathbb{P}(\theta) = \mathbb{I}_{\{\Omega^{-1}(i) \leq p\}} \mathbb{P}(\theta) - \sum_{\sigma \in \Omega} \left(\frac{\exp \left(\sum_{m=1}^p \theta_{\sigma(m)} \right)}{\prod_{l=1}^{\kappa} \left(\sum_{m'=a}^{\kappa} \exp \left(\theta_{\sigma(m')} \right) \right)} \right) \left(\sum_{a=1}^p \frac{\mathbb{I}_{\{\sigma^{-1}(i) \geq a\}} \exp(\theta_i)}{\sum_{m'=a}^{\kappa} \exp \left(\theta_{\sigma(m')} \right)} \right) \quad (85)$$

Define constants A_1, A_2 and A_3 such that

$$A_1 \equiv \mathbb{P}(\theta) \Big|_{\{\theta=0\}} = \frac{(p-1)!}{\kappa(\kappa-1) \cdots (\kappa-p+1)}, \quad (86)$$

$$A_2 \equiv \left(\sum_{a=1}^p \frac{\exp(\theta_i)}{\sum_{m'=a}^{\kappa} \exp \left(\theta_{\sigma(m')} \right)} \right) \Big|_{\{\theta=0\}} = \left(\frac{1}{\kappa} + \frac{1}{\kappa-1} + \cdots + \frac{1}{\kappa-p+1} \right), \quad (87)$$

$$A_3 \equiv \left(\frac{(p-1)(p-2)!}{(p-1)!(\kappa)} + \frac{(p-2)(p-2)!}{(p-1)!(\kappa-1)} + \cdots + \frac{(p-2)!}{(p-1)!(\kappa-p+2)} \right). \quad (88)$$

Observe that, for all $i \in [d]$,

$$\nabla_{\theta_i} \mathbb{P}(\theta) \Big|_{\{\theta=0\}} = A_1 \left(\mathbb{I}_{\{\Omega_j^{-1}(i)=p\}} (1 - A_2) + \mathbb{I}_{\{\Omega_j^{-1}(i)<p\}} (1 - A_3) - \mathbb{I}_{\{\Omega_j^{-1}(i)>p\}} A_2 \right). \quad (89)$$

Further define constants B_1, B_2, B_3 and B_4 such that

$$B_1 \equiv \left(\frac{1}{\kappa^2} + \frac{1}{(\kappa-1)^2} + \cdots + \frac{1}{(\kappa-p+1)^2} \right), \quad (90)$$

$$B_2 \equiv \left(\frac{p-1}{(p-1)\kappa^2} + \frac{p-2}{(p-1)(\kappa-1)^2} + \cdots + \frac{1}{(p-1)(\kappa-p+2)^2} \right), \quad (91)$$

$$B_3 \equiv \left(\frac{(p-1)(p-2)(p-3)!}{(p-1)!\kappa^2} + \frac{(p-2)(p-3)(p-3)!}{(p-1)!(\kappa-1)^2} + \cdots + \frac{2(p-3)!}{(p-1)!(\kappa-p+3)^2} \right), \quad (92)$$

$$B_4 \equiv \frac{(p-3)!}{(p-1)!} \left(\sum_{a,b \in [p-1], b \neq a} \left(\frac{1}{\kappa} + \frac{1}{\kappa-1} + \cdots + \frac{1}{\kappa-a+1} \right) \left(\frac{1}{\kappa} + \frac{1}{\kappa-1} + \cdots + \frac{1}{\kappa-b+1} \right) \right) \quad (93)$$

Observe that,

$$\begin{aligned} & \frac{\partial^2 \mathbb{P}(\theta)}{\partial \theta_i^2} \Big|_{\theta=0} \\ &= \mathbb{I}_{\{\Omega^{-1}(i), \Omega^{-1}(i') > p\}} A_1 \left((-A_2) (-A_2) + B_1 \right) \\ &\quad + \left(\mathbb{I}_{\{\Omega^{-1}(i) > p, \Omega^{-1}(i') = p\}} + \mathbb{I}_{\{\Omega^{-1}(i) = p, \Omega^{-1}(i') > p\}} \right) A_1 \left((-A_2)(1 - A_2) + B_1 \right) \\ &\quad + \left(\mathbb{I}_{\{\Omega^{-1}(i) = p, \Omega^{-1}(i') < p\}} + \mathbb{I}_{\{\Omega^{-1}(i) < p, \Omega^{-1}(i') = p\}} \right) A_1 \left((1 - A_3) + (-A_2)(1 - A_3) + B_2 \right) \\ &\quad + \left(\mathbb{I}_{\{\Omega^{-1}(i) > p, \Omega^{-1}(i') < p\}} + \mathbb{I}_{\{\Omega^{-1}(i) < p, \Omega^{-1}(i') > p\}} \right) A_1 \left((-A_2)(1 - A_3) + B_2 \right) \\ &\quad + \mathbb{I}_{\{\Omega^{-1}(i) < p, \Omega^{-1}(i') < p\}} A_1 \left((1 - A_3) + (-A_3) + B_4 + B_3 \right). \end{aligned} \quad (94)$$

The claims in (81) are easy to verify by combining Equations (89) and (94) with (80). Also, define constants C_1, C_2 and C_3 such that,

$$C_1 \equiv \left(\frac{\kappa-1}{(\kappa)^2} + \frac{\kappa-2}{(\kappa-1)^2} + \cdots + \frac{\kappa-p}{(\kappa-p+1)^2} \right), \quad (95)$$

$$C_2 \equiv \left(\frac{(p-1)(p-2)(\kappa-1)}{(p-1)!(\kappa)^2} + \frac{(p-2)(p-2)(\kappa-2)}{(p-1)!(\kappa-1)^2} + \cdots + \frac{(p-2)(\kappa-p+1)}{(p-1)!(\kappa-p+2)^2} \right), \quad (96)$$

$$C_3 \equiv \frac{(p-2)!}{(p-1)!} \left(\sum_{a,b \in [p-1], b \neq a} \left(\frac{1}{\kappa} + \frac{1}{\kappa-1} + \cdots + \frac{1}{\kappa-a+1} \right) \left(\frac{1}{\kappa} + \frac{1}{\kappa-1} + \cdots + \frac{1}{\kappa-b+1} \right) \right) \quad (97)$$

such that,

$$\begin{aligned} & \frac{\partial^2 \mathbb{P}(\theta)}{\partial \theta_i^2} \Big|_{\theta=0} \\ &= \mathbb{I}_{\{\Omega^{-1}(i) > p\}} A_1 \left((-A_2) (-A_2) - C_1 \right) + \mathbb{I}_{\{\Omega^{-1}(i) = p\}} A_1 \left((1 - A_2) - A_2(1 - A_2) - C_1 \right) \\ &\quad + \mathbb{I}_{\{\Omega^{-1}(i) < p\}} A_1 \left((1 - A_3) - A_3 - C_2 + C_3 \right). \end{aligned} \quad (98)$$

The claims (81) is easy to verify by combining Equations (89) and (98) with (80).

8.4 Proof of Theorem 5

The proof is analogous to the proof of Theorem 8. It differs primarily in the lower bound that is achieved for the second smallest eigenvalue of the Hessian matrix $H(\theta)$, (35).

Lemma 17. *Under the hypotheses of Theorem 5, if $\sum_{j=1}^n \ell_j \geq (2^{12} e^{6b} / \beta \alpha^2) d \log d$ then with probability at least $1 - d^{-3}$,*

$$\lambda_2(-H(\theta)) \geq \frac{\alpha}{2(1 + e^{2b})^2} \frac{1}{d-1} \sum_{j=1}^n \ell_j. \quad (99)$$

Using Lemma 10 that is derived for the general value of $\lambda_{j,a}$ and $p_{j,a}$, and by substituting $\lambda_{j,a} = 1/(\kappa_j - 1)$ and $p_{j,a} = a$ for each $j \in [n]$, we get that with probability at least $1 - 2e^{\alpha} d^{-3}$,

$$\|\nabla \mathcal{L}_{\text{RB}}(\theta^*)\|_2 \leq \sqrt{16 \log d \sum_{j=1}^n \ell_j}. \quad (100)$$

Theorem 5 follows from Equations (100), (99) and (40).

8.4.1 PROOF OF LEMMA 17

Define $M^{(j)} \in \mathbb{S}^d$ as

$$M^{(j)} = \frac{1}{\kappa_j - 1} \sum_{i < i' \in S_j} \mathbb{1}_{\{(i,i') \in G_{j,a}\}} (e_i - e_{i'})(e_i - e_{i'})^\top, \quad (101)$$

and let $M = \sum_{j=1}^n M^{(j)}$. Similar to the analysis carried out in the proof of Lemma 11, we have $\lambda_2(-H(\theta)) \geq \frac{e^{2b}}{(1+e^{2b})^2} \lambda_2(M)$, when $\lambda_{j,a} = 1/(\kappa_j - 1)$ is substituted in the Hessian matrix $H(\theta)$, Equation (35). From Weyl's inequality we have that

$$\lambda_2(M) \geq \lambda_2(\mathbb{E}[M]) - \|M - \mathbb{E}[M]\|. \quad (102)$$

We will show in (107) that $\lambda_2(\mathbb{E}[M]) \geq e^{-2b}(\alpha/(d-1)) \sum_{j=1}^n \ell_j$ and in (112) that $\|M - \mathbb{E}[M]\| \leq 32e^b \sqrt{\frac{\log d}{\beta d} \sum_{j=1}^n \ell_j}$.

$$\lambda_2(M) \geq \frac{\alpha e^{-2b}}{d-1} \sum_{j=1}^n \ell_j - 32e^b \sqrt{\frac{\log d}{\beta d} \sum_{j=1}^n \ell_j} \geq \frac{\alpha e^{-2b}}{2(d-1)} \sum_{j=1}^n \ell_j, \quad (103)$$

where the last inequality follows from the assumption that $\sum_{j=1}^n \ell_j \geq (2^{12} e^{6b} / \beta \alpha^2) d \log d$. This proves the desired claim.

To prove the lower bound on $\lambda_2(\mathbb{E}[M])$, notice that

$$\mathbb{E}[M] = \sum_{j=1}^n \frac{1}{\kappa_j - 1} \sum_{i < i' \in S_j} \mathbb{E} \left[\sum_{\alpha=1}^{\ell_j} \mathbb{1}_{\{(i,i') \in G_{j,a}\}} \right] (e_i - e_{i'})(e_i - e_{i'})^\top. \quad (104)$$

Using the fact that $p_{j,a} = a$ for each $j \in [n]$, and the definition of rank-breaking graph $G_{j,a}$, we have that

$$\begin{aligned} \mathbb{E} \left[\sum_{\alpha=1}^{\ell_j} \mathbb{1}_{\{(i,i') \in G_{j,a}\}} \right] (i, i' \in S_j) &= \mathbb{P} \left[\mathbb{1}_{\{\sigma_j^{-1}(i) \leq \ell_j\}} + \mathbb{1}_{\{\sigma_j^{-1}(i') \leq \ell_j\}} \geq 1 \mid (i, i' \in S_j) \right] \\ &\geq \mathbb{P} \left[(\sigma^{-1}(i) \leq \ell_j) \mid (i, i' \in S_j) \right]. \end{aligned} \quad (105)$$

The following lemma provides a lower bound on $\mathbb{P}[(\sigma^{-1}(i) \leq \ell_j) \mid (i, i' \in S_j)]$.

Lemma 18. *Consider a ranking σ over a set of items S of size κ . For any item $i \in S$,*

$$\mathbb{P}[(\sigma^{-1}(i) \leq \ell] \geq e^{-2b} \frac{\ell}{\kappa}. \quad (106)$$

Therefore, using the fact that $(e_i - e_{i'})(e_i - e_{i'})^\top$ is positive semi-definite, and Equations (104), (105) and (106) we have

$$\mathbb{E}[M] \succeq e^{-2b} \sum_{j=1}^n \frac{\ell_j}{\kappa_j(\kappa_j - 1)} \sum_{i < i' \in S_j} (e_i - e_{i'})(e_i - e_{i'})^\top = e^{-2b} L, \quad (107)$$

where L is the Laplacian defined for the comparison graph \mathcal{H} , Definition 1. Using $\lambda_2(L) = (\alpha/(d-1)) \sum_{j=1}^n \ell_j$ from (5), we get the desired bound $\lambda_2(\mathbb{E}[M]) \geq e^{-2b}(\alpha/(d-1)) \sum_{j=1}^n \ell_j$.

For top- ℓ_j rank breaking, $M^{(j)}$ is also given by

$$M^{(j)} = \frac{1}{\kappa_j - 1} \left((\kappa_j - \ell_j) \text{diag}(e_{\{I_j\}}) + \ell_j \text{diag}(e_{\{S_j\}}) - e_{\{I_j\}} e_{\{S_j\}}^\top - e_{\{S_j\}} e_{\{I_j\}}^\top \right), \quad (108)$$

where $e_{\{S_j\}}, e_{\{I_j\}} \in \mathbb{R}^d$ are zero-one vectors, $e_{\{S_j\}}$ has support corresponding to the set of items S_j and $e_{\{I_j\}}$ has support corresponding to the random top- ℓ_j items in the ranking σ_j . $I_j = \{\sigma_j(1), \sigma_j(2), \dots, \sigma_j(\ell_j)\}$ for $j \in [n]$. $(M^{(j)})^2$ is given by

$$\begin{aligned} (M^{(j)})^2 &= \frac{1}{(\kappa_j - 1)^2} \left((\kappa_j^2 - \ell_j^2) \text{diag}(e_{\{I_j\}}) + \ell_j^2 \text{diag}(e_{\{S_j\}}) - \right. \\ &\quad \left. (\kappa_j + \ell_j)(e_{\{I_j\}} e_{\{S_j\}}^\top + e_{\{S_j\}} e_{\{I_j\}}^\top) - e_{\{I_j\}} e_{\{I_j\}}^\top - e_{\{I_j\}} e_{\{S_j\}}^\top - e_{\{S_j\}} e_{\{I_j\}}^\top \right). \end{aligned}$$

Note that $\mathbb{P}[i \in I_j \mid i \in S_j] \leq \ell_j e^{2b} / \kappa_j$ for all $i \in S_j$. Its proof is similar to the proof of Lemma 18. Therefore, we have $\mathbb{E}[\text{diag}(e_{\{I_j\}})] \preceq \ell_j e^{2b} / \kappa_j \text{diag}(e_{\{I\}})$. To bound $\|\sum_{j=1}^n \mathbb{E}[(M^{(j)})^2]\|$, we use the fact that for $J \in \mathbb{R}^{d \times d}$, $\|J\| \leq \max_{i \in [d]} \sum_{i'=1}^d |J_{i'i'}|$. Maximum of row sums of $\mathbb{E}[e_{\{I_j\}} e_{\{I_j\}}^\top]$ is upper

bounded by $\max_{i \in [d]} \{\ell_j \mathbb{P}[i \in I_j | i \in S_j]\} \leq \ell_j e^{2b} / \kappa_j$. Therefore using triangle inequality, we have,

$$\begin{aligned}
& \left\| \sum_{j=1}^n \mathbb{E}[(M^{(j)})^2] \right\| \\
& \leq \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \frac{1}{(\kappa_j - 1)^2} \left(\frac{(\kappa_j^2 - \ell_j^2) \ell_j e^{2b}}{\kappa_j} + \ell_j^2 + e^{2b} (\kappa_j + \ell_j) (2\ell_j + \ell_j^2 / \kappa_j) + \ell_j \kappa_j \right) \right\} \\
& \leq \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \frac{\ell_j e^{2b}}{\kappa_j} \left(\frac{(\kappa_j^2 - \ell_j^2)}{(\kappa_j - 1)^2} + \frac{\ell_j \kappa_j}{(\kappa_j - 1)^2} + \frac{2(\kappa_j + \ell_j) \kappa_j}{(\kappa_j - 1)^2} + \frac{(\kappa_j + \ell_j) \ell_j}{(\kappa_j - 1)^2} + \frac{\kappa_j^2}{(\kappa_j - 1)^2} \right) \right\} \\
& \leq \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \frac{\ell_j e^{2b}}{\kappa_j} \left(\frac{(\kappa_j^2 - 1)}{(\kappa_j - 1)^2} + \frac{\kappa_j (\kappa_j - 1)}{(\kappa_j - 1)^2} + \frac{4\kappa_j^2}{(\kappa_j - 1)^2} + \frac{2\kappa_j (\kappa_j - 1)}{(\kappa_j - 1)^2} + \frac{\kappa_j^2}{(\kappa_j - 1)^2} \right) \right\} \\
& \leq \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \frac{\ell_j e^{2b}}{\kappa_j} \left(3 + 2 + 16 + 4 + 4 \right) \right\} \\
& \leq 29e^{2b} \max_{i \in [d]} \left\{ \sum_{j: i \in S_j} \frac{\ell_j}{\kappa_j} \right\} \\
& = 29e^{2b} D_{\max} \\
& = \frac{29e^{2b}}{\beta d} \sum_{j=1}^n \ell_j,
\end{aligned} \tag{110}$$

where (109) uses the fact that $\kappa_j \geq 2$ and $1 \leq \ell_j \leq \kappa_j - 1$ for all $j \in [n]$. (110) follows from the definition of D_{\max} , Definition 1 and (111) follows from the Equation (6). Also, note that $\|M_j\| \leq 2$ for all $j \in [n]$. Applying matrix Bernstein inequality, we have,

$$\mathbb{P} \left[\|M - \mathbb{E}[M]\| \geq t \right] \leq d \exp \left(\frac{-t^2/2}{\frac{29e^{2b}}{\beta d} \sum_{j=1}^n \ell_j + 4t/3} \right).$$

Therefore, with probability at least $1 - d^{-3}$, we have,

$$\|M - \mathbb{E}[M]\| \leq 22e^b \sqrt{\frac{\log d}{\beta d} \sum_{j=1}^n \ell_j} + \frac{64 \log d}{3} \leq 32e^b \sqrt{\frac{\log d}{\beta d} \sum_{j=1}^n \ell_j}, \tag{112}$$

where the second inequality follows from the assumption that $\sum_{j=1}^n \ell_j \geq 2^{12} d \log d$ and $\beta \leq 1$.

8.4.2 PROOF OF LEMMA 18

Define $i_{\min} \equiv \arg \min_{i \in S} \theta_i$. We claim the following. For all $i \in S$ and any $1 \leq \ell \leq |S| - 1$,

$$\mathbb{P}[\sigma^{-1}(i) > \ell] \leq \mathbb{P}[\sigma^{-1}(i_{\min}) > \ell] \text{ and } \mathbb{P}[\sigma^{-1}(i_{\min}) = \ell] \geq \mathbb{P}[\sigma^{-1}(i_{\min}) = 1]. \tag{113}$$

Therefore $\mathbb{P}[\sigma^{-1}(i) \leq \ell] \geq \mathbb{P}[\sigma^{-1}(i_{\min}) \leq \ell]$. Using $\mathbb{P}[\sigma^{-1}(i_{\min}) = 1] > e^{-2b} / \kappa$, we get the desired bound $\mathbb{P}[\sigma^{-1}(i) \leq \ell] \geq e^{-2b} \ell / \kappa$.

To prove the claim (113), let $\hat{\sigma}_\ell^i$ denote a ranking of top- ℓ items of the set S and $\mathbb{P}[\hat{\sigma}_\ell^i]$ be the probability of observing $\hat{\sigma}_\ell^i$. Let $i \in (\hat{\sigma}_\ell^i)^{-1}$ denote that $i = (\hat{\sigma}_\ell^i)^{-1}(j)$ for some $1 \leq j \leq \ell$. Let

$$\Omega_1 = \left\{ \hat{\sigma}_\ell^i : i \notin (\hat{\sigma}_\ell^i)^{-1}, i_{\min} \in (\hat{\sigma}_\ell^i)^{-1} \right\} \text{ and } \Omega_2 = \left\{ \hat{\sigma}_\ell^i : i \in (\hat{\sigma}_\ell^i)^{-1}, i_{\min} \notin (\hat{\sigma}_\ell^i)^{-1} \right\}.$$

We have $\mathbb{P}[\sigma^{-1}(i) > \ell] = \mathbb{P}[\sigma^{-1}(i_{\min}) > \ell] = \sum_{\hat{\sigma}_\ell^i \in \Omega_1} \mathbb{P}[\hat{\sigma}_\ell^i] - \sum_{\hat{\sigma}_\ell^i \in \Omega_2} \mathbb{P}[\hat{\sigma}_\ell^i]$. Now, take any ranking $\hat{\sigma}_\ell^i \in \Omega_1$ and construct another ranking $\hat{\sigma}_\ell^i$ from $\hat{\sigma}_\ell^i$ by replacing i_{\min} with i -th item. Observe that $\mathbb{P}[\hat{\sigma}_\ell^i] \leq \mathbb{P}[\hat{\sigma}_\ell^i]$ and $\hat{\sigma}_\ell^i \in \Omega_2$. Moreover, such a construction gives a bijective mapping between Ω_1 and Ω_2 . Hence, the first claim is proved. For the second claim, let

$$\hat{\Omega}_1 = \left\{ \hat{\sigma}_\ell^i : (\hat{\sigma}_\ell^i)^{-1}(i_{\min}) = 1 \right\} \text{ and } \hat{\Omega}_2 = \left\{ \hat{\sigma}_\ell^i : (\hat{\sigma}_\ell^i)^{-1}(i_{\min}) = \ell \right\}.$$

We have $\mathbb{P}[\sigma^{-1}(i_{\min}) = 1] = \mathbb{P}[\sigma^{-1}(i_{\min}) = 1] = \sum_{\hat{\sigma}_\ell^i \in \hat{\Omega}_1} \mathbb{P}[\hat{\sigma}_\ell^i] - \sum_{\hat{\sigma}_\ell^i \in \hat{\Omega}_2} \mathbb{P}[\hat{\sigma}_\ell^i]$. Now, take any ranking $\hat{\sigma}_\ell^i \in \hat{\Omega}_1$ and construct another ranking $\hat{\sigma}_\ell^i$ from $\hat{\sigma}_\ell^i$ by swapping items at 1st position and ℓ -th position. Observe that $\mathbb{P}[\hat{\sigma}_\ell^i] \leq \mathbb{P}[\hat{\sigma}_\ell^i]$ and $\hat{\sigma}_\ell^i \in \hat{\Omega}_2$. Moreover, such a construction gives a bijective mapping between $\hat{\Omega}_1$ and $\hat{\Omega}_2$. Hence, the claim is proved.

8.5 Proof of Theorem 6

The first order partial derivative of $\mathcal{L}(\theta)$, Equation (15), is given by

$$\begin{aligned}
& \nabla_i \mathcal{L}(\theta) \\
& = \sum_{j: i \in S_j} \sum_{m=1}^{\ell_j} \mathbb{I}_{\{\sigma_j^{-1}(i) \geq m\}} \left[\frac{\mathbb{I}_{\{\sigma_j(m)=i\}}}{\exp(\theta_{\sigma_j(m)}) + \exp(\theta_{\sigma_j(m+1)}) + \dots + \exp(\theta_{\sigma_j(\kappa_j)})} \right], \forall i \in [d]
\end{aligned}$$

and the Hessian matrix $H(\theta) \in S^d$ with $H_{ir}(\theta) = \frac{\partial^2 \mathcal{L}(\theta)}{\partial \theta_i \partial \theta_r}$ is given by

$$\begin{aligned}
H(\theta) &= - \sum_{j=1}^n \sum_{i < r \in S_j} (e_i - e_r)(e_i - e_r)^\top \sum_{m=1}^{\ell_j} \frac{\exp(\theta_i + \theta_r) \mathbb{I}_{\{\sigma_j^{-1}(i), \sigma_j^{-1}(r) \geq m\}}}{[\exp(\theta_{\sigma_j(m)}) + \exp(\theta_{\sigma_j(m+1)}) + \dots + \exp(\theta_{\sigma_j(\kappa_j)})]^2}.
\end{aligned} \tag{114}$$

It follows from the definition that $-H(\theta)$ is positive semi-definite for any $\theta \in \mathbb{R}^n$.

The Fisher information matrix is defined as $I(\theta) = -\mathbb{E}_\theta[H(\theta)]$ and given by

$$I(\theta) = \sum_{j=1}^n \sum_{i < r \in S_j} (e_i - e_r)(e_i - e_r)^\top \sum_{m=1}^{\ell_j} \mathbb{E} \left[\frac{\mathbb{I}_{\{\sigma_j^{-1}(i), \sigma_j^{-1}(r) \geq m\}}}{[\exp(\theta_{\sigma_j(m)}) + \dots + \exp(\theta_{\sigma_j(\kappa_j)})]^2} \right] \exp(\theta_i + \theta_r).$$

Since $-H(\theta)$ is positive semi-definite, it follows that $I(\theta)$ is positive semi-definite. Moreover, $\lambda_1(I(\theta))$ is zero and the corresponding eigenvector is the all-ones vector. Fix any unbiased estimator $\hat{\theta}$ of $\theta \in \Omega_n$. Since, $\hat{\theta} \in \mathcal{U}$, $\hat{\theta} - \theta$ is orthogonal to $\mathbf{1}$. The Cramér-Rao lower bound then implies that $\mathbb{E}[\|\hat{\theta} - \theta\|^2] \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\hat{\theta}))}$. Taking the supremum over both sides gives

$$\sup_{\hat{\theta}} \mathbb{E}[\|\hat{\theta} - \theta\|^2] \geq \sup_{\hat{\theta}} \sum_{i=2}^d \frac{1}{\lambda_i(I(\hat{\theta}))} \geq \sum_{i=2}^d \frac{1}{\lambda_i(I(\mathbf{0}))}.$$

If θ equals the all-zero vector, then

$$\mathbb{P}_\theta[\sigma_j^{-1}(i), \sigma_j^{-1}(i') \geq m] = \frac{\binom{\kappa_j - m + 1}{2}}{\binom{\kappa_j}{2}} = \frac{(\kappa_j - m + 1)(\kappa_j - m)}{\kappa_j(\kappa_j - 1)}.$$

It follows from the definition that

$$\begin{aligned} I(0) &= \sum_{j=1}^n \sum_{i < i' \in S_j} (e_i - e_{i'})^T \sum_{m=1}^{\ell_j} \frac{(\kappa_j - m)}{\kappa_j(\kappa_j - 1)(\kappa_j - m + 1)} \\ &\leq \ell \left(1 - \sum_{m=1}^{\ell_j} \frac{1}{\kappa_{\max} - m + 1} \right) \underbrace{\sum_{j=1}^n \frac{1}{\kappa_j(\kappa_j - 1)} \sum_{i < i' \in S_j} (e_i - e_{i'})^T}_{=L}, \end{aligned}$$

where L is the Laplacian defined for the comparison graph \mathcal{H} , Definition 1. By Jensen's inequality, we have

$$\sum_{i=2}^d \lambda_i(L) \geq \frac{(d-1)^2}{\sum_{i=2}^d \lambda_i(L)} = \frac{(d-1)^2}{\text{Tr}(L)} = \frac{(d-1)^2}{n}.$$

8.6 Proof of Theorem 7

We prove a slightly more general result that implies the desired theorem. For $\ell \geq 4$, we can choose $\beta_1 = 1/2$. Then, the condition that $\gamma_{\beta_1} \leq 1$ implies $\bar{d} \leq (\ell/2 + 1)(d-2)/(\kappa-2)$, which implies $\bar{d} \leq \ell d/(2\kappa)$. With the choice of $\bar{d} = \ell d/(2\kappa)$, this implies Theorem 7.

Theorem 19. *Under the bottom- ℓ separators scenario and the PL model, n partial orderings are sampled over d items parametrized by $\theta^* \in \Omega_b$. For any β_1 with $0 \leq \beta_1 \leq \frac{\ell-2}{\ell}$, define*

$$\gamma_{\beta_1} \equiv \frac{\bar{d}(\kappa-2)}{(\lfloor \ell \beta_1 \rfloor + 1)(d-2)}, \quad (115)$$

and for $\gamma_{\beta_1} \leq 1$,

$$\chi_{\beta_1} \equiv (1 - \lfloor \ell \beta_1 \rfloor / \ell)^2 \left(1 - \exp \left(- \frac{(\lfloor \ell \beta_1 \rfloor + 1)^2 (1 - \gamma_{\beta_1})^2}{2(\kappa-2)} \right) \right). \quad (116)$$

If

$$n\ell \geq \left(\frac{2^{12} e^{8b} d^2 \kappa}{\chi_{\beta_1}^2 \bar{d}^2 \ell} \right) d \log d, \quad (117)$$

then the rank-breaking estimator in (18) achieves

$$\frac{1}{\sqrt{\bar{d}}} \|\hat{\theta} - \tilde{\theta}^*\|_2 \leq \frac{32\sqrt{2}(1 + e^{4b})^2 d^{3/2}}{\chi_{\beta_1}} \frac{d^{3/2}}{\bar{d}^{3/2}} \sqrt{\frac{d \log d}{n\ell}}, \quad (118)$$

with probability at least $1 - 3e^3 d^{-3}$.

Proof is very similar to the proof of Theorem 8. It mainly differs in the lower bound that is achieved for the second smallest eigenvalue of the Hessian matrix $H(\tilde{\theta})$ of $\mathcal{L}_{\text{RB}}(\tilde{\theta})$, Equation (17). Equation (17) can be rewritten as

$$\mathcal{L}_{\text{RB}}(\tilde{\theta}) = \sum_{j=1}^n \sum_{\alpha=1}^{\ell} \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,\alpha}\}} \lambda_{j,\alpha} \left(\tilde{\theta}_i \mathbb{I}_{\{\sigma_j^{-1}(i) < \sigma_j^{-1}(i')\}} + \tilde{\theta}_{i'} \mathbb{I}_{\{\sigma_j^{-1}(i) > \sigma_j^{-1}(i')\}} - \log \left(e^{\tilde{\theta}_i} + e^{\tilde{\theta}_{i'}} \right) \right), \quad (119)$$

where $(i, i') \in G_{j,\alpha}$ implies either (i, i') or (i', i) belong to $E_{j,\alpha}$. The Hessian matrix $H(\tilde{\theta}) \in \mathcal{S}^{\bar{d}}$ with $H_{i,i'}(\tilde{\theta}) = \frac{\partial^2 \mathcal{L}_{\text{RB}}(\tilde{\theta})}{\partial \tilde{\theta}_i \partial \tilde{\theta}_{i'}}$ is given by

$$H(\tilde{\theta}) = - \sum_{j=1}^n \sum_{\alpha=1}^{\ell} \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,\alpha}\}} \left((\tilde{e}_i - \tilde{e}_{i'}) (\tilde{e}_i - \tilde{e}_{i'})^T \frac{\exp(\tilde{\theta}_i) + \tilde{\theta}_{i'}}{[\exp(\tilde{\theta}_i) + \exp(\tilde{\theta}_{i'})]^2} \right). \quad (120)$$

The following lemma gives a lower bound for $\lambda_2(-H(\tilde{\theta}))$.

Lemma 20. *Under the hypothesis of Theorem 19, with probability at least $1 - d^{-3}$,*

$$\lambda_2(-H(\tilde{\theta})) \geq \frac{\chi_{\beta_1}}{8(1 + e^{4b})^2} \frac{n\bar{d}\ell^2}{d^2}. \quad (121)$$

Observe that although $\tilde{\theta}^* \in \mathbb{R}^{\bar{d}}$, Lemma 10 can be directly applied to upper bound $\|\nabla \mathcal{L}_{\text{RB}}(\tilde{\theta}^*)\|_2$. It might be possible to tighten the upper bound, given that $\bar{d} \leq d$. However, for $\ell \ll \kappa$, for the smallest preference score item, $i_{\min} \equiv \arg \min_{i \in [d]} \theta_i^*$, the upper bound $\mathbb{P}[\sigma^{-1}(i_{\min}) > \kappa - \ell] \leq 1$ is tight upto constant factor (Lemma 15). Substituting $\lambda_{j,\alpha} = 1$ and $p_{j,\alpha} = \kappa - \ell + a$ for each $j \in [n]$, $a \in [d]$, in Lemma 10, we have that with probability at least $1 - 2e^3 d^{-3}$,

$$\|\nabla \mathcal{L}_{\text{RB}}(\tilde{\theta}^*)\|_2 \leq (\ell - 1) \sqrt{8n\ell \log d}. \quad (122)$$

Theorem 19 follows from Equations (40), (121) and (122).

8.6.1 PROOF OF LEMMA 20

Define $\tilde{M}^{(j)} \in \mathcal{S}^{\bar{d}}$,

$$\tilde{M}^{(j)} = \sum_{i < i' \in S_j} \mathbb{I}_{\{(i, i') \in G_{j,\alpha}\}} (\tilde{e}_i - \tilde{e}_{i'}) (\tilde{e}_i - \tilde{e}_{i'})^T, \quad (123)$$

and let $\tilde{M} = \sum_{j=1}^n \tilde{M}^{(j)}$. Similar to the analysis in Lemma 11, we have $\lambda_2(-H(\tilde{\theta})) \geq \frac{e^{4b}}{(1 + e^{4b})^2} \lambda_2(\tilde{M})$. Note that we have e^{4b} instead of e^{2b} as $\tilde{\theta} \in \tilde{\Omega}_{2b}$. We will show a lower bound on $\lambda_2(\mathbb{E}[\tilde{M}])$ in (129) and an upper bound on $\|\tilde{M} - \mathbb{E}[\tilde{M}]\|$ in (133). Therefore using $\lambda_2(\tilde{M}) \geq \lambda_2(\mathbb{E}[\tilde{M}]) - \|\tilde{M} - \mathbb{E}[\tilde{M}]\|$,

$$\lambda_2(\tilde{M}) \geq \frac{e^{-4b}}{4} \underbrace{(1 - \beta_1)^2 \left(1 - \exp \left(- \frac{(\lfloor \ell \beta_1 \rfloor + 1)^2 (1 - \gamma_{\beta_1})^2}{2(\kappa-2)} \right) \right)}_{\equiv \chi_{\beta_1}} \frac{n\bar{d}\ell^2}{d^2} - 8\ell \sqrt{\frac{n\kappa \log d}{d}}. \quad (124)$$

The desired claim follows from the assumption that $n\ell \geq \left(\frac{2^{12}e^{8\kappa}}{\chi_{\beta_1}^2} \frac{\ell^2 \kappa}{d^2}\right) d \log d$, where χ_{β_1} is defined in (117). To prove the lower bound on $\lambda_2(\mathbb{E}[\widetilde{M}])$, notice that

$$\mathbb{E}[\widetilde{M}] = \sum_{j=1}^n \sum_{i, i' \in [\bar{d}]} \mathbb{E} \left[\sum_{\alpha=1}^{\ell} \mathbb{I}_{\{i, i' \in G_{j,\alpha}\}} \left| (i, i' \in S_j) \right. \right] \mathbb{P} \left[i, i' \in S_j \right] (\tilde{c}_i - \tilde{c}_{i'}) (\tilde{c}_i - \tilde{c}_{i'})^\top. \quad (125)$$

Since the sets S_j are chosen uniformly at random, $\mathbb{P}[i, i' \in S_j] = \kappa(\kappa - 1)/d(d - 1)$. Using the fact that $p_{j,\alpha} = \kappa - \ell + a$ for each $j \in [n]$, and the definition of rank breaking graph $G_{j,\alpha}$, we have that

$$\mathbb{E} \left[\sum_{\alpha=1}^{\ell} \mathbb{I}_{\{i, i' \in G_{j,\alpha}\}} \left| (i, i' \in S_j) \right. \right] = \mathbb{P} \left[(\sigma_j^{-1}(i), \sigma_j^{-1}(i')) > \kappa - \ell \mid (i, i' \in S_j) \right]. \quad (126)$$

The following lemma provides a lower bound on $\mathbb{P}[(\sigma_j^{-1}(i), \sigma_j^{-1}(i')) > \kappa - \ell \mid (i, i' \in S_j)]$.

Lemma 21. *Under the hypotheses of Theorem 19, for any two items $i, i' \in [\bar{d}]$, the following holds:*

$$\mathbb{P} \left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell \mid i, i' \in S \right] \geq \frac{e^{-4b}(1 - \beta_1)^2(1 - \exp(-\eta_{\beta_1}(1 - \gamma_{\beta_1})^2))}{2} \frac{\ell^2}{\kappa^2}, \quad (127)$$

where $\gamma_{\beta_1} \equiv \bar{d}(\kappa - 2)/(\lfloor \ell \beta_1 \rfloor + 1)(d - 2)$ and $\eta_{\beta_1} \equiv (\lfloor \ell \beta_1 \rfloor + 1)^2/2(\kappa - 2)$.

Therefore, using Equations (125), (126) and (127) we have,

$$\mathbb{E}[\widetilde{M}] \succeq \frac{e^{-4b}(1 - \beta_1)^2(1 - \exp(-\eta_{\beta_1}(1 - \gamma_{\beta_1})^2))}{2} \frac{\ell^2 \kappa(\kappa - 1)}{\kappa^2 d(d - 1)} \sum_{j=1}^n \sum_{i, i' \in [\bar{d}]} (\tilde{c}_i - \tilde{c}_{i'}) (\tilde{c}_i - \tilde{c}_{i'})^\top. \quad (128)$$

Define $\tilde{L} = \sum_{j=1}^n \sum_{i, i' \in [\bar{d}]} (\tilde{c}_i - \tilde{c}_{i'}) (\tilde{c}_i - \tilde{c}_{i'})^\top$. We have, $\lambda_1(\tilde{L}) = 0$ and $\lambda_2(\tilde{L}) = \lambda_3(\tilde{L}) = \dots = \lambda_{\bar{d}}(\tilde{L})$. Therefore, using $\lambda_2(\tilde{L}) = \text{Tr}(\tilde{L})/(\bar{d} - 1) = n\bar{d}$. Using the fact that $\mathbb{E}[\widetilde{M}]$ and \tilde{L} are symmetric matrices, we have,

$$\lambda_2(\mathbb{E}[\widetilde{M}]) \geq \frac{e^{-4b}(1 - \beta_1)^2(1 - \exp(-\eta_{\beta_1}(1 - \gamma_{\beta_1})^2))}{4} \frac{n\bar{d}\ell^2}{d^2}. \quad (129)$$

To get an upper bound on $\|\widetilde{M} - \mathbb{E}[\widetilde{M}]\|$, notice that $\widetilde{M}^{(i)}$ is also given by,

$$\widetilde{M}^{(i)} = \ell \text{diag}(\tilde{e}_{i,j}) - \tilde{e}_{i,j} \tilde{e}_{i,j}^\top, \quad (130)$$

where $\tilde{e}_{i,j} \in \mathbb{R}^{\bar{d}}$ is a zero-one vector with support corresponding to the bottom- ℓ subset of items in the ranking σ_j . $I_j = \{\sigma_j(\kappa - \ell + 1), \dots, \sigma_j(\kappa)\}$ for $j \in [n]$. $(\widetilde{M}^{(i)})^2$ is given by

$$(\widetilde{M}^{(i)})^2 = \ell^2 \text{diag}(\tilde{e}_{i,j}) - \ell \tilde{e}_{i,j} \tilde{e}_{i,j}^\top. \quad (131)$$

Using the fact that sets $\{S_j\}_{j \in [n]}$ are chosen uniformly at random and $\mathbb{P}[i \in S_j] \leq 1$, we have $\mathbb{E}[\text{diag}(\tilde{e}_{i,j})] \preceq (\kappa/d) \text{diag}(e_{i,j})$. Maximum of row sums of $\mathbb{E}[\tilde{e}_{i,j}] \tilde{e}_{i,j}^\top$ is upper bounded by

$\ell\kappa/d$. Therefore, from triangle inequality we have $\|\sum_{j=1}^n \mathbb{E}[(\widetilde{M}^{(i)})^2]\| \leq 2n\ell^2\kappa/d$. Also, note that $\|\widetilde{M}^{(i)}\| \leq 2\ell$ for all $j \in [n]$. Applying matrix Bernstein inequality, we have that

$$\mathbb{P} \left[\|\widetilde{M} - \mathbb{E}[\widetilde{M}]\| \geq t \right] \leq d \exp \left(\frac{-t^2/2}{2n\ell^2\kappa/d + 4\ell t/3} \right). \quad (132)$$

Therefore, with probability at least $1 - d^{-3}$, we have,

$$\|\widetilde{M} - \mathbb{E}[\widetilde{M}]\| \leq 4\ell \sqrt{\frac{2n\kappa \log d}{d}} + \frac{64\ell \log d}{3} \leq 8\ell \sqrt{\frac{n\kappa \log d}{d}}, \quad (133)$$

where the second inequality follows from the assumption that $n\ell \geq 2^{12}d \log d$.

8.6.2 PROOF OF LEMMA 21

Without loss of generality, assume that $i' < i$, i.e., $\tilde{\theta}_{i'}^* \leq \tilde{\theta}_i^*$. Define Ω such that $\Omega = \{j : j \in S, j \neq i, i'\}$. For any $\beta_1 \in [0, (\ell - 2)/\ell]$, define event E_{β_1} that occurs if in the randomly chosen set S there are at most $\lfloor \ell \beta_1 \rfloor$ items that have preference scores less than $\tilde{\theta}_{i'}^*$, i.e.,

$$E_{\beta_1} \equiv \left\{ \sum_{j \in \Omega} \mathbb{I}_{\{\tilde{\theta}_j^* > \tilde{\theta}_{i'}^*\}} \leq \lfloor \ell \beta_1 \rfloor \right\}. \quad (134)$$

We have,

$$\begin{aligned} & \mathbb{P} \left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell \mid i, i' \in S \right] \\ & > \mathbb{P} \left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell \mid i, i' \in S; E_{\beta_1} \right] \mathbb{P} \left[E_{\beta_1} \mid i, i' \in S \right] \end{aligned} \quad (135)$$

The following lemma provides a lower bound on $\mathbb{P}[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell \mid i, i' \in S; E_{\beta_1}]$.

Lemma 22. *Under the hypotheses of Lemma 21,*

$$\mathbb{P} \left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell \mid i, i' \in S; E_{\beta_1} \right] \geq \frac{e^{-4b}(1 - \lfloor \ell \beta_1 \rfloor / \ell)^2 \ell^2}{2 \kappa^2}. \quad (136)$$

Next, we provide a lower bound on $\mathbb{P}[E_{\beta_1} \mid i, i' \in S]$. Fix i, i' such that $i, i' \in S$. Selecting a set uniformly at random is probabilistically equivalent to selecting items one at a time uniformly at random without replacement. Without loss of generality, assume that i, i' are the 1st and 2nd pick. Define Bernoulli random variables Y_j for $3 \leq j \leq \kappa$ corresponding to the outcome of the j 'th random pick from the set of $(d - j' - 1)$ items to generate the set Ω such that $Y_j = 1$ if and only if $\tilde{\theta}_j^* > \tilde{\theta}_{i'}^*$.

Recall that $\gamma_{\beta_1} \equiv \bar{d}(\kappa - 2)/(\lfloor \ell \beta_1 \rfloor + 1)(d - 2)$ and $\eta_{\beta_1} \equiv (\lfloor \ell \beta_1 \rfloor + 1)^2/2(\kappa - 2)$. Construct Doob's martingale (Z_2, \dots, Z_κ) from $\{Y_k\}_{3 \leq k \leq \kappa}$ such that $Z_j = \mathbb{E}[\sum_{k=3}^{\kappa} Y_k \mid Y_3, \dots, Y_j]$, for $2 \leq j \leq \kappa$. Observe that, $Z_2 = \mathbb{E}[\sum_{k=3}^{\kappa} Y_k] \leq \frac{(d-2)(\kappa-2)}{d-2} \leq \gamma_{\beta_1}(\lfloor \ell \beta_1 \rfloor + 1)$, where the last inequality follows only if $\tilde{\theta}_{i'}^* > \tilde{\theta}_{i'}^*$.

from the assumption that $i \leq \tilde{d}$. Also, $|Z_{j'} - Z_{j'-1}| \leq 1$ for each j' . Therefore, we have

$$\begin{aligned} \mathbb{P}\left[\sum_{j \in \Omega} \mathbb{1}_{\{\tilde{\theta}_i^* > \tilde{\theta}_{j'}^*\}} \leq \lfloor \ell \beta_1 \rfloor\right] &= \mathbb{P}\left[\sum_{j'=3}^{\kappa} Y_{j'} \leq \lfloor \ell \beta_1 \rfloor\right] \\ &= 1 - \mathbb{P}\left[\sum_{j'=3}^{\kappa} Y_{j'} \geq \lfloor \ell \beta_1 \rfloor + 1\right] \\ &\geq 1 - \mathbb{P}\left[Z_{\kappa-2} - Z_2 \geq (\ell \beta_1 + 1) - \gamma(\lfloor \ell \beta_1 \rfloor + 1)\right] \\ &\geq 1 - \exp\left(-\frac{(\lfloor \ell \beta_1 \rfloor + 1)^2(1 - \gamma_1)^2}{2(\kappa - 2)}\right) \\ &= 1 - \exp\left(-\eta_{\beta_1}(1 - \gamma_{\beta_1})^2\right), \end{aligned} \quad (137)$$

where the inequality follows from the Azuma-Hoeffding bound. Since, the above inequality is true for any fixed $i, i' \in S$, for random indices i, i' we have $\mathbb{P}[E_{\beta_1} \mid i, i' \in S] \geq 1 - \exp(-\eta_{\beta_1}(1 - \gamma_{\beta_1})^2)$. Claim (127) follows by combining Equations (135), (136) and (137).

8.6.3 PROOF OF LEMMA 22

Without loss of generality, assume that $i' < i$, i.e., $\tilde{\theta}_{i'}^* \leq \tilde{\theta}_i^*$. Define $\Omega = \{j : j \in S, j \neq i, i'\}$, and event $E_{\beta_1} = \{i, i' \in S; \sum_{j \in \Omega} \mathbb{1}_{\{\tilde{\theta}_i^* > \tilde{\theta}_j^*\}} \leq \lfloor \ell \beta_1 \rfloor\}$. Since set S is chosen randomly, i, i' and $j \in \Omega$ are random. Throughout this section, we condition on the random indices i, i' and the set Ω such that event E_{β_1} holds. To get a lower bound on $\mathbb{P}[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell]$, define independent exponential random variables $X_j \sim \exp(e^{j'})$ for $j \in S$. Observe that given event E_{β_1} holds, there exists a set $\Omega_1 \subseteq \Omega$ such that

$$\Omega_1 = \left\{j \in S : \tilde{\theta}_i^* \leq \tilde{\theta}_{j'}^*\right\}, \quad (138)$$

and $|\Omega_1| = \kappa - \lfloor \ell \beta_1 \rfloor - 2$. In fact there can be many such sets, and for the purpose of the proof we can choose one such set arbitrarily. Note that $\lfloor \ell \beta_1 \rfloor + 2 \leq \ell$ by assumption on β_1 , so $|\Omega_1| \geq \kappa - \ell$. From the Random Utility Model (RUM) interpretation of the PL model, we know that the PL model is equivalent to ordering the items as per *random cost* of each item drawn from exponential random variable with mean $e^{j'}$. That is, we rank items according to X_j 's such that the lower cost items are ranked higher. From this interpretation, we have that

$$\begin{aligned} \mathbb{P}\left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell\right] &= \mathbb{P}\left[\sum_{j \in \Omega} \mathbb{1}_{\{\min\{X_i, X_{i'}\} > X_j\}} \geq \kappa - \ell\right] \\ &> \mathbb{P}\left[\sum_{j' \in \Omega_1} \mathbb{1}_{\{\min\{X_i, X_{i'}\} > X_{j'}\}} \geq \kappa - \ell\right] \end{aligned} \quad (139)$$

The above inequality follows from the fact that $\Omega_1 \subseteq \Omega$ and $|\Omega_1| \geq \kappa - \ell$. It excludes some of the rankings over the items of the set S that constitute the event $\{\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell\}$. Define $\Omega_2 = \{\Omega_1, i, i'\}$. Observe that items i, i' have the least preference scores among all the items in the set Ω_2 . Therefore, the term in Equation (139) is the probability of the least two preference score items in the set Ω_2 , that is of size $(\kappa - \lfloor \ell \beta_1 \rfloor)$, being ranked in bottom $(\ell - \lfloor \ell \beta_1 \rfloor)$ positions.

The following lemma shows that the probability of the least two preference score items in a set being ranked at any two positions is lower bounded by their probability of being ranked at 1st and 2nd position.

Lemma 23. Consider a set of items S and a ranking σ over it. Define $i_{\min} \equiv \arg \min_{i \in S} \theta_i$, $i_{\min_2} \equiv \arg \min_{i \in S \setminus \{i_{\min}\}} \theta_i$. For all $1 \leq i_1, i_2 \leq |S|$, $i_1 \neq i_2$, following holds:

$$\mathbb{P}\left[\sigma^{-1}(i_{\min}) = i_1, \sigma^{-1}(i_{\min_2}) = i_2\right] \geq \mathbb{P}\left[\sigma^{-1}(i_{\min}) = 1, \sigma^{-1}(i_{\min_2}) = 2\right]. \quad (140)$$

Using the fact that $i' = \arg \min_{j \in \Omega_2} \tilde{\theta}_{j'}^*$, $i = \arg \min_{j \in \Omega_2 \setminus \{i'\}} \tilde{\theta}_j^*$, for all $1 \leq i_1, i_2 \leq \kappa - \lfloor \ell \beta_1 \rfloor$, $i_1 \neq i_2$, we have that

$$\mathbb{P}\left[\sigma^{-1}(i') = i_1, \sigma^{-1}(i) = i_2\right] \geq \mathbb{P}\left[\sigma^{-1}(i') = 1, \sigma^{-1}(i) = 2\right] \geq e^{-4b} \frac{1}{\kappa^2}, \quad (141)$$

where the second inequality follows from the definition of the PL model and the fact that $\tilde{\theta}^* \in \tilde{\Omega}_{2b}$. Together with Equation (141) and the fact that there are a total of $(\ell - \lfloor \ell \beta_1 \rfloor)(\ell - \lfloor \ell \beta_1 \rfloor - 1) \geq (\ell - \lfloor \ell \beta_1 \rfloor)^2/2$ pair of positions that i, i' can occupy in order to be ranked in bottom $(\ell - \lfloor \ell \beta_1 \rfloor)$, we have,

$$\mathbb{P}\left[\sigma^{-1}(i), \sigma^{-1}(i') > \kappa - \ell\right] \geq \frac{e^{-4b}(1 - \lfloor \ell \beta_1 \rfloor / \ell)^2 \ell^2}{2 \kappa^2}. \quad (142)$$

Since, the above inequality is true for any fixed i, i' and $j \in \Omega$ such that event E holds, it is true for random indices i, i' and $j \in \Omega$ such that event E holds, hence the claim is proved.

8.6.4 PROOF OF LEMMA 23

Let $\hat{\sigma}$ denote a ranking over the items of the set S and $\mathbb{P}[\hat{\sigma}]$ be the probability of observing $\hat{\sigma}$. Let

$$\hat{\Omega}_1 = \left\{\hat{\sigma} : \hat{\sigma}^{-1}(i_{\min}) = i_1, \hat{\sigma}^{-1}(i_{\min_2}) = i_2\right\} \text{ and } \hat{\Omega}_2 = \left\{\hat{\sigma} : \hat{\sigma}^{-1}(i_{\min}) = 1, \hat{\sigma}^{-1}(i_{\min_2}) = 2\right\}. \quad (143)$$

Now, take any ranking $\hat{\sigma} \in \hat{\Omega}_1$ and construct another ranking $\tilde{\sigma}$ from $\hat{\sigma}$ as following. If $i_1 = 2, i_2 = 1$, then swap the items at i_1 -th and i_2 -th position in ranking $\hat{\sigma}$ to get $\tilde{\sigma}$. Else, if $i_1 < i_2$, then first: swap items at i_1 -th position and 1st position, and second: swap items at i_2 -th position and 2nd position, to get $\tilde{\sigma}$; if $i_2 < i_1$, then first: swap items at i_2 -th position and 2nd position, and second: swap items at i_1 -th position and 1st position, to get $\tilde{\sigma}$.

Observe that $\mathbb{P}[\tilde{\sigma}] \leq \mathbb{P}[\hat{\sigma}]$ and $\tilde{\sigma}_i^* \in \hat{\Omega}_2$. Moreover, such a construction gives a bijective mapping between $\hat{\Omega}_1$ and $\hat{\Omega}_2$. Hence, the claim is proved.

Abstract

One of the limiting factors of using support vector machines (SVMs) in large scale applications are their super-linear computational requirements in terms of the number of training samples. To address this issue, several approaches that train SVMs on many small chunks separately have been proposed in the literature. With the exception of random chunks, which is also known as divide-and-conquer kernel ridge regression, however, these approaches have only been empirically investigated. In this work we investigate a spatially oriented method to generate the chunks. For the resulting localized SVM that uses Gaussian kernels and the least squares loss we derive an oracle inequality, which in turn is used to deduce learning rates that are essentially minimax optimal under some standard smoothness assumptions on the regression function. In addition, we derive local learning rates that are based on the local smoothness of the regression function. We further introduce a data-dependent parameter selection method for our local SVM approach and show that this method achieves the same almost optimal learning rates. Finally, we present a few larger scale experiments for our localized SVM showing that it achieves essentially the same test error as a global SVM for a fraction of the computational requirements. In addition, it turns out that the computational requirements for the local SVMs are similar to those of a vanilla random chunk approach, while the achieved test errors are significantly better.

Keywords: least squares regression, support vector machines, localization

1. Introduction

Based on a training set $D := ((x_1, y_1), \dots, (x_n, y_n))$ of i.i.d. input/output observations drawn from an unknown distribution P on $X \times Y$, where $X \subset \mathbb{R}^d$ and $Y \subset \mathbb{R}$, the goal of non-parametric least squares regression is to find a function $f_D : X \rightarrow \mathbb{R}$ that is a good estimate of the unknown conditional mean $f^*(x) := \mathbb{E}(Y|x)$, $x \in X$. For this classical estimation problem various methods have been proposed and studied in the literature, see e.g., (Simonoff, 1996) and the book (Györfi et al., 2002) for detailed accounts.

In this paper, we consider kernel-based regularized empirical risk minimizers, also known as support vector machines (SVMs), which solve the regularized problem

$$f_{D,\lambda} \in \arg \min_{f \in H} \lambda \|f\|_H^2 + \mathcal{R}_{L,D}(f). \quad (1)$$

Here, $\lambda > 0$ is a fixed real number and H is a reproducing kernel Hilbert space (RKHS) over X with reproducing kernel $k : X \times X \rightarrow \mathbb{R}$, see e.g., (Aronszajn, 1950; Berlinet and Thomas-Agnan, 2004; Steinwart and Christmann, 2008). The function $L : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ is a loss function, where in the following we either consider the least squares loss $L_{LS} : Y \times \mathbb{R} \rightarrow [0, \infty)$ defined by $(y, t) \mapsto (y - t)^2$, or variants of it that may depend on $x \in X$. Besides, $\mathcal{R}_{L,D}(f)$ denotes the empirical risk of a function $f : X \rightarrow \mathbb{R}$, that is

$$\mathcal{R}_{L,D}(f) = \frac{1}{n} \sum_{i=1}^n L(x_i, y_i, f(x_i)),$$

where D is the empirical measure associated to the data D defined by $D := \frac{1}{n} \sum_{i=1}^n \delta_{(x_i, y_i)}$ with Dirac measure $\delta_{(x_i, y_i)}$ at (x_i, y_i) . Recall that the empirical SVM solution $f_{D,\lambda}$ exists and is unique (cf. Steinwart and Christmann, 2008, Theorem 5.5) whenever the loss L is convex in its last argument, which is true for the least squares loss and its variants that will be considered later on. Moreover, an SVM is L -risk consistent under a few assumptions on the RKHS H and the regularization parameter λ , see (Steinwart and Christmann, 2008, Section 6.4) for more details.

An essential theoretical task, which has attracted many considerations, is the investigation of learning rates for SVMs. For example, such rates for SVMs using the least squares loss and generic kernels can be found in (Cucker and Smale, 2002; De Vito et al., 2005; Smale and Zhou, 2007; Caponnetto and De Vito, 2007; Mendelson and Neuman, 2010; Steinwart et al., 2009) and the references mentioned therein. At this point, we do not want to take a closer look at these results, instead we relegate to (Eberts and Steinwart, 2013), where a detailed discussion can be found. More important for our purposes is the fact that Eberts and Steinwart (2011, 2013) establish (essentially) asymptotically optimal learning rates for least squares SVMs (LS-SVMs) using Gaussian RBF kernels. More precisely, for a domain $X \subset B_{\ell_2}^d$, $Y := [-M, M]$ with $M > 0$, a distribution P on $X \times Y$ such that P_X has a bounded Lebesgue density on X , and for f^* contained in the Sobolev space $W_2^\alpha(P_X)$, $\alpha \in \mathbb{N}$, or in the Besov-like space $B_{2,\infty}^{\alpha}(P_X)$, $\alpha \geq 1$, respectively, the LS-SVM using Gaussian kernels learns for all $\xi > 0$ with rate $n^{-\frac{2\alpha}{2\alpha+7\xi}}$ with a high probability. In other words, it learns at least with a rate that is arbitrarily close to the optimal learning rate.

Although these rates are essentially asymptotically optimal, they depend on the order of smoothness of the regression function on the *entire* input space X . That is, if the regression function f^* is on some area of X smoother than on another area, the learning rate is determined by the part of X , where the regression function f^* is least smooth. In contrast to this, it would be desirable to achieve a learning rate on every region of X that corresponds with the order of smoothness of f^* on this region. Therefore, one of our goals of this paper is to modify the standard SVM approach such that we achieve local learning rates that are asymptotically optimal.

Our technique to achieve such local learning rates is a special data splitting approach, which first creates a geometrically well-behaved partition of the input space X and then finds a separate SVM on each of the resulting cells with the help of the training samples that fall into these cells. Recall that various other *local* splitting approaches have already been extensively investigated in the literature, but mostly to speed-up the training time, see for instance, the early works (Bottou and Vapnik, 1992; Vapnik and Bottou, 1993).

Here the basic idea of most other local approaches is to *a)* split the training data and just consider a few examples near a testing sample, *b)* train on this small subset of the training data, and *c)* use the solution for a prediction w.r.t. the test sample. Here, many up-to-date investigations use SVMs to train on the local data set but, yet there are different ways to split the whole training data set into smaller local sets. For example, Chang et al. (2010); Wu et al. (1999); Bennett and Blhe (1998) use decision trees while in (Hable, 2013; Segata and Blanzieri, 2010, 2008; Blanzieri and Melgani, 2008; Blanzieri and Bryl, 2007a,b; Zhang et al., 2006) local subsets are built considering k nearest neighbors. The latter approaches further vary; for example, Zhang et al. (2006); Blanzieri and Bryl (2007a); Hable (2013) consider different metrics w.r.t. the input space whereas Segata and Blanzieri (2008); Blanzieri and Melgani (2008); Blanzieri and Bryl (2007b) consider metrics w.r.t. the feature space. Nonetheless, the basic idea of all these articles is that an SVM problem based on k training samples is solved for *each* test sample. Another approach using k nearest neighbors is investigated in (Segata and Blanzieri, 2010). Here, k -neighborhoods consisting of training samples and collectively covering the training data set are constructed and an SVM is calculated on each neighborhood. The prediction for a test sample is then made according to the nearest training sample that is a center of a k -neighborhood. As for the other nearest neighbor approaches, however, the results are mainly experimental. An exception to this rule is (Hable, 2013), where universal consistency for localized versions of SVMs, or more precisely, a large class of regularized kernel methods, is proven. Another article presenting theoretical results for localized versions of learning methods is (Zakai and Ritov, 2009). Here, the authors show that a consistent learning method behaves locally, i.e., the prediction is essentially influenced by close by samples. However, this result is based on a localization technique considering only training samples contained in a neighborhood with a fixed radius and center x when an estimate in x is sought. Probably closest to our approach is the one examined in (Cheng et al., 2010) and (Cheng et al., 2007), where the training data is split into clusters and then an SVM is trained on each cluster. However, the presented results are again only of experimental character.

Unlike in the papers mentioned above, our main goal is to theoretically investigate local SVMs based on local splitting. Namely, we establish both global and local learning rates for our local splitting approach (VP-SVM) that do match the best existing and essentially optimal rates for global SVMs derived by Eberts and Steinwart (2013). In addition, we show that these rates can be obtained without knowing characteristics of P by a simple and well-known hold-out technique. Furthermore, we empirically compare our VP-SVM to another data splitting approach known as random chunking (RC-SVM) or divide-and-conquer kernel ridge regression for which learning rates, at least for generic kernels, have been recently established by Zhang et al. (2015); Lin et al. (2016). In these experiments it turns out that for splittings that lead to comparable training times, our VP-SVM has a significantly smaller test error than RC-SVMs.

Investigating other speed-up schemes for SVMs theoretically has been in the focus of research in the last few years. For example, Zhang et al. (2015); Lin et al. (2016) established optimal learning rates in expectation for RC-SVMs under the assumption that the conditional mean f^* is contained in the used RKHS, or in the image of a fractional integral operator, respectively. Although these results are very interesting they are not very useful for SVMs with Gaussian kernels, since for these kernels the imposed assumptions on f^*

imply $f^* \in C^\infty$, which is usually considered to be too restrictive. For a similar reason the results by Rudi et al. (2015) for the popular Nyström method require too restrictive assumptions when applied to SVMs with Gaussian kernels. On a side note, we like to mention that this difference between generic kernels on the one hand and Gaussian kernels on the other hand already appears for the standard global SVMs. Indeed, in the generic case, one usually addresses the approximation error by assuming the conditional mean to be contained in the image of a fractional integral operator, which can in turn be identified as an interpolation space of the real method, see (Steinwart and Scovel, 2012). For certain kernels, the classical theory of interpolation spaces then identifies the considered interpolation spaces as Besov spaces, so that the approximation error assumption has a clear intuitive meaning. On the other hand, for Gaussian kernels with fixed width it has been shown by Smale and Zhou (2003) that their interpolation spaces consist of C^∞ -functions, so that the generic theory would again lead to a too restrictive approximation error assumption. To address this issue, one considers widths that change with the sample size. However, to make this approach successful, one requires both a manual estimation of the approximation error, see (Eberts and Steinwart, 2011), and eigenvalue/entropy number bounds that do depend on the kernel width. For these reasons, learning rates for SVMs with Gaussian kernels under realistic assumptions are, in general, harder to obtain. Nonetheless, they are important, since in practice, Gaussian kernels are by far the most often used kernels.

The rest of this paper is organized as follows: In Section 2 we describe our splitting approach in detail. Section 3 then presents some theoretical results on RKHSs that enable the analysis of our method. After that, Section 4 contains the main results, namely an oracle inequality and learning rates for our localized SVM method. Moreover, a data-dependent parameter selection method is studied that induces the same rates. Section 5 then presents some experimental results w.r.t. the localized SVM technique. Finally, Section 6 collects the proofs for the results of the earlier sections as well as some necessary and important ancillary findings.

2. Description of the Localized SVM Approach

In this section, we introduce some general notations and assumptions. Based on the latter we modify the standard SVM approach. Let us start with the probability measure P on $X \times Y$, where $X \subset \mathbb{R}^d$ is non-empty, $Y := [-M, M]$ for some $M > 0$, and P_X is the marginal distribution of X . Depending on the learning target one chooses a loss function L , i.e., a function $L : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ that is measurable. Then, for a measurable function $f : X \rightarrow \mathbb{R}$, the L -risk is defined by

$$\mathcal{R}_{L,P}(f) = \int_{X \times Y} L(x, y, f(x)) dP(x, y)$$

and the optimal L -risk, called the Bayes risk with respect to P and L , is given by

$$\mathcal{R}_{L,P}^*(f) := \inf \{ \mathcal{R}_{L,P}(f) \mid f : X \rightarrow \mathbb{R} \text{ measurable} \}.$$

A measurable function $f_{L,P}^* : X \rightarrow \mathbb{R}$ with $\mathcal{R}_{L,P}(f_{L,P}^*) = \mathcal{R}_{L,P}^*$ is called a Bayes decision function. For the commonly used losses such as the least squares loss treated in Section 4 the Bayes decision function $f_{L,P}^*$ is P_X -almost surely $[-M, M]$ -valued, since $Y = [-M, M]$.

In this case, it seems obvious to consider estimators with values in $[-M, M]$ on X . To this end, we introduce the concept of clipping the decision function. Let \hat{f} be the clipped value of some $t \in \mathbb{R}$ at $\pm M$ defined by

$$\hat{f} := \begin{cases} -M & \text{if } t < -M \\ t & \text{if } t \in [-M, M] \\ M & \text{if } t > M. \end{cases}$$

Then, a loss is called clippable at $M > 0$ if, for all $(x, y, t) \in X \times Y \times \mathbb{R}$, we have

$$L(x, y, \hat{f}) \leq L(x, y, t).$$

Obviously, the latter implies $\mathcal{R}_{L,P}(\hat{f}) \leq \mathcal{R}_{L,P}(f)$ for all $f : X \rightarrow \mathbb{R}$. In other words, restricting the decision function to the interval $[-M, M]$ containing our labels cannot worsen the risk, in fact, clipping this function typically reduces the risk. Hence, we consider the clipped version \hat{f}_D of the decision function as well as the risk $\mathcal{R}_{L,P}(\hat{f}_D)$ instead of the risk $\mathcal{R}_{L,P}(f_D)$ of the unclipped decision function. Note that this clipping idea does *not* change the required solver since it is performed *after* the training phase.

To modify the standard SVM approach (1), we assume that $(A_j)_{j=1,\dots,m}$ is a partition of X such that all its cells have non-empty interior, that is $A_j \neq \emptyset$ for every $j \in \{1, \dots, m\}$. Now, the basic idea of our approach is to consider for each cell of the partition an individual SVM. To describe this approach in a mathematically rigorous way, we have to introduce some more definitions and notations. Let us begin with the index set

$$I_j := \{i \in \{1, \dots, n\} : x_i \in A_j\}, \quad j = 1, \dots, m,$$

indicating the samples of D contained in A_j , as well as the corresponding data set

$$D_j := \{(x_i, y_i) \in D : i \in I_j\}, \quad j = 1, \dots, m.$$

Moreover, for every $j \in \{1, \dots, m\}$, we define a (local) loss $L_j : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ by

$$L_j(x, y, t) := \mathbb{1}_{A_j}(x)L(x, y, t),$$

where $L : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ is the loss that corresponds to our learning problem at hand. We further assume that H_j is an RKHS over A_j with kernel $k_j : A_j \times A_j \rightarrow \mathbb{R}$. Here, every function $f \in H_j$ is only defined on A_j even though a function $f_D : X \rightarrow \mathbb{R}$ is finally sought. To this end, for $f \in H_j$, we define the zero-extension $\hat{f} : X \rightarrow \mathbb{R}$ by

$$\hat{f}(x) := \begin{cases} f(x), & x \in A_j, \\ 0, & x \notin A_j. \end{cases}$$

Then, the space $\hat{H}_j := \{\hat{f} : f \in H_j\}$ equipped with the norm

$$\|\hat{f}\|_{\hat{H}_j} := \|f\|_{H_j}, \quad \hat{f} \in \hat{H}_j,$$

is an RKHS on X (cf. Lemma 2), which is isometrically isomorphic to H_j . With these preparations we can now formulate our local SVM approach. To this end, for every $j \in \{1, \dots, m\}$, we consider the local SVM optimization problem

$$f_{D_j, \lambda_j} = \arg \min_{f \in H_j} \lambda_j \|f\|_{H_j}^2 + \frac{1}{n} \sum_{i=1}^n L_j(x_i, y_i, \hat{f}(x_i)), \quad (2)$$

where $\lambda_j > 0$ for every $j \in \{1, \dots, m\}$. Based on these empirical SVM solutions, we then define the decision function $f_{D, \lambda} : X \rightarrow \mathbb{R}$ by

$$f_{D, \lambda}(x) := \sum_{j=1}^m f_{D_j, \lambda_j}(x) = \sum_{j=1}^m \mathbb{1}_{A_j}(x) f_{D_j, \lambda_j}(x), \quad (3)$$

where $\lambda := (\lambda_1, \dots, \lambda_m)$. Since all f_{D_j, λ_j} in (2) are usual empirical SVM solutions the common properties hold. Moreover, for arbitrary $j \in \{1, \dots, m\}$, $f_{D_j, \lambda_j}(x_i) = 0$ if $x_i \notin A_j$ for all $i \in \{1, \dots, n\}$. Furthermore, note that the SVM optimization problem (2) equals the SVM optimization problem (1) using H_j , D_j , and the regularization parameter $\lambda_j := \frac{n}{|I_j|} \lambda_j$. That is, f_{D_j, λ_j} as in (2) and $h_{D_j, \tilde{\lambda}_j} := \arg \min_{f \in H_j} \tilde{\lambda}_j \|f\|_{H_j}^2 + \mathcal{R}_{L, P, D_j}(f)$ coincide on A_j . Besides, it is easy to show that, whenever a Bayes decision function $f_{L, P}^*$ w.r.t. P and L exists, it additionally is a Bayes decision function w.r.t. P and L_j .

Let us now briefly discuss the required computing time of our modified SVM. To this end, recall that the costs for solving an usual SVM problem are $\mathcal{O}(n^q)$ where $q \in [2, 3]$. For the new approach we consider m working sets of size n_1, \dots, n_m where for simplicity we assume $n_i \approx \frac{n}{m}$ for all $i \in \{1, \dots, m\}$. Then for each working set an usual SVM problem has to be solved such that, altogether, the modified SVM induces a computational cost of $\mathcal{O}(m(\frac{n}{m})^q)$. Therefore, if $m \approx n^\beta$ for some $\beta > 0$, then our approach is computationally cheaper than a traditional SVM. Note that our strategy using a partition of the input space is a typical way to speed-up SVMs. Other techniques that possess similar properties are, e.g., applied in the articles cited in the introduction. Besides, we refer to (Tsang et al., 2007) and (Tsang et al., 2005) using enclosing ball problems to solve an SVM, to (Graf et al., 2005) presenting a model of multiple filtering SVMs and to (Collobert et al., 2001) investigating a mixture of SVMs based on several subsets of the training set.

To describe the above SVM approach $(A_j)_{j=1,\dots,m}$ only has to be some partition of X . However, for the theoretical investigations concerning learning rates of our new approach, we have to further specify the partition. To this end, we denote the closed unit ball of the d -dimensional Euclidean space \mathbb{R}^d by $B_{\mathbb{R}^d}$ and we define balls B_1, \dots, B_m with radius $r > 0$ and mutually distinct centers $z_1, \dots, z_m \in B_{\mathbb{R}^d}$ by

$$B_j := B_r(z_j) := \{x \in \mathbb{R}^d : \|x - z_j\|_2 \leq r\}, \quad j \in \{1, \dots, m\}, \quad (4)$$

where $\|\cdot\|_2$ is the Euclidean norm in \mathbb{R}^d . Moreover, we choose r and z_1, \dots, z_m such that

$$B_{\mathbb{R}^d} \subset \bigcup_{j=1}^m B_j,$$

i.e., such that the balls B_1, \dots, B_m cover $B_{\rho_d^c}$ and, simultaneously, any non-empty set $X \subset B_{\rho_d^c}$ (cf. Figure 1). The following well-known lemma relates the radius of such a cover with the number of centers.

Lemma 1 For all $c > 0$ and $r \in (0, c]$, there exist balls $(B_r(z_j))_{j=1, \dots, m}$ with radius r and centers $z_1, \dots, z_m \in cB_{\rho_d^c}$ such that $\bigcup_{j=1}^m B_r(z_j)$ covers $cB_{\rho_d^c}$ and $r \leq 3cm^{-\frac{1}{d}}$.

For simplicity of notation, we assume in the following that $X \subset B_{\rho_d^c}$. Thus, according to Lemma 1, there exists a cover $(B_j)_{j=1, \dots, m}$ of X with

$$r \leq 3m^{-\frac{1}{d}}. \quad (5)$$

Let us finally specify the partition $(A_j)_{j=1, \dots, m}$ of X by the following assumption.

(A) Let $r \in (0, 1]$ and $(A'_j)_{j=1, \dots, \tilde{m}}$ be a partition of $B_{\rho_d^c}$ such that $A'_j \neq \emptyset$ as well as $\overline{A'_j} = \overline{A'_j}$ for every $j \in \{1, \dots, \tilde{m}\}$ and such that there exist balls $B_j := B_r(z_j) \supset A'_j$ with radius r and mutually distinct centers $z_1, \dots, z_{\tilde{m}} \in B_{\rho_d^c}$ satisfying (5). In addition, assume that X is a non-empty, closed subset of $B_{\rho_d^c}$ satisfying $\overline{X} = X$. W.l.o.g. we assume that, for some $m \leq \tilde{m}$, $A'_j \cap X \neq \emptyset$ for all $j \in \{1, \dots, m\}$ and $A'_j \cap X = \emptyset$ for all $j \in \{m+1, \dots, \tilde{m}\}$. Then we define $A''_j := A'_j \cap X$ for all $j \in \{1, \dots, m\}$ and assume that $(A_j)_{j=1, \dots, m}$ is a partition of X satisfying $A''_j \subset A_j \subset \overline{A''_j}$.

Note that the partition $(A_j)_{j=1, \dots, m}$ of X in Assumption (A) satisfies, for every $j \in \{1, \dots, m\}$, $A_j \subset B_j$ for B_j as in (A) and $\dot{A}_j \neq \emptyset$, where the latter is shown in Lemma 8 in the Appendix. Obviously, for the partition $(A_j)_{j=1, \dots, m}$, r and m fulfill (5).

In Assumption (A) $(A'_j)_{j=1, \dots, \tilde{m}}$ is a partition of $B_{\rho_d^c}$ from which we build a partition $(A_j)_{j=1, \dots, m}$ of $X \subset B_{\rho_d^c}$. However, for the construction of our local SVM approach and the proofs of the belonging learning rates, it will be negligible whether we first consider a partition $(A'_j)_{j=1, \dots, \tilde{m}}$ of $B_{\rho_d^c}$ or only a partition $(A_j)_{j=1, \dots, m}$ of X , since the cells $A''_{m+1}, \dots, A''_{\tilde{m}}$ which are removed, have zero mass w.r.t. the marginal distribution P_X of X if $P_X(\partial X) = 0$. In the remaining sections we will frequently refer to Assumption (A). Thus, let us illustrate by the following example that (A) is indeed a natural assumption.

Example 1 For some $r \in (0, 1]$, let us consider an r -net z_1, \dots, z_m of $B_{\rho_d^c}$, where z_1, \dots, z_m are mutually distinct. Moreover, we assume that $X \subset B_{\rho_d^c}$ satisfies $\overline{X} = X$. Based on the r -net z_1, \dots, z_m , a Voronoi partition $(A_j)_{j=1, \dots, m}$ of X is defined by

$$A_j := \left\{ x \in X : \min_{k \in \{1, \dots, m\}} \|x - z_k\|_2 = j \right\}, \quad (6)$$

cf. Figure 2. That is, A_j contains all $x \in X$ such that the center z_j is the nearest center to x , and in the case of ties the center with the smallest index is taken. Obviously, $(A_j)_{j=1, \dots, m}$ is a partition of X with $A_j \neq \emptyset$ and $A_j \subset B_k(z_j)$ for all $j \in \{1, \dots, m\}$, and hence it satisfies condition (A), i.e. r and m fulfill (5).

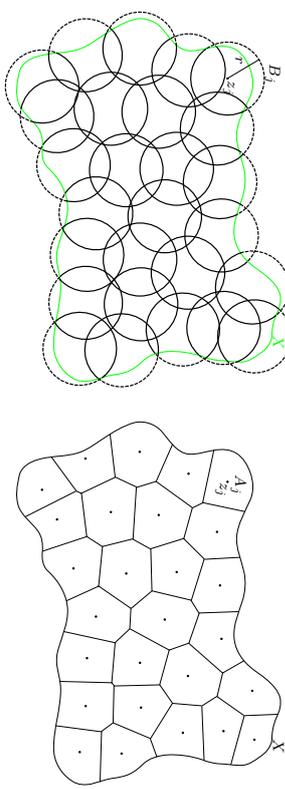

Figure 1: Cover $(B_j)_{j=1, \dots, m}$ of X , where B_1, \dots, B_m are balls with radius r and centers z_j ($j = 1, \dots, m$).

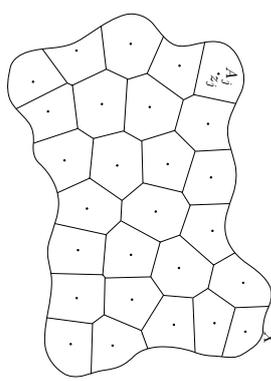

Figure 2: Voronoi partition $(A_j)_{j=1, \dots, m}$ of X defined by (6), where $A_j \subset B_j$ for every $j \in \{1, \dots, m\}$.

Motivated by Example 1, we call the learning method producing \hat{f}_D given by (3) a *Voronoi partition support vector machine*, in short VP-SVM. Despite this name, however, we just take a partition $(A_j)_{j=1, \dots, m}$ satisfying (A) as basis here instead of requesting $(A_j)_{j=1, \dots, m}$ to be a Voronoi partition.

Recall that our goal is to derive not only global but also local learning rates for this VP-SVM approach. To this end, we additionally consider a $T \subset X$ with $P_X(T) > 0$. Then we examine the learning rate of the VP-SVM on this subset T of X . To formalize this, it is necessary to introduce some basic notations related to T . Let us define the index set J_T by

$$J_T := \{j \in \{1, \dots, m\} : A_j \cap T \neq \emptyset\} \quad (7)$$

specifying every set A_j that has at least one common point with T . Note that, for every non-empty set $T \subset X$, the index set J_T is also non-empty, i.e., $|J_T| \geq 1$. Besides, deriving local rates on T requires us to investigate the excess risk of the VP-SVM with respect to the distribution P and the loss $L_T : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ defined by

$$L_T(x, y, t) := \mathbb{1}_T(x)L(x, y, t). \quad (8)$$

However, to manage the analysis we additionally need the loss $L_{J_T} : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ given by

$$L_{J_T}(x, y, t) := \mathbb{1}_{\bigcup_{j \in J_T} A_j}(x)L(x, y, t), \quad (9)$$

which may only be nonzero, if x is contained in some set A_j with $j \in J_T$. Note that the risks $\mathcal{R}_{L_T, P}(f)$ and $\mathcal{R}_{L_{J_T}, P}(f)$ quantify the quality of some function f just on T and

$$A_T := \bigcup_{j \in J_T} A_j \supset T,$$

respectively. Hence, examining the excess risks

$$\mathcal{R}_{L_T, P}(\hat{f}_D, \lambda) - \mathcal{R}_{L_T, P}^*(\hat{f}_D, \lambda) \leq \mathcal{R}_{L_{J_T}, P}(\hat{f}_D, \lambda) - \mathcal{R}_{L_{J_T}, P}^*(\hat{f}_D, \lambda)$$

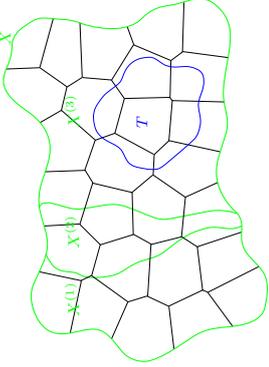

Figure 3: The input space X with the corresponding partition $(A_j)_{j=1, \dots, m}$ and the subset T , where the local learning rate should be examined.

leads to learning rates on A_T and implicitly on T . Recapitulatory, let us declare a set of notations that will be frequently used in the remainder of the paper.

(T) For $T \subset X$, we define an index set J_T by (7), loss functions $L_T, L_{J_T} : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ by (8) and (9), and the set $A_T := \bigcup_{j \in J_T} A_j$.

3. Building Weighted Global Kernels

In this section, we first focus on RKHSs and direct sums of RKHSs. Then, we show that a VP-SVM solution is also the solution of an usual SVM.

Let us begin with some basic notations. For $q \in [1, \infty]$ and a measure ν , we denote by $L_q(\nu)$ the Lebesgue spaces of order q w.r.t. ν and for the Lebesgue measure μ on $X \subset \mathbb{R}^d$ we write $L_q(X) := L_q(\mu)$. In addition, for a measurable space X , the set of all real-valued measurable functions on X is given by $\mathcal{L}_0(X) := \{f : X \rightarrow \mathbb{R} \mid f \text{ measurable}\}$. Moreover, for a measure ν on X and measurable $\tilde{X} \subset X$, we define the trace measure $\nu|_{\tilde{X}}$ of ν in \tilde{X} by $\nu|_{\tilde{X}}(A) = \nu(A \cap \tilde{X})$ for every $A \subset X$.

Our first goal is to show that $f_{D,\lambda}$ in (3) is actually an ordinary SVM solution. To this end, we consider an RKHS on some $A \subset X$ and extend it to an RKHS on X by the following lemma, where we omit the obvious proof.

Lemma 2 Let $A \subset X$ and H_A be an RKHS on A with corresponding kernel k_A . Denote by \tilde{f} the zero-extension of $f \in H_A$ to X defined by

$$\tilde{f}(x) := \begin{cases} f(x), & \text{for } x \in A, \\ 0, & \text{for } x \in X \setminus A. \end{cases}$$

Then, the space $\tilde{H}_A := \{\tilde{f} : f \in H_A\}$ equipped with the norm $\|\tilde{f}\|_{\tilde{H}_A} := \|f\|_{H_A}$ is an RKHS on X and its reproducing kernel is given by

$$\tilde{k}_A(x, x') := \begin{cases} k_A(x, x'), & \text{if } x, x' \in A, \\ 0, & \text{else.} \end{cases} \quad (10)$$

Based on this lemma, we are now able to construct an RKHS by a direct sum of RKHSs \hat{H}_A and \hat{H}_B with $A, B \subset X$ and $A \cap B = \emptyset$. Here, we skip the proof once more, since the assertion follows immediately using, for example, orthonormal bases of \hat{H}_A and \hat{H}_B .

Lemma 3 For $A, B \subset X$ such that $A \cap B = \emptyset$ and $A \cup B \subset X$, let H_A and H_B be RKHSs of the kernels k_A and k_B over A and B , respectively. Furthermore, let \hat{H}_A and \hat{H}_B be the RKHSs of all functions of H_A and H_B extended to X in the sense of Lemma 2 and let k_A and k_B given by (10) be the associated reproducing kernels. Then, $\hat{H}_A \cap \hat{H}_B = \{0\}$ and hence the direct sum

$$H := \hat{H}_A \oplus \hat{H}_B \quad (11)$$

exists. For $\lambda_A, \lambda_B > 0$ and $f \in H$, let $\hat{f}_A \in \hat{H}_A$ and $\hat{f}_B \in \hat{H}_B$ be the unique functions such that $f = \hat{f}_A + \hat{f}_B$. Then, we define the norm $\|\cdot\|_H$ by

$$\|f\|_H^2 := \lambda_A \|\hat{f}_A\|_{\hat{H}_A}^2 + \lambda_B \|\hat{f}_B\|_{\hat{H}_B}^2 \quad (12)$$

and H equipped with the norm $\|\cdot\|_H$ is again an RKHS for which

$$k(x, x') := \lambda_A^{-1} \hat{k}_A(x, x') + \lambda_B^{-1} \hat{k}_B(x, x'), \quad x, x' \in X,$$

is the reproducing kernel.

To relate Lemmas 2 and 3 with (3), we have to introduce some more notations. For pairwise disjoint sets $A_1, \dots, A_m \subset X$, let H_j be an RKHS on A_j for every $j \in \{1, \dots, m\}$. Then, based on RKHSs $\hat{H}_1, \dots, \hat{H}_m$ on X defined by Lemma 2, a joined RKHS can be designed analogously to Lemma 3. That is, for an arbitrary index set $J \subset \{1, \dots, m\}$ and a vector $\lambda = (\lambda_j)_{j \in J} \in (0, \infty)^{|J|}$, the direct sum

$$H_J := \bigoplus_{j \in J} \hat{H}_j = \left\{ f = \sum_{j \in J} f_j : f_j \in \hat{H}_j \text{ for all } j \in J \right\} \quad (13)$$

is again an RKHS equipped with the norm

$$\|f\|_{H_J}^2 = \sum_{j \in J} \lambda_j \|f_j\|_{\hat{H}_j}^2. \quad (14)$$

If $J = \{1, \dots, m\}$, we simply write $H := H_J$. Note that H contains inter alia $f_{D,\lambda}$ given by (3).

Let us briefly investigate the regularized empirical risk of $f_{D,\lambda} = \sum_{j=1}^m \mathbb{1}_{A_j} \hat{f}_{j,\lambda_j}$, where \hat{f}_{j,λ_j} , $j = 1, \dots, m$, are defined by (2). For an arbitrary $f \in H$, we have

$$\begin{aligned} \|f_{D,\lambda}\|_H^2 + \mathcal{R}_{L,D}(\hat{f}_{D,\lambda}) &= \sum_{j=1}^m \left(\lambda_j \|f_{D_j,\lambda_j}\|_{\hat{H}_j}^2 + \mathcal{R}_{L_j,D}(\hat{f}_{D_j,\lambda}) \right) \\ &\leq \sum_{j=1}^m \left(\lambda_j \|\mathbb{1}_{A_j} f\|_{\hat{H}_j}^2 + \mathcal{R}_{L_j,D}(f) \right) \end{aligned}$$

$$= \|f\|_H^2 + \mathcal{R}_{L,D}(f), \quad (15)$$

where we used $\mathcal{R}_{L,D}(f) = \sum_{j=1}^m \mathcal{R}_{L_j,D}(f)$, which immediately follows by Lemma 9 given in the appendix. That is, $f_{D,\lambda}$ is the decision function of an SVM using H and L as well as the regularization parameter $\lambda = 1$. In other words, the latter SVM equals the VP-SVM given by (3). This will be a key insight used in our analysis.

Subsequently, we only consider RKHSs of Gaussian RBF kernels. For this purpose, we summarize some assumptions for the Gaussian case of joined RKHSs in the following assumption set.

(G) For pairwise disjoint subsets A_1, \dots, A_m of X , let $H_j := H_{\gamma_j}(A_j)$, $j \in \{1, \dots, m\}$, be the RKHS of the Gaussian kernel k_{γ_j} with width $\gamma_j \in (0, r]^\dagger$ over A_j . Consequently, for $\lambda := (\lambda_1, \dots, \lambda_m) \in (0, \infty)^m$, we define the joined RKHS $H := \bigoplus_{j=1}^m H_{\gamma_j}(A_j)$ and equip it with the norm (14).

In the following we do not consider SVMs with a fixed kernel, thus, we use a more detailed notation than (2) and (3) specifying the kernel width γ_j of the RKHS $H_{\gamma_j}(A_j)$ at hand. Namely, for all $j \in \{1, \dots, m\}$ and $\gamma := (\gamma_1, \dots, \gamma_m)$, we write

$$f_{D_j, \lambda_j \gamma_j} = \arg \min_{f \in H_{\gamma_j}(A_j)} \|f\|_{H_{\gamma_j}(A_j)}^2 + \frac{1}{n} \sum_{i=1}^n L_{\gamma_j}(x_i, y_i, f(x_i)),$$

and

$$f_{D,\lambda,\gamma} := \sum_{j=1}^m f_{D_j, \lambda_j \gamma_j}$$

instead of f_{D_j, λ_j} and $f_{D,\lambda}$ in the remainder of this work.

4. Learning Rates for Least Squares VP-SVMs

In this section, the non-parametric least squares regression problem is considered using the least squares loss $L : Y \times \mathbb{R} \rightarrow [0, \infty)$ defined by $L(g, t) := (g - t)^2$. It is well known that, in this case, the Bayes decision function $f_{L,P}^* : \mathbb{R}^d \rightarrow \mathbb{R}$ is given by $f_{L,P}^*(x) = \mathbb{E}_P(Y|x)$ for P -almost all $x \in \mathbb{R}^d$. Moreover, this function is unique up to zero-sets. Besides, for the least squares loss the equality

$$\mathcal{R}_{L,P}(f) - \mathcal{R}_{L,P}^* = \|f - f_{L,P}^*\|_{L_2(P^X)}^2$$

can be shown by some simple, well-known transformations. In the first part of Subsection 4.1 we introduce some tools to describe smoothness properties of $f_{L,P}^*$, which are then used in the oracle inequalities and learning rates of the second part. In Subsection 4.2 we then investigate a simple parameter selection strategy for which we will show that it is adaptive.

4.1 Basic Oracle Inequalities for LS-VP-SVMs

To formulate oracle inequalities and derive rates for VP-SVMs using the least squares loss, the target function $f_{L,P}^*$ is assumed to satisfy certain smoothness conditions. To this end, we initially recall the modulus of smoothness, a device to measure the smoothness of functions, see e.g., DeVore and Lorentz, 1993, p. 44; DeVore and Popov, 1988, p. 398; as well as Berens and DeVore, 1978, p. 360. Denote by $\|\cdot\|_2$ the Euclidean norm and let $\Omega \subset \mathbb{R}^d$ be a subset with non-empty interior, ν be an arbitrary measure on Ω , $p \in [0, \infty]$, and $f : \Omega \rightarrow \mathbb{R}$ be contained in $L_p(\nu)$. Then, for $s \in \mathbb{N}$, the s -th modulus of smoothness of f is defined by

$$\omega_{s, L_p(\nu)}(f, t) = \sup_{\|h\|_2 \leq t} \|\Delta_h^s(f, \cdot)\|_{L_p(\nu)}, \quad t \geq 0,$$

where $\Delta_h^s(f, \cdot)$ denotes the s -th difference of f given by

$$\Delta_h^s(f, x) = \begin{cases} \sum_{j=0}^s \binom{s}{j} (-1)^{s-j} f(x + jh) & \text{if } x \in \Omega_{s,h} \\ 0 & \text{if } x \notin \Omega_{s,h} \end{cases}$$

for $h = (h_1, \dots, h_d) \in \mathbb{R}^d$ and $\Omega_{s,h} := \{x \in \Omega : x + th \in \Omega \text{ f.a. } t \in [0, s]\}$. Based on the modulus of smoothness, we introduce Besov-like spaces, i.e., function spaces that provide a finer scale of smoothness than the commonly used Sobolev spaces and that will thus be assumed to contain the target function later on. To this end, let $\alpha > 0$, $s := [\alpha] + 1$, and ν be an arbitrary measure. Then, the Besov-like space $B_{2,\infty}^\alpha(\nu)$ is defined by

$$B_{2,\infty}^\alpha(\nu) := \left\{ f \in L_2(\nu) : \|f\|_{B_{2,\infty}^\alpha(\nu)} < \infty \right\},$$

where the semi-norm $\|\cdot\|_{B_{2,\infty}^\alpha(\nu)}$ is given by

$$\|f\|_{B_{2,\infty}^\alpha(\nu)} := \sup_{t>0} (t^{-\alpha} \omega_{s, L_2(\nu)}(f, t))$$

and the norm by $\|f\|_{B_{2,\infty}^\alpha(\nu)} := \|f\|_{L_2(\nu)} + \|f\|_{B_{2,\infty}^\alpha(\nu)}$. Here, note that we defined Besov-like spaces for arbitrary measures ν on $\Omega \subset \mathbb{R}^d$ whereas in the literature Besov spaces are usually defined for the Lebesgue measure. Nevertheless, our definition of Besov-like spaces is well-defined. Moreover, for the proofs it is important to notice that, if $\Omega = \mathbb{R}^d$ and ν is a distribution on Ω with $\text{supp } \nu \subseteq \Omega$, then $\Omega_{s,h}$ still equals \mathbb{R}^d , i.e., $\Omega_{s,h} = \Omega$. Also note that for the Lebesgue measure on Ω , where $\Omega = \mathbb{R}^d$ or Ω is a bounded Lipschitz domain in \mathbb{R}^d , our definition of Besov-like spaces actually coincides, up to equivalent norms, to the definition of the classical Besov spaces in the literature, see e.g., (Adams and Fournier, 2003, Section 7), (Triebel, 2006, Section 1), (Triebel, 1992, Section 1), and (Triebel, 2010, Sections 2 and 3), where this classical type of Besov spaces is also defined for $1 \leq p, q \leq \infty$ and $\alpha > 0$. For more details on the equivalences of our definition of Besov-like spaces and the classical definitions, we refer to (Ehberts, 2015, Section 3.1). If ν is the Lebesgue measure on Ω , we write $B_{2,\infty}^\alpha(\Omega) := B_{2,\infty}^\alpha(\nu)$. Additionally, let us briefly consider a few embedding properties for Besov-like spaces $B_{2,\infty}^\alpha(\nu)$ where the corresponding proofs can be found in (Ehberts, 2015, Section 3.1). To this end, let ν be a finite measure on \mathbb{R}^d such that $\text{supp } \nu :=: \Omega \subset \mathbb{R}^d$ has non-empty interior and ν has a Lebesgue density g on Ω . If g is bounded away from 0

on Ω , then $B_{2,\infty}^\alpha(\nu) \subset B_{2,\infty}^\alpha(\Omega)$ for $\alpha > 0$. Alternatively, for $g \in L_\infty(\Omega)$ and $\alpha > 0$, we have $B_{2,\infty}^\alpha(\mathbb{R}^d) \subset B_{2,\infty}^\alpha(\nu)$ and $(B_{2,\infty}^\alpha(\Omega^{+\delta}) \cap L_\infty(\mathbb{R}^d)) \subset B_{2,\infty}^\alpha(\nu)$, where $\delta > 0$ and $\Omega^{+\delta} := \{x \in \mathbb{R}^d : \exists x' \in \Omega \text{ such that } \|x - x'\|_2 \leq \delta\}$. For the sake of completeness, recall from, e.g., (Adams and Fournier, 2003, Section 3) and (Triebel, 2010, Sections 2 and 3) the scale of Sobolev spaces $W_2^\alpha(\nu)$ defined by

$$W_2^\alpha(\nu) := \left\{ f \in L_p(\nu) : \partial^{(\beta)} f \in L_2(\nu) \text{ exists for all } \beta \in \mathbb{N}_0^d \text{ with } |\beta| \leq \alpha \right\},$$

where $\alpha \in \mathbb{N}_0$, ν is an arbitrary measure, and $\partial^{(\beta)}$ is the β -th weak derivative for a multi-index $\beta = (\beta_1, \dots, \beta_d) \in \mathbb{N}_0^d$ with $|\beta| = \sum_{i=1}^d \beta_i$. That is, $W_2^\alpha(\nu)$ is the space of all functions in $L_2(\nu)$ whose weak derivatives up to order α exist and are contained in $L_2(\nu)$. Moreover, the Sobolev space is equipped with the Sobolev norm

$$\|f\|_{W_2^\alpha(\nu)}^p := \sum_{|\beta| \leq \alpha} \|\partial^{(\beta)} f\|_{L_2(\nu)}^2,$$

(cf. Adams and Fournier, 2003, p. 60). We write $W_2^0(\nu) = L_2(\nu)$ and, for the Lebesgue measure μ on $\Omega \subset \mathbb{R}^d$, we define $W_2^\alpha(\Omega) := W_2^\alpha(\mu)$. It is well-known, see e.g., (Edmunds and Triebel, 1996, p. 25 and p. 44), that the Sobolev spaces $W_2^\alpha(\mathbb{R}^d)$ fall into the scale of Besov spaces, e.g., $W_2^\alpha(\mathbb{R}^d) \subset B_{2,\infty}^\alpha(\mathbb{R}^d)$ for $\alpha \in \mathbb{N}$. Furthermore, note that functions $f : \Omega \rightarrow \mathbb{R}^d$ can be extended to functions $\tilde{f} : \mathbb{R}^d \rightarrow \mathbb{R}$ such that \tilde{f} inherits the smoothness properties of f , whenever $\Omega \subset \mathbb{R}^d$ is a bounded Lipschitz domain. More precisely, in this case Stein's Extension Theorem (cf. Stein, 1970, p. 181) guarantees the existence of a linear extension operator \mathfrak{E} mapping functions $f : \Omega \rightarrow \mathbb{R}$ to functions $\mathfrak{E}f : \mathbb{R}^d \rightarrow \mathbb{R}$ such that $\mathfrak{E}f|_\Omega = f$ and such that \mathfrak{E} continuously maps $W_2^m(\Omega)$ into $W_2^m(\mathbb{R}^d)$ for all integers $m \geq 0$ and $B_{2,\infty}^\alpha(\Omega)$ into $B_{2,\infty}^\alpha(\mathbb{R}^d)$ for all $\alpha \geq 0$ simultaneously. For more details, we refer to Stein (1970, p. 181), Triebel (2006, Section 1.11.5), and Adams and Fournier (2003, Chapter 5). In this case, Eberts (2015, Corollary 3.4) shows, for a finite measure ν on \mathbb{R}^d such that $\text{supp } \nu =: \Omega \supset \Omega'$ and such that ν has a Lebesgue density g on Ω with $g \in L_\infty(\Omega)$, that $f \in B_{2,\infty}^\alpha(\Omega)$ implies $\mathfrak{E}f \in B_{2,\infty}^\alpha(\nu)$.

Based on the least squares loss and RKHSs using Gaussian kernels over the partition sets A_j , the subsequent theorem presents an oracle inequality for VP-SVMs.

