Similar to other kernel-based algorithms (e.g., SVMs, Gaussian Process Regressions, Splines, etc.), devising a computationally efficient implementation of REG-LSPI/BRM is important to ensure that it is a practical algorithm for large-scale problems. A naive implementation of these algorithms requires the computation time of $O(n^3K)$, which is prohibitive for large sample sizes. One possible workaround is to reduce the effective number of samples by the sparsification technique (Engel et al., 2005; Jung and Polani, 2006; Xu et al., 2007). The other is to use elegant vector-matrix multiplication methods, which are used in iterative methods for matrix inversion, such as those based on the Fast Multipole Methods (Beason and Greengard, 1997) and the Fast Gauss Transform (Yang et al., 2004). These methods can reduce the computational cost of vector-matrix multiplication from $O(n^2)$ to $O(n \log n)$, which results in computation time of $O(n^2K \log n)$ for REG-LSPI/BRM, at the cost of some small, but controlled, numerical error. Another possibility is to use stochastic gradient-like algorithms similar to the works of Lin et al. (2012); Qin et al. (2014). The use of stochastic gradient-like algorithms is especially appealing in the light of results such as Borton and Bousquet (2008); Shalev-Shwartz and Strehl (2008). They analyze the tradeoff between the statistical error and the optimization error caused by the choice of optimization method. They show that one might achieve lower generalization error by using a faster stochastic gradient-like algorithm, which processes more data points less accurately, rather than a slower but more accurate optimization algorithm, which can only process fewer data points. Designing scalable optimization algorithms for REG-LSPI/BRM is a topic for future work.

An important issue in the successful application of any RL/Planning algorithm, including REG-LSPI and REG-BRM, is the proper choice of parameters. In REG-BRM and REG-LSTD we are faced with the choice of $\mathcal{F}^{|\mathcal{A}|}$ and the corresponding regularization parameters $\lambda_{Q,n}$ and $\lambda_{h,n}$. The proper choice of these parameters, however, depends on quantities that are not known, e.g., $J(Q^\pi)$ and the choice of $\mathcal{F}^{|\mathcal{A}|}$ that “matches” with the MDP. This problem in the RL/Planning context has been addressed by Farahmand and Szepesvári (2011). They introduced a complexity-regularization-based model selection algorithm that allows one to design adaptive algorithms: Algorithms that perform almost the same as the one with the prior knowledge of the best parameters.

Another important question is how to extend these algorithms to deal with continuous action MDPs. There are two challenges: Computational and statistical. The computational challenge is finding the greedy action at each state in the policy improvement step. In general, this is an intractable optimization problem, which cannot be solved exactly or even with any suboptimality guarantee. To analyze this inexact policy improvement some parts of the theory, especially the error propagation result, should be modified. Moreover, we also have a statistical challenge: One should specifically control the complexity of the

policy space as the complexity of $\{\max_{a \in \mathcal{A}} Q(\cdot, a) : Q \in \mathcal{F}^{\mathcal{A}}\}$ might be infinity even though $\mathcal{F}^{\mathcal{A}}$ has a finite complexity (Antos et al., 2008a). A properly modified algorithm might be similar to the continuous-action extension of Farahmand et al. (2015), an API algorithm that explicitly controls the complexity of the policy space.

Finally an open theoretical question is to characterize the properties of the MDP that determine the function space to which action-value function belong. A similar question is how the values of L_P and L_R in Assumption A7 are related to the intrinsic properties of the MDP. We partially addressed this question for the convolutional MDPs, but analysis of more general MDPs is remained to be done.

Acknowledgments

We thank the members of the Reinforcement Learning and Artificial Intelligence (RLAI) research group at the University of Alberta and the Reasoning and Learning Lab at McGill University for fruitful discussions. We thank the anonymous reviewers and the editor for their helpful comments and suggestions, which improved the quality of the paper. We gratefully acknowledge funding from the National Science and Engineering Research Council of Canada (NSERC) and Alberta Innovates Centre for Machine Learning (AICML). Shie Mannor was partially supported by the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement 306638 (SUPREL).

Proofs and Auxiliary Results

In these appendices, we first prove Theorem 10, which provides the closed-form solutions for REG-LSTD and REG-BRM when the function space is an RKHS (Appendix A). We then attend to the proof of Theorem 11 (Policy Evaluation error for REG-LSTD). The main body of the proof for Theorem 11 is in Appendix B. To increase the readability and flow, the proofs of some of the auxiliary and more technical results are postponed to Appendices C, D, and E.

More specifically, we prove an extension of Theorem 21.1 of Györfi et al. (2002) in Appendix C (Lemma 15). We present a modified version of Theorem 10.2 of van de Geer (2000) in Appendix D. We then provide a covering number result in Appendix E (Lemma 20). The reason we require these results will become clear in Appendix B. Finally, we introduce convolutional MDPs as an instance of problems that satisfy Assumption A7 (Appendix F).

We would like to remark that the generic ‘‘constants’’ $c, c' > 0$ in the proofs, especially those related to the statistical guarantees, might change from line to line, if their exact value is not important in the bound. These values are constant as a function of important quantities of the upper bound (such as $n, \alpha, J(Q^F)$, etc.), but may depend on Q_{\max} or $|\mathcal{A}|$.

Appendix A. Proof of Theorem 10 (Closed-Form Solutions for RKHS Formulation of REG-LSTD/BRM)

Proof REG-BRM: First, notice that the optimization problem (28) can be written in the form $c_n(Q) + \lambda_{Q,n} \|Q\|_{\mathcal{H}}^2 \stackrel{Q}{\rightarrow} \min!$ with an appropriately defined functional c_n .¹⁹ In order to apply the representer theorem (Schölkopf et al., 2001), we require to show that c_n depends on Q only through the data-points $Z_1, Z'_1, \dots, Z_n, Z'_n$. This is immediate for all the terms that define c_n except the term that involves $\hat{h}_n(\cdot; Q)$. However, since \hat{h}_n is defined as the solution to the optimization problem (27), calling for the representer theorem once again, we observe that \hat{h}_n can be written in the form

$$\hat{h}_n(\cdot; Q) = \sum_{t=1}^n \beta_t^* \kappa(Z_t, \cdot),$$

where $\beta^* = (\beta_1^*, \dots, \beta_n^*)^\top$ satisfies

$$\beta^* = \operatorname{argmin}_{\beta \in \mathbb{R}^n} \left[\left\| \mathbf{K}_h \beta - \hat{T}^\pi Q \right\|_n^2 + \lambda_{h,n} \beta^\top \mathbf{K}_h \beta \right].$$

Solving this minimization problem leads to

$$\beta^* = (\mathbf{K}_h + n\lambda_{h,n} \mathbf{I})^{-1} (\hat{T}^\pi Q).$$

In both equations ($\hat{T}^\pi Q$) is viewed as the n -dimensional vector

$$\left((\hat{T}^\pi Q)(Z_1), \dots, (\hat{T}^\pi Q)(Z_n) \right)^\top = (R_1 + \gamma Q(Z_1), \dots, R_n + \gamma Q(Z_n))^\top.$$

Thus, β^* depends on Q only through $Q(Z_1), \dots, Q(Z_n)$. Plugging this solution into (28), we get that $c_n(Q)$ indeed depends on Q through

$$Q(Z_1), Q(Z'_1), \dots, Q(Z_n), Q(Z'_n),$$

and thus on data points $Z_1, Z'_1, \dots, Z_n, Z'_n$. The representer theorem then implies that the minimizer of $c_n(Q) + \lambda_{Q,n} \|Q\|_{\mathcal{H}}^2$ can be written in the form $Q(\cdot) = \sum_{i=1}^{2n} \hat{\alpha}_i \kappa(\tilde{Z}_i, \cdot)$, where $\tilde{Z}_i = Z_i$ if $i \leq n$ and $\tilde{Z}_i = Z'_{i-n}$, otherwise.

Let $\tilde{\alpha} = (\alpha_1, \dots, \alpha_n, \alpha'_1, \dots, \alpha'_n)^\top$. Using the reproducing kernel property of κ , we get the optimization problem

$$\|C_1 \mathbf{K}_Q \tilde{\alpha} - (r + \gamma C_2 \mathbf{K}_Q \tilde{\alpha})\|_n^2 - \|\mathbf{B}(r + \gamma C_2 \mathbf{K}_Q \tilde{\alpha})\|_n^2 + \lambda_{Q,n} \tilde{\alpha}^\top \mathbf{K}_Q \tilde{\alpha} \stackrel{\tilde{\alpha}}{\rightarrow} \min!.$$

Solving this for $\tilde{\alpha}$ concludes the proof for REG-BRM.

REG-LSTD: The first part of the proof that shows c_n depends on Q only through the data-points $Z_1, Z'_1, \dots, Z_n, Z'_n$ is exactly the same as the proof of REG-BRM. Thus, using the representer theorem, the minimizer of (30) can be written in the form $Q(\cdot) = \sum_{i=1}^{2n} \hat{\alpha}_i \kappa(\tilde{Z}_i, \cdot)$, where $\tilde{Z}_i = Z_i$ if $i \leq n$ and $\tilde{Z}_i = Z'_{i-n}$, otherwise. Let $\tilde{\alpha} = (\alpha_1, \dots, \alpha_n, \alpha'_1, \dots, \alpha'_n)^\top$. Using the reproducing kernel property of κ , we get the optimization problem

$$\|(C_1 - \gamma \mathbf{E} C_2) \mathbf{K}_Q \tilde{\alpha} - \mathbf{E} r\|_n^2 + \lambda_{Q,n} \tilde{\alpha}^\top \mathbf{K}_Q \tilde{\alpha} \stackrel{\tilde{\alpha}}{\rightarrow} \min!.$$

Replacing $C_1 - \gamma \mathbf{E} C_2$ with \mathbf{F} and solving for $\tilde{\alpha}$ concludes the proof. \blacksquare

¹⁹ Here $f(Q) \stackrel{Q}{\rightarrow} \min!$ indicates that Q is a minimizer of $f(Q)$.

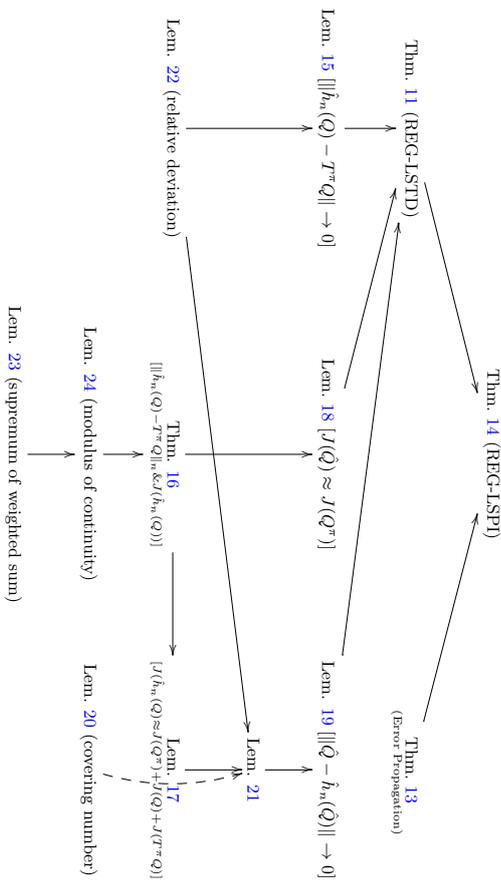

Figure 2: Dependencies of results used to prove the statistical guarantee for REG-LSP (Theorem 14).

Appendix B. Proof of Theorem 11 (Statistical Guarantee for REG-LSTD)

The goal of Theorem 11 is to provide a finite-sample upper bound on the Bellman error $\|\hat{Q} - T^\pi \hat{Q}\|_\pi$ for REG-LSTD defined by the optimization problems (15) and (16). Since $\|\hat{Q} - T^\pi \hat{Q}\|_\pi^2 \leq 2\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\pi^2 + 2\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\pi^2$, we may upper bound the Bellman error by upper bounding each term in the RHS. Recall from the discussion after Theorem 11 that the analysis is more complicated than the conventional supervised learning setting because the corresponding optimization problems are coupled: $\hat{h}_n(\cdot; \hat{Q})$ is a function of \hat{Q} which itself is a function of $\hat{h}_n(\cdot; \hat{Q})$.

Theorem 11 is proven using Lemma 15, which upper bounds $\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\pi$, and Lemma 19, which upper bounds $\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\pi$. We also require to relate the smoothness $J(\hat{Q})$ to the smoothness $J(Q^\pi)$. Lemma 18 specifies this relation. The proof of these lemmas themselves require further developments, which will be discussed when we encounter them. Figure 2 shows the dependencies between all results that lead to the proof of Theorem 11 and consequently Theorem 14.

The following lemma controls the error behavior resulting from the optimization problem (15). This lemma, which is a result on the error upper bound of a regularized regression estimator, is similar to Theorem 21.1 of Györfi et al. (2002) with two main differences. First,

it holds uniformly over $T^\pi Q$ (as opposed to a fixed function $T^\pi Q$); second, it holds for function spaces that satisfy a general metric entropy condition (as opposed to the special case of the Sobolev spaces).

Lemma 15 (Convergence of $\hat{h}_n(\cdot; Q)$ to $T^\pi Q$) For any random $Q \in \mathcal{F}^{|A|}$, let $\hat{h}_n(Q)$ be defined according to (15). Under Assumptions A1–A5 and A7, there exist finite constants $c_1, c_2 > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, we have

$$\|\hat{h}_n(\cdot; Q) - T^\pi Q\|_\pi^2 \leq 4\lambda_{h,n} J^2(T^\pi Q) + 2\lambda_{h,n} J^2(Q) + c_1 \frac{1}{n\lambda_{h,n}^\alpha} + c_2 \frac{\ln(1/\delta)}{n},$$

with probability at least $1 - \delta$.

Proof See Appendix C. \blacksquare

When we use this lemma to prove Theorem 11, the action-value function Q that appears in the bound is the result of the optimization problems defined in (16), that is \hat{Q} , and so is random. Lemma 18, which we will prove later, provides a deterministic upper bound for the smoothness $J(\hat{Q})$ of this random quantity.

It turns out that to derive our main result, we require to know more about the behavior of the regularized regression estimator than what is shown in Lemma 15. In particular, we need an upper bound on the empirical error of the regularized regression estimator $\hat{h}_n(\cdot; Q)$ (cf. (33) below). Moreover, we should bound the random smoothness $J(\hat{h}_n(\cdot; Q))$ by some deterministic quantities, which turns out to be a function of $J(T^\pi Q)$ and $J(Q)$. Theorem 16 provides us with the required upper bounds. This theorem is a modification of Theorem 10.2 by van de Geer (2000), with two main differences: 1) It holds uniformly over Q and 2) $h_n(\cdot; Q)$ uses the same data \mathcal{D}_n that is used to estimate Q itself.

We introduce the following notation: Let $w = (x, a, r, x')$ and define the random variables $w_i = (X_i, A_i, R_i, X'_i)$ for $1 \leq i \leq n$. The data set \mathcal{D}_n would be $\{w_1, \dots, w_n\}$. For a measurable function $g : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}$, let $\|g\|_m^2 = \frac{1}{n} \sum_{i=1}^n |g(w_i)|^2$. Consider the regularized least squares estimator:

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|A|}} \left[\|h - [R_\gamma + \gamma Q(X'_i, \pi(X'_i))]\|_n^2 + \lambda_{h,n} J^2(h) \right], \quad (33)$$

which is the same as (15) with π replacing π_π .

Theorem 16 (Empirical error and smoothness of $\hat{h}_n(\cdot; Q)$) For a random function $Q \in \mathcal{F}^{|A|}$, let $\hat{h}_n(\cdot; Q)$ be defined according to (33). Suppose that Assumptions A1–A5 and A7 hold. Then there exist constants $c_1, c_2 > 0$, such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, we have

$$\|\hat{h}_n(\cdot; Q) - T^\pi Q\|_\pi \leq c_1 \max \left\{ \frac{Q_{\max}^{1+\alpha} \sqrt{\ln(1/\delta)}}{\lambda_{h,n}^{\frac{\alpha}{2}}}, \frac{Q_{\max} (J(Q) + J(T^\pi Q))^{\frac{1+\alpha}{2}}}{\lambda_{h,n}^{\frac{\alpha}{2}}} \left(\frac{\ln(1/\delta)}{n} \right)^{\frac{1}{2(1+\alpha)}} \right\},$$

$$J(\hat{h}_n(\cdot; Q)) \leq c_2 \max \left\{ J(Q) + J(T^\pi Q), \frac{Q_{\max}^{1+\alpha} \sqrt{\frac{\ln(1/\delta)}{n}}}{\lambda_{h,n}^{\frac{1+\alpha}{2}}} \right\},$$

with probability at least $1 - \delta$.

Proof See Appendix D. ■

The following lemma, which is an immediate corollary of Theorem 16, indicates that with the proper choice of the regularization coefficient, the complexity of the regression function $\hat{h}_n(\cdot; Q)$ is in the same order as the complexities of Q , $T^\pi Q$, and Q^π . This result will be used in the proof of Lemma 21, which itself is used in the proof of Lemma 19.

Lemma 17 (Smoothness of $\hat{h}_n(\cdot; Q)$) For a random $Q \in \mathcal{F}^{|\mathcal{A}|}$, let $\hat{h}_n(\cdot; Q)$ be the solution to the optimization problem (15) with the choice of regularization coefficient

$$\lambda_{h,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}}.$$

Let Assumptions A1–A5 and A7 hold. Then, there exists a finite constant $c > 0$, depending on Q_{\max} , such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, the upper bound

$$J(\hat{h}_n(\cdot; Q)) \leq c \left(J(T^\pi Q) + J(Q) + J(Q^\pi) \sqrt{\ln(1/\delta)} \right)$$

holds with probability at least $1 - \delta$.

Proof With the choice of $\lambda_{h,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}}$, Theorem 16 implies that there exist some finite constant $c_1 > 0$ as well as $c_2 > 0$, which depends on Q_{\max} , such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, the inequality

$$\begin{aligned} J(\hat{h}_n(\cdot; Q)) &\leq c_1 \max \left\{ J(Q) + J(T^\pi Q), \frac{Q_{\max}^{1+\alpha} \sqrt{\frac{\ln(1/\delta)}{n}}}{\left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{2}}} \right\} \\ &\leq c_2 \left(J(T^\pi Q) + J(Q) + J(Q^\pi) \sqrt{\ln(1/\delta)} \right) \end{aligned}$$

holds with probability at least $1 - \delta$. ■

An intuitive understanding of this result might be gained if we consider $\hat{h}_n(\cdot; Q^\pi)$, which is the regression estimate for $T^\pi Q^\pi = Q^\pi$. This lemma then indicates that the smoothness of $\hat{h}_n(\cdot; Q^\pi)$ is comparable to the smoothness of its target function Q^π . This is intuitive whenever the regularization coefficients are chosen properly.

The following lemma relates $J(\hat{Q})$ and $J(T^\pi \hat{Q})$, which are random, to the complexity of the action-value function of the policy π , i.e., $J(Q^\pi)$. This result is used in the proof of Theorem 11.

Lemma 18 (Smoothness of \hat{Q}) Let Assumptions A1–A7 hold, and let \hat{Q} be the solution to (16) with the choice of

$$\lambda_{h,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}}.$$

Then, there exists a finite constant $c > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta < e^{-1}$, we have

$$\lambda_{Q,n} J^2(\hat{Q}) \leq \lambda_{Q,n} J^2(Q^\pi) + c \frac{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta)}{n^{\frac{1}{1+\alpha}}},$$

with probability at least $1 - \delta$.

Proof By Assumption A6 we have $Q^\pi \in \mathcal{F}^{|\mathcal{A}|}$, so by the optimizer property of \hat{Q} (cf. (16)), we get

$$\lambda_{Q,n} J^2(\hat{Q}) \leq \left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(\hat{Q}) \leq \left\| Q^\pi - \hat{h}_n(\cdot; Q^\pi) \right\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(Q^\pi). \quad (34)$$

Since $Q^\pi = T^\pi Q^\pi$, we have $\|Q^\pi - \hat{h}_n(\cdot; Q^\pi)\|_{\mathcal{D}_n} = \|T^\pi Q^\pi - \hat{h}_n(\cdot; Q^\pi)\|_{\mathcal{D}_n}$. So Theorem 16 shows that with the choice of $\lambda_{h,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}}$, there exists a finite constant $c > 0$ such that for any $n \in \mathbb{N}$ and for $0 < \delta < e^{-1} \approx 0.3679$, we have

$$\left\| Q^\pi - \hat{h}_n(\cdot; Q^\pi) \right\|_{\mathcal{D}_n}^2 \leq c_1 \left(1 \vee Q_{\max}^2 \right) \frac{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta)}{n^{\frac{1}{1+\alpha}}}, \quad (35)$$

with probability at least $1 - \delta$. Chaining inequalities (34) and (35) finishes the proof. ■

The other main ingredient of the proof of Theorem 11 is an upper bound to $\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\nu$, which is closely related to the optimization problem (16). This task is done by Lemma 19. In the proof of this lemma, we call Lemma 21, which shall be stated and proven right after this result.

Lemma 19 (Convergence of $\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\nu$) Let \hat{Q} be the solution to the set of coupled optimization problems (15)–(16). Suppose that Assumptions A1–A7 hold. Then there exists a finite constant $c > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta < 2e^{-1}$ and with the choice of

$$\lambda_{h,n} = \lambda_{Q,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}},$$

we have

$$\left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_\nu^2 \leq c \frac{(1 + \gamma^2 L_P^2)^\alpha J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta) + L_R^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1}{1+\alpha}}},$$

with probability at least $1 - \delta$.

Proof Decompose

$$\left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\nu}^2 = I_{1,n} + I_{2,n},$$

with

$$\begin{aligned} \frac{1}{2} I_{1,n} &= \left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(\hat{Q}), \\ I_{2,n} &= \left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\nu}^2 - I_{1,n}. \end{aligned} \quad (36)$$

In what follows, we upper bound each of these terms.

$I_{1,n}$: Use the optimizer property of \hat{Q} to get

$$\frac{1}{2} I_{1,n} = \left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(\hat{Q}) \leq \left\| Q^\pi - \hat{h}_n(\cdot; Q^\pi) \right\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(Q^\pi).$$

To upper bound $\left\| Q^\pi - \hat{h}_n(\cdot; Q^\pi) \right\|_{\mathcal{D}_n}^2 = \left\| T^\pi Q^\pi - \hat{h}_n(\cdot; Q^\pi) \right\|_{\mathcal{D}_n}^2$, we evoke [Theorem 16](#). For our choice of $\lambda_{Q,n}$, there exists a constant $c_1 > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta_1 < 1$, we have

$$\frac{1}{2} I_{1,n} \leq \lambda_{Q,n} J^2(Q^\pi) + c_1 \frac{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta_1)}{n^{\frac{1+\alpha}{1+\alpha}}}, \quad (37)$$

with probability at least $1 - \delta_1$.

$I_{2,n}$: With our choice of $\lambda_{Q,n}$ and $\lambda_{h,n}$, [Lemma 21](#), which shall be proven later, indicates that there exist some finite constants $c_2, c_3, c_4 > 0$ such that for any $n \in \mathbb{N}$ and finite $J(Q^\pi)$, L_R , and L_P , and $0 < \delta_2 < 1$, we have

$$I_{2,n} \leq c_2 \frac{L_R^{\frac{2\alpha}{1+\alpha}} + [J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}} [\ln(1/\delta_2)]^{\frac{1+\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}} + c_3 \frac{(1 + \gamma^2 L_P^2)^\alpha}{n \lambda_{Q,n}} + c_4 \frac{\ln(1/\delta_2)}{n}, \quad (38)$$

with probability at least $1 - \delta_2$. For $\delta_2 < e^{-1}$ and $\alpha \geq 0$, we have $[\ln(1/\delta_2)]^{\frac{1+\alpha}{1+\alpha}} \leq \ln(1/\delta_2)$, and also

$$\frac{1}{n \lambda_{Q,n}^\alpha} = \frac{[J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}} \leq \frac{[J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}} \ln(1/\delta_2). \quad (39)$$

With the right choice of constants, $\frac{\ln(1/\delta_2)}{n}$ can be absorbed into the other terms. Select $\delta_1 = \delta_2 = \delta/2$. Inequalities [\(37\)](#), [\(38\)](#), and [\(39\)](#) imply that with the specified choice of $\lambda_{Q,n}$ and $\lambda_{h,n}$, there exists a finite constant $c_5 > 0$ such that for any $0 < \delta < 2e^{-1}$, we have

$$\left\| \hat{Q} - \hat{h}_n(\cdot; \hat{Q}) \right\|_{\nu}^2 \leq c_5 \frac{(1 + \gamma^2 L_P^2)^\alpha J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta) + L_R^{\frac{1+2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}},$$

with probability at least $1 - \delta$. \blacksquare

To upper bound $I_{2,n}$, defined in [\(36\)](#), we simultaneously apply the peeling device (cf. [Section 5.3](#) of [van de Geer 2000](#)) on two different, but coupled, function spaces (one to which

\hat{Q} belongs and the other to which $\hat{h}_n(\cdot; \hat{Q})$ belongs). In each layer of peeling, we apply an exponential tail inequality to control the relative deviation of the empirical mean from the true mean ([Lemma 22](#) in [Appendix C](#)). We also require a covering number result, which is stated as [Lemma 20](#). The final result of this procedure is a tight upper bound on $I_{2,n}$, as stated in [Lemma 21](#).

To prepare for the peeling argument, define the following subsets of \mathcal{F} and $\mathcal{F}^{\mathcal{A}}$:

$$\begin{aligned} \mathcal{F}_\sigma &\triangleq \{f : f \in \mathcal{F}, J^2(f) \leq \sigma\}, \\ \mathcal{F}_\sigma^{\mathcal{A}} &\triangleq \{f : f \in \mathcal{F}^{\mathcal{A}}, J^2(f) \leq \sigma\}. \end{aligned}$$

Let

$$g_{Q,h}(x, a) \triangleq \sum_{j=1}^{|\mathcal{A}|} \mathbb{1}_{\{a=q_j\}} [Q_j(x) - h_j(x)]^2. \quad (40)$$

To simplify the notation, we use $z = (x, a)$ and $Z = (X, A)$ in the rest of this section. Define G_{σ_1, σ_2} as the space of $g_{Q,h}$ functions with $J(Q) \leq \sigma_1$ and $J(h) \leq \sigma_2$, i.e.,

$$G_{\sigma_1, \sigma_2} \triangleq \left\{ g_{Q,h} : \mathbb{R}^d \times \mathcal{A} \rightarrow \mathbb{R}; Q \in \mathcal{F}_{\sigma_1}^{\mathcal{A}}, h \in \mathcal{F}_{\sigma_2}^{\mathcal{A}} \right\}. \quad (41)$$

The following lemma provides an upper bound on the covering numbers of G_{σ_1, σ_2} .

Lemma 20 (Covering Number) *Let Assumptions A3, A4, and A5 hold. Then there exists a constant $c_1 > 0$, independent of $\sigma_1, \sigma_2, \alpha, Q_{\max}$, and $|\mathcal{A}|$, such that for any $u > 0$ and all $((x_1, a_1), \dots, (x_n, a_n)) \in \mathcal{X} \times \mathcal{A}$, the empirical covering number of the class of functions G_{σ_1, σ_2} defined in [\(41\)](#) w.r.t. the empirical norm $\|\cdot\|_{2, z_{1:n}}$ is upper bounded by*

$$\log N_2(u, G_{\sigma_1, \sigma_2}, (x, a)_{1:n}) \leq c_1 |\mathcal{A}|^{1+\alpha} Q_{\max}^{2\alpha} (\sigma_1^\alpha + \sigma_2^\alpha) u^{-2\alpha}.$$

Proof See [Appendix E](#). \blacksquare

Next, we state and prove [Lemma 21](#), which provides a high probability upper bound on $I_{2,n}$.

Lemma 21 *Let $I_{2,n}$ be defined according to [\(36\)](#). Under Assumptions A1–A5 and A7 and with the choice of*

$$\lambda_{h,n} = \lambda_{Q,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}},$$

there exist constants $c_1, c_2, c_3 > 0$, such that for any $n \in \mathbb{N}$, finite $J(Q^\pi)$, L_R , and L_P , and $\delta > 0$ we have

$$I_{2,n} \leq c_1 \frac{L_R^{\frac{2\alpha}{1+\alpha}} + [J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}} [\ln(1/\delta)]^{\frac{1+\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}} + c_2 \frac{(1 + \gamma^2 L_P^2)^\alpha}{n \lambda_{Q,n}} + c_3 \frac{\ln(1/\delta)}{n},$$

with probability at least $1 - \delta$.

Proof Let $Z = (X, A)$ be a random variable with distribution ν that is independent from \mathcal{D}_n . Without loss of generality, we assume that $Q_{\max} \geq 1/2$. We use the peeling device in conjunction with Lemmas 20 and 22 to obtain a tight high-probability upper bound on $I_{2,n}$. Based on the definition of $I_{2,n}$ in (36) we have

$$\mathbb{P}\{I_{2,n} > t\} = \mathbb{P}\left\{\frac{\mathbb{E}\left[g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z)|\mathcal{D}_n\right] - \frac{1}{n}\sum_{i=1}^n g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z_i)}{t + 2\lambda_{Q,n} J^2(\hat{Q})} + \mathbb{E}\left[g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z)|\mathcal{D}_n\right]}\right\} > \frac{1}{2}. \quad (42)$$

To benefit from the peeling device, we relate the complexity of $\hat{h}_n(\cdot; \hat{Q})$ to the complexity of \hat{Q} . For a fixed $\delta_1 > 0$ and some constant $c > 0$, to be specified shortly, define the following event:

$$\mathcal{A}_0 = \left\{\omega : J^2(\hat{h}_n(\cdot; \hat{Q})) \leq c \left(J^2(T^\pi \hat{Q}) + J^2(\hat{Q}) + J^2(Q^\pi) \ln(1/\delta_1)\right)\right\}.$$

Lemma 17 indicates that $\mathbb{P}\{\mathcal{A}_0\} \geq 1 - \delta_1$, where the constant c here can be chosen to be three times of the squared value of the constant in the lemma. We have $\mathbb{P}\{I_{2,n} > t\} = \mathbb{P}\{I_{2,n} > t, \mathcal{A}_0^c\} + \mathbb{P}\{I_{2,n} > t, \mathcal{A}_0\} \leq \delta_1 + \mathbb{P}\{I_{2,n} > t, \mathcal{A}_0\}$, so we focus on upper bounding $\mathbb{P}\{I_{2,n} > t, \mathcal{A}_0\}$.

Since $\hat{Q} \in \mathcal{F}^{|\mathcal{A}|}$, there exists $l \in \mathbb{N}_0$ such that $2^{l\mathbb{H}}(l \neq 0) \leq 2\lambda_{Q,n} J^2(\hat{Q}) < 2^{l+1}t$. Fix $l \in \mathbb{N}_0$. For any $Q \in \mathcal{F}^{|\mathcal{A}|}$, Assumption A7 relates $J(T^\pi Q)$ to $J(Q)$:

$$J^2(Q) \leq \frac{2^l t}{\lambda_{Q,n}} \Rightarrow J^2(T^\pi Q) \leq 2 \left(L_R^2 + \gamma^2 L_P^2 \frac{2^l t}{\lambda_{Q,n}}\right).$$

Thus on the event \mathcal{A}_0 , if $\hat{Q} \in \mathcal{F}_{\sigma_1^l}^{|\mathcal{A}|}$ where $\sigma_1^l = \frac{2^l t}{\lambda_{Q,n}}$, we also have $\hat{h}_n(\hat{Q}) \in \mathcal{F}_{\sigma_2^l}^{|\mathcal{A}|}$ with

$$\sigma_2^l = c \left[2 \left(L_R^2 + (1 + \gamma^2 L_P^2) \frac{2^l t}{\lambda_{Q,n}}\right) + J^2(Q^\pi) \ln(1/\delta_1)\right]. \quad (43)$$

Apply the peeling device on (42). Use (43) and note that if for an $l \in \mathbb{N}_0$ we have $2\lambda_{Q,n} J^2(\hat{Q}) \geq 2^{l\mathbb{H}}(l \neq 0)$, we also have $t + 2\lambda_{Q,n} J^2(\hat{Q}) \geq 2^l t$ to get

$$\begin{aligned} \mathbb{P}\{I_{2,n} > t\} &= \mathbb{P}\{I_{2,n} > t, \mathcal{A}_0^c\} + \mathbb{P}\{I_{2,n} > t, \mathcal{A}_0\} \\ &\leq \delta_1 + \sum_{l=0}^{\infty} \mathbb{P}\left\{\mathcal{A}_0, 2^{l\mathbb{H}}(l \neq 0) \leq 2\lambda_{Q,n} J^2(\hat{Q}) < 2^{l+1}t\right\} \\ &\leq \delta_1 + \sum_{l=0}^{\infty} \mathbb{P}\left\{\frac{\mathbb{E}\left[g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z)|\mathcal{D}_n\right] - \frac{1}{n}\sum_{i=1}^n g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z_i)}{t + 2\lambda_{Q,n} J^2(\hat{Q})} + \mathbb{E}\left[g_{\hat{Q}, \hat{h}_n(\cdot; \hat{Q})}(Z)|\mathcal{D}_n\right]}\right\} > \frac{1}{2} \\ &\leq \delta_1 + \sum_{l=0}^{\infty} \mathbb{P}\left\{\sup_{g_{Q,n} \in \mathcal{G}_{\sigma_1^l, \sigma_2^l}} \frac{\mathbb{E}[g_{Q,h}(Z)|\mathcal{D}_n] - \frac{1}{n}\sum_{i=1}^n g_{Q,h}(Z_i)}{2^l t + \mathbb{E}[g_{Q,h}(Z)|\mathcal{D}_n]}\right\} > \frac{1}{2}. \end{aligned} \quad (44)$$

Let us study the behavior of the l^{th} term of the above summation by verifying the conditions of Lemma 22 with the choice of $\varepsilon = \frac{1}{2}$ and $\eta = 2^l t$.

Condition (A1): Since all functions involved are bounded by Q_{\max} , it is easy to see that $|g_{Q,h}(x, u)| \leq \sum_{j=1}^{|\mathcal{A}|} \mathbb{I}_{\{a=a_j\}} |Q_j(x) - h_j(x)|^2 \leq 4Q_{\max}^2$. Therefore, K_1 , defined in Lemma 22, can be set to $K_1 = 4Q_{\max}^2$.

Condition (A2): We have $\mathbb{E}\left[|Q(Z) - h(Z)|^2\right] \leq 4Q_{\max}^2 \mathbb{E}\left[|Q(Z) - h(Z)|^2\right]$. Therefore, K_2 can be set to $K_2 = 4Q_{\max}^2$.

Condition (A3): We should satisfy $\frac{\sqrt{2}}{4} \sqrt{\eta \eta} \geq 288 \max\{8Q_{\max}^2, \sqrt{8}Q_{\max}\}$. Since $\eta = 2^l t \geq t$, it is sufficient to have

$$t \geq \frac{c}{n}, \quad (C1)$$

in which c is a function of Q_{\max} (we can choose $c = 2 \times 4608^2 Q_{\max}^4$).

Condition (A4): We shall verify that for $\varepsilon' \geq \frac{1}{8}\eta = \frac{1}{8}2^l t$, and $\sigma_1 = \sigma_1^l$ and $\sigma_2 = \sigma_2^l$, the following holds:

$$\begin{aligned} \frac{\sqrt{n}(\frac{1}{2})\varepsilon'}{96\sqrt{2} \max\{K_1, 2K_2\}} &\geq \\ \int_{\frac{1}{16 \max\{K_1, 2K_2\}} \varepsilon'}^{\sqrt{\varepsilon'}} \left(\log \mathcal{N}_2\left(u, \left\{g \in \mathcal{G}_{\sigma_1, \sigma_2} : \frac{1}{n} \sum_{i=1}^n g^2(z_i) \leq 16\varepsilon'\right\}, z_{1:n}\right)\right)^{1/2} &du. \end{aligned} \quad (45)$$

Notice that there exists a constant $c > 0$ such that for any $u, \varepsilon' > 0$

$$\begin{aligned} \log \mathcal{N}_2\left(u, \left\{g \in \mathcal{G}_{\sigma_1, \sigma_2} : \frac{1}{n} \sum_{i=1}^n g^2(z_i) \leq 16\varepsilon'\right\}, z_{1:n}\right) &\leq \log \mathcal{N}_2(u, \mathcal{G}_{\sigma_1, \sigma_2}, z_{1:n}) \\ &\leq c(\sigma_1^l + \sigma_2^l)u^{-2\alpha}, \end{aligned} \quad (46)$$

where we used Lemma 20 in the second inequality.

Plug (46) into (45) with the choice of $\sigma_1 = \sigma_1^l = \frac{2^l t}{\lambda_{Q,n}}$ and $\sigma_2 = \sigma_2^l = c[2(L_R^2 + (1 + \gamma^2 L_P^2) \frac{2^l t}{\lambda_{Q,n}}) + J^2(Q^\pi) \ln(1/\delta_1)]$. Therefore, for some constant $c' = c'(Q_{\max}) > 0$, the inequality

$$c' \sqrt{n} \varepsilon' \geq \int_0^{\sqrt{\varepsilon'}} \underbrace{\left(\frac{2^l t}{\lambda_{Q,n}}\right)^\alpha + c \left[2 \left(L_R^2 + (1 + \gamma^2 L_P^2) \frac{2^l t}{\lambda_{Q,n}}\right) + J^2(Q^\pi) \ln(1/\delta_1)\right]^\alpha}_{(b)} u^{-\alpha} du,$$

implies (45). Because $(a + b)^{\frac{1}{2}} \leq (a^{\frac{1}{2}} + b^{\frac{1}{2}})$ for non-negative a and b , it suffices to verify the following two conditions:

(a) We shall verify that for $\varepsilon' \geq \frac{1}{8}2^l t$, we have

$$c \sqrt{n} \varepsilon' \geq \left(\frac{2^l t}{\lambda_{Q,n}}\right)^\alpha \varepsilon'^{\frac{1-2\alpha}{2}} \Leftrightarrow c \frac{\sqrt{n} \varepsilon'^{\frac{1+2\alpha}{2}} \lambda_{Q,n}^{\frac{\alpha}{2}}}{(2^l t)^{\frac{\alpha}{2}}} \geq 1$$

for some $c > 0$. Substituting ε' with $2^t t$, we see that it is enough if for some constant $c > 0$,

$$t \geq \frac{c}{2^t n \lambda_{Q,n}^{\alpha}}. \quad (D1)$$

(b) We should verify that for $\varepsilon' \geq \frac{5}{8} 2^t t$, the following is satisfied:

$$\sqrt{n\varepsilon'} \geq c \left[\underbrace{L_R^2 + (1 + \gamma^2 L_P^2)}_{(b_1)} \underbrace{\lambda_{Q,n}^{-2t}}_{(b_2)} + \underbrace{J^2(Q^\pi) \ln(1/\delta)}_{(b_3)} \right]^{\alpha/2} \varepsilon'^{\frac{1-\alpha}{2}},$$

for some $c > 0$. After some manipulations, we get that the previous inequality holds if the following three inequalities are satisfied:

$$(b_1) : \quad t \geq c_1' \frac{L_R^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}}, \quad (D2)$$

$$(b_2) : \quad t \geq c_2' \frac{(1 + \gamma^2 L_P^2)^\alpha}{n \lambda_{Q,n}^\alpha}, \quad (D3)$$

$$(b_3) : \quad t \geq c_3' \frac{[J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}} \ln(1/\delta)]^{\frac{\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}}, \quad (D4)$$

for some constants $c_1', c_2', c_3' > 0$.

Fix $\delta > 0$ and let $\delta_1 \equiv \delta/2$. Whenever (C1), (D1), (D2), (D3), and (D4) are satisfied, for some choice of constants $c, c' > 0$ we have

$$\begin{aligned} \mathbb{P}\{I_{2n} > t\} &\leq \frac{\delta}{2} + \sum_{l=0}^{\infty} 60 \exp\left(-\frac{n(2^l)(\frac{1}{4})(1-\frac{1}{2})}{128 \times 2304 \times \max\{16Q_{\max}^4, 4Q_2^2\}}\right) \\ &\leq \frac{\delta}{2} + c \exp(-c'n t). \end{aligned}$$

Let the left-hand side be equal δ and solve for t . Considering all aforementioned conditions, we get that there exist constants $c_1, c_2, c_3 > 0$ such that for any $n \in \mathbb{N}$, finite $J(Q^\pi)$, L_R , and L_P , and $\delta > 0$, we have

$$I_{2n} \leq c_1 \frac{L_R^{\frac{2\alpha}{1+\alpha}} + [J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}} \ln(1/\delta)]^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}} + c_2 \frac{(1 + \gamma^2 L_P^2)^\alpha}{n \lambda_{Q,n}^\alpha} + c_3 \frac{\ln(1/\delta)}{n},$$

with probability at least $1 - \delta$. ■

After developing these tools, we are ready to prove Theorem 11.

Proof [Proof of Theorem 11] We want to show that $\|\hat{Q} - T^\pi \hat{Q}\|_\nu$ is small. Since (15)-(16) minimize $\|h_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu$ and $\|\hat{Q} - h_n(\cdot; \hat{Q})\|_\nu$, we upper bound $\|\hat{Q} - T^\pi \hat{Q}\|_\nu$ in terms of these quantities as follows:

$$\|\hat{Q} - T^\pi \hat{Q}\|_\nu^2 \leq 2 \|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\nu^2 + 2 \|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu^2. \quad (47)$$

Let us upper bound each of these two terms in the RHS. Fix $0 < \delta < 1$. **Bounding** $\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu$: Lemma 15 indicates that there exist constants $c_1, c_2 > 0$ such that for any random $\hat{Q} \in \mathcal{F}^{|\mathcal{A}|}$ and any fixed $n \in \mathbb{N}$, we have

$$\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu^2 \leq \lambda_{h,n} \left(2J^2(\hat{Q}) + 4J^2(T^\pi \hat{Q}) \right) + c_1 \frac{1}{n \lambda_{h,n}^\alpha} + c_2 \frac{\ln(3/\delta)}{n}, \quad (48)$$

with probability at least $1 - \delta/3$. Note that $T^\pi \hat{Q} \in \mathcal{F}^{|\mathcal{A}|}$ is implied by Assumption A7 and $\hat{Q} \in \mathcal{F}^{|\mathcal{A}|}$.

Because \hat{Q} is random itself, the terms $J(\hat{Q})$ and $J(T^\pi \hat{Q})$ in the upper bound of (48) are also random. In order to upper bound them, we use Lemma 18, which states that upon the choice of $\lambda_{h,n} = \lambda_{Q,n} = \lfloor \frac{1}{nJ^2(\hat{Q}^\pi)} \rfloor^{\frac{1}{1+\alpha}}$, there exists a constant $c_3 > 0$ such that for any $n \in \mathbb{N}$,

$$\lambda_{h,n} J^2(\hat{Q}) = \lambda_{Q,n} J^2(\hat{Q}) \leq \lambda_{Q,n} J^2(Q^\pi) + c_3 \frac{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi)}{n^{\frac{1+\alpha}{1+\alpha}}} \ln(3/\delta) \quad (49)$$

holds with probability at least $1 - \delta/3$. We use Assumption A7 to show that we have

$$\lambda_{h,n} J^2(T^\pi \hat{Q}) \leq 2\lambda_{Q,n} L_R^2 + 2(\gamma L_P)^2 \left(\lambda_{Q,n} J^2(Q^\pi) + c_3 \frac{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi)}{n^{\frac{1+\alpha}{1+\alpha}}} \ln(3/\delta) \right), \quad (50)$$

with the same probability. Plugging (49) and (50) into (48) and using the selected schedule for $\lambda_{Q,n}$ and $\lambda_{h,n}$, we get

$$\begin{aligned} \|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu^2 &\leq \\ &\left[(2 + c_1 + 8(\gamma L_P)^2) J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) + c_3 (2 + 8(\gamma L_P)^2) J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(3/\delta) + \frac{8L_R^2}{J^{\frac{2\alpha}{1+\alpha}}(Q^\pi)} \frac{1}{n^{\frac{1+\alpha}{1+\alpha}}} \right. \\ &\quad \left. + c_2 \frac{\ln(3/\delta)}{n} \right] \end{aligned}$$

with probability at least $1 - \frac{2}{3}\delta$. By the proper choice of constants, the term $c_2 n^{-1} \ln(3/\delta)$ can be absorbed into $n^{\frac{1}{1+\alpha}} \ln(3/\delta)$. Therefore, there exists a constant $c_4 > 0$ such that

$$\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_\nu^2 \leq \left[c_4 [1 + (\gamma L_P)^2] J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta) + \frac{8L_R^2}{[J(Q^\pi)]^{\frac{2}{1+\alpha}}} \frac{1}{n^{\frac{1+\alpha}{1+\alpha}}} \right], \quad (51)$$

with probability at least $1 - \frac{2}{3}\delta$.

Bounding $\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\nu$: With our choice of $\lambda_{Q,n}$ and $\lambda_{h,n}$, Lemma 19 states that there exists a constant $c_5 > 0$ such that for any $n \in \mathbb{N}$,

$$\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_\nu^2 \leq c_5 \frac{(1 + \gamma^2 L_P^2)^\alpha J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta) + L_R^{\frac{2\alpha}{1+\alpha}}}{n^{\frac{1+\alpha}{1+\alpha}}}, \quad (52)$$

holds with probability at least $1 - \delta/3$.

Thus, inequality (47) alongside upper bounds (51) and (52) indicate that there exist constants $c_6, c_7 > 0$ such that for any $n \in \mathbb{N}$ and $\delta > 0$, we have

$$\|\hat{Q} - T^\pi \hat{Q}\|_{\infty}^2 \leq \frac{c_6 \left[1 + (\gamma L_P)^2 \right] J_{1+\frac{2}{1-\alpha}}(Q^\pi) \ln(1/\delta) + c_7 \left(\frac{L_R^2}{J(Q^\pi)^{1+\frac{2}{1-\alpha}}} + \frac{L_h^2}{[J(Q^\pi)]^{1+\frac{2}{1-\alpha}}} \right)}{n^{\frac{1}{1+\alpha}}},$$

with probability at least $1 - \delta$. ■

A careful study of the proof of Theorem 11 and the auxiliary results used in it reveals that one can indeed reuse a single data set in all iterations. Recall that at the k^{th} iteration of an API procedure such as REG-LSPI, the policy $\pi = \pi_k$ is the greedy policy w.r.t. $\hat{Q}^{(k-1)}$, so it depends on earlier data sets. This implies that a function such as $T^\pi \hat{Q} = T^{\pi(\cdot; \hat{Q}^{(k-1)})} \hat{Q}$ is random with two sources of randomness: One source is the data set used in the current iteration, which defines the empirical loss functions. This directly affects \hat{Q} . The other source is $\hat{\pi}(\cdot; \hat{Q}^{(k-1)})$, which depends on the data sets in earlier iterations. When we assume that all data sets are independent from each other, the randomness of π does not cause any problem because we can work on the probability space conditioned on the data sets of the earlier iterations. Conditioned on that randomness, the policy π becomes a deterministic function. This is how we presented the statement of Theorem 11 by stating that π is fixed. Nonetheless, the proofs can handle the dependence with no change. Briefly speaking, the reason is that when we want to provide a high probability upper bounds on certain random quantities, we take the supremum over both \hat{Q} and $T^\pi \hat{Q}$ and consider them as two separate functions, even though they are related through a random T^π operator.

To see this more clearly, notice that in the proof of Lemma 15, which is used in the proof of this theorem, we define the function spaces \mathcal{G}_l that chooses the functions h, Q , and $T^\pi Q$ separately. We then take the supremum over all functions in \mathcal{G}_l . This means that for the probabilistic upper bound, the randomness of π in $T^\pi Q$ becomes effectively irrelevant as we are providing a uniform over \mathcal{G}_l guarantee. In the proof of this theorem, we also use Lemma 19, which itself uses Theorem 16 and Lemma 21 that have a similar construct.

Appendix C. Proof of Lemma 15 (Convergence of $\hat{h}_n(\cdot; Q)$ to $T^\pi Q$)

The following lemma, quoted from Györfi et al. (2002), provides an exponential probability tail inequality for the relative deviation of the empirical mean from the true mean. A slightly modified version of this result was published as Theorem 2 of Kohler (2000). This result is used in the proof of Lemmas 15 and 21.

Lemma 22 (Theorem 19.3 of Györfi et al. 2002) *Let Z, Z_1, \dots, Z_n be independent and identically distributed random variables with values in \mathcal{Z} . Let $0 < \varepsilon < 1$ and $\eta > 0$. Assume that $K_1, K_2 \geq 1$ and let \mathcal{F} be a permissible class of functions $f: \mathcal{Z} \rightarrow \mathbb{R}$ with the following properties:*

- (A1) $\|f\|_{\infty} \leq K_1$,
- (A2) $\mathbb{E}[f(Z)^2] \leq K_2 \mathbb{E}[f(Z)]$,

(A3) $\sqrt{n\varepsilon} \sqrt{1 - \varepsilon} \sqrt{\eta} \geq 288 \max\{2K_1, \sqrt{2K_2}\}$,

(A4) For all $z_1, \dots, z_n \in \mathcal{Z}$ and all $\delta \geq \eta/8$,

$$\frac{\sqrt{n\varepsilon(1 - \varepsilon)\delta}}{96\sqrt{2} \max\{K_1, 2K_2\}} \geq \int_{\frac{\varepsilon(1 - \varepsilon)\delta}{16 \max\{K_1, 2K_2\}}}^{\sqrt{\delta}} \log \mathcal{N}_2 \left(u, \left\{ f \in \mathcal{F} : \frac{1}{n} \sum_{i=1}^n f^2(z_i) \leq 16\delta \right\}, z_{1:n} \right) du.$$

Then

$$\mathbb{P} \left\{ \sup_{f \in \mathcal{F}} \frac{|\mathbb{E}[f(Z)] - \frac{1}{n} \sum_{i=1}^n f(Z_i)|}{\eta + \mathbb{E}[f(Z)]} > \varepsilon \right\} \leq 60 \exp \left(- \frac{n \eta \varepsilon^2 (1 - \varepsilon)}{128 \times 2304 \max\{K_1^2, K_2\}} \right).$$

Let us now turn to the proof of Lemma 15. This proof follows similar steps to the proof of Theorem 21.1 of Györfi et al. (2002).

Proof [Proof of Lemma 15] Without loss of generality, assume that $Q_{\max} \geq 1/2$. Denote $z = (x, a)$ and let $Z = (X, A) \sim \nu$, $R \sim \mathcal{R}(\cdot|X, A)$, and $X' \sim P(\cdot|X, A)$ be random variables that are independent of $\mathcal{D}_n = \{(X_i, A_i, R_i, X'_i)\}_{i=1}^n$. Define the following error decomposition

$$\begin{aligned} \int_{\mathcal{X} \times \mathcal{A}} |\hat{h}_n(z; Q) - T^\pi Q(z)|^2 d\nu(z) &= \mathbb{E} \left[|\hat{h}_n(Z; Q) - [R + \gamma Q(X', \pi(X'))]|^2 \middle| \mathcal{D}_n \right] - \\ &= \mathbb{E} \left[|T^\pi Q(Z) - [R + \gamma Q(X', \pi(X'))]|^2 \right] \\ &= I_{1,n} + I_{2,n}, \end{aligned}$$

with

$$\begin{aligned} \frac{1}{2} I_{1,n} &= \frac{1}{n} \sum_{i=1}^n |\hat{h}_n(Z_i; Q) - [R_i + \gamma Q(X'_i, \pi(X'_i))]|^2 - |T^\pi Q(Z_i) - [R_i + \gamma Q(X'_i, \pi(X'_i))]|^2 + \\ &\quad \lambda_{h,n} \left(J^2(\hat{h}_n(\cdot; Q)) + J^2(Q) + J^2(T^\pi Q) \right), \\ I_{2,n} &= \mathbb{E} \left[|\hat{h}_n(Z; Q) - \hat{T}^\pi Q(Z)|^2 - |T^\pi Q(Z) - \hat{T}^\pi Q(Z)|^2 \middle| \mathcal{D}_n \right] - I_{1,n}. \end{aligned}$$

By the optimizer property of $\hat{h}_n(\cdot; Q)$, we get the following upper bound by substituting $\hat{h}_n(\cdot; Q)$ with $T^\pi Q \in \mathcal{F}^{-|A|}$:

$$\begin{aligned} I_{1,n} &\leq 2 \left[\frac{1}{n} \sum_{i=1}^n |T^\pi Q(Z_i) - \hat{T}^\pi Q(Z_i)|^2 - |T^\pi Q(Z_i) - \hat{T}^\pi Q(Z_i)|^2 \right] + \\ &\quad \lambda_{h,n} (J^2(T^\pi Q) + J^2(Q) + J^2(T^\pi Q)) \\ &= 4\lambda_{h,n} J^2(T^\pi Q) + 2\lambda_{h,n} J^2(Q). \end{aligned} \tag{53}$$

We now turn to upper bounding $\mathbb{P}\{I_{2,n} > t\}$. Given a policy π and functions $h, Q, Q' \in \mathcal{F}^{|\mathcal{A}|}$, for $w = (x, a, r, x')$ define $g : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}$ as

$$g_{h,Q,Q'}(w) = |h(z) - [r + \gamma Q(a', \pi(x'))]|^2 - |Q'(z) - [r + \gamma Q(a', \pi(x'))]|^2.$$

Note that $g_{h_n, Q, Q'}(w)$ is the function appearing in the definition of $I_{2,n}$. Define the following function spaces for $l = 0, 1, \dots$:

$$\mathcal{G}_l \triangleq \left\{ g_{h,Q,Q'} : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R} : h, Q, Q' \in \mathcal{F}^{|\mathcal{A}|}, J^2(h), J^2(Q), J^2(Q') \leq \frac{2^l t}{\lambda_{h,n}} \right\}.$$

Denote $W = (X, A, R, X')$ and $W_i = (X_i, A_i, R_i, X'_i)$. Apply the peeling device to get

$$\begin{aligned} \mathbb{P}\{I_{2,n} > t\} &\leq \sum_{l=0}^{\infty} \mathbb{P}\left(\exists h, Q \in \mathcal{F}^{|\mathcal{A}|}, 2^l \mathbb{1}_{\{t \neq 0\}} \leq 2\lambda_{h,n} (J^2(h) + J^2(Q)) + J^2(T^\pi Q)\right) < 2^{l+1} t; \\ &\quad \text{s.t. } \frac{\mathbb{E}[g_{h,Q,T^\pi Q}(W)|\mathcal{D}_n] - \frac{1}{n} \sum_{i=1}^n g_{h,Q,T^\pi Q}(W_i)}{t + 2\lambda_{h,n} (J^2(h) + J^2(Q)) + J^2(T^\pi Q)} + \mathbb{E}[g_{h,Q'}(W)|\mathcal{D}_n] > \frac{1}{2} \\ &\leq \sum_{l=0}^{\infty} \mathbb{P}\left(\sup_{g \in \mathcal{G}_l} \frac{\mathbb{E}[g(W)|\mathcal{D}_n] - \frac{1}{n} \sum_{i=1}^n g(W_i)}{2^l t + \mathbb{E}[g(W)|\mathcal{D}_n]} > \frac{1}{2}\right). \end{aligned}$$

Here we used the simple fact that if $2\lambda_{h,n} (J^2(h) + J^2(Q)) + J^2(T^\pi Q) < 2^{l+1} t$, then $J^2(h)$, $J^2(Q)$, and $J^2(T^\pi Q)$ are also less than $\frac{2^l t}{\lambda_{h,n}}$, so $g_{h,Q,T^\pi Q} \in \mathcal{G}_l$.

We study the behavior of the l th term of the above summation by verifying the conditions of Lemma 22—similar to what we did in the proof of Lemma 21.

It is easy to verify that (A1) and (A2) are satisfied with the choice of $K_1 = K_2 = 4Q_{\max}^2$. Condition (A3) is satisfied whenever

$$t \geq \frac{c_1}{n}, \quad (54)$$

for some constant $c_1 > 0$ depending on Q_{\max} (the constant can be set to $c_1 = 2 \times 4608^2 Q_{\max}^2$).

To verify condition (A4), we first require an upper bound on $N_2^2(u, \mathcal{G}_l, w_{1:n})$ for any sequence $w_{1:n}$. This can be done similar to the proof of Lemma 20: Denote $\mathcal{F}_l = \{f : f \in \mathcal{F}, J^2(f) \leq \frac{2^l t}{\lambda_{h,n}}\}$. For $g_{h_1, Q_1, T^\pi Q_1}, g_{h_2, Q_2, T^\pi Q_2} \in \mathcal{G}_l$ and any sequence $w_{1:n}$ we have

$$\begin{aligned} &\frac{1}{2} \sum_{i=1}^n |g_{h_1, Q_1, T^\pi Q_1}(w_i) - g_{h_2, Q_2, T^\pi Q_2}(w_i)|^2 \\ &\leq 12(2 + \gamma)^2 Q_{\max}^2 \frac{1}{n} \sum_{i=1}^n \left[|h_1(z_i) - h_2(z_i)|^2 + 4\gamma^2 |Q_1(x'_i, \pi(x'_i)) - Q_2(x'_i, \pi(x'_i))|^2 + \right. \\ &\quad \left. |T^\pi Q_1(z_i) - T^\pi Q_2(z_i)|^2 \right] \\ &\leq 12(2 + \gamma)^2 Q_{\max}^2 \frac{1}{n} \sum_{a \in \mathcal{A}} \sum_{i=1}^n \left[|h_1(x_i, a) - h_2(x_i, a)|^2 + 4\gamma^2 |Q_1(x'_i, a) - Q_2(x'_i, a)|^2 + \right. \\ &\quad \left. |T^\pi Q_1(x_i, a) - T^\pi Q_2(x_i, a)|^2 \right]. \end{aligned}$$

With the same covering set argument as in the proof of Lemma 20, we get that for any $u > 0$,

$$N_2(\sqrt{2|\mathcal{A}|} Q_{\max} u, \mathcal{G}_l, w_{1:n}) \leq N_2^2(u, \mathcal{F}_l, x_{1:n})^{|\mathcal{A}|} \times N_2^2(u, \mathcal{F}_l, x'_{1:n})^{|\mathcal{A}|} \times N_2^2(u, \mathcal{F}_l, x_{1:n})^{|\mathcal{A}|}.$$

Invoke Assumption A4 to get

$$\log N_2(u, \mathcal{G}_l, w_{1:n}) \leq c(|\mathcal{A}|, Q_{\max}) \left(\frac{2^l t}{\lambda_{h,n}} \right)^\alpha u^{-2\alpha}.$$

Plugging this covering number result into condition (A4), one can verify that the condition is satisfied if

$$t \geq \frac{c_2}{n \lambda_{h,n}^\alpha}, \quad (55)$$

for a constant $c_2 > 0$, which is only a function of Q_{\max} and $|\mathcal{A}|$. Therefore, Lemma 22 indicates that

$$\mathbb{P}\{I_{2,n} > t\} \leq 60 \sum_{l=0}^{\infty} \exp\left(-\frac{n(2^l t)(1/4)(1/2)}{128 \times 2304 \times \max\{16Q_{\max}^4, 4Q_{\max}^2\}}\right) \leq c_3 \exp(-c_4 n t). \quad (56)$$

for some constants $c_3, c_4 > 0$.

Combining (53), (54), (55), and (56), we find that there exist $c_5, c_6 > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, we have

$$\| \hat{h}_n(Q) - T^\pi Q \|_{\mu}^2 \leq 4\lambda_{h,n} J^2(T^\pi Q) + 2\lambda_{h,n} J^2(Q) + c_5 \frac{1}{n \lambda_{h,n}^\alpha} + c_6 \frac{\ln(1/\delta)}{n}.$$

Here, c_5 is only a function of Q_{\max} and $|\mathcal{A}|$, and c_6 is a function of Q_{\max} . ■

Appendix D. Proof of Theorem 16 (Empirical Error and Smoothness of $\hat{h}_n(\cdot; Q)$)

To prove Theorem 16, which is a modification of Theorem 10.2 by van de Geer (2000), we first need to modify and specialize Lemma 3.2 by van de Geer (2000) to be suitable to our problem. The modification is required because Q in (33) is a random function in $\mathcal{F}^{|\mathcal{A}|}$ as opposed to being a fixed function as in Theorem 10.2 of van de Geer (2000).

Let us denote $z = (x, a) \in \mathcal{Z} = \mathcal{X} \times \mathcal{A}$ and $Z' = (x, a, R, X') \in \mathcal{Z}' = \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X}$ with $(R, X') \sim P(\cdot, \cdot | x, a)$. Let \mathcal{D}_n denote the set $\{(x_i, a_i, R_i, X'_i)\}_{i=1}^n$ of independent random variables. We use z_i to refer to (x_i, a_i) and Z'_i to refer to (x_i, a_i, R_i, X'_i) . Let P_n be the probability measure that puts mass $1/n$ on z_1, \dots, z_n , i.e., $P_n = \frac{1}{n} \sum_{i=1}^n \delta_{z_i}$, in which δ_z is the Dirac's delta function that puts a mass of 1 at z .

Denote $\mathcal{G} : \mathcal{Z} \rightarrow \mathbb{R}$ and $\mathcal{G}' : \mathcal{Z}' \rightarrow \mathbb{R}^{3|\mathcal{A}|}$, which is defined as the set

$$\mathcal{G}' = \left\{ (Q, T^\pi Q, \mathbf{1}) : Q \in \mathcal{F}^{|\mathcal{A}|} \right\}$$

with $\mathbf{1} : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}^{|\mathcal{A}|}$ being a bounded constant function (and not necessarily equal to 1). We use $\|g\|_\infty$ to denote the supremum norm of functions in \mathcal{G} . The supremum norm of vector-valued functions in \mathcal{G}' is defined by taking the supremum norm over the l_∞ -norm of each vector. Similarly, the supremum norm of $(g, g') \in \mathcal{G} \times \mathcal{G}'$ is defined by $\|(g, g')\|_\infty \triangleq \max\{\|g\|_\infty, \|g'\|_\infty\}$.

For $g \in \mathcal{G}$, we define $\|g\|_{P_n} \triangleq [\frac{1}{n} \sum_{i=1}^n g^2(z_i)]^{1/2}$. To simplify the notation, we use the following definition of the inner product: Fix $n \in \mathbb{N}$. Consider z_1, \dots, z_n as a set of points in \mathcal{Z} , and a real-valued sequence $w = (w_1, \dots, w_n)$. For a function $g \in \mathcal{G}$, define $\langle w, g \rangle_n \triangleq \frac{1}{n} \sum_{i=1}^n w_i g(z_i)$.

For any $g' = (Q, T^\pi Q, \mathbf{1}) \in \mathcal{G}'$, define the mapping $\bar{W}(g')(x, a, r, x') : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}$ by $\bar{W}(g')(x, a, r, x') = r + \gamma Q(x', \pi(x')) - T^\pi Q(x, a)$. For any fixed $g' \in \mathcal{G}'$ and $i = 1, \dots, n$, define the random variables $W_i(g') = \bar{W}(g')(Z_i)$ and let $W(g')$ denote the random vector $[W_1(g') \dots W_n(g')]^\top$. Notice that $W_i(g')$ can be re-written as $W_i(g') = (R_i - r(z_i)) + \gamma(Q(X_i, \pi(X_i)) - (P^\pi Q)(z_i))$, thus for any fixed g' , $\mathbb{E}[W_i(g')] = 0$ ($i = 1, \dots, n$). For notational simplification, we use $a \vee b = \max\{a, b\}$.

Lemma 23 (Modified Lemma 3.2 of van de Geer 2000) Fix the sequence $(z_i)_{i=1}^n \subset \mathcal{Z}$ and let $(Z_i)_{i=1}^n \subset \mathcal{Z}'$ be the sequence of independent random variables defined as above. Assume that for some constants $0 < R \leq L$, it holds that $\sup_{g \in \mathcal{G}} \|g\|_{P_n} \leq R$, $\sup_{g' \in \mathcal{G}'} \|g'\|_\infty \leq L$, and $|R_i| \leq L$ ($1 \leq i \leq n$) almost surely. There exists a constant C such that for all $0 \leq \varepsilon < \delta$ satisfying

$$\sqrt{n}(\delta - \varepsilon) \geq C L \left[\int_{\frac{\varepsilon \delta}{25L}}^R \log \mathcal{N}_\infty(u, \mathcal{G} \times \mathcal{G}')^{1/2} du \vee R \right], \quad (57)$$

we have

$$\mathbb{P} \left\{ \sup_{(g, g') \in \mathcal{G} \times \mathcal{G}'} \left| \frac{1}{n} \sum_{i=1}^n W_i(g') g(z_i) \right| \geq \delta \right\} \leq 4 \exp \left(- \frac{n(\delta - \varepsilon)^2}{27 \times 3^5 (RL)^2} \right).$$

The main difference between this lemma and Lemma 3.2 of van de Geer (2000) is that the latter provides a maximal inequality for $\sup_{g \in \mathcal{G}} \frac{1}{n} \sum_{i=1}^n W_i g(z_i)$, with W_i being random variables that satisfy a certain exponential probability inequality, while our result is a maximal inequality for $\sup_{(g, g') \in \mathcal{G} \times \mathcal{G}'} \frac{1}{n} \sum_{i=1}^n W_i(g') g(z_i)$, i.e., the random variables $W_i(g')$ are functions of an arbitrary $g' \in \mathcal{G}'$. The current proof requires us to have a condition on the metric entropy w.r.t. the supremum norm (cf. (57)) instead of w.r.t. the empirical L_2 -norm used in Lemma 3.2 of van de Geer (2000). The possibility of relaxing this requirement is an interesting question. We now prove this result.

Proof First, note that for any $g_1, g_2 \in \mathcal{G}$, and $g'_1, g'_2 \in \mathcal{G}'$ (with the identification of g' with its corresponding Q and $T^\pi Q$), we have

$$\begin{aligned} & \frac{1}{n} \sum_{i=1}^n W_i(g'_1) g_1(z_i) - W_i(g'_2) g_2(z_i) = \\ & \frac{1}{n} \sum_{i=1}^n (R_i - r(z_i))(g_1(z_i) - g_2(z_i)) + \\ & \frac{1}{n} \sum_{i=1}^n \gamma [(Q_1(X'_i, \pi(X'_i)) - P^\pi Q_1(z_i)) - (Q_2(X'_i, \pi(X'_i)) - P^\pi Q_2(z_i))] g_1(z_i) + \\ & \frac{1}{n} \sum_{i=1}^n \gamma (Q_2(X'_i, \pi(X'_i)) - P^\pi Q_2(z_i))(g_1(z_i) - g_2(z_i)) \leq \\ & 2L \|g_1 - g_2\|_{P_n} + \gamma R \|Q_1 - Q_2\|_\infty + \|P^\pi Q_1 - P^\pi Q_2\|_\infty + 3\gamma L \|g_1 - g_2\|_{P_n} = \\ & (2 + 3\gamma)L \|g_1 - g_2\|_{P_n} + \gamma R \|Q_1 - Q_2\|_\infty + R \|T^\pi Q_1 - T^\pi Q_2\|_\infty, \end{aligned} \quad (58)$$

where we used the boundedness assumptions, the definition of the supremum norm, the norm inequality $\frac{1}{n} \sum_{i=1}^n |g_1(z_i) - g_2(z_i)| \leq \|g_1 - g_2\|_{P_n}$, and the fact that $|\gamma(Q(X'_i, \pi(X'_i)) - P^\pi Q(z_i))| = |r(z_i) + \gamma(Q(X'_i, \pi(X'_i)) - T^\pi Q(z_i))| \leq (2 + \gamma)L \leq 3L$ for any L -bounded Q and $T^\pi Q$ to get the inequality. We used $\|P^\pi Q^s - P^\pi Q^{s-1}\|_\infty = \gamma^{-1} \|T^\pi Q^s - T^\pi Q^{s-1}\|_\infty$ to get the last equality.

Let $\{(g'_j, g_j^s)\}_{j=1}^{N_s}$ with $N_s = \mathcal{N}_\infty(2^{-s}R, \mathcal{G} \times \mathcal{G}')$ be a minimal $2^{-s}R$ -covering of $\mathcal{G} \times \mathcal{G}'$ w.r.t. the supremum norm. For any $(g, g') \in \mathcal{G} \times \mathcal{G}'$, there exists a $(g^s, (Q^s, T^\pi Q^s, \mathbf{1})) = (g^s, g^s) \in \{(g'_j, g_j^s)\}_{j=1}^{N_s}$ such that $\|(g, g') - (g^s, g^s)\|_\infty \leq 2^{-s}R$. This implies that both $\|Q^s - Q\|_\infty$ and $\|T^\pi Q^s - T^\pi Q\|_\infty$ are smaller than $2^{-s}R$ as well. Moreover, $\|g^s - g\|_{P_n} \leq \|g^s - g\|_\infty \leq 2^{-s}R$. By (58) we get

$$\begin{aligned} \left| \frac{1}{n} \sum_{i=1}^n W_i(g^s) g^s(z_i) - W_i(g) g(z_i) \right| & \leq [(2 + 3\gamma)L + (1 + \gamma)R](2^{-s}R) \leq (3 + 4\gamma)L(2^{-s}R) \\ & \leq 7RL 2^{-s}. \end{aligned}$$

Choose $S = \min\{s \geq 1 : 2 \cdot 2^{-s} \leq \frac{\varepsilon}{7RL}\}$, which entails that for any $(g, g') \in \mathcal{G} \times \mathcal{G}'$, the covering set defined by $\{(g'_j, g_j^s)\}_{j=1}^{N_s}$ approximates the inner product of $[g(z_1) \dots g(z_n)]^\top$ and $W(g')$ with an error less than ε . So it suffices to prove the exponential inequality for

$$\mathbb{P} \left\{ \max_{j=1, \dots, N_s} \left| \frac{1}{n} \sum_{i=1}^n W_i(g'_j) g_j^s(z_i) \right| \geq \delta - \varepsilon \right\}.$$

We use the chaining technique (e.g., see [van de Geer 2000](#)) as follows (we choose $g^0 = 0$, so $W_i(g^0)g^0(z_i) = 0$ for all $1 \leq i \leq n$):

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n W_i(g^S)g^S(z_i) &= \frac{1}{n} \sum_{i=1}^n \sum_{s=1}^S (W_i(g^s)g^s(z_i) - W_i(g^{s-1})g^{s-1}(z_i)) \\ &= \sum_{s=1}^S \left[\frac{1}{n} \sum_{i=1}^n (R_i - r(z_i))(g^s(z_i) - g^{s-1}(z_i)) + \right. \\ &\quad \left. \frac{1}{n} \sum_{i=1}^n \gamma [(Q^s(X'_i, \pi(X'_i)) - (P^\pi Q^s)(z_i)) - (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))] g^s(z_i) + \right. \\ &\quad \left. \frac{1}{n} \sum_{i=1}^n \gamma (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))(g^s(z_i) - g^{s-1}(z_i)) \right]. \end{aligned}$$

Because each of these summations consists of bounded random variables with expectation zero, we may use Hoeffding's inequality alongside the union bound to upper bound them. To apply Hoeffding's inequality, we require an upper bound on the sum of squared values of random variables involved. To begin, we have $|g^s(z_i) - g^{s-1}(z_i)| = |g^s(z_i) - g(z_i) + g(z_i) - g^{s-1}(z_i)| \leq 2^{-s}R + 2^{-(s-1)}R = 3 \times 2^{-s}R$. Similarly, both $\|Q^s - Q^{s-1}\|_\infty$ and $\|T^\pi Q^s - T^\pi Q^{s-1}\|_\infty$ are smaller than $3 \times 2^{-s}R$. As a result, for the first term we get

$$\frac{1}{n} \sum_{i=1}^n [(R_i - r(z_i))(g^s(z_i) - g^{s-1}(z_i))]^2 \leq 36(RL)^2 2^{-2s}.$$

For the second term we have

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^n |\gamma [(Q^s(X'_i, \pi(X'_i)) - (P^\pi Q^s)(z_i)) - (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))] g^s(z_i)|^2 \\ &\leq 2\gamma^2 \left[\|Q^s - Q^{s-1}\|_\infty^2 + \gamma^{-2} \|T^\pi Q^s - T^\pi Q^{s-1}\|_\infty^2 \right] \|g^s\|_{P_n}^2 \\ &\leq 2(1 + \gamma^2) 3^2 (2^{-s}R)^2 R^2 \leq 36R^4 2^{-2s}, \end{aligned}$$

in which we used $\|P^\pi Q^s - P^\pi Q^{s-1}\|_\infty = \gamma^{-1} \|T^\pi Q^s - T^\pi Q^{s-1}\|_\infty$. And finally,

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^n |\gamma (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))(g^s(z_i) - g^{s-1}(z_i))|^2 \leq (3L)^2 3^2 (2^{-s}R)^2 \\ &= g^s(RL)^2 2^{-2s}, \end{aligned}$$

where we used the fact that $|\gamma Q(X'_i, \pi(X'_i)) - \gamma P^\pi Q(z_i)| \leq 3L$ for any L -bounded Q and $T^\pi Q$.

Let η_s be a sequence of positive real-valued numbers satisfying $\sum_{s=1}^S \eta_s \leq 1$. We continue the chaining argument by the use of the union bound and the fact that $N_s N_{s-1} \leq N_s^2$ to

get

$$\begin{aligned} P_1 &= \mathbb{P} \left\{ \sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \left| \frac{1}{n} \sum_{i=1}^n W_i(g)g(z_i) \right| \geq \delta \right\} \\ &\leq \mathbb{P} \left\{ \max_{j=1, \dots, N_s} \left| \frac{1}{n} \sum_{i=1}^n W_i(g_j^S)g_j^S(z_i) \right| \geq \delta - \varepsilon \right\} \\ &\leq \sum_{s=1}^S \mathbb{P} \left\{ \max_{(g^s, g'^s)} \left| \frac{1}{n} \sum_{i=1}^n (R_i - r(z_i))(g^s(z_i) - g^{s-1}(z_i)) \right| \geq \frac{\eta_s(\delta - \varepsilon)}{3} \right\} + \\ &\quad \mathbb{P} \left\{ \max_{(g^s, g'^s)} \left| \frac{1}{n} \sum_{i=1}^n \gamma [(Q^s(X'_i, \pi(X'_i)) - (P^\pi Q^s)(z_i)) - \right. \right. \\ &\quad \left. \left. (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))] g^s(z_i) \right| \geq \frac{\eta_s(\delta - \varepsilon)}{3} \right\} + \\ &\quad \mathbb{P} \left\{ \max_{(g^s, g'^s)} \left| \frac{1}{n} \sum_{i=1}^n \gamma (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))(g^s(z_i) - g^{s-1}(z_i)) \right| \geq \frac{\eta_s(\delta - \varepsilon)}{3} \right\} \end{aligned}$$

$$\begin{aligned} &\mathbb{P} \left\{ \max_{(g^s, g'^s)} \left| \frac{1}{n} \sum_{i=1}^n \gamma (Q^{s-1}(X'_i, \pi(X'_i)) - (P^\pi Q^{s-1})(z_i))(g^s(z_i) - g^{s-1}(z_i)) \right| \geq \frac{\eta_s(\delta - \varepsilon)}{3} \right\} \\ &\leq \sum_{s=1}^S N_s N_{s-1} \exp \left(-\frac{2(\delta - \varepsilon)^2 \eta_s^2 n}{4 \times g^2 (RL)^2 2^{-2s}} \right) + N_s N_{s-1} \exp \left(-\frac{2(\delta - \varepsilon)^2 \eta_s^2 n}{4 \times g^2 R^2 2^{-2s}} \right) \\ &\leq \sum_{s=1}^S 3 \exp \left(-\frac{2(\delta - \varepsilon)^2 \eta_s^2 n}{3 \times g^2 (RL)^2 2^{-2s}} \right) \\ &\quad N_s N_{s-1} \exp \left(-\frac{2(\delta - \varepsilon)^2 \eta_s^2 n}{3 \times g^2 (RL)^2 2^{-2s}} \right). \end{aligned} \tag{59}$$

Here the $\max_{(g^s, g'^s)}$ is over the corresponding covering set $\{(g_j^s, g_j^s)\}_{j=1}^{N_s}$, which has N_s elements (and the same for $s-1$).

Choose

$$\eta_s = \frac{3^2 \sqrt{6RL} 2^{-s} (\log N_s)^{1/2}}{\sqrt{n}(\delta - \varepsilon)} \vee \frac{2^{-s} \sqrt{s}}{8}. \tag{60}$$

Take C in (57) sufficiently large such that

$$\sqrt{n}(\delta - \varepsilon) \geq 2 \times 3^2 \sqrt{6RL} \sum_{s=1}^S 2^{-s} [\log N_\infty (2^{-s}R, \mathcal{G} \times \mathcal{G}')]^{1/2} \vee 72 \sqrt{6 \log 4 RL}. \tag{61}$$

It can be shown that by this choice of η_s and the condition (61), we have $\sum_{s=1}^S \eta_s \leq 1$.

From (60), we have $\log N_s \leq \frac{n(\delta - \varepsilon)^2 \eta_s^2}{2 \times 3^2 (RL)^2 2^{-2s}}$, so P_1 in (59) can be upper bounded as follows

$$P_1 \leq \sum_{s=1}^S 3 \exp \left(-\frac{n(\delta - \varepsilon)^2 \eta_s^2}{2 \times 3^5 (RL)^2 2^{-2s}} \right).$$

Since $\eta_s \geq 2^{-s}\sqrt{s}/8$ too, we have

$$\begin{aligned} P_1 &\leq 3 \sum_{s=1}^S \exp\left(-\frac{n(\delta-\varepsilon)^2 2^{-2s}}{27 \times 3^5 (RL)^2 2^{-2s}}\right) \leq 3 \sum_{s=1}^{\infty} \exp\left(-\frac{n(\delta-\varepsilon)^2 s}{27 \times 3^5 (RL)^2}\right) \\ &\leq \frac{3 \exp\left(-\frac{n(\delta-\varepsilon)^2}{27 \times 3^5 (RL)^2}\right)}{1 - \exp\left(-\frac{n(\delta-\varepsilon)^2}{27 \times 3^5 (RL)^2}\right)} \leq 4 \exp\left(-\frac{n(\delta-\varepsilon)^2}{27 \times 3^5 (RL)^2}\right), \end{aligned}$$

where in the last inequality we used the assumption that $\sqrt{n}(\delta-\varepsilon) \geq 72\sqrt{6}\log 4 RL$ (cf. (61)).

One can show that (61) is satisfied if

$$\sqrt{n}(\delta-\varepsilon) \geq 36\sqrt{6}L \int_{\frac{\varepsilon}{32L}}^R |\log \mathcal{N}_{\infty}(u, \mathcal{G} \times \mathcal{G}')^{1/2} du| \vee 72\sqrt{6}\log 4 RL,$$

so C can be chosen as $C = 72\sqrt{6}\log 4$. \blacksquare

The following lemma, which is built on Lemma 23, is a result on the behavior of the modulus of continuity and will be used in the proof of Theorem 16. This lemma provides a high-probability upper bound on $\sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g), g)_n|}{\|g\|_{P_n}^{1-\alpha} J^{\alpha}(g,g')}$. Here $J(g, g')$ is a regularizer that is defined on $\mathcal{G} \times \mathcal{G}'$ and is a pseudo-norm.

This result is similar in spirit to Lemma 8.4 of van de Geer (2000), with two main differences: The first is that here we provide an upper bound on

$$\sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g'), g)_n|}{\|g\|_{P_n}^{1-\alpha} J^{\alpha}(g, g')},$$

whereas in Lemma 8.4 of van de Geer (2000), the upper bound is on

$$\sup_{g \in \mathcal{G}} \frac{|(W, g)_n|}{\|g\|_{P_n}^{1-\alpha}}.$$

The normalization by $\|g\|_{P_n}^{1-\alpha} J^{\alpha}(g, g')$ instead of $\|g\|_{P_n}^{1-\alpha}$ is important to get the right error bound in Theorem 16. The other crucial difference is that here W are random variables that are functions of $g' \in \mathcal{G}'$, while the result of van de Geer (2000) is for independent W . The proof technique is inspired by Lemmas 5.13, 5.14, and 8.4 of van de Geer (2000).

Lemma 24 (Modulus of Continuity for Weighted Sums) Fix the sequence $(z_i)_{i=1}^n \subset \mathcal{Z}$ and define $P_n = \frac{1}{n} \sum_{i=1}^n \delta_{z_i}$. Let $(Z_i)_{i=1}^n \subset \mathcal{Z}'$ be the sequence of independent random variables defined as before. Assume that for some constant $L > 0$, it holds that $\sup_{g \in \mathcal{G}} \|g\|_{P_n} \leq L$, $\sup_{g \in \mathcal{G}'} \|g'\|_{\infty} \leq L$, and $|R_i| \leq L$ ($1 \leq i \leq n$) almost surely. Furthermore, suppose that there exist $0 < \alpha < 1$ and a finite constant A such that for all $u > 0$,

$$\log \mathcal{N}_{\infty}(u, \{ (g, g') \in \mathcal{G} \times \mathcal{G}' : J(g, g') \leq B \}) \leq A \left(\frac{B}{u}\right)^{2\alpha}.$$

Then there exists a constant $c > 0$ such that for any $0 < \delta < 1$, we have

$$\sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g'), g)_n|}{\|g\|_{P_n}^{1-\alpha} J^{\alpha}(g, g')} \leq cL^{1+\alpha} \sqrt{\frac{\ln(\frac{1}{\delta})}{n}},$$

with probability at least $1 - \delta$.

Proof The proof uses double-peeling, i.e., we peel on both $J(g, g')$ and $\|g\|_{P_n}$. Without loss of generality, we assume that $L \geq 1$. We use $c_1, c_2, \dots > 0$ as constants. First, we start by peeling on $J(g, g')$:

$$\begin{aligned} \delta &\triangleq \mathbb{P} \left\{ \sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g'), g)_n|}{\|g\|_{P_n}^{1-\alpha} J^{\alpha}(g, g')} \geq t \right\} \\ &\leq \sum_{s=0}^{\infty} \mathbb{P} \left\{ \sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g'), g)_n|}{\|g\|_{P_n}^{1-\alpha}} \geq \underbrace{t \cdot 2^{os}}_{\triangleq \tau_s}, 2^s \mathbb{I}_{\{s \neq 0\}} \leq J(g, g') < 2^{s+1} \right\}. \end{aligned} \quad (62)$$

Let us denote each term in the RHS by δ_s . To upper bound δ_s , notice that by assumption $\|g\|_{P_n} \leq L$. For each term, we peel again, this time on $\|g\|_{P_n}$, and apply Lemma 23:

$$\begin{aligned} \delta_s &\leq \sum_{r \geq 0} \mathbb{P} \left\{ \sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} \frac{|(W(g'), g)_n|}{\|g\|_{P_n}^{1-\alpha}} \geq \tau_s, 2^s \mathbb{I}_{\{s \neq 0\}} \leq J(g, g') < 2^{s+1}, \right. \\ &\quad \left. 2^{-(r+1)}L < \|g\|_{P_n} \leq 2^{-r}L \right\} \\ &\leq \sum_{r \geq 0} \mathbb{P} \left\{ \sup_{(g,g') \in \mathcal{G} \times \mathcal{G}'} |(W(g'), g)_n| \geq \tau_s \left(2^{-(r+1)}L\right)^{1-\alpha}, J(g, g') < 2^{s+1}, \|g\|_{P_n} \leq 2^{-r}L \right\} \\ &\leq \sum_{r \geq 0} 4 \exp \left(-\frac{n \left[\tau_s \left(2^{-(r+1)}L\right)^{1-\alpha} \right]^2}{27 \times 3^5 \left(2^{-r}L\right)^2 L^2} \right) \\ &= \sum_{r \geq 0} 4 \exp \left(-\frac{2^{2r\alpha} n \tau_s^2}{27 \times 3^5 \times 2^{2(1-\alpha)} L^{2(1+\alpha)}} \right) = c_2 \exp \left(-\frac{c_1 n \tau_s^2}{L^{2(1+\alpha)}} \right). \end{aligned} \quad (63)$$

The last inequality holds only if the covering number condition in Lemma 23 is satisfied, which is the case whenever

$$\sqrt{n} \left(\tau_s \left(2^{-(r+1)}L\right)^{1-\alpha} \right) \geq cL \left[\int_0^{2^{-r}L} \sqrt{A} \left(\frac{2^{s+1}}{u}\right)^{\alpha} du \vee 2^{-r}L \right].$$

Substituting $\tau_s = 2^{os}t$ and solving the integral, we get that the condition is

$$\sqrt{nt} 2^{os} \left(2^{-(r+1)}L\right)^{1-\alpha} \geq cL \sqrt{A} \left[(2^{s+1})^{\alpha} \left(2^{-r}L\right)^{1-\alpha} \vee 2^{-r}L\right],$$

which would be satisfied for

$$t \geq \frac{cL \sqrt{A} 2^{1+\alpha}}{\sqrt{n}} \vee \frac{2^{1-\alpha} cL^{1+\alpha}}{\sqrt{n}} = c_3 \frac{L^{1+\alpha}}{\sqrt{n}}. \quad (64)$$

Plug (63) into (62) to get that

$$\delta \leq \sum_{s=0}^{\infty} c_2 \exp\left(-\frac{c_1 n \ell^2 2^{2\alpha s}}{L^{2(1+\alpha)}}\right) = c_4 \exp\left(-\frac{c_1 n \ell^2}{L^{2(1+\alpha)}}\right).$$

Solving for δ , we have $t \leq c_5 L^{1+\alpha} \sqrt{\frac{\ln(1/\delta)}{n}}$ with probability at least $1 - \delta$. This alongside the condition (64) lead to the desired result. \blacksquare

Let us turn to the proof of Theorem 16. The proof is similar to the proof of Theorem 10.2 by van de Geer (2000), but with necessary modifications in order to get a high probability upper bound that holds uniformly over Q . We discuss the differences in more detail after the proof.

Proof [Proof of Theorem 16] Recall that in the optimization problem, we use $w_i = (X_i, A_i, R_i, X_i')$ ($i = 1, \dots, n$) to denote the i th elements of the data set $\mathcal{D}_n = \{(X_i, A_i, R_i, X_i')\}_{i=1}^n$. Also for a measurable function $f : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}$, we denote $\|f\|_n^2 = \frac{1}{n} \sum_{i=1}^n |f(w_i)|^2$. We also let $(X, A) \sim \nu$, $R \sim \mathcal{R}(\cdot | X, A)$, and $X' \sim P(\cdot | X, A)$ be random variables that are independent of \mathcal{D}_n .

For any $Q \in \mathcal{F}^{|\mathcal{A}|}$ and the corresponding $T^\pi Q \in \mathcal{F}^{|\mathcal{A}|}$, define the mapping $\bar{W}(Q, T^\pi Q, \mathbf{1}) : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}$ by $\bar{W}(Q, T^\pi Q, \mathbf{1})(X, A, R, X') = R + \gamma Q(X', \pi(X)) - T^\pi Q(X, A)$, in which $\mathbf{1} \in \mathcal{F}^{|\mathcal{A}|}$ is the constant function defined on $\mathcal{X} \times \mathcal{A}$ with the value of one. For any fixed Q and $t = 1, \dots, n$, define the random variables $W_t(Q) = \bar{W}(Q, T^\pi Q, \mathbf{1})(X_t, A_t, R_t, X_t')$ and let $W(Q)$ denote the random vector $[W_1(Q) \dots W_n(Q)]^\top$. Notice that $|W_t(Q)| \leq 3Q_{\max}$ and we have $\mathbb{E}[W_t(Q) | Q] = 0$ ($t = 1, \dots, n$).

From the optimizer property of $\hat{h}_n(\cdot, Q)$, we have

$$\begin{aligned} \|\hat{h}_n(Q) - [R + \gamma Q(X_i', \pi(X_i'))]\|_n^2 + \lambda_{h_n} J^2(\hat{h}_n(Q)) &\leq \\ \|T^\pi Q - [R + \gamma Q(X_i', \pi(X_i'))]\|_n^2 + \lambda_{h_n} J^2(T^\pi Q). \end{aligned}$$

After expanding and rearranging, we get

$$\|\hat{h}_n(Q) - T^\pi Q\|_n^2 + \lambda_{h_n} J^2(\hat{h}_n(Q)) \leq 2 \left\langle W(Q), \hat{h}_n(Q) - T^\pi Q \right\rangle_n + \lambda_{h_n} J^2(T^\pi Q). \quad (65)$$

We evoke Lemma 24 to upper bound $\left| \left\langle W(Q), \hat{h}_n(Q) - T^\pi Q \right\rangle_n \right|$. The function spaces \mathcal{G} and \mathcal{G}' in that lemma are set as $\mathcal{G} : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$ and $\mathcal{G}' : \mathcal{X} \times \mathcal{A} \times \mathbb{R} \times \mathcal{X} \rightarrow \mathbb{R}^3$ with

$$\begin{aligned} \mathcal{G} &= \left\{ h - T^\pi Q : h, Q \in \mathcal{F}^{|\mathcal{A}|} \right\}, \\ \mathcal{G}' &= \left\{ (Q, T^\pi Q, \mathbf{1}) : Q, T^\pi Q \in \mathcal{F}^{|\mathcal{A}|} \right\}. \end{aligned}$$

All functions in $\mathcal{F}^{|\mathcal{A}|}$ are Q_{\max} -bounded, so the functions in \mathcal{G} and \mathcal{G}' are bounded by $2Q_{\max}$ and $(Q_{\max}, Q_{\max}, 1)$, respectively. Moreover for any $g \in \mathcal{G}$, $\frac{1}{n} \sum_{i=1}^n |g(X_i, A_i)|^2 \leq 4Q_{\max}^2$. So by setting L equal to $2Q_{\max}$ in that lemma, all boundedness conditions are satisfied.

Define $J(g, g') = J(h) + J(Q) + J(T^\pi Q)$ and denote

$$(\mathcal{G} \times \mathcal{G}')_B = \{(g, g') \in \mathcal{G} \times \mathcal{G}' : J(g, g') \leq B\}.$$

Lemma 24 requires an upper bound on $\log \mathcal{N}_\infty(u, (\mathcal{G} \times \mathcal{G}')_B)$. We relate the metric entropy of this space to that of $\mathcal{F}_B = \{f \in \mathcal{F} : J(f) \leq B\}$, which is specified by Assumption A4. Notice that if $J(g, g') \leq B$, each of $J(h)$, $J(Q)$, and $J(T^\pi Q)$ is also less than or equal to B . So we have

$$\begin{aligned} (\mathcal{G} \times \mathcal{G}')_B &= \{(h - T^\pi Q, Q, T^\pi Q, \mathbf{1}) : h, Q, T^\pi Q \in \mathcal{F}^{|\mathcal{A}|}, J(h) + J(Q) + J(T^\pi Q) \leq B\} \subset \\ &\left\{ h - T^\pi Q : h, T^\pi Q \in \mathcal{F}^{|\mathcal{A}|}, J(h) + J(T^\pi Q) \leq B \right\} \times \left\{ Q : Q \in \mathcal{F}^{|\mathcal{A}|}, J(Q) \leq B \right\} \times \\ &\left\{ T^\pi Q : T^\pi Q \in \mathcal{F}^{|\mathcal{A}|}, J(T^\pi Q) \leq B \right\} \times \{\mathbf{1}\}. \end{aligned}$$

Because $J(\cdot)$ is a pseudo-norm, we have $J(h - T^\pi Q) \leq J(h) + J(T^\pi Q)$, so

$$\left\{ h - T^\pi Q : h, T^\pi Q \in \mathcal{F}^{|\mathcal{A}|}, J(h) + J(T^\pi Q) \leq B \right\} \subset \left\{ Q : Q \in \mathcal{F}^{|\mathcal{A}|}, J(Q) \leq B \right\}.$$

As a result $(\mathcal{G} \times \mathcal{G}')_B$ is a subset of the product space $\{Q \in \mathcal{F}^{|\mathcal{A}|} : J(Q) \leq B\}^3$. Therefore by the usual covering argument, we get that

$$\log \mathcal{N}_\infty(u, (\mathcal{G} \times \mathcal{G}')_B) \leq 3 \log \mathcal{N}_\infty\left(u, \left\{ Q \in \mathcal{F}^{|\mathcal{A}|} : J(Q) \leq B \right\}\right).$$

It is easy to see that for finite $|\mathcal{A}|$, if $\log \mathcal{N}_\infty(u, \{f \in \mathcal{F} : J(f) \leq B\}) \leq C \left(\frac{B}{u}\right)^{2\alpha}$, then $\log \mathcal{N}_\infty(u, \{f_1, \dots, f_{|\mathcal{A}|}\} \in \mathcal{F}^{|\mathcal{A}|} : J((f_1, \dots, f_{|\mathcal{A}|})) \leq B\} \leq C_1 \left(\frac{B}{u}\right)^{2\alpha}$ (we benefit from the condition $J(Q(\cdot, a)) \leq J(Q)$ in Assumption A3; the proof is similar to the proof of Lemma 20 in Appendix E). Here the constant C_1 depends on $|\mathcal{A}|$. This along with the previous inequality show that for some constant $A > 0$, we have

$$\log \mathcal{N}_\infty(u, (\mathcal{G} \times \mathcal{G}')_B) \leq A \left(\frac{B}{u}\right)^{2\alpha}.$$

We are ready to apply Lemma 24 to upper bound the inner product term in (65). Fix $\delta > 0$. To simplify the notation, denote $L_n = \|\hat{h}_n(Q) - T^\pi Q\|_n$, set $t_0 = \sqrt{\frac{\ln(1/\delta)}{n}}$, and use \hat{h}_n to refer to $\hat{h}_n(Q)$. There exists a constant $c > 0$ such that with probability at least $1 - \delta$, we have

$$L_n^2 + \lambda_{h_n} J^2(\hat{h}_n) \leq 2cL^{1+\alpha} L_n^{1-\alpha} \left(J(\hat{h}_n) + J(Q) + J(T^\pi Q) \right)^\alpha t_0 + \lambda_{h_n} J^2(T^\pi Q). \quad (66)$$

Either the first term in the RHS is larger than the second one or the second term is larger than the first. We analyze each case separately.

Case 1. $2cL^{1+\alpha} L_n^{1-\alpha} (J(\hat{h}_n) + J(Q) + J(T^\pi Q))^\alpha t_0 \geq \lambda_{h_n} J^2(T^\pi Q)$. In this case we have

$$L_n^2 + \lambda_{h_n} J^2(\hat{h}_n) \leq 4cL^{1+\alpha} L_n^{1-\alpha} \left(J(\hat{h}_n) + J(Q) + J(T^\pi Q) \right)^\alpha t_0. \quad (67)$$

Again, two cases might happen:

Case 1.a. $J(\hat{h}_n) > J(Q) + J(T^\pi Q)$: From (67) we have $L_n^2 \leq 2^{2+\alpha} c L^{1+\alpha} L_n^{1-\alpha} J^\alpha(\hat{h}_n)/t_0$. Solving for L_n , we get that $L_n \leq \frac{2^{2+\alpha} c^{1+\alpha} L^{1+\alpha} J(\hat{h}_n)}{\lambda_{h,n}^{1+\alpha} t_0^{1+\alpha}}$. From (67) we also have $\lambda_{h,n} J^2(\hat{h}_n) \leq 2^{2+\alpha} c L^{1+\alpha} L_n^{1-\alpha} J^\alpha(\hat{h}_n)/t_0$. Plugging-in the recently obtained upper bound on L_n and solving for $J(\hat{h}_n)$, we get that

$$J(\hat{h}_n) \leq \frac{2^{2+\alpha} c L^{1+\alpha} t_0}{\lambda_{h,n}^{\frac{3}{2}}}. \quad (68)$$

Substituting this in the upper bound on L_n , we get that

$$L_n \leq \frac{2^{2+\alpha} c L^{1+\alpha} t_0}{\lambda_{h,n}^{\frac{3}{2}}}. \quad (69)$$

Case 1.b. $J(\hat{h}_n) \leq J(Q) + J(T^\pi Q)$: The upper bound on $J(\hat{h}_n)$ is obvious. From (67) we have $L_n^2 \leq 2^{2+\alpha} c L^{1+\alpha} L_n^{1-\alpha} (J(Q) + J(T^\pi Q))^\alpha t_0$. Solving for L_n , we obtain

$$L_n \leq 2^{\frac{2+\alpha}{1+\alpha}} c^{\frac{1}{1+\alpha}} L (J(Q) + J(T^\pi Q))^{\frac{\alpha}{1+\alpha}} t_0^{\frac{1}{1+\alpha}}. \quad (70)$$

Case 2. $2cL^{1+\alpha} L_n^{1-\alpha} J(\hat{h}_n) + J(Q) + J(T^\pi Q)^\alpha t_0 < \lambda_{h,n} J^2(T^\pi Q)$. In this case we have $L_n^2 + \lambda_{h,n} J^2(\hat{h}_n) \leq 2\lambda_{h,n} J^2(T^\pi Q)$, which implies that

$$L_n \leq \sqrt{2\lambda_{h,n}} J(T^\pi Q), \quad (71)$$

$$J(\hat{h}_n) \leq \sqrt{2} J(T^\pi Q). \quad (72)$$

By (69), (70), and (71) for L_n and (68), (72), and the condition $J(\hat{h}_n) \leq J(Q) + J(T^\pi Q)$ in Case 1.b. for $J(\hat{h}_n)$, we have that for any fixed $0 < \delta < 1$, with probability at least $1 - \delta$, the following inequalities hold:

$$\begin{aligned} \|\hat{h}_n(Q) - T^\pi Q\|_n &\leq \max \left\{ \frac{2^{2+\alpha} c L^{1+\alpha} \sqrt{\frac{\ln(1/\delta)}{n}}}{\lambda_{h,n}^{\frac{3}{2}}}, \right. \\ &\quad \left. \frac{2^{2+\alpha} c^{1+\alpha} L (J(Q) + J(T^\pi Q))^{\frac{\alpha}{1+\alpha}} \left(\frac{\ln(1/\delta)}{n} \right)^{\frac{1}{2(1+\alpha)}}}{\lambda_{h,n}^{\frac{3}{2}}}, \right. \\ &\quad \left. \sqrt{2\lambda_{h,n} J(T^\pi Q)} \right\}, \\ J(\hat{h}_n(Q)) &\leq \max \left\{ \frac{2^{2+\alpha} c L^{1+\alpha} \sqrt{\frac{\ln(1/\delta)}{n}}}{\lambda_{h,n}^{\frac{3}{2}}}, J(Q) + J(T^\pi Q), \sqrt{2} J(T^\pi Q) \right\}. \end{aligned}$$

Comparing this proof with that of Theorem 10.2 by van de Geer (2000), we see that here we do not normalize the function space $\mathcal{G} \times \mathcal{G}'$ to ensure that $J(g, g') \leq 1$ and then

use their Lemma 8.4, which provides a high-probability upper bound on $\sup_{g \in \mathcal{G}} \frac{\langle W, g \rangle_n}{\|g\|_{F_n}^{1-\alpha}}$. Instead we directly apply Lemma 24, which upper bounds $\sup_{(g, g') \in \mathcal{G} \times \mathcal{G}'} \frac{\langle W(g'), g \rangle_n}{\|g\|_{F_n}^{1-\alpha} J^\alpha(g, g')}$, on the (unnormalized) function space $\mathcal{G} \times \mathcal{G}'$. If we went through the former approach, in which the normalization is global, the first term in the RHS of (66) would be $L_n^{1-\alpha} (J(\hat{h}_n) + J(Q) + J(T^\pi Q))^{1+\alpha} t_0$ instead of $L_n^{1-\alpha} (J(\hat{h}_n) + J(Q) + J(T^\pi Q))^\alpha t_0$ of here, which is obtained by local normalization. This extra $J(\hat{h}_n) + J(Q) + J(T^\pi Q)$ would prevent us from getting proper upper bounds on L_n and $J(\hat{h}_n)$ in Case 1.a above. The reason that the original proof does not work is that here $W(g')$ is a function of $g' \in \mathcal{G}'$.

Appendix E. Proof of Lemma 20 (Covering Number of G_{σ_1, σ_2})

Here we prove Lemma 20, which relates the covering number of G_{σ_1, σ_2} to the covering number of \mathcal{F}_{σ_1} and \mathcal{F}_{σ_2} .