Theorem 4 Let $Y := [-M, M]$ for $M > 0$, $L : Y \times \mathbb{R} \rightarrow [0, \infty)$ be the least squares loss, and P be a distribution on $\mathbb{R}^d \times Y$. We denote the marginal distribution of P onto \mathbb{R}^d by P_X , write $X := \text{supp } P_X$, and assume $P_X(\partial X) = 0$. Furthermore, let (\mathbf{A}) and (\mathbf{G}) be satisfied. In addition, for an arbitrary subset $T \subset X$, we assume (\mathbf{T}) . Moreover, let $f_{L,P}^* : \mathbb{R}^d \rightarrow \mathbb{R}$ be a Bayes decision function such that $f_{L,P}^* \in L_2(\mathbb{R}^d) \cap L_\infty(\mathbb{R}^d)$ as well as $f_{L,P}^* \in B_{2,\infty}^\alpha(P_X|_{A_T})$ for some $\alpha \geq 1$. Then, for all $p \in (0, 1)$, $n \geq 1$, $\tau \geq 1$, $\gamma = (\gamma_1, \dots, \gamma_m) \in (0, r]^m$, and $\lambda = (\lambda_1, \dots, \lambda_m) > 0$, the VP-SVM given by (3) using $\hat{H}_{\gamma_1}(A_1), \dots, \hat{H}_{\gamma_m}(A_m)$, and the loss L_{J_T} satisfies

$$\sum_{j=1}^m \lambda_j \|f_{D_{j,\lambda_j,\gamma_j}}\|_{\hat{H}_{\gamma_j}(A_j)}^2 + \mathcal{R}_{L_{J_T},P}(\hat{f}_{D,\lambda,\gamma}) - \mathcal{R}_{L_{J_T},P}^*$$

$$\leq C_{M,\alpha,p} \left(\sum_{j \in J_T} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_T} \gamma_j}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} + r^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} P_X(A_j) \right)^p n^{-1} + \tau n^{-1} \right)$$

with probability P^n not less than $1 - e^{-\tau}$, where $C_{M,\alpha,p} > 0$ is a constant only depending on $M, \alpha, p, d, \|f_{L,P}^*\|_{L_2(\mathbb{R}^d)}, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}$, and $\|f_{L,P}^*\|_{B_{2,\infty}^\alpha(P_X|_{A_T})}$.

We like to emphasize that in the theorem above $X := \text{supp } P_X$ only serves as a notation. Indeed, the partition $(A_j)_{j=1,\dots,m}$ of (\mathbf{A}) can be found without knowing $\text{supp } P_X$, and whether we actually remove the cells that do not intersect the interior of $\text{supp } P_X$ is irrelevant since these cells will neither contain samples nor will they contribute to the overall risk of our decision function $\hat{f}_{D,\lambda,\gamma}$ as we assumed $P_X(\partial X) = 0$. Despite from this, the proofs anyway do not require that X exactly corresponds to the support of the distribution P_X . Instead we can as well assume $\text{supp } P_X \subset X \subset B_{\text{eff}}^d$. Moreover, note for the proofs that the considered Besov-like space $B_{2,\infty}^\alpha(P_X|_{A_T})$ is defined w.r.t. $\Omega = \mathbb{R}^d$.

Theorem 4 only focuses on the least squares loss, however, a similar version can be shown under more general assumptions for generic losses and RKHSs, where we refer the interested reader to (Eberts, 2015, Theorem 4.4). Moreover, considering a trivial partition consisting of only one set A_1 the oracle inequalities for VP-SVMs are comparable to the already known ones, see (Eberts, 2015, p. 81) for more details.

Using the oracle inequality of Theorem 4, we derive learning rates w.r.t. the loss L_{J_T} for the learning method described by (2) and (3) in the following theorem.

Theorem 5 Let $\tau \geq 1$ be fixed and $\beta \geq \frac{2\alpha}{d} + 1$. Under the assumptions of Theorem 4 and with

$$r_n = c_1 n^{-\frac{1}{\beta\alpha}}, \quad (16)$$

$$\lambda_{n,j} = c_2 r_n^d n^{-1}, \quad (17)$$

$$\gamma_{n,j} = c_3 n^{-\frac{1}{2\alpha+d}}, \quad (18)$$

for every $j \in \{1, \dots, m_n\}$, we have, for all $n \geq 1$ and $\xi > 0$,

$$\mathcal{R}_{L_{J_T},P}(\hat{f}_{D,\lambda_n,\gamma_n}) - \mathcal{R}_{L_{J_T},P}^* \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \tau n^{-1} \right)$$

with probability P^n not less than $1 - e^{-\tau}$, where $\lambda_n := (\lambda_{n,1}, \dots, \lambda_{n,m_n})$ as well as $\gamma_n := (\gamma_{n,1}, \dots, \gamma_{n,m_n})$ and C, c_1, c_2, c_3 are positive constants with $c_3 \leq c_1$.

In the latter theorem the condition $\beta \geq \frac{2\alpha}{d} + 1$ is required to ensure $\gamma_{n,j} \leq r_n$, $j = 1, \dots, m_n$, which in turn is a prerequisite arising from Theorem 12 and the used entropy estimate. Let us briefly examine the extreme case $\beta = \frac{2\alpha}{d} + 1$. Using $r_n \approx n^{-\frac{1}{\beta\alpha}}$ and (5) leads to covering numbers of the form $m_n \approx n^{\frac{d}{2\alpha+d}}$ and computational costs of $\mathcal{O}(m_n (\frac{2\alpha}{m_n})^q) = \mathcal{O}(n^{\frac{2\alpha q}{2\alpha+d}})$ which is actually less than the computational cost of order n^q , $q \in [2, 3]$, of an usual SVM. Note that for increasing β the computational costs of an VP-SVM are increasing as well. However, for $\beta > \frac{2\alpha}{d} + 1$, $r_n \approx n^{-\frac{1}{\beta\alpha}}$, and $m_n \approx n^{\frac{d}{\beta}}$, a VP-SVM has costs of $\mathcal{O}(n^{\frac{1+\beta-1/q}{\beta}})$ which still is less than $\mathcal{O}(n^q)$.

Let us finally take a closer look at the VP-SVM given by (3) and the considerations related to (15), where $f_{b,\lambda} \in H = \bigoplus_{j=1}^m H_j$ solves the minimization problem

$$f_{b,\lambda} = \arg \min_{f \in \tilde{H}_1, \dots, f_m \in \tilde{H}_m} \sum_{j=1}^m \lambda_j \|f_j\|_{\tilde{H}_j}^2 + \mathcal{R}_{L,D} \left(\sum_{j=1}^m f_j \right).$$

Choosing $\lambda_1 = \dots = \lambda_m$, the VP-SVM problem can be understood as particular ℓ_2 -multiple kernel learning (MKL) problem using the RKHSs $\tilde{H}_1, \dots, \tilde{H}_m$. Learning rates for MKL have been treated, for example, in (Suzuki, 2011) and (Kloft and Blanchard, 2012). Assuming $f_{L,P}^* \in H$, the learning rate achieved in (Suzuki, 2011) is $mm^{-\frac{1}{1+\alpha}}$ for dense settings, where s is the so-called spectral decay coefficient. In addition, Kloft and Blanchard (2012) obtain essentially the same rates under these assumptions. Let us therefore briefly investigate the above rate of (Suzuki, 2011). For RKHSs that are continuously embedded in a Sobolev space $W_2^s(X)$, we have $s = \frac{d}{2\alpha}$ such that the learning rate reduces to $mn^{-\frac{2\alpha}{2\alpha+d}}$. Note that this learning rate is m times the optimal learning rate $n^{-\frac{2\alpha}{2\alpha+d}}$, where the number $m = mn_n$ of kernels may increase with the sample size n . In particular, if $m_n \rightarrow \infty$ polynomially, then the rates obtained in (Suzuki, 2011) become substantially worse than the optimal rate. In contrast, due to the special choice of the RKHSs, this is not the case for our VP-SVM problem, provided that m_n does not grow faster than $n^{1/\beta}$.

Note that the oracle inequalities and learning rates achieved in Theorems 4 and 5 require $f_{L,P}^* \in B_{2,\infty}^\alpha(\mathbb{P}_X \cup_{j \in J_T} A_j)$. However, for an increasing sample size n , the sets A_j shrink and the index set J_T , indicating every set A_j such that $A_j \cap T \neq \emptyset$ and $T \subset \bigcup_{j \in J_T} A_j$, increases. In particular, this also involves that the set $\bigcup_{j \in J_T} A_j$ covering T changes in tandem with n . Since this is very inconvenient and since it would be desirable to assume a certain level of smoothness of the target function on a fixed region for all $n \in \mathbb{N}$, we consider the set T enlarged by an δ -tube. To this end, for $\delta > 0$, we define $T^{+\delta}$ by

$$T^{+\delta} := \{x \in X \mid \exists k \in T : \|x - k\|_2 \leq \delta\},$$

which implies $T \subset T^{+\delta} \subset X$, cf. Figure 4. Note that, for every $\delta > 0$, there exists an $n_\delta \in \mathbb{N}$ such that, for every $n \geq n_\delta$, the union of all partition sets A_j , having at least one common point with T , is contained in $T^{+\delta}$, i.e.

$$\forall \delta > 0 \quad \exists n_\delta \in \mathbb{N} \quad \forall n \geq n_\delta \quad : \quad \bigcup_{j \in J_T} A_j \subset T^{+\delta}, \quad (19)$$

where $J_T := \{j \in \{1, \dots, m_n\} : A_j \cap T \neq \emptyset\}$. Collectively, this implies $T \subset \bigcup_{j \in J_T} A_j \subset T^{+\delta}$ for all $n \geq n_\delta$. Furthermore, since every set A_j is contained in a ball with radius $r_n = cn^{-\frac{1}{d}}$ satisfying (5), the lowest sample size n_δ in (19) can be determined by choosing the smallest $n_\delta \in \mathbb{N}$ such that $\delta \geq 2r_{n_\delta}$, that is

$$n_\delta = \left\lceil \left(\frac{2c}{\delta} \right)^{\beta d} \right\rceil.$$

This leads to the following corollary, which presents an oracle inequality and learning rates assuming the smoothness level α of the target function on a fixed region.

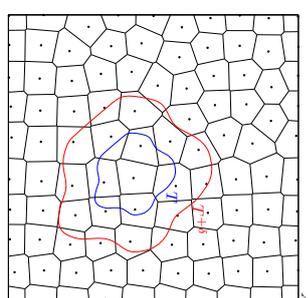

Figure 4: An input space X with a Voronoi partition as well as a subset $T \subset X$ enlarged by an δ -tube to $T^{+\delta}$.

Corollary 6 Let $Y := [-M, M]$ for $M > 0$, $L : Y \times \mathbb{R} \rightarrow [0, \infty)$ be the least squares loss, and \mathbb{P} be a distribution on $\mathbb{R}^d \times Y$. We denote the marginal distribution of \mathbb{P} onto \mathbb{R}^d by \mathbb{P}_X , write $X := \text{supp } \mathbb{P}_X$, and assume $\mathbb{P}_X(\partial X) = 0$. Furthermore, let **(A)** and **(G)** be satisfied. In addition, for an arbitrary subset $T \subset X$, we assume **(T)**. Moreover, let $f_{L,P}^* : \mathbb{R}^d \rightarrow \mathbb{R}$ be a Bayes decision function with $f_{L,P}^* \in L_2(\mathbb{R}^d) \cap L_\infty(\mathbb{R}^d)$ as well as

$$f_{L,P}^* \in B_{2,\infty}^\alpha(\mathbb{P}_X|_{T^{+\delta}})$$

for $\alpha \geq 1$ and some $\delta > 0$. Then, for all $p \in (0, 1)$, $n \geq n_\delta$, $\tau \geq 1$, $\gamma = (\gamma_1, \dots, \gamma_m) \in (0, r]^{m_n}$, and $\lambda = (\lambda_1, \dots, \lambda_m) > 0$, the VP-SVM given by (3) using $\tilde{H}_n(A_1), \dots, \tilde{H}_n(A_{m_n})$, and the loss L_T satisfies

$$\begin{aligned} & \sum_{j=1}^{m_n} \lambda_j \|f_{D_j, \lambda_j \gamma_j}\|_{\tilde{H}_{n_j}(A_j)}^2 + \mathcal{R}_{L_T, \mathbb{P}}(\tilde{f}_{D, \lambda, \gamma}) - \mathcal{R}_{L_T, \mathbb{P}}^* \\ & \leq C_{M, \alpha, p} \left(\sum_{j \in J_T} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_T} \gamma_j}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} + r^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-\frac{d+2\beta}{r}} \mathbb{P}_X(A_j) \right)^p n^{-1+\tau n^{-1}} \right) \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - e^{-\tau}$, where $C_{M, \alpha, p} > 0$ is the same constant as in Theorem 4.

Additionally, let $\beta \geq \frac{2\alpha}{d} + 1$ as well as, for every $j \in \{1, \dots, m_n\}$, r_n , $\lambda_{n,j}$, and $\gamma_{n,j}$ be as in (16), (17), and (18), respectively, where c_1, c_2, c_3 are user-specified positive constants with $c_3 \leq c_1$. Then, for all $n \geq n_\delta = \left\lceil \left(\frac{2c_3}{\delta} \right)^{\beta d} \right\rceil$ and $\xi > 0$, we have

$$\mathcal{R}_{L_T, \mathbb{P}}(\tilde{f}_{D, \lambda_n, \gamma_n}) - \mathcal{R}_{L_T, \mathbb{P}}^* \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \tau n^{-1} \right)$$

with probability \mathbb{P}^n not less than $1 - e^{-\tau}$, where $\lambda_n := (\lambda_{n,1}, \dots, \lambda_{n,m_n})$, $\gamma_n := (\gamma_{n,1}, \dots, \gamma_{n,m_n})$, and C is a positive constant.

Note that the assumption $f_{L,p}^* \in B_{2,\infty}^\alpha(\mathbb{P}_X|_{T^{+\varepsilon}})$ made in Corollary 6 is satisfied if, for example, \mathbb{P}_X has a bounded Lebesgue density on $T^{+\delta}$, $f_{L,p}^* \in L_\infty(T^{+\delta})$, and either $f_{L,p}^* \in B_{2,\infty}^\alpha(T^{+2\delta})$ for $\alpha \geq 1$ or $f_{L,p}^* \in W_2^\alpha(T^{+2\delta}) \subset B_{2,\infty}^\alpha(T^{+2\delta})$ for $\alpha \in \mathbb{N}$ and a bounded Lipschitz domain $\bar{T} \subset \mathbb{R}^d$ such that $T^{+2\delta} \subset \bar{T}$. Moreover, if this density of \mathbb{P}_X is even bounded away from 0, it is well-known that the minimax rate is $n^{-\frac{2\alpha}{2\alpha+1}}$ for $\alpha > d/2$ and target functions $f_{L,p}^* \in W_2^\alpha(T)$ as well as for $\alpha > d$ and $f_{L,p}^* \in B_{2,\infty}^\alpha(T)$. Modulo ξ , our rate is therefore asymptotically optimal in a minimax sense on T .

Although the obtained learning rates are arbitrary close to the optimal rates, it is needless to say that the results are not fully satisfying. Indeed, an ideal result would not contain a gap of the form n^ξ , and a close to ideal result would at least replace the gap n^ξ by a logarithmic factor. Unfortunately, even for global SVMs using Gaussian kernels, such results seem to be currently out of reach, see (Eberts and Steinwart, 2013) for the latter case. Let us briefly describe the technical obstacles. One key ingredient for both the local and the global approach are estimates on the entropy numbers e_i of the embeddings $\text{id} : H_\gamma \rightarrow L_2(P_X)$ or $\text{id} : H_\gamma \rightarrow \ell_\infty(X)$, see Section 6 for a definition. Several such estimates do exist. For example, Zhou (2002) and Kühn (2011) proved (optimal) super-polynomial estimates but unfortunately their bounds have a unfavorable dependence on γ , which makes it impossible to get arbitrarily close to the optimal rates, see e.g., (Xiang and Zhou, 2009) for a similar situation in which this problem occurs. For this reason we followed the path of (Eberts and Steinwart, 2013), in which we employ an entropy estimate of the form

$$e_i(\text{id} : H_\gamma \rightarrow L_2(\mathbb{P}_X)) \leq c_{p,d} \gamma^{-p} i^{-\frac{d}{2}}, \quad i \geq 1, \gamma \in (0, 1],$$

where $c_{p,d} \geq 1$ is a constant only depending on $p \in \mathbb{N}$ and d . Note that this estimate is clearly sub-optimal in i , but it has a significantly better behavior in γ compared to the above mentioned results. Now, using this entropy estimate, Eberts and Steinwart (2013) obtain an oracle inequality of the form

$$\mathcal{R}_{L,p}(f_{D,\lambda,\gamma}) - \mathcal{R}_{L,p}^* \leq K_p \left(\lambda \gamma^{-d} + \gamma^{2\alpha} + \frac{c_{p,d}^{d/p} \gamma^{-d}}{\lambda^{\frac{d}{2p}} n} + \frac{\tau}{n} \right),$$

where the constant K_p is independent of γ , λ , τ , and n , and its dependence on p can be tracked, cf. (Steinwart and Christmann, 2008, p. 267). Note that for the local approach a structurally identical formula is derived implicitly in the proof of Theorem 4. Now, the rates in this paper as well as in (Eberts and Steinwart, 2013) are obtained by optimizing the right hand side with respect to both λ and γ for an arbitrarily large but fixed p . Since the resulting rates become better the larger we pick p it is tempting to consider $p = p_n \rightarrow \infty$. Unfortunately, however, this only becomes feasible if we have an explicit expression describing how $c_{p,d}$ may depend on p . For example, some preliminary considerations suggest that we could already replace the gap n^ξ by a logarithmic factor if we had a rough bound of the form $c_{p,d} \leq c_0 p^{\theta p}$. Unfortunately, we neither could derive such a bound for $c_{p,d}$ nor could we find it in the literature. Even worse, we also asked several experts for bounding entropy numbers of function space embeddings without any success. In addition, we are unaware of any other technique that has the potential to fill the gap in either the global or the local case, and therefore we leave this problem as an open question for future research.

4.2 Data-Dependent Parameter Selection for VP-SVMs

In the previous theorems the choice of the regularization parameters $\lambda_{n,1}, \dots, \lambda_{n,m_n}$ and the kernel widths $\gamma_{n,1}, \dots, \gamma_{n,m_n}$ requires us to know the smoothness parameter α . Unfortunately, in practice, we usually do not know either this value nor its existence. In this subsection, we thus show that a training/validation approach similar to the one examined in (Steinwart and Christmann, 2008, Chapters 6.5, 7.4, 8.2) and (Eberts and Steinwart, 2013) achieves the same rates adaptively, i.e., without knowing α . For this purpose, let $\Lambda := (\Lambda_n)$ and $\Gamma := (\Gamma_n)$ be sequences of finite subsets $\Lambda_n \subset (0, r_n^d]$ and $\Gamma_n \subset (0, r_n]$. For a data set $D := ((x_1, y_1), \dots, (x_n, y_n))$, we define

$$\begin{aligned} D_1 &:= ((x_1, y_1), \dots, (x_l, y_l)), \\ D_2 &:= ((x_{l+1}, y_{l+1}), \dots, (x_n, y_n)), \end{aligned}$$

where $l := \lfloor \frac{n}{2} \rfloor + 1$ and $n \geq 4$. We further split these sets in data sets

$$\begin{aligned} D_j^{(1)} &:= \{(x_i, y_i) \in D_1 : x_i \in A_j\}, & j \in \{1, \dots, m_n\}, \\ D_j^{(2)} &:= \{(x_i, y_i) \in D_2 : x_i \in A_j\}, & j \in \{1, \dots, m_n\}, \end{aligned}$$

and define $l_j := |D_j^{(1)}|$ for all $j \in \{1, \dots, m_n\}$ such that $\sum_{j=1}^{m_n} l_j = l$. For every $j \in \{1, \dots, m_n\}$, we basically use $D_j^{(1)}$ as a training set, i.e., based on D_1 in combination with the loss function $L_j := \mathbb{1}_{A_j} L$ we compute SVM decision functions

$$f_{D_j^{(1)}, \lambda_j, \gamma_j} := \arg \min_{f \in H_{\gamma_j}(A_j)} \lambda_j \|f\|_{H_{\gamma_j}(A_j)}^2 + \mathcal{R}_{L_j, D_1}(f), \quad (\lambda_j, \gamma_j) \in \Lambda_n \times \Gamma_n.$$

Note that $f_{D_j^{(1)}, \lambda_j, \gamma_j} = 0$ if $D_j^{(1)} = \emptyset$. Next, for each j , we use D_2 in tandem with L_j (or essentially $D_j^{(2)}$) to determine a pair $(\lambda_{D_{2,j}}, \gamma_{D_{2,j}}) \in \Lambda_n \times \Gamma_n$ such that

$$\mathcal{R}_{L_j, D_2} \left(\hat{f}_{D_j^{(1)}, \lambda_{D_{2,j}}, \gamma_{D_{2,j}}} \right) = \min_{(\lambda_j, \gamma_j) \in \Lambda_n \times \Gamma_n} \mathcal{R}_{L_j, D_2} \left(\hat{f}_{D_j^{(1)}, \lambda_j, \gamma_j} \right).$$

Finally, combining the decision functions $f_{D_j^{(1)}, \lambda_{D_{2,j}}, \gamma_{D_{2,j}}}$ for all $j \in \{1, \dots, m_n\}$, and defining $\lambda_{D_2} := (\lambda_{D_{2,1}}, \dots, \lambda_{D_{2,m_n}})$ and $\gamma_{D_2} := (\gamma_{D_{2,1}}, \dots, \gamma_{D_{2,m_n}})$, we obtain a function

$$f_{D_1, \lambda_{D_2}, \gamma_{D_2}} := \sum_{j=1}^{m_n} f_{D_j^{(1)}, \lambda_{D_{2,j}}, \gamma_{D_{2,j}}} = \sum_{j=1}^{m_n} \mathbb{1}_{A_j} f_{D_j^{(1)}, \lambda_{D_{2,j}}, \gamma_{D_{2,j}}},$$

and we call every learning method that produces these resulting decision functions $f_{D_1, \lambda_{D_2}, \gamma_{D_2}}$ a *training validation Voronoi partition support vector machine* (TV-VP-SVM) w.r.t. $\Lambda \times \Gamma$. Moreover, we have, for $\lambda := (\lambda_1, \dots, \lambda_{m_n})$ and $\gamma := (\gamma_1, \dots, \gamma_{m_n})$,

$$\mathcal{R}_{L, D_2} \left(\hat{f}_{D_1, \lambda_{D_2}, \gamma_{D_2}} \right) = \sum_{j=1}^{m_n} \mathcal{R}_{L_j, D_2} \left(\hat{f}_{D_j^{(1)}, \lambda_{D_{2,j}}, \gamma_{D_{2,j}}} \right)$$

$$\begin{aligned}
&= \sum_{j=1}^{m_n} \min_{(\lambda_j, \gamma_j) \in \Lambda_n \times \Gamma_n} \mathcal{R}_{L_j, D_2} \left(\widehat{f}_{D_j^{(1)}, \lambda_j, \gamma_j} \right) \\
&= \min_{(\lambda, \gamma) \in (\Lambda_n \times \Gamma_n)^{m_n}} \sum_{j=1}^{m_n} \mathcal{R}_{L_j, D_2} \left(\widehat{f}_{D_j^{(1)}, \lambda_j, \gamma_j} \right) \\
&= \min_{(\lambda, \gamma) \in (\Lambda_n \times \Gamma_n)^{m_n}} \mathcal{R}_{L, D_2} \left(\widehat{f}_{D_1, \lambda, \gamma} \right),
\end{aligned}$$

where $f_{D_1, \lambda, \gamma} := \sum_{j=1}^{m_n} f_{D_j^{(1)}, \lambda_j, \gamma_j}$ with $(\lambda_j, \gamma_j) \in \Lambda_n \times \Gamma_n$ for all $j \in \{1, \dots, m_n\}$. In other words, the function $f_{D_1, \lambda, \gamma, \tau, D_2}$ really minimizes the empirical risk \mathcal{R}_{L, D_2} w.r.t. the validation data set D_2 and the loss L_1 , where the minimum is taken over all functions $\widehat{f}_{D_1, \lambda, \gamma}$ with $(\lambda, \gamma) \in (\Lambda_n \times \Gamma_n)^{m_n}$.

Before we analyze the TV-VP-SVM algorithm, let us briefly discuss the computational complexity of the hyper-parameter selection step. To this end, we first note that the parameter selection on, e.g., the j -th cell is *completely independent* of the parameter selection on all other cells. Maybe the easiest way to visualize this is by thinking of having two cells and candidates $\Lambda = (\lambda_1, \dots, \lambda_k)$, only. Naively, this would give the candidate set $\Lambda \times \Lambda$ for the overall hyper-parameter selection procedure. However, inspecting the candidates on the first cell, we see the same results for the candidates in $\Lambda \times \{\lambda_1\}$ and in $\Lambda \times \{\lambda_2\}$ since any decision we make on the second cell does not influence our situation on the first cell. Consequently, we only need to consider the candidates $\Lambda \times \{\lambda_1\}$, that is the candidates in Λ , when performing parameter selection on the first cell, and analogously we only need to consider the candidates $\{\lambda_1\} \times \Lambda$ for the parameter selection on the second cell. Together this gives $2|\Lambda|$ many candidates, instead of $|\Lambda|^2$ many candidates of the naive approach.

Generalizing the reasoning above to m cells and $\Lambda \times \Gamma$, we easily see that our parameter selection strategy leads to the inspection of $m \times |\Lambda| \times |\Gamma|$ many candidates. Moreover, because of the independence of all cells, we could actually perform parameter selection on the cells in parallel. Clearly such a parallel approach would be easy to implement and would have minimal synchronization and communication overhead.

The following theorem presents learning rates for the above described TV-VP-SVM.

Theorem 7 *Let $r_n := cn^{-\frac{1}{2d}}$ with constants $c > 0$ and $\beta > 1$. Under the assumptions of Theorem 4 we fix sequences $\Lambda := (\Lambda_n)$ and $\Gamma := (\Gamma_n)$ of finite subsets $\Lambda_n \subset (0, r_n^d]$ and $\Gamma_n \subset (0, r_n]$ such that Λ_n is an $(r_n^d \varepsilon_n)$ -net of $(0, r_n^d]$ and Γ_n is a δ_n -net of $(0, r_n]$ with $\varepsilon_n \leq n^{-1}$ and $\delta_n \leq n^{-\frac{1}{2+2d}}$. Furthermore, assume that the cardinalities $|\Lambda_n|$ and $|\Gamma_n|$ grow polynomially in n . Then, for all $\xi > 0$, $\tau \geq 1$, and $\alpha < \frac{\beta-1}{2}d$, the TV-VP-SVM producing the decision functions $f_{D_1, \lambda, \gamma, \tau, D_2}$ satisfies*

$$\mathbb{P}^n \left(\mathcal{R}_{L_{j^*}, P}(\widehat{f}_{D_1, \lambda, \gamma, \tau, D_2}) - \mathcal{R}_{L_{j^*}, P}^* \leq c \left(n^{-\frac{2\alpha}{2d+\tau} + \xi} + \tau n^{-1} \right) \geq 1 - e^{-\tau}, \right.$$

where $c > 0$ is a constant independent of n and τ .

Once more, we can replace the assumption $f_{L^*}^* \in B_{2, \infty}^\alpha(\mathbb{P}_{X|Y})$ by $f_{L, P}^* \in B_{2, \infty}^\alpha(\mathbb{P}_{X|Y+\delta})$ for some $\delta > 0$ and obtain the same learning rate as in Theorem 7 for all $n \geq n_\delta$ although

$T^{+\delta}$ is fixed for all $n \in \mathbb{N}$. Here, recall that $f_{L, P}^* \in B_{2, \infty}^\alpha(\mathbb{P}_{X|Y+\delta})$ whenever \mathbb{P}_X has a bounded Lebesgue density on $T^{+\delta}$, $f_{L, P}^* \in L_\infty(T^{+\delta})$, and either $f_{L, P}^* \in B_{2, \infty}^\alpha(T^{+2\delta})$ for $\alpha \geq 1$ or $f_{L, P}^* \in W_2^\alpha(\widetilde{T}) \subset B_{2, \infty}^\alpha(T^{+2\delta})$ for $\alpha \in \mathbb{N}$ and a bounded Lipschitz domain $\widetilde{T} \subset \mathbb{R}^d$ such that $T^{+2\delta} \subset \widetilde{T}$. Moreover, let us assume that $\widetilde{T} \supseteq T^{+\delta}$ is a bounded Lipschitz domain in \mathbb{R}^d such that Stein's extension operator \mathfrak{E} exists and that P is a distribution on $\mathbb{R}^d \times Y$ such that \mathbb{P}_X has a Lebesgue density g on $T^{+\delta}$ with $g \in L_\infty(T^{+\delta})$. Then, the assumptions $f_{L, P}^* \in B_{2, \infty}^\alpha(T)$ and $f_{L, P}^* \in L_\infty(T)$ yield $\mathfrak{E}f_{L, P}^* \in B_{2, \infty}^\alpha(\mathbb{P}_{X|Y+\delta})$ and $\mathfrak{E}f_{L, P}^* \in L_2(\mathbb{R}^d) \cap L_\infty(\mathbb{R}^d)$, see (Eberts, 2015, Corollary 3.4 and Theorem 3.2) for more details. Thus, applying $\mathcal{R}_{L_{j^*}, P}^* = \mathcal{R}_{L_{j^*}, P}(\mathfrak{E}f_{L, P}^*)$ and choosing $f_0 := \sum_{j \in J_n} \mathbb{1}_{A_j} \cdot (K_j * \mathfrak{E}f_{L, P}^*)$, we obtain the same results as in Corollary 6 and Theorem 7 for $n \geq n_\delta$. Obviously, the same is true, if we assume $f_{L, P}^* \in W_2^\alpha(\widetilde{T})$ instead of $f_{L, P}^* \in B_{2, \infty}^\alpha(T)$. For all these cases, note that, if \mathbb{P}_X has a Lebesgue density that is bounded away from 0 and ∞ and either $f_{L, P}^* \in W_2^\alpha(T)$ for $\alpha > d/2$ or $f_{L, P}^* \in B_{2, \infty}^\alpha(T)$ for $\alpha > d$, the achieved learning rate $n^{-\frac{2\alpha}{2d+\tau}}$ is again asymptotically optimal modulo ξ on T in a minmax sense. Here, we only derived learning rates when using the least squares loss. However, similar rates are shown by Eberts (2015, Section 9) for quantile regression using the pinball loss.

To derive the above learning rates, we need the condition $\alpha < \frac{\beta-1}{2}d$. However, this condition restricts the set of α -values where we obtain learning rates adaptively. To be more precise, there is a trade-off between α and β . On the one hand, for small values of β only a small number of possible values for α is covered. On the other hand, for larger values of β the set of α -values where we achieve rates adaptively is increasing but the savings in terms of computing time is decreasing.

Finally, we note that if we have a fixed computational budget in terms of RAM and/or computing time, this trade-off can be approximately resolved in the following way. First, we consider a couple of candidates for β , or the resulting number of cells m . Then, we pick a suitably sized random subset of the entire training set and build Voronoi partitions of this random subset for the different candidates. For each cell of these partitions we then estimate the computational costs and finally we pick the largest candidate β for which the resulting partition still satisfies our computational budget. This procedure has several benefits: *a)* it is very cheap compared to the subsequent training and parameter selection phase, *b)* the choice of β , or m , has a clear meaning for the user, *c)* it approximately leads to widest adaptivity we can afford by our computational budget, and *d)* our experiments in the next section show that there is no significant risk for the user by focusing on the maximal computational resources.

5. Experimental Results

In this section we report a few experiments for VP-SVMs, which illustrate the influence of the chosen radius and which compare them to standard global SVMs as well as to RC-SVMs in terms of both training time and test error.

In the experiments we report here, we consider the classical COVTYPE data set, which contains 581.012 samples of dimension 54. More experimental results on additional data sets can be found in (Eberts, 2015) and in the earlier arXiv version (Eberts and Steinwart, 2014) of this paper. The code we used was an early version of Steinwart (2016), which provides

Algorithm 1 Determine a Voronoi partition of the input data

Require: Input data set $D_X = \{x_1, \dots, x_n\}$ with sample size $n \in \mathbb{N}$ and some radius $r > 0$.

Ensure: Working sets indicating a Voronoi partition of D_X .

```

1: Pick an arbitrary  $z \in D_X$ 
2:  $Cover_1 \leftarrow z$ 
3:  $m \leftarrow 1$ 
4: while  $\max_{x \in D_X} \|x - Cover\|_2 > r$  do
5:    $z \leftarrow \arg \max_{x \in D_X} \|x - Cover\|_2$ 
6:    $m \leftarrow m + 1$ 
7:    $Cover_m \leftarrow z$ 
8:    $WorkingSet_m \leftarrow \emptyset$ 
9: end while
10: for  $i = 1$  to  $n$  do
11:    $k \leftarrow \arg \min_{j \in \{1, \dots, m\}} \|x_i - Cover_j\|_2$ 
12:    $WorkingSet_k \leftarrow WorkingSet_k \cup \{x_i\}$ 
13: end for
14: return  $WorkingSet_1, \dots, WorkingSet_m$ 

```

highly efficient SVM solvers for different loss functions based on the ideas developed by (Steinwart et al., 2011). In particular, it is easy to repeat every experiment by the current version of the code.

In order to prepare the data set for the experiments, we first merged the split raw data sets so that we obtained one data set. In a next step, we scaled the data component-wise such that all samples including labels lie in $[-1, 1]^{d+1}$, where d is the dimension of the input data. Finally, we generated random subsets that were afterwards randomly split into a training and a test data set. In this manner, we obtained training sets consisting of $n = 1\,000$, $2\,500$, $5\,000$, $10\,000$, $25\,000$, $50\,000$, $100\,000$, $250\,000$, and $500\,000$ samples. The test data sets associated to the various training sets consist of $n_{\text{test}} = 50\,000$ random samples, apart from the training sets with $n_{\text{train}} \leq 5\,000$, for which we took $n_{\text{test}} = 10\,000$ test samples. To minimize random effects, we repeated the experiment for each setting several times. Since experiments using large data sets entail long run times, we reran every experiment using a training set of size $n \geq 50\,000$ only three times while for training sets of size $n = 10\,000$, $25\,000$ we performed ten repetitions and for smaller training sets, namely of size $n = 1\,000$, $2\,500$, $5\,000$, even 100 runs.

To train the global SVM for sufficiently large data sets we used a professional compute server equipped with four INTEL XEON E7-4830 (2.13 GHz) 8-core processor, 256 GB RAM. In order to have comparable run times, we ran the experiments for the VP-SVMs and RC-SVMs on this machine, too. In all experiments we used eight cores to pre-compute the kernel matrix and to evaluate the final decision functions on the test set, but only one core for the actual solver.

Let us quickly illustrate the routines of the VP- and the RC-SVM implemented around the LS-solver. For the VP-SVM, we first split the training set by Algorithm 1 in several working sets representing a Voronoi partition w.r.t. the user-specified radius. For this purpose, Algorithm 1 initially determines a cover of the input data applying the farthest

first traversal algorithm, see (Dasgupta, 2008) and (Gonzalez, 1985) for more details. Note that this procedure induces working sets whose sizes may be considerably varying. In the case of an RC-SVM the working sets form a random partition of the training samples, where their sizes are basically equal and the number of working sets is predefined by the user. Then, for the VP-SVM- as well as for the RC-SVM-algorithm the implemented LS-solver is applied on every working set. For each working set, we randomly split the respective training data set of size n_{train} in five folds to apply 5-fold cross-validation in order to deal with the hyper-parameters λ and γ taken from an 10 by 10 grid geometrically generated in $[0.001 \cdot n_{\text{train}}, 0.1] \times [0.5 \cdot n_{\text{train}}^{-1/d}, 10]$. Finally, we obtain one decision function for each working set. To further process these decision functions the VP-SVM-algorithms picks exactly one decision function depending on the working set affiliation of the input value. On the contrary, the RC-SVM-algorithm simply takes the average of all the decision functions. Moreover, the computed decision functions are clipped at ± 1 . Altogether, note that the usual LS-SVM-algorithm can be interpreted as special case of both the VP-SVM- and the RC-SVM-algorithm using one working set.

The results, which are displayed in Figure 5, can be quickly summarized: Not surprisingly, smaller radii for the VP-SVM lead to less crowded cells, which in turn reduces the training time significantly. In addition, the VP-SVM is, unlike the global SVM, not affected by the amount of available memory, so that runs with more than 100,000 samples, which would require kernel matrix caching for the global SVM, are still very feasible for the VP-SVM. Despite these advantages in terms of required computational resources, however, the test errors of the VP-SVM are only a bit worse than those of the global SVM. Moreover, the test errors become slightly better with increasing radii, so that there is a clear trade-off between computational resources and test accuracy as discussed in the previous section. When comparing the RC-SVM with the global SVM, we see, not surprisingly, the same computational advantages, but the test errors become significantly worse. As a consequence, the VP-SVM clearly outperforms the RC-SVM in terms of test errors, when both approaches have about the same training time. In this respect we also like to mention that in terms of test time, the VP-SVM was significantly faster than the RC-SVM, simply because for the VP-SVM each decision function evaluation only requires the support vector of the corresponding cell, whereas the final decision function of the RC-SVM requires all support vectors. See (Eberts and Steinwart, 2014) for details.

6. Proofs

This section is dedicated to prove the results of the previous sections.

We begin by recalling the definition of entropy and covering numbers. To this end, let (T, d) be a metric space. Then, the i -th (dyadic) entropy number of T is

$$\epsilon_i(T, d) := \inf \left\{ \varepsilon > 0 : \exists s_1, \dots, s_{2^{i-1}} \in T \text{ such that } T \subset \bigcup_{j=1}^{2^{i-1}} B(s_j, \varepsilon) \right\},$$

where $B_d(s, \varepsilon) := \{t \in T : d(t, s) \leq \varepsilon\}$ and $\inf \emptyset := \infty$. Moreover, if $S : E \rightarrow F$ is a bounded linear operator between the normed spaces E and F , then its (dyadic) entropy numbers are defined by $e_i(S : E \rightarrow F) := \epsilon_i(SB_E, \|\cdot\|_F)$, where B_E denotes the closed unit ball of E .

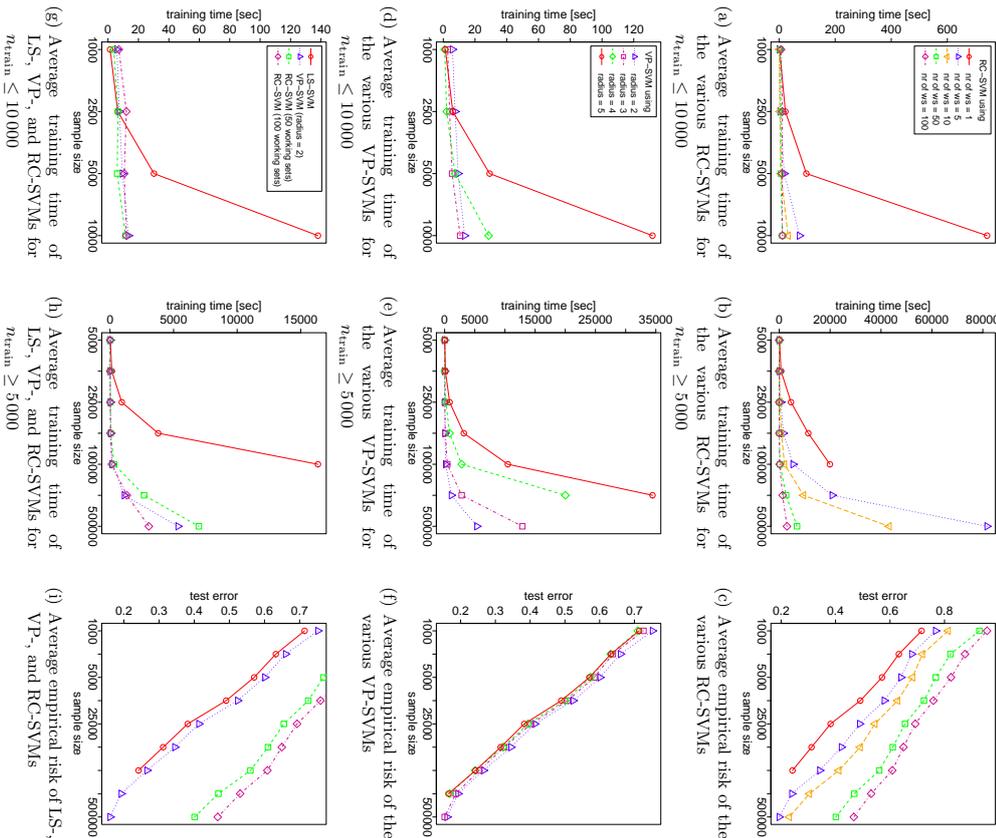

Figure 5: Average training time and test error of LS-, VP-, and RC-SVMs for the real-world data COVTYPE depending on the training set size $n_{\text{train}} = 1,000, \dots, 500,000$. Subfigures (a)–(c) show the results for RC-SVMs using different numbers of working sets and Subfigures (d)–(f) illustrate the results for VP-SVMs using various radii. At the bottom, Subfigures (g)–(i) contain the average training times and the average test errors of the LS-SVM, one VP-SVM and two RC-SVMs. Here, the VP-SVM is the one which trains fastest for $n_{\text{train}} = 500,000$ and the two RC-SVMs are those which achieve for $n_{\text{train}} = 500,000$ roughly the same training time as the chosen VP-SVM. Here, note that, for $n_{\text{train}} = 10,000$, the RC-SVM using one working set trains substantially slower than the LS-SVM, even though this RC-SVM is basically an LS-SVM. As a reason for this phenomenon, we conjecture that the used compute server was busy because of other influences.

Similarly, the ε -covering number of T is defined by

$$\mathcal{N}(T, d, \varepsilon) := \inf \left\{ n \geq 1 : \exists s_1, \dots, s_n \in T \text{ such that } T \subset \bigcup_{i=1}^n B_d(s_i, \varepsilon) \right\},$$

and again, this definition can be applied to bounded linear operators $S : E \rightarrow F$ by considering the set SBE . Moreover, every subset $S \subset T$ for which for all $t \in T$ there exists an $s \in S$ with $d(s, t) \leq \varepsilon$ is called an ε -net of T . Consequently, $\mathcal{N}(T, d, \varepsilon)$ is the size of the smallest ε -net of T . Recall that entropy and covering numbers are in some sense inverse to each other. To be more precise, for all constants $a > 0$ and $q > 0$, the implication

$$e_i(T, d) \leq a i^{-1/q}, \quad i \geq 1 \quad \implies \quad \ln \mathcal{N}(T, d, \varepsilon) \leq \ln(4) \left(\frac{a}{\varepsilon} \right)^q, \quad \forall \varepsilon > 0 \quad (20)$$

holds by (Steinwart and Christmann, 2008, Lemma 6.21). Additionally, (Steinwart and Christmann, 2008, Exercise 6.8) yields the opposite implication, namely

$$\ln \mathcal{N}(T, d, \varepsilon) < \left(\frac{a}{\varepsilon} \right)^q, \quad \varepsilon > 0 \quad \implies \quad e_i(T, d) \leq 3^{1/q} a i^{-1/q}, \quad \forall i \geq 1. \quad (21)$$

With these preparations, we can now prove Lemma 1, which relates the radius r of a cover $B_{r_1}(z_1), \dots, B_{r_m}(z_m)$ of $B_{\tilde{r}} \supset X$ defined by (4) with the number m of centers z_1, \dots, z_m .

Proof [of Lemma 1] It is easy to show that $\mathcal{N}(cB_{\tilde{r}}(c\tilde{r}), r) = \mathcal{N}(B_{\tilde{r}}(c\tilde{r}), \tilde{r})$ holds for all $r, c > 0$. Moreover, applying Proposition 1.1 of (Temlyakov, 2013) yields

$$r^{-d} \leq \mathcal{N}(B_{\tilde{r}}(c\tilde{r}), \tilde{r}) \leq \left(1 + \frac{2}{\tilde{r}} \right)^d, \quad \tilde{r} \in (0, 1].$$

Consequently, we can find a cover $(B_{r_i}(z_i))_{i=1, \dots, m}$ of $X \subset cB_{\tilde{r}}(c\tilde{r})$ with centers $z_j \in cB_{\tilde{r}}(c\tilde{r})$ and radius $r \leq c$ such that

$$\left(\frac{r}{c} \right)^{-d} \leq m \leq \left(1 + \frac{2c}{r} \right)^d.$$

Since $r \leq c$, we thus have $r \leq (r + 2c) m^{-\frac{1}{d}} \leq 3cm^{-\frac{1}{d}}$. \blacksquare

Next, we consider a lemma that is part of our construction of the partition $(A_j)_j$ of X .

Lemma 8 *Let $(A'_j)_{j=1, \dots, m}$ be a partition of $B_{\tilde{r}}(c\tilde{r})$ such that $A'_j \neq \emptyset$ as well as $\overline{A'_j} = \overline{A_j}$ for every $j \in \{1, \dots, m\}$. Let \tilde{X} be some closed subset of $B_{\tilde{r}}(c\tilde{r})$ such that $\tilde{X} \neq \emptyset$ and $\tilde{X} = X$.*

Without loss of generality we further assume that there is an $m_0 \leq m$ such that $A'_j \cap \tilde{X} \neq \emptyset$ for all $j \in \{1, \dots, m_0\}$ and $A'_j \cap \tilde{X} = \emptyset$ for all $j \in \{m_0 + 1, \dots, m\}$. Then, we define $A''_j := A'_j \cap \tilde{X}$ for all $j \in \{1, \dots, m_0\}$. Moreover, let $(A_j)_{j=1, \dots, m_0}$ be a partition of \tilde{X} with $A''_j \subset A_j \subset \overline{A''_j}$. Then, for every $j \in \{1, \dots, m_0\}$, we have $A''_j \neq \emptyset$, and thus $A_j \neq \emptyset$.

Proof Let us assume that there is an $j \in \{1, \dots, m_0\}$ with $\dot{A}_j'' = \emptyset$. By our assumption we then know $A_j'' \cap \dot{X} \neq \emptyset$, i.e., there exists some $x \in A_j'' \cap \dot{X}$. Since

$$\emptyset = \dot{A}_j'' = \text{interior}(A_j'' \cap \dot{X}) = \dot{A}_j'' \cap \text{interior} \dot{X} = \dot{A}_j'' \cap \dot{X},$$

where we used the notation $\text{interior } B := \overset{\circ}{B}$, it immediately follows that $x \in \partial A_j'' \subset \overline{A_j''} = \dot{A}_j''$. Hence, there exists a sequence $(x_n)_n \subset \dot{A}_j''$ such that $x_n \xrightarrow{n \rightarrow \infty} x$. On the other hand, $x \in A_j'' \subset \dot{X}$ together with the fact that \dot{X} is open, gives $x_n \in \dot{X}$ for all sufficiently large n . For such an n , we obtain $x_n \in \dot{A}_j'' \cap \dot{X} = \dot{A}_j''$, which contradicts the assumed $\dot{A}_j'' = \emptyset$. The second assertion follows from $\dot{A}_j'' \subset \dot{A}_j$. ■

Next, let us consider a crucial property of the risk of functions contained in a joined RKHS.

Lemma 9 Let P be a distribution on $X \times Y$ and $L : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ be a loss function. For $A, B \subset X$ such that $A \cup B = X$ and $A \cap B = \emptyset$, define loss functions $L_A, L_B : X \times Y \times \mathbb{R} \rightarrow [0, \infty)$ by $L_A(x, y, t) = \mathbb{1}_A(x)L(x, y, t)$ and $L_B(x, y, t) = \mathbb{1}_B(x)L(x, y, t)$, respectively. Furthermore, let $f_A : X \rightarrow \mathbb{R}$ as well as $f_B : X \rightarrow \mathbb{R}$ be measurable functions and $f : X \rightarrow \mathbb{R}$ be defined by $f(x) = \mathbb{1}_A(x)f_A(x) + \mathbb{1}_B(x)f_B(x)$ for all $x \in X$. Then, we have

$$\mathcal{R}_{L, P}(f) = \mathcal{R}_{L_A, P}(f_A) + \mathcal{R}_{L_B, P}(f_B).$$

as well as

$$\mathcal{R}_{L, P}(f) - \mathcal{R}_{L, P}^*(f) = (\mathcal{R}_{L_A, P}(f_A) - \mathcal{R}_{L_A, P}^*(f_A)) + (\mathcal{R}_{L_B, P}(f_B) - \mathcal{R}_{L_B, P}^*(f_B)).$$

Proof Simple transformations using $A \cup B = X$ and $A \cap B = \emptyset$ show

$$\begin{aligned} \mathcal{R}_{L, P}(f) &= \int_{X \times Y} L(x, y, \mathbb{1}_A(x)f_A(x) + \mathbb{1}_B(x)f_B(x)) dP(x, y) \\ &= \int_{X \times Y} \mathbb{1}_A(x)L(x, y, f_A(x)) + \mathbb{1}_B(x)L(x, y, f_B(x)) dP(x, y) \\ &= \mathcal{R}_{L_A, P}(f_A) + \mathcal{R}_{L_B, P}(f_B). \end{aligned}$$

The second assertion follows immediately. ■

6.1 Some General Estimates on Entropy Numbers

To derive an oracle inequality for VP-SVMs we will have to relate the entropy numbers of H_j , $j \in \{1, \dots, m\}$, to those of H . Our first result establishes such a relationship for covering numbers, instead.

Lemma 10 Let ν be a distribution on X and $A, B \subset X$ with $A \cap B = \emptyset$. Moreover, let H_A and H_B be RKHSs on A and B that are embedded into $L_2(\nu_A)$ and $L_2(\nu_B)$, respectively. Let the extended RKHSs \hat{H}_A and \hat{H}_B be defined as in Lemma 2 and denote their direct sum by H as in (11), where the norm is given by (12) with $\lambda_A, \lambda_B > 0$. Then, for the ε -covering number of H w.r.t. $\|\cdot\|_{L_2(\nu)}$, we have

$$\mathcal{N}(B_H, \|\cdot\|_{L_2(\nu)}, \varepsilon) \leq \mathcal{N}\left(\lambda_A^{-1/2} B_{\hat{H}_A}, \|\cdot\|_{L_2(\nu_A)}, \varepsilon_A\right) \cdot \mathcal{N}\left(\lambda_B^{-1/2} B_{\hat{H}_B}, \|\cdot\|_{L_2(\nu_B)}, \varepsilon_B\right),$$

where $\varepsilon_A, \varepsilon_B > 0$ and $\varepsilon := \sqrt{\varepsilon_A^2 + \varepsilon_B^2}$.

Proof First of all, we assume that there exist $a, b \in \mathbb{N}$ and functions $\hat{f}_1, \dots, \hat{f}_a \in \lambda_A^{-1/2} B_{\hat{H}_A}$ and $\hat{h}_1, \dots, \hat{h}_b \in \lambda_B^{-1/2} B_{\hat{H}_B}$ such that $\{\hat{f}_1, \dots, \hat{f}_a\}$ is an ε_A -cover of $\lambda_A^{-1/2} B_{\hat{H}_A}$ w.r.t. $\|\cdot\|_{L_2(\nu_A)}$, $\{\hat{h}_1, \dots, \hat{h}_b\}$ is an ε_B -cover of $\lambda_B^{-1/2} B_{\hat{H}_B}$ w.r.t. $\|\cdot\|_{L_2(\nu_B)}$,

$$a = \mathcal{N}\left(\lambda_A^{-1/2} B_{\hat{H}_A}, \|\cdot\|_{L_2(\nu_A)}, \varepsilon_A\right) \quad \text{and} \quad b = \mathcal{N}\left(\lambda_B^{-1/2} B_{\hat{H}_B}, \|\cdot\|_{L_2(\nu_B)}, \varepsilon_B\right). \quad (22)$$

That is, for every function $\hat{g}_A \in \lambda_A^{-1/2} B_{\hat{H}_A}$, there exists an $i_A \in \{1, \dots, a\}$ such that

$$\|\hat{g}_A - \hat{f}_{i_A}\|_{L_2(\nu_A)} \leq \varepsilon_A, \quad (22)$$

and for every function $\hat{g}_B \in \lambda_B^{-1/2} B_{\hat{H}_B}$, there exists an $i_B \in \{1, \dots, b\}$ such that

$$\|\hat{g}_B - \hat{h}_{i_B}\|_{L_2(\nu_B)} \leq \varepsilon_B. \quad (23)$$

Let us now consider an arbitrary function $g \in B_H$. Then, there exists an $\hat{g}_A \in \lambda_A^{-1/2} B_{\hat{H}_A}$ and an $\hat{g}_B \in \lambda_B^{-1/2} B_{\hat{H}_B}$ such that $g = \hat{g}_A + \hat{g}_B$. Together with (22) and (23), this implies

$$\begin{aligned} \left\|g - \left(\hat{f}_{i_A} + \hat{h}_{i_B}\right)\right\|_{L_2(\nu)}^2 &= \left\|\left(\hat{g}_A - \hat{f}_{i_A}\right) + \left(\hat{g}_B - \hat{h}_{i_B}\right)\right\|_{L_2(\nu)}^2 \\ &= \left\|\hat{g}_A - \hat{f}_{i_A}\right\|_{L_2(\nu_A)}^2 + \left\|\hat{g}_B - \hat{h}_{i_B}\right\|_{L_2(\nu_B)}^2 \\ &\leq \varepsilon_A^2 + \varepsilon_B^2 \\ &=: \varepsilon^2. \end{aligned}$$

With this, we know that

$$\left\{\hat{f}_{i_A} + \hat{h}_{i_B} : \hat{f}_{i_A} \in \{\hat{f}_1, \dots, \hat{f}_a\} \text{ and } \hat{h}_{i_B} \in \{\hat{h}_1, \dots, \hat{h}_b\}\right\}$$

is an ε -net of H w.r.t. $\|\cdot\|_{L_2(\nu)}$. Concerning the ε -covering number of H , this finally implies $\mathcal{N}(B_H, \|\cdot\|_{L_2(\nu)}, \varepsilon) \leq a \cdot b = \mathcal{N}\left(\lambda_A^{-1/2} B_{\hat{H}_A}, \|\cdot\|_{L_2(\nu_A)}, \varepsilon_A\right) \cdot \mathcal{N}\left(\lambda_B^{-1/2} B_{\hat{H}_B}, \|\cdot\|_{L_2(\nu_B)}, \varepsilon_B\right)$.

Based on Lemma 10, the following theorem relates entropy numbers of H_A and H_B to those of H . ■

Theorem 11 *Let P_X be a distribution on X and $A_1, \dots, A_m \subset X$ be pairwise disjoint. Moreover, for $j \in \{1, \dots, m\}$, let H_j be a separable RKHS of a measurable kernel k_j over A_j such that $\|k_j\|_{L_2(P_{X|A_j})}^2 := \int_X k_j(x, x) dP_{X|A_j}(x) < \infty$. Define RKHSs $\hat{H}_1, \dots, \hat{H}_m$ by Lemma 2 and the joined RKHS H by (13) with the norm (14) and weights $\lambda_1, \dots, \lambda_m > 0$. In addition, assume that there exist constants $p \in (0, 1)$ and $a_j > 0$, $j \in \{1, \dots, m\}$, such that for every $j \in \{1, \dots, m\}$*

$$\epsilon_i(\text{id} : H_j \rightarrow L_2(P_{X|A_j})) \leq a_j i^{-\frac{1}{2p}}, \quad i \geq 1. \quad (24)$$

Then, we have

$$\epsilon_i(\text{id} : H \rightarrow L_2(P_X)) \leq 2\sqrt{m} \left(3 \ln(4) \sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} i^{-\frac{1}{2p}}, \quad i \geq 1,$$

and, for the average entropy numbers,

$$\mathbb{E}_{D_X \sim P_X^n} \epsilon_i(\text{id} : H \rightarrow L_2(D_X)) \leq c_p \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} i^{-\frac{1}{2p}}, \quad i, n \geq 1.$$

Proof First of all, note that the restriction operator $\mathcal{I} : B_{H_j} \rightarrow B_{H_j}$ with $\mathcal{I}f = f$ is an isometric isomorphism. Together with (Steinwart and Christmann, 2008, (A.36)) and assumption (24), this yields

$$\begin{aligned} \epsilon_i(\lambda_j^{-\frac{1}{2}} B_{H_j}, L_2(P_{X|A_j})) &= 2\lambda_j^{-\frac{1}{2}} \epsilon_i(B_{H_j}, L_2(P_{X|A_j})) \\ &\leq 2\lambda_j^{-\frac{1}{2}} \|\mathcal{I} : B_{H_j} \rightarrow B_{H_j}\| \epsilon_i(B_{H_j}, L_2(P_{X|A_j})) \\ &\leq 2\lambda_j^{-\frac{1}{2}} a_j i^{-\frac{1}{2p}}. \end{aligned}$$

Furthermore, we know by (20) that

$$\ln \mathcal{N} \left(\lambda_j^{-\frac{1}{2}} B_{H_j}, \|\cdot\|_{L_2(P_{X|A_j})}, \varepsilon \right) \leq \ln(4) \left(2\lambda_j^{-\frac{1}{2}} a_j \right)^{2p} \varepsilon^{-2p}$$

holds for all $\varepsilon > 0$. With this and $\varepsilon_j := \frac{\varepsilon}{\sqrt{m}}$ for every $j \in \{1, \dots, m\}$, Lemma 10 implies

$$\ln \mathcal{N}(B_H, \|\cdot\|_{L_2(P_X)}, \varepsilon) \leq \ln \left(\prod_{j=1}^m \mathcal{N} \left(\lambda_j^{-\frac{1}{2}} B_{H_j}, \|\cdot\|_{L_2(P_{X|A_j})}, \varepsilon_j \right) \right)$$

$$\begin{aligned} &= \sum_{j=1}^m \ln \mathcal{N} \left(\lambda_j^{-\frac{1}{2}} B_{H_j}, \|\cdot\|_{L_2(P_{X|A_j})}, \frac{\varepsilon}{\sqrt{m}} \right) \\ &\leq \sum_{j=1}^m \ln(4) \left(2\lambda_j^{-\frac{1}{2}} a_j \right)^{2p} \left(\frac{\sqrt{m}}{\varepsilon} \right)^{2p} \\ &= \left(2 \ln(4) \right)^{\frac{1}{2p}} \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} \varepsilon^{-2p}. \end{aligned}$$

Using (21), the latter bound for the covering number of B_H finally implies the following entropy estimate

$$\begin{aligned} \epsilon_i(\text{id} : H \rightarrow L_2(P_X)) &\leq 3^{\frac{1}{2p}} \left(2 \ln(4) \right)^{\frac{1}{2p}} \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} i^{-\frac{1}{2p}} \\ &\leq 2 \left(3 \ln(4) \right)^{\frac{1}{2p}} \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} i^{-\frac{1}{2p}}. \end{aligned}$$

The second assertion immediately follows by (Steinwart and Christmann, 2008, Corollary 7.31). ■

In the following subsections, we first focus on RKHSs using Gaussian RBF kernels and examine the associated entropy numbers to specify (24). Subsequently, we additionally consider the least squares loss to prove Theorem 4.

6.2 Entropy Estimates for Local Gaussian RKHSs

In this subsection, we derive an estimate in terms of assumption (24) for the RKHS $H_{\gamma_1}(A)$ over A of the Gaussian RBF kernel k_{γ_1} on $A \subset \mathbb{R}^d$ given by

$$k_{\gamma_1}(x, x') := \exp(-\gamma^{-2} \|x - x'\|_2^2), \quad x, x' \in A,$$

for some width $\gamma > 0$. More precisely, in the subsequent theorem we determine an upper bound for the entropy numbers of the operator $\text{id} : H_{\gamma_1}(A) \rightarrow L_2(P_{X|A})$.

Theorem 12 *Let $X \subset \mathbb{R}^d$, P_X be a distribution on X and $A \subset X$ be such that $\hat{A} \neq \emptyset$ and such that there exists an Euclidean ball $B \subset \mathbb{R}^d$ with radius $r > 0$ containing A , i.e., $A \subset B$. Moreover, for $0 < \gamma \leq r$, let $H_{\gamma_1}(A)$ be the RKHS of the Gaussian RBF kernel k_{γ_1} over A . Then, for all $p \in (0, 1)$, there exists a constant $c_p > 0$ such that*

$$\epsilon_i(\text{id} : H_{\gamma_1}(A) \rightarrow L_2(P_{X|A})) \leq c_p \sqrt{P_X(A)} r^{\frac{d+2p}{2p}} \gamma^{-\frac{d+2p}{2p}} i^{-\frac{1}{2p}}, \quad i \geq 1.$$

Proof First of all, we consider the commutative diagram

$$\begin{array}{ccc} H_\gamma(A) & \xrightarrow{\text{id}} & L_2(\mathbb{P}_{X|A}) \\ \mathcal{I}_B^{-1} \circ \mathcal{I}_A \downarrow & & \uparrow \text{id} \\ H_\gamma(B) & \xrightarrow{\text{id}} & \ell_\infty(B) \end{array}$$

where the extension operator $\mathcal{I}_A : H_\gamma(A) \rightarrow H_\gamma(\mathbb{R}^d)$ and the restriction operator $\mathcal{I}_B^{-1} : H_\gamma(\mathbb{R}^d) \rightarrow H_\gamma(B)$ given by (Steinwart and Christmann, 2008, Corollary 4.43) are isometric isomorphisms, so that $\|\mathcal{I}_B^{-1} \circ \mathcal{I}_A : H_\gamma(A) \rightarrow H_\gamma(B)\| = 1$. Furthermore, for $f \in \ell_\infty(B)$, where $\ell_\infty(B)$ is the space of all bounded functions on B , we have

$$\|f\|_{L_2(\mathbb{P}_{X|A})} = \left(\int_X \mathbb{1}_A(x) |f(x)|^2 d\mathbb{P}_X(x) \right)^{\frac{1}{2}} \leq \|f\|_\infty \left(\int_X \mathbb{1}_A(x) d\mathbb{P}_X(x) \right)^{\frac{1}{2}} = \sqrt{\mathbb{P}_X(A)} \|f\|_\infty,$$

i.e., $\|\text{id} : \ell_\infty(B) \rightarrow L_2(\mathbb{P}_{X|A})\| \leq \sqrt{\mathbb{P}_X(A)}$. Together with (Steinwart and Christmann, 2008, (A.38) and (A.39)) as well as (Steinwart and Christmann, 2008, Theorem 6.27), we obtain for all $t \geq 1$

$$\begin{aligned} \epsilon_t(\text{id} : H_\gamma(A) &\rightarrow L_2(\mathbb{P}_{X|A})) \\ &\leq \|\mathcal{I}_B^{-1} \circ \mathcal{I}_A : H_\gamma(A) \rightarrow H_\gamma(B)\| \cdot \epsilon_t(\text{id} : H_\gamma(B) \rightarrow \ell_\infty(B)) \cdot \|\text{id} : \ell_\infty(B) \rightarrow L_2(\mathbb{P}_{X|A})\| \\ &\leq \sqrt{\mathbb{P}_X(A)} c_{m,d} t^m \gamma^{-m} t^{-\frac{m}{2}}, \end{aligned}$$

where $m \geq 1$ is an arbitrary integer and $c_{m,d}$ a positive constant. For $p \in (0, 1)$, the choice $m = \lfloor \frac{d}{2p} \rfloor$ finally yields

$$\epsilon_t(\text{id} : H_\gamma(A) \rightarrow L_2(\mathbb{P}_{X|A})) \leq \sqrt{\mathbb{P}_X(A)} c_{m,d} t^m \gamma^{-m} t^{-\frac{m}{2}} \leq c_p \sqrt{\mathbb{P}_X(A)} r^{-\frac{dt}{2p}} \gamma^{-\frac{dt}{2p}} t^{-\frac{1}{2p}}.$$

■

6.3 Proofs Related to the Least Squares VP-SVMs

In this subsection, we prove the results that are linked with the least squares loss, i.e., the results of Section 4. Before we elaborate on the oracle inequality for VP-SVMs using the least squares loss as well as RKHSs of Gaussian kernels, we have to examine the excess risk

$$\mathcal{R}_{L_{J_T, P}}(f_0) - \mathcal{R}_{L_{J_T, P}}^* = \|f_0 - f_{L_T, P}^*\|_{L_2(\mathbb{P}_{X|A_T})}^2. \quad (25)$$

Let us begin by writing for fixed $\gamma_j > 0$

$$K_j : \mathbb{R}^d \rightarrow \mathbb{R}, \quad x \mapsto \sum_{\ell=1}^s \binom{s}{\ell} (-1)^{1-\ell} \left(\frac{2}{\ell^2 \gamma_j^2 \pi} \right)^{\frac{\ell}{2}} \exp\left(-\frac{2\|x\|_2^2}{\ell^2 \gamma_j^2}\right), \quad (26)$$

and choosing $f_0 := \sum_{j=1}^m \mathbb{1}_{A_j} \cdot (K_j * f_{L_T, P}^*)$. Then, (25) can be estimated with the help of the following theorem, which is together with its proof basically a modification of (Eberts and Steinwart, 2013, Theorem 2.2). Indeed, the proofs proceed mainly identically. Note that we use the notation

$$\gamma_{\max} := \max\{\gamma_1, \dots, \gamma_m\} \quad \text{and} \quad \gamma_{\min} := \min\{\gamma_1, \dots, \gamma_m\}$$

in the following theorem and the associated proof. For the sake of generality, we do not only consider the Besov-like space $B_{q, \infty}^{2s}(\nu)$ in the following theorem but instead the Besov-like spaces $B_{q, \infty}^\alpha(\nu)$ for arbitrary $q \in [1, \infty)$. These Besov-like spaces are defined analogously to $B_{2, \infty}^\alpha(\nu)$, however, applying the modulus of smoothness for the $L_q(\nu)$ -norm instead of the $L_2(\nu)$ -norm. For an explicit definition of these spaces we refer to (Eberts, 2015, Section 3.1)

Theorem 13 *Let us fix some $q \in [1, \infty)$. Assume that ν is a finite measure on \mathbb{R}^d with $\text{supp } \nu := X \subset cB_{q, \infty}^d \subset \mathbb{R}^d$ for some $c > 0$. Let $(A'_j)_{j=1, \dots, m}$ be a partition of $cB_{q, \infty}^d$. Then, $A_j := A'_j \cap X$ for all $j \in \{1, \dots, m\}$ defines a partition $(A_j)_{j=1, \dots, m}$ of X . Furthermore, let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be such that $f \in B_{q, \infty}^\alpha(\nu)$ for some $\alpha \geq 1$. For the functions $K_j : \mathbb{R}^d \rightarrow \mathbb{R}$, $j \in \{1, \dots, m\}$, defined by (26), where $s := \lfloor \alpha \rfloor + 1$ and $\gamma_1, \dots, \gamma_m > 0$, we then have*

$$\left\| \sum_{j=1}^m \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)} \leq C_{\alpha, q} \left(\frac{\gamma_{\max}}{\gamma_{\min}} \right)^{\frac{q\alpha}{2}} \gamma_{\max}^{\alpha},$$

where $C_{\alpha, q} := \|f\|_{B_{q, \infty}^\alpha(\nu)}^q \left(\frac{d}{2}\right)^{\frac{q\alpha}{2}} \pi^{-\frac{1}{2}} \Gamma\left(q\alpha + \frac{1}{2}\right)^{\frac{1}{2}}$.

Proof In the following, we write $J := \{1, \dots, m\}$. To show

$$\left\| \sum_{j \in J} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)}^q \leq \|f\|_{B_{q, \infty}^\alpha(\nu)}^q \left(\frac{d}{2}\right)^{\frac{q\alpha}{2}} \pi^{-\frac{1}{2}} \Gamma\left(q\alpha + \frac{1}{2}\right)^{\frac{1}{2}} \left(\frac{\gamma_{\max}}{\gamma_{\min}}\right)^{\frac{q\alpha}{2}} \gamma_{\max}^{\alpha},$$

we have to proceed in a similar way as in the proof of (Eberts and Steinwart, 2013, Theorem 2.2). First of all, we use the translation invariance of the Lebesgue measure and $\exp(-\|u\|_2^2) = \exp(-\| -u \|^2)$ ($u \in \mathbb{R}^d$) to obtain, for $x \in X$ and $j \in J$,

$$\begin{aligned} K_j * f(x) &= \int_{\mathbb{R}^d} \sum_{\ell=1}^s \binom{s}{\ell} (-1)^{1-\ell} \left(\frac{2}{\gamma_j^2 \pi}\right)^{\frac{\ell}{2}} \exp\left(-\frac{2\|x-t\|_2^2}{\ell^2 \gamma_j^2}\right) f(t) dt \\ &= \int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi}\right)^{\frac{\ell}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) \left(\sum_{\ell=1}^s \binom{s}{\ell} (-1)^{1-\ell} f(x+th)\right) dh. \end{aligned}$$

With this we can derive, for $q \geq 1$,

$$\left\| \sum_{j \in J} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)}^q$$

$$\begin{aligned}
&= \int_{\mathbb{R}^d} \left| \sum_{j \in J} \mathbb{1}_{A_j}(x) (K_j * f)(x) - f(x) \right|_{L_q(\nu)}^q dv(x) \\
&\leq \int_{\mathbb{R}^d} \left(\sum_{j \in I} \mathbb{1}_{A_j}(x) |K_j * f(x) - f(x)| \right)^q dv(x) \\
&= \int_{\mathbb{R}^d} \sum_{j \in J} \mathbb{1}_{A_j}(x) |K_j * f(x) - f(x)|^q dv(x) \\
&= \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) |K_j * f(x) - f(x)|^q dv(x) \\
&= \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \left| \int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) \left(\sum_{\ell=0}^s \binom{s}{\ell} (-1)^{2s+1-\ell} f(x+\ell h) \right) dh \right|^q dv(x) \\
&= \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \left| \int_{\mathbb{R}^d} (-1)^{s+1} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) \Delta_h^s(f, x) dh \right|^q dv(x) \\
&\leq \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \left(\int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) |\Delta_h^s(f, x)| dh \right)^q dv(x).
\end{aligned}$$

Then, Hölder's inequality and $\int_{\mathbb{R}^d} \exp(-2\gamma_j^{-2}\|h\|_2^2) dh = \left(\frac{\gamma_j^2 \pi}{2}\right)^{d/2}$ yield, for $q > 1$,

$$\begin{aligned}
&\left\| \sum_{j \in J} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)}^q \\
&\leq \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \left(\int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) dh \right)^{\frac{q-1}{q}} \\
&\quad \left(\int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) |\Delta_h^s(f, x)|^q dh \right)^{\frac{1}{q}} dv(x) \\
&= \sum_{j \in J} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) |\Delta_h^s(f, x)|^q dh dv(x) \\
&= \sum_{j \in J} \int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) |\Delta_h^s(f, x)|^q dv(x) dh \\
&\leq \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) |\Delta_h^s(f, x)|^q dv(x) dh
\end{aligned}$$

$$\begin{aligned}
&= \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \|\Delta_h^s(f, \cdot)\|_{L_q(\nu)}^q dh \\
&\leq \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \omega_{s, L_q(\nu)}^q(f, \|h\|_2) dh.
\end{aligned}$$

Moreover, for $q = 1$, we have

$$\begin{aligned}
&\left\| \sum_{j \in I} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_1(\nu)} \\
&\leq \sum_{j \in I} \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) \int_{\mathbb{R}^d} \left(\frac{2}{\gamma_j^2 \pi} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_j^2}\right) |\Delta_h^s(f, x)| dh dv(x) \\
&\leq \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \int_{\mathbb{R}^d} \mathbb{1}_{A_j}(x) |\Delta_h^s(f, x)| dv(x) dh \\
&\leq \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \omega_{s, L_1(\nu)}(f, \|h\|_2) dh.
\end{aligned}$$

Consequently, we can proceed in the same way for all $q \geq 1$. To this end, note that the assumption $f \in B_{q, \infty}^s(\nu)$ implies $\omega_{s, L_q(\nu)}(f, t) \leq \|f\|_{B_{q, \infty}^s(\nu)} t^{\alpha}$ for $t > 0$. The latter together with Hölder's inequality yields

$$\begin{aligned}
&\left\| \sum_{j \in I} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)}^q \\
&\leq \int_{\mathbb{R}^d} \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) \omega_{s, L_q(\nu)}^q(f, \|h\|_2) dh \\
&\leq \|f\|_{B_{q, \infty}^s(\nu)}^q \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \int_{\mathbb{R}^d} \|h\|_2^{q\alpha} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) dh \\
&\leq \|f\|_{B_{q, \infty}^s(\nu)}^q \left(\frac{2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{2}} \left(\int_{\mathbb{R}^d} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) dh \right)^{\frac{1}{2}} \left(\int_{\mathbb{R}^d} \|h\|_2^{2q\alpha} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) dh \right)^{\frac{1}{2}} \\
&= \|f\|_{B_{q, \infty}^s(\nu)}^q \left(\frac{2\gamma_{\max}^2}{\pi \gamma_{\min}^2} \right)^{\frac{d}{4}} \left(\int_{\mathbb{R}^d} \|h\|_2^{2q\alpha} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) dh \right)^{\frac{1}{2}}.
\end{aligned}$$

Using the embedding constant $d^{\frac{q\alpha-1}{2q\alpha}}$ of $\mathcal{G}_{2q\alpha}^{\beta d}$ to $\mathcal{G}_{2q\alpha}^{\beta d}$, we obtain

$$\begin{aligned}
&\int_{\mathbb{R}^d} \|h\|_2^{2q\alpha} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}^2}\right) dh \leq d^{q\alpha-1} \sum_{\ell=1}^d \int_{\mathbb{R}^d} h_{\ell}^{2q\alpha} \prod_{\ell=1}^d \exp\left(-\frac{2h_{\ell}^2}{\gamma_{\max}^2}\right) d(h_1, \dots, h_d) \\
&= d^{q\alpha-1} \sum_{\ell=1}^d \left(\frac{\gamma_{\max}^2 \pi}{2} \right)^{\frac{d-1}{2}} \int_{\mathbb{R}} h_{\ell}^{2q\alpha} \exp\left(-\frac{2h_{\ell}^2}{\gamma_{\max}^2}\right) dh_{\ell}
\end{aligned}$$

$$= 2d^{q\alpha} \left(\frac{\gamma_{\max}^2 \pi}{2} \right)^{\frac{d-1}{2}} \int_0^\infty t^{2q\alpha} \exp\left(-\frac{2t^2}{\gamma_{\max}}\right) dt.$$

for $\gamma > 0$. With the substitution $t = (\frac{1}{2}\gamma_{\max}^2 u)^{\frac{1}{2}}$, the functional equation $\Gamma(t+1) = t\Gamma(t)$ of the Gamma function Γ , and $\Gamma(\frac{1}{2}) = \sqrt{\pi}$ we further have

$$\begin{aligned} \int_0^\infty t^{2q\alpha} \exp\left(-\frac{2t^2}{\gamma_{\max}}\right) dt &= \frac{1}{2} \frac{\gamma_{\max}}{\sqrt{2}} \left(\frac{\gamma_{\max}^2}{2}\right)^{q\alpha} \int_0^\infty u^{(q\alpha+\frac{1}{2})-1} \exp(-u) du \\ &= \frac{1}{2} \frac{\gamma_{\max}}{\sqrt{2}} \left(\frac{\gamma_{\max}^2}{2}\right)^{q\alpha} \Gamma\left(q\alpha + \frac{1}{2}\right). \end{aligned}$$

Altogether, we finally obtain

$$\begin{aligned} & \left\| \sum_{j \in J} \mathbb{1}_{A_j} \cdot (K_j * f) - f \right\|_{L_q(\nu)}^q \\ & \leq \|f\|_{B_{q,\infty}^{\alpha}(\nu)}^q \left(\frac{2\gamma_{\max}^2}{\pi\gamma_{\min}^4} \right)^{\frac{d}{4}} \left(\int_{\mathbb{R}^d} \|h\|_2^{2q\alpha} \exp\left(-\frac{2\|h\|_2^2}{\gamma_{\max}}\right) dh \right)^{\frac{1}{2}} \\ & \leq \|f\|_{B_{q,\infty}^{\alpha}(\nu)}^q \left(\frac{2\gamma_{\max}^2}{\pi\gamma_{\min}^4} \right)^{\frac{d}{4}} \left(\frac{d}{2} \right)^{q\alpha} \left(\frac{\pi^{d-1}}{2^d} \right)^{\frac{1}{2}} \frac{1}{\gamma_{\max}^{2q\alpha+d}} \Gamma\left(q\alpha + \frac{1}{2}\right) \\ & = \|f\|_{B_{q,\infty}^{\alpha}(\nu)}^q \left(\frac{d}{2} \right)^{\frac{q\alpha}{2}} \pi^{-\frac{1}{4}} \Gamma\left(q\alpha + \frac{1}{2}\right)^{\frac{1}{2}} \left(\frac{\gamma_{\max}}{\gamma_{\min}} \right)^{q\alpha}. \end{aligned}$$

■

Based on Theorems 11, 12, and 13, we can now show Theorem 4, where we denote by $L \circ f$ the function $(x, y) \mapsto L(x, y, f(x))$.

Proof [of Theorem 4] First of all, since H_1, \dots, H_m are RKHSs of Gaussian kernels, the joined RKHS H is separable and its kernel is measurable. Moreover, since Theorem 12 provides $\epsilon_i(\text{id} : H_{\gamma_j}(A_j) \rightarrow L_2(\mathbb{P}_{X|A_j})) \leq a_j t^{-\frac{1}{2p}}$ for $i \geq 1$ with $a_j = \tilde{c}_p \sqrt{\mathbb{P}_X(A_j)} r^{\frac{d+2p}{2p}} \gamma_j^{-\frac{1}{2p}}$, Theorem 11 yields

$$\mathbb{E}_{D_{X \times Y} \sim \mathbb{P}_X^{\otimes n} \times \mathbb{P}_Y^{\otimes n}} \epsilon_i(\text{id} : H \rightarrow L_2(D_X)) \leq c_p \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}} t^{-\frac{1}{2}}, \quad i, n \geq 1.$$

Note that, for the least squares loss, which can be clipped at M with $Y = [-M, M]$, the supremum bound

$$L(x, y, t) \leq B, \quad \forall (x, y) \in X \times Y, t \in [-M, M] \quad (27)$$

holds for $B = 4M^2$ and the variance bound

$$\mathbb{E}_{\mathbb{P}} (L \circ f - L \circ f_{L,P}^*)^2 \leq V \cdot (\mathbb{E}_{\mathbb{P}} (L \circ f - L \circ f_{L,P}^*))^{\theta}, \quad \forall f : X \rightarrow [-M, M] \quad (28)$$

for $V = 16M^2$ and $\theta = 1$ (cf. Steinwart and Christmann, 2008, Example 7.3). Actually, (27) immediately yields the supremum bound for $L_{J,P}$, too. The same holds for the variance bound (28), which can be easily shown by the use of $\tilde{f}(x) := \mathbb{1}_{\bigcup_{j \in J_P} A_j}(x) f(x) + \mathbb{1}_{X \setminus (\bigcup_{j \in J_P} A_j)}(x) f_{L,P}^*(x)$ for all $f : X \rightarrow [-M, M]$. Using the constant B , we now have

$$\begin{aligned} & \left(\max \left\{ c_p \sqrt{m} \left(\sum_{j=1}^m \lambda_j^{-p} a_j^{2p} \right)^{\frac{1}{2p}}, B \right\} \right)^{2p} \\ & = \left(\max \left\{ c_p \tilde{c}_p \sqrt{m} r^{\frac{d+2p}{2p}} \left(\sum_{j=1}^m \left(\lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}_X(A_j) \right)^p \right)^{\frac{1}{2p}}, B \right\} \right)^{2p} \\ & \leq \left(\max \left\{ c_p \tilde{c}_p m^{\frac{1}{2}} r^{\frac{d+2p}{2p}} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}_X(A_j) \right)^{\frac{1}{2}}, B \right\} \right)^{2p} \\ & \leq \left(\max \left\{ c_p \tilde{c}_p 3^{\frac{d}{2p}} r \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}_X(A_j) \right)^{\frac{1}{2}}, B \right\} \right)^{2p} \\ & \leq C_p r^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}_X(A_j) \right)^p + B^{2p} \\ & =: a^{2p}, \end{aligned}$$

where we used $\|\cdot\|_{\ell_p^m} \leq m^{\frac{1-2}{p}} \|\cdot\|_{\ell_1^m}$, $m r^d \leq 3^d$ by (5), and $C_p := \tilde{c}_p^{2p} \tilde{c}_p^{2p} 3^d$. Then, we can apply (Steinwart and Christmann, 2008, Theorem 7.23) using the regularization parameter $\lambda = 1$. That is, for $\lambda_1, \dots, \lambda_m > 0$, all fixed $\tau > 0$, and for an $f_0 \in H$ and a constant $B_0 \geq B$ such that $\|L_{J,P} \circ f_0\|_{\infty} \leq B_0$, we obtain

$$\begin{aligned} & \sum_{j=1}^m \lambda_j \|f_{D_j, \lambda_j}\|_{\tilde{H}_j}^2 + \mathcal{R}_{L_{j,P}}(\hat{f}_{D, \lambda}) - \mathcal{R}_{L_{j,P}}^* \\ & = \|f_{D, \lambda}\|_{\tilde{H}}^2 + \mathcal{R}_{L_{j,P}}(\hat{f}_{D, \lambda}) - \mathcal{R}_{L_{j,P}}^* \\ & \leq 9 \left(\|f_0\|_{\tilde{H}}^2 + \mathcal{R}_{L_{j,P}}(f_0) - \mathcal{R}_{L_{j,P}}^*(f_0) + C \left(a^{2p} n^{-1} \right)^{\frac{1}{2-p-\theta+2p}} + 3 \left(\frac{72V\tau}{n} \right)^{\frac{1}{2-p}} + \frac{15B_0\tau}{n} \right) \\ & \leq 9 \left(\sum_{j=1}^m \lambda_j \| \mathbb{1}_{A_j} f_0 \|_{\tilde{H}_j}^2 + \mathcal{R}_{L_{j,P}}(f_0) - \mathcal{R}_{L_{j,P}}^*(f_0) + C \left(a^{2p} n^{-1} \right)^{\frac{1}{2-p-\theta+2p}} + 3 \left(\frac{72V\tau}{n} \right)^{\frac{1}{2-p}} + \frac{15B_0\tau}{n} \right) \quad (29) \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - 3e^{-\tau}$, where $C > 0$ is the constant of (Steinwart and Christmann, 2008, Theorem 7.23) only depending on p, M, V, θ , and B . To continue estimate (29), we have to choose a function $f_0 \in H$. To this end, we define functions $K_j : \mathbb{R}^d \rightarrow \mathbb{R}$, $j \in \{1, \dots, m\}$, by (26), where $s := [\alpha] + 1$ and $\gamma_j > 0$. Then, we define f_0 by convolving each K_j with the Bayes decision function $f_{L,P}^*$, that is

$$f_0(x) := \sum_{j \in J_P} \mathbb{1}_{A_j}(x) \cdot (K_j * f_{L,P}^*)(x), \quad x \in \mathbb{R}^d.$$

Now, to show that f_0 is indeed a suitable function to bound the approximation error, we first need to ensure that f_0 is contained in H . In addition, we need to derive bounds for both, the regularization term and the excess risk of f_0 . To this end, we apply (Eberts and Steinwart, 2013, Theorem 2.3) and obtain, for every $j \in J_T$,

$$(K_j * f_{L,P}^*)|_{A_j} \in H_{\gamma_j}(A_j)$$

with

$$\begin{aligned} \|\mathbb{1}_{A_j} f_0\|_{H_{\gamma_j}(A_j)} &= \|\mathbb{1}_{A_j}(K_j * f_{L,P}^*)\|_{H_{\gamma_j}(A_j)} \\ &= \|(K_j * f_{L,P}^*)|_{A_j}\|_{H_{\gamma_j}(A_j)} \\ &\leq (\gamma_j \sqrt{\pi})^{-\frac{d}{2}} (2^s - 1) \|f_{L,P}^*\|_{L_2(\mathbb{R}^d)}. \end{aligned}$$

This implies

$$f_0 = \sum_{j \in J_T} \underbrace{\mathbb{1}_{A_j}(K_j * f_{L,P}^*)}_{\in H_{\gamma_j}(A_j)} \in H_{J_T}.$$

Besides, note that $0 \in \hat{H}_{\gamma_j}(A_j)$ for every $j \in \{1, \dots, m\}$ such that f_0 can be written as $f_0 = \sum_{j=1}^m f_j$, where

$$f_j := \begin{cases} \mathbb{1}_{A_j}(K_j * f_{L,P}^*), & j \in J_T, \\ 0, & j \notin J_T. \end{cases}$$

Obviously, the latter implies $f_0 \in H$. Furthermore, for $A_T := \bigcup_{j \in J_T} A_j$, (25) and Theorem 13 yield

$$\begin{aligned} \mathcal{R}_{L_{J_T}, P}(f_0) - \mathcal{R}_{L_{J_T}, P}^* &= \|f_0 - f_{L,P}^*\|_{L_2(P_{X|A_T})}^2 \\ &= \left\| \sum_{j \in J_T} \mathbb{1}_{A_j}(K_j * f_{L,P}^*) - f_{L,P}^* \right\|_{L_2(P_{X|A_T})}^2 \\ &\leq C_{\alpha,2} \left(\frac{\max_{j \in J_T} \gamma_j^{-d}}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha}, \end{aligned}$$

where $C_{\alpha,2}$ is a constant only depending on α , d , and $\|f_{L,P}^*\|_{B_{2,\infty}^2(P_{X|A_T})}$. Next, we derive a bound for $\|L \circ f_0\|_\infty$ using (Eberts and Steinwart, 2013, Theorem 2.3) which provides, for every $x \in X$, the supremum bound

$$|f_0(x)| = \left| \sum_{j \in J_T} \mathbb{1}_{A_j}(x) \cdot (K_j * f_{L,P}^*)(x) \right| \leq \sum_{j \in J_T} \mathbb{1}_{A_j}(x) |K_j * f_{L,P}^*(x)| \leq (2^s - 1) \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}.$$

The latter implies

$$\|L_{J_T} \circ f_0\|_\infty = \sup_{(x,\hat{y}) \in X \times Y} |L(\hat{y}, f_0(x))|$$

$$\begin{aligned} &\leq \sup_{(x,\hat{y}) \in X \times Y} (M^2 + 2M|f_0(x)| + |f_0(x)|^2) \\ &\leq 4^s \max \left\{ M^2, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}^2 \right\}, \end{aligned}$$

i.e., $B_0 := 4^s \max\{M^2, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}^2\}$. Applying (29) then yields

$$\begin{aligned} &\mathcal{R}_{L_{J_T}, P}(\widehat{f}_{D,\lambda,\gamma}) - \mathcal{R}_{L_{J_T}, P}^* \\ &\leq \sum_{j=1}^m \lambda_j \|f_{D_j, \lambda_j, \gamma_j}\|_{H_{\gamma_j}(A_j)}^2 + \mathcal{R}_{L_{J_T}, P}(\widehat{f}_{D,\lambda,\gamma}) - \mathcal{R}_{L_{J_T}, P}^* \\ &\leq 9 \left(\sum_{j=1}^m \lambda_j \| \mathbb{1}_{A_j} f_0 \|_{H_{\gamma_j}(A_j)}^2 + \mathcal{R}_{L_{J_T}, P}(f_0) - \mathcal{R}_{L_{J_T}, P}^* \right) \\ &\quad + C (a^{2p} n^{-1})^{\frac{1}{2-p+\theta p}} + 3 \left(\frac{72V\tau}{n} \right)^{\frac{1}{2-p}} + \frac{15B_0\tau}{n} \\ &\leq 9 \left(\sum_{j \in J_T} \lambda_j (\gamma_j \sqrt{\pi})^{-d} (2^s - 1)^2 \|f_{L,P}^*\|_{L_2(\mathbb{R}^d)}^2 + C_{\alpha,2} \left(\frac{\max_{j \in J_T} \gamma_j^{-d}}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} \right) \\ &\quad + CC_p^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} P_X(A_j) \right)^p n^{-1} + CB^{2p} n^{-1} + \frac{3456M^2\tau}{n} \\ &\quad + 15 \cdot 4^s \max\{M^2, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}^2\} \frac{\tau}{n} \\ &\leq 9(2^s - 1)^2 \pi^{-\frac{d}{2}} \|f_{L,P}^*\|_{L_2(\mathbb{R}^d)}^2 \sum_{j \in J_T} \lambda_j \gamma_j^{-d} + 9C_{\alpha,2} \left(\frac{\max_{j \in J_T} \gamma_j^{-d}}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} \\ &\quad + CC_p^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} P_X(A_j) \right)^p n^{-1} + 16^p C M^{4p} n^{-1} \\ &\quad + (3456M^2 + 15 \cdot 4^s \max\{M^2, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}^2\}) \frac{\tau}{n} \end{aligned}$$

with probability P^n not less than $1 - 3e^{-\tau}$. Finally, for $\hat{\tau} \geq 1$, a variable transformation implies

$$\begin{aligned} &\sum_{j=1}^m \lambda_j \|f_{D_j, \lambda_j, \gamma_j}\|_{H_{\gamma_j}(A_j)}^2 + \mathcal{R}_{L_{J_T}, P}(\widehat{f}_{D,\lambda,\gamma}) - \mathcal{R}_{L_{J_T}, P}^* \\ &\leq C_{M,\alpha,p} \left(\sum_{j \in J_T} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_T} \gamma_j^{-d}}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} + n^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} P_X(A_j) \right)^p n^{-1} + \hat{\tau} n^{-1} \right) \end{aligned}$$

with probability P^n not less than $1 - e^{-\hat{\tau}}$, where the constant $C_{M,\alpha,p}$ is defined by

$$C_{M,\alpha,p} := \max \left\{ 9(2^s - 1)^2 \pi^{-\frac{d}{2}} \|f_{L,P}^*\|_{L_2(\mathbb{R}^d)}^2, 9 \|f_{L,P}^*\|_{B_{2,\infty}^2(P_{X|A_T})}^2 \left(\frac{d}{2} \right)^\alpha \pi^{-\frac{d}{4}} \Gamma \left(2\alpha + \frac{1}{2} \right)^{\frac{1}{2}} \right\},$$

$$3^d C_{\mathcal{P}}^{2p} c_{\mathcal{P}}^{2p}, 16^p C_M^{4p} + (3456M^2 + 15 \cdot 4^p \max\{M^2, \|f_{L,P}^*\|_{L_\infty(\mathbb{R}^d)}^2\}) (1 + \ln(3)) \Big\}. \quad \blacksquare$$

Next, using the just proven oracle inequality presented in Theorem 4, we show the learning rates of Theorem 5 in only a few steps.

Proof [of Theorem 5] First of all, we define sequences $\tilde{\lambda}_n := c_2 n^{-1}$ and $\tilde{\gamma}_n := c_3 n^{-\frac{1}{2\alpha+d}}$ to simplify the presentation. Then, Theorem 4, $\sum_{j=1}^{m_n} \mathbb{P}X(A_j) = 1$, and $|J_T| \leq m_n \leq 3^d r_n^{-d}$ together with $\lambda_{n,j} = r_n^d \tilde{\lambda}_n$ and $\gamma_{n,j} = \tilde{\gamma}_n$ for all $j \in \{1, \dots, m_n\}$ yield

$$\begin{aligned} & \mathcal{R}_{L_{J_T}, P}(\tilde{f}_D, \lambda_n, \tilde{\gamma}_n) - \mathcal{R}_{L_{J_T}, P}^* \\ & \leq C_{M, \alpha, p} \left(\sum_{j \in J_T} \lambda_{n,j} \tilde{\gamma}_n^{-d} + \left(\frac{\max_{j \in J_T} \gamma_{n,j}}{\min_{j \in J_T} \gamma_{n,j}} \right)^d \max_{j \in J_T} \gamma_{n,j}^{2\alpha} + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_{n,j}^{-1} \gamma_{n,j}^{-\frac{d+2p}{p}} \mathbb{P}X(A_j) \right)^p n^{-1} + \frac{\tau}{n} \right) \\ & = C_{M, \alpha, p} \left(|J_T| r_n^d \tilde{\lambda}_n \tilde{\gamma}_n^{-d} + \tilde{\gamma}_n^{2\alpha} + r_n^{(2-d)p} \tilde{\lambda}_n \tilde{\gamma}_n^{-(d+2p)} \left(\sum_{j=1}^{m_n} \mathbb{P}X(A_j) \right)^p n^{-1} + \tau n^{-1} \right) \\ & \leq 3^d C_{M, \alpha, p} \left(\tilde{\lambda}_n \tilde{\gamma}_n^{-d} + \tilde{\gamma}_n^{2\alpha} + \tilde{\lambda}_n^{-p} \tilde{\gamma}_n^{-(d+2p)} r_n^{(2-d)p} n^{-1} + \tau n^{-1} \right). \end{aligned}$$

Using the choices $\tilde{\lambda}_n = c_2 n^{-1}$, $\tilde{\gamma}_n = c_3 n^{-\frac{1}{2\alpha+d}}$, as well as $r_n = c_1 n^{-\frac{1}{\beta d}}$ finally implies

$$\begin{aligned} & \mathcal{R}_{L_{J_T}, P}(\tilde{f}_D, \lambda_n, \tilde{\gamma}_n) - \mathcal{R}_{L_{J_T}, P}^* \\ & \leq 3^d C_{M, \alpha, p} \left(\tilde{\lambda}_n \tilde{\gamma}_n^{-d} + \tilde{\gamma}_n^{2\alpha} + \tilde{\lambda}_n^{-p} \tilde{\gamma}_n^{-(d+2p)} r_n^{(2-d)p} n^{-1} + \tau n^{-1} \right) \\ & \leq \hat{C}_{M, \alpha, p} \left(n^{-1} n^{\frac{d}{2\alpha+d}} + n^{-\frac{2\alpha}{2\alpha+d}} + n^p n^{\frac{d+2p}{2\alpha+d}} n^{-\frac{(2-d)p}{\beta d}} n^{-1} + \tau n^{-1} \right) \\ & = \hat{C}_{M, \alpha, p} \left(n^{-\frac{2\alpha}{2\alpha+d}} + n^{-\frac{2\alpha}{2\alpha+d}} + n^{-\frac{2\alpha}{2\alpha+d}} + \left(1 + \frac{2}{2\alpha+d} + \frac{1}{\beta} - \frac{2}{\beta d}\right) p + \tau n^{-1} \right) \\ & \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \tau n^{-1} \right) \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - e^{-\tau}$, where $C > 0$ is a constant and $\xi \geq \left(1 + \frac{2}{2\alpha+d} + \frac{1}{\beta} - \frac{2}{\beta d}\right) p > 0$. \blacksquare

Proof [of Corollary 6] For simplicity of notation, we write λ , λ_j , γ , and γ_j instead of λ_n , $\lambda_{n,j}$, γ_n , and $\gamma_{n,j}$. Since $\cup_{j \in J_T} A_j \subset T^{+\delta}$ for all $n \geq n_\delta$, the assumption $f_{L,P}^* \in B_{2,\infty}^\alpha(\mathbb{P}X|_{T^{+\delta}})$ implies

$$f_{L,P}^* \in B_{2,\infty}^\alpha(\mathbb{P}X|_{\cup_{j \in J_T} A_j}).$$

With this, Theorems 4 and 5 immediately yield

$$\mathcal{R}_{L_{J_T}, P}(\tilde{f}_D, \lambda, \gamma) - \mathcal{R}_{L_{J_T}, P}^*$$

$$\begin{aligned} & \leq \sum_{j=1}^m \lambda_j \|f_{D_j, \lambda_j, \gamma_j}\|_{H_{r_j}(A_j)}^2 + \mathcal{R}_{L_{J_T}, P}(\tilde{f}_D, \lambda, \gamma) - \mathcal{R}_{L_{J_T}, P}^* \\ & \leq \sum_{j=1}^m \lambda_j \|f_{D_j, \lambda_j, \gamma_j}\|_{H_{r_j}(A_j)}^2 + \mathcal{R}_{L_{J_T}, P}(\tilde{f}_D, \lambda, \gamma) - \mathcal{R}_{L_{J_T}, P}^* \\ & \leq C_{M, \alpha, p} \left(\sum_{j \in J_T} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_T} \gamma_j}{\min_{j \in J_T} \gamma_j} \right)^d \max_{j \in J_T} \gamma_j^{2\alpha} + r^{2p} \left(\sum_{j=1}^m \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}X(A_j) \right)^p n^{-1} + \frac{\tau}{n} \right) \\ & \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \tau n^{-1} \right) \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - e^{-\tau}$, where $\xi \geq \left(1 + \frac{2}{2\alpha+d} + \frac{1}{\beta} - \frac{2}{\beta d}\right) p > 0$. Moreover, the constants $C_{M, \alpha, p} > 0$ and $C > 0$ coincide with those of Theorems 4 and 5. \blacksquare

It remains to prove Theorem 7. However, we previously have to consider the following technical lemma.

Lemma 14 Let $d \geq 1$ and $r_n := cn^{-\frac{1}{\beta d}}$ with $\beta > 1$ and a constant $c > 0$. We fix finite subsets $\Lambda_n \subset (0, r_n^d]$ and $\Gamma_n \subset (0, r_n]$ such that Λ_n is an $(r_n^d \varepsilon_n)$ -net of $(0, r_n^d]$ and Γ_n is an δ_n -net of $(0, r_n]$ with $0 < \varepsilon_n \leq n^{-1}$, $\delta_n > 0$, $r_n^d \in \Lambda_n$, and $r_n \in \Gamma_n$. Moreover, let $J \subset \{1, \dots, m_n\}$ be an arbitrary non-empty index set and $|J| \leq m_n \leq 3^d r_n^{-d}$. Then, for all $0 < \alpha < \frac{\beta-1}{2}d$, $n \geq 1$, and all $p \in (0, 1)$ with $p \leq \frac{\beta d - 2\alpha - d}{2\alpha + d + 2}$, we have

$$\begin{aligned} & \inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \left(\sum_{j \in J} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J} \gamma_j}{\min_{j \in J} \gamma_j} \right)^d \max_{j \in J} \gamma_j^{2\alpha} + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-\frac{d+2p}{p}} \mathbb{P}X(A_j) \right)^p n^{-1} \right) \\ & \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \delta_n^{2\alpha} \right), \end{aligned}$$

where $\xi := \left(\frac{2\alpha(2\alpha+d+2)}{(2\alpha+d)(2\alpha+d)(1+p)+2p} + \max\left\{\frac{d-2}{\beta d}, 0\right\} p \right) p$ and $C > 0$ is a constant independent of n , Λ_n , ε_n , Γ_n , and δ_n .

Proof Without loss of generality, we may assume that Λ_n and Γ_n are of the form $\Lambda_n = \{\lambda^{(1)}, \dots, \lambda^{(v)}\}$ and $\Gamma_n = \{\gamma^{(1)}, \dots, \gamma^{(v)}\}$ with $\lambda^{(v)} = r_n^d$ and $\gamma^{(v)} = r_n$ as well as $\lambda^{(\ell-1)} < \lambda^{(\ell)}$ and $\gamma^{(\ell-1)} < \gamma^{(\ell)}$ for all $i = 2, \dots, v$. With $\lambda^{(0)} := 0$ and $\gamma^{(0)} := 0$ it is easy to see that

$$\lambda^{(\ell)} - \lambda^{(\ell-1)} \leq 2r_n^d \varepsilon_n \quad \text{and} \quad \gamma^{(\ell)} - \gamma^{(\ell-1)} \leq 2\delta_n \quad (30)$$

hold for all $i = 1, \dots, v$ and $\ell = 1, \dots, v$. Furthermore, define $\lambda^* := n^{-\frac{2\alpha+d}{(2\alpha+d)(1+p)+2p}}$ and $\gamma^* := cn^{-\frac{2\alpha+d}{(2\alpha+d)(1+p)+2p}}$. Then, there exist indices $i \in \{1, \dots, v\}$ and $\ell \in \{1, \dots, v\}$ with $\lambda^{(\ell-1)} \leq r_n^d \lambda^* \leq \lambda^{(\ell)}$ and $\gamma^{(\ell-1)} \leq \gamma^* \leq \gamma^{(\ell)}$. Together with (30), this yields

$$r_n^d \lambda^* \leq \lambda^{(\ell)} \leq r_n^d \lambda^* + 2r_n^d \varepsilon_n \quad \text{and} \quad \gamma^* \leq \gamma^{(\ell)} \leq \gamma^* + 2\delta_n. \quad (31)$$

Moreover, the definition of λ^* implies $\varepsilon_n \leq \lambda^*$ and the one of γ^* implies $\gamma^* \leq \tau_n$ for $\alpha < \frac{d-1}{2}d$ and $p \in (0, p^*]$, where $p^* := \frac{2d-2\alpha-d}{2\alpha+d+2}$. Additionally, it is easy to check that

$$\lambda^* (\gamma^*)^{-d} + (\gamma^*)^{2\alpha} + (\lambda^*)^{-p} (\gamma^*)^{-(d+2p)} r_n^{(2-d)p} n^{-1} \leq \tilde{c} n^{-\frac{2\alpha}{(2\alpha+d)(1+2p)} + \max\{\frac{d-2}{\beta d}, 0\}p}, \quad (32)$$

where \tilde{c} is a positive constant. Using (31), the bound $|J| \leq m_n \leq 3^d r_n^{-d}$, and (32), we obtain

$$\begin{aligned} & \inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \left(\sum_{j \in J} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J} \gamma_j^2}{\min_{j \in J} \gamma_j} \right)^d \max_{j \in J} \gamma_j^{2\alpha} + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-p} \mathbb{P}_X(A_j) \right) n^{-1} \right)^p \\ & \leq \sum_{j \in J} \lambda^{(j)} (\gamma^{(j)})^{-d} + (\gamma^{(j)})^{2\alpha} + \left(\sum_{j=1}^{m_n} \lambda^{(j)} \right)^{-1} (\gamma^{(j)})^{-\frac{d+2p}{p}} \mathbb{P}_X(A_j) \Big)^p \\ & \leq |J| \lambda^{(j)} (\gamma^{(j)})^{-d} + (\gamma^{(j)})^{2\alpha} + (\lambda^{(j)})^{-p} (\gamma^{(j)})^{-(d+2p)} r_n^{2p} n^{-1} \\ & \leq |J| \left(r_n^d \lambda^* + 2r_n^d \varepsilon_n \right) (\gamma^*)^{-d} + (\gamma^* + 2\delta_n)^{2\alpha} + \left(r_n^d \lambda^* \right)^{-p} (\gamma^*)^{-(d+2p)} r_n^{2p} n^{-1} \\ & \leq 3^d \cdot 3 \lambda^* (\gamma^*)^{-d} + (\gamma^* + 2\delta_n)^{2\alpha} + (\lambda^*)^{-p} (\gamma^*)^{-(d+2p)} r_n^{(2-d)p} n^{-1} \\ & \leq \tilde{c} \left(\lambda^* (\gamma^*)^{-d} + (\gamma^*)^{2\alpha} + (\lambda^*)^{-p} (\gamma^*)^{-(d+2p)} r_n^{(2-d)p} n^{-1} \right) + \tilde{c} \delta_n^{2\alpha} \\ & \leq \tilde{c} \tilde{c} n^{-\frac{2\alpha}{(2\alpha+d)(1+2p)} + \max\{\frac{d-2}{\beta d}, 0\}p} + \tilde{c} \delta_n^{2\alpha} \\ & \leq C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \delta_n^{2\alpha} \right) \end{aligned}$$

with $\xi := \left(\frac{2\alpha(2\alpha+d+2)}{(2\alpha+d)(2\alpha+d)(1+2p)} + \max\{\frac{d-2}{\beta d}, 0\} \right) p$ and constants $\tilde{c} > 0$ and $C > 0$ independent of n , Λ_n , ε_n , Γ_n , and δ_n . ■

In the end, we show Theorem 7 using Theorem 4 as well as Lemma 14.

Proof [of Theorem 7] Let l be defined by $l := \lfloor \frac{n}{2} \rfloor + 1$, i.e., $l \geq \frac{n}{2}$. With this, Theorem 4 yields with probability \mathbb{P}^l not less than $1 - |\Lambda_n \times \Gamma_n|^{m_n} e^{-\tau}$ that

$$\begin{aligned} & \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda, \gamma}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \\ & \leq \frac{c_1}{2} \left(\sum_{j \in J_n} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_n} \gamma_j^2}{\min_{j \in J_n} \gamma_j} \right)^d \max_{j \in J_n} \gamma_j^{2\alpha} + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-p} \mathbb{P}_X(A_j) \right) \right)^p l^{-1} + \tau l^{-1} \\ & \leq c_1 \left(\sum_{j \in J_n} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_n} \gamma_j^2}{\min_{j \in J_n} \gamma_j} \right)^d \max_{j \in J_n} \gamma_j^{2\alpha} + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-p} \mathbb{P}_X(A_j) \right) \right)^p n^{-1} + \tau n^{-1} \end{aligned} \quad (33)$$

for all $(\lambda_j, \gamma_j) \in \Lambda_n \times \Gamma_n$, $j \in \{1, \dots, m_n\}$, simultaneously, where $c_1 > 0$ is a constant independent of n , τ , λ , and γ . Furthermore, the oracle inequality of Steinwart and Christmann, 2008, Theorem 7.2) for empirical risk minimization, $n - l \geq \frac{n}{2} - 1 \geq \frac{n}{4}$,

and $\tau_n := \tau + \ln(1 + |\Lambda_n \times \Gamma_n|^{m_n})$ yield

$$\begin{aligned} & \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda D_2, \gamma D_2}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \\ & < 6 \left(\inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda, \gamma}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \right) + 512M^2 \frac{\tau_n}{n-1} \\ & < 6 \left(\inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda, \gamma}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \right) + 2048M^2 \frac{\tau_n}{n} \end{aligned} \quad (34)$$

with probability \mathbb{P}^{n-l} not less than $1 - e^{-\tau}$. With (33), (34), and Lemma 14 we can conclude

$$\begin{aligned} & \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda D_2, \gamma D_2}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \\ & < 6 \left(\inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda, \gamma}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \right) + 2048M^2 \frac{\tau_n}{n} \\ & \leq 6c_1 \left(\inf_{(\lambda_j, \gamma_j)_{j=1}^{m_n} \in (\Lambda_n \times \Gamma_n)^{m_n}} \left(\sum_{j \in J_n} \lambda_j \gamma_j^{-d} + \left(\frac{\max_{j \in J_n} \gamma_j^2}{\min_{j \in J_n} \gamma_j} \right)^d \max_{j \in J_n} \gamma_j^{2\alpha} \right. \right. \\ & \quad \left. \left. + r_n^{2p} \left(\sum_{j=1}^{m_n} \lambda_j^{-1} \gamma_j^{-p} \mathbb{P}_X(A_j) \right) \right) n^{-1} + \tau n^{-1} \right) + 2048M^2 \frac{\tau_n}{n} \\ & \leq 6c_1 \left(C \left(n^{-\frac{2\alpha}{2\alpha+d} + \xi} + \delta_n^{2\alpha} \right) + \tau n^{-1} \right) + 2048M^2 \frac{\tau_n}{n} \\ & \leq 12c_1 C n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 \tau + 2048M^2 \tau_n) n^{-1} \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - (1 + |\Lambda_n \times \Gamma_n|^{m_n}) e^{-\tau}$. Finally, a variable transformation yields

$$\begin{aligned} & \mathcal{R}_{L_{J_n, \mathbb{P}}}(\tilde{f}_{D_1, \lambda D_2, \gamma D_2}) - \mathcal{R}_{L_{J_n, \mathbb{P}}}^* \\ & < 12c_1 C n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 (\tau + \ln(1 + |\Lambda_n \times \Gamma_n|^{m_n}))) n^{-1} \\ & \quad + 2048M^2 (\tau + 2 \ln(1 + |\Lambda_n \times \Gamma_n|^{m_n})) n^{-1} \\ & \leq 12c_1 C n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 + 2048M^2) (\tau + 2m_n \ln(1 + |\Lambda_n \times \Gamma_n|)) n^{-1} \\ & \leq 12c_1 C n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 + 2048M^2) (\tau + 2 \cdot 3^d r_n^{-d} \ln(1 + |\Lambda_n \times \Gamma_n|)) n^{-1} \\ & = 12c_1 C n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 + 2048M^2) (\tau n^{-1} + 2 \cdot 3^d c^{-d} \ln(1 + |\Lambda_n \times \Gamma_n|) n^{-\frac{\beta-1}{\beta}}) \\ & < \left(12c_1 C + 2 \cdot 3^d c^{-d} (6c_1 + 2048M^2) \ln(1 + |\Lambda_n \times \Gamma_n|) \right) n^{-\frac{2\alpha}{2\alpha+d} + \xi} + (6c_1 + 2048M^2) \tau n^{-1} \end{aligned}$$

with probability \mathbb{P}^n not less than $1 - e^{-\tau}$, where we used

$$\alpha < \frac{\beta-1}{2} d \iff n^{-\frac{\beta-1}{\beta}} < n^{-\frac{2\alpha}{2\alpha+d}}$$

in the last step. ■

Abstract

We present a systematic study of the bipartite ranking problem, with the aim of explicating its connections to the class-probability estimation problem. Our study focuses on the properties of the statistical risk for bipartite ranking with general losses, which is closely related to a generalised notion of the area under the ROC curve: we establish alternate representations of this risk, relate the Bayes-optimal risk to a class of probability divergences, and characterise the set of Bayes-optimal scorers for the risk. We further study properties of a generalised class of bipartite risks, based on the p -norm push of Rudin (2009). Our analysis is based on the rich framework of proper losses, which are the central tool in the study of class-probability estimation. We show how this analytic tool makes transparent the generalisations of several existing results, such as the equivalence of the minimisers for four seemingly disparate risks from bipartite ranking and class-probability estimation. A novel practical implication of our analysis is the design of new families of losses for scenarios where accuracy at the head of ranked list is paramount, with comparable empirical performance to the p -norm push.

Keywords: bipartite ranking, class-probability estimation, proper losses, Bayes-optimality, ranking the best

1. The Bipartite Ranking Problem

Bipartite ranking problems (Freund et al., 2003; Agarwal et al., 2005; Cléménçon et al., 2008; Kotlowski et al., 2011) have received considerable attention from the machine learning community. In such problems, we have as input a training set of examples, each of which comprises an *instance* (typically a vector of features describing some entity) with an associated *binary label* (typically denoted “positive” or “negative”, describing whether the instance possesses some attribute). The goal is to learn a *scorer*, which assigns to each instance a real number, such that positive instances have a higher score than negative instances. Violations of this condition are penalised according to some loss ℓ , and the *bipartite ranking risk* of a scorer is its expected penalty according to ℓ . When ℓ corresponds to the 0-1 loss, the bipartite ranking risk is one minus the *area under the ROC curve* (AUC) of the scorer (Agarwal and Niyogi, 2005; Cléménçon et al., 2008; Krzanowski and Hand, 2009). Applications of bipartite ranking range from content recommendation, where the goal is to rank a set of items based on an individual’s preference for them, to epidemiological studies, where the goal is to rank a set of individuals based on how likely they are to have a particular disease.

While bipartite ranking has received considerable study, the focus has primarily been on *algorithm design*. There has been relatively little theoretical study of issues such as the properties of its statistical risk, and it is only recently that its relationship to extant supervised learning problems has been formally established (Narasimhan and Agarwal, 2013b). While the design of computationally and statistically efficient methods for bipartite ranking is important, we believe there is value in explicating the statistical risk assumed by the problem, the optimal solutions that result from it, and the implied relationships to other learning problems.

To this end, in this paper,¹ we systematically study bipartite ranking through its statistical risk. In brief, we study the properties of the bipartite risk (and hence the AUC) for an arbitrary scorer, the properties of the Bayes-optimal bipartite risk and the bipartite regret for an arbitrary scorer, and characterise the set of the Bayes-optimal scorers. While some of these topics have been touched upon in prior studies, we aim to

1. A preliminary version of this work appeared in (Menon and Williamson, 2014).

provide a comprehensive, unified treatment of the material. Our analysis rests heavily upon the framework of proper losses (Buja et al., 2005; Reid and Williamson, 2010)—the machinery underlying the analysis of the class-probability estimation problem—which we hope to demonstrate to be the natural lens with which to study bipartite ranking problems. The proper loss framework has previously been employed in the analysis of a reduction of bipartite ranking to class-probability estimation (Agarwal, 2014). In this paper, we show how this framework additionally provides a clean way of generalising existing results on the Bayes-optimal scorers (§7.3, §9.5), makes transparent the connections between bipartite ranking and class-probability estimation (§10.2), and immediately establishes the equivalence of minimisers for seemingly disparate risks (§11). A novel practical implication is a means of designing losses suitable for the task of “ranking the best” (§9.6), which we show to perform favourably compared with existing approaches (§9.7).

Table 1 provides an overview of the material covered in this paper. In more detail:

- We formally define the bipartite ranking problem for a general loss via its statistical risk (§3.3), and derive its equivalence to a classification problem over pairs (§4).
- We study the properties of the ROC curve, such as its connection to the calibration transform (§5.2.5), and its value in determining thresholds for cost-sensitive classification (§5.2.6). We derive a (to our knowledge novel) result (Proposition 13) on how dominance of one calibrated scorer over another in ROC space implies dominance with respect to *any* proper composite loss, which establishes the coherence of using the ROC curve to compare calibrated scorers.
- We discuss several interpretations of the AUC, including its relationship to the bipartite risk (§5.5) and a number of integral representations (§5.6). We show how one of these representations, due to Hand (2009), is related to the integral representation for proper losses, and discuss its implications for the coherence of the use of AUC to compare scorers (§5.6.2).
- We relate the Bayes-optimal bipartite risk to an f -divergence between product measures for the class-conditional distributions (§6.2), generalising a result for the case of 0-1 loss due to Torgersen (1991). We further relate the bipartite regret to a generative Bregman divergence (§6.3).
- We determine the set of Bayes-optimal scorers for surrogate bipartite ranking risks (§7.3, §7.4, §7.5), demonstrating how the proper loss framework helps generalise existing results on the topic. We use these results to derive surrogate regret bounds, and thus AUC-consistency, for algorithms that minimise a suitable surrogate loss over pairs (§8).
- We formalise the “ranking the best” extension to bipartite ranking (§9.1), and the study the Bayes-optimal scorers for the p -norm push risk (§9.5). We show how the risk can be related to a proper composite loss with asymmetric weight function over misclassification costs (§9.6.1).
- We show how the weight function view of a proper composite loss suggests a strategy for designing losses suitable for “ranking the best”. We then describe several such new loss functions (§9.6.3). We evaluate these losses empirically on a number of real-world data sets (§9.7), and demonstrate their favourable empirical performance compared to the p -norm push risk.
- Based on the corresponding Bayes-optimal solutions, we relate bipartite ranking to the learning problems of pairwise ranking, class-probability estimation, and classification (§10.1, §10.2). This formally elucidates the relative “difficulty” of each of these problems.
- Based on the corresponding Bayes-optimal solutions, we establish the equivalence between the minimisers of seemingly disparate risks for four popular approaches to bipartite ranking (§11). This further illustrates the close links between bipartite ranking and class-probability estimation.
- We relate bipartite ranking to axiomatic characterisations of ranking relations, and in particular show how theorems characterising the existence of utility representations describe the class of ranking problems over pairs that it can model (§12.4).

Table 1: Summary of the results on bipartite ranking in this paper.

Before initiating our study with a description of bipartite risk, we fix notation and provide definitions of key quantities that will be used throughout the paper.

2. Preliminary Definitions and Notation

We define the relevant quantities used in the rest of the paper, and fix some notation. Table 2 provides a glossary of some frequently used symbols.

2.1 Notation

We use scripted calligraphic fonts e.g. \mathcal{X}, \mathcal{Y} to denote sets. We use $\mathcal{X} \setminus \mathcal{Y}$ to denote set difference, and \emptyset to denote the empty set.

We denote by \mathbb{R} the set of real numbers, and $\mathbb{R}_+ = [0, \infty)$. For a positive integer n , we write $[n] = \{1, 2, \dots, n\}$. For a function $f: \mathcal{X} \rightarrow \mathbb{R}$, we denote its image or range by $\text{Im}(f)$. If f is differentiable, we denote its derivative by f' . For functions $f, g, f \circ g$ denotes functional composition, so that $(f \circ g)(x) = f(g(x))$. For a nonincreasing function $f: \mathbb{R} \rightarrow \mathbb{R}$, define the pseudo-inverse $f^{-1}: \mathbb{R} \rightarrow \mathbb{R}$ by

$$f^{-1}(y) = \inf\{x \in \mathbb{R} : f(x) \leq y\}. \tag{1}$$

If f is strictly decreasing, this coincides with the standard inverse function. When f is nondecreasing, we replace the inf with a sup in Equation 1. For a constant $c \in \mathbb{R}$, we write $f \equiv c$ to mean that $f(x) = c$ for every $x \in \mathcal{X}$.

Symbol	Meaning	Definition
$\mathbb{1}$	Indicator function	\$2.1
\wedge, \vee	Minimum and maximum	\$2.1
$\sigma(\cdot)$	Sigmoid function	\$2.1
\mathcal{X}	Instance space, typically \mathbb{R}^n	\$2.1
\mathcal{Y}	Label space, typically $\{\pm 1\}$	\$2.1
Δ_S	Set of all distributions over a set S	\$2.2
\mathcal{X}, \mathcal{Y}	Random variables, typically samples from D	\$2.2
D	Distribution over $\mathcal{X} \times \{\pm 1\}$	\$3.1
R	Distribution over $\mathcal{X} \times \mathcal{X} \times \{\pm 1\}$	\$3.4
D_{pair}	Pairwise ranking distribution derived from D	\$3.3
P, Q, μ, q	Class-conditional distributions and densities of D	\$3.2
M, μ	Observation distribution and density of D	\$3.2
η	Observation-conditional distribution of D	\$3.2
η_{pair}	Observation-conditional distribution of D_{pair}	\$3.3
π	Positive class base rate of D	\$3.2
$D = \langle P, Q, \pi \rangle = \langle M, \mu \rangle$	Constituent components of distribution D	\$3.1
$s: \mathcal{X} \rightarrow \mathbb{R}$	Scorer	\$2.4
$s_{\text{pair}}: \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$	Pair-scorer	\$2.4
$\text{Diff}(\phi): \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$	Difference pair-scorer	\$2.4
S_{decomp}	Set of all decomposable pair-scorers	\$2.4
$\text{Pth}(\cdot; D, s): \mathbb{R} \rightarrow [0, 1]$	Score-to-probability transform	Equation 5
$\text{Call}(\cdot; D, s): \mathcal{X} \rightarrow [0, 1]$	Calibration transform	Equation 5
S, S'	Random variable and distribution of scores	\$2.4
$\ell(\cdot, \cdot)$	Loss function	\$2.6
$\ell_{\text{sym}}(\cdot, \cdot)$	Symmetrised loss function	Equation 8
$\psi(\cdot)$	Link function for a proper composite loss	\$2.6
$w(\cdot)$	Weight function for a proper composite loss	\$2.6
\mathcal{L}_{sc}	Set of all strictly proper composite losses	\$2.6
$\mathcal{L}_{\text{sc}}(\Psi)$	Set of all strictly proper composite losses with link ψ	\$2.6
$\mathcal{L}_{\text{decomp}}$	Set of all losses with decomposable Bayes-optimal pair-scorer	Equation 20
$L(\cdot, \cdot; \ell)$	Conditional risk for loss ℓ	\$3.2
$L(\cdot; \ell)$	Bayes-optimal conditional risk for loss ℓ	\$3.2
$L(\cdot; D, \ell)$	Risk for loss ℓ	\$3.2
$L_{\text{pair}}(\cdot; D, \ell)$	Bipartite risk for loss ℓ	\$3.3
$L_{\text{pair}}^*(\cdot; D, \ell)$	Bayes-optimal (minimal) risk for loss ℓ	\$3.2
$L_{\text{pair}}^{\text{min}}(D, \ell)$	Bayes-optimal (minimal) bipartite risk over scorers for loss ℓ	\$3.3
$S^*(D, \ell)$	Set of Bayes-optimal scorers for classification for loss ℓ	\$3.2
$S_{\text{pair}}^*(D, \ell)$	Set of Bayes-optimal scorers for bipartite ranking for loss ℓ	\$3.3
$\text{regret}(\cdot; D, \ell)$	Classification regret of scorer for loss ℓ	\$3.2
$\text{regret}_{\text{pair}}(\cdot; D, \ell)$	Bipartite ranking regret of scorer for loss ℓ	\$3.3
$f(\cdot, \cdot)$	f -divergence between distributions	Equation 3
$B_f(\cdot, \cdot)$	Generative Bregman divergence between distributions	Equation 4
TPR, TNR, FPR, FNR	True (false) positive (negative) rates	Equation 4
AUC, AUC $_c$	Area under the ROC curve, 0-1 and ℓ loss	\$5.3, \$5.4

Table 2: Glossary of frequently used symbols used in this paper.

For any function $f : \mathcal{X} \rightarrow \mathbb{R}$, we denote by $\text{Argmin}_{x \in \mathcal{X}} f(x)$ the set of all minimisers i.e. all $x \in \mathcal{X}$ such that $f(x) \leq f(x')$ for all $x' \in \mathcal{X}$. When the set is a singleton, so that f has a unique minimiser, we denote this minimiser by $\text{argmin}_{x \in \mathcal{X}} f(x)$.

We denote by $\text{Diff}(f) : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ the function satisfying $(\text{Diff}(f))(x, x') = f(x) - f(x')$ for every $x, x' \in \mathcal{X}$. For a set of functions $\mathcal{F} = \{f : \mathcal{X} \rightarrow \mathbb{R}\}$, we define $\text{Diff}(\mathcal{F}) = \{\text{Diff}(f) : f \in \mathcal{F}\}$.

Given any $a, b \in \mathbb{R}$, we use $a \wedge b = \min(a, b)$ and $a \vee b = \max(a, b)$. We use the Iverson bracket $(\text{Knuth}, 1992)$ $[p]$ to denote the indicator function, whose value is 1 if p is true and 0 otherwise. For any $x_0 \in \mathbb{R}$, we use $\delta_{x_0}(\cdot)$ to denote the Dirac delta centred at x_0 , which is a generalised function² satisfying $\int_{\mathbb{R}} \delta_{x_0}(x) dx = f(x_0)$ for any continuous $f : \mathbb{R} \rightarrow \mathbb{R}$.

For any $z \in \mathbb{R}$, we define $\text{sign}(z) = \llbracket z \geq 0 \rrbracket - \llbracket z \leq 0 \rrbracket$. The sigmoid function $\sigma(\cdot)$ is defined by

$$(\forall z \in \mathbb{R}) \sigma(z) = \frac{1}{1 + e^{-z}}, \quad (2)$$

with its inverse $\sigma^{-1}(\cdot)$ being the logit function,

$$(\forall y \in (0, 1)) \sigma^{-1}(y) = \log \frac{y}{1-y}.$$

2.2 Probability Distributions and Random Variables

We use sans-serif fonts e.g. X, Y to denote random variables. We denote by $X \sim D$ that X is a random variable with probability distribution D . We denote by $\mathbb{P}_{x \sim D} [X \in \mathcal{A}]$ the probability that a random draw of X according to D falls in the set \mathcal{A} . We denote by $\mathbb{E}_{x \sim D} [X]$ the expected value of the random variable X .

Given distributions P and Q such that P is absolutely continuous with respect to Q , we use $\frac{dP}{dQ}$ to denote the Radon-Nikodym density of P with respect to Q . When it exists, we refer to the density of a random variable with respect to Lebesgue measure (unless noted otherwise) by p_X . Alternately, when the random variable is clear from context, we refer to the density of the underlying distribution (e.g. Q) by the corresponding lowercase letter (e.g. q).

Given a set \mathcal{S} , we denote by $\Delta_{\mathcal{S}}$ by the set of all probability distributions on \mathcal{S} . We denote by $\text{Ber}(\theta)$ the Bernoulli distribution with parameter $\theta \in [0, 1]$.

2.3 f - and Bregman-Divergences

For convex $f : \mathbb{R}_+ \rightarrow \mathbb{R}$, the f -divergence (Csiszár, 1963) between distributions P, Q is

$$\mathbb{I}_f(P, Q) = \mathbb{E}_{x \sim Q} \left[\frac{dP}{dQ}(x) \right]. \quad (3)$$

This can be seen as a notion of discrepancy between P and Q . For normalisation purposes, one typically enforces $f(1) = 0$.

A *generative Bregman divergence* is a distinct notion of discrepancy between two probability distributions. It relies on the notion of a *Bregman divergence* (Bregman, 1967). For convex, differentiable $f : \mathbb{R} \rightarrow \mathbb{R}$, the Bregman divergence B_f between points $x, y \in \mathbb{R}$ is

$$B_f(x, y) = f(x) - f(y) - f'(y) \cdot (x - y).$$

The generative Bregman divergence B_f between distributions P, Q with densities p, q with respect to some distribution M is then the average divergence between the densities (Reid and Williamson, 2011, Section 3.3),

$$\mathbb{E}_f(P, Q) = \mathbb{E}_{x \sim M} [B_f(p(x), q(x))]. \quad (4)$$

2. Strictly, the Dirac delta is defined as a distribution or functional such that $\delta_{x_0}(f) = f(x_0)$ for every smooth f (Rudin, 1973, pg. 156; Strichartz, 1994, pg. 5), or one interprets the integral $\int_{\mathbb{R}} \delta_{x_0}(x) f(x) dx = \int_{\mathbb{R}} f(x) \mu_{x_0}(dx)$ for μ_{x_0} being the Dirac measure.

2.4 Scorers and Pair-Scorers

We are interested in supervised learning problems involving an instance or feature space \mathcal{X} (often \mathbb{R}^n), and a label space \mathcal{Y} . We call an element $x \in \mathcal{X}$ an *instance* or *feature vector*, and an element $y \in \mathcal{Y}$ a *label*. A *scorer* s for the space $(\mathcal{X}, \mathcal{Y})$ is some (measurable) function $s : \mathcal{X} \rightarrow \mathcal{V}$, where $\mathcal{V} \subseteq \mathbb{R}^{|\mathcal{Y}|}$ is the prediction space of the scorer. The magnitude of each element of s corresponds to the degree of belief in an instance having the corresponding label. A *classifier* is a scorer with $\mathcal{V} = \mathcal{Y}$, so that an instance is directly annotated with one of the labels. A *class-probability estimator* is a scorer with $\mathcal{V} = \Delta_{[|\mathcal{Y}|]}$, so that an instance is annotated by a distribution over its possible labels.

This paper focuses on the setting of *binary labels*, where $\mathcal{Y} = \{\pm 1\}$. In the case of binary labels, a scorer s for some $\mathcal{X} : \mathcal{X} \rightarrow \mathcal{V}$, where $\mathcal{V} \subseteq \mathbb{R}$. Here, classifier c is often derived from a scorer³ s via $c(x; t) = 2 \llbracket s(x) \geq t \rrbracket - 1$ for some threshold $t \in \mathbb{R}$. Similarly, a class-probability estimator f is often derived from a scorer s via $f = \Psi^{-1} \circ s$ for some (inverse) link function $\Psi^{-1} : \mathbb{R} \rightarrow [0, 1]$.

When a scorer is applied to instances drawn from some distribution, one can consider the induced distribution over scores. If X is a random variable over instances with distribution M , we denote by S the induced distribution over the scores. When it exists, we refer to the induced (marginal) distribution of the scorer as M_S , and the distributions on the positive and negative classes by P_S and Q_S respectively. We denote the marginal density of the score distribution by μ_S , and the score densities on the positive and negative classes by p_S and q_S respectively.

A *pair-scorer* s_{pair} for a product space $\mathcal{X} \times \mathcal{X}$ is some function $s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{V}$. The magnitude of s_{pair} corresponds to a degree of belief in the first instance having a “larger” label than the second, according to some metric. A *ranker* is a pair-scorer with $\mathcal{V} = \{\pm 1\}$. A ranker r is typically derived from a pair-scorer s_{pair} via $r(x, x'; t) = 2 \llbracket s(x, x') \geq t \rrbracket - 1$ for some threshold $t \in \mathbb{R}$. Given a (standard, or univariate) scorer s , we can construct a pair-scorer $\text{Diff}(s) : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{V} - \mathcal{V}$ (where $-$ denotes Minkowski subtraction) via

$$(\forall x, x' \in \mathcal{X}) \text{Diff}(s)(x, x') = s(x) - s(x').$$

We call a pair-scorer s_{pair} *decomposable* if

$$s_{\text{pair}} \in \mathcal{S}_{\text{Decomp}} = \{s_{\text{pair}} \in \mathcal{V}^{\mathcal{X} \times \mathcal{X}} : (\exists s : \mathcal{X} \rightarrow \mathbb{R}) s_{\text{pair}} = \text{Diff}(s)\}.$$

We call a pair-scorer *anti-symmetric* if, for every $x, x' \in \mathcal{X}$, $s_{\text{pair}}(x, x') = -s_{\text{pair}}(x', x)$. Every decomposable scorer is anti-symmetric, but not conversely.

2.5 Calibration Transform

Given a scorer s and distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, the *score-to-probability transform* $\text{Prb}(\cdot; D, s) : \mathbb{R} \rightarrow [0, 1]$ maps each score to the actual probability when the score is observed:

$$(\forall a \in \text{Im}(s)) \text{Prb}(a; D, s) = \mathbb{P}_{(X, Y) \sim D} [Y = 1 | s(X) = a].$$

We call a scorer s *calibrated* with respect to D if each predicted score equals the probability of $Y = 1$ when that prediction is made (DeGroot and Fienberg, 1983):

$$(\forall a \in \text{Im}(s)) \text{Prb}(a; D, s) = a.$$

A scorer must be a class-probability estimator to be calibrated (i.e. it cannot output values outside $[0, 1]$). The *calibration transform* $\text{Cal}(\cdot; D, s) : \mathcal{X} \rightarrow [0, 1]$ converts a scorer into a class-probability estimator via

$$(\forall x \in \mathcal{X}) \text{Cal}(x; D, s) = \text{Prb}(s(x); D, s). \quad (5)$$

It is easy to check that for any scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, $\text{Cal}(\cdot; D, s)$ is automatically calibrated.

3. The case of $s(x) = t$ can be considered as a tie, thus requiring a tie-breaking scheme. The above definition corresponds to breaking ties in favour of the positive class.

2.6 Loss Functions and Conditional Risks

A *binary classification loss* ℓ , often just referred to as a *loss*, is some (measurable) function $\ell : \{\pm 1\} \times \mathbb{R} \rightarrow \mathbb{R}_+$. An important example is the 0-1 loss,⁴

$$\ell_{0,1}(y, v) = \mathbb{1}[v < 0] + \frac{1}{2} \cdot \mathbb{1}[v = 0].$$

Given a loss ℓ , we use $\ell_+(v) = \ell(1, v)$ and $\ell_-(v) = \ell(-1, v)$ to denote the individual *partial losses*. We will sometimes refer to a loss via the tuple $\ell^{(0)} = (\ell_-, \ell_+)$.

We define the *conditional ℓ -risk* $L(\cdot, \cdot; \ell)$: $[0, 1] \times \mathbb{R} \rightarrow \mathbb{R}_+$ to be

$$(\forall \eta \in [0, 1], s \in \mathbb{R}) L(\eta, s; \ell) \doteq \mathbb{E}_{Y \sim \text{Ber}(\eta)} [\ell(Y, s)] = \eta \cdot \ell_+(s) + (1 - \eta) \cdot \ell_-(s). \quad (6)$$

The *Bayes-optimal conditional ℓ -risk* $L^*(\cdot; \ell)$: $[0, 1] \rightarrow \mathbb{R}_+$ is then the best possible conditional risk,

$$(\forall \eta \in [0, 1]) L^*(\eta; \ell) \doteq \inf_{s \in \mathbb{R}} L(\eta, s; \ell).$$

For the 0-1 loss, the optimal risk is attained for any score with the same sign as $\eta - \frac{1}{2}$. More generally, we call a loss *classification calibrated* if for every $\eta \in [0, 1] \setminus \{\frac{1}{2}\}$ (Bartlett et al., 2006, Definition 1),

$$L^*(\eta; \ell) < \inf_{s: s \in (2\eta-1) \leq 0} L(\eta, s; \ell), \quad (7)$$

i.e. every optimal prediction has the same sign as $2\eta - 1$.

We call a loss ℓ *symmetric* if, for every $y \in \{\pm 1\}$ and $v \in \mathbb{R}$, $\ell(y, v) = \ell(-y, -v)$. We denote the *symmetrised version* of an arbitrary loss by

$$\ell_{\text{sym}}(v) \doteq \frac{\ell(1, v) + \ell(-1, -v)}{2}. \quad (8)$$

We call a loss ℓ a *margin loss* if $\ell(y, z) = \phi(yz)$ for some function $\phi : \mathbb{R} \rightarrow \mathbb{R}_+$. A loss is symmetric if and only if it is a margin loss; sufficiency is straightforward, and to see necessity, note that for a symmetric loss, $\ell(y, v) = \mathbb{1}[y = 1] \ell_+(v) + \mathbb{1}[y = -1] \ell_-(v) = \phi(yv) = \phi(yv)$ for $\phi(v) = \ell_+^+(v)$.

2.7 Proper and Proper-Composite Losses

A *probability estimation loss* λ is some (measurable) function $\lambda : \{\pm 1\} \times [0, 1] \rightarrow \mathbb{R}_+ \cup \{+\infty\}$. We call a probability estimation loss *proper*⁵ if its conditional risk is optimised by predicting the underlying probability (Buja et al., 2005; Reid and Williamson, 2010),

$$(\forall \eta, \eta' \in [0, 1]) L(\eta, \eta'; \lambda) \leq L(\eta, \eta'; \lambda). \quad (9)$$

We call a loss *strictly proper* if the inequality is strict.

In the following, we assume two mild regularity conditions: that $\lambda_+(1) = \lambda_-(0) = 0$, and

$$\lim_{u \rightarrow 0} u \cdot \lambda_+(u) = \lim_{u \rightarrow 1} (1 - u) \cdot \lambda_-(u) = 0.$$

4. When $V = \{\pm 1\}$, so that we are assessing a classifier, the canonical definition of 0-1 loss is $\ell_{0,1}(y, v) = \mathbb{1}[y \neq v]$. When assessing a scorer with $V = \mathbb{R}$, we simply derive a classifier from the scores and compute the resulting 0-1 loss. The only mild complication is that we consider a score of $v = 0$ to be a tie, which thus requires a tie-breaking scheme. In our definition, we break ties uniformly at random, and thus generate a *randomised classifier*. This results in the extra second term compared to the classification case.

5. Proper losses are sometimes referred to as *proper scoring rules* (Gneiting and Raftery, 2007), especially in the statistics literature. A “scoring rule” is distinct from our notion of a “scorer”: the former is a loss, and the latter is a prediction. In the literature on scoring rules, our notion of a scorer is sometimes referred to as a (probabilistic) “forecast” (Gneiting and Raftery, 2007).

Name	$\lambda_-(u)$	$\lambda_+(u)$	$w(c)$	$L^*(\eta; \lambda)$
0-1	$\mathbb{1}[u > \frac{1}{2}]$	$\mathbb{1}[u < \frac{1}{2}]$	$\delta_{1/2}(c)$	$\eta \wedge (1 - \eta)$
Cost-sensitive	$c^* \cdot \mathbb{1}[u > \frac{1}{2}]$	$(1 - c^*) \cdot \mathbb{1}[u < \frac{1}{2}]$	$\delta_{c^*}(c)$	$((1 - c^*) \cdot \eta) \wedge (c^* \cdot (1 - \eta))$
Brier	u^2	$(1 - u)^2$	2	$\eta \cdot (1 - \eta)$
Log	$-\log(1 - u)$	$-\log u$	$\frac{1}{c(1-c)}$	$-\eta \cdot \log \eta - (1 - \eta) \cdot \log(1 - \eta)$
Boosting	$\left(\frac{u}{1-u}\right)^{1/2}$	$\left(\frac{1-u}{u}\right)^{1/2}$	$\frac{1}{2 \cdot (c(1-c))^{3/2}}$	$2 \cdot \sqrt{\eta \cdot (1 - \eta)}$

Table 3: Examples of proper losses λ with associated weight functions w and conditional Bayes risks $L^*(\cdot; \lambda)$.

Name	Symbol	$\ell(y; v)$	λ	$\Psi(u)$	$\Psi^{-1}(v)$
Square	ℓ_{sq}	$\frac{1}{4} \cdot (1 - yv)^2$	Brier	$2u - 1$	$\left(\frac{v+1}{2} \vee 0\right) \wedge 1$
Logistic	ℓ_{log}	$\log(1 + e^{-yv})$	Log	$\log \frac{u}{1-u}$	$\frac{1}{1+e^v}$
Exponential	ℓ_{exp}	e^{-yv}	Boosting	$\frac{1}{2} \cdot \log \frac{u}{1-u}$	$\frac{1+e^{2v}}{1+e^v}$
Matushita	ℓ_{ms}	$\sqrt{1 + \frac{c^2}{4}} - \frac{yc}{2}$	Boosting	$\frac{2u-1}{\sqrt{u(1-u)}}$	$\frac{1}{2} \cdot \left(1 + \frac{v/2}{\sqrt{1+(v/2)^2}}\right)$

Table 4: Examples of proper composite losses with associated underlying proper loss λ and link function Ψ .

Any proper loss satisfying these conditions admits an integral representation as a weighted combination of cost-sensitive losses (Shuford Jr. et al., 1966; Schervish, 1989, Theorem 4.2),

$$\lambda : (y; u) \mapsto \int_0^1 w(c) \cdot \lambda_{\text{CS}(c)}(y, u) dc, \quad (10)$$

where $w : [0, 1] \rightarrow \mathbb{R}_+ \cup \{+\infty\}$ is called the *weight function* of the loss, and $\lambda_{\text{CS}(c)}$ is the *cost-sensitive loss*

$$\begin{aligned} \lambda_{\text{CS}(c)}(+1, u) &\doteq (1 - c) \cdot \mathbb{1}[u < c] + \frac{1}{2} \cdot \mathbb{1}[u = c] \\ \lambda_{\text{CS}(c)}(-1, u) &\doteq c \cdot \mathbb{1}[u > c] + \frac{1}{2} \cdot \mathbb{1}[u = c]. \end{aligned} \quad (11)$$

We call Equation 10 *Shuford’s representation*. A loss is strictly proper if and only if its weight function is strictly positive. One can relate the weight function and conditional Bayes risk via (Reid and Williamson, 2010, Corollary 3) $w(c) = -(L^*(\cdot; \lambda))'(c)$.

We call a loss ℓ (*strictly*) *proper composite* if there is some invertible *link function* $\Psi : [0, 1] \rightarrow \mathbb{R} \cup \{\pm\infty\}$ such that the probability estimation loss $\lambda(y; u) \doteq \ell(y; \Psi(u))$ is (strictly) proper (Reid and Williamson, 2010). By Equation 10, this implies that a proper composite loss also admits an integral representation; hence, we define the weight function of a proper composite loss as that of its underlying proper loss. We denote the set of strictly proper composite losses with invertible link function Ψ by $\mathcal{L}_{\text{SPC}}(\Psi)$, and the set of all proper composite losses by \mathcal{L}_{SPC} .

When the proper composite loss ℓ is differentiable, we have (Reid and Williamson, 2010, Corollary 12)

$$(\forall u \in \mathbb{R}) \Psi^{-1}(u) = \left(1 - \frac{\ell'(u)}{\ell_+'(u)}\right)^{-1}. \quad (12)$$

Problem	Input space	Output	Risk
Classification	$\mathcal{X} \times \mathcal{Y}$	$c : \mathcal{X} \rightarrow \mathcal{Y}$	$\mathbb{E}_{(\mathcal{X}, \mathcal{Y}) \sim D} [\ell(\mathcal{Y}, s(\mathcal{X}))]$
Class-probability estimation	$\mathcal{X} \times \mathcal{Y}$	$\hat{\eta} : \mathcal{X} \rightarrow \Delta_{ \mathcal{Y} }$	
Bipartite ranking	$\mathcal{X} \times \{\pm 1\}$	$s : \mathcal{X} \rightarrow \mathbb{R}$	$\mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \ell_{\text{symm}}(s(\mathcal{X}) - s(\mathcal{X}'))$
Pairwise ranking	$\mathcal{X} \times \mathcal{X} \times \{\pm 1\}$	$s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \{\pm 1\}$	$\mathbb{E}_{(\mathcal{X}, \mathcal{X}') \sim R} [\ell(\mathcal{Z}, s_{\text{pair}}(\mathcal{X}, \mathcal{X}'))]$

Table 5: Summary of learning problems in terms of input, output, and statistical risk.

Given a proper loss λ , we call a link function $\Psi : [0, 1] \rightarrow \mathbb{R} \cup \{\pm\infty\}$ *canonical* for that loss if

$$(\forall c \in [0, 1]) \Psi'(c) = u(c). \quad (13)$$

The canonical link function is monotone increasing, but is strictly so if and only if the loss λ is strictly proper. For a strictly proper loss λ , the proper composite loss $\ell_{\lambda}(y, v) = \lambda(y, \Psi^{-1}(v))$ is convex (Reid and Williamson, 2010, Theorem 28).

Table 3 provides some examples of popular proper losses, and Table 4 of popular proper composite losses, along with their associated underlying proper loss λ and link function Ψ .

3. Classification and Ranking: Statistical Setups

We now formally define the problems of interest in this paper. For each problem, we state the nature of their assumed input, produced output, and measure of statistical performance (or risk). Table 5 provides a summary of these problems. Our starting point is a general statistical perspective on learning from binary labels.

3.1 Learning from Binary Labels: Distributions and their Decompositions

Most problems of interest in this paper concern learning based on samples from some distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ over binary labels. The precise nature of these problems shall be specified momentarily, but we first note two decompositions of D that shall prove useful. The first involves splitting any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ into

$$\begin{aligned} (\forall A \subseteq \mathcal{X}) P(A) &= \mathbb{P}[X \in A | Y = 1] \\ (\forall A \subseteq \mathcal{X}) Q(A) &= \mathbb{P}[X \in A | Y = -1] \\ \pi &= \mathbb{P}[X \in \mathcal{X}, Y = 1]. \end{aligned}$$

Equivalently, we may decompose $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ into

$$\begin{aligned} (\forall A \subseteq \mathcal{X}) M(A) &= \mathbb{P}[X \in A, Y \in \{\pm 1\}] \\ (\forall x \in \mathcal{X}) \eta(x) &= \mathbb{P}[Y = 1 | X = x]. \end{aligned}$$

We refer to P, Q as the *class conditional distributions*, and π the *base rate*; we refer to M as the *observation distribution* and η as the *observation-conditional distribution* or *class-probability function*. We will denote the densities of P, Q with respect to M by p, q . When M possesses a density, we refer to it as μ . When we wish to refer to these constituent distributions of D and their densities, we will explicitly parameterise D as either $D = \langle P, Q, \pi \rangle$ or $D = \langle M, \eta \rangle$ as appropriate.

We now proceed to formalising the problems considered in this paper.

3.2 Classification and Class-Probability Estimation

Classification is the canonical supervised machine learning task, and has received several decades' worth of study from a theoretical and practical perspective. Classification is often motivated by appealing to several real-world problems, such as predicting whether an email message is spam based on its contents, predicting whether or not a person is sick based on test results, or predicting whether or not an individual will enjoy a movie based on its characteristics.

Formally, in statistical classification (Devroye et al., 1996), we are given samples from some distribution $D \in \Delta_{\mathcal{X} \times \mathcal{Y}}$, and wish to learn a classifier $c : \mathcal{X} \rightarrow \mathcal{Y}$. In *class-probability estimation* (Buja et al., 2005; Reid and Williamson, 2010), the input is identical, except we wish to learn a class-probability estimator $\hat{\eta} : \mathcal{X} \rightarrow \Delta_{|\mathcal{Y}|}$. In the binary case, classification involves learning some $c : \mathcal{X} \rightarrow \{\pm 1\}$ and class-probability estimation involves learning some $\hat{\eta} : \mathcal{X} \rightarrow [0, 1]$. In this setting, one typically first learns a general scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, and performs either thresholding to get a classifier or a monotone transformation to get a class-probability estimator.

It remains to define how the performance of a candidate scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ is assessed for the two problems. Intuitively, as these problems assume examples drawn from a probability distribution, one would like to incur a small *disutility* or *loss* for a *randomly drawn* example. This notion is captured by the notion of *statistical risk*. Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and loss ℓ , we define the *ℓ -classification risk* for a scorer s to be the average loss incurred on a random sample from D ,

$$\mathbb{L}(s; D, \ell) \doteq \mathbb{E}_{(\mathcal{X}, \mathcal{Y}) \sim D} [\ell(\mathcal{Y}, s(\mathcal{X}))] = \mathbb{E}_{\mathcal{X} \sim M} [L(\eta(\mathcal{X}), s(\mathcal{X}); \ell)], \quad (14)$$

recalling that $L(\cdot, \cdot; \ell)$ is the conditional ℓ -risk (Equation 6). The *Bayes-optimal ℓ -classification risk*, or simply the *Bayes risk*, is the infimal ℓ -classification risk:

$$\mathbb{L}^*(D, \ell) \doteq \inf_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(s; D, \ell).$$

Similarly, the *Bayes-optimal conditional risk*, or simply the *conditional Bayes risk* is

$$L^*(\eta; \ell) \doteq \inf_{s \in \mathbb{R}} L(\eta, s; \ell).$$

When the infimum is achievable,⁶ the set of *Bayes-optimal scorers* for a loss ℓ and distribution D comprises scorers that attain the Bayes-optimal ℓ -classification risk:

$$S^*(D, \ell) \doteq \text{Argmin}_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(s; D, \ell).$$

Under appropriate measurability assumptions, this set may be discerned pointwise, by studying the minimisers of the conditional risk $L(\cdot, \cdot; \ell)$ (Steinwart, 2007). Finally, the *ℓ -regret* of a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ is its excess ℓ -classification risk over the Bayes ℓ -classification risk:

$$\text{regret}(s; D, \ell) \doteq \mathbb{L}(s; D, \ell) - \mathbb{L}^*(D, \ell).$$

In binary classification, the canonical goal is to minimise the risk for ℓ_{01} :

$$\mathbb{L}(s; D, \ell_{01}) = \mathbb{P}_{(\mathcal{X}, \mathcal{Y}) \sim D} [Y \cdot s(\mathcal{X}) < 0] + \frac{1}{2} \cdot \mathbb{P}_{(\mathcal{X}, \mathcal{Y}) \sim D} [s(\mathcal{X}) = 0], \quad (15)$$

i.e. we want our scorer s to achieve low misclassification error on future samples. Observe that the second term above encodes that ties in the classification are broken uniformly at random. In class probability estimation on the other hand, the canonical goal is to minimise $\mathbb{L}(s; D, \ell)$ for some proper composite loss ℓ .

6. A simple example where this is not true is the case of separable data, where $\eta(x) \in \{0, 1\}$ for every x . Under log-loss, which is proper, the optimal scorer $s^*(x) = \eta(x)$. Under logistic loss, which is proper composite, the optimal scorer is in general $s^*(x) = \log \frac{\eta(x)}{1-\eta(x)}$. But for separable data, that would require $s^*(x) \in \{\pm\infty\}$, and so the infimum is not attainable. Working with the extended reals $\mathbb{R} \cup \{\pm\infty\}$ is one possible fix, but in the sequel we will always assume the infimum is attainable.

The binary classification ℓ -risk has been extensively studied. Much of the literature has focussed on the design of losses ℓ with favourable computational and statistical properties, with specific focus on margin losses such as in the support vector machine (which employs the hinge loss, $\ell_{\text{hinge}}(y, v) = \max(0, 1 - yv)$), boosting (which employs the exponential loss $\ell_{\text{exp}}(y, v) = e^{-yv}$), and logistic regression (which employs the logistic loss $\ell_{\text{log}}(y, v) = \log(1 + e^{-yv})$). There has also been theoretical study of how regret with respect to a loss ℓ translates into the regret with respect to the 0-1 loss, via *surrogate regret bounds* (Zhang, 2004; Bartlett et al., 2006).

3.3 Instance Ranking

Many applications traditionally used to motivate binary classification are more appropriately cast as *ranking* problems. For example, rather than merely predicting an individual’s enjoyment of a single movie, it is potentially more useful to have a system capable of producing a *ranked list* of movies that the individual may enjoy. Similarly, in epidemiological studies, rather than merely predicting whether a single individual has a disease, it is potentially more useful to have a system that can produce a ranked list of individuals deemed most likely to have a particular disease. Instance ranking is of similar interest in most other settings where classification is, such as credit fraud detection and clickthrough rate analysis.

Formally, in *instance ranking* (Falkner and Hüllermeier, 2010, pg. 6; Grammer and Singer, 2001; Shashua and Levin, 2002), we are given samples from some distribution $D \in \Delta_{\mathcal{X} \times \mathcal{Y}}$, where each sample comprises a single $x \in \mathcal{X}$ and a label $y \in \mathcal{Y}$, where \mathcal{Y} is a (finite) totally ordered set. The goal is to learn a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ such that the ordering of instances by their scores mimics the ordering by their labels. Note that \mathcal{Y} , while ordered, does not necessarily have an associated metric e.g. for $\mathcal{Y} = \{\text{Hate}, \text{Indifferent}, \text{Like}\}$, there is a natural ordering over the outcomes, but it may not be possible to assign numeric values to the comparison of two outcomes. When \mathcal{Y} does not have an associated metric, instance ranking is identical to *ordinal regression* (Agresti, 1984), and thus one can solve ordinal regression problems by ranking methods (Herbrich et al., 2000). When \mathcal{Y} has an associated metric, instance ranking is a hybrid between traditional multi-class classification (where \mathcal{Y} is finite but unordered) and regression (where \mathcal{Y} is ordered but not finite) (Li and Lin, 2006).

When $\mathcal{Y} = \{\pm 1\}$, the goal of instance ranking can be seen as scoring positive examples higher than negative examples. This special case is known as the *bipartite ranking* problem, and has received considerable attention (Freund et al., 2003; Agarwal and Niyogi, 2005; Clémengon et al., 2008; Kotowski et al., 2011). Bipartite ranking is the main focus of this paper.

As per the previous section, to specify the bipartite ranking problem, we begin with its underlying risk. Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and loss ℓ , we define the ℓ -*bipartite risk* for a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ to be

$$\begin{aligned} \mathbb{L}_{\text{BR}}(s; D, \ell) &= \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [\ell_{\text{symm}}(s(\mathcal{X}) - s(\mathcal{X}'))] \\ &= \frac{1}{\pi \cdot (1 - \pi)} \mathbb{E}_{\mathcal{X} \sim M, \mathcal{X}' \sim M'} [h(\mathcal{X}) \cdot (1 - h(\mathcal{X}')) \cdot \ell_{\text{symm}}(s(\mathcal{X}) - s(\mathcal{X}'))]. \end{aligned} \quad (16)$$

The first equation indicates that this risk is *independent* of the base rate π . When the loss ℓ is symmetric, the equation reduces to

$$\mathbb{L}_{\text{BR}}(s; D, \ell) = \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [\ell(s(\mathcal{X}) - s(\mathcal{X}'))]. \quad (17)$$

A canonical goal is to minimise the bipartite risk for ℓ_{01} , which is

$$\mathbb{L}_{\text{BR}}(s; D, \ell_{01}) = \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) - s(\mathcal{X}') < 0] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) - s(\mathcal{X}') = 0],$$

i.e. we want s to achieve low pairwise misclassification error: in the sense of scoring a negative higher than a positive, on future samples. The reader may wonder how, if at all, this relates to the misclassification error of Equation 15; such discussion shall be deferred to §10.

Equipped with a notion of statistical risk, we can define the Bayes-optimal risk, Bayes-optimal scorers, and regret by analogy with the quantities from the previous section:

$$\begin{aligned} \mathbb{L}_{\text{BR}}^*(D, \ell) &= \inf_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(s; D, \ell) \\ S_{\text{BR}}^*(D, \ell) &= \text{Argmin}_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(s; D, \ell) \\ \text{regret}_{\text{BR}}(s; D, \ell) &= \mathbb{L}_{\text{BR}}(s; D, \ell) - \mathbb{L}_{\text{BR}}^*(D, \ell). \end{aligned} \quad (18)$$

As in binary classification, a large body of literature has focussed on the design of losses ℓ with favourable numerical and statistical properties, again with specific focus on margin losses such as in SVMRank (Joachims, 2002; Herbrich et al., 1998) (corresponding to hinge loss), RankBoost (Freund et al., 2003) (corresponding to exponential loss), and RankNet (Burgess et al., 2005) (corresponding to logistic loss).

3.4 Pairwise Ranking

Pairwise ranking problems involve labelled *pairs* of instances, where we only know which of two instances is more likely to possess some characteristic. For example, in web search click-log data, we can elicit pairwise preferences to determine which of two search results is more likely to be clicked (Joachims, 2002). (In information retrieval, the problem is sometimes referred to as “average view paper ranking”, Liu, 2009, pg. 203.)

Formally, in *pairwise ranking* (Cohen et al., 1999; Herbrich et al., 1998; Falkner and Hüllermeier, 2010, pg. 7) we are given samples from some distribution $R \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$, where each sample comprises pairs of instances $(x^{(1)}, x^{(2)})$, and a label $\{\pm 1\}$, denoting that $x^{(1)}$ ranks above or below $x^{(2)}$ respectively. Following the notation used for binary classification, we will write R as either $R = \langle P_{\text{pair}}, Q_{\text{pair}}, \pi_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ or $R = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle$ where for example $(\forall A \subseteq \mathcal{X} \times \mathcal{X}) P_{\text{pair}}(A) = \mathbb{P}[(\mathcal{X}, \mathcal{X}') \in A | Z = 1]$ for random variables $\mathcal{X}, \mathcal{X}', Z$ defined over the instances and label respectively.

The goal in pairwise ranking is to learn a pair-classifier $c_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \{\pm 1\}$ that specifies whether or not the first instance ranks above the second. As with standard classification, this is often done by thresholding a pair-scorer $s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$. A pair-scorer is nothing more than a scorer defined on $\mathcal{X} \times \mathcal{X}$, and thus the notion of risk for pairwise ranking is as expected: given any $R = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ and loss ℓ , we define the ℓ -*pairwise ranking risk* for a pair-scorer s_{pair} to be

$$\mathbb{L}(s_{\text{pair}}; R, \ell) = \mathbb{E}_{(\mathcal{X}, \mathcal{X}') \sim R} [\ell(Z, s_{\text{pair}}(\mathcal{X}, \mathcal{X}'))] = \mathbb{E}_{(\mathcal{X}, \mathcal{X}') \sim M_{\text{pair}}} [L(\eta_{\text{pair}}(\mathcal{X}, \mathcal{X}'), s_{\text{pair}}(\mathcal{X}, \mathcal{X}'), \ell)]. \quad (19)$$

A canonical goal is to minimise this risk for the 0-1 loss,

$$\mathbb{L}(s_{\text{pair}}; R, \ell_{01}) = \mathbb{P}_{(\mathcal{X}, \mathcal{X}') \sim R} [Z \cdot s_{\text{pair}}(\mathcal{X}, \mathcal{X}') < 0] + \frac{1}{2} \mathbb{P}_{(\mathcal{X}, \mathcal{X}') \sim R} [s_{\text{pair}}(\mathcal{X}, \mathcal{X}') = 0],$$

i.e. we want our pair-scorer s_{pair} to achieve low pairwise misclassification error on future samples. Observe that the second term above encodes that ties in the ranking are broken uniformly at random.

As in the previous sections, we may define the Bayes-optimal risk, Bayes-optimal scorers, and regret for pairwise ranking as:

$$\begin{aligned} \mathbb{L}^*(R, \ell) &= \inf_{s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(s_{\text{pair}}; R, \ell) \\ S^*(R, \ell) &= \text{Argmin}_{s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(s_{\text{pair}}; R, \ell) \\ \text{regret}(s_{\text{pair}}; R, \ell) &= \mathbb{L}(s_{\text{pair}}; R, \ell) - \mathbb{L}^*(R, \ell). \end{aligned}$$

7. Nonetheless, making a distinction with a standard scorer shall be useful in our subsequent analysis.

4. Reducing Bipartite to Pairwise Ranking

Having defined the risks for three seemingly disparate problems, it is worth noting how they relate to each other. First, the pairwise ranking risk (Equation 19) is clearly equivalent to the classification risk (Equation 14), except that we operate over pairs of instances $\mathcal{X} \times \mathcal{X}$. Thus, pairwise ranking is equivalent to classification on pairs; see also §10.1. Further, we may view bipartite ranking as a special case of pairwise ranking in the following sense: any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ may be converted to a pairwise ranking distribution, $D_{\text{BR}} \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$, such that the risks of the two problems are equivalent. Thus, the methods described above for pairwise ranking are equally applicable for bipartite ranking.

Definition 1 (Derived pairwise ranking distribution) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, the derived pairwise ranking distribution $D_{\text{BR}} \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ corresponds to drawing $(X, X', Z) \in \mathcal{X} \times \mathcal{X} \times \{\pm 1\}$ via:

- Draw $Z \sim \text{Ber}(1/2)$
- If $Z = +1$, draw $X \sim P, X' \sim Q$
- If $Z = -1$, draw $X \sim Q, X' \sim P$.

An equivalent process is:

- Draw $(X, Y) \sim D$
- Draw $(X', Y') \sim D$.
- If $Y = Y'$, reject and re-sample; else, let $Z = Y$.

The following risk equivalence can be easily verified, and is well-known for the case of ℓ_0 (Balcan et al., 2008; Kotowski et al., 2011; Agarwal, 2014). (See Proposition 62 for a proof of a more general result).

Lemma 2 For any distribution $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, loss ℓ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\mathbb{L}_{\text{BR}}(s; D, \ell) = \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell).$$

Proof By Equation 16,

$$\begin{aligned} \mathbb{L}_{\text{BR}}(s; D, \ell) &= \mathbb{E}_{X \sim P, X' \sim Q} [\ell_{\text{symm}}(s(X) - s(X'))] \\ &= \frac{1}{2} \cdot \mathbb{E}_{X \sim P, X' \sim Q} [\ell_1(s(X) - s(X')) + \ell_{-1}(s(X') - s(X))] \\ &= \frac{1}{2} \cdot \mathbb{E}_{X \sim P, X' \sim Q} [\ell_1(s(X) - s(X'))] + \frac{1}{2} \cdot \mathbb{E}_{X \sim P, X' \sim Q} [\ell_{-1}(s(X') - s(X))] \\ &= \frac{1}{2} \cdot \mathbb{E}_{X \sim P, X' \sim Q} [\ell_1(s(X) - s(X'))] + \frac{1}{2} \cdot \mathbb{E}_{X \sim Q, X' \sim P} [\ell_{-1}(s(X') - s(X))] \\ &= \frac{1}{2} \cdot \mathbb{E}_{(X, X') \sim (P \times Q)} [\ell_1(s(X) - s(X'))] + \frac{1}{2} \cdot \mathbb{E}_{(X, X') \sim (Q \times P)} [\ell_{-1}(s(X') - s(X))], \end{aligned}$$

where in the penultimate equation we have simply renamed the random variables in the second expression. By definition of D_{BR} and the pairwise ranking risk (Equation 19), this is exactly $\mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell)$. ■

We summarise the conditional and marginal probabilities of D_{BR} in Appendix B. For example, if (X, X', Z) denotes the random variables distributed according to D_{BR} , it is not hard to check that

$$\begin{aligned} \mathbb{P}[(X, X') \in \mathcal{A} \times \mathcal{B} | Z = +1] &= P(\mathcal{A}) \cdot Q(\mathcal{B}) \\ \mathbb{P}[(X, X') \in \mathcal{A} \times \mathcal{B} | Z = -1] &= P(\mathcal{B}) \cdot Q(\mathcal{A}). \end{aligned}$$

The risk equivalence in Lemma 2 has a subtlety that will prove important in our subsequent analysis: the bipartite risk for a scorer relates to the pairwise risk of a decomposable pair-scorer. Consequently, we cannot in general equate the Bayes-optimal bipartite risks for the two problems, as the following makes precise.

Proposition 3 For any distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and loss ℓ ,

$$\mathbb{L}_{\text{BR}}^*(D, \ell) = \mathbb{L}^*(D_{\text{BR}}, \ell) \iff S^*(D_{\text{BR}}, \ell) \cap S_{\text{Decomp}} \neq \emptyset.$$

Proof By definition,

$$\begin{aligned} \mathbb{L}_{\text{BR}}^*(D, \ell) &= \inf_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(s; D, \ell) \\ &= \inf_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell) \text{ by Lemma 2} \\ &= \inf_{s_{\text{Pair}} \in S_{\text{Decomp}}} \mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell). \end{aligned}$$

By contrast,

$$\mathbb{L}^*(D_{\text{BR}}, \ell) = \inf_{s_{\text{Pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell).$$

The two Bayes-risks involve minimisation of the same functional, $\mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell)$, but the former requires the constraint $s_{\text{Pair}} \in S_{\text{Decomp}}$. For the results of an unconstrained and constrained minimisation to coincide, at least one solution to the unconstrained minimisation must belong to the constraint set. Thus, the two Bayes-risks will coincide if and only if there is at least one minimiser of $\mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell)$ that is in S_{Decomp} , i.e. $\ell \in \mathcal{L}_{\text{Decomp}}$. ■

The condition in the right hand side above shall prove important in our subsequent analysis, so much so that we shall use $\mathcal{L}_{\text{Decomp}}$ to denote the set of losses satisfying it:

$$\mathcal{L}_{\text{Decomp}} \doteq \{ \ell \mid (\forall D \in \Delta_{\mathcal{X} \times \{\pm 1\}}) S^*(D_{\text{BR}}, \ell) \cap S_{\text{Decomp}} \neq \emptyset \}. \quad (20)$$

We shall revisit this condition when computing the Bayes-optimal scorers for the bipartite ranking risk. In particular, Proposition 44 characterises the set of proper composite losses for which $\ell \in \mathcal{L}_{\text{Decomp}}$, which turns out to involve a condition on the link function for the loss.

5. The Area Under the ROC Curve (AUC) and Bipartite Risk

The canonical performance measure for a scorer in bipartite ranking is the area under the ROC curve (AUC). In this section, we formally define the ROC curve and AUC, and show how the latter is related to the bipartite risk defined in Equation 16. We then establish several properties of the ROC curve and AUC, and contrast them to those of the classification risk for proper composite losses. We also describe a generalisation of the AUC based on our general bipartite risk. While some of these results are not new, presenting them together shall further delineate the distinctions between bipartite ranking and class-probability estimation.

Before describing the ROC curve, we must define the true and false positive rates for a scorer.

5.1 True and False Positive Rates

The goal of bipartite ranking is to produce a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$. However, as many practical applications require a classifier $c : \mathcal{X} \rightarrow \{\pm 1\}$, it is of interest to convert a scorer into a classifier. The simplest approach to doing so is to *threshold* the scorer at some $t \in \mathbb{R}$, producing a classifier $c(x; t) = \mathbb{I}[s(x) \geq t]$. One may assess the performance of the resulting classifier based on the *true* and *false positive rates*,⁸ which intuitively measure the accuracy (error) rates on each of the classes. These are defined below.

⁸ Depending on the literature, different terms may be used for these quantities. The true positive rate is sometimes referred to as the *recall* or *sensitivity*, and the true negative rate the *specificity*. The false positive rate is sometimes referred to as the *Type I error rate*, and the false negative rate the *Type II error rate*.

Definition 4 (True and false positive rates) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, and a scorer $s: \mathcal{X} \rightarrow \mathbb{R}$, define the true (false) positive (negative) rates of the scorer at a threshold $t \in \mathbb{R} \cup \{\pm\infty\}$ to be

$$\begin{aligned} \text{TPR}(t; D, s) &\doteq \mathbb{P}_{\mathcal{X} \sim p}[\mathcal{S}(X) > t] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim p}[\mathcal{S}(X) = t] \\ \text{FPR}(t; D, s) &\doteq \mathbb{P}_{\mathcal{X} \sim q}[\mathcal{S}(X') > t] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim q}[\mathcal{S}(X') = t] \\ \text{TNR}(t; D, s) &\doteq 1 - \text{FPR}(t; D, s) = \mathbb{P}_{\mathcal{X} \sim q}[\mathcal{S}(X') < t] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim q}[\mathcal{S}(X') = t] \\ \text{FNR}(t; D, s) &\doteq 1 - \text{TPR}(t; D, s) = \mathbb{P}_{\mathcal{X} \sim p}[\mathcal{S}(X) < t] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim p}[\mathcal{S}(X) = t]. \end{aligned}$$

When the scorer s and distribution D are clear from context, we use e.g. $\text{TPR}(t)$ to denote $\text{TPR}(t; D, s)$.

In order to describe the properties of the true and false positive rates, it will be convenient to express them in terms of the distribution of the scorer. Denoting by P_S, Q_S the conditional distribution of scores on the positive and negative class when applied to instances drawn from D , we may write the true and false positive rates as:

$$\begin{aligned} \text{TPR}(t; D, s) &= \mathbb{P}_{S \sim P_S}[\mathcal{S} > t] + \frac{1}{2} \cdot \mathbb{P}_{S \sim P_S}[\mathcal{S} = t] \\ \text{FPR}(t; D, s) &= \mathbb{P}_{S' \sim Q_S}[\mathcal{S}' > t] + \frac{1}{2} \cdot \mathbb{P}_{S' \sim Q_S}[\mathcal{S}' = t]. \end{aligned}$$

The second term in each expression encodes that ties are broken uniformly at random between the positive and negative classes. Observe that the second term is zero unless there are isolated scores; i.e., the distribution of scores has a discrete random variable component. It is evident that both rates are non-increasing functions of t , and thus possess pseudo-inverses (Equation 1).

We are now in a position to describe the ROC curve and its basic properties.

5.2 The ROC Curve and Its Properties

As discussed above, given a scorer $s: \mathcal{X} \rightarrow \mathbb{R}$, one may threshold it to produce a classifier. However, it is not *a priori* clear how to choose a suitable threshold. The ROC curve (Egan, 1975; Fawcett, 2006) is a graphical representation of a scorer that spells out the implications of every threshold choice. It is formed by tracing out the relationship between the true and false positive rates of a scorer across all possible thresholds.

Definition 5 (ROC curve) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, and a scorer $s: \mathcal{X} \rightarrow \mathbb{R}$, the ROC curve is defined by the parametric representation⁹

$$\text{ROC}(s; D) = \{(\text{FPR}(t; D, s), \text{TPR}(t; D, s)) : t \in \mathbb{R} \cup \{\pm\infty\}\} \subseteq [0, 1]^2.$$

Equivalently, let $\rho(\alpha; D, s)$ be the power of s at a false-positive rate of α , defined as

$$(\forall \alpha \in [0, 1]) \rho(\alpha; D, s) \doteq \text{TPR}(\text{FPR}^{-1}(\alpha)), \quad (21)$$

where we use the pseudo-inverse (Equation 1) of the false-positive rate. Then,

$$\text{ROC}(s; D) = \{(\alpha, \rho(\alpha; D, s)) : \alpha \in \text{Im}(\text{FPR})\} \subseteq [0, 1]^2.$$

Put plainly, for all possible thresholds $t \in \mathbb{R}$, we create a classifier from s using the threshold, and assess the resulting accuracy on the positive and negative classes respectively. Every point on the ROC curve represents a pair of *realisable* true and false positive rates, i.e., rates that may be attained by a classifier based on an 9. At a threshold $t = +\infty$, both the FPR and TPR are 0, while at $t = -\infty$, the FPR and TPR are both 1. Thus, varying t in this way traces a curve from left to right.

appropriate thresholding of the scorer. Thus, the ROC curve visually summarises the set of realisable error rates for various choices of classifier derived from the underlying scorer s .

In general, two points on the ROC curve represent different tradeoffs in terms of the true and false positive rates. Thus, there is no clear automated mechanism to pick the “best” threshold for generating a classifier without additional information as to one’s underlying utility.

5.2.1 BASIC PROPERTIES OF THE ROC CURVE

We make some basic observations about the ROC curve for any scorer $s: \mathcal{X} \rightarrow \mathbb{R}$ and distribution D .

- (i) we have $\{(0, 0), (1, 1)\} \subseteq \text{ROC}(s; D)$. This is because $\lim_{t \rightarrow -\infty} \text{TPR}(t) = 0$, $\lim_{t \rightarrow -\infty} \text{TPR}(t) = 1$, and similarly for the FPR.
- (ii) the curve does not have self-intersections. This is because FPR and TPR are monotone functions.
- (iii) the curve is invariant to strictly monotone increasing transformations of the scorer s . This is because the FPR and TPR are invariant to strictly monotone increasing transformations¹⁰ (see also Proposition 15).
- (iv) the curve is not necessarily surjective onto $[0, 1]^2$, and may comprise only a finite number of points in $[0, 1]^2$. This is a consequence of the fact that FPR and TPR are not necessarily *strictly* monotone.
- (v) even if the curve is surjective, the set of points below the curve is not necessarily a convex set i.e. $\rho(\cdot)$ is not necessarily a concave function.¹⁰

Figure 1 gives examples of various properties an ROC curve may possess, and in particular illustrates points (iv) and (v). We now discuss these last two points further.

5.2.2 INTERPOLATION OF THE ROC CURVE

In practice, one typically only has access to an empirical distribution \hat{D} with finite support. The resulting empirical ROC curve will thus comprise a number of isolated points. In such situations, it is common to linearly interpolate between these points. To justify this interpolation, recall that each point on the ROC curve summarises the performance of a classifier derived from a specific threshold. Every interpolated point is similarly achievable by some *randomised* classifier derived from s (Scott et al., 1998, Theorem 1, Provost and Fawcett, 2001, Theorem 7). To see why this is so, suppose $\text{ROC}(s; D) = \{(f_i, t_i)\}_{i=1}^n$, where $f_i \leq f_{i+1}$, $t_i \leq t_{i+1}$. For any $t \in [t_n - 1]$, pick any $\alpha \in [0, 1]$, and consider the interpolated point (f^t, t^t) defined by

$$(f^t, t^t) = \alpha \cdot (f_i, t_i) + (1 - \alpha) \cdot (f_{i+1}, t_{i+1}).$$

This corresponds exactly to the false positive and true positive rates of a randomised classifier derived from s using a threshold t^t , where ties are broken in favour of positives with probability α . Therefore, linear interpolation of the ROC curve summarises the performance of *all* possible classifiers with *randomised* tie-breaking that can be derived from the underlying scorer.

5.2.3 THE CONVEXIFIED ROC CURVE

To further build upon linear interpolation, one may construct a *convexified ROC curve* from the convex hull of $\text{ROC}(s; D)$ ¹¹ (Provost and Fawcett, 2001), which we denote by $\text{ROC}_{\text{cvx}}(s; D)$. As with the linearly interpolated ROC curve, every point on this curve is achievable with a suitable randomised classifier derived from the scorer (Provost and Fawcett, 2001, Theorem 7). It is not hard to justify the use of classifiers derived from $\text{ROC}_{\text{cvx}}(s; D)$, rather than those of $\text{ROC}(s; D)$: for every false positive rate, the classifiers derived from the

¹⁰ Recall a function is convex iff its epigraph is a convex set, and is concave iff its negation is convex.

¹¹ Strictly, $\text{cvx}(\cdot)$ denotes the convex hull of a set, one considers $\text{ROC}_{\text{cvx}}(s; D) = ((0, 0), (1, 1)) \cup \text{conv}(\text{ROC}(s; D))$ ($\alpha, \rho \mid \rho > \alpha$), so that only the portion of the convex hull strictly above the diagonal line is retained. When the original curve is entirely below the diagonal line, one just uses the diagonal line itself.

former possess a true positive rate at least as good as that of a classifier derived from the latter. That is, the curve $\text{ROC}_{\text{cvx}}(s; D)$ dominates $\text{ROC}(s; D)$.

When $\text{ROC}(s; D)$ comprises a number of isolated points, $\text{ROC}_{\text{cvx}}(s; D)$ is trivially the linear interpolation of the ROC curve for a scorer whose realisable true and false positive rates are the hull points. Such a scorer may be derived from s by introducing suitable ties. This process can be shown to be equivalent to performing an isotonic regression (Ayer et al., 1955) on the original scorer s (Fawcett and Niculescu-Mizil, 2007).

5.2.4 EXTREMAL ROC CURVES

Given a distribution D , different scorers will induce different ROC curves. It is natural to ask whether there is a “best” possible curve for a given D , that is, a curve that dominates every other one. It turns out that there is such a curve, corresponding to any scorer which is a strictly monotone increasing transformation of the class-probability function η . This fact is a consequence of the classical Neyman-Pearson lemma, which plays an important role in hypothesis testing. Appendix D provides some background on this lemma.

Lemma 6 Given any distribution $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$(\forall \alpha \in [0, 1]) \rho(\alpha; D, s) \leq \rho(\alpha; D, \phi \circ \eta)$$

where ϕ is any strictly monotone increasing function.

Proof By the Neyman-Pearson lemma, the uniformly most powerful test (i.e. the test with maximal $\rho(\cdot)$ value) at any α is given by the likelihood ratio. For the distribution D , this is nothing but a strictly monotone transformation of η . As the ROC curve is invariant to such transformations, the result follows. ■

We may equally consider the “worst” possible curve for a given D , that is, a curve that is dominated by every other one. Since the curve for a scorer s has as mirror image the curve for the scorer $-s$, evidently, such a curve will correspond to any strictly monotone decreasing function of η , such as e.g. $s = -\eta$.

Finally, it is easy to check that a non-informative scorer s that uniformly predicts a constant (e.g. $s \equiv 0$) will induce a ROC curve that is the diagonal, viz. $\rho(\alpha) = \alpha$. Thus, intuitively, a scorer must induce a ROC curve significantly away from the diagonal in order to be useful.

5.2.5 DIFFERENTIABILITY AND CONCAVITY OF THE ROC CURVE

We now consider properties of the derivative of the ROC curve, when it exists. When the curve comprises a number of isolated points, then the derivatives of the interpolated version of the curve can be easily computed. More generally, from the definition of the power function (Equation 21), it is apparent that the differentiability of the ROC curve relies on that of the true- and false-positive rates. The following makes this precise.

Proposition 7 (Cléménçon and Vayatis, 2009, Proposition 24) Given a distribution $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ with M absolutely continuous and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with corresponding induced class-conditional distributions P_S, Q_S , the curve $\text{ROC}(s; D)$ is differentiable if and only if P_S, Q_S are absolutely continuous.

While in practice one’s operating P_S, Q_S may be discrete, it is common to construct continuous approximations to them e.g. the binormal ROC model (Krzyszowski and Hand, 2009, Section 2.5). Observe that when the false and true positive rates are differentiable, we have

$$\begin{aligned} (\forall t \in \mathbb{R}) \text{TPR}'(t) &= -p_S(t) \\ \text{FPR}'(t) &= -q_S(t), \end{aligned} \tag{22}$$

where p_S, q_S are the densities of the class-conditional score distributions. When the ROC curve is differentiable, the derivative turns out to have a well-known form involving the score-to-probability transform of the scorer, as stated below. (Appendix C gives a proof for completeness.)

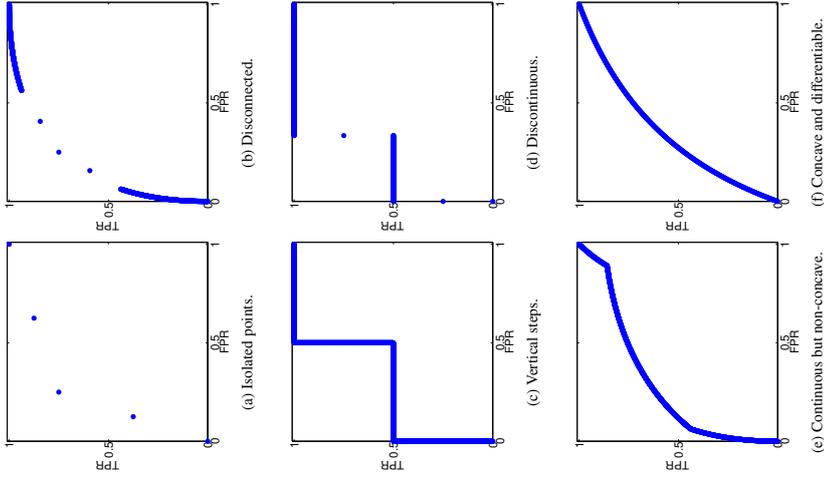

Figure 1: Illustration of various properties an ROC curve may possess. In each example, we use $\mathcal{X} = [0, 1]$, and in most cases fix $\eta(x) = x$. For (a), we use the scorer $s = \text{sign}(2 \cdot \eta - 1)$, so that the score distributions P_S, Q_S are discrete. For (b), we use the scorer $s(x) = \eta(x) \vee 0.75$ when $\eta(x) < 0.5$ and $s(x) = \eta(x) \wedge 0.25$ else, so that the score distributions have isolated areas. For (c), we round η to $\{0, 1\}$ and use the scorer s predicting uniformly 0.5 or 1 when $\eta(x) > 0.5$ and $\frac{3}{8} \cdot \eta(x)$ else, so that the positive score distribution has isolated elements. For (d), we round η to $\{0, 1\}$ and use the scorer s predicting uniformly in $[0.25, 0.5] \cup [0.9, 1]$ when $\eta(x) > 0.5$ and $[0, 0.25] \cup [0.5, 0.75]$ else, so that the score distributions have interleaved support. For (e), we use the scorer $s(x) = \eta(x) - 0.5$ when $\eta(x) < 0.5$ and $s(x) = 4 \cdot \eta(x) - 3$ else, so that the score distributions are overlapping. For (f), we use the scorer $s = \eta$, so that the result is the maximal ROC curve.

Proposition 8 (Krzyszowski and Hand, 2009, pg. 22; Clemençon and Vayatis, 2009b, Lemma 1) Given a distribution $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ such that $\text{ROC}(s; D)$ is differentiable, the slope of the ROC curve at a false positive rate $\alpha \in (0, 1)$ is

$$\begin{aligned} \rho'(\alpha) &= \frac{P_S(\text{FPR}^{-1}(\alpha))}{q_S(\text{FPR}^{-1}(\alpha))} \\ &= \frac{1 - \pi}{\pi} \cdot \frac{\text{Prb}(\text{FPR}^{-1}(\alpha))}{1 - \text{Prb}(\text{FPR}^{-1}(\alpha))}. \end{aligned} \quad (23)$$

Proposition 8 establishes that the score-to-probability transform $\text{Prb}(\cdot; D, s)$, and thus the calibration transform $\text{Cal}(\cdot; D, s)$, may be computed based on the derivatives of the ROC curve. The fact that the ROC curve may be used to obtain a class-probability estimator is well-known (Fawcett and Niculescu-Mizil, 2007; Flach, 2010). Indeed, the relationship implies a characterisation of the monotonicity of the calibration transform when the ROC curve is differentiable.

Corollary 9 Given a distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible rates, $\text{ROC}(s; D)$ is (strictly) concave if and only if the function $\text{Prb}(\cdot; D, s)$ is (strictly) increasing.

Proof By Proposition 8, the derivative of the curve at any point comprises a strictly monotone transform of Prb composed with the invertible and hence strictly monotone function FPR^{-1} . As (strict) concavity of the curve is equivalent to (strict) monotonicity of its derivative, the result follows. ■

Non-concave regions of the ROC curve thus correspond to regions where the function $\text{Prb}(\cdot; D, s)$ is non-invertible. As we have seen, one may compute the convex hull of the ROC curve to remove such regions, which corresponds to introducing ties in the scorer. We note that the assumption of invertibility of rates in Corollary 9 does not by itself imply invertibility of $\text{Prb}(\cdot; D, s)$, as the former relates to the cumulative distributions of the scores, while latter relates to the densities of the scores. For example, when $P_S = Q_S$ and thus $P_S = q_S$, we might have invertibility of the rates, but we will not have invertibility of $\text{Prb}(\cdot; D, s)$.

When the scorer s is calibrated (Equation 5), Equation 23 implies that the slope of $\text{ROC}(s; D)$ at a false positive rate $\alpha \in (0, 1)$ simplifies to

$$\rho'(\alpha) = \frac{1 - \pi}{\pi} \cdot \frac{\text{FPR}^{-1}(\alpha)}{1 - \text{FPR}^{-1}(\alpha)}. \quad (24)$$

Further, Proposition 8 implies the following useful fact.

Corollary 10 Given a distribution $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and calibrated scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible rates, $\text{ROC}(s; D)$ is strictly concave.

Proof As s is calibrated, by definition $\text{Prb}(\cdot; D, s)$ is the identity mapping, and thus strictly monotone. By Corollary 9 the result follows. ■

This implies that for the calibrated scorer $s = \eta$, the ROC curve is concave (provided that the curve is additionally differentiable), as noted before in e.g. (Clemençon and Vayatis, 2009, Proposition 8). We note that Corollary 10 relies crucially on the ROC curve being differentiable: the trivially calibrated scorer $s \equiv \pi$ would have an ROC curve comprising isolated points, whose interpolation would not be strictly concave.

5.2.6 THE ROC CURVE AND COST-SENSITIVE THRESHOLD SELECTION

The true positive and negative rates measure the accuracy of a classifier on the positive and negative classes respectively. Observe that the standard 0-1 classification risk (Equation 15) can be expressed in terms of the

false positive and negative rates using a threshold of 0. More generally, given a cost ratio $c \in [0, 1]$, the cost-sensitive risk of a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ when using a threshold t may be written

$$\mathbb{L}(s; D, \ell_{\text{CS}(c,t)}) = \pi \cdot (1 - c) \cdot \text{FNR}(t; D, s) + (1 - \pi) \cdot c \cdot \text{FPR}(t; D, s), \quad (25)$$

where $\ell_{\text{CS}(c,t)}$ denotes the cost-sensitive loss with cost ratio c and threshold choice t :

$$\begin{aligned} \ell_{\text{CS}(c,t)}(+1, z) &= (1 - c) \cdot \ell_0(+1, z - t) \\ \ell_{\text{CS}(c,t)}(-1, z) &= c \cdot \ell_0(-1, z - t). \end{aligned} \quad (26)$$

Clearly, $\ell_{\text{CS}(c,t)} = \ell_{\text{CS}(c,0)}$, and for $t = 0$ and $c = \frac{1}{2}$ we recover the (scaled) 0-1 loss. The optimal threshold function $t^* : [0, 1] \rightarrow 2^{\mathcal{X}}$ maps costs to the set of thresholds yielding minimal cost-sensitive risk:

$$(\forall c \in [0, 1]) t^*(c; D, s) = \underset{t \in \mathbb{R}}{\text{Argmin}} \mathbb{L}(s; D, \ell_{\text{CS}(c,t)}).$$

Determining the optimal threshold function for a scorer is intimately related to the gradient of the ROC curve. (Appendix C provides a proof for completeness.)

Proposition 11 (Krzyszowski and Hand, 2009, pg. 24) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve, for any cost ratio $c \in (0, 1)$, any optimal threshold $t_0 \in t^*(c; D, s)$ for the cost-sensitive risk $\mathbb{L}(s; D, \ell_{\text{CS}(c,t)})$ satisfies

$$\rho'(\text{FPR}(t_0)) = \frac{c}{1 - c} \cdot \frac{1 - \pi}{\pi},$$

or equivalently, $\text{Prb}(t_0) = c$.

Further, when the score-to-probability mapping $\text{Prb}(\cdot; D, s)$ is invertible,

$$t^*(c) = \{\text{Prb}^{-1}(c)\}.$$

Intuitively, there are multiple optimal thresholds for a given cost c when $\text{Prb}(\cdot; D, s)$ is not invertible, which by Corollary 9 occurs when the ROC curve is not strictly concave. The derivative may also have an image that is a strict subset of \mathbb{R}_+ . In this case, the risk in Equation 25 is monotone as a function of t , and so the optimal threshold is one of $\pm\infty$.

The relationship between the slope of the ROC and the optimal threshold is useful in two ways. First, given a particular c , to find the optimal threshold, we draw a line of slope $\frac{c}{1-c} \cdot \frac{1-\pi}{\pi}$. The point at which it touches the ROC curve corresponds to the optimal threshold. Second, at a given false positive rate α achieved by some threshold, the derivative of the ROC curve gives us the cost for which the given threshold is optimal.

For the case of calibrated scorers, we have a simpler characterisation of the optimal threshold for a cost-sensitive loss: it is simply the corresponding cost itself.

Corollary 12 Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and calibrated scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve, for any cost $c \in (0, 1)$, the optimal threshold function for the cost-sensitive risk is $t^*(c) = \{c\}$.

Proof As s is calibrated, $\text{Prb}(\cdot; D, s)$ is the identity mapping, and thus invertible. Thus, applying Proposition 11, we know there is a unique optimal threshold $t_0(c)$ for each cost ratio c . Applying Equation 24, the optimal threshold satisfies

$$\frac{t_0(c)}{1 - t_0(c)} = \frac{c}{1 - c},$$

i.e. the optimal threshold is $t_0(c) = c$. ■

Corollary 12 is again evident for the trivially calibrated scorer $s = \eta$.

5.2.7 ROC DOMINATION AND CLASSIFICATION RISK

Suppose one scorer dominates another in ROC space. What can one say about the risks of the two scorers with respect to a proper loss? The following establishes that, for calibrated scorers, dominance in ROC space implies dominance with respect to any proper composite risk. This supports the use of the ROC curve as a means of assessing the performance of a scorer. While simple to prove, the result is to our knowledge novel.

Proposition 13 *Pick any distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, and let $s_1, s_2 : \mathcal{X} \rightarrow \mathbb{R}$ be any scorers that are calibrated with respect to D , with differentiable ROC curves. If the ROC curve of s_2 dominates that of s_1 ,*

$$(\forall \alpha \in [0, 1]) \rho(\alpha; D, s_1) \leq \rho(\alpha; D, s_2).$$

then any proper loss λ, s_2 must have risk no larger than s_1 :

$$\mathbb{L}(s_2; D, \lambda) \leq \mathbb{L}(s_1; D, \lambda).$$

Proof Our basic idea will be to show that s_2 has a lower cost-sensitive risk than s_1 for any conceivable cost-ratio, which by Shuford's representation (Equation 10) will yield the desired result. For brevity, in the following we use e.g. $\text{TPR}_c(c)$ as a shorthand for $\text{TPR}(c; D, s)$.

Pick any $c \in (0, 1)$. Consider the cost-sensitive risk of a scorer s using a threshold t (Equation 25). Since s_1, s_2 are calibrated, by Corollary 12, they both have optimal threshold $t^*(c; D, s) = \{c\}$. With this threshold, scorer s_1 achieves a false-positive rate of $\alpha_1 = \text{FPR}_{s_1}(c)$, and true-positive rate $\text{TPR}_{s_1}(c)$. By the ROC domination assumption, we have

$$\text{TPR}_{s_1}(c) = \rho(\alpha_1; D, s_1) \leq \rho(\alpha_1; D, s_2) = \text{TPR}_{s_2}((\text{FPR}_{s_2})^{-1}(\alpha_1)).$$

Thus, the corresponding false negative rate of s_2 must be smaller than that of s_1 , i.e.

$$\text{FNR}_{s_2}((\text{FPR}_{s_2})^{-1}(\alpha_1)) \leq \text{FNR}_{s_1}(c).$$

This implies that using a threshold of $t_2 = (\text{FPR}_{s_2})^{-1}(\alpha_1)$, s_2 achieves a lower cost-sensitive risk than s_1 :

$$\begin{aligned} \mathbb{L}(s_2; \ell_{\text{CS}(c, t_2)}) &= \pi \cdot (1 - c) \cdot \text{FNR}_{s_2}(t_2) + (1 - \pi) \cdot c \cdot \text{FPR}_{s_2}(t_2) \\ &\leq \pi \cdot (1 - c) \cdot \text{FNR}_{s_1}(c) + (1 - \pi) \cdot c \cdot \alpha_1 \\ &= \pi \cdot (1 - c) \cdot \text{FNR}_{s_1}(c) + (1 - \pi) \cdot c \cdot \text{FPR}_{s_1}((\text{FPR}_{s_1})^{-1}(\alpha_1)) \\ &= \mathbb{L}(s_1; c, \ell_{\text{CS}(c)}). \end{aligned}$$

But since c is the optimal threshold for s_2 , we further have

$$\begin{aligned} \mathbb{L}(s_2; \ell_{\text{CS}(c)}) &= \mathbb{L}(s_2; \ell_{\text{CS}(c, c)}) \\ &\leq \mathbb{L}(s_2; \ell_{\text{CS}(c, t_2)}) \\ &\leq \mathbb{L}(s_1; \ell_{\text{CS}(c, c)}) \\ &= \mathbb{L}(s_1; \ell_{\text{CS}(c)}). \end{aligned}$$

Since s_2 has a lower cost-sensitive risk than s_1 for any cost ratio c , by Shuford's representation (Equation 10), it must also have lower risk with respect to any proper loss. ■

An immediate consequence of the above is that for scorers with strictly monotone calibration transforms $\text{Cal}(c; D, s)$ (in turn relying on strict concavity of the ROC curve, by Corollary 10), ROC dominance implies dominance with respect to any proper loss. Note also that for the optimal ROC curve, given by $s^* = \eta$, the above is trivially true as any proper loss will have its risk minimised by exactly η .

Proposition 13 relies on ROC dominance. When the ROC curves for two scorers cross, it is not hard to construct examples of losses where one scorer is superior to the other. This indicates that in such situations, caution must be used before declaring one scorer to be superior to another, as is well known (Hand, 2009).

5.3 The Area Under the ROC Curve (AUC)

The ROC curve is a graphical display of the performance of a scorer. It is often desirable to additionally have a single numeric summary of performance. One such popular summary statistic is the *area under the ROC curve*, or *AUC*.

Definition 14 (Area under the ROC curve (AUC)) *Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, the area under the ROC curve or AUC of s is the area under the curve $\text{ROC}(s; D)$,*

$$\text{AUC}(s; D) \doteq \int_0^1 \rho(\alpha; D, s) d\alpha, \quad (27)$$

where $\rho(\alpha; D, s)$ is the power of s at α (Equation 21).

A subtlety in the above definition is that we only defined $\text{ROC}(s; D)$ in terms of the power when $\alpha \in \text{Im}(\text{FPR})$. However, the power itself is defined for every $\alpha \in [0, 1]$, due to the use of the pseudo-inverse. Thus, the integral is well-defined even when $\text{ROC}(s; D)$ comprises isolated points.

A further subtlety is that the curve traced out by $(\alpha, \text{TPR}(\text{FPR}^{-1}(\alpha))) : \alpha \in [0, 1]$ is *not* always equivalent to that generated by linear interpolation of $\text{ROC}(s; D)$. Nonetheless, the area under the two curves will in general be the same. To see this, suppose P_S, Q_S have an isolated component at some $t \in \mathbb{R}$, with $\text{FPR}(t^-) = \alpha_1, \text{FPR}(t^+) = \alpha_2$ and $\text{TPR}(t^-) = \beta_1, \text{TPR}(t^+) = \beta_2$, and further $\text{TPR}(t) = \frac{1}{2}(\beta_1 + \beta_2)$ due to the breaking of ties uniformly at random. We will then have two consecutive disconnected points in $\text{ROC}(s; D)$, (α_1, β_1) and (α_2, β_2) . With linear interpolation, this region of the ROC curve has area $\frac{1}{2} \cdot (\alpha_2 - \alpha_1) \cdot (\beta_1 + \beta_2)$.

For any $\alpha \in (\alpha_1, \alpha_2)$, we have $(\text{FPR})^{-1}(\alpha) = t$, and so $\text{TPR}((\text{FPR})^{-1}(\alpha)) = \text{TPR}(t) = \frac{1}{2}(\beta_1 + \beta_2)$. Thus with the pseudo-inverse, the corresponding area of this region is that of the corresponding rectangle with height $\frac{1}{2}(\beta_1 + \beta_2)$ and width $(\alpha_2 - \alpha_1)$, which is also exactly $\frac{1}{2} \cdot (\alpha_2 - \alpha_1) \cdot (\beta_1 + \beta_2)$.

5.3.1 BASIC PROPERTIES OF THE AUC

Some basic properties of the AUC are immediate from the above definition. First, the AUC is in $[0, 1]$; as we shall subsequently discuss, higher AUC values indicate a ‘‘better’’ scorer.

Second, the AUC is independent of the base rate π , and only depends on the class-conditional distributions P, Q for a distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$. This means that a scorer s will have the same AUC with respect to all distributions in the family $\{D = \langle P, Q, \pi \rangle\}_{\pi \in [0, 1]}$.

Third, the AUC is invariant to strictly monotone increasing transforms of the scorer, as shown below.

Proposition 15 (Cl em en on and Vayatis, 2009, Proposition 24) *Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, for any strictly monotone increasing $\phi : \mathbb{R} \rightarrow \mathbb{R}$,*

$$\text{AUC}(s; D) = \text{AUC}(\phi \circ s; D).$$

Proof This is because the 0-1 loss is invariant to monotone increasing transformations of the scorer:

$$\begin{aligned} (\forall t \in \mathbb{R}) \text{FPR}(t; D, \phi \circ s) &= \mathbb{E}_{\mathcal{X} \sim Q} [\ell_{01}(-1, \phi(s(X)) - t)] \\ &= \mathbb{E}_{\mathcal{X} \sim Q} [\ell_{01}(-1, s(X) - t)] \\ &= \text{FPR}(t; D, s), \end{aligned}$$

and similarly for TPR. It follows that the power function ρ is unaffected by ϕ , and thus so is the ROC curve and the area under it. ■

Fourth, the AUC is optimised by any strictly monotone transformation of the underlying η .

Corollary 16 Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and any strictly monotone increasing $\phi : [0, 1] \rightarrow \mathbb{R}$,

$$\sup_{s : \mathcal{X} \rightarrow \mathbb{R}} \text{AUC}(s; D) = \text{AUC}(\phi \circ \eta; D).$$

Proof By Lemma 6, the optimal ROC curve is achieved by any $\phi \circ \eta$. Such a scorer must thus have maximal AUC. ■

We now show how the AUC can be viewed in terms of loss functions, which makes apparent its connection to the bipartite ranking risk.

5.3.2 A LOSS REPRESENTATION OF THE AUC

Although not immediately obvious from the above definition, the AUC of a scorer with respect to a distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ is the probability a randomly drawn positive has a higher score than a randomly drawn negative, with ties broken uniformly at random. This observation goes back to at least Hanley and McNeil (1982, Section III), and has been noted in machine learning community in e.g. Cortes and Mohri (2003, Lemma 1), Clévençon et al. (2008).¹²

Proposition 17 (Cortes and Mohri, 2003, Lemma 1) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{AUC}(s; D) = \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) > s(\mathcal{X}')] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) = s(\mathcal{X}')]. \quad (28)$$

Equation 28 is often taken as the starting definition of the AUC, due to its convenience to manipulate. Indeed, on a sample $\hat{D} = \{(\mathcal{x}_i, +1)\}_{i=1}^n \cup \{(\mathcal{x}_j, -1)\}_{j=1}^m$, the empirical AUC is

$$\text{AUC}(s; \hat{D}) = \frac{1}{n \cdot m} \cdot \sum_{i=1}^n \sum_{j=1}^m \mathbb{1}[s(\mathcal{x}_i) > s(\mathcal{x}_j)] + \frac{1}{2} \cdot \mathbb{1}[s(\mathcal{x}_i) = s(\mathcal{x}_j)],$$

which is equivalent to the Mann-Whitney statistic (Mann and Whitney, 1947). The resulting empirical estimate can be computed in $O(N \log N)$ time for $N = n + m$ with a single sort operation, rather than attempting numerical integration of the empirical ROC curve (Hand and Till, 2001).

Observe that Proposition 17 may be expressed in terms of a risk involving 0-1 loss as follows.

Corollary 18 Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\begin{aligned} \text{AUC}(s; D) &= 1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\mathbb{1}[s(\mathcal{X}) - s(\mathcal{X}') < 0] + \frac{1}{2} \mathbb{1}[s(\mathcal{X}) = s(\mathcal{X}')] \right] \\ &= 1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\ell_{01}(1, s(\mathcal{X}) - s(\mathcal{X}')) \right]. \end{aligned} \quad (29)$$

Building on this representation, we now describe a generalisation of the AUC, which will be a useful basis for further analysis.