Proof [Proof of Lemma 20] Let $g_{Q_1, h_1}, g_{Q_2, h_2} \in G_{\sigma_1, \sigma_2}$. By the definition of G_{σ_1, σ_2} (41), the functions Q_1 and h_1 corresponding to g_{Q_1, h_1} satisfy $Q_1 \in \mathcal{F}_{\sigma_1}^{|\mathcal{A}|}$ and $h_1 \in \mathcal{F}_{\sigma_2}^{|\mathcal{A}|}$ (and similarly for Q_2 and h_2). Set $z_i = (x_i, a_i)$. We have

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^n |g_{Q_1, h_1}(z_i) - g_{Q_2, h_2}(z_i)|^2 \\ &= \frac{1}{n} \sum_{i=1}^n [(Q_1(z_i) - h_1(z_i))^2 - (Q_2(z_i) - h_2(z_i))^2]^2 \\ &\leq 16 Q_{\max}^2 \frac{1}{n} \sum_{i=1}^n [(Q_1(z_i) - Q_2(z_i)) + (h_1(z_i) - h_2(z_i))]^2 \\ &\leq 32 Q_{\max}^2 \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^{|\mathcal{A}|} [(Q_{1,j}(x_i) - Q_{2,j}(x_i))^2 + (h_{1,j}(x_i) - h_{2,j}(x_i))^2]. \end{aligned}$$

Assumption A3 implies that for $Q_1, Q_2 \in \mathcal{F}_{\sigma_1}^{|\mathcal{A}|}$, the functions $Q_{1,j}, Q_{2,j}$ are in \mathcal{F}_{σ_1} and for $h_1, h_2 \in \mathcal{F}_{\sigma_2}^{|\mathcal{A}|}$, the functions $h_{1,j}, h_{2,j}$ are in \mathcal{F}_{σ_2} —for all $j = 1, \dots, |\mathcal{A}|$. Therefore the previous inequality shows that u -covers on $Q_j \in \mathcal{F}_{\sigma_1}$ and $h_j \in \mathcal{F}_{\sigma_2}$ (for $j = 1, \dots, |\mathcal{A}|$) w.r.t. the empirical norms $\|\cdot\|_{x_{1:n}}$ define an $8Q_{\max} \sqrt{|\mathcal{A}|}$ u -cover on G_{σ_1, σ_2} w.r.t. $\|\cdot\|_{x_{1:n}}$. Thus,

$$\mathcal{N}_2 \left(8Q_{\max} \sqrt{|\mathcal{A}|} u, G_{\sigma_1, \sigma_2}, (x, a)_{1:n} \right) \leq \mathcal{N}_2(u, \mathcal{F}_{\sigma_1}, x_{1:n})^{|\mathcal{A}|} \times \mathcal{N}_2(u, \mathcal{F}_{\sigma_2}, x_{1:n})^{|\mathcal{A}|}.$$

Assumption A4 then implies that for a constant c_1 , independent of $u, |\mathcal{A}|, Q_{\max}$, and α , and for all $((x_1, a_1), \dots, (x_n, a_n)) \in \mathcal{X} \times \mathcal{A}$ we have

$$\log \mathcal{N}_2(u, G_{\sigma_1, \sigma_2}, (x, a)_{1:n}) \leq c_1 |\mathcal{A}|^{1+\alpha} Q_{\max}^{2\alpha} (\sigma_1^\alpha + \sigma_2^\alpha) u^{-2\alpha}.$$

Appendix F. Convolutional MDPs and Assumption A7

In this appendix, we show that Assumption A7 holds for a certain class of MDPs. This class is defined by one dimensional MDPs in which the increment of the next X' compared to the current state X is a function of chosen action only, i.e., $X' - X \sim W(\pi(X))$.

Proposition 25 Suppose that $\mathcal{X} = [-\pi, \pi]$ is the unit circle and \mathcal{F} is the Sobolev space $\mathcal{W}^{k,2}(\mathcal{X}) = \mathcal{W}^{k,2}(\mathcal{X})$ and $J(\cdot)$ is defined as the corresponding norm $\|\cdot\|_{\mathcal{W}^{k,2}}$. For a function $f \in \mathcal{F}$, let $\hat{f}(n)$ be the n^{th} Fourier coefficient, i.e., $\hat{f}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(x) e^{-jn x} dx$. Consider the MDPs that have the convolutional transition probability kernel, that is, for any policy π and $V \in \mathcal{F}$, there exists $K_{\pi}(x, y) = K_{\pi}(x - y)$ such that

$$\int_{\mathcal{X}} P(dy|x; \pi(x)) V(y) = \int_{\mathcal{X}} K_{\pi}(x - y) V(y) dy = K_{\pi} * V.$$

Moreover, assume that $K_{\pi}, V \in L_1(\mathcal{X})$. For a given policy π , let $r^{\pi}(x) = r(x, \pi(x))$ ($x \in \mathcal{X}$). Assumption A7 is then satisfied with the choice of $L_R = \sup_{\pi} \|r^{\pi}\|_{\mathcal{W}^{k,2}}$ and $L_P = \sup_{\pi} \max_n |\hat{K}_{\pi}(n)|$.

Proof By the convolution theorem, $(\widehat{K_{\pi} * V})(n) = \hat{K}_{\pi}(n) \hat{V}(n)$. It is also known that for $V \in \mathcal{F}$, we have $\|V\|_{\mathcal{W}^{k,2}}^2 = \sum_{n=-\infty}^{\infty} (1 + |n|^2)^k |\hat{V}(n)|^2$. Thus,

$$\begin{aligned} \|K_{\pi} * V\|_{\mathcal{W}^{k,2}}^2 &= \sum_{n=-\infty}^{\infty} (1 + |n|^2)^k |\hat{K}_{\pi}(n)|^2 |\hat{V}(n)|^2 \leq \left[\max_n |\hat{K}_{\pi}(n)|^2 \right] \sum_{n=-\infty}^{\infty} (1 + |n|^2)^k |\hat{V}(n)|^2 \\ &= \left[\max_n |\hat{K}_{\pi}(n)|^2 \right] \|V\|_{\mathcal{W}^{k,2}}^2. \end{aligned}$$

Therefore, $\|r^{\pi} V\|_{\mathcal{W}^{k,2}} \leq \|r^{\pi}\|_{\mathcal{W}^{k,2}} + \gamma \left[\max_n |\hat{K}_{\pi}(n)| \right] \|V\|_{\mathcal{W}^{k,2}}$. Taking supremum over all policies finishes the proof. ■

The interpretation of $\max_n |\hat{K}_{\pi}(n)|$ is the maximum gain of the linear filter K_{π} that is applied to a value function V . The gain here is explicitly written in the frequency domain.

Appendix G. The Metric Entropy and the Covering Number

Definition 26 (Definition 9.3 of Györfi et al. 2002) Let $\varepsilon > 0$, \mathcal{F} be a set of real-valued functions defined on \mathcal{X} , and ν_X be a probability measure on \mathcal{X} . Every finite collection of $N_{\varepsilon} = \{f_1, \dots, f_{N_{\varepsilon}}\}$ defined on \mathcal{X} with the property that for every $f \in \mathcal{F}$, there is a function $f' \in N_{\varepsilon}$ such that $\|f - f'\|_{p, \nu_X} < \varepsilon$ is called an ε -cover of \mathcal{F} w.r.t. $\|\cdot\|_{p, \nu_X}$. Let $\mathcal{N}(\varepsilon, \mathcal{F}, \|\cdot\|_{p, \nu_X})$ be the size of the smallest ε -cover of \mathcal{F} w.r.t. $\|\cdot\|_{p, \nu_X}$. If no finite ε -cover exists, take $\mathcal{N}(\varepsilon, \mathcal{F}, \|\cdot\|_{p, \nu_X}) = \infty$. Then $\mathcal{N}(\varepsilon, \mathcal{F}, \|\cdot\|_{p, \nu_X})$ is called an ε -covering number of \mathcal{F} and $\log \mathcal{N}(\varepsilon, \mathcal{F}, \|\cdot\|_{p, \nu_X})$ is called the metric entropy of \mathcal{F} w.r.t. the same norm.

The ε -covering of \mathcal{F} w.r.t. the supremum norm $\|\cdot\|_{\infty}$ is denoted by $\mathcal{N}_{\infty}(\varepsilon, \mathcal{F})$. For $x_{1:n} = (x_1, \dots, x_n) \in \mathcal{X}^{1:n}$, one may also define the empirical measure $\nu_{X_{1:n}}(A) = \frac{1}{n} \sum_{i=1}^n \mathbb{1}_{\{x_i \in A\}}$ for $A \subset \mathcal{X}$. This leads to the empirical covering number of \mathcal{F} w.r.t. the empirical norm $\|\cdot\|_{p, x_{1:n}}$ and is denoted by $\mathcal{N}_{p,n}(\varepsilon, \mathcal{F}, x_{1:n})$. If $X_{1:n} = (X_1, \dots, X_n)$ is a sequence of random variables, the covering number $\mathcal{N}_{p,n}(\varepsilon, \mathcal{F}, X_{1:n})$ is a random variable too.

Abstract

We introduce a framework for designing multi-scale, adaptive, shift-invariant frames and bi-frames for representing signals. The new framework, called AdaFrame, improves over dictionary learning-based techniques in terms of computational efficiency at inference time. It improves classical multi-scale basis such as wavelet frames in terms of coding efficiency. It provides an attractive alternative to dictionary learning-based techniques for low level signal processing tasks, such as compression and denoising, as well as high level tasks, such as feature extraction for object recognition. Connections with deep convolutional networks are also discussed. In particular, the proposed framework reveals a drawback in the commonly used approach for visualizing the activations of the intermediate layers in convolutional networks, and suggests a natural alternative.

Keywords: AdaFrame, Dictionary Learning, Wavelet Frames/Bi-frames

1. Introduction

It is now well acknowledged that sparse and overcomplete representations of data play a key role in many signal processing applications. The ability to represent a signal as a sparse linear combination of a few atoms from a possibly overcomplete dictionary lies at the heart of many applications including image/audio compression, denoising, as well as higher level tasks such as object recognition.

One popular technique for representing signals is the use of dictionaries. Since the seminal work of Olshausen et al. (1996), the field of dictionary learning has seen many promising advances. The objective is to learn a dictionary such that the input

data can be written as a sparse linear combination of the dictionary atoms. More specifically, given the data represented as a matrix X , one finds the dictionary matrix D and coefficient matrix C simultaneously by solving:

$$\min_{D,C} \|X - DC\|_2^2 + \lambda \|C\|_1. \quad (1)$$

The solution is usually obtained by solving alternatively the minimization problem for D and the sparse coding problem for C with the other variable being kept fixed. After obtaining D , inference can be made by solving a sparse coding problem. Different dictionary learning models differ in the way the dictionary D is updated. Examples include: MOD (Engan et al., 1999a), K-SVD (Aharon et al., 2006) and their variants.

Dictionary learning techniques have been successfully applied to some low level image and video processing tasks, such as image/video denoising (Elad and Aharon, 2006), compression (Bryt and Elad, 2008a; Engan et al., 1999b), inpainting (Mairal et al., 2008) and other restoration tasks (Mairal et al., 2007) with state-of-the-art performances. In addition, dictionary learning and sparse coding techniques have been very popular in high level object recognition tasks where their function is to extract features from raw data. These techniques have been used successfully to extract visual features in Ranzato et al. (2007); Lee et al. (2009); Jarrett et al. (2009). At the other end are the more traditional methodologies of designing analytic tight frames, such as Fourier basis, wavelet frames and bi-frames (Daubechies et al., 2003), curvelets (Candes and Donoho, 2000), contourlets (Do and Vetterli, 2002), etc. These analytic tight frames are robust, easy to use and computationally efficient.

In some sense the analytic tight frames can also be viewed as a dictionary. The set of signals is a particular space of functions. A dictionary is found that gives rise to the optimal representation and approximation of the signals in that function class. The resulted dictionary is highly structured, and in particular, when used into applications, the dictionary atoms are never explicitly used. However, the two approaches do differ fundamentally in several aspects (see Table 1).

- **Computational cost.** For dictionary learning, the computational cost consists of two parts: the one time cost of learning the dictionary atoms and the repeated cost of solving the sparse coding problem for the test signal at inference time. Among the two, it is the latter that prevents it from being used in real time situations. Despite the efforts devoted to seeking more efficient sparse coding algorithms (Daubechies et al., 2004; Lee et al., 2006; Beck and Teboulle, 2009), none of the available techniques is efficient enough for large scale visual feature extraction. In fact, assuming that the signal x is of length N and the trained dictionary $D \in \mathbb{R}^{m \times N}$ is stored and used explicitly, then computing Dx alone requires $O(mN)$ operations. In comparison, analytic transforms are far more efficient: fast Fourier transform takes $O(N \log N)$ operations and one level wavelet transform takes only $O(N)$ operations. This is a huge efficiency gap. In addition, the computational cost of training cannot be ignored either. The

learning procedure requires solving a non-convex optimization problem, limiting dictionary atoms to low dimensions. Partly because of this, in image processing applications, dictionary atoms are only obtained for small image patches.

- **Multi-scale features.** Dictionaries as obtained by MOD and K-SVD operate at a single small scale. Since the dictionary atoms are limited to small sizes, there is not much room for multi-scale features. Past experience with wavelets has taught us that often times it is beneficial to process signals at several scales, and operate at each scale separately.

- **Artifacts.** In low level tasks such as image compression, the dictionary learning approach operates in a patch by patch manner, which produces visually unpleasant block effects along the borders of the patches (Bryt and Elad, 2008a). Post processing is often needed to remove these artifacts (Bryt and Elad, 2008b).

Adapted to data	Dictionary Learning Yes	Wavelet Tight Frames No
Computational speed	Slow	Fast
Multi-scale	No	Yes
Robustness to perturbation	Conditionally	Yes
Performance on real data	Better	Worse

Table 1: Comparison between dictionary learning and wavelet tight frames

Given the relative features of dictionary learning and wavelet tight frames, it is natural to ask whether one can design bases that have the benefits of both and avoid the problems. In other words, can one design bases that are adapted to the data but at the same time have the multi-scale structure that is essential for the efficient algorithms for wavelet tight frames?

We propose a framework of constructing adaptive frames and bi-frames (abbreviated as AdaFrame). This framework gives multi-scale, sparse representations of the signal, with an efficiency comparable to that of the wavelets at inference time.

The proposed framework is formally similar to the first few layers of a convolutional network. As a byproduct, we show that the proposed framework gives a better way of visualizing the activations of the intermediate layers of a neural net in terms of reconstruction error.

The framework presented here is best suited for datasets such that each data point has some structure. Obvious examples include time series, images and videos. However, as in the case of wavelets, it is also possible to extend this kind of ideas to less structured data such as graphs, etc (Coffman and Mlaggoni, 2006).

In Cai et al. (2014), a variational model is proposed to learn a tight frame system that is adapted to the input image. The model in Cai et al. (2014) and our model share

a similar objective and build upon similar mathematical foundations, but our work greatly extends the model proposed in Cai et al. (2014) where a sufficient condition for perfect reconstruction is replaced by a sufficient and necessary condition and the tight frame is extended to bi-frame, which is much more flexible.

Most examples discussed in this paper are still of the low level image processing type. In a subsequent paper, we will discuss more thoroughly higher level tasks such as image classification.

The organization of this paper is as follows. In section 2, we introduce shift-invariant frames and bi-frames. In section 3, we introduce the adaptive construction of shift-invariant frames. In section 4, we introduce the adaptive construction of shift-invariant bi-frames. In section 5, we discuss multi-level constructions. In section 6, we give some simple illustrative examples of the adaptively constructed frames and bi-frames. In section 7, we discuss the connection with predefined wavelets and wavelet frames. In section 8, we discuss applications to image processing and image classification. In section 9, we discuss connection with deconvolutional nets and reconstruction of input data from features in the intermediate layers of the convolutional nets. Some conclusions are drawn in section 10.

2. Shift-invariant Frames and Bi-frames

An important starting point is the concept of multi-resolution analysis (MRA) introduced in Mallat (1989) and Meyer (1995), of which wavelets are particularly popular examples. One main advantage of MRA is that it comes naturally with fast decomposition and reconstruction algorithms, and this has been essential for making wavelets a practical tool in signal processing (Daubechies et al., 2003; Shen, 2010). Although our work builds upon the theory of wavelet frames in the continuous setting, we decide to introduce our model in a purely discrete setup. This has the advantage that it is more direct and more easily linked with existing machine learning models, including dictionary learning and convolutional networks. However, as noted in Han (2010), there is a canonical link between affine systems in the continuous setting and fast algorithms in the discrete framework.

The signals and the filters are all assumed to be discrete sequences in $l_2(\mathbb{Z}^d)$, where d is the dimension. For audio, image and video signals, $d = 1, 2, 3$ respectively. First let us define the up- and down-sampling operators. Let M be an integer. The (one dimensional) down-sampling and up-sampling operator are defined by:

$$\begin{aligned} [v \downarrow_M](n) &:= v(Mn), & n \in \mathbb{Z} \\ [v \uparrow](n) &:= \begin{cases} v(k), & n = Mk, k \in \mathbb{Z} \\ 0, & \text{otherwise} \end{cases} \end{aligned} \quad (2)$$

respectively, for $v \in l_2(\mathbb{Z})$. M is the decimation factor. Similarly if $d > 1$, denote the decimation factor in each dimension by M_1, M_2, \dots, M_d . For convenience we define a matrix $M = \text{Diag}(M_1, \dots, M_d) \in \mathbb{R}^{d \times d}$. A common choice of M in image processing

is $M = 2I$. We call M the *sampling matrix* and use the same notation as in (2) where Mn is understood as the matrix-vector multiplication. In general M can be an invertible matrix whose entries are positive integers or rational numbers that are greater than 1.

Key to the decomposition and reconstruction algorithms are the transition and subdivision operators. For a data sequence $v \in l_2(\mathbb{Z}^d)$, a finitely supported filter $a \in l_2(\mathbb{Z}^d)$ and a sampling matrix $M \in \mathbb{R}^{d \times d}$, the transition operator $\mathcal{T}_a : l_2(\mathbb{Z}^d) \mapsto l_2(\mathbb{Z}^d)$ is defined by

$$(\mathcal{T}_{a,M}v)(n) := \downarrow_M [v * a](n) = \sum_{k \in \mathbb{Z}^d} v(k) \overline{a(k - Mn)}, \quad (3)$$

the subdivision operator $\mathcal{S}_a : l_2(\mathbb{Z}^d) \mapsto l_2(\mathbb{Z}^d)$ is defined by

$$(\mathcal{S}_{a,M}v)(n) := |\det(M)| [a * (\uparrow v)](n) = |\det(M)| \sum_{k \in \mathbb{Z}^d} v(k) a(n - Mk). \quad (4)$$

To make the notations more concise, we omit M in the subscript.

Given a set of finitely supported filters $A = \{a_1, \dots, a_m\}$ and the coefficient sequence $v \in l_2(\mathbb{Z}^d)$, which could be the input signal itself or the coefficients computed at some decomposition level, we compute coefficients of the next level by

$$v_l = \mathcal{T}_{a_l} v, \quad l = 1, \dots, m. \quad (5)$$

With this notation, the one-level decomposition operator $W_A : l_2(\mathbb{Z}^d) \mapsto \underbrace{l_2(\mathbb{Z}^d) \oplus \dots \oplus l_2(\mathbb{Z}^d)}_{m \text{ times}}$

is defined as:

$$W_A v := \{v_1, \dots, v_l\} = \{\mathcal{T}_{a_1} v, \mathcal{T}_{a_2} v, \dots, \mathcal{T}_{a_m} v\}. \quad (6)$$

Given a set of finitely supported filters $B = \{b_1, \dots, b_m\}$, the one-level reconstruction operator $R_B : \underbrace{l_2(\mathbb{Z}^d) \oplus \dots \oplus l_2(\mathbb{Z}^d)}_{m \text{ times}} \mapsto l_2(\mathbb{Z}^d)$ is defined as

$$R_B(v_1, \dots, v_m) := \sum_{l=1}^m \mathcal{S}_{b_l} v_l \quad (7)$$

In wavelet frames, the filters A used for decomposition and the filters B used for reconstruction are connected by : $b_l(\cdot) = a_l(-\cdot)$, $l = 1, \dots, m$, where $a_l(-\cdot)$ means flip the entries of a_l along each dimension. But this does not have to be the case: A and B can be different and together they constitute a *bi-frame*.

The main requirement is that of perfect reconstruction, by which we mean:

$$R_B W_A v = v \quad \forall v \in l_2(\mathbb{Z}^d). \quad (8)$$

The following result is crucial.

Theorem 1 (Ron and Shen, 1997) Let $M \in \mathbb{R}^{d \times d}$ be a sampling matrix, let $A = \{a_1, \dots, a_m\}$ and $B = \{b_1, \dots, b_m\}$ be two sets of finitely supported sequences in $l_2(\mathbb{Z}^d)$. Then the perfect reconstruction property

$$R_B W_A v = v, \quad \forall v \in l_2(\mathbb{Z}^d) \quad (9)$$

holds if and only if, for all $k, j \in \mathbb{Z}^d$,

$$\sum_{l=1}^m \sum_{n \in \mathbb{Z}^d} a_l(Mn + j) \overline{b_l(k + Mn + j)} = |\det(M)|^{-1} \delta_k \quad (10)$$

where $\delta_k = 1$ if $k = 0$ and $\delta_k = 0$ otherwise.

In the case of wavelet tight frames, $b_l(\cdot) = a_l(-\cdot)$, $l = 1, \dots, m$, and we have:

Theorem 2 (Ron and Shen, 1997) Let $M \in \mathbb{R}^{d \times d}$ be a sampling matrix, let $A = \{a_1, \dots, a_m\}$ be a set of finitely supported sequences in $l_2(\mathbb{Z}^d)$. Then the perfect reconstruction property

$$R_A W_A v = v, \quad \forall v \in l_2(\mathbb{Z}^d). \quad (11)$$

holds if and only if, for all $k, j \in \mathbb{Z}^d$,

$$\sum_{l=1}^m \sum_{n \in \mathbb{Z}^d} a_l(Mn + j) \overline{a_l(k + Mn + j)} = |\det(M)|^{-1} \delta_k \quad (12)$$

In particular, if the data are real numbers and no down-sampling is performed, then the perfect reconstruction condition (12) becomes

$$\sum_{i=1}^m \sum_{n \in \mathbb{Z}^d} a_i(k+n) a_i(n) = \delta_k, \quad \forall k \in \mathbb{Z}^d. \quad (13)$$

The proof of Theorem 1 and Theorem 2 can be found in Daubechies et al. (2003). For completeness, we give a direct proof for the discrete case in the appendix. These conditions are referred to as the unitary extension principle (UEP) in wavelet frame theory.

As an example, the linear B-spline wavelet tight frame used in many image restoration tasks is constructed via the UEP. Its associated filters are :

$$a_1 = \frac{1}{4}(1, 2, 1)^T; \quad a_2 = \frac{\sqrt{2}}{4}(1, 0, -1)^T; \quad a_3 = \frac{1}{4}(-1, 2, -1)^T.$$

This kind of tight frames are shift-invariant systems since the transforms are in the form of discrete convolution. They are suited for the case when, below certain scale, the statistical properties of the signals are translation invariant.

3. Adaptive Construction of Frames

Given a set of signals $X = \{x_1, \dots, x_N\}$, the goal is to construct wavelet frames that are adapted to this set of signals in the sense that signals in the given set have a sparse representation.

Define \mathcal{Q} to be the set of filters that satisfy the UEP condition:

$$\mathcal{Q} = \left\{ \{a_k\}_{k=1}^m : \sum_{l=1}^m \sum_{n \in \mathbb{Z}^d} a_l(Mn + j) \overline{a_l(Mn + k + j)} = |\det(M)|^{-1} \delta_k, \forall k, j \in \mathbb{Z}^d \right\}. \quad (14)$$

Filters in this set generate a wavelet frame that provide a faithful representation for all signals in $l_2(\mathbb{Z}^d)$. However, we are not interested in all signals in $l_2(\mathbb{Z}^d)$. We are only interested in X . Among all filters in \mathcal{Q} , we want to select the one that is most adapted to X .

In image restoration tasks, we are mostly interested in wavelet frames that give rise to a sparse representation of the input signal. Therefore we will use sparsity as our guiding principle for selecting the filters. Other guiding principles such as the discriminative criterion can also be used. But in this paper, we will focus on sparsity. Let Φ be a sparsity-inducing function. Examples of Φ include the l_1 norm, l_0 "norm", or the Huber loss function defined (component-wise) by:

$$L_\delta(x) = \begin{cases} \frac{1}{2}x^2, & |x| \leq \delta \\ \delta(|x| - \frac{1}{2}\delta), & \text{otherwise} \end{cases}. \quad (15)$$

Given the data X , the adaptive filters are chosen by solving the following optimization problem:

$$\begin{aligned} & \min_{a_1, \dots, a_m} \sum_{j=1}^N \sum_{i=1}^m \Phi(v_{i,j}) \\ & \text{subject to } v_{i,j} = T_{a_i} x_j, \quad i = 1, \dots, m \\ & \{a_i\}_{i=1}^m \in \mathcal{Q} \end{aligned} \quad (16)$$

In the following, without loss of generality, we will assume that there is only one data point in the signal set, i.e. $N = 1$, and we will omit the subscript j .

To be specific, we use l_1 norm as the measurement of sparsity and we will note the changes required if the l_0 norm is used. The above problem then becomes

$$\begin{aligned} & \min_{a_1, \dots, a_m} \sum_{i=1}^m \|\mathcal{T}_{a_i} x\|_1 \\ & \{a_i\}_{i=1}^m \in \mathcal{Q} \end{aligned} \quad (17)$$

This innocent looking optimization problem is difficult to solve because of the constraint. Consider the simplest case when the signals and the filters are all one-dimensional. Assume each filter has support length r , and we have r of them. For a

real symmetric matrix G , let us denote by $Tr(G; k)$ the sum of entries along the k -th sub-diagonal. For example, $Tr(G; 0)$ is the usual trace of G . Let $A := (a_1, \dots, a_m)$. Then the constraint $\{a_i\}_{i=1}^m \in \mathcal{Q}$ is equivalent to

$$Tr(AA^T, k) = \delta_k, \quad k = 0, \dots, r-1.$$

To see a nontrivial example where this constraint is satisfied, take an orthogonal matrix $U \in \mathbb{R}^{r \times r}$, and let $a_i = \frac{1}{\sqrt{r}} U_{:,i}$, $i = 1, \dots, m$, where $U_{:,i}$ means the i -th column of U . However, in general, the algebraic constraint above is difficult to deal with. Note also that this optimization problem is not convex.

We use the split Bregman algorithm (Goldstein and Osher, 2009) to solve (17). Introduce the auxiliary variable $D = (d_1, \dots, d_m)$ where $d_i = T_{a_i} x$, $i = 1, \dots, m$. Define the norm $\|D\|_{1,1} := \sum_{i=1}^m \|d_i\|_1$. Then (17) is equivalent to:

$$\begin{aligned} & \min_{A, D} \|D\|_{1,1} \\ & \text{subject to } D = W_A x \\ & A \in \mathcal{Q} \end{aligned} \quad (18)$$

Applying the split Bregman method, we obtain the following algorithm:

Algorithm 1 Adaptive construction of frames

- 1: **Input:** x .
- 2: **Initialize** $k = 0, B = 0, A = A^0, D = W_{A^0} x$.
- 3: **while** "not converge" **do**
- 4: $D^{k+1} \leftarrow \arg \min_D \|D\|_{1,1} + \frac{\eta}{2} \|D - W_{A^k} x - B^k\|_F^2$
- 5: $A^{k+1} \leftarrow \arg \min_A \|W_{A^k} x - D^{k+1} + B^k\|_F^2$ **s.t.** $A \in \mathcal{Q}$.
- 6: $B^{k+1} \leftarrow B^k + W_{A^{k+1}} - D^{k+1}$.
- 7: $k \leftarrow k + 1$
- 8: **return** A^k

To implement the algorithm, we must be able to solve each of the subproblems listed in steps 4, 5 and 6.

To solve the subproblem for D , note that the problem decouples for each d_i , $i = 1, \dots, m$. In fact,

$$d_i^{k+1} = \arg \min_d \left(\|d\|_1 + \frac{\eta}{2} \|\mathcal{T}_{a_i} x - d + b_i^k\| \right) \quad (19)$$

for $i = 1, \dots, m$. It is easy to see that (19) has a closed form solution given by

$$d_i^{k+1} = \text{shrink}(\mathcal{T}_{a_i} x + b_i^k, \frac{1}{\eta}) \quad (20)$$

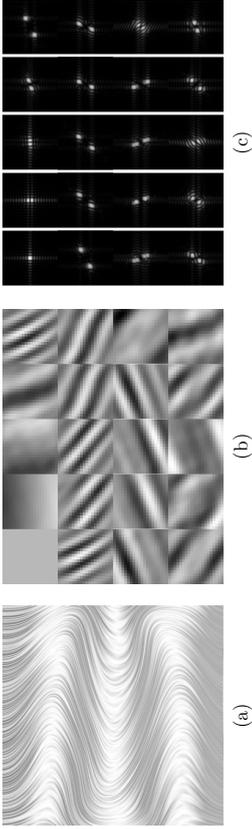

Figure 1: (a) The input image. (b) The filters learned using Algorithm 1, $m = 20$, $r = 20$. (c) The Fourier spectrum of the corresponding filters. Note the first filter is a low-pass filter, all other filters are high-pass filters as can be seen from the Fourier spectrum. The second and third filter look like edge detectors along the axis. Other filters detect oscillations along different directions.

where the function $\text{shrink} : \mathbb{R} \mapsto \mathbb{R}$ is defined as

$$\text{shrink}(x, a) = \begin{cases} (|x| - a)\text{sign}(x), & \text{if } |x| > a \\ 0, & \text{otherwise} \end{cases}. \quad (21)$$

When shrinkage-operator acts on a vector, it acts on each component of the vector according to (21).

The subproblem for updating A is most problematic due to the constraint. We use the interior-point method for this part of the algorithm. There is no guarantee of a global solution to this subproblem.

The update for B is straightforward. This is analogous to the step of “adding the noise back” in the ROF model for denoising (Osher et al., 2005).

Among the three subproblems, the update of A is the most time consuming. But as is observed by many authors, it is not necessary to solve A to full convergence, the intuitive reason being that if the error of the solution to the subproblem is smaller than $\|B^k - B^{k-1}\|$, the extra accuracy will be wasted. In fact, for updating A , we only run a few steps of the interior-point iterations and we still observe numerical convergence.

If we use the l_0 “norm” as the measurement of sparsity, the only change needed in the above algorithm is in the D step, where the soft-shrinkage operator is replaced by hard-thresholding defined as:

$$\text{Hard}(x, a) = \begin{cases} x, & \text{if } |x| > a \\ 0, & \text{otherwise} \end{cases}. \quad (22)$$

To give the readers some intuition about how the filters obtained look like, we show an example in Figure 1. More examples are given in section 5.

In some applications such as object recognition, perfect reconstruction is unnecessary. Instead, writing the input signal as a sparse linear combination of a few dictionary atoms is only a means to extract features to be used by other learning algorithms. Sparse coding has been quite popular in serving this purpose for visual object recognition tasks. In this case, it is possible to relax the constraint in (17). Instead of solving the constrained minimization problem, we can use a penalty method to solve an unconstrained problem. For example, in 1D, we can solve

$$\min_A \sum_{k=1}^m \|W_A x\|_{1,1} + \eta \sum_k (Tr(AA^T, k) - \delta_k)^2 \quad (23)$$

where η is a parameter that depends on our tolerance on the reconstruction error. This unconstrained problem is relatively easy to solve using first-order optimization methods.

The optimization problem may appear similar to reconstruction ICA (RICA) proposed in Le et al. (2011), but they are fundamentally different. There proposed model guarantees perfect reconstruction while RICA approximates the input signal. Perfect reconstruction in RICA can only be achieved in the limit where the weight of the reconstruction term goes to infinity. In addition, RICA does not have a multi-scale structure which is essential in wavelet tight frames. The goals of RICA and AdaFrame are different, in ICA, the goal is to find independent sources where as in AdaFrame, the goal is to build a wavelet tight frame that sparsely represent the signal.

4. Adaptive Construction of Bi-frames

In this section, we introduce the adaptive construction of wavelet bi-frames. Compared with the wavelet frames, the bi-frames offer two distinct advantages: The first is that the constraint for the filters becomes bi-linear making it easier to construct the filters. The second is that the added redundancy introduces more flexibility. These prove to be very important in practice.

Let \mathcal{Q} denote the set of pairs A and B , $A = (a_1, \dots, a_m)$, $B = (b_1, \dots, b_m)$, that satisfy (10):

$$\mathcal{Q} := \left\{ (A, B) : \sum_{l=1}^m \sum_{n \in \mathbb{Z}^d} a_l(Mn + j) \overline{b_l(k + Mn + j)} = |\det(M)|^{-1} \delta_k, \forall k, j \in \mathbb{Z}^d \right\} \quad (24)$$

We want to find filter pairs (A, B) with desired properties while respect the constraint $(A, B) \in \mathcal{Q}$. As before we will only consider sparsity. Given the data x and a sampling matrix M , we aim to solve :

$$\begin{aligned} & \min_{A, B} \|W_A x\|_{1,1} \\ & \text{subject to } (A, B) \in \mathcal{Q} \end{aligned} \quad (25)$$

The constraint $(A, B) \in \mathcal{Q}$ in bi-linear in A and B . Let us first count the number of equations.

We start with the simplest case where the signals and the filters are one dimensional. Let A, B be defined as before and assume that each filter $a_i, b_i, i = 1, \dots, m$ has support size r . Given the decimation factor M , define

$$\mathcal{S}(r) := \{(k, \gamma) : \exists n \in \mathbb{Z}, 1 \leq Mn + k + \gamma \leq r, 1 \leq Mn + \gamma \leq r\}, \quad (26)$$

then each $(k, \gamma) \in \mathcal{S}(r)$ constitutes an equation. This gives

$$|\mathcal{S}(r)| = (2r - M)M. \quad (27)$$

This is the total number of equations. The total number of unknowns in A and B is $2rm$. Therefore for (10) to have a solution, we expect:

$$2rm \geq (2r - M)M. \quad (28)$$

In the general case where the signals and the filters live in d dimensions, we can do a similar counting. Assume the support size of the filter $a_i, b_i, i = 1, \dots, m$ is $\mathbf{r} = (r_1, \dots, r_d)$, and assume that the sampling matrix is $M = \text{Diag}(M_1, \dots, M_d)$. Let

$$\mathcal{S}(\mathbf{r}) := \{(k, \gamma) \in \mathbb{Z}^d : \exists n \in \mathbb{Z}^d, \mathbf{1} \leq Mn + k + \gamma \leq \mathbf{r}, \mathbf{1} \leq Mn + \gamma \leq \mathbf{r}\}, \quad (29)$$

where the inequality is understood component-wise. Each $(k, \gamma) \in \mathcal{S}(\mathbf{r})$ gives rise to an equation. The total number of equations is

$$|\mathcal{S}(\mathbf{r})| = \prod_{i=1}^d (2r_i - M_i)M_i. \quad (30)$$

The number of unknowns in a and b is $2m \prod_{i=1}^d r_i$. Hence to have a solution to (10), we expect:

$$2m \prod_{i=1}^d r_i \geq \prod_{i=1}^d (2r_i - M_i)M_i. \quad (31)$$

Two cases are of special interest.

- **Redundant case.** In this case, the number of filters m is large. The number of decomposition coefficients is larger than the size of the input signal. Hence we call this the *redundant case*. For the optimization problem, we have more unknowns than equations. In particular, if $m \geq 2M - M^2/r$ in one dimension, and $m \prod_{i=1}^d r_i \geq \prod_{i=1}^d (2r_i - M_i)M_i$ in d dimensions, for most A , we expect (10) as a set of linear equations for B , to have a solution. Therefore, we can design A and B separately: We can design A first in whichever way we want as long as it is non-degenerate. We then solve (10) to get B .

- **Critically down-sampled case.** In this case, the number of filters m is small. The number of decomposition coefficients is the same as that of the input signal (depending on the boundary conditions). Hence we call this the *critically down-sampled case*. For example, in one dimension, $m = M$. In this down-sampled case, for a typical A , it is likely that (10), as a linear system for B , does not have a solution. This means that we must consider A and B simultaneously.

4.1 Redundant Case

4.1.1 DESIGN OF THE DECOMPOSITION FILTERS

As discussed above, we can design A in the first phase, and then choose B that satisfies the linear constraint (25) in the second phase.

However, the choice of A has a significant impact on the condition number of (25). Hence some constraints should be added. While there are a lot of flexibilities, we propose the following formulation:

$$\begin{aligned} \min_A \quad & \|W_A x\|_{1,1} \\ \text{subject to} \quad & A^T A = I \end{aligned} \quad (32)$$

The additional constraint $A^T A = I$ is chosen based on the consideration that the filters are most incoherent among themselves.

To solve (32) numerically, we apply the split Bregman method. But we need to handle the extra orthogonality constraint as well. To this end, we introduce the auxiliary variable $P = A$ as a means to split the orthogonality constraint. This trick has been used in other problems, see for example Lai and Osher (2014). The problem then becomes:

$$\begin{aligned} \min_{A, D, P} \quad & \|D\|_{1,1} \\ \text{subject to} \quad & D = W_A x, P = A, P^T P = I. \end{aligned} \quad (33)$$

The algorithm is then:

Algorithm 2 Adaptive construction of bi-frames: redundant case

- 1: **Input:** x .
 - 2: **Initialize** $k = 0, F = \mathbf{0}, C = \mathbf{0}, A = A^0, D = W_{A^0} x, P = A$.
 - 3: **while** “not converge” **do**
 - 4: **for** $n=1:N$ **do**
 - 5: $D^{k+1} \leftarrow \arg \min_D \|D\|_{1,1} + \frac{\lambda}{2} \|D - W_{A^k} x - F^k\|_F^2$
 - 6: $A^{k+1} \leftarrow \arg \min_A \eta \|W_A x - D^{k+1} + F^k\|_F^2 + \lambda \|A - P^k + C^k\|_F^2$
 - 7: $P^{k+1} \leftarrow \arg \min_P \|A^{k+1} - P + C^k\|_F^2$ **s.t.** $P^T P = I$
 - 8: $F^{k+1} \leftarrow F^k + W_{A^{k+1}} x - D^{k+1}$.
 - 9: $C^{k+1} \leftarrow C^k + A^{k+1} - P^{k+1}$
 - 10: $k \leftarrow k + 1$
 - 11: **return** A^k
-

To implement the algorithm, we must be able to solve each of the subproblems for D , A and P . Updating D is the same as in Algorithm 1. The subproblem for A is a quadratic program. It can be decoupled into m smaller problems, each of which involves one column of A . Writing $D = (d_1, \dots, d_m)$, $P = (p_1, \dots, p_m)$, $C = (c_1, \dots, c_m)$ and $F = (f_1, \dots, f_m)$, we can perform the optimization in a column by column fashion:

$$a_i^{k+1} = \arg \min_a \eta \|T_a x - d_i^k\|_2^2 + \lambda \|a - p_i^k + c_i^k\|_2^2, \quad i = 1, \dots, m \quad (34)$$

Each of the m smaller problems is an unconstrained quadratic program. Many optimization techniques can be used to solve this problem. Among the several choices of iterative algorithms, we use conjugate gradient (CG) method because the objective function value tends to decrease very quickly in the first few CG iterations, thus giving a good approximate solution quickly. For the same reason as in Algorithm 1, iteration to convergence is not necessary.

Next, we consider the subproblem for P . This problem is equivalent to:

$$\max_P \text{Trace}((A^{k+1} + C^k)^T P) \quad \text{subject to} \quad P^T P = I. \quad (35)$$

This is the classical orthogonal procrustes problem (Gower and Dijksterhuis, 2004) and has a closed form solution which we summarize in the following lemma. The proof can be found in linear algebra textbooks, e.g. Horn and Johnson, chapter 3.

Lemma 1 Let $Y \in \mathbb{R}^{n \times m}$, $n \geq m$ and $Y = UDV^T$ be the singular value decomposition of Y , then the constrained optimization problem

$$P^* = \arg \min_{P \in \mathbb{R}^{n \times m}} \|P - Y\|_F^2 \quad \text{subject to} \quad P^T P = I \quad (36)$$

has a closed form solution given by $P^* = UI_{n \times m} V^T$.

Substituting Y with $A^{k+1} + C^k$, we get the formula for updating P . Updating the auxiliary variable F and C is straightforward.

An illustration of such filters is shown in Figure 8(b).

4.1.2 DESIGN OF THE RECONSTRUCTION FILTERS

Once $A = (a_1, \dots, a_m)$ is obtained, we move on to second phase of designing the reconstruction filters B .

For fixed A and sampling matrix M , the constraint (10) is a linear system in B . Hence we will write it as $H(A)B = f$, where $H(A)$ denotes the coefficient matrix generated using A . To get some concrete ideas, let us look at a simple example.

Example. Consider a one dimensional situation where $m = 2$, $r = 3$. Assume $A = (a_1, a_2)$, $B = (b_1, b_2) \in \mathbb{R}^{3 \times 2}$,

$$A = \begin{pmatrix} a_{11} & a_{21} \\ a_{12} & a_{22} \\ a_{13} & a_{23} \end{pmatrix}, \quad B = \begin{pmatrix} b_{11} & b_{21} \\ b_{12} & b_{22} \\ b_{13} & b_{23} \end{pmatrix},$$

Assume $M = 1$, that is, no downsampling is performed. Then the linear equation $H(A)B = f$ is

$$\begin{pmatrix} a_{11} & a_{12} & a_{13} & a_{21} & a_{22} & a_{23} \\ 0 & a_{11} & a_{12} & 0 & a_{21} & a_{23} \\ 0 & 0 & a_{11} & 0 & 0 & a_{21} \\ a_{12} & a_{13} & 0 & a_{22} & a_{23} & 0 \\ a_{13} & 0 & 0 & a_{23} & 0 & 0 \end{pmatrix} \begin{pmatrix} b_{11} \\ b_{12} \\ b_{13} \\ b_{21} \\ b_{22} \\ b_{23} \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}.$$

This is a system of 5 equations with 6 unknowns. Therefore, we have one additional degree of freedom left to design B .

In general, since m is large, $H(A)B = f$ is an under-determined linear system. Moreover, since A is obtained by solving (32) with respect to the orthogonality constraint, the coefficient matrix $H(A)$ tend to have a good condition number. This well-behaved under-determined linear system gives us the freedom to design the reconstruction filters B with additional properties. The general formulation is:

$$\min_B G(B) \quad \text{subject to} \quad H(A)B = f \quad \text{and other constraints} \quad (37)$$

where $G(B)$ is the objective function that we use to impose the additional property that we expect B to have. For example, if we want the reconstruction filters to look like piecewise smooth function, we can use the following formulation:

$$\begin{aligned} \min_B \quad G(B) &:= \sum_{l=1}^m \|\nabla b_l\|_1 \\ \text{subject to} \quad & \|b_l\|_2 = \alpha, \quad l = 1, \dots, m \\ & H(A)B = f \end{aligned} \quad (38)$$

where ∇ is a discrete gradient operator and α is a predefined parameter whose purpose is to make the size of B compatible with the constraint $H(A)B = f$.

An illustration of the reconstruction filters is given in Figure 8(b).

4.2 Critically Down-sampled Case

In this case, we have less freedom and must consider the decomposition and reconstruction filters simultaneously. Since the constraint is bi-linear in A and B , in order to avoid the trivial situation where the objective function is minimized by scaling down the decomposition filters A and scaling up the reconstruction filters B , we require the filters A to have unit norm. Adopting the same notation as before, (25) becomes

$$\begin{aligned} \min_{A, B} \quad & \|W_A x\|_{1,1} \\ \text{subject to} \quad & H(A)B = f \\ & \|a_i\|_2 = 1, \quad i = 1, \dots, m \end{aligned} \quad (39)$$

Again, we apply the split Bregman algorithm to solve this problem. The procedures are similar to the redundant case. We will formulate the algorithm directly as follows:

Algorithm 3 Adaptive construction of bi-frames: critically down-sampled case

- 1: **Input:** x .
 - 2: **Initialize** $k = 0, F = \mathbf{0}, C = \mathbf{0}, A = A^0, B = B^0, D = W_{A^0}x$.
 - 3: **while** “not converge” **do**
 - 4: $D^{k+1} \leftarrow \arg \min_D \|D\|_{1,1} + \frac{\lambda}{2} \|D - W_{A^k}x - F^k\|_F^2$
 - 5: $A^{k+1} \leftarrow \arg \min_A \eta \|W_A x - D^{k+1} + F^k\|_F^2 + \lambda \|H(A)B^k - f + C^k\|_F^2$ **s.t.**
 $\|a_i\|_2 = 1, i = 1, \dots, m$
 - 6: $B^{k+1} \leftarrow \arg \min_B \lambda \|H(A^{k+1})B - f + C^k\|_F^2$
 - 7: $F^{k+1} \leftarrow F^k + W_{A^{k+1}}x - D^{k+1}$.
 - 8: $C^{k+1} \leftarrow C^k + H(A^{k+1})B^{k+1} - f - P^{k+1}$
 - 9: $k \leftarrow k + 1$
 - 10: **return** A^k, B^k
-

Updating D is again done by soft thresholding. The update of A is done by running a few iterations of the interior-point method, and updating B is done by running a few iterations of conjugate gradient method. The most computationally intensive step is updating A . But since in our applications, the support size and the number of filters are small, the total number of variables is normally a few hundred, hence the computational cost is reasonable.

5. Multi-level Adaptive Frames

Going to multi-level, the basic idea is to recursively use the framework of adaptive frames on the coefficients obtained by applying the adaptive filters to the signal. There are two practical issues that we need to consider. The first is whether one considers all the coefficients or a subset of coefficients when going to coarser level. In this regard the difference between low-pass and high-pass filters is particularly relevant. Recall that a low pass filter is defined by the condition that the Fourier coefficient $a(0) \neq 0$. The second issue is whether a new set of adaptive filters is learned and used at each level. We will discuss three different strategies that are motivated by three different examples.

5.1 The MRA approach

The basic idea of MRA is to apply the same set of filters at each level to the coefficients from the low-pass filters. When constructing traditional wavelet frames using MRA, there is only one low-pass filter at each level, the scaling function. All other filters are high pass filters associated with the wavelets. Our experience suggests that this is often the case for the adaptively learned filters. To makes sure that this is indeed

the case, we can also add the additional constraint

$$\hat{a}_1(0) \neq 0, \hat{a}_i(0) = 0, i = 2, \dots, m \quad (40)$$

to (17). As a linear constraint, this does not cause much trouble in the optimization algorithm. With this, the adaptive wavelet frames can be used in the same way as classical wavelet frames. Specifically, given the the input signal x , the multi-level decomposition proceeds as follows: We first perform a one-level decomposition to get the coefficients $v_i = T_{a_i}x, i = 1, \dots, m$. v_1 is associated with the low-pass filter, which provides the coarse-grained approximation of the signal, and $v_i, i = 2, \dots, m$ are associated with the high-pass filters, which provide the missing details from the coarse-graining. Next, we treat v_1 as the input signal and perform another one-level decomposition using the same set of filters to get the second-level coefficients. This procedure can then be continued. Schematically, this algorithm can be represented as a tree with one branching point at each level, as shown in Figure 2(a).

5.2 The scattering transform approach

By applying each fixed filter to the signal, one obtains a set of coefficients, called a feature map. If the input signal is an image, the feature map is also an image. One can then treat this new image as the input signal and find the corresponding adaptive filters. In some applications, this can be preceded by some component-wise nonlinear transformation. This is schematically shown in Figure 2(b). This structure is used in the scattering transforms proposed in Bruna and Mallat (2013).

The obvious drawback of this approach is that the degrees of freedom increase exponentially as the number of levels increases. Nevertheless, in classification tasks, it is generally believed that lifting the raw data to a high dimensional space using some nonlinear transforms can help by making the data more linearly separable. This is the underlying principle that makes kernel methods effective. Therefore this approach is potentially useful for classification tasks.

In practice, we can also apply some pruning procedure if there are many layers. For example, we can stop expanding the node if it has very small energy.

5.3 The convolutional net approach

The structure shown in Figure 2(c) resembles the first few layers of a convolutional net. The root node still represents the input signal, the first layer nodes represent the one-level decomposition coefficients. The coefficients together are then regarded as a multi-channel signal. For example, if the input signal is a monochrome two dimensional image, the first layer coefficients can be regards as a three dimensional image by stacking the m features maps. Once viewed as a three dimensional image, we can construct adaptive frames and bi-frames using three dimensional filters, except that the the filters might not be convolutional in the third dimension since the input signal is not expected to be translation invariant in that direction.

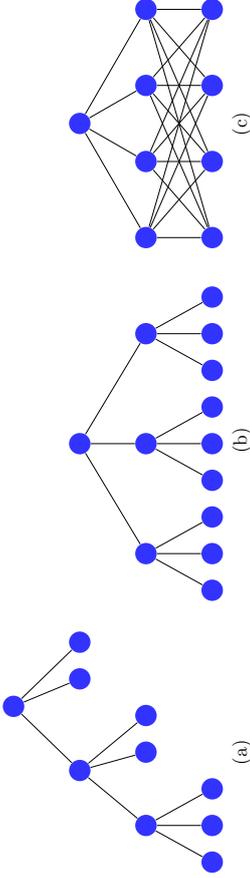

Figure 2: three structures

Figure 3: Illustration of the different multi-level structures. (a) The structure used in the MRA approach. (b) The structure used in the scattering transform approach. (c) The structure used in the convolutional net approach.

Obviously we are not limited by these three examples of multi-level structures. We call this way of representing the signal *multi-scale adaptive frames and bi-frames*. For convenience we abbreviate it as: *AdaFrame*.

6. Examples

6.1 The staircase signal

We consider a simple example where the signals are binary, each consists of long sequences of +1's separated by long sequences of -1's, as shown in Figure 4. Let s be the minimum length of consecutive +1 and -1 blocks. s is a measure of the lowest frequency of the signal. We use Algorithm 1 to learn the filters with $\eta = 10^2$. The filters learned are shown in Figure 5.

Figure 4: A binary signal

In the case when $m = 2, r = 2$, we recover the Haar wavelet basis as shown Figure 6. This example is simple enough to allow for analytic calculations. In fact, one can show that in the large s regime with the assumption that $r = m$, the filters learned should exactly be the ones shown in the figure. This simple example shows that adaptive filters do capture the special features of the data.

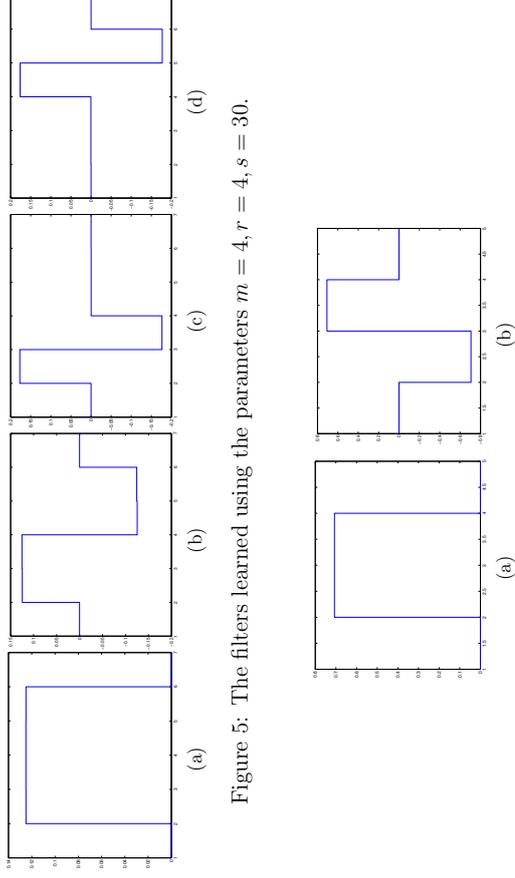

Figure 5: The filters learned using the parameters $m = 4, r = 4, s = 30$.

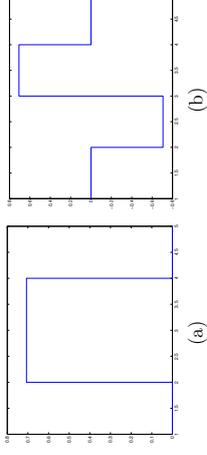

Figure 6: The filters learned using the parameters $m = 2, r = 2, s = 30$. In this case, we recover the Haar wavelets.

6.2 Fingerprint signal

Our next example is the fingerprint dataset (Maltoni et al., 2009). We use a fraction of the database. The input are 80 images of size 364×256 . Some sample images and filters learned are shown in Figure 7. The filters are learned using Algorithm 2 with parameters $\eta = 10^2, \lambda = 10^3$. The main feature of the fingerprint images is that they contain oscillations along different directions. As can be seen from the Figure 7, this feature is indeed captured by the learned filters.

6.3 Another test image

The next example is a well-known natural image shown in Figure 8. This is an example of the redundant bi-frame case. We learn the decomposition filters using Algorithm 2 with $\eta = 10^2, \lambda = 10^3$. Note that some filters look like edge detectors along different directions (e.g. the second and third filters in the first row act like edge detectors along the x and y axis). Most filters look like Gabor wavelets. They detect oscillations along different directions. Because this is an example of the redundant case, hence the reconstruction filters are not unique.

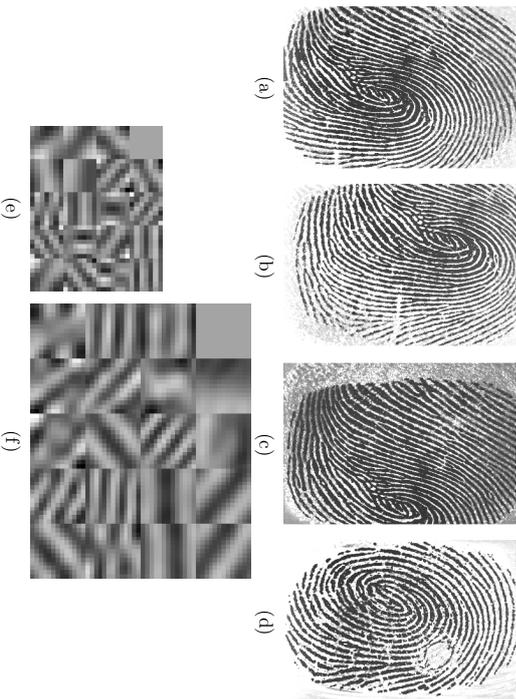

Figure 7: (a)(b)(c)(d) Sample images of finger print. (e) Decomposition filters learned with support size 7×7 . (f) Decomposition filters learned with support size 13×13 .

7. Recover Predefined Wavelets

The proposed framework is an adaptive extension of the well-known wavelets and wavelet frames. It is natural to ask whether the standard wavelet filters can be recovered using this framework. Naturally we expect that if the signal has a sparse representation in a predefined wavelet domain, then the adaptive frames and bi-frames would recover the predefined wavelets.

To see whether this is the case, we generate the signals using linear combinations of different wavelets with different levels of sparsity. Specifically, the signals are generated using 4 Daubechies wavelets of different support size, “db2”, “db3”, “db12”, “db24” in MATLAB syntax. Sparse random vectors with a given sparsity level are generated (the sparsity level is the ratio of the number of nonzero coefficients to the length of the coefficient vector, we also call it the density), and these vectors are used as the coefficients of the signals under the wavelet transform.

Given a signal, the adaptive filters are learned by solving (17). Since (17) is nonconvex, to avoid complications coming from local minimum, we used the simulated annealing algorithm to perform the global optimization. We then compare the filters obtained with the original wavelets used to construct the signal. We declare success if the l_2 norm of the difference between the adaptive filters and the predefined wavelets is smaller than 10^{-4} . Table 2 shows the success rate. 10 trials were performed for

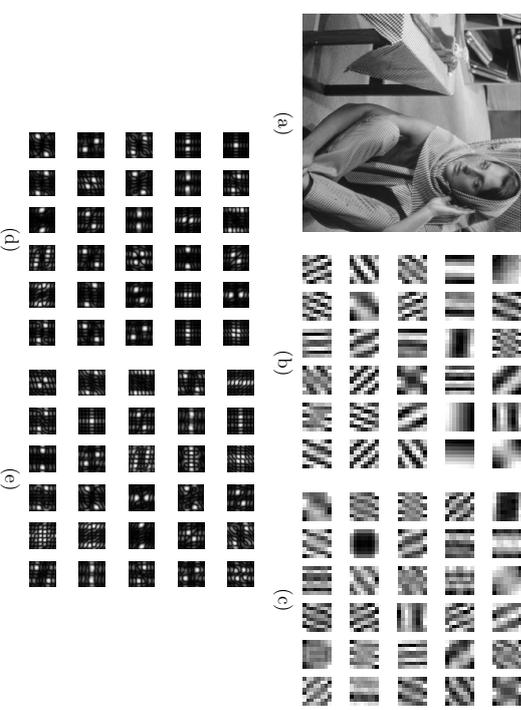

Figure 8: (a) Input image of size 512×512 . (b) 30 decomposition filters with support size 8×8 . (c) A specific set of reconstruction filters. (d) Fourier spectrum of the decomposition filters. (e) Fourier spectrum of the reconstruction filters.

Density	db2	db3	db12	db24
0.1	1	1	1	1
0.2	1	1	1	1
0.3	1	1	1	1
0.4	1	1	0	0
0.5	0	0	0	0

Table 2: Ratio of successful recovery of predefined wavelets.

each case. The result is indeed consistent with our expectation. It is interesting to see that the transition is very sharp.

Figure 9 shows the adaptive filters for the case when the signals are generated using a dense combination of the predefined wavelets. In this case, the predefined wavelets are not optimal, and the signals have a sparser representation under the adaptive filters, as can be seen from Figure 9(c). The L_1 norm of the wavelet coefficients is used as a robust measure of sparsity.

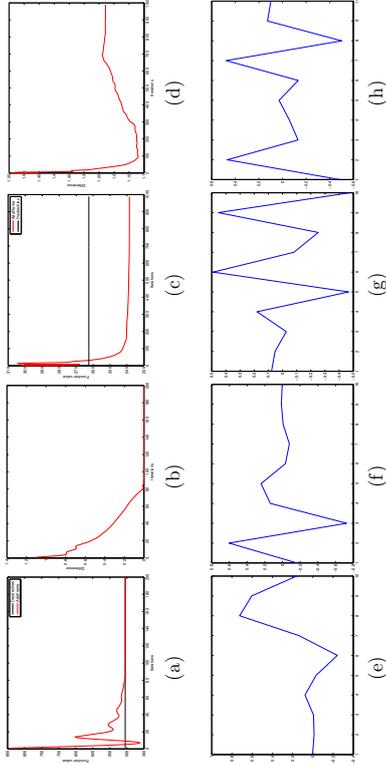

Figure 9: (a) The signal is generated using sparse linear combinations of the Daubechies wavelets. The black line is the objective function value evaluated using the Daubechies wavelets, which is optimal in this case. The value below the black line is due to infeasible intermediate solutions. (b) The filters learned also converge to the Daubechies wavelets, the figure shows the difference of the adaptive filters and the Daubechies wavelets measured in Frobenius norm. (c) The signal is generated using a dense linear combinations of the Daubechies wavelets. In this case, the objective function converges to a value lower than that of the the wavelets, indicated by the horizontal line. (d) The filters learned also converge, but to something different from the Daubechies wavelets. (e)(f) Decomposition filters of the Daubechies wavelet “db5”. The signal is generated using sparse linear combination of this wavelets, the filters learned are the same as the wavelets. (g)(h) The filters learned for signals generated using dense combinations of the “db5” wavelet. They are different from the wavelet filters.

8. Sample Applications

In this section, we discuss some examples of applications of the multi-scale adaptive frames, the AdaFrames. A thorough comparison of the proposed model and other existing models will be postponed to future publications.

8.1 Image Compression

AdaFrames are designed with the objective of making the decomposition coefficients sparse. Therefore they should be naturally suited for image compression tasks. As an initial step, we will compare the performance of AdaFrames with predefined Daubechies wavelets and Haar wavelets. We use the following simple compression scheme: Given an image x and the filters, we perform a decomposition to the coars-

est level to get the coefficients, but we keep only the coefficients with relatively large absolute values and set all the other coefficients to 0. The ratio of the total number of coefficients to the number of coefficients kept is called the “compression ratio” (the entropy coding stage is not considered here). We then perform a reconstruction step to get the reconstructed image \hat{x} . The quality of the compression is measured by the peak signal-to-noise ratio (PSNR). For monochrome 8 bit image, PSNR is defined as

$$\text{PSNR}(x, \hat{x}) = 10 \log_{10} \frac{1}{MN} \sum_{i=1}^M \sum_{j=1}^N (\hat{x}(i, j) - x(i, j))^2 \quad (41)$$

The filters are learned using image 8(a). 4 filters of support size 6×6 are learned using Algorithm 1 with $\eta = 10^2$. The coefficients are critically down-sampled with sampling matrix $M = \text{Diag}(2, 2)$. Initialization is done using the Daubechies filters db3. In general, we have found that using predefined wavelet frames as initialization works quite well. 7 levels of decompositions are performed using the architecture shown in Figure 2 and the same set of filters. The PSNR values are plotted against the “compression ratio” in Figure 10.

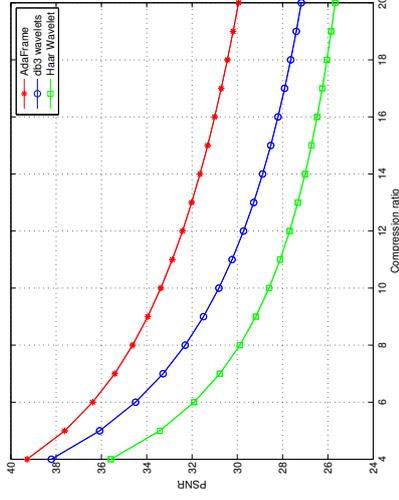

Figure 10: Image compression example. With the same image quality (measured in PSNR), AdaFrames achieves significantly higher compression ratio than the Haar wavelets and the Daubechies wavelets.

8.2 Image Denoising

As one of the simplest inverse problem, image denoising provides a convenient platform over which image processing ideas and techniques can be tested. Indeed, during the past few decades, many ideas from a diverse range of viewpoints have been proposed to address this problem, including wavelet domain thresholding, nonlocal means

(Buades et al., 2005), BM3D (Dabov et al., 2007), and the more recent ones based on dictionary learning (Elad and Aharon, 2006).

Among the various models, we select the K-SVD model (Elad and Aharon, 2006) as a benchmark for comparison since it is closely related to AdaFrames and since it has been shown to achieve the state of the art results.

Assume the image is corrupted by some additive noise:

$$g = f + n$$

where f is the clean image, g is our observation, and n is the noise with unknown distribution. First let us recall the procedure for wavelet domain denoising. Let W_A and R_A be the decomposition and reconstruction operators associated with the filters A respectively. Given an observed image x , the denoised image is then given by:

$$\hat{x} = R_A(\text{shrink}(W_A x)) \quad (42)$$

The procedure for AdaFrame denoising is exactly the same as that of wavelet domain denoising. Given the input image, we first learn the filters from the data using Algorithm 1 (or Algorithm 2 if we want to use bi-frames). We then use (42) to denoise.

In the first example, the input is a single image normalized to $[0, 1]$ and is corrupted with an additive Gaussian white noise with $\sigma = 0.1$. We train the filters both from the noisy image and the clean image with $m = 36, r = 6, \eta = 10^2, \lambda = 10^3$. A two-level decomposition is performed. The soft thresholding parameter is set to be 0.14. Initialization is done by setting the filters to be random orthogonal vectors. The result is shown in Figure 11. The performance of the K-SVD algorithm depends on the number of the atoms in the dictionary. Generally, the performance is better as we increase the number of atoms. In this example, 256 atoms with size 6×6 are used.

It is not surprising that the filters learned from a clean image produces better quality images: One can see from Figure 12 that the fine textures of the image are recovered. At a first sight, one might feel that this is impractical since we normally do not have access to the clean images. Nevertheless, there do exist realistic settings where learning from clean images makes sense. One such a situation is that filters learned from one set of clean images can then be used on another set of noisy images. We tested this idea on the extended Yale human face dataset B (Lee et al., 2005). It contains 16128 images of 28 human subjects. We used a subset of the images by picking the first 20 images of each of the subjects. We then added Gaussian white noise with $\sigma = 0.1$ to get the simulated noisy images. A glimpse of the dataset is in Figure 13.

To learn the filters, we pick the 100 clean images at random and use Algorithm 2 with $m = 36, r = 6, \eta = 10^2, \lambda = 10^3$. Two-levels of decompositions are performed. The soft-thresholding parameter is set to be 0.14. The results for the noisy images are reported in Table 3.

Figure 11: (a) Noisy input image, $\sigma = 0.1$. (b) K-SVD denoising result, PSNR=28.65dB. (c) AdaFrame denoising, filters learned from noisy image, PSNR=28.84dB. (d) AdaFrame denoising, filters learned from the clean image, PSNR=29.34dB.

PSNR	31.4dB	32.01dB	31.35dB	32.07dB

Table 3: Average PSNR on the simulated noisy images on the extended Yale human face dataset B.

In another experiment, we test the performance of AdaFrame and K-SVD with different support sizes. We use some well-known benchmark images as test images. The images are normalized to $[0, 1]$ and the noise is Gaussian with $\sigma = 0.02, 0.05$ and 0.1 respectively. For K-SVD, 256 filters of support size 8×8 and 12×12 are used. For AdaFrame, 64 filters of support size 8×8 and 144 filters of support size 12×12

are learned. λ is chosen based on the noise level and is set to be $\lambda = 0.005, 0.01, 0.025$ respectively. The result is shown in Table 5.

As a last denoising example, we apply AdaFrames to some examples of natural photos with unknown noise. The setting is the same as the previous example. We learn filters directly from the noisy images. Since the image has RGB channels, we learn the filters (of support size 9×9) for each channel separately with the same value of λ , which is chosen to yield a good visual impression. The results are shown in Figure 14.

As we emphasized earlier, the AdaFrame is faster than sparse coding technique at inference time. We record the computation time for the K-SVD denoising algorithm

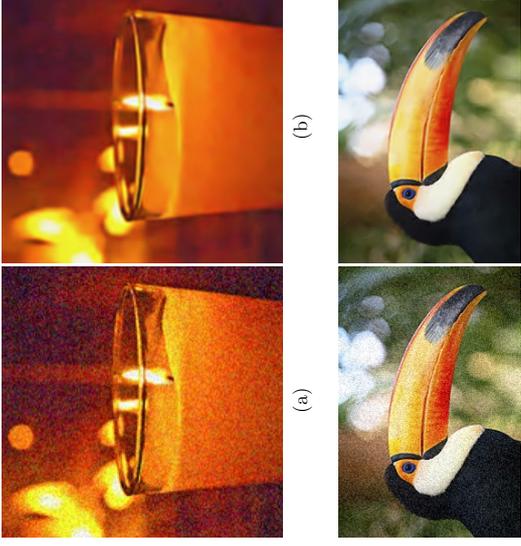

Figure 14: (a)(c) Two images from the Internet. (b)(d) Denoised images using AdaFrame.

and the AdaFrame denoising algorithm. In our laptop with the same setup, the K-SVD algorithm takes 25s to train a dictionary with 256 atoms of support size 8×8 and 6.5s to denoise the image. The software we use is downloaded from <http://www.cs.technion.ac.il/~ronrubin/software>. The AdaFrame takes 3.7s to train 64 filters with support size 8×8 and takes 0.6s to denoise. The time for denoising scales linearly with the number of filters.

8.3 Image Classification

Although AdaFrames are aimed to produce sparse representations, they can also be used to for other tasks such as extracting features for object recognition. In fact, it can provide a faster alternative to sparse coding.

To demonstrate this idea, in the following example, we apply AdaFrames to extract features in order to classify the handwritten digits. The dataset we used is MNIST (LeCun et al., 1998). It contains 70000 28×28 images of digits from 0 to 9, 60000 for training and 10000 for testing. A nonlinear transformation, the rectified linear function defined by $relu(x) = \max(x, 0)$ is applied to the coefficients obtained using

AdaFrames. The results are sent to a linear support vector machine (SVM) to perform the classification task. We discuss three different set of experiments.

In the first setup, we use Algorithm 2 to learn the filters with $m = 6$, $r = 6$, $\eta = 10^2$, $\lambda = 10^3$. Initialization is done with random orthogonal filters. For each image, we perform a one-level decomposition to get the coefficients.

The second setup is identical to the first one, except $m = 12$ instead of $m = 6$. It is generally believed that lifting the raw pixels to some higher-dimensional feature space will be helpful for classification. Since we use more filters in this setup, the features we get have higher dimensions. Indeed the results are better than the results of the previous setup.

In the third setup, we use a two-level decomposition. We use Algorithm 2 to learn the filters with $m = 6$, $r = 6$, $\eta = 10^2$, $\lambda = 10^3$. Same nonlinear transformation as in the previous setups are used. In this way, we obtain 6 feature maps, each of size 28×28 . Then the collection of the feature maps are treated as 6 sets of new input images. For each set, we use Algorithm 2 with $m = 4$, $r = 6$, $\eta = 10^2$, $\lambda = 10^3$ to learn the filters. Hence we have 24 filters in total. For each feature map, we perform a one-level decomposition using the corresponding 4 filters to get 4 feature maps. Again, we keep the positive coefficients and set the negative coefficients to 0. These positive coefficients in the first and second layers are the extracted features.

MNIST	Raw pixel	I	II	III
Precision	88.0 %	97.0 %	97.4 %	99.0 %

Table 5: Results of the MNIST classification. ‘‘Raw pixel’’ means that the features are the raw pixels.

These features are sent to a linear SVM. The results are reported in Table 5. Note that there is a significant reduction in the error rates compared to raw pixel features. As a point of comparison, the state-of-the-art result with preprocessing, is 0.23%, which is obtained using deep convolutional neural networks (Chresan et al., 2012).

9. Connection with De-convolutional net

Convolutional nets have had remarkable successes in a variety of challenging applications (LeCun et al., 1998; Lee et al., 2009; Krizhevsky et al., 2012). A typical supervised convolutional net consists of several convolutional layers and fully connected layers. A convolutional layer has the structure shown in Figure 15. It maps the feature maps produced by the previous layer to another set of feature maps. The input feature maps are first convolved with some filters, which are also obtained from training. A point-wise nonlinear function, called the ‘‘activation function’’, such as a rectified linear function is then applied, followed by a pooling procedure in order to down-sample the set of feature maps. Pooling is usually a local operation. Max pooling, namely picking the feature map with the maximum amplitude in a small

neighborhood of each node, is the most popular. It is similar to simple down-sampling but is nonlinear.

Although convolutional nets are designed for feature extraction and object recognition, it is an interesting question to ask how much of the input data can be reconstructed from the information in the intermediate layers of the network. For one thing, this can help us to gain some intuition about how convolutional nets work.

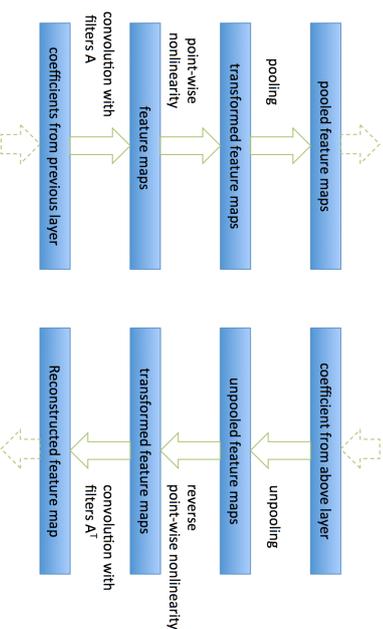

Figure 15: The left figure shows the typical structure of a convolutional layer from a convolutional net, the right figure shows the structure of a de-convolutional layer from a de-convolutional net.

In this regard the most popular approach in the literature is the ‘‘deconvolutional net’’ (Zelner et al., 2010). A deconvolutional net can be thought of as a convolutional net that uses the same components (filtering, nonlinear activation, pooling) but in reverse order. Specifically a deconvolutional net consists of the following steps: First, the pooling procedure is reversed. If averaging or other linear operator is used for pooling, then to reverse it, one simply applies its transpose operator. The max-pooling procedure is a non-linear operation. For an image I , the max-pooling operation has two outputs, the maximum value and the position where the maximum value is obtained, defined as

$$(v, p)(x) = (\text{sign}(I(x)) \cdot \max_{x \in \mathcal{N}} |I(x)|, \arg \max_{x \in \mathcal{N}} |I(x)|)$$

where \mathcal{N} is the neighborhood of x . To reverse max-pooling, we set

$$I(x) = \begin{cases} v & : x = p, x \in \mathcal{N} \\ 0 & : x \neq p, x \in \mathcal{N} \end{cases}$$

The second component is to reverse the activation function. For invertible functions such as the sigmoid or the tanh function (LeCun et al., 1998), we simply take

their inverse. The situation where the activation function is non-invertible as is the case of the absolute value function is more complicated and is discussed in Waldspurger et al. (2012).

The third component is to reverse the convolution operator, hence the name “deconvolution net”. Since convolution is a linear operator, to reverse it, one applies its transpose (Zeiler and Fergus, 2013).

The above procedure is summarized in a diagram in Figure 15. Notice the similarity with applying wavelet frame transforms. A single level decomposition and reconstruction step of the wavelet frame transform can be described as in Figure 16. We see that if we ignore the point-wise nonlinearity, a convolutional or a deconvolutional layer is very similar to a decomposition and reconstruction step in wavelet bi-frame transform respectively.

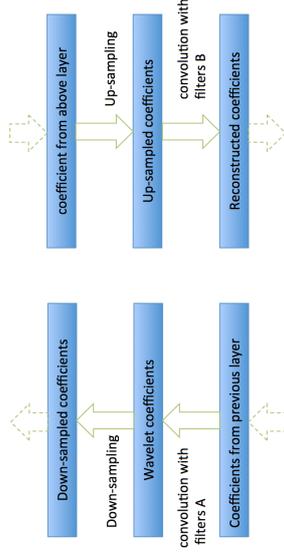

Figure 16: One level decomposition and reconstruction of AdaFrame

There is a subtle but important difference. In deconvolutional net, deconvolution is done by applying the transpose of the convolution operator. In the one level wavelet bi-frame reconstruction, this is done using the reconstruction filters, obtained by solving (10), as required by UEP. Since there is no guarantee that the UEP condition is satisfied by the filters obtained in the convolutional nets, one expects that there will be errors in the reconstruction process, i.e. the deconvolutional nets. This is indeed the case, as we show below.

The similarity between the convolutional layer and one level wavelet frame transform suggests a natural fix for this problem. Instead of using the flipped convolutional filters as the deconvolutional filters, we view the convolutional filters as the decomposition filters and solve (10) to obtain the reconstruction filters. These reconstruction filters are then used as the deconvolutional filters. Everything else is the same as in the original deconvolutional net. The existence of a solution to (10) is guaranteed by the fact that in a typical convolutional net, the number of filters is large, and hence we are in the the redundant case for the wavelet bi-frames. This small change to the deconvolutional net yields much better reconstruction as we now demonstrate.

We implemented a two-layer convolutional network. In the first layer, we have 12 filters of support size 6×6 , the pooling procedure is chosen to be the usual down-sampling with decimation factor (2, 2). To construct the second layer, we stack together the feature maps from the first layer and form a three-dimensional signal. We then learn 12 filters of support size $4 \times 4 \times 2$, the pooling procedure is also down-sampling with decimation factor (2, 1, 2). The activation function is the sigmoid function. The results of reconstructing the input image using the original deconvolutional net and the modified procedure described above are shown in Figure 17. As one can see, using the deconvolutional net approach, we gradually lose information as we ascend in the layers, while using the AdaFrame, we do not lose information.

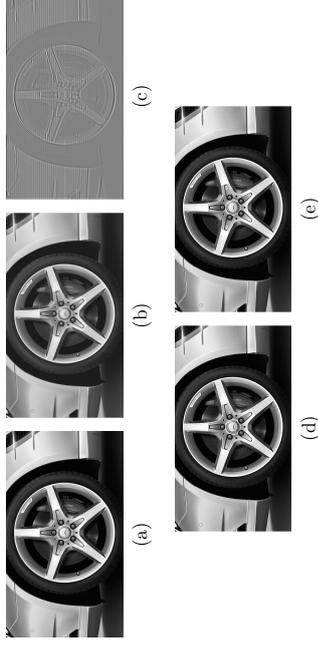

Figure 17: (a) The input image. (b) Reconstruction from the first layer activations using “deconvolutional net” approach. (c) Reconstruction from the second layer activations using the “deconvolutional net” approach. (d) Reconstruction from the first layer activations using the AdaFrame. (e) Reconstruction from the second layer activations using the AdaFrame.

In addition to near perfect reconstruction, AdaFrame has the potential to be used as an initialization method for the convolutional parts of a typical convolutional net. This is a direction for future research.

10. Conclusion

Predefined wavelets and dictionary learning have both been very successful in their own ways. In this paper, we have proposed a framework, the AdaFrame, that naturally combines the advantages of both. It is multi-scale and computationally efficient as pre-defined wavelets and wavelet frames, while being adaptive as in dictionary learning. Unlike dictionary learning, the proposed framework guarantees perfect reconstruction, which is an appealing property in many signal processing tasks.

Between adaptive frames and adaptive bi-frames, our experience suggests that adaptive bi-frames are much easier to use because of the additional flexibility. The

learning procedure is also easier, especially when the system is very redundant in which case the learning procedure can be carried out in two phases by learning the decomposition and reconstruction filters separately.

In addition to the examples given in this paper, we believe that the proposed framework can be useful in many other applications. It is not restricted to image processing, it can be used on time series, videos and even graphs. We will explore these applications in subsequent papers.

Another direction for future investigation is to use the proposed framework as feature extraction tools for machine learning tasks. Sparse coding has been popular for this purpose. But the proposed framework should be a promising alternative since it is more efficient and it has a multi-scale structure. It should be particularly appealing when the computation cost is the main bottleneck, as is the case in some real-time object recognition systems.

Appendix

Proof of Theorem 1

For convenience, we need the following lemma.

Lemma 2 *Let M be $d \times d$ sampling matrix and $a, b \in l_2(\mathbb{Z}^d)$ be finitely supported sequences. Then*

$$\widehat{S_b v}(\xi) = |\det(M)| \widehat{v}(M^T \xi) \widehat{b}(\xi) \quad (43)$$

and

$$\widehat{T_a}(M^T \xi) = |\det(M)|^{-1} \sum_{\omega \in \Omega_M} \widehat{v}(\xi + 2\pi\omega) \overline{\widehat{a}(\xi + 2\pi\omega)} \quad (44)$$

where

$$\widehat{a}(\xi) := \sum_{k \in \mathbb{Z}^d} a(k) e^{-ik \cdot \xi}$$

and

$$\Omega_M := \{[M^T]^{-1} \mathbb{Z}^d\} \cap [0, 1]^d$$

Proof For a sequence $v \in l_2(\mathbb{Z}^d)$,

$$\begin{aligned} \widehat{S_b v}(\xi) &= \sum_{k \in \mathbb{Z}^d} (S_b v)(k) e^{-ik \cdot \xi} \\ &= |\det(M)| \sum_{k \in \mathbb{Z}^d} \sum_{j \in \mathbb{Z}^d} v(j) b(k - Mj) e^{-ik \cdot \xi} \\ &= |\det(M)| \sum_{k \in \mathbb{Z}^d} b(k - Mj) e^{-i(k - Mj) \cdot \xi} \sum_j v(j) e^{-iMj \cdot \xi} \\ &= |\det(M)| \widehat{b}(\xi) \widehat{v}(M^T \xi). \end{aligned} \quad (45)$$

Let $\widehat{u}(\xi) = \sum_{k \in \mathbb{Z}^d} v(k) \overline{\widehat{a}(k - n)}$, then $\widehat{u}(\xi) = \widehat{v}(\xi) \overline{\widehat{a}(\xi)}$. By definition of T_a , we have $(T_a v)(n) = u(Mn)$. So

$$\widehat{T_a v}(M^T \xi) = \sum_{n \in \mathbb{Z}^d} (T_a v)(n) e^{-in \cdot M^T \xi} = \sum_{n \in \mathbb{Z}^d} u(Mn) e^{-kMn \cdot \xi} \quad (46)$$

On the other hand,

$$\begin{aligned} \sum_{\omega \in \Omega_M} \widehat{u}(\xi + 2\pi\omega) &= \sum_{k \in \mathbb{Z}^d} \sum_{\omega \in \Omega_M} e^{-ik \cdot (\xi + 2\pi\omega)} \\ &= \sum_{k \in \mathbb{Z}^d} u(k) e^{-ik \cdot \xi} \sum_{\omega \in \Omega_M} e^{-ik \cdot 2\pi\omega}. \end{aligned} \quad (47)$$

If $k \in M\mathbb{Z}^d$, then $\sum_{\omega \in \Omega_M} e^{-ik \cdot 2\pi\omega} = |\det(M)|$; if $k \in \mathbb{Z}^d \setminus M\mathbb{Z}^d$, $\sum_{\omega \in \Omega_M} e^{-ik \cdot 2\pi\omega} = 0$, so we have

$$\sum_{\omega \in \Omega_M} \widehat{u}(\xi + 2\pi\omega) = |\det(M)| \sum_{k \in M\mathbb{Z}^d} u(k) e^{-ik \cdot \xi} = |\det(M)| \sum_{n \in \mathbb{Z}^d} u(Mn) e^{-iMn \cdot \xi}, \quad (48)$$

Combining this with (46), we get the desired result. \blacksquare

Lemma 3 Let M be $d \times d$ sampling matrix and $a_l, b_l, l = 1, \dots, m$ be m finitely supported sequences. Then

$$\sum_{l=1}^m \mathcal{S}_{b_l} \mathcal{T}_{a_l} v = v, \quad \forall v \in l_2(\mathbb{Z}^d) \quad (49)$$

$$\text{if and only if, for any } \omega \in \Omega_M := [(M^T)^{-1}\mathbb{Z}^d] \cap [0, 1)^d \quad (50)$$

$$\sum_{l=1}^m \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega)} = \delta(\omega).$$

Proof By definition of the decomposition and reconstruction operators W_a and R_b , we have

$$R_b W_a v = \sum_{l=1}^m \mathcal{S}_{b_l} \mathcal{T}_{a_l} v. \quad (51)$$

which is equivalent to

$$\sum_{l=1}^m \widehat{\mathcal{S}_{b_l} \mathcal{T}_{a_l} v}(\xi) = \hat{v}(\xi), \quad \forall v \quad (52)$$

By the above lemma, we have

$$\begin{aligned} \hat{v}(\xi) &= \sum_{l=1}^m (\widehat{\mathcal{S}_{b_l} \mathcal{T}_{a_l} v})(\xi) \\ &= \sum_{l=1}^m |\det(M)| \widehat{\mathcal{T}_{a_l} v}(\xi) (M^T \xi) \hat{b}_l(\xi) \\ &= \sum_{l=1}^m \sum_{\omega \in \Omega_M} \hat{v}(\xi + 2\pi\omega) \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega)} \end{aligned} \quad (53)$$

If (52) holds true, then

$$\sum_{l=1}^m \sum_{\omega \in \Omega} \hat{v}(\xi + 2\pi\omega) \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega)} = \sum_{\omega \in \Omega_M} \hat{v}(\xi + 2\pi\omega) \delta(\omega) = \hat{v}(\xi). \quad (54)$$

holds for all $v \in l_2(\mathbb{Z}^d)$.

Conversely, if (51) is true, we can choose v that is close to a δ -function. Let $B_\epsilon(\xi_0)$ be the open ball centered at ξ_0 with radius ϵ . Fix $\omega_0 \in \Omega_M$ and $\xi_0 \in \mathbb{R}^d$, we can choose $v \in l_2(\mathbb{Z}^d)$ such that

1. $\hat{v}(\xi + 2\pi\omega_0) = 1$, for all $\xi \in B_\epsilon(\xi_0)$.
2. $\hat{v}(\xi + 2\pi\omega) = 0$, for all $\xi \in B_\epsilon(\xi_0), \omega \in \Omega \setminus \{\omega_0\}$.
3. $\text{supp}(\hat{v}) \subset 2\pi\omega_0 + B_{2\epsilon}(\xi_0)$

This is possible because the set Ω is discrete. \blacksquare

Hence, for $\xi \in B_\epsilon(\xi_0)$,

$$\begin{aligned} \hat{v}(\xi) &= \sum_{l=1}^m \sum_{\omega \in \Omega_M} \hat{v}(\xi + 2\pi\omega) \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega)} \\ &= \sum_{l=1}^m \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega_0)} \end{aligned} \quad (55)$$

Hence,

$$\sum_{l=1}^m \hat{b}_l(\xi) \overline{\hat{a}_l(\xi + 2\pi\omega_0)} = \delta(\omega)$$

for all $\xi \in B_\epsilon(\xi_0)$, since ξ_0 and ω_0 are arbitrary, we obtain the desired result. Proof of Theorem 1.

Proof We only need to establish that (10) is equivalent to (52).

$$\begin{aligned} \delta(\omega) &= \sum_{l=1}^m \sum_{k \in \mathbb{Z}^d} \overline{\hat{b}_l(k)} e^{ik \cdot \xi} \sum_{n \in \mathbb{Z}^d} a_l(n) e^{-in \cdot (\xi + 2\pi\omega)} \\ &= \sum_{l=1}^m \sum_{k, n \in \mathbb{Z}^d} \overline{\hat{b}_l(k)} a_l(n) e^{i(k-n) \cdot \xi} e^{-in \cdot 2\pi\omega} \end{aligned} \quad (56)$$

Denote by $\Gamma_M := (M[0, 1)^d) \cap \mathbb{Z}^d$, then we have $\mathbb{Z}^d = \Gamma_M + M\mathbb{Z}^d$, replace n by $Mn + \gamma$, we can rewrite the above equation as

$$\begin{aligned} \delta(\omega) &= \sum_{l=1}^m \sum_{\gamma \in \Gamma_M} \sum_{k, n \in \mathbb{Z}^d} \overline{\hat{b}_l(k)} a_l(Mn + \gamma) e^{i(k-Mn-\gamma) \cdot \xi} e^{-i(Mn+\gamma) \cdot 2\pi\omega} \\ &= \sum_{l=1}^m \sum_{\gamma \in \Gamma_M} \sum_{k, n \in \mathbb{Z}^d} \overline{\hat{b}_l(k + Mn + \gamma)} a_l(Mn + \gamma) e^{ik \cdot \xi} e^{-k\gamma \cdot 2\pi\omega} \end{aligned} \quad (57)$$

Note that $(e^{-i\gamma \cdot 2\pi\omega})_{\omega \in \Omega_M, \gamma \in \Gamma_M}$ is the Fourier matrix, and its inverse matrix is $|\det(M)|^{-1} (e^{i\gamma \cdot 2\pi\omega})_{\omega \in \Omega_M, \gamma \in \Gamma_M}$. Therefore,

$$\begin{aligned} & \left(\sum_{l=1}^m \sum_{k, n \in \mathbb{Z}^d} \overline{\hat{b}_l(k + Mn + \gamma)} a_l(Mn + \gamma) e^{ik \cdot \xi} \right)_{\gamma \in \Gamma_M} \\ &= |\det(M)|^{-1} (e^{i\gamma \cdot 2\pi\omega})_{\omega \in \Omega_M, \gamma \in \Gamma_M} (\delta(\omega))_{\omega \in \Omega} \\ &= |\det(M)|^{-1} (1, 1, \dots, 1)^T. \end{aligned} \quad (58)$$

Hence

$$\sum_{l=1}^m \sum_{k, n \in \mathbb{Z}^d} \frac{1}{b_l(k + Mn + \gamma)} a_l(Mn + \gamma) e^{ik \cdot \xi} = |\det(M)|^{-1} \cdot \forall \gamma \quad (59)$$

taking inverse Fourier transform, we get the desired result. ■

Abstract

In sparse principal component analysis we are given noisy observations of a low-rank matrix of dimension $n \times p$ and seek to reconstruct it under additional sparsity assumptions. In particular, we assume here each of the principal components $\mathbf{v}_1, \dots, \mathbf{v}_r$ has at most s_0 non-zero entries. We are particularly interested in the high dimensional regime wherein p is comparable to, or even much larger than n .

In an influential paper, Johnstone and Lu (2004) introduced a simple algorithm that estimates the support of the principal vectors $\mathbf{v}_1, \dots, \mathbf{v}_r$ by the largest entries in the diagonal of the empirical covariance. This method can be shown to identify the correct support with high probability if $s_0 \leq K_1 \sqrt{n}/\log p$, and to fail with high probability if $s_0 \geq K_2 \sqrt{n}/\log p$ for two constants $0 < K_1, K_2 < \infty$. Despite a considerable amount of work over the last ten years, no practical algorithm exists with provably better support recovery guarantees.

Here we analyze a covariance thresholding algorithm that was recently proposed by Krauthgamer, Nadler, Vitenchik, et al. (2015). On the basis of numerical simulations (for the rank-one case), these authors conjectured that covariance thresholding correctly recover the support with high probability for $s_0 \leq K\sqrt{n}$ (assuming n of the same order as p). We prove this conjecture, and in fact establish a more general guarantee including higher-rank as well as n much smaller than p . Recent lower bounds (Berthet and Rigollet, 2013; Ma and Wigderson, 2015) suggest that no polynomial time algorithm can do significantly better.

The key technical component of our analysis develops new bounds on the norm of kernel random matrices, in regimes that were not considered before. Using these, we also derive sharp bounds for estimating the population covariance, and the principal component (with ℓ_2 -loss).

1. Introduction

In the spiked covariance model proposed by Johnstone and Lu (2004), we are given data $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ with $\mathbf{x}_i \in \mathbb{R}^p$ of the form¹:

$$\mathbf{x}_i = \sum_{q=1}^r \sqrt{\beta_q} u_{q,i} \mathbf{v}_q + \mathbf{z}_i, \quad (1)$$

Here $\mathbf{v}_1, \dots, \mathbf{v}_r \in \mathbb{R}^p$ is a set of orthonormal vectors, that we want to estimate, while $u_{q,i} \sim \mathcal{N}(0, 1)$ and $\mathbf{z}_i \sim \mathcal{N}(0, \mathbf{I}_p)$ are independent and identically distributed. The quantity $\beta_q \in \mathbb{R}_{>0}$ is a measure of signal-to-noise ratio. In the rest of this introduction, in order to simplify the exposition, we will refer to the rank one case and drop the subscript $q \in \{1, 2, \dots, r\}$. Further, we will assume n to be of the same order as p . Our results and proofs hold for a broad range of scalings of r, p, n , and will be stated in general form.

The standard method of principal component analysis involves computing the sample covariance matrix $\mathbf{G} = n^{-1} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top$ and estimates $\mathbf{v} = \mathbf{v}_1$ by its principal eigenvector $\mathbf{v}_{\text{PC}}(\mathbf{G})$. It is a well-known fact that, in the high dimensional regime, this yields an inconsistent estimate (see Johnstone and Lu (2009)). Namely $\|\mathbf{v}_{\text{PC}} - \mathbf{v}\| \not\rightarrow 0$ unless $p/n \rightarrow 0$. Even worse, Baik, Ben Arous, and Pécché (2005) and Paul (2007) demonstrate the following phase transition phenomenon. Assuming that $p/n \rightarrow \alpha \in (0, \infty)$, if $\beta < \sqrt{\alpha}$ the estimate is *asymptotically orthogonal* to the signal, i.e. $\langle \mathbf{v}_{\text{PC}}, \mathbf{v} \rangle \rightarrow 0$. On the other hand, for $\beta > \sqrt{\alpha}$, $\langle \mathbf{v}_{\text{PC}}, \mathbf{v} \rangle$ remains bounded away from zero as $n, p \rightarrow \infty$. This phase transition phenomenon has attracted considerable attention recently within random matrix theory (see, e.g. Féral and Pécché, 2007; Capitaine et al., 2009; Benaych-Georges and Nadakuditi, 2011; Knowles and Yin, 2013).

These inconsistency results motivated several efforts to exploit additional structural information on the signal \mathbf{v} . In two influential papers, Johnstone and Lu (2004, 2009) considered the case of a signal \mathbf{v} that is sparse in a suitable basis, e.g. in the wavelet domain. Without loss of generality, we will assume here that \mathbf{v} is sparse in the canonical basis $\mathbf{e}_1, \dots, \mathbf{e}_p$. In a nutshell, Johnstone and Lu (2009) propose the following:

1. Order the diagonal entries of the Gram matrix $\mathbf{G}_{i(1),i(1)} \geq \mathbf{G}_{i(2),i(2)} \geq \dots \geq \mathbf{G}_{i(p),i(p)}$, and let $J \equiv \{i(1), i(2), \dots, i(k)\}$ be the set of indices corresponding to the s_0 largest entries.
2. Set to zero all the entries $\mathbf{G}_{i,j}$ of \mathbf{G} unless $i, j \in J$, and estimate \mathbf{v} with the principal eigenvector of the resulting matrix.

Johnstone and Lu formalized the sparsity assumption by requiring that \mathbf{v} belongs to a weak ℓ_q -ball with $q \in (0, 1)$. Instead, here we consider a strict sparsity constraint where \mathbf{v} has exactly s_0 non-zero entries, with magnitudes bounded below by $\theta/\sqrt{s_0}$ for some constant $\theta > 0$. Amini and Wainwright (2009) studied the more restricted case when every entry of \mathbf{v} has equal magnitude of $1/\sqrt{s_0}$. Within this restricted model, they proved diagonal thresholding successfully recovers the support of \mathbf{v} provided the sample size n satisfies²

1. Throughout the paper, we follow the convention of denoting scalars by lowercase, vectors by lowercase boldface, and matrices by uppercase boldface letters.

2. Throughout the introduction, we write $f(n) \gtrsim g(n)$ as a shorthand of ' $f(n) \geq K g(n)$ for a some constant $K = K(r, \beta)$ '.

$n \gtrsim s_0^2 \log p$ (see Amini and Wainwright, 2009). This result is a striking improvement over vanilla PCA. While the latter requires a number of samples scaling with the number of parameters $n \gtrsim p$, sparse PCA via diagonal thresholding achieves the same objective with a number of samples that scales with the number of *non-zero* parameters, $n \gtrsim s_0^2 \log p$.

At the same time, this result is not as strong as might have been expected. By searching exhaustively over all possible supports of size s_0 (a method that has complexity of order p^{s_0}) the correct support can be identified with high probability as soon as $n \gtrsim s_0 \log p$. No method can succeed for much smaller n , because of information theoretic obstructions. We refer the reader to Amini and Wainwright (2009) for more details.

Over the last ten years, a significant effort has been devoted to developing practical algorithms that outperform diagonal thresholding, see e.g. Moghaddam et al. (2005); Zou et al. (2006); d’Aspremont et al. (2007, 2008); Witten et al. (2009). In particular, d’Aspremont et al. (2007) developed a promising M-estimator based on a semidefinite programming (SDP) relaxation. Amini and Wainwright (2009) also carried out an analysis of this method and proved that, if³ (i) $n \geq K(\beta) s_0 \log(p - s_0)p$, and (ii) the SDP solution has rank one, then the SDP relaxation provides a consistent estimator of the support of \mathbf{v} .

At first sight, this appears as a satisfactory solution of the original problem. No procedure can estimate the support of \mathbf{v} from less than $s_0 \log p$ samples, and the SDP relaxation succeeds in doing it from –at most– a constant factor more samples. This picture was upset by a recent, remarkable result by Krauthgamer et al. (2015) who showed that the rank-one condition assumed by Amini and Wainwright does not hold for $\sqrt{n} \lesssim s_0 \lesssim (n/\log p)$. This result is consistent with recent work of Berthet and Rigollet (2013) demonstrating that sparse PCA cannot be performed in polynomial time in the regime $s_0 \gtrsim \sqrt{n}$, under a certain computational complexity conjecture for the so-called planted clique problem.

In summary, the sparse PCA problem demonstrates a fascinating interplay between computational and statistical barriers.

From a statistical perspective, and disregarding computational considerations, the support of \mathbf{v} can be estimated consistently if and only if $s_0 \lesssim n/\log p$. This can be done, for instance, by exhaustive search over all the $\binom{p}{s_0}$ possible supports of \mathbf{v} . We refer to Vu and Lei (2012); Cai et al. (2013) for a minimax analysis.

From a computational perspective, the problem appears to be much more difficult. There is rigorous evidence (Berthet and Rigollet, 2013; ?; Ma and Wigderson, 2015; Wang et al., 2014) that no polynomial algorithm can reconstruct the support unless $s_0 \lesssim \sqrt{n}$. On the positive side, a very simple algorithm (Johnstone and Lu’s diagonal thresholding) succeeds for $s_0 \lesssim \sqrt{n}/\log p$.

Of course, several elements are still missing in this emerging picture. In the present paper we address one of them, providing an answer to the following question:

Is there a polynomial time algorithm that is guaranteed to solve the sparse PCA problem with high probability for $\sqrt{n}/\log p \lesssim s_0 \lesssim \sqrt{n}$?

³ Throughout the paper, we denote by K constants that can depend on problem parameters r and β . We denote by upper case C (lower case c) generic absolute constants that are bigger (resp. smaller) than 1, but which might change from line to line.

We answer this question positively by analyzing a covariance thresholding algorithm that proceeds, briefly, as follows. (A precise, general definition, with some technical changes is given in the next section.)

1. Form the empirical covariance matrix \mathbf{G} and set to zero all its entries that are in modulus smaller than τ/\sqrt{n} , for τ a suitably chosen constant.
2. Compute the principal eigenvector $\hat{\mathbf{v}}_1$ of this thresholded matrix.
3. Denote by $\mathbf{B} \subseteq \{1, \dots, p\}$ be the set of indices corresponding to the s_0 largest entries of $\hat{\mathbf{v}}_1$.
4. Estimate the support of \mathbf{v} by ‘cleaning’ the set \mathbf{B} . (Briefly, \mathbf{v} is estimated by thresholding $\mathbf{G}^{\mathbf{B}} \hat{\mathbf{v}}_{\mathbf{B}}$ with $\hat{\mathbf{v}}_{\mathbf{B}}$ obtained by zeroing the entries outside \mathbf{B} .)

Such a covariance thresholding approach was proposed in Krauthgamer et al. (2015), and is in turn related to earlier work by Bickel and Levina (2008B); Cai et al. (2010). The formulation discussed in the next section presents some technical differences that have been introduced to simplify the analysis. Notice that, to simplify proofs, we assume s_0 to be known: this issue is discussed in the next two sections.

The rest of the paper is organized as follows. In the next section we provide a detailed description of the algorithm and state our main results. The proof strategy for our results is explained in Section 3. Our theoretical results assume full knowledge of problem parameters for ease of proof. In light of this, in Section 4 we discuss a practical implementation of the same idea that does not require prior knowledge of problem parameters, and is data-driven. We also illustrate the method through simulations. The complete proofs are in Sections 5, 7 and 6 respectively.

A preliminary version of this paper appeared in (Deshpande and Montanari, 2014). This paper extends significantly the results in Deshpande and Montanari (2014). In particular, by following an analogous strategy, we improve greatly the bounds obtained by Deshpande and Montanari (2014). This significantly improves the regimes of (s_0, p, n) on which we can obtain non-trivial results. The proofs follow a similar strategy but are, correspondingly, more careful.

2. Algorithm and main results

We provide a detailed description of the covariance thresholding algorithm for the general model (1) in Table 1. For notational convenience, we shall assume that $2n$ sample vectors are given (instead of n): $\{\mathbf{x}_j\}_{1 \leq j \leq 2n}$.

We start by splitting the data into two halves: $(\mathbf{x}_j)_{1 \leq j \leq n}$ and $(\mathbf{x}_j)_{n+1 \leq j \leq 2n}$ and compute the respective sample covariance matrices \mathbf{G} and \mathbf{G}' respectively. Define Σ to be the population covariance minus identity, i.e.

$$\Sigma \equiv \sum_{q=1}^r \beta_q \mathbf{v}_q \mathbf{v}_q^\top. \quad (2)$$

Throughout, we let \mathbf{Q}_q and s_q denote the support of \mathbf{v}_q and its size respectively, for $q \in \{1, 2, \dots, r\}$. We further let $\mathbf{Q} = \cup_{q=1}^r \mathbf{Q}_q$ and $s_0 = |\mathbf{Q}|$. The matrix \mathbf{G} is used, in steps 1 to

Algorithm 1 Covariance Thresholding

- 1: **Input:** Data $(\mathbf{x}_i)_{1 \leq i \leq 2n}$, parameter $s_0 \in \mathbb{N}$, $\tau, \rho \in \mathbb{R}_{>0}$;
- 2: Compute the empirical covariance matrices $\mathbf{G} \equiv \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top / n$, $\mathbf{G}' \equiv \sum_{i=n+1}^{2n} \mathbf{x}_i \mathbf{x}_i^\top / n$;
- 3: Compute $\widehat{\Sigma} = \mathbf{G} - \mathbf{I}_p$ (resp. $\widehat{\Sigma}' = \mathbf{G}' - \mathbf{I}_p$);
- 4: Compute the matrix $\eta(\widehat{\Sigma})$ by soft-thresholding the entries of $\widehat{\Sigma}$;

$$\eta(\widehat{\Sigma})_{ij} = \begin{cases} \widehat{\Sigma}_{ij} - \frac{\tau}{\sqrt{n}} & \text{if } \widehat{\Sigma}_{ij} \geq \tau / \sqrt{n}, \\ 0 & \text{if } -\tau / \sqrt{n} < \widehat{\Sigma}_{ij} < \tau / \sqrt{n}, \\ \widehat{\Sigma}_{ij} + \frac{\tau}{\sqrt{n}} & \text{if } \widehat{\Sigma}_{ij} \leq -\tau / \sqrt{n}, \end{cases}$$

- 5: Let $(\widehat{\mathbf{v}}_q)_{q \leq r}$ be the first r eigenvectors of $\eta(\widehat{\Sigma})$;
- 6: **Output:** $\widehat{\mathbf{Q}} = \{i \in [p] : \exists q \text{ s.t. } |(\widehat{\Sigma}' \widehat{\mathbf{v}}_q)_i| \geq \rho\}$.

4 to obtain a good estimate $\eta(\widehat{\Sigma})$ for the low rank part of the population covariance Σ . The algorithm first computes $\widehat{\Sigma}$, a centered version of the empirical covariance of the samples as follows:

$$\widehat{\Sigma} \equiv \mathbf{G} - \mathbf{I}_p, \quad (3)$$

where $\mathbf{G} = n^{-1} \sum_{i \leq n} \mathbf{x}_i \mathbf{x}_i^\top$ is the sample covariance matrix.

It then obtains the estimate $\eta(\widehat{\Sigma}) \in \mathbb{R}^{p \times p}$ by *soft thresholding* each entry of $\widehat{\Sigma}$ at a threshold τ / \sqrt{n} . Explicitly:

$$(\eta(\widehat{\Sigma}))_{ij} \equiv \eta\left(\widehat{\Sigma}_{ij}; \frac{\tau}{\sqrt{n}}\right). \quad (4)$$

Here $\eta: \mathbb{R} \times \mathbb{R}_+ \rightarrow \mathbb{R}$ is the soft thresholding function

$$\eta(z; \lambda) = \begin{cases} z - \lambda & \text{if } z \geq \lambda \\ -z + \lambda & \text{if } z \leq -\lambda \\ 0 & \text{otherwise.} \end{cases} \quad (5)$$

In step 5 of the algorithm, this estimate is used to construct good estimates $\widehat{\mathbf{v}}_q$ of the eigenvectors \mathbf{v}_q . Finally, in step 6, these estimates are combined with the (independent) second half of the data \mathbf{G}' to construct estimators $\widehat{\mathbf{Q}}_q$ for the support of the individual eigenvectors \mathbf{v}_q . In the first two subsections we will focus on the estimation of Σ and the individual principal components. Our results on support recovery are provided in the final subsection.

2.1 Estimating the population covariance

Our first result bounds the estimation error of the soft thresholding procedure in operator norm.

Theorem 1 *There exist numerical constants $C_1, C_2, C > 0$ such that the following happens. Assume $n > C \log p$, $n > s_0^2$ and let $\tau_* = C_1(\beta \vee 1)\sqrt{\log(p/s_0^2)}$. We keep the thresholding level τ according to*

$$\tau = \begin{cases} \tau_* & \text{when } \tau_* \leq \sqrt{\log p}/2, s_0^2 \leq p/e \\ C_2 \tau_* & \text{when } \tau_* \geq \sqrt{\log p}/2, s_0 \leq p/e \\ 0 & \text{otherwise.} \end{cases} \quad (6)$$

. Then with probability $1 - o(1)$:

$$\|\eta(\widehat{\Sigma}) - \Sigma\|_{op} \leq C \sqrt{\frac{s_0^2(\beta^2 \vee 1)}{n}} \left(\log \frac{p}{s_0^2} \vee 1 \right). \quad (7)$$

At this point, it is useful to compare Theorem 1 with available results in the literature. Classical denoising theory (Donoho and Johnstone, 1994; Johnstone, 2015) provides upper bounds on the estimation error of soft-thresholding. However, estimation error is measured by (element-wise) ℓ_p norm, while here we are interested in operator norm.

Bickel and Levina (2008a,b); Karoui (2008); Cai, Zhang, Zhou, et al. (2010); Cai and Liu (2011) considered the operator norm error of thresholding estimators for structured covariance matrices. Specializing to our case of exact sparsity, the result of Bickel and Levina (2008a) implies that, with high probability:

$$\|\eta(\widehat{\Sigma}) - \Sigma\|_{op} \leq C_0 \sqrt{\frac{s_0^2 \log p}{n}}. \quad (8)$$

Here $\eta_H(\cdot, \cdot)$ is the hard-thresholding function: $\eta_H(z) = z \mathbb{1}(|z| \geq \tau / \sqrt{n})$, and the threshold is chosen to be $\tau = C_1 \sqrt{\log p}$. Also, $\eta_H(\mathbf{M})$ is the matrix obtained by thresholding the entries of \mathbf{M} . In fact, Cai et al. (2012) showed that the rate in (8) is minimax optimal over the class of sparse population covariance matrices, with at most s_0 non-zero entries per row, under the assumption $s_0^2/n \leq C(\log p)^{-3}$.

Theorem 1 ensures consistency under a weaker sparsity condition, viz. $s_0^2/n \rightarrow 0$ is sufficient. Also, the resulting rate depends on $\log(p/s_0^2)$ instead of $\log p$. In other words, in order to achieve $\|\eta(\widehat{\Sigma}) - \Sigma\|_{op} < \varepsilon$ for a fixed ε , it is sufficient $s_0 \lesssim \varepsilon \sqrt{n}$ as opposed to $s_0 \lesssim \sqrt{n} / \log p$.

Crucially, in this regime for $s_0 = \Theta(\varepsilon \sqrt{n})$, Theorem 1 suggests a threshold of order $\tau = \Theta(\sqrt{\log(1/\varepsilon)})$ as opposed to $\tau = C_1 \sqrt{\log p}$ which is used in Bickel and Levina (2008a); Cai et al. (2012). As we will see in Section 3, this regime mathematically more challenging than the one of Bickel and Levina (2008a); Cai et al. (2012). By setting $\tau = C_1 \sqrt{\log p}$ for a large enough constant C_1 , all the entries of $\widehat{\Sigma}$ outside the support of Σ are set to 0. In contrast, a large part of our proof is devoted to control the operator norm of the noise part of $\widehat{\Sigma}$.

2.2 Estimating the principal components

We next turn to the question of estimating the principal components $\mathbf{v}_1, \dots, \mathbf{v}_r$. Of course, these are not identifiable if there are degeneracies in the population eigenvalues $\beta_1, \beta_2, \dots, \beta_r$. We thus introduce the following identifiability condition.

A1 The spike strengths $\beta_1 > \beta_2 > \dots > \beta_r$ are all *distinct*. We denote by $\beta \equiv \max(\beta_1, \dots, \beta_r)$ and $\beta_{\min} \equiv \min_{q \neq d'}(\beta_1 - \beta_2, \beta_2 - \beta_3, \dots, \beta_r)$. Namely, β is the largest signal strength and β_{\min} is the minimum gap.

We measure estimation error through the following loss, defined for $\mathbf{x}, \mathbf{y} \in S^{p-1} \equiv \{\mathbf{v} \in \mathbb{R}^p : \|\mathbf{v}\| = 1\}$:

$$L(\mathbf{x}, \mathbf{y}) \equiv \frac{1}{2} \min_{s \in \{+1, -1\}} \|\mathbf{x} - s\mathbf{y}\|^2 \quad (9)$$

$$= 1 - |\langle \mathbf{x}, \mathbf{y} \rangle|. \quad (10)$$

Notice the minimization over the sign $s \in \{+1, -1\}$. This is required because the principal components $\mathbf{v}_1, \dots, \mathbf{v}_r$ are only identifiable up to a sign. Analogous results can obtained for alternate loss functions such as the projection distance:

$$L_p(\mathbf{x}, \mathbf{y}) \equiv \frac{1}{\sqrt{2}} \|\mathbf{x}\mathbf{x}^\top - \mathbf{y}\mathbf{y}^\top\|_F = \sqrt{1 - \langle \mathbf{x}, \mathbf{y} \rangle^2}. \quad (11)$$

The theorem below is an immediate consequence of Theorem 1. In particular, it uses the guarantee of Theorem 1 to show that the corresponding principal components of $\eta(\widehat{\Sigma})$ provide good estimates of the principal components \mathbf{v}_q , $1 \leq q \leq r$.

Theorem 2 *There exists a numerical constant C such that the following holds. Suppose that Assumption A1 holds in addition to the conditions $n > C \log p$, $s_0^2 < n$, and $s_0^2 < p/e$. Set τ as according to Theorem 1, and let $\widehat{\mathbf{v}}_1, \dots, \widehat{\mathbf{v}}_r$ denote the r principal eigenvectors of $\eta(\widehat{\Sigma}; \tau/\sqrt{n})$. Then, with probability $1 - o(1)$*

$$\max_{q \in [r]} L(\widehat{\mathbf{v}}_q, \mathbf{v}_q) \leq \frac{C}{\beta_{\min}^2} \frac{s_0^2(\beta^2 \vee 1)}{n} \log \frac{p}{s_0^2}. \quad (12)$$

Proof Let $\Delta \equiv \eta(\widehat{\Sigma}; \tau/\sqrt{n}) - \Sigma$. By Davis-Kahn sin-theta theorem (Davis and Kahn, 1970), we have, for $\beta_{\min} > \|\Delta\|_{op}$,

$$L(\widehat{\mathbf{v}}_q, \mathbf{v}_q) \leq \frac{1}{2} \left(\frac{\|\Delta\|_{op}}{\beta_{\min} - \|\Delta\|_{op}} \right)^2. \quad (13)$$

For $\beta_{\min}^2 > 2C(s_0^2(\beta^2 \vee 1)/n) \log(p/s_0^2)$, the claim follows by using Theorem 1. If $\beta_{\min}^2 \leq 2C(s_0^2(\beta^2 \vee 1)/n) \log(p/s_0^2)$, the claim is obviously true since $L(\widehat{\mathbf{v}}_q, \mathbf{v}_q) \leq 1$ always. ■

2.3 Support recovery

Finally, we consider the question of support recovery of the principal components \mathbf{v}_q . The second phase of our algorithm aims at estimating union of the supports $\mathbf{Q} = \mathbf{Q}_1 \cup \dots \cup \mathbf{Q}_r$ from the estimated principal components $\widehat{\mathbf{v}}_q$. Note that, although $\widehat{\mathbf{v}}_q$ is not even expected to be sparse, it is easy to see that the largest entries of $\widehat{\mathbf{v}}_q$ should have significant overlap with $\text{supp}(\mathbf{v}_q)$. Step 6 of the algorithm exploit this property to construct a consistent estimator $\widehat{\mathbf{Q}}_q$ of the support of the spike \mathbf{v}_q .

We will require the following assumption to ensure support recovery.

A2 There exist constants $\theta, \gamma > 0$ such that the following holds. The non-zero entries of the spikes satisfy $|v_{q,i}| \geq \theta/\sqrt{s_0}$ for all $i \in \mathbf{Q}_q$. Further, for any q, q' $|v_{q,i}|/|v_{q',i}| \leq \gamma$ for every $i \in \mathbf{Q}_q \cap \mathbf{Q}_{q'}$. Without loss of generality, we will assume $\gamma \geq 1$.

Theorem 3 *Assume the spiked covariance model of Eq. (1) satisfying assumptions A1 and A2, and further $n > C \log p$, $s_0^2 < n$, and $s_0^2 < p/e$ for C a large enough numerical constant. Consider the Covariance Thresholding algorithm of Table 1, with τ as in Theorem 1 $\rho = \beta_{\min} \theta / (2\sqrt{s_0})$.*

Then there exists $K_0 = K_0(\theta, \gamma, \beta, \beta_{\min})$ such that, if

$$n \geq K_0 s_0^2 r \log \frac{p}{s_0^2} \quad (14)$$

then the algorithm recovers the union of supports of \mathbf{v}_q with probability $1 - o(1)$ (i.e. we have $\widehat{\mathbf{Q}} = \mathbf{Q}$).

The proof in Section 7 also provides an explicit expression for the constant K_0 .

Remark 4 *In Assumption A2, the requirement on the minimum size of $|v_{q,i}|$ is standard in support recovery literature (see, e.g. Wainwright, 2009; Memshausen and Billmann, 2006). Additionally, however, we require that when the supports of $\mathbf{v}_q, \mathbf{v}_{q'}$ overlap, they are of the same order, quantified by the parameter γ . Relaxing this condition is a potential direction for future work.*

Remark 5 *Recovering the signed supports $\mathbf{Q}_{q,+} = \{i \in [p] : v_{q,i} > 0\}$ and $\mathbf{Q}_{q,-} = \{i \in [p] : v_{q,i} < 0\}$, up to a sign flip, is possible using the same technique as recovering the supports $\text{supp}(\mathbf{v}_q)$ above, and poses no additional difficulty.*

3. Algorithm intuition and proof strategy

For the purposes of exposition, throughout this section, we will assume that $r = 1$ and drop the corresponding subscript q .

Denoting by $\mathbf{X} \in \mathbb{R}^{n \times p}$ the matrix with rows $\mathbf{x}_1, \dots, \mathbf{x}_n$, by $\mathbf{Z} \in \mathbb{R}^{n \times p}$ the matrix with rows $\mathbf{z}_1, \dots, \mathbf{z}_n$, and letting $\mathbf{u} = (u_1, u_2, \dots, u_n)$, the model (1) can be rewritten as

$$\mathbf{X} = \sqrt{\beta} \mathbf{u} \mathbf{v}^\top + \mathbf{Z}. \quad (15)$$

Recall that $\widehat{\Sigma} = n^{-1} \mathbf{X}^\top \mathbf{X} - I_p = \mathbf{G} - I_p$. For $\beta > \sqrt{p/n}$, the principal eigenvector of \mathbf{G} , and hence of $\widehat{\Sigma}$ is positively correlated with \mathbf{v} , i.e. $|\langle \widehat{\mathbf{v}}_1(\widehat{\Sigma}), \mathbf{v} \rangle|$ is bounded away from zero. However, for $\beta < \sqrt{p/n}$, the noise component in $\widehat{\Sigma}$ dominates and the two vectors become asymptotically orthogonal, i.e. for instance $\lim_{n \rightarrow \infty} |\langle \widehat{\mathbf{v}}_1(\widehat{\Sigma}), \mathbf{v} \rangle| = 0$. In order to reduce the noise level, we must exploit the sparsity of the spike \mathbf{v} .

Now, letting $\beta' \equiv \beta \|\mathbf{u}\|^2/n \approx \beta$, and $\mathbf{w} \equiv \sqrt{\beta} \mathbf{Z}^\top \mathbf{u}/n$, we can rewrite $\widehat{\Sigma}$ as

$$\widehat{\Sigma} = \beta' \mathbf{v} \mathbf{v}^\top + \mathbf{v} \mathbf{w}^\top + \mathbf{w} \mathbf{v}^\top + \frac{1}{n} \mathbf{Z}^\top \mathbf{Z} - I_p. \quad (16)$$

For a moment, let us neglect the cross terms $(\mathbf{v}\mathbf{v}^\top + \mathbf{w}\mathbf{w}^\top)$. The ‘signal’ component $\beta' \mathbf{v}\mathbf{v}^\top$ is sparse with s_0^2 entries of magnitude $\beta'\theta^2/s_0$, which (in the regime of interest $s_0 = \sqrt{n}/C$) is equivalent to $C\theta^2\beta/\sqrt{n}$. The ‘noise’ component $\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p$ is dense with entries of order $1/\sqrt{n}$. Assuming $s_0/\sqrt{n} < c$ for some small constant c , it should be possible to remove most of the noise by thresholding the entries at level of order $1/\sqrt{n}$. For technical reasons, we use the soft thresholding function $\eta: \mathbb{R} \times \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}$, $\eta(z; \tau) = \text{sgn}(z)(|z| - \tau)_+$. We will omit the second argument from $\eta(\cdot; \cdot)$ wherever it is clear from context.

Consider again the decomposition (16). Since the soft thresholding function $\eta(z; \tau/\sqrt{n})$ is affine when $z \gg \tau/\sqrt{n}$, we would expect that the following decomposition holds approximately (for instance, in operator norm):

$$\eta(\widehat{\Sigma}) \approx \eta(\beta' \mathbf{v}\mathbf{v}^\top) + \eta\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right). \quad (17)$$

Since $\beta' \approx \beta$ and each entry of $\mathbf{v}\mathbf{v}^\top$ has magnitude at least θ^2/s_0 , the first term is still approximately rank one, with

$$\left\| \eta(\beta' \mathbf{v}\mathbf{v}^\top) - \beta \mathbf{v}\mathbf{v}^\top \right\|_{op} \leq \frac{s_0\tau}{\sqrt{n}}. \quad (18)$$

This is straightforward to see since soft thresholding introduces a maximum bias of τ/\sqrt{n} per entry of the matrix, while the factor s_0 comes due to the support size of $\mathbf{v}\mathbf{v}^\top$ (see Proposition 14 below for a rigorous argument).

The main technical challenge now is to control the operator norm of the perturbation $\eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$. We know that $\eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$ has entries of variance $\delta(\tau)/n$, for $\delta(\tau) \approx \exp(-c\tau^2)$. If entries were independent with mild tail conditions, this would imply –with high probability–

$$\left\| \eta\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right) \right\|_{op} \lesssim C\delta(\tau)\sqrt{\frac{p}{n}} = C\exp(-c\tau^2)\sqrt{\frac{p}{n}}, \quad (19)$$

for some constant C . Combining the bias bound from Eq. (18) and the heuristic decomposition of Eq. (19) with the decomposition (17) results in the bound

$$\left\| \eta(\widehat{\Sigma}) - \beta \mathbf{v}\mathbf{v}^\top \right\|_{op} \leq \frac{s_0\tau}{\sqrt{n}} + C\exp(-c\tau^2)\sqrt{\frac{p}{n}}. \quad (20)$$

Our analysis formalizes this argument and shows that such a bound is correct when $p < n$.

The matrix $\eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$ is a special case of so-called inner-product kernel random matrices, which have attracted recent interest within probability theory (see El Karoui, 2010a,b; Cheng and Singer, 2013; Fan and Montanari, 2015). The basic object of study in this line of work is a matrix $\mathbf{M} \in \mathbb{R}^{p \times p}$ of the type:

$$M_{ij} = f_n\left(\frac{\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{z}}_j \rangle}{n} - \mathbb{1}(i = j)\right). \quad (21)$$

In other words, $f_n: \mathbb{R} \rightarrow \mathbb{R}$ is a kernel function and is applied entry-wise to the matrix $\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p$, with \mathbf{Z} a matrix with independent standard normal entries as above and $\tilde{\mathbf{z}}_i \in \mathbb{R}^n$ are the columns of \mathbf{Z} .

The key technical challenge in our proof is the analysis of the operator norm of such matrices, when f_n is the soft-thresholding function, with threshold of order $1/\sqrt{n}$. Earlier results are not general enough to cover this case. El Karoui (2010a,b) provide conditions under which the spectrum of $f_n(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$ is close to a rescaling of the spectrum of $(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$. We are interested instead in a different regime in which the spectrum of $f_n(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$ is very different from the one of $(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$. Cheng and Singer (2013) consider n -dependent kernels, but their results are asymptotic and concern the weak limit of the empirical spectral distribution of $f_n(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$. This does not yield an upper bound on the spectral norm of $f_n(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$. Finally, Fan and Montanari (2015) consider the spectral norm of kernel random matrices for smooth kernels f , only in the proportional regime $n/p \rightarrow c \in (0, \infty)$.

Our approach to proving Theorem 1 follows instead the ε -net method: we develop high probability bounds on the maximum Rayleigh quotient:

$$\max_{\mathbf{y} \in \mathbb{S}^{p-1}} \langle \mathbf{y}, \eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)\mathbf{y} \rangle = \max_{\mathbf{y} \in \mathbb{S}^{p-1}} \eta\left(\frac{\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{z}}_j \rangle}{n}, \frac{\tau}{\sqrt{n}}\right) y_i y_j, \quad (22)$$

by discretizing $\mathbb{S}^{p-1} = \{\mathbf{y} \in \mathbb{R}^p : \|\mathbf{y}\| = 1\}$, the unit sphere in p dimensions. For a fixed \mathbf{y} , the Rayleigh quotient $\langle \mathbf{y}, \eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)\mathbf{y} \rangle$ is a (complicated) function of the underlying Gaussian random variables \mathbf{Z} . One might hope that it is Lipschitz continuous with some Lipschitz constant $B = B(n, p, \tau, \mathbf{y})$, thereby implying, by Gaussian isoperimetry (Ledoux, 2005), that it concentrates to the scale B around its expectation (i.e. 0). Then, by a standard union bound argument over a discretization of the sphere, one would obtain that the operator norm of $\eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)$ is typically no more than $\sqrt{p} \sup_{\mathbf{y} \in \mathbb{S}^{p-1}} B(n, p, \tau, \mathbf{y})$.

Unfortunately, this turns out not to be true over the whole space of \mathbf{Z} , i.e. the Rayleigh quotient is not Lipschitz continuous in the underlying Gaussian variables \mathbf{Z} . Our approach, instead, shows that for *typical* values of \mathbf{Z} , we can control the gradient of $\langle \mathbf{y}, \eta(\mathbf{Z}^\top\mathbf{Z}/n - \mathbf{I}_p)\mathbf{y} \rangle$ with respect to \mathbf{Z} , and extract the required concentration only from such local information of the function. This is formalized in our concentration lemma 9, which we apply extensively while proving Theorem 1. This lemma is a significantly improved version of the analogous result in Deshpande and Montanari (2014).

4. Practical aspects and empirical results

Specializing to the rank one case, Theorems 2 and 3 show that Covariance Thresholding succeeds with high probability for a number of samples $n \gtrsim s_0^2$, while Diagonal Thresholding requires $n \gtrsim s_0^2 \log p$. The reader might wonder whether eliminating the $\log p$ factor has any practical relevance or is a purely conceptual improvement. Figure 1 presents simulations on synthetic data under the strictly sparse model, and the Covariance Thresholding algorithm of Table 1, used in the proof of Theorem 3. The objective is to check whether the $\log p$ factor has an impact at moderate p . We compare this with Diagonal Thresholding.

We plot the empirical success probability as a function of s_0/\sqrt{n} for several values of p , with $p = n$. The empirical success probability was computed by using 100 independent instances of the problem. A few observations are of interest: (i) Covariance Thresholding appears to have a significantly larger success probability in the ‘difficult’ regime where Diagonal Thresholding starts to fail; (ii) The curves for Diagonal Thresholding appear to

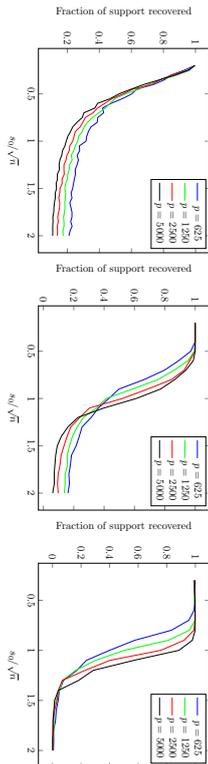

Figure 1: The support recovery phase transitions for Diagonal Thresholding (left) and Covariance Thresholding (center) and the data-driven version of Section 4 (right). For Covariance Thresholding, the fraction of support recovered correctly *increases* monotonically with p , as long as $s_0 \leq c\sqrt{n}$ with $c \approx 1.1$. Further, it appears to converge to one throughout this region. For Diagonal Thresholding, the fraction of support recovered correctly *decreases* monotonically with p for all s_0 of order \sqrt{n} . This confirms that Covariance Thresholding (with or without knowledge of the support size s_0) succeeds with high probability for $s_0 \leq c\sqrt{n}$, while Diagonal Thresholding requires a significantly sparser principal component.

decrease monotonically with p indicating that s_0 proportional to \sqrt{n} is not the right scaling for this algorithm (as is known from theory); (iii) In contrast, the curves for Covariance Thresholding become steeper for larger p , and, in particular, the success probability increases with p for $s_0 \leq 1.1\sqrt{n}$. This indicates a sharp threshold for $s_0 = \text{const} \cdot \sqrt{n}$, as suggested by our theory.

In terms of practical applicability, our algorithm in Table 1 has the shortcomings of requiring knowledge of problem parameters s_0, β, θ . Furthermore, the thresholds ρ, τ suggested by theory need not be optimal. We next describe a principled approach to estimating (where possible) the parameters of interest and running the algorithm in a purely data-dependent manner. Assume the following model, for $i \in [n]$

$$\mathbf{x}_i = \boldsymbol{\mu} + \sum_q \sqrt{\beta_q} u_{q,i} \mathbf{v}_q + \sigma \mathbf{z}_i,$$

where $\boldsymbol{\mu} \in \mathbb{R}^p$ is a fixed mean vector, $u_{q,i}$ have mean 0 and variance 1, and \mathbf{z}_i have mean 0 and covariance \mathbf{I}_p . Note that our focus in this section is not on rigorous analysis, but instead to demonstrate a principled approach to applying covariance thresholding in practice. We proceed as follows:

Estimating $\boldsymbol{\mu}, \sigma$: We let $\hat{\boldsymbol{\mu}} = \sum_{i=1}^n \mathbf{x}_i/n$ be the empirical mean estimate for $\boldsymbol{\mu}$. Further letting $\hat{\mathbf{X}} = \mathbf{X} - 1\hat{\boldsymbol{\mu}}^\top$ we see that $pm - (\sum_q k_q/n) \approx pm$ entries of $\hat{\mathbf{X}}$ are mean 0 and variance σ^2 . We let $\hat{\sigma} = \text{MAD}(\hat{\mathbf{X}})/\nu$ where $\text{MAD}(\cdot)$ denotes the median absolute deviation of the entries of the matrix in the argument, and ν is a constant scale factor. Guided by the Gaussian case, we take $\nu = \Phi^{-1}(3/4) \approx 0.6745$.

Choosing τ : Although in the statement of the theorem, our choice of τ depends on the SNR β/σ^2 , it is reasonable to instead threshold ‘at the noise level’, as follows. The

noise component of entry i, j of the sample covariance (ignoring lower order terms) is given by $\sigma^2 \langle \mathbf{z}_i, \mathbf{z}_j \rangle / n$. By the central limit theorem, $\langle \mathbf{z}_i, \mathbf{z}_j \rangle / \sqrt{n} \stackrel{d}{\sim} \mathcal{N}(0, 1)$. Consequently, $\sigma^2 \langle \mathbf{z}_i, \mathbf{z}_j \rangle / n \approx \mathcal{N}(0, \sigma^4/n)$, and we need to choose the (rescaled) threshold proportional to $\sqrt{\sigma^4} = \sigma^2$. Using previous estimates, we let $\tau = \nu' \cdot \hat{\sigma}^2$ for a constant ν' . In simulations, a choice $3 \lesssim \nu' \lesssim 4$ appears to work well.

Estimating τ : We define $\hat{\Sigma} = \hat{\mathbf{X}}^\top \hat{\mathbf{X}} / n - \hat{\sigma}^2 \mathbf{I}_p$ and soft threshold it to get $\eta(\hat{\Sigma})$ using τ as above. Our proof of Theorem 2 relies on the fact that $\eta(\hat{\Sigma})$ has τ eigenvalues that are separated from the bulk of the spectrum. Hence, we estimate τ using $\hat{\tau}$: the number of eigenvalues separated from the bulk in $\eta(\hat{\Sigma})$. The edge of the spectrum can be computed numerically using the Stieltjes transform method as in Cheng and Singer (2013).

Estimating \mathbf{v}_q : Let $\hat{\mathbf{v}}_q$ denote the q^{th} eigenvector of $\eta(\hat{\Sigma})$. Our theoretical analysis indicates that $\hat{\mathbf{v}}_q$ is expected to be close to \mathbf{v}_q . In order to denoise $\hat{\mathbf{v}}_q$, we assume $\hat{\Sigma} \hat{\mathbf{v}}_q \approx (1 - \delta) \mathbf{v}_q + \boldsymbol{\epsilon}_q$, where $\boldsymbol{\epsilon}_q$ is additive random noise (perhaps with some sparse correlations). We then threshold $\hat{\Sigma} \hat{\mathbf{v}}_q$ ‘at the noise level’ to recover a better estimate of \mathbf{v}_q . To do this, we estimate the standard deviation of the ‘noise’ $\boldsymbol{\epsilon}$ by $\hat{\sigma}_{\boldsymbol{\epsilon}} = \text{MAD}(\hat{\mathbf{v}}_q) / \nu$. Here we set –again guided by the Gaussian heuristic– $\nu \approx 0.6745$. Since \mathbf{v}_q is sparse, this procedure returns a good estimate for the size of the noise deviation. We let $\hat{\mathbf{v}}_q^*$ denote the vector obtained by hard thresholding $\hat{\mathbf{v}}_q$: set $\hat{\mathbf{v}}_q^* = \hat{\mathbf{v}}_q$, if $|\hat{v}_{q,i}| \geq \nu' \hat{\sigma}_{\boldsymbol{\epsilon}_q}$ and 0 otherwise. We then let $\hat{\mathbf{v}}_q^* = \hat{\mathbf{v}}_q^* / \|\hat{\mathbf{v}}_q^*\|$ and return $\hat{\mathbf{v}}_q^*$ as our estimate for \mathbf{v}_q .

Note that –while different in several respects– this empirical approach shares the same philosophy of the algorithm in Table 1. On the other hand, the data-driven algorithm presented in this section is less straightforward to analyze, a task that we defer to future work.

Figure 1 also shows results of a support recovery experiment using the ‘data-driven’ version of this section. Covariance thresholding in this form also appears to work for supports of size $s_0 \leq \text{const} \sqrt{n}$. Figure 2 shows the performance of vanilla PCA, Diagonal Thresholding and Covariance Thresholding on the ‘Three Peak’ example of Johnstone and Lu (2004). This signal is sparse in the wavelet domain and the simulations employ the data-driven version of covariance thresholding. A similar experiment with the ‘box’ example of Johnstone and Lu is provided in Figure 3. These experiments demonstrate that, while for large values of n both Diagonal Thresholding and Covariance Thresholding perform well, the latter appears superior for smaller values of n .

5. Proof preliminaries

In this section we review some notation and preliminary facts that we will use throughout the paper.

5.1 Notation

We let $[m] = \{1, 2, \dots, m\}$ denote the set of first m integers. We will represent vectors using boldface lower case letters, e.g. $\mathbf{u}, \mathbf{v}, \mathbf{x}$. The entries of a vector $\mathbf{u} \in \mathbb{R}^n$ will be represented

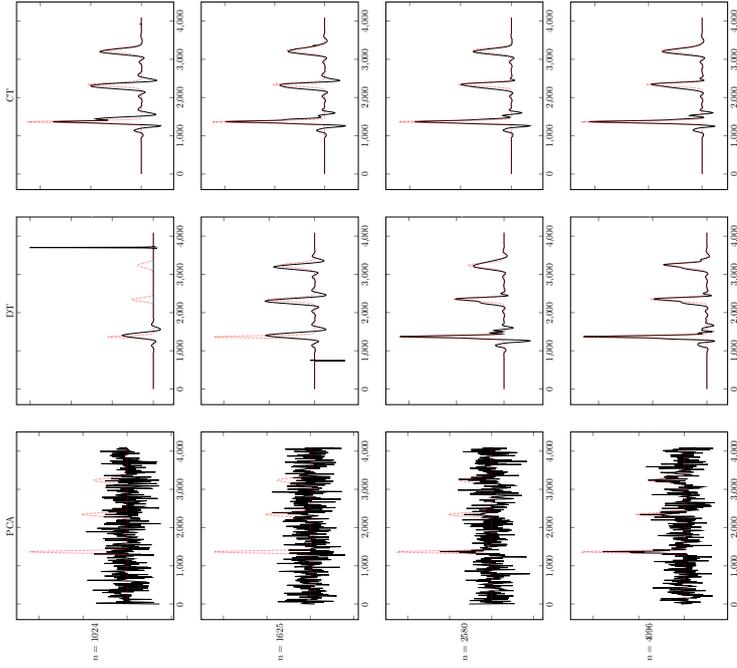

Figure 2: The results of Simple PCA, Diagonal Thresholding and Covariance Thresholding (respectively) for the “Three Peak” example of Johnstone and Lu (2009) (see Figure 1 of the paper). The signal is sparse in the ‘Symmet 8’ basis. We use $\beta = 1.4$, $p = 4096$, and the rows correspond to sample sizes $n = 1024, 1625, 2580, 4096$ respectively. Parameters for Covariance Thresholding are chosen as in Section 4, with $\nu' = 4.5$. Parameters for Diagonal Thresholding are from Johnstone and Lu (2009). On each curve, we superpose the clean signal (dotted).

by $u_i, i \in [n]$. Matrices are represented using boldface upper case letters e.g. \mathbf{A}, \mathbf{X} . The entries of a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$ are represented by \mathbf{A}_{ij} for $i \in [m], j \in [n]$. Given a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$, we generically let $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m$ denote its rows, and $\tilde{\mathbf{a}}_1, \tilde{\mathbf{a}}_2, \dots, \tilde{\mathbf{a}}_n$ its columns.

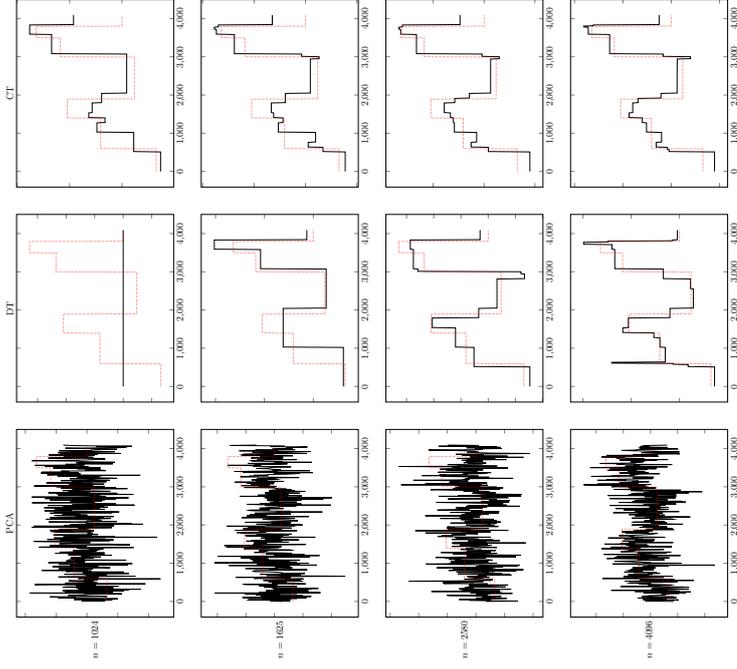

Figure 3: The results of Simple PCA, Diagonal Thresholding and Covariance Thresholding (respectively) for a synthetic block-constant function (which is sparse in the Haar wavelet basis). We use $\beta = 1.4, p = 4096$, and the rows correspond to sample sizes $n = 1024, 1625, 2580, 4096$ respectively. Parameters for Covariance Thresholding are chosen as in Section 4, with $\nu' = 4.5$. Parameters for Diagonal Thresholding are from Johnstone and Lu (2009). On each curve, we superpose the clean signal (dotted).

For $E \subseteq [m] \times [n]$, we define the projector operator $\mathcal{P}_E : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}^{m \times n}$ by letting $\mathcal{P}_E(\mathbf{A})$ be the matrix with entries

$$\mathcal{P}_E(\mathbf{A})_{ij} = \begin{cases} \mathbf{A}_{ij} & \text{if } (i, j) \in E, \\ 0 & \text{otherwise.} \end{cases} \quad (23)$$

For a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$, and a set $E \subseteq [n]$, we define its column restriction $\mathbf{A}_E \in \mathbb{R}^{m \times n}$ to be the matrix obtained by setting to 0 columns outside E :

$$(\mathbf{A}_E)_{ij} = \begin{cases} \mathbf{A}_{ij} & \text{if } j \in E, \\ 0 & \text{otherwise.} \end{cases}$$

Similarly \mathbf{y}_E is obtained from \mathbf{y} by setting to zero all indices outside E . The operator norm of a matrix \mathbf{A} is denoted by $\|\mathbf{A}\|$ (or $\|\mathbf{A}\|_{op}$) and its Frobenius norm by $\|\mathbf{A}\|_F$. We write $\|\mathbf{x}\|$ for the standard ℓ_2 norm of a vector \mathbf{x} . Other vector norms such as ℓ_1 or ℓ_∞ are denoted with appropriate subscripts.

We let \mathbf{Q}_q denotes the support of the q^{th} spike \mathbf{v}_q . Also, we denote the union of the supports of \mathbf{v}_q by $\mathbf{Q} = \cup_q \mathbf{Q}_q$. The complement of a set $E \subseteq [n]$ is denoted by E^c .

We write $\eta(\cdot; \cdot)$ for the soft-thresholding function. By $\partial\eta(\cdot; \tau)$ we denote the derivative of $\eta(\cdot; \tau)$ with respect to the *first* argument, which exists Lebesgue almost everywhere. To simplify the notation, we omit the second argument when it is understood from context.

For a random variable Z and a measurable set \mathcal{A} we write $\mathbb{E}\{Z; \mathcal{A}\}$ to denote $\mathbb{E}\{Z\mathbb{1}(Z \in \mathcal{A})\}$, the expectation of Z constrained to the event \mathcal{A} .

In the statements of our results, consider the limit of large p and large n with certain conditions on p, n (as in Theorem 2). This limit will be referred to either as “*n* large enough” or “*p* large enough” where the phrase “large enough” indicates dependence of p (and thereby n) on specific problem parameters.

The Gaussian distribution function will be denoted by $\Phi(x) = \int_{-\infty}^x e^{-t^2/2} dt / \sqrt{2\pi}$.

5.2 Preliminary facts

Let \mathbb{S}^{N-1} denote the unit sphere in N dimensions, i.e. $\mathbb{S}^{N-1} = \{\mathbf{x} \in \mathbb{R}^N : \|\mathbf{x}\| = 1\}$. We use the following definition (see Vershynin, 2012, Definition 5.2) of the ε -net of a set $X \subseteq \mathbb{R}^n$:

Definition 6 (Nets, Covering numbers) A subset $T^\varepsilon(X) \subseteq X$ is called an ε -net of X if every point in X may be approximated by one in $T^\varepsilon(X)$ with error at most ε . More precisely:

$$\forall x \in X, \quad \inf_{y \in T^\varepsilon(X)} \|x - y\| \leq \varepsilon.$$

The minimum cardinality of an ε -net of X , if finite, is called its covering number.

The following two facts are useful while using ε -nets to bound the spectral norm of a matrix. For proofs, we refer the reader to (see Vershynin, 2012, Lemmas 5.2, 5.4).

Lemma 7 Let \mathbb{S}^{n-1} be the unit sphere in n dimensions. Then there exists an ε -net of \mathbb{S}^{n-1} , $T^\varepsilon(\mathbb{S}^{n-1})$ satisfying:

$$|T^\varepsilon(\mathbb{S}^{n-1})| \leq \left(1 + \frac{2}{\varepsilon}\right)^n.$$

Lemma 8 Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be a symmetric matrix. Then, there exists $\mathbf{x} \in T^\varepsilon(\mathbb{S}^{n-1})$ such that

$$|\langle \mathbf{x}, \mathbf{A}\mathbf{x} \rangle| \geq (1 - 2\varepsilon)\|\mathbf{A}\|. \quad (24)$$

Proof Firstly, we have $\|\mathbf{A}\| = \max_{\mathbf{x} \in \mathbb{S}^{n-1}} |\langle \mathbf{x}, \mathbf{A}\mathbf{x} \rangle| = \max_{\mathbf{x} \in \mathbb{S}^{n-1}} \|\mathbf{A}\mathbf{x}\|$. Let \mathbf{x}_* be the maximizer (which exists as \mathbb{S}^{n-1} is compact and $|\langle \mathbf{x}, \mathbf{A}\mathbf{x} \rangle|$ is continuous in \mathbf{x}). Choose $\mathbf{x} \in T_n^\varepsilon$ so that $\|\mathbf{x} - \mathbf{x}_*\| \leq \varepsilon$. Then:

$$\langle \mathbf{x}, \mathbf{A}\mathbf{x} \rangle = \langle \mathbf{x} - \mathbf{x}_*, \mathbf{A}(\mathbf{x} + \mathbf{x}_*) \rangle + \langle \mathbf{x}_*, \mathbf{A}\mathbf{x}_* \rangle. \quad (25)$$

The lemma then follows as $|\langle \mathbf{x}, \mathbf{A}(\mathbf{x} - \mathbf{x}_*) \rangle| \leq \|\mathbf{x} + \mathbf{x}_*\| \|\mathbf{A}\| \|\mathbf{x} - \mathbf{x}_*\| \leq 2\varepsilon \|\mathbf{A}\|$. ■

Throughout the paper we will denote by T_N^ε an ε -net on the unit sphere \mathbb{S}^{N-1} that satisfies Lemma 7. For a subset of indices $S \subseteq [N]$ we denote by $T_N^\varepsilon(S)$ the natural isometric embedding of T_S^ε in \mathbb{S}^{N-1} .

We now state a general concentration lemma. This will be our basic tool to establish Theorem 2, and thereby Theorem 3.

Lemma 9 Let $\mathbf{z} \sim \mathcal{N}(0, \mathbf{I}_N)$ be the vector of N i.i.d. standard normal variables. Suppose S is a finite set and we have functions $F_s : \mathbb{R}^N \rightarrow \mathbb{R}$ for every $s \in S$. Assume $\mathcal{G} \in \mathbb{R}^N \times \mathbb{R}^N$ is a Borel set such that for Lebesgue-almost every $(\mathbf{x}, \mathbf{y}) \in \mathcal{G}$:

$$\max_{s \in S} \max_{t \in [0, 1]} \|\nabla F_s(\sqrt{t}\mathbf{x} + \sqrt{1-t}\mathbf{y})\| \leq L. \quad (26)$$

Then, for any $\Delta > 0$:

$$\mathbb{P}\left\{ \max_{s \in S} |F_s(\mathbf{z}) - \mathbb{E}F_s(\mathbf{z})| \geq \Delta \right\} \leq C|S| \exp\left(-\frac{\Delta^2}{CL^2}\right) + \frac{C}{\Delta^2} \mathbb{E}\left\{ \max_{s \in S} [(F_s(\mathbf{z}) - F_s(\mathbf{z}'))^2]; \mathcal{G}^c \right\}. \quad (27)$$

Here \mathbf{z}' is an independent copy of \mathbf{z} .

Proof We use the Mauney-Pisier method along with symmetrization. By centering, assume that $\mathbb{E}F_s(\mathbf{z}) = 0$ for all $s \in S$. Further, by including the functions $-F_s$ in the set S (at most doubling its size), it suffices to prove the one-sided version of the inequality:

$$\mathbb{P}\left\{ \max_{s \in S} F_s(\mathbf{z}) \geq \Delta \right\} \leq C|S| \exp\left(-\frac{\Delta^2}{CL^2}\right) + \frac{C}{\Delta^2} \mathbb{E}\left\{ \max_{s \in S} (F_s(\mathbf{z}) - F_s(\mathbf{z}'))^2; \mathcal{G}^c \right\}. \quad (28)$$

We first implement the symmetrization. Note that:

$$\{\mathbf{x} : \max_s F_s(\mathbf{x}) \geq \Delta\} \subseteq \{\mathbf{x} : \max_{x \in \mathbb{R}, s \in S} [2xF_s(\mathbf{x}) - x^2] \geq \Delta^2\} \quad (29)$$

$$\{\mathbf{x}, \mathbf{y} : \max_s [F_s(\mathbf{x}) - F_s(\mathbf{y})] \geq \Delta\} \subseteq \{\mathbf{x}, \mathbf{y} : \max_{x \in \mathbb{R}, s \in S} [2x(F_s(\mathbf{x}) - F_s(\mathbf{y})) - x^2] \geq \Delta^2\}. \quad (30)$$

Furthermore, by centering, $F_s(\mathbf{z}) = \mathbb{E}\{F_s(\mathbf{z}) - F_s(\mathbf{z}')|\mathbf{z}\}$. Hence for any non-decreasing convex function $\phi(z)$:

$$\mathbb{E}\left\{\phi\left(\max_{x,s} [2xF_s(\mathbf{z}) - x^2]\right)\right\} \leq \mathbb{E}\left\{\phi\left(\max_{x,s} [\mathbb{E}\{2xF_s(\mathbf{z}) - 2xF_s(\mathbf{z}') - x^2|\mathbf{z}\}]\right)\right\} \quad (31)$$

$$\stackrel{(a)}{\leq} \mathbb{E}\left\{\phi\left(\mathbb{E}\left\{\max_{x,s} [2x(F_s(\mathbf{z}) - F_s(\mathbf{z}') - x^2)|\mathbf{z}]\right\}\right)\right\} \quad (32)$$

$$\stackrel{(b)}{\leq} \mathbb{E}\left\{\phi\left(\max_{x,s} [2x(F_s(\mathbf{z}) - F_s(\mathbf{z}') - x^2)]\right)\right\}. \quad (33)$$

Here we use Jensen's inequality with the monotonicity of $\phi(\cdot)$ to obtain (a) and with the convexity of $\phi(\cdot)$ to obtain (b).

Now we choose $\phi(z) = (z - a)_+$, for $a = \Delta^2/2$.

$$\mathbb{P}\{\max_s F_s(\mathbf{z}) \geq \Delta\} \leq \mathbb{P}\{\max_{x,s} [2xF_s(\mathbf{z}) - x^2] \geq \Delta^2\} \quad (34)$$

$$\stackrel{(a)}{\leq} \phi(\Delta^2)^{-1} \mathbb{E}\left\{\phi\left(\max_{x,s} [2xF_s(\mathbf{z}) - x^2]\right)\right\} \quad (35)$$

$$\stackrel{(b)}{\leq} \phi(\Delta^2)^{-1} \mathbb{E}\left\{\phi\left(\max_{x,s} [2x(F_s(\mathbf{z}) - F_s(\mathbf{z}') - x^2)]\right)\right\} \quad (36)$$

$$= \phi(\Delta^2)^{-1} \mathbb{E}\left\{\phi\left(\max_s [(F_s(\mathbf{z}) - F_s(\mathbf{z}'))^2]\right)\right\} \quad (37)$$

$$= \phi(\Delta^2)^{-1} \left(\mathbb{E}\left\{\phi\left(\max_s [(F_s(\mathbf{z}) - F_s(\mathbf{z}')^2)]\right)\right\} \right. \\ \left. + \mathbb{E}\left\{\phi\left(\max_s [(F_s(\mathbf{z}) - F_s(\mathbf{z}'))^2]\right)\right\} \right). \quad (38)$$

Here (a) is Markov's inequality, and (b) is the symmetrization bound Eq.(33), where we use the fact that $\phi(z) = (z - a)_+$ is non-decreasing and convex in z .

At this point, it is easy to see that the lemma follows if we are able to control the first term in Eq.(38). We establish this via the Maurey-Pisier method. Define the path $\mathbf{z}(\theta) \equiv \mathbf{z} \sin \theta + \mathbf{z}' \cos \theta$, the velocity $\dot{\mathbf{z}} \equiv d\mathbf{z}/d\theta = \mathbf{z} \cos \theta - \mathbf{z}' \sin \theta$.

$$\mathbb{E}\left\{\phi\left(\max_s [(F_s(\mathbf{z}) - F_s(\mathbf{z}')^2)]\right)\right\} = \int_0^\infty \mathbb{P}\left\{\left(\max_s [(F_s(\mathbf{z}) - F_s(\mathbf{z}')^2)] - a\right)_+ \mathbb{I}(\mathcal{G}) \geq x\right\} dx \\ (39) \\ = \int_0^\infty \mathbb{P}\left\{\max_s [|F_s(\mathbf{z}) - F_s(\mathbf{z}')|] \geq \sqrt{x+a}; \mathcal{G}\right\} dx \quad (40) \\ \leq 2|S| \int_a^\infty e^{-\lambda\sqrt{x}} \max_s \left[\mathbb{E}\left\{\exp\{\lambda(F_s(\mathbf{z}) - F_s(\mathbf{z}'))\}; \mathcal{G}\right\} \right] dx, \quad (41)$$

where, in the last inequality we use the union bound followed by Markov's inequality. To control the exponential moment, note that $F_s(\mathbf{z}) - F_s(\mathbf{z}') = \int_0^{\pi/2} \langle \nabla F(\mathbf{z}(\theta)), \dot{\mathbf{z}}(\theta) \rangle d\theta$ whence,

using Jensen's inequality:

$$\mathbb{E}\left\{\exp\left\{\lambda(F_s(\mathbf{z}) - F_s(\mathbf{z}'))\right\}; \mathcal{G}\right\} = \mathbb{E}\left\{\exp\left(\int_0^{\pi/2} \lambda \langle \nabla F_s(\mathbf{z}(\theta)), \dot{\mathbf{z}}(\theta) \rangle d\theta\right); \mathcal{G}\right\} \quad (42)$$

$$\leq \frac{2}{\pi} \int_0^{\pi/2} \mathbb{E}\left\{\exp\left(\lambda\pi \langle \nabla F_s(\mathbf{z}(\theta)), \dot{\mathbf{z}}(\theta) \rangle / 2\right); \mathcal{G}\right\} d\theta. \quad (43)$$

Define the set $\mathcal{G}_\theta = \{(\mathbf{z}, \mathbf{z}') : \max_s \|\nabla F_s(\mathbf{z}(\theta))\| \leq L\}$. Then:

$$\mathbb{E}\left\{\exp\left\{\lambda(F_s(\mathbf{z}) - F_s(\mathbf{z}'))\right\}; \mathcal{G}\right\} \stackrel{(a)}{\leq} \frac{2}{\pi} \int_0^{\pi/2} \mathbb{E}\left\{\exp\left(\lambda\pi \langle \nabla F_s(\mathbf{z}(\theta)), \dot{\mathbf{z}}(\theta) \rangle / 2\right); \mathcal{G}_\theta\right\} d\theta \quad (44)$$

$$\stackrel{(b)}{=} \frac{2}{\pi} \int_0^{\pi/2} \mathbb{E}\left\{\exp\left(\frac{\lambda^2 \pi^2 \|\nabla F_s(\mathbf{z}(\theta))\|^2}{8}; \mathcal{G}_\theta\right)\right\} d\theta \quad (45)$$

$$\stackrel{(c)}{\leq} \exp\left(\frac{\lambda^2 \pi^2 L^2}{8}\right). \quad (46)$$

Here (a) follows as $\mathcal{G}_\theta \supseteq \mathcal{G}$. Equality (b) follows from noting that \mathcal{G}_θ is measurable with respect to $\mathbf{z}(\theta)$ and, hence, first integrating with respect to $\dot{\mathbf{z}}(\theta) = \mathbf{z} \cos \theta - \mathbf{z}' \sin \theta$, a Gaussian random variable that is independent of $\mathbf{z}(\theta)$. The final inequality (c) follows by using the fact that $\|\nabla F_s(\mathbf{z}(\theta))\| \leq L$ on the set \mathcal{G}_θ .

Since this bound is uniform over $s \in S$, we can use it in (41):

$$\mathbb{E}\left\{\phi\left(\max_s (F_s(\mathbf{z}) - F_s(\mathbf{z}'))\right); \mathcal{G}\right\} \leq 2|S| \int_a^\infty \exp\left(-\lambda\sqrt{x} + \frac{\lambda^2 \pi^2 L^2}{8}\right) dx \quad (47)$$

$$\leq \frac{4|S|}{\lambda^2} (1 + \lambda\sqrt{a}) \exp\left(-\lambda\sqrt{a} + \frac{\lambda^2 \pi^2 L^2}{8}\right) \quad (48)$$

We can now set $\lambda = 4\sqrt{a}/\pi^2 L^2$, to obtain the exponent above as $-2a/\pi^2 L^2 = -\Delta^2/\pi^2 L^2$. The prefactor $(1 + \lambda\sqrt{a})\lambda^{-2}$ is bounded by $CL^2 \max(L^2/\Delta^2)$ when $a = \Delta^2/2$. Therefore, as required, we obtain:

$$\mathbb{E}\left\{\phi\left(\max_s (F_s(\mathbf{z}) - F_s(\mathbf{z}'))\right); \mathcal{G}\right\} \leq C \max(1, L^4/\Delta^4) \exp\left(-\frac{\Delta^2}{CL^2}\right) \quad (49)$$

Combining this with Eq. (38) and the fact that $\phi(\Delta^2)^{-1} \leq C\Delta^{-2}$ gives Eq. (28) and, consequently, the lemma. \blacksquare

By a simple application of Cauchy-Schwarz, this lemma implies the following.

Corollary 10 *Under the same conditions as Lemma 9,*

$$\mathbb{P}\left\{\max_{s \in S} |F_s(\mathbf{z}) - \mathbb{E}F_s(\mathbf{z})| \geq \Delta\right\} \leq C|S| \exp\left(-\frac{\Delta^2}{CL^2}\right) \\ + \frac{C}{\Delta^2} \mathbb{P}\left\{\max_{s \in S} [(F_s(\mathbf{z}) - F_s(\mathbf{z}'))^4]^{1/2}\right\} \mathbb{P}\{\mathcal{G}^c\}^{1/2}. \quad (50)$$

The following two lemmas are well-known concentration of measure results. The forms below can be found in (Vershynin, 2012, Corollary 5.35), (Laurent and Massart, 2000, Lemma 1) respectively.

Lemma 11 Let $\mathbf{A} \in \mathbb{R}^{M \times N}$ be a matrix with i.i.d. standard normal entries, i.e. $\mathbf{A}_{ij} \sim \mathcal{N}(0, 1)$. Then, for every $t \geq 0$:

$$\mathbb{P}\left\{\|\mathbf{A}\|_{\text{op}} \geq \sqrt{M} + \sqrt{N} + t\right\} \leq \exp\left(-\frac{t^2}{2}\right). \quad (51)$$

Lemma 12 Let $\mathbf{z} \sim \mathcal{N}(0, \mathbf{I}_N)$. Then

$$\mathbb{P}\{\|\mathbf{z}\|^2 \geq N + 2\sqrt{N}t + 2t\} \leq \exp(-t). \quad (52)$$

6. Proof of Theorem 1

Since $\widehat{\Sigma} = \mathbf{X}^T \mathbf{X} / n - \mathbf{I}_p$, we have:

$$\begin{aligned} \widehat{\Sigma} &= \sum_{q=1}^r \left\{ \frac{\beta_q \|\mathbf{u}_q\|^2}{n} \mathbf{v}_q(\mathbf{v}_q)^T + \frac{\sqrt{\beta_q}}{n} (\mathbf{z}^T \mathbf{u}_q)^T + (\mathbf{z}^T \mathbf{u}_q) \mathbf{v}_q^T \right\} \\ &\quad + \sum_{q \neq q'} \left\{ \frac{\sqrt{\beta_q \beta_{q'}} \langle \mathbf{u}_q, \mathbf{u}_{q'} \rangle}{n} \mathbf{v}_q(\mathbf{v}_{q'})^T \right\} + \frac{\mathbf{z}^T \mathbf{z}}{n} - \mathbf{I}_p. \end{aligned} \quad (53)$$

We let $\mathbf{D} = \{(i, j) : i \in [p] \setminus \mathbf{Q}\}$ be the diagonal entries not included in any support. (Recall that $\mathbf{Q} = \cup_q \mathbf{Q}_q$ denote the union of the supports.) Further let $\mathbf{E} = \mathbf{Q} \times \mathbf{Q}$, $\mathbf{F} = (\mathbf{Q}^c \times \mathbf{Q}^c) \setminus \mathbf{D}$, and $\mathbf{G} = [p] \times [p] \setminus (\mathbf{D} \cup \mathbf{E} \cup \mathbf{F})$, or, equivalently $\mathbf{G} = (\mathbf{Q} \times \mathbf{Q}^c) \cup (\mathbf{Q}^c \times \mathbf{Q})$. Since these are disjoint we have:

$$\eta(\widehat{\Sigma}) = \underbrace{\mathcal{P}_{\mathbf{E}}\{\eta(\widehat{\Sigma})\}}_{\mathbf{S}} + \underbrace{\mathcal{P}_{\mathbf{F}}\{\eta(\widehat{\Sigma})\}}_{\mathbf{N}} + \underbrace{\mathcal{P}_{\mathbf{G}}\{\eta(\widehat{\Sigma})\}}_{\mathbf{C}} + \underbrace{\mathcal{P}_{\mathbf{D}}\{\eta(\widehat{\Sigma})\}}_{\mathbf{D}}. \quad (54)$$

The first term corresponds to the ‘signal’ component, while the last three terms correspond to the ‘noise’ component.

Theorem 1 is a direct consequence of the next five propositions. The first demonstrates that, even for a low level of thresholding, viz. $\tau < \sqrt{\log p/2}$, the term \mathbf{N} has small operator norm. The second demonstrates that the soft thresholding operation preserves the signal in the term \mathbf{S} . The next two propositions show that the cross and diagonal terms \mathbf{C} and \mathbf{D} are negligible as well. Finally, in the last proposition, we demonstrate that, for the regime of thresholding far above the noise level, i.e. $\tau > C\sqrt{\log p}$, the noise terms \mathbf{N} and \mathbf{C} vanish entirely.

Proposition 13 Let \mathbf{N} denote the second term of Eq. (54). Since $\mathbf{F} = \mathbf{Q}^c \times \mathbf{Q}^c \setminus \mathbf{D}$,

$$\mathbf{N} = \mathcal{P}_{\mathbf{F}}\left(\eta(\widehat{\Sigma})\right) = \mathcal{P}_{\mathbf{F}}\left\{\eta\left(\frac{1}{n}\mathbf{Z}^T \mathbf{z}\right)\right\}. \quad (55)$$

Then, there exists an absolute constant C such that the following happens. Assuming that (i) $\tau < \sqrt{\log p/2}$ and (ii) $n > C \log p$, then with probability $1 - o(1)$

$$\|\mathbf{N}\|_{\text{op}} \leq C \left(\sqrt{\frac{p}{n}} \vee \frac{p}{n} \right) e^{-\tau^2/C}. \quad (56)$$

Proposition 14 Let \mathbf{S} denote the first term in Eq. (54):

$$\mathbf{S} = \mathcal{P}_{\mathbf{E}}\left\{\eta(\widehat{\Sigma})\right\}. \quad (57)$$

Assume that (i) $s_0/n < 1$ and (ii) $n > C \log p$. Then with probability $1 - o(1)$:

$$\|\mathbf{S} - \Sigma\|_{\text{op}} \leq \frac{2\tau s_0}{\sqrt{n}} + C(\beta \vee 1) \sqrt{\frac{s_0}{n}}. \quad (58)$$

Proposition 15 Let \mathbf{C} denote the matrix corresponding to the third term of Eq. (54):

$$\mathbf{C} = \mathcal{P}_{\mathbf{G}}\left\{\eta(\widehat{\Sigma})\right\}.$$

Assuming the conditions of Proposition 13 and, additionally, that $s_0^2 \leq p$, there exist constants C, c such that with probability $1 - o(1)$

$$\|\mathbf{C}\|_{\text{op}} \leq C \tau e^{-c\tau^2/(\beta \vee 1)} \sqrt{\frac{p}{n}} \vee \frac{p}{n}. \quad (59)$$

Proposition 16 Let \mathbf{D} denote the matrix corresponding to the third term of Eq. (54):

$$\mathbf{D} = \mathcal{P}_{\mathbf{D}}\left\{\eta(\widehat{\Sigma})\right\}.$$

With probability $1 - o(1)$ we have that $\|\mathbf{D}\|_{\text{op}} \leq C\sqrt{n-1} \log p$.

Proposition 17 For some absolute constant C_0 , we have for $\tau \geq C_0(\beta \vee 1)\sqrt{\log p}$ that, with probability $1 - o(1)$:

$$\forall i, j \quad N_{ij} = C_{ij} = 0. \quad (60)$$

Therefore, $\|\mathbf{N}\|_{\text{op}} = 0$ and $\|\mathbf{C}\|_{\text{op}} = 0$.

Remark 18 At this point we remark that the probability $1 - o(1)$ can be made quantitative, for e.g. of the form $1 - \exp(-\min(\sqrt{\beta}, n)/C_1)$, for every n large enough. For simplicity of exposition we do not pursue this in the paper.

We defer the proofs of Propositions 13, 14, 15, 16 and 17 to Sections 6.1, 6.2, 6.3, 6.4 and 6.5 respectively. By combining them for $\beta = O(1)$, we immediately obtain the following bound.

Theorem 19 There exist numerical constants C_0, C_1 such that the following happens. Assume $\beta \leq C_0$, $n > C_1 \log p$ and $\tau \leq \sqrt{\log p/2}$. Then with probability $1 - o(1)$:

$$\|\eta(\widehat{\Sigma}) - \Sigma\|_{\text{op}} \leq \frac{2\tau s_0}{\sqrt{n}} + C \left(\sqrt{\frac{p}{n}} \vee \frac{p}{n} \right) e^{-\tau^2/C} + C \sqrt{\frac{s_0 \vee \log p}{n}}. \quad (61)$$

Proof The proof is obtained by adding the error terms from Propositions 13, 14, 15 and 16, and noting that β is bounded. \blacksquare

Using Propositions 13, 14, 15 and 16, together with a suitable choice of τ , we obtain the proof of Theorem 1.

Proof [Proof of Theorem 1] Note that in the case $s_0^2 > p/e$ there is no thresholding and hence the result follows from the fact that $\|\tilde{\Sigma} - \Sigma\|_{op} \leq C\sqrt{p}/n$ (Vershynin, 2012, Remark 5.40).

We assume now that $s_0^2 \leq p/e$ and the case that $\tau_* = C_1(\beta \vee 1)\sqrt{\log(p/s_0^2)} \leq \sqrt{\log p}/2$. In that case we set $\tau = \tau_* \leq \sqrt{\log p}/2$. Below we will keep C_1 a large enough constant, and check that each of the error terms in Propositions 13, 14, 15 and 16 is upper bounded by (a constant times) the right-hand side of Eq. (7). Throughout C will denote a generic constant that can be made as large as we want, and can change from line to line.

We start from Proposition 13:

$$\|\mathbf{N}\|_{op} \leq C \left(\sqrt{\frac{p}{n}} \vee \frac{p}{n} \right) \left(\frac{s_0^2}{p} \right)^C \quad (62)$$

$$\leq C \sqrt{\frac{p}{n}} \left(\frac{p}{s_0^2} \right)^{-C-1} \vee C \sqrt{\left(\frac{p}{n} \right)^2 \left(\frac{p}{s_0^2} \right)^{-C-2}} \quad (63)$$

$$\leq C \sqrt{\frac{s_0^2}{n}} \left(\frac{p}{s_0^2} \right)^{-C} \vee C \sqrt{\left(\frac{s_0^2}{n} \right)^2 \left(\frac{p}{s_0^2} \right)^{-C}} \quad (64)$$

$$\leq C \sqrt{\frac{s_0^2}{n}} \log \frac{p}{s_0^2}, \quad (65)$$

where in the last step we used $(e s_0^2/p), (s_0^2/n) \leq 1$.

Next consider Proposition 14:

$$\begin{aligned} \|\mathbf{S} - \Sigma\|_{op} &\leq C \sqrt{\frac{s_0^2 \tau^2}{n}} + C \sqrt{\frac{s_0(\beta \vee 1)^2}{n}} \\ &\leq C \sqrt{\frac{s_0^2(\beta^2 \vee 1)}{n}} \log \frac{p}{s_0^2}. \end{aligned} \quad (66)$$

From Proposition 15, we get, using the same argument as in Eq. (65)

$$\begin{aligned} \|\mathbf{C}\|_{op} &\leq C \sqrt{\beta \vee 1} \left(\sqrt{\frac{p}{n}} \vee \frac{p}{n} \right) \left(\frac{s_0^2}{p} \right)^C \\ &\leq C(\beta \vee 1) \sqrt{\frac{s_0^2}{n}} \log \frac{p}{s_0^2}. \end{aligned} \quad (68)$$

Finally, the term of Proposition 16 is also bounded as desired using $\log p \leq s_0^2 \log(p/s_0^2)$ (dividing both sides by p and using the fact that $x \mapsto x \log(1/x)$ is increasing).

The case of $\tau_* \geq \sqrt{\log p}/2$ is easier. In that case, we can keep $\tau = C_2 \tau_*$ with C_2 large enough so that $\tau \geq C_0(\beta \vee 1)\sqrt{\log p}$ for C_0 of Proposition 17. Then, by Proposition 17, we

know that $\mathbf{N} = 0$ and $\mathbf{C} = 0$. Therefore we only need consider the terms $\mathbf{S} - \Sigma$ and \mathbf{D} . For these terms we can use Propositions 14 and 16 respectively and, arguing as in the earlier case $\tau_* \leq \sqrt{\log p}$, we obtain the desired result. \blacksquare

6.1 Proof of Proposition 13

Define $\tilde{\mathbf{N}}$ as

$$\tilde{\mathbf{N}} = \mathcal{P}_{nd} \left\{ \eta \left(\frac{1}{n} \mathbf{Z}^\top \mathbf{Z} \right) \right\}.$$

Since \mathbf{N} is a principal submatrix of $\tilde{\mathbf{N}}$, it suffices to prove the same bound for $\tilde{\mathbf{N}}$. Our main tool in the proof will be the concentration lemma 9 which we use on multiple occasions. With a view to using the lemma, we let $\mathbf{Z}' \in \mathbb{R}^{n \times p}$ denote an independent copy of \mathbf{Z} , and $\tilde{\mathbf{z}}'_i$ its i^{th} column. The proof relies on two preliminary lemmas. For some $A \geq 1$ (to be chosen later), we first state and prove the following lemma that controls the norm of *any principal submatrix* of $\tilde{\mathbf{N}}$ of size at most p/A .

Lemma 20 Fix any $A \geq 1$. There exists an absolute constants C, c such that:

$$\mathbb{P} \left\{ \max_{\mathbf{S} \subseteq [p], |\mathbf{S}| \leq p/A} \|\mathcal{P}_{\mathbf{S} \times \mathbf{S}}(\tilde{\mathbf{N}})\|_{op} \geq \Delta \right\} \leq C \exp \left(\frac{\log CA}{A} - \frac{n^2 \Delta^2}{C(n+p)} \right) + C \frac{(np)^C}{\Delta^2} \exp(-cn). \quad (70)$$

Proof For any subset $\mathbf{S} \subset [p]$ recall that $T_p^\varepsilon(\mathbf{S})$ denotes an ε -net of unit vectors in \mathbb{S}^{p-1} supported on the subset \mathbf{S} . For simplicity let $T(A) = \cup_{\mathbf{S}: |\mathbf{S}| \leq p/A} T_p^\varepsilon(\mathbf{S})$. It suffices, by Lemma 8, to control $\langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle$ on the set $T(A)$. In particular:

$$\mathbb{P} \left\{ \max_{\mathbf{S} \subseteq [p], |\mathbf{S}| \leq p/A} \|\mathcal{P}_{\mathbf{S} \times \mathbf{S}}(\tilde{\mathbf{N}})\|_{op} \geq \Delta \right\} \leq \mathbb{P} \left\{ \max_{\mathbf{y} \in T(A)} |\langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle| \geq \Delta(1 - 2\varepsilon) \right\}. \quad (71)$$

Consider the good set \mathcal{G}_1 given by:

$$\mathcal{G}_1 = \{(\mathbf{Z}, \mathbf{Z}') : \max(\|\mathbf{Z}\|, \|\mathbf{Z}'\|) \leq \sqrt{2}(\sqrt{n} + \sqrt{p})\}. \quad (72)$$

To use Lemma 9, we need to compute $\mathbb{E}\langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle$ and the gradient of $\langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle$ with respect to the underlying random variables \mathbf{Z} . Since $\eta(\cdot)$ is an odd function the expectation vanishes. To compute the gradient, we let $t \in [0, 1]$ and $\mathbf{W} = \sqrt{t} \mathbf{Z} + \sqrt{1-t} \mathbf{Z}'$, and consider $\langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle = \langle \mathbf{y}, \eta(\mathbf{W}^\top \mathbf{W}/n) \mathbf{y} \rangle$ as a function of the \mathbf{W} . Taking the gradient with respect to a column $\tilde{\mathbf{w}}_\ell$ for $\ell \in \mathbf{S}$:

$$\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}, \tilde{\mathbf{N}} \mathbf{y} \rangle = \frac{y_\ell}{n} \sum_{i \neq \ell, i \in \mathbf{S}} \tilde{\mathbf{w}}_{ij} \partial \eta(\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_\ell \rangle / n) \quad (73)$$

$$= \frac{y_\ell}{n} \mathbf{W} \boldsymbol{\sigma}, \quad (74)$$

where

$$\sigma_i = \begin{cases} y_i \partial \eta(\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_\ell \rangle / n) & \text{if } i \neq \ell, i \in S \\ 0 & \text{otherwise.} \end{cases} \quad (75)$$

Since $\|\sigma\| \leq \|\mathbf{y}\| = 1$, we have that $\|\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle\|^2 \leq y_\ell^2 \|\mathbf{W}\|^2 / n^2$. Summing over $\ell \in S$ we obtain the gradient bound, holding on the good set \mathcal{G}_1 :

$$\|\nabla_{\mathbf{W}} \langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle\|^2 \leq \frac{\sum_{\ell} y_\ell^2}{n^2} \|\mathbf{W}\|^2 \quad (76)$$

$$\leq \frac{C(n+p)}{n^2}, \quad (77)$$

which holds because of triangle inequality and the fact that $\sqrt{t} + \sqrt{1-t} \leq \sqrt{2}$. We can now apply Lemma 9 to bound the RHS of Eq. (71) and get:

$$\begin{aligned} \mathbb{P}\left\{ \max_{S \subseteq [p], |S| \leq p/4} \mathcal{R}_{S \times S}(\tilde{\mathbf{N}}) \geq \Delta \right\} &\leq C|T(A)| \exp\left(-\frac{n^2 \Delta^2}{C(n+p)}\right) \\ &+ \frac{C}{\Delta^2} \mathbb{E}\left\{ \max_{y \in T} \langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle^2; \mathcal{G}_1^c \right\}. \end{aligned} \quad (78)$$

We can simplify the terms on the right-hand side to obtain the result of the lemma. With $\varepsilon = 1/4$, Stirling's approximation and Lemma 7 we have:

$$|T(A)| \leq \exp\left(p \frac{\log C A}{A}\right). \quad (79)$$

We use a crude bound on the complement of the good set \mathcal{G}_1 . It is easy to see that, for any unit vector \mathbf{y} , $\langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle^2 \leq \|\tilde{\mathbf{N}}\|_F^2 \leq \|\mathbf{Z}^T \mathbf{Z}\|_F^2 / n^2$. Cauchy-Schwarz then implies that

$$\mathbb{E}\{\max\langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle^2; \mathcal{G}_1^c\} \leq n^{-2} (\mathbb{E}\{\|\mathbf{Z}^T \mathbf{Z}\|_F^2\})^{1/2} \mathbb{P}\{\mathcal{G}_1^c\}^{1/2} \quad (80)$$

$$\leq (np)^C \exp(-c(n+p)), \quad (81)$$

where the bound on $\mathbb{P}\{\mathcal{G}_1^c\}$ follows from Lemma 11. This concludes the lemma. \blacksquare

Note that Lemma 20, with $A = 1$, tells us that $\|\tilde{\mathbf{N}}\|_{\text{op}}$ is of order $\sqrt{p/n} + (p/n)^2$ (uniformly in τ) with high probability. Already this non-asymptotic bound is non-trivial, since the previous results of Cheng and Singer (2013) and Fan and Montanari (2015) do not extend to this case. However, Proposition 13 is stronger, and establishes a rate of decay with the thresholding level τ .

The second lemma we require controls the Rayleigh quotient $\langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle$ when the entries of \mathbf{y} are ‘‘spread out’’.

Lemma 21 *Assume that $\tau \leq \sqrt{\log p}/2$. Given $A \geq 1$ and a unit vector \mathbf{y} , let $S = \{i : |y_i| \leq \sqrt{A/p}\}$ and $\mathbf{y}_S, \mathbf{y}_{S^c}$ denote the projections of \mathbf{y} onto supports S, S^c respectively. We have:*

$$\mathbb{P}\left\{ \max_{y \in T_p^{1/4}} |\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle| \geq \Delta \right\} \leq C \exp\left(-\frac{n^2 \Delta^2}{L_1^2} + C p\right) + (np)^C \exp\left(-c \min(\sqrt{p}, n)\right), \quad (82)$$

for any $\Delta \geq L_1$ where $L_1 = C_1 \sqrt{A \exp(-\tau^2/16)(n+p)/n^2}$. The same bound holds for $\mathbb{P}\left\{ \max_{y \in T_p^{1/4}} |\langle \mathbf{y}_{S^c}, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle| \geq \Delta \right\}$.

Proof We first prove the claim for $\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle$. Firstly, we have $\mathbb{E}\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle = 0$. Consider the ‘‘good set’’ \mathcal{G}_2 of pairs $(\mathbf{W}, \mathbf{W}') \in \mathbb{R}^{n \times p} \times \mathbb{R}^{n \times p}$ satisfying the conditions:

$$\|\mathbf{W}\|, \|\mathbf{W}'\| \leq \sqrt{2}(\sqrt{n} + \sqrt{p}), \quad (83)$$

$$\forall i \in [p], \quad \frac{1}{p} \sum_{j \in [p] \setminus i} \mathbb{I}(|\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_j \rangle| \geq \tau \sqrt{n}/2) \leq 2 \exp(-\tau^2/16), \quad (84)$$

$$\forall i \in [p], \quad \frac{1}{p} \sum_{j \in [p] \setminus i} \mathbb{I}(|\langle \tilde{\mathbf{w}}'_i, \tilde{\mathbf{w}}'_j \rangle| \geq \tau \sqrt{n}/2) \leq 2 \exp(-\tau^2/16), \quad (85)$$

$$\forall i \in [p], \quad \frac{1}{p} \sum_{j \in [p]} \mathbb{I}(|\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_j \rangle| \geq \tau \sqrt{n}/2) \leq 2 \exp(-\tau^2/16). \quad (86)$$

Also, for any pair $\mathbf{W}, \mathbf{W}' \in \mathcal{G}_2$, for $\mathbf{W}(t) = \sqrt{t}\mathbf{W} + \sqrt{1-t}\mathbf{W}'$ (and its columns $\tilde{\mathbf{w}}(t)_i$ defined appropriately) we have:

$$\|\mathbf{W}(t)\| \leq \max(\sqrt{t} + \sqrt{1-t})(\sqrt{2n} + \sqrt{2p}) + \sqrt{2p} = 2(\sqrt{n} + \sqrt{p}), \quad (87)$$

$$\forall i \in [p] \quad \frac{1}{p} \sum_{j \in [p] \setminus i} \mathbb{I}(|\langle \tilde{\mathbf{w}}(t)_i, \tilde{\mathbf{w}}(t)_j \rangle| \geq \tau \sqrt{n}) \leq 6 \exp(-\tau^2/16). \quad (88)$$

Equation (87) follows by a simple application of triangle inequality and condition (83) defining \mathcal{G}_2 . For inequality (88), expanding the product $\langle \tilde{\mathbf{w}}(t)_i, \tilde{\mathbf{w}}(t)_j \rangle$:

$$\langle \tilde{\mathbf{w}}(t)_i, \tilde{\mathbf{w}}(t)_j \rangle = t \langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_j \rangle + (1-t) \langle \tilde{\mathbf{w}}'_i, \tilde{\mathbf{w}}'_j \rangle + \sqrt{t(1-t)} \langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}'_j \rangle, \quad (89)$$

whence, by triangle inequality and $\sqrt{t(1-t)} < 1$

$$\begin{aligned} \mathbb{I}(|\langle \tilde{\mathbf{w}}(t)_i, \tilde{\mathbf{w}}(t)_j \rangle| \geq \tau \sqrt{n}) &\leq \mathbb{I}(|\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_j \rangle| \geq \tau \sqrt{n}/2) + \mathbb{I}(|\langle \tilde{\mathbf{w}}'_i, \tilde{\mathbf{w}}'_j \rangle| \geq \tau \sqrt{n}/2) \\ &+ \mathbb{I}(|\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}'_j \rangle| \geq \tau \sqrt{n}/2). \end{aligned} \quad (90)$$

The gradient of $\langle \mathbf{y}_S, \eta(\mathbf{W}^T \mathbf{W}/n) \mathbf{y}_S \rangle$ with respect to a column $\tilde{\mathbf{w}}_\ell$ of \mathbf{W} is given by:

$$\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}_S, \eta(\mathbf{W}^T \mathbf{W}/n) \mathbf{y}_S \rangle = \frac{y_\ell}{n} \sum_{j \in S \setminus \ell} y_j \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right) \tilde{\mathbf{w}}_j \quad (91)$$

$$= \frac{y_\ell}{n} \mathbf{W} \boldsymbol{\sigma}, \quad (92)$$

$$\text{where } \sigma_i = \begin{cases} \partial \eta(\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_\ell \rangle / n; \tau / \sqrt{n}) y_i & \text{when } i \in S \setminus \ell \\ 0 & \text{otherwise.} \end{cases} \quad (93)$$

Therefore

$$\|\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle\|^2 \leq \frac{y_\ell^2}{n^2} \|\mathbf{W}\|^2 \|\boldsymbol{\sigma}\|^2 \quad (94)$$

$$\leq \frac{y_\ell^2 \|\mathbf{W}\|^2}{n^2} \sum_{i \neq \ell} (y_i \partial \eta(\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_\ell \rangle / n))^2 \quad (95)$$

$$\stackrel{(a)}{\leq} \frac{y_\ell^2 \|\mathbf{W}\|^2}{n^2} \sum_{i \neq \ell} \frac{A}{p} \mathbb{I}(|\langle \tilde{\mathbf{w}}_i, \tilde{\mathbf{w}}_\ell \rangle| \geq \tau \sqrt{n}) \quad (96)$$

$$\stackrel{(b)}{\leq} \frac{y_\ell^2}{n^2} C(n+p) A \exp(-\tau^2/16) \quad (97)$$

Here (a) follows from fact that the entries of \mathbf{y}_S are bounded by $\sqrt{A/p}$ and the definition of the soft thresholding function. Inequality (b) follows when we set $\mathbf{W} = \mathbf{Z}(t) = \sqrt{t}\mathbf{Z} + \sqrt{1-t}\mathbf{Z}'$ and $(\mathbf{Z}, \mathbf{Z}') \in \mathcal{G}_2$. Therefore, summing over ℓ we obtain the following bound for the gradient of $\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle$

$$\|\nabla_{\mathbf{Z}(t)} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle\|^2 \leq C_1 \frac{A \exp(-\tau^2/16)(n+p)}{n^2} \equiv L_1^{-1}. \quad (98)$$

We can use now Lemma 9, to get, for $L_1 > 0$ as defined above and any $\Delta \geq L_1$:

$$\begin{aligned} \mathbb{P}\left\{ \max_{\mathbf{y} \in \mathcal{T}_1^{1/4}} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle \geq \Delta \right\} &\leq C \exp\left(-\frac{\Delta^2}{CL_1^2} + Cp\right) \\ &\quad + CL_1^{-2} \mathbb{E}\left\{ \max_{\mathbf{y} \in \mathcal{T}_1^{1/4}} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle^2; \mathcal{G}_2 \right\} \\ &\leq C \exp\left(-\frac{\Delta^2}{CL_1^2} + Cp\right) + C(np)^C \mathbb{P}\{\mathcal{G}_2^c\}^{1/2}, \end{aligned} \quad (100)$$

where the last line follows by Cauchy-Schwarz, as in the proof of Lemma 20, and the fact that $L_1 \geq (np)^{-C_2}$ using the upper bound $\tau \leq \sqrt{\log p/2}$.

To obtain the thesis, we need to now bound $\mathbb{P}\{\mathcal{G}_2^c\}$. It suffices to control the failure probability of conditions (83), (84), (85), (86) of the good set \mathcal{G}_2 individually, and apply the union bound. For \mathbf{Z}, \mathbf{Z}' independent, $\max(\|\mathbf{Z}\|, \|\mathbf{Z}'\|) \geq \sqrt{2}(\sqrt{n} + \sqrt{p})$ with probability at most $2 \exp(-c(n+p))$ by Lemma 11. Now consider condition (84) with $i = 1$, without loss of generality. First, for any $h > 0$ we have:

$$\begin{aligned} \mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq h \right\} &\leq \mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq 2h; \|\tilde{\mathbf{z}}_1\| \leq 2\sqrt{n} \right\} \\ &\quad + \mathbb{P}\{\|\tilde{\mathbf{z}}_1\| \geq \sqrt{2n}\}. \end{aligned} \quad (101)$$

Lemma 12 guarantees that the second term is at most $\exp(-cn)$. To control the first term, we note that, conditional on $\tilde{\mathbf{z}}_1, \langle \tilde{\mathbf{z}}_j, \tilde{\mathbf{z}}_1 \rangle, j \neq 1$ are independent Gaussian random variables with variance $\|\tilde{\mathbf{z}}_1\|^2$. Therefore, conditional on $\tilde{\mathbf{z}}_1, \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2)$ are independent Bernoulli random variables with success probability $h_0 = 2\Phi(-\tau \sqrt{n}/(2\|\tilde{\mathbf{z}}_1\|))$, where $\Phi(\cdot)$ is

the Gaussian cumulative distribution function. It follows, by the Chernoff-Hoeffding bound for Bernoulli random variables that

$$\mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq h \mid \tilde{\mathbf{z}}_1 \right\} \leq \exp(-pD(h\|\tilde{\mathbf{z}}_1\|h_0)), \quad (102)$$

where $D(a\|b) = a \log(a/b) + (1-a) \log(1-a)/(1-b)$. Choosing $h = 4\Phi(-\tau/(2\sqrt{2}))$, and conditional on $\|\tilde{\mathbf{z}}_1\| \leq \sqrt{2n}$, $D(h\|h_0) \geq ch$ for a constant c , implying that

$$\mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq h; \|\tilde{\mathbf{z}}_1\| \leq \sqrt{2n} \right\} \leq \exp(-cph). \quad (103)$$

By standard bounds $h = 4\Phi(-\tau/(2\sqrt{2})) \leq 2 \exp(-\tau^2/16)$ and, as $\tau \leq \sqrt{\log p/2}$, $h \geq 1/\sqrt{p}$, we have

$$\mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq h; \|\tilde{\mathbf{z}}_1\| \leq \sqrt{2n} \right\} \leq \exp(-c\sqrt{p}). \quad (104)$$

Combining this with Eq. (101) we now get:

$$\mathbb{P}\left\{ \frac{1}{p} \sum_{j \neq 1} \mathbb{I}(|\langle \tilde{\mathbf{z}}_1, \tilde{\mathbf{z}}_j \rangle| \geq \tau \sqrt{n}/2) \geq h \right\} \leq 2 \exp(-c \min(n, \sqrt{p})). \quad (105)$$

A similar bound holds for $i \neq 1$ and the other conditions (85) and (86), whence we have by the union bound that $\mathbb{P}\{\mathcal{G}_2^c\} \leq p^2 \exp(-c \min(\sqrt{p}, n))$. This completes the proof of the claim (82).

The proof of the claim for $\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle$ is analogous, so we only sketch the points at which it differs from that of Eq. (82). We use the same good set \mathcal{G}_2 , as defined earlier. Computing the gradient as for $\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle$ we obtain:

$$\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle = \frac{y_\ell}{n} \sum_{j \in \mathcal{S}(\ell)} y_j \tilde{\mathbf{w}}_j \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right). \quad (106)$$

Here $\mathcal{S}(\ell) = \mathcal{S}^c$ if $\ell \in \mathcal{S}$ and \mathcal{S} otherwise. Define the vector $\boldsymbol{\sigma}(\ell) \in \mathbb{R}^p$ as

$$(\boldsymbol{\sigma}(\ell))_j = \begin{cases} y_\ell y_j \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right) & \text{if } j \in \mathcal{S}(\ell) \\ 0 & \text{otherwise.} \end{cases} \quad (107)$$

As before, we have that $\|\nabla_{\tilde{\mathbf{w}}_\ell} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle\| = n^{-1} \|\mathbf{W}\boldsymbol{\sigma}(\ell)\| \leq n^{-1} \|\mathbf{W}\| \|\boldsymbol{\sigma}(\ell)\|$. Therefore, summing over $\ell \in [p]$:

$$\|\nabla_{\mathbf{W}} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle\|^2 \leq \frac{\|\mathbf{W}\|^2}{n^2} \sum_{\ell \in [p]} \|\boldsymbol{\sigma}(\ell)\|^2 \quad (108)$$

$$\leq \frac{\|\mathbf{W}\|^2}{n^2} \sum_{\ell \in [p]} \sum_{j \in \mathcal{S}(\ell)} y_\ell^2 y_j^2 \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right) \quad (109)$$

$$= 2 \frac{\|\mathbf{W}\|^2}{n^2} \sum_{\ell \in \mathcal{S}} \sum_{j \in \mathcal{S}^c} y_\ell^2 y_j^2 \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right) \quad (110)$$

$$\leq \frac{2\|\mathbf{W}\|^2 A}{n^2} \max_{\ell \in [p]} \sum_{j \neq \ell} \partial \eta\left(\frac{\langle \tilde{\mathbf{w}}_j, \tilde{\mathbf{w}}_\ell \rangle}{n}; \frac{\tau}{\sqrt{n}}\right). \quad (111)$$

Under the condition of \mathcal{G}_2 , the gradient also satisfies, when evaluated at $\mathbf{W} = \mathbf{Z}(t) = \sqrt{t}\mathbf{Z} + \sqrt{1-t}\mathbf{Z}'$:

$$\|\nabla_{\mathbf{Z}(t)} \langle \mathbf{Y}_S, \tilde{\mathbf{N}}\mathbf{Y}_{S^c} \rangle\|^2 \leq \frac{CA \exp(-\tau^2/16)(n+p)}{n^2}. \quad (112)$$

The rest of the proof is then the same as before. \blacksquare

Given these lemmas, we can now establish Proposition 13.

Proof [Proof of Proposition 13] We use a variant of the ε -net argument of Lemma 20. To bound the probability that $\|\tilde{\mathbf{N}}\|_{op}$ is large, with Lemma 8, we obtain:

$$\mathbb{P}\{\|\tilde{\mathbf{N}}\|_{op} \geq \Delta\} \leq \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle \geq \Delta(1-2\varepsilon)\right\}. \quad (113)$$

Let $\mathbf{S} = \{i : |y_i| \leq \sqrt{A/p}\}$ for some $A \geq 1$ to be chosen later. Then let $\mathbf{y} = \mathbf{y}_S^c + \mathbf{y}_S$ denote the projections of \mathbf{y} onto supports S, S^c respectively. Since $\langle \mathbf{y}, \tilde{\mathbf{N}}\mathbf{y} \rangle = \langle \mathbf{y}_{S^c}, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle + \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle + 2\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle$ by triangle inequality and union bound:

$$\mathbb{P}\{\|\tilde{\mathbf{N}}\|_{op} \geq \Delta\} \leq \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_{S^c}, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle + \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle + 2\langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle \geq \Delta(1-2\varepsilon)\right\} \quad (114)$$

$$\leq \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_{S^c}, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle \geq \Delta(1-2\varepsilon)/4\right\} + \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle \geq \Delta(1-2\varepsilon)/4\right\} \\ + \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle \geq \Delta(1-2\varepsilon)/4\right\} \quad (115)$$

$$\leq \mathbb{P}\left\{\max_{S: |S| \leq p/4} \|\mathcal{P}_{S^c \times S}(\tilde{\mathbf{N}})\| \geq \Delta(1-2\varepsilon)/4\right\} + \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_S \rangle \geq \Delta(1-2\varepsilon)/4\right\} \\ + \mathbb{P}\left\{\max_{\mathbf{y} \in T_p^S} \langle \mathbf{y}_S, \tilde{\mathbf{N}}\mathbf{y}_{S^c} \rangle \geq \Delta(1-2\varepsilon)/4\right\}. \quad (116)$$

With $\varepsilon = 1/4$, the first term is controlled by Lemma 20 while the final two are controlled by Lemma 21. We choose $\varepsilon = 1/4$ in Eq. (116), and

$$\Delta = \Delta_* \equiv C \sqrt{\frac{p}{n} \left(1 + \frac{p}{n}\right) \left(\frac{\log A}{A} + A \exp\left(-\frac{\tau^2}{16}\right)\right)}, \quad (117)$$

for large enough C so that, using the bounds of Lemmas 20 and 21, we have:

$$\mathbb{P}\{\tilde{\mathbf{N}} \geq \Delta_*\} \leq C(np)^C \exp\left[-c \min\left(\sqrt{p}, n, p \frac{\log A}{A}\right)\right]. \quad (118)$$

This probability bound is $o(1)$ provided A is not too large: we choose $A = 0.25\sqrt{\tau \exp(\tau^2/16)} \ll \sqrt{p}$ which guarantees that the bound above is $o(1)$ when $n > C \log p$ for some C large enough. This concludes the proposition. \blacksquare

6.2 Proof of Proposition 14

We decompose the empirical covariance matrix (53) as

$$\mathcal{P}_E(\hat{\Sigma}) = \Sigma + \Delta_1 + \Delta_2 + \Delta_2^\top + \mathcal{P}_E\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right), \quad (119)$$

$$\Delta_1 \equiv \sum_{q,q'=1}^r \sqrt{\beta_q \beta_{q'}} \left(\frac{1}{n} \langle \mathbf{u}_q, \mathbf{u}_{q'} \rangle - \mathbf{1}_{q=q'}\right) \mathbf{v}_q \mathbf{v}_{q'}^\top, \quad (120)$$

$$\Delta_2 \equiv \sum_{q=1}^r \frac{\sqrt{\beta_q}}{n} \mathbf{v}_q (\mathbf{Z}^\top \mathbf{u}_q)^\top. \quad (121)$$

Next notice that, for any $x \in \mathbb{R}$,

$$|\eta(x) - x| \leq \frac{\tau}{\sqrt{n}}. \quad (122)$$

With a view to employing this inequality, we use Eq. (119) and the triangle inequality:

$$\|\mathcal{P}_E(\eta(\hat{\Sigma})) - \Sigma\|_{op} = \left\| \mathcal{P}_E(\eta(\hat{\Sigma})) - \mathcal{P}_E(\hat{\Sigma}) - \Delta_1 - \Delta_2 - \Delta_2^\top - \mathcal{P}_E\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right) \right\|_{op} \quad (123)$$

$$\leq \|\mathcal{P}_E(\eta(\hat{\Sigma}) - \hat{\Sigma})\|_{op} + \|\Delta_1\|_{op} + 2\|\Delta_2\|_{op} + \left\| \mathcal{P}_E\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right) \right\|_{op} \quad (124)$$

$$\leq \frac{80\tau}{\sqrt{n}} + \|\Delta_1\|_{op} + 2\|\Delta_2\|_{op} + \left\| \mathcal{P}_E\left(\frac{1}{n}\mathbf{Z}^\top\mathbf{Z} - \mathbf{I}_p\right) \right\|_{op}, \quad (125)$$

where the last line follows by noticing that the first term is supported on \mathbf{E} of size 80×80 and then using bias bound Eq. (122) entry-wise. We next bound each of the three terms on the right hand side.

For the first term in Eq (125), note that with a change of basis to the orthonormal set $\mathbf{v}_1, \dots, \mathbf{v}_r$, Δ_1 is equivalent to an $r \times r$ matrix with entries $M_{qq'} \sqrt{\beta_q \beta_{q'}}$, where $M_{qq'} = \langle \mathbf{u}_q, \mathbf{u}_{q'} \rangle / n - \mathbf{1}_{q=q'}$. Denote by $\mathbf{B} \in \mathbb{R}^{r \times r}$ the diagonal matrix with $B_{qq} = \sqrt{\beta_q}$ and by $\mathbf{U} \in \mathbb{R}^{r \times n}$, the matrix with columns $\mathbf{u}_1, \dots, \mathbf{u}_r$. Then, we have, with high probability

$$\|\Delta_1\|_{op} = \|\mathbf{B}\mathbf{M}\mathbf{B}\|_{op} \quad (126)$$

$$\leq \|\mathbf{B}\|_{op}^2 \|\mathbf{M}\|_{op} = \beta \left\| \frac{1}{n} \mathbf{U}^\top \mathbf{U} - \mathbf{I}_{r \times r} \right\|_{op} \quad (127)$$

$$\leq C\beta \sqrt{\frac{\tau}{n}}. \quad (128)$$

The last inequality follows from the Bat-Yin law on eigenvalues of Wishart matrices (see Vershynin, 2012, Corollary 5.35).

Consider the second term in Eq (125). By orthonormality of $\mathbf{v}_1, \dots, \mathbf{v}_r$, the matrix Δ_2 is orthogonally equivalent to $\mathbf{B}\mathbf{Z}_Q^\top \mathbf{U} / n$, where we recall that \mathbf{Z}_Q denotes the submatrix of \mathbf{Z} formed by the columns in Q . Denoting by \mathbf{P}_U the orthogonal projector onto the column

space of \mathbf{U} , we then have, with high probability,

$$\|\Delta_2\|_{op} \leq \frac{1}{n} \|\mathbf{B}\|_{op} \|\mathbf{Z}_Q^T \mathbf{P}_U \mathbf{U}\|_{op} \quad (129)$$

$$\leq \frac{\beta}{n} \|\mathbf{P}_U \mathbf{Z}_Q\|_{op} \|\mathbf{U}\|_{op} \quad (130)$$

$$\leq \frac{C\beta}{n} (\sqrt{s_0} + \sqrt{r}) (\sqrt{n} + \sqrt{r}) \leq C\beta \sqrt{\frac{s_0}{n}}. \quad (131)$$

Here the penultimate inequality follows by Lemma 11 noting that, by invariance under rotations (and since \mathbf{P}_U project onto a random subspace of r dimensions independent of \mathbf{Z}), $\|\mathbf{P}_U \mathbf{Z}_Q\|_{op}$ is distributed as the norm of a matrix with i.i.d. standard normal entries, with dimensions $|\mathbf{Q}| \times r$, $|\mathbf{Q}| \leq s_0$.

Finally, for the third term of Eq. (125) we use the Bai-Yin law of Wishart matrices (see Vershynin, 2012, Corollary 5.35) to obtain, with high probability:

$$\left\| \mathcal{P}_E \left(\frac{1}{n} \mathbf{Z}^T \mathbf{Z} - \mathbf{I}_p \right) \right\|_{op} = \left\| \frac{1}{n} \mathbf{Z}_Q^T \mathbf{Z}_Q - \mathbf{I}_{s_0} \right\|_{op} \quad (132)$$

$$\leq C \sqrt{\frac{s_0}{n}}. \quad (133)$$

Finally, substituting the above bounds in Eq. (125), we get

$$\left\| \mathcal{P}_E(n\widehat{\Sigma}) - \Sigma \right\|_{op} = \frac{\tau s_0}{\sqrt{n}} + C(1 + \beta) \sqrt{\frac{s_0}{n}}, \quad (134)$$

which implies the proposition.

6.3 Proof of Proposition 15

Note that $\mathbf{C} = \widehat{\mathbf{C}} + \mathbf{C}^T$ where $\widehat{\mathbf{C}} = \mathcal{P}_{\mathbf{Q} \times \mathbf{Q}^c}(n\widehat{\Sigma})$. It is therefore sufficient to control $\widehat{\mathbf{C}}$, and then use triangle inequality. The proof is similar to that of Proposition 13. We let $\mathbf{U} \in \mathbb{R}^{n \times r}$ denote the matrix with columns $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_r$, and introduce the set

$$\mathcal{U} \equiv \left\{ \mathbf{U} \in \mathbb{R}^{n \times r} : \left\| \frac{1}{n} \mathbf{U}^T \mathbf{U} - \mathbf{I}_{r \times r} \right\|_{op} \leq 5 \sqrt{\frac{r}{n}} \right\}. \quad (135)$$

We then have

$$\mathbb{P}(\|\widehat{\mathbf{C}}\|_{op} \geq \Delta) \leq \sup_{\mathbf{U} \in \mathcal{U}} \mathbb{P}(\|\widehat{\mathbf{C}}\|_{op} \geq \Delta | \mathbf{U}) + \mathbb{P}(\mathbf{U} \notin \mathcal{U}). \quad (136)$$

Notice that, by the Bai-Yin law on eigenvalues of Wishart matrices (see Vershynin, 2012, Corollary 5.35), $\lim_{n \rightarrow \infty} \mathbb{P}(\mathbf{U} \in \mathcal{U}) = 1$ (throughout $r < cn$ for c a small constant). It is therefore sufficient to show $\sup_{\mathbf{U} \in \mathcal{U}} \mathbb{P}(\|\widehat{\mathbf{C}}\|_{op} \geq \Delta | \mathbf{U}) \rightarrow 0$ for Δ as in the statement of the theorem.

In order to lighten the notation, we will write $\widehat{\mathbb{P}}(\cdot) \equiv \mathbb{P}(\cdot | \mathbf{U})$ and bound the above probability uniformly over $\mathbf{U} \in \mathcal{U}$. (In other words $\widehat{\mathbb{P}}$ denotes expectation over \mathbf{Z} with \mathbf{U} fixed). We first control the norms of small submatrices of $\widehat{\mathbf{C}}$, following which we control the full matrix.

Lemma 22 Fix an $A \in [1, p^{1/3}]$, and let $L = \sqrt{((\beta \vee 1)n + p)/n^2}$. Then, there exists an absolute constant $C > 0$ such that, for any $\Delta > 0$:

$$\begin{aligned} \widehat{\mathbb{P}} \left\{ \max_{\mathbf{Q}^c \ni \mathbf{S}: |\mathbf{S}| \leq p/A} \|\mathcal{P}_{\mathbf{Q} \times \mathbf{S}}(n\widehat{\Sigma})\|_{op} \geq \Delta \right\} &\leq C \exp \left(C s_0 + \frac{p \log(CA)}{A} - \frac{\Delta^2}{CL^2} \right) \\ &\quad + L^{-2} (np)^C \exp(-n/C). \end{aligned} \quad (137)$$

Proof Let, as before, $T_p^{\varepsilon}(\mathbf{S})$ denote the ε -net of unit vectors supported on $\mathbf{S} \subset \mathbf{Q}^c$ of size at most p/A and let $T = \cup_{\mathbf{S} \in T_p^{\varepsilon}(\mathbf{S})}$. Then, by Lemma 8, with $\varepsilon = 1/4$:

$$\widehat{\mathbb{P}} \left\{ \max_{\mathbf{S} \subseteq \mathbf{Q}^c: |\mathbf{S}| \leq p/A} \|\mathcal{P}_{\mathbf{Q} \times \mathbf{S}}(n\widehat{\Sigma})\|_{op} \geq \Delta \right\} \leq \widehat{\mathbb{P}} \left\{ \max_{y \in T, \mathbf{w} \in T_p^{\varepsilon}} \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle \geq \Delta(1 - 2\varepsilon)/2 \right\}. \quad (138)$$

It now suffices to control the right hand side via Lemma 9. We first compute the gradients with respect to $\bar{\mathbf{z}}_{\ell}$ as before:

$$\nabla_{\bar{\mathbf{z}}_{\ell}} \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle = \begin{cases} \frac{w_{\ell}}{n} \sum_{i \in \mathbf{Q}^c} y_i \partial \eta(\langle \bar{\mathbf{x}}_{\ell}, \bar{\mathbf{z}}_i \rangle / n) \bar{\mathbf{z}}_i & \text{when } \ell \in \mathbf{Q}, \\ \frac{w_{\ell}}{n} \sum_{i \in \mathbf{Q}} w_i \partial \eta(\langle \bar{\mathbf{z}}_{\ell}, \bar{\mathbf{x}}_i \rangle / n) \bar{\mathbf{x}}_i & \text{when } \ell \in \mathbf{Q}^c, \end{cases} \quad (139)$$

Therefore, arguing as in proof of Proposition 13 (see Lemma 20):

$$\|\nabla_{\mathbf{Z}} \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle\|_F^2 = \sum_{\ell} \|\nabla_{\bar{\mathbf{z}}_{\ell}} \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle\|^2 \leq \frac{\|\mathbf{Z}\|^2 + \|\mathbf{X}_Q\|^2}{n^2}. \quad (140)$$

Let $\mathbf{B} \in \mathbb{R}^{r \times r}$ be the diagonal matrix with entries $B_{q,q} = \sqrt{\beta_{q,r}}$ and $\mathbf{V} \in \mathbb{R}^{p \times r}$ be the matrix with columns $\mathbf{v}_1, \dots, \mathbf{v}_r$. We then have $\mathbf{X} = \mathbf{UBV}^T + \mathbf{Z}$, whence, recalling $\mathbf{U} \in \mathcal{U}$, and $r \leq cn$ with c small enough

$$\|\mathbf{X}_Q\| \leq \|\mathbf{X}\| \leq \|\mathbf{UBV}^T\| + \|\mathbf{Z}\| \quad (141)$$

$$\leq \sqrt{\beta} \|\mathbf{U}\| + \|\mathbf{Z}\| \leq 5\sqrt{\beta}n + \|\mathbf{Z}\|. \quad (142)$$

Consider the good set \mathcal{G}_4 of pairs $(\mathbf{Z}, \mathbf{Z}')$ satisfying:

$$\max(\|\mathbf{Z}\|, \|\mathbf{Z}'\|) \leq \sqrt{2n} + \sqrt{2p}, \quad (143)$$

$$\max(\|\mathbf{Z}_Q\|, \|\mathbf{Z}'_Q\|) \leq \sqrt{2n} + \sqrt{2k}. \quad (144)$$

For $(\mathbf{Z}, \mathbf{Z}') \in \mathcal{G}_4$, and $t \in [0, 1]$, define $\mathbf{Z}(t) = \sqrt{t}\mathbf{Z} + \sqrt{1-t}\mathbf{Z}'$. Now Using Eqs. (140) and (142), the gradient $\nabla \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle$ evaluated at $\mathbf{Z}(t)$ satisfies:

$$\|\nabla \langle \mathbf{w}, \widehat{\mathbf{C}} \mathbf{y} \rangle\|^2 \leq \frac{3\|\mathbf{Z}(t)\|^2 + 10\beta n}{n^2} \quad (145)$$

$$\leq C \frac{(n+p) + \beta n}{n^2} \quad (146)$$

$$\leq C \frac{(\beta \vee 1)n + p}{n^2}. \quad (147)$$

Now applying Corollary 10, for $L = C\sqrt{((\beta \vee 1)n + p)/n^2}$:

$$\begin{aligned} \mathbb{P}^c \left\{ \max_{S \subseteq \mathcal{Q}^c, |S| \leq p/A} \|\mathbf{P}_{\mathcal{Q} \times S}(\eta(\hat{\Sigma}))\|_{op} \geq \Delta \right\} &\leq C|T| \exp\left(-\frac{\Delta^2}{CL^2}\right) \\ &\quad + CL^{-2} \mathbb{E} \left[\max_{\mathbf{w}, \mathbf{y}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y} \rangle^4 \right]^{1/4} \mathbb{P}\{G_A\}^{1/2}. \end{aligned} \quad (148)$$

Let $\varepsilon = 1/4$, observing that $T \subseteq \cup_{S: |S| \leq p/A} \mathcal{T}_p^\varepsilon(S)$, we have the bound (using Lemma 7 and Stirling's approximation):

$$|T| \leq \exp(Cs_0 + A^{-1}p \log CA), \quad (149)$$

for some absolute C . Now, as in the proof of Proposition 13, $|\langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y} \rangle| \leq \|\mathbf{C}\| \leq \|\mathbf{C}\|_F \leq \|\hat{\Sigma}\|_F$. From this it follows that $\mathbb{E} \left[\max_{\mathbf{w}, \mathbf{y}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y} \rangle^4 \right] \leq (np)^C$ for some C . Finally $\mathbb{P}\{G_A\} \leq \exp(-cn)$ using Lemmas 11, 12 and the union bound. Combining these bounds in Eq. (148) yields the lemma. \blacksquare

Now we prove a similar lemma when \mathbf{y} has entries that are ‘‘spread out’’.