5.4 Generalisation: the ℓ -AUC

We define the following generalisation of the AUC, which uses any loss function $\ell : \{\pm 1\} \times \mathbb{R} \rightarrow \mathbb{R}_+$.

Definition 19 (ℓ -AUC) Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and a loss $\ell : \{\pm 1\} \times \mathbb{R} \rightarrow \mathbb{R}_+$, define the ℓ -AUC of a scorer s with respect to $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ as

$$\text{AUC}(s; D, \ell) = 1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\ell_{\text{sym}}(s(\mathcal{X}) - s(\mathcal{X}')) \right],$$

¹² Compared to the cited works, we have introduced an extra term that accounts for ties.

ℓ	$\text{AUC}(s; D, \ell)$
ℓ_{01}	$1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\mathbb{1}[s(\mathcal{X}) < s(\mathcal{X}')] + \frac{1}{2} \cdot \mathbb{1}[s(\mathcal{X}) = s(\mathcal{X}')] \right]$
ℓ_{sq}	$1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[(1 - s(\mathcal{X}) + s(\mathcal{X}'))^2 \right]$
ℓ_{\log}	$1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\log \left(1 + e^{s(\mathcal{X}') - s(\mathcal{X})} \right) \right]$
ℓ_{exp}	$1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[e^{s(\mathcal{X}') - s(\mathcal{X})} \right]$

Table 6: Examples of ℓ -AUC for various losses, given some $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$.

recalling that ℓ_{sym} is the symmetrised version of ℓ (Equation 8). When ℓ is symmetric, this simplifies to

$$\text{AUC}(s; D, \ell) = 1 - \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\ell(s(\mathcal{X}) - s(\mathcal{X}')) \right].$$

Table 6 provides some examples of the ℓ -AUC. Clearly, $\text{AUC}(s; D, \ell_{01})$ is the standard AUC as defined earlier (see e.g. Equation 28). When we do not explicitly refer to the loss, it is understood that we are referring to the standard AUC.

When using the cost-sensitive loss $\ell_{\text{CS}(c)}$ of Equation 26 with a threshold of $\tau = 0$ and any $c \in (0, 1)$, we also recover the standard AUC. This is because the symmetrised version of such a loss is

$$\begin{aligned} \ell_{\text{CS}(c;0)}(1, v) + \ell_{\text{CS}(c;0)}(-1, -v) &= (1 - c) \cdot \mathbb{1}[v < 0] + c \cdot \mathbb{1}[-v > 0] + \frac{1}{2} \cdot \mathbb{1}[v = 0] \\ &= (1 - c) \cdot \mathbb{1}[v < 0] + c \cdot \mathbb{1}[v < 0] + \frac{1}{2} \cdot \mathbb{1}[v = 0] \\ &= \mathbb{1}[v < 0] + \frac{1}{2} \cdot \mathbb{1}[v = 0] \\ &= \ell_{01}(1, v) \end{aligned}$$

This is intuitively because of the symmetry inherent in the bipartite ranking problem: scoring a positive below a negative is equivalent to scoring a negative above a positive. Therefore, one cannot expect to have different costs associated with the two errors.

We have assumed the prediction space for the loss ℓ above to be \mathbb{R} because we require the prediction space to be closed under negation, and for an arbitrary scorer that requires we can compute the loss for any real valued prediction. This rules out using a proper loss (or indeed any probability estimation loss), which is only defined on the prediction space $[0, 1]$. However, we may use a proper composite loss, which operates on a real-valued prediction space but converts this to $[0, 1]$ via a link function.

5.4.1 THE ℓ -AUC AS AN AREA

One property of the AUC that is inherited is that the ℓ -AUC may be interpreted as the area under a curve parameterised by the false positive rate, and a smoothed version of the true positive and false positive rates, defined below.

Definition 20 Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, loss ℓ , and a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, define the ℓ -true (false) positive (negative) rates at a threshold $t \in \mathbb{R}$ to be

$$\begin{aligned} \text{FNR}(t; D, s, \ell) &= \mathbb{E}_{\mathcal{X} \sim P} [\ell_1(s(\mathcal{X}) - t)] \\ \text{FPR}(t; D, s, \ell) &= \mathbb{E}_{\mathcal{X} \sim Q} [\ell_{-1}(s(\mathcal{X}) - t)] \\ \text{TPR}(t; D, s, \ell) &= 1 - \text{FNR}(t; D, s, \ell) \end{aligned}$$

$$\text{TNr}(t; D, s, \ell) = 1 - \text{FPr}(t; D, s, \ell).$$

When the scorer s and distribution D are clear from context, we shall use e.g. $\text{TPR}_\ell(t)$ to denote $\text{TPR}(t; D, s, \ell)$. We then have the following analogue to Equation 27 for a general loss.

Proposition 21 Given any $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$, loss ℓ , and scorer $s : \mathbb{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible false- and true-positive rates¹³,

$$\text{AUC}(s; D, s, \ell) = \int_0^1 \rho(\alpha; D, s, \ell) d\alpha, \quad (30)$$

where $\rho(\alpha; D, s, \ell)$ is the ℓ -power of s at α , defined for $\alpha \in [0, 1]$ as

$$\rho(\alpha; D, s, \ell) = \frac{1}{2} \cdot (\text{TPR}_\ell(\text{FPr}^{-1}(\alpha)) + \text{TNr}_\ell(\text{TPR}^{-1}(\alpha))). \quad (31)$$

When ℓ is symmetric, this simplifies to

$$\text{AUC}(s; D, \ell) = \int_0^1 \text{TPR}_\ell(\text{FPr}^{-1}(\alpha)) d\alpha = \int_0^1 \text{TNr}_\ell(\text{TPR}^{-1}(\alpha)) d\alpha.$$

Proof The proof is a generalisation of e.g. Cortes and Mohri (2003, Lemma 1); Cléménçon et al. (2008, Proposition B.2) to cover an arbitrary loss $\ell : \{\pm 1\} \times \mathbb{R} \rightarrow \mathbb{R}_+$. Recall that for any $t \in \mathbb{R}$,

$$\begin{aligned} \text{TPR}_\ell(t) &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} [\ell_1(s(X) - t)] \\ \text{TNr}_\ell(t) &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} [\ell_{-1}(s(X) - t)]. \end{aligned}$$

Starting from the definition, and by swapping the expectation and integral (which is justified by Tonelli's theorem Folland, 1999, pg. 67, since ℓ_1 is nonnegative and measurable):

$$\begin{aligned} \int_0^1 \text{TPR}_\ell(\text{FPr}^{-1}(\alpha)) d\alpha &= 1 - \int_0^1 \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} [\ell_1(s(X) - \text{FPr}^{-1}(\alpha))] d\alpha \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} \left[\int_0^1 \ell_1(s(X) - \text{FPr}^{-1}(\alpha)) d\alpha \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} \left[- \int_{-\infty}^{\infty} \ell_1(s(X) - t) \cdot \text{FPr}'(t) dt \right] \text{ with } \alpha = \text{FPr}(t) \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} \left[\int_{-\infty}^{\infty} \ell_1(s(X) - t) \cdot q_S(t) dt \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} \left[\int_{-\infty}^{\infty} \ell_1(s(X) - t) \cdot \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} [\delta_{s(X)}(t)] dt \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow P \times \mathbb{X} \rightarrow Q} [\ell_1(s(X) - s(X'))], \end{aligned}$$

where the last line follows from the definition of Dirac delta. Similarly,

$$\begin{aligned} \int_0^1 \text{TNr}_\ell(\text{TPR}^{-1}(\alpha)) d\alpha &= 1 - \int_0^1 \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} [\ell_{-1}(s(X') - \text{TPR}^{-1}(\alpha))] d\alpha \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} \left[\int_0^1 \ell_{-1}(s(X') - \text{TPR}^{-1}(\alpha)) d\alpha \right] \end{aligned}$$

¹³. This restriction ensures that we can employ the integral substitution formula in the proof.

$$\begin{aligned} &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} \left[- \int_{-\infty}^{\infty} \ell_{-1}(s(X') - t) \cdot \text{TPR}'(t) dt \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} \left[\int_{-\infty}^{\infty} \ell_{-1}(s(X') - t) \cdot p_S(t) dt \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q} \left[\int_{-\infty}^{\infty} \ell_{-1}(s(X') - t) \cdot \frac{\mathbb{E}}{\mathbb{X} \rightarrow P} [\delta_{s(X)}(t)] dt \right] \\ &= 1 - \frac{\mathbb{E}}{\mathbb{X} \rightarrow Q \times \mathbb{X} \rightarrow P} [\ell_{-1}(s(X') - s(X))]. \end{aligned}$$

Thus,

$$\text{AUC}(s; D, \ell) = \frac{1}{2} \int_0^1 (\text{TPR}_\ell(\text{FPr}^{-1}(\alpha)) + \text{TNr}_\ell(\text{TPR}^{-1}(\alpha))) d\alpha. \quad \blacksquare$$

For a symmetric loss, we can thus interpret the ℓ -AUC as being the area under a curve that plots the false positive rates of a scorer against the ℓ -true positive rates, or equivalently, the true positive rates against the ℓ -true negative rates. (These two curves are not equivalent in general, but the area under them is.) Clearly, when $\ell = \ell_{0,1}$, the ℓ -power is the standard power (Equation 21), and the above is exactly the standard AUC.

5.4.2 BASIC PROPERTIES OF THE ℓ -AUC

Like the standard AUC, the ℓ -AUC does not depend on the base rate x . However, the ℓ -AUC does not inherit all properties of the standard AUC. First, in general the ℓ -AUC lies in \mathbb{R} , not necessarily $[0, 1]$. Second, the ℓ -AUC is not invariant to strictly monotone increasing transforms of the scoring functions. Indeed, the ℓ -AUC penalises the *magnitude* of differences between predictions. Intuitively, this makes the ℓ -AUC closer to a classification or class-probability estimation risk, as it is not sufficient to simply order instances well. Similar magnitude-sensitive metrics have been explored by Wu and Flach (2005); Ferri et al. (2005); for example, Wu and Flach (2005, Equation 5) proposed the ‘‘scored AUC’’,

$$\text{AUC}_{\text{scor}}(s; D) \doteq \frac{\mathbb{E}}{\mathbb{X} \rightarrow P \times \mathbb{X} \rightarrow Q} [\max(0, s(X) - s(X'))].$$

corresponding to the ℓ -AUC with non-convex loss $\ell_1(v) = (1 - v) \wedge 1$.

5.5 The ℓ -AUC and Bipartite Ranking Risk

As mentioned, the AUC is a canonical measure of performance for bipartite ranking problems. Thus far, we have used the bipartite risk (Equation 16) as our measure of performance. In fact, these measures are equivalent: from the definition of the ℓ -AUC for a scorer s (Definition 19), it is apparent that it is a linear transformation of the bipartite ranking risk for the pair-scorer $\text{Diff}(s)$. Equivalently, by Lemma 2, the ℓ -AUC may be seen as a linear transformation of the pairwise ranking risk over D_{BR} .

Lemma 22 For any $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$, loss ℓ , and scorer $s : \mathbb{X} \rightarrow \mathbb{R}$,

$$\begin{aligned} \text{AUC}(s; D, \ell) &= 1 - \mathbb{L}_{\text{BR}}(s; D, \ell) \\ &= 1 - \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell), \end{aligned} \quad (32) \quad (33)$$

so that the ℓ -AUC can be seen as a linear transform of ℓ -bipartite ranking risk.

We may further relate the Bayes-optimal scorers for AUC and bipartite risk. For a distribution $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$, define the Bayes-optimal ℓ -AUC to be the supremal ℓ -AUC:

$$\text{AUC}^*(D, \ell) = \sup_{s : \mathbb{X} \rightarrow \mathbb{R}} \text{AUC}(s; D, \ell).$$

Representation of $\text{AUC}(s; D)$	Interpretation	Reference
$\int_0^1 \text{TPR}(\text{FPR}^{-1}(a)) da$	Area under ROC curve	Equation 27
$\int_{\mathbb{X} \sim P \times \mathbb{X}' \sim Q} [s(\mathbb{X}) > s(\mathbb{X}')] + \frac{1}{2} \cdot \mathbb{P}_{\mathbb{X} \sim P \times \mathbb{X}' \sim Q} [s(\mathbb{X}) = s(\mathbb{X}')]$	Probability of random positive scoring higher than random negative	Equation 28
$1 - \mathbb{E}_{\mathbb{X} \sim P \times \mathbb{X}' \sim Q} [\ell_{01}(1, s(\mathbb{X}) - s(\mathbb{X}'))]$	Average 0-1 accuracy on pairs	Equation 29
$1 - \mathbb{L}_{\text{BR}}(\text{Diff}(s); D, \ell_{01})$	One minus bipartite ranking risk	Equation 32
$1 - \frac{1}{2\pi(1-\pi)} \mathbb{E}_{\mathbb{X} \times \mathbb{X}' \sim D} \left[\int_0^1 \mathcal{H}_{\text{Cal}(c; D, s)}(c) dc \right]$	Weighted combination of cost-sensitive losses	Equation 34
$2 \cdot \mathbb{E}_{\mathbb{X} \sim P} [\text{BACC}(c; \mathbb{X}; D, s)] - \frac{1}{2}$	Average balanced accuracy	Equation 39
$\mathbb{E}_{\mathbb{X} \sim P} [\text{TPR}(c; \mathbb{X})]$	Average rank of positive examples	Equation 37
$\mathbb{E}_{\mathbb{X}' \sim Q} [\text{TPR}(c; \mathbb{X}')]$	Average rank of negative examples	Equation 38

Table 7: Various representations for the AUC of a scorer $s: \mathbb{X} \rightarrow \mathbb{R}$ with respect to a distribution $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$. Each gives a different interpretation, and possibly means of estimating the AUC.

This supremal AUC is simply one minus the Bayes-optimal bipartite ranking risk: thus, it is a measure of the inherent difficulty of bipartite ranking with a given distribution D .

Corollary 23 For any $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$ and loss ℓ ,

$$\text{AUC}^*(D, \ell) = 1 - \mathbb{L}_{\text{BR}}^*(D, \ell).$$

Proof Take the supremum of both terms in Equation 32. ■

5.6 Alternate Representations of the AUC

We now outline several equivalent representations of the AUC, summarised in Figure 7. Each gives a different perspective about how it measures the performance of a scorer, as well as potentially different means of estimating it from samples. Many of these representations are specific to ℓ_{01} , but we begin with two related representations that hold for general ℓ .

5.6.1 THE SHUFORD REPRESENTATION

Suppose the loss ℓ is proper composite with link Ψ . Recall Shuford’s integral representation (Equation 10),

$$\ell(y; v) = \int_0^1 u(c) \cdot \lambda_{\text{CS}(c)}(y; \Psi^{-1}(c)) dc.$$

We can apply this to the definition of pairwise ranking risk (Equation 19) to get a representation of the bipartite ranking risk in terms of cost-sensitive bipartite ranking risks, assuming Ψ has some symmetry.

Proposition 24 For any $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$, $\ell \in \mathcal{L}_{\text{SRC}}(\Psi)$ where $\Psi^{-1}(-v) = 1 - \Psi^{-1}(v)$ and scorer $s: \mathbb{X} \rightarrow \mathbb{R}$,

$$\mathbb{L}_{\text{BR}}(s; D, \ell) = \int_0^1 u(c) \cdot \mathbb{L}(\Psi^{-1} \circ \text{Diff}(s); D_{\text{BR}}, \lambda_{\text{symm,CS}(c)}) dc.$$

where $u(\cdot)$ is the weight function corresponding to the proper loss $\lambda = \ell \circ \Psi^{-1}$, and

$$(\forall c \in [0, 1]) (\forall u \in [0, 1]) \lambda_{\text{symm,CS}(c)}(u) = \frac{\lambda_{\text{CS}(c)}(+1, u) + \lambda_{\text{CS}(c)}(-1, 1 - u)}{2}.$$

Proof By the equivalence of bipartite ranking and classification on pairs, the given condition on the link function, and applying Shuford’s representation to the partial losses $\ell_{\pm 1}$,

$$\begin{aligned} \mathbb{L}_{\text{BR}}(s; D, \ell) &= \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell) \\ &= \mathbb{E}_{(\mathbb{X}, \mathbb{X}') \sim (P \times Q)} [\ell_{\text{symm}}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}')] \\ &= \mathbb{E}_{(\mathbb{X}, \mathbb{X}') \sim (P \times Q)} \left[\frac{\ell_1(\text{Diff}(s))(\mathbb{X}, \mathbb{X}') + \ell_{-1}(-\text{Diff}(s))(\mathbb{X}, \mathbb{X}')}{2} \right] \\ &= \mathbb{E}_{(\mathbb{X}, \mathbb{X}') \sim (P \times Q)} \left[\frac{\ell_1(\Psi^{-1}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}')) + \lambda_{-1}(\Psi^{-1}(-\text{Diff}(s))(\mathbb{X}, \mathbb{X}'))}{2} \right] \\ &= \mathbb{E}_{(\mathbb{X}, \mathbb{X}') \sim (P \times Q)} \left[\frac{\lambda_1(\Psi^{-1}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}')) + \lambda_{-1}(1 - \Psi^{-1}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}'))}{2} \right] \\ &= \mathbb{E}_{(\mathbb{X}, \mathbb{X}') \sim (P \times Q)} \left[\frac{\lambda_{\text{CS}(c)}(1, \Psi^{-1}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}')) + \lambda_{\text{CS}(c)}(-1, 1 - \Psi^{-1}(\text{Diff}(s))(\mathbb{X}, \mathbb{X}'))}{2} \right] \\ &= \int_0^1 u(c) \cdot \mathbb{L}(\Psi^{-1} \circ \text{Diff}(s); D_{\text{BR}}, \lambda_{\text{symm,CS}(c)}) dc, \end{aligned}$$

where

$$\lambda_{\text{symm,CS}(c)}(u) = \frac{\lambda_{\text{CS}(c)}(+1, u) + \lambda_{\text{CS}(c)}(-1, 1 - u)}{2}.$$

Without the assumption on Ψ above, one can still obtain an integral representation, but it will not cleanly relate to weighted combination of probability estimation loss risks.

Given the connection between the ℓ -AUC and bipartite ranking risk (Lemma 22), one might hope for a result of the form

$$\text{AUC}(s; D, \ell) = \int_0^1 u(c) \cdot \text{AUC}(s; D, \lambda_{\text{CS}(c)}) dc.$$

However, the AUC can only be equated with the pairwise ranking risk when the latter uses a decomposable scorer (Equation 33). In the above equation, if we require $\Psi^{-1} \circ \text{Diff}(s)$ to be decomposable, then it must be that Ψ^{-1} is the identity function, i.e. the loss ℓ must be proper, and not merely proper composite. But recall that the ℓ -AUC is not defined for a proper loss, because its prediction space is not closed under negation. Thus, an integral representation cannot be found here, either.

Interestingly, if we allow the weights to depend on the scorer s , it is possible to get an expression for the AUC with strong resemblance to Shuford’s result for proper losses, as we now explore.

5.6.2 HAND’S REPRESENTATION

We now generalise a result of Hand (2009, Section 4) to the case of general ℓ -AUC. Informally, the result is a representation of the ℓ -AUC as a weighted combination of cost-sensitive risks, where the weighting is distribution and scorer dependent. More specifically, the result states that the AUC of a scorer s is a weighted combination of cost-sensitive risks, where the weighting factor on costs depends on s , and the threshold for cost c is set to the optimal choice (c.f. Proposition 11) of $\text{Prb}^{-1}(c)$.

Proposition 25 Given any $D \in \Delta_{\mathbb{X} \times \{\pm 1\}}$, loss ℓ , and scorer $s: \mathbb{X} \rightarrow \mathbb{R}$ such that $\text{ROC}(s; D)$ is differentiable and $\text{Prb}: D, s$ is differentiable and invertible,

$$\text{AUC}(s; D, \ell) = 1 - \frac{1}{2\pi(1-\pi)} \int_0^1 Y_s(c) \cdot \mathbb{L}(s; D, \ell_{\text{trans}(c)}) dc$$

where the transformed loss $\ell_{\text{trans}(c)}$ with parameter c is

$$\begin{aligned} (\ell_{\text{trans}(c)})(y, v) &= (\mathbb{T}(\ell, c, \text{Prb}^{-1}(c)))(y, v) \\ (\mathbb{T}(\ell, c, t))(y, v) &= (1 - c) \cdot \mathbb{I}[y = 1] \cdot \ell_1(v - t) + c \cdot \mathbb{I}[y = -1] \cdot \ell_{-1}(v - t), \end{aligned}$$

and the weighting factor is

$$V_S(c) = (\text{Prb}^{-1})'(c) \cdot \mu_S(\text{Prb}^{-1}(c))$$

for marginal distribution over scores μ_S .

Proof By the rate-based representation from Equations 30, 31,

$$1 - \text{AUC}(s; D, \ell) = \frac{1}{2} \int_{-\infty}^{\infty} (\text{TNR}'(t) \cdot \text{FNR}'_\ell(t) + \text{FNR}'(t) \cdot \text{FPR}'_\ell(t)) dt.$$

Recall from §2.4 that we refer to the marginal density of scores by μ_S , and the class-conditional densities by p_S, q_S . Recall from Equation 22 that for any $t \in \mathbb{R}$,

$$\begin{aligned} \text{TNR}'(t) &= q_S(t) \\ &= \frac{1}{1 - \pi} \cdot \mu_S(t) \cdot (1 - \text{Prb}(t)), \end{aligned}$$

and similarly,

$$\text{FNR}'(t) = \frac{1}{\pi} \cdot \mu_S(t) \cdot \text{Prb}(t).$$

Thus, the integrand is

$$\begin{aligned} \ell(t) &= \text{TNR}'(t) \cdot \text{FNR}'_\ell(t) + \text{FNR}'(t) \cdot \text{FPR}'_\ell(t) \\ &= \frac{1}{\pi(1 - \pi)} \cdot \mu_S(t) \cdot (\pi \cdot (1 - \text{Prb}(t)) \cdot \text{FNR}'_\ell(t) + (1 - \pi) \cdot \text{Prb}(t) \cdot \text{FPR}'_\ell(t)) \\ &= \frac{1}{\pi(1 - \pi)} \cdot \mu_S(t) \cdot \mathbb{L}(s; D, \ell_{\text{trans}(\text{Prb}(t))}), \end{aligned}$$

where

$$\begin{aligned} (\ell_{\text{trans}(c)})(y, v) &= (\mathbb{T}(\ell, c, \text{Prb}^{-1}(c)))(y, v) \\ (\mathbb{T}(\ell, c, t))(y, v) &= (1 - c) \cdot \mathbb{I}[y = 1] \cdot \ell_1(v - t) + c \cdot \mathbb{I}[y = -1] \cdot \ell_{-1}(v - t), \end{aligned}$$

transforms the loss ℓ to use a cost weighting c and corresponding optimal threshold $\text{Prb}^{-1}(c)$ (c.f. Proposition 11). Thus, returning the original integral,

$$\begin{aligned} 1 - \text{AUC}(s; D, \ell) &= \frac{1}{2\pi(1 - \pi)} \int_{-\infty}^{\infty} \mu_S(t) \cdot \mathbb{L}(s; D, \ell_{\text{trans}(\text{Prb}(t))}) dt \\ &= \frac{1}{2\pi(1 - \pi)} \int_0^1 V_S(c) \cdot \mathbb{L}(s; D, c) dc, \end{aligned}$$

using the substitution $c = \text{Prb}(t)$, with $V_S(c) = (\text{Prb}^{-1})'(c) \cdot \mu_S(\text{Prb}^{-1}(c))$. ■

The right hand side above features two seemingly opaque objects: a transformed version of the loss and a weighting factor, both of which depend on the score-to-probability transformation $\text{Prb}(c; D, s)$. Fortunately, both of these simplify when we consider ℓ_{01} (corresponding to the standard AUC), and calibrated scorers. First, it is easy to check that for ℓ_{01} , the transformed loss is the cost-sensitive loss with threshold t ,

$$(\mathbb{T}(\ell, c, t))(y, v) = \ell_{\text{CS}(c,t)}(y, v)$$

where $\ell_{\text{CS}(c,t)}$ is as in Equation 26. Further, if we calibrate our scorer, we find

$$\begin{aligned} (\text{Prb} \circ \text{Cal})(t) &= \mathbb{P}[Y = 1 | s(X) = \text{Prb}^{-1}(t)] = t \\ V_{\text{Cal}(c; D, s)}(c) &= \mu_C(c), \end{aligned}$$

where C is the distribution of the calibrated scorer $\text{Cal}(\cdot; D, s)$. When the calibration transform is invertible, we may use this to express the standard AUC as the following, which is also a consequence of Hand (2009, Equation 6).

Corollary 26 Given any $D \in \Delta_{\mathcal{X} \times (\pm 1)}$, loss ℓ , and scorer $s: \mathcal{X} \rightarrow \mathbb{R}$ such that $\text{ROC}(s; D)$ is differentiable and $\text{Cal}(\cdot; D, s)$ is strictly monotone increasing,

$$\text{AUC}(s; D) = 1 - \frac{1}{2\pi(1 - \pi)} \cdot \mathbb{E}_{(X, Y) \sim D} \left[\int_0^1 \mu_C(c) \cdot \mathcal{A}_{\text{CS}(c)}(Y, \text{Cal}(X; D, s)) dc \right]. \quad (34)$$

If in particular s is calibrated with respect to D ,

$$\text{AUC}(s; D) = 1 - \frac{1}{2\pi(1 - \pi)} \cdot \mathbb{E}_{(X, Y) \sim D} \left[\int_0^1 \mu_S(c) \cdot \mathcal{A}_{\text{CS}(c)}(Y, s(X)) dc \right].$$

Equation 34 gives two interesting perspectives on the AUC. First, when it is possible to calibrate a scorer without losing information, the AUC can be thought of as implicitly calibrating a scorer before computing a particular risk. Second, by Shuford's representation (Equation 10), the risk computed is in fact identical to that for a proper loss, with the caveat that one considers a *score- and distribution-dependent* weight function $w(c) = \mu_C(c)$. Thus, the AUC is equivalent to the risk of a score- and distribution-dependent proper loss. (This is the finding of, for example, Hernández-Orallo et al. (2012, Theorem 34), which equates the AUC to the squared loss risk under a special case. We illustrate this equivalence empirically in Appendix K.) In particular, for a fixed distribution D , the AUC employs a different weighting for different scorers. Consequently, Hand (2009) calls the AUC an ‘‘incoherent’’ measure of classifier performance. Hand (2009, Section 6) proposes replacing this scorer dependent weight with one derived from the Beta family:

$$w(c; \alpha, \beta) = \frac{1}{B(\alpha, \beta)} \cdot c^{\alpha-1} \cdot (1 - c)^{\beta-1},$$

where $B(\alpha, \beta)$ is the normaliser for the Beta distribution. From Shuford's integral representation, it is apparent that the corresponding risk exactly corresponds to that of a proper composite loss. Indeed, the Beta family was proposed as a template for generating a proper loss in Buja et al. (2005, Section 11). For another perspective on this issue from the perspective of threshold selection, see Flach et al. (2011); Hernández-Orallo et al. (2012).

Another perspective on the ‘‘incoherence’’ can be gained from Proposition 13. Suppose we have (calibrated) scorers s_1, s_2 such that $\text{AUC}(s_1; D) > \text{AUC}(s_2; D)$. If it is further true that the ROC curve of s_1 dominates that of s_2 , then we know that s_1 will have lower risk than s_2 with respect to any proper composite risk, or equivalently any (distribution-independent) weighted combination of cost-sensitive risks. Thus, it is ‘‘coherent’’ to compare the two scorers based on their AUC in this case, because every other measure will result in s_1 being adjudged superior. When the ROC curves of the two scorers cross, however, the AUC is an incomplete measure of performance; with some proper losses, s_1 will be favoured over s_2 , and vice versa.

5.6.3 RATE-BASED REPRESENTATIONS

We proceed with some rate-based representations for the AUC. From a graphical perspective, these all derive from the fact that the AUC is the area under the ROC curve, and that this area is invariant to rotation of the horizontal and vertical axes i.e. instead of plotting the false positive versus true positive rate, we can equally plot the true negative versus false negative rate.

14. By definition $\int_0^1 \mu_S(c) dc = 1$, and so this equivalence can only be established to proper losses that satisfy $\int_0^1 w(c) dc < \infty$. This rules out, for example, logistic and exponential risk being equivalent to AUC.

Proposition 27 Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible false- and true-positive rates,

$$\begin{aligned} \text{AUC}(s; D) &= \int_0^1 \text{TPR}(\text{FPR}^{-1}(\alpha)) d\alpha \\ &= \int_0^1 \text{TPR}(\text{TNR}^{-1}(\alpha)) d\alpha \\ &= \int_0^1 \text{TNR}(\text{TPR}^{-1}(\alpha)) d\alpha \\ &= \int_0^1 \text{TNR}(\text{FNR}^{-1}(\alpha)) d\alpha. \end{aligned}$$

Proof The first equation is simply Equation 27. The subsequent expressions follow from a few simple facts. First, if $f(x) = 1 - g(x)$ and f is invertible with inverse f^{-1} , then

$$g^{-1}(x) = f^{-1}(1 - x).$$

This implies that

$$\begin{aligned} \text{FPR}^{-1}(\alpha) &= \text{TNR}^{-1}(1 - \alpha) \\ \text{TPR}^{-1}(\alpha) &= \text{FNR}^{-1}(1 - \alpha). \end{aligned}$$

Second, for any f ,

$$\int_0^1 f(1 - x) dx = \int_0^1 f(x) dx.$$

Combined with the above, this implies

$$\begin{aligned} \int_0^1 \text{TPR}(\text{FPR}^{-1}(\alpha)) d\alpha &= \int_0^1 \text{TPR}(\text{TNR}^{-1}(\alpha)) d\alpha \\ \int_0^1 \text{TNR}(\text{TPR}^{-1}(\alpha)) d\alpha &= \int_0^1 \text{TNR}(\text{FNR}^{-1}(\alpha)) d\alpha. \end{aligned}$$

Third, for any f, g , integration by parts implies that

$$\int_a^b f'(x)g(x) dx = f(b)g(b) - f(a)g(a) - \int_a^b f(x)g'(x) dx. \quad (35)$$

Fourth, for any f, g such that $g(a) = 0, g(b) = 1$,

$$\int_0^1 f(g^{-1}(t)) dt = \int_a^b g'(x)f(x) dx. \quad (36)$$

This implies that:

$$\begin{aligned} \int_0^1 \text{TPR}(\text{TNR}^{-1}(\alpha)) d\alpha &= \int_{-\infty}^{\infty} \text{TNR}'(t) \cdot \text{TPR}(t) dt \\ &= - \int_{-\infty}^{\infty} \text{TPR}'(t) \cdot \text{TNR}(t) dt \text{ by Equation 35} \\ &= \int_0^1 \text{TNR}(\text{TPR}^{-1}(\alpha)) d\alpha \text{ by Equation 36.} \end{aligned}$$

Now recalling the definition of the AUC (Definition 14) as $\int_0^1 \text{TPR}(\text{FPR}^{-1}(\alpha)) d\alpha$, we see that we have proved the proposition. ■

From the above proof, we see that one can equivalently express the AUC as a weighted average of individual rates over a range of thresholds.

Corollary 28 Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible false- and true-positive rates,

$$\begin{aligned} \text{AUC}(s; D) &= - \int_{-\infty}^{\infty} \text{FPR}'(t) \cdot \text{TPR}(t) dt \\ &= \int_{-\infty}^{\infty} \text{TNR}'(t) \cdot \text{TPR}(t) dt \\ &= - \int_{-\infty}^{\infty} \text{TPR}'(t) \cdot \text{TNR}(t) dt \\ &= \int_{-\infty}^{\infty} \text{FNR}'(t) \cdot \text{TNR}(t) dt. \end{aligned}$$

The weighting over thresholds as expressed above is not particularly intuitive, but recall from Equation 22 that the derivatives of the rates are the corresponding class-conditional densities of the scores. That means that we can interpret the above choice as equivalently drawing thresholds from these distributions. This is explored in the next section.

5.6.4 RANK REPRESENTATION

We now show how the AUC can be interpreted as the average of ranks of the instances, where the average is over thresholds drawn in accordance with the distribution of scores.

Corollary 29 Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{AUC}(s; D) = \mathbb{E}_{\mathcal{X} \sim P} [\text{TNR}(s(\mathcal{X}))] \quad (37)$$

$$= \mathbb{E}_{\mathcal{X} \sim Q} [\text{TPR}(s(\mathcal{X}'))]. \quad (38)$$

Proof This follows immediately from Corollary 28 and the definition of the derivatives of the rates. Alternatively, by Proposition 17, and rewriting probabilities as expectations,

$$\begin{aligned} \text{AUC}(s; D) &= \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) > s(\mathcal{X}')] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [s(\mathcal{X}) = s(\mathcal{X}')] \\ &= \mathbb{E}_{\mathcal{X} \sim P} \left[\mathbb{E}_{\mathcal{X}' \sim Q} \left[\mathbb{1}[s(\mathcal{X}) > s(\mathcal{X}')] + \frac{1}{2} \mathbb{1}[s(\mathcal{X}) = s(\mathcal{X}')] \right] \right] \\ &= \mathbb{E}_{\mathcal{X} \sim P} [\text{TNR}(s(\mathcal{X}))]. \end{aligned}$$

Swapping the order of expectations in the other direction gives Equation 38. ■

On a finite training set, the empirical version of $\text{TNR}(s(\mathcal{X}))$ is related to the (normalised version of) what is typically called the “rank” of an instance $x \in \mathcal{X}$, where a higher rank is better. Specifically, the empirical $\text{TNR}(s(\mathcal{X}))$ counts the fraction of negative instances that x is scored higher than. In this sense, the AUC can be seen as measuring the average rank of the positive examples.

5.6.5 BALANCED ACCURACY REPRESENTATION

Our final representation of the AUC more explicitly relates it to a measure of classification performance: we show how to rewrite it as the average “balanced accuracy” across a range of thresholds, where the balanced accuracy is the average of the accuracies on the positive and negative class individually (Chan and Stolfo, 1998).

$$\text{BACC}(t; D, s) = \frac{\text{TPR}(t; D, s) + \text{TNR}(t; D, s)}{2}.$$

This suggests that the AUC explicitly considers good performance on both classes simultaneously, which indicates it is useful for problems with class imbalance (Ling and Li, 1998). For a related representation on a finite training set, see Flach et al. (2011, Theorem 4, 5), while for a different proof strategy, see Menon et al. (2015, Proposition 20).

Proposition 30 For any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible false- and true-positive rates,

$$\begin{aligned} \text{AUC}(s; D) &= 2 \cdot \mathbb{E}_{\mathcal{X} \sim P} [\text{BACC}(s(X); D, s)] - \frac{1}{2} \\ &= 2 \cdot \mathbb{E}_{\mathcal{X}' \sim Q} [\text{BACC}(s(X'); D, s)] - \frac{1}{2}. \end{aligned} \quad (39)$$

Proof This is from Corollary 29 and the fact that

$$\begin{aligned} \mathbb{E}_{\mathcal{X} \sim P} [\text{TPR}(s(X); D, s)] &= \mathbb{E}_{S \sim P_S} [\text{TPR}(S; D, s)] \\ &= \int_{-\infty}^{\infty} -\text{TPR}'(t) \cdot \text{TPR}(t) dt \\ &= \int_0^1 u du \text{ with } u = \text{TPR}(t) \\ &= \frac{1}{2}. \end{aligned} \quad (40)$$

■ A similar argument yields the second identity.

The representation of Equation 39 can be contrasted with the risk for a proper composite loss. Using Shuford’s formula (Equation 10), for a proper composite loss ℓ with surjective and differentiable link Ψ , we have (Reid and Williamson, 2011, Proposition 20)

$$\begin{aligned} \mathbb{L}(s; D, \ell) &= \mathbb{E}_{(\mathcal{X}, \mathcal{Y}) \sim D} [\lambda(\mathcal{Y}, \Psi^{-1}(s(\mathcal{X})))] \\ &= \int_0^1 u(c) \cdot \mathbb{E}_{(\mathcal{X}, \mathcal{Y}) \sim D} [\lambda_{\text{CSI}(c)}(\mathcal{Y}, \Psi^{-1}(s(\mathcal{X})))] \\ &= \int_0^1 u(c) \cdot ((1 - \pi) \cdot c \cdot \text{FPR}(\Psi(c); D, s) + \pi \cdot (1 - c) \cdot \text{FNR}(\Psi(c); D, s)) dc \\ &= \int_{-\infty}^{\infty} \frac{u(\Psi^{-1}(t))}{\Psi(\Psi^{-1}(t))} \cdot ((1 - \pi) \cdot \Psi^{-1}(t) \cdot \text{FPR}(t; D, s) + \pi \cdot (1 - \Psi^{-1}(t)) \cdot \text{FNR}(t; D, s)) dt. \end{aligned}$$

Compared to Equation 39, we see that the proper composite risk has potentially asymmetric, but distribution independent, weights on the FPR and FNR. We also observe that the weights on the FPR and FNR are not equal, and vary with the thresholds. As per Hand’s representation (Equation 34), we may find that for a fixed distribution, there is a choice of link Ψ and weight u such that the two representations agree.

5.7 Relation to Existing Work

Lemma 22, which relates the AUC with the pairwise ranking (and hence pairwise classification) risk, is well known for the case of 0-1 loss (Kotowski et al., 2011; Agarwal, 2014). The extension to an arbitrary loss ℓ , while simple, is to our knowledge new. More generally, our definition of the ℓ -AUC as a generalisation of the standard AUC appears to be new, although in the special case where ℓ is a convex margin loss, the risk counterpart has been discussed (Cléménçon et al., 2008). The study of integral representations of the ℓ -AUC is to our knowledge new.

The representations in §5.6 are not new, although several of them only appear to have been stated for a finite training set.

6. Relating the Bayes Risk and Regret to Divergences

The previous sections studied the bipartite risk for an arbitrary scorer. In this section, we study the bipartite risk for the *Bayes-optimal* scorer, as well as the *regret* or *excess* risk for an arbitrary scorer. These help understand the inherent difficulty of a bipartite ranking problem, and formalise the sense in which “closeness” to the optimal scorer relates to the minimisation of the risk. Our characterisations rely on two classes of divergences between distributions, namely, the f - and Bregman-divergences. A review of the role of these divergences in characterising Bayes-risk and regret for classification is provided in Appendix E.

6.1 Warm-up: Bayes-Optimal Pairwise Ranking Risk and Regret

As pairwise ranking is readily shown to be equivalent to binary classification over pairs of instances (see §10.4), plugging in a pairwise ranking distribution $R \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ into existing results for classification immediately implies the following.

Proposition 31 For any $R = \langle P_{\text{pair}}, Q_{\text{pair}}, \pi_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$, convex $f : \mathbb{R}_+ \rightarrow \mathbb{R}$, and loss ℓ with conditional Bayes risk

$$(\forall \eta \in (0, 1)) L^*(\eta; \ell) = -\frac{1 - \eta}{1 - \pi_{\text{pair}}} \cdot f\left(\frac{1 - \pi_{\text{pair}}}{\pi_{\text{pair}}} \cdot \frac{\eta}{1 - \eta}\right),$$

the Bayes pairwise ranking risk can be written

$$\mathbb{L}^*(R, \ell) = L^*(\pi_{\text{pair}}; \ell) - \mathbb{J}_f(P_{\text{pair}}, Q_{\text{pair}}). \quad (41)$$

Conversely, Equation 41 holds for any $R = \langle P_{\text{pair}}, Q_{\text{pair}}, \pi_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$, loss ℓ with concave conditional Bayes risk $L^* : [0, 1] \rightarrow \mathbb{R}_+$, and $f : \mathbb{R}_+ \rightarrow \mathbb{R}$ defined by

$$(\forall t \in \mathbb{R}) f(t) = L^*(\pi_{\text{pair}}; \ell) - (\pi_{\text{pair}} \cdot t + 1 - \pi_{\text{pair}}) \cdot L^*\left(\frac{\pi_{\text{pair}} \cdot t}{\pi_{\text{pair}} \cdot t + 1 - \pi_{\text{pair}}}; \ell\right).$$

An important example of the above is for the case of the 0-1 loss ℓ_{01} , where the corresponding f -divergence is the variational divergence (or total variation distance) $V(\cdot, \cdot)$, given by

$$V(P, Q) = \sup_{A \subseteq \mathcal{X}} 2 \cdot |P(A) - Q(A)| = \int_{\mathcal{X}} |p(x) - q(x)| dx.$$

Proposition 31 thus implies that the Bayes pairwise ranking risk is an affine transformation of $V(P_{\text{pair}}, Q_{\text{pair}})$. We similarly have a simple expression for the pairwise ranking regret with a proper loss.

Proposition 32 For any $R = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$, $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$, and pair-scorer $s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{regret}(s_{\text{pair}}; R, \ell) = \mathbb{B}_{-f}(\eta_{\text{pair}}, \Psi^{-1} \circ s_{\text{pair}})$$

where in an abuse of notation $L^* = L^*(\cdot; \ell)$.

We now see how these results can be translated to the bipartite ranking setting.

6.2 Bayes-Optimal Bipartite Risk as an f -Divergence

For bipartite ranking, we can hope to exploit the connection between bipartite and pairwise ranking (Lemma 2), and derive analogues of the above for the distribution D_{BR} . A subtlety is that, as noted in Proposition 3, it is *not* necessarily true that $\mathbb{L}_{\text{BR}}^*(D, \ell) = \mathbb{L}^*(D_{\text{BR}}, \ell)$. Therefore, to translate the previous results, we need an additional condition ensuring this holds, which simply that $\ell \in \mathcal{L}_{\text{Decomp}}$:

Proposition 33 For any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, convex $f : \mathbb{R}_+ \rightarrow \mathbb{R}$, and loss $\ell \in \mathcal{L}_{\text{Decomp}}$ with conditional Bayes risk

$$(\forall \eta \in (0, 1)) L^*(\eta; \ell) = -2 \cdot (1 - \eta) \cdot f\left(\frac{\eta}{1 - \eta}\right),$$

the Bayes-risk can be written

$$\mathbb{L}_{\text{BR}}^*(D, \ell) = L^*(1/2; \ell) - \mathbb{J}_f(P \times Q, Q \times P). \quad (42)$$

Conversely, Equation 42 holds for any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, loss $\ell \in \mathcal{L}_{\text{Decomp}}$ with concave conditional Bayes risk $L^*(\cdot; \ell) : [0, 1] \rightarrow \mathbb{R}_+$, and $f : \mathbb{R}_+ \rightarrow \mathbb{R}$ defined by

$$(\forall t \in \mathbb{R}) f(t) \doteq L^*(1/2; \ell) - \frac{1+t}{2} \cdot L^*\left(\frac{t}{1+t}; \ell\right).$$

Proof By Proposition 3, the assumption on ℓ inducing a decomposable Bayes-optimal pair-scorer for D_{BR} implies we can equate $\mathbb{L}_{\text{BR}}^*(D, \ell)$ and $\mathbb{L}^*(D_{\text{BR}}, \ell)$. We then apply Proposition 31 to D_{BR} , so that

$$\begin{aligned} \mathbb{L}_{\text{BR}}^*(D, \ell) &= \mathbb{L}^*(D_{\text{BR}}, \ell) \text{ by Proposition 3} \\ &= L^*(P_{\text{pair}}; \ell) - \mathbb{J}_f(P_{\text{pair}}, Q_{\text{pair}}) \text{ by Proposition 31} \\ &= L^*(1/2; \ell) - \mathbb{J}_f(P \times Q, Q \times P) \text{ by Appendix B.} \end{aligned}$$

The other direction follows similarly. \blacksquare

As we shall see in Proposition 44, the requirement that $\ell \in \mathcal{L}_{\text{Decomp}}$ for a proper composite loss is equivalent to a condition on its link function. Importantly, there is *no* restriction on the underlying proper-loss itself. Therefore, the above holds for a large class of losses. One such example is the 0-1 loss $\ell = \ell_{01}$, where we have following relationship between the Bayes-optimal AUC and the variational divergence between the product measures $P \times Q$ and $Q \times P$.

Corollary 34 Given any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, the Bayes-optimal bipartite ranking risk is related to the variational divergence between the product distributions $P \times Q$ and $Q \times P$ via:

$$\mathbb{L}^*(D_{\text{BR}}, \ell_{01}) = \frac{1}{2} - \frac{1}{4} \cdot V(P \times Q, Q \times P).$$

Proof This follows from Proposition 33 and the fact that for ℓ_{01} ,

$$(\forall \eta \in [0, 1]) L^*(\eta; \ell_{01}) = \eta \wedge (1 - \eta) = \frac{1}{2} - \left| \eta - \frac{1}{2} \right|,$$

with $L^*(1/2; \ell_{01}) = 1/2$. It is easy to check that this corresponds to $f(t) = |t - 1/4 + (1 - t)/4|$, which is a scaled version of the convex generator for the variational divergence. \blacksquare

By Corollary 23 and Equation 48, Corollary 34 is equivalent to a result of Torgersen (1991, pg. 582),

$$\text{AUC}^*(D) = \frac{1}{2} + \frac{1}{4} \cdot V(P \times Q, Q \times P).$$

This may be further manipulated to explicitly express the Bayes-optimal AUC in terms of the concentration of the values of η (Clemençon et al., 2008),

$$\text{AUC}^*(D) = \frac{1}{2} + \frac{1}{4\pi(1 - \pi)} \cdot \mathbb{E}_{\mathcal{X} \sim M, \mathcal{X}' \sim M} [|\eta(\mathcal{X}) - \eta(\mathcal{X}')|].$$

This expression may be further related to the earth mover's distance (or L_1 -Wasserstein metric) between the class-conditional distribution of scores (Clemençon et al., 2009).

6.3 Bipartite Ranking Regret as a Generative Bregman Divergence

The bipartite ranking regret for proper composite losses may similarly be re-expressed by exploiting the reduction to classification on pairs. We again need to restrict ourselves to those proper composite losses that induce a decomposable Bayes-optimal pair-scorer.

Proposition 35 Pick any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ with derived pairwise ranking distribution $D_{\text{BR}} = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle$ and any $\ell \in \mathcal{L}_{\text{SPC}}(\mathcal{Y}) \cap \mathcal{L}_{\text{Decomp}}$. Then, for any scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{regret}_{\text{BR}}(s; D, \ell) = \mathbb{E}_{L^*}(\eta_{\text{pair}}, \mathbf{y}^{-1} \circ \text{Diff}(s))$$

where in an abuse of notation $L^* \doteq L^*(\cdot; \ell)$.

Proof By definition of the bipartite regret (Equation 18),

$$\begin{aligned} \text{regret}_{\text{BR}}(s; D, \ell) &= \mathbb{L}_{\text{BR}}(s; D, \ell) - \mathbb{L}_{\text{BR}}^*(D, \ell) \\ &= \mathbb{L}(\text{Diff}(s); D_{\text{BR}}; \ell) - \mathbb{L}_{\text{BR}}^*(D, \ell) \\ &= \text{regret}(\text{Diff}(s); D_{\text{BR}}, \ell) + \mathbb{L}^*(D_{\text{BR}}, \ell) - \mathbb{L}_{\text{BR}}^*(D, \ell) \\ &= \mathbb{E}_{L^*}(\eta_{\text{pair}}, \mathbf{y}^{-1} \circ \text{Diff}(s)) + \mathbb{L}^*(D_{\text{BR}}, \ell) - \mathbb{L}_{\text{BR}}^*(D, \ell), \end{aligned}$$

where the last line is by the standard expression for the regret with respect to a proper composite loss (Proposition 78). We thus need $\mathbb{L}^*(D_{\text{BR}}, \ell) = \mathbb{L}_{\text{BR}}^*(D, \ell)$, which by Proposition 3 is true iff $\ell \in \mathcal{L}_{\text{Decomp}}$. \blacksquare

In the case of $\ell = \ell_{01}$, the regret can be seen to measure the concentration of η in the region where the candidate scorer s disagrees with η , as is well known.

Corollary 36 (Clemençon et al., 2008; Agarwal, 2014, Theorem 11) For any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{regret}_{\text{BR}}(s; D, \ell_{01}) = \mathbb{E}_{\mathcal{X} \sim M, \mathcal{X}' \sim M} [|\eta(\mathcal{X}) - \eta(\mathcal{X}')| \cdot \mathbb{I}(s, \eta; \mathcal{X}, \mathcal{X}')]]$$

where

$$\mathbb{I}(s, \eta; \mathcal{X}, \mathcal{X}') = \mathbb{I}(\eta(\mathcal{X}) - \eta(\mathcal{X}') \cdot (s(\mathcal{X}) - s(\mathcal{X}')) < 0] + \frac{1}{2} \cdot \mathbb{I}[\eta(\mathcal{X}) = \eta(\mathcal{X}')].$$

6.4 Relation to Existing Work

As noted above, the connection between Bayes risks and f -divergences in classification is well known (Osercher and Vajda, 1993). For the bipartite ranking problem, the connection between the AUC and variational divergence has been made by (Torgersen, 1991; Reid and Williamson, 2011). The extension to the case of general ℓ -bipartite risk (Proposition 33) is simple in hindsight, as the variational divergence is well known to correspond to the use of 0-1 loss; however, to our knowledge, the extension is novel.

7. Bayes-Optimal Scorers for Bipartite Ranking

The previous section studied the risk associated with a Bayes-optimal scorer for bipartite ranking. We now characterise the set of Bayes-optimal scorers itself. Knowledge of the optimal scorers gives further insight into the problem, and helps relate it to the more familiar tasks of binary classification and class-probability estimation. As we shall see in the next section, this will also help in establishing the statistical consistency of the minimisation of surrogate losses on pairs for the task of AUC maximisation.

Before proceeding, we first recall the Bayes-optimal scorers for the latter problems given some $D = \langle P, Q, \pi \rangle = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$. Table 8 summarises the findings of this section.

Loss type	Bayes-optimal (pair-)scorers	Reference
Classification-calibrated	$S^*(D, \ell) \subseteq \left\{ s : \mathcal{X} \rightarrow \mathbb{R} : \begin{array}{l} \eta(x) \neq 1/2 \implies \\ \text{sign}(s(x)) = \text{sign}(2\eta(x) - 1) \end{array} \right\}$	Equation 43
	$S^*(D_{\text{BR}}, \ell) \subseteq \left\{ s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : \begin{array}{l} \eta(x) \neq \eta(x') \implies \\ \text{sign}(s_{\text{pair}}(x, x')) = \\ \text{sign}(\eta(x) - \eta(x')) \end{array} \right\}$	Equation 49
	$\{\phi \circ \eta\} \subseteq S_{\text{BR}}^*(D, \ell_{01}) = \{s : \mathcal{X} \rightarrow \mathbb{R} : \eta = \phi \circ s\}$	Proposition 42
Proper composite with link Ψ	$\{\Psi \circ \eta\} \subseteq S^*(D, \ell)$	Equation 44
	$\{\Psi \circ \sigma \circ \text{Diff}(\sigma^{-1} \circ \eta)\} \subseteq S^*(D_{\text{BR}}, \ell)$	Equation 50
	$S_{\text{BR}}^*(D, \ell) = \{\Psi \circ \eta + b : b \in \mathbb{R}\}$ for $\Psi \in \Sigma_{\text{sig}}$	Corollary 45

Table 8: Bayes-optimal scorers and pair-scorers for various classification and bipartite ranking risks.

7.1 Binary Classification

Consider a binary classification problem with distribution $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$. If the loss ℓ is classification-calibrated (Equation 7), every Bayes-optimal scorer must have the same sign as $\eta(x) - 1/2$, with the prediction for $\eta(x) = 1/2$ being irrelevant (Bartlett et al., 2006):

$$S^*(D, \ell) \subseteq \{s : \mathcal{X} \rightarrow \mathbb{R} : \eta(x) \neq 1/2 \implies \text{sign}(s(x)) = \text{sign}(2\eta(x) - 1)\}. \quad (43)$$

When ℓ is the 0-1 loss, the above is an equality (Devroye et al., 1996). Thus, for ℓ_{01} , what is of interest is determining whether or not each instance has a greater than random chance of being labelled positive.

When ℓ is a proper composite loss with link Ψ , from the definition of properness (Equation 9) we can specify one minimiser of the conditional risk, which applied pointwise gives:

$$\{\Psi \circ \eta\} \subseteq S^*(D, \ell). \quad (44)$$

This is an equality if and only if ℓ is strictly proper composite. Thus, a strictly proper composite loss requires precise information about η , unlike ℓ_{01} . Observe that $\Psi \circ \eta$ may be trivially transformed to give an optimal scorer for ℓ_{01} ; thus, exactly solving class-probability estimation also solves binary classification. For an approximate solution, one can bound the excess ℓ_{01} error via a surrogate regret bound (Reid and Williamson, 2009).

7.2 Pairwise Ranking

Recall from §3.4 that pairwise ranking is identical to binary classification over pairs of instances. Thus, in the pairwise ranking setting with distribution $R = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$, the above results can be

translated. For a classification-calibrated loss, the Bayes-optimal pair-scorers must have the same sign as $\eta_{\text{pair}}(x, x') - 1/2$, with the prediction for $\eta_{\text{pair}}(x, x') = 1/2$ being irrelevant:

$$S^*(R, \ell) \subseteq \{s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : \eta_{\text{pair}}(x, x') \neq 1/2 \implies \text{sign}(s_{\text{pair}}(x, x')) = \text{sign}(2\eta_{\text{pair}}(x, x') - 1)\}. \quad (45)$$

When ℓ is the 0-1 loss, the above is an equality.

When ℓ is a proper composite loss with link Ψ , by definition we can specify one Bayes-optimal pair-scorer, though there may be others:

$$\{\Psi \circ \eta_{\text{pair}}\} \subseteq S^*(R, \ell). \quad (46)$$

This is an equality if and only if ℓ is strictly proper composite.

7.3 Bipartite Ranking

The relationship between bipartite and pairwise ranking (Lemma 2) suggests we can simply compute the Bayes-optimal scorers for pairwise ranking with D_{BR} . Specifically, let $D_{\text{BR}} = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle$. To determine $S^*(D_{\text{BR}}, \ell)$, we need the following elementary but important property of η_{pair} .

Lemma 37 For any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$, D_{BR} has observation-conditional distribution given by

$$\eta_{\text{pair}} = \sigma \circ \text{Diff}(\sigma^{-1} \circ \eta), \quad (47)$$

where $\sigma(\cdot)$ denotes the sigmoid function (Equation 2).

Proof Suppose $(X, X', Z) \sim D_{\text{BR}}$. Recall $\mathbb{P}[Z = +1] = \frac{1}{2}$. Then,

$$\begin{aligned} (\forall x, x' \in \mathcal{X}) \eta_{\text{pair}}(x, x') &= \mathbb{P}[Z = +1 | X = x, X' = x'] \\ &= \frac{\mathbb{P}[X = x, X' = x' | Z = +1] \cdot \mathbb{P}[Z = +1]}{\mathbb{P}[X = x, X' = x']} \\ &= \frac{\mathbb{P}[X = x | Z = +1] \cdot \mathbb{P}[X' = x' | Z = +1] \cdot \mathbb{P}[Z = +1]}{\mathbb{P}[X = x, X' = x']} \\ &= \frac{\mathbb{P}[X = x | Z = +1] \cdot \mathbb{P}[X' = x' | Z = +1] + \mathbb{P}[X = x | Z = -1] \cdot \mathbb{P}[X' = x' | Z = -1]}{1 + \frac{\mathbb{P}[X = x | Z = -1] \cdot \mathbb{P}[X' = x' | Z = -1]}{\mathbb{P}[X = x | Z = +1] \cdot \mathbb{P}[X' = x' | Z = +1]}} \\ &= \sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x'))). \end{aligned}$$

The last identity follows because

$$\sigma^{-1}(\eta(x)) = \log \frac{\pi}{1 - \pi} + \log \frac{\mathbb{P}[X = x | Z = +1]}{\mathbb{P}[X = x' | Z = -1]}.$$

From Lemma 37, the Bayes-optimal scorers for a classification-calibrated loss are immediate. ■

Lemma 38 For any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$, and any classification-calibrated ℓ ,

$$S^*(D_{\text{BR}}, \ell) \subseteq \{s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : \eta(x) \neq \eta(x') \implies \text{sign}(s_{\text{pair}}(x, x')) = \text{sign}(\eta(x) - \eta(x'))\}.$$

When ℓ is the 0-1 loss, the above is an equality.

Proof For a classification calibrated loss ℓ , for every $x, x' \in \mathcal{X}$ such that $\eta(x) \neq \eta(x')$, any Bayes-optimal pair-scorer $s_{\text{Pair}}^* \in \mathcal{S}^*(D_{\text{BR}}, \ell)$ must satisfy

$$\begin{aligned} \text{sign}(s_{\text{Pair}}^*(x, x')) &= \text{sign}(2\eta_{\text{Pair}}(x, x') - 1) \\ &= \text{sign}(2\sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x')) - 1)) \text{ by Lemma 37} \\ &= \text{sign}(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x'))) \\ &= \text{sign}(\eta(x) - \eta(x')). \end{aligned} \quad (48)$$

When $\eta(x) = \eta(x')$, we can pick any $s_{\text{Pair}}^*(x, x') \in \mathbb{R}$. Thus, for all $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and classification-calibrated losses ℓ ,

$$\mathcal{S}^*(D_{\text{BR}}, \ell) \subseteq \{s_{\text{Pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : \eta(x) \neq \eta(x') \implies \text{sign}(s_{\text{Pair}}(x, x')) = \text{sign}(\eta(x) - \eta(x'))\}. \quad (49)$$

For ℓ_{01} , every pair-scorer satisfying the above is optimal, thus yielding an equality. ■

When ℓ is a proper composite loss with link Ψ , by definition we can specify one Bayes-optimal pair-scorer, though there may be others:

$$\{\Psi \circ \eta_{\text{Pair}}\} = \{\Psi \circ \sigma \circ \text{Diff}(\sigma^{-1} \circ \eta)\} \subseteq \mathcal{S}^*(D_{\text{BR}}, \ell). \quad (50)$$

This is an equality if and only if ℓ is strictly proper composite.

Having computed the optimal pair-scorers, when attempting to translate the results to bipartite ranking, we immediately face a challenge, as

$$\begin{aligned} \text{Argmin}_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(s; D, \ell) &= \text{Argmin}_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell) \\ &= \text{Argmin}_{s_{\text{Pair}} \in \mathcal{S}_{\text{Decomp}}^*} \mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell). \end{aligned}$$

That is, finding the set of scorers s that minimise $\mathbb{L}_{\text{BR}}(\text{Diff}(s))$ is equivalent to finding the set of pair-scorers s_{Pair} that minimise $\mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell)$, *subject to* the pair-scorers being decomposable. Formally, in the notation of Equation 20, we need every such optimal $s_{\text{Pair}}^* \in \mathcal{L}_{\text{Decomp}}^*$. While the latter constraint seems innocuous, it means we need to reason about a minimiser in a *restricted* function class. Thus, in general, it is no longer possible to simply study the conditional risk and make a pointwise analysis.

Of course, we can easily make progress in the special case where the optimal pair-scorer is in fact decomposable. In this case, we can effectively ignore the restricted function class, because the optimal pair-scorer must be the difference of the optimal univariate scorer. The following makes this precise.

Proposition 39 *Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and loss ℓ ,*

$$\ell \in \mathcal{L}_{\text{Decomp}} \iff \mathcal{S}^*(D_{\text{BR}}, \ell) \cap \mathcal{S}_{\text{Decomp}}^* = \text{Diff}(\mathcal{S}_{\text{BR}}^*(D, \ell)).$$

Proof The (\implies) direction is immediate, since $\mathcal{S}_{\text{BR}}^*(D, \ell) \neq \emptyset$ and thus $\text{Diff}(\mathcal{S}_{\text{BR}}^*(D, \ell)) \neq \emptyset$. We show the (\impliedby) direction.

(C). Pick any $s_{\text{Pair}}^* \in \mathcal{S}^*(D_{\text{BR}}, \ell) \cap \mathcal{S}_{\text{Decomp}}^*$. Then $s_{\text{Pair}}^* = \text{Diff}(s)$ for some $s : \mathcal{X} \rightarrow \mathbb{R}$. By optimality of s_{Pair}^*

$$(\forall s : \mathcal{X} \rightarrow \mathbb{R}) \mathbb{L}_{\text{BR}}(s) = \mathbb{L}(s_{\text{Pair}}^*; D_{\text{BR}}, \ell) \leq \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell) = \mathbb{L}_{\text{BR}}(s).$$

Thus $s \in \mathcal{S}_{\text{BR}}^*(D, \ell)$, and so $s_{\text{Pair}}^* \in \text{Diff}(\mathcal{S}_{\text{BR}}^*(D, \ell))$.

(D). Pick any $s^* \in \mathcal{S}_{\text{BR}}^*(D, \ell)$, and let $s_{\text{Pair}}^* = \text{Diff}(s^*)$. Then, by definition,

$$s_{\text{Pair}}^* \in \text{Argmin}_{s_{\text{Pair}} \in \mathcal{S}_{\text{Decomp}}^*} \mathbb{L}(s_{\text{Pair}}; D_{\text{BR}}, \ell).$$

This is a constrained optimisation problem. When $\ell \in \mathcal{L}_{\text{Decomp}}$, there is at least one solution to the *unconstrained* optimisation that lies in $\mathcal{S}_{\text{Decomp}}^*$; call it r_{Pair} . Clearly r_{Pair} is a feasible solution for the constrained problem above. Thus, it must have an identical risk to s_{Pair}^* . But then s_{Pair}^* is a solution to the unconstrained problem as well, and so $s_{\text{Pair}}^* \in \mathcal{S}^*(D_{\text{BR}}, \ell) \cap \mathcal{S}_{\text{Decomp}}^*$. ■

The result simplifies somewhat when *every* Bayes-optimal pair-scorer is decomposable, which occurs when there is a unique optimal pair-scorer.

Corollary 40 *Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and loss ℓ ,*

$$\mathcal{S}^*(D_{\text{BR}}, \ell) \subseteq \mathcal{S}_{\text{Decomp}}^* \iff \mathcal{S}^*(D_{\text{BR}}, \ell) = \text{Diff}(\mathcal{S}_{\text{BR}}^*(D, \ell)).$$

Proof (\implies) follows by Proposition 39, and (\impliedby) follows by definition of decomposability. ■

Simply put, the decomposable Bayes-optimal pair-scorers are exactly the Bayes-optimal scorers passed through $\text{Diff}(\cdot)$. Thus, if we can show that $\mathcal{S}_{\text{BR}}^*(D, \ell) \cap \mathcal{S}_{\text{Decomp}}^* \neq \emptyset$ for a loss ℓ , we automatically deduce the Bayes-optimal scorer from the results of the previous section. We determine when this condition holds below.

7.4 Bipartite ranking: Decomposable Case

We study the Bayes-optimal scorers for losses that induce a decomposable Bayes-optimal pair-scorer. We begin with the case ℓ_{01} .

7.4.1 OPTIMAL UNIVARIATE SCORER FOR 0-1 LOSS

For ℓ_{01} , it is not hard to see that our earlier results imply that D_{BR} has at least one decomposable Bayes-optimal pair-scorer.

Lemma 41 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$,*

$$\mathcal{S}^*(D_{\text{BR}}, \ell_{01}) \cap \mathcal{S}_{\text{Decomp}}^* \neq \emptyset.$$

Proof By Equation 49, we see that $\{\text{Diff}(\eta)\} \subseteq \mathcal{S}^*(D_{\text{BR}}, \ell_{01}) \cap \mathcal{S}_{\text{Decomp}}^*$. That is, ℓ_{01} induces at least one decomposable Bayes-optimal pair-scorer in the pairwise ranking risk. ■

We can now show that the optimal scorers for the 0-1 bipartite risk are those that preserve the ordering of the class-probability η , which includes all strictly monotone transformations of η .

Proposition 42 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$,*

$$\mathcal{S}_{\text{BR}}^*(D, \ell_{01}) = \{s : \mathcal{X} \rightarrow \mathbb{R} : \eta = \phi \circ s \text{ for } \phi : \mathbb{R} \rightarrow [0, 1] \text{ non-decreasing}\}.$$

Proof Let $\mathcal{A} = \mathcal{S}^*(D_{\text{BR}}, \ell_{01}) \cap \mathcal{S}_{\text{Decomp}}^*$. Since \mathcal{A} is nonempty by Proposition 41, $\mathcal{A} = \text{Diff}(\mathcal{S}_{\text{BR}}^*(D, \ell_{01}))$ by Proposition 39. Equivalently, by Lemma 38,

$$\begin{aligned} \mathcal{A} &= \{s_{\text{Pair}} \in \mathcal{S}_{\text{Decomp}}^* : \eta(x) \neq \eta(x') \implies \text{sign}(s_{\text{Pair}}(x, x')) = \text{sign}(\eta(x) - \eta(x'))\} \\ &= \text{Diff}(\{s : \mathcal{X} \rightarrow \mathbb{R} : \eta(x) \neq \eta(x') \implies \text{sign}(s(x) - s(x')) = \text{sign}(\eta(x) - \eta(x'))\}) \\ &= \text{Diff}(\{s : \mathcal{X} \rightarrow \mathbb{R} : \eta = \phi \circ s \text{ for non-decreasing } \phi\}) \text{ by Lemma 72.} \end{aligned}$$

We thus have equality of the differences of the sets of interest. But for any sets of scorers $\mathcal{S}_1, \mathcal{S}_2$, $\text{Diff}(\mathcal{S}_1) = \text{Diff}(\mathcal{S}_2) \implies (\forall s_1 \in \mathcal{S}_1)(\exists s_2 \in \mathcal{S}_2, c \in \mathbb{R}) s_1 = s_2 + c$, i.e. the scorers in the two sets must be related by a

linear translation. But if for a scorer s we have $\eta = \phi \circ s$ for some monotone ϕ , then it must also be true that $\eta = \tilde{\phi} \circ (s + c)$ where $\tilde{\phi} : x \mapsto \phi(x - c)$ is also monotone. Thus, the result follows. ■

The transform ϕ in Proposition 42 is not required to be strictly monotone increasing since if $\eta(x) = \eta(x')$ for some $x \neq x' \in \mathcal{X}$, it is allowed for $s(x) \neq s(x')$. (In the extreme case where $\eta(x) \equiv c$ for every x , then every scorer will trivially be Bayes-optimal.) Nonetheless, an immediate corollary is that any strictly monotone increasing transform of η is necessarily an optimal univariate scorer.¹⁵

Corollary 43 Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and any strictly monotone increasing $\phi : [0, 1] \rightarrow \mathbb{R}$,

$$\phi \circ \eta \in S_{\text{BR}}^*(D, \ell_{01}).$$

We see that like class-probability estimation, bipartite ranking with ℓ_{01} aims to find a transformation of η . Unlike class-probability estimation, one is satisfied with *any* strictly monotone transformation, not necessarily one specified by the loss itself. Loosely, then, bipartite ranking is less “strict” than class-probability estimation. (See also §10.)

7.4.2. OPTIMAL UNIVARIATE SCORER FOR STRICTLY PROPER COMPOSITE LOSSES

We now proceed to the case where ℓ is a strictly proper composite loss. To apply Corollary 40, we characterise the subset of proper composite losses for which there exists a decomposable pair-scorer. This shall turn out to rely on the following set of inverse link functions from the sigmoid family,

$$\Sigma_{\text{sig}} := \left\{ \Psi^{-1} : \mathbb{R} \rightarrow [0, 1] \mid (\exists a \in \mathbb{R} \setminus \{0\}) (\forall v \in \mathbb{R}) \Psi^{-1}(v) = \frac{1}{1 + e^{-av}} \right\}. \quad (51)$$

Proposition 44 (Decomposability of Bayes-optimal bipartite pair-scorer.) Given any $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$ with Ψ differentiable,

$$(\forall D \in \Delta_{\mathcal{X} \times \{\pm 1\}}) S^*(D_{\text{BR}}, \ell) \subseteq S_{\text{Decomp}} \iff \Psi^{-1} \in \Sigma_{\text{sig}}.$$

Proof (\Leftarrow) Let the link function of ℓ have the specified form, so that $\Psi(v) = \frac{1}{a} \log \frac{v}{1-v} = \frac{1}{a} \sigma^{-1}(v)$, and so $(\Psi \circ \sigma)(v) = \frac{v}{a}$. From Equation 50, the¹⁶ Bayes-optimal pair-scorer is

$$\begin{aligned} s_{\text{Pair}}^* &= \frac{1}{a} \cdot \text{Diff}(\sigma^{-1} \circ \eta) \\ &= \text{Diff} \left(\left(\frac{1}{a} \cdot \sigma^{-1} \right) \circ \eta \right) \\ &\in S_{\text{Decomp}}. \end{aligned}$$

Thus $s_{\text{Pair}}^* \in S^*(D_{\text{BR}}, \ell) \cap S_{\text{Decomp}}$.

(\Rightarrow) The proof here uses a similar idea to Uematsu and Lee (2012, Theorem 7). If $\ell \in \mathcal{L}_{\text{Decomp}}$

$$\Psi \circ \sigma \circ \text{Diff}(\sigma^{-1} \circ \eta) \in S_{\text{Decomp}}.$$

We wish to determine the nature of Ψ that permits this to hold. Let $f = \Psi \circ \sigma \circ \log$, so that the above becomes

$$(\forall x, x' \in \mathcal{X}) f \left(\frac{e^{\sigma^{-1}(\eta(x))}}{e^{\sigma^{-1}(\eta(x'))}} \right) = g(x) - g(x')$$

15. Combined with the connection between the 0-1 optimal scorer for the bipartite ranking risk and AUC (Corollary 23), this constitutes an alternate proof of Corollary 16, without an appeal to the Neyman-Pearson lemma.

16. For a *non-strict* proper composite loss, the following argument holds, but only for one possible optimal pair-scorer. Thus, it may not be true that *all* Bayes-optimal pair-scorers are decomposable; however, for the choice of link function above, we can guarantee that there is *at least* one that is. Nonetheless, for a *strictly* proper composite loss, there is a unique Bayes-optimal pair-scorer. Thus, the above result characterises when this pair-scorer is decomposable.

for some $g : \mathcal{X} \rightarrow \mathbb{R}$. Now note that

$$\begin{aligned} (\forall x, x', x'' \in \mathcal{X}) f \left(\frac{e^{\sigma^{-1}(\eta(x))}}{e^{\sigma^{-1}(\eta(x'))}} \right) &= g(x) - g(x'') + g(x'') - g(x') \\ &= f \left(\frac{e^{\sigma^{-1}(\eta(x))}}{e^{\sigma^{-1}(\eta(x'))}} \right) + f \left(\frac{e^{\sigma^{-1}(\eta(x''))}}{e^{\sigma^{-1}(\eta(x'))}} \right). \end{aligned}$$

We require this to hold for any D , and thus for any η . Therefore, equivalently, we have

$$(\forall a, b \in \mathbb{R}_+) f(a \cdot b) = f(a) + f(b).$$

Note that f is continuous by assumed differentiability of Ψ . Thus the only solution to the equation is $f(z) = \frac{1}{a} \cdot \log z$ for some $a \in \mathbb{R}$ (Kannappan, 2009, Corollary 1.43), or equivalently that $\Psi^{-1}(v) = \sigma(a \cdot v) = \frac{1}{1 + e^{-av}}$. Note that the case $a = 0$ is ruled out by assumed invertibility of Ψ , and thus equivalently of f . ■

We emphasise that the class of proper composite losses satisfying the above condition is “large” in the following sense: one may take *any* strictly proper loss and compose it with any member of the given link family. Two specific implications are noteworthy. First, the loss ℓ need not be symmetric; Appendix G has an empirical illustration of this fact. Second, the loss ℓ may be non-convex; nonetheless, we can easily determine the optimal scorers for all such losses, as below.

Corollary 45 Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$ with inverse link function $\Psi^{-1} \in \Sigma_{\text{sig}}$,

$$S_{\text{BR}}^*(D, \ell) = \{\Psi \circ \eta + b : b \in \mathbb{R}\}.$$

Consequently, when Ψ is monotone increasing (viz. when $a \in \mathbb{R}_+$ in Equation 51),

$$S_{\text{BR}}^*(D, \ell) \subseteq S_{\text{BR}}^*(D, \ell_{01}).$$

Proof By Proposition 44 and Corollary 40,

$$\text{Diff}(S_{\text{BR}}^*(D, \ell)) = S_{\text{BR}}^*(D, \ell).$$

Further, by Equation 50, and letting $\Psi^{-1} : v \mapsto \sigma(a \cdot v)$,

$$S_{\text{BR}}^*(D, \ell) = \text{Diff} \left(\frac{1}{a} \cdot \sigma^{-1} \circ \eta \right) = \text{Diff}(\Psi \circ \eta).$$

The result follows because

$$\text{Diff}(f) = \text{Diff}(g) \iff (\exists b \in \mathbb{R}) f = g + b.$$

The admissible family of links Σ_{sig} can be easily checked to contain those employed for the logistic and exponential losses, and thus we can deduce the decomposability of the Bayes-optimal scorers for these losses.

Corollary 46 For the strictly proper composite logistic and exponential losses,

$$\begin{aligned} \ell_{\log}(y, z) &= \log(1 + e^{-yz}) \\ \ell_{\exp}(y, z) &= e^{-yz}, \end{aligned}$$

with inverse link functions $\Psi^{-1}(v) = \frac{1}{1+e^{-2v}}$ and $\Psi^{-1}(v) = \frac{1}{1+e^{-2v}}$ respectively, the Bayes-optimal pair-scorer is decomposable for any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ i.e.

$$S^*(D_{\text{BR}}, \ell) \subseteq S_{\text{Decomp}}.$$

While Proposition 44 follows easily from the proper loss machinery, the requirement on the link function is *a priori* non-obvious. What is special about link functions that are scaled versions of the sigmoid? The answer is simply that the score η_{pair} , inherently involves a sigmoid link function (Lemma 3.7). This form of η_{pair} in turn can be understood via utility representations for binary relations on sets, as we discuss in §12.

7.4.3 COMMENT ON CONVEXITY

In general, an invertible link function Ψ can be composed with any proper loss to yield a proper composite loss. For numerical convenience, it is useful to consider only those proper losses which yield a convex proper composite loss. For a proper loss λ , let $\ell(Y, v) = \lambda(Y, \Psi^{-1}(v))$ for $\Psi^{-1}(v) \in \Sigma_{\text{sig}}$ i.e. $\Psi^{-1}(v) = \frac{1+e^{-v}}{2}$ for some v . Such a loss will have Bayes-optimal scorer as given by Proposition 44, but when will such a loss be additionally convex? Suppose the weight function w for λ is normalised such that $w(\frac{1}{2}) = 1$. Then, ℓ is convex only if the weight function w satisfies (Reid and Williamson, 2010, Theorem 29)

$$w(c) \in \left[\min \left(\frac{1}{a \cdot c^2 \cdot (1-c)}, \frac{1}{a \cdot c \cdot (1-c)^2} \right), \max \left(\frac{1}{a \cdot c^2 \cdot (1-c)}, \frac{1}{a \cdot c \cdot (1-c)^2} \right) \right].$$

The above gives necessary conditions¹⁷ for obtaining a convex proper composite loss with the given link.

As a sanity check, two losses encountered earlier in Corollary 46 will indeed satisfy the above. For the admissible weight function $w(c) = \frac{1}{a \cdot c \cdot (1-c)^{3/2}}$, it is easy to check that with a sigmoidal link we recover a generalised version of the exponential loss, $\ell(Y, v) = \frac{1}{a} e^{-v/w}$. (We will revisit these family of losses in a different context in §9.5.) Recall from Equation 13 that a link Ψ is canonical for a given proper loss λ with weight function w when $w(c) = \Psi'(c)$. For $\Psi^{-1}(v) = \frac{1}{1+e^{-v/w}}$, we have $w(c) = \frac{1}{a} \cdot \left(\log \frac{c}{1-c} \right)' = \frac{1}{a \cdot c \cdot (1-c)}$. The resulting proper composite loss is

$$\ell(Y, v) = \lambda(Y; \Psi^{-1}(v)) = \frac{1}{a} \cdot \log(1 + e^{-v/w}),$$

which is a generalised logistic loss. (Masmadi-Shirazi and Vasconcelos (2010) call this the canonical logistic loss.) Note that $\lim_{v \rightarrow -\infty} \frac{1}{a} \log(1 + e^{-v/w}) = \max(0, -v)$, which is the perceptron loss.

7.5 Bipartite Ranking: Non-Decomposable Case

We now turn to the case where the loss ℓ does *not* have a decomposable Bayes-optimal pair-scorer. As noted earlier, we can no longer resort to reasoning solely via the conditional risk. Fortunately, the simple structure of $\mathcal{S}_{\text{Decomp}}$ means that we can hope to directly compute the risk minimiser via an appropriate derivative. Under some assumptions on the loss, it turns out that the Bayes-optimal scorer is still a strictly monotone transform of η ; however, the transform is now *distribution dependent*, rather than simply the fixed link function Ψ .

Proposition 47 Pick any $D = \langle M, \eta \rangle = \langle P, Q, \pi \rangle \in \Delta^{\mathcal{X} \times \mathcal{Y} \times \{+1\}}$ and a differentiable, convex, symmetric strictly proper composite loss $\ell(Y, v) = \phi(Yv)$. If ϕ' is bounded,¹⁸ or the support of D is finite,

$$\mathcal{S}_{\text{BR}}^*(D, \ell) = \{s^* : \mathcal{X} \rightarrow \mathbb{R} \mid \eta = f_{D, s^*} \circ s^*\},$$

where

$$(vD \in \mathcal{Y}) f_{D, s^*}(v) = \frac{\pi \cdot \mathbb{E}_{\mathcal{X} \sim P} [e^{\ell'}_{-1}(v - s^*(X))] }{\pi \cdot \mathbb{E}_{\mathcal{X} \sim P} [e^{\ell'}_{-1}(v - s^*(X))] - (1 - \pi) \cdot \mathbb{E}_{\mathcal{X} \sim Q} [e^{\ell'}(v - s^*(X))]}.$$

¹⁷ More complex sufficient conditions may also be derived; see (Reid and Williamson, 2010, Theorem 24).

¹⁸ We suspect this requirement may be dropped, but defer to future work investigating minimal conditions for the result to hold.

Proof The basic proof strategy follows Uematsu and Lee (2012, Theorem 3), although the subsequent steps and connection to proper loss concepts are novel; we will shortly discuss the connection to the results of that paper.

Let $\ell(Y, v) = \phi(Yv)$. For fixed D , let $\mathcal{S}(D)$ denote the space of all Lebesgue-measurable scorers $s : \mathcal{X} \rightarrow \mathbb{R}$, with addition and scalar multiplication defined pointwise, such that

$$\mathbb{L}_{\text{BR}}(s; D, \ell) = \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [\phi(s(X) - s(X'))] < \infty.$$

Then $\mathbb{L}_{\text{BR}} : \mathcal{S}(D) \rightarrow \mathbb{R}$ is a convex functional, by virtue of ϕ being convex. Thus, its minimisers may be determined by considering an appropriate notion of functional derivative. We shall employ the Gâteaux variation.

Pick any $s, t \in \mathcal{S}(D)$. For any $\epsilon > 0$, define

$$\begin{aligned} F_s(\epsilon) &= \mathbb{L}_{\text{BR}}(s + \epsilon t) \\ &= \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [\phi(s(X) - s(X') + \epsilon(t(X) - t(X')))]. \end{aligned}$$

The Gâteaux variation of \mathbb{L}_{BR} at s in the direction of t is (Trotman, 1996, pg. 45; Giacomini and Hildbrandt, 2004, pg. 10)

$$\begin{aligned} \delta \mathbb{L}_{\text{BR}}(s; t) &= \lim_{\epsilon \rightarrow 0} \frac{\mathbb{L}_{\text{BR}}(s + \epsilon t) - \mathbb{L}_{\text{BR}}(s; D, \ell)}{\epsilon} \\ &= F'_s(0), \end{aligned}$$

assuming the latter exists. To show that $F'_s(0)$ exists, we will justify interchange of the derivative and expectation. For any $\epsilon \in (0, 1]$ and $x, x' \in \mathcal{X}$, by convexity and nonnegativity of ϕ ,

$$\begin{aligned} \left| \frac{\phi(\text{Diff}(s + \epsilon t)(x, x')) - \phi(\text{Diff}(s))(x, x')}{\epsilon} \right| &\leq |\phi(\text{Diff}(s + t)(x, x')) - \phi(\text{Diff}(s)(x, x'))| \\ &\leq \phi(|\text{Diff}(s + t)(x, x')|) + \phi(|\text{Diff}(s)(x, x')|). \end{aligned}$$

By assumption, $\mathbb{L}_{\text{BR}}(s + t)$ and $\mathbb{L}_{\text{BR}}(s; D, \ell)$ are both finite. Further,

$$\lim_{\epsilon \rightarrow 0} \frac{\phi(s(x) - s(x') + \epsilon(t(x) - t(x'))) - \phi(s(x) - s(x'))}{\epsilon} = (t(x) - t(x')) \cdot \phi'(s(x) - s(x')).$$

Thus, by the dominated convergence theorem (Folland, 1999, pg. 56), we have

$$\begin{aligned} F'_s(0) &= \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [t(X) - t(X')] \cdot \phi'(s(X) - s(X')) \\ &= \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [t(X) \cdot \phi'(s(X) - s(X'))] - \mathbb{E}_{\mathcal{X} \sim Q, \mathcal{X}' \sim P} [t(X) \cdot \phi'(s(X') - s(X))] \\ &= \int_{\mathcal{X}} t(x) \cdot r(x) dx, \end{aligned}$$

where

$$(vX \in \mathcal{X}) r(x) = \rho(x) \cdot \mathbb{E}_{\mathcal{X}' \sim Q} [\phi'(s(x) - s(X'))] - q(x) \cdot \mathbb{E}_{\mathcal{X} \sim P} [\phi'(s(X) - s(x))].$$

Now suppose $s^* : \mathcal{X} \rightarrow \mathbb{R}$ minimises the functional \mathbb{L}_{BR} . By convexity of \mathbb{L}_{BR} , it is necessary and sufficient that the Gâteaux variation is zero for $t \in \mathcal{L}(D)$ (Gelfand and Fomin, 2000, Theorem 2; Trotman, 1996, Proposition 3.3). That is,

$$(\forall t \in \mathcal{L}(D)) 0 = \int_{\mathcal{X}} t(x) \cdot r(x) dx.$$

A sufficient condition for this to hold is that r is zero (almost) everywhere, and this is in fact necessary as well (Lemma 7.1). That is, for (almost) every $x_0 \in \mathcal{X}$, we equivalently need

$$p(x_0) \cdot \mathbb{E}_{\mathcal{X} \sim Q} [\phi'(s^*(x_0) - s^*(X'))] = q(x_0) \cdot \mathbb{E}_{\mathcal{X} \sim P} [\phi'(s^*(X) - s^*(x_0))],$$

which means for (almost) every $x_0 \in \mathcal{X}$,

$$\begin{aligned} & \frac{\eta(x_0)}{1 - \eta(x_0)} \cdot \frac{1 - \pi}{\pi} = \frac{p(x_0)}{q(x_0)} \\ &= \frac{\mathbb{E}_{\mathcal{X} \sim P} [\phi'(s^*(X) - s^*(x_0))]}{\mathbb{E}_{\mathcal{X}' \sim Q} [\phi'(s^*(x_0) - s^*(X'))]} \\ &= \frac{\mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(s^*(X) - s^*(x_0)) - \ell'_{-1}(s^*(x_0) - s^*(X))]}{\mathbb{E}_{\mathcal{X}' \sim Q} [-\ell'_{-1}(s^*(x_0) - s^*(X')) + \ell'_{-1}(s^*(X) - s^*(x_0))]} \\ &= \frac{\mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(s^*(x_0) - s^*(X)) - \ell'_{-1}(s^*(X) - s^*(x_0))]}{\mathbb{E}_{\mathcal{X}' \sim Q} [\ell'_{-1}(s^*(x_0) - s^*(X)) - \ell'_{-1}(s^*(X) - s^*(x_0))]} \\ &= \frac{\mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(s^*(x_0) - s^*(X))]}{\mathbb{E}_{\mathcal{X}' \sim Q} [\ell'_{-1}(s^*(x_0) - s^*(X))]} \text{ since } \ell' \text{ is symmetric,} \end{aligned}$$

which means

$$\eta = f_{D,s^*} \circ s^*,$$

where f_{D,s^*} is given by

$$(f_{D,s^*})(v) = \frac{\pi \cdot \mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(v - s^*(X))]}{\pi \cdot \mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(v - s^*(X)) - (1 - \pi) \cdot \mathbb{E}_{\mathcal{X}' \sim Q} [\ell'_{-1}(v - s^*(X'))]}.$$

In order to express any optimal scorer s^* in terms of η , as we have done for the previous cases, it remains to check whether or not the above the function f_{D,s^*} defined above is invertible. The following corollary provides sufficient conditions for this to hold.

Corollary 48 *Pick any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and margin-based strictly proper composite loss $\ell(y, v) = \phi(yv)$, where ϕ is differentiable, strictly convex, and satisfies*

$$(\forall v \in \mathbb{R}) \phi'(v) = 0 \iff \phi'(-v) \neq 0.$$

Then if ϕ' is bounded or the support of D is finite, f_{D,s^} is invertible and*

$$S_{\text{BR}}^*(D, \ell) = \{s^* : \mathcal{X} \rightarrow \mathbb{R} \mid s^* = (f_{D,s^*})^{-1} \circ \eta\} \subseteq S_{\text{BR}}^*(D, \ell_0),$$

where f_{D,s^} is defined as in Proposition 47.*

Proof We show that f_{D,s^*} strictly monotone, by establishing the strict monotonicity of

$$g : v \mapsto \frac{\mathbb{E}_{\mathcal{X}' \sim Q} [\ell'_{-1}(v - s^*(X'))]}{\mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(v - s^*(X))]}.$$

The derivative of this function is

$$g'(v) = \frac{1}{\left(\mathbb{E}_{\mathcal{X} \sim P} [\ell'_{-1}(v - s^*(X))] \right)^2} \cdot \left(\mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} \left[\ell''_{-1}(v - s^*(X)) \ell''_{-1}(v - s^*(X')) \right] - \ell''_{-1}(v - s^*(X)) \ell''_{-1}(v - s^*(X')) \right).$$

By convexity of ℓ , the terms $\ell''_{-1}(v - s^*(X'))$ and $\ell''_{-1}(v - s^*(X))$ are positive. Further, by (Vernet et al., 2011, Proposition 15), ℓ_{-1} and ℓ_{-1} are increasing and decreasing respectively, or vice-versa. By assumption their derivatives cannot simultaneously be zero. Therefore the expectand is always positive or negative for every v , and hence $g'(v)$ is always strictly positive or negative. Thus g is strictly monotone, which means f_{D,s^*} is as well. Therefore, $s^* = (f_{D,s^*})^{-1} \circ \eta$. ■

The link function f_{D,s^*} is at first glance peculiar because it depends on the distribution D , as well as the optimal scorer s^* . From a practical perspective, the result is thus not helpful in terms of helping quickly discover the optimal scorer s^* . However, what is of interest to us is simply that this function is strictly monotone. This means that from an AUC perspective, using a proper composite surrogate loss asymptotically results in a desirable score i.e. if we rank examples according to s^* , it is equivalent to ranking them according to η .

As before, any optimal scorer for such a proper composite loss is also optimal for ℓ_{01} , despite the link function f_{D,s^*} depending on the distribution D . Appendix H provides an empirical illustration that this link is indeed invertible under the specified conditions, albeit distribution dependent. The results of this section established that a suitably restricted notion of convexity is *sufficient* for the optimal scorer to be a strictly monotone transform of η , while the previous section established convexity is *not necessary*, since one can have a non-convex loss resulting from a suitable link $\Psi = \frac{1}{t} \sigma^{-1}$.

7.5.1 COMPARISON WITH STANDARD LINK FUNCTION

Recall from Equation 12 that the link function Ψ associated with a proper composite loss ℓ satisfies

$$\Psi^{-1}(v) = \frac{\ell'_{-1}(v)}{\ell'_{-1}(v) - \ell'_1(v)}.$$

This is in general *not* the same as the inverse link function $(f_{D,s^*})^{-1}$ from the above result for a simple reason: the latter potentially depends on the distribution D , and the optimal scoring function s^* itself. However, the forms of the two functions are closely related: in $(f_{D,s^*})^{-1}$, each quantity from the inverse link Ψ^{-1} is replaced by its expected value under an appropriate distribution.

In the previous section, we saw that under certain conditions $s^* = \Psi \circ \eta$, where Ψ is the standard link function associated with ℓ . In such cases, it is of interest to see whether f_{D,s^*} simplifies. For example, for the case of exponential loss $\ell(y, v) = e^{-yv}$, with inverse link function $\Psi^{-1}(v) = \frac{1}{1 + e^{-2v}}$, we get

$$(f_{D,s^*})^{-1}(v) = \frac{\mathbb{E}_{\mathcal{X} \sim M} [\eta(X) \cdot e^{s^*(X)}]}{\mathbb{E}_{\mathcal{X} \sim M} [\eta(X) \cdot e^{s^*(X)}] + e^{-2v} \cdot \mathbb{E}_{\mathcal{X} \sim M} [(1 - \eta(X)) \cdot e^{-s^*(X)}]}.$$

It can be verified that when plugging in $s^* = \Psi \circ \eta$, one finds $(f_{D,s^*})^{-1}(v) = \Psi^{-1}(v)$ as expected, and therefore the dependence on the distribution “disappears”. Determining conditions beyond $\Psi \in \Sigma_{\text{sig}}$ for which f_{D,s^*} simplifies would be of interest.

In class-probability estimation with a proper composite loss, there is a separation of concerns between the underlying proper loss and the link function Ψ , with the latter primarily chosen for computational convenience, and not affecting statistical properties of the proper loss (Reid and Williamson, 2010). For bipartite ranking,

however, such a separation of concerns is guaranteed only when one operates with the family of link functions from Proposition 44. For this family, the Bayes-optimal scorer is any translation of $\Psi \circ \eta$, while Corollary 48 indicates that outside this family, the optimal scorer may be a distribution-dependent transformation of η . Thus, changing the link function in bipartite ranking can change the optimal solutions to the risk in a non-trivial way.

7.6 Relation to Existing Work

The study of Bayes-optimal scorers for pairwise and bipartite ranking problems does not seem as extensive as for the binary classification setting. The study of the Bayes-optimal scorers for both problems under proper composite losses appears to be novel, although Agarwal (2014) employs proper losses in theoretical analysis related to the bipartite ranking problem. Even our derivation of the form of η_{pair} does not have many precedents, though Uematsu and Lee (2012) implicitly derive the formula.

This section generalised and unified several earlier results through the theory of proper losses. For ℓ_{01} -our Corollary 43 is well-known in the context of scorers that maximise the AUC, which is one minus the bipartite ℓ_{01} risk. The result is typically established by the Neyman-Pearson lemma (Torgersen, 1991), whereas we simply use a reduction to binary classification over pairs. For exponential loss with a linear hypothesis class, Erekin and Rudin (2011) studied the (empirical) Bayes-optimal solutions. For a convex margin loss, Uematsu and Lee (2012) and Gao and Zhou (2012, 2015) independently studied conditions for the Bayes-optimal scorers to be transformations of η . Our Proposition 44 is a generalisation of Uematsu and Lee (2012, Theorem 7); Gao and Zhou (2012, Lemma 3); Gao and Zhou, 2015, (Corollary 1), where our result holds for non-symmetric and non-convex proper composite losses; Appendix G has an empirical illustration of this. Our Corollary 48 is essentially equivalent to Uematsu and Lee (2012, Theorem 3); Gao and Zhou (2012, Theorem 5); Gao and Zhou (2015, Theorem 2), although we explicitly provide the form of the link function relating η and s^* . (We translate these results in terms of proper losses so that the connection is more apparent in Appendix F.)

Uematsu and Lee (2012, Theorem 5) also showed that for the hinge loss, which is classification calibrated, there are possibly ties introduced in the ranking, which is not covered by our results as the hinge loss is not proper; Gao and Zhou (2012, Theorem 2, 3); Gao and Zhou (2015, Lemma 3) similarly show that hinge and absolute loss do not produce a consistent ranking.

8. Surrogate Regret Bounds for Pairwise Surrogate Minimisation

At this stage, we have established that for suitable ℓ , minimisers of the ℓ -bipartite risk will also minimise the ℓ_{01} bipartite risk. Equivalently, these scorers will maximise the AUC. This can be seen as a justification for the minimisation of a pairwise surrogate to ℓ_{01} for the task of maximising the AUC; this is sometimes referred to as the pairwise approach to bipartite ranking.

In practice, of course, we cannot expect to perfectly minimise L_{BR} due to having access to a finite sample, and (or) using a restricted function class of scorers. Thus, we would ideally like a bound as to how much worse the AUC can be when using a *suboptimal* minimiser of $L_{\text{BR}}(s; D, \ell)$. This is the analogue of *surrogate regret bounds* for classification, which establish that convex risk minimisation is consistent for the problem of 0-1 minimisation (Zhang, 2004; Bartlett et al., 2006; Reid and Williamson, 2009).

Surrogate regret bounds have previously been shown for bipartite ranking by Cléménçon et al. (2008, Section 7), under the implicit assumption of decomposable scorers, and for the symmetric exponential and logistic losses by Gao and Zhou (2012, Corollary 6, 7); Gao and Zhou (2015, Corollary 5). It turns out that the analysis of the previous section automatically implies the existence of surrogate regret bounds for pairwise minimisation of suitable (possibly asymmetric) proper composite losses. Formally, we have the following.

Proposition 49 *Pick any $D \in \Delta_{\mathcal{X} \times \mathcal{X}}^{\pm 1}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$. Given any $\ell \in \mathcal{L}_{\text{SPEC}}(\Psi)$ with inverse link function $\Psi^{-1} \in \Sigma_{\text{SIG}}^+$, there exists a convex function $F_{\ell} : [0, 1] \rightarrow \mathbb{R}_+$ with $F_{\ell}(0) = 0$ such that,*

$$F_{\ell}(\text{regret}_{\text{BR}}(s; D, \ell_{01})) \leq \text{regret}_{\text{BR}}(s; D, \ell).$$

Proof For any $s : \mathcal{X} \rightarrow \mathbb{R}$, $s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, recall that

$$\begin{aligned} \text{regret}(s_{\text{pair}}; D_{\text{BR}} \cdot \ell) &= \mathbb{L}(s_{\text{pair}}; D_{\text{BR}} \cdot \ell) - \inf_{f_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(f_{\text{pair}}; D_{\text{BR}} \cdot \ell) \\ \text{regret}_{\text{BR}}(s; D, \ell) &= \mathbb{L}_{\text{BR}}(s; D, \ell) - \inf_{f : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(f). \end{aligned}$$

Existing surrogate regret bounds for proper composite losses (Reid and Williamson, 2009) imply that there exists some convex $F_{\ell} : [0, 1] \rightarrow \mathbb{R}_+$ such that, for any $D \in \Delta_{\mathcal{X} \times \mathcal{X}}^{\pm 1}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$F_{\ell}(\text{regret}(\text{Diff}(s); D_{\text{BR}} \cdot \ell_{01})) \leq \text{regret}(\text{Diff}(s); D_{\text{BR}} \cdot \ell).$$

By the reduction of bipartite ranking to classification over pairs (Lemma 2), for any ℓ satisfying the conditions of the proposition,

$$\begin{aligned} \text{regret}_{\text{BR}}(s; D, \ell) &= \mathbb{L}_{\text{BR}}(s; D, \ell) - \inf_{f : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}_{\text{BR}}(f) \\ &= \mathbb{L}(\text{Diff}(s); D_{\text{BR}} \cdot \ell) - \inf_{f_{\text{pair}} \in \mathcal{S}_{\text{Decomp}}} \mathbb{L}(f_{\text{pair}}; D_{\text{BR}} \cdot \ell) \\ &= \mathbb{L}(\text{Diff}(s); D_{\text{BR}} \cdot \ell) - \inf_{f_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}} \mathbb{L}(f_{\text{pair}}; D_{\text{BR}} \cdot \ell) \\ &= \text{regret}(\text{Diff}(s); D_{\text{BR}} \cdot \ell), \end{aligned}$$

where in the penultimate line we have used the fact that the restriction to $\mathcal{S}_{\text{Decomp}}$ can be removed by virtue of the loss ℓ inducing a decomposable Bayes-optimal pair-scorer for D_{BR} (by Proposition 44). We similarly know that ℓ_{01} induces a decomposable pair-scorer (Proposition 41). Thus, we can write the regret bound as

$$F_{\ell}(\text{regret}_{\text{BR}}(s; D, \ell_{01})) \leq \text{regret}_{\text{BR}}(s; D, \ell). \quad \blacksquare$$

The function $F_{\ell} : [0, 1] \rightarrow \mathbb{R}_+$ in Proposition 49 is exactly that which appears in bounds relating 0-1 to ℓ classification regret for proper composite losses, and may be specified in terms of the conditional Bayes-risk of ℓ as (Reid and Williamson, 2009, Theorem 3)

$$\begin{aligned} F_{\ell} : u &\mapsto L^*\left(\frac{1}{2}\right) + G_{\ell}(u) \vee G_{\ell}(-u) \\ G_{\ell} : u &\mapsto -L^*\left(\frac{1}{2} + u\right) + (L^*)'\left(\frac{1}{2}\right) \cdot u. \end{aligned}$$

We make three observations about this result. First, the bound implies the consistency of pairwise surrogate minimisation for losses satisfying the conditions of the proposition, and whose underlying proper loss λ additionally satisfy the regularity condition $L^*(0) = 0$, as

$$\begin{aligned} \text{regret}_{\text{BR}}(s; D, \ell) \rightarrow 0 &\implies F_{\ell}(\text{regret}_{\text{BR}}(s; D, \ell_{01})) \rightarrow 0 \\ &\implies \text{regret}_{\text{BR}}(s; D, \ell_{01}) \rightarrow 0, \end{aligned}$$

where the second line is because $L^*(u) > 0$ on $(0, 1/2]$ by strict concavity of the conditional Bayes risk (a consequence of strict properness of the loss), and $L^*(0) = 0$ by assumption.