Lemma 23 Fix an $A \in [1, p^{1/3}]$, and a unit vector $\mathbf{y} \in \mathbb{R}^{\mathcal{Q}^c}$ let $\mathbf{S} = \{i : |y_i| \leq \sqrt{A}/p\}$, and \mathbf{y}_S denote the projection of \mathbf{y} on the set of indices S . Then there exists a numerical constant C such that, assuming $\tau \leq \sqrt{\log p}/2$, we have

$$\mathbb{P}^c \left\{ \max_{\mathbf{w} \in \mathcal{T}_{\mathcal{Q}^c}^c} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}_S \rangle \geq \Delta \right\} \leq C \exp\left(-\frac{\Delta^2}{CL_*^2} + Cp\right) + (np)^C \exp(-c \min(\sqrt{p}, n)), \quad (150)$$

where $L_* = \sqrt{A \exp(-\tau^2/C(\beta \vee 1))(n(\beta \vee 1) + p)/n^2}$.

Proof For simplicity of notation, it is convenient to introduce the vector $\mathbf{y}' = \mathbf{y}_S$. Throughout the proof, we will use that $\|\mathbf{y}'\| \leq 1$ and $\|\mathbf{y}'\|_\infty \leq \sqrt{A}/p$. We compute the gradients as follows:

$$\nabla_{z_\ell} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle = \begin{cases} \frac{w_\ell}{n} \sum_{i \in \mathcal{Q}^c} y'_i \partial \eta(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_i \rangle / n) \tilde{\mathbf{z}}_i & \text{when } \ell \in \mathcal{Q} \\ \frac{w_\ell}{n} \sum_{i \in \mathcal{Q}^c} w_i \partial \eta(\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{x}}_i \rangle / n) \tilde{\mathbf{x}}_i & \text{when } \ell \in \mathcal{Q}^c. \end{cases} \quad (151)$$

Therefore we have

$$\sum_{\ell \in \mathcal{Q}} \|\nabla_{z_\ell} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle\|^2 \leq \sum_{\ell \in \mathcal{Q}} \frac{w_\ell^2}{n^2} \|\mathbf{Z}\|^2 \sum_{i \in \mathcal{Q}^c} (y'_i \partial \eta(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_i \rangle))^2 \quad (152)$$

$$\leq \frac{A \|\mathbf{Z}\|^2}{pn^2} \max_{\ell \in \mathcal{Q}} \sum_{i \in \mathcal{Q}^c} \partial \eta(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_i \rangle / n), \quad (153)$$

where we used the fact that $|y'_i| \leq \sqrt{A}/p$ and that $\partial \eta(\cdot) \in \{0, 1\}$. Similarly, for $\ell \in \mathcal{Q}^c$:

$$\sum_{\ell \in \mathcal{Q}^c} \|\nabla_{z_\ell} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle\|^2 \leq \sum_{\ell \in \mathcal{Q}^c} \frac{(y'_\ell)^2 \|\mathbf{X}_{\mathcal{Q}}\|^2}{n^2} \sum_{i \in \mathcal{Q}} (w_i \partial \eta(\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{x}}_i \rangle / n))^2 \quad (154)$$

$$= \sum_{i \in \mathcal{Q}} \frac{w_i^2 \|\mathbf{X}_{\mathcal{Q}}\|^2}{n^2} \sum_{\ell \in \mathcal{Q}^c} (y'_\ell)^2 \partial \eta(\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{x}}_i \rangle / n)^2 \quad (155)$$

$$\leq \frac{A \|\mathbf{X}_{\mathcal{Q}}\|^2}{pn^2} \max_{\ell \in \mathcal{Q}} \sum_{i \in \mathcal{Q}^c} \partial \eta(\langle \tilde{\mathbf{z}}_i, \tilde{\mathbf{x}}_i \rangle / n), \quad (156)$$

Combining the bounds in Eqs. (153), (156), we obtain

$$\|\nabla_{\mathbf{z}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle\|_F^2 = \sum_{\ell \in [p]} \|\nabla_{z_\ell} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle\|^2 \quad (157)$$

$$\leq \frac{2A}{pn^2} (\|\mathbf{X}_{\mathcal{Q}}\|^2 + \|\mathbf{Z}\|^2) \max_{i \in \mathcal{Q}} \sum_{j \in \mathcal{Q}^c} \partial \eta(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_j \rangle / n). \quad (158)$$

With $K = C\beta \vee 1$, we define the good set \mathcal{G}_5 of pairs $(\mathbf{Z}, \mathbf{Z}')$ satisfying

$$\|\mathbf{Z}\|, \|\mathbf{Z}'\| \leq \sqrt{2n} + \sqrt{2p} \quad (159)$$

$$\forall i \in \mathcal{Q}, \quad \frac{1}{p} \sum_{j \in \mathcal{Q}^c} \mathbb{I}(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_j \rangle \geq \tau\sqrt{n}/2) \leq 2 \exp(-\tau^2/K) \quad (160)$$

$$\forall i \in \mathcal{Q}, \quad \frac{1}{p} \sum_{j \in \mathcal{Q}^c} \mathbb{I}(\langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}'_j \rangle \geq \tau\sqrt{n}/2) \leq 2 \exp(-\tau^2/K) \quad (161)$$

$$\forall i \in \mathcal{Q}, \quad \frac{1}{p} \sum_{j \in \mathcal{Q}^c} \mathbb{I}(\langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}_j \rangle \geq \tau\sqrt{n}/4) \leq 2 \exp(-\tau^2/K) \quad (162)$$

$$\forall i \in \mathcal{Q}, \quad \frac{1}{p} \sum_{j \in \mathcal{Q}^c} \mathbb{I}(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}'_j \rangle \geq \tau\sqrt{n}/4) \leq 2 \exp(-\tau^2/K). \quad (163)$$

Define $\mathbf{Z}(t) = \sqrt{t}\mathbf{Z} + \sqrt{1-t}\mathbf{Z}'$ with $(\mathbf{Z}, \mathbf{Z}') \in \mathcal{G}_5$. By Eq. (158) the gradient evaluated at $\mathbf{Z}(t)$ is bounded by

$$\|\nabla \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y} \rangle\|^2 \leq \frac{2A}{pn^2} (\|\mathbf{X}_{\mathcal{Q}}(t)\|^2 + \|\mathbf{Z}(t)\|^2) \max_{i \in \mathcal{Q}} \sum_{j \in \mathcal{Q}^c} \partial \eta(\langle \tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j \rangle / n) \quad (164)$$

$$\leq \frac{CA}{pn^2} ((\beta \vee 1)n + p) \max_{i \in \mathcal{Q}} \sum_{j \in \mathcal{Q}^c} \partial \eta(\langle \tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j \rangle / n), \quad (165)$$

where we bounded $\|\mathbf{X}_{\mathcal{Q}}(t)\|$ as in Eq. (142), and used $\|\mathbf{Z}(t)\|_{\text{op}} \leq 2(\sqrt{n} + \sqrt{p})$, which follows from Eq. (159) and triangle inequality. Furthermore, as $\langle \tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j \rangle = t \langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_j \rangle + (1-t) \langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}'_j \rangle + \sqrt{t(1-t)} \langle \langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}'_j \rangle + \langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}_j \rangle \rangle$, we have that:

$$\partial \eta(\langle \tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j \rangle / n) = \mathbb{I}(\langle \tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j \rangle \geq \tau\sqrt{n}) \quad (166)$$

$$\begin{aligned} &\leq \mathbb{I}(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_j \rangle \geq \tau\sqrt{n}/2) + \mathbb{I}(\langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}'_j \rangle \geq \tau\sqrt{n}/2) \\ &\quad + \mathbb{I}(\langle \tilde{\mathbf{x}}_i, \tilde{\mathbf{z}}_j \rangle \geq \tau\sqrt{n}/4) + \mathbb{I}(\langle \tilde{\mathbf{x}}'_i, \tilde{\mathbf{z}}'_j \rangle \geq \tau\sqrt{n}/4). \end{aligned} \quad (167)$$

Hence on the good set \mathcal{G}_5 , we have:

$$\max_{i \in \mathbf{Q}} \sum_{j \in \mathbf{Q}^c} \partial \eta_i(\tilde{\mathbf{x}}(t)_i, \tilde{\mathbf{z}}(t)_j/n) \leq 4p e^{-\tau^2/K}. \quad (168)$$

Therefore the gradient satisfies, on the good set:

$$\|\nabla_{\mathbf{Z}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle\|^2 \leq C \frac{A}{n^2} ((\beta \vee 1)n + p) e^{-\tau^2/K} = CL_*^2. \quad (169)$$

Hence, by Lemma 9, we obtain:

$$\begin{aligned} \tilde{\mathbb{P}} \left\{ \max_{\mathbf{w} \in T_{\mathbf{Q}}^{\varepsilon}, \mathbf{y} \in T_{\mathbf{Q}^c}^{\varepsilon}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle \geq \Delta \right\} &\leq C |T_{\mathbf{Q}}^{\varepsilon}| |T_{\mathbf{Q}^c}^{\varepsilon}| \exp\left(-\frac{\Delta^2}{CL_*^2}\right) \\ &+ CL_*^{-2} \tilde{\mathbb{P}} \left\{ \max_{\mathbf{w}, \mathbf{y}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle^4 \right\}^{1/4} \mathbb{P}\{\mathcal{G}_5^c\}^{1/2}. \end{aligned} \quad (170)$$

By Lemma 7, keeping $\varepsilon = 1/4$ we have that the first term is at most $C \exp(Cp + \exp(-\Delta^2/CL_*^2))$. For the second term, we have $\langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle \leq \|\bar{\mathbf{C}}\|_F \leq \|\bar{\mathbf{C}}\|_F \leq \|\bar{\mathbf{C}}\|_F \leq \|\bar{\mathbf{C}}\|_F \leq \|\bar{\mathbf{C}}\|_F \leq (np)^C$, we have that $\mathbb{E}\{\max_{\mathbf{w}, \mathbf{y}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle^4\}^{1/4} \leq (np)^C$. Also as $\tau < \sqrt{\log p}$, $L_* \geq (np)^{-C}$, implying that the second term is bounded above by $(np)^C \mathbb{P}\{\mathcal{G}_5^c\}^{1/2}$. Therefore:

$$\tilde{\mathbb{P}} \left\{ \max_{\mathbf{w} \in T_{\mathbf{Q}}^{\varepsilon}, \mathbf{y} \in T_{\mathbf{Q}^c}^{\varepsilon}} \langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}' \rangle \geq \Delta \right\} \leq C \exp\left(Cp - \frac{\Delta^2}{CL_*^2}\right) + (np)^C \mathbb{P}\{\mathcal{G}_5^c\}^{1/2}. \quad (171)$$

It remains to control the probability of the bad set \mathcal{G}_5^c . For this, we control the probability of violating any one condition among (159), (160), (161), (162) and (163) defining \mathcal{G}_5 and then use the union bound. By Lemmas 11, condition (159) hold with probability $1 - C \exp(-cn)$. The argument controlling the probability for conditions (160), (161), (162) and (163) to hold are essentially the same, so we restrict ourselves to condition (160) keeping $i = 1 \in \mathbf{Q}$, without loss of generality. Conditional on $\tilde{\mathbf{x}}_1, (\tilde{\mathbf{x}}_1, \tilde{\mathbf{z}}_j)$ for $j \in \mathbf{Q}^c$ are independent $\mathcal{N}(0, \|\tilde{\mathbf{x}}_1\|^2)$ variables. Therefore, conditional on $\tilde{\mathbf{x}}_1$, $\mathbb{I}(\|\tilde{\mathbf{x}}_1, \tilde{\mathbf{z}}_j\| \geq \tau\sqrt{n}/2)$ are independent Bernoulli random variables with success probability $\Phi\{-\tau\sqrt{n}/2\|\tilde{\mathbf{x}}_1\|\}$. Define h_1 to be the success probability, i.e. $h_1 = \Phi(-\tau\sqrt{n}/(2\|\tilde{\mathbf{x}}_1\|))$.

Since $K = C(\beta \vee 1)$ we can enlarge C to a large absolute constant. Letting $\mathbf{V} \in \mathbb{R}^{n \times r}$ be the matrix with columns $\mathbf{v}_1, \dots, \mathbf{v}_r$, and \mathbf{B} the diagonal matrix with $B_{q,q} = \sqrt{\beta}_q$, we have, with probability at least $1 - \exp(-n/C)$,

$$\|\tilde{\mathbf{x}}_1\| \leq \|\mathbf{UBV}^T \mathbf{e}_1\| + \|\tilde{\mathbf{z}}_1\| \leq \|\mathbf{B}\| \|\mathbf{U}\| + \|\tilde{\mathbf{z}}_1\| \leq \sqrt{\frac{Kn}{4}}, \quad (172)$$

where the last equality holds since $\mathbf{U} \in \mathcal{U}$ and by tail bounds on chi-squared random variables. Further

$$\begin{aligned} \tilde{\mathbb{P}} \left\{ \sum_{j \in \mathbf{Q}^c} \mathbb{I}(\|\tilde{\mathbf{x}}_1, \tilde{\mathbf{z}}_j\| \geq \tau\sqrt{n}/2) \geq |\mathbf{Q}^c| h \right\} &\leq \tilde{\mathbb{P}} \left\{ \|\tilde{\mathbf{x}}_1\| \geq Kn \right\} \\ &+ \sup_{\|\tilde{\mathbf{x}}_1\|^2 \leq Kn} \tilde{\mathbb{P}} \left\{ \sum_{j \in \mathbf{Q}^c} \mathbb{I}(\|\tilde{\mathbf{x}}_1, \tilde{\mathbf{z}}_j\| \geq \tau\sqrt{n}/2) \geq |\mathbf{Q}^c| h \mid \tilde{\mathbf{x}}_1 \right\}. \end{aligned} \quad (173)$$

By the above argument, the first term is at most $\exp(-n/C)$ and we turn to the second term. By the Chernoff bound

$$\tilde{\mathbb{P}} \left\{ \sum_{j \in \mathbf{Q}^c} \mathbb{I}(\|\tilde{\mathbf{x}}_1, \tilde{\mathbf{z}}_j\| \geq \tau\sqrt{n}/2) \geq |\mathbf{Q}^c| h \mid \tilde{\mathbf{x}}_1 \right\} \leq \exp(-|\mathbf{Q}^c| D(h\|\tilde{\mathbf{x}}_1)), \quad (174)$$

with $h_1 < \exp(-\tau^2/K)$ when $\|\tilde{\mathbf{x}}_1\|^2 \leq Kn/4$. Choosing $h = 2 \exp(-\tau^2/K)$ implies that $h_1 \leq h/2$ when and, thereby, that $D(h\|\tilde{\mathbf{x}}_1) \geq h/C$. Further since $\tau < \sqrt{\log p}/2$, $h \geq 1/\sqrt{p}$. This implies that

$$\exp(-|\mathbf{Q}^c| D(h - h_1\|\tilde{\mathbf{x}}_1)) = \exp(-(p - s_0)h/C) \geq \exp(-\sqrt{p}/C). \quad (175)$$

Combining this with Eq. (173) we have that $\mathbb{P}\{\mathcal{G}_5^c\} \leq Cp^2 \exp(-\min(n, \sqrt{p})/C)$ for some absolute C . Plugging this in Eq. (171) yields the lemma. \blacksquare

We are now ready to prove Proposition 15. Indeed, as in Proposition 13, for any unit vector $\mathbf{y} \in \mathbb{R}^{\mathbf{Q}^c}$, let $\mathbf{S} = \{i : |y_i| \geq \sqrt{A/p}\}$ and $\mathbf{y}_S, \mathbf{y}_{S^c}$ denote the projections on the indices in \mathbf{S}, \mathbf{S}^c respectively.

$$\tilde{\mathbb{P}} \left\{ \|\bar{\mathbf{C}}_1\| \geq \Delta \right\} \leq \tilde{\mathbb{P}} \left\{ \max_{\mathbf{w} \in T_{\mathbf{Q}}^{\varepsilon}, \mathbf{y} \in T_{\mathbf{Q}^c}^{\varepsilon}} |\langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y} \rangle| \geq \Delta(1 - 2\varepsilon) \right\} \quad (176)$$

$$\begin{aligned} &\leq \tilde{\mathbb{P}} \left\{ \max_{\mathbf{w} \in T_{\mathbf{Q}}^{\varepsilon}, \mathbf{y} \in T_{\mathbf{Q}^c}^{\varepsilon}} |\langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}_S \rangle| \geq \Delta(1 - 2\varepsilon)/2 \right\} \\ &\quad + \mathbb{P} \left\{ \max_{\mathbf{w} \in T_{\mathbf{Q}}^{\varepsilon}, \mathbf{y} \in T_{\mathbf{Q}^c}^{\varepsilon}} |\langle \mathbf{w}, \bar{\mathbf{C}}\mathbf{y}_{S^c} \rangle| \geq \Delta(1 - 2\varepsilon)/2 \right\}. \end{aligned} \quad (177)$$

As before, we will let $\varepsilon = 1/4$. The first term is controlled via Lemma 22, while the second is controlled by Lemma 23. We keep $\Delta = \Delta_*$ where

$$\Delta_* = C \left(L_* \sqrt{p} + L \sqrt{\frac{p \log A}{A}} \right). \quad (178)$$

so that, via the bounds of Lemmas 22, 23 and that $s_0^2 \leq p$:

$$\mathbb{P}\{\|\mathbf{C}_1\| \geq \Delta_*\} \leq C \exp\left(-c \frac{p \log A}{A}\right) + L_*^{-2} (np)^C \exp(-c \min(\sqrt{p}, n)). \quad (179)$$

We now set $A = ((\tau^2/K) \exp(\tau^2/K))^{1/2}$ with $K = C(\beta \vee 1)$ for a suitable constant C and, since $\tau \leq \sqrt{\log p}/2$, we get that $A \leq p^{1/3}$. Furthermore, it is straightforward to see that $L \geq (np)^{-C}$, and this implies that

$$\mathbb{P}\{\|\mathbf{C}_1\| \geq \Delta_*\} \leq (np)^C \exp(-c \min(\sqrt{p}, n)) = o(1). \quad (180)$$

With this setting of A , we get the form of Δ_* below, as required for the proposition.

$$\Delta_* \leq C e^{-c\tau^2/K} \sqrt{\frac{\tau^2 \vee 1}{K}} \cdot \frac{pm(\beta \vee 1) + p^2}{n^2} \quad (181)$$

$$\leq C (\tau \vee 1) e^{-c\tau^2/K} \sqrt{\frac{p}{n}} \vee \frac{p}{n}. \quad (182)$$

6.4 Proof of Proposition 16

Since \mathbf{D} is a diagonal matrix, its spectral norm is bounded by the maximum of its entries. This is easily done as, for every $i \in \mathbf{Q}^c$:

$$|(\mathbf{D})_{ii}| = \left| \eta \left(\frac{\|\tilde{\mathbf{z}}_i\|^2}{n} - 1; \frac{\tau}{\sqrt{n}} \right) \right| \quad (183)$$

$$\leq \frac{\|\tilde{\mathbf{z}}_i\|^2 - n}{n}. \quad (184)$$

By the Chernoff bound for χ^2 -squared random variables as in Lemma 12 followed by the union bound, with probability $1 - o(1)$:

$$\max_i \left| \frac{\|\tilde{\mathbf{z}}_i\|^2}{n} - 1 \right| \leq C \sqrt{\frac{\log p}{n}} \quad (185)$$

for some absolute C . Here we used the fact that $(\log p)/n < 1$.

6.5 Proof of Proposition 17

It suffices to show that with probability $1 - o(1)$

$$\max_{i,j \in \mathbf{U} \cap \mathbf{Q}} |\hat{\Sigma}_{ij}| \leq \frac{\tau}{\sqrt{n}} = C_0(\beta \vee 1) \sqrt{\frac{\log p}{n}}. \quad (186)$$

This is a standard argument (see Bickel and Levina, 2008b, Lemma A.3) where (following the dependence on β) it suffices to take $\tau \geq C_0(\beta \vee 1) \sqrt{\log p}$ for C_0 a sufficiently large absolute constant. We note here that the same can also be proved via the conditioning technique applied in the proofs of Propositions 13 and 15.

7. Proof of Theorems 3

Throughout this section, to lighten notation, we drop the prime from $\hat{\Sigma}'$ and \mathbf{X}' while keeping in mind that these are independent from $\hat{\mathbf{V}}_1, \dots, \hat{\mathbf{V}}_r$. We further write $\mathbf{X} = \mathbf{U}\mathbf{B}\mathbf{V}^T + \mathbf{Z}$, where $\mathbf{U} \in \mathbb{R}^{n \times r}$ is the matrix with columns $\mathbf{u}_1, \dots, \mathbf{u}_r$, \mathbf{B} is diagonal with $B_{ii} = \sqrt{\beta_i}$ and $\mathbf{V} \in \mathbb{R}^{p \times r}$ has columns $\mathbf{v}_1, \dots, \mathbf{v}_r$.

Define the event

$$\mathcal{U} \equiv \left\{ \mathbf{U} \in \mathbb{R}^{n \times r} : \left\| \frac{1}{n} \mathbf{U}^T \mathbf{U} - \mathbf{I}_{r \times r} \right\|_{\text{op}} \leq 3 \sqrt{\frac{\tau}{n}} \right\}. \quad (187)$$

By the Bai-Yin law on eigenvalues of Wishart matrices (see Vershynin, 2012), $\lim_{n \rightarrow \infty} \mathbb{P}(\mathbf{U} \in \mathcal{U}) = 1$. In the rest of the proof, we will therefore assume $\mathbf{U} \in \mathcal{U}$ fixed, and denote by $\mathbb{P}(\cdot) = \mathbb{P}(\cdot | \mathbf{U})$ the expectation conditional on \mathbf{U} . In other words, $\mathbb{E}(\cdot)$ denotes expectation with respect to \mathbf{Z} .

Note that

$$\hat{\Sigma} = \frac{1}{n} \mathbf{V}\mathbf{B}\mathbf{U}^T \mathbf{U}\mathbf{B}\mathbf{V}^T + \frac{1}{n} \mathbf{Z}^T \mathbf{U}\mathbf{B}\mathbf{V}^T + \frac{1}{n} \mathbf{V}\mathbf{B}\mathbf{U}^T \mathbf{Z} + \frac{1}{n} \mathbf{Z}^T \mathbf{Z} - \mathbf{I}. \quad (188)$$

We then have, for $q \in \{1, \dots, r\}$ and $i \in \{1, \dots, p\}$,

$$\left| \langle \hat{\Sigma} \hat{\mathbf{v}}_q \rangle_i - \beta_q \langle \mathbf{v}_q, \hat{\mathbf{v}}_q \rangle_{q_{q,i}} \right| \leq T_{i,q}^{(1)} + T_{i,q}^{(2)} + T_{i,q}^{(3)}, \quad (189)$$

$$T_{i,q}^{(1)} \equiv \left| \frac{1}{n} \langle \mathbf{e}_i, \mathbf{V}\mathbf{B}\mathbf{U}^T \mathbf{U}\mathbf{B}\mathbf{V}^T \hat{\mathbf{v}}_q \rangle - \beta_q \langle \mathbf{v}_q, \hat{\mathbf{v}}_q \rangle_{q_{q,i}} \right|, \quad (190)$$

$$T_{i,q}^{(2)} \equiv \left| \frac{1}{n} \langle \mathbf{Z}, [\mathbf{U}\mathbf{B}\mathbf{V}^T \mathbf{e}_i] \hat{\mathbf{v}}_q^T + (\mathbf{U}\mathbf{B}\mathbf{V}^T \hat{\mathbf{v}}_q) \mathbf{e}_i^T \rangle \right|, \quad (191)$$

$$T_{i,q}^{(3)} \equiv \left| \langle \mathbf{e}_i, \left(\frac{1}{n} \mathbf{Z}^T \mathbf{Z} - \mathbf{I} \right) \hat{\mathbf{v}}_q \rangle \right|. \quad (192)$$

We next bound, with high probability, $\max_{i,q} T_{i,q}^{(a)}$ for $a \in \{1, 2, 3\}$. Throughout we let $\varepsilon \equiv \max_{q \in [r]} \|\hat{\mathbf{v}}_q - \mathbf{v}_q\|$.

Considering the first term, we have

$$\begin{aligned} T_{i,q}^{(1)} &\leq \left| \langle \mathbf{e}_i, \mathbf{V}\mathbf{B} \left(\frac{1}{n} \mathbf{U}^T \mathbf{U} - \mathbf{I} \right) \mathbf{B}\mathbf{V}^T \hat{\mathbf{v}}_q \rangle \right| + \left| \langle \mathbf{e}_i, \mathbf{V}\mathbf{B}^2 \mathbf{V}^T \hat{\mathbf{v}}_q \rangle - \beta_q \langle \mathbf{v}_q, \hat{\mathbf{v}}_q \rangle_{q_{q,i}} \right| \\ &\leq 2\beta \sqrt{\frac{\tau}{n}} + \beta \varepsilon \sqrt{\tau} \max_{q \in [r]} \max_{i \in [p]} |v_{q,i}|, \end{aligned} \quad (194)$$

where in the last inequality we used $\sum_{q \in [r] \setminus \{q\}} \langle \mathbf{v}_q, \hat{\mathbf{v}}_q \rangle^2 \leq 1 - \langle \mathbf{v}_q, \hat{\mathbf{v}}_q \rangle^2 \leq \varepsilon^2/2$.

Consider next the second term. Since $Z_{ij} \sim_{iid} \mathcal{N}(0, 1)$, it follows that $T_{i,q}^{(2)} = |W_{i,q}|$ for $W_{i,q} \sim \mathcal{N}(0, \sigma_{i,q}^2)$ a Gaussian random variable with variance

$$\sigma_{i,q}^2 = \frac{1}{n^2} \left\| (\mathbf{U}\mathbf{B}\mathbf{V}^T \mathbf{e}_i) \hat{\mathbf{v}}_q^T + (\mathbf{U}\mathbf{B}\mathbf{V}^T \hat{\mathbf{v}}_q) \mathbf{e}_i^T \right\|^2 \quad (195)$$

$$\leq \frac{2}{n^2} \left\{ \|\mathbf{U}\mathbf{B}\mathbf{V}^T \mathbf{e}_i\|^2 + \|\mathbf{U}\mathbf{B}\mathbf{V}^T \hat{\mathbf{v}}_q\|^2 \right\} \quad (196)$$

$$\leq \frac{4}{n^2} \|\mathbf{U}\mathbf{B}\mathbf{V}^T\|_{\text{op}}^2 \quad (197)$$

$$\leq \frac{4}{n^2} \|\mathbf{U}\|_{\text{op}}^2 \|\mathbf{B}\|_{\text{op}}^2 \leq \frac{8\beta^2}{n}. \quad (198)$$

By union bound over $i \in [p]$, $q \in [r]$ we obtain

$$\max_{i \in [p], q \in [r]} T_{i,q}^{(2)} \leq 8\beta \sqrt{\frac{\log p}{n}}. \quad (199)$$

Finally, consider the last term. By rotational invariance of \mathbf{Z} , the distribution of $T_{i,q}^{(3)}$ only depends on the angle between \mathbf{e}_i and $\hat{\mathbf{v}}_q$. Calling this angle ϑ , we have

$$T_{i,q}^{(3)} \stackrel{d}{=} \left| \langle \mathbf{e}_i, \left(\frac{1}{n} \mathbf{Z}^T \mathbf{Z} - \mathbf{I} \right) \mathbf{e}_1 \rangle \cos \vartheta + \langle \mathbf{e}_i, \left(\frac{1}{n} \mathbf{Z}^T \mathbf{Z} - \mathbf{I} \right) \mathbf{e}_2 \rangle \sin \vartheta \right| \quad (200)$$

$$\leq \left| \frac{1}{n} \|\mathbf{z}_1\|^2 - 1 \right| + \left| \frac{1}{n} \langle \mathbf{z}_1, \mathbf{z}_2 \rangle \right|. \quad (201)$$

Both of these terms have Bernstein-type tail bounds, whence

$$\mathbb{P} \left(T_{i,q}^{(3)} \geq \frac{t}{\sqrt{n}} \right) \leq 2 \exp \left\{ -c \min(t\sqrt{n}, t^2) \right\}. \quad (202)$$

Using $t = C_0\sqrt{\log p}$, and recalling that $n \geq C \log p$ for C a large constant, we obtain $\mathbb{P}(T_{i,q}^{(3)} \geq C_0\sqrt{(\log p)/n}) \leq 2p^{-10}$. Hence by union bound

$$\max_{i \in [p], q \in [r]} T_{i,q}^{(3)} \leq C_0\sqrt{\frac{\log p}{n}}. \quad (203)$$

By putting together Eqs. (194), (199), (203), and using assumption A2, we get

$$|(\widehat{\Sigma}\widehat{\mathbf{v}}_q)_i - \beta_q \langle \mathbf{v}_q, \widehat{\mathbf{v}}_q \rangle v_{q,i}| \leq C\beta\sqrt{\frac{r}{n}} + C(\beta \vee 1)\sqrt{\frac{\log p}{n}} + \beta\epsilon\gamma\sqrt{r} |v_{q,i}| \mathbb{I}(i \in \mathbf{Q}). \quad (204)$$

Let $\widehat{\mathbf{Q}}_q = \{i \in [p] : |(\widehat{\Sigma}\widehat{\mathbf{v}}_q)_i| \geq \rho\}$. We claim that the above implies that, with high probability, $\mathbf{Q}_q \subseteq \widehat{\mathbf{Q}}_q \subseteq \mathbf{Q}$ for all q .

For $i \notin \mathbf{Q}$, we have

$$|(\widehat{\Sigma}\widehat{\mathbf{v}}_q)_i| \leq C\beta\sqrt{\frac{r}{n}} + C(\beta \vee 1)\sqrt{\frac{\log p}{n}} \quad (205)$$

$$< \frac{\beta_{\min}\theta}{2\sqrt{s_0}}, \quad (206)$$

where the last inequality follows from Eq. (14).

On the other hand, By Theorem 2 and using the assumption (14), we can guarantee

$$\epsilon \leq \frac{1}{8} \left(\frac{\beta_{\min}}{\beta\gamma\sqrt{r}} \wedge 1 \right). \quad (207)$$

Hence for $i \in \mathbf{Q}_q$, and considering –to be definite– $v_{q,i} > 0$, we get

$$(\widehat{\Sigma}\widehat{\mathbf{v}}_q)_i \geq \beta_q \langle \mathbf{v}_q, \widehat{\mathbf{v}}_q \rangle v_{q,i} - C\beta\sqrt{\frac{r}{n}} - C(\beta \vee 1)\sqrt{\frac{\log p}{n}} - \beta\epsilon\gamma\sqrt{r} |v_{q,i}| \quad (208)$$

$$\geq \beta_{\min} \left(1 - \epsilon - \frac{\beta}{\beta_{\min}} \epsilon\gamma\sqrt{r} \right) v_{q,i} - C\beta\sqrt{\frac{r}{n}} - C(\beta \vee 1)\sqrt{\frac{\log p}{n}} \quad (209)$$

$$\geq \frac{3\beta_{\min}\theta}{4\sqrt{s_0}} - C\beta\sqrt{\frac{r}{n}} - C(\beta \vee 1)\sqrt{\frac{\log p}{n}} \quad (210)$$

$$> \frac{\beta_{\min}\theta}{2\sqrt{s_0}}. \quad (211)$$

where, in the first inequality, we used $\langle \mathbf{v}_q, \widehat{\mathbf{v}}_q \rangle \geq 1 - \epsilon$.

This concludes the proof. Keeping track of the dependence on θ , γ , β , β_{\min} , we get that the following conditions are sufficient for the theorem's conclusion to hold (with C a

suitable numerical constant):

$$n \geq C \frac{(\beta^2 \vee 1)}{\beta_{\min}^2 \theta^2} s_0 \log p, \quad (212)$$

$$n \geq C \frac{\beta^2}{\beta_{\min}^2 \theta^2} r s_0, \quad (213)$$

$$n \geq C \left\{ \frac{\beta^4 \vee \beta^2}{\beta_{\min}^2} \gamma^2 \right\} r s_0^2 \log \frac{p}{s_0^2}, \quad (214)$$

$$n \geq C \frac{(\beta^2 \vee 1)}{\beta_{\min}^2} s_0^2 \log \frac{p}{s_0^2}. \quad (215)$$

All of these conditions are implied by the assumptions of Theorem 3, namely Eq. (14). In particular, this is shown by using the fact that $s_0 \log p \leq s_0^2 \log(p/s_0^2)$ for $s_0 \leq \sqrt{p}$.

Abstract

A major barrier towards scaling visual recognition systems is the difficulty of obtaining labeled images for large numbers of categories. Recently, deep convolutional neural networks (CNNs) trained used 1.2M+ labeled images have emerged as clear winners on object classification benchmarks. Unfortunately, only a small fraction of those labels are available with bounding box localization for training the detection task and even fewer pixel level annotations are available for semantic segmentation. It is much cheaper and easier to collect large quantities of image-level labels from search engines than it is to collect scene-centric images with precisely localized labels. We develop methods for learning large scale recognition models which exploit joint training over both weak (image-level) and strong (bounding box) labels and which transfer learned perceptual representations from strongly-labeled auxiliary tasks. We provide a novel formulation of a joint multiple instance learning method that includes examples from object-centric data with image-level labels when available, and also performs domain transfer learning to improve the underlying detector representation. We then show how to use our large scale detectors to produce pixel level annotations. Using our method, we produce a >7.6K category detector and release code and models at lsva.berkeleyvision.org.

Keywords: Computer Vision, Deep Learning, Transfer Learning, Large Scale Learning

1. Introduction

It is well known that contemporary visual models thrive on large amounts of training data, especially those that directly include labels for the desired tasks. Many real world settings contain labels with varying specificity, e.g., “strong” bounding box detection labels,

and “weak” labels indicating presence somewhere in the image. We tackle the problem of *joint detector and representation learning*, and develop models which cooperatively exploit heterogeneous sources of training data, where some classes have no “strong” annotations. Our model optimizes a latent variable multiple instance learning model over image regions while simultaneously transferring a shared representation from detection-domain models to classification-domain models. The latter provides a key source of automatic and accurate initialization for latent variable optimization, which has heretofore been unavailable in such methods.

Both classification and detection are key visual recognition challenges, though historically very different architectures have been deployed for each. Recently, the R-CNN model (Girshick et al., 2014) showed how to adapt an ImageNet classifier into a detector, but required bounding box data for all categories. We ask, is there something generic in the transformation from classification to detection that can be learned on a subset of categories and then transferred to other classifiers?

One of the fundamental challenges in training object detection systems is the need to collect a large amount of images with bounding box annotations. The introduction of detection challenge datasets, such as PASCAL VOC (Everingham et al., 2010), has propelled progress by providing the research community a dataset with enough fully annotated images to train competitive models although only for 20 classes. Even though the more recent ILSVRC13 detection dataset (Russakovsky et al., 2014) has extended the set of annotated images, it only contains data for 200 categories. The larger ImageNet dataset contains some localization information for around 3000 object categories, though these are not exhaustively labeled. As we look forward towards the goal of scaling our systems to human-level category detection, it becomes impractical to collect a large quantity of bounding box labels for tens or hundreds of thousands of categories.

In contrast, image-level annotation is comparatively easy to acquire. The prevalence of image tags allows search engines to quickly produce a set of images that have some correspondence to any particular category. ImageNet (Berg et al., 2012), for example, has made use of these search results in combination with manual outlier detection to produce a large classification dataset comprised of over 20,000 categories. While this data can be effectively used to train object classifier models, it lacks the supervised annotations needed to train state-of-the-art detectors.

Previous methods employ varying combinations of weak and strong labels of the same object category to learn a detector. Such methods seldom exploit available strong-label data of different, auxiliary categories, despite the fact that such data is very often available in many practical scenarios. Deselaers et al. (2012) uses auxiliary data to learn generic objectness information just as an initial step, but doesn’t optimize jointly for weakly labeled data.

We introduce a new model for large-scale learning of detectors that can jointly exploit weak and strong labels, perform inference over latent regions in weakly labeled training examples, and can transfer representations learned from related tasks (see Figure 1). In practical settings, such as learning visual detector models for all available ImageNet categories, or for learning detector versions of other defined categories such as Sentibank’s adjective-noun-phrase models (Borth et al., 2013), our model makes greater use of available data and labels than previous approaches. Our method takes advantage of such data by

*. Now at Google Research.

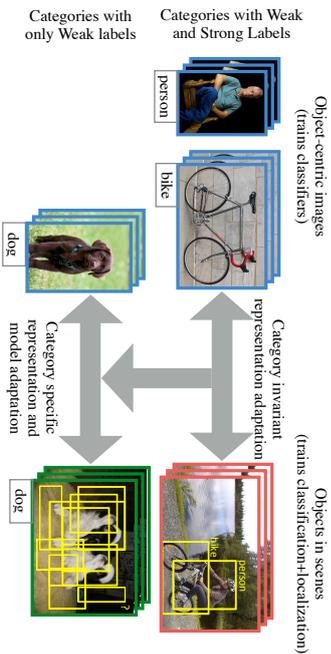

Figure 1: We learn detectors (models which classify and localize) for categories with only weak labels (*bottom row*). We use auxiliary categories with available paired strong and weak annotations (*top row*) to learn to adapt a visual representation from whole image classification to localized region detection. We then use the adapted representation to transform the classifiers trained for the categories with only weak labels and jointly solve an MIL problem to mine localized training data from the weakly labeled scene-centric training data (*green – bottom right*).

using the auxiliary strong labels to improve the feature representation for detection tasks, and uses the improved representation to learn a stronger detector from weak labels in a deep architecture.

We cast the task as a domain adaptation problem, considering the data used to train classifiers (images with category labels) as our source domain, and the data used to train detectors (images with bounding boxes and category labels) as our target domain. We then seek to find a general transformation from the source domain to the target domain, that can be applied to any image classifier to adapt it into a object detector (see Figure 1). R-CNN (Girshick et al., 2014) demonstrated that adaptation, in the form of fine-tuning, is very important for transferring deep features from classification to detection and partially inspired our approach. However, the R-CNN algorithm uses classification data only to pre-train a deep network and then requires a large number of bounding boxes to train each detection category.

To learn detectors, we exploit weakly labeled data for a concept, including both object-centric images (e.g., from ImageNet classification training data), and weakly labeled scene-centric imagery (e.g., from PASCAL or ImageNet detection training data with bounding box metadata removed). We define a novel multiple instance learning (MIL) framework that includes bags defined on both types of data, and also jointly optimizes an underlying perceptual representation using strong detection labels from related categories. We demonstrate that a good perceptual representation for detection tasks can be learned from a set of paired weak and strong labeled examples and the resulting adaptation can be transferred to new categories, even those for which no strong labels were available.

We additionally show that our large-scale detection models can be directly converted into models which produce pixel-level localization for each category. Following the recent result of Long et al. (2015), we run our models fully-convolutionally and directly use the learned detection weights to predict per-pixel labels.

We evaluate our detection model empirically on the largest set of available ground-truth visual data labeled with bounding box annotations, the ILSVRC13 detection dataset. Our method outperforms the previous best MIL-based approaches for weakly labeled detector learning (Wang et al., 2014) on ILSVRC13 (Russakovsky et al., 2014) by 200%. Our model is directly applicable to learning improved “detectors in the wild”, including categories in ImageNet but not in the ILSVRC13 detection dataset, or categories defined ad-hoc for a particular user or task with just a few training examples to fine-tune a new classification model. Such models can be promoted to detectors with no (or few) labeled bounding boxes.

The article builds on two conference publications. The generic feature adaptation for transforming a classifier into a detector was first presented in Hoffman et al. (2014). Hoffman et al. (2015) presented a further category specific detector and representation refinement with mined localization labels. In this work, we present and compare the two works and additionally present a novel extension for further producing per-pixel predictions for adapting to the semantic segmentation task.

2. Related Work

Since its inception, the multiple instance learning (MIL) problem (Diettrich et al., 1997), or learning from a set of labels that specify at least one instance in a bag of instances, has been attempted in several frameworks, including Noisy-OR and boosting (Ali and Saenko, 2014; Zhang et al., 2005). However, most commonly, it has been framed as a max-margin classification problem (Andrews et al., 2002), with latent parameters optimized using alternating optimization (Felzenszwalb et al., 2010; Yu and Joachims, 2009).

Recently, MIL has also been used in computer vision to train detectors using weak labels, i.e. images with category labels but without bounding box labels. The MIL paradigm estimates latent labels of examples in positive training bags, where each positive bag is known to contain at least one positive example. For example, Galleguillos et al. (2008) and Ali and Saenko (2014) construct positive bags from all object proposal regions in a weakly labeled image that is known to contain the object and use a version of MIL to learn an object detector. Overall, MIL is tackled in two stages: first, finding a good initialization, and second, using good heuristics for optimization. A number of methods have been proposed for initialization which include using a large image region excluding boundary (Pandey and Lazebnik, 2011), using a candidate set which covers the training data space (Song et al., 2014a,b), using unsupervised patch discovery (Siva et al., 2013; Singh et al., 2012), learning generic objectness knowledge from auxiliary categories (Alexe et al., 2010; Deselaers et al., 2012), learning latent categories from background to suppress it (Wang et al., 2014), or using class-specific similarity (Siva et al., 2012). Approaches to better optimize the non-convex problem involve using multi-fold learning as a measure of regularizing overfitting (Cimbis et al., 2014), optimizing Latent SVM for the area under the ROC curve (AUC) (Bilen et al., 2014), and training with easy examples initially to avoid bad local optima (Bengio et al., 2009; Kumar et al., 2010; Guillaumein et al., 2014).

While these approaches are promising, they often underperform on the full detection task in more challenging settings such as the PASCAL VOC dataset (Everingham et al., 2010), where objects only cover small portions of images, and many candidate bounding boxes contain no objects whatsoever. The major challenges faced by solutions to the MIL problem are the limitations of fixed feature representations and poor initializations, particularly in non-object centric images. Our algorithm provides solutions to both of these issues. We also provide an evaluation on the large-scale ILSVRC13 detection dataset, which many previous methods have not been evaluated on.

Deep convolutional neural networks (CNNs) have emerged as state of the art on popular object classification benchmarks such as ILSVRC (Krizhevsky et al., 2012) and MNIST. In fact, “deep features” extracted from CNNs trained on the object classification task are also state of the art on other tasks such as subcategory classification, scene classification, domain adaptation (Donahue et al., 2014), and even image matching (Fischer et al., 2014). Unlike the previously dominant features (SIFT (Lowe, 2004), HOG (Dalal and Triggs, 2005)), deep CNN features can be learned for each specific task, but only if sufficient labeled training data is available. R-CNN (Girshick et al., 2014) showed that fine-tuning deep features, pre-trained for classification, on a large amount of bounding box labeled data significantly improves detection performance.

Domain adaptation methods aim to reduce dataset bias caused by a difference in the statistical distributions between training and test domains. In this paper, we treat the transformation of classifiers into detectors as a domain adaptation task. Many approaches have been proposed for classifier adaptation, such as feature space transformations (Saenko et al., 2010; Kulis et al., 2011; Gong et al., 2012; Fernando et al., 2013), model adaptation approaches (Yang et al., 2007a; Aytar and Zisserman, 2011), and joint feature and model adaptation (Hoffman et al., 2013a; Duan et al., 2012). However, even the joint learning models are not able to modify the feature extraction process and so are limited to shallow adaptation techniques. Additionally, these methods only adapt between visual domains, keeping the task fixed, while we adapt both from a large visual domain to a smaller visual domain and from a classification task to a detection task.

However, domain adaptation techniques have seen recent success through the merger with deep CNNs. Hoffman et al. (2013b) showed that, when training data in the target domain is severely limited or unavailable, domain adaptation techniques as applied to CNNs can be more effective than the standard practice of fine-tuning. More recent works have seen success in augmenting deep architectures with additional regularization layers that are robust to the negative effects of domain shift (Chifary et al., 2014; Tzeng et al., 2014; Long and Wang, 2015; Ganin and Lempitsky, 2015). However, all of these methods focus on the standard visual domain adaptation problem, where one adapts between two versions of the same task with different statistics, and do not investigate the task adaptation setting.

Several supervised domain adaptation models have been proposed for object detection. Given a detector trained on a source domain, they adjust its parameters on labeled target domain data. These include variants for linear support vector machines (Yang et al., 2007b; Aytar and Zisserman, 2011; Donahue et al., 2013), as well as adaptive latent SVMs (Xu et al., 2014) and adaptive exemplar SVM (Aytar and Zisserman, 2012). A related recent method (Gochring et al., 2014) proposes a fast adaptation technique based on Linear Discriminant Analysis. These methods require strongly labeled data with bounding box an-

notations for all object categories, both in the source and target domains, which is absent in our scenario.

Other methods have been proposed that use the underlying semantic hierarchy of ImageNet to transfer localization information to classes for strong labels are available (Guillaumin and Ferrari, 2012; Vezhnevets and Ferrari, 2014). However, this necessarily limits their approaches to settings in which additional semantic information is available.

2.1 Background: MIL

We begin by briefly reviewing a standard solution to the multiple instance learning problem, Multiple Instance SVMs (MI-SVMs) (Andrews et al., 2002) or Latent SVMs (Felzenszwalb et al., 2010; Yu and Joachims, 2009). In this setting, each weakly labeled image is considered a collection of bounding boxes which form a positive ‘bag’. For a binary classification problem, the task is to maximize the bag margin which is defined by the instance with highest confidence. For each weakly labeled image $I \in \mathcal{W}$, we collect a set of bounding boxes and define the index set of those boxes as R_I . We next define a bag as $B_I = \{\mathbf{x}_i | i \in R_I\}$, with label Y_I , and let the i^{th} instance in the bag be $(\mathbf{x}_i, y_i) \in \mathcal{R}^p \times \{-1, +1\}$.

For an image with a negative image-level label, $Y_I = -1$, we label all bounding boxes in the image as negative. For an image with a positive image-level label, $Y_I = 1$, we create a constraint that at least one positive instance occurs in the image bag.

In a typical detection scenario, R_I corresponds to the set of possible bounding boxes inside the image, and maximizing over R_I is equivalent to discovering the bounding box that contains the positive object. We define a representation $\phi(\mathbf{x}_i) \in \mathcal{R}^d$ for each instance, which is the feature descriptor for the corresponding bounding box, and formulate the MI-SVM objective as follows:

$$\min_{\mathbf{w} \in \mathcal{R}^d} \frac{1}{2} \|\mathbf{w}\|_2^2 + \alpha \sum_I \ell \left(Y_I, \max_{i \in R_I} \phi(\mathbf{x}_i) \right) \quad (1)$$

where α is a hyper-parameter and $\ell(y, \hat{y})$ is the hinge loss. Interestingly, for negative bags i.e. $Y_I = -1$, the knowledge that all instances are negative allows us to unfold the max operation into a sum over each instance. Thus, Equation (1) reduces to a standard QP with respect to \mathbf{w} . For the case of positive bags, this formulation reduces to a standard SVM if the maximum scoring instance is known.

Based on this idea, Equation (1) is optimized using a classic concave-convex procedure (Yuille and Rangarajan, 2003), which decreases the objective value monotonically with a guarantee to converge to a local minima or saddle point. Due to this reason, weakly trained MIL detectors are sensitive to the feature representation and initial detector weights (i.e. initialization in MIL) (Cinbis et al., 2014; Song et al., 2014a). With our algorithm we mitigate these sensitivities by learning a representation that works well for detection and by proposing an initialization technique for the weakly trained detectors which proves to avoid many of the pitfalls of prior MIL techniques (see Fig 7).

3. Large Scale Detection through Adaptation

We propose a learning algorithm that uses a heterogeneous data source, containing only weak labels for some tasks, to produce strong visual recognition models for all. Our approach

is to cast the shift from tasks that require weak labels to tasks that require strong labels as a domain adaptation problem. We then consider transforming the models for the weakly labeled task into the models for the strongly labeled task. For concreteness, we will present our algorithm applied to the specific task shift of classification to detection, called Large Scale Detection through Adaptation (LSDA). In the following section, we will explain how to shift to a different strongly labeled task of semantic segmentation.

Let the set of images with only weak labels be denoted as \mathcal{W} and the set of images with strong labels (bounding box annotations) from auxiliary tasks be denoted as \mathcal{S} . We assume that the set of object categories that appear in the weakly labeled set, C_W , do not overlap with the set of object categories that appear in the strongly labeled set, C_S . For each image in the weakly labeled set, $I \in \mathcal{W}$, we have an image-level label per category, $k: Y_I^k \in \{1, -1\}$. For each image in the strongly labeled set, $I \in \mathcal{S}$, we have a label per category, k , per region in the image, $i \in R_I: y_i^k \in \{1, -1\}$. We seek to learn a representation, $\phi(\cdot)$ that can be used to train detectors for all object categories, $C = \{C_W \cup C_S\}$. For a category $k \in C$, we denote the category specific detection parameter as w_k and compute our final detection scores per region, x , as $score_k(x) = w_k^T \phi(x)$.

We propose a joint optimization algorithm which learns a feature representation, $\phi(\cdot)$, and detection model parameters, w_k , using the combination of strongly labeled scene-centric data, \mathcal{S} , with weakly labeled object and scene-centric data, \mathcal{W} . For a fixed representation, one can directly train detectors for all categories represented in the strongly labeled set, $k \in C_S$. Additionally, for the same fixed representations, we reviewed in the previous section techniques to train detectors for the categories in the weakly labeled data set, $k \in C_W$. Our insight is that the knowledge from the strong label set can be used to help guide the optimization for the weak labeled set, and we can explicitly adapt our representation for the categories of interest and for the generic detection task.

Below, we state our overall objective:

$$\min_{\substack{w_k, \phi \\ k \in C}} \sum_k \Gamma(w_k) + \alpha_1 \sum_{I \in \mathcal{W}, p \in C_W} \mathcal{F}(Y_I^p, w_p) + \alpha_2 \sum_{I \in \mathcal{S}} \sum_{i \in R_I, q \in C_S} \ell(y_i^q, w_q^T \phi(x_i)) \quad (2)$$

where $\ell(\cdot)$ is the cross-entropy loss function, \mathcal{F} is the region-based loss function over weak categories, α_1, α_2 are scalar hyper-parameters and $\Gamma(\cdot)$ is a regularization over the detector weights. We use convolutional neural networks (CNNs) to define our representation ϕ and thus the last layer weights serve as detection weights w . We adopt the CNN architecture of Krizhevsky et al. (2012) (referred to as *AlexNet*).

This formulation is difficult to optimize directly, so we propose to solve this objective by sequentially optimizing easier sub-problems which are less likely to diverge (see Figure 2).

Lets describe the sub-problems for our overall approach. We begin by initializing a feature representation ϕ and the detection weights w using auxiliary weakly labeled data (Figure 2: *blue boxes*). These weights can be used to compute scores per region proposal to produce initial detection scores. We next use available strongly labeled data from auxiliary tasks to transfer category invariant information about the detection problem. We accomplish this through further optimizing our feature representation and learning generic background detection weights, w, ϕ , (Figure 2: *red boxes*). We then use the well tuned detection feature space to perform MIL on our weakly labeled data to find positive instances (Figure 2: *yellow boxes*). Finally, we use our discovered positive instances together with the

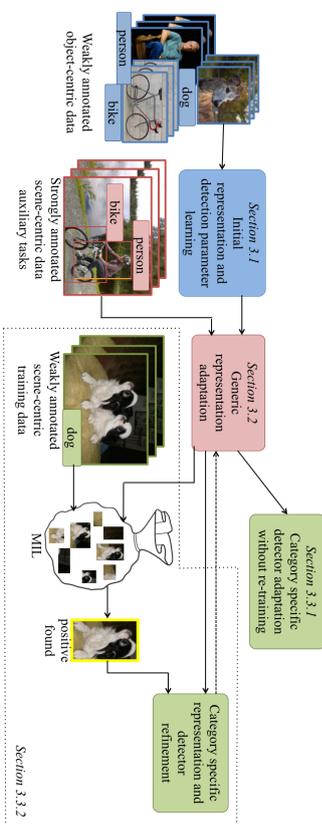

Figure 2: Our method (LSDA) jointly optimizes a representation and category specific detection parameters for categories with only weakly labeled data. We first learn a feature representation conducive to adaptation by initializing all parameters with weakly labeled data. We then collectively refine the feature space with strongly labeled data from auxiliary tasks to adapt the category invariant representation from classification to detection (red boxes). Finally, we perform category specific adaptation (green boxes) either without re-training or by solving MIL in our detection feature space and using the discovered bounding boxes to further refine the representation and detection weights.

strongly labeled data from auxiliary tasks to jointly optimize all parameters corresponding to feature representation and detection weights. We now describe each of these steps in detail in the follow subsections.

3.1 Initializing representation and detection parameters

As mentioned earlier, we use the AlexNet architecture to describe representation ϕ and detection weights w . Since this network requires a large amount of data and time to train its approximately 60 million parameters, we start by pre-training on the ILSVRC2012 classification dataset, which we refer to as auxiliary weakly labeled data. It contains 1.2 million weakly labeled images of 1000 categories. Pre-training on this dataset has been shown to be a very effective technique (Donahue et al., 2014; Sermanet et al., 2013; Girschick et al., 2014), both in terms of performance and in terms of limiting the amount of in-domain labeled data needed to successfully tune the network. This data is usually object centric and is therefore effective for training a network that is able to discriminate between different categories. Next, we replace the last weight layer (1000 linear classifiers) with $K = |C|$ randomly initialized linear classifiers, one for each category in our task.

We next learn initial values for all of the detection parameters for our particular categories of interest, $w_k, \forall k \in C$. We obtain such initialization by solving the simplified learning problem of image-level classification. The image, $I \in \mathcal{S}$, is labeled as positive for a category k if any of the regions in the image are labeled as positive for k and is labeled as negative otherwise, we denote the image level label as in the weakly labeled case: Y_I^k . Now, we can optimize over all images to refine the representation and learn category specific

parameters that can be used per region proposal to produce detection scores:

$$\min_{\mathbf{w}_k, \phi} \sum_k \left[\Gamma(\mathbf{w}_k) + \alpha \sum_{I \in \{W \cup S\}} \ell(Y_I^k, \mathbf{w}_k^T \phi(I)) \right] \quad (3)$$

We optimize Equation (3) through fine-tuning our CNN architecture with a new K -way last fully connected layer, where $K = |C|$. This serves as our initialization for solving sequential sub-problems to optimize overall objective (2). We find that even using the net trained on weakly labeled data in this way produces a strong baseline. We will refer this baseline as ‘*Classification Network*’ in the experiments; see Table 2.

3.2 Learning category specific representation and detection parameters

We next transform our classification network into a detection network and learn a representation which makes it possible to separate objects of interest from background and makes it easy to distinguish different object categories. We proceed by modifying the representation (layers 1-7), $\phi(\cdot)$, through finetuning, using the available strongly labeled data for categories in set C_S . Following the Regions-based CNN (R-CNN) (Girshick et al., 2014) algorithm, we collect positive bounding boxes for each category in set C_S as well as a set of background boxes using a region proposal algorithm, such as selective search (Uijlings et al., 2013). We use each labeled region as a fine-tuning input to the CNN after padding and warping it to the CNN’s input size. Note that the R-CNN fine-tuning algorithm requires bounding box annotated data for all categories and so can not directly be applied to train all K detectors. Fine-tuning transforms all network weights (except for the linear classifiers for categories in C_W) and produces a softmax detector for categories in set C_S , which includes a weight vector for the new background class. We find empirically that fine-tuning induces a generic, category invariant transformation of the classification network into a detection network. That is, even though fine-tuning sees no strongly labeled data for categories in set C_W , the network transforms in a way that automatically makes the original set C_W image classifiers much more effective at detection (see Figure 9). Fine-tuning for detection also learns a background weight vector that encodes a generic “background” category, \mathbf{w}_b . This background model is important for modeling the task shift from image classification, which does not include background distractors, to detection, which is dominated by background patches. This detector explicitly attempts to recognize all data labeled as negative in our bags. Since we initialize this detector with the strongly labeled data, we know precisely which regions correspond to background.

This can be summarized as the following intermediate sub-problem for objective (2):

$$\min_{\mathbf{w}_q, \phi} \sum_q \left[\Gamma(\mathbf{w}_q) + \alpha \sum_{I \in S} \sum_{i \in R_I} \ell(y_i^q, \mathbf{w}_q^T \phi(\mathbf{x}_i)) \right] \quad (4)$$

This is accomplished by fine-tuning our CNN architecture with the strongly labeled data, while keeping the detection weights for the categories with only weakly labeled data fixed. We will call this method as ‘*LSDA rep only*’ in our experiments.

3.3 Adapting category specific representation and detection parameters

Finally, we seek to adapt the category dependent representation and model parameters for the categories in our weakly labeled set, C_W . We will present two approaches to this problem of learning detection weights for weak categories. Specifically, we aim to update the weakly labeled category specific parameters. Section 3.3.1 presents a heuristic adaptation approach that requires no further CNN training with gradient descent and updates only the weakly labeled classification parameters. Section 3.3.2 describes a separate adaptation approach that directly optimizes a subproblem of our overall objective (2). It uses multiple instance learning to discover localized labeled regions in the weakly labeled training data and uses the discovered labels to adapt both the representation and the classification parameters for categories in the weakly labeled set.

3.3.1 K-NEAREST NEIGHBORS BASED ADAPTATION

In this section, we describe a technique for adapting the category specific parameters of the classifier model into the detector model parameters that are better suited for use with the detection feature representation based on a k -NN heuristic. We will determine a similarity metric between each category in the weakly labeled set, C_W , to the strongly labeled categories, C_S .

For simplicity, we separate the category specific output layer (8th layer of the network - f_{CS}) of the classification model into two components f_{CS} and f_{CW} , corresponding to model parameters for the categories in the strongly labeled set C_S and the weakly labeled set C_W , respectively. During our generic category adaptation of Section 3.1, we trained a new background prediction layer, f_{Cb} .

For categories in set C_S , adaptation to detectors can be learned directly through fine-tuning the category specific model parameters f_{CS} . This is equivalent to fixing f_{CS} and learning a new layer, zero initialized, δS , with equivalent loss to f_{CS} , and adding together the outputs of δS and f_{CS} .

Let us define the weights of the output layer of the original classification network as W^c , and the weights of the output layer of the adapted detection network as W^d . We know that for a category $i \in C_S$, the final detection weights should be computed as $W_i^d = W_i^c + \delta S_i$. However, since there is no strongly labeled data for categories in C_W , we cannot directly learn a corresponding δW layer during fine-tuning. Instead, we can approximate the fine-tuning that would have occurred to f_{CW} had strongly labeled data been available. We do this by finding the nearest neighbors categories in set C_S for each category in set C_W and applying the average change. We assume that there are categories in set C_S that are similar to those in set C_W and therefore have similar weights and similar gradient descent updates.

Here we define nearest neighbors as those categories with the nearest (minimal Euclidean distance) ℓ_2 -normalized f_{CS} parameters in the classification network. This corresponds to the classification model being most similar and hence, we assume, the detection model should be most similar. We denote the k^{th} nearest neighbor in set C_S of category $j \in C_W$ as $N_S(j, k)$, then we compute the final output detection weights for categories in set C_W as:

$$\forall j \in C_W : W_j^d = W_j^c + \frac{1}{k} \sum_{i=1}^k \delta S_{N_S(j, i)} \quad (5)$$

Thus, we adapt the category specific parameters even without bounding boxes for categories in set C_W . In section 5 we experiment with various values of k , including taking the full average: $k = |S|$. We will now refer to this method as ‘*LSDA rep+kNN*’ in our experiments.

3.3.2 MLL TRAINING BASED ADAPTATION

The previous section provides a technique for adapting the category specific model parameters for the weakly labeled categories without any further CNN training. However, we may want to modify our representation and model parameters by explicitly retraining with the weakly labeled data. To do this, we need to discover localization information from the image-level labels. Therefore, we will begin by solving a multiple instance learning (MIL) problem to discover the portion of each image most likely corresponding to the weak image-level label.

With the representation, ϕ , that has now been directly tuned for detection, we fix the parameter weights, $\phi(\cdot)$ and solve for the regions of interest in each weak labeled image. This corresponds to solving the following objective:

$$\mathcal{F} = \max_{I \in R_I} \min_{p \in \{C_W, I\}} \left[\Gamma(\mathbf{w}_p) + \alpha \sum_{I \in \mathcal{V}} \mathcal{F}(Y_I^p, \mathbf{w}_p) \right] \quad (6)$$

$$\mathcal{F} = \max_{I \in R_I} \mathbf{w}_p^T \phi(\mathbf{x}_I) \quad (7)$$

Note, we can decouple this optimization problem and independently solve for each category in our weakly labeled data set, $p \in C_W$. Let’s consider a single category p . Our goal is to minimize the loss for category p over images $I \in \mathcal{W}$. We will do this by considering two cases. First, if p is not in the weak label set of an image ($Y_I^p = -1$), then all regions in that image should be considered negative for category p . Second, if $Y_I^p = 1$, then we positively label a region \mathbf{x}_i if it has the highest confidence of containing object and negatively label all other regions. We perform the discovery of this top region in two steps. At first, we narrow down the set of candidate bounding boxes using the score, $\mathbf{w}_p^T \phi(\mathbf{x}_i)$, from our fixed representation and detectors from the previous optimization step. This set is then refined to estimate the most likely region to contain a positive instance in a Latent SVM formulation. The implementation details are discussed section 5.4.

Our final optimization step is to use the discovered bounding boxes from our weak dataset to refine our detectors and feature representation from the previous optimization step. This amounts to the subsequent step for minimization of the joint objective described in Equation (2). We collectively utilize the strong labels of images in S and estimated bounding boxes for the weakly labeled set, \mathcal{W} , to optimize for detector weights and feature representation, as follows:

$$\min_{\mathbf{w}_k, \phi} \sum_{k \in \{C, B\}} \left[\Gamma(\mathbf{w}_k) + \alpha \sum_{I \in \{\mathcal{W}, S\}} \sum_{r \in R_I} \ell(y_i^k, \mathbf{w}_k^T \phi(\mathbf{x}_i)) \right] \quad (8)$$

This is achieved by re-fine-tuning the CNN architecture. This final method is referred to as ‘*LSDA rep+joint fit*’ in our experiments.

Thus, the overall non-convex objective (2) is first approximated through initialization in (3). This initialization is then used to solve the sequential optimization problems defined in (4) and (6). Further, we present two ways to solve (6): k-NN based heuristic approach in (5) and MLL-based re-training approach in (7).

The sub-problem defined in (4) decreases the loss for strongly labeled categories and (8) decreases the loss for both weak-strong categories. Thus, this ensures that the overall objective (2) decreases. The refined detector weights and representation can be used to discover the bounding box annotations for weakly labeled data again, and this process can be iterated over (see Figure 2). We discuss re-training strategies and evaluate the contribution of this final optimization step in Section 5.5.

3.4 Detection with LSDA models

We now describe how our adapted network is used for detection at test time (depicted in Figure 3). For each test image we extract region proposals and generate $K + 1$ scores per region (similar to the R-CNN (Girshick et al., 2014) pipeline), one score for each category and an additional score for the background category. The score is generated by passing the properly warped image patch through our adapted representation layers and then through one of our proposed category specific adapted layers (described in the previous sections). Finally, for a given region, the score for category i is computed by linearly combining the per category score with the background score: $score_i - score_{Bg}$.

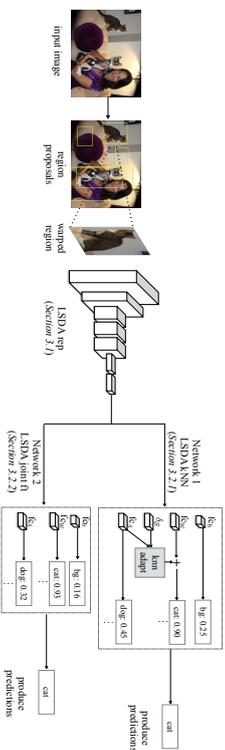

Figure 3: Detection with the LSDA network (test time). Given an image, extract region proposals, reshape the regions to fit into the network size and pass through our adapted network. Use the adapted representation and the category specific adaptation either through the no retraining nearest neighbor method or by retraining with our MLL based method. Finally produce detection scores per category for the region by considering background and category scores.

In contrast to the R-CNN (Girshick et al., 2014) model which trains SVMs on the extracted features from layer 7 and bounding box regression on the extracted features from layer 5, we directly use the final score vector to produce the prediction scores without either of the retraining steps. This choice results in a small performance loss, but offers the flexibility of being able to directly combine the classification portion of the network that has no detection labeled data, and reduces the training time from 3 days to roughly 5.5 hours.

4. Recognition Beyond Detection

In the previous section we outline an algorithm for producing weakly supervised detection models which label and coarsely localize objects in scene-centric images. While a bounding box around an object offers significantly more information than an image-level label, it is not sufficiently localized for tasks such as robotic manipulation and full scene parsing. Instead, we would like to produce semantic segmentation models which are capable of labeling each pixel in an image with the object category or background label.

Prior work has shown that convolutional networks can also be applied to arbitrary-sized inputs to allow for per-pixel spatial output. For example, Matan et al. (1992) augmented the LeNet digit classification model (LeCun et al., 1989), enabling recognition of strings of digits, and Wolf and Platt (1994) use networks to output 2-dimensional maps in order to identify the locations of postal address blocks. This technique has been used to produce semantic segmentation outputs of *C. elegans* (Ning et al., 2005) and more recently for generic object categories (Long et al., 2015). These “fully convolutional” networks can also be finetuned end-to-end on segmentation ground truth to produce fully supervised segmentation models (Long et al., 2015).

As we would like to produce pixel level labels from our LSDA model, we will build off of our recent work for object category semantic segmentation (Long et al., 2015). However, Long et al. (2015) requires full semantic segmentation (pixel-level) annotations to train the corresponding fully connected network. This form of supervision is particularly expensive to collect and in general very few data sources exist with these annotations.

Instead, we argue that much of the knowledge gained through training with pixel-level annotations can be transferred from the much weaker bounding box annotations. Therefore, we demonstrate that a reasonable semantic segmentation is possible by directly using detection parameters in a fully convolutional framework. Further, we show that even our weakly supervised detection models presented in the previous section are able to localize objects more precisely than a bounding box, despite never receiving pixel-level annotations and for many categories never even receiving bounding box annotations.

To produce such a network we take our final adapted LSDA model, which for the purpose of our experiments was trained using an AlexNet basic architecture (Krizhevsky et al., 2012), and we convert the model into the corresponding fully convolutional 32 stride network (FCN-32s) presented by Long et al. (2015). This amounts to relatively few changes to the network architecture. First, each input image is padded with 100 pixels before features are extracted. Next each of the three fully connected layers are converted into convolutional layers, where layer 6 has 4096 convolutions with 6×6 sized kernels, layer 7 has 4096 convolutions with 1×1 sized kernels, and the final score layer has $K + 1$ convolutions with 1×1 sized kernels (where K is the number of categories, plus one for background). Finally, additional deconvolution and crop layers are added which upsample the score map produced by the 8th layer (bilinear interpolation) and crops the pixel level score map to be the size of the input image. This means the final output of the network is a score per category per pixel, which allows us to perform semantic segmentation.

5. Experiments

To demonstrate the effectiveness of our approach we present quantitative results on the ILSVRC2013 detection dataset. The dataset offers images exhaustively labeled with bounding box annotations for 200 relevant object categories. The training set has $\sim 400K$ labeled images and on average 1.534 object classes per image. The validation set has 20K labeled images with $\sim 50K$ labeled objects. We simulate having access to weak labels for all 200 categories and having strong labels for only the first 100 categories (alphabetically sorted).

5.1 Experiment Setup & Implementation Details

We start by separating our data into classification and detection sets for training and a validation set for testing. Since the ILSVRC2013 training set has on average fewer objects per image than the validation set, we use this data as our classification data. To balance the categories we use ≈ 1000 images per class (200,000 total images). **Note:** for classification data we only have access to a single image-level annotation that gives a category label. In effect, since the training set may contain multiple objects, this single full-image label is a weak label, even compared to other classification training data sets. Next, we split the ILSVRC2013 validation set in half as (Girshick et al., 2014) did, producing two sets: `val1` and `val2`. To construct our detection training set, we take the images with bounding box labels from `val1` for only the first 100 categories (≈ 5000 images). Since the validation set is relatively small, we augment our detection set with 1000 bounding box labeled images per category from the ILSVRC2013 training set (following the protocol of (Girshick et al., 2014)). Finally we use the second half of the ILSVRC2013 validation set (`val2`) for our evaluation.

We implemented our CNN architectures and execute all fine-tuning using the open source software package Caffe (Jia et al., 2014) and have made our model definitions weights publicly available.

Train	Num images	395905
	Num objects	345854
Val	Num images	20121
	Num objects	55502

Table 1: Statistics of the ILSVRC13 detection dataset. Training set has fewer objects per image than validation set.

We use the ILSVRC13 detection dataset (Russakovsky et al., 2014) for our experiments. This dataset provides bounding box annotations for 200 categories. The dataset is separated into three pieces: `train`, `val`, `test` (see Table 1). The training images have fewer objects per image on an average than validation set images, so they constitute classification style data (Hoffman et al., 2014). Following prior work (Girshick et al., 2014), we use the further separation of the validation set into `val1` and `val2`. Overall, we use the `train` and `val1` set for our training data source and evaluate our performance of the data in `val2`.

Layers Adapted using Strongly Labeled Data	mAP (%) Weak Categories	mAP (%) All Categories
No Adapt (Classification Network)	10.31	11.90
f_{bgnd}	12.22	13.60
f_{bgnd}, f_{c6}	13.72	19.20
f_{bgnd}, f_{c7}	14.57	19.00
f_{bgnd}, f_{c5}	11.74	14.90
$f_{\text{bgnd}}, f_{c6}, f_{c7}$	14.20	20.00
$f_{\text{bgnd}}, f_{c6}, f_{c7}, f_{c5}$	14.42	20.40
$f_{\text{bgnd}}, \text{layers 1-7}, f_{c5}$	15.85	21.83

Table 2: Ablation study for different techniques for category independent adaptation of our model (LSDA rep only). We consider training with the first 100 (alphabetically) categories of the ILSVRC2013 detection validation set (on val) and report mean average precision (mAP) over the 100 weakly labeled categories (on val2). We find the best improvement is from fine-tuning all layers.

5.2 Quantitative Analysis of Adapted Representation

We evaluate the importance of each component of our algorithm through an ablation study. As a baseline, we consider training the network with only the weakly labeled data (no adaptation) and applying the network to the region proposals.

In Table 2, we present a detailed analysis of the different category independent adaptation techniques we could use to train the network. We call this method LSDA rep only. We find that the best category invariant adaptation approach is to learn the background category layer and adapt all convolutional and fully connected layers, bringing mAP on the weakly labeled categories from 10.31% up to 15.85% i.e. this achieves a 54% relative mAP boost over the classification only network. We later observe that the most important step of our algorithm proved to be adapting the feature representation, while the least important was adapting the category specific parameter. This fits with our intuition that the main benefit of our approach is to transfer category invariant information from categories with known bounding box annotation to those without the bounding box annotations.

We find that one of the biggest reasons our algorithm improves is from reducing localization error. For example, in Figure 4, we show that while the classification only trained net tends to focus on the most discriminative part of an object (ex: face of an animal) after our adaptation, we learn to localize the whole object (ex: entire body of the animal).

5.3 Error Analysis on Weakly Labeled Categories

We next present an analysis of the types of errors that our system (LSDA) makes on the weakly labeled object categories. First, in Figure 5, we consider three types of false positive errors: Loc (localization errors), BG (confusion with background), and Oth (other error types, which is essentially correctly localizing an object, but misclassifying it). After separating all false positives into one of these three error types we visually show the percentage

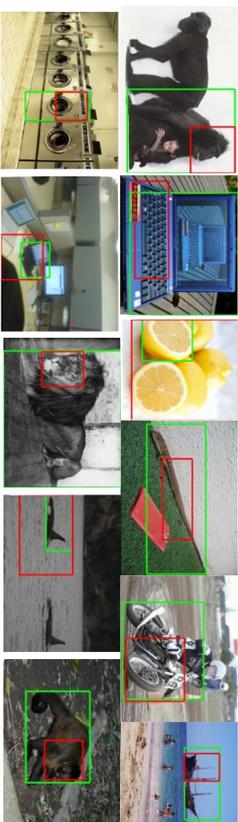

Figure 4: We show example detections on weakly labeled categories, for which we have **no detection training data**, where LSDA (shown with green box) correctly localizes and labels the object of interest, while the classification network baseline (shown in red) incorrectly localizes the object. This demonstrates that our algorithm learns to adapt the classifier into a detector which is sensitive to localization and background rejection.

of errors found in each type as you look at the top scoring 25-3200 false positives.¹ We consider the baseline of starting with the classification only network and show the false positive breakdown in Figure 5a. Note that the majority of false positive errors are confusion with background and localization errors. In contrast, after adapting the network using LSDA we find that the errors found in the top false positives are far less due to localization and background confusion (see Figure 5b). Arguably one of the biggest differences between classification and detection is the ability to accurately localize objects and reject background. Therefore, we show that our method successfully adapts the classification parameters to be more suitable for detection.

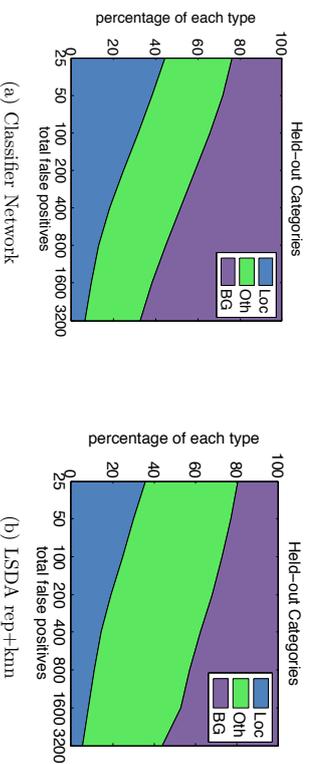

Figure 5: Comparison of error type breakdown on the categories which have no training bounding boxes available (weakly labeled data). After adapting all the layers in the network (LSDA), the percentage of false positive errors due to localization and background confusion is reduced (b) as compared to directly using the classification network for detection (a).

1. We modified the analysis software made available by Hoein et al. (2012) to work on ILSVRC-2013 detection

In Figure 6, we show examples of the top scoring O_{th} error types for LSDA on the weakly labeled data. This means the detector localizes an incorrect object type. For example, the motorcycle detector localized and mislabeled bicycle and the lemon detector localized and mislabeled an orange. In general, we noticed that many of the top false positives from the O_{th} error type were confusion with very similar categories. This is discussed in detail in next subsection.

Figure 6: Examples of the top scoring false positives from our LSDA rep+km network. Many of our top scoring false positives come from confusion with other categories.

5.4 Analysis of Discovered Boxes

We now analyze the quality of boxes discovered using adaptation of all layers including the background class. One of the key components of our system is using strong labels from auxiliary tasks to learn a representation where it’s possible to discover bounding boxes that correspond to the objects of interest in our weakly labeled data source. We begin our analysis by studying the bounding box discovery that our feature space enables, using selective search (Uijlings et al., 2013) to produce candidate regions. We optimize the bounding box discovery (Equations (6),(7)) using a one vs all Latent SVM formulation and optimize the formulation for AUC criterion (Bilen et al., 2014). This ensures that the top candidate regions chosen for joint fine-tuning have high precision. The feature descriptor used is the output of the fully connected layer, f_{cr} , of the CNN which is produced after fine-tuning the feature representation with strongly labeled data from auxiliary tasks. Following our alternating minimization approach, these discovered top boxes are then used to re-estimate the weights and feature representations of our CNN architecture.

	CorLoc over full dataset			Localization mAP (%)		
	ov=0.3	ov=0.5	ov=0.7	ov=0.9	ov=0.5	ov=0.5
Classification Network	29.63	26.10	24.28	23.43	13.13	
LSDA rep only	32.69	28.81	26.27	24.78	22.81	

Table 3: CorLoc over dataset and localization mAP (i.e. given the labels) performance of discovered bounding boxes in our weakly labeled training set (val1) of ILSVRC13 detection dataset. Comparison with varying amount of overlap with ground truth box. About 25% of our discovered boxes have an overlap of at least 0.9. Our method is able to significantly improve the quality of discovered boxes after incorporating strong labels from auxiliary tasks.

To evaluate the quality of discovered boxes, we do ablation study analyzing their overlap with ground truth which is measured using the standard intersection over union (IOU)

metric. Table 3 reports the CorLoc for varying overlapping thresholds. CorLoc across full dataset is defined as the accuracy of discovered boxes i.e. the accuracy that the box is correctly localized per image at different thresholds. Our optimization approach produces one positive bounding box per image with a weak label, and a discovered box is considered a true positive if it overlaps sufficiently with the ground truth box that corresponds to that label. Since each bounding box, once discovered, is considered an equivalent positive (regardless of score) for the purpose of retraining the ‘LSDA rep only’ model, this simple CorLoc metric is a good indication of the usefulness of our discovered bounding boxes. We note here that after re-training with our mined boxes the CorLoc will further improve, as indicated in the detection mAP reported in the next section. It is interesting that a significant fraction of discovered boxes have high overlap with the ground truth regions. For reference, we also computed the standard mean average precision over the discovered boxes for localization task i.e. when label is known. It is important to note that the improvement in localization mAP is much more significant than the CorLoc. This is because mAP is obtained by averaging over recall values, and the ‘LSDA rep only’ model achieves better overall recall than the ‘Classification Network’ model.

It is important to understand not only that our new feature space improves the quality of the resulting bounding boxes, but also what type of errors our method reduces. In Figure 7, we show the top 5 scoring discovered bounding boxes before and after modifying the feature space with strong labels from auxiliary tasks. We find that in many cases the improvement comes from better localization. For example without auxiliary strong labels we mostly discover the face of a lion rather than the body that we discover after our algorithm. Interestingly, there is also an issue with co-occurring classes. We are better able to localize “lion” body rather than the face. Most amazing results are for the “ping-pong” and “rugby” (second and third row) category where we are actually able to mine boxes for the racket and ball, while the classification net could only get the person boxes which is incorrect. Once we incorporate strong labels from auxiliary tasks we begin to be able to distinguish the person playing from the racket/ball itself. In the bottom row of Figure 7, we show the top 5 discovered bounding boxes for “tennis racket” where we are partially able to correct the images. Finally, there are some example discovered bounding boxes where we reduce quality after incorporating the strong labels from auxiliary tasks. For example, one of our strongly labeled categories is “computer keyboard”. Due to the strong training with keyboard images, some of our discovered boxes for “laptop” start to have higher scores on the keyboard rather than the whole laptop (see Figure 8). Also for the “water-craft” category, our adapted network ignores the mast but better localizes the boat itself, which slightly decreases the IOU of obtained box.

5.5 Detection Performance on ILSVRC13

Now that we have analyzed the intermediate result of our algorithm, we next study the full performance of our system. Figure 9 shows the mean average precision (mAP) percentage computed over the categories in val2 of ILSVRC13 for which we only have weakly labeled training data (categories 101-200). Previous method, LCL (Wang et al., 2014), detects in the standard weakly supervised setting – having no bounding box annotations for any of the 200 categories. This method also only reports results across all 200 categories on the full

Figure 7: Example discovered bounding boxes learned using our method. Left side shows the discovered boxes after fine-tuning with images in classification settings only, and right side shows the discovered boxes after fine-tuning with auxiliary strongly labeled dataset. We show top 5 discovered boxes across the dataset for corresponding category. Examples with a **green** outline are categories for which our algorithm was able to correctly discover bounding boxes of the object, while the feature space with only weak label training was not able to produce correct boxes. After incorporating the strong labels from auxiliary tasks, our method starts discovering “ping-pong” racket/ball and “rugby” ball, though still has some confusion with the person playing tennis. None of the discovered boxes from the original feature space correctly located racket/ball and instead included the person as well. In **yellow** we highlight the specific example of “tennis racket”, where some of the boxes get corrected not all top boxes.

Figure 8: Example discovered boxes of the category “laptop” where using auxiliary strongly labeled data causes bounding box discovery to diverge. *Left*: The discovered boxes obtained after fine-tuning with images in classification settings only. *Right*: The discovered boxes obtained after fine-tuning with the auxiliary strongly labeled dataset that contains the category “computer keyboard”. These boxes were low scoring examples, but we show them here to demonstrate a potential failure case – specifically, when one of the strongly labeled classes is a part of one of the weakly labeled classes. In the second example, adapted network better localizes the “water-craft” but misses the mast which decreases the IOU slightly.

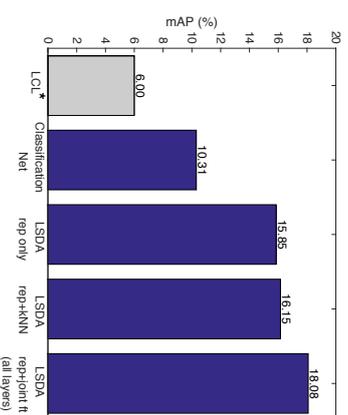

Figure 9: Comparison of mAP (%) for categories without any bounding box annotations (101-200 of val2) of ILSVRC13. The Joint representation and category-specific learning using MIL outperforms all other approaches. *As a reference we report the performance of LCL (Wang et al., 2014) which was computed across all 200 categories of the full validation set (val1+val2).

validation set. Our experiments indicate that the first 100 categories are easier on average than the second 100 categories, therefore the 6.0% mAP may actually be an upper bound of the performance of this approach. We also compare our algorithm against the scenario when the class-specific layer is adapted using nearest neighbors across all categories (LSDA rep+km). The joint representation and multiple instance learning approach achieves the highest results (LSDA rep+joint ft).

We next consider different re-training strategies for learning new features and detection weights after discovering the bounding boxes in the weakly labeled data. Table 4 reports the

Category Specific Adaptation Strategy	mAP (%) Weak Categories	mAP (%) All Categories
LSDA rep only	15.85	21.83
LSDA rep+kNN (k=5)	15.97	22.05
LSDA rep+kNN (k=10)	16.15	22.05
LSDA rep+kNN (k=100= fcs)	15.96	21.94
LSDA rep+joint fit (fcw)	17.01	22.43
LSDA rep+joint fit (all layers)	18.08	22.74
Baseline: Classification Network	10.31	11.90
Oracle: RCNN Full Detection Network	26.25	28.00

Table 4: Comparison of different ways to re-train after discovery of bounding boxes. We show mAP on val2 set from ILSVRC13. We find that the most effective way to re-train with discovered boxes is to modify the detectors and the feature representation.

mean average precision (mAP) percentage for no re-training (directly using the feature space learned after incorporating the strong labels), LSDA rep only, no retraining but last layer weights of weak categories adapted using nearest neighbors, LSDA rep+knn, re-training only the category-specific detection parameters, LSDA rep+joint fit (fcw), and retraining feature representations jointly with category-specific weights, LSDA rep+joint fit (all layers). In our experiments the improved performance is due to the first iteration of the overall algorithm. We find that the best approach is to jointly learn to refine the feature representation and the category-specific detection weights. More specifically, we learn a new feature representation by fine-tuning all fully connected layers in the CNN architecture. The last row shows the performance achievable by our detection network if it had access to bounding box annotated data for all 200 categories, and serves as a performance upper bound.² Our method achieves **18.08%** mAP on weakly labeled categories as compared to **10.31%** of baseline, but it is still significantly lower than fully-supervised oracle which gives **26.25%**.

We finally analyze examples where our full algorithm which jointly learns representation and class-specific layer using MIL (LSDA rep+joint fit) outperforms the previous approach where only representation is adapted without joint learning over weak labels (LSDA rep+knn). Figure 10 shows a sample of the types of errors our algorithm improves on. These include localization errors, confusion with other categories, and interestingly, confusion with co-occurring categories. In particular, our algorithm provides improvement when searching for a small object (ball or helmet) in a sports scene. Training only with weak labels causes the previous state-of-the-art to confuse the player and the object, resulting in a detection that includes both. Our algorithm is able to localize only the small object and recognize that the player is a separate object of interest.

2. To achieve R-CNN performance requires additionally learning SVMs on the activations of layer 7 and bounding box regression on the activations of layer 5. Each of these steps adds between 1-2mAP at high computation cost and using the SVMs removes the adaptation capacity of the system.

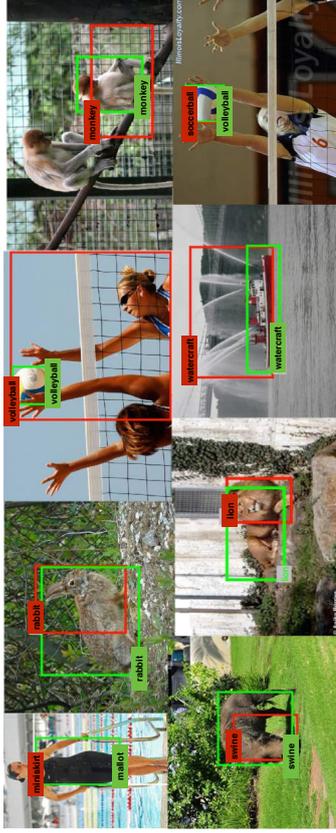

Figure 10: Examples where our algorithm after joint MIL adaptation (LSDA rep+joint fit) outperforms the representation only adaptation (LSDA rep only). We show the top scoring detection from LSDA rep only with a Red box and label, and the top scoring detection from LSDA rep+joint fit, as a Green box and label. Our algorithm improves localization (ex: rabbit, lion etc), confusion with other categories (ex: miniskirt vs maillot), and confusion with co-occurring classes (ex: volleyball vs volleyball player)

5.6 Large Scale Detection

To showcase the capabilities of our technique we produced a 7604 category detector. The first categories correspond to the 200 categories from the ILSVRC2013 challenge dataset which have bounding box labeled data available. The other 7404 categories correspond to leaf nodes in the ImageNet database and are trained using the available full image weakly labeled classification data. We trained a full detection network using the 200 strongly labeled categories and trained the other 7404 last layer nodes using only the weak labels. Note, the ImageNet dataset does contain other non-exhaustively labeled images for around 3000 object categories, 1825 of which overlap with the 7404 leaf node categories in our model. We do not use these labels during training of our large scale model. Quantitative evaluation for these categories is difficult to compute since they are not exhaustively labeled, however a followup work by Mrowca et al. (2015) evaluated F1 score of our model for the few object instances labeled per image to be 9.59%. Also note that while we have no bounding box annotations for the 7404 fine-grained categories, some may be related to the 200 basic level categories for which we use bounding box data to train – for example a particular breed of dog from 7404 weakly labeled data while ‘dog’ appears in the 200 strongly labeled categories.

We show qualitative results of our large scale detector by displaying the top detections per image in Figure 11. The results are filtered using non-max suppression across categories to only show the highest scoring categories.

The main contribution of our algorithm is the joint representation and multiple instance learning approach for modifying a convolutional neural network for detection. However, the choice of network and how the net is used at test time both effect the detection time

Figure 11: Example top detections from our 7604 category detector. Detections from the 200 categories that have bounding box training data available are shown in blue. Detections from the remaining 7404 categories for which only weakly labeled data is available are shown in red.

computation. We have therefore also implemented and released a version of our algorithm running with fast region proposals (Krishenbühl and Kohm, 2014) on a spatial pyramid pooling network (He et al., 2014), reducing our detection time down to half a second per image (from 4s per image) with nearly the same performance. We hope that this will allow the use of our 7.6K model on large data sources such as videos. We have released the 7.6K model and code to run detection (both the way presented in this paper and our faster version) at lsda.berkeleyvision.org.

5.7 Fully Convolutional LSDA for Semantic Segmentation

Bounding boxes localize objects to an inherently limited degree. While the system presented so far produces remarkably accurate bounding boxes from weak training labels, it does not address the ultimate goal of knowing exactly which pixels correspond to which objects.

Segmentation ground truth is unavailable for all but a few of the 7604 categories in our large scale detector, and segmentations are even more costly to annotate than bounding boxes. Nevertheless, as described in Section 5.7, we can convert our detection-adapted network into a fully-convolutional model following Long et al. (2015) and produce dense outputs for each of the 7604 categories plus 1 for background. We call this model LSDA7k FCN-32s since we use the 32 stride version of the fully convolutional networks proposed in Long et al. (2015). We next evaluate our semantic segmentation model using the PASCAL dataset Everingham et al. (2010) and the following metrics.

Metrics We compute both the commonly used mean intersection over union (mean IU) metric for semantic segmentation as well as three other metrics used by Long et al. (2015). The metrics are defined below, where n_{ij} denotes the number of pixels from class i predicted to belong to class j so that the number of pixels belonging to class i are $m_i = \sum_j n_{ij}$, and K denotes the number of classes.

- pixel accuracy: $\sum_i n_{ii} / \sum_i m_i$
- mean accuracy: $1/K \sum_i n_{ii} / t_i$
- mean IU: $1/K \sum_i n_{ii} / (m_i + \sum_j n_{ji} - n_{ii})$

- frequency weighted IU: $(\sum_i m_i)^{-1} \sum_i m_i n_{ii} / (m_i + \sum_j n_{ji} - n_{ii})$

We would like to understand how well our model can localize weakly trained objects so for each of the PASCAL 20 object categories we manually find the set of fine-grained categories from the 7404 weakly labeled leaf nodes in ImageNet that correspond to that category. Since layer 8 of our LSDA7k FCN-32s network produces 7605 outputs per region of the image, we insert an additional mapping layer which for each category c is the maximum score across all weakly labeled categories which correspond to that PASCAL category. Next, this reduced score map where each image region now has 21 scores is run through the deconvolution layer to produce the corresponding PASCAL per pixel scores. Finally, for each pixel we choose a label based on which of the categories or background has the highest pixel score.

We report results on both the PASCAL 2011 and 2012 validation sets. Note, our method was not trained on any PASCAL images and in general was trained for classification of 7404 fine-grained categories and then adapted using our algorithm for detection. Additionally, our model is trained using the AlexNet architecture while most state-of-the-art semantic segmentation models are trained using the larger VGG network (Simonyan and Zisserman, 2014).

For the PASCAL 2011 validation set, shown in Table 5, we first compare against the classification model trained for the 7404 category full image labels. We run this model fully convolutionally using the FCN-32s approach (AlexNet) and report the segmentation performance in the first row as *Classification 7K FCN-32s (AlexNet)*. This method gives a baseline for our LSDA approach which uses this model as the initialization prior to our adaptation approach. Next, we compare against the reported performance of the weakly trained models of Pathak et al. (2014) and for reference, the fully supervised AlexNet and VGG FCN-32s presented by Long et al. (2015). We report all four metrics for our work and report all available metrics for competing works. We see that our weakly trained model outperforms the baseline classification model run fully convolutionally and almost reaches the performance of the MIU-FCN method which uses the higher capacity VGG model and trains specifically for the segmentation task.

The per-category results of our method on the PASCAL 2012 validation set as compared to two state-of-the-art weakly trained semantic segmentation models is shown in Table 6. Not surprisingly, our LSDA7k FCN-32s underperforms these methods. No doubt adding the multiple instance loss of Pathak et al. (2014) or the object constraints of Pathak et al. (2015), while training directly on the PASCAL dataset would further improve our method. The purpose of these experiments is to give the reader an accurate picture of how well our large scale model performs at pixel level annotation without any tuning to the new situation.

We next show qualitative segmentation results across the fine-grained 7404 categories of our LSDA7k FCN-32s network in Figure 12³ and compare against the baseline Classification 7K FCN-32s network. We find that often the segmentation masks from our LSDA network are more precise (see “American egret” example) and the top scoring predicted class is often more accurately labeled. For example, the bottom image is labeled as “air conditioner” by the classification network and correctly as “venetian blind” by our network. These category models were trained without ever seeing any associated

3. The full network without the mapping layer to pascal 20 categories.

adaptation algorithm. Given the significant improvement on the weakly labeled categories, our algorithm enables detection of tens of thousands of categories. We produce a 7.6K

category detector and have released both code and models at lsda.berkeleyvision.org.

Our approach significantly reduces the overhead of producing a high quality detector. We hope that in doing so we will be able to minimize the gap between having strong large-scale classifiers and strong large-scale detectors. Further we show that large-scale detectors can be used to produce large-scale semantic segmenters. We present semantic segmentation performance for the large scale model on PASCAL VOC with a manual mapping from the 7404 weakly labeled object categories to the 20 categories in the PASCAL dataset. For future work we would like to experiment with incorporating some pixel-level annotations for a few object categories. Our intuition is that by doing so we will be able to further improve our large-scale models with minimal extra supervision.

Abstract

In this paper we propose a new algorithm to perform clustering of multivariate and functional data. We study the case of two populations different in their covariances, rather than in their means. The algorithm relies on a proper quantification of distance between the estimated covariance operators of the populations, and subdivides data in two groups maximising the distance between their induced covariances. The naive implementation of such an algorithm is computationally forbidding, so we propose a heuristic formulation with a much lighter complexity and we study its convergence properties, along with its computational cost. We also propose to use an enhanced estimator for the estimation of discrete covariances of functional data, namely a linear shrinkage estimator, in order to improve the precision of the clustering. We establish the effectiveness of our algorithm through applications to both synthetic data and a real data set coming from a biomedical context, showing also how the use of shrinkage estimation may lead to substantially better results.

Keywords: Clustering, covariance operator, operator distance, shrinkage estimation, functional data analysis

1. Introduction

The goal of performing clustering of data, in order to point out groups of observations based on some notion of similarity, has been of primary interest in applied statistics since ages. Literature is plenty of methods focusing their attention on the aggregation and separation of a sample into groups depending on similarities in locations of data (e.g., hierarchical clustering, *k*-means, PAM; see for instance Hartigan, 1975). Considerably less work can be found on methods attaining the clustering entirely on the basis of differences in the covariance structures of random models generating data. This target is not trivial, and less easy to translate into practice, since it calls for a proper quantification of differential correlation or distances between covariances of data. Nevertheless, it might happen to analyse groups

of data that are scarcely distinguishable in terms of locations, while showing differences in their variability.

Examples can be found in biostatistics where, for instance, the dichotomy between physiological and pathological features often shows an interesting change in pattern of variability. Also, this is of great interest in genomics, where instead of focusing on gene expression levels, one could be interested in finding different correlation structures among subsets of data. This is the core task in the analysis of the differential co-expression of genes, namely the differential correlation structure among expression levels in different subsets of experimental conditions. In (Watson, 2006), for instance, the author proposes a method to identify groups of genes that are correlated in a first group of microarrays, and are not in a second one. In (Mitra et al., 2016), the authors provide a more complex modeling strategy that is able to specify the differential dependence structure by using Bayesian graphical models, and in (Cai and Zhang, 2016) authors provide, within a supervised framework, a way to estimate the differential correlation matrices of data belonging to two differentially expressed groups.

In this paper we tackle the problem from a different point of view, and focus on differences between global covariance structures of data belonging to two unknown groups, which will also be identified. We focus on the specific case of a set of observations from two populations whose probability distributions have the same mean but differ in terms of covariances. The method we propose can be applied both to the traditional case of random vectors, and to the recently developed setting of functional data, arising as outcomes of infinite-dimensional stochastic processes (see, for instance, the monographs Ramsay and Silverman, 2005; Horváth and Kokoszka, 2012). We will introduce the method according to the latter case.

In particular, we first introduce a suitable notion of distance between covariance operators, i.e. the functional generalisation of covariance matrices, which is the instrument we use to measure dissimilarities. Then we make use of such distance to search, among two-class partitions of data, the one maximising the distance between the class-specific covariances, under the assumption that, if the two populations can be distinguished from their covariances, this would be the most likely subdivision detecting the true groups.

A naive implementation of this algorithm, involving an exhaustive sampling strategy inside the set of subsets of data, would face a combinatorial complexity with respect to the number of observations, thus forbidding the analysis of data sets with common sizes. We therefore transform the method into a heuristic, greedy algorithm, with greatly reduced complexity, which can be efficiently implemented and effectively applied.

Due to its construction, our algorithm benefits from the accuracy of the estimation of covariances. Owing to the typically large dimensionality (compared to the number of data available) of discrete approximations of functional observations, covariance estimation through classical sample estimators may be non-optimal. To remedy this shortcoming, we propose to replace standard, unbiased covariance estimator with a shrinkage estimator with enhanced accuracy properties (see, for instance, Ledoit and Wolf, 2003, 2004 and Schafer and Strimmer, 2005). We show through experiments that this choice leads to a substantially improved clustering.

The paper is organised as follows: in Section 2 we briefly recall some properties of covariance operators for functional data. In Section 3 we introduce the new clustering method for two groups of data which differ in variance-covariance structures, we derive its heuristic formulation and describe the shrinkage strategy we used to enhance the estimation performances. In Section 4 we assess the clustering performances through the application to both synthetic and real data sets. Discussion and conclusions are presented in Section 5.

2. Covariance Operators for Functional Data

Whenever our data can be interpreted as finite-dimensional samples of quantities that are intrinsically dependent on some continuous variable, such as time, we may resort to the model of functional data (see, for instance, Ramsay and Silverman, 2005; Horváth and Kokoszka, 2012). At its core is the assumption that data are sample measurements of trajectories of stochastic processes valued in suitable function spaces.

In the following we recall the definition of covariance operator for functional data, along with its most important properties (for more details see, e.g., Bosq, 2000). Let \mathcal{X} be a stochastic process taking values in $L^2(I)$, with $I \subset \mathbb{R}$ a compact interval, having mean function $\mathbb{E}[\mathcal{X}] = \mu$ and such that $\mathbb{E}\|\mathcal{X}\|^2 < \infty$, where we denote by $\|\cdot\|$ the $L^2(I)$ norm induced by the scalar product $\langle \cdot, \cdot \rangle$. Without loss of generality we can assume $\mu = 0$ and define the following covariance operator $\mathcal{C} \in \mathcal{L}(L^2(I); L^2(I))$:

$$\langle y, \mathcal{C}x \rangle = \mathbb{E}[\langle x, \mathcal{X} \rangle \langle y, \mathcal{X} \rangle], \quad \forall x, y \in L^2(I). \quad (1)$$

\mathcal{C} is a compact, self-adjoint, positive semidefinite linear operator between $L^2(I)$ and $L^2(I)$. Therefore it can be decomposed into:

$$\mathcal{C} = \sum_{k=1}^{\infty} \lambda_k e_k \otimes e_k, \quad (2)$$

where \otimes indicates an outer product in $L^2(I)$, $\{e_k\}_{k=1}^{\infty}$ is the sequence of orthonormal eigenfunctions, forming a basis of $L^2(I)$, and $\{\lambda_k\}_{k=1}^{\infty}$ is the sequence of eigenvalues. We assume that eigenvalues are sorted in decreasing order, so that:

$$\lambda_1 \geq \lambda_2 \geq \dots \geq 0.$$

By expressing \mathcal{X} with respect to the eigenfunctions basis, $\mathcal{X} = \sum_{k=1}^{\infty} \xi_k e_k$, it holds

$$\lambda_k = \langle e_k, \mathcal{C}e_k \rangle = \mathbb{E}[\xi_k^2],$$

thus, the covariance operator is nuclear, meaning that

$$\mathbb{E}\|\mathcal{X}\|^2 = \sum_{k=1}^{\infty} \lambda_k = \sum_{k=1}^{\infty} |\lambda_k| < \infty.$$

\mathcal{C} is also a Hilbert-Schmidt operator (see, for instance, Bosq, 2000), since it holds:

$$\sum_{k=1}^{\infty} \lambda_k^2 < \infty. \quad (3)$$

We equip the space of Hilbert-Schmidt operators with the Hilbert-Schmidt norm, defined as $\|\mathcal{U}\|_S^2 = \sum_{k=1}^{\infty} \lambda_k^2$, where $\{\lambda_k\}_{k=1}^{\infty}$ are the eigenvalues of \mathcal{U} . This is induced by the following scalar product:

$$\langle \mathcal{U}, \mathcal{V} \rangle_S = \sqrt{\text{Tr}(\mathcal{U} - \mathcal{V})(\mathcal{U} - \mathcal{V})^*}, \quad (4)$$

where $\text{Tr}(\cdot)$ denotes the trace operator, and \mathcal{U}^* is the Hilbertian adjoint of \mathcal{U} , i.e.,

$$\langle \mathcal{U}(x), y \rangle = \langle x, \mathcal{U}^*(y) \rangle \quad \forall x, y \in L^2(I).$$

The space of Hilbert-Schmidt operators on $L^2(I)$, endowed with the scalar product (4) and the associated norm, becomes a separable Hilbert space itself.

Within this theoretic framework, a natural definition of dissimilarity between Hilbert-Schmidt operators (among which are covariance operators) may be the Hilbert-Schmidt distance:

$$d(\mathcal{U}, \mathcal{V}) = \|\mathcal{U} - \mathcal{V}\|_S^2 = \sum_{k=1}^{\infty} \eta_k^2, \quad (5)$$

where $\{\eta_k\}_{k=1}^{\infty}$ is the sequence of eigenvalues of $\mathcal{U} - \mathcal{V}$.

3. Covariance-based Clustering

We face now the problem of classifying observations belonging to two different functional populations. Let \mathcal{X} and \mathcal{Y} be stochastic processes on $L^2(I)$ generated by the laws $\mathcal{P}_{\mathcal{X}}$ and $\mathcal{P}_{\mathcal{Y}}$. We imagine to have a set of N data in some data set D (i.e., a collection of observations) composed in the following way by an equal number of observations from two families: $D = \{X_1, \dots, X_K, Y_1, \dots, Y_K\}$ with $K = N/2$ and where $\{\mathcal{X}_j\}_{j=1}^K$ are i.i.d and follow respectively $\mathcal{P}_{\mathcal{X}}$ and $\mathcal{P}_{\mathcal{Y}}$. We introduce the following quantities:

$$\begin{aligned} \mu_1 &= \mathbb{E}[X_1], & C_1 &= \mathbb{E}[X_i \otimes X_i], & \forall i &= 1, \dots, K, \\ \mu_2 &= \mathbb{E}[Y_1], & C_2 &= \mathbb{E}[Y_j \otimes Y_j], & \forall j &= 1, \dots, K. \end{aligned}$$

Let us consider the vector of indexes of units constituting the two populations in D :

$$I^{(0)} = \left(\underbrace{1, 2, \dots, K}_{I_1^{(0)}}, \underbrace{K+1, \dots, N}_{I_2^{(0)}} \right), \quad (6)$$

which is unique, provided we don't distinguish among permutations of sub-intervals $I_1^{(0)}$ and $I_2^{(0)}$. In the following we shall consider recombinations of these indexes into two subsets:

$$I^{(i)} = \left(I_1^{(i)}, I_2^{(i)} \right), \quad i \in \{1, \dots, N_C\}, \quad (7)$$

where $I^{(i)}$ denotes the i -th combination out of $N_C = \binom{N}{K}$, however enumerated.

The sample estimators of means and covariance operators induced by this subdivision are denoted, respectively, with $\hat{\mu}_1^{(i)}, \hat{\mu}_2^{(i)}$ and $\hat{C}_1^{(i)}, \hat{C}_2^{(i)}$. We point out that, when $i = 0$, we recover the estimators of μ_1, μ_2 and C_1 and C_2 . For this reason we rename the latter quantities as

$\mu_1^{(0)}, \mu_2^{(0)}$, and $\mathcal{C}_1^{(0)}, \mathcal{C}_2^{(0)}$.

Our clustering method is based on the following, crucial assumption:

Assumption 1 *We assume that observations drawn from families $P_{\mathcal{X}}$ and $P_{\mathcal{Y}}$ constituting the data set D may be distinguished on the basis of their covariances, but not of their means, i.e. $\mu_1^{(0)} = \mu_2^{(0)}$ and $\mathcal{C}_1^{(0)} \neq \mathcal{C}_2^{(0)}$, and therefore $\|\mu_1^{(0)} - \mu_2^{(0)}\| = 0$ and $d(\mathcal{C}_1^{(0)}, \mathcal{C}_2^{(0)}) \gg 0$.*

As a consequence of this assumption we conveniently center data and assume they have zero means.

In order to illustrate the clustering method we propose, let us consider a situation where the original data set has been split according to a vector of indices $I^{(g)} = [I_1^{(g)}, I_2^{(g)}]$. For the sake of simplicity, let us encode this through the binary variables $w_{j,g} = \mathbb{1}(X_j \in I_g^{(g)})$, $j = 1, \dots, K$, $g = 1, 2$, and $v_{j,g} = \mathbb{1}(Y_j \in I_g^{(g)})$, $j = 1, \dots, K$, $g = 1, 2$. In other words, such variables express the fact that observation j from the original population \mathcal{X} or \mathcal{Y} belongs to the first ($I_1^{(g)}$) or second ($I_2^{(g)}$) group into which data are split. According to the setting previously introduced, it is:

$$\begin{aligned} K &= \sum_{g=1}^2 \sum_{j=1}^K w_{j,g}, & K &= \sum_{j=1}^2 \sum_{g=1}^K v_{j,g}, \\ K &= \sum_{j=1}^K w_{j,1} + \sum_{j=1}^K v_{j,1}, & K &= \sum_{j=1}^K w_{j,2} + \sum_{j=1}^K v_{j,2}. \end{aligned}$$

Then, we can re-write the sample covariances $\widehat{\mathcal{C}}_1^{(g)}$ and $\widehat{\mathcal{C}}_2^{(g)}$ as:

$$\begin{aligned} \widehat{\mathcal{C}}_1^{(g)} &= \frac{\sum_{j=1}^K w_{j,1} X_j \otimes X_j + \sum_{k=1}^K v_{k,1} Y_k \otimes Y_k}{K}, \\ \widehat{\mathcal{C}}_2^{(g)} &= \frac{\sum_{j=1}^K w_{j,2} X_j \otimes X_j + \sum_{k=1}^K v_{k,2} Y_k \otimes Y_k}{K}. \end{aligned}$$

If we compute the difference $\widehat{\mathcal{C}}_1^{(g)} - \widehat{\mathcal{C}}_2^{(g)}$, we obtain:

$$\widehat{\mathcal{C}}_1^{(g)} - \widehat{\mathcal{C}}_2^{(g)} = \frac{1}{K} \sum_{j=1}^K (w_{j,1} - w_{j,2}) X_j \otimes X_j + \frac{1}{K} \sum_{k=1}^K (v_{k,1} - v_{k,2}) Y_k \otimes Y_k,$$

hence, exploiting the distance between covariance operators:

$$\begin{aligned} K^2 \|\widehat{\mathcal{C}}_1^{(g)} - \widehat{\mathcal{C}}_2^{(g)}\|_S^2 &= \left\| \sum_{j=1}^K (w_{j,1} - w_{j,2}) X_j \otimes X_j \right\|_S^2 + \left\| \sum_{j=1}^K (v_{j,1} - v_{j,2}) Y_j \otimes Y_j \right\|_S^2 + \\ &+ 2 \sum_{j=1}^K \sum_{k=1}^K (w_{j,1} - w_{j,2})(v_{k,1} - v_{k,2}) \langle X_j, Y_k \rangle^2 \\ &= \sum_{j=1}^K \|X_j \otimes X_j\|_S^2 + 2 \sum_{j < k} (w_{j,1} - w_{j,2})(w_{k,1} - w_{k,2}) \langle X_j, X_k \rangle^2 + \\ &+ \sum_{j=1}^K \|Y_j \otimes Y_j\|_S^2 + 2 \sum_{j < k} (v_{j,1} - v_{j,2})(v_{k,1} - v_{k,2}) \langle Y_j, Y_k \rangle^2 + \\ &+ 2 \sum_{j=1}^K \sum_{k=1}^K (w_{j,1} - w_{j,2})(v_{k,1} - v_{k,2}) \langle X_j, Y_k \rangle^2. \end{aligned} \quad (8)$$

Let us now call $\delta_{j,k}^X = (w_{j,1} - w_{j,2})(w_{k,1} - w_{k,2})$, $\delta_{j,k}^Y = (v_{j,1} - v_{j,2})(v_{k,1} - v_{k,2})$ and $\delta_{j,k}^{XY} = (w_{j,1} - w_{j,2})(v_{k,1} - v_{k,2})$. Now, it is: $\delta_{j,k}^X = +1$ if observations X_j and X_k are assigned to the same group, while on the contrary it is $\delta_{j,k}^X = -1$. The same applies for $\delta_{j,k}^Y$ with Y_j and Y_k . Finally, $\delta_{j,k}^{XY} = +1$ if X_j and Y_k are assigned to different groups, and $\delta_{j,k}^{XY} = -1$ on the contrary. It is now clear that, the distance between covariance operators is increased when two observations of populations \mathcal{X} or \mathcal{Y} are both assigned to the same group, or when two observations of the opposite populations \mathcal{X} and \mathcal{Y} are assigned to different groups. These remarks suggest the idea that, under the previous assumption, by recovering the original labelling of the two populations \mathcal{X} and \mathcal{Y} the distance between the induced covariance operators is increased.

If we replace the estimators of covariance operators in (8) with their expected values,

$$\begin{aligned} \mathbb{E}[\widehat{\mathcal{C}}_1^{(g)}] &= \mathcal{C}_1^{(g)} = \frac{\sum_{j=1}^N w_{j,1}}{K} \mathcal{C}_1 + \frac{\sum_{j=1}^K v_{j,1}}{K} \mathcal{C}_2, \\ \mathbb{E}[\widehat{\mathcal{C}}_2^{(g)}] &= \mathcal{C}_2^{(g)} = \frac{\sum_{j=1}^N w_{j,2}}{K} \mathcal{C}_1 + \frac{\sum_{j=1}^K v_{j,2}}{K} \mathcal{C}_2, \end{aligned}$$

then, by denoting $N_{1,2} = \sum_{j=1}^K w_{j,2}$ and also considering the relations among the variables $w_{j,g}$ and $v_{j,g}$ we get:

$$d(\mathcal{C}_1^{(g)}, \mathcal{C}_2^{(g)}) = \left\| \mathbb{E}[\widehat{\mathcal{C}}_1^{(g)}] - \mathbb{E}[\widehat{\mathcal{C}}_2^{(g)}] \right\|_S^2 = \left(1 - 2 \frac{N_{1,2}}{K}\right)^2 \|\mathcal{C}_1 - \mathcal{C}_2\|_S^2, \quad (9)$$

specifying that the maximum distance between (exact) covariances is attained when the groupings coincide with the original but unknown indexing of the data set.

If assumption (1) is true and in view of (9), a natural way to recover the true indexing can be to find the recombination of data in two groups maximising the distance between the induced covariance operators, i.e., to solve the optimization problem:

$$[I_1^*; I_2^*] = \arg \max_{i \in R_C} \left\{ d \left(\mathcal{C}_1^{(i)}, \mathcal{C}_2^{(i)} \right) \right\}, \quad R_C = \{1, \dots, N_C\}. \quad (\mathbf{P})$$

Identity (9) ensures that either $I_1^* = I_1^{(0)}$ and $I_2^* = I_2^{(0)}$, or $I_1^* = I_2^{(0)}$ and $I_2^* = I_1^{(0)}$. The double solution is due to the symmetry of (9), yet the groups represent the same partition of data, for this reason in the following we will not distinguish between them.

Practically, only approximate estimates of $\mathcal{C}_1^{(i)}$ and $\mathcal{C}_2^{(i)}$ are available, thus we must recast problem (\mathbf{P}) into:

$$\left[\tilde{I}_1^*; \tilde{I}_2^* \right] = \arg \max_{i \in R_C} \left\{ d \left(\tilde{\mathcal{C}}_1^{(i)}, \tilde{\mathcal{C}}_2^{(i)} \right) \right\}, \quad R_C = \{1, \dots, N_C\}, \quad (\tilde{\mathbf{P}})$$

The method we propose coincides with finding a solution to problem $(\tilde{\mathbf{P}})$.

In general \tilde{I}_1^* and \tilde{I}_2^* may differ from $I_1^{(0)}$ and $I_2^{(0)}$, since they are determined based on estimates of covariance operators. Indeed, provided that the chosen distance is capable of emphasizing the actual differences between covariances of the two populations, results could be improved by enhancing the accuracy of estimators. In Subsection 3.2 we will address the former issue.

3.1 Greedy formulation

In order to solve problem $(\tilde{\mathbf{P}})$, it would be required to test each of the N_C recombinations of indexes in order to find the desired pair \tilde{I}_1^* and \tilde{I}_2^* . Of course, the number of tests to be performed, $N_C = \binom{N}{K}$, with $K = N/2$, undergoes a combinatorially-fast growth, as N increases. Thus, unless we have only a small number of observations in our data set, the naive approach of performing an exhaustive search in the set of recombinations is not feasible. This calls for a proper complexity-reduction strategy, aimed at restraining the complexity and enabling the application of our method also to data sets with a common size.

3.1.1 MAX-SWAP ALGORITHM

We propose to rephrase problem $(\tilde{\mathbf{P}})$ into a greedy algorithm, with a greatly reduced complexity: The driving idea is to interpret $d(\tilde{\mathcal{C}}_1^{(i)}, \tilde{\mathcal{C}}_2^{(i)})$ as an objective function of i , and, starting from an initial guess (I_1^0, I_2^0) , to iteratively increase it by allowing exchanges of units between the two groups. The exchange of data must preserve the total number of units inside each group, so each group discards and receives an equal number of units, say up to J per group.

We propose to choose the swapping units in such a way that the distance between the estimated covariance operators at the next step be strictly higher than the previous one and, heuristically, the highest possible. Convergence is reached when no further swap can increase that distance.

This strategy can be also motivated by (8), since it performs swaps between observations in order to increase $\|\tilde{\mathcal{C}}_1^{(i)} - \tilde{\mathcal{C}}_2^{(i)}\|$, thus trying to assign the correct values to $v_{j,g}$ and $v_{j,g}$.

Algorithm 1: Max-Swap algorithm

Input: Initial guess: (I_1^0, I_2^0)

Output: Estimated indexing $(\tilde{I}_1^*, \tilde{I}_2^*)$

Compute $(\tilde{\mathcal{C}}_1^0, \tilde{\mathcal{C}}_2^0)$ induced by (I_1^0, I_2^0) ;

$d^0 = d(\tilde{\mathcal{C}}_1^0, \tilde{\mathcal{C}}_2^0)$;

$k = 1$;

$(\Delta d)^k = 1$;

while $(\Delta d)^k > 0$ **do**

for $s \in 1, \dots, K$ **do**

for $t \in 1, \dots, K$ **do**

 Swap in first group: $\tilde{I}_1 = \bigcup_{p \neq s} I_1^{k-1}(p) \cup I_2^{k-1}(t)$;

 Swap in second group: $\tilde{I}_2 = \bigcup_{p \neq t} I_2^{k-1}(q) \cup I_1^{k-1}(s)$;

 Compute $(\tilde{\mathcal{C}}_1, \tilde{\mathcal{C}}_2)$ induced by $(\tilde{I}_1, \tilde{I}_2)$;

$D_{s,t} = d(\tilde{\mathcal{C}}_1, \tilde{\mathcal{C}}_2)$;

$(s^*, t^*) = \arg \max_{s,t} D_{s,t}$;

$d^k = D_{s^*, t^*}$;

$(\Delta d)^k = d^k - d^{k-1}$;

$I_1^k = \bigcup_{p \neq s^*} I_1^{k-1}(p) \cup I_2^{k-1}(t^*)$;

$I_2^k = \bigcup_{q \neq t^*} I_2^{k-1}(q) \cup I_1^{k-1}(s^*)$;

$k = k + 1$;

$d^{**} = d^{k-1}$;

$I_1^{**} = I_1^{k-1}$;

$I_2^{**} = I_2^{k-1}$;

When searching the best swap of size up to J , we must explore a number of combinations of the current groups equal to $\sum_{i=1}^J \binom{K}{i}^2$. Therefore it is evident that J affects both the computational effort and the robustness of our algorithm: the lower is J , the less permutations we have to search among to find the optimal swap; the greater is J , the more likely we are to detect and exchange at once a block of truly extraneous units. We point out that, for $J = K$ we recover the original complexity of solving problem $(\tilde{\mathbf{P}})$ in just one step, since it holds:

$$\binom{N}{K} = \sum_{i=0}^K \binom{K}{i}^2 = \sum_{i=1}^K \binom{K}{i}^2 + 1.$$

We propose to set $J = 1$, in order to save computations, and to choose the units to be exchanged by exploring the K^2 swaps of one unit from the first group with another unit of

the second group. Then we select the one yielding the maximum increment in the distance. The complete formulation of our Max-Swap algorithm is summarised in Algorithm 1, where we specify for the sake of clarity that the symbol $I_1^k(p)$, for instance, indicates the p -th element of the set of indexes I_1^k . In the following we will denote the estimated set of indexes at step k of algorithm with superscript k without brackets, (I_1^k, I_2^k) .

3.1.2 CONVERGENCE

We turn now to the study of the convergence of our proposed algorithm. With reference to the notation of Algorithm 1, it is easy to prove that

$$\textbf{Proposition 1} \quad \textit{The monotonicity constraint:} \quad (\Delta d)^k > 0 \quad \forall k \geq 1, \quad (10)$$

ensures that convergence always happens, at least to a local maximum of $d(\widehat{\mathcal{C}}_1^{(t)}, \widehat{\mathcal{C}}_2^{(t)})$.

Proof As a simple consequence of (10), the list of intermediate indexings:

$$(I_1^0, I_2^0), (I_1^1, I_2^1), \dots, (I_1^k, I_2^k), \dots$$

does not have cycles (a contiguous sub-sequence with equal extrema). In fact, let there be a cycle of minimal period L starting at iteration k_0 , then it should hold:

$$0 = d^{k_0+L} - d^{k_0} = \sum_{j=1}^L (\Delta d)^{j+k_0} > 0,$$

which is a contradiction. Thus each element in the list is unique and contained in the set of all the possible recombinations of data:

$$(I_1^{(0)}, I_2^{(0)}), (I_1^{(1)}, I_2^{(1)}), \dots, (I_1^{(N_C)}, I_2^{(N_C)}),$$

which has a finite number of elements. Therefore the algorithm, however initialised, converges. ■

Now that convergence has been established, we can formulate the following proposition:

Proposition 2 *When estimates of covariance operators, $\widehat{\mathcal{C}}_1$ and $\widehat{\mathcal{C}}_2$, are exact, i.e., when $\widehat{\mathcal{C}}_1 = \mathcal{C}_1$ and $\widehat{\mathcal{C}}_2 = \mathcal{C}_2$, the greedy algorithm converges to the exact solution (I_1^*, I_2^*) of problem (\mathbf{P}) in at most $K/2$ steps.*

Proof This is a consequence of Proposition 1 and the convexity of the objective function $d(\widehat{\mathcal{C}}_1^{(t)}, \widehat{\mathcal{C}}_2^{(t)})$ w.r.t $N_{1,2}$ showed in (9), making it impossible that local maxima exist. ■

A consequence of Proposition 1 is that in general $(I_1^{**}, I_2^{**}) \neq (\widehat{I}_1^*, \widehat{I}_2^*)$, since the algorithm may converge only to a local maximizer of the covariances' distance. This is a well-known drawback affecting greedy methods for optimization problems based on local-search patterns

and the development of possible remedies is a very active research field in algorithmics and optimization disciplines. A simple way to correct for the possibility to select only a local optimum is to implement a *restart*-like strategy, namely run multiple instances of the algorithm with different initialisations and to select the best results in terms of optimised objective function. This is a simple and classic solution to the drawbacks of general local-optimisation algorithms.

However, Proposition 2 assures that the algorithm converges to the exact solution, provided that we have a thorough knowledge of covariance operators. Therefore, the possible non-convexity of the objective function $d(\mathcal{C}_1^{(t)}, \mathcal{C}_2^{(t)})$, being the reason why local maxima exist, would be a direct consequence of the small precision in estimating covariances.

Under this light, we can rephrase the problem of enhancing our method from finding an algorithmics-like remedy to the aforementioned drawback, to the study of accuracy properties of covariance estimators. This will be the focus of Subsection 3.2. Another possibility to reduce the risk of selecting only local maximisers, which we don't investigate in the following, would be to assess the stability of the maximiser found when running a standard Max-Swap algorithm by running a general version of Max-Swap with $J > 1$.

3.1.3 RATE OF CONVERGENCE AND COMPLEXITY

Max-Swap algorithm increases the objective function starting from an initial guess, (I_1^0, I_2^0) . In general, we have no prior knowledge on the distribution of true groups among the data set, then we should choose the initial guess at random, and in particular by drawing from the set of indexes without replacement, assigning equal probability to each outcome. This strategy causes the quantity $N_{1,2}$ in (9) to follow a hypergeometric distribution:

$$N_{1,2} \sim \text{Hyper}(N, K, K),$$

i.e.,

$$\mathbb{P}(N_{1,2} = h) = \frac{\binom{K}{h} \binom{K-h}{K-h}}{\binom{N}{K}}, \quad \mathbb{E}[N_{1,2}] = \frac{K}{2},$$

with typically large values of N and $K = N/2$. Owing to the fast decay of hypergeometric mass function away from its mean, we can presume that the random initial draw will cause $N_{1,2}$ to be most likely in some neighbourhood of $K/2$ (we imagine K to be even).

Let us assume that hypotheses of Proposition 2 are true, then if we consider a value for $N_{1,2}$ resulting from the initial guess, the number of iterations to convergence is $N_{\text{it}} = \min(N_{1,2}, K - N_{1,2})$, corresponding to N_{it} consecutive and correct swaps. Then, by initialising at random the algorithm:

$$N_{\text{it}} \leq \frac{K}{2}.$$

If we summarise the complexity of solving problem (\mathbf{P}) with the number of combinations N_{comb} processed to recover the estimated groups (I_1^*, I_2^*) , and we compare our proposed method (MS) with the naive, exhaustive strategy (N), we have:

$$N_{\text{comb}}^{MS} = K^2 \quad N_{\text{it}} \leq \frac{K^3}{2}, \quad N_{\text{comb}}^N = \binom{N}{K},$$

where the multiplicative factor K^2 in $N^{M/S}_{\text{comb}}$ accounts for the number of combinations searched for to find the best swap at each step of Max-Swap algorithm. This shows how Max-Swap algorithm entails a far lower complexity than the brute force approach.

3.1.4 CLASSIFICATION OF NEW OBSERVATIONS

Once the algorithm has been run and the two groups constituting the mixed data set have been found, a simple rule can be applied to use the clusters in order to classify new observations. We suggest to consider each new unit separately, and compute the covariances obtained by including the unit either in the first or second group. For the sake of simplicity, we denote them, respectively, by \hat{C}_1 and \hat{C}_2 . Then we compute the distances $d_1 = d(\hat{C}_1, \hat{C})$ and $\tilde{d}_2 = d(\hat{C}_2, \hat{C}_2)$, where here we indicate by \hat{C}_1 and \hat{C}_2 the covariances of the two groups determined at the end of the clustering stage. Then we attribute the new unit to the group for which the distance d is minimum.

3.2 Shrinkage estimation of covariance

In this subsection we consider the problem of improving the estimation of covariance operators, so that clustering is more accurate. In particular, we will describe an alternative estimator of data covariance than the sample covariance, which is better conditioned and in some circumstances achieves lower MSE. We will make use of it in our clustering algorithm as an alternative to sample covariance.

Let us consider a generic family of functional data $\mathcal{X} \sim P_{\mathcal{X}}$, such that $\mathbb{E}[\mathcal{X}] = 0$, $\mathbb{E}\|\mathcal{X}\|^2 < \infty$. We denote its covariance with \mathcal{C} and we imagine to estimate it with $\hat{\mathcal{C}}$. Our purpose is to find its best possible approximation, or saying it otherwise, being:

$$\text{MSE}_{\mathcal{S}}(\hat{\mathcal{C}}) := \mathbb{E}\|\hat{\mathcal{C}} - \mathcal{C}\|_{\mathcal{S}}^2,$$

our measure of the estimation error of $\hat{\mathcal{C}}$, to solve the following estimation problem **(E)**:

$$\hat{\mathcal{C}}^* = \arg \min_{\hat{\mathcal{C}}} \text{MSE}_{\mathcal{S}}(\hat{\mathcal{C}}) = \arg \min_{\hat{\mathcal{C}}} \mathbb{E}\|\hat{\mathcal{C}} - \mathcal{C}\|_{\mathcal{S}}^2, \quad (\text{E})$$

where the minimum is sought among all possible estimators $\hat{\mathcal{C}}$ of \mathcal{C} . We point out that in MSE $_{\mathcal{S}}$ we use our selected distance to measure the discrepancy of estimation.

Of course, from a practical viewpoint, only a finite-dimensional estimation of \mathcal{C} can be attained, given data. In addition, functional data are often available from sources as discrete measurements of a signal over some one dimensional grid. Let us indicate by X_i the i -th (out of N) sample realisation of process \mathcal{X} , i.e.:

$$X_i = (X_i(t_j))_{j=1}^P, \quad I^h = [t_1, \dots, t_P], \quad (11)$$

where, for the sake of simplicity, we have imagined the grid I^h to be regularly spaced (although this is not mandatory), i.e., $t_{j+1} - t_j = h > 0$ for $j = 1, \dots, P - 1$. A crucial point when analysing functional data is to reconstruct functions from scattered measurements

X_i , which requires the use of some proper smoothing technique. Furthermore, the so called *phase variability* of reconstructed signals, involving the dispersion of features along the grid axis, can be separated from *amplitude variability*, appearing as the dispersion of magnitudes of values of X_i . This process is known as registration (see, for instance, Ramsay and Silverman, 2005). Once data have been smoothed and registered, they can be re-evaluated onto another one dimensional grid. To save notation we will assume that discrete representations in (11) have already been preprocessed.

It is clear that, within this habit, covariance estimators of \mathcal{C} are discrete, matrix-type approximations obtained starting from pointwise observations X_i . For instance, standard sample covariance estimator for zero-mean data is:

$$\mathbf{S} = \frac{1}{N} \sum_{i=1}^N X_i X_i^T. \quad (12)$$

If we denote the true, discrete covariance structure related to each X_i by \mathbf{C} the discrete version of problem **(E)** is:

$$\mathbf{C}^* = \arg \min_{\hat{\mathbf{C}}} \mathbb{E}\|\hat{\mathbf{C}} - \mathbf{C}\|_F^2, \quad (\text{E})$$

where the minimum is sought inside the set of symmetric and positively defined matrix-type estimators of dimension P . We point out that the subscript F in **(E)** indicates the Frobenius norm, that is the finite-dimensional counterpart of the Hilbert-Schmidt norm for operators.

When the sample size N is low compared to the number of features P , sample covariance may loose in accuracy, meaning that the actual estimate might be quite distant from the true covariance \mathbf{C} (this can be seen as a consequence of the so-called *Stein's phenomenon*, Stein, 1956).

A typical remedy to the poor performances of sample covariance, often used in the setting of *Large P - Small N* problems, is to replace it with a biased, shrinkage estimator. Other solutions might be jackknife or bootstrap, but their computational cost renders them practically useless in our clustering algorithm, which requires to repeatedly estimate covariance matrices. Shrinkage estimation has been explicitly applied to the context of large covariance matrices in (Ledoit and Wolf, 2003, 2004) and (Schäfer and Strimmer, 2005), turning out in a sufficiently lightweight procedure. In those works, authors start from problem **(E)** and build an estimator that is asymptotically more accurate and better conditioned than sample covariance. We follow the approach described in (Ledoit and Wolf, 2004) and consider the class of linear shrinkage estimators of the form:

$$\hat{\mathbf{C}} = \mu\gamma\mathbf{I} + (1 - \gamma)\mathbf{S}, \quad (13)$$

where \mathbf{I} is the $P \times P$ identity matrix and $\gamma \in [0, 1]$, $\mu \in \mathbb{R}^+$ and \mathbf{S} is the sample covariance estimator. Obviously, the class contains the sample covariance estimator itself. Then **(E)** is solved with respect to the optimal values of μ and γ :

$$(\mu^*, \gamma^*) = \arg \min_{\mu, \gamma} \frac{\mathbb{E}\|\mathbf{C} - \mu\gamma\mathbf{I} - (1 - \gamma)\mathbf{S}\|_F^2}{P}. \quad (14)$$

If we introduce the quantities:

$$\alpha^2 = \frac{\|\mathbf{C} - \mu\mathbf{I}\|_F^2}{P}, \quad \beta^2 = \frac{\mathbb{E}\|\mathbf{S} - \mathbf{C}\|_F^2}{P}, \quad \delta^2 = \frac{\mathbb{E}\|\mathbf{S} - \mu\mathbf{I}\|_F^2}{P}, \quad (15)$$

and note that these are subjected to $\alpha^2 + \beta^2 = \delta^2$, we can perform the explicit minimization in equation (14). The expressions of μ^* and γ^* are:

$$\mu^* = \frac{\langle \mathbf{C}; \mathbf{I} \rangle_F}{P} = \frac{\text{Tr}(\mathbf{C})}{P}, \quad \gamma^* = \frac{\beta^2}{\delta^2}, \quad (16)$$

where we have used $\mu = \mu^*$ in the computation of δ . The desired shrinkage estimator becomes:

$$\mathbf{S}^* = \mu^* \frac{\beta^2}{\delta^2} \mathbf{I} + \frac{\alpha^2}{\delta^2} \mathbf{S}. \quad (17)$$

Of course, estimator (17) depends on the unknown exact covariance matrix \mathbf{C} , even though only through four scalar functions. In (Ledoit and Wolf, 2004) authors solve this problem by proposing the following estimators for α , β , δ and μ^* :

$$\hat{\mu}^* = \frac{\text{Tr}(\mathbf{S})}{P}, \quad \hat{\delta}^2 = \frac{\|\mathbf{S} - \hat{\mu}^* \mathbf{I}\|_F^2}{P}, \quad (18)$$

$$\hat{\beta}^2 = \min \left(\hat{\delta}^2; \frac{1}{N^2} \sum_{k=1}^N \frac{\|X_k X_k^T - \mathbf{S}\|_F^2}{P} \right), \quad (19)$$

and $\hat{\alpha}^2 = \hat{\delta}^2 - \hat{\beta}^2$.

Then, the actual shrinkage estimator is:

$$\hat{\mathbf{S}}^* = \widehat{\mu}^* \frac{\hat{\beta}^2}{\hat{\delta}^2} \mathbf{I} + \frac{\hat{\alpha}^2}{\hat{\delta}^2} \mathbf{S}. \quad (20)$$

In (Ledoit and Wolf, 2004) authors show how estimates (18) are consistent, in the sense that they converge to the exact values in quadratic mean, under the general asymptotic limits of P and N , i.e., when both P and N are allowed to go to infinity but there exists a $c \in \mathbb{R}$ independent on N such that $P/N < c$ (see Ledoit and Wolf, 2004 and references therein for theoretical details on general asymptotics). Moreover, estimator $\hat{\mathbf{S}}^*$ is an asymptotically optimal linear shrinkage estimator for covariance matrix \mathbf{C} with respect to quadratic loss. Besides its asymptotic properties, extensive use in applications shows that the accuracy gain resulting from $\hat{\mathbf{S}}^*$ in terms of decrease in MSE is substantial also in many finite sample cases, and that standard covariance is almost always matched and often outperformed by $\hat{\mathbf{S}}^*$. For a detailed description of how and when shrinkage estimation of covariance is recommended over the sample estimation, see for instance (Ledoit and Wolf, 2004).

4. Case Studies

In this section we provide three simulations involving our proposed clustering method. In Subsection 4.1 we show a first example, regarding standard bivariate data, in order to

give a clear geometric idea of clustering based on covariance structures. In Subsection 4.2 we show an application to synthetic functional data. In these former two examples the true subdivision of samples is known, so the goodness of the clustering arising from Max-Swap algorithm is assessed against the true identities of data. In Subsection 4.3, instead, we apply the clustering algorithm on real functional data expressing the concentration of deoxygenated hemoglobin measured in human subjects' brains.

4.1 Multivariate data

This test is meant to provide a first, visual example of the features of the clustering arising from using Max-Swap algorithm. In order to ease the geometrical interpretation, we chose to focus on two bivariate data sets, composed of simulated data with a-priori designed covariances. Indeed, by representing bi-dimensional data we are able to support our considerations with a clear graphical counterpart.

We exploit two reference data sets having the same means but different variance-covariance structures. In particular, a generic clustering based on locations run on these data is meant to fail. The first set of data, hereafter *hourglass* data, has covariances whose difference lies in the directions along which variability expresses. We generated it according to the following laws:

$$X = \rho_x (\cos \theta_x, \sin \theta_x), \quad \rho_x \sim \mathcal{U}[-1, 1], \quad \theta_x \sim \mathcal{U} \left[\frac{\pi}{12}, \frac{5\pi}{12} \right], \\ Y = \rho_y (\cos \theta_y, \sin \theta_y), \quad \rho_y \sim \mathcal{U}[-1, 1], \quad \theta_y \sim \mathcal{U} \left[\frac{7\pi}{12}, \frac{11\pi}{12} \right],$$

where the four random variables, $\rho_x, \rho_y, \theta_x, \theta_y$ are independent. Simple calculations reveal that $\mathbb{E}[X] = 0$ and $\mathbb{E}[Y] = 0$, while covariances are:

$$\mathbf{C}_x = \begin{pmatrix} 1/6 & \sqrt{3}/4\pi \\ \sqrt{3}/4\pi & 1/6 \end{pmatrix}, \quad \mathbf{C}_y = \begin{pmatrix} 1/6 & -\sqrt{3}/4\pi \\ -\sqrt{3}/4\pi & 1/6 \end{pmatrix}.$$

Note that X and Y differ only in their covariances. Moreover, since only off-diagonal terms of \mathbf{C}_x and \mathbf{C}_y are different (and indeed opposed), the two families have the same kind of variability, only expressed along orthogonal directions in the plane. We generate a data set D of $N = 400$ data, according to the previous laws, made up of $K = 200$ samples from X and $K = 200$ samples from Y , which are displayed in Figure 1.

We considered also another data set, referred to as *bull's eye*, whose features are somehow complementary to the ones of *hourglass*, since variabilities of *bull's eye* sub-populations express along the same directions, though with different magnitudes. In particular, we considered the following laws:

$$X = \rho_x (\cos \theta_x, \sin \theta_x), \quad \rho_x \sim \mathcal{U} \left[0, \frac{1}{2} \right], \quad \theta_x \sim \mathcal{U} [0, 2\pi], \\ Y = \rho_y (\cos \theta_y, \sin \theta_y), \quad \rho_y \sim \mathcal{U} \left[2, \frac{5}{2} \right], \quad \theta_y \sim \mathcal{U} [0, 2\pi],$$

where, still, the four random variables $\rho_x, \rho_y, \theta_x, \theta_y$ are independent. This leads to covariances:

$$\mathbf{C}_x = \frac{1}{24} \mathbf{I}, \quad \mathbf{C}_y = \frac{61}{24} \mathbf{I}$$

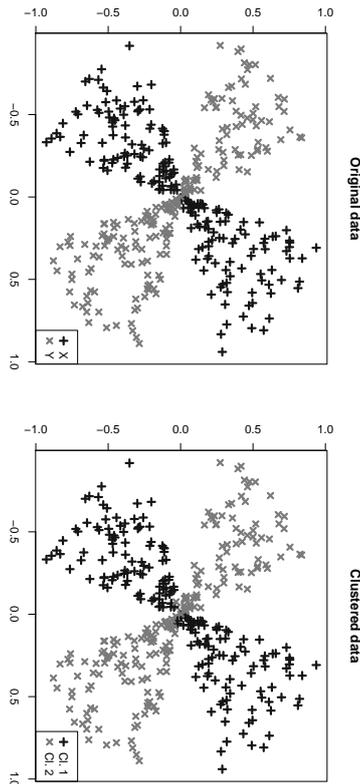

Figure 1: *Left*: Hourglass data set used in the first multivariate experiment, collecting $N = 400$ points subdivided into family X ($K = 200$ points, marked by +) and family Y ($K = 200$ points, marked by x). *Right*: Outcome of clustering via Max-Swap algorithm.

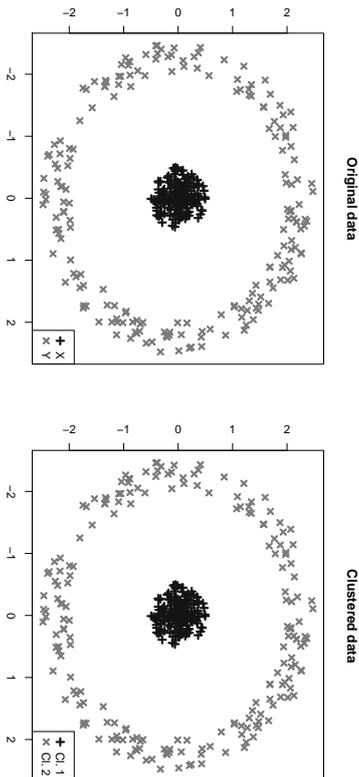

Figure 2: Bull's eye data set used in the second multivariate experiment, collecting $N = 400$ points subdivided into family X ($K = 200$ points, marked by +) and family Y ($K = 200$ points, marked by x). *Right*: Outcome of clustering via Max-Swap algorithm.

that clearly differ only in terms of their variability's magnitude. *Bull's eye* data set is generated according to these laws for an overall cardinality of $N = 400$ data subdivided in two groups of size $K = 200$ each, and it is shown in Figure 2.

We point out that, in order to improve the robustness of results with respect to the chance of selecting only a local maximiser of the distance between variance-covariance structures, Max-Swap algorithm was run for 10 times, keeping the result for which the objective function was highest. Since the number of data in each sub-population, K , is high with respect to their dimensionality, $P = 2$, we used Max-Swap algorithm in combination with the standard sample estimator of covariance, \mathbf{S} . The results of the clustering procedure are also shown in Figure 1 and Figure 2 (right panels), where it is clear how the clustering method is able to detect the observations belonging to the two populations, whose difference is its only in their covariances. Since in this simulated scenario we know the law generating observations, and therefore the labels of the generated data, we are able to assess the performances of the clustering procedure by comparing the two identified groups of data with the original labels. In particular, in the case of hourglass data, only 3 observations out of 200 in each cluster belong to the other population, and are all located very close to the data centre. In the bull's eye example, instead, the two clusters are composed of elements coming from only one population.

The outcome of standard clustering algorithms, like K-means or hierarchical clustering, show the complete inefficacy of location-based clustering for such data sets, where data are mostly different in terms of their variability. In particular, 20 K-means ($K = 2$) runs on Bull's eye and Hourglass data sets yield, if compared with the true labelling of observations, a mis-classification rate of 0.27 ± 0.01 and 0.47 ± 0.01 , respectively, while 20 runs of a hierarchical clustering with euclidean distance and Ward linkage give a mis-classification rate of 0.29 ± 0.05 and 0.46 ± 0.04 , respectively.

4.2 Synthetic functional data

In this subsection we apply our clustering algorithm to functional data. We use a data set composed of two populations of functions, \mathcal{X} and \mathcal{Y} , with null means and covariance operators:

$$C_x = \sum_{i=1}^L \sigma_i \varepsilon_i \otimes \varepsilon_i, \quad C_y = \sum_{i=1}^L \eta_i \varepsilon_i \otimes \varepsilon_i, \quad (21)$$

where $\{\varepsilon_i\}_{i=1}^L$ are the first L elements of the orthonormal Fourier basis on the interval $I = [0, 1]$, save for the constant, i.e.,:

$$e_{2k-1} = \sqrt{2} \sin(2k\pi x), \quad e_{2k} = \sqrt{2} \cos(2k\pi x), \quad x \in I,$$

for $k = 1, \dots, L/2$, and the eigenvalues are chosen as:

$$\sigma_i = 1, \quad \eta_i = \frac{\sigma_i}{\sqrt{5}}, \quad \forall i = 1, \dots, L. \quad (22)$$

In what follows we considered $L = 30$. A visual representation of the related covariance functions is in Figure 3. It is clear from (21) and from Figure 3 that covariances C_x and

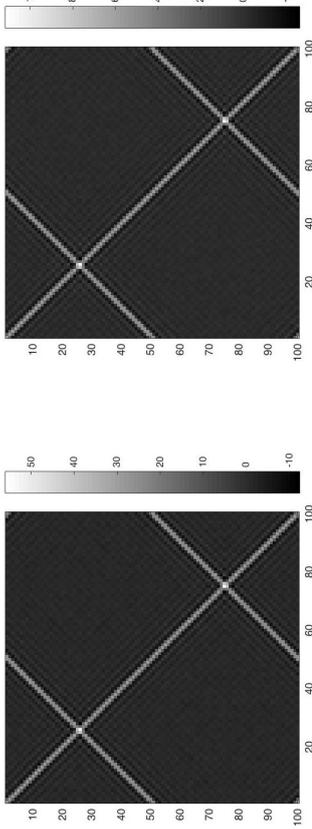

Figure 3: Contour plot of covariances \mathcal{C}_x and \mathcal{C}_y for the experiment with synthetic functional data. The different scales of contour plots show that the difference between the variance-covariance structures is only in magnitude.

\mathcal{C}_y are different only in terms of variability's magnitudes, while their eigenfunctions are the same.

We generated several sets of the following synthetic families of Gaussian functional data having covariances like in (21):

$$X_i = \sum_{j=1}^L \xi_{ij} \sqrt{\sigma_j} \epsilon_j, \quad Y_i = \sum_{j=1}^L \zeta_{ij} \sqrt{\tau_j} \epsilon_j, \quad (23)$$

for $i = 1, \dots, K$, where $\xi_{ij} \sim \mathcal{N}(0, 1)$, and are independent from $\zeta_{ij} \sim \mathcal{N}(0, 1)$. Each synthetic functional unit has been evaluated on a grid of $P = 100$ points, evenly spaced on I . The different sets have been generated choosing $K \in \{20, 25, 30, 35, 40, 45, 50\}$, corresponding to total cardinalities of $N \in \{40, 50, 60, 70, 80, 90, 100\}$.

We applied our clustering algorithm to each synthetic data set. The different values of K (i.e., of N) allow to study the performances of clustering as the sample size increases. This is of interest since our method relies on the estimation of covariance matrices, thus we expect that when the number of data increases the performances tends to improve. We used Max-Swap algorithm both with the standard sample covariance estimator, \mathbf{S} , and with the shrinkage covariance estimator $\hat{\mathbf{S}}^*$.

Like in the case of multivariate data, we know the laws generating observations, hence their original labels, therefore we can analyse the identified clusters in terms of the composition of units from X and Y . This allows us to understand whether the algorithm is able to detect groups of observations that we know *a priori* are different only in their variability. We report the results of the clustering procedure in Tab. 1. Similarly to the case of multivariate synthetic data of Subsection 4.1, each of them is related to the one trial in a set of 10 for which the distance between covariances was highest. This was done in order to take

N		K		Sample covariance (S)		Shrinkage estimator ($\hat{\mathbf{S}}^*$)	
		Misc.	(1, 2)	Err.	Misc.	(1, 2)	Err.
40	20	2	(1, 1)	5%	0	(0, 0)	0%

100	50	0	(0, 0)	0%	0	(0, 0)	0%

Table 1: Clustering performances results for the application with synthetic functional data.

account of the heuristic nature of the algorithm.

Results undoubtedly highlight that covariance-based clustering is effective, yielding groups which can easily be interpreted as the original ones up to an error always lower than 10%, also for challenging cases of scarce data. In addition, for reasonable sample sizes, the error tends to get lower. The results are even more satisfactory if related to the dimension of the covariance matrices of these data, i.e. $P = 100$, since a successful clustering may be carried out with only 25-30 units per family.

If we compare the performances gained when using \mathbf{S} with those attained by using $\hat{\mathbf{S}}^*$, we see that a substantial improvement in accuracy has been achieved. Moreover, in this experiment the performances of Max-Swap combined with \mathbf{S}^* were more stable across the trials, and almost always close to the best one for all trials. This may be an advantage with respect to \mathbf{S} , which in turn gave results more variable from trial to trial. On the contrary, from a computational point of view, resorting to \mathbf{S} leads to faster simulations, while using $\hat{\mathbf{S}}^*$ requires higher effort, especially when K is large.

4.3 Deoxygenated hemoglobin data

In this subsection we apply our clustering method to a real data set belonging to a biomedical context. In particular, we deal with data produced by functional near-infrared spectroscopy (fNIRS), an optical technique able to noninvasively monitor the cerebral hemodynamic at cortical level. Exploiting the relatively low absorption of biological tissues, light in the red and near-infrared wavelength range can penetrate the human head down to some centimeters and reach the cerebral cortex. Therefore, fNIRS can provide a measure of oxy- and deoxy-hemoglobin, the main chromophores contributing to light absorption at this wavelength range. In particular we study the measurements along time of the concentration of deoxygenated hemoglobin in the brain of a group of six right-handed healthy subjects (male, 44 years old) while they are carrying out a motor task (i.e., squeezing a soft ball in the right hand) at a rate of 2 Hz guided by a metronome. The measures of each subject were made on eight different points of the brain, four located in the central part of the left hemisphere and another four located in the central part of the right hemisphere. The

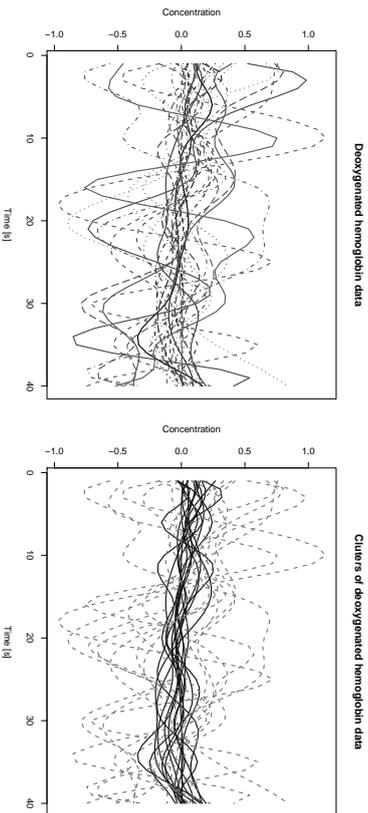

Figure 4: Deoxygenated hemoglobin's concentration data. In the left panel are represented the preprocessed data on which the clustering is carried out. In the right panel is shown the output.

measurement and preprocessing techniques as well as the experimental instruments used to collect data are described in (Torricelli et al., 2014; Zucchelli et al., 2013; Re et al., 2013).

Each statistical unit of the data set consists of a sampling along 40 seconds of deoxygenated hemoglobin's concentration at the related location on the brain. Our clustering purpose is to recognize the signals of patients whose trends in hemoglobin's concentration show wide fluctuations across their mean profiles from signals where the concentration varies little. The aim of the study was in fact to detect different behaviours corresponding to activated vs. non activated cerebral areas. This activation is reflected in difference in covariance operators more than in difference in the mean level of deoxygenated hemoglobin concentration, thus we wish to apply our clustering algorithm in order to detect the two clusters. In a pre-processing stage, signals affected by artifacts due to the measurement procedure were removed, while the others were de-trended and smoothed thanks to a B-Spline smoothing basis.

At the end of the pre-processing stage, a set of $N = 30$ signals, subdivided into two groups of $K = 15$ are available with a sampling rate of 1s, so that $P = 40$. These data are depicted in Figure 4.

We run the Max-Swap clustering algorithm on these data to perform clustering, both using \mathbf{S} and \mathbf{S}^* estimators, finding equal partitions of initial data. The results are shown in Figure 4, and highlight how the algorithm is able to answer to our request, i.e., to detect two clusters of functions that are well distinguishable in terms of their different variability. We interpret these as activated versus non activated brain regions and our results are in agreement with those obtained in (Bonomini et al., 2015).

5. Conclusions

In this paper we have studied the problem of performing clustering on two groups of data whose difference lies in their variance-covariance structures rather than in their means. We have formulated it according to the general statistical framework of functional data, yet it can be of interest also in other contexts, such as for multivariate data. We have shown how the naive clustering strategy is computationally intractable and we have proposed a new heuristic algorithm to override such issue. The algorithm is based on a proper quantification of the distance between estimates of covariance operators, which we assumed to be the natural Hilbert-Schmidt norm, and seeks for the partition of data producing the highest possible distance among estimated covariances. The partition is sought by modifying two initial guesses of the true groups with subsequent exchanges of units, in order to maximise the distance between estimated covariances. We have given its pseudo-code formulation and studied its convergence properties and complexity. A crucial point of the algorithm is the estimation of covariance operators, which can be done by standard sample covariance, but we have proposed a variant involving a linear shrinkage estimator, which promises to be at least as accurate as sample covariance, and often better in terms of mean square error. By means of some examples we have collected empirical evidence to prove that the algorithm is able to solve suitably the clustering problem, both when the variabilities are different in their magnitudes or in their directions. We compared the performances gained on functional data under the use of the sample estimator and of the linear shrinkage one, and found that both of them give definitely satisfactory results and that the use of linear shrinkage may provide a substantial improvement in terms of clustering performances.

Abstract

Many optimization problems arising in high-dimensional statistics decompose naturally into a sum of several terms, where the individual terms are relatively simple but the composite objective function can only be optimized with iterative algorithms. In this paper, we are interested in optimization problems of the form $F(Kx) + G(x)$, where K is a fixed linear transformation, while F and G are functions that may be nonconvex and/or nondifferentiable. In particular, if either of the terms are nonconvex, existing alternating minimization techniques may fail to converge; other types of existing approaches may instead be unable to handle nondifferentiability. We propose the MOCCA (mirrored convex/concave) algorithm, a primal/dual optimization approach that takes a local convex approximation to each term at every iteration. Inspired by optimization problems arising in computed tomography (CT) imaging, this algorithm can handle a range of nonconvex composite optimization problems, and offers theoretical guarantees for convergence when the overall problem is approximately convex (that is, any concavity in one term is balanced out by convexity in the other term). Empirical results show fast convergence for several structured signal recovery problems.

Keywords: MOCCA, ADMM, nonconvex, penalized likelihood, total variation, computed tomography

1. Introduction

We consider the problem of minimizing a composite objective function of the form

$$F(Kx) + G(x) \tag{1}$$

over $x \in \mathbb{R}^d$, where $K \in \mathbb{R}^{m \times d}$ is a fixed linear operator, and F and G are functions which are potentially nonconvex and/or nondifferentiable. Optimization problems of this form arise in many applications, and in particular, the algorithm developed here was motivated by an

image reconstruction problem for computed tomography (CT), an imaging technology used often in medicine and in other domains.

When F and G are both convex, many existing methods are well-equipped to handle this optimization problem, even in high dimensions. For example, the Alternating Direction Method of Multipliers (ADMM) (Boyd et al., 2011) and related primal/dual methods yield effective algorithms when the functions F and G both have inexpensive proximal maps, defined as

$$\text{Prox}_F(u) = \arg \min_w \left\{ \frac{1}{2} \|w - u\|^2 + F(w) \right\}$$

for any $u \in \mathbb{R}^m$, and same for Prox_G defined on \mathbb{R}^d . Methods such as ADMM are especially effective if F has an inexpensive proximal map but the linear transformation of the same function, i.e. the function $x \mapsto F(Kx)$, does not. If F does not offer an inexpensive proximal map but is instead smoothly differentiable (even if nonconvex), while G does have a fast proximal map, then methods such as proximal gradient descent (see e.g. Nesterov, 2013; Beck and Teboulle, 2009) can be applied instead of a primal/dual method.

In this paper, we consider a more challenging setting where F and G may both be nonconvex and nondifferentiable. For instance, we can consider working with functions that can be decomposed as $F = F_{\text{cox}} + F_{\text{diff}}$ and $G = G_{\text{cox}} + G_{\text{diff}}$, where we assume that $F_{\text{cox}}, G_{\text{cox}}$ are convex but do not need to be differentiable, while $F_{\text{diff}}, G_{\text{diff}}$ are potentially nonconvex but are differentiable. (If F_{diff} and G_{diff} are concave, then this type of optimization problem is often referred to as ‘‘convex/concave’’.) As we will see, this formulation arises naturally in a range of applications, but in general, cannot be handled by existing methods that are designed with convexity in mind. In this work, we generalize to a more flexible framework where F and G can each be locally approximated at any point with a convex function.

A special case is the setting where G is convex while F is nonconvex, but $x \mapsto F(Kx)$ is convex (i.e. if F is twice differentiable, then this is equivalent to assuming that $K^\top (\nabla^2 F) K \succeq 0$ but $\nabla^2 F \not\succeq 0$). In this case, the overall optimization problem, i.e. minimizing $F(Kx) + G(x)$, is a convex problem, that is, any local minimum is guaranteed to be a global minimum, and thus we might expect that this problem would be simple to optimize. Surprisingly, this may not be the case—if F is nondifferentiable, then we cannot use gradient descent on F , while the nonconvexity of F means that existing primal/dual optimization techniques might not be applicable.

In the nonconvex, or more specifically, convex/concave setting, one of the most common techniques used in place of convex methods is the majorization/minimization approach (Ortega and Rheinboldt, 1970; Hunter and Lange, 2000), where at each iteration, we work with a convex upper bound on the nonconvex objective function. Specifically, for the setting considered here, at iteration t we would choose some convex functions $F^{(t)}, G^{(t)}$ satisfying $F^{(t)} \geq F$ and $G^{(t)} \geq G$, then solve the modified optimization problem $\min_x \{F^{(t)}(Kx) + G^{(t)}(x)\}$. However, the modified optimization problem may itself be very challenging to solve in this setting, so we often cannot apply the majorization/minimization technique in a straightforward way. Our work combines the ideas of majorization/minimization with primal/dual techniques to handle this composite optimization problem.

1.1 The MOCCA Algorithm

In this work, we propose the mirrored convex/concave (MOCCA) algorithm, which offers an approach that combines some of the techniques described above. We work with a primal/dual formulation of the problem, and incorporate a majorization/minimization type step at each iteration. To motivate our method, we first present an existing method for the case where F and G are both convex, the Chambolle-Pock (CP) algorithm (Chambolle and Pock, 2011) (this method is closely related to other existing algorithms, which we discuss later on).

The CP algorithm is derived by considering the problem in a different form. From this point on, for clarity, we will use variables x, y, z to denote points in \mathbb{R}^d and u, v, w to denote points in \mathbb{R}^m . Since we are considering the setting where F is convex, by duality we can write

$$\min_x \{F(Kx) + G(x)\} = \min_w \max_x \{Kx, w\} - F^*(w) + G(x).$$

where F^* is the conjugate to F (Rockafellar, 1997), also known as the Legendre-Fenchel transform of F , and is defined as

$$F^*(w) = \max_v \{ \langle w, v \rangle - F(v) \}. \quad (2)$$

The primal variable x and dual variable w define a saddle-point problem. Given step sizes Σ, T which are positive diagonal matrices, the (preconditioned) CP algorithm (Chambolle and Pock, 2011; Pock and Chambolle, 2011) iterates the following steps:

$$\begin{cases} x_{t+1} = \arg \min_x \{ \langle Kx, w_t \rangle + G(x) + \frac{1}{2} \|x - x_t\|_{\Sigma^{-1}}^2 \}, \\ w_{t+1} = \arg \min_w \{ -\langle K\bar{x}_{t+1}, w \rangle + F^*(w) + \frac{1}{2} \|w - w_t\|_{\Sigma^{-1}}^2 \}, \end{cases} \quad (3)$$

where $\bar{x}_{t+1} = x_{t+1} + \theta(x_{t+1} - x_t)$ is an extrapolation term for some parameter $\theta \in [0, 1]$ (generally $\theta = 1$). Here the two norms are calculated via the definition $\|x\|_A := \sqrt{x^T A x}$ (for any positive semidefinite matrix $A \succeq 0$). When $\|\Sigma^{1/2} K^T T^{1/2}\| < 1$, convergence properties for this algorithm have been proved, e.g. Chambolle and Pock (2011); Pock and Chambolle (2011); He and Yuan (2012).¹ Setting $\theta = 0$ reduces to an earlier approach, the Primal-Dual Hybrid Gradient algorithm (Esser et al., 2009); with $\theta = 1$, the CP algorithm is equivalent to a modification of ADMM (discussed later in Section 3.1).

We now ask how we could modify the discussed methods to handle nonconvexity of F and/or G . One approach would be to approximate the problem with a convex optimization problem, that is, to take some approximation to F and G that are chosen to be a convex function. Of course, in general, there may not be a convex function that will provide a globally accurate approximation to a nonconvex function, but local convex approximations may be possible.

Consider a family of approximations to the functions F and G , indexed by $(z, v) \in \mathbb{R}^d \times \mathbb{R}^m$, the (primal) points at which the local approximations are taken. We write

1. The original form of the Chambolle-Pock algorithm (Chambolle and Pock, 2011), without preconditioning, can be obtained from (3) by replacing Σ, T with $\sigma I, \tau I$ for scalar step size parameters $\sigma, \tau > 0$, with convergence results proved if $\sigma\tau \|K\|^2 < 1$; however, in general the preconditioned form gives better performance and we only consider the preconditioned version here.

$F_v : \mathbb{R}^m \rightarrow \mathbb{R}$ and $G_z : \mathbb{R}^d \rightarrow \mathbb{R}$ for these approximations, and from this point on, we implicitly assume that the approximations satisfy, for any points $(z, v) \in \text{dom}(G) \times \text{dom}(F)$,

$$\begin{cases} \text{dom}(F_v) = \text{dom}(F) \text{ and } \text{dom}(G_z) = \text{dom}(G); \\ F_v \text{ and } G_z \text{ are convex and continuous functions}; \\ F_v \text{ and } G_z \text{ are accurate up to first order: } F - F_v \text{ and } G - G_z \text{ are differentiable,} \\ \text{with } (F - F_v)(v) = 0, \nabla(F - F_v)(v) = 0, (G - G_z)(z) = 0, \nabla(G - G_z)(z) = 0. \end{cases} \quad (4)$$

(Here $\text{dom}(\cdot)$ denotes the domain of a function, i.e. all points at which the function takes a finite value.) In particular this assumption implicitly requires that F and G both have convex domains.

As a special case, in some settings we can consider decomposing each function into the sum of a convex and a differentiable term, $F = F_{\text{cov}} + F_{\text{diff}}$ and $G = G_{\text{cov}} + G_{\text{diff}}$, as mentioned before; we can then take linear approximations to F_{diff} and to G_{diff} at the points v and z , respectively, to obtain

$$\begin{cases} F_v(w) := F_{\text{cov}}(w) + [F_{\text{diff}}(v) + \langle w - v, \nabla F_{\text{diff}}(v) \rangle], \\ G_z(x) := G_{\text{cov}}(x) + [G_{\text{diff}}(z) + \langle x - z, \nabla G_{\text{diff}}(z) \rangle]. \end{cases} \quad (5)$$

In particular, if F_{diff} and G_{diff} are both concave (and thus F and G are each convex/concave), these two approximations are standard convex majorizations to F and G taken at points v and z (as might be used in a majorization/minimization algorithm in some settings).

Since F_v, G_z are convex, we can substitute them in place of F, G in the iterations of the CP algorithm (3):

$$\begin{cases} x_{t+1} = \arg \min_x \{ \langle Kx, w_t \rangle + G_z(x) + \frac{1}{2} \|x - x_t\|_{\Sigma^{-1}}^2 \}, \\ w_{t+1} = \arg \min_w \{ -\langle K\bar{x}_{t+1}, w \rangle + F_v^*(w) + \frac{1}{2} \|w - w_t\|_{\Sigma^{-1}}^2 \}. \end{cases} \quad (6)$$

We will see later on (in Section 3.3) that this formulation is closely related to the ADMM algorithm, and in fact in the special case given in (5), if F_{diff} and G_{diff} are concave, then MOCCA can be viewed as a special case of Bregman ADMM (Wang and Banerjee, 2014; Wang et al., 2014a).

Of course, a key question remains: which primal points (z, v) should we use for constructing the convex approximations to F and to G , at iteration t of the algorithm? We find that, before solving for (x_{t+1}, w_{t+1}) , we should use expansion points

$$(z, v) = (x_t, \Sigma^{-1}(w_{t-1} - w_t) + K\bar{x}_t).$$

We will return shortly to the question of how these values were chosen; with this choice in place, the MOCCA algorithm is defined in Algorithm 1.

For reasons of stability, it may sometimes be desirable to update the expansion points (z, v) only periodically, and we will incorporate this option into a more general version of MOCCA, given in Algorithm 2. Specifically, at the t th stage, we repeat the (x, w) updates L_t many times; we refer to these repeated updates as the “inner loop”. In fact, the t th “inner

Algorithm 1 MOCCA algorithm

Input: Functions F, G with local convex approximations F_v, G_z , linear operator K , positive diagonal step size matrices Σ, T , extrapolation parameter $\theta \in [0, 1]$.

Initialize: Primal point $x_0 \in \mathbb{R}^d$, dual point $w_0 \in \mathbb{R}^m$, expansion points $(z_0, v_0) \in \mathbb{R}^d \times \mathbb{R}^m$.

for $t = 0, 1, 2, \dots$ **do**

Update x and w variables: writing $\bar{x}_{t+1} = x_{t+1} + \theta(x_{t+1} - x_t)$, define

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ \langle Kx, w_t \rangle + G_z(x) + \frac{1}{2} \|x - x_t\|_{T^{-1}}^2 \right\}, \\ w_{t+1} = \arg \min_w \left\{ -\langle K\bar{x}_{t+1}, w \rangle + F_v^*(w) + \frac{1}{2} \|w - w_t\|_{\Sigma^{-1}}^2 \right\}. \end{cases}$$

Update expansion points: define

$$\begin{cases} z_{t+1} = x_{t+1}, \\ v_{t+1} = \Sigma^{-1}(w_t - w_{t+1}) + K\bar{x}_{t+1} \in \partial F_v^*(w_{t+1}). \end{cases}$$

until some convergence criterion is reached.

Algorithm 2 MOCCA algorithm (stable version with “inner loop”)

Input / Initialize: Same as for Algorithm 1, along with inner loop lengths L_1, L_2, \dots

for $\ell = 0, 1, 2, \dots$ **do**

Define $(x_{t+1;0}, w_{t+1;0}) = (x_t, w_t)$.

for $\ell = 1, 2, \dots, L_{t+1}$ **do**

Update x and w variables: writing $\bar{x}_{t+1;\ell} = x_{t+1;\ell} + \theta(x_{t+1;\ell} - x_{t+1;\ell-1})$, define

$$\begin{cases} x_{t+1;\ell} = \arg \min_x \left\{ \langle Kx, w_{t+1;\ell-1} \rangle + G_z(x) + \frac{1}{2} \|x - x_{t+1;\ell-1}\|_{T^{-1}}^2 \right\}, \\ w_{t+1;\ell} = \arg \min_w \left\{ -\langle K\bar{x}_{t+1;\ell}, w \rangle + F_v^*(w) + \frac{1}{2} \|w - w_{t+1;\ell-1}\|_{\Sigma^{-1}}^2 \right\}. \end{cases}$$

end for

Define $(x_{t+1}, w_{t+1}) = \frac{1}{L_{t+1}} \sum_{\ell=1}^{L_{t+1}} (x_{t+1;\ell}, w_{t+1;\ell})$.

Update expansion points: define

$$\begin{cases} z_{t+1} = \frac{1}{L_{t+1}} \sum_{\ell=1}^{L_{t+1}} x_{t+1;\ell}, \\ v_{t+1} = \frac{1}{L_{t+1}} \sum_{\ell=1}^{L_{t+1}} (\Sigma^{-1}(w_{t+1;\ell-1} - w_{t+1;\ell}) + K\bar{x}_{t+1;\ell}). \end{cases}$$

until some convergence criterion is reached.

loop” is simply running the CP algorithm for the convex problem $\min_x \{F_v(Kx) + G_z(x)\}$. Then, we average over the inner loop and calculate a single update of the expansion points (z, v) . Observe that, if we set $L_t = 1$ for all t , we do only a single (x, w) update in each “inner loop” and thus have reduced to the basic form of MOCCA. In practice, the basic form (Algorithm 1) performs well, and the more stable version (Algorithm 2) is primarily

proposed here for theoretical purposes, as some of our convergence guarantees do not hold for the basic version. However, in some settings the added stability does help empirically.

We remark that F, G (and their approximations F_v, G_z) are allowed to take the value $+\infty$, for instance, to reflect a constraint. For example we might have $G(x) = \delta(\|x\|_2 \leq 1)$, the convex indicator function taking the value $+\infty$ if the constraint $\|x\|_2 \leq 1$ is violated and zero otherwise; this has the effect of imposing a constraint on the x update step of our algorithm. Furthermore, in settings where F_v may not be strongly convex, its conjugate F_v^* may not be finitely valued; we would have $F_v^*(w) = +\infty$ (for some, but not all, w). For instance if $F_v(w) = \|w\|_1$ then $F_v^* = \delta\{\|w\|_\infty \leq 1\}$, which has the effect of imposing a constraint on w in the w update step of our algorithm. Our theoretical results in this paper hold across all these settings, i.e. we do not assume that any of the functions F, G, F_v, G_z, F_v^* are everywhere finite, but instead work in the domains of these functions.

1.1.1 SIMPLE SPECIAL CASES

Before discussing the implementation and behavior of MOCCA for general nonconvex and/or nonsmooth problems, we pause to illustrate that MOCCA can be viewed as a generalization of many existing techniques.

- If F, G are both convex with easy proximal maps, then we can of course choose the trivial convex families $F_v = F$ and $G_z = G$; the MOCCA algorithm then reduces to the Chambolle-Pock (Chambolle and Pock, 2011) or Primal-Dual Hybrid Gradient (Esser et al., 2009) algorithm (depending on our choice of the extrapolation parameter θ). These methods can handle composite objective functions with convex terms; MOCCA extends these methods to a setting with nonconvex terms.

- In the setting where we want to minimize a function $G(x)$ which is a sum of a convex term and a differentiable term, $G(x) = g(x) + h(x)$, we can show that MOCCA reduces to proximal gradient descent (Nesterov, 2013; Beck and Teboulle, 2009) as a special case. Specifically, we define the approximations $G_z(x) = g(x) + h(z) + \langle \nabla h(z), x - z \rangle$. In this setting there is no F function, and hence no w variable; taking $T = \tau \cdot \mathbf{I}_d$, the steps of Algorithm 1 become

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ G_z(x) + \frac{1}{2\tau} \|x - x_t\|_2^2 \right\} \\ = \arg \min_x \left\{ g(x) + \langle \nabla h(z_t), x \rangle + \frac{1}{2\tau} \|x - x_t\|_2^2 \right\}, \\ z_{t+1} = x_{t+1}, \end{cases}$$

which simplifies to the update scheme

$$x_{t+1} = \text{Prox}_{\tau \cdot g}(x_t - \tau \cdot \nabla h(x_t)). \quad (7)$$

This is exactly the proximal gradient descent algorithm with step size τ .

Proximal gradient descent can handle a function which combines a differentiable term with a convex term as long as the convex term has an easy proximal map; MOCCA extends this method to a setting where the convex terms lack an easy proximal map due to linear transformations, leading to composite optimization problems.

We will discuss other existing methods in more detail later on in Section 3.

1.1.2 STEP SIZE PARAMETERS Σ AND \mathbf{T}

We now turn to the question of choosing the diagonal step size matrices Σ and \mathbf{T} . As we will see later on, good convergence properties are attained when Σ, \mathbf{T} are chosen sufficiently small, to satisfy $\|\Sigma^{1/2}KT^{1/2}\| < 1$ —this condition on Σ and \mathbf{T} is derived by Pock and Chambolle (2011) for the preconditioned CP algorithm, and appears in our theory as well. Here $\|\cdot\|$ is the matrix operator norm (i.e. the largest singular value). To choose matrices that satisfy this requirement, Pock and Chambolle (2011) propose a parametrized family of choices: after fixing some parameter $\lambda > 0$, define²

$$\Sigma_{ii} = \frac{\lambda}{\sum_j |K_{ij}|} \quad \text{and} \quad \mathbf{T}_{jj} = \frac{\lambda^{-1}}{\sum_i |K_{ij}|}. \quad (8)$$

Empirically, we find that higher values of λ are more stable but lead to slower convergence; it seems that the best choice is the smallest possible λ such that the algorithm does not diverge. It may also be interesting to consider varying λ adaptively over the iterations of the algorithm, but we do not study this extension here.

1.1.3 UNDERSTANDING THE CHOICE OF EXPANSION POINTS

We now return to our choice of the expansion points $(z, v) \in \mathbb{R}^d \times \mathbb{R}^m$. We will give an intuition for the choices of these points in the MOCCA algorithm. To examine this question, first consider the goal for optimization: we would like to find

$$x^* \in \arg \min_x \{F(Kx) + G(x)\},$$

or if this problem is nonconvex then we may be satisfied to let x^* be a local minimizer or critical point of this objective function. We then need to find primal points $z \in \mathbb{R}^d$ and $v \in \mathbb{R}^m$, such that replacing F with F_v and G with G_z still yields the same solution, i.e. so that

$$x^* \in \arg \min_x \{F_v(Kx) + G_z(x)\}. \quad (9)$$

Examining the first-order optimality conditions for each of these problems, it follows that we should set $(z, v) = (x^*, Kx^*)$ to ensure that (9) holds.

Of course, x^* is unknown and so we cannot set $(z, v) = (x^*, Kx^*)$. Instead, a logical approach would be to set $(z_i, v_i) = (x_i, Kx_i)$, before solving for (x_{i+1}, w_{i+1}) . Then, hopefully, as x_i converges to x^* we will also have (z_i, v_i) converging to (x^*, Kx^*) . However, in practice, we find that this approach does not always perform as well as expected. Specifically, the problem lies with the choice $v_i = Kx_i$, relative to the primal/dual structure of the algorithm.

To understand why, imagine that F and G are actually convex, but we nonetheless are taking local approximations F_v and G_z (which are also convex). Perhaps for computational reasons. Then we would like our x and w update steps (6) to coincide with the updates (3) of the original CP algorithm. Examining the optimality conditions, this will occur when

$$\partial G(x_{i+1}) = \partial G_{z_i}(x_{i+1}) \quad \text{and} \quad \partial F^*(w_{i+1}) = \partial F_{v_i}^*(w_{i+1}). \quad (10)$$

² In fact these choices for Σ, \mathbf{T} satisfy the matrix norm constraint more weakly, with $\|\Sigma^{1/2}KT^{1/2}\| \leq 1$ rather than a strict inequality, but this is sufficient in practice.

(Here we are ignoring issues of multivalued subdifferentials since our aim is only to give intuition.) Using the definitions of G and G_{z_i} , for the x step our requirement in (10) is equivalent to

$$\nabla(G - G_{z_i})(x_{i+1}) = 0,$$

which will certainly hold if $z_i = x_{i+1}$ by our assumption (4) on the function G_{z_i} . Since we have not yet solved for x_{i+1} , we instead choose the expansion point $z_i = x_i$ for the function G , as previously proposed.

For the w step, our outcome will be different. Subgradients satisfy a duality property, namely, $w \in \partial F(w)$ if and only if $u \in \partial F^*(w)$ for any convex function F and its conjugate F^* . The requirement $\partial F^*(w_{i+1}) = \partial F_{v_i}^*(w_{i+1})$ in (10) therefore yields $w_{i+1} \in \partial F(\partial F_{v_i}^*(w_{i+1}))$ by this duality property, and so we have

$$\begin{aligned} w_{i+1} &\in \partial F(\partial F_{v_i}^*(w_{i+1})) \\ &= \partial F_{v_i}(\partial F_{v_i}^*(w_{i+1})) + \nabla(F - F_{v_i})(\partial F_{v_i}^*(w_{i+1})) \\ &= w_{i+1} + \nabla(F - F_{v_i})(\partial F_{v_i}^*(w_{i+1})) \end{aligned}$$

where the last step again holds from the duality property of subgradients. So, we see that we would like

$$\nabla(F - F_{v_i})(\partial F_{v_i}^*(w_{i+1})) = 0$$

which, according to our assumption (4) on the expansions F_{v_i} , will hold if

$$v_i \in \partial F_{v_i}^*(w_{i+1}).$$

In other words, we would like v_i to be the primal point that corresponds to the dual point w_{i+1} —that is, the primal point that *mirrors* the dual point w_{i+1} . Of course, this is not possible since we have not yet computed w_{i+1} , and furthermore v_i appears on both sides of this equation. Instead, we take $v_i \in \partial F_{v_i-1}^*(w_i)$. Looking at the first-order optimality conditions for the update step for w_i , we see that we can satisfy this expression by choosing

$$v_i = \Sigma^{-1}(w_{i-1} - w_i) + Kx_i \in \partial F_{v_i-1}^*(w_i).$$

In fact, we will see in Section 3.3 that this choice for v_i is very logical in light of the connection between the CP algorithm and the Alternating Direction Method of Multipliers (ADMM) (Boyd et al., 2011).

For the stable form of MOCCA, Algorithm 2, our choice for expansion points (z, v) takes an average over each inner loop, which we will see gives sufficient stability for our convergence results to hold.

1.1.4 CHECKING CONVERGENCE

Here we give a simple way to check whether the basic MOCCA algorithm, Algorithm 1, is near a critical point (e.g. a local minimum). (We treat this question more formally, for the more general Algorithm 2, in our theoretical results later on.) Due to the first-order accuracy of the convex approximations to F and G as specified in (4), a critical point $x \in \mathbb{R}^d$ for the objective function $F(Kx) + G(x)$ is characterized by the first-order condition

$$0 \in K^\top \partial F_{Kx}(Kx) + \partial G_x(x). \quad (11)$$

Equivalently, we can search for a dual variable $w \in \mathbb{R}^m$ such that

$$-K^\top w \in \partial \mathbf{G}_x(x) \quad \text{and} \quad w \in \partial \mathbf{F}_{Kx}(Kx).$$

We can expand this condition to include additional variables $(z, v) \in \mathbb{R}^d \times \mathbb{R}^m$:

$$\begin{cases} -K^\top w \in \partial \mathbf{G}_z(x), \\ w \in \partial \mathbf{F}_v(Kx) \Leftrightarrow Kx \in \partial \mathbf{F}_v^*(w), \\ z = x, \\ v = Kx. \end{cases}$$

To check whether these conditions hold approximately, we can take the following ‘‘optimality gap’’:

$$\text{OptimalityGap}(x, w, z, v) = \left\| -K^\top w - \partial \mathbf{G}_z(x) \right\|_2^2 + \left\| Kx - \partial \mathbf{F}_v^*(w) \right\|_2^2 + \|z - x\|_2^2 + \|v - Kx\|_2^2.$$

Here, if any of the subdifferentials are multivalued, we can interpret these norms as choosing some element of the corresponding subdifferentials. Now we consider the value of this gap at an iteration of the MOCCA algorithm (in its original form, Algorithm 1). By the definitions of $x_{t+1}, w_{t+1}, z_t, v_t$, we can show that

$$\begin{cases} 0 \in K^\top w_t + \partial \mathbf{G}_{z_t}(x_{t+1}) + \mathbf{T}^{-1}(x_{t+1} - x_t), \\ 0 \in -K\bar{x}_{t+1} + \partial \mathbf{F}_{v_t}^*(w_{t+1}) + \Sigma^{-1}(w_{t+1} - w_t), \\ z_t = x_t, \\ v_t = \Sigma^{-1}(w_t - w_{t-1}) + K\bar{x}_t. \end{cases}$$

Therefore, plugging these calculations in to the definition of the optimality gap, we see that

$$\begin{aligned} \text{OptimalityGap}(x_{t+1}, w_{t+1}, z_t, v_t) &= \left\| -K(w_t - w_{t+1}) + \mathbf{T}^{-1}(x_t - x_{t+1}) \right\|_2^2 + \left\| K(x_t - x_{t+1}) + \Sigma^{-1}(w_t - w_{t+1}) \right\|_2^2 \\ &\quad + \|x_t - x_{t+1}\|_2^2 + \left\| K(x_{t-1} - 2x_t + x_{t+1}) + \Sigma^{-1}(w_{t-1} - w_t) \right\|_2^2 \\ &= \mathcal{O} \left(\left\| \begin{pmatrix} x_{t-1} - x_t \\ w_{t-1} - w_t \end{pmatrix} \right\|_2^2 + \left\| \begin{pmatrix} x_t - x_{t+1} \\ w_t - w_{t+1} \end{pmatrix} \right\|_2^2 \right). \end{aligned}$$

In other words, if the change in the variables (x_t, w_t) converges to zero as $t \rightarrow \infty$, then the optimality gap is also converging to zero.

1.1.5 PREVIEW OF THEORETICAL RESULTS

We present two theoretical results in this work. The first is fairly standard in the related literature: in Theorem 1 we show that if the algorithm does converge to a point, then we have reached a critical point of the original optimization problem. (Since the simple form, Algorithm 1, is a special case of the stable form, Algorithm 2, we prove this result for the stable algorithm only.)

The novelty of our theory lies in our convergence guarantee, given in Theorem 2, where we prove that the stable form of MOCCA, given in Algorithm 2, is guaranteed to converge to a nearly-globally-optimal solution, under some assumptions on convexity and curvature. Specifically, we consider a scenario where convexity and nonconvexity in \mathbf{F} and \mathbf{G} counter-balance each other, so that the overall function

$$x \mapsto \mathbf{F}(Kx) + \mathbf{G}(x) \quad (12)$$

is itself either strongly convex or satisfies restricted strong convexity assumptions (which we will discuss in detail in Section 4.2.1). It is important to note that even the globally convex setting is by no means trivial—even if (12) is strongly convex, if \mathbf{F} itself is nonconvex it may be the case that ADMM and other primal/dual or alternating minimization algorithms diverge or converge to the wrong solution, as we discuss later in Section 3.2. Crucially, our results allow \mathbf{F} and \mathbf{G} to be nondifferentiable as well as nonconvex, a setting that is necessary in practice but is not covered by existing theory.

1.1.6 OUTLINE OF PAPER

The remainder of the paper is organized as follows. In Section 2, we present several important applications where the minimization problem considered here, with a nonconvex composite objective function as in (1), arises naturally: regression problems with errors in covariates, isotropic total variation penalties, nonconvex total variation penalties, and image reconstruction problems in computed tomography (CT) imaging. In Section 3 we give background on several types of existing algorithms for convex and nonconvex composite objective functions, and compare a range of existing results to the work presented here. Theoretical results on the convergence properties of our algorithm are given in Section 4. We study the empirical performance of MOCCA in Section 5. Proofs are given in Section 6, with technical details deferred to the Appendix. In Section 7 we discuss our findings and outline directions for future research.

2. Applications

We now highlight several applications of the MOCCA algorithm, in high-dimensional statistics and in imaging.

2.1 Regression with Errors in Variables

Recent work by Loh and Wainwright (2013) considers optimization for nonconvex statistical problems, proving that under some special conditions, nonconvexity may not pose a challenge to recovering optimal parameters. In particular, they consider the following example (Loh and Wainwright, 2011, 2013): suppose that we observe a response $y \in \mathbb{R}^n$ which is generated with a Gaussian linear model,

$$b = Ax_{\text{true}} + \epsilon \quad \text{with} \quad \epsilon \sim \mathcal{N}(0, \sigma^2 \mathbf{I}_n),$$

where $A \in \mathbb{R}^{n \times d}$ is a design matrix and $x_{\text{true}} \in \mathbb{R}^d$ is the unknown vector of coefficients. In this case, we might seek to recover x_{true} with the least squares estimator, perhaps with

some penalty added to promote some desired structure in x ,

$$\begin{aligned} \hat{x} = \arg \min_x & \left\{ \frac{1}{2\eta} \|b - Ax\|_2^2 + \text{Penalty}(x) \right\} \\ & = \arg \min_x \left\{ \frac{1}{2} x^\top \left(\frac{A^\top A}{\eta} \right) x - x^\top \left(\frac{A^\top b}{\eta} \right) + \text{Penalty}(x) \right\}. \end{aligned} \quad (13)$$

In some settings, however, the design matrix A itself may not be known with perfect accuracy. Instead, suppose we observe

$$Z = A + W$$

where $W \perp A$ has independent mean-zero entries, with $\mathbb{E}[W_{ij}^2] = \sigma_A^2$ for all i, j . In this case, a naive approach might be to substitute Z for A in (13), before finding the minimizer. However, unless σ_A^2 is negligible, this may not produce a good approximation to \hat{x} since, when substituting $Z^\top Z$ for $A^\top A$ in the quadratic term in (13), we have

$$\mathbb{E} \left[Z^\top Z \mid A \right] = \mathbb{E} \left[(A + W)^\top (A + W) \mid A \right] = A^\top A + \mathbb{E} \left[W^\top W \right] = A^\top A + n\sigma_A^2 \mathbf{I}_d \neq A^\top A.$$

In contrast, for the linear term in (13), we have $\mathbb{E}[Z^\top b \mid A] = A^\top b$, as desired. To correct for the bias in $Z^\top Z$, we should take

$$\hat{x}_{\text{noisy}} = \arg \min_x \{ \mathcal{L}(x) + \text{Penalty}(x) \},$$

where

$$\mathcal{L}(x) := \frac{1}{2} x^\top \left(Z^\top Z - \sigma_A^2 \mathbf{I}_d \right) x - x^\top \left(Z^\top b \right).$$

Of course, this optimization problem is no longer convex due to the negative quadratic term, and in particular, for a Lipschitz penalty and a high-dimensional setting ($n < d$), the value tends to $-\infty$ as x grows large in any direction in the null space of Z . Remarkably, Loh and Wainwright (2013) show that, if x_{true} is sparse and $\text{Penalty}(x)$ is similar to the ℓ_1 norm, then as long as $(Z^\top Z)$ satisfies a restricted strong convexity assumption (as is standard in the sparse regression literature), then x_{true} can be accurately recovered from *any* local minimum or critical point of the constrained optimization problem

$$\hat{x}_{\text{noisy}} = \arg \min_{\|x\|_1 \leq R} \{ \mathcal{L}(x) + \text{Penalty}(x) \}. \quad (14)$$

The approach taken by Loh and Wainwright (2013) is to perform proximal gradient descent, with steps taking the form

$$x_{t+1} = \arg \min_{\|x\|_1 \leq R} \left\{ \frac{1}{2} \left\| x - \left(x_t - \frac{1}{\eta} \nabla \mathcal{L}(x_t) \right) \right\|_2^2 + \frac{1}{\eta} \text{Penalty}(x) \right\}$$

where $\frac{1}{\eta}$ is a step size parameter. When $\text{Penalty}(x)$ is (some multiple of) the ℓ_1 norm, or some other function with a simple proximal operator (that is, it is simple to compute $\arg \min_x \{ \frac{1}{2} \|x - z\|_2^2 + \text{Penalty}(x) \}$ for any z), this algorithm is very efficient.

2.1.1 TOTAL VARIATION AND GENERALIZED CONVEX ℓ_1 PENALTIES

Consider a setting where the penalty term in (14) is given by a generalized ℓ_1 norm,

$$\text{Penalty}(x) = \nu \cdot \|Kx\|_1$$

for some matrix $K \in \mathbb{R}^{m \times d}$. In particular, if K is the one-dimensional differences matrix $\nabla_{1d} \in \mathbb{R}^{(d-1) \times d}$, which has entries $(\nabla_{1d})_{ii} = 1$ and $(\nabla_{1d})_{i,i+1} = -1$ for each i , then this defines the (one-dimensional) total variation norm on x , $\|x\|_{\text{TV}} = \|\nabla_{1d} x\|_1$; this method is also known as the fused Lasso (Tibshirani et al., 2005). We can also consider a two- or three-dimensional total variation norm, $K = \nabla_{2d}$ or $K = \nabla_{3d}$, defined analogously as the differences matrix for a two- or three-dimensional grid. Total variation type penalties are commonly used in imaging applications and many other fields to obtain solutions that are locally constant or locally smooth.

In this setting, proximal gradient descent is not practical except in some special cases, such as when K is diagonal, because the proximal operator $\arg \min_x \{ \frac{1}{2} \|z - x\|_2^2 + \nu \cdot \|Kx\|_1 \}$ does not have a closed form solution for general K and would itself require an iterative algorithm to be run to convergence. For a total variation penalty on a one-dimensional grid of points, e.g. $K = \nabla_{1d}$, some fast algorithms do exist for the proximal map (Johnson, 2013). Additional methods for convex problems with two-dimensional total variation and related penalties such as total variation over a graph can be found in Chambolle and Darbon (2009); Wang et al. (2014b, 2015b). We are not aware of a non-iterative algorithm for general K . Here we apply MOCCA to allow for arbitrary K and for a nonconvex loss term $\mathcal{L}(x)$.

2.1.2 APPLYING THE MOCCA ALGORITHM

We consider applying the MOCCA algorithm to this nonconvex optimization problem with $\text{Penalty}(x) = \nu \|Kx\|_1$. We define the convex function

$$F(w) = \nu \|w\|_1$$

with the trivial convex approximations $F_\nu(w) = F(w)$ at any expansion point $v \in \mathbb{R}^m$. We also let

$$G(x) = \begin{cases} \mathcal{L}(x), & \text{if } \|x\|_1 \leq R, \\ +\infty, & \text{if } \|x\|_1 > R, \end{cases}$$

with convex approximations given by taking the linear approximation to the loss,

$$G_z(x) = \begin{cases} \mathcal{L}(z) + \langle x - z, \nabla \mathcal{L}(z) \rangle, & \text{if } \|x\|_1 \leq R, \\ +\infty, & \text{if } \|x\|_1 > R, \end{cases}$$

for any expansion point $z \in \mathbb{R}^d$. Then the optimization problem (14) can be expressed as

$$\hat{x}_{\text{noisy}} = \arg \min_x \{ F(Kx) + G(x) \}.$$

Applying Algorithm 1, the update steps take the form

$$\begin{cases} x_{t+1} = \arg \min_{\|x\|_1 \leq R} \left\{ \|x - [x_t - \nabla(\mathcal{L}(x_t) + K^\top w_t)]\|_{l_1}^2 \right\}, \\ w_{t+1} = \text{Truncate}_\nu(w_t + \Sigma \hat{K} x_{t+1}), \\ z_{t+1} = x_{t+1}. \end{cases} \quad (15)$$

where $\text{Truncate}_\nu(w)$ truncates the entries of the vector w to the range $[-\nu, \nu]$. Note that the x update step is a simple shrinkage step and therefore easy to solve (and $\nabla \mathcal{L}(x_t)$ is simple to compute), while the w and z updates are computationally trivial.

As a second option, we can incorporate more convexity into our approximations \mathbf{G}_z by taking

$$\mathbf{G}_z(x) = \begin{cases} \mathcal{L}(x) + \frac{\sigma_z^2}{2} \|x - z\|_2^2, & \text{if } \|x\|_1 \leq R, \\ +\infty, & \text{if } \|x\|_1 > R, \end{cases}$$

which is convex since $\mathcal{L}(x)$ has negative curvature bounded by $\frac{\sigma_z^2}{2}$. In this case, after simplifying, our update steps become

$$\begin{cases} x_{t+1} = \arg \min_{\|x\|_1 \leq R} \left\{ \left\| x - \left[x_t - \left(\mathbf{T}^{-1} + \frac{z^T z}{n} \right)^{-1} (\nabla \mathcal{L}(x_t) + K^T w_t) \right] \right\|_{\left(\mathbf{T}^{-1} + \frac{z^T z}{n} \right)} \right\}^2, \\ w_{t+1} = \text{Truncate}_\nu(w_t + \Sigma K \bar{x}_{t+1}), \\ z_{t+1} = x_{t+1}. \end{cases} \quad (16)$$

While the x update step may appear difficult due to the combination of the non-diagonal matrix $\left(\mathbf{T}^{-1} + \frac{z^T z}{n} \right)$ which scales the norm, combined with the ℓ_1 constraint, in practice the constraint R is chosen to be large so that it is inactive in all or most steps; the x update step is then solved by $x_{t+1} = x_t - \left(\mathbf{T}^{-1} + \frac{z^T z}{n} \right)^{-1} (\nabla \mathcal{L}(x_t) + K^T w_t)$.

An important point is that MOCCA can be applied to this problem for arbitrary K , including a difference operator such as \mathbf{V}_{2d} or \mathbf{V}_{3d} ; in contrast, proximal gradient descent can only be performed approximately except for certain special cases, as mentioned above. We explore this setting's theoretical properties in Section 4.2.3, and give empirical results for this problem in Section 5.

2.2 Isotropic Total Variation and Generalized ℓ_1/ℓ_2 Penalties

For locally constant images or signals in two dimensions, the form of the total variation penalty given above is known as ‘anisotropic’, meaning that it imposes a sparsity pattern which is specific to the alignment of the image onto a horizontal and vertical axis. In contrast, the isotropic total variation penalty (Rudin et al., 1992), on an image x parametrized with values $x_{i,j}$ at grid location (i, j) , is given by

$$\|x\|_{\text{isoTV}} = \sum_{(i,j)} \sqrt{(x_{i,j} - x_{i,j+1})^2 + (x_{i,j} - x_{i+1,j})^2}.$$

Optimization methods for the denoising problem with an isotropic total variation penalty, i.e. problems of the form $\min_x \left\{ \frac{1}{2} \|b - x\|_2^2 + \nu \cdot \|x\|_{\text{isoTV}} \right\}$, were studied in Chambolle and Pock (2015). In practice the isotropic penalty is often preferred as it leads to smoother contours, avoiding the artificial horizontal or vertical edges that may result from anisotropic total variation regularization.

The isotropic total variation penalty can be generalized to penalties of the form

$$\text{Penalty}(x) = \nu \cdot \sum_{\ell=1}^L \|K_\ell x\|_2,$$

where each $K_\ell \in \mathbb{R}^{m_\ell \times d}$ is some fixed matrix. To see how this determines an isotropic total variation penalty in two dimensions, we let ℓ index all locations (i, j) ; then the corresponding matrix K_ℓ has two rows, which when multiplying the image x , extracts the differences $x_{i,j} - x_{i,j+1}$ and $x_{i,j} - x_{i+1,j}$. To see how this specializes to the usual generalized ℓ_1 penalty, $\|Kx\|_1$ for some fixed matrix $K \in \mathbb{R}^{m \times d}$, simply take K_ℓ to be the ℓ th row of the matrix K for each $\ell = 1, \dots, m$.

2.2.1 APPLYING THE MOCCA ALGORITHM

We now show the steps of the MOCCA algorithm to the problem of minimizing

$$\mathcal{L}(x) + \nu \cdot \sum_{\ell=1}^L \|K_\ell x\|_2, \quad (17)$$

where $\mathcal{L}(x)$ is a differentiable likelihood term (such the nonconvex likelihood for regression with errors in variables as above). We define the matrix K by vertically stacking the K_ℓ 's, and define the convex function

$$\mathbf{F}(w) = \nu \cdot \sum_{\ell=1}^L \|w_{B_\ell}\|_2,$$

where w_{B_ℓ} is understood to be the ℓ th block of the vector w , i.e.

$$w_{B_\ell} = (w_{m_1+\dots+m_{\ell-1}+1}, \dots, w_{m_1+\dots+m_\ell}).$$

We take the trivial convex approximations $\mathbf{F}_v(w) = \mathbf{F}(w)$ at any expansion point $v \in \mathbb{R}^m$, and define $\mathbf{G}(x)$ and $\mathbf{G}_z(x)$ exactly as before (as for the previous application, we allow the option of restricting to $\|x\|_1 \leq R$ if desired). Then the objective function (17) is equivalent to minimizing $\mathbf{F}(Kx) + \mathbf{G}(x)$.

Applying Algorithm 1, the update steps take the form

$$\begin{cases} x_{t+1} = \arg \min_{\|x\|_1 \leq R} \left\{ \|x - [x_t - \mathbf{T}(\nabla \mathcal{L}(x_t) + K^T w_t)]\|_{\mathbf{T}^{-1}} \right\}^2, \\ w_{t+1} = \text{Truncate}_{\nu, (\mathbb{B}_{m_1} \times \dots \times \mathbb{B}_{m_L})} (w_t + \Sigma K \bar{x}_{t+1}), \\ z_{t+1} = x_{t+1}, \end{cases}$$

where $\text{Truncate}_{\nu, (\mathbb{B}_{m_1} \times \dots \times \mathbb{B}_{m_L})}(w)$ projects each block $w_{B_\ell} \in \mathbb{R}^{m_\ell}$ of the vector w to the ball of radius ν , $\nu \cdot \mathbb{B}_{m_\ell} \subseteq \mathbb{R}^{m_\ell}$ (here \mathbb{B}_{m_ℓ} is the unit ball of dimension m_ℓ in the ℓ_2 norm). Specifically, the w update step can be computed for each block as

$$(w_{t+1})_{B_\ell} = (w_t + \Sigma K \bar{x}_{t+1})_{B_\ell} \cdot \min \left\{ 1, \frac{\nu}{\|(w_t + \Sigma K \bar{x}_{t+1})_{B_\ell}\|_2} \right\}$$

for each $\ell = 1, \dots, L$, and is therefore trivial to compute.

2.3 Nonconvex Total Variation Penalties

As discussed in Section 2.1, total variation penalties are common in many applications where the underlying signal exhibits smooth or locally constant spatial structure (in one, two, or more dimensions). In convex optimization, we are faced with a well-known tradeoff between sparsity and bias—using $\nu \cdot \|x\|_{\text{TV}}$ as our penalty function for some parameter $\nu > 0$, we want to be sure to choose ν large enough that the resulting solution is total-variation-sparsity, to avoid overfitting when the sample size is small relative to the dimension of the image; however, larger ν leads to increased shrinkage of the signal, leading to an estimate that is biased towards zero. One way to avoid this tradeoff is to use a nonconvex penalty, which should behave like the total variation norm in terms of promoting sparsity, but reduce the amount of shrinkage for larger signal strength. In this section, we will use ∇_{TV} to denote the differences matrix in the appropriate space (e.g. $\nabla_{\text{TV}} = \nabla_{2d}$ in two dimensions), so that $\|x\|_{\text{TV}} = \|\nabla_{\text{TV}}x\|_1$.

For sparse regression problems (i.e. where the signal x is itself sparse, rather than sparsity in $\nabla_{\text{TV}}x$), many nonconvex alternatives to the ℓ_1 norm penalty $\|x\|_1$ have been studied, demonstrating more accurate signal recovery empirically as well as theoretical properties of reduced bias, such as the Smoothly Clipped Absolute Deviation (SCAD) penalty (Fan and Li, 2001), the ℓ_q penalty which penalizing $\sum_i |x_i|^q$ for some $q \in (0, 1)$ (Knight and Fu, 2000; Chartrand, 2007), and the Minimax Concave Penalty (MCP) which seeks to minimize concavity while avoiding bias (Zhang, 2010). Another option is to use a reweighted ℓ_1 norm (Candès et al., 2008), where signals estimated to be large at the first pass are then penalized less in the next pass to reduce bias in their estimates; in fact, Candès et al. (2008) show that this procedure is related to a nonconvex log-sum penalty, given by penalizing each component of x_i as $\log(|x_i| + \epsilon)$ for some fixed $\epsilon > 0$. For the problem of total variation sparsity, a variety of nonconvex approaches have also been studied, including applying SCAD (Chopra and Lian, 2010), an ℓ_q norm penalty for $0 < q < 1$ (Sidky et al., 2014; Lu and Hwang, 2014), or a log-sum total variation penalty (Selesnick et al., 2015; Parekh and Selesnick, 2015) to the total variation sparsity setting.

We now consider the problem applying a log-sum penalty to the problem of total variation sparsity. Here we consider the form of this penalty given by

$$\log \text{TV}_{\beta}(x) = \log \mathbb{L}_{\beta}(\nabla_{\text{TV}}x) \text{ where } \log \mathbb{L}_{\beta}(w) = \sum_i \beta \log(1 + |w_i|/\beta),$$

where $\beta > 0$ is a nonconvexity parameter. (We can also consider applying this nonconvex penalty to the isotropic version of total variation, as discussed in Section 2.2, but for simplicity we do not give that version explicitly here.)

To understand this function, observe that for any t , the function

$$t \mapsto \beta \log(1 + |t|/\beta)$$

is approximately equal to $|t|$ when $t \approx 0$ (that is, near zero it behaves like the ℓ_1 norm), but is nonconvex and penalizes large values of t much less heavily than an absolute value penalty of $|t|$. The parameter β controls the amount of nonconvexity: small β gives a highly nonconvex penalty, while for large β the penalty is nearly convex, with $\log \text{TV}_{\beta}(x) \approx \|x\|_{\text{TV}}$; see Figure 1 for an illustration.

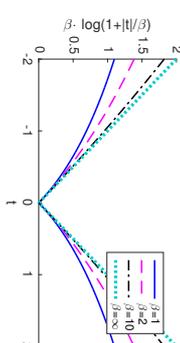

Figure 1: Illustration of the nonconvex sparsity-promoting penalty discussed in Section 2.3. The figure plots the function $t \mapsto \beta \cdot \log(1 + |t|/\beta)$ across a range of values of t , for $\beta \in \{1, 2, 10, \infty\}$; for $\beta = \infty$, we should interpret this as the absolute value function, $t \mapsto |t|$. We see that all the functions appear similar for $t \approx 0$, with a nondifferentiable point at $t = 0$ which ensures sparsity when this function is used as a penalty. For larger values of t , smaller values of β correspond to greater nonconvexity.

Consider the problem of minimizing an objective function

$$\mathcal{L}(x) + \nu \cdot \log \text{TV}_{\beta}(x), \quad (18)$$

where $\mathcal{L}(x)$ is some likelihood or loss term. In the image denoising setting, where $\mathcal{L}(x) = \frac{1}{2} \|y - x\|_2^2$ (i.e. when y is a noisy observation of the signal x), Parekh and Selesnick (2015) approach this optimization problem with a majorization/minimization algorithm, iterating the steps: (1) find a majorization of $\log \text{TV}_{\beta}(x)$ at the current estimate x_n , which takes the form of a reweighted TV norm, (2) compute x_{n+1} as the minimizer of $\mathcal{L}(x) + \nu \cdot$ (the majorized penalty). In other settings, however, for a general loss $\mathcal{L}(x)$, step (2) may not be possible.

We now show how the MOCCA algorithm can be used to optimize objective functions of the form (18). For simplicity we show the steps for the case that $\mathcal{L}(x)$ is convex and has a simple proximal operator, but this can be generalized as needed.