Second, the bound places no convexity restriction on ℓ . This is akin to similar regret bounds for classification (Bartlett et al., 2006, Theorem 1), where the surrogate loss need not be convex. Of course, for non-convex ℓ , guaranteeing $\text{regret}_{\text{BR}}(s; D, \ell) \rightarrow 0$ is more challenging.

Third, when the optimal pair-scorer is *not* decomposable, the proof breaks when attempting to equate $\text{regret}_{\text{BR}}(s; D, \ell)$ and $\text{regret}(\text{Diff}(s); D_{\text{BR}} \cdot \ell)$, and so more effort is needed to derive a surrogate regret bound. This further illustrates the value of the decomposability of the Bayes-optimal pair-scorer as studied in the previous section. Note that while we do not have a regret bound for such losses, Corollary 48 established a

sufficient condition for agreement of the Bayes-optimal scorers. Further, [Gao and Zhou \(2012\)](#), [Theorem 2](#) showed that for a subset of such losses, one has asymptotic consistency of the surrogate minimisation (even when a regret bound is elusive).

As a final note, the above is distinct from [Agarwal \(2014\)](#) as the latter bounds the AUC regret in terms of the regret with respect to a proper composite loss. That is, the result shows the consistency of the class-probability estimation approach to bipartite ranking. This is distinct to our bound, which shows the consistency of the surrogate pairwise ranking approach to bipartite ranking.

9. Ranking the Best Instances

In most practical applications of ranking, accuracy at the head of the ranked list is more important than accuracy at the tail. For example, in information retrieval, typically only the first few elements of the ranked result set for a query are considered by a user of the system. It is thus of interest to consider notions of risk that focus on accuracy at the head of the list. This problem is sometimes called *ranking the best* ([Cléménçon and Vayatis, 2007](#)) or *accuracy at the top* ([Boyd et al., 2013](#)). We will use the terminology “ranking the best”.

We will now formalise the ranking the best problem, and see how the tools we have developed thus far may be applied to address it.

9.1 Formal Definition of Ranking the Best

[Corollary 43](#) shows the AUC is maximised by any strictly monotone increasing transformation of η , the observation-conditional distribution. Thus, from the perspective of the AUC, the optimal ranked list in bipartite problems involves ordering instances based on their η values. In the ranking the best problem, our goal is to ensure that instances $x \in \mathcal{X}$ for which $\eta(x)$ is large are correctly ordered relative to other instances, potentially at the expense of incorrectly ordering instances $x' \in \mathcal{X}$ for which $\eta(x')$ is small.

Formally, given any $q \in [0, 1]$, we call a loss ℓ a q -RTB loss (for q -rank-the-best) if the Bayes-optimal scorer for $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ is

$$S^*(D, \ell) = \{\Psi_q \circ \eta\},$$

where

$$(\forall z \in [0, 1]) \Psi_q(z) \in \begin{cases} \{z\} & \text{if } z \geq q \\ [0, z] & \text{if } z < q, \end{cases} \quad (52)$$

Such a scorer does not demand accurate estimation of η below the fixed threshold q : all that is required is that the ordering is preserved relative to those instances with score bigger than q .

According to [Equation 52](#), any loss for which $S^*(D, \ell) = \{\Psi_{\text{opt}}\}$ for some invertible Ψ is also a $\Psi^{-1}(q)$ -RTB loss for any $q \in [0, 1]$. This simply says that if we accurately model *all* ranks, then by definition we accurately model ranks at the head of the list. Indeed, if we could operate on the distribution directly, there would be no tradeoff to be made between accurately modelling any particular portion of the list: η would be recovered exactly, and thus the entire list could be ranked perfectly. The value of a loss that relaxes the modelling requirements for $\eta < q$ arises when we have either finite samples or a misspecified hypothesis class, in which case tradeoffs are necessary.

Having defined the goal of the ranking the best problem, we look to review some performance measures for this task. We then explore alternate risks that have similar characteristics, but are designed using the theory of proper composite losses. We shall begin with a general framework that follows [Cléménçon and Vayatis \(2008\)](#); [Rudin \(2009\)](#).

9.2 The (Reverse) (ℓ, g)-Push Framework for Ranking the Best

Most established performance measures encourage focussing on the head of the ranked list in one of two (related) ways:

- (i) ensuring that most negative instances appear below the positive instances, or

- (ii) ensuring that most positive instances appear near the head of the list.

The former approach involves ensuring that the false negative rate is small for certain negative instances. The latter approach relies on minimising the following quantity: given an instance $x \in \mathcal{X}$, we define its *normalised rank* under a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ and distribution $D = \langle M, \eta \rangle$ to be the fraction of examples that have a higher score than it:

$$\begin{aligned} \text{NRank}(x; D, s) &= \mathbb{P}_{\mathcal{X} \sim M} [s(X) > s(x)] + \frac{1}{2} \cdot \mathbb{P}_{\mathcal{X} \sim M} [s(X) = s(x)] \\ &= \pi \cdot \text{TPR}(s(x); D, s) + (1 - \pi) \cdot \text{FPR}(s(x); D, s). \end{aligned} \quad (53)$$

Small normalised ranks are desired for positive examples, and large ranks for negative examples. Our definition of the normalised rank is simply called the “rank” by [Rudin \(2009\)](#), [Section 7](#).

For each of the above approaches, we consider a general family of risks that can be specialised to yield various performance measures of interest. For approach (i), [Rudin \(2009\)](#); [Swamidass et al. \(2010\)](#) studied a family of risks parameterised by a monotone increasing function.¹⁹ Generalising these proposals to the case of an arbitrary symmetric loss ℓ , and a pair-scorer $s_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, we obtain the (ℓ, g)-push risk:

$$\text{Push}(s_{\text{pair}}; D, \ell, g) = \mathbb{E}_{\mathcal{X} \sim Q} \left[g \left(\mathbb{E}_{\mathcal{X}' \sim P} [\ell_1(s_{\text{pair}}(X, X'))] \right) \right],$$

where $g : \mathbb{R} \rightarrow \mathbb{R}_+$ is a monotone increasing function. For decomposable pair-scorers,

$$\text{Push}(\text{Diff}(s); D, \ell, g) = \mathbb{E}_{\mathcal{X}' \sim Q} \left[g \left(\text{FNR}_{\ell}(s(X')) \right) \right].$$

Compared to the standard bipartite ℓ -ranking risk ([Equation 16](#)), the difference is that the inner expectation is transformed by the function $g(\cdot)$. Intuitively, if $g(\cdot)$ is convex with a sharply increasing slope, the risk penalises high false negative rates, or equally encourages high true positive rates when thresholding around the negatives.

For approach (ii), following [Cléménçon and Vayatis \(2008\)](#); [Rudin \(2009\)](#), [Section 7](#), we have an analogous *reverse*²⁰ (ℓ, g)-push risk, where the order of expectations is reversed, and one uses the normalised rank in place of a rate:

$$\text{RevPush}(s_{\text{pair}}; D, \ell, g) = \mathbb{E}_{\mathcal{X} \sim P} \left[g \left(\mathbb{E}_{\mathcal{X}' \sim M} [\ell_1(s_{\text{pair}}(X, X'))] \right) \right],$$

where $g : \mathbb{R} \rightarrow \mathbb{R}_+$ is a monotone increasing function. For decomposable pair-scorers,

$$\text{RevPush}(\text{Diff}(s); D, \ell, g) = \mathbb{E}_{\mathcal{X} \sim P} \left[g \left(\text{NRank}_{\ell}(s(X)) \right) \right],$$

where NRank_{ℓ} involves replacing the TPR and FPR in [Equation 53](#) with their TPR_{ℓ} and FPR_{ℓ} counterparts. To gain some intuition for these approaches, we show how the AUC is a special case of each.

9.3 The AUC and the (Reverse) (ℓ, g)-Push Risk

We first relate the AUC to the (ℓ, g)-push risk. Recall from [Equation 38](#) that the AUC is

$$\text{AUC}(s; D) = \mathbb{E}_{\mathcal{X}' \sim Q} \left[\text{TPR}(s(X'); D, s) \right].$$

A high AUC thus means that the negative instances, on average, are placed below the positive instances: were this not the case, then we would achieve only a low true positive rate when thresholding scores around the negatives. Formally, we have

$$\text{AUC}(s; D) = \text{Push}(\text{Diff}(s); D, \ell_{01}, g)$$

¹⁹ This family has also been considered, in a different context, by [Xie and Priebe \(2002\)](#).

²⁰ Our use of the word “reverse” is as per [Rudin \(2009\)](#), [Section 7](#).

where $g : x \mapsto 1 - x$.

We next relate the AUC to the reverse (ℓ, g) -push risk. At first glance, the AUC appears to involve a different consideration, as

$$\text{AUC}(g; D) = \mathbb{E}_{X \sim P} [\text{TNR}(g(X); D, s)],$$

so that the AUC focusses on placing positives ahead of negatives, while when maximising the normalised rank, we also consider the relationship of positives to other positives. (A similar observation is made by Rudin (2009, Section 7), where the false positive rate is called the “reverse height”). However, note that

$$\begin{aligned} \mathbb{E}_{X \sim P} [\text{NRank}(X; D, s)] &= \pi \cdot \mathbb{E}_{X \sim P} [\text{TPR}(g(X); D, s)] + (1 - \pi) \cdot \mathbb{E}_{X \sim P} [\text{FPR}(g(X); D, s)] \\ &= \pi \cdot \mathbb{E}_{X \sim P} [\text{TPR}(g(X); D, s)] + (1 - \pi) \cdot (1 - \text{AUC}(g; D)) \text{ by Equation 37} \\ &= \frac{\pi}{2} + (1 - \pi) \cdot (1 - \text{AUC}(g; D)) \text{ following Equation 40,} \end{aligned}$$

and so

$$\text{AUC}(g; D) = \frac{2 - \pi}{2 \cdot (1 - \pi)} - \frac{1}{1 - \pi} \cdot \mathbb{E}_{X \sim P} [\text{NRank}(X; D, s)].$$

A high AUC thus means that on average, the positive instances have a small normalised rank i.e. they appear near the head of the list. Formally, we thus have

$$\text{AUC}(g; D) = \text{RevPush}(\text{Dif}(g); D, g)$$

where $g : x \mapsto \frac{2 - \pi}{2(1 - \pi)} - \frac{1}{1 - \pi} \cdot x$.

9.4 Established Performance Measures for Ranking the Best

In both the above interpretations of the AUC, one focusses on average case behaviour. This is manifest in the AUC having a linear dependence on the true positive rate, as well as on the normalised rank. The basic idea of adapting the measure to focus on the head of the list is to consider a suitable nonlinear transformation $g(\cdot)$ in the (reverse) (ℓ, g) -push risk, so as to strongly penalise errors at the head over the tail. We now define some popular measures²¹ for ranking the best that do precisely this. Table 9 summarises the measures considered.

9.4.1 PARTIAL AUC

The *partial AUC* (PAUC) (McClish, 1989; Dodd and Pepe, 2003; Narasimhan and Agarwal, 2013a) of a scorer only computes the area under the ROC curve for false positive rates between $[a, b] \subseteq [0, 1]$:

$$\begin{aligned} \text{PAUC}(g; D, a, b) &= \int_a^b \text{TPR}(\text{FPR}^{-1}(a)) da \\ &= \mathbb{E}_{X \sim P} [\text{TPR}(g(X)) \cdot \mathbb{1}[a \leq \text{FPR}(g(X)) \leq b]]. \end{aligned}$$

When $a = 0$ and $b \ll 1$, this intuitively focusses only on performance at the head of the ranked list (as this corresponds to thresholds with low false positive rate). This measure is evidently related to the special case of the reverse (ℓ_0, g) -push risk for $g : x \mapsto (x \vee a) \wedge b$, where one uses the true positive rate in place of the normalised rank.

²¹ Most of these measures have their origins in information retrieval. Here, they are typically stated in terms of results for “queries”. We effectively treat our labelled samples as the set of results for a single query. Measures that average across multiple queries, which would correspond to a multilabel learning problem, are thus not considered.

Performance measure	Symbol	Definition
Partial AUC	$\text{PAUC}(g; D, b)$	$\mathbb{E}_{X \sim P} [\text{TPR}(g(X)) \cdot \mathbb{1}[\text{FPR}(g(X)) \leq b]]$
Average precision	$\text{AP}(g; D)$	$\mathbb{E}_{X \sim P} \left[\frac{\text{TPR}(g(X; D, s))}{\text{NRank}(X; D, s)} \right]$
Discounted cumulative gain	$\text{DCG}(g; D)$	$\mathbb{E}_{X \sim P} \left[\frac{1}{\log(1 + \text{NRank}(X; D, s))} \right]$
Average reciprocal rank	$\text{ARR}(g; D)$	$\mathbb{E}_{X \sim P} \left[\frac{1}{\text{NRank}(X; D, s)} \right]$
Reciprocal rank	$\text{RR}(g; D)$	$\sup_{Y \in \text{supp}(P)} \frac{1}{\text{NRank}(X; D, s)}$
(Negated) p -norm push	$\text{Push}(g; D, p)$	$\mathbb{E}_{X \sim Q} \left[-(\text{NRank}(g(X); D, s))^p \right]$
Positives at top	$\text{PTop}(g; D)$	$\inf_{Y \in \text{supp}(Q)} \text{TPR}(g(X^*); D, s)$

Table 9: Performance measures for ranking the best. For each measure, larger values are desirable.

9.4.2 AVERAGE PRECISION

Our next measure relies on the following two quantities.

Definition 50 Given any distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, define the *precision and recall at a threshold* $t \in \mathbb{R} \cup \{\pm\infty\}$ to be

$$\begin{aligned} \text{Prec}(t; D, s) &= \mathbb{P}[Y = 1 | s(X) > t] \\ \text{Rec}(t; D, s) &= \text{TPR}(t; D, s) = \mathbb{P}[s(X) > t | Y = 1] + \frac{1}{2} \cdot \mathbb{P}[s(X) = t | Y = 1]. \end{aligned}$$

When the scorer and distribution are clear from context, we shall drop the dependence on them and simply write $\text{Prec}(t)$, $\text{Rec}(t)$.

The precision may be related to the more familiar rates introduced earlier: if the distribution of scores has no discrete components, then by Bayes’ rule,

$$\begin{aligned} \text{Prec}(t; D, s) &= \frac{\mathbb{P}[s(X) > t | Y = 1] \cdot \mathbb{P}[Y = 1]}{\mathbb{P}[s(X) > t]} \\ &= \frac{\pi \cdot \text{TPR}(t) + (1 - \pi) \cdot \text{FPR}(t)}{\pi \cdot \text{TPR}(t)} \\ &= \left(1 + \frac{1 - \pi}{\pi} \cdot \frac{\text{FPR}(t)}{\text{TPR}(t)} \right)^{-1}. \end{aligned} \tag{54}$$

Note that if we use as threshold $t = s(x)$ for some $x \in \mathcal{X}$, then the denominator of Equation 54 is nothing but $\text{NRank}(t)$.

We now define the *average precision* (AP) of a scorer s (Yue et al., 2007; Chakrabarti et al., 2008; Agarwal, 2011; Boyd et al., 2012) to be the average of the precisions obtained using the scores of positive examples as thresholds:

$$\begin{aligned} \text{AP}(g; D) &= \mathbb{E}_{X \sim P} [\text{Prec}(g(X); D, s)] \\ &= \pi \cdot \mathbb{E}_{X \sim P} \left[\frac{\text{TPR}(g(X); D, s)}{\text{NRank}(X; D, s)} \right], \end{aligned} \tag{55}$$

where the second equation follows from Equations 53 and 54.

The average precision can be shown to favour accuracy at the head of the list more than the AUC (Yue et al., 2007). Intuitively, this is because when there is a spurious negative example high in the ranked list, it will substantially affect the precision of the nearby positive examples. This may also be seen through Equation 55: we encourage very low normalised ranks for the positive examples, which corresponds to placing them at the very top of the list. Compared to the AUC, placing a few positives at the very top gives a greater gain than placing many positives only roughly near the top.

Further intuition for the average precision can be gained by considering the precision-recall curve, a complement to the ROC curve.

Definition 51 Given any distribution $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s: \mathcal{X} \rightarrow \mathbb{R}$, the *precision-recall curve* is defined by the *parametric representation*

$$\text{PR}(s; D) \doteq \{(\text{Rec}(t; D, s), \text{Prec}(t; D, s)) : t \in \mathbb{R} \cup \{\pm\infty\}\} \subseteq [0, 1]^2.$$

The area under the precision recall curve (AUPRC) of s is the area under the curve $\text{PR}(s; D)$ (Boyd et al., 2013):

$$\text{AUPRC}(s; D) \doteq \int_0^1 \text{Prec}(\text{Rec}^{-1}(\alpha)) d\alpha.$$

We immediately see that compared to the ROC curve, the PR curve depends on the base rate π . We also see that like the ROC curve, the curve can be computed from the TPR and FPR. Following the Neyman-Pearson analysis (Corollary 16), we can conclude that the area under the PR curve is optimized by any strictly monotone increasing transform of $\eta(x)$ (Cléménçon and Vayatis, 2009a).

In fact, the average precision is exactly equal to the AUPRC.

Lemma 52 (Boyd et al., 2013) Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and scorer $s: \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible rates,

$$\text{AUPRC}(s; D) = \text{AP}(s; D).$$

Proof By definition,

$$\begin{aligned} \text{AUPRC}(s; D) &= \int_0^1 \text{Prec}(\text{Rec}^{-1}(\alpha)) d\alpha \\ &= - \int_{-\infty}^{\infty} \text{TPR}'(t) \cdot \text{Prec}(t) dt \text{ using } \alpha = \text{TPR}(t) \\ &= \int_{-\infty}^{\infty} p_S(t) \cdot \text{Prec}(t) dt \text{ by Equation 22} \\ &= \mathbb{E}_{\mathcal{X} \sim P} \left[\int_{-\infty}^{\delta_{s(X)}(t)} \text{Prec}(t) dt \right] \\ &= \mathbb{E}_{\mathcal{X} \sim P} [\text{Prec}(s(X))]. \end{aligned}$$

■

9.4.3 DISCOUNTED CUMULATIVE GAIN

The *discounted cumulative gain* (DCG) of a scorer s (Järvelin and Kekäläinen, 2002; Agarwal, 2011; Boyd et al., 2012) is the average of the inverse logarithm of the normalised rank for all positive examples:

$$\text{DCG}(s; D) \doteq \mathbb{E}_{\mathcal{X} \sim P} \left[\frac{1}{\lg(1 + \text{NRank}(X; D, s))} \right].$$

Compared to average precision (Equation 55), the DCG applies a nonlinear decay on the effect of lower ranked positives. It is evident that the DCG is a special case of the reverse $(\ell_{0,1}, g)$ -push risk with $g: x \mapsto 1/\log(1+x)$. It may also be seen as a limiting case of the family of risks with $g_p: x \mapsto (1/p)/((1+x)^p/p - 1)$ as $p \rightarrow \infty$.

9.4.4 AVERAGE RECIPROCAL RANK

The *average reciprocal rank* (ARR) of a scorer s (Rudin, 2009, Section 7) is the inverse of the harmonic mean of the normalised ranks for all positive examples:

$$\text{ARR}(s; D) = \mathbb{E}_{\mathcal{X} \sim P} \left[\frac{1}{\text{NRank}(X; D, s)} \right].$$

This measure encourages small normalised rank values for the positives, meaning that spurious negatives near the head of the list will adversely affect the scores for several examples. Compared to the average precision (Equation 55), one does not additionally weigh this inverse rank by the true positive rate. It is evident that the ARR is a special case of the reverse $(\ell_{0,1}, g)$ -push risk with $g: x \mapsto 1/x$.

9.4.5 RECIPROCAL RANK

The *reciprocal rank* (RR) of a scorer s (Voorhees, 2001; Chakrabarti et al., 2008) is the inverse of the rank of the top positive:

$$\text{RR}(s; D) \doteq \sup_{x \in \text{supp}(P)} \frac{1}{\text{NRank}(x; D, s)}.$$

where $\text{supp}(\cdot)$ denotes the support of a distribution. This measure directly encourages the first element of the ranked list to be a positive. Compared to average precision (Equation 55), roughly, we replace the average performance over all positives with simply the performance of the best positive. The RR can be seen as a limiting case of a family of reverse $(\ell_{0,1}, g)$ -push risks with $g = g_p: x \mapsto 1/x^p$ as $p \rightarrow \infty$.

Compared to the RR, the ARR considers the ranks of *all* positives, not just the top one. This intuitively makes the ARR more suitable when one is interested not just at the very first element of the list, but rather on the first k elements for some small constant k .

9.4.6 THE p -NORM PUSH

Rudin (2009) provides a detailed study of the p -norm push, which the (ℓ, g) -push risk for the choice $g: x \mapsto x^p$ for $p \in [1, \infty)$ and symmetric ℓ , leading to the p -norm push risk:

$$\begin{aligned} \text{Push}(\text{Diff}(s); D, \ell, \cdot^p) &= \mathbb{E}_{\mathcal{X}' \sim Q} \left[(\text{FNR}_{\ell}(s(X')))^p \right] \\ &= \mathbb{E}_{\mathcal{X}' \sim Q} \left[\left(\mathbb{E}_{\mathcal{X} \sim P} [\ell_1(s(X) - s(X'))] \right)^p \right]. \end{aligned} \quad (56)$$

By increasing the value of p , one strongly penalises high false negative rates.

9.4.7 POSITIVES AT THE TOP

The *fraction of positives at the top* (PTop) of a scorer s (Agarwal, 2011; Boyd et al., 2012) is typically defined on an empirical sample $\mathcal{D} = \{(x_j, 1)\}_{j=1}^m \cup \{(x_j, -1)\}_{j=1}^m$ as the number of positive instances ranked above the highest negative instance, or equally, the minimum over all negative instances of the number of positives ranked above that instance.

$$\text{PTop}(s; \mathcal{D}) \doteq \min_{1 \leq j \leq m} \ell_{01}(s(x_j) - s(x_j)).$$

Li et al. (2014) provided an efficient algorithm to optimise surrogates to this measure. Evidently, its population counterpart is

$$\text{PTop}(s; D) = \inf_{s' \in \text{Supp}(Q)} \text{TPR}(s(s'; D, s),$$

with negation

$$1 - \text{PTop}(s; D) = \sup_{s' \in \text{Supp}(Q)} \text{FNR}(s(s'; D, s). \quad (57)$$

Compared to the AUC (Equation 38), which looks to make the *average* rank of all negative instances small, the PTop looks to make the *worst possible* rank over all negative instances small. The PTop can be related to the p -norm push risk, as

$$\lim_{p \rightarrow \infty} \text{Push}(s; D, \ell, \rho)^{1/p} = \sup_{s' \in \text{Supp}(Q)} \text{FNR}_{\rho}(s(s'; D).$$

For the case of ℓ_{01} , this is exactly the negation of the positives at the top measure (Equation 57).

9.5 Bayes-Optimal Scorers for the (ℓ, g) -Push Risk

Having introduced a number of performance measures, we now study why suitable choices of g for the (ℓ, g) -push risk can be seen to focus attention at the head of the list. This is done by analysing the Bayes-optimal scorers for this family of risks, and seeing how they align with Equation 52. Specifically, we aim to determine the Bayes-optimal pair and univariate scorers for the (ℓ, g) -push risk, and study them in light of Equation 52. Unlike bipartite ranking, the risk in this case cannot (obviously) be expressed as a classification risk over pairs of instances; therefore, we separately consider the optimal pair- and univariate-scorers,

$$\begin{aligned} \text{S}_{\text{push}}^{\text{pair}^*}(D, \ell, g) &= \underset{\text{S}_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}}{\text{Argmin}} \text{Push}(\text{S}_{\text{pair}}; D, \ell, g) \\ \text{S}_{\text{push}}^*(D, \ell, g) &= \underset{s : \mathcal{X} \rightarrow \mathbb{R}}{\text{Argmin}} \text{Push}(\text{Diff}(s); D, \ell, g). \end{aligned}$$

We first analyse the case of pair-scorers, and then proceed to univariate scorers. While most of our analysis is for general ℓ and g , we shall find the p -norm push risk of Equation 56 to be particularly amenable to analysis when combined with the exponential loss.

9.5.1 BAYES-OPTIMAL PAIR-SCORERS

As with the standard bipartite risk, determining the Bayes-optimal scorer for the (ℓ, g) push is challenging due to the implicit restricted function class $\mathcal{S}_{\text{Decomp}}$. In fact, this is difficult even for the pair-scorer case: the (ℓ, g) push risk is not easily expressible in terms of a conditional risk. Thus, we explicitly compute the derivative of the risk, as in the proof of Proposition 47. We end up with the following distribution-dependent transformation of η_{pair} as our optimal scorer.

Proposition 53 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{ \pm 1 \} }$, a differentiable function $g : \mathbb{R} \rightarrow \mathbb{R}$, and a differentiable strictly proper composite loss ℓ with link function Ψ , if ℓ' , ℓ'' are bounded or \mathcal{X} is finite,*

$$\text{S}_{\text{push}}^{\text{pair}^*}(D, \ell, g) = \{ s_{\text{pair}}^* : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : s_{\text{pair}}^* = \Psi \circ \sigma \circ (\text{Diff}(\sigma^{-1} \circ \eta) - G(D, s_{\text{pair}}^*)) \}, \quad (58)$$

where

$$\begin{aligned} G(x, x'; D, s_{\text{pair}}) &= \log \frac{g'(F(x; D, s_{\text{pair}}))}{g'(F(x'; D, s_{\text{pair}}))} \\ F(x; D, s_{\text{pair}}) &= \mathbb{E}_{x \sim p} \left[\frac{\ell_+(s_{\text{pair}}(x, x)) + \ell_-(s_{\text{pair}}(x, X))}{2} \right]. \end{aligned}$$

$$\text{Push}_{\text{S}_{\text{pair}}^*}(D, \ell, g) = \mathbb{E}_{x \sim Q} \left[g(F(X'; D, s_{\text{pair}}^*)) \right].$$

Proof First, in the notation above,

$$\begin{aligned} R(\epsilon; \text{S}_{\text{pair}}^*, r_{\text{pair}}) &= \text{Push}(\text{S}_{\text{pair}}^* + \epsilon \cdot r_{\text{pair}}; D, \ell) \\ &= \mathbb{E}_{x \sim Q} \left[g(F(X'; D, s_{\text{pair}}^* + \epsilon \cdot r_{\text{pair}})) \right]. \end{aligned}$$

For fixed D , let $\mathcal{S}(D)$ denote the space of all Lebesgue-measurable pair-scorers $\text{S}_{\text{pair}} : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, with addition and scalar multiplication defined pointwise, such that $\text{Push}(\text{S}_{\text{pair}}; D, \ell, g) < \infty$. As before, we consider the Gateaux variation of the functional. Pick any $\text{S}_{\text{pair}}^*, r_{\text{pair}} \in \mathcal{S}(D)$. For any $\epsilon > 0$, define

For simplicity, in the following we shall not explicitly write the dependence of F and G on $D, \text{S}_{\text{pair}}^*$. Now consider

$$\begin{aligned} R'(0; \text{S}_{\text{pair}}^*, r_{\text{pair}}) &= \mathbb{E}_{x \sim Q} \left[g'(F(X')) \cdot \mathbb{E}_{x \sim p} \left[r_{\text{pair}}(X, X') \cdot \frac{\ell'_{\text{S}_{\text{pair}}^*}(X, X')}{2} \right] \right] + \\ &\quad r_{\text{pair}}(X', X) \cdot \frac{\ell'_{\text{S}_{\text{pair}}^*}(X', X)}{2} \\ &= \frac{1}{2} \int_{\mathcal{X} \times \mathcal{X}} r_{\text{pair}}(x, x') \cdot (\rho(x)q(x') \cdot g'(F(x')) \cdot \ell'_{\text{S}_{\text{pair}}^*}(x, x') + \\ &\quad \rho(x')q(x) \cdot g'(F(x')) \cdot \ell'_{\text{S}_{\text{pair}}^*}(x', x)) dx dx', \end{aligned}$$

where as in the proof of Proposition 47, the interchange of derivative and expectation is justified when \mathcal{X} is finite, or when the derivatives $\ell'_{\text{S}_{\text{pair}}^*}, \ell''_{\text{S}_{\text{pair}}^*}$ are bounded.

For the optimal pair-scorer S_{pair}^* , the derivative must be zero for every r_{pair} . A sufficient condition for this to hold is that the second term in the integrand is zero for (almost) every $x, x' \in \mathcal{X}$.

Now, since ℓ is strictly proper composite, for any $\eta \in [0, 1]$, the solution to

$$\eta \cdot \ell'(s) + (1 - \eta) \cdot \ell'_{-1}(s) = 0$$

is $s = \Psi(\eta)$, by virtue of the above being the derivative of the conditional risk. Thus, the solution to

$$\frac{a}{a+b} \cdot \ell'(s) + \frac{b}{a+b} \cdot \ell'_{-1}(s) = 0$$

for $a, b > 0$ is $s = \Psi(a/(a+b)) = \Psi(\sigma(\log(a/b)))$. Letting

$$\begin{aligned} a &= g'(F(x')) \cdot \rho(x) \cdot q(x') \\ b &= g'(F(x)) \cdot q(x) \cdot \rho(x'), \end{aligned}$$

the optimal pair-scorer is, for every $x, x' \in \mathcal{X}$,

$$\begin{aligned} \text{S}_{\text{pair}}^*(x, x') &= \Psi \circ \sigma \circ \log \frac{\rho(x) \cdot q(x') \cdot g'(F(x'))}{\rho(x') \cdot q(x) \cdot g'(F(x))} \\ &= \Psi \circ \sigma \circ (\sigma^{-1}(\rho(x)) - \sigma^{-1}(\rho(x')) - G(D, s_{\text{pair}}^*)), \end{aligned}$$

where the second line is since

$$\frac{\rho(x)}{q(x)} = \frac{\eta(x)}{1 - \eta(x)} \cdot \frac{1 - \pi}{\pi}.$$

Thus,

$$\text{S}_{\text{pair}}^* = \Psi \circ \sigma \circ (\text{Diff}(\sigma^{-1} \circ \eta) - G(D, s_{\text{pair}}^*)).$$

The result follows by dividing through by the numerator. ■

Requiring differentiability of the loss means that we cannot compute the optimal solution for ℓ_{01} . However, we can compute the Bayes-optimal pair-scorers for a sequence of proper composite losses that approach ℓ_{01} . Consider a sequence of losses $\{\ell^{(p)}\}_{p \in \mathbb{N}}$ with corresponding links $\{\Psi^{(p)}\}_{p \in \mathbb{N}}$, with $(\forall v \in \mathbb{R}) \lim_{p \rightarrow \infty} (\Psi^{(p)})^{-1}(v) = [v > 0]$. This suggests the optimal scorer of

$$S_{\text{push}}^{\text{pair},*}(D, \ell_{01}, g) = \left\{ s_{\text{pair}}^* : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R} : \text{sign}(s_{\text{pair}}^*) = \text{sign}(\text{Diff}(\sigma^{-1} \circ \eta)) - G(D, s_{\text{pair}}^*) \right\},$$

but we defer a formal proof to future work.

When $g : x \mapsto x$, which corresponds to the standard ℓ -bipartite ranking risk, the term G above is $\equiv 0$ and so $s_{\text{pair}}^* = \Psi \circ \eta_{\text{pair}}$ as expected. For general (ℓ, g) , however, it is unclear how to simplify the term G any further. In general, s_{pair}^* appears to be a strictly monotone transform of η_{pair} , where the transform is distribution dependent. However, surprisingly, for the special case of ℓ being the exponential loss and $g : x \mapsto x^p$, the optimal scorer is explicitly determinable as a simple transform of the conditional probability.

Proposition 54 *Pick any distribution $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$. Let $\ell(y, v) = e^{-yv}$ be the exponential loss and $g : x \mapsto x^p$ for any $p \geq 1$. Then, the optimal pair-scorer s_{pair}^* for the (ℓ, g) -push bipartite ranking risk is*

$$s_{\text{pair}}^* = \frac{1}{p+1} \cdot \text{Diff}(\sigma^{-1} \circ \eta).$$

Proof We establish this by verifying that $s_{\text{pair}} = \frac{1}{p+1} \text{Diff}(\sigma^{-1} \circ \eta)$ satisfies the implicit equation in Equation 58. We begin with the term $F(x; D, s_{\text{pair}})$ as defined in Proposition 53. Plugging in $g : x \mapsto x^p$ and

$$s_{\text{pair}} = \frac{1}{p+1} \cdot \sigma^{-1} \circ \eta_{\text{pair}} = \frac{1}{p+1} \cdot \text{Diff}(\sigma^{-1} \circ \eta),$$

we get

$$\begin{aligned} (\forall x \in \mathcal{X}) F(x; D, s_{\text{pair}}) &= \mathbb{E}_{\mathcal{X} \times \mathcal{P}} \left[\frac{\ell_1(s_{\text{pair}}(X, x)) + \ell_{-1}(s_{\text{pair}}(x, X))}{2} \right] \\ &= \mathbb{E}_{\mathcal{X} \times \mathcal{P}} \left[\frac{e^{-s_{\text{pair}}(X, x)} + e^{s_{\text{pair}}(x, X)}}{2} \right] \\ &= \frac{1}{2} \mathbb{E}_{\mathcal{X} \times \mathcal{P}} \left[\left(\frac{\eta_{\text{pair}}(X, x)}{1 - \eta_{\text{pair}}(X, x)} \right)^{-1/(p+1)} + \left(\frac{\eta_{\text{pair}}(x, X)}{1 - \eta_{\text{pair}}(x, X)} \right)^{1/(p+1)} \right] \\ &= \mathbb{E}_{\mathcal{X} \times \mathcal{P}} \left[\exp(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(X))) / (p+1) \right] \\ &= \exp(\sigma^{-1}(\eta(x)) / (p+1)) \cdot \mathbb{E}_{\mathcal{X} \times \mathcal{P}} \left[\exp(-\sigma^{-1}(\eta(X))) / (p+1) \right], \end{aligned}$$

where crucially the dependence on η is separated from the dependence on the rest of the distribution.

Thus, for $g : x \mapsto x^p$,

$$(\forall x, x' \in \mathcal{X}) \frac{g'(F(x; D, s_{\text{pair}}))}{g'(F(x'; D, s_{\text{pair}}))} = \frac{\exp(\sigma^{-1}(\eta(x)) \cdot (p-1) / (p+1))}{\exp(\sigma^{-1}(\eta(x')) \cdot (p-1) / (p+1))}$$

with the result now a simple function of η , and

$$(\forall x, x' \in \mathcal{X}) \log \frac{g'(F(x; D, s_{\text{pair}}))}{g'(F(x'; D, s_{\text{pair}}))} = \frac{p-1}{p+1} \cdot (\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x'))),$$

Now recall that the link function for exponential loss is $\Psi = \frac{1}{2} \sigma^{-1}$. Plugging the above into the right hand side of Equation 58, we get

$$\begin{aligned} \Psi \circ \sigma \circ (\text{Diff}(\sigma^{-1} \circ \eta)) - G(D, s_{\text{pair}}^*) &= \left(\frac{1}{2} - \frac{p-1}{2(p+1)} \right) \cdot \text{Diff}(\sigma^{-1} \circ \eta) \\ &= \frac{1}{p+1} \cdot \text{Diff}(\sigma^{-1} \circ \eta) \\ &= s_{\text{pair}}^*. \end{aligned}$$

Therefore $s_{\text{pair}} = \frac{1}{p+1} \text{Diff}(\sigma^{-1} \circ \eta)$ satisfies the implicit equation of Proposition 53, and hence must be an optimal pair-scorer for exponential loss. ■

To see why exponential loss simplifies matters, we note that the risk can be decomposed into

$$\text{Push}(\text{Diff}(s); D, \exp, \cdot^p) = \left(\mathbb{E}_{\mathcal{X} \times \mathcal{P}} [e^{-s(X)}] \right)^p \cdot \left(\mathbb{E}_{\mathcal{X} \times \mathcal{Q}} [e^{p \cdot s(X')}] \right).$$

This decomposition into the product of two expectations simplifies the derivatives considerably. In fact, an alternate strategy to determine the minimisers of the risk is to consider

$$\arg \max_{s : \mathcal{X} \rightarrow \mathbb{R}} \mathbb{E}_{\mathcal{X} \times \mathcal{Q}} [e^{p \cdot s(X')}] : \left(\mathbb{E}_{\mathcal{X} \times \mathcal{P}} [e^{-s(X)}] \right)^p \leq C;$$

this is reminiscent of the Neyman-Pearson approach to arguing for the optimal scorers for the AUC (which incidentally is the strategy we shall employ for proving Proposition 56).

As with Proposition 47, we suspect the finiteness assumption on \mathcal{X} can be dropped, although we have been unsuccessful in establishing this. Nonetheless, for this special case, the optimal scorer can be expressed as $\frac{2}{p+1} \cdot \Psi \circ \eta_{\text{pair}}$, where Ψ is the link function corresponding to exponential loss; comparing this to the optimal pair-scorer for the standard bipartite risk (Equation 50), we see that the effect of the function $g : x \mapsto x^p$ is equivalent to slightly transforming the loss ℓ ; we will explore this more in the next section.

For other losses, the optimal pair-scorer appears to be a genuinely distribution specific transformation of η_{pair} , as we illustrate in Appendix I.

9.5.2 BAYES-OPTIMAL UNIVARIATE SCORERS

We now turn attention to computing $S_{\text{push}}^*(D, \ell, g)$. For ℓ_{01} , we were unsuccessful in computing the optimal pair-scorer; nonetheless, a different technique lets us establish the optimal univariate scorers. The basic observation is that the (ℓ_{01}, g) -push risk can be interpreted as the area under the parametric curve

$$\{ (\text{FPR}(t; D, s), g(\text{FNR}(t; D, s))) : t \in \mathbb{R} \},$$

which, compared to the ROC curve $\text{ROC}(s; D)$, transforms the true positive rates (or, equivalently, one minus the true negative rates) at each corresponding false positive rate. By manipulating the choice of g , the area under this curve can thus be focus more attention on certain ranges of false negative rates. The equivalence is formalised below.

Proposition 55 *Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, $g : \mathbb{R} \rightarrow \mathbb{R}$, and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$ with differentiable ROC curve and invertible rates,*

$$\text{Push}(\text{Diff}(s); D, \ell_{01}, g) = \int_0^1 g(\text{FNR}(\text{FPR}^{-1}(a))) da.$$

Proof The proof follows how we established the 0-1 bipartite risk to an area under the curve (Proposition 21):

$$\begin{aligned} \text{Push}(\text{Diff}(s); D, \ell_{01}, g) &= \mathbb{E}_{X^{\sim}Q} \left[g(\text{FNR}(s(X))) \right] \\ &= \mathbb{E}_{X^{\sim}Q} \left[\int_{-\infty}^{\infty} \delta_{s(X)}(t) \cdot g(\text{FNR}(t)) dt \right] \\ &= \int_{-\infty}^{\infty} \mathbb{E}_{X^{\sim}Q} \left[\delta_{s(X)}(t) \cdot g(\text{FNR}(t)) \right] dt \\ &= \int_{-\infty}^{\infty} q_S(t) \cdot g(\text{FNR}(t)) dt \\ &= \int_{-\infty}^{\infty} -\text{FPR}'(t) \cdot g(\text{FNR}(t)) dt \text{ by Equation 22} \\ &= \int_0^1 g(\text{FNR}(\text{FPR}^{-1}(\alpha))) d\alpha. \end{aligned}$$

■

We can now establish the Bayes-optimal univariate scorers. (A similar result for the case of the reverse (ℓ, g) -push risk was shown in Cléménçon and Vayatis 2008, Proposition 7.)

Proposition 56 *Let g be a nonnegative, monotone increasing function. Given any $D = \langle M, \eta \rangle \in \Delta_{X \times \{\pm 1\}}$,*

$$\phi_{\text{opt}} \in \mathcal{S}_{\text{push}}^*(D, \ell_{01}, g),$$

for any strictly monotone increasing $\phi : [0, 1] \rightarrow \mathbb{R}$.

Proof Recall from Proposition 55 that the p -norm risk for the case of 0-1 loss is simply an area under the parametric curve

$$(\text{FPR}(t), g(\text{FNR}(t))) : t \in \mathbb{R} \cup \{\pm\infty\}.$$

Following the Neyman-Pearson approach to ROC maximisation (Proposition 76), maximisation of the 0-1 risk is thus equivalent to solving, for each $\alpha \in [0, 1]$

$$\underset{s : X \rightarrow \mathbb{R}}{\text{Argmin}} \quad g(\text{FNR}(t; D, s)) \text{ subject to } \text{FPR}(t; D, s) \leq \alpha.$$

Since g is a monotone increasing function, it preserves the optimal solution of the case of $g(x) = x$ (although potentially introducing new ones), which is the standard Neyman-Pearson problem. This means that for monotone increasing g , one family of optimal solutions is given by $s^* = \phi \circ \eta$, where ϕ is strictly monotone increasing. ■

Proposition 56 says that the (ℓ_{01}, g) -push objective is optimised by accurately recovering the entire ranked list. However, while they share the same optimal solution, the ordering over scorers induced by the (ℓ_{01}, g) -push risk is different from that induced by the standard bipartite ranking risk. This means that under misspecification or with finite samples, one will likely choose a different scorer by optimising the (ℓ_{01}, g) -push objective rather than the standard bipartite ranking objective. The examples in Rudin (2009) indicate that in many such cases, the solutions of the (ℓ_{01}, g) -push objective are superior to those of bipartite ranking at the head of the list.

The above trick does not work when we use a general proper composite loss ℓ , as we need to analyse a generalised Neyman-Pearson problem. However, for exponential loss and $g : x \mapsto x^p$, we can use the results of the previous section.

$$\mathcal{S}_{\text{push}}^*(D, \ell_{\text{exp}}, \eta) = \left\{ \frac{1}{p+1} \cdot (\sigma^{-1} \circ \eta) + b : b \in \mathbb{R} \right\}.$$

Proposition 57 *Pick any $D = \langle M, \eta \rangle \in \Delta_{X \times \{\pm 1\}}$. Let $\ell = \ell_{\text{exp}}$ and $p > 0$. Then, η^{opt} is finite.*

Proof By Proposition 54, the unique optimal pair-scorer is $s_{\text{Fair}}^* = \frac{1}{p+1} \cdot \text{Diff}(\sigma^{-1} \circ \eta) = \text{Diff}\left(\frac{1}{p+1}(\sigma^{-1} \circ \eta)\right)$, which is decomposable. Corollary 40 may be adapted here to argue that any optimal univariate scorer s^* must satisfy $s_{\text{Fair}}^* = \text{Diff}(s^*)$, and so $s^* = \frac{1}{p+1} \cdot (\sigma^{-1} \circ \eta) + b$ for some $b \in \mathbb{R}$. ■

For other losses, the optimal univariate scorer again appears to be distribution specific, as we illustrate in Appendix 1.

As before, the Bayes-optimal scorers for the p -norm push are closely related to those for appropriate proper composite losses (namely, those with link functions given by $\Psi = \frac{1}{p+1} \cdot \sigma$). We now study how the theory of proper composite losses suggests a recipe for constructing a family of alternate losses suitable for the ranking the best tasks.

9.6 Proper Composite Losses for Ranking the Best

Having studied the Bayes-optimality properties of the p -norm push, we now examine what this implies about the design of alternate proper composite losses for ranking the best. As shall be made precise, the p -norm push can be understood in terms of a suitable weight function over misclassification costs.

9.6.1 A WEIGHT FUNCTION PERSPECTIVE OF THE p -NORM PUSH

From Proposition 57, we see that changing p results in a scaling of the link function Ψ that is composed with η . Thus, the p -norm push has equivalent Bayes-optimal solutions, up to translation, as any strictly proper composite loss with the same link function $\Psi^{(p)} = \frac{1}{p+1} \cdot \sigma^{-1}$. One might then hope to understand the p -norm push risk by considering the risks corresponding to a family of proper composite losses $\{\ell^{(p)}\}_{p \in \mathbb{N}}$, where each member of the family comprises some fixed proper loss λ composed with an appropriately scaled sigmoidal link $\Psi^{(p)}$. However, for any $p > 0$, the resulting proper composite loss is

$$\ell^{(p)}(y, v) = \lambda(y, \Psi^{(p)}(v)) = \lambda(y, \sigma((p+1) \cdot v)) = \ell^{(0)}(y, (p+1)v).$$

That is, changing p simply scales the prediction space, and has no real impact on learning. This means that even on a finite sample, and with a restricted function class, the family of proper composite losses given by $\{\ell^{(p)}\}_{p \in \mathbb{N}}$ will have risks whose optimal solutions that are scalings of one another.

As with the ℓ_{01} case, this is not surprising. It merely indicates that the p -norm push risk must be understood in terms of its behaviour under a restricted function class or finite sample. Doing so requires that one move away from Bayes-optimal scorers, which assume access to infinite samples and an unrestricted function class. Our standard analysis based on the conditional risk thus cannot be applied.

Remarkably, it is possible to show that the p -norm push risk is equivalent to a specific proper composite risk even when minimising over a linear function class: Erekin and Rudin (2011, Theorem 1) shows that for a linear function class, the p -norm push risk with exponential loss is equivalent to the proper composite risk corresponding to the p -classification loss, defined by

$$(\forall v \in \mathbb{R}) \ell_{\text{pd}}(v; p) = \left(\frac{1}{p} \cdot e^{pv}, e^{-v} \right). \quad (59)$$

Interestingly, this loss is proper composite.

Lemma 58 For any $p > 0$, let $\ell = \ell_{\text{ped}}(\cdot; p)$ be the p -classification loss of Equation 59. Then, $\ell \in \mathcal{L}_{\text{SPC}}(\Psi^{(p)})$, where $(\Psi^{(p)})^{-1} : v \mapsto \sigma((p+1) \cdot v)$. Further, the underlying proper-loss $\lambda_{\text{ped}}(\cdot; p)$ is

$$(\forall u \in [0, 1]) \lambda_{\text{ped}}(u; p) = \left(\frac{1}{p} \cdot \left(\frac{u}{1-u} \right)^{1-\frac{1}{p+1}}, \left(\frac{1-u}{u} \right)^{\frac{1}{p+1}} \right).$$

Proof We can check that for $\Psi = \Psi^{(p)}$,

$$\begin{aligned} (\forall v \in \mathbb{R}) \Psi^{-1}(v) &= \frac{1}{1 - \frac{\ell(v)}{\sigma(v)}} \\ &= \frac{1}{1 + e^{-(p+1)v}} \\ &= \sigma((p+1) \cdot v), \end{aligned}$$

which is invertible, thus guaranteeing that ℓ is proper composite. It may be checked that the underlying proper loss is

$$\begin{aligned} (\forall u \in [0, 1]) \lambda_{\text{ped}}(u; p) &= \ell_{\text{ped}}(\Psi^{(p)}(u); p) \\ &= \left(\frac{1}{p} \cdot \left(\frac{u}{1-u} \right)^{1-\frac{1}{p+1}}, \left(\frac{1-u}{u} \right)^{\frac{1}{p+1}} \right). \end{aligned}$$

Given the loss ℓ_{ped} is proper composite, the agreement of the p -norm and p -classification risk minimisers is trivial in the unrestricted function class setting; however, it is not obvious in the linear class setting. The equivalence to p -classification is valuable, since we can analyse the proper composite loss to understand how it focusses accuracy at the head of the ranked list. We will do this by considering the corresponding weight function for the proper loss $\lambda = \lambda_{\text{ped}}(\cdot; p)$,

$$\begin{aligned} (\forall c \in (0, 1)) u_{\text{ped}}(c; p) &= -\frac{\lambda'(c)}{1-c} \text{ (by (Reid and Williamson, 2010), Theorem 1))} \\ &= \frac{1}{p+1} \cdot \frac{1}{c^{1+\frac{1}{p+1}} \cdot (1-c)^{2-\frac{1}{p+1}}}. \end{aligned}$$

This is a generalised version of the weight for the boosting loss (Table 3), which corresponds to $p = 1$.

The above weight function view has at least three benefits. First, given the equivalence of the p -classification and p -norm push risk, we have some insight as to how the latter encourages solutions to maximise accuracy at the head of the ranked list: as p increases, the loss is seen to place relatively more weight on larger values of c . That is, we pay attention to those instances with high η values, as accurate modelling of these is essential for determining the behaviour about the boundary $\eta(x) = c$.

Second, we can design normalised versions of the p -classification loss that have more interpretable behaviour when $p \rightarrow \infty$. Evidently, $u_{\text{ped}}(c; p)$ above tends to the trivial zero weight as $p \rightarrow \infty$, owing to the scaling factor of $(p+1)^{-1}$. Removing this scaling factor ensures that the weights are normalised for every $p > 0$, in the sense that $w(1/2; p) = 8$. Further, the resulting proper loss is easily verified to be

$$(\forall u \in [0, 1]) \lambda(u; p) = \left(\left(1 + \frac{1}{p} \right) \cdot \left(\frac{u}{1-u} \right)^{1-\frac{1}{p+1}}, (p+1) \cdot \left(\frac{1-u}{u} \right)^{\frac{1}{p+1}} - 1 \right),$$

with non-trivial limiting case as $p \rightarrow \infty$ of

$$(\forall u \in [0, 1]) \lambda(u; +\infty) = \left(\frac{u}{1-u}, -\log \frac{u}{1-u} \right).$$

When composed with the sigmoid link $\sigma(\cdot)$, this normalised family of proper losses results in the proper composite family

$$(\forall v \in \mathbb{R}) \ell(v; p) = \left(\left(1 + \frac{1}{p} \right) \cdot e^{\frac{p}{p+1}v}, (p+1) \cdot \left(e^{-\frac{v}{p+1}} - 1 \right) \right), \quad (60)$$

with non-trivial limiting case as $p \rightarrow \infty$ of

$$(\forall v \in \mathbb{R}) \ell(v; +\infty) = (e^v, -v).$$

Third, the weight function view suggests a scheme of *designing new losses* for ranking the best, by constructing appropriate weight functions emphasising large values of η . We now pursue this idea.

9.6.2 STRICT PROPERNESS AND q -RTB LOSSES

We now study the design of q -RTB losses based on the theory of proper composite losses. We begin with the simple observation that any strictly proper composite loss is a q -RTB loss for every $q \in [0, 1]$, by virtue of choosing the corresponding link function Ψ in Equation 52. More generally, the set of q -RTB losses is exactly the set of proper composite losses ℓ for which $\lambda = \ell \circ \Psi^{-1}$ is strictly proper on the interval $\eta \in [q, 1]$ and (not necessarily strictly) proper on the interval $[0, q]$. This suggests a simple recipe for designing q -RTB losses; however, as we shall see, not enforcing strict properness poses computational challenges.

A key difficulty in designing q -RTB losses is the following. Suppose λ is a proper loss that is not strictly proper on an interval $I \subseteq [0, 1]$. Then, λ is non-convex, and more importantly, cannot be made convex via a link function. To see this, recall that the canonical link function Ψ for a proper loss λ is the function for which $\lambda \circ \Psi^{-1}$ has the largest modulus of convexity. The weight function w of λ is related to the canonical link function Ψ by $w = \Psi'$. As λ is not strictly proper on I , we must have that $w \equiv 0$ on I . But then Ψ must be constant on I , and hence not invertible. Thus, to maintain convexity, it is essential to maintain strictness of the proper composite loss.

As a simple example, suppose λ is some strictly proper loss with weight function w . Now for some $q > 0$, consider the loss $\lambda_{\text{RTB}}(\cdot; q)$ with weight function

$$u_{\text{RTB}}(c; q) = \mathbb{I}[c \geq q] \cdot w(c). \quad (61)$$

This loss is not strictly proper on the interval $[0, q]$, and is strict on $[q, 1]$. Therefore, the loss aims to accurately model instances x for which $\eta(x) \geq q$. We can explicitly compute the partial losses for $\lambda_{\text{RTB}}(\cdot; q)$ as follows.

Lemma 59 Pick any proper loss λ with weight function w . For any $q > 0$, let $w_{\text{RTB}}(c; q)$ be the weight function given by Equation 61. Then, this weight has corresponding proper loss

$$\begin{aligned} (\forall u \in [0, 1]) \lambda_{\text{RTB}}(-1, u; q) &= \lambda_{-1}(u) - \lambda_{-1}(u \wedge q) \\ \lambda_{\text{RTB}}(+1, u; q) &= \lambda_1(u \vee q). \end{aligned}$$

Proof By Shuford's integral representation (Equation 10),

$$\begin{aligned} \lambda_{\text{RTB}}(-1, u; q) &= \int_0^1 \mathbb{I}[c < u] \cdot \mathbb{I}[c \geq q] \cdot c \cdot w(c) dc \\ &= \int_0^1 \mathbb{I}[c < u] \cdot c \cdot w(c) dc - \int_0^1 \mathbb{I}[c < u] \cdot \mathbb{I}[c < q] \cdot c \cdot w(c) dc \end{aligned}$$

$$\begin{aligned}
&= \int_0^1 \llbracket c < u \rrbracket \cdot c \cdot w(c) dc - \int_0^1 \llbracket c < u \wedge q \rrbracket \cdot c \cdot w(c) dc \\
&= \lambda_{-1}(u) - \lambda_{-1}(u \wedge q). \\
\lambda_{\text{RTB}(q)}(+1, u; q) &= \int_0^1 \llbracket c > u \rrbracket \cdot \llbracket c \geq q \rrbracket \cdot (1 - c) \cdot w(c) dc \\
&= \int_0^1 \llbracket c > u \vee q \rrbracket \cdot (1 - c) \cdot w(c) dc \\
&= \lambda_1(u \vee q).
\end{aligned}$$

When the prediction $u \geq q$, the partial losses of $\lambda_{\text{RTB}}(\cdot; q)$ are unchanged from those of λ , barring a translation for λ_{-1} . However, when $u < q$, the partial loss for the positive class plateaus, whereas the partial loss for the negative class drops to zero. The resulting loss is clearly non-convex, and further, *no* invertible link function can be applied to make it convex: composing $\lambda_{\text{RTB}}(\cdot; q)$ with an invertible link function Ψ yields a loss ℓ_{RTB} with partial losses

$$\begin{aligned}
\ell_{\text{RTB}}(-1, v; q) &= \ell_{-1}(v) - \ell_{-1}(v \wedge \Psi(q)) \\
\ell_{\text{RTB}}(+1, v; q) &= \ell_1(v \vee \Psi(q)).
\end{aligned}$$

which are not convex for any choice of Ψ .

A natural alternative to a loss that is not strictly proper is one that is “nearly” so, i.e. one whose weight function w is close to, but never exactly 0. However, this must be done with the following fact in mind: for any $\alpha > 0$, the proper loss with scaled weight function $\alpha \cdot w$ is simply the scaled loss $\alpha \cdot \lambda$. Thus, uniformly scaling a weight function does not affect the strict properness of the underlying loss. Scaling a loss on an interval $I \subset [0, 1]$ will however induce a qualitatively different loss: minimally, the new loss will be asymmetric, and have a non-trivially different set of Bayes-optimal scorers compared to the original loss. We now explore how proper composite losses can be designed to approximate a q -RTB loss.

9.6.3 PROPER COMPOSITE q -RTB SURROGATES

Our basic recipe for generating a q -RTB loss will be to combine the weight functions for two existing losses. Specifically, let w_ν, w_μ be weight functions corresponding to proper losses ν, μ . We assume that w_μ grows faster near 1 than w_ν does near 0, i.e. $\lim_{\alpha \rightarrow -1} \frac{w_\mu(\alpha)}{w_\nu(1-\alpha)} > 1$. (We will typically be interested in the case where the limit is $+\infty$.) We now consider a hybrid weight function of the form

$$\begin{aligned}
(\forall c \in (0, 1)) w(c; q) &= \begin{cases} w_\nu(c) & \text{if } c < q \\ \alpha(q) \cdot w_\mu(c) & \text{if } c \geq q \end{cases} \\
&= w_\nu(c) \cdot \llbracket c < q \rrbracket + \alpha(q) \cdot w_\mu(c) \cdot \llbracket c \geq q \rrbracket,
\end{aligned} \tag{62}$$

where $\alpha(q) = \frac{w_\nu(q)}{w_\mu(q)}$ so that there is no discontinuity at $c = q$.

Since $w(c; q)$ is the sum of two weights, we can compute the corresponding proper losses for each component to get the form of the corresponding proper loss.

Lemma 60 *Pick any weight functions $w_\nu, w_\mu : [0, 1] \rightarrow \mathbb{R}_+$ with corresponding proper losses ν, μ . For any $q > 0$, let $w(\cdot; q)$ be as per Equation 62. Then, the proper loss corresponding to this weight is*

$$\begin{aligned}
(\forall u \in [0, 1]) \bar{\lambda}_{-1}(u; q) &= \alpha(q) \cdot \mu_{-1}(u) + \nu_{-1}(u \wedge q) - \alpha(q) \cdot \mu_{-1}(u \wedge q) \\
\bar{\lambda}_1(u; q) &= \nu_1(u) + \alpha(q) \cdot \mu_1(u \vee q) - \nu_1(u \vee q),
\end{aligned} \tag{63}$$

where $\alpha(q) = \frac{w_\nu(q)}{w_\mu(q)}$.

Proof By Lemma 59, the weight $w_\nu(c) \cdot \llbracket c < q \rrbracket = w_\nu(c) - w_\nu(c) \cdot \llbracket c \geq q \rrbracket$ corresponds to the proper loss

$$\bar{\nu}(u) = (\nu_{-1}(u \wedge q), \nu_1(u) - \nu_1(u \vee q))$$

while the weight $\alpha(q) \cdot w_\mu(c) \cdot \llbracket c \geq q \rrbracket$ corresponds to the proper loss

$$\bar{\mu}(u) = (\alpha(q) \cdot \mu_{-1}(u) - \alpha(q) \cdot \mu_{-1}(u \wedge q), \alpha(q) \cdot \mu_1(u \vee q)).$$

Thus, the weight w corresponds to the sum of these losses, which is of the given form. \blacksquare

We may similarly combine proper composite losses corresponding to the underlying weights into a continuous proper composite loss corresponding to the weight $w(\cdot; q)$:

Lemma 61 *Suppose that proper losses ν, μ have corresponding proper composite losses $\bar{\nu}, \bar{\mu}$ using invertible link functions Ψ, Φ . For any $q > 0$, let $w(\cdot; q)$ be as per Equation 62. Then, $w(\cdot; q)$ has corresponding proper composite loss ℓ with components*

$$\begin{aligned}
(\forall v \in \mathbb{R}) \bar{\ell}_{-1}(v; q) &= \begin{cases} \rho_{-1}(v) & \text{if } v < v_0(q) \\ \bar{\kappa}_{-1}(v; q) + \rho_{-1}(v_0) - \bar{\kappa}_{-1}(v_0; q) & \text{else} \end{cases} \\
\bar{\ell}_1(v; q) &= \begin{cases} \rho_1(v) + \bar{\kappa}_1(v_0; q) - \rho_1(v_0) & \text{if } v < v_0(q) \\ \bar{\kappa}_1(v; q) & \text{else,} \end{cases}
\end{aligned}$$

where $v_0(q) = \Psi(q)$, and

$$\begin{aligned}
\bar{\kappa}(y; v; q) &= \alpha(q) \cdot \kappa \left(y, \frac{v - \beta(q)}{\gamma(q)} \right) \\
\beta(q) &= \Psi(q) - \gamma(q) \cdot \Phi(q) \\
\gamma(q) &= \frac{\Psi'(q)}{\Phi'(q)}.
\end{aligned}$$

Proof By definition, we have

$$\begin{aligned}
\rho(y; v) &= \nu(y, \Psi^{-1}(v)) \\
\kappa(y; v) &= \mu(y, \Phi^{-1}(v)).
\end{aligned}$$

Given any $q > 0$, we will construct a proper composite loss using the proper loss $\bar{\lambda}(\cdot; q)$ of Equation 63, composed with a link function Π that is a suitable combination of Ψ and Φ . The technical detail to attend to is to ensure there are no discontinuities with the resulting loss.

First, to ensure that the link for the two pieces of $\bar{\lambda}$ coincide, with the same derivative at the threshold q , we modify the link for the second loss to

$$\bar{\Phi}(c; q) \doteq \gamma(q) \cdot \Phi(c) + \beta(q),$$

where

$$\begin{aligned}
\beta(q) &= \Psi(q) - \gamma(q) \cdot \Phi(q) \\
\gamma(q) &= \frac{\Psi'(q)}{\Phi'(q)}.
\end{aligned}$$

Note that if $\Psi'(q) = \Phi'(q)$, this simplifies to the translated link $\Phi(c) + \Psi(q) - \Phi(q)$. This modified link has inverse

$$\tilde{\Phi}^{-1}(v; q) = \Phi^{-1}\left(\frac{v - \beta(q)}{\gamma(q)}\right).$$

Now define the hybrid link

$$\Pi(c; q) = \llbracket c < q \rrbracket \cdot \Psi(c) + \llbracket c \geq q \rrbracket \cdot \tilde{\Phi}(c; q)$$

with corresponding inverse

$$\Pi^{-1}(v; q) = \llbracket v < v_0(q) \rrbracket \cdot \Psi^{-1}(v) + \llbracket v \geq v_0(q) \rrbracket \cdot \tilde{\Phi}^{-1}(v; q)$$

for $v_0(q) = \Psi(q) = \tilde{\Phi}(q; q)$. Then, the proper loss corresponding to \tilde{w} can be made proper composite, with

$$\begin{aligned} \tilde{\ell}(-1, v; q) &= \bar{\kappa}_{-1}(v; q) + \rho_{-1}(v \wedge v_0) - \bar{\kappa}_{-1}(v \wedge v_0; q) \\ \tilde{\ell}(+1, v; q) &= \rho_1(v) + \bar{\kappa}_1(v \vee v_0; q) - \rho_1(v \vee v_0), \end{aligned}$$

where

$$\begin{aligned} \bar{\kappa}(y, v; q) &= \alpha(q) \cdot \mu(y; (\tilde{\Phi}^{-1}(v))) \\ &= \alpha(q) \cdot \kappa\left(y, \frac{v - \beta(q)}{\gamma(q)}\right). \end{aligned}$$

The basic idea of the loss ℓ' in Equation 63 is intuitive: one switches between choosing one of the underlying losses based on some threshold on the scores. The only additional ingredient is that scaling and translating one of the losses to ensure continuity of the end result. We provide examples that illustrate the basic idea.

- Consider the weight function

$$w(c) = \begin{cases} \frac{1}{c^{1-\alpha}} & \text{if } c < q \\ \frac{2\sqrt{q(1-q)}}{c^{3/2}(1-c)^{3/2}} & \text{if } c \geq q, \end{cases}$$

which is a hybrid of the weights for logistic and exponential loss. Using the sigmoid link yields the loss (for $q = \frac{1}{2}$)

$$\ell(v) = \begin{cases} \log(1 + e^v) & \text{if } v < 0 \\ e^{v/2} + \log 2 - 1 & \text{if } v \geq 0 \end{cases}, \begin{cases} \log(1 + e^{-v}) - \log 2 + 1 & \text{if } v < 0 \\ e^{-v/2} & \text{if } v \geq 0 \end{cases}.$$

- Consider the weight function

$$w(c) = \begin{cases} 4 & \text{if } c < q \\ \frac{2\sqrt{q(1-q)}}{c^{3/2}(1-c)^{3/2}} & \text{if } c \geq q, \end{cases}$$

which is a hybrid of the weights for square and exponential loss. Using an appropriate hybrid of the identity and sigmoid link yields the loss (for $q = \frac{1}{2}$)

$$\ell(v) = \begin{cases} \frac{1}{2} \cdot (1 + v)^2 & \text{if } v < 0 \\ e^{v/2} - \frac{1}{2} & \text{if } v \geq 0 \end{cases}, \begin{cases} \frac{1}{2} \cdot (1 - v)^2 + \frac{1}{2} & \text{if } v < 0 \\ e^{-v/2} & \text{if } v \geq 0 \end{cases}.$$

- Consider for $p > 0$ the family of weights

$$w(c; p) = \frac{1}{c \cdot (1 - c)^{2 - \frac{1}{p}}},$$

which are similar to those employed by p -classification, except that the behaviour near $c = 0$ is fixed, and does not vary with p . Though not explicitly a hybrid, the weight is asymmetric, and thus the role of p is to tune the degree of focus on large values of η . For example, when $p = 1$, with the sigmoid link we have the proper composite loss

$$\ell(v) = \left(\frac{2}{\sqrt{\sigma(-v)}}, 2 \tanh^{-1}(\sqrt{\sigma(-v)}) \right).$$

As another example, when $p = 3$, we get

$$\ell(v) = \left(\frac{4}{3\sigma(-v)^{3/4}}, 2 \tanh^{-1}((\sigma(-v))^{1/4}) + 2 \tanh^{-1}((\sigma(-v))^{1/4}) \right).$$

It is clear that the above recipe can be applied for any suitable combination of weight functions, which we have argued to focus attention at the head of the ranked list. How do we choose amongst several such candidate weight functions? Put another way, can we characterise which hybrid weight function is the “best”? Answering such a question requires a precise sense in which one loss is “better” than another. This issue is only superficially simple, as even in binary classification for example, one cannot expect any given surrogate to be uniformly superior to all others in terms of resulting misclassification error (Reid and Williamson, 2010, Appendix A). Nonetheless, relating for example the weight function of a proper loss to generalisation ability in terms of a performance measure such as PTop would be of interest.

We emphasise also that the above represents just one recipe for generating suitable proper composite losses. If one can generate a suitable parametrised family of weights and link function generating a convex loss (e.g. the scaled p -classification loss of Equation 60), these would also be suitable for ranking the best problems.

9.7 Experiments with Proper Composite Losses for Ranking the Best

We present experiments that assess the efficacy of several proper composite losses proposed in the previous section for the problem of maximising accuracy at the head of the ranked list. The aim of our experiments is *not* to position the new losses as a superior alternative to the existing p -classification and p -norm push approaches. Rather, we wish to demonstrate that the proper composite interpretation gives one way of generating a family of losses for this problem, with the p -classification loss being but one example of this family. An attraction of these losses is that they are simple to optimise using gradient-based methods, with complexity linear in the number of training examples (as opposed to methods that operate on pairs of examples).

To clarify the effect of the choice of loss and choice of risk, we consider all combinations of the three risk types considered in this paper—proper composite (Equation 14), bipartite (Equation 17), and p -norm push (Equation 56)—and the loss functions of interest. On the one hand, one expects the p -norm push risk to perform best when combined with a loss suitable for ranking the best. On the other hand, our analysis in the previous section indicates that there is promise in the minimisation of a suitable proper composite risk.

For our losses, we experiment with the standard logistic and exponential losses, as well as the p -classification loss. Based on our hybrid loss proposal in Lemma 61, we consider the following:

- The proper composite loss with weight $w(c) = \frac{1}{c^{2-\frac{1}{p}}}$, and sigmoid link, which we term the “Log-classification Hybrid”;
- The proper composite loss with weight being a hybrid of $\frac{1}{c(1-c)}$ and $\frac{1}{2 \cdot e^{v/2} \cdot (1-c)^{3/2}}$ about threshold $\frac{1}{p+1}$, and sigmoid link, which we term the “Log-Exp Hybrid”;

- The proper composite loss with weight being a hybrid of 4 and $\frac{1}{2 \cdot \sigma^{1/2} \cdot (1 - \sigma)^{1/2}}$ about threshold $\frac{1}{p+1}$ and link being a hybrid of the identity and sigmoid link, which we term the ‘‘Square-Exp Hybrid’’.

We compare these methods on four UCI data sets: ionosphere, housing, german and car. Each method was trained with a regularised linear model, where the training objective was minimised using L-BFGS (Nocedal and Wright, 2006, pg. 177). For each data set, we created 5 random train-test splits in the ratio 2 : 1. For each split, we performed 5-fold cross-validation on the training set to tune the strength of regularisation $\lambda \in \{10^{-6}, 10^{-5}, \dots, 10^2\}$, and where appropriate the constant 22 $p \in \{1, 2, 4, 8, 16, 32, 64\}$. We then evaluated performance on the test set, and report the average across all splits. As performance measures, we used the AUC, ARR, DCG, AP, and PTop (Agarwal, 2011; Boyd et al., 2012). For all measures, a higher score is better. Parameter tuning was done based on the AP on the test folds.

The results are summarised in Tables 10–13, with the average ranks of each method with respect to each metric summarised in Table 14. No single method clearly outperforms all others in all metrics. However, we observe that the candidate proper composite losses are very competitive with the p -classification loss—the ‘‘Log-exp hybrid’’ and ‘‘Square-exp’’ hybrid in particular consistently perform comparably, and often better than p -classification. We especially find that the newly proposed proper composite losses perform well even when used as a surrogate loss as part of the bipartite risk. This confirms that the weight function perspective of the p -classification loss, and thus the p -norm push, is potentially practically useful for the design of losses suitable for ranking the best.

9.8 Existing Work

Clemenson and Vayatis (2007) identified two subproblems in ranking the best instances. The first problem is determining which instances qualify as the best. The second problem is ranking amongst these identified best instances. The first problem can be thought of as simply recovering an appropriate level set of $\eta(x)$, without determining the specific $\eta(x)$ value, i.e. we simply wish to discover

$$\{x \in \mathcal{X} : \eta(x) \geq q\}.$$

When q is fixed, this can be solved by reducing the problem to cost-sensitive classification (Scott andavenport, 2007). More generally, Clemenson and Vayatis (2007) considered the setting where q depends on the quantile of the scoring function. This poses challenges for analysis and estimation. The quantile version of the problem has been studied theoretically by Clemenson and Vayatis (2007), and (Boyd et al., 2012) gave a practical convex optimisation solution for the case of hinge loss. In both cases, the threshold q was specified as a quantile of the η .

The problem of ranking amongst the best instances with a quantile-based threshold was studied theoretically by Clemenson and Vayatis (2007), who proposed that the optimal univariate scoring function here must satisfy

$$s^*(x) \in \begin{cases} \{\eta(x)\} & \text{if } \eta(x) \geq q_p \\ [0, q_p] & \text{if } \eta(x) < q_p \end{cases}$$

Observe that this is identical to our Equation 52, except that q is now a function of η . They showed that two ‘‘local’’ versions of the AUC criterion, one of which is related to the partial AUC mentioned earlier, are optimised by this scorer. To our knowledge, our analysis in terms of proper losses for the simpler case where q is a fixed constant has not been done before.

Ertekin and Rudin (2011, Theorem 1) showed that for the case of a linear hypothesis class and $p \geq 1$, the Bayes optimal scorer for the p -norm push coincides with the classification risk for the asymmetric p -classification loss function of Equation 59. The optimal scorer for this loss is easily checked to be $s^* = \frac{1}{p+1} \cdot (\sigma^{-1} \circ \eta)$, and so in the unrestricted hypothesis class setting, the result agrees with ours. Our result is

22. We have observed that the parameter p selected by cross-validation may not necessarily correspond to the one that gives best test set performance, possibly a result of the limited sizes of the data sets in consideration. Treating each choice of p as resulting in a separate loss might therefore reveal slightly different rankings of the (loss, risk) combinations we consider.

Table 14: Average ranks of various “ranking the best” methods for each performance measure across all data sets.

more general in the sense of being for an unrestricted hypothesis class, and uses proper loss techniques. The result of [Erekin and Rudin \(2011\)](#) holds for the case of a linear (possibly misspecified) function class.

Variants of the p -norm push have been proposed, although the focus has been on algorithmic issues ([Rudin, 2009; Agarwal, 2011; Li et al., 2014](#)).

[Cossock and Zhang \(2008\)](#) proposed to use an importance weighting approach to the problem of focussing on the head of the ranked list, and showed that the DCG of a ranking can be bounded by importance weighted squared error:

10. Exact Compositional Reductions Between Classification and Ranking

We have introduced several seemingly distinct problems above, among them classification, class-probability estimation, pairwise ranking, and bipartite ranking. We now map out the relationships between these problems.²³ Our focus is on whether the Bayes-optimal solution for one of these problems can be transformed to give the optimal solution for another problem. Formally, for some pair of problems (A, B) —where we understand a “problem” to mean a specification of a distribution and loss, and hence the Bayes-optimal solutions—we would like to know if

$$(\forall s \in \mathcal{S}^{B \rightarrow \mathbb{R}})(\exists f : \mathbb{R} \rightarrow \mathbb{R}) f \circ s \in \mathcal{S}^{A*}$$

and vice-versa. When the above is true, we have an *exact compositional reduction* from A to B , in the sense of [problem A providing an optimal solution for problem B via a transformational \$f\$](#) .²⁴ According to our definition,

23. We will focus on the case of 0-1 loss for bipartite ranking, as this is the canonical performance measure in most studies. Recalling that the ℓ -bipartite ranking risk has equivalent Bayes-optimal solutions to class-probability estimation for certain strictly proper composite ℓ , the results derived here for class-probability estimation can be translated to the ℓ -bipartite ranking risk as well.

24. In practice, one must consider the impact misspecified hypothesis classes and finite samples have on transforming the solution of one problem to another. The recent work of [Narasimhan and Agarwal \(2013b\)](#) considers regret and generalisation bounds to this end.

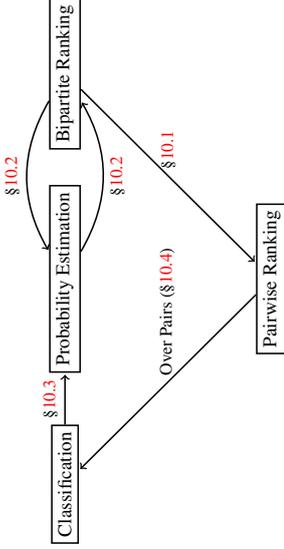

Figure 2: Relationships amongst various ranking and classification problems. An arrow $A \rightarrow B$ denotes that A is a special case of B , with the label on the arrow providing context on the relationship.

the transformation f may depend on the distribution specified by B . When this is so, the reduction is “weak” in the terminology of Narasimhan and Agarwal (2013b). When f is independent of B , the reduction is “strong” in the terminology of Narasimhan and Agarwal (2013b).

A sufficient condition for two problems to have the same Bayes-optimal solutions is the equivalence of the risks for the two problems. In some cases, this equivalence will be apparent from the specifications of the problem.

Figure 2 summarises the relationships amongst the various classification and ranking problems discussed in this paper. We now discuss these relationships in more detail.

10.1 Bipartite Ranking \subset Pairwise Ranking

The bipartite ranking risk for a pair-scorer is defined with respect to a classification distribution D , while the pairwise ranking risk is defined with respect to a ranking distribution R . Therefore, in general for the two quantities to be equal, we need to have some relationship between the distributions $D \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$ and $R \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$. The following shows that bipartite ranking is strictly a special case of pairwise ranking.

Proposition 62 *Pick any loss ℓ and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$. Then, for every $D \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$ there is some $R \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$ such that*

$$\mathbb{L}_{\text{BR}}(s; D, \ell) = \mathbb{L}(\text{Diff}(s); R, \ell).$$

Further, there exists some $R \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}$ such that

$$(\exists D \in \Delta_{\mathcal{X} \times \mathcal{X}(\pm 1)}) \mathbb{L}_{\text{BR}}(s; D, \ell) = \mathbb{L}(\text{Diff}(s); R, \ell).$$

Proof The first statement is immediate by setting $R = D_{\text{BR}}$, from Lemma 2. For the second statement, suppose there were such a D . Then by Lemma 2, it must be true that

$$\mathbb{L}(\text{Diff}(s); R, \ell) = \mathbb{L}(\text{Diff}(s); D_{\text{BR}}, \ell).$$

Thus, it must be true that $R = D_{\text{BR}}$. However, if we choose R with base rate different from $\frac{1}{2}$, this cannot be possible, since D_{BR} has base rate $\frac{1}{2}$ by construction. We have a contradiction, and the result is shown. ■

Proposition 62 formalises the intuition that pairwise ranking is more general than bipartite ranking: there exist instances of the former (even when operating over decomposable pair-scorers) that cannot be solved by the latter.

10.2 Bipartite Ranking = Class-Probability Estimation

We show that the Bayes-optimal solutions for bipartite ranking and class-probability estimation (with a strictly proper composite loss) may be transformed to one another. For bipartite ranking, the Bayes-optimal solution must be transformed in a distribution dependent manner (specifically, it must be calibrated with respect to the distribution).

Proposition 63 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and $\ell \in \mathcal{L}_{\text{SPC}}$,*

$$\begin{aligned} & (\forall s \in S^*(D, \ell)) s \in S_{\text{BR}}^*(D, \ell_{01}) \\ & (\forall s \in S_{\text{BR}}^*(D, \ell_{01})) (\exists f^D) f^D \circ s \in S^*(D, \ell). \end{aligned}$$

Proof Pick $s \in S^*(D, \ell)$. By Equation 44, this s is unique, and satisfies $s = \Psi \circ \eta$. Thus, by Corollary 43, $s \in S_{\text{BR}}^*(D, \ell_{01})$.

Now pick $s \in S_{\text{BR}}^*(D, \ell_{01})$. By Proposition 42, $\eta = \phi \circ s$ for some non-decreasing ϕ . Thus, by Lemma 74, the calibrated version $\text{Cal}(s; D)$ of s must equal η . Letting $f^D = \Psi \circ \text{Cal}(\cdot; D)$ gives the result. ■

The strict properness of the proper composite loss is essential for these results. Given a non-strictly proper composite loss, such as 0-1 loss, it is not true that every Bayes-optimal solution is also optimal for bipartite ranking, as we will now see.

10.3 Classification \subset Class-Probability Estimation

Class-probability estimation can be shown to be a more general problem than binary classification, in the sense that an optimal solution for the former can be transformed to one for the latter, but the other direction is only true for certain classes of distributions.

Proposition 64 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ and $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$,*

$$\begin{aligned} & (\forall s \in S^*(D, \ell)) (\exists f) f \circ s \in S^*(D, \ell_{01}) \\ & (\forall s \in S^*(D, \ell_{01})) (\exists f^D) f^D \circ s \in S^*(D, \ell) \iff (\forall x \in \mathcal{X}) \eta(x) \in \{a, b\}, \end{aligned}$$

where $a = b \neq \frac{1}{2}$ or $(2a - 1)(2b - 1) < 0$, i.e. η is constant or takes on exactly two values on different sides of $1/2$.

Proof For the first result, pick $s \in S^*(D, \ell)$. By Equation 44, this s is unique, and satisfies

$$s = \Psi \circ \eta.$$

Since $2\eta - 1 \in S^*(D, \ell_{01})$ (Equation 43), we can transform s to get an optimal solution for 0-1 loss.

For the second result, suppose that $\eta \in \{\frac{1}{2}, 1\}$. Then the scorer $\lfloor \eta \geq 1/2 \rfloor \equiv 1$ is in $S^*(D, \ell_{01})$ by Equation 43. This scorer takes on exactly one value. Therefore, it cannot be transformed to a function that takes on two or more values. (Note that there may exist some scorers that can be transformed to give η , but this is not the proposition in question.) A similar argument shows that we cannot handle the case where η takes on three or more values.

Now suppose that η satisfies the given conditions, and pick any $s \in S^*(D, \ell_{01})$. We know that $\text{sign}(s) = \text{sign}(2\eta - 1)$. Supposing without loss of generality that $a \leq b$, we have

$$\Psi \circ f^D \circ s = \Psi \circ \eta \in S^*(D, \ell)$$

where $f^D(x) = b \cdot \lfloor x > 0 \rfloor + a \cdot \lfloor x < 0 \rfloor$. ■

The restriction on η above is satisfied by *separable* or *noiseless* distributions, where for every $x \in \mathcal{X}$, $\eta(x) \in \{0, 1\}$. The above thus shows the intuitive fact that in the absence of noise, classification and class-probability estimation are equivalent in terms of their end goals.²⁵

10.4 Classification Over Pairs = Pairwise Ranking

We can confirm that pairwise ranking is equivalent to binary classification over the instance space $\mathcal{X} \times \mathcal{X}$ by simply comparing the risks for the two problems (Equations 19 and 14). This implies that bipartite ranking is also a special case of binary classification over $\mathcal{X} \times \mathcal{X}$, due to the relationship between bipartite and pairwise ranking established in §10.1.

10.5 Classification Over Singletons \subset Bipartite Ranking

While bipartite ranking reduces to classification over *pairs*, it does not reduce to classification over *singletons*, except in special cases. We now present conditions for the equivalence of the Bayes-optimal solutions of the two problems.

Proposition 65 *Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{1\}}$:*

$$\begin{aligned} (\forall s \in \mathcal{S}_{\text{BR}}^*(D, \ell_{01})) (\exists f) f \circ s \in \mathcal{S}^*(D, \ell_{01}) \\ (\forall s \in \mathcal{S}^*(D, \ell_{01})) (\exists f) f \circ s \in \mathcal{S}_{\text{BR}}^*(D, \ell_{01}) \iff (\forall x \in \mathcal{X}) \eta(x) \in \{a, b\}, \end{aligned}$$

where $a = b \neq \frac{1}{2}$ or $(2a - 1)(2b - 1) < 0$, i.e. η is constant or takes on exactly two values on different sides of 1/2.

Proof The result follows by the established relationships between classification and class-probability estimation (§10.3), and class-probability estimation and bipartite ranking (§10.2). ■

As with class-probability estimation, the above shows that for separable distributions, bipartite ranking is equivalent to binary classification in terms of the end goal.

10.6 Relation to Existing Work

For the case of 0-1 loss, the fact that the bipartite ranking risk exactly equals a specific pairwise classification risk (and hence a specific pairwise ranking risk) is well known (Clemençon et al., 2008; Kotowski et al., 2011; Demaiusi and Lee, 2012; Agarwal, 2014). The derived ranking distribution D_{BR} , which explicitly specifies the pairwise ranking distribution for which this holds, has been invoked by Balcan et al. (2008); Kotowski et al. (2011); Agarwal (2014), among others. Our generalisation to an arbitrary loss ℓ , while simple, appears novel.

Our study of the relationship between the bipartite and pairwise ranking problems differs from that of Balcan et al. (2008); Ailon and Mohri (2007) in at least two aspects. First, those works look at a *subset* version of bipartite ranking, where the goal is to rank a given subset of instances. Second, those works consider the goal of bipartite ranking to produce a univariate scorer rather than a pair-scorer. Therefore, they consider the question of how one can derive a univariate scoring function suitable for ranking from a classifier over pairs. The main result of Balcan et al. (2008) is that, given a classifier of pairs that achieves small classification risk, one can produce a univariate scorer with bipartite ranking risk that is worse by at most a factor of two.

11. Four Bipartite Ranking Risks With Equivalent Minimisers

Consider the following approaches to producing a pair-scorer, given a strictly proper composite ℓ :

²⁵ However, as noted earlier, for separable data the infimum in the definition of the Bayes risk may be unattainable for a strictly proper composite loss.

$$\begin{array}{ll} (1) \text{ Diff} \left(\underset{s: \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{R}}{\text{argmin}} \mathbb{E}_{X \sim P_X, X' \sim Q} [e^{-\langle s(X), X' \rangle}] \right) & (2) \text{ Diff} \left(\underset{s: \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{R}}{\text{argmin}} \mathbb{E}_{X \sim P_X, X' \sim Q} [e^{-\langle s(X), -s(X') \rangle}] \right) \\ (3) \underset{\Psi_{\text{BR}}: \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{R}}{\text{argmin}} \mathbb{E}_{X \sim P_X, X' \sim Q} [e^{-\langle \Psi_{\text{BR}}(X, X') \rangle}] & (4) \text{ Diff} \left(\underset{s: \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{R}}{\text{argmin}} \mathbb{E} \left[\left(\mathbb{E}_{X \sim P} [e^{-\langle s(X), -s(X') \rangle}] \right)^p \right] \right) \end{array}$$

Table 15: Four approaches for obtaining a pair-scorer in a bipartite ranking problem, using exponential loss. Our results show that the all approaches have the same theoretical minimiser.

- (1) Minimise the ℓ -classification risk $L(\mathcal{G}; D, \ell)$, and Diff (·) the result.
- (2) Minimise the ℓ -bipartite ranking risk $L_{\text{BR}}(\mathcal{G}; D, \ell)$ over all scorers, and Diff (·) the result.
- (3) Minimise the ℓ -pairwise ranking risk $L(\mathcal{S}_{\text{Pair}}; D_{\text{BR}}, \ell)$ over all pair-scorers.
- (4) Minimise the p -norm push risk $\text{Push}(S_{\text{Pair}}; D, \ell_{\text{exp}}, g^p)$ over decomposable pair-scorers.

Superficially, these appear very different: method (4) is the only one that departs from the standard conditional risk framework, method (3) is the only one to use a pair-scorer during minimisation, and method (1) is the only one to operate on single instances rather than pairs. It is thus surprising that our results provide conditions under which all methods have the *same* output; it is further surprising that the condition involves the choice of link function in the loss ℓ , which is typically chosen for computational rather than statistical reasons (Reid and Williamson, 2010).

Proposition 66 *Given any $D \in \Delta_{\mathcal{X} \times \{1\}}$ and $\ell \in \mathcal{L}_{\text{Spec}}(\Psi)$ with $\Psi \in \Sigma_{\text{sig}}$, methods (1), (2) and (3) produce the same pair-scorer, if \mathcal{X} is finite and $p = a - 1$ for $a > 1$, method (4) also produces the same pair-scorer.*

Proof By Equation 44 and Corollary 45, methods (1) and (2) produce the same scorer Ψ_{opt} , up to a translation which is nullified by the Diff operator. By Equation 50, this pair-scorer is equivalent to that produced by method (3). Further, if $p = a - 1$ for $a > 1$, then by Proposition 57, method (4) returns Ψ_{opt} up to a translation which is nullified by the Diff operator. ■

In hindsight, these equivalences are not surprising by virtue of the Bayes-optimal scorer for each type of risk depending on the observation-conditional distribution η . They are not however *a priori* obvious, given how ostensibly different the risks appear. To illustrate these superficial differences, Table 15 provides a concrete example of the four methods when $\ell = \ell^{\text{exp}}$ is the exponential loss, whose link $\Psi = \frac{1}{2} \sigma^{-1}$ satisfies the required condition of Proposition 66.

11.1 Implications of Equivalences

The above shows the “equivalence” between four seemingly disparate risks, where our definition of “equivalent” is that two methods have the same optimal scorer. This does not imply that the methods are interchangeable in practice. A statistical caveat to these equivalences is that they ignore the issues of finite samples and a restricted function class. When one or both of these situations hold, it may be that one of these methods is more preferable. A computational caveat is that methods (2)—(4) rely on minimisation over pairs of examples. On a finite training set, this requires roughly quadratic complexity, compared to the linear complexity of method (1). These practical issues deserve investigation, but are beyond the scope of this paper.

This caveat in mind, we believe the results at least illuminate similarities between seemingly disparate approaches. For the problem of minimising the ℓ -bipartite risk for an appropriate surrogate ℓ , the above provides evidence that minimising the ℓ -classification risk is a suitable proxy. That is, performing class-probability estimation is a suitable proxy for ranking; this can be formalised with surrogate regret bounds (Agarwal, 2014; Narasimhan and Agarwal, 2013b). Similarly, for the problem of minimising the p -norm push

Type	Property ($\forall x, x', x'' \in \mathcal{X}$)
Total	$\neg(R(x, x') = -1 \text{ and } R(x', x) = -1)$
Anti-symmetric	$\neg(R(x, x') = +1 \text{ and } R(x', x) = +1)$
Transitive	$R(x, x') = +1 \text{ and } R(x', x'') = +1 \implies R(x, x'') = +1$
Reflexive	$R(x, x) = +1$
Continuous	for every pair of convergent sequences $(x_n), (y_n)$, $(\forall n \in \mathbb{N}) R(x_n, y_n) = +1 \implies R\left(\lim_{n \rightarrow \infty} x_n, \lim_{n \rightarrow \infty} y_n\right) = +1$
Preorder	Reflexive, Transitive
Total preorder	Total, Transitive
Partial order	Reflexive, Transitive, Anti-symmetric
Total order	Total, Transitive, Anti-symmetric

Table 16: Some common types of binary relation R , and their defining properties.

objective, we have evidence that minimising the ℓ -classification or bipartite risk is a suitable proxy. As seen in §9.7, certain proper composite losses do indeed give comparable performance to the p -norm push.

11.2 Relation to Existing Work

Subsets of the above equivalences have been observed earlier for special cases. For the specific case of exponential loss and a linear hypothesis class, the equivalence between methods (1) and (2) was made by [Ertekin and Rudin \(2011, Theorem 3\)](#); [Gao and Zhou \(2012, Lemma 4\)](#); [Gao and Zhou \(2015, Theorem 7\)](#), while the equivalence between method (1) and (4) was shown by [Ertekin and Rudin \(2011, Theorem 1\)](#); here, method (1) represents AdaBoost, and method (2) RankBoost. For the special case of convex margin losses, the equivalence between methods (2) and (3) was shown by [Uematsu and Lee \(2012\)](#). [Ertekin and Rudin \(2011, Section 4.4\)](#) conjectured a lack of an equivalence between LogitBoost and logistic regression, based on empirical findings; this apparent contradiction with our results is because the latter focusses on the case of a linear hypothesis class, which is possibly misspecified, while our results are for an unrestricted hypothesis class, or equally for a correctly specified one.

12. A Utility Representation Perspective of Bipartite Ranking

Our final topic of study is what the theory of *utility representations* tells us about the bipartite ranking problem. In particular, we look at how this theory provides insight into the particular form of the observation-conditional distribution $\mathcal{P}_{\text{pair}}$ of D_{PAR} (Equation 47), which we saw had non-obvious implications for the derivation of Bayes-optimal scorers (§7.4.2) and surrogate regret bounds (§8).

12.1 Binary Relations

Given a set \mathcal{X} , a *binary relation* \mathcal{R} on \mathcal{X} is some subset of $\mathcal{X} \times \mathcal{X}$. There are two standard ways of referring to a relation. The first is the operator $\succeq_{\mathcal{R}}$, with the semantics $x \succeq_{\mathcal{R}} x' \iff (x, x') \in \mathcal{R}$. The second is the function $r: \mathcal{X} \times \mathcal{X} \rightarrow \{\pm 1\}$, with the semantics $r(x, x') = +1 \iff (x, x') \in \mathcal{R}$. We will use these two representations interchangeably. Table 16 summarises some standard properties of binary relations, and examples of specific types of binary relations.

A *probabilistic binary relation* (sometimes called a *reciprocal* or *ipsodual binary relation*) ([Baets et al., 2005, pg. 419](#)) on a set \mathcal{X} is some function $p: \mathcal{X} \times \mathcal{X} \rightarrow [0, 1]$ satisfying $p(x, x') + p(x', x) = 1$ for every $x, x' \in \mathcal{X}$. The pair (\mathcal{X}, p) is sometimes referred to as a *forced choice pair comparison system* ([Roberts, 1984, pg. 273](#)). Every probabilistic binary relation has an induced binary relation \succeq_p , with

$$x \succeq_p x' \iff p(x, x') \geq \frac{1}{2}.$$

Suppose $g: \left[\frac{1}{2}, 1\right] \times \left[\frac{1}{2}, 1\right] \rightarrow [0, 1]$ is some function that is commutative (i.e. $g(x, y) = g(y, x) \forall x, y$) and monotone increasing in both arguments. A probabilistic binary relation p is said to be *g-stochastically transitive* ([Baets et al., 2005, pg. 419](#)) if

$$(\forall x, x', x'' \in \mathcal{X}) x \succeq_p x' \text{ and } x' \succeq_p x'' \implies p(x, x'') \geq g(p(x, x'), p(x', x'')).$$

Special cases of the function g correspond to popular notions of stochastic transitivity: the case $g(x, y) = 1/2$ is known as *weak stochastic transitivity* ([Roberts, 1984, pg. 283](#)), $g(x, y) = x \wedge y$ as *moderate stochastic transitivity* ([Roberts, 1984, pg. 284](#)), and $g(x, y) = x \vee y$ as *strong stochastic transitivity* ([Roberts, 1984, pg. 284](#)). It is easy to check that weak stochastic transitivity of p corresponds to transitivity of the associated binary relation \succeq_p , provided ties are broken in favour of the relation existing.

12.2 Utility Representations for Binary Relations

Let $\succeq_{\mathcal{R}}$ be a binary relation on \mathcal{X} . We say that $\succeq_{\mathcal{R}}$ has a *utility representation* if there is some $s: \mathcal{X} \rightarrow \mathbb{R}$ such that

$$(\forall x, x' \in \mathcal{X}) x \succeq_{\mathcal{R}} x' \iff s(x) \geq s(x').$$

We say that a probabilistic binary relation p has a *generalised utility representation* if there is some function $H: \mathbb{R} \times \mathbb{R} \rightarrow [0, 1]$ and some function $s: \mathcal{X} \rightarrow \mathbb{R}$ such that

$$(\forall x, x' \in \mathcal{X}) p(x, x') = H(s(x), s(x')), \tag{64}$$

where H is increasing in its first argument, decreasing in its second argument. In [Świątalski \(2003\)](#), it is additionally assumed that H is concave-convex. In psychometrics, such a model is sometimes also referred to as a simple scalability assumption ([Krantz, 1967](#)).

Table 17 summarises various special cases of the generalised utility representation that have been studied; see ([Roberts, 1984, pg. 273–280](#)) for details. The utility representations are ordered as follows:

$$\text{Strict} \subsetneq \text{Fechnerian} \subseteq \text{Strong} \subsetneq \text{Weak}.$$

Note that the inclusions above are all strict, except for that of Fechnerian and Strong representations. In fact, p has a strong utility representation if and only if it has a *restricted* Fechnerian utility representation, where the restriction is that the strictly monotone increasing ϕ for the Fechnerian representation is only defined on the Minkowski self-difference $f(\mathcal{C}) - f(\mathcal{C})$ ([Roberts, 1984, pg. 279](#)).

12.3 Existence of Utility Representations

A key question is whether one can characterise when a given (probabilistic) binary relation possesses a specific type of utility representation. This lets us relate the ordering properties of the relation—such as whether it is symmetric, transitive, *et cetera*—with its mathematical representation as a function.

A classical result of [Debreu \(1954\)](#) (which generalises a result of [Eilenberg \(1941\)](#)) characterises, when a (non-probabilistic) binary relation may be expressed via a real-valued utility function. Recall that a binary relation $\succeq_{\mathcal{R}}$ is a total preorder if it is total (and hence reflexive) and transitive. The theorem is as follows.

26. More generally, one may define a family of relations, where each member specifies a different scheme for how ties—corresponding to $p(x, x') = \frac{1}{2}$ —are broken.

Utility type	Definition	Characterisation
Weak	$H(a, b) \geq \frac{1}{2} \iff a \geq b$	Weak stochastic transitivity, contour sets closed
Strong	$H(a, b) \geq H(c, d) \iff a - b \geq c - d$	Quadruple condition (under stochastic continuity)
Fechnerian	$H(a, b) = \phi(a - b)$, ϕ monotone	Quadruple or bicancellative condition
Strict	$H(a, b) = \frac{a}{a+b}$	Product rule

Table 17: Summary of various types of utility representations for binary probabilistic relations, from most to least general. By “definition” we mean the conditions required of H in the general utility representation of Equation 64. By “characterisation” we mean necessary and sufficient conditions on a probabilistic binary relation for the representation to hold. See text for details.

Proposition 67 (Eilenberg, 1941; Debreu, 1954; Debreu, 1964; Bridges and Mehta, 1995, pg. 46) Let \mathcal{X} be a topological space that is either (a) connected and separable, or (b) second countable. Let $\succeq_{\mathcal{R}}$ be a binary relation on \mathcal{X} . Then $\succeq_{\mathcal{R}}$ defines a continuous total preorder if and only if there is some $s : \mathcal{X} \rightarrow \mathbb{R}$ such that

$$x \succeq_{\mathcal{R}} x' \iff s(x) \geq s(x').$$

The result characterises precisely the class of binary relations that may be represented via a utility function $s : \mathcal{X} \rightarrow \mathbb{R}$. While the “if” direction is straightforward, the “only if” direction is not: it implies that any continuous total preorder can be perfectly represented via the standard ordering relation \geq on the reals, for an appropriate choice of utility function $s : \mathcal{X} \rightarrow \mathbb{R}$.

For probabilistic binary relations, we will focus on the case of a strict utility representation,²⁷ for which

$$H(a, b) = \frac{a}{a+b} = \frac{1}{1 + \frac{b}{a}} = \sigma(\sigma^{-1}(a') - \sigma^{-1}(b')),$$

where $d' = \frac{a}{a+1}$, $b' = \frac{b}{b+1}$. Thus, if a probabilistic binary relation p possesses this representation,

$$(\exists s : \mathcal{X} \rightarrow \mathbb{R})(\forall x, x' \in \mathcal{X}) p(x, x') = \sigma(\sigma^{-1}(s(x)) - \sigma^{-1}(s(x'))). \quad (65)$$

We have the following characterisation of the existence of a strict utility representation.

Proposition 68 (Luce and Suppes, 1965; Theorem 48, pg. 350) Suppose η_{pair} is a binary probabilistic relation. Then, η_{pair} has a strict utility representation (Equation 65) if and only if it satisfies the product rule,

$$(\forall x, x', x'' \in \mathcal{X}) \eta_{\text{pair}}(x, x') \cdot \eta_{\text{pair}}(x', x'') \cdot \eta_{\text{pair}}(x'', x) = \eta_{\text{pair}}(x, x'') \cdot \eta_{\text{pair}}(x'', x') \cdot \eta_{\text{pair}}(x', x), \quad (66)$$

which, when $\eta_{\text{pair}} \neq \{0, 1\}$, is equivalently

$$(\forall x, x', x'' \in \mathcal{X}) \eta_{\text{pair}}(x, x') = \sigma(\sigma^{-1}(\eta_{\text{pair}}(x, x'')) + \sigma^{-1}(\eta_{\text{pair}}(x'', x')) - \sigma^{-1}(\eta_{\text{pair}}(x', x))).$$

The product rule encodes that the probability of an intransitive cycle of relations $\{x \succeq_p x', x' \succeq_p x'', x'' \succeq_p x\}$ equals the probability of the cycle $\{x \succeq_p x', x' \succeq_p x'', x'' \succeq_p x\}$. The product rule necessarily implies the quadruple condition introduced earlier (and hence strong stochastic transitivity), since a strict utility implies a Fechnerian one.