First, we define a new function

$$h_{\beta}(w) = \log \mathbb{L}_{\beta}(w) - \|w\|_1 = \sum_i \beta \log(1 + |w_i|/\beta) - \|w\|_1.$$

We note an important property of this function: $h_{\beta}(w)$ is differentiable with $(\nabla h_{\beta}(w))_i = \frac{-\frac{w_i}{|w_i|}}{\beta + |w_i|}$. For a first approach, we will take

$$F(w) = \nu \cdot \log \mathbb{L}_{\beta}(w) \text{ and } G(x) = \mathcal{L}(x).$$

Now we define a local convex approximation to F by writing $F(w) = \nu (\|w\|_1 + h_{\beta}(w))$ and taking the linear approximation to h_{β} , namely,

$$F_v(w) = \nu \cdot \|w\|_1 + \nu [h_{\beta}(v) + \langle w - v, \nabla h_{\beta}(v) \rangle].$$

And, since by assumption $\mathcal{L}(x)$ is convex and has a simple proximal operator, we can simply define

$$\mathbf{G}_z(x) = \mathbf{G}(x) = \mathcal{L}(x).$$

Then the objective function (18) is equal to $\mathbf{F}(\nabla_{\text{TV}}x) + \mathbf{G}(x)$, and can be minimized with MOCCA. Applying Algorithm 1, the update steps take the form

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ \mathcal{L}(x) + \frac{1}{2} \|x - [x_t - \text{TV}_{\text{TV}}^{\top} w_t]\|_{\Gamma^{-1}}^2 \right\}, \\ w_{t+1} = \text{Truncate}_{\nu} (w_t + \Sigma \nabla_{\text{TV}} \bar{x}_{t+1} - \nu \nabla h_{\beta}(v_t)) + \nu \nabla h_{\beta}(v_t), \\ v_{t+1} = \Sigma^{-1}(w_t - w_{t+1}) + K \bar{x}_{t+1}. \end{cases}$$

Of course, we have the flexibility to arrange the functions differently if we wish—for example, we could instead define

$$\mathbf{F}(w) = \nu \cdot \|w\|_1 \quad \text{and} \quad \mathbf{G}(x) = \mathcal{L}(x) + \nu \cdot h_{\beta}(\nabla_{\text{TV}}x).$$

In this case, we will define the local approximations as

$$\mathbf{F}_v(w) = \mathbf{F}(w) = \nu \cdot \|w\|_1$$

and

$$\mathbf{G}_z(w) = \mathcal{L}(x) + \nu [h_{\beta}(\nabla_{\text{TV}}z) + \langle \nabla_{\text{TV}}(x - z), \nabla h_{\beta}(\nabla_{\text{TV}}z) \rangle].$$

In this case the objective function (18) is equal to $\mathbf{F}(\nabla_{\text{TV}}x) + \mathbf{G}(x)$ as before. In this case, the update steps are

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ \mathcal{L}(x) + \frac{1}{2} \|x - [x_t - \text{TV}_{\text{TV}}^{\top}(\nu \nabla h_{\beta}(\nabla_{\text{TV}}z_t) + w_t)]\|_{\Gamma^{-1}}^2 \right\}, \\ w_{t+1} = \text{Truncate}_{\nu} (w_t + \Sigma \nabla_{\text{TV}} \bar{x}_{t+1}), \\ z_{t+1} = x_{t+1}. \end{cases}$$

However, in a sense this decomposition is less natural as it splits the penalty $\log \text{TV}_{\beta}(x)$ across \mathbf{F} and \mathbf{G} , and in fact in our experiments in Section 5, we will see that this second formulation gives poorer convergence results when the MOCCA algorithm is applied.

2.4 Application to CT Image Reconstruction

The initial motivation for developing the algorithm presented here, is a problem arising in computed tomography (CT) imaging. Here we briefly summarize the problem and our approach via the MOCCA algorithm; we describe this setting fully, and give detailed results, in Barber et al. (2016).

In CT imaging, an X-ray beam is sent along many rays through the object of interest. Typically, the measurement is the total energy that has passed through the object, along each ray; comparing the energy retrieved against the energy of the entering X-ray beam, gives information about the materials inside the object, since different materials have different beam attenuation properties. A recent technological development is the photon counting

detector, which measures the raw number of photons that successfully pass through the object rather than the total integrated energy. As a first pass, this transmission model can be written as follows, where the location $\vec{r}_{\ell}(t)$ inside the object parametrizes the ray ℓ :

$$\text{Count}_{\ell} \sim \text{Poisson} \left(\int_{\text{energy } E} \left(\frac{\text{beam intensity at energy } E}{\text{detector sensitivity (to energy } E)} \right) \cdot \exp \left\{ - \int_t \mu(E, \vec{r}_{\ell}(t)) dt \right\} dE \right), \quad (19)$$

where the only unknowns are the coefficients $\mu = (\mu(E, \vec{r}))$, indexed over energy level E and location \vec{r} inside the object. Here $\mu(E, \vec{r})$ is the attenuation for photons at energy E at the location \vec{r} —higher values of $\mu(E, \vec{r})$ indicate that a photon (at energy E) is more likely to be absorbed (at location \vec{r}). The expression $\exp\{-\int_t \mu(E, \vec{r}_{\ell}(t)) dt\}$ determines, for a photon at energy E that enters the object along the trajectory defined by ray ℓ , the probability that the photon will not be absorbed by the object (i.e. will pass through the object). These coefficients $\mu(E, \vec{r})$ can be further decomposed as

$$\mu(E, \vec{r}) = \sum_{\text{materials } m} \mu_m(E) \cdot x_m(\vec{r}) \quad (20)$$

where $\mu_m(E)$ is a known quantity determining the absorption properties of material m at energy E , while $x_m(\vec{r})$ is unknown, representing the amount of material m that is present at location \vec{r} . In practice, the object space is discretized into pixels, so that x is finite-dimensional.

In this application, the optimization problem is then given by

$$\hat{x} = \arg \min_x \left\{ \mathcal{L}(x) + \sum_{\text{materials } m} (\text{total variation constraint on material map } x_m) \right\},$$

perhaps with other constraints added as well (e.g. nonnegativity of the material maps). Here $\mathcal{L}(x)$ is the negative log-likelihood of x given the Poisson model for the observed photon counts as a function of x , given by (19) and (20). $\mathcal{L}(x)$ is a nonconvex function due to the integration across energy levels. Both $\mathcal{L}(x)$ and the total variation constraints are better represented as functions of linear transformations of x ; the presence of these multiple terms, including nonconvexity (from \mathcal{L}) and nondifferentiability (from total variation), mean that existing methods cannot be applied to solve this optimization problems.

The MOCCA algorithm, applied to this problem, gives strong performance in terms of fast convergence and accurate image reconstruction on simulated and real imaging data. We do not give the details of the algorithm implementation or any empirical results in this paper, but instead refer the reader to our work in Barber et al. (2016) for more details on the method and for empirical results on simulated CT image data (results on real data are forthcoming).

3. Background: Optimizing Convex and Nonconvex Composite Functions

In this sections, we give background on several related algorithms for solving the minimization problem in the simpler setting where \mathbf{F} and \mathbf{G} are convex, and in the more challenging nonconvex setting.

3.1 Optimization When F is Convex

When F is convex, a variety of existing methods are available to recover the (possibly non-unique) minimizer

$$x^* = \arg \min \{F(Kx) + G(x)\}.$$

In many settings, the functions F and G may each have easily computable proximal operators, but the linear transformation inside $x \rightarrow F(Kx)$ might make the function difficult to optimize directly—for example, we might have $F(u) = \|u\|_1$ with $K = \nabla_{2d}$ chosen so that $F(Kx) = \|x\|_{TV}$, the two-dimensional total variation norm of x . For this type of setting, the Alternating Direction Method of Multipliers (ADMM) reframes the problem as

$$(x^*, u^*) = \arg \min_{x, u} \{F(u) + G(x) : Kx = u\}$$

and solves for (x^*, u^*) by working with the augmented Lagrangian

$$\min_{x, u} \max_{\Delta} L(x, u, \Delta) = \left\{ F(u) + G(x) + \langle \Delta, Kx - u \rangle + \frac{\rho}{2} \|Kx - u\|_2^2 \right\}.$$

Here $\Delta \in \mathbb{R}^m$ is the dual variable whose role is to enforce the constraint $Kx = u$. The steps of the algorithm are, for each $t \geq 1$,

$$\begin{cases} x_t = \arg \min_x \{L(x, u_{t-1}, \Delta_{t-1})\}, \\ u_t = \arg \min_u \{L(x_t, u, \Delta_{t-1})\}, \\ \Delta_t = \Delta_{t-1} + \rho(Kx_t - u_t). \end{cases}$$

Examining the update step for for u , we see that this step entails a single use of the proximal map for F. However, the x update step is more complicated due to the linear operator K ; this step cannot be solved with one use of the proximal map for G, except in the special case that $K^T K$ is a multiple of the identity matrix. To resolve this, we can add additional curvature to the x update step:

$$x_t = \arg \min_x \left\{ L(x, u_{t-1}, \Delta_{t-1}) + \frac{1}{2} (x - x_{t-1})^T (\lambda \mathbf{I} - \rho K^T K) (x - x_{t-1}) \right\},$$

where $\lambda \geq \rho \|K\|^2$. In this setting, the x update step now becomes solvable with the proximal map for G. In fact, this preconditioned form of the ADMM algorithm is equivalent to the CP algorithm (3); for details of the equivalence, see Chambolle and Pock (2011).

In addition to the ADMM and CP algorithms, and their variants, we mention one other option here. If F is differentiable, then proximal gradient descent offers a simple procedure, alternating between taking a gradient descent step on the term $F(Kx)$ and a proximal operator step on G. As we discussed in Section 1.1.1, the proximal gradient descent algorithm can be viewed as a simple special case of MOCCA (in that section, the terms were arranged slightly differently, with both differentiable and convex terms all included in G, but the scenarios are equivalent). Of course, this type of method cannot handle scenarios with a non-differentiable F, which can arise through total variation penalties and in other settings.

3.2 The Issue of Nonconvexity

Next, we turn to the setting where F and/or G may be nonconvex.

To begin, we consider the following interesting scenario, introduced in Section 1: suppose that G is itself convex, with trivial approximations $G_2 = G$, and that $x \rightarrow F(Kx)$ is strictly convex even though F is nonconvex. Since $x \rightarrow F(Kx) + G(x)$ is therefore strictly convex, the optimization problem has a unique global minimizer $x^* \in \mathbb{R}^d$. However, since F itself is nonconvex, then the strategies for optimization described in Section 3.1 may not be directly applicable for the task of finding x^* .

Here we outline the difficulties faced by the main existing approaches outlined in Section 3.1 for settings where F and/or G are nonconvex (including the scenario outlined above), and summarize the most relevant results in the literature.

To see this, first consider the ADMM algorithm. Suppose that F is nonconvex, and in particular, for some vector $w \in \mathbb{R}^m$, the function $s \mapsto F(s \cdot w)$ is strongly concave—specifically,

$$F(s \cdot w) \leq C - c \cdot s^2 \tag{21}$$

for some $C < \infty, c > 0$ and all $s > 0$. Then we see that the update step

$$u_t = \arg \min_u \{L(x_t, u, \Delta_{t-1})\}$$

is not well-defined: the function $u \rightarrow L(x_t, u, \Delta_{t-1})$ diverges to $-\infty$ when we set $u = s \cdot w$ and let $s \rightarrow \infty$. Therefore, for some types of nonconvex functions, the ADMM algorithm will not be implementable due to this divergence.

In the literature, theoretical guarantees for the performance of ADMM on nonconvex objective functions have been considered under several different settings. Broadly speaking, we can summarize existing work as falling into one of two categories. First, there are settings where the original form of the ADMM updates perform well. For instance, Magidson et al. (2015) proves convergence results (for a slightly different algorithm) when optimization is over a bounded set, thus avoiding the issue of divergence arising from directions of strong concavity in F as mentioned above; this paper also proves results guaranteeing optimality of any limit point, if one exists, in the unbounded optimization setting, but does not guarantee that a limit point is reached. In Li and Pong (2015), convergence results are proved assuming that one of the two terms (i.e. F or G) is smooth; in contrast, for the applications considered here, including total variation type penalties incorporated into F or hard constraints in G, it is critical to allow for nondifferentiable F and G. The special case of applying ADMM to nonconvex consensus problems is considered by Hong et al. (2016), with convergence guarantees again in a bounded setting, in this case assuming that any nonconvex functions must obey a lower bound.

Second, when the original ADMM updates cannot be expected to perform well—if for instance F has directions of strong concavity—then the ADMM can be modified by adding curvature to each update via a Bregman divergence term, as studied by Wang et al. (2014a) (with extensions to multi-block ADMM, with more than two terms in the objective function (Wang et al., 2015a)). This work proves convergence guarantees for the algorithm, but requires that the function F (after converting to our notation) is differentiable and smooth, in contrast to our work where allowing for nondifferentiable F is critical.

Next, consider the CP algorithm. When F is nonconvex, it is no longer the case in general that $F(Kx) = \max_w \{ \langle Kx, w \rangle - F^*(w) \}$. In fact, by definition of conjugate functions, this maximum defines the “conjugate of the conjugate”, i.e.

$$F^{**}(Kx) = \max_w \{ \langle Kx, w \rangle - F^*(w) \}.$$

It is known that any conjugate function must be convex, i.e. F^{**} is convex. This implies that $F^{**} \neq F$. Therefore, the saddle-point problem does not correspond to the original optimization problem: we have

$$\min_x \max_w \{ \langle Kx, w \rangle - F^*(w) + G(x) \} = \min_x \{ F^{**}(Kx) + G(x) \},$$

which is different from the original optimization problem since $F^{**} \neq F$. If $F^*(w)$ and $F^{**}(w)$ take finite values on some domain, then the CP algorithm can be expected to converge, but it will converge to the solution of an optimization problem that is different from the one intended due to the issue that $F^{**} \neq F$. Problems also arise in a setting where F exhibits negative curvature as in (21), in which case $F^*(w) = \infty$ for all w , so we do not have a well-defined saddle point problem to begin with.

To our knowledge, no general results exist for the CP algorithm with nonconvex and nondifferentiable F and/or G . Valkonen (2014) considers an interesting related problem, namely, a variant of the CP algorithm, where the objective function is now $F(\mathcal{K}(x)) + G(x)$, for convex F, G but with a nonlinear map $\mathcal{K}(x)$ in place of the previous linear map Kx , as the argument to F . In this case, convergence to a stationary point is proved, even when the nonlinearity of $\mathcal{K}(x)$ may make the overall problem nonconvex. Relatedly, Ochs et al. (2015) study the setting where $F(\mathcal{K}(x))$ is a nonconvex elementwise penalty on the convex transform $\mathcal{K}(x)$ while G is convex; their approach uses the CP algorithm as a subroutine for solving convex approximations of the objective function, at each step.

Next, we consider the option of proximal gradient descent, in the case that G has a simple proximal operator. Loh and Wainwright (2013) study penalized likelihood problems,

$$\min_x \{ \mathcal{L}(x) + \text{Penalty}(x) \},$$

where the likelihood term $\mathcal{L}(x)$ and/or the penalty term $\text{Penalty}(x)$ may exhibit nonconvexity. In many settings that arise in high-dimensional statistics, for instance, the likelihood term $\mathcal{L}(x)$ may be strongly concave in some directions, but will be strongly convex in all “plausible” directions, that is, all directions x that are not prohibited by the penalty term $\text{Penalty}(x)$. For instance, if $\text{Penalty}(x)$ is a sparsity-promoting penalty, with low values only at solutions x with many (near-zero) values, then $\mathcal{L}(x)$ might be strongly convex in all sparse directions. This relates to the notion of *restricted strong concavity*, introduced by Negalban et al. (2009), which we discuss in greater detail in Section 4.2.1. Under restricted convexity and smoothness assumptions on the likelihood term, and with bounds on the amount of nonconvexity allowed in the penalty term, Loh and Wainwright (2013) prove convergence to a point that is near the global optimum, for a proximal gradient descent method, with some additional details restricting steps to a bounded set to avoid diverging towards directions of strong concavity. Ochs et al. (2014)’s iPiano method gives an inertial (i.e. accelerated) proximal gradient descent method for this same setting where the loss is

differentiable with the penalty has an easy proximal map. The (accelerated) proximal gradient descent method for nonconvex problems is studied also by Ghadimi and Lan (2016); Li and Lin (2015). Note that these algorithms are applicable only when the terms in the objective function are all either differentiable (the likelihood) or have an easy-to-compute proximal operator (the penalty), and therefore, cannot be applied to many of the problems that that we have considered.

Finally, Bolte et al. (2014) propose an algorithm, Proximal Alternating Linearized Minimization (PALM), to solve a related problem of the form

$$\min_{x,w} \{ F(w) + G(x) + H(w, x) \}, \quad (22)$$

where H is differentiable while F, G each have easy to compute proximal maps (and may be nonconvex); this formulation is related to the problem we study, but PALM cannot be used to solve general problems of the form $F(Kx) + G(x)$ where F is nondifferentiable (since, if we add a variable $w = Kx$, the constraint $w = Kx$ cannot be enforced with any differentiable function $H(w, x)$ unless we allow modifications such as a relaxation to a penalty on $\|w - Kx\|_2^2$), and therefore again cannot be applied to some of the problems considered here.

3.3 Connection Between MOCCA and ADMM

In the convex setting, the CP method with parameter $\theta = 1$ is known to be equivalent to a preconditioned ADMM algorithm (Chambolle and Pock, 2011). Specifically, reformulating the original optimization problem in the ADMM form

$$\min_{x,u} \{ F(u) + G(x) : u = Kx \} = \min_{x,u} \max_{\Delta} \left\{ F(u) + G(x) + \langle \Delta, Kx - u \rangle + \frac{1}{2} \|Kx - u\|_2^2 \right\},$$

the CP iterations given in (3) are equivalent to the following preconditioned ADMM iterations, where we choose a preconditioning matrix $T^{-1} = K^T \Sigma K \succeq 0$:

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ G(x) + \langle K^T \Delta_t, x \rangle + \frac{1}{2} \|Kx - u_t\|_2^2 + \frac{1}{2} \|x - x_t\|_{T^{-1} - K^T \Sigma K}^2 \right\}, \\ \Delta_{t+1} = \Delta_t + \Sigma(Kx_{t+1} - u_t), \\ u_{t+1} = \arg \min_u \left\{ F(u) - \langle \Delta_{t+1}, u \rangle + \frac{1}{2} \|Kx_{t+1} - u\|_2^2 \right\}, \end{cases}$$

(Here we use a slightly nonstandard indexing, writing the variable updates in the order x, Δ, u for later convenience.) We do not derive the equivalence here (see Chambolle and Pock, 2011, for details), but remark that the variables (x_t, u_t) at iteration t of the CP algorithm (3) can be recovered by taking $(x_t, \Sigma(Kx_t - u_t) + \Delta_t)$ from the ADMM iterations.

Similarly, in the more general nonconvex setting considered here, we can equivalently formulate the MOCCA method as a combination of the preconditioned ADMM iterations and taking convex expansions to F and G . The steps are given in Algorithm 3. This algorithm is exactly equivalent to the basic version of MOCCA, Algorithm 1, with extrapolation parameter $\theta = 1$, but is expressed as an ADMM type algorithm with preconditioning and with convex approximations to F and G . (The stable “inner loop” version of MOCCA, Algorithm 2, can also be interpreted as an extension of ADMM, but we do not give details here). The

equivalence between Algorithms 1 and 3 is simply an extension of the connection between the Chambolle-Pock algorithm and a preconditioned ADMM, as shown in Chambolle and Pock (2011).

Algorithm 3 MOCCA algorithm: ADMM version

Input: Convex functions $F_{\text{cov}}, G_{\text{cov}}$, differentiable functions $F_{\text{diff}}, G_{\text{diff}}$, linear operator K , positive diagonal step size matrices Σ, Γ .

Initialize: Primal variables $x_0 \in \mathbb{R}^d$, $u_0 \in \mathbb{R}^m$, dual variable $\Delta_0 \in \mathbb{R}^m$.

for $t = 0, 1, 2, \dots$ **do**

Update all variables:

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ G_{\text{cov}}(x) + \langle x, K^\top \Delta_t \rangle + \frac{1}{2} \|Kx - u_t\|_{\Sigma}^2 + \frac{1}{2} \|x - x_t\|_{\Gamma^{-1} - K^\top \Sigma K}^2 \right\}, \\ \Delta_{t+1} = \Delta_t + \Sigma(Kx_{t+1} - u_t), \\ u_{t+1} = \arg \min_u \left\{ F_{\text{cov}}(u) - \langle \Delta_{t+1}, u \rangle + \frac{1}{2} \|Kx_{t+1} - u\|_{\Sigma}^2 \right\}, \end{cases}$$

until some convergence criterion is reached.

This ADMM formulation of MOCCA gives us a clearer understanding of the choice of the expansion points (z, v) in the MOCCA algorithm. Recalling the simpler form of the MOCCA algorithm given in Algorithm 1 where the expansion points are updated at each iteration (i.e. there is no “inner loop”), the expansion points were defined as

$$z_{t+1} = x_{t+1} \text{ and } v_{t+1} = \Sigma^{-1}(u_t - u_{t+1}) + K\bar{x}_{t+1}.$$

Using our conversion between the CP variables (x, w) and the ADMM variables (x, Δ, u) , we see that

$$\begin{aligned} v_{t+1} &= \Sigma^{-1}(u_t - u_{t+1}) + K(2x_{t+1} - x_t) \quad \text{since } \theta = 1 \text{ so } \bar{x}_{t+1} = 2x_{t+1} - x_t \\ &= \Sigma^{-1}(\Sigma(Kx_t - u_t) + \Delta_t - \Sigma(Kx_{t+1} - u_{t+1}) - \Delta_{t+1}) + K(2x_{t+1} - x_t) \\ &= \Sigma^{-1}(\Sigma(Kx_t - u_t) + \Delta_t - \Sigma(Kx_{t+1} - u_{t+1})) \\ &\quad - (\Delta_t + \Sigma(Kx_{t+1} - u_t)) + K(2x_{t+1} - x_t) \\ &= u_{t+1}, \end{aligned}$$

where the next-to-last step uses the definition of the update step for Δ_{t+1} . In other words, after the t th step, our estimated minimizers for $\{F(u) + G(x) : Kx = u\}$ are given by u_{t+1} and x_{t+1} , and our convex approximations to F and to G for the next step are consequently taken at the values $v = u_{t+1}$ and $z = x_{t+1}$.

4. Theoretical Results

In this section we present our two main theoretical results.

4.1 Convergence to a Critical Point

First, we show that if the algorithm converges, then its limit point is a solution to our original problem.

Theorem 1 Assume that the families of approximations F_v and G_z satisfy (4), and furthermore that

$$\begin{cases} (v, w) \mapsto \nabla(F - F_v)(w) \text{ is continuous jointly in } (v, w), \text{ and} \\ (z, x) \mapsto \nabla(G - G_z)(x) \text{ is continuous jointly in } (z, x). \end{cases} \quad (23)$$

Suppose that Algorithm 2 converges to a point, with

$$\begin{aligned} x_{t;\ell} &\rightarrow \hat{x} \quad \text{where the sequence } (x_{t;\ell}) \text{ is interpreted as } (x_{1;0}, x_{1;1}, \dots, x_{1;L_1}, x_{2;0}, \dots), \\ u_{t;\ell} &\rightarrow \hat{w} \quad \text{where } (u_{t;\ell}) \text{ is interpreted analogously,} \\ z_t &\rightarrow \hat{z}, \\ v_t &\rightarrow \hat{v}. \end{aligned} \quad (23)$$

Then \hat{x} is a critical point of the original optimization problem, in the sense that

$$0 \in K^\top \partial F_{K\hat{x}}(K\hat{x}) + \partial G_{\hat{x}}(\hat{x}).$$

4.2 Guarantees of Convergence

We now turn to theoretical results proving that the algorithm converges (and proving rates of convergence) under specific assumptions on F and G . In this section, we only consider the “inner loop” form of MOCCA, given in Algorithm 2. We show that if our inner loop length (i.e. L_t) tends to infinity, then we can bound the error of the algorithm.

We begin with an assumption on the step size parameters:

Assumption 1 The extrapolation parameter is set at $\theta = 1$, and the diagonal matrices Σ and Γ are chosen such that

$$M = \begin{pmatrix} \Gamma^{-1} & -K^\top \\ -K & \Sigma^{-1} \end{pmatrix} \succ 0.$$

Pock and Chambolle (2011) introduce this assumption for the (convex) preconditioned Chambolle-Pock algorithm, and give a simple construction for one choice of Σ, Γ to satisfy this without calculating any matrix norms or other high-cost operations, specified in (8) above.

Next, we turn to the convexity and smoothness assumptions required for our convergence guarantee.

4.2.1 RESTRICTED CONVEXITY AND SMOOTHNESS

In practice, F and/or G may each consist of multiple terms, combining characteristics of the problem such as a likelihood calculation or a penalty or constraint on the underlying signal. To accommodate a range of potential applications, in particular those arising in the regression and imaging applications described in Section 2, we consider a broad setting where our main assumptions involve the interplay between convexity and negative curvature in the functions F, G .

The notion of restricted strong convexity (RSC), introduced by Negahban et al. (2009), has often been used in high-dimensional statistics to express the idea that likelihood functions and optimization problems, which may not have desirable strong convexity properties

globally, nonetheless exhibit strong convexity in “directions of interest”. For example, in a least-squares regression problem with design matrix $A \in \mathbb{R}^{n \times d}$, with $n \ll d$, the least squares loss function $\mathcal{L}(x) = \frac{1}{2} \|y - Ax\|_2^2$ is not strongly convex since $A^\top A$ is rank deficient, but can yield good statistical properties if $A^\top A$ is strongly convex in all sparse directions, that is, $x^\top A^\top A x \geq c \cdot \|x\|_2^2$ for all sparse (or approximately sparse) vectors x . In this case, the loss function is globally convex, but it is the RSC property that ensures high accuracy for sparse regression problems. More recently, Loh and Wainwright (2013) proved that the RSC property, along with an analogous restricted smoothness property, can in fact be leveraged even in nonconvex optimization problems, such as the regression-with-errors-in-variables scenario described in Section 2.1. Their work relies on optimizing the variable x within some bounded set, to ensure that the RSC property will push x towards a good (local) minimum rather than allowing x to diverge. For instance, if the loss function has some directions of strong concavity—as is the case for regression-with-errors-in-variables in (14)—then staying within a bounded set is critical. In theory, their work focuses on problems that take the form of minimizing a penalized loss function over a bounded set $\{x : \|x\|_1 \leq R\}$, where we think of R as a large bound, requiring only a loose bound on the ℓ_1 norm of the true signal. In practice, if an optimization algorithm is initialized at zero, then it is often the case that the iterations will never leave a bounded region, without imposing any explicit constraint.

In general, results using the RSC condition take the following form: first, the loss function or objective function $\mathcal{L}(x)$ is shown to satisfy a RSC property of the form

$$\langle x - x', \nabla \mathcal{L}(x) - \nabla \mathcal{L}(x') \rangle \geq c \|x - x'\|_2^2 - \tau^2 \|x - x'\|_{\text{restrict}}^2,$$

for some structured norm $\|\cdot\|_{\text{restrict}}$ (for example, the ℓ_1 norm). Here $c > 0$ is a constant while τ is vanishingly small, for instance $c \sim 1$ and $\tau \sim \sqrt{\frac{\log(d)}{n}}$ in many high dimensional regression applications with sample size n . The solution \hat{x} is then shown to converge to the true signal x^* up to an error of size τR , where R is some bound on the signal complexity, for instance $R \sim \sqrt{k}$ where k is the true sparsity level of a sparse regression problem. In these settings, it is assumed that $\tau R = o(1)$, and that errors of this magnitude are negligible. We will follow this general framework in our convergence guarantee as well. However, since we consider settings where the signals may not have natural sparsity but would instead have a different type of structure (such as total variation sparsity), we replace the ℓ_1 norm with a general measure of signal complexity, $\|\cdot\|_{\text{restrict}}$ chosen with respect to the problem at hand (for instance, a total variation norm).

We now specify our assumptions on convexity and smoothness for the functions involved in the optimization, using the restricted strong convexity / restricted smoothness framework from the literature. Roughly speaking, the following assumption requires that the errors of the convex approximations $F - F_v$, $G - G_z$ are counterbalanced by strong convexity in the composite approximations $F_v(Kx) + G_z(x)$. For the term G , we allow for some flexibility by considering restricted strong convexity and restricted smoothness, relative to the structured norm $\|x\|_{\text{restrict}}$.

Assumption 2 *The approximations F_v and G_z satisfy the conditions (4), with additional assumptions as follows. For the function F and its family of local approximations F_v , we*

assume that F_v is strongly convex, while $F - F_v$ is smooth: for all u, v, w ,

$$\begin{cases} \text{Strong convexity of } F_v: \langle u, \partial F_v(w + u) - \partial F_v(w) \rangle \geq \|u\|_{\Lambda_F}^2, \\ \text{Smoothness of } F - F_v: |\langle u, \nabla(F - F_v)(v + w) \rangle| \leq \frac{1}{2} (\|u\|_{\Theta_F}^2 + \|w\|_{\Theta_F}^2), \end{cases}$$

for some $\Lambda_F, \Theta_F \succeq 0$.⁴ We also assume a gradient condition on F_v ,

$$\left\{ F_v \text{ satisfies a gradient condition: } \|\partial F_v(w) - \partial F_v(w')\|_2 \leq C_{\text{Lip}} + C_{\text{grad}} \|w - w'\|_2, \right.$$

for some $C_{\text{Lip}}, C_{\text{grad}} < \infty$. (For example, this is satisfied if F_v can be written as the sum of a Lipschitz function and a smooth function.)

For the function G and its family of local approximations G_z , we assume that G_z satisfies restricted strong convexity, while $G - G_z$ satisfies a restricted smoothness assumption: for all x, y, z ,

$$\begin{cases} \text{Restricted strong convexity of } G_z: \langle y, \partial G_z(x + y) - \partial G_z(x) \rangle \geq \|y\|_{\Lambda_G}^2 - \tau^2 \|y\|_{\text{restrict}}^2, \\ \text{Restricted smoothness of } G - G_z: |\langle y, \nabla(G - G_z)(z + x) \rangle| \leq \frac{1}{2} (\|x\|_{\Theta_G}^2 + \|y\|_{\Theta_G}^2) + \frac{\tau^2}{2} (\|x\|_{\text{restrict}}^2 + \|y\|_{\text{restrict}}^2), \end{cases}$$

for some $\Lambda_G, \Theta_G \succeq 0$ and $\tau < \infty$.

Finally, the total convexity in the local approximations F_v and G_z must (approximately) outweigh the total curvature of the differences $F - F_v$ and $G - G_z$. Specifically, for all $x \in \mathbb{R}^d$, we require

$$x^\top (K^\top \Lambda_F K + \Lambda_G) x \geq x^\top (K^\top \Theta_F K + \Theta_G) x + C_{\text{cvx}} \|x\|_2^2 - \tau^2 \|x\|_{\text{restrict}}^2,$$

for some $C_{\text{cvx}} > 0$ and $\tau < \infty$.

In general, greater convexity (i.e. Λ_F, Λ_G as strongly positive definite as possible) and tighter bounds on smoothness (i.e. Θ_F, Θ_G as small as possible) allow for a better (i.e. larger) constant C_{cvx} and, therefore, faster convergence of the algorithm. The value of τ is typically of a very small order in many problems arising in high-dimensional statistics, as discussed above for the sparse regression setting.

It is critical to note that this assumption does *not* require either F_v or G_z to be strictly convex—if the matrices Λ_F or Λ_G are not full rank, then strict convexity has not been assumed. Instead, F_v is strongly convex in any direction of \mathbb{R}^m contained in the column span of Λ_F , and similarly for G_z and Λ_G in \mathbb{R}^d . Our assumption essentially requires that the combination of these directions leads to overall (approximate) convexity, after accounting for concavity that might be introduced by the errors $F - F_v$ and $G - G_z$.

For simplicity in the statements and proofs of our results, we group the norms of all matrices from Assumptions 1 and 2 into a single constant:

$$C_{\text{matrix}} = \max \{ \|\Lambda_F\|, \|\Theta_F\|, \|\Lambda_G\|, \|\Theta_G\|, \|M\|, \|M^{-1}\| \}.$$

Throughout, we will treat $C_{\text{matrix}}, C_{\text{cvx}}, C_{\text{Lip}}$, and C_{grad} as fixed finite positive constants, and dependence on these values will not be given explicitly except in the proofs. On the other hand, the role of the restricted convexity/smoothness parameter τ will be shown explicitly.

3. We implicitly restrict all variables to the domain of the appropriate function, throughout.

4. For a function F with a multivalued subdifferential, this notation is taken to mean that the statement must hold for any elements of the subdifferentials, throughout the paper.

4.2.2 CONVERGENCE GUARANTEE

Choose any point $x^* \in \mathbb{R}^d$ with $\|x^*\|_{\text{restrict}} \leq R$, which is a critical point for the optimization problem

$$\min_{\|x\|_{\text{restrict}} \leq R} \{F(Kx) + G(x)\}.$$

For convenience, we will now absorb the constraint $\|x\|_{\text{restrict}} \leq R$ into the functions themselves, by replacing G with the function

$$x \mapsto \begin{cases} G(x), & \text{if } \|x\|_{\text{restrict}} \leq R, \\ +\infty, & \text{if } \|x\|_{\text{restrict}} > R. \end{cases}$$

and replacing G_z (for each z) with the function

$$x \mapsto \begin{cases} G_z(x), & \text{if } \|x\|_{\text{restrict}} \leq R, \\ +\infty, & \text{if } \|x\|_{\text{restrict}} > R. \end{cases}$$

In practice, as mentioned before, we typically do not need to explicitly incorporate this constraint into the optimization algorithm, as we will generally only see updates that all lie within a bounded region. However, in our statements and proofs of theoretical results from this point onward, we will assume that G, G_z restrict the domain of the variable x , that is,

$$G(x) = G_z(x) = +\infty \text{ whenever } \|x\|_{\text{restrict}} > R. \quad (24)$$

We will also assume that τR is bounded by a constant without further comment, since our results give convergence guarantees up to the accuracy level τR , the results are meaningful only if τR is small.

We now state our convergence guarantee for the stable form of the MOCCA algorithm, given in Algorithm 2:

Theorem 2 *Assume that Assumptions 1 and 2, and that G, G_z satisfy (24). Then there exists constants $C_{\text{converge}}, L_{\text{min}} < \infty$ and $\delta > 0$, such that if $\min_{t \geq 1} L_t \geq L_{\text{min}}$, then for all $t \geq 1$, the iterations of Algorithm 2 satisfy*

$$\|x_t - x^*\|_2 \leq C_{\text{converge}} \left(\frac{1}{\sqrt{L_t}} + \tau R \right)$$

where

$$L_t' = \min \{L_t, (1 + \delta)L_{t-1}, \dots, (1 + \delta)^{t-1}L_1\}.$$

As an example, we can set $L_t \sim (1 + \delta)^t$. Then after the t th inner loop, $\|x_t - x^*\|_2 \sim (1 + \delta)^{-t/2} + \tau R$, and the total number of iterations taken is $L_1 + \dots + L_t \sim (1 + \delta)^t$. In other words, the error $\|x - x^*\|_2$ scales as $\frac{1}{\sqrt{T}} + \tau R$ where T is the total number of update steps, i.e. error is inversely proportional to the square root of computational cost, up to the accuracy level τR .

We also remark that, if we were to assume additionally that F is differentiable and smooth, the result would improve dramatically: we would obtain error decaying exponentially in the number of update steps (up to the accuracy level τR). The resulting convergence

guarantee would then be comparable to the results obtained in Loh and Wainwright (2013, Theorem 3), which show a result with error at time t scaling as $c^t + \tau R$ (for a constant $c < 1$). However, convergence in this setting is of limited interest for the applications we have in mind, since total variation penalties, and many other natural penalties or losses falling into the F term of the composite objective functions, are not differentiable.

4.2.3 CONVEXITY AND SMOOTHNESS ASSUMPTIONS: AN EXAMPLE

To illustrate the many different matrices and constants appearing in Assumption 2 with a concrete example, we return to the problem studied in Section 2.1, where a least squares regression with errors in variables is combined with a total variation (or generalized ℓ_1) penalty. Recalling this setting, we seek to minimize $\mathcal{L}(x) + \nu \cdot \|Kx\|_1$, and we set $F_\nu(w) = F(w) = \nu \cdot \|w\|_1$, and

$$G(x) = \begin{cases} \mathcal{L}(x), & \text{if } \|x\|_1 \leq R, \\ +\infty, & \text{if } \|x\|_1 > R, \end{cases}$$

and

$$G_z(x) = \begin{cases} \mathcal{L}(x) + \frac{\sigma^2}{2} \|x - z\|_2^2, & \text{if } \|x\|_{\text{restrict}} \leq R, \\ +\infty, & \text{if } \|x\|_1 > R, \end{cases}$$

where

$$\mathcal{L}(x) = \frac{1}{2} x^T \left(\frac{Z^T Z}{n} - \sigma_A^2 \mathbf{I}_d \right) x - x^T \left(\frac{Z^T b}{n} \right).$$

Under the Gaussian noise model, the noisy design matrix given by entries $Z_{ij} = A_{ij} + \text{Normal}(0, \sigma_A^2)$ and the response is given by $b = A \cdot \text{true} + \text{Normal}(0, \sigma^2 \mathbf{I}_d)$. The MOCCA update steps for this problem are given in (16).

In this setting, Assumption 2 is satisfied with the following parameters. First, since F is convex but not strongly convex, we set $A_F = \mathbf{0}$; we can also set $\Theta_F = \mathbf{0}$ as $F_\nu = F$ for any expansion point v . F is ν -Lipschitz so we can take $C_{\text{Lip}} = 2\nu, C_{\text{grad}} = 0$. Next, for G , we see that

$$G_z(x) = \frac{1}{2} x^T \left(\frac{Z^T Z}{n} \right) x - x^T \left(\frac{Z^T b}{n} + \sigma_A^2 z \right)$$

(on the domain $\|x\|_{\text{restrict}} \leq R$), and so we can set $A_G = \frac{Z^T Z}{n}$. To check the smoothness condition, we have

$$\langle y, \nabla(G - G_z)(z + x) \rangle = \langle y, \sigma_A^2 x \rangle \leq \sigma_A^2 \cdot \frac{1}{2} (\|x\|_2^2 + \|y\|_2^2),$$

and so we can take $\Theta_G = \sigma_A^2 \mathbf{I}_d$.

Finally, for the ‘‘total convexity’’ condition of Assumption 2, we need to check that $K^T(A_F - \Theta_F)K + (A_G - \Theta_G) = \frac{Z^T Z}{n} - \sigma_A^2 \mathbf{I}_d$ satisfies restricted strong convexity. In Loh and Wainwright (2011, Corollary 1), it is shown that if the rows of the (original) design matrix A are drawn i.i.d. from a subgaussian distribution with covariance Σ_A then, assuming that the sample size n satisfies $n \gg \log(d)$, the matrix $\frac{Z^T Z}{n} - \sigma_A^2 \mathbf{I}_d$ (which is an unbiased estimate of the desired term $\frac{A^T A}{n}$ using the unknown original design matrix A) satisfies

$$x^T \left(\frac{Z^T Z}{n} - \sigma_A^2 \mathbf{I}_d \right) x \geq \frac{1}{2} \lambda_{\min}(\Sigma_A) \cdot \|x\|_2^2 - (\text{constant}) \cdot \frac{\log(d)}{n} \cdot \|x\|_{\text{restrict}}^2 \quad \text{for all } x \in \mathbb{R}^d \quad (25)$$

with high probability, when we choose $\|x\|_{\text{restrict}} = \|x\|_1$; similar results will hold for other structured choices of $\|\cdot\|_{\text{restrict}}$ such as total variation norm or a generalized ℓ_1 norm. Therefore we can set $C_{\text{cvx}} = \frac{1}{2}\lambda_{\min}(\Sigma_A)$ and $\tau \sim \sqrt{\frac{\log(d)}{n}}$ to obtain the desired condition in Assumption 2. Note that the guarantees of Theorem 2 give a meaningful convergence result even if we choose a fairly large radius R .

5. Experiments

We now implement the MOCCA algorithm to examine its performance in practice. Throughout this section, we work with the simpler formulation of MOCCA, given in Algorithm 1, with no “inner loop”. All computations were performed in MATLAB (MATLAB, 2015).⁵

For all simulations, we choose not to place a bound on $\|x\|_{\text{restrict}}$, although technically this is required by our convergence guarantees and those of the related results in Loh and Wainwright (2013) (which we compare to, in Simulation 2). Empirically we observe good convergence without imposing such a bound, but can easily add such a bound if desired.

We consider two examples: Simulation 1 studies nonconvex total variation regularization with a least squares loss (as described in Section 2.3), and Simulation 2 considers convex total variation regularization with a nonconvex loss arising from regression with errors in variables (as described in Section 2.1). While other algorithms which are developed specifically for these problems are available—for example, denoising with total variation penalties is studied by e.g. Chambolle and Darbon (2009); Wang et al. (2014b, 2015b), and could be combined with a proximal gradient method for Simulation 2—here our purpose is simply to illustrate applications of MOCCA to several concrete examples in order to demonstrate its flexibility for a broad range of problems. Specific problems will often have specialized algorithms which would far outperform our general-purpose method; however, slight modifications to the optimization problem (for example, replacing total variation regularization with a more general penalty $\|Kx\|_1$ for a generic dense matrix K , or with isotropic total variation) will often mean that specialized algorithms can no longer be applied, while MOCCA can adapt easily to accommodate these changes.

5.1 Simulation 1: Nonconvex Total Variation Penalty

In the first simulation, we study the nonconvex total variation penalty considered in Section 2.3, using a two-dimensional spatial structure. We generate data as follows: first, we define the true signal $x_{\text{true}} \in \mathbb{R}^d$ with dimension $d = 625$, obtained by vectorizing the two-dimensional locally constant array

$$\begin{pmatrix} \mathbf{1}_{5 \times 5} & \mathbf{0}_{5 \times 15} & \mathbf{0}_{5 \times 5} \\ \mathbf{0}_{15 \times 5} & \mathbf{1}_{15 \times 15} & \mathbf{0}_{15 \times 5} \\ \mathbf{0}_{5 \times 5} & \mathbf{0}_{5 \times 15} & \mathbf{1}_{5 \times 5} \end{pmatrix} \in \mathbb{R}^{25 \times 25}.$$

The two-dimensional total variation of the true signal is very low, because $\nabla_{2d} x_{\text{true}}$ is sparse. We then take a linear regression model with $n = 200$ observations, with design matrix

$A \in \mathbb{R}^{n \times d}$ with $A_{ij} \stackrel{\text{iid}}{\sim} \text{Normal}(0, 1)$ and $b \in \mathbb{R}^n$ with entries

$$b_i = (A \cdot x_{\text{true}})_i + \text{Normal}(0, 1).$$

We would then like to solve a penalized least-squares problem using the nonconvex total variation penalty introduced in Section 2.3, namely,

$$\hat{x} = \arg \min_x \{\text{Obj}(x)\} \text{ for } \text{Obj}(x) = \frac{1}{2} \|b - Ax\|_2^2 + \nu \cdot \log \text{TV}_\beta(x), \quad (26)$$

where we choose penalty parameter $\nu = 20$ and nonconvexity parameter $\beta = 3$ (recall that a low value of β corresponds to greater nonconvexity), and where the $\log \text{TV}_\beta(\cdot)$ penalty is defined with respect to two-dimensional total variation—recall

$$\log \text{TV}_\beta(x) = \log \mathbf{L}_{1,\beta}(\nabla_{2d} x) = \sum_i \beta \log(1 + |(\nabla_{2d} x)_i|/\beta).$$

Here $\nabla_{2d} \in \mathbb{R}^{m \times d}$ is the two-dimensional first differences matrix for the vectorized $d_1 \times d_2$ grid, where $d = d_1 \cdot d_2$ is the total dimension of the signal while $m = d_1(d_2 - 1) + d_2(d_1 - 1)$ is the number of first-order differences measured; in our case, we have $d_1 = d_2 = 25$, $d = 625$, and $m = 1200$.

Next, we implement the MOCCA algorithm with the two variants described in Section 2.3: setting $K = \nabla_{2d}$, we consider the more natural form where the penalty term is contained in F , given by

$$\begin{cases} F(w) = \nu \cdot \log \mathbf{L}_{1,\beta}(w), & \text{with } F_v(w) = \nu \cdot \|w\|_1 + \nu [h_\beta(w) + \langle w - v, \nabla h_\beta(v) \rangle], \\ G(x) = G_z(x) = \frac{1}{2} \|b - Ax\|_2^2, \end{cases} \quad (27)$$

where $h_\beta(w) = \log \mathbf{L}_{1,\beta}(w) - \|w\|_1$ is a differentiable concave function as discussed in Section 2.3. We also consider the less natural form where the penalty term is split across F and G , given by

$$\begin{cases} F(w) = F_v(w) = \nu \cdot \|w\|_1, \\ G(x) = \frac{1}{2} \|b - Ax\|_2^2 + \nu \cdot h_\beta(\nabla_{2d} x), \\ \quad \text{with } G_z(x) = \frac{1}{2} \|b - Ax\|_2^2 + \nu [h_\beta(\nabla_{2d} z) + \langle \nabla_{2d}(x - z), \nabla h_\beta(\nabla_{2d} z) \rangle], \end{cases} \quad (28)$$

We will refer to these two versions as MOCCA(natural) and MOCCA(split), respectively. Finally, we choose step size parameters

$$\Sigma = \lambda \cdot \frac{1}{2} \mathbf{I}_m \quad \text{and} \quad \mathbf{T} = \lambda^{-1} \cdot \frac{1}{4} \mathbf{I}_d,$$

which ensures that the positive semidefinite assumption, Assumption 1, will hold (although perhaps not strictly) as in Pock and Chambolle (2011). We test the algorithm across a range of λ values, $\lambda \in \{4, 8, 16, 32, 64\}$.

The results are shown in Figure 2, which plots the log value of the objective function $\text{Obj}(x)$ at each iteration, and also plots the log of the change in each iteration,

$$\text{Change}_t = \left\| \begin{pmatrix} x_{t-1} - x_t \\ w_{t-1} - w_t \end{pmatrix} \right\|_2. \quad (29)$$

⁵ Code for fully reproducing these simulations is available at <http://www.stat.uchicago.edu/~rina/mocca.html>.

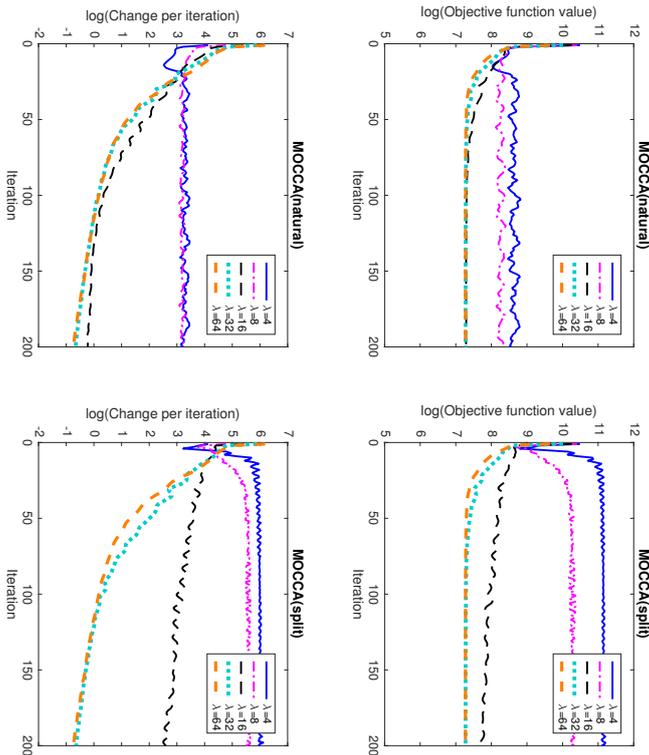

Figure 2: Results from Simulation 1. The top row plots the log of the objective function value defined in (26) against iteration number, while the bottom row plots the log of the change in the (x, u) variables (29) at each iteration, for several step size parameters λ . (Section 1.1.4 gives a direct correspondence between convergence of the (x, u) variables, and the optimality of the x variable.) The plots show results from the “natural” (left) and “split” (right) versions of the MOCCA algorithm, defined in (27) and (28), respectively.

(Recall from Section 1.1.4 that, if $\text{Change} \rightarrow 0$, then the optimality gap of the solution tends to zero; that is, the x variable is close to being a critical point for the optimization problem.) Looking first at the results for MOCCA(natural), we see that smaller λ values tend to lead to faster convergence at the very early stages, but poorer performance or instability at later stages. (In fact, this suggests the possibility of varying λ as we run more iterations, which we leave to future work.)

Turning to MOCCA(split), we see that the performance is worse at all λ values as compared with MOCCA(natural); the difference is minor for the largest λ values, but the lower λ values give far poorer results and far more instability for MOCCA(split) as compared to MOCCA(natural). This highlights the importance of the “mirroring” step in our algorithm,

which gives us the flexibility of placing the nonconvex terms into F , i.e. the function which will be optimized via the dual variable. In other scenarios, of course, a different arrangement of the terms may be preferable.

5.2 Simulation 2: Total Variation Penalty, with Errors in Variables

In the second simulation, we treat the errors-in-variables setting discussed in Section 2.1. We generate the signal x_{true} , the design matrix A , and the response vector b as in Simulation 1. Next, suppose our measurement of A is itself noisy: define $Z \in \mathbb{R}^{n \times d}$ with $Z_{ij} = A_{ij} + \text{Normal}(0, \sigma_A^2)$, where $\sigma_A = 0.2$. Finally, we would like to minimize the objective function

$$\frac{1}{2} x^T \left(Z^T Z - n \cdot \sigma_A^2 \mathbf{I}_d \right) x - x^T Z^T b + \nu \|x\|_{\text{TV}}, \quad (30)$$

with penalty parameter $\nu = 20$, where again we use two-dimensional total variation, $\|x\|_{\text{TV}} = \|\nabla_{2d} x\|_1$. (Here we use a different scaling of the likelihood term relative to Section 2.1 for simpler implementation and tuning.) Of course, due to the negative quadratic term, this objective function is strongly concave in some directions and so its global minimum is “at infinity”; within a bounded set, however, the penalty will ensure that the objective function is approximately convex. In practice, initializing our algorithm at $x = 0$ does not lead to any problems, and we converge to a bounded solution that can be viewed as a local minimum within a bounded set, e.g. $\{x : \|x\|_{\text{TV}} \leq R\}$ for some appropriate choice of R , as discussed in the context of restricted strong convexity in Section 4.2.1.

A proximal gradient descent method, as proposed by Loh and Wainwright (2013) for this type of nonconvex penalized likelihood, would in theory iterate the steps

$$\begin{cases} \tilde{x}_{t+1} = x_t - \frac{1}{\eta} \left((Z^T Z - n\sigma_A^2 \mathbf{I}_d) x_t - (Z^T b) \right), \\ x_{t+1} = \arg \min_x \left\{ \frac{1}{2} \|x - \tilde{x}_{t+1}\|_2^2 + \frac{\eta}{2} \|x\|_{\text{TV}} \right\}, \end{cases}$$

where $\frac{1}{\eta}$ is a step size parameter. However, the second step is a proximal operator for the total variation norm $\|x\|_{\text{TV}} = \|\nabla_{2d} x\|_1$, which cannot be calculated in closed form. Instead, we could apply the CP algorithm to the convex (sub)problem of this proximity operator with parameters $\Sigma = \lambda \cdot \frac{1}{2} \mathbf{I}_m$ and $\mathbf{T} = \lambda^{-1} \cdot \frac{1}{4} \mathbf{I}_d$, and could terminate this inner “prox loop” after some convergence criterion is reached, e.g. after some fixed number n_{step} of steps, or once the relative change in x is below ϵ_{mesh} . We do not show details of the derivation, but the complete procedure iterates these steps (taking extrapolation parameter $\theta = 1$):

$$\begin{cases} \text{Gradient step: } \tilde{x}_{t+1} = x_t - \frac{1}{\eta} \left((Z^T Z - n\sigma_A^2 \mathbf{I}_d) x_t - (Z^T b) \right), \\ \text{Initialize prox loop: } x_{t+1,0}^l = x_t, u_{t+1,0}^l = u_t, \\ \text{Run prox loop: for } \ell = 1, 2, \dots, \text{ writing } \tilde{x}_{t+1,\ell}^l = 2x_{t+1,\ell-1}^l - x_{t+1,\ell-1}^l, \\ \left\{ \begin{aligned} x_{t+1,\ell}^l &= (1 + \frac{1}{\lambda})^{-1} \left(x_{t+1,\ell-1}^l + \frac{1}{\lambda} \tilde{x}_{t+1} - \frac{1}{\lambda} \nabla_{2d}^T (u_{t+1,\ell-1}^l) \right), \\ u_{t+1,\ell}^l &= \text{Truncate}_{[-\nu/\eta, \nu/\eta]} \left(u_{t+1,\ell-1}^l + \frac{\nu}{2} \nabla_{2d} \tilde{x}_{t+1,\ell}^l \right), \end{aligned} \right. \\ \text{until a convergence criterion is reached} \\ \text{(i.e. } \ell = n_{\text{step}} \text{ OR } \left\| x_{t+1,\ell}^l - x_{t+1,\ell-1}^l \right\|_2 / \left\| x_{t+1,\ell-1}^l \right\|_2 \leq \epsilon_{\text{thresh}} \text{).} \end{cases} \quad (31)$$

Gather results from prox loop: $x_{t+1} = x_{t+1,n_{\text{step}}}^l$, $u_{t+1} = u_{t+1,n_{\text{step}}}^l$.

We will refer to this method as the Approximate Proximal Gradient Descent (APGD) algorithm, where “approximate” describes the fact that the proximal operator step is only ever solved approximately via a finite number of steps in the inner loop.

In fact, if we examine this algorithm carefully, we can find that by taking a single step of the inner “prox loop” (that is, setting $n_{\text{step}} = 1$), we arrive back at the steps of the MOCCA algorithm. Specifically, as in the implementation (15) in Section 2.1, we choose $K = \nabla_{2d}$, $F(w) = F_v(w) = \nu \|w\|_1$, and

$$G(x) = \frac{1}{2} x^\top (Z^\top Z - n\sigma_A^2 \mathbf{I}_d) x - x^\top (Z^\top b)$$

with local approximations given by linear expansions,

$$\begin{aligned} G_z(x) &= G(z) + \langle x - z, \nabla G(x) \rangle \\ &= \langle x, (Z^\top Z - n\sigma_A^2 \mathbf{I}_d) z - Z^\top b \rangle + (\text{terms constant with respect to } x). \end{aligned}$$

The update steps of the MOCCA algorithm are then given by

$$\begin{cases} x_{t+1} = \arg \min_x \left\{ \langle \nabla_{2d} x, w_t \rangle + G_z(x) + \frac{1}{2} \|x - x_t\|_{\mathbf{T}^{-1}}^2 \right\}, \\ w_{t+1} = \arg \min_y \left\{ -\langle \nabla_{2d} \bar{x}_{t+1}, w \rangle + F^*(w) + \frac{1}{2} \|w - w_t\|_{\Sigma^{-1}}^2 \right\}, \\ z_{t+1} = x_{t+1}, \end{cases}$$

which we can simplify to

$$\begin{cases} x_{t+1} = x_t - \mathbf{T} (\nabla_{2d}^\top w_t + (Z^\top Z - n\sigma_A^2 \mathbf{I}_d) x_t - (Z^\top b)), \\ w_{t+1} = \text{Truncate}_{[-\nu, \nu]} (w_t + \Sigma \nabla_{2d} \bar{x}_{t+1}). \end{cases}$$

If we choose

$$\Sigma = \frac{\lambda \eta}{2} \cdot \mathbf{I}_{d-1} \quad \text{and} \quad \mathbf{T} = \frac{1}{(4\lambda + 1)\eta} \cdot \mathbf{I}_d,$$

it can be shown that this is equivalent to the proximal gradient algorithm (31) with a single inner loop step, i.e. with $n_{\text{step}} = 1$ (specifically, the iterates x_t stay the same, while the other variables are related as $w_t = \eta \cdot u_t$).

Now we compare the performance of the approximate proximal gradient descent (APGD) algorithm, with various stopping criteria for the inner “prox loop”, against the performance of the MOCCA algorithm, which we can view as the APGD algorithm taking exactly one step in each inner “prox loop”. For simplicity, we consider only a few values for the step size parameters, setting $\eta = \lambda = 100$ or $\eta = \lambda = 200$. As for Simulation 1, we will see that higher values for these parameters gives more stability at the cost of slower convergence.

We consider stopping rules for the inner loop as follows: either we run the inner loop for a fixed number of steps, $n_{\text{step}} \in \{1, 5\}$ (with $n_{\text{step}} = 1$ yielding MOCCA), or we use a convergence criterion $\epsilon_{\text{fresh}} \in \{0.1, 0.05, 0.01\}$. Figure 3 shows the results; for the figure on the left, we see that running the inner loop longer does help to make our solutions more accurate (i.e. the objective function is lower) over the range of iterations. However, each iteration has greater computational cost when we increase the time spent running the inner loop. Since we would like to see the performance as a function of computational cost, the

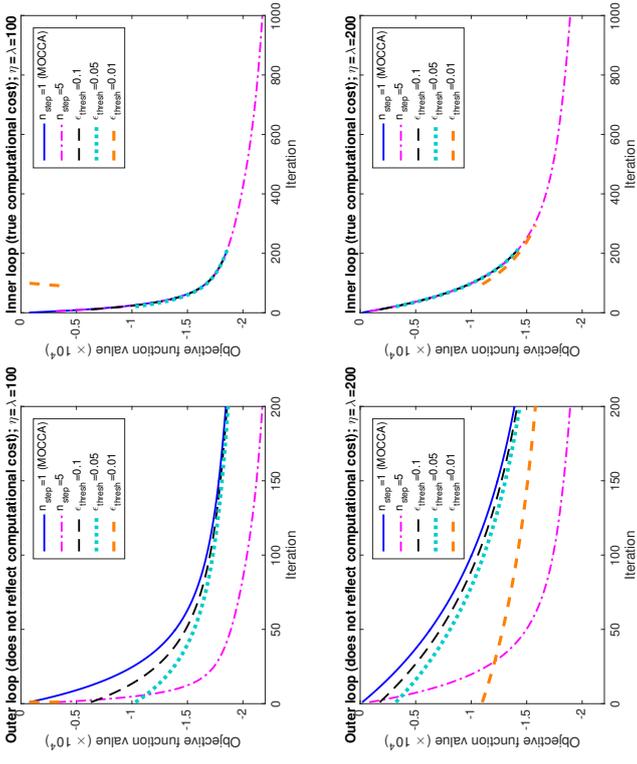

Figure 3: Results from Simulation 2, plotting the value of the objective function (30) against iteration number, counting either iterations of the “outer loop” (left) or of the “inner loop” (right), for various stopping rules for the inner loop in (31). Parameters are set as $\eta = \lambda = 100$ (top) or $\eta = \lambda = 200$ (bottom). Counting the number of passes through the inner loop is an accurate reflection of the true computational cost of (31), and so the right-hand plots give the correct interpretation of the results, where the various versions of the algorithms perform nearly identically in both settings (the lines are indistinguishable) except for the setting $\epsilon_{\text{fresh}} = 0.01$ which diverges for the setting $\eta = \lambda = 100$. Setting $n_{\text{step}} = 1$ yields the MOCCA algorithm as discussed in the text.

plot on the right-hand side of Figure 3 shows the same results plotted against the true number of iterations, i.e. where we count each pass through the inner loop of (31) rather than counting only passes through the outer loop of (31). In this setting, we see that in fact the various versions of the algorithms perform nearly identically—in other words, a one-step approximation to the proximal map performs just as well as a more conservative inner loop that is run for longer—with the exception of setting $\epsilon_{\text{fresh}} = 0.01$ and $\eta = \lambda = 100$, in which case the algorithm diverges immediately. It is interesting to note that this small

choice for ϵ_{fresh} is closest in spirit to proximal gradient descent (that is, the proximal step is the most accurate), although of course there may be some effect of tuning parameters. The choice ϵ_{fresh} does achieve convergence with the more conservative choice $\eta = \lambda = 200$, but convergence is noticeably slower in this case. Thus, we can conclude that when the proximal step does not have a closed form solution, it may be better to use a coarse approximation (which, implicitly, is the strategy taken by MOCCA for this problem) rather than aiming for near-convergence in the proximal step for each iteration.

6. Proofs

6.1 Critical Points (Theorem 1)

For this proof we will use two facts: for a continuous convex function h ,

$$\text{If } a_t \in \partial h(b_t) \text{ and } a_t \rightarrow a, b_t \rightarrow b \text{ then } a \in \partial h(b), \quad (32)$$

and

$$a \in \partial h(b) \text{ if and only if } b \in \partial h^*(a). \quad (33)$$

First, by definition of the w_{t+1} update step,

$$\partial \mathbf{F}_{v_t}^*(w_{t+1}) \ni \Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1},$$

and therefore by (33),

$$w_{t+1,1} \in \partial \mathbf{F}_{v_t}(\Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1}).$$

We can rewrite this as

$$w_{t+1,1} \in \underbrace{\partial \mathbf{F}_{\hat{v}}(\Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1})}_{(\text{Term 1})} + \underbrace{\nabla(\mathbf{F}_{v_t} - \mathbf{F}_{\hat{v}})(\Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1})}_{(\text{Term 2})}. \quad (34)$$

Next, since the solution converges, we see that

$$w_{t+1,1} \rightarrow \hat{w}, v_t \rightarrow \hat{v}, \Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1} \rightarrow K\hat{x}.$$

Our assumption (23) implies that

$$(v, w) \mapsto \nabla(\mathbf{F}_v - \mathbf{F}_{\hat{v}})(w) = -\nabla(\mathbf{F} - \mathbf{F}_{\hat{v}})(w) + \nabla(\mathbf{F} - \mathbf{F}_{\hat{v}})(w)$$

is jointly continuous in (v, w) , and so

$$(\text{Term 2}) = \nabla(\mathbf{F}_{v_t} - \mathbf{F}_{\hat{v}})(\Sigma^{-1}(w_{t+1,0} - w_{t+1,1}) + K\bar{x}_{t+1,1}) \rightarrow \nabla(\mathbf{F}_{\hat{v}} - \mathbf{F}_{\hat{v}})(K\hat{x}) = 0.$$

Therefore, applying the property (32) to the expression in (34), we see that

$$\hat{w} \in \partial \mathbf{F}_{\hat{v}}(K\hat{x}). \quad (35)$$

Next, for each t , by definition,

$$\begin{aligned} v_{t+1} &= \frac{1}{L_{t+1}} \sum_{\ell=1}^{L_{t+1}} (\Sigma^{-1}(w_{t+1,\ell-1} - w_{t+1,\ell}) + K\bar{x}_{t+1,\ell}) \\ &= \frac{1}{L_{t+1}} (\Sigma^{-1}(w_{t+1,0} - w_{t+1,L_{t+1}}) + K(x_{t+1,L_{t+1}} - x_{t+1,0})) + Kx_{t+1}. \end{aligned}$$

Taking limits on each side, we see that $\hat{v} = K\hat{x}$. Returning to (35) above this proves that

$$\hat{w} \in \partial \mathbf{F}_{K\hat{x}}(K\hat{x}).$$

Next, by definition of the x_{t+1} update step,

$$\partial \mathbf{G}_{z_t}(x_{t+1}) = \mathbf{T}^{-1}(x_{t+1,0} - x_{t+1,1}) - K^{\top} w_{t+1,0}.$$

Taking limits on each side as $t \rightarrow \infty$, and applying (32) as before,

$$\partial \mathbf{G}_{\hat{z}}(\hat{x}) \ni -K^{\top} \hat{w}.$$

And, we know that $z_{t+1} = x_{t+1}$ for each t , therefore $\hat{z} = \hat{x}$, and so

$$\partial \mathbf{G}_{\hat{z}}(\hat{x}) \ni -K^{\top} \hat{w}.$$

Combining the work above, then,

$$0 = K^{\top} \hat{w} - K^{\top} \hat{w} \in K^{\top} \partial \mathbf{F}_{K\hat{x}}(K\hat{x}) + \partial \mathbf{G}_{\hat{z}}(\hat{x}),$$

as desired.

6.2 Convergence Guarantee (Theorem 2)

We first introduce some notation and supporting lemmas before turning to the main proof.

6.2.1 NOTATION

Fixing any expansion points $(z, w) \in \mathbb{R}^d \times \mathbb{R}^m$, we define a primal-dual update step:

$$(x', w') = \text{Step}_{z,w}(x, w),$$

given by

$$\begin{cases} x' = \arg \min_{x''} \left\{ Kx'', w \right\} + G_z(x'') + \frac{1}{2} \|x'' - x\|_{\Sigma^{-1}}^2, \\ w' = \arg \min_{w''} \left\{ -(K(2w' - x), w'') + \mathbf{F}_{v'}^*(w'') + \frac{1}{2} \|w'' - w\|_{\Sigma^{-1}}^2 \right\}. \end{cases}$$

This is one step of the CP algorithm applied to the convex objective function

$$\min_x \{ \mathbf{F}_{v'}(Kx) + G_z(x) \}$$

with extrapolation parameter $\theta = 1$.

Next, defining x^* to be any critical point of the original problem as before, let $w^* \in \partial \mathbf{F}_{Kx^*}(Kx^*)$ be an element of the subdifferential such that

$$0 \in K^\top w^* + \partial \mathbf{G}_{x^*}(x^*).$$

Finally, for any expansion points (z, v) , define the (not necessarily unique) solution for the convex optimization problem when the we use approximations $\mathbf{F}_v, \mathbf{G}_z$:

$$x_{z,v}^* = \arg \min_x \{ \mathbf{F}_v(Kx) + \mathbf{G}_z(x) \},$$

and let $w_{z,v}^* \in \partial \mathbf{F}_v(Kx_{z,v}^*)$ be an element of the subdifferential such that

$$0 \in K^\top w^* + \partial \mathbf{G}_z(x_{z,v}^*).$$

6.2.2 LEMMAS

The proof of Theorem 2 can be split into several key results. First we state these lemmas and explain their role, then we will formally prove the theorem. The lemmas are proved in Appendix A.

The first lemma shows that, if we use expansion points (z, v) close to the true solution, i.e. $(z, v) \approx (x^*, Kx^*)$, then the minimizer $x_{z,v}^*$ for the convex approximation will be close to x^* .

Lemma 3 *Suppose that Assumptions 1 and 2 hold. Define*

$$\Theta = \begin{pmatrix} \Theta_G & 0 \\ 0 & \Theta_F \end{pmatrix} + \frac{C_{\text{cvx}}}{(C_{\text{matrix}})^2} \mathbf{I} \succ 0.$$

Then there exist constants $C_{\text{contr}} > 0, C_{\text{excess}} < \infty$, which depend only on $C_{\text{matrix}}, C_{\text{cvx}}, C_{\text{Lip}}, C_{\text{grad}}$, such that for any $(z, v) \in \text{dom}(\mathbf{G}) \times \text{dom}(\mathbf{F})$,

$$\left\| \begin{pmatrix} x_{z,v}^* - x^* \\ Kx_{z,v}^* - Kx^* \end{pmatrix} \right\|_{\Theta} \leq (1 - C_{\text{contr}}) \left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta} + C_{\text{excess}} \cdot \tau R$$

and

$$\left\| \begin{pmatrix} x_{z,v}^* - x^* \\ w_{z,v}^* - w^* \end{pmatrix} \right\|_2 \leq C_{\text{Lip}} + C_{\text{excess}} \left(\left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta} + \tau R \right).$$

The second lemma shows that, after running an ‘‘inner loop’’, the (x, w) variables are nearly optimal for the current convex approximation, and the next expansion points are also near this optimum.

Lemma 4 *Suppose that Assumptions 1 and 2 hold. For any $L \geq 1$, and any points $(x^{(0)}, w^{(0)}), (z, v) \in \text{dom}(\mathbf{G}) \times \text{dom}(\mathbf{F})$, suppose we iterate $\text{Step}_{z,v}(\cdot)$ for L times,*

$$(x^{(1)}, w^{(1)}) = \text{Step}_{z,v}(x^{(0)}, w^{(0)}), (x^{(2)}, w^{(2)}) = \text{Step}_{z,v}(x^{(1)}, w^{(1)}), \dots, \\ (x^{(L)}, w^{(L)}) = \text{Step}_{z,v}(x^{(L-1)}, w^{(L-1)}),$$

and then define the averages $(\tilde{x}, \tilde{w}) = \frac{1}{L} \sum_{\ell=1}^L (x^{(\ell)}, w^{(\ell)})$ and averaged expansion points (\tilde{z}, \tilde{v}) as

$$\tilde{z} = \frac{1}{L} \sum_{\ell=1}^L x^{(\ell)} \quad \text{and} \quad \tilde{v} = \frac{1}{L} \sum_{\ell=1}^L \left(\sum^{-1} (w^{(\ell-1)} - w^{(\ell)}) + K(2x^{(\ell)} - x^{(\ell-1)}) \right).$$

Then there exists a constant $C_{\text{iter}} < \infty$, depending only on $C_{\text{matrix}}, C_{\text{cvx}}, C_{\text{Lip}}, C_{\text{grad}}$ (and in particular, not dependent on L), such that

$$\left\| \begin{pmatrix} \tilde{z} - x_{z,v}^* \\ \tilde{v} - Kx_{z,v}^* \end{pmatrix} \right\|_{\Theta} \leq C_{\text{iter}} \left\| \begin{pmatrix} 1 \\ \sqrt{L} \end{pmatrix} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_2 + \tau R \right).$$

and

$$\left\| \begin{pmatrix} \tilde{x} - x_{z,v}^* \\ \tilde{w} - w_{z,v}^* \end{pmatrix} \right\|_2 \leq C_{\text{Lip}} + C_{\text{iter}} \left(\frac{1}{\sqrt{L}} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_2 + \tau R \right)$$

6.2.3 PROOF OF THEOREM 2

We will assume for simplicity that the expansion point is initialized with some z_0 satisfying $\|z_0\|_{\text{restrict}} \leq R$; if this is not the case at step $t = 0$, then our results can be easily adjusted since we will have $z_1 = x_1 \in \text{dom}(\mathbf{G}_{z_0})$ and therefore $\|z_1\|_{\text{restrict}} \leq R$, so we can simply shift our calculations by one time point.

First, choose any δ such that $0 < \delta < (1 - C_{\text{contr}})^{-2} - 1$. Define constants

$$C_1 = \max \left\{ \left\| \begin{pmatrix} x_1 - x_{z_1, v_1}^* \\ w_1 - w_{z_1, v_1}^* \end{pmatrix} \right\|_2, \right. \\ \left. 6C_{\text{Lip}} + 4C_{\text{excess}} + 2 \left(C_{\text{iter}} + 2C_{\text{excess}} \left(\frac{C_{\text{iter}} + C_{\text{excess}}}{C_{\text{contr}}} + 1 \right) \right) \tau R \right\}, \\ C_2 = \max \left\{ \sqrt{L_1} \cdot \left\| \begin{pmatrix} z_1 - x^* \\ v_1 - Kx^* \end{pmatrix} \right\|_{\Theta}, \frac{C_{\text{iter}} C_1}{1 - (1 - C_{\text{contr}}) \sqrt{1 + \delta}} \right\}, \\ C_3 = \frac{C_{\text{iter}} + C_{\text{excess}}}{C_{\text{contr}}},$$

and define

$$L_{\min} = \max\{4(C_{\text{iter}})^2, (C_2)^2\}.$$

To prove the desired result, we will prove that

$$\left\| \begin{pmatrix} x_{t+1} - x_{z_{t+1}, v_{t+1}}^* \\ w_{t+1} - w_{z_{t+1}, v_{t+1}}^* \end{pmatrix} \right\|_2 \leq C_1 \quad (36)$$

and

$$\left\| \begin{pmatrix} z_{t+1} - x^* \\ v_{t+1} - Kx^* \end{pmatrix} \right\|_{\Theta} \leq \frac{C_2}{\sqrt{L_{t+1}}} + C_3 \tau R \quad (37)$$

for all $t \geq 0$.

Assuming that these bounds hold, we then have

$$\|x_{t+1} - x^*\|_2 = \|z_{t+1} - x^*\|_2 \leq \|\Theta^{-1}\| \cdot \left(\frac{C_2}{\sqrt{L_{t+1}}} + C_3\tau R \right),$$

where the first step holds by definition of z_{t+1} ; this proves the desired theorem with $C_{\text{converge}} := \|\Theta^{-1}\| \cdot \max\{C_2, C_3\}$.

Now we prove (36) and (37) by induction. For $t = 0$, both statements are true trivially by our definitions of C_1 and C_2 . Now we will assume that the statements are true for all $t = 0, \dots, m-1$ and will prove that they hold for $t = m$. First, for (37), we have

$$\begin{aligned} & \left\| \begin{pmatrix} z_{m+1} - x^* \\ v_{m+1} - Kx^* \end{pmatrix} \right\|_{\Theta} \\ & \leq \left\| \begin{pmatrix} z_{m+1} - x_{z_m, v_m}^* \\ v_{m+1} - Kx_{z_m, v_m}^* \end{pmatrix} \right\|_{\Theta} + \left\| \begin{pmatrix} x_{z_m, v_m}^* - x^* \\ Kx_{z_m, v_m}^* - Kx^* \end{pmatrix} \right\|_{\Theta} \quad \text{by the triangle inequality} \\ & \leq \left\| \begin{pmatrix} z_{m+1} - x_{z_m, v_m}^* \\ v_{m+1} - Kx_{z_m, v_m}^* \end{pmatrix} \right\|_{\Theta} \\ & \quad + (1 - C_{\text{contr}}) \cdot \left\| \begin{pmatrix} z_m - x^* \\ v_m - Kx^* \end{pmatrix} \right\|_{\Theta} + C_{\text{excess}}\tau R \quad \text{by Lemma 3} \\ & \leq C_{\text{lier}} \left(\frac{1}{\sqrt{L_{m+1}}} \left\| \begin{pmatrix} x_m - x_{z_m, v_m}^* \\ v_m - u_{z_m, v_m}^* \end{pmatrix} \right\|_2 + \tau R \right) \\ & \quad + (1 - C_{\text{contr}}) \cdot \left\| \begin{pmatrix} z_m - x^* \\ v_m - Kx^* \end{pmatrix} \right\|_{\Theta} + C_{\text{excess}}\tau R \quad \text{by Lemma 4} \\ & \leq C_{\text{lier}} \left(\frac{1}{\sqrt{L_{m+1}}} C_1 + \tau R \right) + (1 - C_{\text{contr}}) \cdot \left(\frac{C_2}{\sqrt{L_m}} + C_3\tau R \right) \\ & \quad + C_{\text{excess}}\tau R \quad \text{by (36) and (37) applied with } t = m-1 \\ & \leq C_{\text{lier}} \left(\frac{1}{\sqrt{L_{m+1}}} C_1 + \tau R \right) + (1 - C_{\text{contr}}) \cdot \left(C_2\sqrt{1+\delta} + C_3\tau R \right) \\ & \quad + C_{\text{excess}}\tau R \quad \text{since } L'_{m+1} \leq L_{m+1}, (1+\delta)L'_m \\ & \leq \frac{C_2}{\sqrt{L'_{m+1}}} + C_3\tau R, \end{aligned}$$

where the last step holds by our definition of the constants C_2, C_3 . This concludes the proof of (37) for $t = m$.

Next, we turn to the proof of (36). For both $t = m-1$ and $t = m$,

$$\begin{aligned} & \left\| \begin{pmatrix} x_{z_{t+1}, v_{t+1}}^* - x^* \\ u_{z_{t+1}, v_{t+1}}^* - u^* \end{pmatrix} \right\|_2 \leq C_{\text{lip}} + C_{\text{excess}} \left(\left\| \begin{pmatrix} z_{t+1} - x^* \\ v_{t+1} - Kx^* \end{pmatrix} \right\|_{\Theta} + \tau R \right) \quad \text{by Lemma 3} \\ & = C_{\text{lip}} + C_{\text{excess}} \left(\frac{C_2}{\sqrt{L'_{t+1}}} + (C_3 + 1)\tau R \right) \quad \text{by (37) at step } t \\ & \leq C_{\text{lip}} + C_{\text{excess}} \left(\frac{C_2}{\sqrt{L_{\min}}} + (C_3 + 1)\tau R \right) \quad \text{since } L'_{t+1} \geq L_{\min}, \end{aligned}$$

and also, we have

$$\begin{aligned} & \left\| \begin{pmatrix} x_{m+1} - x_{z_m, v_m}^* \\ u_{m+1} - u_{z_m, v_m}^* \end{pmatrix} \right\|_2 \\ & \leq C_{\text{lip}} + C_{\text{lier}} \left(\frac{1}{\sqrt{L_{m+1}}} \left\| \begin{pmatrix} x_m - x_{z_m, v_m}^* \\ u_m - u_{z_m, v_m}^* \end{pmatrix} \right\|_2 + \tau R \right) \quad \text{by Lemma 4} \\ & \leq C_{\text{lip}} + C_{\text{lier}} \left(\frac{1}{\sqrt{L_{m+1}}} C_1 + \tau R \right) \quad \text{by (36) applied with } t = m-1 \\ & \leq C_{\text{lip}} + C_{\text{lier}} \left(\frac{1}{\sqrt{L_{\min}}} C_1 + \tau R \right) \quad \text{since } L_{m+1} \geq L_{\min}. \end{aligned}$$

Therefore, combining these calculations,

$$\begin{aligned} & \left\| \begin{pmatrix} x_{m+1} - x_{z_{m+1}, v_{m+1}}^* \\ u_{m+1} - u_{z_{m+1}, v_{m+1}}^* \end{pmatrix} \right\|_2 \\ & \leq \left\| \begin{pmatrix} x_{m+1} - x_{z_m, v_m}^* \\ u_{m+1} - u_{z_m, v_m}^* \end{pmatrix} \right\|_2 + \left\| \begin{pmatrix} x_{z_m, v_m}^* - x^* \\ u_{z_m, v_m}^* - u^* \end{pmatrix} \right\|_2 + \left\| \begin{pmatrix} x_{z_{m+1}, v_{m+1}}^* - x^* \\ u_{z_{m+1}, v_{m+1}}^* - u^* \end{pmatrix} \right\|_2 \\ & \leq 3C_{\text{lip}} + C_{\text{lier}} \left(\frac{1}{\sqrt{L_{\min}}} C_1 + \tau R \right) + 2C_{\text{excess}} \left(\frac{C_2}{\sqrt{L_{\min}}} + (C_3 + 1)\tau R \right) \\ & \leq 3C_{\text{lip}} + C_{\text{lier}} \left(\frac{1}{\sqrt{4(C_{\text{lier}})^2}} C_1 + \tau R \right) \\ & \quad + 2C_{\text{excess}} \left(\frac{C_2}{\sqrt{(C_2)^2}} + \left(\frac{C_{\text{lier}} + C_{\text{excess}}}{C_{\text{contr}}} + 1 \right) \tau R \right) \quad \text{by definition of } C_3 \text{ and of } L_{\min} \\ & \leq C_1, \end{aligned}$$

by definition of C_1 . This proves the desired bound (36) for $t = m$, and thus we have proved the theorem.

7. Discussion

We have developed a primal/dual algorithm for minimizing composite objective functions of the form $F(Kx) + G(x)$, which is able to handle nondifferentiability and nonconvexity (even strong concavity) in each individual term, beyond what is possible with many existing

approaches based on alternating minimization or proximal gradient methods. The key step of the MOCCA algorithm is the careful choice of local convex approximations to F and G at each step, which respects the mirroring between the primal and dual variables of the algorithm. Our method allows for accurate and efficient optimization for a range of problems arising in high-dimensional statistics, such as nonconvex total variation penalties (which reduce the bias caused by shrinkage, when compared to using a convex total variation norm), as well as inverse problems in computed tomography (CT) imaging.

Our present theoretical results give a convergence guarantee, in the case that the overall objective function is approximately convex, for a more stable form of the MOCCA algorithm. In future work, we hope to better understand the relative performance of the various forms of the algorithm, and to find a tighter characterization of the convergence behavior of the algorithm. It would also be interesting to consider a more general form of objective function, $F(w) + G(x)$ where F, G are nonconvex and nondifferentiable, and where instead of the linear constraint $w = Kx$, the variables w and x are linked via a nonlinear map; such an extension would greatly increase the range of applications of the method.

Appendix A. Proofs of Lemmas

A.1 Proof of Lemma 3

By definition of $x_{z,v}^*$

$$0 \in K^\top \partial F_v(Kx_{z,v}^*) + \partial \mathcal{G}_z(x_{z,v}^*) \quad (38)$$

and since x^* is a critical point of the original objective function,

$$0 \in K^\top \partial F_{Kx^*}(Kx^*) + \partial \mathcal{G}_{x^*}(x^*) . \quad (39)$$

Since $(F_v - F_{Kx^*}) = (F - F_{Kx^*}) - (F - F_v)$ and $(G_z - G_{x^*}) = (G - G_{x^*}) - (G - G_z)$ are differentiable, we can rewrite (39) as

$$0 \in K^\top \partial F_v(Kx^*) + K^\top \nabla(F - F_v)(Kx^*) - K^\top \nabla(F - F_{Kx^*})(Kx^*) \\ + \partial \mathcal{G}_z(x^*) + \nabla(G - G_z)(x^*) - \nabla(G - G_{x^*})(x^*) .$$

By the first-order conditions (4), we know that $\nabla(F - F_{Kx^*})(Kx^*) = 0$ and $\nabla(G - G_{x^*})(x^*) = 0$, so this reduces to

$$0 \in K^\top \partial F_v(Kx^*) + K^\top \nabla(F - F_v)(Kx^*) + \partial \mathcal{G}_z(x^*) + \nabla(G - G_z)(x^*) . \quad (40)$$

We also see that $\|x^*\|_{\text{restrict}}, \|x_{z,v}^*\|_{\text{restrict}} \leq R$, since $x^*, x_{z,v}^*$ must lie in $\text{dom}(G) = \text{dom}(G_z)$.

Then we have

$$\begin{aligned} & \|x_{z,v}^* - x^*\|_{\Theta_G}^2 + \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 + C_{\text{cvx}} \|x_{z,v}^* - x^*\|_2^2 - 2\tau^2 \cdot \|x_{z,v}^* - x^*\|_{\text{restrict}}^2 \\ & \leq \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 + \|x_{z,v}^* - x^*\|_{\Lambda_G}^2 - \tau^2 \cdot \|x_{z,v}^* - x^*\|_{\text{restrict}}^2 \quad \text{by Assumption 2} \\ & \leq \langle Kx_{z,v}^* - Kx^*, \partial F_v(Kx_{z,v}^*) - \partial F_v(Kx^*) \rangle \\ & \quad + \langle x_{z,v}^* - x^*, \partial \mathcal{G}_z(x_{z,v}^*) - \partial \mathcal{G}_z(x^*) \rangle \quad \text{by Assumption 2} \\ & = \langle Kx_{z,v}^* - Kx^*, \nabla(F - F_v)(Kx^*) \rangle + \langle x_{z,v}^* - x^*, \nabla(G - G_z)(x^*) \rangle \quad \text{by (38) and (40)} \\ & \leq \frac{1}{2} \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 + \frac{1}{2} \|v - Kx^*\|_{\Theta_F}^2 + \frac{1}{2} \|x_{z,v}^* - x^*\|_{\Theta_G}^2 + \frac{1}{2} \|z - x^*\|_{\Theta_G}^2 \\ & \quad + \frac{\tau^2}{2} \left(\|x_{z,v}^* - x^*\|_{\text{restrict}}^2 + \|z - x^*\|_{\text{restrict}}^2 \right) \quad \text{by Assumption 2} . \end{aligned}$$

Next, recall that $\|x_{z,v}^*\|_{\text{restrict}}, \|x^*\|_{\text{restrict}} \leq R$ from before and $\|z\|_{\text{restrict}} \leq R$ by assumption. After rearranging terms and multiplying by 2, this gives

$$\begin{aligned} & \|x_{z,v}^* - x^*\|_{\Theta_G}^2 + \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 + 2C_{\text{cvx}} \|x_{z,v}^* - x^*\|_2^2 \\ & \leq \|z - x^*\|_{\Theta_G}^2 + \|v - Kx^*\|_{\Theta_F}^2 + \|v - Kx^*\|_{\Theta_F}^2 + 24\tau^2 R^2 . \quad (41) \end{aligned}$$

Now, using the definition of Θ , we see that

$$\begin{pmatrix} \Theta_G & 0 \\ 0 & \Theta_F \end{pmatrix} \preceq (1 - C_{\text{contr}})^2 \cdot \Theta$$

where

$$C_{\text{contr}} := \frac{C_{\text{cvx}}}{2 \left(1 + \frac{C_{\text{cvx}}}{(C_{\text{matrix}})^3} \right)} > 0 .$$

We then get

$$\begin{aligned} & (1 - C_{\text{contr}})^2 \left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta}^2 + 24\tau^2 R^2 \\ & \geq \|z - x^*\|_{\Theta_G}^2 + \|v - Kx^*\|_{\Theta_F}^2 + 24\tau^2 R^2 \\ & \geq \|x_{z,v}^* - x^*\|_{\Theta_G}^2 + \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 + 2C_{\text{cvx}} \|x_{z,v}^* - x^*\|_2^2 \quad \text{from (41)} \\ & \geq \|x_{z,v}^* - x^*\|_{\Theta_G}^2 + \|Kx_{z,v}^* - Kx^*\|_{\Theta_F}^2 \\ & \quad + C_{\text{cvx}} \|x_{z,v}^* - x^*\|_2^2 + \frac{C_{\text{cvx}}}{(C_{\text{matrix}})^2} \|Kx_{z,v}^* - Kx^*\|_2^2 \quad \text{since } \|K\| \leq C_{\text{matrix}} \\ & \geq \|x_{z,v}^* - x^*\|_{\Theta_G + C_{\text{cvx}}/(C_{\text{matrix}})^2}^2 + \|Kx_{z,v}^* - Kx^*\|_{\Theta_F + C_{\text{cvx}}/(C_{\text{matrix}})^2}^2 \quad \text{since } C_{\text{matrix}} \geq 1 \\ & = \left\| \begin{pmatrix} x_{z,v}^* - x^* \\ Kx_{z,v}^* - Kx^* \end{pmatrix} \right\|_{\Theta} . \end{aligned}$$

Using the fact that $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$, we obtain

$$\left\| \begin{pmatrix} x_{z,v}^* - x^* \\ Kx_{z,v}^* - Kx^* \end{pmatrix} \right\|_{\Theta} \leq (1 - C_{\text{contr}}) \left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta} + \sqrt{24\tau} R . \quad (42)$$

Next, by definition, we also have

$$u_{z,v}^* \in \partial F_v(Kx_{z,v}^*) \text{ and } w^* \in \partial F_{Kx^*}(Kx^*).$$

This second expression can be rewritten as

$$w^* \in \partial F_v(Kx^*) + \nabla(F - F_v)(Kx^*) - \nabla(F - F_{Kx^*})(Kx^*) = \partial F_v(Kx^*) + \nabla(F - F_v)(Kx^*),$$

where the last step uses the first-order condition (4) to see that $\nabla(F - F_{Kx^*})(Kx^*) = 0$. Therefore,

$$\begin{aligned} \|u_{z,v}^* - w^*\|_2 &\leq \|\partial F_v(Kx^*) - \partial F_v(Kx_{z,v}^*)\|_2 + \|\nabla(F - F_v)(Kx^*)\|_2 \\ &\leq C_{\text{Lip}} + C_{\text{grad}} \|Kx_{z,v}^* - Kx^*\|_2 + \sqrt{\|\Theta_F\|} \|v - Kx^*\|_{\Theta_F} \quad \text{by Assumption 2} \\ &\leq C_{\text{Lip}} + C_{\text{grad}} C_{\text{matrix}} \|x_{z,v}^* - x^*\|_2 + \sqrt{C_{\text{matrix}}} \|v - Kx^*\|_{\Theta_F}, \end{aligned}$$

and so

$$\begin{aligned} \left\| \begin{pmatrix} x_{z,v}^* - x^* \\ u_{z,v}^* - w^* \end{pmatrix} \right\|_2 &\leq C_{\text{Lip}} + (1 + C_{\text{grad}} C_{\text{matrix}}) \|x_{z,v}^* - x^*\|_2 + \sqrt{C_{\text{matrix}}} \|v - Kx^*\|_{\Theta_F} \\ &\leq C_{\text{Lip}} + \frac{1 + C_{\text{grad}} C_{\text{matrix}}}{\sqrt{C_{\text{cov}}}/C_{\text{matrix}}} \left\| \begin{pmatrix} x_{z,v}^* - x^* \\ Kx_{z,v}^* - Kx^* \end{pmatrix} \right\|_{\Theta} \\ &\quad + \sqrt{C_{\text{matrix}}} \|v - Kx^*\|_{\Theta_F} \quad \text{since } \Theta \supseteq \frac{C_{\text{cov}}}{(C_{\text{matrix}})^2} \mathbf{I} \\ &\leq C_{\text{Lip}} + \frac{1 + C_{\text{grad}} C_{\text{matrix}}}{\sqrt{C_{\text{cov}}}/C_{\text{matrix}}} \left((1 - C_{\text{contr}}) \left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta} + \sqrt{24}\tau R \right) \\ &\quad + \sqrt{C_{\text{matrix}}} \left\| \begin{pmatrix} z - x^* \\ v - Kx^* \end{pmatrix} \right\|_{\Theta}, \end{aligned}$$

where the last step applies (42) from above. Setting

$$C_{\text{cess}} = \max \left\{ \sqrt{24}, \sqrt{C_{\text{matrix}}} + (1 - C_{\text{contr}}) \cdot \frac{1 + C_{\text{grad}} C_{\text{matrix}}}{\sqrt{C_{\text{cov}}}/C_{\text{matrix}}}, \sqrt{24} \cdot \frac{1 + C_{\text{grad}} C_{\text{matrix}}}{\sqrt{C_{\text{cov}}}/C_{\text{matrix}}} \right\},$$

this is sufficient to prove the lemma.

A.2 Proof of Lemma 4

First we state and prove a supporting lemma which considers only a single step of the ‘‘inner loop’’.

Lemma 5 *There exists a constant $C_{\text{monotone}} > 0$, which depends only on C_{matrix} , C_{cov} , C_{Lip} , C_{grad} , such that, for any x, y, z with $\|x\|_{\text{restrict}} \leq R$, if $(x', w') = \text{Step}_{z,v}(x, w)$, then*

$$\begin{aligned} C_{\text{monotone}} \left(\|x' - x_{z,v}^*\|_2^2 + \left\| \begin{pmatrix} x - x' \\ w - w' \end{pmatrix} \right\|_2^2 \right) \\ \leq \left\| \begin{pmatrix} x - x_{z,v}^* \\ w - w_{z,v}^* \end{pmatrix} \right\|_M^2 - \left\| \begin{pmatrix} x' - x_{z,v}^* \\ w' - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2. \end{aligned}$$

Proof By definition of the (x, w) update step, we have

$$\mathbb{T}^{-1}(x - x') - K^{\text{T}} w \in \partial \mathcal{G}_z(x') \quad (43)$$

and

$$\Sigma^{-1}(w - w') + K(2x' - x) \in \partial F_v^*(w'),$$

and from (33) we know that this last expression implies

$$w' \in \partial F_v(\Sigma^{-1}(w - w') + K(2x' - x)). \quad (44)$$

Similarly, by definition of $(x_{z,v}^*, w_{z,v}^*)$, we also have

$$-K^{\text{T}} w_{z,v}^* \in \partial \mathcal{G}_z(x_{z,v}^*) \quad (45)$$

and

$$u_{z,v}^* \in \partial F_v(Kx_{z,v}^*). \quad (46)$$

Therefore, combining these expressions, we have

$$\begin{aligned} &\left\langle \left\langle \Sigma^{-1}(w - w') + K(2x' - x) - Kx_{z,v}^* \right\rangle, \left(\partial F_v(K(2x' - x) + \Sigma^{-1}(w - w')) - \partial F_v(Kx_{z,v}^*) \right) \right\rangle \\ &\quad \ni \left\langle \left\langle \Sigma^{-1}(w - w') + K(2x' - x) - Kx_{z,v}^* \right\rangle, \left(\mathbb{T}^{-1}(x - x') - K^{\text{T}}(w - w_{z,v}^*) \right) \right\rangle \\ &\quad = \left\langle \left\langle \begin{pmatrix} x' - x_{z,v}^* \\ w' - w_{z,v}^* \end{pmatrix}, \left(\mathbb{T}^{-1}(x - x') - K^{\text{T}}(w - w') \right) \right\rangle, \left(\Sigma^{-1}(w - w') - K(x - x') \right) \right\rangle \quad \text{by reorganizing terms} \\ &\quad = \left(\begin{pmatrix} x' - x_{z,v}^* \\ w' - w_{z,v}^* \end{pmatrix} \right)^{\text{T}} M \begin{pmatrix} x - x' \\ w - w' \end{pmatrix}. \end{aligned} \quad (47)$$

As in Chambolle and Pock (2011) we can calculate

$$\begin{aligned} &\left| \left(\begin{pmatrix} x' - x_{z,v}^* \\ w' - w_{z,v}^* \end{pmatrix} \right)^{\text{T}} M \begin{pmatrix} x - x' \\ w - w' \end{pmatrix} \right| \\ &= \frac{1}{2} \left\| \begin{pmatrix} x - x_{z,v}^* \\ w - w_{z,v}^* \end{pmatrix} \right\|_M^2 - \frac{1}{2} \left\| \begin{pmatrix} x' - x_{z,v}^* \\ w' - w_{z,v}^* \end{pmatrix} \right\|_M^2 - \frac{1}{2} \left\| \begin{pmatrix} x - x' \\ w - w' \end{pmatrix} \right\|_M^2. \end{aligned}$$

On the other hand, by the convexity of F_v and G_z as stated in Assumption 2, we have

$$\begin{aligned}
& \left\langle \left(\Sigma^{-1}(w-w') + K(2x' - x) - Kx_{z,v}^* \right), \left(\partial F_v(K(2x' - x) + \Sigma^{-1}(w-w')) - \partial F_v(Kx_{z,v}^*) \right) \right\rangle \\
& \geq \|x' - x_{z,v}^*\|_{\Lambda_C}^2 + \|\Sigma^{-1}(w-w') + K(2x' - x) - Kx_{z,v}^*\|_{\Lambda_F}^2 - \tau^2 \|x' - x_{z,v}^*\|_{\text{restrict}}^2 \\
& \geq \|x' - x_{z,v}^*\|_{\Lambda_C}^2 + \frac{1}{2} \|Kx' - Kx_{z,v}^*\|_{\Lambda_F}^2 - \|\Sigma^{-1}(w-w') - K(x-x')\|_{\Lambda_F}^2 \\
& \quad - \tau^2 \|x' - x_{z,v}^*\|_{\text{restrict}}^2 \quad \text{using the fact that } (a+b)^2 \geq \frac{1}{2}a^2 - b^2 \text{ for all } a, b \\
& \geq \frac{C_{\text{Cvx}}}{2} \|x' - x_{z,v}^*\|_2^2 - \frac{3\tau^2}{2} \|x' - x_{z,v}^*\|_{\text{restrict}}^2 \\
& \quad - \|\Sigma^{-1}(w-w') - K(x-x')\|_{\Lambda_F}^2 \quad \text{by Assumption 2} \\
& \geq \frac{C_{\text{Cvx}}}{2} \|x' - x_{z,v}^*\|_2^2 - \frac{3\tau^2}{2} \|x' - x_{z,v}^*\|_{\text{restrict}}^2 - \left\| \begin{pmatrix} x-x' \\ w-w' \end{pmatrix} \right\|_{\Lambda_F}^2 \cdot \|M^{-1}\| \|\Lambda_F\| (\|\Sigma^{-1}\| + \|K\|) \\
& \geq \frac{C_{\text{Cvx}}}{2} \|x' - x_{z,v}^*\|_2^2 - 6\tau^2 R^2 - \left\| \begin{pmatrix} x-x' \\ w-w' \end{pmatrix} \right\|_{\Lambda_F}^2 \cdot 2(C_{\text{matrix}})^3,
\end{aligned}$$

where the last step holds because $\|x'\|_{\text{restrict}}, \|x_{z,v}^*\|_{\text{restrict}} \leq R$, since x' and $x_{z,v}^*$ must both lie in $\text{dom}(G) = \text{dom}(G_z)$ by their definitions. Now, examining these calculations, we see that the left-hand side must be nonnegative, so we can also write

$$\begin{aligned}
& \left\langle \left(\Sigma^{-1}(w-w') + K(2x' - x) - Kx_{z,v}^* \right), \left(\partial F_v(K(2x' - x) + \Sigma^{-1}(w-w')) - \partial F_v(Kx_{z,v}^*) \right) \right\rangle \\
& \geq c \left(\frac{C_{\text{Cvx}}}{2} \|x' - x_{z,v}^*\|_2^2 - 6\tau^2 R^2 - \left\| \begin{pmatrix} x-x' \\ w-w' \end{pmatrix} \right\|_{\Lambda_F}^2 \cdot 2(C_{\text{matrix}})^3 \right)
\end{aligned}$$

for any $c \in [0, 1]$. Choosing $c = \frac{1}{\max\{12, 8C_{\text{matrix}}\}}$, we obtain

$$\begin{aligned}
& \left\langle \left(\Sigma^{-1}(w-w') + K(2x' - x) - Kx_{z,v}^* \right), \left(\partial F_v(K(2x' - x) + \Sigma^{-1}(w-w')) - \partial F_v(Kx_{z,v}^*) \right) \right\rangle \\
& \geq \frac{C_{\text{Cvx}}}{2 \max\{12, 8C_{\text{matrix}}\}} \|x' - x_{z,v}^*\|_2^2 - \frac{1}{2} \tau^2 R^2 - \frac{1}{4} \left\| \begin{pmatrix} x-x' \\ w-w' \end{pmatrix} \right\|_{\Lambda_F}^2
\end{aligned}$$

Combining all our work, then,

$$\begin{aligned}
& \frac{C_{\text{Cvx}}}{4 \max\{12, 8C_{\text{matrix}}\}} \|x' - x_{z,v}^*\|_2^2 \\
& \leq \left\| \begin{pmatrix} x-x_{z,v}^* \\ w-w_{z,v}^* \end{pmatrix} \right\|_M^2 - \left\| \begin{pmatrix} x'-x_{z,v}^* \\ w'-w_{z,v}^* \end{pmatrix} \right\|_M^2 - \frac{1}{2} \left\| \begin{pmatrix} x-x' \\ w-w' \end{pmatrix} \right\|_M^2 + \tau^2 R^2.
\end{aligned}$$

Setting $C_{\text{monotone}} = \min \left\{ \frac{1}{2C_{\text{matrix}}}, \frac{1}{4 \max\{12, 8C_{\text{matrix}}\}} \right\}$, we have proved the lemma. \blacksquare

Now we turn to the proof of Lemma 4. By Lemma 5, for each $\ell = 1, \dots, L$, we have

$$\begin{aligned}
C_{\text{monotone}} & \left(\|x^{(\ell)} - x_{z,v}^*\|_2^2 + \left\| \begin{pmatrix} x^{(\ell-1)} - x^{(\ell)} \\ w^{(\ell-1)} - w^{(\ell)} \end{pmatrix} \right\|_2^2 \right) \\
& \leq \left\| \begin{pmatrix} x^{(\ell-1)} - x_{z,v}^* \\ w^{(\ell-1)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 - \left\| \begin{pmatrix} x^{(\ell)} - x_{z,v}^* \\ w^{(\ell)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2.
\end{aligned}$$

Summing this inequality over $\ell = 1, \dots, L$, taking a telescoping sum on the right-hand side, and dividing by L , we have

$$\frac{C_{\text{monotone}}}{L} \sum_{\ell=1}^L \left(\|x^{(\ell)} - x_{z,v}^*\|_2^2 + \left\| \begin{pmatrix} x^{(\ell-1)} - x^{(\ell)} \\ w^{(\ell-1)} - w^{(\ell)} \end{pmatrix} \right\|_2^2 \right) \leq \frac{1}{L} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2.$$

Next, by convexity of $w \mapsto \|w\|_2^2$, we have

$$\|\tilde{x} - x_{z,v}^*\|_2^2 \leq \frac{1}{L} \sum_{\ell=1}^L \|x^{(\ell)} - x_{z,v}^*\|_2^2$$

and

$$\left\| \frac{1}{L} \begin{pmatrix} x^{(0)} - x^{(L)} \\ w^{(0)} - w^{(L)} \end{pmatrix} \right\|_2^2 \leq \frac{1}{L} \sum_{\ell=1}^L \left\| \begin{pmatrix} x^{(\ell-1)} - x^{(\ell)} \\ w^{(\ell-1)} - w^{(\ell)} \end{pmatrix} \right\|_2^2.$$

So,

$$C_{\text{monotone}} \left(\|\tilde{x} - x_{z,v}^*\|_2^2 + \left\| \frac{1}{L} \begin{pmatrix} x^{(0)} - x^{(L)} \\ w^{(0)} - w^{(L)} \end{pmatrix} \right\|_2^2 \right) \leq \frac{1}{L} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2.$$

Next, by definition of \tilde{z}, \tilde{v} , we can write

$$\begin{aligned}
& \left\| \begin{pmatrix} \tilde{z} - x_{z,v}^* \\ \tilde{v} - Kx_{z,v}^* \end{pmatrix} \right\|_{\Theta} \leq \left\| \begin{pmatrix} \tilde{x} - x_{z,v}^* \\ K\tilde{x} - Kx_{z,v}^* \end{pmatrix} \right\|_{\Theta} \\
& \quad + \frac{1}{L} \left\| \begin{pmatrix} 0 \\ \Sigma^{-1}(w^{(0)} - w^{(L)}) + K(x^{(L)} - x^{(0)}) \end{pmatrix} \right\|_{\Theta}
\end{aligned}$$

and so,

$$\begin{aligned}
& \left\| \begin{pmatrix} \tilde{z} - x_{z,v}^* \\ \tilde{v} - Kx_{z,v}^* \end{pmatrix} \right\|_{\Theta}^2 \leq \|\Theta\| (1 + 2\|K\| + \|\Sigma^{-1}\|)^2 \left(\|\tilde{x} - x_{z,v}^*\|_2^2 + \left\| \frac{1}{L} \begin{pmatrix} x^{(0)} - x^{(L)} \\ w^{(0)} - w^{(L)} \end{pmatrix} \right\|_2^2 \right) \\
& \leq \frac{\|\Theta\| (1 + 2\|K\| + \|\Sigma^{-1}\|)^2}{C_{\text{monotone}}} \left(\frac{1}{L} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2 \right) \\
& \leq \frac{C_{\text{matrix}}(1 + 3C_{\text{matrix}})^2}{C_{\text{monotone}}} \left(\frac{1}{L} \left\| \begin{pmatrix} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{pmatrix} \right\|_M^2 + \tau^2 R^2 \right).
\end{aligned}$$

Finally, for each ℓ , by definition of the step,

$$w^{(\ell)} \in \partial \mathbf{F}_v \left(\Sigma^{-1}(w^{(\ell-1)} - w^{(\ell)}) + K\bar{x}^{(\ell)} \right)$$

while

$$w_{z,v}^* \in \partial \mathbf{F}_v(Kx_{z,v}^*).$$

Therefore, by Assumption 2,

$$\|w^{(\ell)} - w_{z,v}^*\|_2 \leq C_{\text{Lip}} + C_{\text{grad}} \left\| \Sigma^{-1}(w^{(\ell-1)} - w^{(\ell)}) + K\bar{x}^{(\ell)} - Kx_{z,v}^* \right\|_2.$$

By convexity, then,

$$\begin{aligned} & \|\tilde{w} - w_{z,v}^*\|_2 \\ & \leq \frac{1}{L} \sum_{\ell=1}^L \left(C_{\text{Lip}} + C_{\text{grad}} \left\| \Sigma^{-1}(w^{(\ell-1)} - w^{(\ell)}) + K\bar{x}^{(\ell)} - Kx_{z,v}^* \right\|_2 \right) \\ & \leq C_{\text{Lip}} + C_{\text{grad}} (\|K\| + \|\Sigma^{-1}\|) \sqrt{\frac{1}{L} \sum_{\ell=1}^L \left\| \left(\begin{array}{c} x^{(\ell-1)} - x^{(\ell)} \\ w^{(\ell-1)} - w^{(\ell)} \end{array} \right) \right\|_2^2} \\ & \leq C_{\text{Lip}} + C_{\text{grad}} (\|K\| + \|\Sigma^{-1}\|) \sqrt{\frac{1}{C_{\text{monotone}}} \left(\frac{1}{L} \left\| \left(\begin{array}{c} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{array} \right) \right\|_M^2 + \tau R^2 \right)} \\ & \leq C_{\text{Lip}} + \frac{C_{\text{grad}} (\|K\| + \|\Sigma^{-1}\|)}{C_{\text{monotone}}} \left(\frac{1}{\sqrt{L}} \left\| \left(\begin{array}{c} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{array} \right) \right\|_M + \tau R \right). \end{aligned}$$

Combining everything, this proves that

$$\begin{aligned} & \left\| \left(\begin{array}{c} \tilde{x} - x_{z,v}^* \\ \tilde{w} - w_{z,v}^* \end{array} \right) \right\|_2 \leq C_{\text{Lip}} + \frac{1 + C_{\text{grad}} (\|K\| + \|\Sigma^{-1}\|)}{C_{\text{monotone}}} \left(\frac{1}{\sqrt{L}} \left\| \left(\begin{array}{c} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{array} \right) \right\|_M + \tau R \right) \\ & \leq C_{\text{Lip}} + \max\{1, \sqrt{\|M\|}\} \frac{1 + C_{\text{grad}} (\|K\| + \|\Sigma^{-1}\|)}{C_{\text{monotone}}} \left(\frac{1}{\sqrt{L}} \left\| \left(\begin{array}{c} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{array} \right) \right\|_2 + \tau R \right) \\ & \leq C_{\text{Lip}} + \max\{1, \sqrt{C_{\text{matrix}}}\} \frac{1 + 2C_{\text{grad}} C_{\text{matrix}}}{C_{\text{monotone}}} \left(\frac{1}{\sqrt{L}} \left\| \left(\begin{array}{c} x^{(0)} - x_{z,v}^* \\ w^{(0)} - w_{z,v}^* \end{array} \right) \right\|_2 + \tau R \right). \end{aligned}$$

Finally, defining

$$C_{\text{iter}} = \max \left\{ \sqrt{\frac{C_{\text{matrix}}(1 + 3C_{\text{matrix}})^2}{C_{\text{monotone}}}}, \max\{1, \sqrt{C_{\text{matrix}}}\} \frac{1 + 2C_{\text{grad}} C_{\text{matrix}}}{C_{\text{monotone}}} \right\},$$

we have proved the lemma.