²⁷ In psychometrics, the strict utility representation is referred to as the Bradley-Terry-Luce model (Luce, 1959; Bradley and Terry, 1952).

12.4 Implications for Bipartite Ranking

Bipartite ranking is fundamentally concerned with learning a scorer $s : \mathcal{X} \rightarrow \mathbb{R}$, and using this to rank instances. We can equivalently think of the problem as a special case of pairwise ranking, where we restrict attention to decomposable pair-scorers (Lemma 2). The pairwise ranking problem can in turn be interpreted as one of learning a binary relation: if $r : \mathcal{X} \times \mathcal{X} \rightarrow \{\pm 1\}$ is a binary relation on $\mathcal{X} \times \mathcal{X}$, then for any $R \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ such that the Bayes-optimal 0-1 pair-scorers match r in sign, i.e.

$$(\forall x, x' \in \mathcal{X}) r(x, x') = \text{sign}(\mathcal{Q}_{\text{pair}}(x, x') - 1),$$

learning a pair-scorer from R is equivalent to learning the binary relation r . Thus, one can then ask what implications the decomposability restriction has on learning a binary relation. Observe that when thresholded at 0, the pair-scorer $\text{Diff}(s)$ yields a binary relation r over $\mathcal{X} \times \mathcal{X}$, with

$$r(x, x') = +1 \iff (\text{Diff}(s))(x, x') \geq 0 \iff s(x) \geq s(x').$$

By Proposition 67, the resulting relation r is a continuous, total preorder, as can be easily checked by the properties of $\text{Diff}(s)$. Less obviously, Proposition 67 implies that for any continuous, total preorder $\succeq_{\mathcal{R}}$ over $\mathcal{X} \times \mathcal{X}$ (for \mathcal{X} with suitable topological properties), the problem of learning $\succeq_{\mathcal{R}}$ can be expressed as a bipartite ranking problem.

Proposition 69 Let \mathcal{X} be a topological space that is either (a) connected and separable, or (b) second countable. Let $\succeq_{\mathcal{R}}$ be a continuous, total preorder on \mathcal{X} . Then, there is a $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ for which the Bayes-optimal bipartite scorer for 0-1 loss induces the same ranking as $\succeq_{\mathcal{R}}$.

Proof For any continuous, total preorder $\succeq_{\mathcal{R}}$, there is a corresponding utility representation $s : \mathcal{X} \rightarrow \mathbb{R}$ (by Proposition 67). Pick any strictly monotone increasing $\phi : \mathbb{R} \rightarrow [0, 1]$, and let $\eta = \phi \circ s$. Further, pick any marginal distribution M over \mathcal{X} . Then, $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ with corresponding D_{GR} has

$$(\forall x, x' \in \mathcal{X}) \text{sign}(\mathcal{Q}_{\text{pair}}(x, x') - 1) = \text{sign}(\eta(x) - \eta(x')) = \text{sign}(s(x) - s(x')) = r(x, x'),$$

so that the Bayes-optimal bipartite scorer for 0-1 loss induces an ordering over $\mathcal{X} \times \mathcal{X}$ identical to $\succeq_{\mathcal{R}}$. ■

One can also consider the implications of utility representation theory for learning a probabilistic binary relation. As above, it is clear that the problem of learning a probabilistic binary relation p that satisfies the product rule can be expressed as finding $\text{SGR}(D, \ell)$ for some suitable D and proper composite ℓ with decomposable Bayes-optimal scorer. Equation 47 implies that for any D with derived distribution D_{GR} , the corresponding η_{pair} possesses a strict utility representation. Thus, setting η_{pair} to coincide with the utility representation of p gives a means of learning the relation p .

Conversely, we can gain some insight as to the form of observation-conditional distribution η_{pair} of D_{GR} is of the special form given by Equation 47, which in turn explains why the sigmoidal family of links arises in §7.4.2.

Proposition 70 Given any $D \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, the resulting $D_{\text{GR}} = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$ satisfies the product rule, and has

$$(\forall x, x' \in \mathcal{X}) \eta_{\text{pair}}(x, x') = \sigma(\sigma^{-1}(s(x)) - \sigma^{-1}(s(x')))$$

for some $s : \mathcal{X} \rightarrow \mathbb{R}$.

Proof For $D = \langle P, Q, \pi \rangle$, from the construction of $D_{\text{GR}} = \langle M_{\text{pair}}, \eta_{\text{pair}} \rangle = \langle P_{\text{pair}}, Q_{\text{pair}}, \pi_{\text{pair}} \rangle$, it is immediate that the probabilistic relation η_{pair} it represents satisfies the product rule—this is because Bayes’ rule and the nature of P_{pair} implies that

$$(\forall x, x' \in \mathcal{X}) \eta_{\text{pair}}(x, x') = \frac{P_{\text{pair}}(x, x') \cdot \pi_{\text{pair}}}{M_{\text{pair}}(x, x')}$$

$$= \frac{p(x) \cdot q(x')}{2\eta_{\text{pair}}(x, x')},$$

so that the condition for the product rule (Equation 66) may be written

$$(\forall x, x' \in \mathcal{X}) \frac{p(x) \cdot q(x')}{\eta_{\text{pair}}(x, x')} \cdot \frac{p(x') \cdot q(x'')}{\eta_{\text{pair}}(x', x'')} \cdot \frac{p(x'') \cdot q(x)}{\eta_{\text{pair}}(x'', x)} = \frac{p(x) \cdot q(x'')}{\eta_{\text{pair}}(x, x'')} \cdot \frac{p(x'') \cdot q(x)}{\eta_{\text{pair}}(x'', x)} \cdot \frac{p(x') \cdot q(x)}{\eta_{\text{pair}}(x', x)}$$

The numerators are clearly identical, and the denominators can be shown to be identical by explicit multiplication of the form of η_{pair} in Appendix B. Consequently, Proposition 68 thus implies that η_{pair} must possess a strict utility representation, meaning it is of the form

$$(\forall x, x' \in \mathcal{X}) \eta_{\text{pair}}(x, x') = \sigma(\sigma^{-1}(s(x)) - \sigma^{-1}(s(x')))$$

for some $s : \mathcal{X} \rightarrow \mathbb{R}$. ■

Thus, we have an explanation for the specific form of Equation 47—it is due to the probabilistic relation implicitly underlying the bipartite ranking problem satisfying the product rule, in conjunction with the utility representation theorem (Proposition 68) for all such relations.

13. Conclusion and Future Work

We have provided a systematic study of the bipartite ranking problem through its statistical risk. In particular:

- We described a fundamental connection between bipartite ranking and classification over pairs (§4).
- We studied several properties of the ROC curve, including a to our knowledge novel result (Proposition 13) on how dominance in ROC space implies dominance with respect to *any* proper composite loss.
- We derived a number of integral representations of the AUC (§5.6), relating them to the integral representation for proper losses, (§5.6.2).
- We related the Bayes-optimal bipartite risk to an f -divergence between product measures for the class-conditional densities (§6.2), generalising a result for the case of 0-1 loss due to Torgersen (1991).
- We determined the set of Bayes-optimal scorers for bipartite ranking (§7.3, §7.4, §7.5), and thus surrogate regret bounds for the minimisation of pairwise surrogates (§8).
- We studied Bayes-optimal scorers for the p -norm push risk (§9.5), and explained the risk in terms of the weight function for proper losses (§9.6.3). We used this to derive several new loss functions (§9.6), which demonstrated favourable empirical performance compared to the p -norm push risk on a number of real data sets (§9.7).
- We mapped out the relationships between bipartite ranking and other learning problems, such as pairwise ranking, class-probability estimation, and classification (§10.1, §10.2), and the equivalence between several seemingly disparate risks for popular approaches in bipartite ranking (§11).
- We showed how theorems of utility representation describe the class of ranking problems over pairs that can be modelled by bipartite ranking (§12.4).

Our results built upon the rich framework of proper composite losses, which are central to the study of class-probability estimation. We hope our results illustrate the value of the proper loss machinery in studying bipartite ranking problems.

We outline several possible areas for future work.

- *Beyond the Bayes-risk.* We acknowledge that the study of the risk is only an initial step in the broader understanding of the bipartite ranking problem. For example, in the study of the Bayes-optimal scorers, we have assumed no restrictions of the set of allowed scorers and pair-scorers. In practice, we have access to only a finite number of samples, and typically use a restricted function class. Understanding the impact this has on the risk equivalences we have established is of interest. For example, can we characterise when one risk is more preferable from a statistical or computational point of view?
 - *From the AUC to AUPRC.* One may hope to extend our analysis to other popular performance metrics for bipartite ranking, such as the area under the precision-recall curve (AUPRC). While we briefly touched upon the AUPRC in §9.4.2, we deferred detailed study due to difficulties in expressing it as a risk. Understanding the properties this broader class of performance measures is of interest.
 - *Extension to instance ranking.* A natural extension of our results would be the study of the more general instance ranking problem, where the label space \mathcal{Y} is not binary. With suitable assumptions on \mathcal{Y} , it is possible to leverage some analysis from bipartite ranking for such problems (Clémentçon et al., 2013). It is possible that tools from multi-class probability estimation (Vernet et al., 2011) may also be a useful tool in the study of this problem.
 - *Converting pair-scorers to a univariate scorer.* Given a pair-scorer, it may be desirable to construct a procedure that converts it to a univariate scorer. Balean et al. (2008) devises such a procedure and provides guarantees on its performance for the standard AUC. It is of interest whether this can be generalised.
 - *Applications.* We believe there is scope for our analysis to be extended to problems where both class-probability estimation and bipartite ranking are heavily employed. For example, a challenging learning scenario is where one has access to only positive and unlabelled examples. Recent work has shown the value of class-probability estimation (Elkan and Noto, 2008) and bipartite ranking methods (Sella-manickam et al., 2011) for this task. We hope that our analysis can offer directions for theoretical and algorithmic development for this and related problems.
- More broadly, by focussing on the statistical risk and abstracting away finite sample and optimisation issues, we have aimed to perform a *problem-oriented* rather than *method-oriented* analysis, as per Platt (1962). We believe this gives deeper insight into the connections between problems, and disentangles computational and statistical concerns. For example, akin to the distributional analysis of the probing reduction (Langford and Zadrozny, 2005) in Reid and Williamson (2009), we have seen in §10 the broad theoretical connections between bipartite ranking, class-probability estimation and classification, such as the use of a calibration transform to convert a scorer that ranks instances optimally to a class-probability estimator. We hope our results demonstrate the value and encourage further pursuit of this style of analysis for other learning problems.

Acknowledgments

This work was conducted as part of NICTA, and was supported by the Australian Research Council (RCW) and NICTA (AKM and RCW). NICTA was funded by the Australian Government through the Department of Communications and the Australian Research Council through the ICT Centre of Excellence Program. Thanks to Cynthia Rudin and the COLT referees for their helpful comments on a preliminary version of this work, to the JMLR referees for their valuable suggestions, and to Brendan van Rooyen for suggesting a simple proof of Lemma 72.

Appendix A. Assorted Lemmas

We collect some assorted lemmas that are employed in proofs, but are not directly related to bipartite ranking.

Lemma 71 Let $s : \mathcal{X} \rightarrow \mathbb{R}$ be any scorer. If

$$(\forall t : \mathcal{X} \rightarrow \mathbb{R}) \int_{\mathcal{X}} s(x) \cdot t(x) dx = 0,$$

then s is zero almost everywhere.

Proof This is in fact a special case of the fundamental lemma of the calculus of variations, which in turn is a special case of the du Bois-Reymond lemma (Trounman, 1996, pg. 99; Giacquinta and Hildebrandt, 2004, pg. 16), both of which only require the statement hold for all infinitely differentiable t . We show the contrapositive. Suppose $\varepsilon \neq 0$ on a set of nonzero measure. Then $t = s^2 : \mathcal{X} \rightarrow \mathbb{R}_+$ is > 0 on this same set of nonzero measure. Thus,

$$\int_{\mathcal{X}} s(x) \cdot s(x) dx = \int_{\mathcal{X}} s(x)^2 dx > 0,$$

where the inequality holds by Folland (1999, Proposition 2.16). Thus, the statement holds. ■

Lemma 72 Let $f, g : \mathcal{X} \rightarrow \mathbb{R}$. Then,

$$(\forall x, x' \in \mathcal{X}) f(x) < f(x') \implies g(x) < g(x')$$

if and only if $f = \phi \circ g$ for some non-decreasing $\phi : \mathbb{R} \rightarrow \mathbb{R}$.

Proof (\Leftarrow). This is easily verified by the definition of ϕ being non-decreasing (\implies). We will construct such a non-decreasing ϕ . For any $y \in \text{Im}(g)$, let

$$\mathcal{J}(y) = \{x \in \mathcal{X} : g(x) = y\}$$

be the preimage of y under g . For any $y \in \mathbb{R}$, let

$$\phi(y) \doteq \min\{f(x) : x \in \mathcal{J}(y)\}.$$

We will check that $f = \phi \circ g$, and that ϕ is non-decreasing.

First, note that for any $x, x' \in \mathcal{J}(y)$, by definition $g(x) = g(x')$. By the contrapositive of the assumption,

$$g(x) \geq g(x') \implies f(x) \geq f(x')$$

and by swapping x, x' ,

$$g(x) \leq g(x') \implies f(x) \leq f(x')$$

so that

$$g(x) = g(x') \implies f(x) = f(x').$$

Thus for any $x, x' \in \mathcal{J}(y)$, $f(x) = f(x')$. Thus, for any $x \in \mathcal{J}(y)$,

$$\phi(y) = f(x).$$

Now, for any $x_0 \in \mathcal{X}$,

$$\begin{aligned} \phi(g(x_0)) &= \min\{f(x) : x \in \mathcal{J}(g(x_0))\} \\ &= f(x_0). \end{aligned}$$

Thus, $f = \phi \circ g$. To see that ϕ is non-decreasing, pick $y < y'$ and $x \in \mathcal{J}(y)$, $x' \in \mathcal{J}(y')$. Then $y = g(x) < g(x') = y'$. Since $g(x) < g(x')$ implies $f(x) = \phi(y) < \phi(y') = f(x')$, we see that $y < y' \implies \phi(y) < \phi(y')$. ■

Lemma 73 Let $f, g : \mathcal{X} \rightarrow \mathbb{R}$. Then,

$$(\forall x, x' \in \mathcal{X}) \text{sign}(f(x) - f(x')) = \text{sign}(g(x) - g(x'))$$

if and only if $f = \phi \circ g$ for some strictly monotone increasing $\phi : \mathbb{R} \rightarrow \mathbb{R}$.

Proof We can equivalently write the condition as

$$(\forall x, x' \in \mathcal{X}) f(x) < f(x') \iff g(x) < g(x').$$

Thus, by Lemma 72, $f = \phi \circ g$ for some monotone increasing ϕ , and $g = \phi_2 \circ f$ for some monotone increasing ϕ_2 . Thus $f = \phi_1 \circ \phi_2 \circ f$, and so $\phi_1 = \phi_2^{-1}$. This implies that ϕ_1 and ϕ_2 are invertible, or equivalently, that they both correspond to strictly monotone increasing transforms. ■

Lemma 74 Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, and any $s : \mathcal{X} \rightarrow \mathbb{R}$ such that $\eta = \phi \circ s$ for some non-decreasing ϕ ,

$$(\forall x \in \mathcal{X}) \text{Cal}(x; D, s) = \eta(x).$$

In particular, the above equation holds for any s such that $s = \phi \circ \eta$ for some strictly monotone ϕ .

Proof Assuming that the distribution of scores is discrete, for every $x \in \mathcal{X}$,

$$\begin{aligned} \text{Cal}(x; D, s) &= \mathbb{P}[Y = 1 | s(X) = s(x)] \\ &= \frac{\mathbb{E}_{(X,Y) \sim D} \mathbb{1}[Y = 1, s(X) = s(x)]}{\mathbb{E}_{(X,Y) \sim D} \mathbb{1}[s(X) = s(x)]} \\ &= \frac{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\eta(X) \cdot \mathbb{1}[s(X) = s(x)]]}{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\mathbb{1}[s(X) = s(x)]]} \\ &= \frac{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\phi(s(X)) \cdot \mathbb{1}[s(X) = s(x)]]}{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\mathbb{1}[s(X) = s(x)]]} \quad \text{by assumption on } \eta \\ &= \frac{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\phi(s(x)) \cdot \mathbb{1}[s(X) = s(x)]]}{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\mathbb{1}[s(X) = s(x)]]} \\ &= \frac{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\mathbb{1}[s(X) = s(x)]]}{\mathbb{E}_{X \sim M} \mathbb{E}_{Y \sim D} [\mathbb{1}[s(X) = s(x)]]} \\ &= \phi(s(x)) \\ &= \eta(x). \end{aligned}$$

When the distribution of scores is continuous, we repeat the above, but using Dirac delta instead of indicator functions. ■

Appendix B. Properties of the Derived Ranking Distribution D_{gr}

Suppose we have a distribution $D = \langle P, Q, \rho \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$. Assume that M, P, Q have densities μ, p, q . We summarise some properties of the resulting distribution over pairs, $D_{gr} \in \Delta_{\mathcal{X} \times \mathcal{X} \times \{\pm 1\}}$. We will

associate this distribution with the random variable triplet (X, X', Z) . By definition, we have

$$\begin{aligned}\mathbb{P}[Z = 1] &= \frac{1}{2} \\ p_{X|Z=z}(x) &= \mathbb{I}[z = 1] \cdot p(x) + \mathbb{I}[z = -1] \cdot q(x) \\ p_{X'|Z=z}(x') &= \mathbb{I}[z = 1] \cdot q(x') + \mathbb{I}[z = -1] \cdot p(x').\end{aligned}$$

From these, we may derive other marginals and conditionals for D_{BIR} , and relate them to those of D :

$$\begin{aligned}p_{X, X'|Z=z}(x, x') &= p_{X|Z=z}(x) \cdot p_{X'|Z=z}(x') \\ &= \mathbb{I}[z = 1] \cdot p(x) \cdot q(x') + \mathbb{I}[z = -1] \cdot p(x') \cdot q(x) \\ p_{X, X'}(x, x') &= \frac{p(x) \cdot q(x') + p(x') \cdot q(x)}{2} \\ &= \frac{1}{2\pi(1-\pi)} \cdot \mu(x) \cdot \mu(x') \cdot (\eta(x) \cdot (1-\eta(x')) + \eta(x') \cdot (1-\eta(x))) \\ p_X(x) &= \frac{p(x) + q(x)}{2} \\ p_{X|X'=x'}(x) &= \frac{p(x) \cdot q(x') + p(x') \cdot q(x)}{p(x') + q(x)} \\ \mathbb{P}[Z = 1|X = x] &= \frac{p(x)}{p(x) + q(x)} \\ &= \sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\pi)) \\ \mathbb{P}[Z = 1|X = x, X' = x'] &= \frac{p(x) \cdot q(x') + p(x') \cdot q(x)}{p(x') \cdot q(x')} \\ &= \frac{1 + \frac{q(x)}{p(x)} \cdot \frac{p(x')}{q(x')}}{\sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x')))} \\ &= \sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x'))).\end{aligned}$$

The last identity follows because

$$\sigma^{-1}(\eta(x)) = \log \frac{\pi}{1-\pi} + \log \frac{p(x)}{q(x)}.$$

Thus, the distributions of primary interest in the paper are:

$$\begin{aligned}P_{\text{pair}} &= P \times Q \\ Q_{\text{pair}} &= Q \times P \\ \pi_{\text{pair}} &= \frac{1}{2} \\ M_{\text{pair}} &= \frac{P \times Q + Q \times P}{2}\end{aligned}$$

$$(\forall x, x' \in \mathcal{X}) \eta_{\text{pair}}(x, x') = \sigma(\sigma^{-1}(\eta(x)) - \sigma^{-1}(\eta(x'))).$$

Appendix C. Properties of the ROC Curve

For completeness we present two well known results about the derivative of the ROC curve, and its relationship to the optimal threshold for cost-sensitive learning.

Proof [Proof of Proposition 8] By the chain rule,

$$(\forall \alpha \in (0, 1)) \rho'(\alpha) = (\text{FPR}^{-1})'(\alpha) \cdot \text{TPR}(\text{FPR}^{-1}(\alpha))$$

$$\begin{aligned}&= \frac{\text{TPR}(\text{FPR}^{-1}(\alpha))}{\text{FPR}(\text{FPR}^{-1}(\alpha))} \\ &= \frac{p_S(\text{FPR}^{-1}(\alpha))}{q_S(\text{FPR}^{-1}(\alpha))} \text{ by Equation 22.}\end{aligned}$$

By Bayes' rule, for a random variable $S \sim S$ for S the distribution of scores,

$$(\forall a \in \mathbb{R}) p_S(a) = p_{S|Y=a}(a) = \frac{\mathbb{P}[Y = 1|S = a] \cdot \mathbb{P}[S = a]}{\mathbb{P}[Y = 1]},$$

and similarly for q_S . Thus

$$\frac{p_S(a)}{q_S(a)} = \frac{1-\pi}{\pi} \cdot \frac{\mathbb{P}[Y = 1|S = a]}{1-\mathbb{P}[Y = 1|S = a]},$$

and by definition, $\text{Prb}(a; D, s) = \mathbb{P}[Y = 1|S = a]$. ■

Proof [Proof of Proposition 11] Let

$$\begin{aligned}(\forall t \in \mathbb{R}) R(t) &\doteq \mathbb{L}(s-t; D, \mathcal{L}_{\text{CS}(c)}) \\ &= \pi \cdot (1-c) \cdot \text{FNR}(t) + (1-\pi) \cdot c \cdot \text{FPR}(t)\end{aligned}$$

be the risk for a fixed scorer s when using a threshold t . Pick any optimal threshold $t_0 \in \mathcal{I}^*(c; D, s)$. This must satisfy

$$0 = R'(t_0) = \pi \cdot (1-c) \cdot \text{FNR}'(t_0) + (1-\pi) \cdot c \cdot \text{FPR}'(t_0),$$

i.e.

$$\frac{\pi}{1-\pi} \cdot \frac{\text{TPR}'(t_0)}{\text{FPR}'(t_0)} = \frac{c}{1-c}.$$

This is exactly

$$\rho'(\text{FPR}(t_0)) = \frac{c}{1-c} \cdot \frac{1-\pi}{\pi}.$$

By Proposition 8, this implies

$$\frac{\text{Prb}(t_0)}{1-\text{Prb}(t_0)} = \frac{c}{1-c}.$$

When $\text{Prb}(\cdot; D, s)$ is invertible, we thus have

$$t_0 = \text{Prb}^{-1}(c),$$

and since the choice of t_0 was arbitrary from the set of optimal thresholds, we conclude that $\mathcal{I}^*(c) = \{\text{Prb}^{-1}(c)\}$. ■

Appendix D. Relationship Between the ROC Curve and the Neyman-Pearson Problem

The maximal ROC curve is intimately related to the following classical hypothesis testing problem. Suppose we have (known) probability distributions P_{+1}, P_{-1} over an instance space \mathcal{X} , with densities p_{+1}, p_{-1} with respect to some reference measure (this could simply be $(P_{+1} + P_{-1})/2$). We are given a sample x drawn from one of $P_{\pm 1}$. We wish to determine whether or not $t = 1$, i.e. conduct a hypothesis test between $H_0 : i = -1$ and $H_1 : i = +1$. The Neyman-Pearson problem (Lehmann and Romano, 2005, pg. 59) asks for the test that has the most *power* in discriminating between the two alternatives, assuming the false positive rate is fixed at some value $\alpha \in [0, 1]$.

Definition 75 (Neyman-Pearson problem) Pick any $\pi \in (0, 1)$, and let $D = \langle P_+, P_- \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$. For a fixed $\alpha \in [0, 1]$, the Neyman-Pearson problem is

$$\max_{h \in \{\pm 1\}^{\mathcal{X}}} \text{TPR}(h; D) : \text{FPR}(h; D) \leq \alpha,$$

where in an abuse of notation

$$\begin{aligned} \text{TPR}(h; D) &= \mathbb{P}_{\mathcal{X} \sim P_+} [h(X) = +1] \\ \text{FPR}(h; D) &= \mathbb{P}_{\mathcal{X} \sim P_-} [h(X) = +1]. \end{aligned}$$

The optimal classifier $h^*(x)$ is called the uniformly most powerful test at α .

From a learning perspective, a test h is simply a classifier $h : \mathcal{X} \rightarrow \{\pm 1\}$ that specifies which of the two hypotheses is preferred. Further, we can view the densities as being class-conditionals $p_y(x) = P_{\mathcal{X}|Y=y}(x)$. Thus, given a distribution $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, the Neyman-Pearson problem arises when we wish to find a classifier that has maximal true positive rate for a fixed false positive rate.

D.1 The Neyman-Pearson Lemma

The Neyman-Pearson lemma (Lehmann and Romano, 2005, pg. 60) specifies the optimal solution to the Neyman-Pearson problem.

Lemma 76 (Neyman-Pearson lemma) Pick any $\pi \in (0, 1)$, and let $D = \langle P_+, P_- \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$ where $P_{\{\pm 1\}}$ have densities $P_{\{\pm 1\}}$ with respect to some reference measure. For any $\alpha \in [0, 1]$, the uniformly most powerful test at α is

$$h^*(x; \alpha, D) = \begin{cases} P_+(x) \\ P_-(x) \end{cases} \geq r^*(\alpha; D) \Bigg]$$

where $r^*(\alpha; D)$ is such that the classifier achieves desired false positive rate,

$$\text{FPR}(h^*(x; \alpha, D); D) = \alpha.$$

92). For completeness, we present a proof based on Lagrange multipliers, following Hippensiefel (2001, pg. 92).

Proof Given a classifier h , let

$$A_h = \{x \in \mathcal{X} : h(x) = +1\}.$$

Then,

$$\begin{aligned} \text{TPR}(h; D) &= \mathbb{P}_{\mathcal{X} \sim P_+} [\mathbf{X} \in A_h] \\ \text{FPR}(h; D) &= \mathbb{P}_{\mathcal{X} \sim P_-} [\mathbf{X} \in A_h]. \end{aligned}$$

Thus, the problem is equivalent to

$$\max_{A \subseteq \mathcal{X}} \int_{x \in A} p_+(x) dx \text{ subject to } \int_{x \in A} p_-(x) dx \leq \alpha.$$

Now consider the Lagrangian

$$\mathcal{L}(A, \lambda) = \int_{x \in A} (p_+(x) - \lambda \cdot p_-(x)) dx + \lambda \cdot \alpha.$$

Clearly, the A which maximises \mathcal{L} is such that the integrand is always nonnegative:

$$A^*(\lambda^*) = \left\{ x \in \mathcal{X} : \frac{p_+(x)}{p_-(x)} \geq \lambda^* \right\} = \left\{ x \in \mathcal{X} : \phi \left(\frac{p_+(x)}{p_-(x)} \right) \geq \phi(\lambda^*) \right\},$$

for any ϕ strictly monotone increasing. Thus, the optimal test or classifier is based on thresholding a scorer of the form

$$s^*(x) = \phi \left(\frac{p_+(x)}{p_-(x)} \right)$$

with the threshold λ^* being the solution to the equation

$$\alpha = \int_{x \in A^*(\lambda^*)} p_-(x).$$

■

In practical learning settings, the optimal solution to the Neyman-Pearson problem cannot be computed as it assumes full knowledge of the underlying distributions. A natural approach is to use empirical versions of the appropriate distributions. For a fixed false positive rate α , various optimisation schemes have been proposed such as neural network based density estimation (Streit, 1990), SVMs (Davenport et al., 2010) and non-convex optimisation (Casso et al., 2011).

D.2 Implications of the Neyman-Pearson Lemma

From a hypothesis testing perspective, the optimal scoring function is seen to be a strictly monotone increasing transform of the likelihood ratio

$$(\forall x \in \mathcal{X}) \Lambda(x) = \frac{p_+(x)}{p_-(x)}.$$

From an ROC perspective, the Neyman-Pearson problem can be seen as picking a particular point on the horizontal axis (by virtue of fixing the FPR), and asking for the scoring function that yields the maximum value along the vertical axis (by virtue of maximising the TPR). The Neyman-Pearson lemma concludes that this is achieved by a strictly monotone increasing transformation of $\Lambda(x)$ regardless of the FPR value. Thus, maximising the AUC can be seen as solving a Neyman-Pearson problem for every possible false positive rate, as in Corollary 16.

Appendix E. Bayes-Optimal Classification Risk and Regret

A classical result establishes that the Bayes 0-1 risk can be expressed in terms of the variational divergence between the class-conditional distributions P and Q (Devroye et al., 1996, pg. 14). This gives an interpretation of the Bayes 0-1 risk, which is the inherent ‘‘difficulty’’ of the problem, in terms of amount of overlap between the distributions for the two classes. In fact, the variational divergence can be replaced by any f -divergence, with the Bayes 0-1 risk being replaced by the Bayes ℓ -classification risk for suitable ℓ .

Proposition 77 (Österreicher and Vajda, 1993; Reid and Williamson, 2011, Theorem 9) For any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, convex $f : \mathbb{R}_+ \rightarrow \mathbb{R}$, and loss ℓ with conditional Bayes risk

$$(\forall \eta \in (0, 1)) L^*(\eta; \ell) = \frac{1-\eta}{1-\pi} \cdot f \left(\frac{1-\pi}{\pi} \cdot \frac{\eta}{1-\eta} \right),$$

$$L^*(D, \ell) = L^*(\alpha; \ell) - \mathbb{I}_f(P, Q), \tag{67}$$

the Bayes-risk can be written

Conversely, Equation 67 holds for any $D = \langle P, Q, \pi \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, loss ℓ with concave conditional Bayes risk $L^*(\cdot; \ell) : [0, 1] \rightarrow \mathbb{R}_+$, and $f : \mathbb{R}_+ \rightarrow \mathbb{R}$ defined by

$$(\forall t \in \mathbb{R}) f(t) = L^*(\alpha; \ell) - (\alpha \cdot t + 1 - \pi) \cdot L^* \left(\frac{\pi \cdot t}{\pi \cdot t + 1 - \pi}; \ell \right).$$

Recalling that for a proper composite loss ℓ with underlying proper loss λ , the conditional Bayes risks coincide i.e. $L_\eta^* = L_\eta^*$, we see that for a proper loss λ Proposition 77 holds for any choice of proper composite ℓ resulting from the composition of λ with an invertible link function Ψ .

One can also relate the regret with respect to any proper composite loss to an appropriate generative Bregman divergence.

Proposition 78 (Baja et al., 2005; Reid and Williamson, 2011) For any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$, and scorer $s : \mathcal{X} \rightarrow \mathbb{R}$,

$$\text{regret}(s; D, \ell) = \mathbb{E}_{-L^*(\eta, \Psi^{-1} \circ s)}$$

where in an abuse of notation $L^* = L^*(\cdot; \ell)$.

Proposition 78 shows that if a scorer has low ℓ -risk with respect to some proper composite loss, then $\hat{\eta} = \Psi^{-1} \circ s$ is a good estimate of η in a precise sense: it has low average Bregman divergence to η .

Appendix F. Interpretation of Uematsu and Lee (2012) in Terms of Proper Losses

The following are the results shown in Uematsu and Lee (2012).

Proposition 79 (Uematsu and Lee, 2012, Theorem 3) Suppose $\ell(y, v) = \phi(yv)$ for some $\phi : \mathbb{R} \rightarrow \mathbb{R}_+$, where ϕ is differentiable, monotone decreasing, convex, and $\phi'(0) < 0$. For a given distribution $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$, let

$$s^* \in S_{\text{BR}}^*(D, \ell).$$

Then,

$$(\forall x, x' \in \mathcal{X}) \eta(x) \neq \eta(x') \implies \text{sign}(\text{Diff}(s^*)(x, x')) = \text{sign}(\eta(x) - \eta(x')).$$

If ϕ is strictly convex, then the above also holds when $\eta(x) = \eta(x')$.

Proposition 80 (Uematsu and Lee, 2012, Theorem 7) Suppose $\ell(y, v) = \phi(yv)$ for some $\phi : \mathbb{R} \rightarrow \mathbb{R}_+$, where ϕ is differentiable, strictly monotone decreasing, convex, and $f : s \mapsto \frac{\phi(-s)}{\phi(s)}$ is strictly increasing. Given any $D = \langle M, \eta \rangle \in \Delta_{\mathcal{X} \times \{\pm 1\}}$,

$$S_{\text{BR}}^*(D, \ell) \subseteq S_{\text{Decomp}}$$

if and only if $\phi'(-s)/\phi'(s) = e^{as}$ for some $a > 0$.

We show how to interpret these results in terms of proper composite losses. First, we show that the conditions of their theorems imply that ℓ is a proper composite margin loss.

Proposition 81 Let ϕ be differentiable with $\phi'(0) < 0$, monotone decreasing, and strictly convex. Then, $\ell(y, v) = \phi(yv)$ is strictly proper composite.

Proof Let ϕ meet the stated conditions. Since ϕ is convex and monotone decreasing with $\phi'(0) < 0$, then it must be true that

$$(\forall v \in \mathbb{R}) (\phi'(v) \neq 0 \vee \phi'(-v) \neq 0).$$

Further, the function

$$f(v) = \frac{\phi'(v)}{\phi'(-v)}$$

is continuous by differentiability of ϕ , and monotone by monotonicity and convexity of ϕ , since

$$f'(v) = \frac{1}{(\phi'(v))^2} \cdot (\phi'(-v)\phi''(v) + \phi'(-v)\phi''(v)) \leq 0.$$

When ϕ is strictly convex, f is strictly monotone because the numerator above cannot be 0. Thus, the conditions of Corollary 16 in Vernet et al. (2011) hold, and so ℓ is strictly proper composite. ■

Lemma 82 Let ϕ be differentiable, strictly monotone decreasing, convex, and such that $f : s \mapsto \frac{\phi'(-s)}{\phi'(s)}$ is strictly increasing. Then, $\ell(y, v) = \phi(yv)$ is strictly proper composite.

Proof The proof follows by the conditions of Corollary 16 in Vernet et al. (2011), as before, with invertibility $f : s \mapsto \frac{\phi'(-s)}{\phi'(s)}$ directly assumed rather than derived as a consequence of strict convexity. ■

By Lemma 73, the statement of Uematsu and Lee (2012, Theorem 3) is equivalent to saying that $\eta = g \circ s^*$ for some non-decreasing g when ϕ is convex, and g is strictly increasing when ϕ is strictly convex. Thus, this strictly convex part of the result is as per Corollary 48, except that the latter explicitly provides the form of the link function relating η and s^* .

The following shows that the conditions in their Theorem 7 imply that the inverse link function is of the form $\Psi^{-1}(v) = \frac{1}{1+e^{-av}}$, which means the result is a special case of Proposition 44 where ℓ is a margin loss.

Lemma 83 Let $\ell \in \mathcal{L}_{\text{SPC}}(\Psi)$ be such that $\ell(y, v) = \phi(yv)$ for some differentiable $\phi : \mathbb{R} \rightarrow \mathbb{R}_+$. Then,

$$(\forall a \in \mathbb{R} \setminus \{0\}) (\forall v \in \mathbb{R}) \Psi^{-1}(v) = \frac{1}{1+e^{-av}} \iff \phi'(-v)/\phi'(v) = e^{av}.$$

Proof The link function for a differentiable proper composite loss satisfies

$$\begin{aligned} (\forall v \in \mathbb{R}) \Psi^{-1}(v) &= \frac{1}{1 - \frac{\phi'(v)}{\phi'(-v)}} \\ &= \frac{1}{1 + \frac{\phi'(v)}{\phi'(-v)}} \\ &= \frac{1}{1 + e^{-av}} \end{aligned}$$

where the last line is true iff the asserted statement holds. ■

Appendix G. Empirical Illustration of Corollary 45

We present an empirical illustration of the fact that Corollary 45 holds for an asymmetric proper composite loss. We work with a discrete distribution over N instances, where the instance i has probability M_i of being drawn, and has an associated probability η_i of having a positive label. A scorer s is then some vector in \mathbb{R}^N . Given a loss ℓ , the bipartite risk of the scorer s is

$$\begin{aligned} \mathbb{L}_{\text{BR}}(s; D, \ell) &= \mathbb{E}_{\mathcal{X} \sim P, \mathcal{X}' \sim Q} [\ell_{\text{symm}}(s(\mathcal{X}) - s(\mathcal{X}'))], \\ &= \sum_{i=1}^N \sum_{j=1}^N [\eta_i \cdot (1 - \eta_j) \cdot (\ell_+(s_i - s_j) + \ell_-(s_j - s_i))] \\ &= \sum_{i=1}^N \sum_{j=1}^N [\eta_i \cdot (1 - \eta_j) \cdot (\ell_+(s, e_i - e_j) + \ell_-(s, e_j - e_i))], \end{aligned}$$

where e_i is the i th standard basis vector in \mathbb{R}^N . The Bayes-optimal risk is simply the minimiser of the above objective, and may be computed by numerical optimisation.

We performed 20 repetitions of the following experiment: for $N = 10$ instances, we draw $\eta_i \sim \text{Beta}(4, 3)$, $Z_i \sim \text{Beta}(6, 2)$, and set $M_i = Z_i / \sum_j Z_j$. We then scaled the η_i 's to lie in $[0.01, 0.99]$, ensuring that the

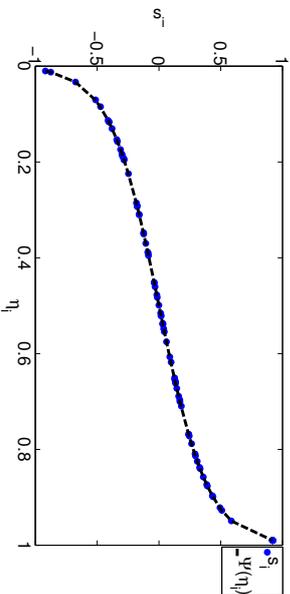

Figure 3: Results of 20 simulation trials to illustrate Bayes-optimal scorer (Corollary 45) for the case of an asymmetric loss. Here, the distribution D is varied across each trial, and the relationship between the (η, s^*) pairs across all trials is plotted. The relationship exactly matches that of $s^* = \Psi(\eta)$.

minimum and maximum values are attained. Given this distribution, we minimised the bipartite risk using L-BFGS, obtaining the Bayes-optimal scorer s^* . As the risk is invariant to translations, we transformed the solution so that its minimum value equals $\Psi(0.01)$ (thus agreeing with that of the expected optimal solution). We collected the corresponding pairs of (η, s^*) values for all 20 repetitions. We then plotted the graph of the resulting η values versus the s^* values. If s^* is a strictly monotone transform of η , then the plot will reflect this (as the different η values from the trials represent different sampling points of the domain of this function).

Figure 3 shows the results where ℓ is the asymmetric p -classification loss for $p = 2$.

$$f(\eta) = \left(\frac{1}{2} \cdot e^{2\eta}, e^{-\eta} \right)$$

We see that the relationship between the two is strictly monotone. Also shown on the graph is the plot of η versus $\Psi(\eta)$, where $\Psi = \frac{1}{2}\sigma^{-1}$; this perfectly agrees with the observed s^* values, as predicted by the theory.

Appendix H. Empirical Illustration of Corollary 48

We now present an empirical illustration of the facts that for a proper composite loss whose Bayes-optimal pair-scorer is non-decomposable, (a) the optimal univariate scorer is a strictly monotone transform of η , and (b) the transformation is distribution dependent. We repeated the setup of Appendix G, except that we worked with ℓ being the squared loss, $f(y, v) = (1 - yv)^2$, and the canonical boosting loss (Bujia et al., 2005).

$$f(y, v) = \frac{yv}{2} + \sqrt{1 + \frac{v^2}{4}}$$

Squared loss employs the identity link, while the canonical boosting loss uses the link $\Psi(\eta) = \frac{2\eta-1}{\sqrt{\eta(1-\eta)}}$, and thus neither induce a decomposable pair-scorer according to Proposition 44.

Figure 4 shows that the relationship between η and s^* for these losses across multiple trials is *not* monotone, and significantly deviates from the optimal solution in the class-probability estimation setting, viz. $s^* = \Psi(\eta)$ for Ψ the identity mapping. This indicates that in general, the relationship between η and s^* is distribution dependent.

Figures 5 and 6 further studies the relationship between the two quantities for each individual trial. We see that, for a given trial (or equivalently for a given distribution), the relationship between η and s^* is strictly

monotone, as expected. However, across different trials, it is evident that the precise monotone transformation is different.

Appendix I. Empirical Illustration of Optimal p -Norm Push Pair-Scorer

We now present an empirical illustration of the fact that for a general proper composite loss, (a) the optimal p -norm push pair-scorer is a strictly monotone transform of η_{pair} and (b) the transformation is distribution dependent. We repeated the setup of Appendix G, except that we worked with the p -norm push risk for $p = 4$, with ℓ being logistic loss, and considered $n = 5$ to reduce the number of η_{pair} values.

Figure 7 shows the relationship between η_{pair} and s_{pair}^* across multiple trials is *not* monotone, and significantly deviates from the optimal solution in the class-probability estimation setting, viz. $s^* = \Psi(\eta)$ for $\Psi = \frac{1}{p}\sigma^{-1}$. This indicates that in general, the relationship between η_{pair} and s_{pair}^* is distribution dependent. Figure 8 further studies the relationship between the two quantities for each individual trial. We see that, for a given trial (or equivalently for a given distribution), the relationship between η_{pair} and s_{pair}^* is strictly monotone, as expected.

Appendix J. Empirical Illustration of Optimal p -Norm Push Univariate Scorer

We now present an empirical illustration of the fact that for a general proper composite loss, the optimal p -norm push univariate scorer is a distribution dependent transform of η . We repeat the setup of Appendix G, except that we worked with the p -norm push risk for $p = 4$, with ℓ being logistic loss, and considered $n = 5$ to reduce the number of η_{pair} values.

Figure 9 shows the relationship between η and s^* across multiple trials is *not* monotone, and significantly deviates from the optimal solution in the class-probability estimation setting, viz. $s^* = \Psi(\eta)$ for $\Psi = \frac{1}{p}\sigma^{-1}$.

Appendix K. Illustration of Hand's Representation and Proper Loss Equivalence

We illustrate empirically that the AUC for certain calibrated scorers is equivalent to a suitable risk with respect to a proper loss, owing to Hand's representation (Equation 34). For a fixed n , we consider a finite instance space $\mathcal{X} = \{0, 1/n, 2/n, \dots, 1\}$. We consider a distribution D over \mathcal{X} where the marginal M is uniform and the class-probability function η is of a pre-specified form. Specifically, we considered $\mathbb{P}(\eta|X) = c] \propto w(c)$, where $w(c)$ is the weight function corresponding to a proper loss. We considered two choices of $w(c) = 1$, corresponding to square loss, and $w(c) = 1/\sqrt{c} \cdot (1 - c)$, corresponding to the arcsin loss of Bujia et al. (2005, Section 11).

For a given n , we then computed the AUC of the scorer $s^* = \eta$, and compared it to the corresponding proper loss of the scorer. Hand's representation (Equation 34) suggests that as $n \rightarrow \infty$, so that the distribution of the scores is exactly the weight of the proper loss, the two will be equivalent.

Figure 10 shows that for a large n , one minus the AUC and the appropriate proper risk converge. The results compare the two over 100 trials, where each trial corresponds to a different random draw of η from the distribution with density given by the appropriately normalised weight $w(\cdot)$.

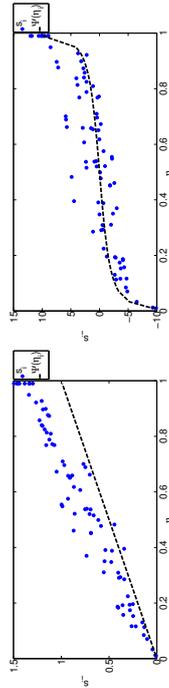

Figure 4: Results of 20 simulation trials to illustrate distribution dependent Bayes-optimal scorer (Proposition 47) for the case of squared and canonical boosting losses. Here, the distribution D is varied across each trial, and the relationship between the (η, s^*) pairs across all trials is plotted.

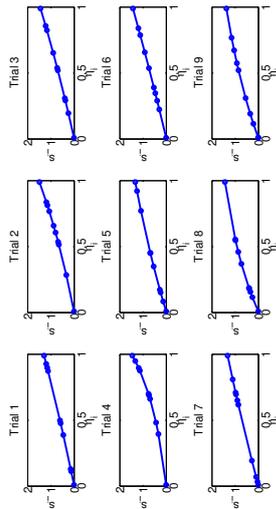

Figure 5: Results of 9 simulation trials to illustrate order preserving Bayes-optimal scorer (Corollary 48) for the case of squared loss. Here, the distribution D is varied across each trial, and each panel represents the relationship between η and s^* for a *specific* trial.

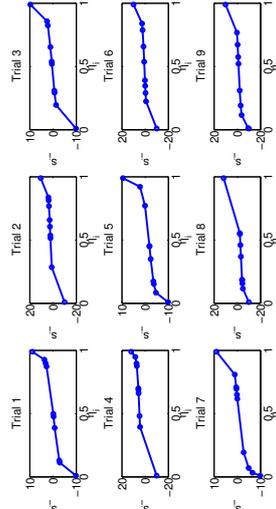

Figure 6: Results of 9 simulation trials to illustrate order preserving Bayes-optimal scorer (Corollary 48) for the case of canonical boosting loss. Here, the distribution D is varied across each trial, and each panel represents the relationship between η and s^* for a *specific* trial.

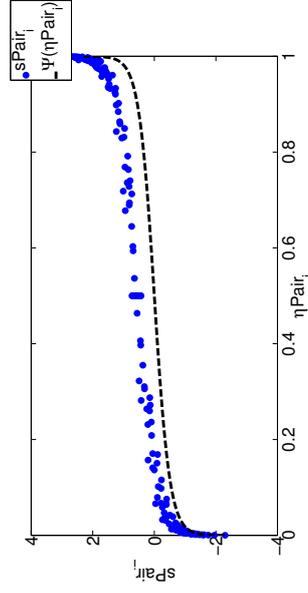

Figure 7: Results of 9 simulation trials to illustrate the relationship between η_{Pair_i} and $s_{\text{Pair}_i}^*$ for p -norm push with logistic loss. Here, the distribution D is varied across each trial, and the relationship between the $(\eta_{\text{Pair}_i}, s_{\text{Pair}_i}^*)$ pairs across all trials is plotted.

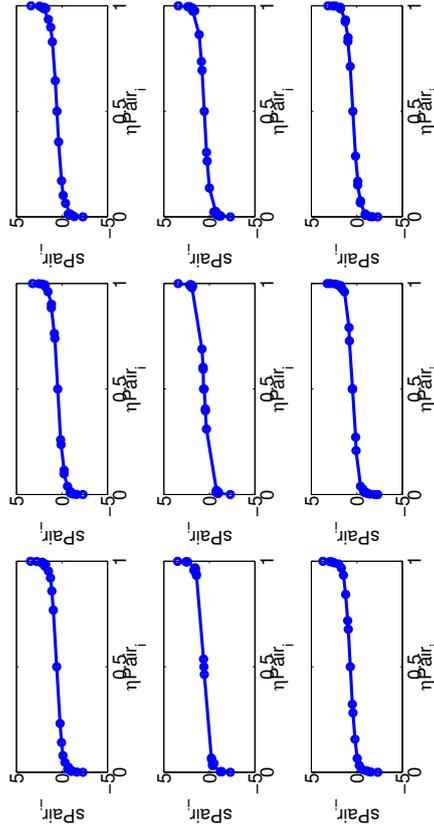

Figure 8: Results of 9 simulation trials to illustrate the distribution dependent relationship between η_{Pair_i} and $s_{\text{Pair}_i}^*$ for p -norm push with logistic loss. Here, the distribution D is varied across each trial, and each panel represents the relationship between η_{Pair_i} and $s_{\text{Pair}_i}^*$ for a *specific* trial.

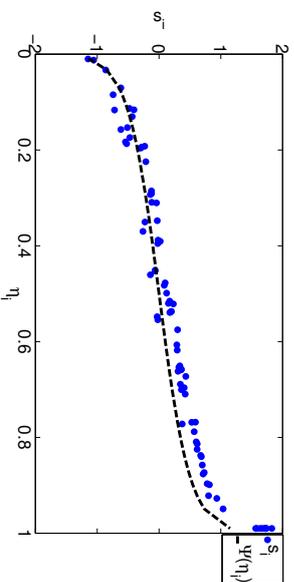

Figure 9: Results of 20 simulation trials to illustrate the relationship between η and s^* for p -norm push with logistic loss. Here, the η_i and M_i values were varied across each trial, and each panel represents the relationship between η and s^* for a specific trial.

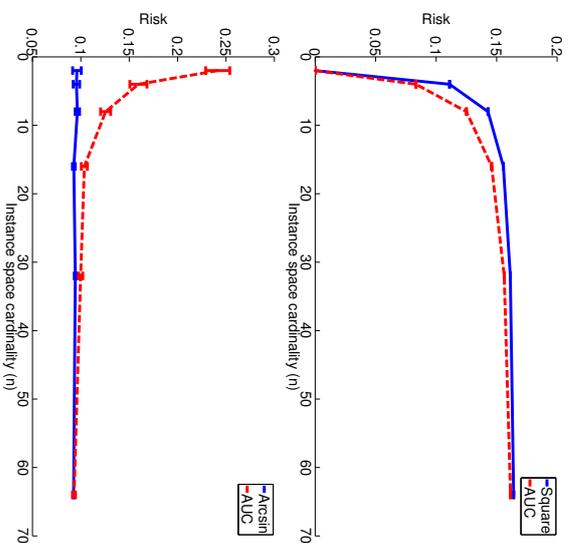

Figure 10: Results of 100 simulation trials to illustrate the relationship between the AUC and a proper risk, for different choices of distribution on the underlying optimal scorer $s^* = \eta$ on an instance space with n elements.

Abstract

Latent factor models are the canonical statistical tool for exploratory analyses of low-dimensional linear structure for a matrix of p features across n samples. We develop a structured Bayesian group factor analysis model that extends the factor model to multiple coupled observation matrices; in the case of two observations, this reduces to a Bayesian model of canonical correlation analysis. Here, we carefully define a structured Bayesian prior that encourages both element-wise and column-wise shrinkage and leads to desirable behavior on high-dimensional data. In particular, our model puts a structured prior on the joint factor loading matrix, regularizing at three levels, which enables element-wise sparsity and unsupervised recovery of latent factors corresponding to structured variance across arbitrary subsets of the observations. In addition, our structured prior allows for both dense and sparse latent factors so that covariation among either all features or only a subset of features can be recovered. We use fast parameter-expanded expectation-maximization for parameter estimation in this model. We validate our method on simulated data with substantial structure. We show results of our method applied to three high-dimensional data sets, comparing results against a number of state-of-the-art approaches. These results illustrate useful properties of our model, including i) recovering sparse signal in the presence of dense effects; ii) the ability to scale naturally to large numbers of observations; iii) flexible observation- and factor-specific regularization to recover factors with a wide variety of sparsity levels and percentage of variance explained; and iv) tractable inference that scales to modern genomic and text data sizes.

Keywords: Bayesian structured sparsity, canonical correlation analysis, sparse priors, sparse and low-rank matrix decomposition, mixture models, parameter expansion

1. Introduction

Factor analysis models have attracted attention recently due to their ability to perform exploratory analyses of the latent linear structure in high-dimensional data (West, 2003; Carvalho et al., 2008; Engelhardt and Stephens, 2010). A latent factor model finds a low-dimensional representation $\mathbf{x}_i \in \mathbb{R}^{k \times 1}$ of high-dimensional data with p features, $\mathbf{y}_i \in \mathbb{R}^{p \times 1}$ in $i = 1, \dots, n$ samples. A sample in the low-dimensional space is linearly projected to the original high-dimensional space through a *loadings matrix* $\mathbf{A} \in \mathbb{R}^{p \times k}$ with Gaussian noise $\boldsymbol{\epsilon}_i \in \mathbb{R}^{p \times 1}$:

$$\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i, \quad (1)$$

for $i = 1, \dots, n$. It is often assumed that \mathbf{x}_i follows a $\mathcal{N}_k(\mathbf{0}, \mathbf{I}_k)$ distribution, where \mathbf{I}_k is the identity matrix of dimension k , and $\boldsymbol{\epsilon}_i \sim \mathcal{N}_p(\mathbf{0}, \boldsymbol{\Sigma})$, where $\boldsymbol{\Sigma}$ is a $p \times p$ diagonal covariance matrix with σ_j^2 for $j = 1, \dots, p$ on the diagonal. In many applications of factor analysis, the number of latent factors k is much smaller than the number of features p and the number of samples n . Integrating over factor \mathbf{x}_i , this model produces a low-rank estimation of the feature covariance matrix. In particular, the covariance of \mathbf{y}_i , $\boldsymbol{\Omega} \in \mathbb{R}^{p \times p}$, is estimated as

$$\boldsymbol{\Omega} = \mathbf{A}\mathbf{A}^T + \boldsymbol{\Sigma} = \sum_{h=1}^k \boldsymbol{\lambda}_h \boldsymbol{\lambda}_h^T + \boldsymbol{\Sigma},$$

where $\boldsymbol{\lambda}_h$ is the h^{th} column of \mathbf{A} . This factorization suggests that each factor contributes to the covariance of the sample through its corresponding loading. Traditional exploratory data analysis methods including principal component analysis (PCA) (Hotelling, 1933), independent component analysis (ICA) (Comon, 1994), and canonical correlation analysis (CCA) (Hotelling, 1936) all have interpretations as latent factor models. Indeed, the field of latent variable models is extremely broad, and robust unifying frameworks are desirable (Cunningham and Ghahramani, 2015).

Considering latent factor models (Equation 1) as capturing a low-rank estimate of the feature covariance matrix, we can characterize canonical correlation analysis (CCA) as modeling paired observations $\mathbf{y}_i^{(1)} \in \mathbb{R}^{p_1 \times 1}$ and $\mathbf{y}_i^{(2)} \in \mathbb{R}^{p_2 \times 1}$ across n samples to identify a linear latent space for which the correlations between the two observations are maximized (Hotelling, 1936; Bach and Jordan, 2005). The Bayesian CCA (BCCA) model extends this covariance representation to two observations: the combined loading matrix jointly models covariance structure shared across both observations and covariance local to each observation (Klami et al., 2013). Group factor analysis (GFA) models further extend this representation to m coupled observations for the same sample, modeling, in its fullest generality, the covariance associated with every subset of observations (Virtanen et al., 2012; Klami et al., 2014b). GFA becomes intractable when m is large due to exponential explosion of covariance matrices to estimate.

In a latent factor model, the loading matrix \mathbf{A} plays an important role in the subspace mapping. In applications where there are fewer samples than features—the $n \ll p$ scenario (West, 2003)—it is essential to include strong regularization on the loading matrix

because the optimization problem is under-constrained and has many equivalent solutions that optimize the data likelihood. In the machine learning and statistics literature, priors or penalties are used to regularize the elements of the loading matrix, occasionally by inducing sparsity. Element-wise sparsity corresponds to *feature selection*. This has the effect that a latent factor contributes to variation in only a subset of the observed features, generating interpretable results (West, 2003; Carvalho et al., 2008; Knowles and Ghahramani, 2011). For example, in gene expression analysis, sparse factor loadings are interpreted as non-disjoint clusters of co-regulated genes (Pounnara and Wernisch, 2007; Lucas et al., 2010; Gao et al., 2013).

Element-wise sparsity has been imposed in latent factor models through regularization via l_1 type penalties (Zou et al., 2006; Witten et al., 2009; Salzmänn et al., 2010). More recently, Bayesian shrinkage methods using sparsity-inducing priors have been introduced for latent factor models (Archambeau and Bach, 2009; Carvalho et al., 2008; Virtanen et al., 2012; Bhattacharya and Dunson, 2011; Klami et al., 2013). The spike-and-slab prior (Mitchell and Beauchamp, 1988), the classic two-groups Bayesian sparsity-inducing prior, has been used for sparse Bayesian latent factor models (Carvalho et al., 2008). A computationally tractable one-group prior, the automatic relevance determination (ARD) prior (Neal, 1995; Tipping, 2001), has also been used to induce sparsity in latent factor models (Engelhardt and Stephens, 2010; Pritchard-Malinici et al., 2011). More sophisticated structured regularization approaches for linear models have been studied in classical statistics (Zou and Hastie, 2005; Kowalski and Torrésani, 2009; Jenatton et al., 2011; Huang et al., 2011).

Global structured regularization of the loading matrix, in fact, has been used to extend latent factor models to multiple observations. The BCCA model (Klami et al., 2013) assumes a latent factor model for each observation through a shared latent vector $\mathbf{x}_i \in \mathbb{R}^{k \times 1}$. This BCCA model may be written as a latent factor model by vertical concatenation of observations, loading matrices, and Gaussian residual errors. By inducing group-wise sparsity—explicit blocks of zeros—in the combined loading matrix, the covariance shared across the two observations and the covariance local to each observation are estimated (Klami and Kaski, 2008; Klami et al., 2013). Extensions of this approach to multiple coupled observations $\mathbf{y}_i^{(1)} \in \mathbb{R}^{p \times 1}, \dots, \mathbf{y}_i^{(m)} \in \mathbb{R}^{p_m \times 1}$ have resulted in group factor analysis models (GFA) (Archambeau and Bach, 2009; Salzmänn et al., 2010; Jia et al., 2010; Virtanen et al., 2012).

In addition to linear factor models, flexible non-linear latent factor models have been developed. The Gaussian process latent variable model (GPLVM) (Lawrence, 2005) extends Equation (1) to non-linear mappings with a Gaussian process prior on latent variables. Extensions of GPLVM include models that allow multiple observations (Shon et al., 2005; Ek et al., 2008; Salzmänn et al., 2010; Danahon et al., 2012). Although our focus will be on linear maps, we will keep the non-linear possibility open for model extensions, and we will include the GPLVM model in our model comparisons.

The primary contribution of this study is that we develop a GFA model using Bayesian shrinkage with hierarchical structure that encourages both element-wise and column-wise sparsity; the resulting flexible Bayesian GFA model is called BASS (Bayesian group factor Analysis with Structured Sparsity). The structured sparsity in our model is achieved with multi-scale application of a hierarchical sparsity-inducing prior that has a computa-

tionally tractable representation as a scale mixture of normals; the three parameter beta prior (\mathcal{TPB}) (Armagan et al., 2011; Gao et al., 2013). Our BASS model i) shrinks the loading matrix globally; removing factors that are not supported in the data; ii) shrinks loading columns to decouple latent spaces from arbitrary subsets of observations; iii) allows factor loadings to have either an element-wise sparse or a non-sparse prior, combining interpretability with dimension reduction. In addition, we developed a parameter-expanded expectation maximization (PX-EM) method based on rotation augmentation to tractably find *maximum a posteriori* estimates of the model parameters (Rocková and George, 2015). PX-EM has the same computational complexity as the standard EM algorithm, but produces more robust solutions by enabling fast searching over posterior modes.

In Section 2 we review current work in sparse latent factor models and describe our BASS model. In Sections 3 and 4, we briefly review Bayesian shrinkage priors and introduce the structured hierarchical prior in BASS. In Section 5, we introduce our PX-EM algorithms for parameter estimation. In Section 6, we show the behavior of our model for recovering simulated sparse signals among m observation matrices and compare the results from BASS with state-of-the-art methods. In Section 7, we present results that illustrate the performance of BASS on three high-dimensional data sets. We first show that the estimates of shared factors from BASS can be used to perform multi-label learning and prediction in the Mutan Library data and the 20 Newsgroups data. Then we demonstrate that BASS can be used to find biologically meaningful structure and construct condition-specific co-regulated gene networks using the sparse factors specific to observations. We conclude by considering possible extensions to this model in Section 8.

2. Bayesian group factor model

Here, we review current work in sparse latent factor models and describe our Bayesian group factor Analysis with Structured Sparsity (BASS) model in the context of related work.

2.1 Latent factor models

Factor analysis has been extensively used for dimension reduction and low-dimensional covariance matrix estimation. For concreteness, we re-write the basic factor analysis model here as

$$\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \epsilon_i,$$

where $\mathbf{y}_i \in \mathbb{R}^{p \times 1}$ is modeled as a linear transformation of a latent vector $\mathbf{x}_i \in \mathbb{R}^{k \times 1}$ through loading matrix $\mathbf{A} \in \mathbb{R}^{p \times k}$ (Figure 1A). Here, \mathbf{x}_i is assumed to follow a $\mathcal{N}_{\mathbf{A}}(\mathbf{0}, \mathbf{I}_k)$ distribution, where \mathbf{I}_k is the k -dimensional identity matrix, and $\epsilon_i \sim \mathcal{N}_\epsilon(\mathbf{0}, \mathbf{\Sigma})$, where $\mathbf{\Sigma}$ is a $p \times p$ diagonal matrix. With an isotropic noise assumption, $\mathbf{\Sigma} = \mathbf{I}_p \sigma^2$, this model has a probabilistic principal components interpretation (Roweis, 1998; Tipping and Bishop, 1999b). For factor analysis, and in this work, it is assumed that $\mathbf{\Sigma} = \text{diag}(\sigma_1^2, \dots, \sigma_p^2)$ representing independent idiosyncratic noise (Tipping and Bishop, 1999a).

Integrating over the factors \mathbf{x}_i , we see that the covariance of \mathbf{y}_i is estimated with a low-rank matrix factorization: $\mathbf{A}\mathbf{A}^T + \mathbf{\Sigma}$. We further let $\mathbf{Y} = [\mathbf{y}_1, \dots, \mathbf{y}_n]$ be the collection of n samples \mathbf{y}_i , and similarly let $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$ and $\mathbf{E} = [\epsilon_1, \dots, \epsilon_n]$. Then the factor

analysis model for the observation \mathbf{Y} is written as

$$\mathbf{Y} = \mathbf{\Lambda}\mathbf{X} + \mathbf{E}. \quad (2)$$

2.2 Probabilistic canonical correlation analysis

In the context of two paired observations $\mathbf{y}_i^{(1)} \in \mathbb{R}^{p_1 \times 1}$ and $\mathbf{y}_i^{(2)} \in \mathbb{R}^{p_2 \times 1}$ on the same n samples, canonical correlation analysis (CCA) seeks to find linear projections (canonical directions) such that the sample correlations in the projected space are mutually maximized (Hotelling, 1936). The work of interpreting CCA as a probabilistic model can be traced back to classical descriptions (Bach and Jordan, 2005). With a common latent factor, $\mathbf{x}_i \in \mathbb{R}^{k \times 1}$, $\mathbf{y}_i^{(1)}$ and $\mathbf{y}_i^{(2)}$ are modeled as

$$\begin{aligned} \mathbf{y}_i^{(1)} &= \mathbf{\Lambda}^{(1)}\mathbf{x}_i + \boldsymbol{\epsilon}_i^{(1)}, \\ \mathbf{y}_i^{(2)} &= \mathbf{\Lambda}^{(2)}\mathbf{x}_i + \boldsymbol{\epsilon}_i^{(2)}. \end{aligned} \quad (3)$$

In this model, the errors are distributed as $\boldsymbol{\epsilon}_i^{(1)} \sim \mathcal{N}_{p_1}(\mathbf{0}, \boldsymbol{\Psi}^{(1)})$ and $\boldsymbol{\epsilon}_i^{(2)} \sim \mathcal{N}_{p_2}(\mathbf{0}, \boldsymbol{\Psi}^{(2)})$, where $\boldsymbol{\Psi}^{(1)}$ and $\boldsymbol{\Psi}^{(2)}$ are positive semi-definite matrices, and not necessarily diagonal, allowing dependencies among the residual errors within an observation. The maximum likelihood estimates of the loading matrices in the classical CCA framework, $\mathbf{\Lambda}^{(1)}$ and $\mathbf{\Lambda}^{(2)}$, are the first k canonical directions up to orthogonal transformations (Bach and Jordan, 2005).

2.3 Bayesian CCA with group-wise sparsity

Building on the probabilistic CCA model, a Bayesian CCA (BCCA) model has the following form (Klami et al., 2013)

$$\begin{aligned} \mathbf{y}_i^{(1)} &= \mathbf{A}^{(1)}\mathbf{x}_i^{(0)} + \mathbf{B}^{(1)}\mathbf{x}_i^{(1)} + \boldsymbol{\epsilon}_i^{(1)}, \\ \mathbf{y}_i^{(2)} &= \mathbf{A}^{(2)}\mathbf{x}_i^{(0)} + \mathbf{B}^{(2)}\mathbf{x}_i^{(2)} + \boldsymbol{\epsilon}_i^{(2)}, \end{aligned} \quad (4)$$

with $\mathbf{x}_i^{(0)} \in \mathbb{R}^{k_0 \times 1}$, $\mathbf{x}_i^{(1)} \in \mathbb{R}^{k_1 \times 1}$ and $\mathbf{x}_i^{(2)} \in \mathbb{R}^{k_2 \times 1}$ (Figure 1B). The latent vector $\mathbf{x}_i^{(0)}$ is shared by both $\mathbf{y}_i^{(1)}$ and $\mathbf{y}_i^{(2)}$, and captures their common variation through loading matrices $\mathbf{A}^{(1)}$ and $\mathbf{A}^{(2)}$. Two additional latent vectors, $\mathbf{x}_i^{(1)}$ and $\mathbf{x}_i^{(2)}$, are specific to each observation; they are multiplied by observation-specific loading matrices $\mathbf{B}^{(1)}$ and $\mathbf{B}^{(2)}$. The two residual error terms are $\boldsymbol{\epsilon}_i^{(1)} \sim \mathcal{N}_{p_1}(\mathbf{0}, \boldsymbol{\Sigma}^{(1)})$ and $\boldsymbol{\epsilon}_i^{(2)} \sim \mathcal{N}_{p_2}(\mathbf{0}, \boldsymbol{\Sigma}^{(2)})$, where $\boldsymbol{\Sigma}^{(1)}$ and $\boldsymbol{\Sigma}^{(2)}$ are diagonal matrices. This model was originally called inter-battery factor analysis (IBFA) (Browne, 1979) and recently has been studied under a full Bayesian inference framework (Klami et al., 2013). It may be interpreted as the probabilistic CCA model (Equation 3) with an additional low-rank factorization of the observation-specific error covariance matrices. In particular, we re-write the residual error term specific to observation w ($w = 1, 2$) from the probabilistic CCA model (Equation 3) as $\boldsymbol{\epsilon}_i^{(w)} = \mathbf{B}^{(w)}\mathbf{x}_i^{(w)} + \boldsymbol{\epsilon}_i^{(w)}$; then marginally $\boldsymbol{\epsilon}_i^{(w)} \sim \mathcal{N}_{p_w}(\mathbf{0}, \boldsymbol{\Psi}^{(w)})$ where $\boldsymbol{\Psi}^{(w)} = \mathbf{B}^{(w)}(\mathbf{B}^{(w)})^T + \boldsymbol{\Sigma}^{(w)}$.

Recent work has re-written the BCCA model as a factor analysis model with group-wise sparsity in the loading matrix (Klami et al., 2013). Let $\mathbf{y}_i \in \mathbb{R}^{p \times 1}$ (where $p = p_1 + p_2$) be the vertical concatenation of $\mathbf{y}_i^{(1)}$ and $\mathbf{y}_i^{(2)}$; let $\mathbf{x}_i \in \mathbb{R}^{k \times 1}$ (where $k = k_0 + k_1 + k_2$) be the vertical concatenation of $\mathbf{x}_i^{(0)}$, $\mathbf{x}_i^{(1)}$ and $\mathbf{x}_i^{(2)}$; and let $\boldsymbol{\epsilon}_i \in \mathbb{R}^{p \times 1}$ be the vertical concatenation of the two residual errors. Then, the BCCA model (Equation 4) may be written as a factor analysis model

$$\mathbf{y}_i = \mathbf{\Lambda}\mathbf{x}_i + \boldsymbol{\epsilon}_i,$$

with $\boldsymbol{\epsilon}_i \sim \mathcal{N}_p(\mathbf{0}, \boldsymbol{\Sigma})$, where

$$\mathbf{\Lambda} = \begin{bmatrix} \mathbf{A}^{(1)} & \mathbf{B}^{(1)} & \mathbf{0} \\ \mathbf{A}^{(2)} & \mathbf{0} & \mathbf{B}^{(2)} \end{bmatrix}, \quad \boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}^{(1)} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma}^{(2)} \end{bmatrix}.$$

The structure in the loading matrix $\mathbf{\Lambda}$ has a specific meaning: the non-zero columns (i.e., $\mathbf{A}^{(1)}$ and $\mathbf{A}^{(2)}$) project the shared latent factors (i.e., the first k_0 elements of \mathbf{x}_i) to $\mathbf{y}_i^{(1)}$ and $\mathbf{y}_i^{(2)}$, respectively; these latent factors represent the covariance shared across the observations. The columns with zero blocks (i.e., $[\mathbf{B}^{(1)}; \mathbf{0}]$ or $[\mathbf{0}; \mathbf{B}^{(2)}]$) relate factors to only one of the two observations; they model covariance specific to that observation. Under this model, the block sparse structure of $\mathbf{\Lambda}$ is imposed via observation-wise sparsity on each factor.

2.4 Extensions to multiple observations

Classical and Bayesian extensions of the CCA model to allow multiple observations ($m > 2$) have been proposed (McDonald, 1970; Browne, 1980; Archambeau and Bach, 2009; Qu and

Chen, 2011; Ray et al., 2014). Generally, these approaches partition the latent variables into those that are shared and those that are observation-specific as follows:

$$\mathbf{y}_i^{(w)} = \mathbf{A}^{(w)} \mathbf{x}_i^{(0)} + \mathbf{B}^{(w)} \mathbf{x}_i^{(w)} + \boldsymbol{\epsilon}_i^{(w)} \quad \text{for } w = 1, \dots, m.$$

By vertical concatenation of $\mathbf{y}_i^{(w)}$, $\mathbf{x}_i^{(w)}$ and $\boldsymbol{\epsilon}_i^{(w)}$, this model can be viewed as a latent factor model (Equation 1) with the joint loading matrix \mathbf{A} having a similar observation-wise sparsity pattern as the BCGA model

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}^{(1)} & \mathbf{B}^{(1)} & \dots & \mathbf{0} \\ \mathbf{A}^{(2)} & \mathbf{0} & \dots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{A}^{(m)} & \mathbf{0} & \dots & \mathbf{B}^{(m)} \end{bmatrix}. \quad (5)$$

Here, the first column of blocks ($\mathbf{A}^{(w)}$) is a non-zero loading matrix across the features of all observations; the remaining columns have a block diagonal structure with observation-specific loading matrices ($\mathbf{B}^{(w)}$) on the diagonal. However, those extensions are limited by the strict diagonal structure of the loading matrix. Structuring the loading matrix in this way prevents this model from capturing covariance structure among arbitrary subsets of observations. On the other hand, there are an exponential number of possible subsets intractable for large m .

The structure on \mathbf{A} in Equation (5) has been relaxed to model covariance among subsets of the observations (Jia et al., 2010; Virtanen et al., 2012; Klami et al., 2014b). In the relaxed formulation, each observation $\mathbf{y}_i^{(w)}$ is modeled by its own loading matrix $\mathbf{A}^{(w)}$ and a shared latent vector \mathbf{x}_i (Figure 1D):

$$\mathbf{y}_i^{(w)} = \mathbf{A}^{(w)} \mathbf{x}_i + \boldsymbol{\epsilon}_i^{(w)} \quad \text{for } w = 1, \dots, m. \quad (6)$$

By allowing columns in $\mathbf{A}^{(w)}$ to be zero, the model decouples certain latent factors from certain observations. The covariance structure of an arbitrary subset of observations is modeled by factors with non-zero loading columns corresponding to the observations in that subset. Factors that correspond to non-zero entries for only one observation capture covariance specific to that observation. Two different approaches have been proposed to achieve column-wise shrinkage in this framework: Bayesian shrinkage (Virtanen et al., 2012; Klami et al., 2014b) and explicit penalties (Jia et al., 2010). The group factor analysis (GFA) model puts an ARD prior (Tipping, 2001) on the loading column for each observation to allow column-wise shrinkage (Virtanen et al., 2012; Klami et al., 2014b):

$$\begin{aligned} \lambda_{j/h}^{(w)} &\sim \mathcal{N}\left(0, \left(\alpha_{j/h}^{(w)}\right)^{-1}\right) & \text{for } j = 1, \dots, p_w, \\ \alpha_{j/h}^{(w)} &\sim \text{Ga}(a_0, b_0), \end{aligned}$$

for observation $w = 1, \dots, m$ and loading column $h = 1, \dots, k$. This prior assumes that each element of observation-specific loading $\lambda_{j/h}^{(w)}$ is jointly regularized. This prior encourages the

parameter $\alpha_{j/h}^{(w)}$ to have large values or values near zero, either pushing elements of $\lambda_{j/h}^{(w)}$ toward zero or imposing minimal shrinkage, and enabling observation-specific, column-wise sparsity.

Other work puts alternative structured regularizers on $\mathbf{A}^{(w)}$ (Jia et al., 2010). To induce observation-specific, column-wise sparsity, GFA used mixed norms: an l_1 norm penalizes each observation-specific column, and either l_2 or l_∞ norms penalize the elements in an observation-specific column:

$$\phi(\mathbf{A}^{(w)}) = \sum_{h=1}^k \|\lambda_{j/h}^{(w)}\|_2 \quad \text{or} \quad \phi(\mathbf{A}^{(w)}) = \sum_{h=1}^k \|\lambda_{j/h}^{(w)}\|_\infty.$$

The l_1 norm penalty achieves observation-specific column-wise shrinkage. Both of these mixed-norm penalties create a bi-convex problem in \mathbf{A} and \mathbf{X} .

These two approaches of adaptive structured regularization in GFA models capture covariance uniquely shared among arbitrary subsets of the observations and avoid modeling shared covariance in non-maximal subsets. But neither the ARD approach nor the mixed-norm penalties encourages element-wise sparsity within loading columns. Adding element-wise sparsity is important because it results in interpretable latent factors, where features with non-zero loadings in a specific factor have an interpretation as a cluster (West, 2003; Carralho et al., 2008). To induce element-wise sparsity, one can either use Bayesian shrinkage on each loading (Carralho et al., 2010) or a mixed norm with l_1 type penalties on each element (i.e., $\sum_{h=1}^k \sum_{j=1}^p |\lambda_{j/h}^{(w)}|$).

A more recent GFA model is a step toward both column-wise and element-wise sparsity (Khan et al., 2014). In this model, element-wise sparsity is achieved by putting independent ARD priors on each loading element, and column-wise sparsity is achieved by a spike-and-slab prior on the loading columns. However, ARD priors do not allow the model to adjust shrinkage levels within each factor, and this approach does not include sparse and dense factors. One contribution of our work is to define a carefully structured Bayesian shrinkage prior on the loading matrix of a GFA model that encourages both element-wise and column-wise shrinkage, and that includes both sparse and dense factors.

3. Bayesian structured sparsity

The column-wise sparse structure of \mathbf{A} in GFA models belongs to a general class of structured sparsity methods that has drawn attention recently (Zou and Hastie, 2005; Yan and Lin, 2006; Jenatton et al., 2011, 2010; Kowalski, 2009; Kowalski and Torrèsani, 2009; Zhao et al., 2009; Huang et al., 2011; Jia et al., 2010). For example, in structured sparse PCA, the loading matrix is constrained to have specific patterns (Jenatton et al., 2010). Later work discussed more general structured variable selection methods in a regression framework (Jenatton et al., 2011; Huang et al., 2011). However, there has been little work in using Bayesian structured sparsity, with some exceptions (Kyung et al., 2010; Engelhardt and Adams, 2014; Wu et al., 2014). Starting from Bayesian sparse priors, we propose a structured hierarchical sparse prior that includes three levels of shrinkage, which is conceptually similar to tree structured shrinkage (Romberg et al., 2001), or global-local priors in the regression framework (Polson and Scott, 2011).

3.1 Bayesian sparsity-inducing priors

Bayesian shrinkage priors have been widely used in latent factor models due to their flexible and interpretable solutions (West, 2003; Carvalho et al., 2008; Polson and Scott, 2011; Knowles and Ghahramani, 2011; Bhattacharya and Dunson, 2011). In Bayesian statistics, a regularizing term, $\phi(\mathbf{A})$, may be viewed as a marginal prior proportional to $\exp(-\phi(\mathbf{A}))$; the regularized optimum then becomes the maximum a posteriori (MAP) solution (Polson and Scott, 2011). For example, the well known ℓ_2 penalty for coefficients in linear regression models corresponds to Gaussian priors, also known as ridge regression or Tikhonov regularization (Hoerl and Kennard, 1970). In contrast, an ℓ_1 penalty corresponds to double exponential or Laplace priors, also known as the Bayesian Lasso (Tibshirani, 1996; Park and Casella, 2008; Hans, 2009).

When the goal of regularization is to induce sparsity, the prior distribution should be chosen so that it has substantial probability mass around zero, which draws small effects toward zero, and heavy tails, which allows large signals to escape from substantial shrinkage (O’Hagan, 1979; Carvalho et al., 2010; Armagan et al., 2011). The canonical Bayesian sparsity-inducing prior is the spike-and-slab prior, which is a mixture of a point mass at zero and a flat distribution across the space of real values, often modeled as a Gaussian with a large variance term (Mitchell and Beauchamp, 1988; West, 2003). The spike-and-slab prior has elegant interpretability by estimating the probability that certain loadings are excluded, modeled by the ‘spike’ distribution, or included, modeled by the ‘slab’ distribution (Carvalho et al., 2008). This interpretability comes at the cost of having exponentially many possible configurations of model inclusion parameters in the loading matrix.

Recently, scale mixtures of normal priors have been proposed as a computationally efficient alternative to the two component spike-and-slab prior (West, 1987; Carvalho et al., 2010; Polson and Scott, 2011; Armagan et al., 2013, 2011; Bhattacharya et al., 2014). Such priors generally assume normal distributions with a mixed variance term. The mixing distribution of the variance allows strong shrinkage near zero but weak regularization away from zero. For example, an inverse gamma distribution on the variance term results in an ARD prior (Tipping, 2001), and an exponential distribution on the variance term results in a Laplace prior (Park and Casella, 2008). The horseshoe prior, with a half Cauchy distribution on the standard deviation as the mixing density, has become popular due to its strong shrinkage and heavy tails (Carvalho et al., 2010).

A more general class of beta mixtures of normals is the three parameter beta distribution (Armagan et al., 2011). Although these continuous shrinkage priors do not directly model the probability of feature inclusion, it has been shown in the regression framework that two layers of regularization—global regularization, across all coefficients, and local regularization, specific to each coefficient (Polson and Scott, 2011)—has behavior that is similar to the spike-and-slab prior in effectively modeling signal and noise separately, but with computational tractability (Carvalho et al., 2009). In this study, we extend and structure the beta mixture of normals prior to three levels of hierarchy to induce desirable behavior in the context of GFA models.

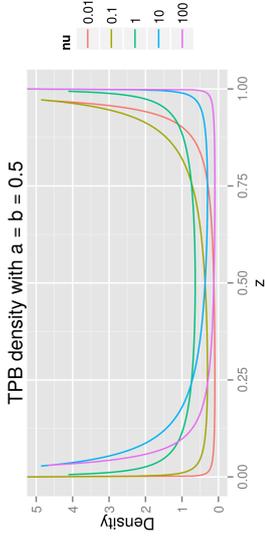

Figure 2: **Density of the three parameter beta (TPB) distribution with different values of ν .** Five different values of $\nu = \{0.01, 0.1, 1, 10, 100\}$ for the three parameter beta distribution with $a = b = 0.5$. The x-axis represents the value of random variable z , and the y-axis represents the density of random variable z .

3.2 Three parameter beta prior

The three parameter beta (TPB) distribution for a random variable $Z \in (0, 1)$ has the following density (Armagan et al., 2011):

$$f(z; a, b, \nu) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \nu^z b^{-1} (1-z)^{a-1} \{1 + (\nu-1)z\}^{-(a+b)}, \quad (7)$$

where $a, b, \phi > 0$. We denote this distribution as $\mathcal{TPB}(a, b, \nu)$. When $0 < a < 1$ and $0 < b < 1$, the distribution is bimodal, with modes at 0 and 1 (Figure 2). The variance parameter ν gives the distribution freedom: with fixed a and b , smaller values of ν put greater probability on $z = 1$, while larger values of ν move the probability mass towards $z = 0$ (Armagan et al., 2011). With $\nu = 1$, this distribution is identical to a beta distribution (i.e., $Be(b, a)$).

Let λ denote the parameter to which we are applying sparsity-inducing regularization. We assign the following TPB normal scale mixture distribution, \mathcal{TPBN} , to λ :

$$\lambda | \varphi \sim \mathcal{N}\left(0, \frac{1}{\varphi} - 1\right), \quad \text{with} \quad \varphi \sim \mathcal{TPB}(a, b, \nu),$$

where the *shrinkage parameter* φ follows a TPB distribution. With $a = b = 1/2$ and $\nu = 1$, this prior becomes the horseshoe prior (Carvalho et al., 2010; Armagan et al., 2011; Gao et al., 2013). The bimodal property of φ induces two distinct shrinkage behaviors: the mode near one encourages $\frac{1}{\varphi} - 1$ towards zero and induces strong shrinkage on λ ; the mode near zero encourages $\frac{1}{\varphi} - 1$ large, creating a diffuse prior on λ . Further decreasing the variance parameter ν supports stronger shrinkage (Armagan et al., 2011; Gao et al., 2013). If we let $\theta = \frac{1}{\varphi} - 1$, then this mixture has the following hierarchical representation:

$$\lambda \sim \mathcal{N}(0, \theta), \quad \theta \sim Ga(a, \delta), \quad \delta \sim Ga(b, \nu).$$

Note the difference between the ARD prior and the \mathcal{TPB} : the ARD prior induces sparsity using an inverse gamma prior on θ , whereas the \mathcal{TPB} induces sparsity by using a gamma prior on the θ variable and then regularizing the rate parameter δ using a second gamma prior. These differences lead to different behavior of ARD and the \mathcal{TPB} in theory (Polson and Scott, 2011) and in practice, as we show below.

3.3 Global-factor-local shrinkage

The flexible representation of the \mathcal{TPB} prior makes it an ideal choice for latent factor models. Our recent work extended the \mathcal{TPB} prior to three levels of regularization on a loading matrix (Gao et al., 2013):

$$\begin{aligned} \varrho &\sim \mathcal{TPB}(c, f, \nu), & (\text{Global}) \\ \zeta_h &\sim \mathcal{TPB}\left(c, d, \frac{1}{\varrho} - 1\right), & (\text{Factor-specific}) \\ \varphi_{jh} &\sim \mathcal{TPB}\left(a, b, \frac{1}{\zeta_h} - 1\right), & (\text{Local}) \\ \lambda_{jh} &\sim \mathcal{N}\left(0, \frac{1}{\varphi_{jh}} - 1\right). \end{aligned} \tag{8}$$

At each of the three levels, a \mathcal{TPB} distribution is used to induce sparsity via its estimated variance parameter (ν in Equation 7), which in turn is regularized using a \mathcal{TPB} distribution. Specifically, the global shrinkage parameter ϱ applies strong shrinkage across the k columns of the loading matrix and jointly adjusts the support of column-specific parameter ζ_h , $h \in \{1, \dots, k\}$ close to either zero or one. This can be interpreted as inducing sufficient shrinkage across loading columns to recover the number of factors supported by the observed data. In particular, when ζ_h is close to one, all elements of column h are close to zero, effectively removing the h^{th} component. When near zero, the factor-specific regularization parameter ζ_h adjusts the shrinkage applied to each element of the h^{th} loading column, estimating the column-wise shrinkage by borrowing strength across all elements (i.e., features) in that column. The local shrinkage parameter, φ_{jh} , creates element-wise sparsity in the loading matrix through a \mathcal{TPBN} . Three levels of shrinkage allow us to model both column-wise and element-wise shrinkage simultaneously, and give the model nonparametric behavior in the number of factors via model selection.

Equivalently, this global-factor-local shrinkage prior can be written as (Ammagan et al., 2011; Gao et al., 2013):

$$\begin{aligned} &\text{Global} && \begin{cases} \gamma \sim \text{Gal}(f, \nu), \\ \eta \sim \text{Gal}(c, \gamma), \end{cases} \\ &\text{Factor-specific} && \begin{cases} \tau_h \sim \text{Gal}(d, \eta), \\ \phi_h \sim \text{Gal}(c, \tau_h), \end{cases} \\ &\text{Local} && \begin{cases} \delta_{jh} \sim \text{Gal}(b, \phi_h), \\ \theta_{jh} \sim \text{Gal}(a, \delta_{jh}), \end{cases} \\ &&& \lambda_{jh} \sim \mathcal{N}(0, \theta_{jh}). \end{aligned} \tag{9}$$

We further extend our prior to jointly model sparse and dense components by assigning to the local shrinkage parameter a two-component mixture distribution (Gao et al., 2013):

$$\theta_{jh} \sim \pi \text{Gal}(a, \delta_{jh}) + (1 - \pi) \delta_{\phi_h}(\cdot), \tag{10}$$

where $\delta_{\phi_h}(\cdot)$ is the Dirac delta function centered at ϕ_h . The motivation for this two component mixture is that, in real applications such as the analysis of gene expression data, it has been shown that much of the variation in the observation is due to technical (e.g., batch, platform) or biological effects (e.g., sex, ethnicity), which impact a large number of features (Leek et al., 2010). Therefore, loadings corresponding to these effects will often not be sparse. A two-component mixture (Equation 10) allows the prior on the loading (Equation 8) to select between element-wise sparsity or column-wise sparsity. Element-wise sparsity is encouraged via the \mathcal{TPBN} prior. Column-wise sparsity jointly regularizes each element of the column with a shared variance term: $\lambda_{jh} \sim \mathcal{N}\left(0, \frac{1}{\zeta_h} - 1\right)$. Modeling each element in a column using a shared regularized variance term has two possible behaviors: i) ζ_h in Equation (8) is close to 1 and the entire column is shrunk towards zero, effectively removing this factor; ii) ζ_h is close to zero, and all elements of the column have a shared Gaussian distribution, inducing only non-zero elements in that loading. We call included factors that have only non-zero elements *dense factors*.

Jointly modeling sparse and dense factors effectively combines low-rank covariance factorization with interpretability (Zou et al., 2006; Parkhomenko et al., 2009). The dense factors capture the broad effects of observation confounders, model a low-rank approximation of the covariance matrix, and usually account for a large proportion of variance explained (Chandrasekaran et al., 2011). The sparse factors, on the other hand, capture the small groups of interacting features in a (possibly) high-dimensional sparse space, and usually account for a small proportion of the variance explained.

We introduce indicator variables z_h , $h = 1, \dots, k$, to indicate which mixture component each θ_{jh} is generated from in Equation (10), where $z_h = 1$ means $\theta_{jh} \sim \text{Gal}(a, \delta_{jh})$ and $z_h = 0$ means $\theta_{jh} \sim \delta_{\phi_h}(\cdot)$. Thus, a component is a sparse factor when $z_h = 1$ and either a dense factor or eliminated when $z_h = 0$. We let $\mathbf{z} = [z_1, \dots, z_k]$ and put a Bernoulli distribution with parameter π on z_h . We further let π have a flat beta distribution $\text{Bet}(1, 1)$. This construct allows us to quantify the posterior probability that each factor h is generated from each mixture component type via z_h .

4. Bayesian group factor analysis with structured sparsity

In this work, we use global-factor-local \mathcal{TPB} priors in the GFA model to enable both element-wise and column-wise shrinkage. Specifically, we put a \mathcal{TPB} prior independently on each loading matrix corresponding to the w^{th} observation, $\mathbf{A}^{(w)}$. Let $\mathbf{Z} = [\mathbf{z}^{(1)}, \dots, \mathbf{z}^{(m)}] \in \mathbb{R}^{m \times k}$. The indicator variable $z_h^{(w)}$ is associated with the h^{th} factor and specific to observation w . When $z_h^{(w)} = 1$, the h^{th} factor has a sparse loading for observation w ; when $z_h^{(w)} = 0$, then either the h^{th} factor has a dense loading column for observation w , or observation w is not represented in that loading column. A zero loading column for observation w effectively decouples the factor from that observation, leading to the column-wise sparse behavior in previous GFA models (Virtanen et al., 2012; Klami et al., 2014b). In our model, factors

that include no observations in the associated loading column are removed from the model. We refer to this model as Bayesian group factor Analysis with Structured Sparsity (BASS).

We summarize BASS as follows. The generative model for m coupled observations $\mathbf{y}_i^{(w)}$ with $w = 1, \dots, m$ and $i = 1, \dots, n$ is

$$\mathbf{y}_i^{(w)} = \mathbf{\Lambda}^{(w)} \mathbf{x}_i + \boldsymbol{\epsilon}_i^{(w)}, \quad \text{for } w = 1, \dots, m.$$

This model is written as a latent factor model by concatenating the m feature vectors into vector \mathbf{y}_i .

$$\begin{aligned} \mathbf{y}_i &= \mathbf{\Lambda} \mathbf{x}_i + \boldsymbol{\epsilon}_i, \\ \mathbf{x}_i &\sim \mathcal{N}_k(0, \mathbf{I}_k), \\ \boldsymbol{\epsilon}_i &\sim \mathcal{N}_n(0, \boldsymbol{\Sigma}), \end{aligned} \quad (11)$$

where $\boldsymbol{\Sigma} = \text{diag}(\sigma_1^2, \dots, \sigma_p^2)$ and $p = \sum_{w=1}^m p_w$. We put independent global-factor-local \mathcal{TPB} priors (Equation 9) on $\mathbf{\Lambda}^{(w)}$:

$$\begin{aligned} \text{Global} & \begin{cases} \gamma^{(w)} \sim Ga(f, \nu), \\ \eta^{(w)} \sim Ga(c, \gamma^{(w)}), \end{cases} \\ \text{Factor-specific} & \begin{cases} \tau_h^{(w)} \sim Ga(d, \eta^{(w)}), \\ \phi_h^{(w)} \sim Ga(c, \tau_h^{(w)}), \end{cases} \\ \text{Local} & \begin{cases} \delta_{jh}^{(w)} \sim Ga(b, \phi_h^{(w)}), \\ \theta_{jh}^{(w)} \sim Ga(a, \delta_{jh}^{(w)}), \end{cases} \\ & \lambda_{jh}^{(w)} \sim \mathcal{N}(0, \theta_{jh}^{(w)}). \end{aligned}$$

We allow local shrinkage to follow a two-component mixture

$$\theta_{jh}^{(w)} \sim \pi^{(w)} Ga(a, \delta_{jh}^{(w)}) + (1 - \pi^{(w)}) \delta_{\phi_h^{(w)}}^{(w)}(\cdot),$$

where the mixture proportion has a beta distribution

$$\pi^{(w)} \sim B\epsilon(1, 1).$$

We put a conjugate inverse gamma distribution on the residual variance parameters

$$\sigma_j^{-2} \sim Ga(a_\sigma, b_\sigma).$$

In our application of BASS, we set the hyperparameters of the global-factor-local \mathcal{TPB} prior to $a = b = c = d = e = f = 0.5$, which recapitulates the horseshoe prior at all three levels of the hierarchy. The hyperparameters for the error variances, a_σ and b_σ , were set to 1 and 0.3 respectively to allow a relatively wide support of variances (Bhattacharya and Dunson, 2011). When there are two coupled observations, the BASS framework is a Bayesian CCA model (Equation 4) based on its column-wise shrinkage.

5. Parameter estimation

Given our setup, the full joint distribution of the BASS model factorizes as

$$\begin{aligned} p(\mathbf{Y}, \mathbf{X}, \mathbf{\Lambda}, \boldsymbol{\Theta}, \boldsymbol{\Delta}, \boldsymbol{\Phi}, \mathbf{T}, \boldsymbol{\eta}, \boldsymbol{\gamma}, \mathbf{Z}, \boldsymbol{\Sigma}, \boldsymbol{\pi}) \\ = p(\mathbf{Y} | \mathbf{\Lambda}, \mathbf{X}, \boldsymbol{\Sigma}) p(\mathbf{X}) \\ \times p(\mathbf{\Lambda} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta} | \boldsymbol{\Delta}, \mathbf{Z}, \boldsymbol{\Phi}) p(\boldsymbol{\Delta} | \boldsymbol{\Phi}) p(\boldsymbol{\Phi} | \mathbf{T}) p(\mathbf{T} | \boldsymbol{\eta}) p(\boldsymbol{\eta} | \boldsymbol{\gamma}) \\ \times p(\boldsymbol{\Sigma}) p(\mathbf{Z} | \boldsymbol{\pi}) p(\boldsymbol{\pi}), \end{aligned}$$

where $\boldsymbol{\Theta} = \{\theta_{jh}^{(w)}\}$, $\boldsymbol{\Delta} = \{\delta_{jh}^{(w)}\}$, $\boldsymbol{\Phi} = \{\phi_h^{(w)}\}$, $\mathbf{T} = \{\tau_h^{(w)}\}$, $\boldsymbol{\eta} = \{\eta^{(w)}\}$ and $\boldsymbol{\gamma} = \{\gamma^{(w)}\}$ are the collections of the global-factor-local \mathcal{TPB} prior parameters. The posterior distributions of model parameters may be either simulated through Markov chain Monte Carlo (MCMC) methods or approximated using variational Bayes approaches. We derive an MCMC algorithm based on a Gibbs sampler (Appendix A). The MCMC algorithm updates the joint loading matrix row by row using block updates, enabling relatively fast mixing (Bhattacharya and Dunson, 2011).

In many applications, we are interested in a single point estimate of the parameters instead of the complete posterior estimate; thus, often an expectation maximization (EM) algorithm is used to find a *maximum a posteriori* (MAP) estimate of model parameters using conjugate gradient optimization (Dempster et al., 1977). In EM, the latent factors \mathbf{X} and the indicator variables \mathbf{Z} are treated as missing data and their expectations estimated in the E-step conditioned on the current values of the parameters; then the model parameters are optimized in the M-step conditioning on the current expectations of the latent variables. Let $\boldsymbol{\Xi} = \{\mathbf{\Lambda}, \boldsymbol{\Theta}, \boldsymbol{\Delta}, \boldsymbol{\Phi}, \mathbf{T}, \boldsymbol{\eta}, \boldsymbol{\pi}, \boldsymbol{\Sigma}\}$ be the collection of the parameters optimized in the M-step. The expected complete log likelihood, denoted $Q(\cdot)$, may be written as

$$Q(\boldsymbol{\Xi} | \boldsymbol{\Xi}_{(-s)}) = \mathbb{E}_{\mathbf{X}, \mathbf{Z} | \boldsymbol{\Xi}_{(-s)}, \mathbf{Y}} [\log p(\boldsymbol{\Xi}, \mathbf{X}, \mathbf{Z} | \mathbf{Y})].$$

Since \mathbf{X} and \mathbf{Z} are conditionally independent given $\boldsymbol{\Xi}$, the expectation may be calculated using the full conditional distributions of \mathbf{X} and \mathbf{Z} derived for the MCMC algorithm. The derivation of the EM algorithm for BASS is then straightforward (Appendix B); note that, when estimating $\mathbf{\Lambda}$, the loading columns specific to each observation are estimated jointly.

5.1 Identifiability

The latent factor model (Equation 1) is identifiable up to orthonormal rotations: for any orthogonal matrix \mathbf{P} with $\mathbf{P}^T \mathbf{P} = \mathbf{I}$, letting $\mathbf{\Lambda}' = \mathbf{\Lambda} \mathbf{P}^T$ and $\mathbf{x}' = \mathbf{P} \mathbf{x}$ produces the same estimate of the data covariance matrix and has an identical likelihood. When using factor analysis for prediction or covariance estimation, rotational invariance is irrelevant. However, for all applications that interpret the factors or use individual factors or loadings for downstream analysis, this rotational invariance cannot be ignored. One traditional solution is to restrict the loading matrix to be lower triangular (West, 2003; Carvalho et al., 2008). This solution gives a special role to the first $k - 1$ features in \mathbf{y} , namely, that the h^{th} feature does not contribute to the $k - h^{\text{th}}$ through the k^{th} factor. For this reason, the lower triangular approach does not generalize easily and requires domain knowledge that may not be available (Carvalho et al., 2008).

In the BASS model, we have rotational invariance when we right multiply the joint loading matrix by \mathbf{P}^T and left multiply \mathbf{x} by \mathbf{P} , producing an identical covariance matrix and likelihood. This rotational invariance is addressed in BASS because the non-sparse rotations of the loading matrix violates the prior structure induced by the observation-wise and element-wise sparsity.

Scale invariance is a second identifiability problem inherent in latent factor models. In particular, scale invariance means that a loading can be multiplied by a non-zero constant and the corresponding factor by the inverse of that constant, and this will result in the same data likelihood. This problem we and others have addressed satisfactorily by using posterior probabilities as optimization objectives instead of likelihoods and by including regularizing priors on the factors that restrict the magnitude of the constant. We make an effort to not interpret the relative or absolute scale of the factors or loadings including sign beyond setting a reasonable threshold for zero.

Finally, factor analysis is identifiable up to *label switching*, or shuffling the $h = 1, \dots, k$ indices of the loadings and factors, assuming we do not take the lower triangular approach. Other approaches put distributions on the loading sparsity or proportion of variance explained in order to address this problem (Bhattacharya and Dunson, 2011). We do not explicitly order or interpret the order of the factors, so we do not address this non-identifiability in the model. Label switching is handled here and elsewhere by a post-processing step, such as ordering factors according to proportion of variance explained. In our simulation studies, we interpret results with this non-identifiability in mind.