Abstract

The temporal-difference methods TD(λ) and Sarsa(λ) form a core part of modern reinforcement learning. Their appeal comes from their good performance, low computational cost, and their simple interpretation, given by their forward view. Recently, new versions of these methods were introduced, called true online TD(λ) and true online Sarsa(λ), respectively (van Seijen & Sutton, 2014). Algorithmically, these true online methods only make two small changes to the update rules of the regular methods, and the extra computational cost is negligible in most cases. However, they follow the ideas underlying the forward view much more closely. In particular, they maintain an exact equivalence with the forward view at all times, whereas the traditional versions only approximate it for small step-sizes. We hypothesize that these true online methods not only have better theoretical properties, but also dominate the regular methods empirically. In this article, we put this hypothesis to the test by performing an extensive empirical comparison. Specifically, we compare the performance of true online TD(λ)/Sarsa(λ) with regular TD(λ)/Sarsa(λ) on random MRPs, a real-world myoelectric prosthetic arm, and a domain from the Arcade Learning Environment. We use linear function approximation with tabular, binary, and non-binary features. Our results suggest that the true online methods indeed dominate the regular methods. Across all domains/representations the learning speed of the true online methods are often better, but never worse than that of the regular methods. An additional advantage is that no choice between traces has to be made for the true online methods. Besides the empirical results, we provide an in-depth analysis of the theory behind true online temporal-difference learning. In addition, we show that new true online temporal-difference methods can be derived by making changes to the online forward view and then rewriting the update equations.

Keywords: temporal-difference learning, eligibility traces, forward-view equivalence

1. Introduction

Temporal-difference (TD) learning is a core learning technique in modern reinforcement learning (Sutton, 1988; Kaelbling et al., 1996; Sutton & Barto, 1998; Szepesvári, 2010). One of the main challenges in reinforcement learning is to make predictions, in an initially unknown environment, about the (discounted) sum of future rewards, the return, based on currently observed feature values and a certain behaviour policy. With TD learning it is possible to learn good estimates of the expected return quickly by bootstrapping from other expected-return estimates. TD(λ) (Sutton, 1988) is a popular TD algorithm that combines basic TD learning with eligibility traces to further speed learning. The popularity of TD(λ) can be explained by its simple implementation, its low-computational complexity and its conceptually straightforward interpretation, given by its forward view. The forward view of TD(λ) states that the estimate at each time step is moved towards an update target known as the λ -return, with λ determining the fundamental trade-off between bias and variance of the update target. This trade-off has a large influence on the speed of learning and its optimal setting varies from domain to domain. The ability to improve this trade-off by adjusting the value of λ is what underlies the performance advantage of eligibility traces.

Although the forward view provides a clear intuition, TD(λ) closely approximates the forward view only for appropriately small step-sizes. Until recently, this was considered an unfortunate, but unavoidable part of the theory behind TD(λ). This changed with the introduction of true online TD(λ) (van Seijen & Sutton, 2014), which computes exactly the same weight vectors as the forward view at any step-size. This gives true online TD(λ) full control over the bias-variance trade-off. In particular, true online TD(λ) can achieve fully unbiased updates. Moreover, true online TD(λ) only requires small modifications to the TD(λ) update equations, and the extra computational cost is negligible in most cases.

We hypothesize that true online TD(λ), and its control version true online Sarsa(λ), not only have better theoretical properties than their regular counterparts, but also dominate them empirically. We test this hypothesis by performing an extensive empirical comparison between true online TD(λ), regular TD(λ) (which is based on accumulating traces), and the common variation based on replacing traces. In addition, we perform comparisons between true online Sarsa(λ) and Sarsa(λ) (with accumulating and replacing traces). The domains we use include random Markov reward processes, a real-world myoelectric prosthetic arm, and a domain from the Arcade Learning Environment (Bellemare et al., 2013). The representations we consider range from tabular values to linear function approximation with binary and non-binary features.

Besides the empirical study, we provide an in-depth discussion on the theory behind true online TD(λ). This theory is based on a new online forward view. The traditional forward view, based on the λ -return, is inherently an offline forward view meaning that updates only occur at the end of an episode, because the λ -return requires data up to the end of an episode. We extend this forward view to the online case, where updates occur at every time step, by using a bounded version of the λ -return that grows over time. Whereas TD(λ) approximates the traditional forward view only at the end of an episode, we show that TD(λ) approximates this new online forward view at all time steps. True online TD(λ) is equivalent to this new online forward view at all time steps. We prove this by deriving the true online TD(λ) update equations directly from the online forward

view update equations. This derivation forms a blueprint for the derivation of other true online methods. By making variations to the online forward view and following the same derivation as for true online TD(λ), we derive several other true online methods.

This article is organized as follows. We start by presenting the required background in Section 2. Then, we present the new online forward view in Section 3, followed by the presentation of true online TD(λ) in Section 4. Section 5 presents the empirical study. Furthermore, in Section 6, we present several other true online methods. In Section 7, we discuss in detail related papers. Finally, Section 8 concludes.

2. Background

Here, we present the main learning framework. As a convention, we indicate scalar-valued random variables by capital letters (e.g. S_t, R_t), vectors by bold lowercase letters (e.g. θ, ϕ), functions by non-bold lowercase letters (e.g. v, γ), and sets by calligraphic font (e.g. S, \mathcal{A}).¹

2.1 Markov Decision Processes

Reinforcement learning (RL) problems are often formalized as *Markov decision processes* (MDPs), which can be described as 5-tuples of the form $(S, \mathcal{A}, p, r, \gamma)$, where S indicates the set of all states; \mathcal{A} indicates the set of all actions; $p(s'|s, a)$ indicates the probability of a transition to state $s' \in S$, when action $a \in \mathcal{A}$ is taken in state $s \in S$; $r(s, a, s')$ indicates the expected reward for a transition from state s to state s' under action a ; the discount factor γ specifies how future rewards are weighted with respect to the immediate reward.

Actions are taken at discrete time steps $t = 0, 1, 2, \dots$ according to a *policy* $\pi : S \times \mathcal{A} \rightarrow [0, 1]$, which defines for each action the selection probability conditioned on the state. The *return* at time t is defined as the discounted sum of rewards, observed after t :

$$G_t := R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \dots = \sum_{i=1}^{\infty} \gamma^{i-1} R_{t+i},$$

where R_{t+1} is the reward received after taking action A_t in state S_t . Some MDPs contain special states called *terminal states*. After reaching a terminal state, no further reward is obtained and no further state transitions occur. Hence, a terminal state can be interpreted as a state where each action returns to itself with a reward of 0. An interaction sequence from the initial state to a terminal state is called an *episode*.

Each policy π has a corresponding state-value function v_π , which maps any state $s \in S$ to the expected value of the return from that state, when following policy π :

$$v_\pi(s) := \mathbb{E}\{G_t | S_t = s, \pi\}.$$

In addition, the action-value function q_π gives the expected return for policy π , given that action $a \in \mathcal{A}$ is taken in state $s \in S$:

$$q_\pi(s, a) := \mathbb{E}\{G_t | S_t = s, A_t = a, \pi\}.$$

¹ An exception to this convention is the TD error, a scalar-valued random variable that we indicate by δ_t .

Because no further rewards can be obtained from a terminal state, the state-value and action-values for a terminal state are always 0.

There are two tasks that are typically associated with an MDP. First, there is the task of determining (an estimate of) the value function v_π for some given policy π . The second, more challenging task is that of determining (an estimate of) the optimal policy π_* , which is defined as the policy whose corresponding value function has the highest value in each state:

$$v_{\pi_*}(s) := \max_{\pi} v_{\pi}(s), \quad \text{for each } s \in S.$$

In RL, these two tasks are considered under the condition that the reward function r and the transition-probability function p are unknown. Hence, the tasks have to be solved using samples obtained from interacting with the environment.

2.2 Temporal-Difference Learning

Let's consider the task of learning an estimate V of the value function v_π from samples, where v_π is being estimated using linear function approximation. That is, V is the inner product between a feature vector $\phi(s) \in \mathbb{R}^n$ of s , and a weight vector $\theta \in \mathbb{R}^n$:

$$V(s, \theta) = \theta^\top \phi(s).$$

If s is a terminal state, then by definition $\phi(s) := \mathbf{0}$, and hence $V(s, \theta) = 0$.

We can formulate the problem of estimating v_π as an error-minimization problem, where the error is a weighted average of the squared difference between the value of a state and its estimate:

$$E(\theta) := \frac{1}{2} \sum_{\delta} d_\pi(s_t) \left(v_\pi(s_t) - \theta^\top \phi(s_t) \right)^2,$$

with d_π the stationary distribution induced by π . The above error function can be minimized by using stochastic gradient descent while sampling from the stationary distribution, resulting in the following update rule:

$$\theta_{t+1} = \theta_t - \alpha \frac{1}{2} \nabla_{\theta} \left(v_\pi(S_t) - \theta^\top \phi_t \right)^2,$$

using ϕ_t as a shorthand for $\phi(S_t)$. The parameter α is called the *step-size*. Using the chain rule, we can rewrite this update as:

$$\begin{aligned} \theta_{t+1} &= \theta_t + \alpha \left(v_\pi(S_t) - \theta^\top \phi_t \right) \nabla_{\theta} \left(\theta^\top \phi_t \right), \\ &= \theta_t + \alpha \left(v_\pi(S_t) - \theta^\top \phi_t \right) \phi_t. \end{aligned}$$

Because v_π is in general unknown, an estimate U_t of $v_\pi(S_t)$ is used, which we call the *update target*, resulting in the following general update rule:

$$\theta_{t+1} = \theta_t + \alpha (U_t - \theta^\top \phi_t) \phi_t. \quad (1)$$

There are many different update targets possible. For an unbiased estimator the full return can be used, that is, $U_t = G_t$. However, the full return has the disadvantage that its

variance is typically very high. Hence, learning with the full return can be slow. Temporal-difference (TD) learning addresses this issue by using update targets based on other value estimates. While the update target is no longer unbiased in this case, the variance is typically much smaller, and learning much faster. TD learning uses the Bellman equations as its mathematical foundation for constructing update targets. These equations relate the value of a state to the values of its successor states:

$$v_\pi(s) = \sum_a \pi(s, a) \sum_{s'} p(s' | s, a) (r(s, a, s') + \gamma v_\pi(s')).$$

Writing this equation in terms of an expectation yields:

$$v_\pi(s) = \mathbb{E}\{R_{t+1} + \gamma v_\pi(S_{t+1}) | S_t = s\}_{\pi, p, r}.$$

Sampling from this expectation, while using linear function approximation to approximate v_π , results in the update target:

$$U_t = R_{t+1} + \gamma \boldsymbol{\theta}^\top \boldsymbol{\phi}_{t+1}.$$

This update target is called a one-step update target, because it is based on information from only one time step ahead. Applying the Bellman equation multiple times results in update targets based on information further ahead. Such update targets are called multi-step update targets.

2.3 TD(λ)

The TD(λ) algorithm implements the following update equations:

$$\delta_t = R_{t+1} + \gamma \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_t, \quad (2)$$

$$\mathbf{e}_t = \gamma \lambda \mathbf{e}_{t-1} + \boldsymbol{\phi}_t, \quad (3)$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t + \alpha \delta_t \mathbf{e}_t, \quad (4)$$

for $t \geq 0$, and with $\mathbf{e}_{-1} = \mathbf{0}$. The scalar δ_t is called the *TD error*, and the vector \mathbf{e}_t is called the *eligibility-trace* vector. The update of \mathbf{e}_t shown above is referred to as the *accumulating-trace* update. As a shorthand, we will refer to this version of TD(λ) as ‘accumulate TD(λ)’, to distinguish it from a slightly different version that is discussed below. While these updates appear to deviate from the general, gradient-descent-based update rule given in (1), there is a close connection to this update rule. This connection is formalized through the forward view of TD(λ), which we discuss in detail in the next section. Algorithm 1 shows the pseudocode for accumulate TD(λ).

Accumulate TD(λ) can be very sensitive with respect to the α and λ parameters. Especially, a large value of λ combined with a large value of α can easily cause divergence, even on simple tasks with bounded rewards. For this reason, a variant of TD(λ) is sometimes used that is more robust with respect to these parameters. This variant, which assumes binary features, uses a different trace-update equation:

$$\mathbf{e}_t[i] = \begin{cases} \gamma \lambda \mathbf{e}_{t-1}[i], & \text{if } \boldsymbol{\phi}_t[i] = 0; \\ 1, & \text{if } \boldsymbol{\phi}_t[i] = 1, \end{cases} \quad \text{for all features } i.$$

Algorithm 1 accumulate TD(λ)

INPUT: $\alpha, \lambda, \gamma, \boldsymbol{\theta}_{init}$

$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta}_{init}$

Loop (over episodes):

 obtain initial $\boldsymbol{\phi}$

$\mathbf{e} \leftarrow \mathbf{0}$

 While terminal state has not been reached, do:

 obtain next feature vector $\boldsymbol{\phi}'$ and reward R

$\delta \leftarrow R + \gamma \boldsymbol{\theta}^\top \boldsymbol{\phi}' - \boldsymbol{\theta}^\top \boldsymbol{\phi}$

$\mathbf{e} \leftarrow \gamma \lambda \mathbf{e} + \boldsymbol{\phi}$

$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \alpha \delta \mathbf{e}$

$\boldsymbol{\phi} \leftarrow \boldsymbol{\phi}'$

where $\mathbf{x}[i]$ indicates the i -th component of vector \mathbf{x} . This update is referred to as the *replacing-trace* update. As a shorthand, we will refer to the version of TD(λ) using the replacing-trace update as ‘replace TD(λ)’.

3. The Online Forward View

The traditional forward view relates the TD(λ) update equations to the general update rule shown in Equation (1). Specifically, for small step-sizes the weight vector at the end of an episode computed by accumulate TD(λ) is approximately the same as the weight vector resulting from a sequence of Equation (1) updates (one for each visited state) using a particular multi-step update target, called the λ -return (Sutton & Barto, 1998; Bertsekas & Tsitsiklis, 1996). The λ -return for state S_t is defined as:

$$G_t^{(\lambda)} := (1 - \lambda) \sum_{n=1}^{T-t-1} \lambda^{n-1} G_t^{(n)} + \lambda^{T-t-1} G_t, \quad (5)$$

where T is the time step the terminal state is reached, and $G_t^{(n)}$ is the n -step return, defined as:

$$G_t^{(n)} := \sum_{k=1}^n \gamma^{k-1} R_{t+k} + \gamma^n V(S_{t+n} | \boldsymbol{\theta}_{t+n-1}).$$

We call a method that updates the value of each visited state at the end of the episode an *offline* method; we call a method that updates the value of each visited state immediately after the visit (i.e., at the time step after the visit) an *online* method. TD(λ) is an online method. The update sequence of the traditional forward view, however, corresponds with an offline method, because the λ -return requires data up to the end of an episode. This leaves open the question of how to interpret the weights of TD(λ) *during* an episode. In this section, we provide an answer to this long-standing open question. We introduce a bounded version of the λ -return that only uses information up to a certain horizon and we use this to construct an online forward view. This online forward view approximates the weight vectors of accumulate TD(λ) at *all* time steps, instead of only at the end of an episode.

3.1 The Online λ -Return Algorithm

The concept of an online forward view contains a paradox. On the one hand, multi-step update targets require data from time steps far beyond the time a state is visited; on the other hand, the online aspect requires that the value of a visited state is updated immediately. The solution to this paradox is to assign a sequence of update targets to each visited state. The first update target in this sequence contains data from only the next time step, the second contains data from the next two time steps, the third from the next three time steps, and so on. Now, given an initial weight vector and a sequence of visited states, a new weight vector can be constructed by updating each visited state with an update target that contains data up to the current time step. Below, we formalize this idea.

We define the *interim λ -return* for state S_k with horizon $h \in \mathbb{N}^+$, $h > k$ as follows:

$$G_k^{\lambda|h} := (1 - \lambda) \sum_{n=1}^{h-k-1} \lambda^{n-1} G_k^{(n)} + \lambda^{h-k-1} G_k^{(h-k)}. \quad (6)$$

Note that this update target does not use data beyond the horizon h . $G_k^{\lambda|h}$ implicitly defines a sequence of update targets for S_k : $\{G_k^{\lambda|k+1}, G_k^{\lambda|k+2}, G_k^{\lambda|k+3}, \dots\}$. As time increases, update targets based on data further away become available for state S_k . At a particular time step t , a new weight vector is computed by performing an Equation (1) update for each visited state using the interim λ -return with horizon t , starting from the initial weight vector θ_{init} . Hence, at time step t , a sequence of t updates occurs. To describe this sequence mathematically, we use weight vectors with two indices: θ_k^t . The superscript indicates the time step at which the updates are performed (this value corresponds with the horizon of the interim λ -returns that are used in the updates). The subscript is the iteration index of the sequence (it corresponds with the number of updates that have been performed at a particular time step). As an example, the update sequences for the first three time steps are:

$$\begin{aligned} t = 1 : \quad & \theta_1^1 = \theta_0^1 + \alpha(G_0^{\lambda|1} - (\theta_0^1)^\top \phi_0) \phi_0, \\ t = 2 : \quad & \theta_1^2 = \theta_0^2 + \alpha(G_0^{\lambda|2} - (\theta_0^2)^\top \phi_0) \phi_0, \\ & \theta_2^2 = \theta_1^2 + \alpha(G_1^{\lambda|2} - (\theta_1^2)^\top \phi_1) \phi_1, \\ t = 3 : \quad & \theta_1^3 = \theta_0^3 + \alpha(G_0^{\lambda|3} - (\theta_0^3)^\top \phi_0) \phi_0, \\ & \theta_2^3 = \theta_1^3 + \alpha(G_1^{\lambda|3} - (\theta_1^3)^\top \phi_1) \phi_1, \\ & \theta_3^3 = \theta_2^3 + \alpha(G_2^{\lambda|3} - (\theta_2^3)^\top \phi_2) \phi_2, \end{aligned}$$

with $\theta_0^t := \theta_{init}$ for all t . More generally, the update sequence at time step t is:

$$\theta_{k+1}^t := \theta_k^t + \alpha \left(G_k^{\lambda|t} - (\theta_k^t)^\top \phi_k \right) \phi_k, \quad \text{for } 0 \leq k < t. \quad (7)$$

We define θ_t (without superscript) as the final weight vector of the update sequence at time t , that is, $\theta_t := \theta_t^t$. We call the algorithm implementing Equation (7) the *online λ -return*

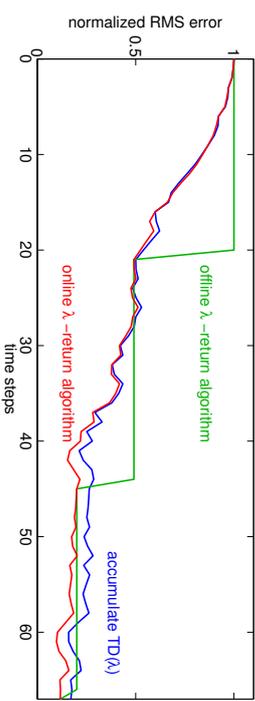

Figure 1: RMS error as function of time for the first 3 episodes of a random walk task, for $\lambda = 1$ and $\alpha = 0.2$. The error shown is the RMS error over all states, normalized by the initial RMS error.

algorithm. By contrast, we call the algorithm that implements the traditional forward view the *offline λ -return algorithm*.

The update sequence performed by the online λ -return algorithm at time step T (the time step that a terminal state is reached) is very similar to the update sequence performed by the offline λ -return algorithm. In particular, note that $G_t^{\lambda|T}$ and G_t^λ are the same, under the assumption that the weights used for the value estimates are the same. Because these weights are in practise not exactly the same, there will typically be a small difference.²

Figure 1 illustrates the difference between the online and offline λ -return algorithm, as well as accumulate TD(λ), by showing the RMS error on a random walk task. The task consists of 10 states laid out in a row plus a terminal state on the left. Each state transitions with 70% probability to its left neighbour and with 30% probability to its right neighbour (or to itself in case of the right-most state). All rewards are 1 and $\gamma = 1$. Furthermore, $\lambda = 1$ and $\alpha = 0.2$. The right-most state is the initial state. Whereas the offline λ -return algorithm only makes updates at the end of an episode, the online λ -return algorithm, as well as accumulate TD(λ), make updates at every time step.

The comparison on the random walk task shows that accumulate TD(λ) behaves similar to the online λ -return algorithm. In fact, the smaller the step-size, the smaller the difference between accumulate TD(λ) and the online λ -return algorithm. This is formalized by Theorem 1. The proof of the theorem can be found in Appendix A. The theorem uses the term Δ_t^f , which is defined as:

$$\Delta_t^f := (G_t^{\lambda|t} - \theta_0^\top \phi_t) \phi_t,$$

with $G_t^{\lambda|t}$ the interim λ -return for state S_t with horizon t that uses θ_0 for all value evaluations. Note that Δ_t^f is independent of the step-size.

² If $\lambda = 1$ there is never a difference because there is no bootstrapping.

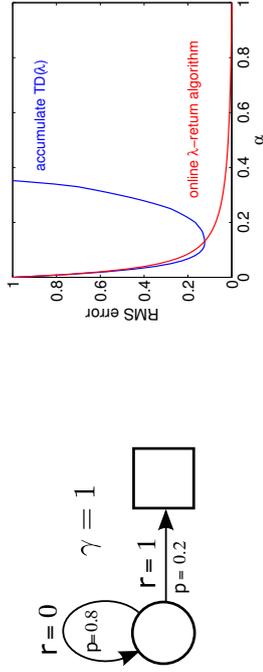

Figure 2: *Left:* One-state example (the square indicates a terminal state). *Right:* The RMS error of the state value at the end of an episode, averaged over the first 10 episodes, for $\lambda = 1$.

Theorem 1 Let θ_0 be the initial weight vector, θ_t^{id} be the weight vector at time t computed by accumulate TD(λ), and θ_t^λ be the weight vector at time t computed by the online λ -return algorithm. Furthermore, assume that $\sum_{i=0}^{t-1} \Delta_i^i \neq \mathbf{0}$. Then, for all time steps t :

$$\frac{\|\theta_t^{id} - \theta_t^\lambda\|}{\|\theta_t^{id} - \theta_0\|} \rightarrow 0, \quad \text{as } \alpha \rightarrow 0.$$

Theorem 1 generalizes the traditional result to arbitrary time steps. The traditional result states that the difference between the weight vector at the end of an episode computed by the offline λ -return algorithm and the weight vector at the end of an episode computed by accumulate TD(λ) goes to 0, if the step-size goes to 0 (Bertsekas & Tsitsiklis, 1996).

3.2 Comparison to Accumulate TD(λ)

While accumulate TD(λ) behaves like the online λ -return algorithm for small step-sizes, small step-sizes often result in slow learning. Hence, higher step-sizes are desirable. For higher step-sizes, however, the behaviour of accumulate TD(λ) can be very different from that of the online λ -return algorithm. And as we show in the empirical section of this article (Section 5), when there is a difference, it is almost exclusively in favour of the online λ -return algorithm. In this section, we analyze why the online λ -return algorithm can outperform accumulate TD(λ), using the one-state example shown in the left of Figure 2.

The right of Figure 2 shows the RMS error over the first 10 episodes of the one-state example for different step-sizes and $\lambda = 1$. While for small step-sizes accumulate TD(λ) behaves indeed like the online λ -return algorithm—as predicted by Theorem 1—, for larger step-sizes the difference becomes huge. To understand the reason for this, we derive an analytical expression for the value at the end of an episode.

First, we consider accumulate TD(λ). Because there is only one state involved, we indicate the value of this state simply by V . The update at the end of an episode is $V_T =$

$V_{T-1} + \alpha e_{T-1} \delta_{T-1}$. In our example, $\delta_t = 0$ for all time steps t , except for $t = T - 1$, where $\delta_{T-1} = 1 - V_{T-1}$. Because δ_t is 0 for all time steps except the last, $V_{T-1} = V_0$. Furthermore, $\phi_t = \mathbf{1}$ for all time steps t , resulting in $e_{T-1} = T$. Substituting all this in the expression for V_T yields:

$$V_T = V_0 + T\alpha(1 - V_0), \quad \text{for accumulate TD}(\lambda). \quad (8)$$

So for accumulate TD(λ), the total value difference is simply a summation of the value difference corresponding to a single update.

Now, consider the online λ -return algorithm. The value at the end of an episode, V_T , is equal to V_T^T , resulting from the update sequence:

$$V_{k+1}^T = V_k^T + \alpha(G_k^{\lambda|T} - V_k^T), \quad \text{for } 0 \leq k < T.$$

By incremental substitution, we can directly express V_T in terms of the initial value, V_0 , and the update targets:

$$V_T = (1 - \alpha)^T V_0 + \alpha(1 - \alpha)^{T-1} G_0^{\lambda|T} + \alpha(1 - \alpha)^{T-2} G_1^{\lambda|T} + \dots + \alpha G_{T-1}^{\lambda|T}.$$

Because $G_k^{\lambda|T} = \mathbf{1}$ for all k in our example, the weights of all update targets can be added together and the expression can be rewritten as a single pseudo-update, yielding:

$$V_T = V_0 + (1 - (1 - \alpha)^T) \cdot (1 - V_0), \quad \text{for the online } \lambda\text{-return algorithm.} \quad (9)$$

The term $1 - (1 - \alpha)^T$ in (9) acts like a pseudo step-size. For larger α or T this pseudo step-size increases in value, but as long as $\alpha \leq 1$ the value will never exceed 1. By contrast, for accumulate TD(λ) the pseudo step-size is $T\alpha$, which can grow much larger than 1 even for $\alpha < 1$, causing divergence of values. This is the reason that accumulate TD(λ) can be very sensitive to the step-size and it explains why the optimal step-size for accumulate TD(λ) is much smaller than the optimal step-size for the online λ -return algorithm in Figure 2 ($\alpha \approx 0.15$ versus $\alpha = 1$, respectively). Moreover, because the variance on the pseudo step-size is higher for accumulate TD(λ) the performance at the optimal step-size for accumulate TD(λ) is worse than the performance at the optimal step-size for the online λ -return algorithm.

3.3 Comparison to Replace TD(λ)

The sensitivity of accumulate TD(λ) to divergence, demonstrated in the previous subsection, has been known for long. In fact, replace TD(λ) was designed to deal with this. But while replace TD(λ) is much more robust with respect to divergence, it also has its limitations. One obvious limitation is that it only applies to binary features, so it is not generally applicable. But even in domains where replace TD(λ) can be applied, it can perform poorly. The reason is that replacing previous trace values, rather than adding to it, reduces the multi-step characteristics of TD(λ).

To illustrate this, consider the two-state example shown in the left of Figure 3. It is easy to see that the value of the left-most state is 2 and of the other state is 0. The state representation consists of only a single, binary feature that is 1 in both states and 0 in the terminal state. Because there is only a single feature, the state values cannot be represented

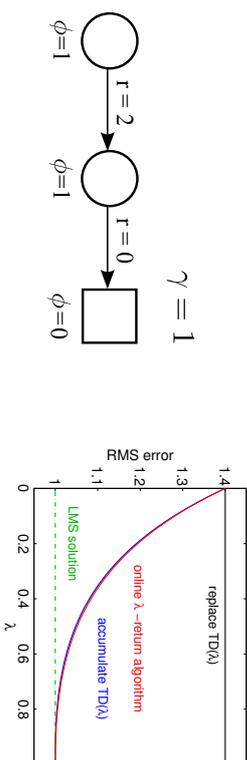

Figure 3: *Left*: Two-state example. *Right*: The RMS error after convergence for different λ (at $\alpha = 0.01$). We consider values to be converged if the error changed less than 1% over the last 100 time steps.

exactly. The weight that minimizes the mean squared error assigns a value of 1 to both states, resulting in an RMS error of 1. Now consider the graph shown in the right of Figure 3, which shows the asymptotic RMS error for different values of λ . The error for accumulate TD(λ) converges to the least mean squares (LMS) error for $\lambda = 1$, as predicted by the theory (Dayan, 1992). The online λ -return algorithm has the same convergence behaviour (due to Theorem 1). By contrast, replace TD(λ) converges to the same value as TD(0) for any value of λ . The reason for this behaviour is that because the single feature is active at all time steps, the multi-step behaviour of TD(λ) is fully removed, no matter the value of λ . Hence, replace TD(λ) behaves exactly the same as TD(0) for any value of λ at all time steps. As a result, it also behaves like TD(0) asymptotically.

The two-state example very clearly demonstrates that there is a price payed by replace TD(λ) to achieve robustness with respect to divergence: a reduction in multi-step behaviour. By contrast, the online λ -return algorithm, which is also robust to divergence, does not have this disadvantage. Of course, the two-state example, as well as the one-state example from the previous section, are extreme examples, merely meant to illustrate what can go wrong. But in practise, a domain will often have some characteristics of the one-state example and some of the two-state example, which negatively impacts the performance of both accumulate and replace TD(λ).

4. True Online TD(λ)

The online λ -return algorithm is impractical on many domains: the memory it uses, as well as the computation required per time step increases linearly with time. Fortunately, it is possible to rewrite the update equations of the online λ -return algorithm to a different set of update equations that can be implemented with a computational complexity that is independent of time. In fact, this alternative set of update equations differs from the update equations of accumulate TD(λ) only by two extra terms, each of which can be computed

Algorithm 2 true online TD(λ)

```

INPUT:  $\alpha, \lambda, \gamma, \theta_{init}$ 
 $\theta \leftarrow \theta_{init}$ 
Loop (over episodes):
  obtain initial  $\phi$ 
   $e \leftarrow 0$ ;  $V_{old} \leftarrow 0$ 
  While terminal state has not been reached, do:
    obtain next feature vector  $\phi'$  and reward  $R$ 
     $V \leftarrow \theta^\top \phi$ 
     $V' \leftarrow \theta'^\top \phi'$ 
     $\delta \leftarrow R + \gamma V' - V$ 
     $e \leftarrow \gamma \lambda e + \phi - \alpha \gamma \lambda (e^\top \phi)$ 
     $\theta \leftarrow \theta + \alpha (\delta + V - V_{old}) e - \alpha (V - V_{old}) \phi$ 
     $V_{old} \leftarrow V$ 
     $\phi \leftarrow \phi'$ 

```

efficiently. The algorithm implementing these equations is called true online TD(λ) and is discussed below.

4.1. The Algorithm

For the online λ -return algorithm, at each time step a sequence of updates is performed. The length of this sequence, and hence the computation per time step, increases over time. However, it is possible to compute the weight vector resulting from the sequence at time step $t + 1$ directly from the weight vector resulting from the sequence at time step t . This results in the following update equations (see Appendix B for the derivation):

$$\delta_t = R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t, \quad (10)$$

$$e_t = \gamma \lambda e_{t-1} + \phi_t - \alpha \gamma \lambda (e_{t-1}^\top \phi_t) \phi_t, \quad (11)$$

$$\theta_{t+1} = \theta_t + \alpha \delta_t e_t + \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) (e_t - \phi_t), \quad (12)$$

for $t \geq 0$, and with $e_{-1} = 0$. Compared to accumulate TD(λ), both the trace update and the weight update have an additional term. We call a trace updated in this way a *dutch trace*: we call the term $\alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) (e_t - \phi_t)$ the *TD-error time-step correction*, or simply the δ -correction. Algorithm 2 shows pseudocode that implements these equations.³

In terms of computation time, true online TD(λ) has a (slightly) higher cost due to the two extra terms that have to be accounted for. While the computation-time complexity of true online TD(λ) is the same as that of accumulate/replace TD(λ)— $\mathcal{O}(n)$ per time step with n being the number of features—the actual computation time can be close to twice as much in some cases. In other cases (for example if sparse feature vectors are used), the computation time of true online TD(λ) is only a fraction more than that of

³ When using a time-dependent step-size (e.g., when annealing the step-size) use the pseudocode from Section 6.1. For reasons explained in that section this requires a modified trace update. That pseudocode is the same as the pseudocode from van Seijen & Sutton (2014).

accumulate/replace $\text{TD}(\lambda)$. In terms of memory, true online $\text{TD}(\lambda)$ has the same cost as accumulate/replace $\text{TD}(\lambda)$.

4.2 When Can a Performance Difference be Expected?

In Section 3, a number of examples were shown where the online λ -return algorithm outperforms accumulate/replace $\text{TD}(\lambda)$. Because true online $\text{TD}(\lambda)$ is simply an efficient implementation of the online λ -return algorithm, true online $\text{TD}(\lambda)$ will outperform accumulate/replace $\text{TD}(\lambda)$ on these examples as well. But not in all cases will there be a performance difference. For example, it follows from Theorem 1 that when appropriately small step-sizes are used, the difference between the online λ -return algorithm/true online $\text{TD}(\lambda)$ and accumulate $\text{TD}(\lambda)$ is negligible. In this section, we identify two other factors that affect whether or not there will be a performance difference. While the focus of this section is on performance *difference* rather than performance *advantage*, our experiments will show that true online $\text{TD}(\lambda)$ performs always at least as well as accumulate $\text{TD}(\lambda)$ and replace $\text{TD}(\lambda)$. In other words, our experiments suggest that whenever there is a performance difference, it is in favour of true online $\text{TD}(\lambda)$.

The first factor is the λ parameter and follows straightforwardly from the true online $\text{TD}(\lambda)$ update equations.

Proposition 1 For $\lambda = 0$, accumulate $\text{TD}(\lambda)$, replace $\text{TD}(\lambda)$ and the online λ -return algorithm / true online $\text{TD}(\lambda)$ behave the same.

Proof For $\lambda = 0$, the accumulating-trace update, the replacing-trace update and the dutch-trace update all reduce to $\mathbf{e}_t = \boldsymbol{\phi}_t$. In addition, because $\mathbf{e}_t = \boldsymbol{\phi}_t$, the δ -correction of true online $\text{TD}(\lambda)$ is 0. ■

Because the behaviour of $\text{TD}(\lambda)$ for small λ is close to the behaviour of $\text{TD}(0)$, it follows that significant performance differences will only be observed when λ is large.

The second factor is related to how often a feature has a non-zero value. We start again with a proposition that highlights a condition under which the different $\text{TD}(\lambda)$ versions behave the same. The proposition makes use of an accumulating trace at time step $t-1$, $\mathbf{e}_{t-1}^{\text{acc}}$, whose non-recursive form is:

$$\mathbf{e}_{t-1}^{\text{acc}} = \sum_{k=0}^{t-1} (\gamma\lambda)^{t-1-k} \boldsymbol{\phi}_k. \quad (13)$$

Furthermore, the proposition uses $\boldsymbol{x}[i]$ to denote the i -th element of vector \boldsymbol{x} .

Proposition 2 If for all features i and at all time steps t

$$\mathbf{e}_{t-1}^{\text{acc}}[i] \cdot \boldsymbol{\phi}_t[i] = 0, \quad (14)$$

then accumulate $\text{TD}(\lambda)$, replace $\text{TD}(\lambda)$ and the online λ -return algorithm / true online $\text{TD}(\lambda)$ behave the same (for any λ).

Proof Condition (14) implies that if $\boldsymbol{\phi}_t[i] \neq 0$, then $\mathbf{e}_{t-1}^{\text{acc}}[i] = 0$. From this it follows that for binary features the accumulating-trace update can be written as a replacing-trace

update at every time step:

$$\begin{aligned} \mathbf{e}_t^{\text{acc}}[i] &:= \gamma\lambda\mathbf{e}_{t-1}^{\text{acc}}[i] + \boldsymbol{\phi}_t[i], \\ &= \begin{cases} \gamma\lambda\mathbf{e}_{t-1}^{\text{acc}}[i], & \text{if } \boldsymbol{\phi}_t[i] = 0; \\ 1, & \text{if } \boldsymbol{\phi}_t[i] = 1. \end{cases} \end{aligned}$$

Hence, accumulate $\text{TD}(\lambda)$ and replace $\text{TD}(\lambda)$ perform exactly the same updates.

Furthermore, condition (14) implies that $(\mathbf{e}_{t-1}^{\text{acc}})^\top \boldsymbol{\phi}_t = 0$. Hence, the accumulating-trace update can also be written as a dutch trace update at every time step:

$$\begin{aligned} \mathbf{e}_t^{\text{acc}} &:= \gamma\lambda\mathbf{e}_{t-1}^{\text{acc}} + \boldsymbol{\phi}_t, \\ &= \gamma\lambda\mathbf{e}_{t-1}^{\text{acc}} + \boldsymbol{\phi}_t - \alpha\gamma\lambda((\mathbf{e}_{t-1}^{\text{acc}})^\top \boldsymbol{\phi}_t) \boldsymbol{\phi}_t. \end{aligned}$$

In addition, note that the δ -correction is proportional to $\boldsymbol{\theta}_t^\top \boldsymbol{\phi}_t - \boldsymbol{\theta}_{t-1}^\top \boldsymbol{\phi}_t$, which can be written as $(\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top \boldsymbol{\phi}_t$. The value $(\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top \boldsymbol{\phi}_t$ is proportional to $(\mathbf{e}_{t-1}^{\text{acc}})^\top \boldsymbol{\phi}_t$ for accumulate $\text{TD}(\lambda)$. Because $(\mathbf{e}_{t-1}^{\text{acc}})^\top \boldsymbol{\phi}_t = 0$, accumulate $\text{TD}(\lambda)$ can add a δ -correction at every time step without any consequence. This shows that accumulate $\text{TD}(\lambda)$ makes the same updates as true online $\text{TD}(\lambda)$. ■

An example of a domain where the condition of Proposition 2 holds is a domain with tabular features (each state is represented with a unique standard-basis vector), where a state is never revisited within the same episode.

The condition of Proposition 2 holds approximately when the value $|\mathbf{e}_{t-1}^{\text{acc}}[i] \cdot \boldsymbol{\phi}_t[i]|$ is close to 0 for all features at all time steps. In this case, the different $\text{TD}(\lambda)$ versions will perform very similarly. It follows from Equation (13) that this is the case when there is a long time delay between the time steps that a feature has a non-zero value. Specifically, if there is always at least n time steps between two subsequent times that a feature i has a non-zero value with $\gamma\lambda^n$ being very small, then $|\mathbf{e}_{t-1}^{\text{acc}}[i] \cdot \boldsymbol{\phi}_t[i]|$ will always be close to 0. Therefore, in order to see a large performance difference, the same features should have a non-zero value often and within a small time frame (relative to $\gamma\lambda$).

Summarizing the analysis so far: in order to see a performance difference α and λ should be sufficiently large, and the same features should have a non-zero value often and within a small time frame. Based on this summary, we can address a related question: on what type of domains will there be a performance difference between true online $\text{TD}(\lambda)$ with optimized parameters and accumulate/replace $\text{TD}(\lambda)$ with optimized parameters. The first two conditions suggest that the domain should result in a relatively large optimal α and optimal λ . This is typically the case for domains with a relatively low variance on the return. The last condition can be satisfied in multiple ways. It is for example satisfied by domains that have non-sparse feature vectors (that is, domains for which at any particular time step most features have a non-zero value).

4.3 True Online Sarsa(λ)

$\text{TD}(\lambda)$ and true online $\text{TD}(\lambda)$ are policy evaluation methods. However, they can be turned into control methods in a straightforward way. From a learning perspective, the main difference is that the prediction of the expected return should be conditioned on the state

Algorithm 3 true online Sarsa(λ)

INPUT: $\alpha, \lambda, \gamma, \theta_{init}$
 $\theta \leftarrow \theta_{init}$
Loop (over episodes):
 obtain initial state S
 select action A based on state S (for example ϵ -greedy)
 $\psi \leftarrow$ features corresponding to S, A
 $e \leftarrow \mathbf{0}$; $Q_{old} \leftarrow \mathbf{0}$
 While terminal state has not been reached, do:
 take action A , observe next state S' and reward R
 select action A' based on state S'
 $\psi' \leftarrow$ features corresponding to S', A' (if S' is terminal state, $\psi' \leftarrow \mathbf{0}$)
 $Q \leftarrow \theta^\top \psi$
 $Q' \leftarrow \theta'^\top \psi'$
 $\delta \leftarrow R + \gamma Q' - Q$
 $e \leftarrow \gamma \lambda e + \psi - \alpha \gamma \lambda (e^\top \psi) \psi$
 $\theta \leftarrow \theta + \alpha (\delta + Q - Q_{old}) e - \alpha (Q - Q_{old}) \psi$
 $Q_{old} \leftarrow Q'$
 $\psi \leftarrow \psi'$; $A \leftarrow A'$

and action, rather than only on the state. This means that an estimate of the action-value function q_π is being learned, rather than of the state-value function v_π .

Another difference is that instead of having a fixed policy that generates the behaviour, the policy depends on the action-value estimates. Because these estimates typically improve over time, so does the policy. The (on-policy) control counterpart of TD(λ) is the popular Sarsa(λ) algorithm. The control counterpart of true online TD(λ) is ‘true online Sarsa(λ)’. Algorithm 3 shows pseudocode for true online Sarsa(λ).

To ensure accurate estimates for all state-action values are obtained, typically some exploration strategy has to be used. A simple, but often sufficient strategy is to use an ϵ -greedy behaviour policy. That is, given current state S_t , with probability ϵ a random action is selected, and with probability $1 - \epsilon$ the greedy action is selected:

$$A_t^{greedy} = \arg \max_a \theta_t^\top \psi(S_t, a),$$

with $\psi(s, a)$ an action-feature vector, and $\theta_t^\top \psi(s, a)$ a (linear) estimate of $q_\pi(s, a)$ at time step t . A common way to derive an action-feature vector $\psi(s, a)$ from a state-feature vector $\phi(s)$ involves an action-feature vector of size $n|\mathcal{A}|$, where n is the number of state features and $|\mathcal{A}|$ is the number of actions. Each action corresponds with a block of n features in this action-feature vector. The features in $\psi(s, a)$ that correspond to action a take on the values of the state features; the features corresponding to other actions have a value of 0.

5. Empirical Study

This section contains our main empirical study, comparing TD(λ), as well as Sarsa(λ), with their true online counterparts. For each method and each domain, a scan over the step-size

α and the trace-decay parameter λ is performed such that the optimal performance can be compared. In Section 5.4, we discuss the results.

5.1 Random MRPs

For our first series of experiments we used randomly constructed Markov reward processes (MRPs).⁴ An MRP can be interpreted as an MDP with only a single action per state. Consequently, there is only one policy possible. We represent a random MRP as a 3-tuple (k, b, σ) , consisting of k , the number of states; b , the branching factor (that is, the number of next states with a non-zero transition probability); and σ , the standard deviation of the reward. An MRP is constructed as follows. The b potential next states for a particular state are drawn from the total set of states at random, and without replacement. The transition probabilities to those states are randomized as well (by partitioning the unit interval at $b - 1$ random cut points). The expected value of the reward for a transition is drawn from a normal distribution with zero mean and unit variance. The actual reward is drawn from a normal distribution with a mean equal to this expected reward and standard deviation σ . There are no terminal states.

We compared the performance of TD(λ) on three different MRPs: one with a small number of states, (10, 3, 0.1), one with a larger number of states, (100, 10, 0.1), and one with a larger number of states but a low branching factor and no stochasticity for the reward, (100, 3, 0). The discount factor γ is 0.99 for all three MRPs. Each MRP is evaluated using three different representations. The first representation consists of *tabular* features, that is, each state is represented with a unique standard-basis vector of k dimensions. The second representation is based on *binary* features. This binary representation is constructed by first assigning indices, from 1 to k , to all states. Then, the binary encoding of the state index is used as a feature vector to represent that state. The length of a feature vector is determined by the total number of states: for $k = 10$, the length is 4; for $k = 100$, the length is 7. As an example, for $k = 10$ the binary feature vectors of states 1, 2 and 3 are (0, 0, 0, 1), (0, 0, 1, 0) and (0, 0, 1, 1), respectively. Finally, the third representation uses non-binary features. For this representation each state is mapped to a 5-dimensional feature vector, with the value of each feature drawn from a normal distribution with zero mean and unit variance. After all the feature values for a state are drawn, they are normalized such that the feature vector has unit length. Once generated, the feature vectors are kept fixed for each state. Note that replace TD(λ) cannot be used with this representation, because replacing traces are only defined for binary features (tabular features are a special case of this).

In each experiment, we performed a scan over α and λ . Specifically, between 0 and 0.1, α is varied according to 10^i with i varying from -3 to -1 with steps of 0.2, and from 0.1 to 2.0 (linearly) with steps of 0.1. In addition, λ is varied from 0 to 0.9 with steps of 0.1 and from 0.9 to 1.0 with steps of 0.01. The initial weight vector is the zero vector in all domains. As performance metric we used the mean-squared error (MSE) with respect to the LMS solution during early learning (for $k = 10$, we averaged over the first 100 time steps; for k

⁴ The code for the MRP experiments is published online at: <https://github.com/armahmood/todd-trmdp-experiments>. The process we used to construct the MRPs is based on the process used by Bhatnagar, Sutton, Ghahraman and Lee (2009).

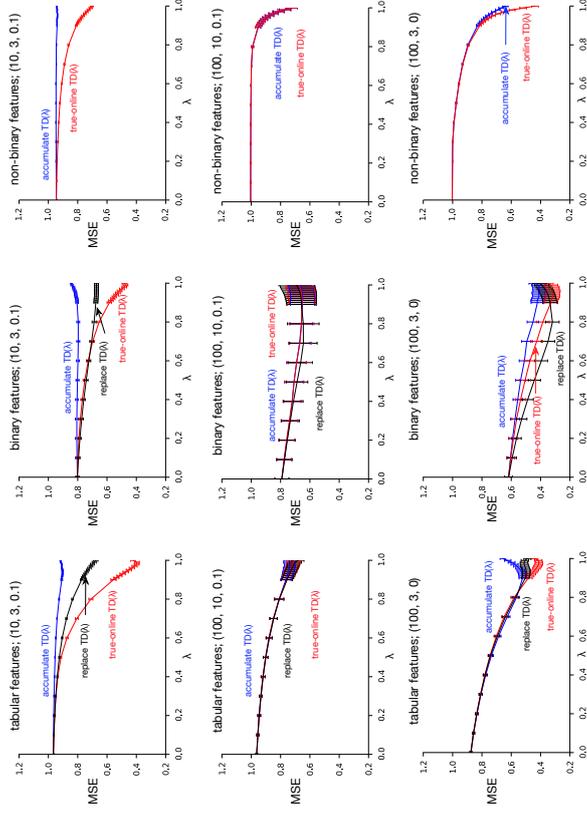

Figure 4: MSE error during early learning for three different MRPs, indicated by (k, b, σ) , and three different representations. The error shown is at optimal α value.

$= 100$, we averaged over the first 1000 time steps). We normalized this error by dividing it by the MSE under the initial weight estimate.

Figure 4 shows the results for different λ at the best value of α . In Appendix C, the results for all α values are shown. The optimal performance of true online TD(λ) is at least as good as the optimal performance of accumulate TD(λ) and replace TD(λ), on all domains and for all representations. A more in-depth discussion of these results is provided in Section 5.4.

5.2 Predicting Signals From a Myoelectric Prosthetic Arm

In this experiment, we compared the performance of true online TD(λ) and TD(λ) on a real-world data-set consisting of sensorimotor signals measured during the human control of an electromechanical robot arm. The source of the data is a series of manipulation tasks performed by a participant with an amputation, as presented by Pilarski et al. (2013). In this study, an amputee participant used signals recorded from the muscles of their residual

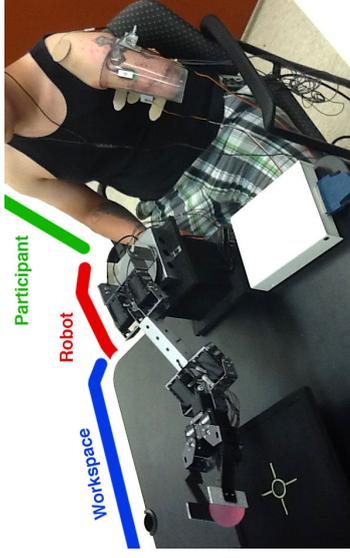

Figure 5: Source of the input data stream and predicted signals used in this experiment: a participant with an amputation performing a simple grasping task using a myoelectrically controlled robot arm, as described in Pilarski et al. (2013). More detail on the subject and experimental setting can be found in Hebert et al. (2014).

limb to control a robot arm with multiple degrees-of-freedom (Figure 5). Interactions of this kind are known as *myoelectric control* (see, for example, Parker et al., 2006).

For consistency and comparison of results, we used the same source data and prediction learning architecture as published in Pilarski et al. (2013). In total, two signals are predicted: grip force and motor angle signals from the robot’s hand. Specifically, the target for the prediction is a discounted sum of each signal over time, similar to return predictions (see general value functions and nexting; Sutton et al., 2011; Modayil et al., 2014). Where possible, we used the same implementation and code base as Pilarski et al. (2013). Data for this experiment consisted of 58,000 time steps of recorded sensorimotor information, sampled at 40 Hz (i.e., approximately 25 minutes of experimental data). The state space consisted of a tile-coded representation of the robot gripper’s position, velocity, recorded gripping force, and two muscle contraction signals from the human user. A standard implementation of tile-coding was used, with ten bins per signal, eight overlapping tilings, and a single active bias unit. This results in a state space with 800,001 features, 9 of which were active at any given time. Hashing was used to reduce this space down to a vector of 200,000 features that are then presented to the learning system. All signals were normalized between 0 and 1 before being provided to the function approximation routine. The discount factor for predictions of both force and angle was $\gamma = 0.97$, as in the results presented by Pilarski et al. (2013). Parameter sweeps over λ and α are conducted for all three methods. The performance metric is the mean absolute return error over all 58,000 time steps of learning, normalized by dividing by the error for $\lambda = 0$.

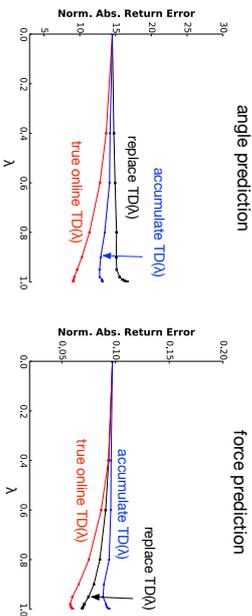

Figure 6: Performance as function of λ at the optimal α value, for the prediction of the servo motor angle (left), as well as the grip force (right).

Figure 6 shows the performance for the angle as well as the force predictions at the best α value for different values of λ . In Appendix D, the results for all α values are shown. The relative performance of replace TD(λ) and accumulate TD(λ) depends on the predictive question being asked. For predicting the robot’s grip force signal—a signal with small magnitude and rapid changes—replace TD(λ) is better than accumulate TD(λ) at all λ values larger than 0. However, for predicting the robot’s hand actuator position, a smoothly changing signal that varies between a range of ~ 300 –500, accumulate TD(λ) dominates replace TD(λ). On both prediction tasks, true online TD(λ) dominates accumulate TD(λ) and replace TD(λ).

5.3 Control in the ALE Domain Asterix

In this final experiment, we compared the performance of true online Sarsa(λ) with that of accumulate Sarsa(λ) and replace Sarsa(λ), on a domain from the Arcade Learning Environment (ALE) (Bellemare et al., 2013; Defazio & Graepel, 2014; Minh et al., 2015), called Asterix. The ALE is a general testbed that provides an interface to hundreds of Atari 2600 games.⁵

In the Asterix domain, the agent controls a yellow avatar, which has to collect ‘potion’ objects, while avoiding ‘harp’ objects (see Figure 7 for a screenshot). Both potions and harps move across the screen horizontally. Every time the agent collects a potion it receives a reward of 50 points, and every time it touches a harp it loses a life (it has three lives in total). The agent can use the actions *up*, *right*, *down*, and *left*, combinations of two directions, and a *no-op* action, resulting in 9 actions in total. The game ends after the agent has lost three lives, or after 5 minutes, whichever comes first.

We use linear function approximation using features derived from the screen pixels. Specifically, we use what Bellemare et al. (2013) call the *Basic* feature set, which ‘encodes

⁵ We used ALE version 0.4.4 for our experiments. The code for the Asterix experiments is published online at: <https://github.com/mcmachado/TrueOnlineSarsa>.

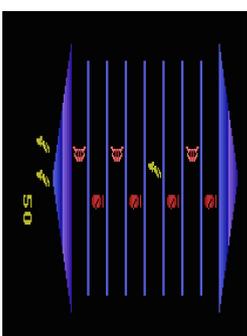

Figure 7: Screenshot of the game ASTERIX.

the presence of colours on the Atari 2600 screen.” It is obtained by first subtracting the game screen background (see Bellemare et al., 2013, sec. 3.1.1) and then dividing the remaining screen in to 16×14 tiles of size 10×15 pixels. Finally, for each tile, one binary feature is generated for each of the 128 available colours, encoding whether a colour is active or not in that tile. This generates 28,672 features (plus a bias term).

Because episode lengths can vary hugely (from about 10 seconds all the way up to 5 minutes), constructing a fair performance metric is non-trivial. For example, comparing the average return on the first N episodes of two methods is only fair if they have seen roughly the same amount of samples in those episodes, which is not guaranteed for this domain. On the other hand, looking at the total reward collected for the first X samples is also not a good metric, because there is no negative reward associated to dying. To resolve this, we look at the return per episode, averaged over the first X samples. More specifically, our metric consists of the average score per episode while learning for 20 hours (4,320,000 frames). In addition, we averaged the resulting number over 400 independent runs.

As with the evaluation experiments, we performed a scan over the step-size α and the trace-decay parameter λ . Specifically, we looked at all combinations of $\alpha \in \{0.20, 0.50, 0.80, 1.10, 1.40, 1.70, 2.00\}$ and $\lambda \in \{0.00, 0.50, 0.80, 0.90, 0.95, 0.99\}$ (these values were determined during a preliminary parameter sweep). We used a discount factor $\gamma = 0.999$ and ϵ -greedy exploration with $\epsilon = 0.01$. The weight vector was initialized to the zero vector. Also, as Bellemare et al. (2013), we take an action at each 5 frames. This decreases the algorithms running time and avoids ‘super-human’ reflexes. The results are shown in Figure 8. On this domain, the optimal performance of all three versions of Sarsa(λ) is similar.

Note that the way we evaluate a domain is computationally very expensive: we perform scans over λ and α , and use a large number of independent runs to get a low standard error. In the case of Asterix, this results in a total of $7 \cdot 6 \cdot 400 = 16,800$ runs per method. This rigorous evaluation prohibits us unfortunately to run experiments on the full suite of ALE domains.

5.4 Discussion

Figure 9 summarizes the performance of the different TD(λ) versions on all evaluation domains. Specifically, it shows the error for each method at its best settings of α and λ . The error is normalized by dividing it by the error at $\lambda = 0$ (remember that all versions of

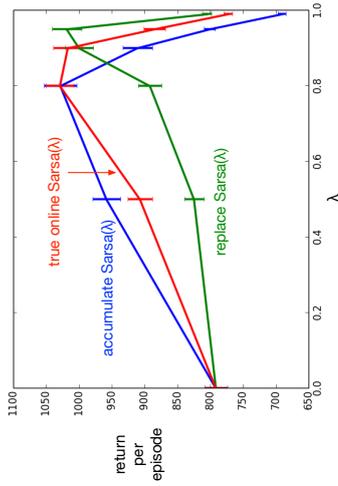

Figure 8: Return per episode, averaged over the first 4,320,000 frames as well as 400 independent runs, as function of λ , at optimal α , on the Asterix domain.

TD(λ) behave the same for $\lambda = 0$). Because $\lambda = 0$ lies in the parameter range that is being optimized over, the normalized error can never be higher than 1. If for a method/domain the normalized error is equal to 1, this means that setting λ higher than 0 either has no effect, or that the error gets worse. In either case, eligibility traces are not effective for that method/domain.

Overall, true online TD(λ) is clearly better than accumulate TD(λ) and replace TD(λ) in terms of optimal performance. Specifically, for each considered domain/representation, the error for true online TD(λ) is either smaller or equal to the error of accumulate/replace TD(λ). This is especially impressive, given the wide variety of domains, and the fact that the computational overhead for true online TD(λ) is small (see Section 4.1 for details).

The observed performance differences correspond well with the analysis from Section 4.2. In particular, note that MRP (10, 3, 0.1) has less states than the other two MRPs, and hence the chance that the same feature has a non-zero value within a small time frame is larger. The analysis correctly predicts that this results in larger performance differences. Furthermore, MRP (100, 3, 0) is less stochastic than MRP (100, 10, 0.1), and hence it has a smaller variance on the return. Also here, the experiments correspond with the analysis, which predicts that this results in a larger performance difference.

On the Asterix domain, the performance of the three Sarsa(λ) versions is similar. This is in accordance with the evaluation results, which showed that the size of the performance difference is domain dependent. In the worst case, the performance of the true online method is similar to that of the regular method.

The optimal performance is not the only factor that determines how good a method is; what also matters is how easy it is to find this performance. The detailed plots in appendices C and D reveal that the parameter sensitivity of accumulate TD(λ) is much higher than

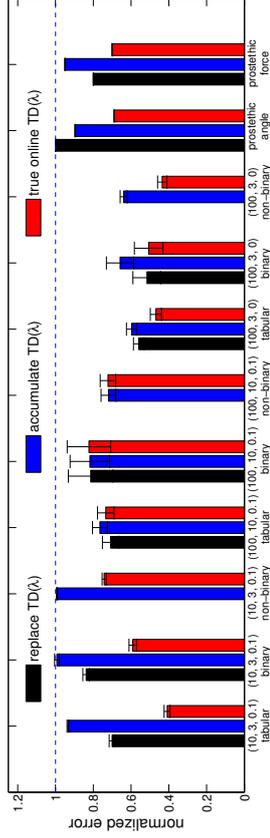

Figure 9: Summary of the evaluation results: error at optimal (α, λ) -settings for all domains/representations, normalized with the TD(0) error.

that of true online TD(λ) or replace TD(λ). This is clearly visible for MRP (10, 3, 0.1) (Figure 10), as well as the experiments with the myoelectric prosthetic arm (Figure 13).

There is one more thing to take away from the experiments. In MRP (10, 3, 0.1) with non-binary features, replace TD(λ) is not applicable and accumulate TD(λ) is ineffective. However, true online TD(λ) was still able to obtain a considerable performance advantage with respect to TD(0). This demonstrates that true online TD(λ) expands the set of domains/representations where eligibility traces are effective. This could potentially have far-reaching consequences. Specifically, using non-binary features becomes a lot more interesting. Replacing traces are not applicable to such representations, while accumulating traces can easily result in divergence of values. For true online TD(λ), however, non-binary features are not necessarily more challenging than binary features. Exploring new, non-binary representations could potentially further improve the performance for true online TD(λ) on domains such as the myoelectric prosthetic arm or the Asterix domain.

6. Other True Online Methods

In Appendix B, it is shown that the true online TD(λ) equations can be derived directly from the online forward view equations. By using different online forward views, new true online methods can be derived. Sometimes, small changes in the forward view, like using a time-dependent step-size, can result in surprising changes in the true online equations. In this section, we look at a number of such variations.

6.1 True Online TD(λ) with Time-Dependent Step-Size

When using a time-dependent step-size in the base equation of the forward view (Equation 7) and deriving the update equations following the procedure from Appendix B, it turns out that a slightly different trace definition appears. We indicate this new trace using a '+' superscript: e_t^+ . For fixed step-size, this new trace definition is equal to:

$$e_t^+ = \alpha e_t, \quad \text{for all } t.$$

Algorithm 4 true online TD(λ) with time-dependent step-size

INPUT: $\lambda, \theta_{init}, \alpha_t$ for $t \geq 0$
 $\theta \leftarrow \theta_{init}$; $t \leftarrow 0$
 Loop (over episodes):
 obtain initial ϕ
 $e^+ \leftarrow \mathbf{0}$; $V_{old} \leftarrow 0$
 While terminal state is not reached, do:
 obtain next feature vector ϕ' and reward R
 $V \leftarrow \theta^\top \phi$
 $V' \leftarrow \theta'^\top \phi'$
 $\delta' \leftarrow R + \gamma V' - V_{old}$
 $e^+ \leftarrow \gamma \lambda e^+ + \alpha_t \phi - \alpha_t \gamma \lambda ((e^+)^T \phi) \phi$
 $\theta \leftarrow \theta + \delta' e^+ - \alpha_t (V - V_{old}) \phi$
 $V_{old} \leftarrow V'$
 $\phi \leftarrow \phi'$
 $t \leftarrow t + 1$

Of course, using e_t^+ instead of e_t also changes the weight vector update slightly. Below, the full set of update equations is shown:

$$\begin{aligned} \delta_t &= R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t, \\ e_t^+ &= \gamma \lambda e_{t-1}^+ + \alpha_t \phi_t - \alpha_t \gamma \lambda ((e_{t-1}^+)^T \phi_t) \phi_t, \\ \theta_{t+1} &= \theta_t + \delta_t e_t^+ + (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) (e_t^+ - \alpha_t \phi_t). \end{aligned}$$

In addition, $e_{-1}^+ := 0$. We can simplify the weight update equation slightly, by using

$$\delta_t' = \delta_t + \theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t,$$

which changes the update equations to:⁶

$$\delta_t' = R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_{t-1}^\top \phi_t, \quad (15)$$

$$e_t^+ = \gamma \lambda e_{t-1}^+ + \alpha_t \phi_t - \alpha_t \gamma \lambda ((e_{t-1}^+)^T \phi_t) \phi_t, \quad (16)$$

$$\theta_{t+1} = \theta_t + \delta_t' e_t^+ - \alpha_t (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) \phi_t. \quad (17)$$

Algorithm 2 shows the corresponding pseudocode. Of course, this pseudocode can also be used for constant step-size.

6.2 True Online Version of Watkins's $Q(\lambda)$

So far, we just considered *on-policy* methods, that is, methods that evaluate a policy that is the same as the policy that generates the samples. However, the true online principle can also be applied to *off-policy* methods, for which the evaluation policy is different from the behaviour policy. As a simple example, consider Watkins's $Q(\lambda)$ (Watkins, 1989). This is an off-policy method that evaluates the greedy policy given an arbitrary behaviour policy.

6. These equations are the same as in the original true online paper (van Seijen & Sutton, 2014).

Algorithm 5 true online version of Watkins's $Q(\lambda)$

INPUT: $\alpha, \lambda, \gamma, \theta_{init}, \Psi$
 $\theta \leftarrow \theta_{init}$
 Loop (over episodes):
 obtain initial state S
 select action A based on state S (for example ϵ -greedy)
 $\psi \leftarrow$ features corresponding to S, A
 $e \leftarrow \mathbf{0}$; $Q_{old} \leftarrow 0$
 While terminal state has not been reached, do:
 take action A , observe next state S' and reward R
 select action A' based on state S'
 $A^* \leftarrow \arg \max_a \theta^\top \psi(S', a)$ (if A' tries for the max, then $A^* \leftarrow A'$)
 $\psi' \leftarrow$ features corresponding to S', A^* (if S' is terminal state, $\psi' \leftarrow \mathbf{0}$)
 $Q \leftarrow \theta^\top \psi$
 $Q' \leftarrow \theta'^\top \psi'$
 $\delta \leftarrow R + \gamma Q' - Q$
 $e \leftarrow \gamma \lambda e + \psi - \alpha \gamma \lambda (e^\top \psi) \psi$
 $\theta \leftarrow \theta + \alpha (\delta + Q - Q_{old}) e - \alpha (Q - Q_{old}) \psi$
 if $A' \neq A^*$: $e \leftarrow \mathbf{0}$
 $Q_{old} \leftarrow Q$
 $\psi \leftarrow \psi'$; $A \leftarrow A'$

It does this by combining accumulating traces with a TD error that uses the maximum state-action value of the successor state:

$$\delta_t = R_{t+1} + \max_a Q(S_t, a) - Q(S_t, A_t).$$

In addition, traces are reset to 0 whenever a non-greedy action is taken.

From an online forward-view perspective, the strategy of Watkins's $Q(\lambda)$ method can be interpreted as a growing update target that stops growing once a non-greedy action is taken. Specifically, let τ be the first time step *after* time step t that a non-greedy action is taken, then the interim update target for time step t can be defined as:

$$U_t^h := (1 - \lambda) \sum_{n=1}^{z-t-1} \lambda^{n-1} \tilde{G}_t^{(n)} + \lambda^{z-t-1} \tilde{G}_t^{(z-t)}, \quad z = \min\{h, \tau\},$$

with

$$\tilde{G}_t^{(n)} = \sum_{k=1}^n \gamma^{k-1} R_{t+k} + \gamma^n \max_a \theta_{t+n-1}^\top \psi(S_{t+n}, a).$$

Algorithm 5 shows the pseudocode for the true online method that corresponds with this update target definition. A problem with Watkins's $Q(\lambda)$ is that if the behaviour policy is very different from the greedy policy traces are reset very often, reducing the overall effect of the traces. In Section 7, we discuss more advanced off-policy methods.

Algorithm 6 tabular true online TD(λ)

```

initialize  $v(s)$  for all  $s$ 
Loop (over episodes):
  initialize  $S$ 
   $e(s) \leftarrow 0$  for all  $s$ 
   $V_{old} \leftarrow 0$ 
  While  $S$  is not terminal, do:
    obtain next state  $S'$  and reward  $R$ 
     $\Delta V \leftarrow V(S) - V_{old}$ 
     $V_{old} \leftarrow V(S)$ 
     $\delta \leftarrow R + \gamma V(S') - V(S)$ 
     $e(S) \leftarrow (1 - \alpha)e(S) + 1$ 
    For all  $s$ :
       $V(s) \leftarrow V(s) + \alpha(\delta + \Delta V)e(s)$ 
       $e(s) \leftarrow \gamma\lambda e(s)$ 
     $V(S) \leftarrow V(S) - \alpha\Delta V$ 
   $S \leftarrow S'$ 

```

6.3 Tabular True Online TD(λ)

Tabular features are a special case of linear function approximation. Hence, the update equations for true online TD(λ) that are presented so far also apply to the tabular case. However, we discuss it here separately, because the simplicity of this special case can provide extra insight.

Rewriting the true online update equations (equations 10 – 12) for the special case of tabular features results in:

$$\begin{aligned} \delta_t &= R_{t+1} + \gamma V_t(S_{t+1}) - V_t(S_t), \\ e_t(s) &= \begin{cases} \gamma\lambda e_{t-1}(s), & \text{if } s \neq S_t; \\ (1 - \alpha)\gamma\lambda e_{t-1}(s) + 1, & \text{if } s = S_t, \end{cases} \\ V_{t+1}(s) &= \begin{cases} V_t(s) + \alpha(\delta_t + V_t(S_t) - V_{t-1}(S_t))e_t(s), & \text{if } s \neq S_t; \\ V_t(s) + \alpha(\delta_t + V_t(S_t) - V_{t-1}(S_t))e_t(s) - \alpha(V_t(S_t) - V_{t-1}(S_t)), & \text{if } s = S_t. \end{cases} \end{aligned}$$

What is interesting about the tabular case is that the dutch-trace update reduces to a particularly simple form. In fact, for the tabular case, a dutch-trace update is equal to the weighted average between an accumulating-trace update and a replacing-trace update, with the weight of the former $(1 - \alpha)$ and the latter α . Algorithm 6 shows the corresponding pseudocode.

7. Related Work

Since the first publication on true online TD(λ) (van Seijen & Sutton, 2014), several related papers have been published, extending the underlying concepts and improving the presentation. In sections 7.1, 7.2 and 7.3, we review those papers. In Section 7.4, we discuss other variations of TD(λ).

7.1 True Online Learning and Dutch Traces

As mentioned before, the traditional forward view, which is based on the λ -return, is inherently an offline forward view, because the λ -return is constructed from data up to the end of an episode. As a consequence, the work regarding equivalence between a forward view and a backward view traditionally focused on the final weight vector θ_T . This changed in 2014, when two papers introduced an *online* forward view with a corresponding backward view that has an exact equivalence at each moment in time (van Seijen & Sutton, 2014; Sutton et al., 2014). While both papers introduced an online forward view, the two forward views presented are very different from each other. One difference is that the forward view introduced by van Seijen & Sutton is an on-policy forward view, whereas the forward view by Sutton et al. is an off-policy forward view. However, there is an even more fundamental difference related to how the forward views are constructed. In particular, the forward view by van Seijen & Sutton is constructed in such a way that at each moment in time the weight vector can be interpreted as the result of a sequence of updates of the form:

$$\theta_{k+1} = \theta_k + \alpha(U_k - \theta_k^\top \phi_k)\phi_k, \quad \text{for } 0 \leq k < t. \quad (18)$$

By contrast, the forward view by Sutton et al. gives the following interpretation:

$$\theta_t = \theta_0 + \alpha \sum_{k=0}^{t-1} \delta_k \phi_k, \quad (19)$$

with δ_k some multi-step TD error. Of course, the different forward views also result in different backward views. Whereas the backward view of Sutton et al. uses a generalized version of an accumulating trace, the backward view of van Seijen & Sutton introduced a completely new type of trace.

The advantage of a forward view based on (18) instead of (19) is that it results in much more stable updates. In particular, the sensitivity to divergence of accumulate TD(λ) is a general side-effect of (19), whereas (18) is much more robust with respect to divergence. As a result, true online TD(λ) not only has the property that it has an exact equivalence with an online forward view at all times, it consistently dominates TD(λ) empirically.

The strong performance of true online TD(λ) motivated van Hasselt et al. (2014) to construct an off-policy version of the forward view of true online TD(λ). The corresponding backward view resulted in the algorithm true online GTD(λ), which empirically outperforms GTD(λ). They also introduced the term ‘dutch traces’ for the new eligibility trace.

Van Hasselt & Sutton (2015) showed that dutch traces are not only useful for TD learning. In an offline setting with no bootstrapping using dutch traces can result in certain computational advantages. To understand why, consider the Monte Carlo algorithm (MC), which updates state values at the end of an episode using (18), with the full return as update target. MC requires storing all the feature vectors and rewards during an episode, so the memory complexity is linear in the length of the episode. Moreover, the required computation time is distributed very unevenly: during an episode almost no computation is required, but at the end of an episode there is a huge peak in computation time due to all the updates that need to be performed. With dutch traces an alternative implementation can be made that results in the same final weight vector but that does not require storing all

the feature vectors and where the required computation time is spread out evenly over all the time steps. Van Hasselt & Sutton refer to this appealing property as span-independence: the memory and computation time required per time step is constant and independent of the span of the prediction.⁷

7.2 Backward View Derivation

The task of finding an efficient backward view that corresponds exactly with a particular online forward view is not easy. Moreover, there is no guarantee that there exists an efficient implementation of a particular online forward view. Often, minor changes in the forward view determine whether or not an efficient backward view can be constructed. This created the desire to somehow automate the process of constructing an efficient backward view.

Van Seijen & Sutton (2014) did not provide a direct derivation of the backward view update equations; they simply proved that the forward view and the backward view equations result in the same weight vectors. Sutton et al. (2014) were the first to attempt to come up with a general strategy for deriving a backward view (although for forward views based on Equation 19). Van Hasselt et al. (2014) took the approach of providing a theorem that proves equivalence between a general forward view and a corresponding general backward view. They showed that the forward/backward view of true online TD(λ) is a special case of this general forward/backward view. They showed the same for the off-policy method that they introduced—true online GTD(λ). Recently, Mahmood & Sutton (2015) extended this theorem further by proving equivalence between an even more general forward view and backward view.

Furthermore, van Hasselt & Sutton (2015) derived backward views for a series of increasingly complex forward views. The derivation of the true online TD(λ) equations in Appendix B is similar to those derivations.

7.3 Extension to Non-Linear Function Approximation

The linear update equations of the online forward view presented in Section 3.1 can be easily extended to the case of non-linear function approximation. Unfortunately, it appears to be impossible to construct an efficient backward view with exact equivalence in the case of non-linear function approximation. The reason is that the derivation in Appendix B makes use of the fact that the gradient with respect to the value function is independent of the weight vector; this does not hold for non-linear function approximation.

Fortunately, van Seijen (2016) shows that many of the benefits of true online learning can also be achieved in the case of non-linear function approximation by using an alternative forward view (but still based on Equation 18). While this alternative forward view is not fully online (there is a delay in the updates), it can be implemented efficiently.

7.4 Other Variations on TD(λ)

Several variations on TD(λ) other than those treated in this article have been suggested in the literature. Schapire & Warmuth (1996) introduced a variation of TD(λ) for which

⁷ The span of the prediction refers to the time difference between the first prediction and the moment its target is known (e.g., for episodic tasks it corresponds to the length of an episode).

upper and lower bounds on performance can be derived and proven. Konidaris et al. (2011) introduced TD _{γ} , a parameter-free alternative to TD(λ) based on a multi-step update target called the γ -return. TD _{γ} is an offline algorithm with a computational cost proportional to the episode-length. Furthermore, Thomas et al. (2015) proposed a method based on a multi-step update target, which they call the Ω -return. The Ω -return can account for the correlation of different length returns, something that both the λ -return and the γ -return cannot. However, it is expensive to compute and it is open question whether efficient approximations exist.

8. Conclusions

We tested the hypothesis that true online TD(λ) (and true online Sarsa(λ)) dominates TD(λ) (and Sarsa(λ)) with accumulating as well as with replacing traces by performing experiments over a wide range of domains. Our extensive results support this hypothesis. In terms of learning speed, true online TD(λ) was often better, but never worse than TD(λ) with either accumulating or replacing traces, across all domains/representations that we tried. Our analysis showed that especially on domains with non-sparse features and a relatively low variance on the return a large difference in learning speed can be expected. More generally, true online TD(λ) has the advantage over TD(λ) with replacing traces that it can be used with non-binary features, and it has the advantage over TD(λ) with accumulating traces that it is less sensitive with respect to its parameters. In terms of computation time, TD(λ) has a slight advantage. In the worst case, true online TD(λ) is twice as expensive. In the typical case of sparse features, it is only fractionally more expensive than TD(λ). Memory requirements are the same. Finally, we outlined an approach for deriving new true online methods, based on rewriting the equations of an online forward view. This may lead to new, interesting methods in the future.

Acknowledgments

The authors thank Hado van Hasselt for extensive discussions leading to the refinement of these ideas. Furthermore, the authors thank the anonymous reviewers for their valuable suggestions, resulting in a substantially improved presentation. Appendix A. Proof of Theorem 1

Theorem 1 *Let θ_0 be the initial weight vector, θ_t^{id} be the weight vector at time t computed by accumulate TD(λ), and θ_t^λ be the weight vector at time t computed by the online λ -return algorithm. Furthermore, assume that $\sum_{i=0}^{t-1} \Delta_i^t \neq \mathbf{0}$. Then, for all time steps t :*

$$\frac{\|\theta_t^{id} - \theta_t^\lambda\|}{\|\theta_t^{id} - \theta_0\|} \rightarrow 0, \quad \text{as } \alpha \rightarrow 0.$$

Proof We prove the theorem by showing that $\|\theta_t^{id} - \theta_t^\lambda\| / \|\theta_t^{id} - \theta_0\|$ can be approximated by $\mathcal{O}(\alpha) / (C + \mathcal{O}(\alpha))$ as $\alpha \rightarrow 0$, with $C > 0$. For readability, we will not use the ‘td’ and ‘ λ ’ superscripts; instead, we always use weights with double indices for the online λ -return algorithm and weights with single indices for accumulate TD(λ).

The update equations for accumulate TD(λ) are:

$$\begin{aligned} \delta_t &= R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t, \\ \mathbf{e}_t &= \gamma \lambda \mathbf{e}_{t-1} + \phi_t, \\ \theta_{t+1} &= \theta_t + \alpha \delta_t \mathbf{e}_t. \end{aligned}$$

By incremental substitution, we can write θ_t directly in terms of θ_0 :

$$\begin{aligned} \theta_t &= \theta_0 + \alpha \sum_{j=0}^{t-1} \delta_j \mathbf{e}_j, \\ &= \theta_0 + \alpha \sum_{j=0}^{t-1} \delta_j \sum_{i=0}^j (\gamma \lambda)^{j-i} \phi_i, \\ &= \theta_0 + \alpha \sum_{j=0}^{t-1} \sum_{i=0}^j (\gamma \lambda)^{j-i} \delta_j \phi_i. \end{aligned} \tag{20}$$

Using the summation rule $\sum_{j=k}^n \sum_{i=k}^j a_{i,j} = \sum_{i=k}^n \sum_{j=i}^n a_{i,j}$ we can rewrite this as:

$$\theta_t = \theta_0 + \alpha \sum_{i=0}^{t-1} \sum_{j=i}^{t-1} (\gamma \lambda)^{j-i} \delta_j \phi_i. \tag{21}$$

As part of the derivation shown in Appendix B, we prove the following (see Equation 26):

$$G_i^{\lambda|h+1} = G_i^{\lambda|h} + (\lambda \gamma)^{h-i} \delta_i^h,$$

with

$$\delta_i^h := R_{h+1} + \gamma \theta_i^\top \phi_{h+1} - \theta_i^\top \phi_h.$$

By applying this sequentially for $i+1 \leq h < t$, we can derive:

$$G_i^{\lambda|h} = G_i^{\lambda|h+1} + \sum_{j=i+1}^{t-1} (\gamma \lambda)^{j-i} \delta_j^h. \tag{22}$$

Furthermore, $G_i^{\lambda|h+1}$ can be written as:

$$\begin{aligned} G_i^{\lambda|h+1} &= R_{i+1} + \gamma \theta_i^\top \phi_{i+1}, \\ &= R_{i+1} + \gamma \theta_i^\top \phi_{i+1} - \theta_{i-1}^\top \phi_i + \theta_{i-1}^\top \phi_i, \\ &= \delta_i^i + \theta_{i-1}^\top \phi_i. \end{aligned}$$

Substituting this in (21) yields:

$$G_i^{\lambda|h} = \theta_{i-1}^\top \phi_i + \sum_{j=i}^{t-1} (\gamma \lambda)^{j-i} \delta_j^i.$$

Using that $\delta_j^i = \delta_j + \theta_{j-1}^\top \phi_j - \theta_{j-1}^\top \phi_j$, it follows that

$$\sum_{j=i}^{t-1} (\gamma \lambda)^{j-i} \delta_j^i = G_i^{\lambda|h} - \theta_{i-1}^\top \phi_i - \sum_{j=i}^{t-1} (\gamma \lambda)^{j-i} (\theta_j - \theta_{j-1})^\top \phi_j.$$

As $\alpha \rightarrow 0$, we can approximate this as:

$$\begin{aligned} \sum_{j=i}^{t-1} (\gamma \lambda)^{j-i} \delta_j^i &= G_i^{\lambda|h} - \theta_{i-1}^\top \phi_i + \mathcal{O}(\alpha), \\ &= \bar{G}_i^{\lambda|h} - \theta_0^\top \phi_i + \mathcal{O}(\alpha), \end{aligned}$$

with $\bar{G}_i^{\lambda|h}$ the interim λ -return that uses θ_0 for all value evaluations. Substituting this in (20) yields:

$$\theta_t = \theta_0 + \alpha \sum_{i=0}^{t-1} (\bar{G}_i^{\lambda|h} - \theta_0^\top \phi_i + \mathcal{O}(\alpha)) \phi_i. \tag{23}$$

For the online λ -return algorithm, we can derive the following by sequential substitution of Equation (7):

$$\theta_t^i = \theta_0 + \alpha \sum_{i=0}^{t-1} (G_i^{\lambda|h} - (\theta_i^i)^\top \phi_i) \phi_i.$$

As $\alpha \rightarrow 0$, we can approximate this as:

$$\theta_t^i = \theta_0 + \alpha \sum_{i=0}^{t-1} (\bar{G}_i^{\lambda|h} - \theta_0^\top \phi_i + \mathcal{O}(\alpha)) \phi_i. \tag{24}$$

Combining (22) and (23), it follows that as $\alpha \rightarrow 0$:

$$\frac{\|\theta_t - \theta_t^i\|}{\|\theta_t - \theta_0\|} = \frac{\|(\theta_t - \theta_t^i)/\alpha\|}{\|(\theta_t - \theta_0)/\alpha\|} = \frac{\mathcal{O}(\alpha)}{C + \mathcal{O}(\alpha)},$$

with

$$C = \left\| \sum_{i=0}^{t-1} (\bar{G}_i^{\lambda|h} - \theta_0^\top \phi_i) \phi_i \right\| = \left\| \sum_{i=0}^{t-1} \Delta_i^t \right\|.$$

From the condition $\sum_{i=0}^{t-1} \Delta_i^t \neq \mathbf{0}$ it follows that $C > 0$. ■

Appendix B. Derivation Update Equations

In this subsection, we derive the update equations of true online TD(λ) directly from the online forward view, defined by equations (6) and (7) (and $\theta_0^i := \theta_{mit}$). The derivation is based on expressing θ_{t+1}^i in terms of θ_t^i .

We start by writing θ_t^i directly in terms of the initial weight vector and the interim λ -returns. First, we rewrite (7) as:

$$\theta_{k+1}^i = (\mathbf{I} - \alpha\phi_k\phi_k^\top)\theta_k^i + \alpha\phi_kG_k^{\lambda|t},$$

with \mathbf{I} the identity matrix. Now, consider θ_k^i for $k = 1$ and $k = 2$:

$$\begin{aligned}\theta_1^i &= (\mathbf{I} - \alpha\phi_0\phi_0^\top)\theta_{mit} + \alpha\phi_0G_0^{\lambda|t}, \\ \theta_2^i &= (\mathbf{I} - \alpha\phi_1\phi_1^\top)\theta_1^i + \alpha\phi_1G_1^{\lambda|t}, \\ &= (\mathbf{I} - \alpha\phi_1\phi_1^\top)(\mathbf{I} - \alpha\phi_0\phi_0^\top)\theta_{mit} + \alpha(\mathbf{I} - \alpha\phi_1\phi_1^\top)\phi_0G_0^{\lambda|t} + \alpha\phi_1G_1^{\lambda|t}.\end{aligned}$$

For general $k \leq t$, we can write:

$$\theta_k^i = \mathbf{A}_0^{k-1}\theta_{mit} + \alpha\sum_{i=0}^{k-1}\mathbf{A}_{t+1}^{k-1}\phi_iG_i^{\lambda|t},$$

where \mathbf{A}_j^i is defined as:

$$\mathbf{A}_j^i := (\mathbf{I} - \alpha\phi_j\phi_j^\top)(\mathbf{I} - \alpha\phi_{j-1}\phi_{j-1}^\top)\dots(\mathbf{I} - \alpha\phi_i\phi_i^\top), \quad \text{for } j \geq i,$$

and $\mathbf{A}_{j+1}^j := \mathbf{I}$. We are now able to express θ_t^i as:

$$\theta_t^i = \mathbf{A}_0^{t-1}\theta_{mit} + \alpha\sum_{i=0}^{t-1}\mathbf{A}_{t+1}^{t-1}\phi_iG_i^{\lambda|t}, \quad (24)$$

Because for the derivation of true online TD(λ), we only need (24) and the definition of $G_i^{\lambda|t}$, we can drop the double indices for the weight vectors and use $\theta_i := \theta_t^i$.

We now derive a compact expression for the difference $G_i^{\lambda|t+1} - G_i^{\lambda|t}$:

$$\begin{aligned}G_i^{\lambda|t+1} - G_i^{\lambda|t} &= (1 - \lambda)\sum_{n=1}^{t-i}\lambda^{n-1}G_i^{(n)} + \lambda^{t-i}G_i^{(t+1-i)}, \\ &\quad - (1 - \lambda)\sum_{n=1}^{t-i-1}\lambda^{n-1}G_i^{(n)} - \lambda^{t-i-1}G_i^{(t-i)}, \\ &= (1 - \lambda)\lambda^{t-i-1}G_i^{(t-i)} + \lambda^{t-i}G_i^{(t+1-i)} - \lambda^{t-i-1}G_i^{(t-i)}, \\ &= \lambda^{t-i}G_i^{(t+1-i)} - \lambda^{t-i}G_i^{(t-i)}, \\ &= \lambda^{t-i}\left(G_i^{(t+1-i)} - G_i^{(t-i)}\right), \\ &= \lambda^{t-i}\left(\sum_{k=1}^{t+1-i}\gamma^{k-1}R_{t+k} + \gamma^{t+1-i}\theta_t^\top\phi_{t+1} - \sum_{k=1}^{t-i}\gamma^{k-1}R_{t+k} - \gamma^{t-i}\theta_{t-1}^\top\phi_t\right), \\ &= \lambda^{t-i}\left(\gamma^{t-i}R_{t+1} + \gamma^{t+1-i}\theta_t^\top\phi_{t+1} - \gamma^{t-i}\theta_{t-1}^\top\phi_t\right), \\ &= (\lambda\gamma)^{t-i}\left(R_{t+1} + \gamma\theta_t^\top\phi_{t+1} - \theta_{t-1}^\top\phi_t\right).\end{aligned}$$

Note that the difference $G_i^{\lambda|t+1} - G_i^{\lambda|t}$ is naturally expressed using a term that looks like a TD error but with a modified time step. We call this the modified TD error, δ_t^i :

$$\delta_t^i := R_{t+1} + \gamma\theta_t^\top\phi_{t+1} - \theta_{t-1}^\top\phi_t.$$

The modified TD error relates to the regular TD error, δ_t , as follows:

$$\begin{aligned}\delta_t^i &= R_{t+1} + \gamma\theta_t^\top\phi_{t+1} - \theta_{t-1}^\top\phi_t, \\ &= R_{t+1} + \gamma\theta_t^\top\phi_{t+1} - \theta_t^\top\phi_t + \theta_t^\top\phi_t - \theta_{t-1}^\top\phi_t, \\ &= \delta_t + \theta_t^\top\phi_t - \theta_{t-1}^\top\phi_t.\end{aligned} \quad (25)$$

Using δ_t^i , the difference $G_i^{\lambda|t+1} - G_i^{\lambda|t}$ can be compactly written as:

$$G_i^{\lambda|t+1} - G_i^{\lambda|t} = (\lambda\gamma)^{t-i}\delta_t^i. \quad (26)$$

To get the update rule, θ_{t+1} has to be expressed in terms of θ_t . This is done below, using (24), (25) and (26):

$$\begin{aligned}
\theta_{t+1} &= \mathbf{A}_0^t \theta_0 + \alpha \sum_{i=0}^t \mathbf{A}_{i+1}^t \phi_i G_i^{\lambda|t+1}, \\
&= \mathbf{A}_0^t \theta_0 + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i G_i^{\lambda|t+1} + \alpha \phi_t G_t^{\lambda|t+1}, \\
&= \mathbf{A}_0^t \theta_0 + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i G_i^{\lambda|t} + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (G_i^{\lambda|t+1} - G_i^{\lambda|t}) + \alpha \phi_t G_t^{\lambda|t+1}, \\
&= (\mathbf{I} - \alpha \phi_t \phi_t^\top) \left(\mathbf{A}_0^{t-1} \theta_0 + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^{t-1} \phi_i G_i^{\lambda|t} \right) \\
&\quad + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (G_i^{\lambda|t+1} - G_i^{\lambda|t}) + \alpha \phi_t G_t^{\lambda|t+1}, \\
&= (\mathbf{I} - \alpha \phi_t \phi_t^\top) \theta_t + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (G_i^{\lambda|t+1} - G_i^{\lambda|t}) + \alpha \phi_t G_t^{\lambda|t+1}, \\
&= (\mathbf{I} - \alpha \phi_t \phi_t^\top) \theta_t + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} \delta_i' + \alpha \phi_t (R_{t+1} + \gamma \theta_t^\top \phi_{t+1}), \\
&= \theta_t + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} \delta_i' + \alpha \phi_t (R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t), \\
&= \theta_t + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} \delta_i' \\
&\quad + \alpha \phi_t (R_{t+1} + \gamma \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t + \theta_t^\top \phi_t - \theta_t^\top \phi_t), \\
&= \theta_t + \alpha \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} \delta_i' + \alpha \phi_t \delta_t' - \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) \phi_t, \\
&= \theta_t + \alpha \sum_{i=0}^t \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} \delta_i' - \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) \phi_t, \\
&= \theta_t + \alpha e_t \delta_t' - \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) \phi_t, \quad \text{with } e_t := \sum_{i=0}^t \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i}, \\
&= \theta_t + \alpha e_t (\delta_t + \theta_{t-1}^\top \phi_t - \theta_{t-1}^\top \phi_t) - \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) \phi_t, \\
&= \theta_t + \alpha e_t \delta_t + \alpha (\theta_t^\top \phi_t - \theta_{t-1}^\top \phi_t) (e_t - \phi_t). \tag{27}
\end{aligned}$$

We now have the update rule for θ_t , in addition to an explicit definition of e_t . Next, using this explicit definition, we derive an update rule to compute e_t from e_{t-1} :

$$\begin{aligned}
e_t &= \sum_{i=0}^t \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i}, \\
&= \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^t \phi_i (\gamma \lambda)^{t-i} + \phi_t, \\
&= (\mathbf{I} - \alpha \phi_t \phi_t^\top) \gamma \lambda \sum_{i=0}^{t-1} \mathbf{A}_{i+1}^{t-1} \phi_i (\gamma \lambda)^{t-i-1} + \phi_t, \\
&= (\mathbf{I} - \alpha \phi_t \phi_t^\top) \gamma \lambda e_{t-1} + \phi_t, \\
&= \gamma \lambda e_{t-1} + \phi_t - \alpha \gamma \lambda (e_{t-1}^\top \phi_t) \phi_t. \tag{28}
\end{aligned}$$

Equations (27) and (28), together with the definition of δ_t , form the true online TD(λ) update equations.

Appendix C. Detailed Results Random MRPs

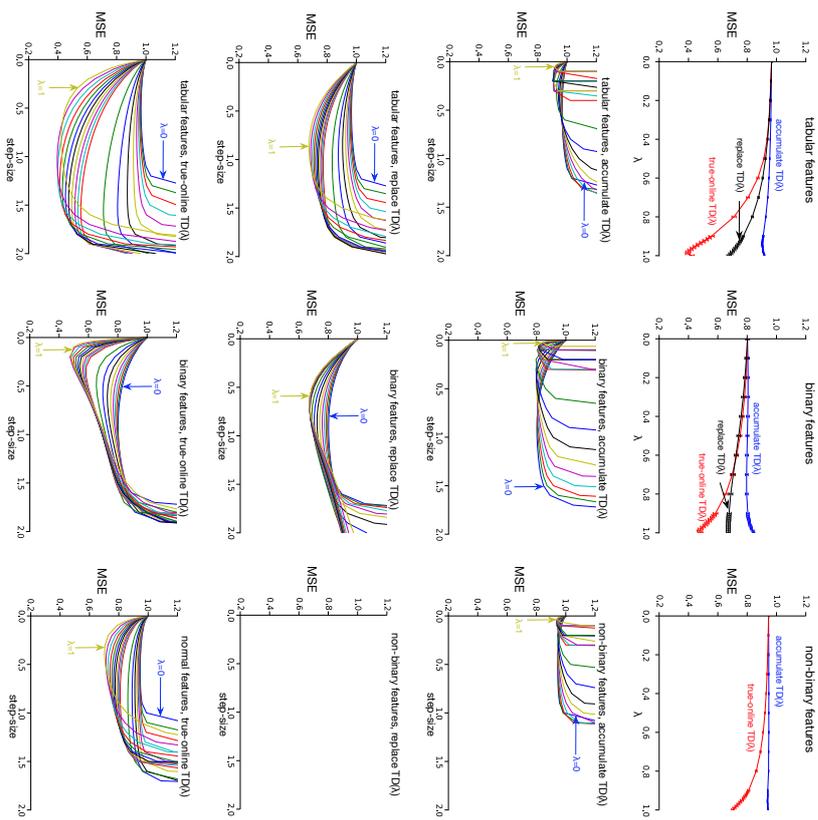

Figure 10: Results on a random MRP with $k = 10$, $b = 3$ and $\sigma = 0.1$. MSE is the mean squared error averaged over the first 100 time steps, as well as 50 runs, and normalized using the initial error. The top graphs summarize the results from the graphs below it; they show the MSE error, for each λ , at the best step-size.

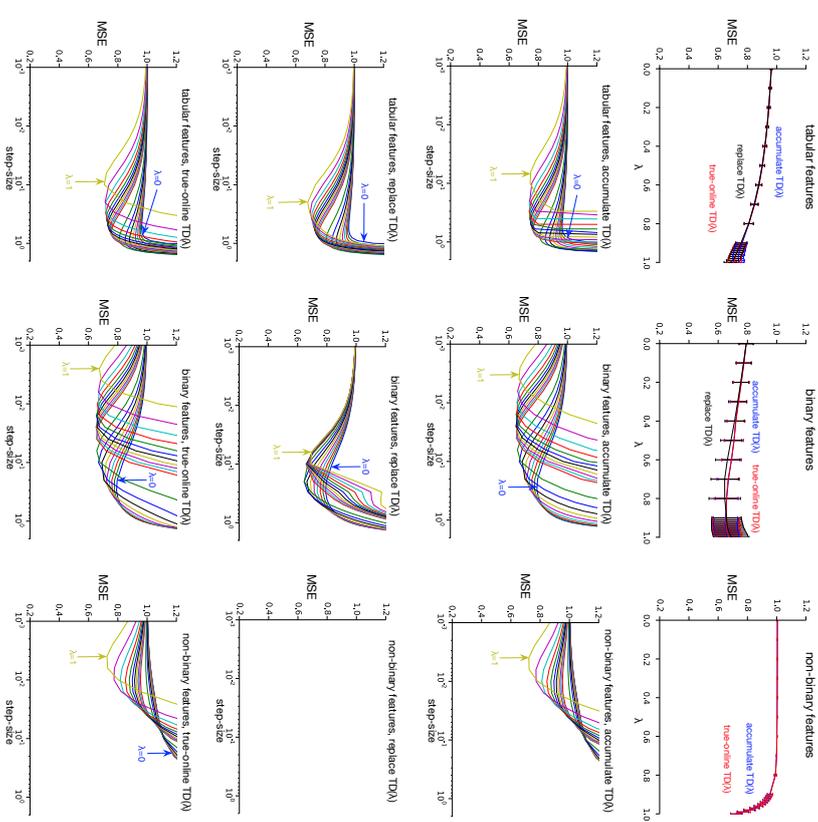

Figure 11: Results on a random MRP with $k = 100$, $b = 10$ and $\sigma = 0.1$. MSE is the mean squared error averaged over the first 1000 time steps, as well as 50 runs, and normalized using the initial error.

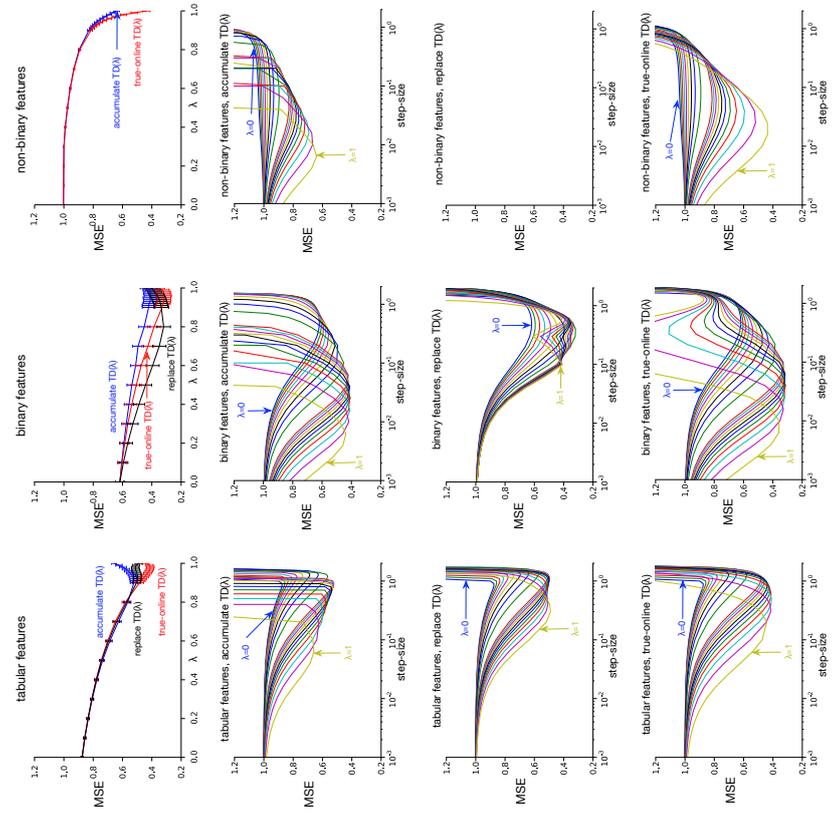

Figure 12: Results on a random MRP with $k = 100$, $b = 3$ and $\sigma = 0$. MSE is the mean squared error averaged over the first 1000 time steps, as well as 50 runs, and normalized using the initial error.