5.2 Sparse rotations via PX-EM

Another general problem with latent factor models, including BASS, is the convergence to local optima and sensitivity to parameter initializations. Once the model parameters are initialized, the EM algorithm may be stuck in locally optimal but globally suboptimal regions with undesirable factor orientations. To address this problem, we take advantage of the rotational invariance of the factor analysis framework. Parameter expansion (PX) has been shown to reduce the initialization dependence by introducing auxiliary variables that rotate the current estimate of the loading matrix to best respect the prior while keeping the likelihood stable (Liu et al., 1998; Dyk and Meng, 2001).

We extend our model (Equation 11) using parameter expansion \mathbf{R} , a positive definite $k \times k$ matrix, as

$$\begin{aligned} \mathbf{y}_i &= \mathbf{A}\mathbf{R}_L^{-1}\mathbf{x}_i + \epsilon_i, \\ \mathbf{x}_i &\sim N_k(\mathbf{0}, \mathbf{R}), \\ \epsilon_i &\sim N_k(\mathbf{0}, \mathbf{\Sigma}), \end{aligned}$$

where \mathbf{R}_L is the lower triangular matrix of the Cholesky decomposition of \mathbf{R} . The covariance of \mathbf{y}_i is invariant under this expansion, and, correspondingly, the likelihood is stable. Note \mathbf{R}_L^{-1} is not an orthogonal matrix; however, because it is full rank, it can be transformed into an orthogonal matrix times a rotation matrix via a polar decomposition (Rocková and George, 2015). We let $\mathbf{A}^* = \mathbf{A}\mathbf{R}_L^{-1}$ and assign our BASS \mathcal{TPPEN} prior to this *rotated* loading matrix.

We let $\mathbf{\Xi}^* = \{\mathbf{A}^*, \Theta, \Delta, \Phi, \mathbf{T}, \eta, \gamma, \pi, \Sigma\}$, and the parameters of our expanded model are $\{\mathbf{\Xi}^* \cup \mathbf{R}\}$. The EM algorithm in this expanded parameter space generates a sequence of parameter estimates $\{\mathbf{\Xi}^{*(1)} \cup \mathbf{R}^{(1)}, \mathbf{\Xi}^{*(2)} \cup \mathbf{R}^{(2)}, \dots\}$, which corresponds to a sequence of parameter estimates in the original space $\{\mathbf{\Xi}^{(1)}, \mathbf{\Xi}^{(2)}, \dots\}$, where \mathbf{A} is recovered via $\mathbf{A}^*\mathbf{R}_L$ (Rocková and George, 2015). We initialize $\mathbf{R}_{(0)} = \mathbf{I}_k$. The expected complete log likelihood of this PX BASS model is

$$Q(\mathbf{\Xi}^*, \mathbf{R} | \mathbf{\Xi}^{(s)}) = \mathbb{E}_{\mathbf{X}, \mathbf{Z} | \mathbf{\Xi}^{(s)}, \mathbf{Y}, \mathbf{R}_0} \log(p(\mathbf{\Xi}^*, \mathbf{R}, \mathbf{X}, \mathbf{Z} | \mathbf{Y})). \quad (12)$$

In our parameter-expanded EM (PX-EM) for BASS, the conditional distributions of \mathbf{X} and \mathbf{Z} still factorize in the expectation. However, the distribution of x_i depends on expansion parameter \mathbf{R} . The full joint distribution (Equation 11) has a single change in $p(\mathbf{X})$, with \mathbf{A}^* in the place of \mathbf{A} . In the M-step, the \mathbf{R} that maximizes Equation (12) is

$$\mathbf{R}_{(s)} = \arg \max_{\mathbf{R}} Q(\mathbf{\Xi}^*, \mathbf{R} | \mathbf{\Xi}^{(s)}) = \arg \max_{\mathbf{R}} \left(\text{const} - \frac{n}{2} \log |\mathbf{R}| - \frac{1}{2} \text{tr}(\mathbf{R}^{-1} \mathbf{S}^{\mathbf{X}\mathbf{X}}) \right),$$

where $\mathbf{S}^{\mathbf{X}\mathbf{X}} = \sum_{i=1}^n \langle \mathbf{x}_i, \mathbf{x}_i^T \rangle$. The solution is $\mathbf{R}_{(s)} = \frac{1}{n} \mathbf{S}^{\mathbf{X}\mathbf{X}}$. For the E-step, \mathbf{A} is first calculated and the expectation is taken in the original space (details in Appendix C).

Note that the proposed PX-EM for the BASS model keeps the likelihood invariant but does not keep the prior invariant after transformation of \mathbf{A} . This is different from the earlier PX-EM algorithm (Lin et al., 1998), as discussed in recent work (Rocková and George, 2015). Because the resulting posterior is not invariant, we run PX-EM only for a few iterations and then switch to the EM algorithm. The effect is that the BASS model is substantially less sensitive to initialization (see simulation results). By introducing expansion parameter \mathbf{R} , the posterior modes in the original space are intersected with equal likelihood curves indexed by \mathbf{R} in expanded space. Those curves facilitate traversal between posterior modes in the original space and encourage initial parameter estimates with appropriate sparse structure in the loading matrix (Rocková and George, 2015).

5.3 Computational complexity

The computational complexity of the block Gibbs sampler for the BASS model is demanding. Updating each loading row requires the inversion of a $k \times k$ matrix with $O(k^3)$ complexity and then calculating means with $O(k^2n)$ complexity. The complexity of updating the full loading matrix repeats this calculation p times. Other updates are of lower order relative to updating the loading. Our Gibbs sampler has $O(k^3p + k^2pn)$ complexity per iteration, which makes MCMC difficult to apply when p is large.

In the BASS EM algorithm, the E-step has complexity $O(k^3)$ for a matrix inversion, complexity $O(k^2p + kpn)$ for calculating the first moment, and complexity $O(k^2n)$ for calculating the second moment. Calculations in the M-step are all of a lower order. Thus, the EM algorithm has complexity $O(k^3 + k^2p + k^2n + kpn)$ per iteration.

Our PX-EM algorithm for the BASS model requires an additional Cholesky decomposition with complexity $O(k^3)$ and a matrix multiplication with complexity $O(k^2p)$ above the EM algorithm. The total complexity is therefore the same as the original EM algorithm, although in practice we note that the constants have a negative impact on the running time.

6. Simulations and comparisons

We demonstrate the performance of our model on simulated data in three settings: paired observations, four observations, and ten observations.

6.1 Simulations

We describe the details of the three types of simulations here.

6.1.1 SIMULATIONS WITH PAIRED OBSERVATIONS (CCA)

We simulated two data sets with $p_1 = 100$, $p_2 = 120$ in order to compare results from our method to results from state-of-the-art CCA methods. The number of samples in these simulations was $n = \{20, 30, 40, 50\}$, chosen to be smaller than both p_1 and p_2 to reflect the large p , small n regime (West, 2003) that motivated our structured approach. We first simulated observations with only sparse latent factors (*Sim1*). In particular, we set $k = 6$, where two sparse factors are shared by both observations (factors 1 and 2; Table 1), two sparse factors are specific to $\mathbf{y}^{(1)}$ (factors 3 and 4; Table 1), and two sparse factors are specific to $\mathbf{y}^{(2)}$ (factors 5 and 6; Table 1). The elements in the sparse loading matrix were randomly generated from a $\mathcal{N}(0, 4)$ Gaussian distribution, and sparsity was induced by setting 90% of the elements in each loading column to zero at random (Figure 3A). We zeroed values of the sparse loadings for which the absolute values were less than 0.5. Latent factors \mathbf{x} were generated from $\mathcal{N}_6(0, \mathbf{I}_6)$. Residual error was generated by first generating the $p = p_1 + p_2$ diagonals on the residual covariance matrix Σ from a uniform distribution on $(0.5, 1.5)$, and then generating each column of the error matrix from $\mathcal{N}_p(\mathbf{0}, \Sigma)$.

We performed a second simulation that included both sparse and dense latent factors (*Sim2*). In particular, we extended *Sim1* to $k = 8$ latent factors, where one of the shared sparse factors is now dense, and two dense factors, each specific to one observation, were added. For all dense factors, each loading was generated according to a $\mathcal{N}(0, 4)$ Gaussian distribution (Table 1; Figure 3B).

Factors	<i>Sim1</i>						<i>Sim2</i>							
	1	2	3	4	5	6	1	2	3	4	5	6	7	8

Table 1: **Latent factors in *Sim1* and *Sim2* with two observation matrices.** S represents a sparse vector; D represents a dense vector; - represents no contribution to that observation from the factor.

6.1.2 SIMULATIONS WITH FOUR OBSERVATIONS (GFA)

We performed two simulations (*Sim3* and *Sim4*) including four observations with $p_1 = 70$, $p_2 = 60$, $p_3 = 50$ and $p_4 = 40$. The number of samples, as above, was set to $n = \{20, 30, 40, 50\}$. In *Sim3*, we let $k = 6$ and only simulated sparse factors: the first three factors were specific to $\mathbf{y}^{(1)}$, $\mathbf{y}^{(2)}$ and $\mathbf{y}^{(3)}$, respectively, and the last three corresponded to different subsets of the observations (Table 2). In *Sim4* we let $k = 8$, and, as with *Sim2*,

Factors	<i>Sim3</i>						<i>Sim4</i>							
	1	2	3	4	5	6	1	2	3	4	5	6	7	8

Table 3: **Latent factors in *Sim5* and *Sim6* with four observation matrices.** S represents a sparse vector; D represents a dense vector; - represents no contribution to that observation from the factor.

included both sparse and dense factors (Table 2). Samples from these two simulations were generated following the same procedure as the simulations with two observations.

6.1.3 SIMULATIONS WITH TEN OBSERVATIONS (GFA)

To further evaluate BASS on multiple observations, we performed two additional simulations (*Sim5* and *Sim6*) on ten coupled observations with $p_w = 50$ for $w = 1, \dots, 10$. The number of samples was set to $n = \{20, 30, 40, 50\}$. In *Sim5*, we let $k = 8$ and only simulated sparse factors (Table 3). In *Sim6* we let $k = 10$ and simulated both sparse and dense factors (Table 3). Samples in these two simulations were generated following the same method as in the simulations with two observations.

6.2 Methods for comparison

We compared BASS to five available linear models that accept multiple observations: the Bayesian group factor analysis model with an ARD prior (GFA) (Klami et al., 2013), an extension of GFA that allows element-wise sparsity with independent ARD priors (sGFA) (Khan et al., 2014; Suvritaval et al., 2014), a regularized version of CCA (RCCA) (González et al., 2008), sparse CCA (SCCA) (Witten and Tibshirani, 2009), and Bayesian joint factor

analysis (JFA) (Ray et al., 2014). We also included the linear version of a flexible non-linear model, manifold relevance determination (MRD) (Dannanoun et al., 2012). To evaluate the sensitivity of BASS to initialization, we compared three different initialization methods: random initialization (EM), 50 iterations of MCMC (MCMC-EM), and 20 iterations of PX-EM (PX-EM); each of these were followed with EM until convergence, reached when both the number of non-zero loadings do not change for t iterations and the log likelihood changes $< 1 \times 10^{-5}$ within t iterations. We performed 20 runs for each version of inference in BASS: EM, MCMC-EM, and PX-EM. In *Sim1* and *Sim2*, we set the initial number of factors to $k = 10$. In *Sim2*, *Sim4*, *Sim5*, and *Sim6*, we set the initial number of factors to 15.

The GFA model (Klami et al., 2013) uses an ARD prior to encourage column-wise shrinkage of the loading matrix, but not sparsity within the loadings. The computational complexity of this GFA model with variational updates is $O(k^3m + k^2p + k^2n + kpn)$ per iteration, which is nearly identical to BASS but includes an additional factor m , the number of observations, scaling the k^3 term. In our simulations, we ran the GFA model with the factor number set to the correct value.

The sGFA model (Khan et al., 2014) encourages element-wise sparsity using independent ARD priors on loading elements. Loading columns are modeled with a spike-and-slab type mixture to encourage column-wise sparsity. Inference is performed with a Gibbs sampler without using block updates. Its complexity is $O(k^3 + k^2pn)$ per iteration, which, when k is large, will dominate the per-iteration complexity of BASS; furthermore, Gibbs samplers typically require greater numbers of iterations than EM-based methods. We ran the sGFA model with the correct number of factors in our six simulations.

We ran the regularized version of classical CCA (RCCA) for comparison in *Sim1* and *Sim2* (González et al., 2008). Classical CCA tries to find k canonical projection directions \mathbf{u}_h and \mathbf{v}_h ($h = 1, \dots, k$) for $\mathbf{Y}^{(1)}$ and $\mathbf{Y}^{(2)}$ respectively such that i) the correlation between $\mathbf{u}_h^T \mathbf{Y}^{(1)}$ and $\mathbf{v}_h^T \mathbf{Y}^{(2)}$ is maximized for $h = 1, \dots, k$; and ii) $\mathbf{u}_h^T \mathbf{Y}^{(1)}$ is orthogonal to $\mathbf{u}_{h'}^T \mathbf{Y}^{(1)}$ with $h' \neq h$, and similarly for \mathbf{v}_h and $\mathbf{Y}^{(2)}$. Let these two projection matrices be denoted $\mathbf{U} = [\mathbf{u}_1, \dots, \mathbf{u}_k] \in \mathbb{R}^{p_1 \times k}$ and $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_k] \in \mathbb{R}^{p_2 \times k}$. These matrices are the maximum likelihood estimates of the shared loading matrices in the Bayesian CCA model up to orthogonal transformations (Bach and Jordan, 2005). However, classical CCA requires the observation covariance matrices to be non-singular and thus is not applicable in the current simulations where $n < p_1, p_2$.

Here, we used a regularized version of CCA (RCCA) (González et al., 2008), which regularizes CCA using an ℓ_2 -type penalty by adding $\lambda_1 \mathbf{I}_{p_1}$ and $\lambda_2 \mathbf{I}_{p_2}$ to the two sample covariance matrices. The effect of this penalty is not to induce sparsity but instead to allow application to $p \gg n$ data sets. The two regularization parameters (λ_1 and λ_2) were chosen according to leave-one-out cross-validation with the search space defined on a 11×11 grid from 0.0001 to 0.01. The projection directions \mathbf{U} and \mathbf{V} were estimated using the best regularization parameters. We let $\mathbf{A}' = [\mathbf{U}; \mathbf{V}]$; this matrix was comparable to the simulated loading matrix up to orthogonal transformations. We calculated the matrix \mathbf{P} such that the Frobenius norm between $\mathbf{A}' \mathbf{P}^T$ and simulated \mathbf{A} was minimized, with the constraint that $\mathbf{P}^T \mathbf{P} = \mathbf{I}$. This was done by the constraint-preserving updates of the objective function (Wen and Yin, 2013). After finding the optimal orthogonal transformation matrix, we recovered $\mathbf{A}' \mathbf{P}^T$ as the estimated loading matrix. We set the number of projections to

6 and 8 in *Sim1* and *Sim2*, respectively, representing the true number of latent factors. RCCA does not apply to multiple coupled observations, and therefore it was not included in further simulations.

The sparse CCA (SCCA) method (Witten and Tibshirani, 2009) maximizes correlation between two observations after projecting the original space with a sparsity-inducing penalty onto the latent components, producing sparse matrices \mathbf{U} and \mathbf{V} . This method is encoded in the R package PMA (Witten et al., 2013). For *Sim1* and *Sim2*, as with RCCA, we found an optimal orthogonal transformation matrix \mathbf{P} such that the Frobenius norm between $\mathbf{A}' \mathbf{P}^T$ and simulated \mathbf{A} was minimized, where \mathbf{A}' was the vertical concatenation of the recovered sparse \mathbf{U} and \mathbf{V} . We chose 6 and 8 sparse projections in *Sim1* and *Sim2*, respectively, representing the true number of linear factors. Because both RCCA and SCCA are both deterministic and greedy, the results for $k < 6$ are all implicitly available by subsetting the factors in the $k = 6$ results.

An extension of SCCA allows for multiple observations (Witten and Tibshirani, 2009). For *Sim3* and *Sim4*, we recovered four sparse projection matrices $\mathbf{U}^{(1)}, \mathbf{U}^{(2)}, \mathbf{U}^{(3)}, \mathbf{U}^{(4)}$, and for *Sim5* and *Sim6*, we recovered ten projection matrices. \mathbf{A}_s was calculated with the concatenation of those projection matrices. Then the orthogonal transformation matrix \mathbf{P} was calculated similarly by minimizing the Frobenius norm between $\mathbf{A}_s \mathbf{P}^T$ and the true loading matrix \mathbf{A} . The number of canonical projections was set to 6 in *Sim3*, 8 in *Sim4* and *Sim5*, and 10 in *Sim6*, corresponding to the true number of latent factors.

The Bayesian joint factor analysis model (JFA) (Ray et al., 2014) puts an Indian buffet process (IBP) prior (Griffiths and Ghahramani, 2011) on the factors, inducing element-wise sparsity, and an ARD prior on the variance of the loadings. The idea of putting an IBP on a latent factor model, which gives desirable nonparametric behavior in the number of latent factors and also produces element-wise sparsity in the loading matrix, was described for the Nonparametric Sparse Factor Analysis (NSEFA) model (Knowles and Ghahramani, 2011). Similarly, in JFA, element-wise sparsity is encouraged both in the factors and in the loadings. JFA partitions latent factors into a fixed number of observation-specific factors and factors shared by all observations, and does not include column-wise sparsity. Its complexity is $O(k^3 + k^2pn)$ per iteration of the Gibbs sampler. We ran JFA on our simulations with the number of factors set to the correct values. Because the JFA model uses a sparsity-inducing prior instead of an independent Gaussian prior on the latent factors, the resulting model does not have a closed form posterior predictive distribution (Equation 13); therefore, we excluded the JFA model from prediction results.

The non-linear manifold relevance determination (MRD) model (Dannanoun et al., 2012) extends the notable Gaussian process latent variable (GPLVM) model (Lawrence, 2005) to include multiple observations. A GPLVM puts a Gaussian process prior on the latent variable space. GPLVM has an interpretation of a dual probabilistic PCA model that marginalizes loading columns using Gaussian priors. MRD extends GPLVM by putting multiple weight vectors on the latent variables using a Gaussian process kernel. Each of the weight vectors corresponds to one observation, therefore they determine a soft partition of latent variable space. The complexity of MRD is quadratic in the number of samples n per iteration using a sparse Gaussian process. Posterior inference and prediction using the MRD model was performed with Matlab package `varGPLM` (Dannanoun et al., 2012). We used the linear kernel with feature selection (i.e., `Linard2` kernel), meaning that we

used the linear version of this model for a fair comparison. We ran the MRD model on our simulated data with the correct number of factors.

We summarize the parameter choices for all methods here:

sGFA: We used the `getDefaultOpts` function in the `sGFA` package to set the default parameters. In particular, the ARD prior was set to $G\alpha(10^{-3}, 10^{-3})$. The prior on the inclusion probabilities was set to $\text{beta}(1, 1)$. *Total MCMC iterations* were set to 10^5 with *sampling iterations* set to 1,000 and *thinning steps* set to 5.

GFA: We used the `getDefaultOpts()` function in the `GFA` package to set the default parameters. In particular, the ARD prior for both loading and error variance was set to $G\alpha(10^{-14}, 10^{-14})$. The *maximum iteration* parameter was set to 10^5 , and the ‘‘L-BFGS’’ optimization method was used.

RCCA: The regularization parameter was chosen using leave-one-out cross-validation on an 11×11 grid from 0.0001 to 0.01 using the function `est.im.regul` in the `CCA` package.

SCCA: We used the `PMA` package with Lasso penalty (the `typex` and `typez` parameters in the function `CCA` were set to ‘‘standard’’). This corresponds to setting the ℓ_1 bound of the projection vector to $0.3\sqrt{p_w}$ for $w = 1, 2$.

JFA: The ARD priors for both the loading and factor scores were set to $G\alpha(10^{-5}, 10^{-5})$. The parameters of the beta process prior were set to $\alpha = 0.1$ and $c = 10^4$. The MCMC iterations were set to 1,000 with 200 iterations of burn-in. As is the default settings, we did not thin the chain.

MRD: We used the `svargplvm_init` function in the `GPLVM` package to initialize parameters. The `linear2` kernel was chosen for all observations. Latent variables were initialized by concatenating the observation matrices first (the ‘‘concatenated’’ option) and then performing PCA. Other parameters were set by `svargplvm_init` with default options.

6.3 Metrics for comparison

To compare the results of BASS with the alternative methods, we used the sparse and dense stability indices (Gao et al., 2013) to quantify the distance between the simulated loadings and the recovered loadings. The sparse stability index (SSI) measures the similarity between columns of sparse matrices. SSI is invariant to column scale and label switching, but it penalizes factor splitting and matrix rotation; larger values of SSI indicate better recovery. Let $\mathbf{C} \in \mathbb{R}^{k_1 \times k_2}$ be the absolute correlation matrix of columns of two sparse loading matrices. Then SSI is calculated by

$$SSI = \frac{1}{2k_1} \sum_{h_1=1}^{k_1} \left(\max(\mathbf{c}_{h_1, \cdot}) - \frac{\sum_{h_2=1}^{k_2} I(\mathbf{c}_{h_1, h_2} > \bar{\mathbf{c}}_{h_1, \cdot}) \mathbf{c}_{h_1, h_2}}{k_2 - 1} \right) + \frac{1}{2k_2} \sum_{h_2=1}^{k_2} \left(\max(\mathbf{c}_{\cdot, h_2}) - \frac{\sum_{h_1=1}^{k_1} I(\mathbf{c}_{h_1, h_2} > \bar{\mathbf{c}}_{\cdot, h_2}) \mathbf{c}_{h_1, h_2}}{k_1 - 1} \right).$$

The dense stability index (DSI) quantifies the difference between dense matrix columns, and is invariant to orthogonal matrix rotation, factor switching, and scale; DSI values closer to zero indicate better recovery. Let \mathbf{M}_1 and \mathbf{M}_2 be the dense matrices. DSI is calculated by

$$DSI = \frac{1}{p^2} \text{tr}(\mathbf{M}_1 \mathbf{M}_1^T - \mathbf{M}_2 \mathbf{M}_2^T).$$

We extended the stability indices to allow multiple coupled observations as in our simulations. In *Sim1*, *Sim3*, and *Sim5*, all factors are sparse, and SSIs were calculated between the true sparse loading matrices and recovered sparse loading matrices. In *Sim2*, *Sim4*, and *Sim6*, because none of the methods other than BASS explicitly distinguished sparse and dense factors, we categorized each recovered factor as follows. We first selected a global sparsity threshold on the elements of the combined loading matrix; here we set that value to 0.15. Elements below this threshold were set to zero in the loading matrix. Then we chose the first five loading columns with the fewest non-zero elements as the sparse loadings in *Sim2*, first four such loadings as the sparse loadings in *Sim4*, and first six such loadings as sparse in *Sim6*. The remaining loading columns were considered dense loadings and were not zeroed according to the global sparsity threshold. We found that varying the sparsity threshold did not affect the separation of sparse and dense loadings significantly across methods. SSIs were then calculated for the true sparse loading matrix and the recovered sparse loadings across methods.

To calculate DSIs, we treated the loading matrices $\mathbf{\Lambda}^{(w)}$ for each observation separately, and calculated the DSI for the recovered dense components of each observation. The DSI for each method was the sum of the m separate DSIs. Because the loading matrix is marginalized out in MRD (Lawrence, 2005), we excluded MRD from this comparison.

We further evaluated the prediction performance of BASS and other methods. In the BASS model (Equation 6), the joint distribution of any one observation $\mathbf{y}_i^{(w)}$ and all other observations $\mathbf{y}_i^{(-w)}$ can be written as

$$\begin{pmatrix} \mathbf{y}_i^{(w)} \\ \mathbf{y}_i^{(-w)} \end{pmatrix} \sim \mathcal{N} \left[\begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix}, \begin{pmatrix} \mathbf{\Lambda}^{(w)}(\mathbf{\Lambda}^{(w)})^T + \mathbf{\Sigma}^{(w)} & \mathbf{\Lambda}^{(w)}(\mathbf{\Lambda}^{(-w)})^T \\ \mathbf{\Lambda}^{(-w)}(\mathbf{\Lambda}^{(w)})^T & \mathbf{\Lambda}^{(-w)}(\mathbf{\Lambda}^{(-w)})^T + \mathbf{\Sigma}^{(-w)} \end{pmatrix} \right],$$

where $\mathbf{\Lambda}^{(-w)}$ and $\mathbf{\Sigma}^{(-w)}$ are the loading matrix and residual covariance excluding the w^{th} observation. Therefore, the conditional distribution of $\mathbf{y}_i^{(w)}$ is a multivariate response in a multivariate linear regression model, where $\mathbf{y}_i^{(-w)}$ are the predictors; the mean term takes the form

$$\mathbb{E}(\mathbf{y}_i^{(w)} | \mathbf{y}_i^{(-w)}) = \mathbf{\Lambda}^{(w)}(\mathbf{\Lambda}^{(-w)})^T (\mathbf{\Lambda}^{(-w)}(\mathbf{\Lambda}^{(-w)})^T + \mathbf{\Sigma}^{(-w)})^{-1} \mathbf{y}_i^{(-w)} \\ = \sum_{h=1}^k \boldsymbol{\lambda}_h^{(w)} (\boldsymbol{\lambda}_h^{(-w)})^T (\mathbf{\Lambda}^{(-w)}(\mathbf{\Lambda}^{(-w)})^T + \mathbf{\Sigma}^{(-w)})^{-1} \mathbf{y}_i^{(-w)}. \quad (13)$$

We used this conditional distribution to predict specific observations given others. For the six simulations, we used the simulated data as training data for training sample sizes $n_t = \{30, 50\}$, and, additionally, simulated data sets with training sample sizes $n_t =$

	EM	MCMC-EM	PX-EM
<i>Sim1</i>	79.17%	99.17%	91.67%
<i>Sim2</i>	61.25%	93.75%	85.62%
<i>Sim3</i>	50.00%	78.57%	73.57%
<i>Sim4</i>	62.78%	86.11%	82.78%
<i>Sim5</i>	17.22%	86.67%	66.67%
<i>Sim6</i>	13.64%	60.45%	62.73%

{10, 100, 200}. Then, we generated $n_s = 200$ samples as test data using the true model parameters, simulating the corresponding test data factors $\mathbf{X} \sim \mathcal{N}(0, \mathbf{I})$. For each simulation study, we chose at least one observation in the test data as the response and used the other observations and model parameters estimated from the training data to perform prediction. Mean squared error (MSE) was used to evaluate the prediction performance. For *Sim1* and *Sim2*, $\mathbf{y}_i^{(2)}$ was the response; for *Sim3* and *Sim4*, $\mathbf{y}_i^{(3)}$ was the response; and for *Sim5* and *Sim6*, $\mathbf{y}_i^{(8)}$, $\mathbf{y}_i^{(9)}$ and $\mathbf{y}_i^{(10)}$ were the responses.

6.4 Results of the simulation comparison

We first evaluated the performance of BASS and the other methods in terms of recovering the correct number of sparse and dense factors in the six simulations (Figures S3-S8). We calculated the percentage of correctly identified factors across 20 runs in the simulations with $n = 40$ (Table 4). Qualitatively, BASS recovered the closest matches to the simulated loading matrices across all methods (Figures 3, S1, S2). The correctly estimated loading matrices by the three different BASS initializations produced similar results, we only plot matrices from the PX-EM method.

6.4.1 RESULTS ON SIMULATIONS WITH TWO OBSERVATIONS (CCA)

Comparing results with two observations (*Sim1* and *Sim2*), our model produced the best SSIs and DSIs among all methods across all sample sizes (Figures 4). sGFA’s performance was limited for these simulations because the ARD prior does not produce sufficient element-wise sparsity, resulting in low SSIs (Figure 4). As a consequence of not matching sparse loadings well, sGFA had difficulty recovering dense loadings, especially with small sample sizes (Figure 4). GFA had difficulty recovering sparse loadings because of column-wise ARD priors with the same limitation (Figure 3, Figure 4). Its dense loadings were indirectly affected by the lack of sufficient sparsity for small sample sizes (Figure 4). RCCA also had difficulty in the two simulations because the recovered loadings were not sufficiently sparse using the ℓ_2 -type penalty (Figure 3).

SCCA recovered shared sparse loadings well in *Sim1* (Figure 3). However SCCA does not model local covariance structure, and therefore was unable to recover the sparse loadings specific to either of the observations in *Sim1* (Figure 3A) resulting in poor SSIs (Figure

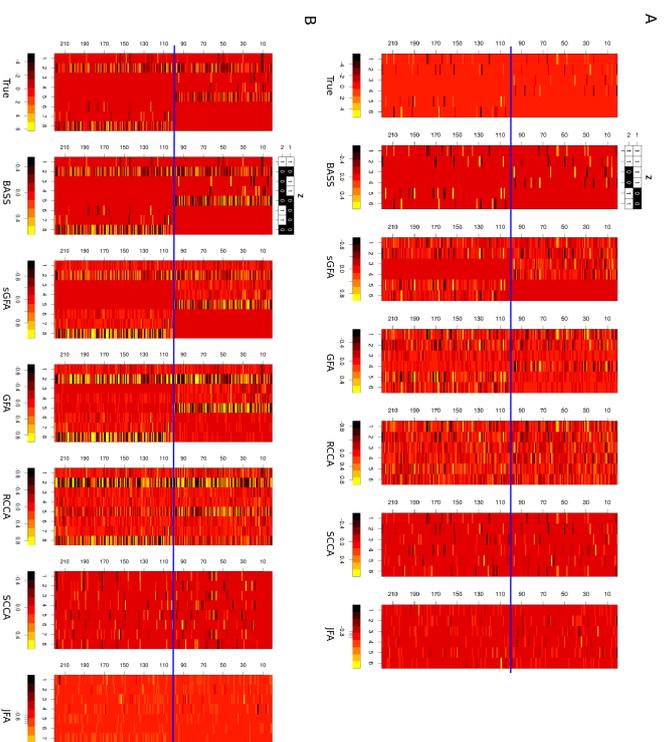

Figure 3: **Simulation results with two paired observations.** We reordered the columns of the recovered matrices and, where necessary, multiplied columns by -1 for easier visual comparisons. Horizontal lines separate the two observations. Panel A: Comparison of the recovered loading matrices using different models on *Sim1*. Panel B: Comparison of the recovered loading matrices using different models on *Sim2*.

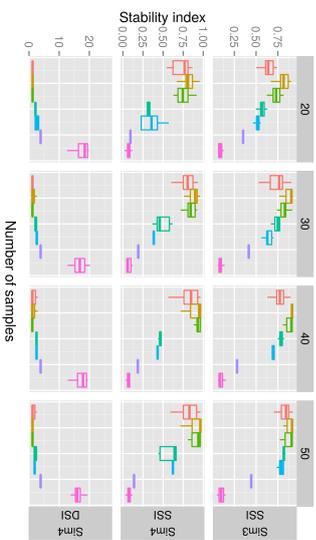

Figure 5: Comparison of stability indices on recovered loading matrices with four observations. Each stability index is plotted across 20 runs. For SSL, a larger value indicates better recovery; for DSL, a smaller value indicates better recovery. The boundaries of the box are the first and third quartiles. The line extends to the highest and lowest values that are within 1.5 times the distance of the first and third quartiles beyond the box boundaries.

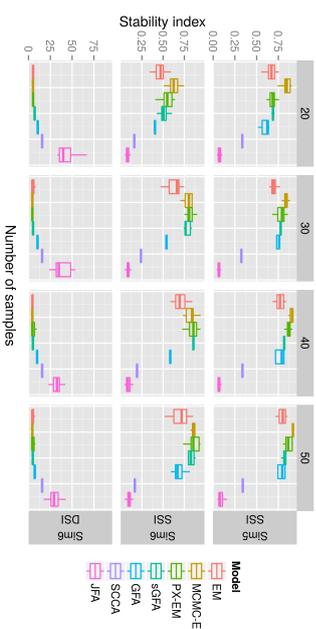

Figure 6: Comparison of stability indices on recovered loading matrices with ten observations. Each stability index is plotted across 20 runs. For SSL, a larger value indicates better recovery; for DSL, a smaller value indicates better recovery. The boundaries of the box are the first and third quartiles. The line extends to the highest and lowest values within 1.5 times the distance of the first and third quartiles beyond the box boundaries.

Table 7: Prediction mean squared error with ten observations on $n_s = 200$ test samples. Test samples $y_i^{(s)}$, $y_i^{(9)}$ and $y_i^{(10)}$ are treated as the response and the rest of the observations are used as the training data to estimate parameters used to predict the response. Prediction accuracy is measured by mean squared error (MSE) between simulated responses and predicted responses. Values presented are the mean MSE (Err) and standard deviation (SD) across 20 runs of each method. Standard deviation (SD) is missing for SCCA because the method is deterministic.

S2). For the stability indices, BASS with MCMC-EM and PX-EM produced the best SSIs in *Sim5* across all methods and for almost all sample sizes (Figures 6). Here sGFA achieved equal or better SSIs than BASS EM, highlighting the sensitivity of BASS EM to initializations. GFA had equivalent or worse SSIs than BASS EM. In this pair of simulations, the advantages of BASS for flexible and robust column-wise and element-wise shrinkage are apparent (Figures 6). BASS also achieved the best prediction performance in *Sim5* and *Sim6* with ten observations (Table 6).

Across the three BASS methods, MCMC-EM had the most accurate performance across nearly all simulation settings. However, this performance boost comes with the price of running a small number of Gibbs sampling iterations with complexity of $O(k^3p + k^2pn)$ per iteration. When p is large, even a few iterations are computationally infeasible. PX-EM, on the other hand, has the same complexity as EM, and showed robust and accurate simulation results relative to EM. In the following real applications, we used BASS EM initialized with a small number of iterations of PX-EM.

7. Applying BASS to Mulan Library, genomics data, and text analysis

In this section we considered three real data applications of BASS. In the first application, we evaluated the prediction performance for multiple correlated response variables in the Mulan Library (Tosumakas et al., 2011). In the second application, we applied BASS to gene expression data from the Cholesterol and Pharmacogenomic (CAP) study. The data consist of expression measurements for about ten thousands genes in 480 lymphoblastoid cell lines (LCLs) under two experimental conditions (Mangravite et al., 2013; Brown et al., 2013). BASS was used to detect sparse covariance structures specific to each experimental condition. In the third application, we applied BASS to approximately 20,000 newsgroup posts to 20 newsgroups (Joachims, 1997) in order to perform multiclass classification.

7.1 Multivariate response prediction: The Mulan Library

The Mulan Library consists of multiple data sets collected for the purpose of evaluating multi-label predictions (Tosumakas et al., 2011). This library was used to test the Bayesian CCA model (GFA in our simulations) for multi-label prediction vectors converted to multi-label binary label vectors (one-hot encoding) (Klami et al., 2013). There are two observations

($m = 2$): the matrix of labels were treated as one observation ($\mathbf{Y}^{(1)}$) and the features were treated as another ($\mathbf{Y}^{(2)}$). Recently Mulan added multiple regression data sets with continuous variables. We chose ten benchmark data sets from the Mulan Library. Four of them (`bibtex`, `delicious`, `mediamill`, `scene`) have binary responses and were studied previously (Klami et al., 2013). Another six data sets (`rf1`, `rf2`, `scmid`, `scm20d`, `atp1d`, `atp7d`) have continuous responses (Table 8). For all data sets, we removed features with identical values for all samples in the training set as uninformative. For the continuous response data sets, for each value, we subtracted the mean and divided by the standard deviation of each feature.

We ran BASS, sGFA, GFA, and MRD-lin on the ten data sets, and compared the results using prediction accuracy. For data sets with binary labels, we quantified prediction error using the Hamming loss between the predicted labels and true labels. The predicted labels on the test samples were calculated using the same thresholding rules as in earlier work (Klami et al., 2013). The value of the threshold was chosen so that the Hamming loss between the estimated labels and the true labels in the training set was minimized. We used the R package `PresenceAbsence` and Matlab function `perfcurve` to find the thresholds to produce binary classifications from continuous predictions. In particular, the R package `PresenceAbsence` selects the threshold by maximizing the percent correctly classified, which corresponds to minimizing the Hamming loss. For continuous variables, mean squared error (MSE) was used to evaluate prediction accuracy. We initialized BASS with 500 factors and 50 PX-EM iterations. The other models were set to the default parameters with the number of factors set to $\min(p_1, p_2, 50)$ (see Simulations for details). All methods were run 20 times, and minimum errors were reported (Tables S1-S11).

BASS achieved the best prediction accuracy in five of the ten data sets (Table 8). For the data sets with a binary response, sGFA produced the best performance compared with other methods, achieving the smallest MSE in all four data sets. GFA had the most stable results in terms of SD in the four data sets. For the continuous response, BASS outperformed the other models in four out of six data sets. GFA again had the most stable MSE compared with other methods. The good performance of BASS on the data sets with continuous response variables may be attributed to the structured sparsity on the loading matrix, achieving the intended gains in generalization error from flexible regularization. Although the ARD prior used in GFA did not produce consistently sparse loadings, this model generated the most stable predictive results.

7.2 Gene expression data analysis

We applied our BASS model to gene expression data from the Cholesterol and Pharmacogenomic (CAP) study, consisting of expression measurements for 10,195 genes in 480 lymphoblastoid cell lines (LCLs) after 24-hour exposure to either a control buffer ($\mathbf{Y}^{(1)}$) or $2\mu M$ simvastatin acid ($\mathbf{Y}^{(2)}$) (Mangravite et al., 2013; Brown et al., 2013). In this example, the number of observations ($m = 2$) represents gene expression levels on the same samples and genes after the two different exposures. The expression levels were preprocessed to adjust for experimental traits (batch effects and cell growth rate) and clinical traits of donors (age, BMI, smoking status, and sex). We projected the adjusted expression levels to the quantiles of a standard normal within gene to control for outlier effects and applied BASS

Table 8: **Multi-variate response prediction in the Mulan library.** p_1 : the number of features; p_2 : the number of responses; n_t : the number of training samples; n_s : the number of test samples. The first four data sets have binary responses, and the final six are continuous responses. For binary responses, error (Err) is evaluated using Hamming loss between predicted labels and test labels in test samples. For continuous responses, mean squared error (MSE) is used to quantify error. Values shown are the minimum Hamming loss or MSE across 20 runs, and the standard deviation (SD).

with the initial number of factors set to $k = 2, 000$. We performed parameter estimation 100 times on these data with 100 iterations of PX-EM to initialize EM. Across these 100 runs, the estimated number of recovered factors was approximately 870 (Table S2), with only a few dense factors (Table S12) likely due to the adjustments made in the preprocessing step. The total percentage of variance explained (PVE) by the recovered latent structure was 14.73%, leaving 85.27% of the total variance to be captured in the residual error.

We computed the PVE of the sparse factors alone (Figure S9A). The PVE for the h^{th} factor was calculated as the variance explained by the h^{th} factor divided by the total variance: $\text{tr}(\boldsymbol{\Lambda}_h \boldsymbol{\Lambda}_h^T) / \text{tr}(\boldsymbol{\Lambda} \boldsymbol{\Lambda}^T + \boldsymbol{\Sigma})$. Shared sparse factors explained more variance than observation-specific sparse factors, suggesting that variation in expression levels across genes was driven by structure shared across the exposures to a greater degree than by exposure-specific structure. Moreover, 87.5% of the observation-specific sparse factors contained fewer than 100 genes, and 0.7% had more than 500 genes. The shared sparse factors had on average, more genes than the observation-specific factors: 72% shared sparse factors had fewer than 100 genes, and 4.5% had more than 500 genes. (Figure S9B).

The sparse factors specific to each observation characterized the local sparse covariance estimates. As we pursue more carefully elsewhere (Gao et al., 2014), we used observation-specific sparse factors to construct a gene co-expression network that is uniquely found in the samples from that exposure while explicitly controlling for shared covariance across exposures (Zou et al., 2013). The problem of constructing condition specific co-expression networks has been studied by both machine learning and computational biology communities (Li, 2002; Ma et al., 2011). BASS provides an alternative approach to solve this problem. We denote $\mathbf{B}_s^{(w)}$ as the sparse loadings in $\mathbf{B}^{(w)}$ ($w \in \{1, 2\}$) and $\mathbf{X}_s^{(w)}$ as the factors corresponding to sparse loadings for observation w . Then, $\boldsymbol{\Omega}_s^{(w)} = \mathbf{B}_s^{(w)} \text{Var}(\mathbf{X}_s^{(w)}) \mathbf{B}_s^{(w)T} + \boldsymbol{\Sigma}^{(w)}$ represents the regularized estimate of the covariance matrix specific to each observation after controlling for the contributions of the dense factors.

In our model, $\text{Var}(\mathbf{X}_s^{(w)}) = \mathbf{I}$, and so the covariance matrix becomes $\mathbf{\Omega}_s^{(w)} = \mathbf{B}_s^{(w)}(\mathbf{B}_s^{(w)})^T + \mathbf{\Sigma}^{(w)}$. We inverted this positive definite covariance matrix to get a precision matrix $\mathbf{R}^{(w)} = (\mathbf{\Omega}_s^{(w)})^{-1}$. The partial correlation between gene j_1 and j_2 , representing the correlation between the two features conditioned on the remaining features, is then calculated by normalizing each entry in the precision matrix (Edwards, 2000; Schäfer and Sührmer, 2005):

$$\rho_{j_1 j_2}^{(w)} = -\frac{r_{j_1 j_2}^{(w)}}{\sqrt{r_{j_1 j_1}^{(w)} r_{j_2 j_2}^{(w)}}}.$$

A partial correlation that is (near) zero for two genes (j_1, j_2) suggests that they are conditionally independent; non-zero partial correlation implies a direct relationship between two genes, and a network edge is added between the genes. The resulting undirected network is an instance of a Gaussian Markov random field, also known as a Gaussian graphical model (Edwards, 2000; Koller and Friedman, 2009). We note that BASS was the only method that enables construction of a condition specific network: sGFA could not be applied to data of this magnitude, GFA did not shrink the column selection sufficiently to recover sparsity in the condition specific covariance matrix, and SCGA only recovers shared sparse projections.

We used the following method to combine the results of 100 runs to construct a single observation-specific gene co-expression network for each observation. For each run, we first constructed a network by connecting genes with partial correlation greater than a threshold (0.01). Then we combined the 100 run-specific networks to construct a single network by removing all network edges that appeared in fewer than 50 (50%) of the networks. The two observation-specific gene co-expression networks contained 160 genes and 1,244 edges (buffer treated, Figure 7A), and 154 genes and 1,030 edges (statin-treated, Figure 7B), respectively.

7.3 Twenty newsgroups analysis

In this application, we used BASS and related methods for multiclass classification in the 20 Newsgroups data (Joachims, 1997). The documents were processed so that duplicates and headers were removed, resulting 18,846 documents. The data were downloaded using the `scikit-learn` Python package (Pedregosa et al., 2011). We converted the raw data into TF-IDF feature vectors and selected 319 words using SVM feature selection from `scikit-learn`. One document had a zero vector across the subset of vocabulary words and was removed. We held out 10 documents at random from each newsgroup as test data (Table S14).

We applied BASS to the transposed data matrices with the 20 newsgroups as 20 observations. We set the initial number of factors to $k = 1,000$ and ran EM 100 times from random starting points, each with 100 initial PX-EM iterations. There were on average 820 factors recovered across the runs.

To analyze the newsgroup-specific words, we calculated the Pearson correlation of each estimated loading and newsgroup indicator vectors consisting of ones for all of the documents in one newsgroup and zeros for documents in the other groups. Then, for each newsgroup, the loadings with the ten largest absolute value correlation coefficients were used to find the

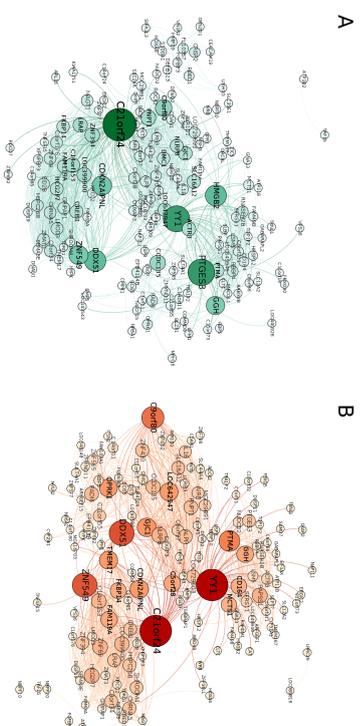

Figure 7: **Observation-specific gene co-expression networks from the CAP data.** The two networks represent the co-expressed genes specific to buffer-treated samples (Panel A) and statin-treated samples (Panel B). The node size is scaled according to the number of shortest paths from all vertices to all others that pass through that node (*betweenness centrality*).

ten words with the largest absolute value factor scores. The results from one run include, for example, the `rec.autos` newsgroup with ‘car’, ‘dealer’ and ‘oil’ as top words, and the `rec.sport.baseball` newsgroup with ‘baseball’, ‘braves’, and ‘runs’ as top words (Table 9).

We further partitioned the newsgroups into six classes according to subject matter to analyze the top words across newsgroups subgroups (Table 10). As above, we calculated the Pearson correlation with the binary indicator vectors for documents in newsgroup subgroups, and we analyzed the top ten words in the ten factors with largest absolute value correlation coefficients with these subsets of newsgroups (Table 10). We found, for example, that the newsgroups `talk.religion.misc`, `alt.athelism` and `soc.religion.christian` had ‘god’, ‘bible’ and ‘christian’ as top shared words. Examining one of the selected shared loadings for this newsgroup subgroup (Figure 8A), we noticed that documents outside of these three newsgroups, for the most part, have negligible loadings. This analysis highlights the ability of BASS to recover meaningful shared structure among 20 observations.

Table 10: Top ten words in the factors shared among specific subgroups of news-groups. In the shared recovered components corresponding to subsets of news groups, we show the ten most significant words in these shared components for six different subsets of news groups.

To assess prediction quality, we used the factors estimated from the training set to classify documents in the test set into one of 20 news groups. To estimate the loadings in the test set, we left-multiplied the test data matrix by the Moore-Penrose pseudoinverse of factors estimated from training data. This gave a rough estimate of the loading matrix for test data. Then test labels were predicted using the ten nearest neighbors in the loading rows estimated for the training documents. For the 200 test documents, BASS achieved 58.3% accuracy (Hamming loss; Figure 8B). Because some of the news groups were closely related to each other with respect to topic, we partitioned the 20 news groups into six topics according to subject matter. Then, the ten nearest neighbors were used to predict the topic of the test data. In this experiment, BASS achieved approximately 74.12% accuracy (Hamming loss; Figure 8C; Table S3).

8. Discussion

There exists a rich set of methods to explore latent structure in paired or multiple observations jointly (e.g., Parkhomenko et al., 2009; Witten and Tibshirani, 2009; Zhao and Li, 2012, among others). The multiple trajectories of interpretation of these approaches as linear factor analysis models includes the original inter-battery and multi-battery models (Browne, 1979, 1980), the probabilistic CCA model (Bach and Jordan, 2005), the sparse probabilistic projection (Archambeau and Bach, 2009), and, most recently, the Bayesian CCA model (Klami et al., 2013) and GFA model (Klami et al., 2014b). Only recently has the idea of column-wise shrinkage, or group-wise sparsity, been applied to develop useful

Table 9: Most significant words in the news group-specific factors for 20 news groups. For each news group, we include the top ten words in the news group-specific components.

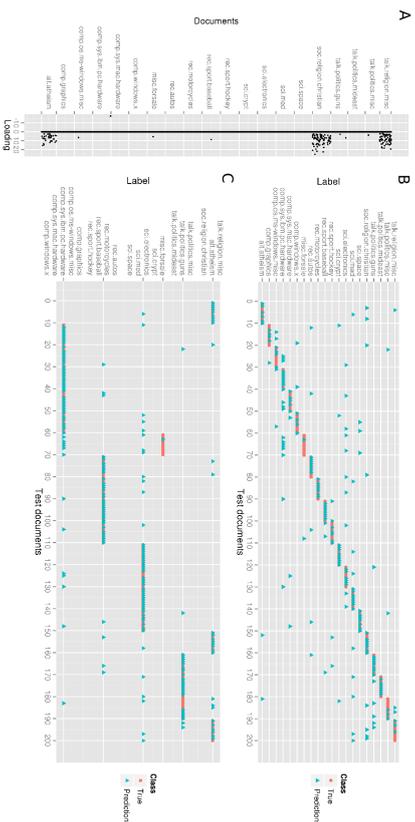

Figure 8: **Newsrroup prediction on 200 test documents.** Panel A: One factor loading selected as shared by three newsgroups (`talk.religion.misc`, `alt.atheism` and `soc.religion.christian`). Panel B: 20 Newsrroups predictions on 200 test documents using ten nearest neighbors from loadings estimated from the training data. Panel C: Document subgroup predictions based on six groups of similar newsgroups using ten nearest neighbors based on loadings estimated from the training data.

models for this problem. The advantage of column-wise shrinkage is to decouple portions of the latent space from specific observations and adaptively select the number of factors.

While the innovation of column-wise sparsity is primarily due to the ideas developed in the Bayesian CCA model (Virtanen et al., 2011), additional layers of shrinkage were required to create both column-wise and element-wise sparsity as is essential in real data analyses. The most recent attempt to develop such combined effects is the sGFA model (Khan et al., 2014) using a combination of an element-wise ARD prior with spike-and-slab prior for column selection. In our work here, we developed the necessary Bayesian prior and methodology framework to realize these advantages for the analysis of large data sets. In particular, we developed a structured sparse prior using three hierarchical layers of the three parameter beta (TPB) distribution. This carefully formulated prior combines both column-wise and element-wise shrinkage with global shrinkage to adapt the level of sparsity—both column-wise and element-wise—to the underlying data, creating robustness to parameter settings that cannot be achieved using a single-layer ARD prior. The resulting BASS model also allows sparse and dense factor loadings, which proved essential for data scenarios that have this low-rank and sparse structure and has been pursued in classical statistics (Chandrasekaran et al., 2009; Candès et al., 2011; Zhou et al., 2011). We showed in the simulations that this regularization is essential for problems in the $p \gg n$ data scenario, which motivated this work. With the assumption of full column rank of dense loadings and one single observation, our model provides a Bayesian solution to the sparse and low-rank decomposition problem.

Column-wise shrinkage in BASS was achieved using the observation-specific global and column-specific TPB priors. With current parameter settings, it is equivalent to the horseshoe prior put on the entire column. The horseshoe prior has been shown to induce better shrinkage effects compared to the ARD prior, the Laplace prior (Bayesian lasso), and other similar shrinkage priors while remaining computationally tractable (Carvalho et al., 2010). In addition, our local shrinkage encourages element-wise sparsity. A two component mixture allows both dense and sparse factors to be recovered for any subset of observations. These shared factors have an interpretation as a supervised low-rank projection when one observation is supervised labels (e.g., the Mulan Library data). To the best of our knowledge, the BASS model is the first model in either the Bayesian or classical statistical literature that is able to capture low-rank and sparse decompositions among multiple observations.

We developed three algorithms that estimate the posterior distribution of our model or MAP parameter values. We found that EM with random initialization would occasionally get stuck in poor local optima. This motivated the development of a fast and robust PX-EM algorithm by introducing an auxiliary rotation matrix (Rocková and George, 2015). Initializing EM with PX-EM enabled EM to escape from poor initializations, illustrated in simulations. Our PX-EM and EM algorithms have better computational complexity than two competing approaches, GFA and sGFA, allowing for large-scale data application.

Extending multiple observation linear factor models to non-linear or non-Gaussian models has been studied recently (Salomatin et al., 2009; Damianou et al., 2012; Klami et al., 2014a; Klami, 2014). The ideas in this paper of inducing structured sparsity in the loadings has parallels in both of these settings. For example, we may consider structured Gaussian process kernels in the non-linear setting, where structure corresponds to known shared and observation-specific structure. A number of issues remain, including robustness of the recovered sparse factors across runs, scaling these methods to current studies in genomics, neuroscience, or text analysis, allowing for missing data, and developing approaches to include domain-specific structure across samples or features.

Acknowledgments

SM was supported in part by NSF DMS-1418261, NSF DMS-1209155, NSF IIS-1320357, and AFOSR under Grant FA9550-10-1-0436. All code and data are publicly available. The software for BASS is available at <https://github.com/judyboon/BASS>. The gene expression data were acquired through Gene Expression Omnibus (GEO) Accession number GSE36868. We acknowledge the PARC investigators and research team, supported by NHLBI, for collection of data from the Cholesterol and Pharmacogenetics clinical trial.

Appendix A. Markov chain Monte Carlo (MCMC) algorithm for posterior inference

We first derive the MCMC algorithm with Gibbs sampling steps for BASS. We write the joint distribution of the full model as

$$\begin{aligned} p(\mathbf{Y}, \mathbf{X}, \Lambda, \Theta, \Delta, \Phi, \mathbf{T}, \eta, \gamma, \mathbf{Z}, \Sigma, \pi) \\ = p(\mathbf{Y} | \Lambda, \mathbf{X}, \Sigma) p(\mathbf{X}) \\ \times p(\Lambda | \Theta) p(\Theta | \Delta, \mathbf{Z}, \Phi) p(\Delta | \Phi | \mathbf{T}) p(\mathbf{T} | \eta) p(\eta | \gamma) \\ \times p(\Sigma) p(\mathbf{Z} | \pi) p(\pi), \end{aligned}$$

where $\Theta = \{\delta_{jh}^{(w)}\}$, $\Delta = \{\phi_h^{(w)}\}$, $\Phi = \{\tau_h^{(w)}\}$, $\mathbf{T} = \{\eta^{(w)}\}$, and $\gamma = \{\gamma^{(w)}\}$ are the collections of global-factor-local TPB prior parameters.

The full conditional distribution for latent factor \mathbf{x}_i is

$$\mathbf{x}_i | - \sim \mathcal{N}_k \left((\Lambda^T \Sigma^{-1} \Lambda + \mathbf{I})^{-1} \Lambda^T \Sigma^{-1} \mathbf{y}_i, (\Lambda^T \Sigma^{-1} \Lambda + \mathbf{I})^{-1} \right), \quad (14)$$

for $i = 1, \dots, n$.

For Λ , we derive the full conditional distributions of its p rows, λ_j , for $j = 1, \dots, p$,

$$\lambda_j^T | - \sim \mathcal{N}_k \left((\sigma_j^{-2} \mathbf{X} \mathbf{X}^T + \mathbf{D}_j + \mathbf{D}_j^{-1})^{-1} \sigma_j^{-2} \mathbf{X} \mathbf{y}_j^T, (\sigma_j^{-2} \mathbf{X} \mathbf{X}^T + \mathbf{D}_j^{-1})^{-1} \right),$$

where

$$\mathbf{D}_j^{-1} = \text{diag} \left((\theta_{j1}^{(w)}) I_{(z_1^{(w)})} I_{(z_1^{(w)})=1}, (\theta_{j2}^{(w)}) I_{(z_2^{(w)})=0}, \dots, (\theta_{jk}^{(w)}) I_{(z_k^{(w)})=1}, (\theta_{jk}^{(w)}) I_{(z_k^{(w)})=0} \right),$$

and w_j represents the observation that the j^{th} row belongs to.

The full conditional distributions of $\theta_{jh}^{(w)}$, $\delta_{jh}^{(w)}$ and $\phi_h^{(w)}$ with $z_h^{(w)} = 1$ are

$$\begin{aligned} \theta_{jh}^{(w)} | - &\sim \mathcal{IG} \left(a - 1/2, 2\delta_{jh}^{(w)}, (\lambda_{jh}^{(w)})^2 \right), \\ \delta_{jh}^{(w)} | - &\sim \mathcal{Ga} \left(a + b, \phi_h^{(w)} + \theta_{jh}^{(w)} \right), \\ \phi_h^{(w)} | - &\sim \mathcal{Ga} \left(p_w b + c, \sum_{j=1}^{p_w} \delta_{jh}^{(w)} + \tau_h^{(w)} \right), \end{aligned}$$

where \mathcal{IG} is the generalized inverse Gaussian distribution.

The full conditional distribution of $\phi_h^{(w)}$ with $z_h^{(w)} = 0$ is

$$\phi_h^{(w)} | - \sim \mathcal{IG} \left(c - p_w/2, 2\tau_h^{(w)}, \sum_{j=1}^{p_w} (\lambda_{jh}^{(w)})^2 \right).$$

The full conditional distributions of the remaining parameters are

$$\tau_h^{(w)} | - \sim \mathcal{Ga}(c + d, \phi_h^{(w)} + \eta^{(w)}),$$

$$\begin{aligned} \eta^{(w)} | - &\sim \mathcal{Ga} \left(kd + e, \gamma^{(w)} + \sum_{h=1}^k \tau_h^{(w)} \right), \\ \gamma^{(w)} | - &\sim \mathcal{Ga}(e + f, \eta^{(w)} + \nu), \\ \pi^{(w)} | - &\sim \text{beta} \left(1 + \sum_{h=1}^k z_h^{(w)}, 1 + k - \sum_{h=1}^k z_h^{(w)} \right). \end{aligned}$$

The full conditional distribution of $z_h^{(w)}$ is

$$\begin{aligned} \Pr(z_h^{(w)} = 1 | -) &\propto \pi^{(w)} \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \theta_{jh}^{(w)}) \mathcal{Ga}(\theta_{jh}^{(w)}; a, \delta_{jh}^{(w)}) \mathcal{Ga}(\delta_{jh}^{(w)}; b, \phi_h^{(w)}), \\ \Pr(z_h^{(w)} = 0 | -) &\propto (1 - \pi^{(w)}) \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \phi_h^{(w)}). \end{aligned}$$

We further integrate out $\delta_{jh}^{(w)}$ in $\Pr(z_h^{(w)} = 1 | -)$:

$$\begin{aligned} \Pr(z_h^{(w)} = 1 | -) &\propto \pi^{(w)} \prod_{j=1}^{p_w} \int \mathcal{N}(\lambda_{jh}^{(w)}; 0, \theta_{jh}^{(w)}) \mathcal{Ga}(\theta_{jh}^{(w)}; a, \delta_{jh}^{(w)}) \mathcal{Ga}(\delta_{jh}^{(w)}; b, \phi_h^{(w)}) d\delta_{jh}^{(w)} \\ &= \pi^{(w)} \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \theta_{jh}^{(w)}) \frac{\Gamma(a+b) \Gamma(\theta_{jh}^{(w)})^{a-1} (\phi_h^{(w)})^b}{\Gamma(a)\Gamma(b) (\theta_{jh}^{(w)} + \phi_h^{(w)})^{a+b}}. \end{aligned}$$

The full conditional distribution of σ_j^{-2} for $j = 1, \dots, p$ is

$$\sigma_j^{-2} | - \sim \mathcal{Ga} \left(n/2 + a_\sigma, \frac{1}{2} (\mathbf{y}_j - \lambda_j \cdot \mathbf{X})(\mathbf{y}_j - \lambda_j \cdot \mathbf{X})^T + b_\sigma \right).$$

Appendix B. Variational expectation maximization (EM) algorithm for MAP estimates

Expectation Step: Given model parameters, the distribution of latent factor \mathbf{X} was written in Appendix A (Equation 14). The expected sufficient statistics of \mathbf{X} is

$$\begin{aligned} \langle \mathbf{x}_i \rangle &= (\Lambda^T \Sigma^{-1} \Lambda + \mathbf{I})^{-1} \Lambda^T \Sigma^{-1} \mathbf{y}_i, \\ \langle \mathbf{x}_i \mathbf{x}_i^T \rangle &= \langle \mathbf{x}_i \rangle \langle \mathbf{x}_i \rangle^T + (\Lambda^T \Sigma^{-1} \Lambda + \mathbf{I})^{-1}. \end{aligned} \quad (15) \quad (16)$$

The expectation of the indicator variable $\rho_h^{(w)} = \langle z_h^{(w)} \rangle$ is

$$\rho_h^{(w)} = \frac{\pi^{(w)} \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \theta_{jh}^{(w)}) \mathcal{Ga}(\theta_{jh}^{(w)}; a, \delta_{jh}^{(w)}) \mathcal{Ga}(\delta_{jh}^{(w)}; b, \phi_h^{(w)})}{(1 - \pi^{(w)}) \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \phi_h^{(w)}) + \pi^{(w)} \prod_{j=1}^{p_w} \mathcal{N}(\lambda_{jh}^{(w)}; 0, \theta_{jh}^{(w)}) \mathcal{Ga}(\theta_{jh}^{(w)}; a, \delta_{jh}^{(w)}) \mathcal{Ga}(\delta_{jh}^{(w)}; b, \phi_h^{(w)})}.$$

Maximization Step: The log posterior of Λ is written as

$$\log(p(\Lambda | -)) \propto \text{tr}(\Sigma^{-1} \Lambda \mathbf{S} \mathbf{X}^Y) - \frac{1}{2} \text{tr}(\Lambda^T \Sigma^{-1} \Lambda \mathbf{S} \mathbf{X} \mathbf{X}) - \frac{1}{2} \sum_{h=1}^k \lambda_h^T \mathbf{D}_h \lambda_{-h},$$

where

$$\begin{aligned} \mathbf{D}_h &= \text{diag} \left(\frac{\rho_h^{(1)}}{\phi_h^{(1)}} + \frac{1 - \rho_h^{(1)}}{\phi_h^{(m)}}, \dots, \frac{\rho_h^{(m)}}{\phi_{p_m h}^{(m)}} + \frac{1 - \rho_h^{(m)}}{\phi_h^{(m)}} \right), \\ \mathbf{S}^{\mathbf{X}^{\mathbf{Y}}} &= \sum_{i=1}^n \langle \mathbf{x}_i; \mathbf{y}_i^T \rangle, \text{ and } \mathbf{S}^{\mathbf{X}^{\mathbf{X}}} = \sum_{i=1}^n \langle \mathbf{x}_i; \mathbf{x}_i^T \rangle. \end{aligned}$$

We take the derivative with respect to the loading column λ_h to get the MAP estimate. The derivative of first part in the right hand side is

$$\begin{aligned} \frac{\partial \text{tr}(\boldsymbol{\Sigma}^{-1} \mathbf{A} \mathbf{S}^{\mathbf{X}^{\mathbf{Y}}})}{\partial \lambda_h} &= (\mathbf{1}_k^h \otimes \mathbf{I}_p) \times \text{vec}[\boldsymbol{\Sigma}^{-1} \mathbf{S}^{\mathbf{Y}^{\mathbf{X}}}] = \text{vec} \left(\boldsymbol{\Sigma}^{-1} \mathbf{S}^{\mathbf{Y}^{\mathbf{X}}} \mathbf{1}_k^h \right) \\ &= \boldsymbol{\Sigma}^{-1} \mathbf{S}^{\mathbf{Y}^{\mathbf{X}}} \mathbf{1}_k^h, \end{aligned}$$

where vec is the vectorization of a matrix. $\mathbf{1}_k^h \in \mathbb{R}^{k \times 1}$ is a zero vector with a single 1 in the h^{th} element, and $\mathbf{S}^{\mathbf{Y}^{\mathbf{X}}} = (\mathbf{S}^{\mathbf{X}^{\mathbf{Y}}})^T$. For the second part

$$\begin{aligned} \frac{\partial \text{tr}(\mathbf{A}^T \boldsymbol{\Sigma}^{-1} \mathbf{A} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}})}{\partial \lambda_h} &= 2(\mathbf{1}_k^h \otimes \mathbf{I}_p) \times \text{vec}[\boldsymbol{\Sigma}^{-1} \mathbf{A} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}}] = 2 \times \text{vec} \left(\boldsymbol{\Sigma}^{-1} \mathbf{A} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}} \mathbf{1}_k^h \right) \\ &= 2\boldsymbol{\Sigma}^{-1} \mathbf{A} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}} \mathbf{1}_k^h. \end{aligned}$$

For the third part, the derivative is $\mathbf{D}_h \lambda_h$. The MAP estimates for λ_h are found by setting the derivative to zero:

$$\hat{\lambda}_h = |\mathbf{S}^{\mathbf{X}^{\mathbf{X}}} \mathbf{I}_p + \boldsymbol{\Sigma} \mathbf{D}_h|^{-1} \left(\mathbf{S}^{\mathbf{Y}^{\mathbf{X}}} - \sum_{h' \neq h} \lambda_{h'} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}} \right),$$

where $\mathbf{S}_{ij}^{\mathbf{X}^{\mathbf{X}}}$ is the $(i, j)^{\text{th}}$ element of $\mathbf{S}^{\mathbf{X}^{\mathbf{X}}}$, and $\mathbf{S}_{jh}^{\mathbf{Y}^{\mathbf{X}}}$ is the h^{th} column of $\mathbf{S}^{\mathbf{Y}^{\mathbf{X}}}$. The matrix inverse is for a diagonal matrix; thus $\hat{\lambda}_h$ can be calculated efficiently. The MAP estimate for the other model parameters are found from their full conditional distributions with the latent variables replaced by their expectations. We list the parameter updates for those variables here

$$\begin{aligned} \hat{\phi}_{jh}^{(w)} &= \frac{2a - 3 + \sqrt{(2a - 3)^2 + 8(\lambda_{jh}^{(w)})^2 \delta_{jh}^{(w)}}}{4\delta_{jh}^{(w)}}, \\ \hat{\delta}_{jh}^{(w)} &= \frac{a + b}{\theta_{jh}^{(w)} + \phi_{jh}^{(w)}}, \\ \hat{\phi}_h^{(w)} &= \frac{p' - 1 + \sqrt{(p' - 1)^2 + a'H}}{a'}, \text{ with} \\ p' &= \rho_h^{(w)} p_{wb} - (1 - \rho_h^{(w)}) p_{w2} / 2 + c, \\ a' &= 2(\rho_h^{(w)} \sum_{j=1}^{p_w} \delta_{jh}^{(w)} + \tau_h^{(w)}), \end{aligned}$$

$$b' = (1 - \rho_h^{(w)}) \sum_{j=1}^{p_w} (\lambda_{jh}^{(w)})^2$$

$$\hat{\gamma}_h^{(w)} = \frac{c + d}{\phi_h^{(w)} + \eta^{(w)}},$$

$$\hat{\eta}^{(w)} = \frac{dk + e}{\gamma^{(w)} + \sum_{h=1}^k \tau_h^{(w)}},$$

$$\hat{\gamma}^{(w)} = \frac{e + f}{\eta^{(w)} + \nu},$$

$$\hat{\pi}^{(w)} = \frac{\sum_{h=1}^k \rho_h^{(w)}}{k},$$

$$\hat{\sigma}_j^{-2} = \frac{n/2 + a_\sigma - 1}{1/2(\mathbf{y}_j - \lambda_j \langle \mathbf{X} \rangle)(\mathbf{y}_j - \lambda_j \langle \mathbf{X} \rangle)^T + b_\sigma}.$$

Appendix C. Parameter-expanded EM (PX-EM) algorithm for robust MAP estimates

We introduce a positive semidefinite matrix \mathbf{R} in our original model to obtain a parameter-expanded version:

$$\begin{aligned} \mathbf{y}_i &\sim \mathbf{A} \mathbf{R}_L^{-1} \mathbf{x}_i + \epsilon_i, \\ \mathbf{x}_i &\sim \mathcal{N}_k(\mathbf{0}, \mathbf{R}), \\ \epsilon_i &\sim \mathcal{N}_k(\mathbf{0}, \boldsymbol{\Sigma}). \end{aligned}$$

Here, \mathbf{R}_L is the lower triangular part of the Cholesky decomposition of \mathbf{R} . Marginally, the covariance matrix is still $\boldsymbol{\Omega} = \mathbf{A} \mathbf{A}^T + \boldsymbol{\Sigma}$, as this additional parameter keeps the likelihood invariant. This additional parameter reduces the coupling effects between the updates of loading matrix and latent factors (Liu et al., 1998; Dyk and Meng, 2001) and serves to connect different posterior modes with equal likelihood curves indexed by \mathbf{R} (Rocková and George, 2015).

Let $\mathbf{A}^* = \mathbf{A} \mathbf{R}_L^{-1}$ and $\boldsymbol{\Xi}^* = \{\mathbf{A}^*, \boldsymbol{\Theta}, \boldsymbol{\Delta}, \boldsymbol{\Phi}, T, \boldsymbol{\eta}, \boldsymbol{\gamma}, \boldsymbol{\pi}, \boldsymbol{\Sigma}\}$. Then the parameters of our expanded model are $\{\boldsymbol{\Xi}^* \cup \mathbf{R}\}$. We assign our structured prior on \mathbf{A}^* . Thus, the updates of $\boldsymbol{\Xi}^*$ are unchanged given the estimates of the first and second moments of \mathbf{X} . The estimates of $\langle \mathbf{X} \rangle$ and $\langle \mathbf{X} \mathbf{X}^T \rangle$ are calculated using Equations (15 and 16) in Appendix B after mapping the loading matrix back to the original matrix: $\mathbf{A} = \mathbf{A}^* \mathbf{R}_L$. It remains to estimate \mathbf{R} . Write the expected complete log likelihood in the expanded model as

$$Q(\boldsymbol{\Xi}^*, \mathbf{R} | \boldsymbol{\Xi}^{(s)}) = \mathbb{E}_{\mathbf{X}, \mathbf{Z} | \boldsymbol{\Xi}^{(s)}, \mathbf{Y}, \mathbf{R}_0} \log(p(\boldsymbol{\Xi}^*, \mathbf{R}, \mathbf{X}, \mathbf{Z} | \mathbf{Y})).$$

The only term involving \mathbf{R} is $p(\mathbf{X})$. Therefore, the \mathbf{R} that maximizes this function is

$$\mathbf{R}_{(s)} = \arg \max_{\mathbf{R}} Q(\boldsymbol{\Xi}^*, \mathbf{R} | \boldsymbol{\Xi}^{(s)}) = \arg \max_{\mathbf{R}} \left(\text{const} - \frac{n}{2} \log |\mathbf{R}| - \frac{1}{2} \text{tr}(\mathbf{R}^{-1} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}}) \right).$$

The solution is $\mathbf{R}_{(s)} = \frac{1}{n} \mathbf{S}^{\mathbf{X}^{\mathbf{X}}}$.

The EM algorithm in this parameter-expanded space generates the sequence $\{\Xi^*(1) \cup \mathbf{R}_{(1)}, \Xi^*(2) \cup \mathbf{R}_{(2)}, \dots\}$. This sequence corresponds to a sequence of parameter estimates in the original space $\{\Xi_{(1)}, \Xi_{(2)}, \dots\}$, where \mathbf{A} in the original space is equal to $\mathbf{A}^* \mathbf{R}_l$ (Rocková and George, 2015). We initialize $\mathbf{R}_{(0)} = \mathbf{I}_k$.

Abstract

We consider a model of repeated online auctions in which an ad with an uncertain click-through rate faces a random distribution of competing bids in each auction and there is discounting of payoffs. We formulate the optimal solution to this explore/exploit problem as a dynamic programming problem and show that efficiency is maximized by making a bid for each advertiser equal to the advertiser's expected value for the advertising opportunity plus a term proportional to the variance in this value divided by the number of impressions the advertiser has received thus far. We then use this result to illustrate that the value of incorporating active exploration in an auction environment is exceedingly small.

Keywords: Auctions, Explore/exploit, Machine learning, Online advertising

1. Introduction

In standard Internet auctions in which bidders bid by specifying how much they are willing to pay per click, it is standard to rank the advertisers by a product of their bid and their click-through rate, or their expected cost-per-1000-impressions (eCPM) bids. While this is a sensible way to determine the best ad to show for a particular query, it is potentially a suboptimal approach if one cares about showing the best possible ads in the long run. In online auctions, new ads are constantly entering the system, and for these ads one will typically have uncertainty in the true eCPM of the ad due to the fact that one will not know the click-through rate of a brand new ad with certainty. In this case, it can be desirable to show an ad where one has a high amount of uncertainty about the true eCPM of the ad so one can learn more about the ad's true eCPM by observing whether the ad received a click. Thus even if one believes that a high uncertainty ad is not the best ad for this particular query, it may be valuable to show this ad so one can learn more about the eCPM of the ad and make better decisions about whether to show this ad in the future.

While there is an extensive literature that analyzes strategic experimentation in these types of multi-armed bandit problems, the online advertising setting differs substantially from these existing models. In online auctions there is a tremendous amount of random variation in the quality of competition that an ad with unknown eCPM faces in the auction

due to the fact that the ad is constantly competing in a wide variety of different auctions. In these settings, there will always be a certain amount of free exploration that takes place due to the fact that there will be some auctions in which there are no ads with eCPMs that are known to be high, and one can use these opportunities to explore ads with uncertain eCPMs. Almost all existing models of multi-armed bandits that can be applied to online auctions fail to take this possibility into account.

This paper presents a model of repeated auctions in which an ad with an uncertain click-through rate faces a random distribution of competing bids in each auction and there is discounting of payoffs in the sense that an auctioneer values a dollar received in the distant future less highly than a dollar received today. We formulate this problem as a dynamic programming problem and show that the optimal solution to this problem takes a remarkably simple form. In each period, the auctioneer should rank the advertisers on the basis of the sum of an advertiser's expected eCPM plus a term that represents the value of learning about the eCPM of a particular ad. One then runs the auction by ranking the ads by these social values rather than their expected eCPMs.

While there have been previous papers on multi-armed bandits that have proposed ranking arms by a term equal to the expected value of showing an ad plus an additional term representing the value of learning about the true value of that arm,¹ the value of learning in the problem that we consider is dramatically different from the value of learning in standard multi-armed bandit problems. In standard multi-armed bandit problems (Auer et al., 2002) where there is no discounting of payoffs and no random variation in the competition that an arm faces, typical solutions involve ranking the ads according to a sum of the expected value of the arm plus a term proportional to the standard deviation in the arm's value. By contrast, we find that the value of learning in our setting is proportional to the variance in an ad's expected eCPM divided by the number of impressions that an ad has received. Thus the incremental increase in the probability that a particular ad is shown varies with $\frac{1}{k^2}$, where k denotes the number of impressions this ad has received so far. This is an order of magnitude smaller than the corresponding incremental increase in standard machine learning algorithms. In fact, we show that if we attempted to rank the ads on the basis of the sum of an advertiser's expected eCPM plus a term equal to a constant times the standard deviation in the advertiser's eCPM, the optimal constant would be zero.

Our baseline model considers a simple situation in which there is a single advertiser with unknown eCPM that competes in each period against an advertiser with known eCPM whose eCPM bid is a random draw from some distribution. But our conclusions about the value of learning are not restricted to this simple model. We show that our conclusions about the optimal bidding strategies extend to a variety of more complicated models including models in which there are multiple advertisers with unknown eCPMs as well as models in which there is correlation between the unknown eCPMs of multiple different advertisers and information from showing one advertiser can help one refine one's estimate of the eCPM for some other advertiser. We also illustrate an asymptotic equivalence between

1. In addition, Iyer et al. (2014) illustrate that bidders may have an incentive to make a bid equal to their expected value plus a term proportional to their value of learning about their value if bidders have uncertainty about their own value. This paper differs from ours in that it considers an environment in which bidders are attempting to learn their own values rather than an auctioneer attempting to learn the eCPMs.

the theoretically optimal strategies and the strategies that would be selected by a simple one-step look ahead policy often referred to as “knowledge gradients” (Prazier et al., 2009; Ryzhov et al., 2010, 2012).

A consequence of these small incremental changes in the probability that an ad is shown is that the total value from adding active exploration in the online auction setting is exceedingly small. Not only does the incremental increase in the probability that a particular ad is shown vary with $\frac{1}{k^2}$, but on top of that, the expected payoff increase that one obtains conditional on showing a different ad than would be shown without active learning also varies with $\frac{1}{k^2}$. This implies that the total value of adding active exploration in the setting we consider will vary with $\frac{1}{k^4}$ for large numbers of impressions k , an exceedingly small amount.

We further obtain finite sample results illustrating that for realistic amounts of uncertainty in the eCPMs of ads, the maximum total efficiency gain that could ever be achieved by adding active learning in this auction environment is exceedingly small, typically only a few hundredths of a percentage point. Finally, we empirically verify these findings through simulations and illustrate that adding active learning in the auction environment we consider only changes overall efficiency by a few hundredths of a percentage point.

Perhaps the most closely related paper to our work is a paper by Li et al. (2010). This paper is the only other paper we are aware of that considers questions related to the value of learning about the eCPMs of ads with uncertain eCPMs in a setting where there is discounting in payoffs as well as random variation in the quality of the competition that an ad faces from competing ads in the auction. Li et al. (2010) demonstrate that the value of showing an ad with an uncertain eCPM will generally exceed the immediate value of showing that ad because one will learn information about the eCPM of the ad that will enable one to make better ranking decisions in the future. However, Li et al. (2010) do not attempt to characterize the optimal solution in this setting, as we do in the present paper.

There is also an extensive literature in statistics and machine learning that addresses questions related to multi-armed bandits (Audibert and Bubeck, 2010; Auer et al., 2002, 2003; Gittins, 1979; Hazan and Kale, 2011; Lai and Robbins, 1985; Mannor and Tsiitsiklis, 2004; May et al., 2012; Shivkins, 2014) as well as some papers that focus specifically on the auction context (Agrawal et al., 2009; Babaioff et al., 2009; Devanur and Kakade, 2009; Wortman et al., 2007). However, none of these papers considers appropriate methods for exploring ads in a context where there is random variation in the quality of the competition that an ad faces in an auction. The optimal methods for exploring ads in such a scenario turn out to be completely different from the methods considered in any of these previous papers, and as such, our work is completely different from existing machine learning literature.

Finally, there is an extensive literature in economics related to questions on strategic experimentation. Within economics, this literature has considered a variety of questions including consumers trying to learn about the quality of various products (Bergemann and Välimäki, 1996, 1997, 2000), firms and sellers trying to learn about demand (Aghion et al., 1993; Fishman and Rob, 1998; Ghate, 2015; Keller and Rady, 1999; Mirman et al., 1993; Rustichini and Wolinsky, 1995), learning to play repeated games (Anthoussen, 2002; Gale and Rosenthal, 1999), learning about untried policies in political economy (Callander, 2011; Callander and Hummel, 2014; Strulovici, 2010), learning from the actions of others (Banerjee and Fudenberg, 2004; Gale, 1996; Vives, 1997), as well as general results on experimentation

(Aghion et al., 1991; Banks and Sundaram, 1992; Bergemann and Välimäki, 2001; Bolton and Harris, 1999; Brezzi and Lai, 2002; Keller and Rady, 2010; Keller et al., 2005; Moscarini and Smith, 2001; Rothschild, 1974; Schlag, 1998; Weitzman, 1979). However, the economics literature has not considered strategic experimentation in auctions, as we do in the present paper.

2. The Model

There is a new ad with an uncertain eCPM that will bid into a second-price auction for a single advertising opportunity with competing advertisers.² Throughout we let x denote the actual unknown but fixed value (or eCPM) for showing the new ad, z denote the eCPM bid the auctioneer places on behalf of this advertiser,³ and let k denote the number of impressions the ad has received so far. We also suppose that the highest eCPM bid that this advertiser competes against may vary from auction to auction, and that in each auction, this highest competing eCPM bid is a random draw from some cumulative distribution function $F(\cdot)$ with corresponding continuous and twice differentiable density $f(\cdot)$.

At any given point in time, the auctioneer does not necessarily know the exact value of x . Instead the auctioneer only knows that x is drawn from some distribution. We let \bar{x} denote a generic distribution corresponding to the auctioneer’s estimate of the distribution of possible values of x . This distribution will evolve over time as an ad has received more impressions and we have a better sense of the underlying eCPM of the ad.

Throughout we also let \bar{x} denote an unbiased estimate of the true value of x given the auctioneer’s estimate of the distribution of possible values of x . We also let σ_k^2 denote the variance in our estimate of the eCPM for the new ad when the ad has been shown k times. In the limit when k is large, σ_k^2 will be well approximated by $\frac{s^2(\bar{x})}{k}$ for some constant $s^2(\bar{x})$ that depends only on \bar{x} , and we assume that $\sigma_k^2 = \frac{s^2(\bar{x})}{k} + \frac{h(\bar{x})}{k^2} + o(\frac{1}{k^2})$ for some continuously differentiable functions $s^2(\bar{x})$ and $h(\bar{x})$.⁴

In addition, we let $\delta \in (0, 1)$ denote the per-period discount rate so the auctioneer only values advertising opportunities that take place at time T by a factor of δ^T as much as opportunities that take place at the present time period. Throughout we assume that the auctioneer wishes to maximize total efficiency; that is, if v_t denotes the total value of the ad displayed in period t (the true eCPM of this ad), then the auctioneer’s payoff is $\sum_{t=0}^{\infty} \delta^t v_t$. Since online ad auctions are typically designed to select the efficiency-maximizing allocation, this is a logical objective to optimize.

2. These second-price auctions for a single advertising slot are ubiquitous throughout the display advertising industry. In such auctions, advertisers have an incentive to make a bid equal to their true value for a click.
3. Typically advertisers bid by indicating how much they are willing to pay per click, and the auctioneer then uses this cost-per-click bid as well as an estimate of the probability the ad will be clicked to calculate an eCPM bid for the advertiser that the auctioneer then places on behalf of the advertiser in the auction.
4. This assumption will hold for most common priors about the distribution from which the uncertain eCPM of the ad is drawn, such as a beta prior. It is also worth noting that the weaker assumption that $\sigma_k^2 = \frac{s^2(\bar{x})}{k} + O(\frac{1}{k^2})$ for some constant $s^2(\bar{x})$ is sufficient to prove our main result about the value of learning being $O(\frac{1}{k^2})$. The additional assumption that $\sigma_k^2 = \frac{s^2(\bar{x})}{k} + \frac{h(\bar{x})}{k^2} + o(\frac{1}{k^2})$ is only used to further prove that the value of learning is of the form $\frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$ for some function $v(\bar{x})$.

3. Preliminaries

Before proceeding to analyze the precise model given above, we first address a closely related question about the extent to which a particular advertising opportunity increases total welfare if the eCPM of this advertising opportunity is known. In particular, we consider a concept that we refer to as the *long-term value* of a particular advertisement. The long-term value of a particular advertisement gives the total increase in the auctioneer's payoff that arises as a result of this ad being in the system from the various auctions that take place over time. Understanding the long-term value of a particular advertisement when the eCPM of that ad is known will serve as a useful benchmark for understanding how one should behave when there is uncertainty about the eCPM of the ad.

Theorem 1 *If the eCPM of an ad is known, then the total long-term value of this ad is a convex function of the eCPM of the ad and a strictly convex function for regions where the eCPM of the ad is within the support of the distribution of the highest competing eCPM.*

All proofs are in the appendix. The fact that the value for any particular advertisement is a convex function of the eCPM of the ad if the eCPM of the ad is known indicates that if there is uncertainty about the eCPM of the ad, then the expected long-term value of this ad will be greater than the long-term value of the expected eCPM of the ad. From this it follows that if there is uncertainty about the eCPM of the ad, then it will be optimal to behave as if this particular ad had a known eCPM that is greater than the expected eCPM of the ad. The precise additional amount that this advertiser's bid should be increased will be pinned down by the solution to the dynamic programming problem governed by the game described in the model.

4. Dynamic Programming Problem

In this section, we formulate the value of a particular ad as a dynamic programming problem and use this formulation to derive the optimal bidding strategy. First we derive the auctioneer's payoff that arises in a particular period when the auctioneer makes a particular bid on behalf of the advertiser with uncertain eCPM.

Note that if the auctioneer places a bid of z on behalf of the advertiser with uncertain eCPM in the auction and the actual value of showing this particular ad is x , then the auctioneer's payoff from running the auction once is

$$\begin{aligned} u(z, x) &= \int_z^\infty yf(y) dy + \int_0^z xf(y) dy = -y(1-F(y))\Big|_z^\infty + \int_z^\infty (1-F(y)) dy + xF(z) \\ &= z(1-F(z)) + \int_z^\infty (1-F(y)) dy + xF(z). \end{aligned}$$

In general placing a bid of z rather than x in a one-shot auction will result in some inefficiencies in the one-shot auction since it would be optimal for efficiency to place a bid exactly equal to x on behalf of this advertiser in a one-shot auction. The payoff loss that arises in a one-shot auction as a result of placing a bid of z instead of x is

$$L = u(x, x) - u(z, x)$$

$$\begin{aligned} &= x(1-F(x)) + \int_x^\infty (1-F(y)) dy + xF(x) - z(1-F(z)) - \int_z^\infty (1-F(y)) dy - xF(z) \\ &= (x-z)(1-F(z)) + \int_x^z (1-F(y)) dy = \int_x^z F(z) - F(y) dy. \end{aligned}$$

If we define the per-period reward to be the negative of this per-period loss, then the auctioneer seeks to maximize the discounted sum of these per period rewards. Let $V_k(\bar{x})$ denote the value of this discounted sum when the auctioneer follows the optimal bidding strategy. Also note that, from the perspective of the auctioneer, x is a random variable that can be expressed as $x = \bar{x} + \sigma_k \epsilon$, where σ_k denotes the standard deviation in our estimate of the ad with uncertain eCPM when the ad has been shown k times, and ϵ is a random variable with mean zero and variance one. We use this notation to prove the following:

Lemma 2 $V_k(\bar{x})$ can be expressed as the value of a dynamic programming problem by

$$V_k(\bar{x}) = \frac{1}{1-\delta} \left(\max_z E_\epsilon \left[- \int_{\bar{x} + \sigma_k \epsilon}^z F(z) - F(y) dy + \delta F(z) (E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x})) \right] \right),$$

where \bar{x} denotes the uncertain realization of \bar{x} after an ad receives an additional impression.

By using the expression for the value of the dynamic programming problem in the previous lemma, we can derive the bid that the auctioneer should place on behalf of the advertiser to maximize the auctioneer's payoff. This is done in the theorem below:

Theorem 3 *The optimal bidding strategy in the dynamic programming problem when an ad has been shown k times entails setting $z = \bar{x} + \delta(E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x}))$.*

Thus the optimal bidding strategy in this dynamic programming problem can be written in a form where the bid the auctioneer makes on behalf of the bidder with uncertain eCPM is equal to the bidder's expected eCPM plus a term that represents the value of learning about the true eCPM of that bidder, $\delta(E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x}))$. In order to calculate this value of learning, we need to get a sense of the size of the $V_k(\bar{x})$ terms.

5. Value of Dynamic Program for Large Numbers of Impressions

In the previous section, we have given exact expressions for the value of the dynamic program and the optimal bidding strategy that should be followed under this dynamic programming problem. In this section, we seek to derive accurate estimates of the value of this dynamic program in the limit when an ad has already been shown a large number of times.

The main purpose of this section is to illustrate that the value of learning term given in the previous section will vary with $\frac{1}{k^2}$ for large k . We prove this by first showing that the expected efficiency loss arising due to the uncertainty in the eCPM of the ad varies with $\frac{1}{k}$ for large k , and then use this to show that the value of learning term varies with $\frac{1}{k} - \frac{1}{k+1}$, which varies with $\frac{1}{k^2}$ for large k .

When an ad has already been shown a large number of times, the value of σ_k that is estimated for the ad is likely to be very small. For small values of σ_k , we can use a Taylor expansion to approximate the value of the above dynamic programming problem. In particular, we obtain the following result:

Lemma 4 $E_c \int_{\bar{x}-\sigma_k \epsilon}^{\bar{x}} F(z) - F(y) dy = \int_{\bar{x}}^z F(z) - F(y) dy + \frac{1}{2} \sigma_k^2 f(\bar{x}) + a(\bar{x}) \sigma_k^4 + o(\sigma_k^4)$ for some constant $a(\bar{x})$ for large k .

Using the results from the previous lemma, one can immediately illustrate that V_k must be on the order of $\frac{1}{k}$ for large values of k .

Theorem 5 $V_k(\bar{x}) = \Theta(\frac{1}{k})$ for large k .

To understand the intuition behind this result, note that the average error in the estimate of the eCPM of the ad is proportional to the standard error of this estimate, σ_k , which varies with $\frac{1}{\sqrt{k}}$, so the probability that the auctioneer will display the wrong ad as a result of miscalculating the eCPM of the ad varies with $\frac{1}{\sqrt{k}}$. At the same time, conditional on displaying the wrong ad as a result of miscalculating the eCPM of the ad, the average efficiency loss that one suffers varies with $\frac{1}{\sqrt{k}}$. Thus the expected efficiency loss that the auctioneer incurs varies with $\frac{1}{k}$, which in turn implies the result in Theorem 5.

Theorem 5 suggests that we may be able to write $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + o(\frac{1}{k})$ for large k , where v is a function that depends only on \bar{x} . To prove that $V_k(\bar{x})$ can be expressed this way, it is necessary to show that $kV_k(\bar{x})$ indeed converges to a function of \bar{x} in the limit as $k \rightarrow \infty$. This is done in the following theorem:

Theorem 6 $kV_k(\bar{x})$ converges to a function of \bar{x} in the limit as $k \rightarrow \infty$. Furthermore, it must be the case that $kV_k(\bar{x}) = -\frac{v(\bar{x})}{2(1-\delta)} s^2(\bar{x}) f(\bar{x}) + O(\frac{1}{k})$ for large k .

From Theorem 6, it follows that we can express $V_k(\bar{x})$ by $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + O(\frac{1}{k^2})$ for large k , where v is a function that satisfies $v(\bar{x}) = \frac{v(\bar{x})}{2(1-\delta)} s^2(\bar{x}) f(\bar{x})$. In order to complete our approximation of the solution the dynamic programming problem for large k , it is also necessary to bound the expression $E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x})$ that appears in the dynamic programming problem. This is done in the following theorem:

Theorem 7 $E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$ for large k .

The intuition behind this result is that since the efficiency loss that the auctioneer incurs due to uncertainty in the eCPM of an ad varies with $\frac{1}{k}$, the value of learning will be proportional to the reduction in the future efficiency loss that the auctioneer suffers as a result of learning more about the eCPM of the ad, meaning the value of learning will vary with $\frac{1}{k} - \frac{1}{k+1}$, which varies with $\frac{1}{k^2}$. The fact that $E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x})$ varies with $\frac{1}{k^2}$ indicates that the incremental increase in an advertiser's bid also varies with $\frac{1}{k^2}$ in the limit when k is large. This in turn implies that the incremental increase in an advertiser's probability of winning the auction will also vary with $\frac{1}{k^2}$ for large k .

The result in Theorem 7 suggests that the optimal method for adding active exploration will only rarely have an effect on which ad wins the auction, as the probability that this active exploration changes which ad is shown varies with $\frac{1}{k^2}$ for large k . This result about the value of learning varying with $\frac{1}{k^2}$ for large k stands in marked contrast to algorithms that have been proposed for active exploration in standard multi-armed bandit problems with no discounting of payoffs and no random variation in the competition that an arm faces

in a given period (Auer et al., 2002). In these types of algorithms, the value of learning tends to vary with $\frac{1}{\sqrt{k}}$, which means the value of learning is an order of magnitude smaller in our setting than in standard multi-armed bandit problems.

Ultimately we seek to use these insights to derive results about the change in payoff that would result from incorporating active learning in this setting. Before doing this, we first illustrate how the conclusions of this section about the value of the dynamic programming problem and the optimal bidding strategy extend to a variety of more complicated scenarios including settings where there are multiple different ads with uncertain eCPMs whose true eCPMs may be correlated and we also illustrate a natural correspondence between the optimal solution to the full dynamic programming problem and a simple one-step look-ahead strategy. First we tackle the problem of computing the value of the dynamic program when an ad with an uncertain eCPM has only received a small number of impressions.

6. Value of Dynamic Program for Small Numbers of Impressions

To calculate the value of $V_k(\bar{x})$ for small values of k , we apply backwards induction. At some large value of k , it will necessarily be the case that the incremental value of additional exploration is so small that the advertiser simply bids $z = \bar{x}$ because the smallest possible increment the advertiser would be allowed to adjust its bid exceeds the tiny incremental value of additional exploration. Thus if K denotes the earliest stage at which an advertiser always sets $z = \bar{x}$, then for all $k \geq K$, it is necessarily the case that the value of learning is zero, and $V_k(\bar{x}) = \frac{1}{1-\delta} \left(E_c \left[-\int_{\bar{x}-\sigma_k \epsilon}^{\bar{x}} F(\bar{x}) - F(y) dy \right] \right) \approx 0$.

For values of $k < K$, we have

$$(1 - \delta) V_k(\bar{x}) = E_c \left[-\int_{\bar{x}+\sigma_k \epsilon}^{z_k} F(z_k) - F(y) dy \right] + \delta F(z_k) (E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x}))$$

or

$$V_k(\bar{x}) = \frac{E_c \left[-\int_{\bar{x}+\sigma_k \epsilon}^{z_k} F(z_k) - F(y) dy \right] + \delta F(z_k) E_{\bar{x}}[V_{k+1}(\bar{x}')] }{1 - \delta + \delta F(z_k)}.$$

Thus by empirically measuring the values of σ_k and $F(\cdot)$, we can apply backward induction to approximate $V_k(\bar{x})$ for small values of k . We now address the question of what these values of $V_k(\bar{x})$ will be approximately equal to for an important class of advertisers.

Many ads that have only received a small number of impressions are ads that typically fail to win auctions because the machine learning system is pessimistic about the ad's true eCPM. The estimated eCPMs for these ads may be several orders of magnitude smaller than the typical eCPMs of the ads that have been shown many times. In these cases, even if the percentage uncertainty in the eCPMs of these ads is quite high, the absolute amount of uncertainty in the eCPMs of these ads will be small compared to the typical eCPMs of the ads that have been shown many times. Thus in these cases, \bar{x} will be close to zero, and $F(\bar{x})$ and σ_k^2 will be close to zero as well. Under these circumstances, we have the following result:

Theorem 8 If \bar{x} (and σ_k^2) are close to zero for small values of k , then $V_k(\bar{x}) = -\frac{v(\bar{x})}{2(1-\delta)} f(\bar{x}) \sigma_k^2 + o(f(\bar{x}) \sigma_k^2)$ for small values of k .

Theorem 8 indicates that even in small sample environments, it is still frequently reasonable to approximate $V_k(\bar{x})$ by writing $V_k(\bar{x}) \approx -\frac{1}{2(1-\delta)} f(\bar{x}) \sigma_k^2$, where σ_k^2 denotes the variance in our estimate of the ad's eCPM for a particular value of k . This theorem in turn implies that if a machine learning system is quite pessimistic about the true eCPM of a new ad, then there will be little value to actively exploring the ad because the value of learning term, $E_{\mathcal{F}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x})$, will be quite small.

7. Ads with Correlated Values

So far we have restricted attention settings in which we only seek to learn the eCPM of one advertiser's ad. However, in many situations we may seek to learn the eCPMs of multiple advertisers' ads and the eCPMs of the various advertisers may be correlated. In these situations, information about one ad's eCPM may help one learn about the eCPMs of other related advertisers. On top of this, even if there is only one ad for which we are uncertain about the advertiser's eCPM, this ad may bid in several different contexts where the ad has substantially different eCPMs and the ad faces substantially different competing landscapes of bids.⁵ In these cases, information about an ad's eCPM in one context may also help one learn about the ad's eCPM in other contexts.

To address how this affects the results, we extend the model to allow for the possibility that there are multiple different ads that bid in multiple different contexts where we seek to learn the eCPMs of the ads and these eCPMs may be correlated. In particular, we suppose that there are m different ad-context pairs where we seek to learn the eCPM of the ad in that particular context. For the ad-context pair a , we let x_a denote the actual, unknown value of the eCPM of that ad in that context, and we let $x = (x_1, \dots, x_m)$ denote the actual unknown eCPMs of the ads in all m contexts. We also let k denote the total number of impressions that these advertisers have received in the various contexts and let β_a denote the fraction of these impressions that were received in context a . Thus we have $\sum_{a=1}^m \beta_a = 1$.

We again assume the auctioneer does not know the exact value of x , and instead the auctioneer only knows that x is drawn from some distribution. We again let \bar{x} denote a generic distribution corresponding to the auctioneer's estimate of the distribution of possible values of x . This distribution allows for the possibility that the auctioneer may believe there is correlation in the unknown eCPMs of the advertisers in the different contexts, and the distribution will again evolve over time as an ad has received more impressions and we have a better sense of the underlying eCPM of the ad.

Throughout we also let \bar{x} denote an unbiased estimate of the true value of x given the auctioneer's estimate of the distribution of possible values of x and we let \bar{x}_a denote an unbiased estimate of the true value of x_a given this distribution. We also let σ_{a,k_a}^2 denote the variance in our estimate of the eCPM of the ad-context pair a when there have been a total of k_a impressions in this ad-context pair. In the limit when k_a is large, σ_{a,k_a}^2 will be well approximated by $\frac{s_a^2(\bar{x}_a)}{k_a} = \frac{s_a^2(\bar{x}_a)}{\beta_a k}$ for some constant $s_a^2(\bar{x}_a)$ that depends only on \bar{x}_a , and

5. Contextual bandit problems in which an arm's payoff may vary from context to context have appeared in the literature before in different settings. See, for example, work by May et al. (2012) and Shlivkins (2014).

we again let $\sigma_{a,k_a}^2 = \frac{s_a^2(\bar{x}_a)}{\beta_a k_a} + \frac{h_a(\bar{x}_a)}{\beta_a^2 k_a^2} + o(\frac{1}{k_a^2})$ for some continuously differentiable functions $s_a^2(\bar{x}_a)$ and $h_a(\bar{x}_a)$. In addition, we let $\delta \in (0, 1)$ denote the per-period discount rate so that the mechanism designer only values advertising opportunities that take place at time T by a factor of δ^T as much as opportunities that take place at the present time period.

In each period t , there is an auction for a single advertising opportunity. The auction can involve any one of the m possible ad-context pairs for which we do not know the eCPM of the ad in that context. We let π_a denote the probability that there will be an auction involving ad-context pair a in any given time period. Thus we have $\sum_{a=1}^m \pi_a = 1$. We further suppose that if there is an auction involving ad-context pair a , then the distribution of the values of the competing advertisers is such that the highest eCPM for a competing ad is a random draw from some cumulative distribution function $F_a(\cdot)$ with corresponding continuous and twice differentiable density $f_a(\cdot)$.

In this setting, the total long-term value of a particular ad-context pair is again a convex function of the eCPM of the ad for the same reasons as in Theorem 1 and we can again formulate this problem as a dynamic program. To do this, let $\vec{k} \equiv (k_1, \dots, k_m)$ denote a vector that gives the number of impressions that have been received by the various ad-context pairs $1, \dots, m$. Also let $V_{a,\vec{k}}(\bar{x})$ denote the value of the dynamic program when the next auction involves the advertiser-context pair a , the eCPMs of the ads are \bar{x} , and there have been \vec{k} impressions in each of the various ad-context pairs, and let $V_{\vec{k}}(\bar{x}) \equiv E_a[V_{a,\vec{k}}(\bar{x})]$ denote the value of the same dynamic program unconditional on which ad-context pair is involved in the next auction. By using similar reasoning to that in Lemma 2, we know that $V_{\vec{k}}(\bar{x})$ equals

$$\frac{1}{1-\delta} E_a \left[\max_{z_a} E_{\epsilon} \left[- \int_{\bar{x}_a + \sigma_{a,k_a \epsilon}}^{z_a} F_a(z_a) - F_a(y) dy + \delta F_a(z_a)(E_{\mathcal{F}'}(a)[V_{\vec{k}'(a,\vec{k})}(\bar{x}'(a))] - V_{\vec{k}}(\bar{x})) \right] \right],$$

where $\vec{k}'(a, \vec{k}) \equiv (k'_1, \dots, k'_m)$ is a vector that satisfies $k'_b = k_b$ for all $b \neq a$ and $k'_a = k_a + 1$, and $\bar{x}'(a)$ denotes the uncertain realization of \bar{x} if the advertiser-context pair a receives an additional impression. Furthermore, the optimal bid z_a if there is an auction involving the advertiser-context pair a satisfies $z_a = \bar{x}_a + \delta F_a(z_a)(E_{\mathcal{F}'}(a)[V_{\vec{k}'(a,\vec{k})}(\bar{x}'(a))] - V_{\vec{k}}(\bar{x}))$ by similar logic to that given in Theorem 3, and the result in Lemma 4 is just a general mathematical result that holds regardless of the model we are considering. Thus natural analogs of Theorems 1 and 3 and Lemmas 2 and 4 continue to hold in this revised model.

By using these insights, one can further show that $V_{\vec{k}}(\bar{x})$ must be on the order of $\frac{1}{k}$ for large k . This is done in the following theorem:

Theorem 9 *When there are multiple ads with correlated values, $V_{\vec{k}}(\bar{x}) = \Theta(\frac{1}{k})$.*

While this result indicates that $V_{\vec{k}}(\bar{x})$ varies with $\frac{1}{k}$ for large values of k , this alone does not guarantee the convergence of this function for large values of k . We verify that this function does indeed converge for large values of k in the following theorem:

Theorem 10 *When there are multiple ads with correlated values, $kV_{\vec{k}}(\bar{x})$ converges to a function of \bar{x} in the limit as $k \rightarrow \infty$. Furthermore, it must be the case that $kV_{\vec{k}}(\bar{x}) = -\frac{1}{2(1-\delta)} \sum_{a=1}^m \pi_a \frac{1}{\beta_a} s_a^2(\bar{x}_a) f_a(\bar{x}_a) + O(\frac{1}{k})$ for large k .*

Theorem 10 indicates that the results about the limiting value of $kV_k(\bar{x})$ derived in Theorem 6 extend naturally to the case where there are multiple ads with possibly correlated values. When there are multiple ad-context pairs that we must learn about, the value function corresponding to that in Theorem 6 differs only in that we take a weighted sum over the various possible advertiser-context pairs, where the weights are a function of the relative probabilities with which each advertiser-context pair arises. Thus there is a clear analog between the limiting properties of the value function when there are multiple advertiser-context pairs and the value function in the main model.

By using the results in the previous theorem, one can further derive properties of the limiting value of $E_{\bar{x}(a)}[V_{k(a,\bar{k})}(\bar{x}(a))] - V_k(\bar{x})$ that is proportional to the additional amount that one should bid in the auction beyond the expected value that one has for the advertising opportunity. This is stated below in the following theorem:

Theorem 11 *When there are multiple ads with correlated values, $E_{\bar{x}(a)}[V_{k(a,\bar{k})}(\bar{x}(a))] - V_k(\bar{x}) = -\frac{\sigma_{\bar{x}}}{2(1-\delta)\beta k^2} s_a^2(\bar{x}_a) f_a(\bar{x}_a) + o(\frac{1}{k^2})$ for large k .*

The proof of this result is substantively identical to the proof of Theorem 7 and is thus omitted. Theorem 11 illustrates that the substantive conclusions of Theorem 7 extend to this alternative environment in which there are multiple ads with possibly correlated values. When there are multiple ads, it remains optimal to increase one's bid by an amount proportional to the variances in our estimates of the eCPMs of the ads or $\frac{\sigma_{\bar{x}}}{k^2}$ for large k .

8. Knowledge Gradients

Throughout the paper so far, we have considered a standard dynamic programming approach in which the optimal decision at any given point in time is affected in part by how this decision will affect future decisions when looking at the infinite horizon ahead. While this is a standard approach to take in these types of problems, recently there has been work considering an alternative approach often referred to as "knowledge gradients" in which the decision one takes in a given period is the decision that one would take if one faced an infinite-horizon game but this period was the last period in which the information one learned could be used to inform future actions.

The main advantage of these knowledge gradients over the standard dynamic programming approach is that they have the virtue of being much easier to calculate than the optimal bidding strategy under the standard dynamic programming problem. This simplicity does potentially come at a performance cost. However, various papers have illustrated that using this simple one-step look-ahead approach can nonetheless achieve a performance that is competitive with that of other standard methods in contexts unrelated to advertising (Frazier et al., 2009; Ryzhov et al., 2010, 2012). In this section, we investigate whether this alternative knowledge gradient approach can indeed achieve a performance comparable to that of the theoretically optimal dynamic programming approach.

To address this question, for simplicity we consider the baseline model in which there is one advertisement for which we are seeking to learn the eCPM of the ad, though similar results can easily be derived under the more general model we have considered with multiple ads and correlated values. Let $U_k(\bar{x})$ denote the value that one would obtain for the rest of

the game when an ad has received k impressions so far, one's estimate of the eCPM of the ad is \bar{x} , and one will not be able to use information that one learns in the future to inform future bidding decisions. Note that in this case, the optimal bidding strategy will be to submit a bid of $z = \bar{x}$ in every remaining period, and the auctioneer's expected per-period payoff will be $E_\epsilon \left[-\int_{\bar{x}+\sigma_{k\epsilon}}^z F(z) - F(y) dy \right]$ in every future period, where ϵ denotes some random variable with mean zero and variance one, and $z \equiv \bar{x}$. The total value the auctioneer will obtain for the rest of the game is then $U_k(\bar{x}) = \frac{1}{1-\delta} E_\epsilon \left[-\int_{\bar{x}+\sigma_{k\epsilon}}^{\bar{x}} F(\bar{x}) - F(y) dy \right]$.

Also let $U_{k+1}(\bar{x})$ denote the value that one would obtain for the rest of the game when an ad has received $k+1$ impressions so far, one's estimate of the eCPM of the ad is \bar{x} , and one will not be able to use information that one learns in the future to inform future bidding decisions. The total value the auctioneer will obtain for the rest of the game is then $U_{k+1}(\bar{x}) = \frac{1}{1-\delta} E_\epsilon \left[-\int_{\bar{x}+\sigma_{k+1\epsilon}}^{\bar{x}} F(\bar{x}) - F(y) dy \right]$.

Now consider the bidding strategy that one would employ if one faced an infinite-horizon game but this period was the last period in which the information one learned could be used to inform future actions. The auctioneer's payoff from bidding z that arises in the current period equals $-\int_{\bar{x}+\sigma_{k\epsilon}}^z F(z) - F(y) dy$. And the expected value that the auctioneer obtains from future periods by bidding z in the current period is $F(z) E_{\bar{x}}[U_{k+1}(\bar{x})] + (1 - F(z)) U_k(\bar{x})$ by the same reasoning used in the proof of Lemma 2. From this it follows that the expected payoff from placing a bid of z in a given period is

$$E_\epsilon \left[-\int_{\bar{x}+\sigma_{k\epsilon}}^z F(z) - F(y) dy + \delta(F(z) E_{\bar{x}}[U_{k+1}(\bar{x})] + (1 - F(z)) U_k(\bar{x})) \right].$$

There is a clear similarity between this expression and the expression for the expected payoff from placing a bid of z in the standard dynamic programming approach. The main difference is that the terms $U_{k+1}(\bar{x})$ and $U_k(\bar{x})$ have replaced the terms $V_{k+1}(\bar{x})$ and $V_k(\bar{x})$ in the standard dynamic programming approach.

It is worth noting, however, that the payoffs that result from the one-step look ahead strategies in the model in this paper take a different form than those given in other knowledge gradient papers (Frazier et al., 2009; Ryzhov et al., 2010, 2012). The reason for this difference is that in the model in our paper, there is a competing ad whose eCPM is known in each period but is also a random draw from some distribution in each period. No such random changes in the values of the arms from period to period are present in existing knowledge gradient papers, so the payoffs and strategies in our paper are formulated differently than those given in existing knowledge gradient papers.

From the equation we've derived for the auctioneer's payoff from bidding z , we can calculate the optimal bidding strategy under the knowledge gradient formulation. This bidding strategy is given in the following theorem:

Theorem 12 *The optimal bidding strategy in the knowledge gradient framework when an ad has been shown k times entails setting $z = \bar{x} + \delta(E_{\bar{x}}[U_{k+1}(\bar{x})] - U_k(\bar{x}))$.*

The proof of this result is substantively identical to that in Theorem 3 and is thus omitted. This result indicates that in the knowledge gradient framework, the incremental amount that one increases one's bid beyond the immediate expected reward is again of the

form $\delta[E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x})]$, the only difference being that $U_k(\bar{x})$ corresponds to the value of the dynamic program under the knowledge gradient framework.

To better understand the incremental amount that one would increase one's bid, we present two results that illustrate how the incremental amount that one would increase one's bid under the knowledge gradient framework compares to the incremental amount that one would increase one's bid under the full dynamic programming problem. First we present a finite sample result about how these incremental bid increases compare in the two frameworks.

In our first result, we consider what we refer to as the expected value of all future learning. To reflect the fact that $V_k(\bar{x})$ gives the auctioneer's payoff from the full dynamic programming problem when the auctioneer is able to make use of additional information in future periods, whereas $U_k(\bar{x})$ gives the auctioneer's payoff from the corresponding game in which the auctioneer is not able to make use of information that he learns, we define this expected value of all future learning term to be the difference between $V_k(\bar{x})$ and $U_k(\bar{x})$. With this definition in mind, we obtain the following result:

Theorem 13 *Suppose the expected value of all future learning is lower after the ad has been shown $k + 1$ times than it is after the ad has been shown k times. Then the incremental amount by which one would increase one's bid under the knowledge gradient framework is greater than it is under the full dynamic programming problem.*

Theorem 13 indicates that the solution to the one-step look ahead problem will generally involve increasing one's bid beyond the immediate expected value of the advertising opportunity by a greater amount than one would do so under the full dynamic programming problem. This makes sense intuitively. If the current period were the last period in which one could ever use information that one learns to inform future actions, then one would place quite a high premium on being able to learn this information while one still can. By contrast, in the full dynamic programming problem, there will always be plenty of opportunities to learn this information later, so there is relatively less incentive to substantially increase one's bid beyond the immediate expected reward. This explains the result in Theorem 13.

Theorem 13 requires a technical condition that the expected value of all future learning is lower if an ad has been shown $k + 1$ times than if the ad has been shown k times, but this is just a mild technical constraint that we would expect to hold in virtually any situation. When an ad has been shown $k + 1$ times, one has more precise information about the true eCPM of the ad than when the ad has only been shown k times, so there is less value to learning more about the true eCPM of the ad.

While Theorem 13 suggests that one might increase one's bid by too much under the knowledge gradient framework compared to the strategy that one should follow under the full dynamic programming problem, these differences in bidding strategies turn out to be relatively small. We illustrate this by characterizing the value of $E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x})$:

Theorem 14 *In the knowledge gradient framework, $E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o\left(\frac{1}{k^2}\right)$ for large k , where $v(\bar{x}) \equiv \frac{1}{2(1-\beta)} s^2(\bar{x}) f(\bar{x})$.*

This result also immediately implies the following corollary:

Corollary 15 *The ratio of the incremental amount by which one wants to increase one's bid in the knowledge gradient framework and the incremental amount by which one wants to increase one's bid in the standard dynamic programming approach becomes arbitrarily close to 1 in the limit as the amount of uncertainty in an ad's eCPM becomes arbitrarily small.*

Thus using the knowledge gradient to formulate one's bidding strategy will result in payoffs that are asymptotically equivalent to those that would result from using the theoretically optimal bidding strategy. These results suggest that the knowledge gradient framework is indeed an appealing framework for computing bidding strategies in an environment where one wishes to learn about the unknown eCPMs of advertisers, as using this approach will result in little loss from the theoretically optimal approach.

9. Learning About Multiple Advertisers in the Same Auction

In the analysis so far, we have assumed that in any given auction, there is only one advertiser whose eCPM is unknown. But in many real-life auctions there may be multiple advertisers with unknown eCPMs. In these cases, an auctioneer must decide both which advertiser with unknown eCPM will have the highest bid as well as what bid to submit for this advertiser.

In this setting, it is not clear whether the decision maker's optimal strategy can simply be represented by submitting a bid for each advertiser that is equal to the sum of the best estimate of the advertiser's eCPM as well as a value of learning term. It may be the case that the optimal bid for advertiser i if advertiser i submits the highest bid of the advertisers with unknown eCPMs is higher than the optimal bid for some other advertiser j if advertiser j submits the highest bid of the advertisers with unknown eCPMs, even though the decision maker would prefer to submit a higher bid for advertiser j than for advertiser i . We address whether this possibility can arise in this section.

To address this question, suppose that in each auction, there are n ads with unknown eCPMs. The actual eCPMs of these ads are x_1, \dots, x_n , and we let z_1, \dots, z_n denote the bids placed by these advertisers in the auction. Also let i denote the advertiser who submits the highest eCPM bid amongst these n bidders and let j denote the advertiser who actually has the highest eCPM amongst these advertisers. In each auction, these advertisers with unknown eCPMs compete against other advertisers and the highest such competing eCPM is drawn from a cumulative distribution function $F(\cdot)$ with corresponding density $f(\cdot)$.

Note that in this case, the utility that the decision maker obtains in a given period from having advertiser i submit a bid of z_i that is the highest eCPM bid amongst these n bidders is $u = z_i(1 - F(z_i)) + \int_{z_i}^{\infty} (1 - F(y)) dy + x_i F(z_i)$. At the same time, this decision maker would obtain a utility of $u = x_j(1 - F(x_j)) + \int_{x_j}^{\infty} (1 - F(y)) dy + x_j F(x_j)$ in a given period from making the optimal decision in a given period. Thus the loss that this decision maker obtains in a given period as a result of having advertiser i submit a bid of z_i that is the highest eCPM bid amongst these n bidders is the difference between these two utilities or $L = x_j - z_i + (z_i - x_j)F(z_i) + \int_{x_j}^{z_i} (1 - F(y)) dy = \int_{x_j}^{z_i} F(z_i) dy - \int_{x_j}^{z_i} F(y) dy$.

Now let k_i denote the number of impressions that advertiser i has received so far, let $\vec{k} \equiv (k_1, \dots, k_n)$ denote a vector that gives the number of times each of these ads has been shown, let \bar{x}_i denote our best estimate of the expected value of the eCPM of advertiser i ,

and let $\bar{x} \equiv (\bar{x}_1, \dots, \bar{x}_n)$ denote a vector of these best estimates. Also let $V_k^c(\bar{x})$ denote the value of the dynamic program as a function of these quantities.

By similar reasoning to that in the proof of Lemma 2, it follows that if i denotes the advertiser who submits the highest eCPM bid amongst the n bidders with unknown eCPMs, $R^c(i) \equiv (k_1^i, \dots, k_n^i)$ is the vector where $k_j^i = k_j$ for all $j \neq i$ and $k_i^i = k_i + 1$, and $\bar{x}^c(i)$ denotes the uncertain realization of \bar{x} if advertiser i receives an additional impression, then $V_k^c(\bar{x})$ equals

$$\frac{1}{1-\delta} \left(\max_{z_i} E_{R_i, \bar{x}_i} \left[\int_{\bar{x}_i}^{z_i} F(y) dy - \int_{\bar{x}_i}^{z_i} F(z_i) dy + \delta F(z_i) (E_{R^c(i)}[V_k^c(\bar{x}^c(i))] - V_k^c(\bar{x})) \right] \right),$$

where the difference in the values of the dynamic programs is due to the fact that the loss in a given period is now $\int_{\bar{x}_i}^{z_i} F(z_i) dy - \int_{\bar{x}_i}^{z_i} F(y) dy$. Similarly, the optimal bid for advertiser i if advertiser i submits the highest eCPM bid amongst the n bidders with unknown eCPMs still satisfies $z_i = \bar{x}_i + \delta (E_{R^c(i)}[V_k^c(\bar{x}^c(i))] - V_k^c(\bar{x}))$. We use these insights to prove the following:

Theorem 16 *Suppose the optimal bid for advertiser i if advertiser i submits the highest bid of the advertisers with unknown eCPMs is higher than the optimal bid for all other advertisers with unknown eCPMs if one of these other advertisers submits the highest bid of the advertisers with unknown eCPMs. Then it is also optimal for advertiser i to have the highest bid of all the advertisers with unknown eCPMs.*

Theorem 16 guarantees that if there are multiple ads with unknown eCPMs, then one can simply compute the optimal bids for each of these ads in the case where the ad in question was guaranteed to have a higher bid than the other ads with unknown eCPMs. The ad that has the highest such optimal bid will then be guaranteed to be the ad for which the mechanism designer would want to submit the highest such bid. Thus even when there are multiple ads in the same auction with unknown eCPMs, one can continue to make optimal decisions by computing bids for the advertisers equal to their estimated eCPMs plus a value of learning term for the ad and then rank the advertisers on this basis.

10. Performance Guarantees

We now return to the baseline setting in Section 2. The results in the previous sections suggest a possible algorithm that will approximate the optimal bidding strategies for an auctioneer who seeks to maximize long-run efficiency. This algorithm would compute the expected eCPM for an advertiser with unknown eCPM, \bar{x} , the density for the distribution of competing eCPM bids at this value of \bar{x} , $f(\bar{x})$, the variance $s^2(\bar{x})$ in the eCPM for an ad with estimated eCPM \bar{x} that has only received one impression, and the number of impressions k that the ad has received. One then decides which ad to show by computing a score equal to $\bar{x} + \frac{\delta}{2(1-\delta)^{k/(k+1)}} s^2(\bar{x}) f(\bar{x})$ for each ad, where δ is the auctioneer's discount factor, and showing the ad with the highest such score. We refer to this strategy as the *approximately optimal bidding strategy*, and in this section we address questions related to the size of the performance guarantees that can be obtained by using this algorithm and related algorithms.

First we address questions related to how the algorithms we have considered in this paper will compare to other plausible algorithms in the machine learning literature. One other algorithm that is standard for multi-armed bandit problems involves ranking the arms by a term equal to the expected value of the arm plus a term proportional to the standard deviation in the arm (Auer et al., 2002). More generally, one can rank advertisers by a term equal to the eCPM of the advertiser plus a term proportional to $\frac{1}{k^\alpha}$ for any $\alpha \leq \frac{1}{2}$, where k denotes the number of impressions that the ad has received so far. However, these algorithms are not well-suited towards the auction environment, as the following theorem illustrates:

Theorem 17 *Suppose the auctioneer uses a bid for the advertiser with unknown eCPM of the form $z = \bar{x} + \frac{c(\bar{x})}{k^\alpha}$, where $\alpha \leq \frac{1}{2}$ and $c(\bar{x})$ is a bounded non-negative constant that depends only on \bar{x} and the distribution of competing bids. Then the optimal constant $c(\bar{x})$ for any such algorithm is $c(\bar{x}) = 0$ for sufficiently large k .*

This result immediately implies that standard existing algorithms for exploration which involve adding a term proportional to the standard deviation to the eCPM of the ad, such as the UCB algorithm, are actually dominated by the simple greedy approach of always making a bid equal to the eCPM of the ad. These existing algorithms do too much exploration, and as a result, lead to lower payoffs than not doing any active exploration at all.⁶

Next we turn to the question of what guarantees can be made about the size of the performance improvement that could be obtained by using the approximately optimal bidding strategy rather than the simple greedy algorithm. Our next result illustrates that one will indeed obtain a performance improvement by using the approximately optimal bidding strategy, but the size of the performance improvement is likely to be very small.

Theorem 18 *Suppose the auctioneer follows the approximately optimal bidding strategy. Then the expected payoff that the auctioneer will obtain by using this algorithm will exceed the expected payoff that the auctioneer would obtain by using the purely greedy approach by an amount $\frac{\delta^2}{8(1-\delta)^{k/\alpha}} s^4(\bar{x}) f^3(\bar{x}) + o(\frac{1}{k^\alpha})$.⁷*

Theorem 18 indicates that the performance improvement that can be obtained as a result of using the approximately optimal bidding strategy is only on the order of $\frac{1}{k^\alpha}$, where k denotes the number of impressions that an ad has received. This follows from the fact that the incremental increase in the probability that a particular ad is shown varies with $\frac{1}{k^\alpha}$, and on top of that, the expected payoff increase that one obtains conditional on showing a different ad than would be shown without active learning also varies with $\frac{1}{k^\alpha}$. Since this represents a fourth-order improvement in performance relative to the purely greedy approach, this result indicates that the performance improvement that can be obtained by following our algorithm rather than simply ranking the ads by their eCPMs is small.

6. Similarly, an algorithm such as epsilon-greedy, in which the ad with the highest eCPM is chosen with probability $1 - \epsilon$, and an ad is chosen uniformly at random with probability ϵ , will also lead to lower payoffs than not doing any active exploration at all for large k . We prove this in Observation 23 in the appendix.

7. The expected payoff increase that we refer to in this theorem is for the subgame beginning from the point when the ad with uncertain eCPM has already received k impressions.

It is worth noting, however, that the result in Theorem 18 is not due to our algorithm being a suboptimal implementation of incorporating active exploration. Our next result illustrates that while the size of the performance improvement that can be obtained by using our algorithm is small, this algorithm will, in fact, obtain nearly the maximum possible performance improvement over the purely greedy approach of ranking ads by their eCPMs.

Theorem 19 *Suppose the auctioneer uses the approximately optimal bidding strategy. Then the difference between the auctioneer’s payoff under this strategy and the maximum possible payoff the auctioneer could obtain under the theoretically optimal strategy becomes vanishingly small compared to the difference between the auctioneer’s payoff under this strategy and the auctioneer’s payoff under the greedy strategy for large k .*

The results in the previous theorems suggest that the maximum possible payoff increase that can be achieved by incorporating active exploration is quite small for auctions involving ads that have already received a large number of impressions. However, in many auctions, there are frequently advertisers that have only received a small number of impressions, so it is desirable to know whether these conclusions for ads that have received large numbers of impressions will also hold for ads that have only received a small number of impressions. Under the mild technical condition discussed in Theorem 13, where the expected value of future learning is lower after the advertiser with unknown eCPM has been shown once rather than never having been shown at all, we obtain the following result:

Theorem 20 *Suppose the bidder with unknown eCPM has a cost-per-click bid of 1 and a click-through rate drawn from a beta distribution. Also suppose that this bidder’s expected eCPM is ω and the standard deviation in this bidder’s true eCPM is $\gamma\omega$. Then the difference between the maximum possible payoff the auctioneer could obtain under the theoretically optimal strategy and the auctioneer’s payoff from the greedy strategy is no greater than $\frac{\delta^2 \gamma^2 \omega^2 \bar{f}^3}{8(1-\delta)^3(1-\omega)^2}$, where \bar{f} denotes the supremum of $f(\cdot)$.*

Theorem 20 presents bounds on the maximum performance improvement that can be achieved over the purely greedy strategy by using active learning, but it is not immediately clear from this result whether these bounds imply there are significant limitations on the performance improvement that can be achieved by using active learning. We thus seek to shed some light on this under empirically realistic values of the parameters.

If the typical eCPM bids for the winning advertisers are roughly $\xi\omega$, then the auctioneer’s total payoff for the game will be roughly $\frac{\xi\omega}{1-\delta}$, and the result in Theorem 20 indicates that the maximum fractional increase in expected payoff that one can achieve from using the theoretically optimal strategy rather than the greedy strategy is roughly $\frac{\delta^2 \gamma^2 \omega^2 \bar{f}^3}{8\xi(1-\delta)^2(1-\omega)^2}$.

Furthermore, if the typical eCPM bids for the highest competing advertisers in an auction are roughly $\xi\omega$, then \bar{f} is likely to also be on the order of $\frac{1}{\xi\omega}$. This holds, for example, if the highest competing eCPM bids are drawn from a lognormal distribution, as the largest value of the density of a lognormal distribution with parameters μ and σ^2 is equal to $\frac{c(\sigma^2)}{\xi\omega}$, where $\xi\omega$ is the expected value of the lognormal distribution and $c(\sigma^2) \equiv \frac{e^{-\sigma^2/2}}{\sqrt{2\pi\sigma^2}}$ is a constant that depends only on σ^2 . Furthermore $c(\sigma^2)$ is likely to be close to 1 for realistic values of σ^2 since $c(\sigma^2) \in [0.93, 1.09]$ for values of $\sigma^2 \in [0.2, 1.1]$. The lognormal distribution

is a realistic representation of the distribution of highest competing bids in online auctions since both Lahate and McAfee (2011) and Ostrovsky and Schwarz (2009) have noted that the distribution of highest bids can be well-represented by a lognormal distribution using data from sponsored search auctions at Yahoo!.

By using the facts that the value of \bar{f} is likely to be on the order of $\frac{1}{\xi\omega}$, and the maximum fractional increase in expected payoff that one can achieve from using the theoretically optimal strategy rather than the greedy strategy is roughly $\frac{\delta^2 \gamma^2 \omega^2 \bar{f}^3}{8\xi(1-\delta)^2(1-\omega)^2}$, it then follows that the maximum fractional increase in expected payoff that one can achieve from using the theoretically optimal strategy rather than the greedy strategy is roughly $\frac{\delta^2 \gamma^2 \omega^2}{8\xi(1-\delta)^2(1-\omega)^2}$.

There is empirical evidence that indicates that the typical click-through rates for ads in online auctions tend to be on the order of $\frac{1}{100}$ or $\frac{1}{1000}$ for search ads and display ads respectively (Bax et al., 2011), so $(1-\omega)^2$ will be very close to 1 and ω^2 is likely to be less than 10^{-4} (for search ads) or 10^{-6} (for display ads). Furthermore, even for a brand new ad, the typical errors in a machine learning system’s predictions are unlikely to exceed 30% of the true click-through rate of the ad, so $\gamma \leq 0.3$ is likely to hold in most practical applications. Finally, ξ is a measure of by how much the highest bid in an auction exceeds the typical eCPM bid of an average ad in the auction. Since there are normally hundreds of ads competing in online auctions, it seems that one can conservatively estimate that $\xi \geq 3$ is likely to hold in most real-world online auctions.

By combining the estimates in the previous paragraph, it follows that $\frac{\delta^2 \gamma^2 \omega^2}{8\xi(1-\omega)^2}$ will almost certainly be less than 10^{-11} in search auctions and 10^{-13} in display auctions. Now if $\delta \leq 0.9999$, $\frac{\delta^2}{(1-\delta)^2}$ will be no greater than 10^8 , and if $\delta \leq 0.99999$, $\frac{\delta^2}{(1-\delta)^2}$ will be no greater than 10^{10} . Thus even for values of δ that are exceedingly close to 1 ($\delta = 0.9999$ for search ads and $\delta = 0.99999$ for display ads), $\frac{\delta^2 \gamma^2 \omega^2}{8\xi(1-\omega)^2(1-\delta)^2}$ will be no greater than 0.001. Thus as long as $\delta \leq 0.9999$ (or $\delta \leq 0.99999$ for display auctions), the bound given in Theorem 20 guarantees that under empirically realistic scenarios, the maximum possible performance improvement that can be achieved by incorporating active learning into a machine learning system is at most a few hundredths of a percentage point. This is a finite sample result that does not require a diverging number of impressions in order to hold.

11. Simulations

The results of the previous section suggest that the overall benefit that can be obtained by incorporating active exploration in an auction environment is exceedingly small. We now seek to empirically verify that the benefit that can be obtained from active exploration is indeed quite small by conducting simulations under some empirically realistic scenarios.

To do this, we consider a scenario in which there is a repeated auction in which a cost-per-click (CPC) bidder competes against CPM bidders in each auction. The CPC bidder has a CPC bid of 1 and a fixed unknown click-through rate. The CPM bidders’ CPM bids vary from period to period, and in each period, we assume that the highest CPM bid is a random draw from a distribution with probability density function $f(\cdot)$. Throughout we assume that payoffs are discounted at a rate of $\delta = 0.9995$ and that there are $T = 10000$ time periods.

While we are not aware of any empirical evidence regarding the form of the uncertainty of an advertiser’s click-through rate, for simplicity we assume that the CPC bidder’s click-through rate is initially drawn from a beta distribution with parameters α and β . The auctioneer may refine this estimate over time. In particular, just before the auction in period t , the auctioneer believes that the CPC bidder’s true click-through rate is a random draw from the beta distribution with parameters α_t and β_t where α_t is equal to α plus the number of clicks the CPC bidder has received so far and β_t is equal to β plus the number of times the CPC bidder’s ad was shown but did not receive a click.

We compare total welfare under two possible scenarios. The first scenario we consider is a standard ranking algorithm in which the ads are ranked purely on the basis of their expected eCPM bids. The second scenario we consider is one in which the CPC bidder makes a bid of the form $\bar{x}_t + \frac{\delta(1-\delta^{T-t})}{2(1-\delta)} \frac{\alpha_t/\beta_t}{(\alpha_t+\beta_t)^2(\alpha_t+\beta_t+1)^2} f(\bar{x}_t)$ in each period t , where \bar{x}_t denotes the CPC bidder’s expected click-through rate just before the auction in period t . This second scenario corresponds to adding a term equal to the value of learning to the CPC bidder’s expected eCPM bid in the game with finite time horizons.

Throughout we focus on scenarios that are motivated by empirical evidence on the likely expected click-through rates for ads in online auctions. In particular, since empirical evidence indicates that the typical click-through rates for ads in online auctions tend to be on the order of $\frac{1}{100}$ or $\frac{1}{1000}$ (Bax et al., 2011), we focus on situations in which the expected click-through rate of the CPC bidder is on the order of $\frac{1}{100}$.

Similarly, since it is unlikely that there will be substantial errors in the estimate of a new ad’s predicted click-through rate, we focus on situations in which there is only moderate uncertainty in the click-through rate of a new ad. In particular, we consider distributions of the CPC bidder’s bid such that the standard deviation in the advertiser’s click-through rate is no greater than 20 or 30% of the expected value. We thus consider values of α and β satisfying $(\alpha, \beta) = (10, 1000)$ and $(20, 2000)$ (for 30% and 20% standard errors respectively).

Finally, since there is evidence that the distribution of highest bids is well modeled by a lognormal distribution (Lahaie and McAfee, 2011; Ostrovsky and Schwarz, 2009), we assume throughout that the CPM bidder’s bid is drawn from a lognormal distribution with parameters μ and σ^2 . We use a value of $\sigma^2 = \log(2)$ to match the variance in the lognormal distribution estimated by Ostrovsky and Schwarz (2009). And Varian (2009) has noted that the total value enjoyed by advertisers is typically about 2 – 2.3 times their total expenditure. If the auction consisted of only two advertisers, this would suggest that the appropriate value of μ would be such that the highest competing bidder had a CPM bid that is roughly double that of the CPC bidder in expectation. However, since there are more than two bidders in most real auctions, the appropriate value of μ will be larger than this. We thus consider a range of values of μ from -4.25 (for the case in which the highest competing CPM bid is roughly double that of the CPC bidder in expectation) to -3.5 (for the case in which the highest competing CPM bid is roughly four times that of the CPC bidder in expectation).

Table 1 reports the results our simulations. The conclusions from these simulations are striking. While we have conducted enough simulations to estimate the efficiency gain that can be obtained from adding active exploration to within a few hundredths of a percentage point, none of the resulting estimated efficiency gains in Table 1 are statistically significant. Indeed one can conclude from these simulations that the maximum possible efficiency gain

Conditions	Percentage increase in efficiency
$\alpha = 10, \beta = 1000, \mu = -4.25, \sigma^2 = \log(2)$	0.021% (0.017%)
$\alpha = 10, \beta = 1000, \mu = -4, \sigma^2 = \log(2)$	-0.016% (0.011%)
$\alpha = 10, \beta = 1000, \mu = -3.75, \sigma^2 = \log(2)$	-0.008% (0.007%)
$\alpha = 10, \beta = 1000, \mu = -3.5, \sigma^2 = \log(2)$	0.003% (0.004%)
$\alpha = 20, \beta = 2000, \mu = -4.25, \sigma^2 = \log(2)$	0.003% (0.009%)
$\alpha = 20, \beta = 2000, \mu = -4, \sigma^2 = \log(2)$	0.001% (0.006%)
$\alpha = 20, \beta = 2000, \mu = -3.75, \sigma^2 = \log(2)$	0.001% (0.004%)
$\alpha = 20, \beta = 2000, \mu = -3.5, \sigma^2 = \log(2)$	-0.002% (0.002%)

Table 1: Average percentage increase in efficiency from incorporating active learning (with standard errors in parentheses) after 2500 simulations. None of these results are statistically significant at the $p < .05$ level.

that could be achieved in these settings is at most a few hundredths of a percentage point. These empirical results provide further support for our theoretical conclusions that the value of adding active exploration in an auction setting is exceedingly small.

The reason for the results observed in Table 1 is that an optimal exploration algorithm will only do a tiny additional amount of exploration compared to the greedy strategy of always submitting a bid for the CPC bidder equal to the CPC bidder’s estimated eCPM. For instance, for the first simulation considered in Table 1, the incremental increase in an advertiser’s bid in the first period of the game as a result of active exploration is only 4.2%, implying only a 1.8% increase in the probability that the CPC bidder will be shown as well as only a 2.1% increase in expected payoff conditional on the auctioneer showing a different ad under active exploration than under the purely greedy strategy. Thus the incremental expected payoff increase that can be achieved by incorporating active exploration in this auction setting is at most a few hundredths of a percentage point.

The results in Table 1 make use of distributions that we regard as empirically realistic in the sense that there is a realistic amount of uncertainty in the click-through rate of the CPC bidder as well as a realistic amount of variation in the distribution of competing CPM bids. It is worth noting that if one relaxes the requirement that there be a realistic amount of uncertainty about these variances, then it is possible for the algorithm we have proposed to substantially outperform the purely greedy strategy of making a bid for the CPC bidder that always equals the CPC bidder’s expected eCPM. In particular, if we instead assume that there is substantially more uncertainty about the CPC bidder’s click-through rate than

we have assumed in the simulations in Table 1 and we also assume that there is substantially less variance in the distribution of competing CPM bids than we have allowed for in Table 1, then there will be considerably greater benefits to adding active exploration because there is both more to learn about the CPC bidder's true eCPM bid as well as less exploration that will take place for free solely due to random variation in the competing bids. In this case, there may well be significant benefits to adding active exploration.

Conditions	Percentage increase in efficiency
$\alpha = 2, \beta = 200, \mu = -4, \sigma^2 = \log(2)/4$	0.15% (0.05%)
$\alpha = 2, \beta = 200, \mu = -3.75, \sigma^2 = \log(2)/4$	0.17% (0.05%)

Table 2: Average percentage increase in efficiency from incorporating active learning (with standard errors in parentheses) after 10000 simulations. These results are both statistically significant at the $p < .005$ level.

Table 2 reports the results of simulations that were conducted using distributions in which there is substantially more uncertainty about the CPC bidder's click-through rate and substantially less variance in the CPM bidder's competing CPM bid than in the distributions considered in Table 1. These simulations indeed reveal statistically significant efficiency gains as a result of active exploration. Nonetheless it is worth noting that the efficiency gains reported in Table 2 are still fairly small. Even when we make assumptions that bias the case in favor of active exploration being important, none of the efficiency gains reported in Table 2 are greater than a few tenths of a percentage point.

Finally, while the gains achieved through active exploration in Table 2 are small, one would not achieve greater gains by using a standard algorithm such as UCB. To test this, we considered the same setting in the first row of this table, but instead of making a bid for the CPC bidder of the form $\bar{x}_t + \frac{\delta(1-\delta^{T-t})}{2(1-\delta)} \frac{\alpha t \beta_t}{(\alpha + \beta_t)^2 (\alpha + \beta_t + 1)^2} f(\bar{x}_t)$ in each period t , we made a bid of the form $\bar{x}_t + c(\bar{x}_t) \frac{1}{\sqrt{\alpha + \beta_t}}$, where the constant $c(\bar{x}_t)$ was chosen so that this bid would equal $\bar{x}_t + \frac{\delta(1-\delta^{T-t})}{2(1-\delta)} \frac{\alpha t \beta_t}{(\alpha + \beta_t)^2 (\alpha + \beta_t + 1)^2} f(\bar{x}_t)$ in time period $t = 1$. Thus our implementation of UCB performed the same amount of exploration as the main algorithm we considered in the very first period of the game, while performing more exploration in later periods due to the fact that the rate of exploration declines with $\frac{1}{(\alpha + \beta_t)^2}$ under our proposed algorithm, while only declining with $\frac{1}{\sqrt{\alpha + \beta_t}}$ under UCB.

In this setting, we found that using the UCB algorithm rather than the purely greedy strategy resulted in an average efficiency loss of 1.04% (with a standard error of 0.07%). Thus while we were able to achieve an improvement by using the new algorithm we have proposed, using the UCB algorithm instead resulted in significant efficiency losses. The fact that UCB performed worse than the purely greedy strategy is not surprising since we know from Theorem 17 that UCB performs worse than the purely greedy strategy once an ad has received enough impressions.

12. Conclusion

In online auctions, there may be value to exploring ads with uncertain eCPMs to learn about the true eCPM of the ad and be able to make better ranking decisions in the future. But the online auction setting is very different from standard multi-armed bandit problems because there may be considerable variation in the quality of competition that an advertiser with unknown eCPM faces in an auction, and as a result there will typically be plenty of free opportunities to explore an ad with uncertain eCPM in auctions where there simply are no ads with eCPM bids that are known to be high.

We have presented a model of the explore/exploit problem in online auctions that explicitly considers this random variation in competing bids that is present in real auctions. We find that the optimal solution for ranking the ads is dramatically different than the optimal solution in standard multi-armed bandit problems, and in particular, that the optimal amount of active exploration is considerably smaller than in standard multi-armed bandit problems. This in turn implies that the improvement in the auctioneer's payoff that can be achieved by adding active learning in online auctions is also exceedingly small. Thus while it is theoretically possible to improve efficiency by incorporating active learning, in a practical exchange environment, a purely greedy strategy of simply ranking the ads by their expected eCPMs is likely to perform nearly as well as any other strategy.

We conclude by discussing one other point. Throughout our analysis we have focused on the problem of an auctioneer who wants to maximize efficiency. Although this is a sensible objective, one might also envision scenarios in which the mechanism designer wishes to maximize a weighted average of efficiency and revenue. While incorporating active exploration in online auctions can only have a small effect on efficiency, this active exploration may significantly improve revenue. The reason for this is that if we rank the ads by the sum of their expected eCPMs and a value of learning term, the value of learning term may be larger for ads that typically lose the auctions, and incorporating this value of learning term may increase pricing pressure for the winning ads and thereby increase revenue.⁸ In fact, in several of the simulations considered in the previous section in which incorporating active exploration failed to show significant efficiency gains, the algorithm that we considered still showed significant revenue gains over the purely greedy strategy of ranking the ads by their expected eCPMs. But while it is still possible to achieve significant revenue gains by incorporating active exploration in the type of environment considered in this paper, the maximum possible efficiency gains are likely to be exceedingly small.

Acknowledgments

We especially thank Martin Zinkevich for numerous helpful discussions. We are also grateful to Joshua Dillon, Pierre Griaupan, Chris Harris, Tim Lipus, Mohammad Mahdian, Hal Varian, and the anonymous referees for helpful comments and discussions.

This work is based on an earlier work: "Machine Learning in an Auction Environment", in *Proceedings of the 23rd International Conference on the World Wide Web (WWW)* (2014) ©ACM, 2014. <http://doi.acm.org/10.1145/2566486.2567974>.

Appendix A. Proofs of Theorems

Proof of Theorem 1: Suppose it is known that the eCPM of the ad is x . If the highest eCPM for a competing ad is p , then the presence of this ad with eCPM x increases total welfare by $x - p$ if $x > p$ and 0 otherwise. Thus the expected increase in total welfare from this ad with eCPM of x competing in the auction is $\int_0^x (x - p) f(p) dp$. The total long-term value from having this advertisement is then the discounted sum of this expected total increase in welfare or $\frac{1}{1-\delta} \int_0^x (x - p) f(p) dp$.

Now if $V(x) \equiv \frac{1}{1-\delta} \int_0^x (x-p) f(p) dp$, then $V'(x) = \frac{1}{1-\delta} \int_0^x f(p) dp$ and $V''(x) = \frac{1}{1-\delta} f(x)$. From this it follows that $V''(x) \geq 0$ for all x and $V''(x) > 0$ if x is contained in the support of F . Thus the long-term value of the advertisement is a convex function of the eCPM of the ad and a strictly convex function if the eCPM of the ad is contained within the support of the distribution of the highest competing eCPM. ■

Proof of Lemma 2: Suppose an ad has been shown k times. The value of the dynamic program that arises from placing the optimal bid z in the current period, $V_k(\bar{x})$, equals the immediate reward from bidding z (or the negative of the loss function) in the current period plus δ times the expected value of the dynamic program that arises in the next period.

Now if the new advertiser places a bid of z , then the probability the advertiser wins the auction is $F(z)$, in which case the expected value of the dynamic program that arises next period is $E_{\bar{x}'}[V_{k+1}(\bar{x}')]]$, where the expectation is taken over the randomness in the changes in the estimates of the eCPM of the ad \bar{x}' that arise as a result of showing this ad. The probability the advertiser does not win the auction is $1 - F(z)$, in which case the value of the dynamic program remains at $V_k(\bar{x})$. Thus the expected value of the dynamic program that arises in the next period is $F(z)E_{\bar{x}'}[V_{k+1}(\bar{x}')] + (1 - F(z))V_k(\bar{x})$.

At the same time, we have already seen that the reward from bidding z that arises in the current period equals $-\int_{\bar{x}+z}^z E_{\bar{x}'}[V_{k+1}(\bar{x}')] - F(y) dy$. By combining this with the insights in the previous paragraphs, it follows that

$$V_k(\bar{x}) = \max_z E_{\bar{x}'} \left[-\int_{\bar{x}+z}^z F(z) - F(y) dy + \delta(F(z)E_{\bar{x}'}[V_{k+1}(\bar{x}')] + (1 - F(z))V_k(\bar{x})) \right].$$

By subtracting $\delta V_k(\bar{x})$ from both sides and dividing by $1 - \delta$, it follows that

$$V_k(\bar{x}) = \frac{1}{1-\delta} \left(\max_z E_{\bar{x}'} \left[-\int_{\bar{x}+z}^z F(z) - F(y) dy + \delta F(z)(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x})) \right] \right). \quad \blacksquare$$

Proof of Theorem 3: By differentiating the expression in Lemma 2 with respect to z , we see that the first order condition for z to be an optimal bid is

$$\begin{aligned} 0 &= E_{\bar{x}'} \left[-\int_{\bar{x}+z}^z f(z) dy + \delta f(z)(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x})) \right] \\ &= E_{\bar{x}'} \left[-f(z)(z - \bar{x} - \sigma_k \epsilon) + \delta f(z)(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x})) \right] \\ &= f(z)(\bar{x} - z + \delta(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x}))) \end{aligned}$$

From this it follows that $z = \bar{x} + \delta(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x}))$ satisfies the first order conditions. Moreover, at this value of z , the second order conditions are also satisfied. Thus optimal bidding entails setting $z = \bar{x} + \delta(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x}))$. ■

Proof of Lemma 4: Let $\Phi(\cdot|\sigma_k)$ denote the distribution from which ϵ is drawn for any given value of σ_k . For any given σ_k , we know that $\Phi(\cdot|\sigma_k)$ has mean zero and variance one. We also know from the Bayesian central limit theorem that as $\sigma_k \rightarrow 0$ (and $k \rightarrow \infty$) that $\Phi(\cdot|\sigma_k)$ converges to the standard normal distribution. For any given σ_k , we can write $E_{\epsilon}[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy] = E_{\epsilon}[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k)]$. We seek to show that $J(\sigma_k)$ is of the form given in the statement of the lemma.

First note that

$$J'(\sigma_k) = -E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\sigma_k)] + \frac{d}{d\Phi} E_{\epsilon} \left[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k) \right]$$

where $\frac{d}{d\Phi} E_{\epsilon}[Z(\epsilon, \sigma_k) | \epsilon \sim \Phi(\cdot|\sigma_k)]$ denotes the derivative of the expectation of $Z(\epsilon, \sigma_k)$ arising through the changes in $\Phi(\cdot|\sigma_k)$ induced by changes in σ_k (that is, if $\partial(\epsilon; \sigma_k)$ denotes the density corresponding to $\Phi(\cdot|\sigma_k)$, then $\frac{d}{d\Phi} E_{\epsilon}[Z(\epsilon, \sigma_k) | \epsilon \sim \Phi(\cdot|\sigma_k)] \equiv \int_{-\infty}^{\infty} Z(\epsilon, \sigma_k) \frac{\partial \partial_{\sigma_k}}{\partial \sigma_k}(\epsilon; \sigma_k) d\epsilon$). Similarly, letting $\frac{d^m}{d\Phi^m} E_{\epsilon}[Z(\epsilon, \sigma_k) | \epsilon \sim \Phi(\cdot|\sigma_k)] \equiv \int_{-\infty}^{\infty} Z(\epsilon, \sigma_k) \frac{\partial^m \partial_{\sigma_k}}{\partial \sigma_k^m}(\epsilon; \sigma_k) d\epsilon$ for all m , we have

$$\begin{aligned} J''(\sigma_k) &= E_{\epsilon}[\epsilon^2 f(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] - 2 \frac{d}{d\Phi} E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad + \frac{d^2}{d\Phi^2} E_{\epsilon} \left[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k) \right], \end{aligned}$$

$$\begin{aligned} J'''(\sigma_k) &= E_{\epsilon}[\epsilon^3 f'(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] + 3 \frac{d}{d\Phi} E_{\epsilon}[\epsilon^2 f(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad - 3 \frac{d^2}{d\Phi^2} E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad + \frac{d^3}{d\Phi^3} E_{\epsilon} \left[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k) \right], \end{aligned}$$

and

$$\begin{aligned} J^{(m)}(\sigma_k) &= E_{\epsilon}[\epsilon^4 f^{(m)}(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] + 4 \frac{d}{d\Phi} E_{\epsilon}[\epsilon^3 f'(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad + 6 \frac{d^2}{d\Phi^2} E_{\epsilon}[\epsilon^2 f(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad - 4 \frac{d^3}{d\Phi^3} E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\cdot|\sigma_k)] \\ &\quad + \frac{d^4}{d\Phi^4} E_{\epsilon} \left[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k) \right], \end{aligned}$$

Note that when $\sigma_k = 0$, we have $E_{\epsilon}[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k)] = \int_{\bar{x}}^z F(z) - F(y) dy$ for any distribution $\Phi(\cdot|\sigma_k)$, $E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\cdot|\sigma_k)] = E_{\epsilon}[\epsilon(F(z) - F(\bar{x})) | \epsilon \sim \Phi(\cdot|\sigma_k)] = 0$ for any distribution $\Phi(\cdot|\sigma_k)$ with mean zero, and $E_{\epsilon}[\epsilon^2 f(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] = E_{\epsilon}[\epsilon^2 f(\bar{x}) | \epsilon \sim \Phi(\cdot|\sigma_k)] = f(\bar{x})$ for any distribution $\Phi(\cdot|\sigma_k)$ with mean zero and variance one. Thus $\frac{d^m}{d\Phi^m} E_{\epsilon}[\int_{\bar{x}+\sigma_k \epsilon}^z F(z) - F(y) dy | \epsilon \sim \Phi(\cdot|\sigma_k)] = 0$, $\frac{d^m}{d\Phi^m} E_{\epsilon}[\epsilon(F(z) - F(\bar{x} + \sigma_k \epsilon)) | \epsilon \sim \Phi(\cdot|\sigma_k)] = 0$, and $\frac{d^m}{d\Phi^m} E_{\epsilon}[\epsilon^2 f(\bar{x} + \sigma_k \epsilon) | \epsilon \sim \Phi(\cdot|\sigma_k)] = 0$ for all m when evaluated at $\sigma_k = 0$.

By using these facts, the fact that $\Phi(\cdot|0)$ is standard normal, and the above expressions for $J(\sigma_k)$ and its derivatives, it follows that $J(0) = \int_{\bar{x}}^z F(z) - F(y) dy$, $J'(0) = 0$, $J''(0) = F(\bar{x})$, $J'''(0) = 0$, and $J''''(0) = E_\epsilon[\epsilon^4 J''(\bar{x})] + 4 \frac{d}{d\sigma_k} E_\epsilon[\epsilon^3 J'(\bar{x})] + 4 \frac{d^2}{d\sigma_k^2} E_\epsilon[\epsilon^2 J(\bar{x})] + 4 \frac{d^3}{d\sigma_k^3} E_\epsilon[\epsilon J(\bar{x})] + 4 \frac{d^4}{d\sigma_k^4} E_\epsilon[J(\bar{x})]$. This in turn implies that the fourth-order Taylor approximation to $E_\epsilon[\int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy]$ is

$$E_\epsilon \left[\int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy \right] = \int_{\bar{x}}^z F(z) - F(y) dy + \frac{1}{2} \sigma_k^2 f(\bar{x}) + a(\bar{x}) \sigma_k^4 + o(\sigma_k^4),$$

where $a(\bar{x}) \equiv \frac{1}{24} [E_\epsilon[\epsilon^4 J''(\bar{x})] + 4 \frac{d}{d\sigma_k} E_\epsilon[\epsilon^3 J'(\bar{x})] + 4 \frac{d^2}{d\sigma_k^2} E_\epsilon[\epsilon^2 J(\bar{x})] + 4 \frac{d^3}{d\sigma_k^3} E_\epsilon[\epsilon J(\bar{x})] + 4 \frac{d^4}{d\sigma_k^4} E_\epsilon[J(\bar{x})]]$. ■

Proof of Theorems 5 and 6: Since these results are special cases of Theorems 9 and 10 respectively, the proofs of these results are omitted.

Before proving Theorem 7, we first introduce some notation for the finite-horizon version of this game. If the game has a finite time horizon and will last an additional T periods, we let $V_{k,T}(\bar{x})$ denote the value of the dynamic program that arises when the auctioneer follows the optimal strategy. By analogy to Lemma 2, we know that

$$V_{k,T}(\bar{x}) = \frac{1}{1-\delta} \left(\max_z \left[- \int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy + \delta F(z) (E_{\bar{x}}[V_{k+1,T-1}(\bar{x})] - V_{k,T-1}(\bar{x})) \right] \right)$$

when $T > 0$ and $V_{k,T}(\bar{x}) = -E_\epsilon[\int_{\bar{x}+\sigma_k\epsilon}^z F(\bar{x}) - F(y) dy]$ when $T = 0$. Also note that $\lim_{T \rightarrow \infty} V_{k,T}(\bar{x}) = V_k(\bar{x})$, where $V_k(\bar{x})$ is the value of the dynamic program for the original infinite-horizon game. Finally note that

Lemma 21 $V_{k,T}(\bar{x})$ is twice differentiable in \bar{x} for all k and T . Furthermore, $\lim_{k \rightarrow \infty} V_{k,T}(\bar{x}) = 0$ and $\lim_{k \rightarrow \infty} V_{k,T}'(\bar{x}) = 0$ for all T .

Proof We prove this result by induction on T . The base case, $T = 0$, holds because the fact that $f(\cdot)$ is continuously differentiable implies $F(\cdot)$ is twice differentiable and $V_{k,T}(\bar{x}) = -E_\epsilon[\int_{\bar{x}+\sigma_k\epsilon}^z F(\bar{x}) - F(y) dy]$ is also twice differentiable in \bar{x} . Furthermore, $V_{k,T}'(\bar{x}) = E_\epsilon[F(\bar{x}) - F(\bar{x} + \sigma_k\epsilon) - \int_{\bar{x}+\sigma_k\epsilon}^{\bar{x}} f(\bar{x}) - F(\bar{x} + \sigma_k\epsilon)]$ and $V_{k,T}''(\bar{x}) = E_\epsilon[f(\bar{x}) - f(\bar{x} + \sigma_k\epsilon)]$, which both tend to zero as $k \rightarrow \infty$. Thus the result holds for $T = 0$. Now suppose the result is true for $T - 1$ and use this to prove the result must also hold for T . Since

$$V_{k,T}(\bar{x}) = \frac{1}{1-\delta} \left(\max_z \left[- \int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy + \delta F(z) (E_{\bar{x}}[V_{k+1,T-1}(\bar{x})] - V_{k,T-1}(\bar{x})) \right] \right),$$

we know from analogy to Theorem 3 that the optimal bid z satisfies $z = \bar{x} + \delta [E_{\bar{x}}[V_{k+1,T-1}(\bar{x})] - V_{k,T-1}(\bar{x})]$. From the induction hypothesis, we thus know that the optimal bid $z_k(\bar{x})$ is twice differentiable in \bar{x} and that $\lim_{k \rightarrow \infty} z_k'(\bar{x}) = 1$ and $\lim_{k \rightarrow \infty} z_k''(\bar{x}) = 0$.

This in turn implies that $E_\epsilon[- \int_{\bar{x}+\sigma_k\epsilon}^{z_k(\bar{x})} F(z_k(\bar{x})) - F(y) dy]$ is twice differentiable in \bar{x} and that $\frac{d}{d\bar{x}} E_\epsilon[- \int_{\bar{x}+\sigma_k\epsilon}^{z_k(\bar{x})} F(z_k(\bar{x})) - F(y) dy] = E_\epsilon[F(z_k(\bar{x})) - F(\bar{x} + \sigma_k\epsilon) - \int_{\bar{x}+\sigma_k\epsilon}^{z_k(\bar{x})} f(z_k(\bar{x})) dy]$, which tends to zero as $k \rightarrow \infty$ since $\lim_{k \rightarrow \infty} z_k(\bar{x}) = \bar{x}$. This also further implies that $\frac{d^2}{d\bar{x}^2} E_\epsilon[- \int_{\bar{x}+\sigma_k\epsilon}^{z_k(\bar{x})} F(z_k(\bar{x})) - F(y) dy] = E_\epsilon[z_k'(\bar{x}) f(z_k(\bar{x})) - f(\bar{x} + \sigma_k\epsilon)] - (z_k'(\bar{x}) - 1) z_k'(\bar{x}) f(z_k(\bar{x})) -$

$\int_{\bar{x}+\sigma_k\epsilon}^{z_k(\bar{x})} f(z_k(\bar{x})) + (z_k'(\bar{x}))^2 f'(z_k(\bar{x})) dy]$, which tends to zero as $k \rightarrow \infty$ since $\lim_{k \rightarrow \infty} z_k(\bar{x}) = \bar{x}$ and $\lim_{k \rightarrow \infty} z_k'(\bar{x}) = 1$.

From the induction hypothesis, we also know that $F(z_k(\bar{x})) (E_{\bar{x}}[V_{k+1,T-1}(\bar{x})] - V_{k,T-1}(\bar{x}))$ is twice differentiable in \bar{x} and that the first and second derivatives of this expression with respect to \bar{x} tend to zero as $k \rightarrow \infty$. By combining this with the results in the previous two paragraphs, it follows that $V_{k,T}(\bar{x})$ is twice differentiable in \bar{x} and $\lim_{k \rightarrow \infty} V_{k,T}'(\bar{x}) = 0$ and $\lim_{k \rightarrow \infty} V_{k,T}''(\bar{x}) = 0$ for all T . The result follows by induction. ■

We use these observations about the finite-horizon game to first prove that $E[V_{k+1}(\bar{x}') - V_k(\bar{x})] = O(\frac{1}{k^2})$ in Lemma 22. Then we use this preliminary result to prove Theorem 7.

Lemma 22 $E[V_{k+1}(\bar{x}') - V_k(\bar{x})] = O(\frac{1}{k^2})$ for large k .

Proof Note that if an ad is displayed, then one of two possible things will happen to the ad—either the ad will receive a click or the ad will not receive a click. Let p denote the probability that the ad will receive a click, let \bar{x}_c denote the estimated eCPM of the ad if the ad receives a click, and let \bar{x}_n denote the estimated eCPM of the ad if the ad does not receive a click. Note that $p\bar{x}_c + (1-p)\bar{x}_n = \bar{x}$.

From Lemma 21 we know that $V_{k,T}(\bar{x})$ is twice differentiable in \bar{x} for all k and T . Thus the second-order Taylor approximations for $V_{k+1,T}(\bar{x}_c)$ and $V_{k+1,T}(\bar{x}_n)$ are

$$V_{k+1,T}(\bar{x}_c) = V_{k+1,T}(\bar{x}) + V_{k+1,T}'(\bar{x})(\bar{x}_c - \bar{x}) + \frac{1}{2} V_{k+1,T}''(\bar{x})(\bar{x}_c - \bar{x})^2 + o(\bar{x}_c - \bar{x})^2$$

and

$$V_{k+1,T}(\bar{x}_n) = V_{k+1,T}(\bar{x}) + V_{k+1,T}'(\bar{x})(\bar{x}_n - \bar{x}) + \frac{1}{2} V_{k+1,T}''(\bar{x})(\bar{x}_n - \bar{x})^2 + o(\bar{x}_n - \bar{x})^2.$$

Thus if \bar{x}' denotes the actual realization of the estimated eCPM after the ad has been shown $k+1$ times (\bar{x}' will equal \bar{x}_c with probability p and \bar{x}_n with probability $1-p$), then by using the fact that $p\bar{x}_c + (1-p)\bar{x}_n = \bar{x}$ and by taking a weighted average of the two previous equations, we find that

$$\begin{aligned} E[V_{k+1,T}(\bar{x}')] &= pV_{k+1,T}(\bar{x}_c) + (1-p)V_{k+1,T}(\bar{x}_n) \\ &= V_{k+1,T}(\bar{x}) + \frac{1}{2} V_{k+1,T}''(\bar{x}) E[(\bar{x}' - \bar{x})^2] + o(E[(\bar{x}' - \bar{x})^2]). \end{aligned}$$

From this it follows that

$$E[V_{k+1,T}(\bar{x}') - V_k(\bar{x})] = V_{k+1,T}(\bar{x}) - V_k(\bar{x}) + \frac{1}{2} V_{k+1,T}''(\bar{x}) E[(\bar{x}' - \bar{x})^2] + o(E[(\bar{x}' - \bar{x})^2]). \quad (1)$$

If c denotes the number of clicks that an ad has received so far, then the predicted click-through rate for an ad that has received a large number of impressions, k , will be approximately $\frac{c}{k}$. Thus if b denotes the bid per click that the ad places, then the eCPM for an ad that has received c clicks and has been shown k times will be $\bar{x} \approx \frac{bc}{k}$. From this it follows that $\bar{x}_c \approx \frac{b(c+1)}{k+1}$, $\bar{x}_n \approx \frac{bc}{k+1}$, $\bar{x}_c - \bar{x} \approx \frac{bc}{k(k+1)}$, and $\bar{x}_n - \bar{x} \approx -\frac{bc}{k(k+1)}$. Thus

$\bar{x}' - \bar{x} = O(\frac{1}{k})$ for all possible realizations of \bar{x}' , and $(\bar{x}' - \bar{x})^2 = O(\frac{1}{k^2})$. Furthermore, from Lemma 21 we know that $\lim_{k \rightarrow \infty} V_{k+1,T}^{\#}(\bar{x}) = 0$. Thus we can rewrite equation (1) as

$$E[V_{k+1,T}(\bar{x}) - V_k,T(\bar{x})] = V_{k+1,T}(\bar{x}) - V_k,T(\bar{x}) + o\left(\frac{1}{k^2}\right).$$

By using the fact that $\lim_{T \rightarrow \infty} V_k,T(\bar{x}) = V_k(\bar{x})$, where $V_k(\bar{x})$ denotes the value of the dynamic program in the original infinite horizon game, we then know that

$$\begin{aligned} E[V_{k+1}(\bar{x}) - V_k(\bar{x})] &= V_{k+1}(\bar{x}) - V_k(\bar{x}) + o\left(\frac{1}{k^2}\right) \\ &= \frac{v(\bar{x})}{k} - \frac{v(\bar{x})}{k+1} + O\left(\frac{1}{k^2}\right) \\ &= O\left(\frac{1}{k^2}\right). \end{aligned}$$

■

Proof of Theorem 7: We have seen in the proof of Lemma 22 that $E[V_{k+1}(\bar{x}') - V_k(\bar{x})] = V_{k+1}(\bar{x}) - V_k(\bar{x}) + o(\frac{1}{k^2})$. When combined with the fact that $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + O(\frac{1}{k^2})$, this immediately implied that $E[V_{k+1}(\bar{x}') - V_k(\bar{x})] = O(\frac{1}{k^2})$. If we are able to further prove that we can write $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + \frac{w(\bar{x})}{k^2} + o(\frac{1}{k^2})$ for some function $w(\bar{x})$, it will then follow that $V_{k+1}(\bar{x}) - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$. Thus we first seek to show that we can write $V_k(\bar{x})$ as $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + \frac{w(\bar{x})}{k^2} + o(\frac{1}{k^2})$.

Since $E[V_{k+1}(\bar{x}) - V_k(\bar{x})] = O(\frac{1}{k^2})$ for large k and the optimal bidding strategy entails setting $z = \bar{x} + \delta(E[V_{k+1}(\bar{x}') - V_k(\bar{x})])$, it must be the case that $z = \bar{x} + O(\frac{1}{k^2})$ for large k . From this it follows that $\int_{\bar{x}}^z F(z) - F(y) dy = o(\frac{1}{k^2})$ under the optimal bidding strategy z for large k .

Now we have seen in Lemma 4 that $E_\epsilon[\int_{\bar{x}+\alpha_k^\epsilon}^z F(z) - F(y) dy] = \int_{\bar{x}}^z F(z) - F(y) dy + \frac{1}{2}\sigma_k^2 f(\bar{x}) + o(a(\bar{x})\sigma_k^4 + o(\sigma_k^4))$ for some constant $a(\bar{x})$ for large k . Since $\int_{\bar{x}}^z F(z) - F(y) dy = o(\frac{1}{k^2})$ under the optimal bidding strategy z and $\sigma_k^2 = \frac{s^2(\bar{x})}{k} + \frac{h(\bar{x})}{k^2} + o(\frac{1}{k^2})$ for large k , it then follows that $E_\epsilon[\int_{\bar{x}+\alpha_k^\epsilon}^z F(z) - F(y) dy] = \frac{1}{2k}s^2(\bar{x})f(\bar{x}) + \frac{1}{k^2}[\frac{h(\bar{x})f(\bar{x})}{2} + a(\bar{x})s^4(\bar{x})] + o(\frac{1}{k^2})$ for large k , which we can rewrite as $E_\epsilon[\int_{\bar{x}+\alpha_k^\epsilon}^z F(z) - F(y) dy] = \frac{1}{2k}s^2(\bar{x})f(\bar{x}) + \frac{1}{k^2}w(\bar{x}) + o(\frac{1}{k^2})$, where $w(\bar{x}) \equiv \frac{h(\bar{x})f(\bar{x})}{2} + a(\bar{x})s^4(\bar{x})$.

But $-E_\epsilon[\int_{\bar{x}+\alpha_k^\epsilon}^z F(z) - F(y) dy]$ represents the auctioneer's per-period payoff in the next auction. Thus if \bar{x}' denotes the estimated eCPM of the ad after an additional j periods have passed and k' denotes the number of impressions the ad has received after an additional j periods have passed, then the auctioneer's per-period payoff in the period after an additional j periods have passed is $-\frac{1}{2k'}s^2(\bar{x}')f(\bar{x}') - \frac{1}{2k'}u(\bar{x}') + o(\frac{1}{k'^2})$. The difference between this and $-\frac{1}{2k}s^2(\bar{x})f(\bar{x})$ is

$$-\frac{1}{2k'}s^2(\bar{x}')f(\bar{x}') - \frac{1}{2k'}u(\bar{x}') + \frac{1}{2k}s^2(\bar{x})f(\bar{x}) + o\left(\frac{1}{k^2}\right)$$

$$\begin{aligned} &= \frac{k's^2(\bar{x})f(\bar{x}) - ks^2(\bar{x}')f(\bar{x}')}{2kk'} - \frac{1}{2k^2}u(\bar{x}) + \left[\frac{1}{2k^2}u(\bar{x}) - \frac{1}{2kk'^2}u(\bar{x}')\right] + o\left(\frac{1}{k^2}\right) \\ &= \frac{k's^2(\bar{x})f(\bar{x}) - ks^2(\bar{x}')f(\bar{x}')}{2kk'} - \frac{1}{2k^2}u(\bar{x}) + \frac{k'^2u(\bar{x}) - k^2u(\bar{x}')}{2k^2k'^2} + o\left(\frac{1}{k^2}\right) \\ &= \frac{k's^2(\bar{x})f(\bar{x}) - k[s^2(\bar{x})f(\bar{x}) + (\bar{x}' - \bar{x})d(\bar{x}) + o(\bar{x}' - \bar{x})]}{2kk'} - \frac{1}{2k^2}u(\bar{x}) \\ &\quad + \frac{k'^2u(\bar{x}) - k^2[u(\bar{x}) + O(\bar{x}' - \bar{x})]}{2k^2k'^2} + o\left(\frac{1}{k^2}\right), \end{aligned} \tag{2}$$

where $d(\bar{x})$ denotes the derivative of the function $s^2(\bar{x})f(\bar{x})$ with respect to \bar{x} . By the same reasoning as in the proof of Lemma 22, we know that $\bar{x}' - \bar{x} = O(\frac{1}{k})$ for all possible realizations of \bar{x}' . Thus we can rewrite the expression in equation (2) as

$$\begin{aligned} &\frac{(k' - k)s^2(\bar{x})f(\bar{x}) - k(\bar{x}' - \bar{x})d(\bar{x})}{2kk'} - \frac{1}{2k^2}u(\bar{x}) + \frac{(k'^2 - k^2)u(\bar{x})}{2k^2k'^2} + o\left(\frac{1}{k^2}\right) \\ &= \frac{(k' - k)s^2(\bar{x})f(\bar{x}) - k(\bar{x}' - \bar{x})d(\bar{x})}{2kk'} - \frac{1}{2k^2}u(\bar{x}) + o\left(\frac{1}{k^2}\right). \end{aligned} \tag{3}$$

Now note that $E[\bar{x}'] = \bar{x}$, where the expectation is taken over the uncertain realization of \bar{x}' in another j periods. Thus the expectation of the expression in equation (3) is

$$E\left[\frac{(k' - k)s^2(\bar{x})f(\bar{x})}{2kk'}\right] - \frac{1}{2k^2}u(\bar{x}) + o\left(\frac{1}{k^2}\right), \tag{4}$$

where the expectation is taken over the uncertain realization of k' . This expression can in turn be written as

$$\frac{\bar{\pi}_j(\bar{x})s^2(\bar{x})f(\bar{x}) - u(\bar{x})}{2k^2} + o\left(\frac{1}{k^2}\right), \tag{5}$$

where $\bar{\pi}_j(\bar{x})$ denotes the expected number of additional impressions that the ad with uncertain eCPM receives after an additional j periods have passed (which will equal 0 when $j = 0$ and vary approximately linearly with j for large k).

The expression in equation (5) gives the difference between the auctioneer's actual expected payoff in the period after an additional j periods have passed and $-\frac{1}{2k}s^2(\bar{x})f(\bar{x})$. From this it follows that the difference between the auctioneer's actual payoff $V_k(\bar{x})$ and the payoff the auctioneer would receive if the auctioneer obtained a payoff of $-\frac{1}{2k}s^2(\bar{x})f(\bar{x})$ in every future period is $\sum_{j=0}^{\infty} \delta^j \frac{\bar{\pi}_j(\bar{x})s^2(\bar{x})f(\bar{x}) - u(\bar{x})}{2k^2} + o(\frac{1}{k^2})$, which can be written as $\frac{w(\bar{x})}{k^2} + o(\frac{1}{k^2})$ for some function $w(\bar{x})$. Thus we can write $V_k(\bar{x})$ as $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + \frac{w(\bar{x})}{k^2} + o(\frac{1}{k^2})$ for some function $w(\bar{x})$.

But we have seen in the proof of Lemma 22 that $E[V_{k+1}(\bar{x}') - V_k(\bar{x})] = V_{k+1}(\bar{x}) - V_k(\bar{x}) + o(\frac{1}{k^2})$. Since $V_k(\bar{x}) = -\frac{v(\bar{x})}{k} + \frac{w(\bar{x})}{k^2} + o(\frac{1}{k^2})$, it then follows that $V_{k+1}(\bar{x}') - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$. ■

Proof of Theorem 8: Recall that

$$V_k(\bar{x}) = \frac{1}{1 - \delta} \left(\max_z E_\epsilon \left[- \int_{\bar{x}+\alpha_k^\epsilon}^z F(z) - F(y) dy + \delta F(z)(E_{\bar{x}'}[V_{k+1}(\bar{x}')] - V_k(\bar{x})) \right] \right)$$

and a second-order Taylor approximation for $E_\epsilon[\int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy] =$

$$E_\epsilon \left[\int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy \right] = \int_{\bar{x}}^z F(z) - F(y) dy + \frac{1}{2} \sigma_k^2 f(\bar{x}) + o(\sigma_k^2)$$

Now $z = \bar{x} + \delta(E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x}))$, so $z - \bar{x} \leq -\delta V_k(\bar{x})$, a term which is $O(f(\bar{x})\sigma_k^2)$. From this it follows that $\int_{\bar{x}}^z F(z) - F(y) dy = O(F(\bar{x})f(\bar{x})\sigma_k^2) = o(f(\bar{x})\sigma_k^2)$. And we also know that $\delta F(z)(E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x})) \leq -\delta F(z)V_k(\bar{x}) = O(F(\bar{x})f(\bar{x})\sigma_k^2) = o(f(\bar{x})\sigma_k^2)$.

Combining these results gives $E_\epsilon[\int_{\bar{x}+\sigma_k\epsilon}^z F(z) - F(y) dy] = \frac{1}{2} \sigma_k^2 f(\bar{x}) + o(f(\bar{x})\sigma_k^2)$ and $F(z)(E_{\bar{x}}[V_{k+1}(\bar{x})] - V_k(\bar{x})) = o(f(\bar{x})\sigma_k^2)$. Substituting this in to our expression for $V_k(\bar{x})$ then gives $V_k(\bar{x}) = -\frac{1}{2(1-\delta)} f(\bar{x})\sigma_k^2 + o(f(\bar{x})\sigma_k^2)$. ■

Proof of Theorem 9: First note that it must be the case that $V_k(\bar{x}) = \Omega(\frac{1}{k})$ for large k . We know that $\sigma_{a, k_a}^2 = \Theta(\frac{1}{k_a}) = \Theta(\frac{1}{\bar{x}k})$ for large k , so the immediate reward in any given period is at least on the same order as $\frac{1}{k}$ regardless of which ad-context pair a arises in the auction. Thus we know that $V_k(\bar{x}) = \Omega(\frac{1}{k})$ for large k .

We also know that $V_k(\bar{x}) = O(\frac{1}{k})$ for large k . To see this, note that the auctioneer can ensure that his loss in an auction involving the ad-context pair a in any given period is $O(\frac{1}{k_a}) = O(\frac{1}{k})$ by bidding $z_a = \bar{x}_a$, so the auctioneer can thus ensure that his expected loss in any given period is $O(\frac{1}{k})$ unconditional on the precise ad-context pair that arises. And if the auctioneer's loss in any given period is $O(\frac{1}{k})$, then the player's total loss from the game will also be no greater than $O(\frac{1}{k})$ because the present value of the sum of losses that are $O(\frac{1}{k})$, $\sum_{j=k}^{\infty} \delta^{j-k} \frac{1}{j}$, is also $O(\frac{1}{k})$ since $1 < \sum_{j=k}^{\infty} \delta^{j-k} \frac{1}{j} < \sum_{j=k}^{\infty} \delta^{j-k} = \frac{1}{1-\delta}$ implies $\frac{1}{k} < \sum_{j=k}^{\infty} \delta^{j-k} \frac{1}{j} < \frac{1}{(1-\delta)k}$. Thus $V_k(\bar{x}) = \Theta(\frac{1}{k})$ for large k . ■

Proof of Theorem 10: Since $V_k(\bar{x}) = \Theta(\frac{1}{k})$ for large k , we have $E_{\bar{x}(a), \bar{x}}[V_{k(a), \bar{x}}(\bar{x}(a))] - V_k(\bar{x}) = O(\frac{1}{k})$ for large k . Thus since the optimal bidding strategy entails setting $z_a = \bar{x}_a + \delta(E_{\bar{x}(a)}[V_{k(a), \bar{x}}(\bar{x}(a))] - V_k(\bar{x}))$, it must be the case that $z_a = \bar{x}_a + O(\frac{1}{k})$ for large k . From this it follows that $\int_{\bar{x}_a}^{z_a} F_a(z_a) - F_a(y) dy = O(\frac{1}{k^2})$ under the optimal bidding strategy for large k .

Now we have seen in Lemma 4 that $E_\epsilon[\int_{\bar{x}_a+\sigma_{a, k_a}\epsilon}^{z_a} F_a(z_a) - F_a(y) dy] = \int_{\bar{x}_a}^{z_a} F_a(z_a) - F_a(y) dy + \frac{1}{2} \sigma_{a, k_a}^2 f_a(\bar{x}_a) + O(\sigma_{a, k_a}^4)$ for large k . Since $\int_{\bar{x}_a}^{z_a} F_a(z_a) - F_a(y) dy = O(\frac{1}{k^2})$ under the optimal bidding strategy z_a and $\sigma_{a, k_a}^2 = \frac{\sigma_a^2(\bar{x}_a)}{k_a} + O(\frac{1}{k^2})$ for large k , it then follows that $E_\epsilon[\int_{\bar{x}_a+\sigma_{a, k_a}\epsilon}^{z_a} F_a(z_a) - F_a(y) dy] = \frac{\sigma_a^2(\bar{x}_a)}{2k_a} f_a(\bar{x}_a) + O(\frac{1}{k^2})$ for large k .

But $-E_\epsilon[\int_{\bar{x}_a+\sigma_{a, k_a}\epsilon}^{z_a} F_a(z_a) - F_a(y) dy]$ represents the auctioneer's per-period payoff if the next auction is an auction for the advertiser-context pair a . Thus the auctioneer's expected per-period payoff unconditional on what ad-context pair appears in the next auction is $\sum_{a=1}^m \pi_a \frac{\sigma_a^2(\bar{x}_a)}{2k_a} f_a(\bar{x}_a) + O(\frac{1}{k^2}) = \sum_{a=1}^m \pi_a \frac{1}{2\bar{x}_a k_a} \sigma_a^2(\bar{x}_a) f_a(\bar{x}_a) + O(\frac{1}{k^2})$ for large k . From this it follows that if $g(\bar{x}) \equiv \sum_{a=1}^m \pi_a \frac{1}{2\bar{x}_a} \sigma_a^2(\bar{x}_a) f_a(\bar{x}_a)$, then the expected per-period utility that one obtains at each point in the game unconditional on what ad-context pair appears in the next auction is $\frac{1}{k} g(\bar{x}) + O(\frac{1}{k^2})$.

Since $V_k(\bar{x})$ can alternatively be expressed as the discounted sum of the per-period utility that one can obtain at each point in the game, it then follows that $|kV_k(\bar{x})| \leq \sum_{j=k}^{\infty} \delta^{j-k} [g(\bar{x}) + O(\frac{1}{k})]$, meaning $|kV_k(\bar{x})| \leq \frac{1}{1-\delta} g(\bar{x}) + O(\frac{1}{k})$ and $|kV_k(\bar{x})| \geq \sum_{j=k}^{\infty} \delta^{j-k} \frac{1}{j} g(\bar{x}) +$

$O(\frac{1}{k}) = \frac{1}{1-\delta} g(\bar{x}) + O(\frac{1}{k})$ in the limit as $k \rightarrow \infty$. From this it follows that $|kV_k(\bar{x})| = \frac{1}{1-\delta} g(\bar{x}) + O(\frac{1}{k})$ and $kV_k(\bar{x}) = -\frac{1}{1-\delta} g(\bar{x}) + O(\frac{1}{k}) = -\frac{1}{2(1-\delta)} \sum_{a=1}^m \pi_a \frac{1}{\bar{x}_a} \sigma_a^2(\bar{x}_a) f_a(\bar{x}_a) + O(\frac{1}{k})$. ■

Proof of Theorem 13: Under the knowledge gradient framework, the incremental amount that one increases one's bid by beyond the expected value of the advertising opportunity is $\delta(E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x}))$. And under the full dynamic programming problem, the incremental amount that one increases one's bid is $\delta(E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x}))$. Thus if ΔV_{k+1} denotes the difference between the values of $E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x})$ and $E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x})$ denotes the difference between the values of $V_k(\bar{x})$ and $U_k(\bar{x})$, then the difference between the incremental amount that one increases one's bid under the full dynamic programming problem and under the knowledge gradient framework is $\delta(\Delta V_{k+1} - \Delta V_k)$.

But a condition of the theorem is that $\Delta V_{k+1} < \Delta V_k$. Thus $\delta(\Delta V_{k+1} - \Delta V_k) < 0$, and the difference between the incremental amount that one increases one's bid under the full dynamic programming problem and the incremental amount that one increases one's bid under the knowledge gradient framework is negative. From this it follows that the incremental amount by which one would increase one's bid under the knowledge gradient framework is indeed greater than it is under the full dynamic programming problem. ■

Proof of Theorem 14: In the knowledge gradient framework, $U_k(\bar{x})$ is just the discounted sum of the value of simply bidding $z = \bar{x}$ in each period when an ad has received k impressions so far and one's best estimate for the eCPM of the ad is \bar{x} . Now we know from applying Lemma 4 to the special case in which $z = \bar{x}$ that the per-period payoff from bidding $z = \bar{x}$ in each period when an ad has received k impressions so far and one's best estimate for the eCPM of the ad is \bar{x} is $-\frac{1}{2} \sigma_k^2 f(\bar{x}) - a(\bar{x})\sigma_k^4 + o(\sigma_k^4) = -\frac{1}{2k} \sigma_k^2(\bar{x}) f(\bar{x}) + O(\frac{1}{k^2})$. Thus $U_k(\bar{x}) = -\frac{1}{2(1-\delta)k} \sigma_k^2(\bar{x}) f(\bar{x}) + O(\frac{1}{k^2})$.

But we have seen in Theorem 7 that when $V_k(\bar{x}) = -\frac{1}{2(1-\delta)k} \sigma_k^2(\bar{x}) f(\bar{x}) + O(\frac{1}{k^2})$ and the per-period payoff from making the optimal bid is $-\frac{1}{2} \sigma_k^2 f(\bar{x}) - a(\bar{x})\sigma_k^4 + o(\sigma_k^4)$, then it must be the case that $E_{\bar{x}}[V_{k+1}(\bar{x}')] - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$ for large k , where $v(\bar{x}) \equiv \frac{1}{2(1-\delta)} \sigma_k^2(\bar{x}) f(\bar{x})$. An identical argument illustrates that when $U_k(\bar{x}) = -\frac{1}{2(1-\delta)k} \sigma_k^2(\bar{x}) f(\bar{x}) + O(\frac{1}{k^2})$ and the per-period payoff from making the optimal bid is $-\frac{1}{2} \sigma_k^2 f(\bar{x}) - a(\bar{x})\sigma_k^4 + o(\sigma_k^4)$, then it must be the case that $E_{\bar{x}}[U_{k+1}(\bar{x}')] - U_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$ for large k , where $v(\bar{x}) \equiv \frac{1}{2(1-\delta)} \sigma_k^2(\bar{x}) f(\bar{x})$. The result then follows. ■

Proof of Theorem 16: Since the optimal bid for advertiser i if advertiser i submits the highest eCPM bid amongst the bidders with unknown eCPMs satisfies $z_i = \bar{x}_i + \delta(E_{\bar{x}(i)}[V_{k(i)}(\bar{x}(i))] - V_k(\bar{x})) = 0$ when advertiser i submits the optimal bid z_i . By substituting this into the equation for the value of the dynamic programming problem $V_k(\bar{x})$, it follows that the value of this dynamic programming problem is always equal to $\int_{\bar{x}}^{z_i} F(y) dy$, which is an increasing function of z_i . From this it follows that if the optimal bid for advertiser i if advertiser i submits the highest bid of the advertisers with unknown eCPMs is higher than the optimal bid for all other advertisers with unknown eCPMs if one of these other advertisers submits the highest bid of the advertisers with unknown eCPMs, then the decision maker's

payoff from the game is maximized by having advertiser i submit the highest bid of all the advertisers with unknown eCPMs. ■

Proof of Theorem 17: Recall from Lemma 4 that the auctioneer’s per-period payoff if the auctioneer uses a bid for the advertiser with unknown eCPM that is equal to z is $-E_c[\int_{\bar{x}+o(\frac{1}{k})}^z F(z) - F(y)] dy = -\int_{\bar{x}}^z F(z) - F(y) dy - \frac{1}{2}\sigma_k^2 f(\bar{x}) + o(\sigma_k^2)$ for large k . Now if $z = \bar{x} + \frac{c(\bar{x})}{k\alpha}$ for some constant $c(\bar{x}) \neq 0$, then $\int_{\bar{x}}^z F(z) - F(y) dy = \int_{\bar{x}}^{\bar{x} + \frac{c(\bar{x})}{k\alpha}} f(\bar{x})(\bar{x} + \frac{c(\bar{x})}{k\alpha} - y) dy + o(\frac{1}{k\alpha}) = f(\bar{x})\frac{c(\bar{x})^2}{2k\alpha^2} + o(\frac{1}{k\alpha})$. Thus the auctioneer’s per-period payoff if the auctioneer uses a bid for the ad with unknown eCPM of the form $z = \bar{x} + \frac{c(\bar{x})}{k\alpha}$ is $-\frac{c(\bar{x})^2}{2k\alpha^2} f(\bar{x}) - \frac{1}{2}\sigma_k^2 f(\bar{x}) + o(\frac{1}{k\alpha})$ if $c(\bar{x}) \neq 0$ and $-\frac{1}{2}\sigma_k^2 f(\bar{x}) + o(\sigma_k^2)$ if $c(\bar{x}) = 0$.

Thus if $c(\bar{x}) = 0$, the auctioneer’s per-period payoff is $-\frac{1}{2k} s^2(\bar{x}) f(\bar{x}) + o(\frac{1}{k})$. We then know from similar reasoning to that in the proof of Theorem 10 that if this is the auctioneer’s per-period payoff, then the auctioneer’s total payoff from the game is $-\frac{1}{2(1-\delta)k} s^2(\bar{x}) f(\bar{x}) + o(\frac{1}{k})$ regardless of the learning rate. Similarly, if $c(\bar{x}) \neq 0$ and $\alpha = \frac{1}{2}$, then the auctioneer’s per-period payoff is $-\frac{1}{2k} f(\bar{x})(\sigma^2(\bar{x}) + c^2(\bar{x})) + o(\frac{1}{k})$, and we know from identical reasoning that the auctioneer’s total payoff is $-\frac{1}{2(1-\delta)k} f(\bar{x})(s^2(\bar{x}) + c^2(\bar{x})) + o(\frac{1}{k})$, which is strictly less than the auctioneer’s total payoff from the game when $c(\bar{x}) = 0$ for sufficiently large k .

Finally, if $c(\bar{x}) \neq 0$ and $\alpha < \frac{1}{2}$, the auctioneer’s per-period payoff is $-\frac{c(\bar{x})^2}{2k\alpha^2} f(\bar{x}) + o(\frac{1}{k\alpha})$. Since the auctioneer’s total payoff is the discounted sum of the auctioneer’s per-period payoffs, it follows that if $V_k(\bar{x})$ denotes the auctioneer’s total payoff from using this strategy, then $k^{2\alpha} V_k(\bar{x}) \leq \sum_{j=k}^{\infty} \delta^{j-k} [-\frac{1}{2}(\frac{k}{j})^{2\alpha} c^2(\bar{x}) f(\bar{x})] + o(1) = -\frac{1}{2(1-\delta)^{1-\alpha}} c^2(\bar{x}) f(\bar{x}) + o(1)$ in the limit as $k \rightarrow \infty$. Thus if $c(\bar{x}) \neq 0$ and $\alpha < \frac{1}{2}$, the auctioneer’s total payoff is no greater than $-\frac{1}{2(1-\delta)^{1-\alpha}} c^2(\bar{x}) f(\bar{x}) + o(\frac{1}{k\alpha})$, which is less than $-\frac{1}{2k} s^2(\bar{x}) f(\bar{x}) + o(\frac{1}{k})$, the auctioneer’s payoff from using the constant $c(\bar{x}) = 0$ for sufficiently large k . From this and the result in the previous paragraph it follows that if the auctioneer uses the strategy in the statement of this theorem, the auctioneer’s payoff will be maximized when $c(\bar{x}) = 0$ for sufficiently large k . ■

Observation 23 Suppose the auctioneer displays the ad with the highest eCPM bid with probability $1 - \epsilon$ and displays an ad uniformly at random with probability $\epsilon > 0$. Then the optimal constant ϵ for such an algorithm is $\epsilon = 0$ for sufficiently large k .

Proof Recall from Lemma 4 that the auctioneer’s per-period payoff if the auctioneer uses a bid for the advertiser with unknown eCPM that is equal to z is $-E_c[\int_{\bar{x}+o(\frac{1}{k})}^z F(z) - F(y)] dy = -\int_{\bar{x}}^z F(z) - F(y) dy - \frac{1}{2}\sigma_k^2 f(\bar{x}) + o(\sigma_k^2)$ for large k . Note that displaying an ad uniformly at random is equivalent to making a bid of 0 for the ad with unknown eCPM with probability $\frac{1}{2}$ and making a bid of ∞ for the ad with unknown eCPM with probability $\frac{1}{2}$. Since $\int_{\bar{x}}^{\infty} F(z) - F(y) dy > 0$ for either $z = 0$ or $z = \infty$, it follows that the auctioneer’s expected per-period payoff if the auctioneer follows the strategy in the statement of the observation is no greater than $-c\epsilon$ for some constant $c > 0$ for large k .

However, if the auctioneer always uses a bid of $z = \bar{x}$ (as would be the case when $\epsilon = 0$), then we know from the proof of Theorem 17 that the auctioneer’s per-period payoff is $-\frac{1}{2k} s^2(\bar{x}) f(\bar{x}) + o(\frac{1}{k})$ for large k . Thus for sufficiently large k , the auctioneer always

achieves a larger per-period payoff by setting $\epsilon = 0$ than by using any positive value of ϵ , so the optimal constant for this algorithm is $\epsilon = 0$. ■

Proof of Theorem 18: We know from Theorem 7 that $E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2})$ for large k , where $v(\bar{x}) = \frac{1}{2(1-\delta)} s^2(\bar{x}) f(\bar{x})$, and we also know from the proof of Theorem 3 that the derivative of the seller’s expected payoff from making a bid of z with respect to z is $f(z)(\bar{x} - z + \delta(E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x})))$. Thus if $\Delta V \equiv E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x})$, then the difference between the auctioneer’s expected payoff from making a bid of \bar{x} and a bid of $\bar{x} + \frac{\delta}{2(1-\delta)k(k+1)} s^2(\bar{x}) f(\bar{x})$ is

$$\frac{1}{1-\delta} \int_{\bar{x}}^{\bar{x} + \delta \Delta V + o(\Delta V)} f(z)(\bar{x} - z + \delta(\Delta V) + o(\Delta V)) dz = \frac{f(\bar{x})\delta^2(\Delta V)^2}{2(1-\delta)} + o((\Delta V)^2).$$

And since $\Delta V = E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x}) = \frac{v(\bar{x})}{k(k+1)} + o(\frac{1}{k^2}) = \frac{s^2(\bar{x})f(\bar{x})}{2(1-\delta)k(k+1)} + o(\frac{1}{k^2})$, it follows that the difference between the auctioneer’s payoff from making a bid of \bar{x} and a bid of $\bar{x} + \frac{\delta}{2(1-\delta)k(k+1)} s^2(\bar{x}) f(\bar{x})$ is $\frac{\delta^2}{8(1-\delta)^3 k^4} s^4(\bar{x}) f^3(\bar{x}) + o(\frac{1}{k^4})$. ■

Proof of Theorem 19: The theoretically optimal strategy for the auctioneer would entail submitting a bid of $z = \bar{x} + \delta(E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x}))$ in each time period. By the same reasoning as in the proof of Theorem 18, we know the difference between the auctioneer’s expected payoff from making a bid of \bar{x} and making a bid of $z = \bar{x} + \delta(E_{\pi} [V_{k+1}(\bar{x})] - V_k(\bar{x}))$ is $\frac{f(\bar{x})\delta^2(\Delta V)^2}{2(1-\delta)} + o((\Delta V)^2)$. Since the auctioneer’s payoff from using the approximately optimal bidding strategy is also $\frac{f(\bar{x})\delta^2(\Delta V)^2}{2(1-\delta)} + o((\Delta V)^2)$, it follows that the difference between the auctioneer’s payoff under the approximately optimal bidding strategy and the maximum possible payoff the auctioneer could obtain theoretically is $o((\Delta V)^2) = o(\frac{1}{k^4})$.

But we know from Theorem 18 that the difference between the auctioneer’s payoff under the approximately optimal bidding strategy and the greedy strategy is $\frac{\delta^2}{8(1-\delta)^3 k^4} s^4(\bar{x}) f^2(\bar{x}) + o(\frac{1}{k^4})$. Thus the difference between the auctioneer’s payoff under this strategy and the maximum possible payoff the auctioneer could obtain under the theoretically optimal strategy becomes vanishingly small compared to the difference between the auctioneer’s payoff under this strategy and the auctioneer’s payoff under the greedy strategy for large k . ■

Proof of Theorem 20: A consequence of Theorem 13 is that the difference between the auctioneer’s payoff under the theoretically optimal strategy and the auctioneer’s payoff from the greedy strategy is no greater than the difference between the auctioneer’s payoff from the theoretically optimal strategy and the auctioneer’s payoff under the greedy strategy when no learning is possible in future periods. Thus we seek to bound the difference between the auctioneer’s payoff from the theoretically optimal strategy and the auctioneer’s payoff under the greedy strategy when no learning is possible in future periods.

Let α and β denote the parameters of the beta distribution. If no learning ever took place and the auctioneer followed the greedy strategy, then in all periods the auctioneer would show the highest competing bidder if this bidder had an eCPM bid p satisfying $p > \frac{\alpha+1}{\alpha+\beta}$ and show the bidder with unknown eCPM otherwise. If the auctioneer showed the ad with unknown eCPM in the first period, this ad received a click, and no learning

took place in future periods, then in future periods the auctioneer would show the highest competing bidder if and only if this bidder had an eCPM bid p satisfying $p > \frac{\alpha+1}{\alpha+\beta+1}$. And if the auctioneer showed the ad with unknown eCPM, this ad did not receive a click, and no learning took place in future periods, then in future periods the auctioneer would show the highest competing bidder if and only if this bidder had an eCPM bid p satisfying $p > \frac{\alpha}{\alpha+\beta+1}$.

From this it follows that if no learning takes place in future periods, then the auctioneer's payoff in any given period in the future is guaranteed to be the same regardless of whether the ad with unknown eCPM was shown in the first period if either $p > \frac{\alpha+1}{\alpha+\beta+1}$ or $p < \frac{\alpha}{\alpha+\beta+1}$ in that particular period. The only circumstances under which the auctioneer's expected payoff in a future period t will differ as a result of showing the ad with unknown eCPM in the first period is if this ad receives a click in the first period and $p \in (\frac{\alpha}{\alpha+\beta}, \frac{\alpha+1}{\alpha+\beta+1})$ in period t or if the ad does not receive a click in the first period and $p \in (\frac{\alpha}{\alpha+\beta+1}, \frac{\alpha}{\alpha+\beta})$ in period t . In the first case, the auctioneer's payoff in period t as a result of showing the ad with unknown eCPM in the first period exceeds the auctioneer's payoff under normal circumstances by $\frac{\alpha+1}{\alpha+\beta+1} - p$, and in the second case the auctioneer's payoff in period t as a result of showing the ad with unknown eCPM in the first period exceeds the auctioneer's payoff under normal circumstances by an amount $p - \frac{\alpha}{\alpha+\beta+1}$.

Now the probability the ad with unknown eCPM receives a click in the first period if this ad is shown is $\frac{\alpha}{\alpha+\beta}$ and the probability this ad does not receive a click in the first period if this ad is shown is $\frac{\beta}{\alpha+\beta}$. By combining this with the result in the previous paragraph, it follows that the maximum possible expected payoff difference that the auctioneer can obtain from future periods as a result of showing the ad with unknown eCPM in the first period is $\frac{\delta}{1-\delta} [\frac{\alpha}{\alpha+\beta} \int_{\frac{\alpha}{\alpha+\beta}}^{\frac{\alpha+1}{\alpha+\beta+1}} (\frac{\alpha+1}{\alpha+\beta+1} - p) \bar{f} dp + \frac{\beta}{\alpha+\beta} \int_{\frac{\alpha}{\alpha+\beta+1}}^{\frac{\alpha+\beta}{\alpha+\beta+1}} (p - \frac{\alpha}{\alpha+\beta+1}) \bar{f} dp]$, where $\bar{f} \equiv \sup_p f(p)$. This payoff difference equals $\frac{\delta \bar{f}}{2(1-\delta)} [\frac{\alpha}{\alpha+\beta} (\frac{\alpha+1}{\alpha+\beta+1} - \frac{\alpha}{\alpha+\beta})^2 + \frac{\beta}{\alpha+\beta} (\frac{\alpha}{\alpha+\beta+1})^2]$, which is $\frac{\delta \bar{f}}{2(1-\delta)} \frac{\alpha \beta}{(\alpha+\beta)^2 (\alpha+\beta+1)^2} = \frac{\delta \bar{f}}{2(1-\delta)} \frac{\alpha \beta}{(\alpha+\beta)^2 (\alpha+\beta+1)^2}$.

Now the expected value for a beta distribution is $\frac{\alpha}{\alpha+\beta}$ and the variance in a beta distribution is $\frac{\alpha \beta}{(\alpha+\beta)^2 (\alpha+\beta+1)}$. Thus since the bidder's expected eCPM is ω and the standard deviation in the bidder's expected eCPM is $\gamma \omega$, it follows that $\frac{\alpha}{\alpha+\beta} = \frac{1}{\omega}$, $\frac{\beta}{\alpha+\beta} = \frac{1}{\omega}$, and $\frac{\alpha \beta}{(\alpha+\beta)^2 (\alpha+\beta+1)^2} = \gamma^4 \omega^4$. From this it follows that $\frac{\delta \bar{f}}{2(1-\delta)} \frac{\alpha \beta}{(\alpha+\beta)^2 (\alpha+\beta+1)^2} = \frac{\delta \bar{f}}{2(1-\delta)} \frac{\gamma^4 \omega^4}{1-\omega}$. Thus the maximum additional payoff increase that one can obtain from future periods as a result of showing the ad with unknown eCPM in the first period is no greater than $\frac{\delta \bar{f}}{2(1-\delta)} \frac{\gamma^4 \omega^4}{1-\omega}$.

Now if ΔV denotes the change in payoff that one obtains from future periods as a result of showing the ad with uncertain eCPM in the first period, then the value of showing the ad with uncertain eCPM in the first period is $\omega + \Delta V$. Thus the theoretically optimal strategy will specify a bid of $\omega + \Delta V$ for the bidder with uncertain eCPM, whereas the greedy strategy will specify a bid of ω , so the theoretically optimal strategy will only show a different ad when the highest competing eCPM bid, p , satisfies $p \in [\omega, \omega + \Delta V]$. Furthermore, in the cases where the theoretically optimal strategy specifies a different bid, the theoretically optimal strategy achieves a payoff that exceeds that of the greedy strategy by an amount $\omega + \Delta V - p$, where p denotes the highest competing eCPM bid. From this it follows that the

difference in expected payoff that one obtains as a result of using the theoretically optimal strategy rather than the greedy strategy is no greater than $\frac{1}{1-\delta} \int_{\omega}^{\omega+\Delta V} (\omega + \Delta V - p) f(p) dp$.

Thus if $\bar{f} \equiv \sup_p f(p)$, this payoff difference is no greater than $\frac{1}{1-\delta} \int_{\omega}^{\omega+\Delta V} (\omega + \Delta V - p) dp = \frac{\bar{f} (\Delta V)^2}{1-\delta}$. Thus the difference between the auctioneer's payoff under the theoretically optimal strategy and the auctioneer's payoff from the greedy strategy is no greater than $\frac{\bar{f} (\Delta V)^2}{1-\delta}$.