Appendix D. Detailed Results for Myoelectric Prosthetic Arm

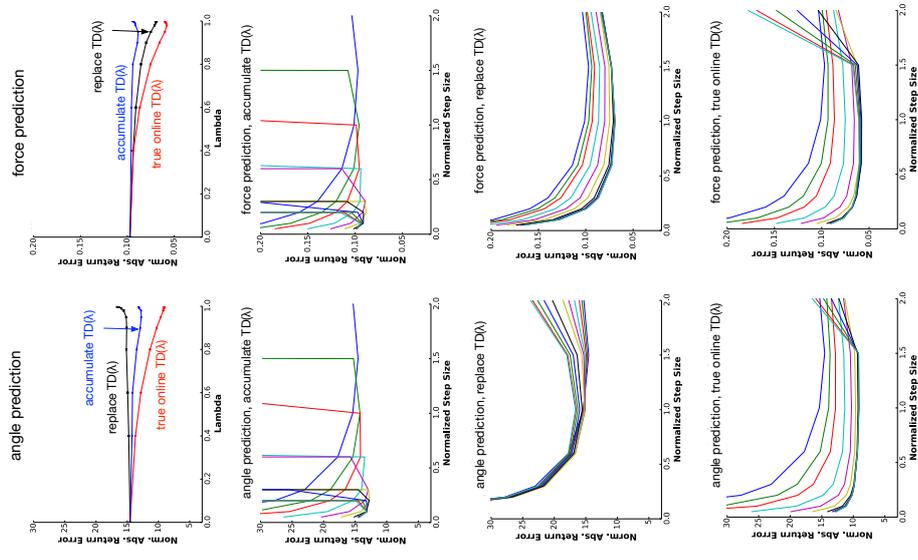

Figure 13: Results on prosthetic data from the single amputee subject described in Pilarski et al. (2013), for the prediction of servo motor angle (*left column*) and grip force (*right column*) as recorded from the amputee’s myoelectrically controlled robot arm during a grasping task.

Abstract

Analyzing multi-layered graphical models provides insight into understanding the conditional relationships among nodes within layers after adjusting for and quantifying the effects of nodes from other layers. We obtain the penalized maximum likelihood estimator for Gaussian multi-layered graphical models, based on a computational approach involving screening of variables, iterative estimation of the directed edges between layers and undirected edges within layers and a final refitting and stability selection step that provides improved performance in finite sample settings. We establish the consistency of the estimator in a high-dimensional setting. To obtain this result, we develop a strategy that leverages the biconvexity of the likelihood function to ensure convergence of the developed iterative algorithm to a stationary point, as well as careful uniform error control of the estimates over iterations. The performance of the maximum likelihood estimator is illustrated on synthetic data.

Keywords: graphical models, penalized likelihood, block coordinate descent, convergence, consistency

1. Introduction.

The estimation of directed and undirected graphs from high-dimensional data has received a lot of attention in the machine learning and statistics literature (e.g., see [Bühlmann and Van De Geer, 2011](#), and references therein), due to their importance in diverse applications including understanding of biological processes and disease mechanisms, financial systems stability and social interactions, just to name a few ([Sachs et al., 2005](#); [Wang et al., 2007](#); [Sobel, 2000](#)). In the case of undirected graphs, the edges capture conditional dependence relationships between the nodes, while for directed graphs they are used to model causal relationships ([Bühlmann and Van De Geer, 2011](#)).

However, in a number of applications the nodes can be *naturally partitioned* into sets that exhibit interactions both between them and amongst them. As an example, consider an experiment where one has collected data for both genes and metabolites for the same set of patient specimens. In this case, we have three types of interactions between genes and metabolites: regulatory interactions between the two of them and co-regulation within the gene and within the metabolic compartments. The latter two types of relationships can be expressed through undirected graphs within the sets of genes and metabolites, respectively, while the regulation of metabolites by genes corresponds to directed edges. Note that in principle there are feedback mechanisms from the metabolic compartment to the gene one, but these are difficult to detect and adequately estimate in the absence of carefully collected time course data. Another example comes from the area of financial economics, where one collects data on returns of financial assets (e.g. stocks, bonds) and also on key macroeconomic indicators (e.g. interest rate, prices indices, various measures of money supply and various unemployment indices). Once again, over short time periods there is influence from the economic variables to the returns (directed edges), while there are co-dependence relationships between the asset returns and the macroeconomic variables, respectively, that can be modeled as undirected edges.

Technically, such *layered* network structures correspond to multi-partite graphs that possess undirected edges and exhibit a directed acyclic graph structure between the layers, as depicted in [Figure 1](#), where we use directed solid edges to denote the dependencies across layers and dashed undirected edges to denote within-layer conditional dependencies.

Selected properties of such so-called *chain graphs* have been studied in the work of [Drton and Perlman \(2008\)](#), with an emphasis on two alternative Markov properties including the LWF Markov property ([Lauritzen and Wermuth, 1989](#); [Frydenberg, 1990](#)) and the AMP Markov property ([Andersson et al., 2001](#)).

While layered networks being interesting from a theoretical perspective and having significant scope for applications, their estimation has received little attention in the literature. Note that for a 2-layered structure, the directed edges can be obtained through a multivariate regression procedure, while the undirected edges in both layers through existing procedures for graphical models (for more technical details see [Section 2.2](#)). This is the strategy leveraged in the work of [Rothman et al. \(2010\)](#), where for a 2-layered network structure they proposed a multivariate regression with covariance estimation (MRCE) method for estimating the undirected edges in the second layer and the directed edges between them. A block coordinate descent algorithm was introduced to estimate the directed edges, while the popular glasso estimator ([Friedman et al., 2008](#)) was used for the undirected edges.

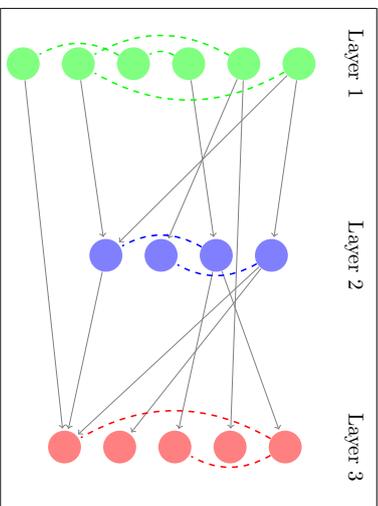

Figure 1: Diagram for a three-layered network

However, this method does not scale well according to the simulation results presented and no theoretical properties of the estimates were provided.

In follow-up work, Yin and Li (2011) used a cyclic block coordinate descent algorithm and claimed convergence to a stationary point leveraging a result in Tseng (2001) (see Proposition 2 in the Supplemental material). Unfortunately, a key assumption in Tseng (2001) –namely, that a corresponding coordinate wise optimization problem that is given by a high-dimensional lasso regression has unique minimum– fails and hence the convergence result does not go through.

In related work, Lee and Lin (2012) proposed the Plug-in Joint Weighted Lasso (PWL) and the Plug-in Joint Graphical Weighted Lasso (PWGL) estimator for estimating the same 2-layered structure, where they use a weighted version of the algorithm in Rothman et al. (2010) and also provide theoretical results for the low dimensional setting, where the number of samples exceeds the number of potential directed and undirected edges to be estimated. Finally, Cai et al. (2012) proposed a method for estimating the same 2-layered structure and provided corresponding theoretical results in the high dimensional setting. The Dantzig-type estimator (Candes and Tao, 2007) was used for the regression coefficients and the corresponding residuals were used as surrogates, for obtaining the precision matrix through the CLIME estimator (Cai et al., 2011). In another line of work (Sohn and Kim, 2012; Yuan and Zhang, 2014; McCarter and Kim, 2014), structured sparsity of directed edges was considered and the edges were estimated with a different parametrization of the objective function. We further elaborate on the connections of our work with these three papers in Section 5.

The above work assumed a Gaussian distribution for the data, in more recent work by Yang et al. (2014), the authors constructed the model under a general *mixed graphical model* framework, which allows each node-conditional distribution to belong to a potentially different univariate exponential family. In particular, with an underlying *mixed MRF* graph structure, instead of maximizing the joint likelihood, the authors proposed to esti-

mate the homogeneous and heterogeneous neighborhood for each node, by obtaining the l_1 regularized M -estimator of the node-conditional distribution parameters, using traditional approaches (e.g. Meinshausen and Bühlmann, 2006) for neighborhood estimation. However, rather than estimating directed edges directly, the directed edges are obtained from a nonlinear transformation of the estimated homogeneous and heterogeneous neighborhood, whose sparsity pattern gets compromised during the process.

In this work, we obtain the regularized maximum likelihood estimator under a sparsity assumption on both directed and undirected parameters for multi-layered Gaussian graphical models and establish its consistency properties in a high-dimensional setting. As discussed in Section 3, the problem is *not jointly convex* on the parameters, but convex on selected subsets of them. Further, it turns out that the problem is *biconvex* if we consider a recursive multi-stage estimation approach that at each stage involves only regression parameters (directed edges) from preceding layers and precision matrix parameters (undirected edges) for the *last layer considered* in that stage. Hence, we decompose the multi-layer network structure estimation into a sequence of 2-layer problems that allows us to establish the desired results. Leveraging the biconvexity of the 2-layer problem, we establish the convergence of the iterates to the maximum-likelihood estimator, which under certain regularity conditions is arbitrarily close to the true parameters. The theoretical guarantees provided require a *uniform control* of the precision of the regression and precision matrix parameters, which poses a number of theoretical challenges resolved in Section 3.

In summary, despite the lack of overall convexity, we are able to provide theoretical guarantees for the MLE in a high dimensional setting. We believe that the proposed strategy is generally applicable to other non-convex statistical estimation problems that can be decomposed to two biconvex problems. Further, to enhance the numerical performance of the MLE in finite (and small) sample settings, we introduce a screening step that selects active nodes for the iterative algorithm used and that leverages recent developments in the high-dimensional regression literature (e.g., Van de Geer et al., 2014; Javanmard and Montanari, 2014; Zhang and Zhang, 2014). We also post-process the final MLE estimate through a stability selection procedure. As mentioned above, the screening and stability selection steps are beneficial to the performance of the MLE in finite samples and hence recommended for similarly structured problems.

The remainder of the paper is organized as follows. In Section 2, we introduce the proposed methodology, with an emphasis on how the multi-layered network estimation problem is decomposed into a sequence of two-layered network estimation problem(s). In Section 3, we provide theoretical guarantees for the estimation procedure posited. In particular, we show consistency of the estimates and convergence of the algorithm, under a number of common assumptions in high-dimensional settings. In Section 4, we show the performance of the proposed algorithm with simulation results under different simulation settings, and introduce several acceleration techniques which speed up the convergence of the algorithm and reduce the computing time in practical settings.

2. Problem Formulation.

Consider an M -layered Gaussian graphical model. Suppose there are p_m nodes in Layer m , denoted by

$$\mathbf{X}^m = (X_1^m, \dots, X_{p_m}^m)', \quad \text{for } m = 1, \dots, M.$$

The structure of the model is given as follows:

- Layer 1. $\mathbf{X}^1 = (X_1^1, \dots, X_{p_1}^1)' \sim \mathcal{N}(0, \Sigma^1)$.
- Layer 2. For $j = 1, \dots, p_2$: $X_j^2 = (B_j^{12})' \mathbf{X}^1 + \epsilon_j^2$, with $B_j^{12} \in \mathbb{R}^{p_1}$, and $\epsilon^2 = (\epsilon_1^2, \dots, \epsilon_{p_2}^2)' \sim \mathcal{N}(0, \Sigma^2)$.
- ⋮
- Layer M . For $j = 1, 2, \dots, p_M$:

$$X_j^M = \sum_{m=1}^{M-1} \{(B_j^{mM})' \mathbf{X}^m\} + \epsilon_j^M, \quad \text{where } B_j^{mM} \in \mathbb{R}^{p_m} \text{ for } m = 1, \dots, M-1,$$

$$\text{and } \epsilon^M = (\epsilon_1^M, \dots, \epsilon_{p_M}^M)' \sim \mathcal{N}(0, \Sigma^M).$$

The parameters of interest are *all directed edges* that encode the dependencies across layers, that is,

$$B^{st} := [B_1^{st} \ \dots \ B_{p_s}^{st}], \quad \text{for } 1 \leq s < t \leq M,$$

and *all undirected edges* that encode the conditional dependencies within layers after adjusting for the effects from directed edges, that is:

$$\Theta^m := (\Sigma^m)^{-1}, \quad \text{for } m = 1, \dots, M.$$

It is assumed that B^{st} and Θ^m are *sparse* for all $1, \dots, M$ and $1 \leq s < t \leq M$.

Given centered data for all M layers, denoted by $X^m = [X_1^m, \dots, X_{p_m}^m] \in \mathbb{R}^{n \times p_m}$ for all $m = 1, \dots, M$, we aim to obtain the MLE for all B^{st} , $1 \leq s < t \leq M$ and all Θ^m , $m = 1, \dots, M$ parameters. Henceforth, we use \mathbf{X}^m to denote random vectors, and X_j^m to denote the j th column in the data matrix $X_n^{m \times p_m}$ whenever there is no ambiguity.

Through Markov factorization (Lauritzen, 1996), the full log-likelihood function can be decomposed as

$$\begin{aligned} \ell(X^m, B^{st}, \Theta^m, 1 \leq s < t \leq M, 1 \leq m \leq M) &= \ell(X^M | X^{M-1}, \dots, X^1, B^{1M}, \dots, B^{M-1,M}, \Theta^M) \\ &\quad + \ell(X^{M-1} | X^{M-2}, \dots, X^1, B^{1,M-1}, \dots, B^{M-2,M-1}, \Theta^{M-1}) \\ &\quad + \dots + \ell(X^2 | X^1, B^{12}, \Theta^2) + \ell(X^1; \Theta^1) \\ &= \ell(X^1; \Theta^1) + \sum_{m=2}^M \ell(X^m | X^1, \dots, X^{m-1}, \Theta^{m-1}; B^{1,m}, \dots, B^{m-1,m}, \Theta^m). \end{aligned}$$

Note that the summands share no common parameters, which enables us to maximize the likelihood with respect to individual parameters in the M terms separately. More importantly, by conditioning Layer m nodes on nodes in its previous $(m-1)$ layers, we can treat Layer m nodes as the “response” layer, and all nodes in the previous $(m-1)$ layer

combined as a super “parent” layer. If we ignore the structure within the bottom layer (X^1) for the moment, the M -layered network can be viewed as $(M-1)$ two-layered networks, each comprising a response layer and a parent layer. Thus, the network structure in Figure 1 can be viewed as a 2 two-layered network: for the first network, Layer 3 is the response layer, while Layers 1 and 2 combined form the “parent” layer; for the second network, Layer 2 is the response layer, and Layer 1 is the “parent” layer. Therefore, the problem for estimating all $\binom{M}{2}$ coefficient matrices and M precision matrices can be translated into estimating $(M-1)$ two-layered network structures with directed edges from the parent layer to the response layer, and undirected edges within the response layer, and finally estimating the undirected edges within the bottom layer separately.

Since all estimation problems boil down to estimating the structure of a 2-layered network, we focus the technical discussion on introducing our proposed methodology for a 2-layered network setting.¹ The theoretical results obtained extend in a straightforward manner to an M -layered Gaussian graphical model.

Remark 1. For the M -layer network structure, we impose certain identifiability-type condition on the largest “parent” layer (encompassing $M-1$ layers), so that the directed edges of the entire network are estimable. The imposed condition translates into a minimum eigenvalue-type condition on the population precision matrix within layers, and conditions on the magnitude of dependencies across layers. Intuitively, consider a three-layered network: if \mathbf{X}^1 and \mathbf{X}^2 are highly correlated, then the proposed (as well as any other) method will exhibit difficulties in distinguishing the effect of \mathbf{X}^1 on \mathbf{X}^3 from that of \mathbf{X}^2 on \mathbf{X}^3 . The (group) identifiability-type condition is thus imposed to obviate such circumstances. An in-depth discussion on this issue is provided in Section 3.4.

2.1 A Two-layered Network Setup.

Consider a two-layered Gaussian graphical model with p_1 nodes in the first layer, denoted by $\mathbf{X} = (X_1, \dots, X_{p_1})'$, and p_2 nodes in the second layers, denoted by $\mathbf{Y} = (Y_1, \dots, Y_{p_2})'$. The model is defined as

- $\mathbf{X} = (X_1, \dots, X_{p_1})' \sim \mathcal{N}(0, \Sigma_X)$.
- For $j = 1, 2, \dots, p_2$: $Y_j = B_j' \mathbf{X} + \epsilon_j$, $B_j \in \mathbb{R}^{p_1}$ and $\epsilon = (\epsilon_1, \dots, \epsilon_{p_2})' \sim \mathcal{N}(0, \Sigma_\epsilon)$.

The parameters of interest are: $\Theta_X := \Sigma_X^{-1}$, $\Theta_\epsilon := \Sigma_\epsilon^{-1}$ and $B = [B_1, \dots, B_{p_2}]$. As with most estimation problems in the high dimensional setting, we assume these parameters to be sparse.

Now given data $X = [X_1, \dots, X_{p_1}] \in \mathbb{R}^{n \times p_1}$ and $Y = [Y_1, \dots, Y_{p_2}] \in \mathbb{R}^{n \times p_2}$, both centered, we would like to use the penalized maximum likelihood approach to obtain estimates for Θ_X , Θ_ϵ and B . Throughout this paper, we use X , Y and E to denote the size- n realizations of the random vectors \mathbf{X} , \mathbf{Y} and ϵ , respectively. Also, with a slight abuse of notation, we use X_i , $i = 1, 2, \dots, p_1$ and Y_j , $j = 1, 2, \dots, p_2$ to denote the columns of the data matrix X and Y , respectively, whenever there is no ambiguity.

1. In Appendix D we give a detail example on how our proposed method works under a 3-layered network setting.

The full log-likelihood can be written as

$$\ell(X, Y; B, \Theta_\epsilon, \Theta_X) = \ell(Y|X; \Theta_\epsilon, B) + \ell(X; \Theta_X) \quad (1)$$

Note that the first term only involves Θ_ϵ and B , and the second term only involves Θ_X . Hence, (1) can be maximized by maximizing $\ell(Y|X)$ w.r.t. (Θ_ϵ, B) , and maximizing $\ell(X)$ w.r.t. Θ_X , respectively. $\widehat{\Theta}_X$ can be obtained using traditional methods for estimating undirected graphs, e.g., the Graphical Lasso (Friedman et al., 2008) or the Node-wise Regression procedure (Meinshausen and Bühlmann, 2006). Therefore, the rest of this paper will mainly focus on obtaining estimates for Θ_ϵ and B . In the next subsection, we introduce our estimation procedure for obtaining the MLE for Θ_ϵ and B .

Remark 2. Our proposed method is targeted towards maximizing $\ell(Y|X; \Theta_\epsilon, B)$ (with proper penalization) in (1) only, which gives the estimates for across-layers dependencies between the response layer and the parent layer, as well as estimates for the conditional dependencies within the response layer each time we solve a 2-layered network estimation problem. For an M -layered estimation problem, the maximization regarding $\ell(X; \Theta_X)$ occurs only when we are estimating the within-layer conditional dependencies for the bottom layer.

2.2 Estimation Algorithm.

The conditional likelihood for response Y given X can be written as

$$L(Y|X) = \left(\frac{1}{\sqrt{2\pi}}\right)^{np_2} |\Sigma_\epsilon \otimes I_n|^{-1/2} \exp\left\{-\frac{1}{2}(\mathcal{Y} - \mathcal{X}\beta)^\top (\Sigma_\epsilon \otimes I_n)^{-1}(\mathcal{Y} - \mathcal{X}\beta)\right\},$$

where $\mathcal{Y} = \text{vec}(Y_1, \dots, Y_{p_2})$, $\mathcal{X} = I_{p_2} \otimes X$ and $\beta = \text{vec}(B_1, \dots, B_{p_2})$. After writing out the Kronecker product, the log-likelihood can be written as

$$\ell(Y|X) = \text{constant} + \frac{n}{2} \log \det \Theta_\epsilon - \frac{1}{2} \sum_{j=1}^{p_2} \sum_{i=1}^{p_2} \sigma_\epsilon^{ij} (Y_i - XB_j)^\top (Y_j - XB_j).$$

Here, σ_ϵ^{ij} denotes the ij -th entry of Θ_ϵ . With ℓ_1 penalization which induces sparsity, we formulate the following optimization problem using penalized log-likelihood, which was initially proposed in Rothman et al. (2010), and has also been examined in Lee and Lin (2012):

$$\min_{\substack{B \in \mathbb{R}^{p_1 \times p_2} \\ \Theta_\epsilon \in \mathbb{S}_{p_2}^{++}}} \left\{ \frac{1}{n} \sum_{j=1}^{p_2} \sum_{i=1}^{p_2} \sigma_\epsilon^{ij} (Y_i - XB_j)^\top (Y_j - XB_j) - \log \det \Theta_\epsilon + \lambda_n \sum_{j=1}^{p_2} \|B_j\|_1 + \rho_n \|\Theta_\epsilon\|_{1,\text{off}} \right\}, \quad (2)$$

and the first term in (2) can be equivalently written as

$$\text{tr} \left\{ \frac{1}{n} \begin{bmatrix} (Y_1 - XB_1)^\top \\ \vdots \\ (Y_{p_2} - XB_{p_2})^\top \end{bmatrix} \begin{bmatrix} (Y_1 - XB_1) & \cdots & (Y_{p_2} - XB_{p_2}) \end{bmatrix} \Theta_\epsilon \right\} =: \text{tr}(\mathcal{S}\Theta_\epsilon).$$

where \mathcal{S} is defined as the sample covariance matrix of $E \equiv Y - XB$. This gives rise to the following optimization problem:

$$\min_{\substack{B \in \mathbb{R}^{p_1 \times p_2} \\ \Theta_\epsilon \in \mathbb{S}_{p_2}^{++}}} \left\{ \text{tr}(\mathcal{S}\Theta_\epsilon) - \log \det \Theta_\epsilon + \lambda_n \sum_{j=1}^{p_2} \|B_j\|_1 + \rho_n \|\Theta_\epsilon\|_{1,\text{off}} \right\} =: f(B, \Theta_\epsilon), \quad (3)$$

where $\|\Theta\|_{1,\text{off}}$ is the absolute sum of the off-diagonal entries in Θ , λ_n and ρ_n are both positive tuning parameters.

Note that the objective function (3) is *not jointly convex* in (B, Θ_ϵ) , but only convex in B for fixed Θ_ϵ and in Θ_ϵ for fixed B ; hence, it is bi-convex, which in turn implies that the proposed algorithm may fail to converge to the global optimum, especially in settings where $p_1 > n$, as pointed out by Lee and Lin (2012). As is the case with most non-convex problems, good initial parameters are beneficial for fast convergence of the algorithm, a fact supported by our numerical work on the present problem. Further, a good initialization is critical in establishing convergence of the algorithm for this problem (see Section 3.1). To that end, we introduce a *screening step* for obtaining a good initial estimate for B . The theoretical justification for employing the screening step is provided in Section 3.3.

An outline of the computational procedure is presented in Algorithm 1, while the details of each step involved are discussed next.

Screening. For each variable Y_j , $j = 1, \dots, p_2$ in the response layer, regress Y_j on X via the de-biased Lasso procedure proposed by Javanmard and Montanari (2014). The output consists of the p -value(s) for each predictor in each regression, denoted by P_j , with $P_j \in [0, 1]^{p_1}$. To control the family-wise error rate of the estimates, we do a Bonferroni correction at level α : define $\alpha^* = \alpha/p_1 p_2$ and set $B_{j,k} = 0$ if the p -value obtained for the k 'th predictor in the j 'th regression $P_{j,k}$ exceeds α^* . Further, let

$$B_j = \{B_j \in \mathbb{R}^{p_1} : B_{j,k} = 0 \text{ if } k \in \widehat{S}_j^c\} \subseteq \mathbb{R}^{p_1}, \quad (4)$$

where \widehat{S}_j is the collection of indices for those predictors deemed ‘‘active’’ for response Y_j :

$$\widehat{S}_j = \{k : P_{j,k} < \alpha^*\}, \quad \text{for } j = 1, \dots, p_2.$$

Therefore, subsequent estimation of the elements of B will be restricted to $B_1 \times \dots \times B_{p_2}$.

Alternating Search. In this step, we utilize the bi-convexity of the problem and estimate B and Θ_ϵ by minimizing in an iterative fashion the objective function with respect to (w.r.t.) one set of parameters, while holding the other set fixed within each iteration.

As with most iterative algorithms, we need an initializer; for $\widehat{B}^{(0)}$ it corresponds to a Lasso/Ridge regression estimate with a small penalty, while for Θ_ϵ we use the Graphical Lasso procedure applied to the residuals obtained from the first stage regression. That is, for each $j = 1, \dots, p_2$,

$$\widehat{B}_j^{(0)} = \arg \min_{B_j \in \mathcal{S}_j} \left\{ \|Y_j - XB_j\|_2^2 + \lambda_n^0 \|B_j\|_1 \right\}, \quad (5)$$

-

where λ_n^0 is some small tuning parameter for initialization, and set $\tilde{E}_j^{(0)} := Y_j - X\tilde{B}_j^{(0)}$. An initial estimate for $\hat{\Theta}_\epsilon$ is then given by solving for the following optimization problem with the graphical lasso ([Friedman et al., 2008](#)) procedure:

$$\hat{\Theta}_\epsilon^{(0)} = \underset{\Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}{\text{argmin}} \left\{ \log \det \Theta_\epsilon - \text{tr}(\tilde{S}^{(0)} \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1,\text{off}} \right\},$$

where $\tilde{S}^{(0)}$ is the sample covariance matrix based on $(\tilde{E}_1^{(0)}, \dots, \tilde{E}_{p_2}^{(0)})$.

Next, we use an alternating block coordinate descent algorithm with ℓ_1 penalization to reach a stationary point of the objective function [\(3\)](#).

- Update B as

$$\tilde{B}^{(k+1)} = \underset{B \in \mathcal{B}_1 \times \dots \times \mathcal{B}_{p_2}}{\text{argmin}} \left\{ \frac{1}{n} \sum_{i=1}^{p_2} \sum_{j=1}^{p_2} (\hat{\sigma}_\epsilon^{ij})^{(k)} (Y_i - XB_i)^\top (Y_j - XB_j) + \lambda_n \sum_{j=1}^{p_2} \|B_j\|_1 \right\}, \quad (6)$$

which can be obtained by cyclic coordinate descent w.r.t each column B_j of B , that is, update each column B_j by:

$$\tilde{B}_j^{(k+1)} = \underset{B_j \in \mathcal{B}_j}{\text{argmin}} \left\{ \frac{(\hat{\sigma}_\epsilon^{jj})^{(k)}}{n} \|Y_j + r_j^{(k+1)} - XB_j\|_2^2 + \lambda_n \|B_j\|_1 \right\}, \quad (7)$$

where

$$r_j^{(k+1)} = \frac{1}{(\hat{\sigma}_\epsilon^{jj})^{(k)}} \left[\sum_{i=1}^{j-1} (\hat{\sigma}_\epsilon^{ij})^{(k)} (Y_i - X\tilde{B}_i^{(k+1)}) + \sum_{i=j+1}^{p_2} (\hat{\sigma}_\epsilon^{ij})^{(k)} (Y_i - X\tilde{B}_i^{(k)}) \right],$$

and iterate over all columns until convergence. Here, we use k to index the outer iteration while minimizing w.r.t. B or Θ_ϵ , and use t to index the inner iteration while cyclically minimizing w.r.t. each column of B .

— Update Θ_ϵ as

$$\hat{\Theta}_\epsilon^{(k+1)} = \underset{\Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}{\text{argmin}} \left\{ \log \det \Theta_\epsilon - \text{tr}(\tilde{S}^{(k+1)} \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1,\text{off}} \right\}, \quad (8)$$

where $\tilde{S}^{(k+1)}$ is the sample covariance matrix based on $\tilde{E}_j^{(k+1)} = Y_j - X\tilde{B}_j^{(k+1)}$, $j = 1, \dots, p_2$.

Refitting and Stabilizing. As noted in the introduction, this step is beneficial in applications, especially when one deals with large scale multi-layer networks and relatively smaller sample sizes. Denote the solution obtained by the above iterative procedure by B^∞ and Θ_ϵ^∞ . For each $j = 1, \dots, p_2$, set $\tilde{B}_j := \{B_j : B_{j,i} = 0 \text{ if } B_{j,i}^\infty = 0, B_j \in \mathbb{R}^{p_1}\}$ and the final estimate for B_j is given by ordinary least squares:

$$\tilde{B}_j = \underset{B_j \in \mathcal{B}_j}{\text{argmin}} \|Y_j - XB_j\|^2. \quad (9)$$

For Θ_ϵ , we obtain the final estimate by a combination of stability selection ([Meinshausen and Bühlmann, 2010](#)) and graphical lasso ([Friedman et al., 2008](#)). That is, after obtaining the refitted residuals $\tilde{E}_j := Y_j - X\tilde{B}_j$, $j = 1, \dots, p_2$, based on the stability selection procedure with the graphical lasso, we obtain the stability path, or probability matrix W for each edge, which records the proportion of each edge being selected based on bootstrapped samples of \tilde{E}_j 's. Then, using this probability matrix W as a weight matrix, we obtain the final estimate of $\tilde{\Theta}_\epsilon$ as follow:

$$\tilde{\Theta}_\epsilon = \underset{\Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}{\text{argmin}} \left\{ \log \det \Theta_\epsilon - \text{tr}(\tilde{S} \Theta_\epsilon) + \tilde{\rho}_n \|(1 - W) * \Theta_\epsilon\|_{1,\text{off}} \right\}, \quad (10)$$

where we use $*$ to denote the element-wise product of two matrices, and \tilde{S} is the sample covariance matrix based on the refitted residuals \tilde{E} . Again, [\(10\)](#) can be solved by the graphical lasso procedure ([Friedman et al., 2008](#)), with $\tilde{\rho}_n$ properly chosen.

2.3 Tuning Parameter Selection.

To select the tuning parameters (λ_n, ρ_n) , we use the Bayesian Information Criterion (BIC), which is the summation of a goodness-of-fit term (log-likelihood) and a penalty term. The explicit form of BIC (as a function of B and Θ_ϵ) in our setting is given by

$$\text{BIC}(B, \Theta_\epsilon) = -\log \det \Theta_\epsilon + \text{tr}(S\Theta_\epsilon) + \frac{\log n}{n} \left(\frac{\|\Theta_\epsilon\|_0 - p_2}{2} + \|B\|_0 \right)$$

where

$$S := \frac{1}{n} \begin{bmatrix} (Y_1 - XB_1)^\top \\ \vdots \\ (Y_{p_2} - XB_{p_2})^\top \end{bmatrix} [(Y_1 - XB_1) \ \cdots \ (Y_{p_2} - XB_{p_2})],$$

and $\|\Theta_\epsilon\|_0$ is the total number of nonzero entries in Θ_ϵ . Here we penalize the non-zero elements in the upper-triangular part of Θ_ϵ and the non-zero ones in B . We choose the combination (λ_n^*, ρ_n^*) over a grid of (λ, ρ) values, and (λ_n^*, ρ_n^*) should minimize the BIC evaluated at $(\mathcal{B}^\infty, \Theta_\epsilon^\infty)$.

3. Theoretical Results.

In this section, we establish a number of theoretical results for the proposed iterative algorithm. We focus the presentation on the two-layer structure, since as explained in the previous section the multi-layer estimation problem decomposes to a series of two-layer ones. As mentioned in the introduction, one key challenge for establishing the theoretical results comes from the fact that the objective function (3) is not jointly convex in B and Θ_ϵ . Consequently, if we simply used properties of block-coordinate descent algorithms, we would not be able to provide the necessary theoretical guarantees for the estimates we obtain. On the other hand, the biconvex nature of the objective function allows us to establish convergence of the alternating algorithm to a stationary point, provided it is initialized from a point close enough to the true parameters. This can be accomplished using a Lasso-based initializer for B and Θ_ϵ as previously discussed. The details of algorithmic convergence are presented in Section 3.1.

Another technical challenge is that each update in the alternating search step relies on estimated quantities—namely the regression and precision matrix parameters—rather than the raw data, whose estimation precision needs to be controlled *uniformly* across all iterations. The details of establishing consistency of the estimates for both fixed and random realizations are given in Section 3.2.

Next, we outline the structure of this section. In Section 3.1 Theorem 1, we show that for any fixed set of realization of X and E ,² the iterative algorithm is guaranteed to converge to a stationary point if estimates for all iterations lie in a compact ball around the true value of the parameters. In Section 3.2, we show in Theorem 4 that for any random X and E , with high probability, the estimates for all iterations lie in a compact ball around the true value of the parameters. Then in Section 3.3, we show that asymptotically with

² We actually observe X and Y , which is given by a corresponding set of realization in X and E based on the model.

$\log(p_1 p_2)/n \rightarrow 0$, while keeping the family-wise type I error under some pre-specified level, the screening step correctly identifies the true support set for each of the regressions, based upon which the iterative algorithm is provided with an initializer that is close to the true value of the parameters. Finally in Section 3.4, we provide sufficient conditions for both directed and undirected edges to be identifiable (estimable) for multi-layered network.

To aid the readability of the main results, we only present statements of theorems and propositions, while all proofs are relegated to the Appendix (Section A and B).

Throughout this section, to distinguish the estimates from the true values, we use B^* and Θ_ϵ^* to denote the true values.

3.1 Convergence of the Iterative Algorithm.

In this subsection, we prove that the proposed block relaxation algorithm converges to a stationary point for any fixed set of data, provided that the estimates for all iterations lie in a compact ball around the true value of the parameters. This requirement is shown to be satisfied with high probability in the next subsection 3.2.

Decompose the optimization problem in (3) as follows:

$$\min_{\substack{B \in \mathbb{R}^{p_1 \times p_2} \\ \Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}} f(B, \Theta_\epsilon) \equiv f_0(B, \Theta_\epsilon) + f_1(B) + f_2(\Theta_\epsilon),$$

where

$$f_0(B, \Theta_\epsilon) = \frac{1}{n} \sum_{j=1}^{p_2} \sum_{i=1}^{p_2} \sigma_{ij}^2 (Y_i - XB_j)(Y_j - XB_j) - \log \det \Theta_\epsilon = \text{tr}(S\Theta_\epsilon) - \log \det \Theta_\epsilon,$$

$$f_1(B) = \lambda_n \|B\|_1, \quad f_2(\Theta_\epsilon) = \rho_n \|\Theta_\epsilon\|_{1,\text{off}}.$$

and $\mathbb{S}_{++}^{p_2 \times p_2}$ is the collection of $p_2 \times p_2$ symmetric positive definite matrices. Further, denote the limit point (if there is any) of $\{\widehat{B}^{(k)}\}$ and $\{\widehat{\Theta}_\epsilon^{(k)}\}$ by $B^\infty = \lim_{k \rightarrow \infty} \widehat{B}^{(k)}$ and $\Theta_\epsilon^\infty = \lim_{k \rightarrow \infty} \widehat{\Theta}_\epsilon^{(k)}$, respectively.

Definition 1 (stationary point (Tseung, 2001) pp.479). Define z to be a stationary point of f if $z \in \text{dom}(f)$ and $f'(z; d) \geq 0, \forall$ direction $d = (d_1, \dots, d_N)$ where d_t is the t^{th} coordinate block.

Definition 2 (Regularity (Tseung, 2001) pp.479). f is regular at $z \in \text{dom}(f)$ if $f'(z; d) \geq 0$ for all $d = (d_1, \dots, d_N)$ such that

$$f'(z; (0, \dots, d_t, \dots, 0)) \geq 0, \quad t = 1, 2, \dots, N.$$

Definition 3 (Coordinate-wise minimum). Define $(B^\infty, \Theta_\epsilon^\infty)$ to be a coordinate-wise minimum if

$$\begin{aligned} f(B^\infty, \Theta_\epsilon^\infty) &\geq f(B^\infty, \Theta_\epsilon^\infty), & \forall \Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}, \\ f(B, \Theta_\epsilon^\infty) &\geq f(B^\infty, \Theta_\epsilon^\infty), & \forall B \in \mathbb{R}^{p_1 \times p_2}. \end{aligned}$$

Note for our iterative algorithm, we only have two blocks, hence with the above notation, $N = 2$.

Remark 3. Tseng (2001) proved that if the level set $\{x : f(x) \leq f(x^0)\}$ is compact and f satisfies certain conditions (Tseng, 2001, see Theorem 4.1 (a), (b) and (c) for details), the limit point given by the general block-coordinate descent algorithm (with $N \geq 2$ blocks) is a stationary point of f . However, the conditions given in Theorem 4.1 (a), (b) and (c) are not satisfied for the objective function at hand. Hence, for the problem under consideration, a different strategy is needed to prove convergence of the 2-block alternating algorithm to a stationary point, and the resulting statements hold true for all problems that use a 2-block coordinate descent algorithm.

Since $\text{dom}(f_0)$ is open and f_0 is Gâteaux-differentiable on the $\text{dom}(f_0)$, by Tseng (2001) Lemma 3.1, f is regular in the $\text{dom}(f)$. From the discussion on Page 479 of (Tseng, 2001), we then have:

Fact 1: Every coordinate-wise minimum is a stationary point of f .

The following theorem shows that any limit point $(B^\infty, \Theta_\epsilon^\infty)$ of the iterative algorithm described in Section 2.2 is a stationary point of f , as long as all the iterates are within a closed ball around the truth.

Theorem 1 (Convergence for fixed design). *Suppose for any fixed realization of X and E , the estimates $\{(\hat{B}^{(k)}, \hat{\Theta}_\epsilon^{(k)})\}_{k=1}^\infty$ obtained by implementing the alternating search step satisfy the following bound for some $\bar{R} > 0$ that only depends on p_1, p_2 and n :*

$$\|(\hat{B}^{(k)}, \hat{\Theta}_\epsilon^{(k)}) - (B^*, \Theta^*)\|_F \leq R(p_1, p_2, n), \quad \forall k \geq 1.$$

Then any limit point $(B^\infty, \Theta_\epsilon^\infty)$ of the iterative algorithm is a stationary point of f .

Remark 4. Recall that in classical parametric statistics, MLE-type asymptotics are derived after establishing that with probability tending to 1 as the sample size n goes to infinity, the likelihood equation has a sequence of roots (hence stationary points of the likelihood function) that converges in probability to the true value. Any such sequence of roots is shown to be asymptotically normal and efficient. Note that such (a sequence of) roots may not be global maximizers since parametric likelihoods are not globally log-concave (see Chapter 6 Lehmann and Casella, 1998). Here we show that the $(B^\infty, \Theta_\epsilon^\infty)$ obtained by the iterative algorithm is a stationary point which satisfies the first-order condition for being a maximizer of the penalized log-likelihood function (which is just the negative of the penalized least-squares function). Moreover, if we let n go to infinity, $(B^\infty, \Theta_\epsilon^\infty)$ converges to the true value in probability (shown in Theorem 4), and therefore behaves the same as the sequence of roots in the classical parametric problem alluded to above. Thus, while $(B^\infty, \Theta_\epsilon^\infty)$ may not be the global maximizer, it can, nevertheless, to all intents and purposes, be deemed as the MLE.

Remark 5. The above convergence result is based upon solving the optimization problem on the “entire” space, that is, we don’t restrict B to live in any subspace. However, when actually implementing the proposed computational procedure, the optimization of the B coordinate is restricted to $\mathcal{B}_1 \times \dots \times \mathcal{B}_{p_2}$ (as defined in eqn.4). It should be noted that the

same convergence property still holds, since for all $k \geq 1$, the following bound holds, for some $R' > 0$:

$$\|(\hat{B}^{(k)}_{\text{restricted}}, \hat{\Theta}_\epsilon^{(k)}) - (B^*, \Theta_\epsilon^*)\|_F \leq R'(p_1, p_2, n). \quad (11)$$

Consequently, the rest of the derivation in Theorem 1 follows, leading to the convergence property. The bound in eqn (11) will be shown at the end of Section 3.2.

3.2 Estimation Consistency.

In this subsection, we show that given a random realization of X and E , with high probability, the sequence $\{(\hat{B}^{(k)}, \hat{\Theta}_\epsilon^{(k)})\}_{k=1}^\infty$ lies in a non-expanding ball around (B^*, Θ_ϵ^*) , thus satisfying the condition of Theorem 1 for convergence of the alternating algorithm.

It should be noted that for the alternating search procedure, we restrict our estimation on a subspace identified by the screening step. However, for the remaining of this subsection, the main propositions and theorems are based on the procedure without such restriction, i.e., we consider “generic” regressions on the entire space of dimension $p_1 \times p_2$. Notwithstanding, it can be easily shown that the theoretical results for the regression parameters on a restricted domain follow easily from the generic case, as explained in Remark 9.

Before providing the details of the main theorem statements and proofs, we first introduce additional notations. Let $\beta = \text{vec}(B)$ be the vectorized version of the regression coefficient matrix. Correspondingly, we have $\tilde{\beta}^{(k)} = \text{vec}(\tilde{B}^{(k)})$ and $\beta^* = \text{vec}(B^*)$. Moreover, we drop the superscripts and use β and Θ_ϵ to denote the generic estimators given by (12) and (13), as opposed to those obtained in any specific iteration:

$$\hat{\beta} \equiv \underset{\beta \in \mathbb{R}^{p_1 p_2}}{\text{argmin}} \left\{ -2\beta' \hat{\gamma} + \beta' \hat{\Gamma} \beta + \lambda_n \|\beta\|_1 \right\}, \quad (12)$$

$$\hat{\Theta}_\epsilon \equiv \underset{\Theta_\epsilon \in \mathbb{S}_+^{p_1 p_2}}{\text{argmin}} \left\{ -\log \det \Theta_\epsilon + \text{tr}(\hat{S} \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1, \text{off}} \right\}, \quad (13)$$

where

$$\hat{\Gamma} = \left(\hat{\Theta}_\epsilon \otimes \frac{X'X}{n} \right), \quad \hat{\gamma} = \left(\hat{\Theta}_\epsilon \otimes X' \right) \text{vec}(Y)/n, \quad \hat{S} = \frac{1}{n} (Y - X\hat{B})' (Y - X\hat{B}).$$

Remark 6. As opposed to (12) and (13), if $\hat{\gamma}$ and $\hat{\Gamma}$ are replaced by plugging in the true values of the parameters, the two problems in (12) and (13) become

$$\tilde{\beta} \equiv \underset{\beta \in \mathbb{R}^{p_1 p_2}}{\text{argmin}} \left\{ -2\beta' \tilde{\gamma} + \beta' \tilde{\Gamma} \beta + \lambda_n \|\beta\|_1 \right\}, \quad (14)$$

$$\tilde{\Theta}_\epsilon \equiv \underset{\Theta_\epsilon \in \mathbb{S}_+^{p_1 p_2}}{\text{argmin}} \left\{ -\log \det \Theta_\epsilon + \text{tr}(S \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1, \text{off}} \right\}, \quad (15)$$

where

$$\tilde{\Gamma} = \left(\Theta_\epsilon^* \otimes \frac{X'X}{n} \right), \quad \tilde{\gamma} = \left(\Theta_\epsilon^* \otimes X' \right) \text{vec}(Y)/n, \quad S = \frac{1}{n} (Y - XB^*)' (Y - XB^*) \equiv \tilde{\Sigma}_\epsilon.$$

In (14), we obtain $\tilde{\beta}$ using a penalized maximum likelihood regression estimate, and (15) corresponds to the generic setting for using the graphical Lasso. A key difference between

the estimation problems in (12) and (13) versus those in (14) and (15) is that to obtain $\widehat{\beta}$ and Θ_ϵ we use *estimated quantities* rather than the raw data. This is exactly how we implement our iterative algorithm, namely, we obtain $\widehat{\beta}^{(k)}$ using $\widehat{S}^{(k-1)}$ as a surrogate for the sample covariance of the true error (which is unavailable), then estimate $\widehat{\Theta}_\epsilon^{(k)}$ using the information in $\widehat{\beta}^{(k)}$. This adds complication for establishing the consistency results. Original consistency results for the estimation problem in (14) and (15) are available in Basu and Michailidis (2015) and Ravikumar et al. (2011), respectively. Here we borrow ideas from corresponding theorems in those two papers, but need to tackle concentration bounds of relevant quantities with additional care. This part of the result and its proof are shown in Theorem 4.

As a road map toward our desired result established in Theorem 4, we first show in Theorem 2 that for any fixed realization of X and E , under a number of conditions on (or related to) X and E , when $\|\widehat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty$ is small (up to a certain order), the error of $\widehat{\beta}$ is well-bounded. We then verify in Proposition 1 and 2 that for random X and E , the above-mentioned conditions hold with high probability. Similarly in Theorem 3, we show that for fixed realizations in X and E , under certain conditions (verified for random X and E in Proposition 3), the error of $\widehat{\Theta}_\epsilon$ is also well-bounded, given $\|\widehat{\beta} - \beta^*\|_1$ being small. Finally in Theorem 4, we show that for random X and E , with high probability, the iterative algorithm gives $\{(\widehat{\beta}^{(k)}, \Theta_\epsilon^{(k)})\}$ that lies in a small ball centered at $(\beta^*, \Theta_\epsilon^*)$, whose radius depends on p_1, p_2, n and the sparsity levels.

Next, for establishing the main propositions and theorems, we introduce some additional notations.

- Sparsity level of β^* : $s^{**} := \|\beta^*\|_0 = \sum_{j=1}^{p_2} \|\beta_j^*\|_0 = \sum_{j=1}^{p_2} s_j^*$. As a reminder of the previous notation, we have $s^* = \max_{j=1, \dots, p_2} s_j^*$.
- True edge set of Θ_ϵ^* : S_ϵ^* and let $s_\epsilon^* := |S_\epsilon^*|$ be its cardinality.
- Hessian of the log-determinant barrier $\log \det \Theta$ evaluated at Θ_ϵ^* :

$$H^* := \frac{d^2}{d\Theta^2} \log |\Theta|_{\Theta_\epsilon^*} = \Theta_\epsilon^{*-1} \otimes \Theta_\epsilon^{*-1}.$$
- Matrix infinity norm of the true error covariance matrix Σ_ϵ^* :

$$\kappa_{\Sigma_\epsilon^*} := \|\Sigma_\epsilon^*\|_\infty = \max_{i=1, 2, \dots, p_2} \sum_{j=1}^{p_2} |\Sigma_{\epsilon, ij}^*|.$$

- Matrix infinity norm of the Hessian restricted to the true edge set:

$$\kappa_{H^*} := \left\| \left(H_{S_\epsilon^* S_\epsilon^*}^* \right) \right\|_\infty = \max_{i=1, 2, \dots, p_2} \sum_{j=1}^{p_2} \left| H_{S_\epsilon^* S_\epsilon^*}^* \right|.$$

- Maximum degree of Θ_ϵ^* : $d := \max_{i=1, 2, \dots, p_2} \|\Theta_{\epsilon, i}^*\|_0$.
- We write $A \gtrsim B$ if there exists some absolute constant c that is independent of the model parameters such that $A \geq cB$.

Definition 4 (Incoherence condition (Ravikumar et al., 2011)). Θ_ϵ^* satisfies the incoherence condition if:

$$\max_{e \in (S_\epsilon^*)^c} \|H_{e S_\epsilon^*}^* (H_{S_\epsilon^* S_\epsilon^*}^*)^{-1}\|_1 \leq 1 - \xi, \quad \text{for some } \xi \in (0, 1).$$

Definition 5 (Restricted eigenvalue (RE) condition (Loh and Wainwright, 2012)). A symmetric matrix $A \in \mathbb{R}^{m \times m}$ satisfies the RE condition with curvature $\varphi > 0$ and tolerance $\phi > 0$, denoted by $A \sim RE(\varphi, \phi)$ if

$$\theta^* A \theta \geq \varphi \|\theta\|^2 - \phi \|\theta\|_1^2, \quad \forall \theta \in \mathbb{R}^m.$$

Definition 6 (Diagonal dominance). A matrix $A \in \mathbb{R}^{m \times m}$ is strictly diagonally dominant if

$$|a_{ii}| > \sum_{j \neq i} |a_{ij}|, \quad \forall i = 1, \dots, m.$$

Based on the model in Section 2.1, since we are assuming $\mathbf{X} = (X_1, \dots, X_{p_1})'$ and $\epsilon = (\epsilon_1, \dots, \epsilon_{p_2})$ come from zero-mean Gaussian distributions, it follows that \mathbf{X} and ϵ are zero-mean sub-Gaussian random vectors with parameters (Σ_X, σ_X^2) and $(\Sigma_\epsilon, \sigma_\epsilon^2)$, respectively. Moreover, throughout this section, all results are based on the assumption that Θ_ϵ^* is diagonally dominant.

Remark 7. Before moving on to the main statements of Theorem 2, we would like to point out that with a slight abuse of notation, for Theorem 2 and its related propositions and corollaries, the statements and analyses are based on equation (12) only, with any deterministic symmetric matrix Θ_ϵ within a small ball around Θ_ϵ^* . Similarly in Theorem 3, Proposition 3 and Corollary 2, the analyses are based on equation (13) only, for any given deterministic $\widehat{\beta}$ within a small ball around β^* . The randomness of $\widehat{\beta}$ and $\widehat{\Theta}_\epsilon$ during the iterative procedure will be taken into consideration comprehensively in Theorem 4.

Theorem 2 (Error bound for $\widehat{\beta}$ with fixed realizations of X and E). Consider $\widehat{\beta}$ given by (12). For any fixed pair of realizations of X and E , assume the following:

A1. $\widehat{\Theta}_\epsilon$ is a deterministic matrix satisfying the bound $\|\widehat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty \leq \eta_\Theta$ where $\eta_\Theta = \eta_\Theta \left(\sqrt{\frac{\log p_2}{n}} \right)$ and η_Θ is some constant depending only on Θ_ϵ^* ;

A2. $\widehat{\Gamma} \sim RE(\varphi, \phi)$, with $s^{**} \phi \leq \varphi/32$;

A3. $(\widehat{\Gamma}, \widehat{\gamma})$ satisfies the deviation bound

$$\|\widehat{\gamma} - \widehat{\Gamma} \beta^*\|_\infty \leq \mathbb{Q}(\eta_\Theta) \sqrt{\frac{\log(p_1 p_2)}{n}},$$

where $\mathbb{Q}(\eta_\Theta)$ is some quantity depending on η_Θ .

Then, for any $\lambda_n \geq 4\mathbb{Q}(\eta_\Theta) \sqrt{\frac{\log(p_1 p_2)}{n}}$, the following bound holds:

$$\|\widehat{\beta} - \beta^*\|_1 \leq 64 s^{**} \lambda_n / \varphi.$$

The following two propositions verify the RE condition for $\hat{\Gamma}$ and deviation bound for $(\hat{\Gamma}, \hat{\gamma})$ hold with high probability for a random pair (X, E) , given any symmetric, matrix $\hat{\Theta}_\epsilon$ satisfying (A1).

Proposition 1 (Verification of RE condition for random X and E). *Consider any deterministic matrix $\hat{\Theta}_\epsilon$ satisfying (A1). Let the sample size satisfy $n \gtrsim \max\{s^{**} \log p_1, d^2 \log p_2\}$. With probability at least $1 - 2 \exp(-c_3 n)$ for some constant $c_3 > 0$, $\hat{\Gamma}$ satisfies the following RE condition:*

$$\hat{\Gamma} \equiv \hat{\Theta}_\epsilon \otimes (X'X/n) \sim RE \left(\varphi^* (\min_i \psi^i - d\nu_\Theta), \phi^* \max_i (\psi^i + d\nu_\Theta) \right),$$

where $\varphi^* = \frac{\Lambda_{\min}(\Sigma_X^*)}{2}$, $\phi^* = (\varphi^* \log p_1)/n$, and ψ^i is defined as:

$$\psi^i := \sigma_\epsilon^i - \sum_{j \neq i}^{p_2} \sigma_\epsilon^{ij},$$

where σ_ϵ^{ij} 's denote the entries in Θ_ϵ^* hence ψ^i is the gap between its diagonal entry and the sum of off-diagonal entries for row i .

Proposition 2 (Deviation bound for $(\hat{\Gamma}, \hat{\gamma})$ for random X and E). *Consider any deterministic matrix $\hat{\Theta}_\epsilon$ satisfying (A1). Let sample size n satisfy $n \gtrsim \log(p_1 p_2)$. With probability at least*

$$1 - 12c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] \text{ for some } c_1 > 0, c_2 > 1,$$

the following bound holds:

$$\begin{aligned} \|\hat{\Gamma} - \hat{\Gamma}\beta^*\|_\infty &= \frac{1}{n} \|X'E\hat{\Theta}_\epsilon\|_\infty \leq \mathbb{Q}(\nu_\Theta) \sqrt{\frac{\log(p_1 p_2)}{n}}, \\ \mathbb{Q}(\nu_\Theta) &= c_2 \left\{ d\nu_\Theta [\Lambda_{\max}(\Sigma_X^*) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} + \left[\frac{\Lambda_{\max}(\Sigma_X^*)}{\Lambda_{\min}(\Sigma_\epsilon^*)} \right]^{1/2} \right\}. \end{aligned} \quad (16)$$

where

Remark 8. In Proposition 1, the quantity $d^2 \log p_2$ that shows up in the sample size requirement is a result of $\nu_\Theta = O(\sqrt{\log p_2/n})$, which is the common order of error in a generic graphical Lasso problem. Hence here we explicitly list it for the purpose of showing results for the generic graphical Lasso estimation problem. In our iterative algorithm, the order of $\nu_\Theta^{(k)}$ depends on the relative order of p_1 and p_2 , which may potentially make the sample size requirement more stringent. This will be discussed in more detail in the proof of Theorem 4.

Given the results in Theorem 2, Proposition 1 and Proposition 2, next we provide Corollary 1, which gives the error bound for $\hat{\beta}$ for random realizations of X and E .

Corollary 1 (Error Bound for $\hat{\beta}$ for random X and E). *Consider any deterministic $\hat{\Theta}_\epsilon$ satisfying the following element-wise ℓ_∞ -bound:*

$$\|\hat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty \leq \nu_\Theta,$$

with $\nu_\Theta = \eta_\Theta \sqrt{\frac{\log p_2}{n}}$. Then for sample size $n \gtrsim \log(p_1 p_2)$ and for any regularization parameter $\lambda_n \geq 4\mathbb{Q}(\nu_\Theta) \sqrt{\frac{\log(p_1 p_2)}{n}}$ with the expression of $\mathbb{Q}(\cdot)$ given in (16), there exists $c_1 > 0$ and $c_2 > 1$ such that with probability at least:

$$1 - 12c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] - 2 \exp(-c_3 n), \quad (17)$$

the following bound holds:

$$\|\hat{\beta} - \beta^*\|_1 \leq 64s^{**} \lambda_n / \varphi,$$

where $\varphi = \frac{1}{2} \Lambda_{\min}(\Sigma_\epsilon^*) (\min_i \psi^i - d\nu_\Theta)$.

Next, we move onto analyzing the error bound of the other component, for a fixed given $\hat{\beta}$.

Theorem 3 (Error bound for $\hat{\Theta}_\epsilon$ for fixed realizations of X and E). *Consider $\hat{\Theta}_\epsilon$ given by (13). For any fixed pair of realization (X, E) , assume the following:*

B1. $\hat{\beta}$ is a deterministic vector satisfying $\|\hat{\beta} - \beta^*\|_1 \leq \nu_\beta$, where $\nu_\beta = \eta_\beta \left(\sqrt{\frac{\log(p_1 p_2)}{n}} \right)$, with η_β being some constant depending only on β^* ;

B2. $\|\hat{S} - \Sigma_\epsilon^*\|_\infty \leq g(\nu_\beta)$ where

$$\hat{S} = \frac{1}{n} (Y - X\hat{B})(Y - X\hat{B}),$$

and $g(\nu_\beta)$ is some quantity depending on ν_β ;

B3. Incoherence condition holds for Θ_ϵ^* .

Then, for $\rho_n = (8/\xi)g(\nu_\beta)$ and sample size n satisfying $n \gtrsim \log(p_1 p_2)$, the following error bound for $\hat{\Theta}_\epsilon$ holds:

$$\|\hat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty \leq \{2(1 + 8\xi^{-1})\kappa_H\}g(\nu_\beta), \quad (18)$$

where ξ is the incoherence parameter as defined in Definition 4.

Proposition 3 gives an explicit expression for $g(\nu_\beta)$ under condition (B1). Specifically, it shows how well \hat{S} concentrates around Σ_ϵ^* for random X and E , given some \hat{B} exhibiting a small error from its true value (or $\hat{\beta}$, equivalently),

Proposition 3. *Consider any deterministic $\hat{\beta}$ satisfying (B1). Then for sample size n satisfying $n \gtrsim \log(p_1 p_2)$, with probability at least*

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)], \text{ for some } c_1 > 0, c_2 > 1, \tau_1, \tau_2 > 2,$$

the following bound holds:

$$\|\hat{S} - \Sigma_\epsilon^*\|_\infty \leq g(\nu_\beta), \quad (19)$$

where

$$g(\nu_\beta) = \sqrt{\frac{\log 4 + \tau_2 \log p_2}{c_\epsilon^* n} + \nu_\beta^2} \left(\sqrt{\frac{\log 4 + \tau_1 \log p_1}{c_X^* n} + \max_i (\Sigma_{X,i}^*)} \right) + 2c_2 \nu_\beta [\Lambda_{\max}(\Sigma_X^*) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}, \quad (20)$$

c_ϵ^* and c_X^* are population quantities given in (57) and (62), respectively.

Given Theorem 3 and Proposition 3, we provide Corollary 2, which gives the error bound for $\hat{\Theta}_\epsilon$ for random realizations of X and E :

Corollary 2 (Error bound for $\hat{\Theta}$ for random X and E). Consider any deterministic $\hat{\beta}$ satisfying the following bound

$$\|\hat{\beta} - \beta^*\|_1 \leq \nu_\beta,$$

with $\nu_\beta = \eta_\beta \sqrt{\frac{\log(p_1 p_2)}{n}}$. Also suppose the incoherence condition (B3) is satisfied. Then, for sample size $n \gtrsim \log(p_1 p_2)$ and regularization parameter $\rho_n = (8/\xi)g(\nu_\beta)$ with $g(\nu_\beta)$ given in (20), with probability at least

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)], \quad \text{for some } c_1 > 0, c_2 > 1, \tau_1, \tau_2 > 2,$$

the following bound holds:

$$\|\hat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty \leq \{2(1 + 8\xi^{-1})\kappa_{H^*}\}g(\nu_\beta).$$

After providing the error bound for (12) and (13), in Theorem 4 we establish that with high probability, the error of the sequence of estimates obtained in the alternating search step of the algorithm described in Section 2.2 is uniformly bounded; that is, the sequence of estimates lie in a non-expanding ball around the true value of the parameters uniformly with a radius that does not depend on the iteration number k .

Theorem 4 (Error bound for $\{\hat{\beta}^{(k)}\}$ and $\{\hat{\Theta}_\epsilon^{(k)}\}$). Consider the iterative algorithm given in Section 2.2 that gives rise to sequences of $\{\hat{\beta}^{(k)}\}$ and $\{\hat{\Theta}_\epsilon^{(k)}\}$ alternately. For random realization of X and E , we assume the following:

C1. The incoherence condition holds for Θ_ϵ^* .

C2. Θ_ϵ^* is diagonally dominant.

C3. The maximum sparsity level for all p_2 regression s^* satisfies $s^* = o(n/\log p_1)$.

(1) For sample size satisfying $n \gtrsim \log(p_1 p_2)$, there exist constants $c_1 > 0, c_2 > 1, c_3 > 0$ such that for any

$$\lambda_n^0 \geq 4c_2 [\Lambda_{\max}(\Sigma_X^*) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}},$$

with probability at least $1 - 2 \exp(-c_3 n) - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$, the initial estimate $\hat{\beta}^{(0)} \equiv \text{vec}(\hat{B}^{(0)})$ satisfies the following bound

$$\|\hat{\beta}^{(0)} - \beta^*\|_1 \leq 64s^{**} \lambda_n^0 / \varphi^* \equiv \nu_\beta^{(0)}, \quad (21)$$

where $\varphi^* = \Lambda_{\min}(\Sigma_X^*)/2$. Moreover, by choosing $\rho_n^0 = (\frac{\xi}{2})g(\nu_\beta^{(0)})$ where the expression for $g(\cdot)$ is given in (20), with probability at least

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 2 \exp(-c_3 n) - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)], \quad \text{for some } \tau_1, \tau_2 > 2,$$

the following bound holds:

$$\|\hat{\Theta}_\epsilon^{(0)} - \Theta_\epsilon^*\|_\infty \leq \{2(1 + 8\xi^{-1})\kappa_{H^*}\}g(\nu_\beta^{(0)}) \equiv \tau_\Theta^{(0)}. \quad (22)$$

(II) For sample size satisfying $n \gtrsim d^2 \log(p_1 p_2)$, for any iteration $k \geq 1$, with probability at least

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 12c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] - 2 \exp[-c_3 n],$$

the following bounds hold for all $\hat{\beta}^{(k)}$ and $\hat{\Theta}_\epsilon^{(k)}$:

$$\begin{aligned} \|\hat{\beta}^{(k)} - \beta^*\|_1 &\leq C_\beta \left(s^{**} \sqrt{\frac{\log(p_1 p_2)}{n}} \right), \\ \|\hat{\Theta}_\epsilon^{(k)} - \Theta_\epsilon^*\|_\infty &\leq C_\Theta \left(\sqrt{\frac{\log(p_1 p_2)}{n}} \right). \end{aligned}$$

where s^{**} is the sparsity of β^* , C_β and C_Θ are constants depending only on β^* and Θ_ϵ^* , respectively.

As a direct result of Proposition 1 in Basu and Michailidis (2015) and Corollary 3 in Ravikumar et al. (2011), the following bound also holds:

Corollary 3. Under the same set of conditions C1, C2 and C3 in Theorem 4, there exists $\tau_1, \tau_2 > 2, c_1 > 0, c_2 > 1, c_3 > 0$ and constants C'_β and C'_Θ such that for all iterations k , the following bound holds:

$$\begin{aligned} \|\hat{\beta}^{(k)} - \beta^*\|_F &\leq C'_\beta \left(\sqrt{\frac{s^{**} \log(p_1 p_2)}{n}} \right), \\ \|\hat{\Theta}_\epsilon^{(k)} - \Theta_\epsilon^*\|_F &\leq C'_\Theta \sqrt{\frac{(s_\epsilon^* + p_2) \log(p_1 p_2)}{n}}, \end{aligned}$$

with probability at least

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 12c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] - 2 \exp[-c_3 n],$$

where s^{**} and s_ϵ^* are the sparsity for β^* and Θ_ϵ^* , respectively.

Remark 9. As mentioned earlier in this subsection, the actual implementation of the alternating search step is restricted to a subspace of $\mathbb{R}^{p_1 \times p_2}$. Next, we outline the corresponding theoretical results for this specific scenario in which for each regression j , some fixed superset of the indices of true covariates is given, and the regressions are restricted to these supersets, respectively. Note that we need to make sure that the restricted subspace contains all the true covariates for the results below to be valid.

Let S_j denote the given *fixed superset* for each regression j , and we consider regressing the response on X_{S_j} . We use $\widehat{\beta}_R^{(k)}$ to denote the corresponding vectorized estimator of iteration k , that is,

$$\widehat{\beta}_R^{(k)} = (\widehat{B}_{1,\text{Restricted}}^{(k)}, \dots, \widehat{B}_{p_2,\text{Restricted}}^{(k)})',$$

where $\widehat{B}_{j,\text{Restricted}}^{(k)}$ is obtained by doing the regression in (7), however with the indices of covariates restricted to S_j . Also, we let β_R^* be the corresponding true value of $\widehat{\beta}_R^{(k)}$. Note that always holds that

$$\|\widehat{\beta}_R^{(k)} - \beta_R^*\| = \|\widehat{\beta}^{(k)} - \beta^*\|.$$

Now let

$$\bar{S} = \bigcup_{j \in \{1, \dots, p_2\}} S_j,$$

and let \bar{s} be its cardinality. It can be shown that the best achievable error bound for $\widehat{\beta}_R^{(k)}$ is identical to $\widehat{\beta}_S^{(k)}$, where $\widehat{\beta}_S^{(k)}$ is obtained by considering covariates $X_{\bar{S}}$ for all p_2 regressions, instead of the entire X . For this specific reason, formally, we state the theoretical results for the case where we consider regressing on $X_{\bar{S}}$, which is almost identical to the generic case.

Suppose conditions C1, C2 and C3 in Theorem 4 hold, then there exists constants $c_1 > 0, c_2 > 1, c_3 > 0, \tau_1 > 2, \tau_2 > 2$ such that: (I) for sample size satisfying $n \gtrsim \log(\bar{s}p_2)$, w.p. at least $1 - 2 \exp(-c_3 n) - 6c_1 \exp[-(c_2^2 - 1) \log(\bar{s}p_2)]$, for any

$$\lambda_n^0 \geq 4c_2 \left[\Lambda_{\max}(\Sigma_{X_{\bar{S}}}^*) \Lambda_{\max}(\Sigma_\epsilon^*) \right]^{1/2} \sqrt{\frac{\log(\bar{s}p_2)}{n}},$$

the initial estimate $\widehat{\beta}_S^{(0)}$ satisfies the following bound:

$$\|\widehat{\beta}_S^{(0)} - \beta_S^*\|_1 \leq 64s^{**} \lambda_n^0 / \varphi_S^* \equiv \nu_{\beta_S}^{(0)},$$

where $\varphi_S^* = \Lambda_{\min}(\Sigma_{X_{\bar{S}}}^*)/2$. Moreover, by choosing $\rho_n^0 = \binom{\bar{s}}{\xi} g(\nu_{\beta_S}^{(0)})$ where the expression for $g(\cdot)$ is given in (20), with probability at least

$$1 - 1/\bar{s}^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 2 \exp(-c_3 n) - 6c_1 \exp[-(c_2^2 - 1) \log(\bar{s}p_2)],$$

the following bound holds:

$$\|\widehat{\Theta}_\epsilon^{(0)} - \Theta_\epsilon^*\|_\infty \leq \{2(1 + 8\xi^{-1})\kappa_{H^*}\} g(\nu_{\beta_S}^{(0)}) \equiv \nu_\Theta^{(0)}.$$

(II) For sample size satisfying $n \gtrsim d^2 \log(\bar{s}p_2)$, for any iteration $k \geq 1$, with probability at least

$$1 - 1/\bar{s}^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 12c_1 \exp[-(c_2^2 > 1) \log(\bar{s}p_2)] - 2 \exp[-c_3 n],$$

the following bound hold for all $\widehat{\beta}_S^{(k)}$ and $\widehat{\Theta}_\epsilon^{(k)}$:

$$\begin{aligned} \|\widehat{\beta}_S^{(k)} - \beta_S^*\|_1 &\leq C_\beta \left(s^{**} \sqrt{\frac{\log(\bar{s}p_2)}{n}} \right), \quad \|\widehat{\beta}_S^{(k)} - \beta_S^*\|_F \leq C'_\beta \left(\sqrt{\frac{s^{**} \log(\bar{s}p_2)}{n}} \right), \\ \|\widehat{\Theta}_\epsilon^{(k)} - \Theta_\epsilon^*\|_\infty &\leq C_\Theta \left(\sqrt{\frac{\log(\bar{s}p_2)}{n}} \right), \quad \|\widehat{\Theta}_\epsilon^{(k)} - \Theta_\epsilon^*\|_F \leq C'_\Theta \sqrt{\frac{(c_\epsilon^* + p_2) \log(\bar{s}p_2)}{n}}, \end{aligned}$$

where s^{**} is the sparsity of β^* , $C_\beta, C_\beta', C_\Theta, C_\Theta'$ and C'_Θ are all constants that do not depend on n, \bar{S}, p_2 .

3.3 Family-wise Error Rate Control of the Screening Step.

As mentioned in the Introduction, for the iterative algorithm to work effectively, it is crucial to initialize from points that are close to the true parameters. Our screening step provides such guarantees *asymptotically*. Based on the screening step described in Section 2.2, initial estimates for each column of the regression matrix are obtained by Lasso or Ridge regression with the support set restricted to the one identified by the screening step. It is desirable for the screening step to correctly identify the true support set. In particular, we would like to retain as many true positive predictor variables as possible without discovering too many false positive ones. The following theorem states that as long as $\log(p_1 p_2)/n = o(1)$ and the sparsity is not beyond a specified level, the screening step will be able to recover all true positive predictors, while keeping the family-wise type I error under control.

Theorem 5. *Let S_j^* denote the true support set of the j th regression and s_j^* be its cardinality. Suppose that $\log(p_1 p_2)/n \rightarrow 0$ and the following condition for sparsity holds:*

$$\max\{s_j^*, j = 1, \dots, p_2\} = o(\sqrt{n}/\log p_1).$$

Then, the screening step described in Section 2.2 will correctly recover S_j^ for all $j = 1, \dots, p_2$ with probability approaching to 1, while keeping the family-wise type I error rate under the pre-specified level α .*

Remark 10. The specified level for sparsity is necessary for the de-biased Lasso procedure in Javanmard and Montanari (2014) to produce unbiased estimates for the regression coefficients. In terms of support recovery for the screening step, with $\log(p_1 p_2)/n = o(1)$, we only require $s^* = o(p_1)$, which is much weaker and easily satisfied.

The following corollary connects the screening step with the alternating search step, under the discussed asymptotic regime :

Corollary 4. *Consider the model set-up given in Section 2.1. Let s^* denote the maximum sparsity for all $B_{j,j}^*, j = 2, \dots, p_2$, and d denote the maximum degree of Θ_ϵ^* . Also, let s^{**} denote the sparsity for β^* and s_ϵ^* denote the sparsity for Θ_ϵ^* . Assume there exist positive constants $c_s^*, c_{s^{**}}, c_d, c_{\bar{s}}, c_{p_2}$ satisfying*

$$0 < c_{s^*} + c_{\bar{s}} < 1/2; \quad 0 < c_{s^{**}} + c_{\bar{s}} < 1; \quad 0 < 2c_d + c_{\bar{s}} < 1; \quad 0 < \max\{c_{s_\epsilon^*}, c_{p_2}\} + c_{\bar{s}} < 1$$

such that

$$s^* = O(n^{c_s}); \quad s^{**} = O(n^{c_{s^{**}}}); \quad s_\epsilon^* = O(n^{c_{s_\epsilon^*}}); \quad d = O(n^{c_d}); \quad \bar{s} = O(e^{n^{c_{\bar{s}}}}); \quad p_2 = O(n^{c_{p_2}}).$$

As $n \rightarrow \infty$,

$\mathbb{P}(\{\text{The screening step correctly recovers the true support set for all } B_{j,j}, j = 1, \dots, p\}) \rightarrow 1,$

and for all iterations k :

$$\max_{k \geq 1} \left\| (\widehat{\beta}_R, \widehat{\Theta}_\epsilon^{(k)}) - (\beta_R^*, \Theta_\epsilon^*) \right\| \xrightarrow{P} 0.$$

The proof of this corollary follows along the same lines as Theorem 4, and we leave the details to the reader.

3.4 Estimation Error and Identifiability.

In this subsection, we discuss in detail the conditions needed for the parameters in our multi-layered network to be identifiable (estimable). We focus the presentation for ease of exposition on a three-layer network and then discuss the general M -layer case.

Consider a 3-layer graphical model. Let $\tilde{X} = [(X^1)^\top, (X^2)^\top]^\top$ be the $(p_1 + p_2)$ dimensional random variable, which represents the ‘‘super’’-layer on which we regress X^3 to estimate B^{13} , B^{23} and Σ^3 . As shown in Theorem 2, the estimation error for β takes the following form:

$$\|\hat{\beta} - \beta^*\|_1 \leq 64s^{**} \lambda_{n_l}/\varphi,$$

where φ is the curvature parameter for RE condition that scales with $\Lambda_{\min}(\Sigma_{\tilde{X}})$ (see Proposition 1). Therefore, the error of estimating these regression parameters is higher when $\Lambda_{\min}(\Sigma_{\tilde{X}})$ is smaller. In this section, we derive a lower bound on this quantity to demonstrate how the estimation error depends on the underlying structure of the graph.

For the undirected subgraph within a layer k , we denote its maximum node capacity by $v(\Theta^k) := \max_{1 \leq i \leq p_k} \sum_{j=1}^{p_k} |\Theta_{ij}^k|$. For the directed bipartite subgraph consisting of Layer $s \rightarrow t$ edges ($s < t$), we similarly define the maximum incoming and outgoing node capacities by $v_{in}(B^{st}) := \max_{1 \leq i \leq p_s} \sum_{j=1}^{p_t} |B_{ij}^{st}|$ and $v_{out}(B^{st}) := \max_{1 \leq i \leq p_s} \sum_{j=1}^{p_t} |B_{ij}^{st}|$. The following proposition establishes the lower bound in terms of these node capacities

Proposition 4.

$$\Lambda_{\min}(\Sigma_{\tilde{X}}) \geq v(\Theta^1)^{-1} v(\Theta^2)^{-1} [1 + (v_{in}(B^{12}) + v_{out}(B^{12})) / 2]^{-2}$$

The three components in the lower bound demonstrate how the structure of Layers 1 and 2 impact the accurate estimation of directed edges to Layer 3. Essentially, the bound suggests that accurate estimation is possible when the total effect (incoming and outgoing edges) at every node of each of the three subgraphs is not very large.

This is inherently related to the identifiability of the multi-layered graphical models and our ability to distinguish between the parents from different layers. For instance, if a node in Layer 2 has high partial correlation with nodes of Layer 1, i.e., a node in Layer 2 has parents from many nodes in Layer 1 and yields a large $v_{in}(B^{12})$; or similarly, a node in Layer 1 is the parent of many nodes in Layer 2, yielding a large $v_{out}(B^{12})$. In either case, we end up with some large lower bound for $\Lambda_{\min}(\Sigma_{\tilde{X}})$ and it can be hard to distinguish Layer 1 \rightarrow 3 edges from Layer 2 \rightarrow 3 edges.

For a general M -layer network, the argument in the proof of Proposition 4 (see Section B for details) can be generalized in a straightforward manner. In the 2-layer network setting, with the notation defined in Section 2, by setting $e^1 = X^1$, we have

$$\begin{bmatrix} e^1 \\ e^2 \end{bmatrix} = P \begin{bmatrix} X^1 \\ X^2 \end{bmatrix}, \quad \text{where } P = \begin{bmatrix} I & 0 \\ -(B^{12})^\top & I \end{bmatrix}.$$

For an M -layer network, a modified P is given in the following form:

$$P = \begin{bmatrix} I & 0 & \cdots & 0 \\ -(B^{12})^\top & I & \cdots & 0 \\ \vdots & \vdots & \vdots & 0 \\ -(B^{1,M-1})^\top & -(B^{2,M-1})^\top & \cdots & I \end{bmatrix}$$

and combines node capacities for different layers. The conclusion is qualitatively similar, i.e., the estimation error of an M -layer graphical model is small as long as the maximum node capacities of different inter-layer and intra-layer subgraphs are not too large.

4. Performance Evaluation and Implementation Issues.

In this section, we present selected simulation results for our proposed method, in two-layer and three-layer network settings. Further, we introduce some acceleration techniques that can speed up the algorithm and reduce computing time.

4.1 Simulation Results.

For the 2-layer network, as mentioned in Section 2.1, since the main target of our proposed algorithm is to provide estimates for B^* and Θ_ε^* (since Θ_X can be estimated separately), we only present evaluation results for B^* and Θ_ε^* estimates. Similarly, for the three-layer network, we only present evaluation results involving Layer 3, using the notation in Section 3.4, that is, B_{XZ}^* , B_{YZ}^* and $\Theta_{\varepsilon Z}^*$ estimates, which is sufficient to show how our proposed algorithm works in the presence of a ‘‘super’’-layer, taking advantage of the separability of the log-likelihood.

2-layered Network. To compare the proposed method with the most recent methodology that also provides estimates for the regression parameters and the precision matrix (CAPME, Cai et al. (2012)), we use the exact same model settings that have been used in that paper. Specifically, we consider the following two models:

- Model A: Each entry in B^* is nonzero with probability $5/p_1$, and off-diagonal entries for Θ_ε^* are nonzero with probability $5/p_2$.
- Model B: Each entry in B^* is nonzero with probability $30/p_1$, and off-diagonal entries for Θ_ε^* are nonzero with probability $5/p_2$.

As in Cai et al. (2012), for both models, nonzero entries of B^* and Θ_ε^* are generated from $\text{Unif}([-1, -0.5] \cup [0.5, 1])$, and diagonals of Θ_ε^* are set identical such that the condition number of Θ_ε^* is p_2 .

	(p_1, p_2, n)
Model A	$p_1 = 30, p_2 = 60, n = 100$
	$p_1 = 60, p_2 = 30, n = 100$
	$p_1 = 200, p_2 = 200, n = 150$
Model B	$p_1 = 300, p_2 = 300, n = 150$
	$p_1 = 200, p_2 = 200, n = 100$
	$p_1 = 200, p_2 = 200, n = 200$

Table 1: Model Dimensions for Model A and B

To evaluate the selection performance of the algorithm, we use sensitivity (SEN), specificity (SPE) and Matthews Correlation Coefficient (MCC) as criteria:

$$\text{SEN} = \frac{\text{TN}}{\text{TN} + \text{FP}}, \quad \text{SPE} = \frac{\text{TP}}{\text{TP} + \text{FN}}, \quad \text{MCC} = \frac{\text{TP} \times \text{TN} - \text{FP} \times \text{FN}}{\sqrt{(\text{TP} + \text{FP})(\text{TP} + \text{FN})(\text{TN} + \text{FP})(\text{TN} + \text{FN})}}.$$

Further, to evaluate the accuracy of the magnitude of the estimates, we use the relative error in Frobenius norm:

$$\text{rel-Fnorm} = \frac{\|\tilde{B} - B^*\|_F}{\|B^*\|_F} \quad \text{or} \quad \frac{\|\tilde{\Theta}_\epsilon - \Theta_\epsilon^*\|_F}{\|\Theta_\epsilon^*\|_F}.$$

Tables 2 and 3 show the results for both the regression matrix and the precision matrix. For the precision matrix estimation, we compare our result with those available in Cai et al. (2012), denoted as CAPME.

	(p_1, p_2, n)	SEN	SPE	MCC	rel-Fnorm
Model A	(30,60,100)	0.96(0.018)	0.99(0.004)	0.93(0.014)	0.22(0.029)
	(60,30,100)	0.99(0.009)	0.99(0.003)	0.93(0.017)	0.18(0.021)
	(200,200,150)	0.99(0.001)	0.99(0.001)	0.88(0.009)	0.18(.007)

Table 3: Performance evaluation for estimated precision matrix, over 50 replications

As it can be seen from Tables 2 and 3, the sample size is a key factor that affects the performance. Our proposed algorithm performs extremely well in its selection properties on B and strikes a good balance between sensitivity and specificity in estimating Θ_ϵ .³ For most settings, it provides substantial improvements over the CAPME estimator.

3-layer Network. For a 3-layer network, we consider the following data generation mechanism: for all three models A, B and C, each entry in B_{XY} is nonzero with probability

$5/p_1$, each entry in B_{XZ} and B_{YZ} is nonzero with probability $5/(p_1 + p_2)$, and off-diagonal entries in $\Theta_{\epsilon,Z}$ are nonzero with probability $5/p_3$. Similar to the 2-layered set-up, the nonzero entries in $\Theta_{\epsilon,Z}$ are generated from $\text{Unif}([-1, -0.5] \cup (0.5, 1])$ with its diagonals set identical such that its condition number is p_3 . For the regression matrices in the three models, nonzeros in B_{XY} are generated from $\text{Unif}([-1, -0.5] \cup (0.5, 1])$, and nonzeros in B_{XZ} and B_{YZ} are generated from $\{\text{Unif}([-1, -0.5] \cup (0.5, 1]) * \text{SignalStrength}\}$, where the signal strength in the three models are given by 1, 1.5 and 2, respectively. More specifically, for Model A, B and C, nonzeros in B_{XZ} or B_{YZ} are generated from $\text{Unif}([-1, -0.5] \cup (0.5, 1])$, $\text{Unif}([-1.5, -0.75] \cup (0.75, 1.5])$ and $\text{Unif}([-2, -1] \cup (1, 2])$, respectively.

	Layer 3 SignalStrength	(p_1, p_2, p_3, n)
Model A	1	(50,50,50,200)
Model B	1.5	(50,50,50,200)
Model C	2	(50,50,50,200)
		(20,80,50,200)
		(80,20,50,200)
		(100,100,100,200)

Table 4: Model Dimensions and Signal Strength for Model A, B and C

As mentioned in the beginning of this subsection, we only evaluate the algorithm's performance on B_{XZ}, B_{YZ} and $\Theta_{\epsilon,Z}$.

Based on the results shown in Tables 5, 6 and 7, the signal strength across layers affects the accuracy of the estimation, which is in accordance with what has been discussed regarding identifiability. Overall, the MLE estimator performs satisfactorily across a fairly wide range of settings and in many cases achieving very high values for the MCC criterion.

4.1.1 SIMULATION RESULTS FOR NON-GAUSSIAN DATA

In many applications, the data may not be exactly Gaussian, but approximately Gaussian. Next, we present selected simulation results when the data comes from some distribution that deviates from Gaussian. Specifically, we consider two types of deviations based on the following transformations: (i) a truncated empirical cumulative distribution function and (ii) a shrunken empirical cumulative distribution functions as discussed in Zhao et al. (2015). In both simulation settings, we consider Model A with $(p_1, p_2, n) = (30, 60, 100)$ under the two-layer setting, and the transformation is applied to errors in Layer 2. Table 8 shows the simulation results for these two scenarios over 50 replications.

Based on the results in Table 8, relatively small deviations from the Gaussian distribution do not affect the performance of the MLE estimates under the examined settings that are comparable to those obtained with Gaussian distributed data.

4.2 A comparison with the two-step estimator in Cai et al. (2012)

Next, we present a comparison between the MLE estimator and the two-step estimator of Cai et al. (2012). Specifically, we use the CAPME estimate as an initializer for the

3. In practice, for the debias Lasso procedure, we use the default choice of tuning parameters suggested in the implementation of the code provided in Javanmard and Montanari (2014); for FWER, we suggest using $\alpha = 0.1$ as the thresholding level; for tuning parameter selection, we suggest doing a grid search for (λ_n, ρ_n) on $[0, 0.5\sqrt{\log p_1/n}] \times [0, 0.5\sqrt{\log p_2/n}]$ with BIC.

Table 8: Simulation results for B and Θ_{ϵ} over 50 replications under npn transformation

MLE procedure and examine its evolution over successive iterations. We evaluate the value of the objective function at each iteration, and also compare it to the value of the objective function evaluated at our initializer (screening + Lasso/Ridge) and the estimates

afterward. For illustration purposes, we only show the results for a single realization under Model A with $p_1 = 30, p_2 = 60, n = 100$, although similar results were obtained in other simulation settings. Figure 2 shows the value of the objective function as a function of the iteration under both initialization procedures, while Table 9 shows how the cardinality of the estimates changes over iterations for both initializers. It can be seen that the iterative MLE algorithm significantly improves the value of the objective function over the CAPME initialization and also that the set of directed and undirected edges stabilizes after a couple iterations.

Figure 2: Comparison between Cai's estimate and our estimate

	0	1	2	3	4	5	6	refit
Our initializer	$\hat{B}^{(k)}$	275	275	275	275	275	275	275
	$\hat{\Theta}_{\epsilon}^{(k)}$	282	255	247	248	248	248	260
CAPME initializer	$\hat{B}^{(k)}$	433	275	275	275	275	275	275
	$\hat{\Theta}_{\epsilon}^{(k)}$	979	267	250	249	249	248	260

Table 9: Change in cardinality over iterations for B and Θ_{ϵ}

Based on Figure 2 and Table 9, we notice that Cai et. al's two-step estimator yields larger value of the objective function compared with our initializer that is obtained through screening followed by Lasso. However, over subsequent iterations, both initializers yield the same value in the objective function, which keeps decreasing according to the nature of block-coordinate descent.

4.3 Implementation issues

Next, we introduce some acceleration techniques for the MLE algorithm aiming to reduce computing time, yet maintaining estimation accuracy over iterations.

($p_2 + 1$)-block update. In Section 2, we update B and Θ_ϵ by (6) and (8), respectively, and within each iteration, the updated B is obtained by an application of cyclic p_2 -block coordinate descent with respect to each of its columns until convergence. As shown in Section 3.1, the outer 2-block update guarantees the MLE iterative algorithm to converge to a stationary point. However in practice, we can speed up the algorithm by updating B without waiting for it to reach the minimizer for every iteration other than the first one. More precisely, for the alternating search step, we take the following steps when actually implementing the proposed algorithm with initializer $\widehat{B}^{(0)}$ and $\widehat{\Theta}_\epsilon^{(0)}$:

- Iteration 1: update B and Θ_ϵ as follows, respectively:

$$\widehat{B}^{(1)} = \underset{B \in \mathcal{B}_1 \times \dots \times \mathcal{B}_{p_2}}{\operatorname{argmin}} \left\{ \frac{1}{n} \sum_{i=1}^{p_2} \sum_{j=1}^{p_2} (\sigma_\epsilon^{ij})^{(0)} (Y_i - X B_i)^\top (Y_j - X B_j) + \lambda_n \sum_{j=1}^{p_2} \|B_j\|_1 \right\},$$

and

$$\widehat{\Theta}_\epsilon^{(1)} = \underset{\Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}{\operatorname{argmin}} \left\{ \log \det \Theta_\epsilon - \operatorname{tr}(\widehat{S}^{(1)} \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1, \text{off}} \right\},$$

where $\widehat{S}^{(1)}$ is the sample covariance matrix of $\widehat{E}^{(1)} \equiv Y - X \widehat{B}^{(1)}$.

- For iteration $k \geq 2$, while not converged:

• For $j = 1, \dots, p_2$, update B_j once by

$$\widehat{B}_j^{(k)} = \underset{B_j \in \mathcal{B}_j}{\operatorname{argmin}} \left\{ \frac{(\sigma_\epsilon^{jj})^{(k-1)}}{n} \|Y_j + r_j^{(k)} - X B_j\|_2^2 + \lambda_n \|B_j\|_1 \right\},$$

where

$$r_j^{(k)} = \frac{1}{(\sigma_\epsilon^{jj})^{(k-1)}} \left[\sum_{i=1}^{j-1} (\sigma_\epsilon^{ij})^{(k-1)} (Y_i - X \widehat{B}_i^{(k)}) + \sum_{i=j+1}^{p_2} (\sigma_\epsilon^{ij})^{(k-1)} (Y_i - X \widehat{B}_i^{(k-1)}) \right]. \quad (23)$$

• Update Θ_ϵ by

$$\widehat{\Theta}_\epsilon^{(k)} = \underset{\Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}}{\operatorname{argmin}} \left\{ \log \det \Theta_\epsilon - \operatorname{tr}(\widehat{S}^{(k)} \Theta_\epsilon) + \rho_n \|\Theta_\epsilon\|_{1, \text{off}} \right\},$$

where $\widehat{S}^{(k)}$ is defined similarly.

Intuitively, for the first iteration, we wait for the algorithm to complete the whole cyclic p_2 block-coordinate descent step, as the first iteration usually achieves a big improvement in the value of the objective function compared to the initialization values, as depicted in

Figure 2. However, in subsequent iterations, the changes in the objective function become relatively small, so we do $(p_2 + 1)$ successive block-updates in every iteration, and start to update Θ_ϵ once a full p_2 block update in B is completed, instead of waiting for the update in B proceeds cyclically until convergence. In practice, this way of updating B and Θ_ϵ leads to faster convergence in terms of total computing time, yet yields the same estimates compared with the exact 2-block update shown in Section 2.

Parallelization. A number of steps of the MLE algorithm is parallelizable. In the screening step, when applying the de-biased Lasso procedure (Javanmard and Montanari, 2014) to obtain the p -values, we need to implement p_2 separate regressions, which can be distributed to different compute nodes and carried out in parallel. So does the refitting step, in which we refit each column in B in parallel.

Moreover, according to Bradley et al. (2011); Richtárik and Takáč (2012); Scherrer et al. (2012) and a series of similar studies, though the block update in the alternating search step is supposed to be carried out sequentially, we can implement the update in parallel to speed up convergence, yet empirically yield identical estimates. This parallelization can be applied to either the minimization with respect to B within the 2-block update method, or the minimization with respect to each column of B for the $(p_2 + 1)$ -block update method. Either way, $r_j^{(k)}$ in (23) is substituted by

$$r_{j, \text{parallel}}^{(k)} = \frac{1}{(\sigma_\epsilon^{jj})^{(k-1)}} \sum_{i \neq j}^{p_2} (\sigma_\epsilon^{ij})^{(k-1)} (Y_i - X \widehat{B}_i^{(k-1)}),$$

which is not updated until we have updated B_j 's once for all $j = 1, \dots, p_2$ in parallel.

Table 10 shows the elapsed time for carrying out our proposed algorithm using 2-block/ $(p_2 + 1)$ -block update with/without parallelization, under the simulation setting where we have $p_1 = p_2 = 200, n = 150$. The screening step and refitting step are both carried out in parallel for all four different implementations.⁴

elapsed time (sec)	2-block	$(p_2 + 1)$ -block	2-block in parallel	$(p_2 + 1)$ -block in parallel
	5074	2556	848	763

Table 10: Computing time with different update methods

As shown in the table, using $(p_2 + 1)$ -block update and parallelization both can speed up convergence and reduce computing time, which takes only 1/7 of the computing time compared with using 2-block update without parallelization.

Remark 11. The total computing time depends largely on the number of bootstrapped samples we choose for the stability selection step. For the above displayed results, we used 50 bootstrapped samples to obtain the weight matrix. Nevertheless, one can select the number of bootstrap samples judiciously and reduce them if performance would not be seriously impacted.

⁴ For parallelization, we distribute the computation on 8 cores.

5. Discussion.

In this paper, we examined multi-layered Gaussian networks, proposed a provably converging algorithm for obtaining the estimates of the key model parameters and established their theoretical properties in high-dimensional settings. Note that we focused on ℓ_1 penalties for both the directed and undirected edges, since it was assumed that the multi-layer network was sparse both between layers and within layers. In many scientific applications, external information may require imposing group penalties, primarily on the directed edge parameters (B). For example, in a gene-protein 2-layer network, genes can be grouped according to their function in pathways and one may be interested in assessing the pathway's impact on proteins. In that case, a group lasso penalty can be imposed. In general, the proposed framework can easily accommodate other types of penalties in accordance to the underlying data generating procedure. The exact form of the error bounds established would be different, depending on the exact choice of penalty selected. Nevertheless, as long as the penalty is convex, all arguments regarding bi-convexity and convergence follow, and we can use similar strategies to bound the statistical error of the estimators, obtained via the iterative algorithm.

Next, we discuss connections of this work to that in [Sohn and Kim \(2012\)](#); [Yuan and Zhang \(2014\)](#); [McCarter and Kim \(2014\)](#). In these papers, an alternative parameterization of the 2-layer network is adopted. Specifically, all nodes in layers 1 and 2 are considered jointly and assumed to be drawn from the following Gaussian distribution:

$$\begin{pmatrix} \mathbf{X} \\ \mathbf{Y} \end{pmatrix} \sim \mathcal{N} \left(0, \begin{pmatrix} \Omega_X & \Omega_{XY} \\ \Omega_{YX} & \Omega_Y \end{pmatrix}^{-1} \right),$$

and by conditioning \mathbf{Y} on \mathbf{X} , one obtains

$$\mathbf{Y}|\mathbf{X} \sim \mathcal{N}(-\Omega_Y^{-1}\Omega_{XY}\mathbf{X}, \Omega_Y^{-1}). \quad (24)$$

Compare [\(24\)](#) with our model set-up in [Section 2.1](#), the following correspondence holds:

$$B = -\Omega_{XY}\Omega_Y^{-1}, \quad \Omega_Y = \Theta_e. \quad (25)$$

Note that the correspondence in [\(25\)](#) is only guaranteed to hold in selective settings. Specifically: at the population level, the correspondence between (Ω_{XY}, Ω_Y) and (B, Θ_e) holds in the absence of any sparsity penalization. Further, in a low-dimensional data setting without penalty terms in the objective function, the estimates from the two parameterizations would be similar provided that the problem is well-conditioned and the sample size reasonably large.

However, the situation is different in high-dimensional settings and in the presence of sparsity penalties. Specifically, given data X and Y , instead of parameterizing the model in terms of (B, Θ_e) , the authors in [Sohn and Kim \(2012\)](#); [Yuan and Zhang \(2014\)](#); [McCarter and Kim \(2014\)](#) consider the following optimization problem, parameterized in (Ω_{XY}, Ω_Y) :

$$\min_{\Omega_{XY}, \Omega_Y} g(\Omega_{XY}, \Omega_Y) \equiv g_0(\Omega_{XY}, \Omega_Y) + \mathcal{R}(\Omega_{XY}, \Omega_Y) \quad (26)$$

where $g_0(\Omega_{XY}, \Omega_Y) = -\log \det \Omega_Y + \frac{1}{n} \text{tr} \left[(Y + \Omega_{XY}\Omega_Y^{-1}X)' \Omega_Y (Y + \Omega_{XY}\Omega_Y^{-1}X) \right]$ is jointly convex in (Ω_{XY}, Ω_Y) , and $\mathcal{R}(\Omega_{XY}, \Omega_Y)$ is some regularization term. In particular, the

element-wise ℓ_1 norm on Ω_Y , and the element-wise ℓ_1 or column-wise ℓ_1 norm (matrix 2, 1 norm) on Ω_{XY} are the main penalties under consideration in those papers.

Despite the convex formulation in [\(26\)](#), we would like to point out that in general, the sparsity pattern in B and Ω_{XY} are not transferable through the regularization term, which induces a major difference between the formulation in [\(26\)](#) and the one presented in this paper. Given the correspondence in [\(25\)](#), there are two cases where B and Ω_{XY} share the same sparsity pattern: 1) Ω_Y (or Θ_e , equivalently) is diagonal, or 2) both the i^{th} row in B and Ω_{XY} are identically zero, for an arbitrary $i = 1, \dots, p_1$. However, both settings are fairly restrictive and unlike to occur in many applications.

Note that the linear model represents a natural modeling tool for a number of problems and the regression coefficients have a specific scientific interpretation. This is easily accomplished through the (B, Θ_e) -parameterization, by adding proper regularization to B (e.g., penalty which enforces element-wise sparsity or group-Lasso type of sparsity, etc) if necessary. However, with the (Ω_{XY}, Ω_Y) -parameterization, the underlying sparsity in the true data generating procedure, encoded by B , will not be easily incorporated, and to add a regularization term on Ω_{XY} may lose the scientific interpretability, and may also lead to an estimated B whose sparsity pattern is completely mis-specified, obtained from [\(25\)](#) with $\hat{\Omega}_{XY}, \hat{\Omega}_Y$ plugged in.

Another difference we would like to point out is that once we add penalty terms to the objective function in the low dimensional setting, or switch to the high dimensional setting (as considered in [Sohn and Kim \(2012\)](#) and [Yuan and Zhang \(2014\)](#)), the correspondence between the optimizer(s) of [\(1\)](#) and the optimizer(s) of [\(26\)](#) become difficult to connect analytically.

Appendix A. Proofs for Main Theorems

Proof of Theorem 1. We initialize the algorithm at $(\widehat{B}^{(0)}, \widehat{\Theta}_\epsilon^{(0)}) \in \text{dom}(f)$. Then for all $k \geq 1$,

$$\widehat{B}^{(k)} = \underset{B}{\text{argmin}} f(B, \widehat{\Theta}_\epsilon^{(k-1)}), \quad (27)$$

$$\widehat{\Theta}_\epsilon^{(k)} = \underset{\Theta_\epsilon}{\text{argmin}} f(\widehat{B}^{(k)}, \Theta_\epsilon). \quad (28)$$

Now, consider a limit point $(B^\infty, \Theta_\epsilon^\infty)$ of the sequence $\{(\widehat{B}^{(k)}, \widehat{\Theta}_\epsilon^{(k)})\}_{k \geq 1}$. Note that such limit point exists by Bolzano-Weierstrass theorem since the sequence $\{(\widehat{B}^{(k)}, \widehat{\Theta}_\epsilon^{(k)})\}_{k \geq 1}$ is bounded. Consider a subsequence $\mathcal{K} \subseteq \{1, 2, \dots\}$ such that $(\widehat{B}^{(k)}, \widehat{\Theta}_\epsilon^{(k)})_{k \in \mathcal{K}}$ converges to $(B^\infty, \Theta_\epsilon^\infty)$. Now for the bounded sequence $\{(\widehat{B}^{(k+1)}, \widehat{\Theta}_\epsilon^{(k)})\}_{k \in \mathcal{K}}$, without loss of generality,⁵ we can say that

$$\{(\widehat{B}^{(k+1)}, \widehat{\Theta}_\epsilon^{(k)})\}_{k \in \mathcal{K}} \rightarrow (\widetilde{B}^\infty, \widetilde{\Theta}_\epsilon^\infty), \quad \text{for some } (\widetilde{B}^\infty, \widetilde{\Theta}_\epsilon^\infty) \in \text{dom}(f).$$

By (27) it follows immediately that $\widetilde{\Theta}_\epsilon^\infty = \Theta_\epsilon^\infty$. Also, the following inequality holds:

$$f(\widehat{B}^{(k+1)}, \widehat{\Theta}_\epsilon^{(k+1)}) \leq f(\widehat{B}^{(k+1)}, \widehat{\Theta}_\epsilon^{(k)}) \leq f(\widehat{B}^{(k)}, \widehat{\Theta}_\epsilon^{(k)}).$$

Thus, by letting $k \rightarrow \infty$ over \mathcal{K} , we have

$$f(B^\infty, \Theta_\epsilon^\infty) \leq f(\widetilde{B}^\infty, \Theta_\epsilon^\infty) \leq f(B^\infty, \Theta_\epsilon^\infty),$$

since f is continuous. This implies that

$$f(\widetilde{B}^\infty, \Theta_\epsilon^\infty) = f(B^\infty, \Theta_\epsilon^\infty). \quad (29)$$

Next, since $f(\widehat{B}^{(k+1)}, \widehat{\Theta}_\epsilon^{(k)}) \leq f(B, \widehat{\Theta}_\epsilon^{(k)})$, for all $B \in \mathbb{R}^{p_1 \times p_2}$, let k grow along \mathcal{K} , and we obtain the following:

$$f(\widetilde{B}^\infty, \Theta_\epsilon^\infty) \leq f(B, \Theta_\epsilon^\infty), \quad \forall B \in \mathbb{R}^{p_1 \times p_2}.$$

It then follows from (29) that

$$f(B^\infty, \Theta_\epsilon^\infty) \leq f(B, \Theta_\epsilon^\infty), \quad \forall B \in \mathbb{R}^{p_1 \times p_2}. \quad (30)$$

Finally, note that $f(\widehat{B}^{(k)}, \widehat{\Theta}_\epsilon^{(k)}) \leq f(\widehat{B}^{(k)}, \Theta_\epsilon)$, for all $\Theta \in \mathbb{S}_{++}^{p_2 \times p_2}$. As before, let k grow along \mathcal{K} and with the continuity of f , we obtain:

$$f(B^\infty, \Theta_\epsilon^\infty) \leq f(B^\infty, \Theta_\epsilon), \quad \forall \Theta_\epsilon \in \mathbb{S}_{++}^{p_2 \times p_2}. \quad (31)$$

Now, (30) and (31) together imply that $(B^\infty, \Theta_\epsilon^\infty)$ is a coordinate-wise minimum of f and by Fact 1, also a stationary point of f . \square

⁵ switching to some further subsequence of \mathcal{K} if necessary.

Proof of Theorem 2. The statement of Theorem 2 is a variation of Proposition 4.1 in Basu and Michailidis (2015), and its proof follows directly from the proof of the proposition in Basu and Michailidis (2015, Appendix B). We only outline how the statement differs. In the original statement of Proposition 4.1 in Basu and Michailidis (2015), the authors provide the error bound for $\widehat{\beta}$, obtained as per (14) whose dimension is qp^2 with q denoting the true lag of the vector-autoregressive process, under an RE condition for $\bar{\Gamma}$ and a deviation bound for $(\widehat{\gamma}, \widehat{\Gamma})$. For our problem, we impose a similar RE condition on $\widehat{\Gamma}$ and deviation bound on $(\widehat{\gamma}, \widehat{\Gamma})$, so as to yield a bound on $\widehat{\beta}$ that lies in a $p_1 p_2$ -dimensional space. \square

Proof of Theorem 3. The statement of this theorem is a variation of Theorem 1 in Ravikumar et al. (2011), so here, instead of providing a complete proof of the theorem, we only outline how the estimation problem differs in our setting, as well as the required changes in its proof.

In Ravikumar et al. (2011), the authors consider the optimization problem in (15), and show that for a random realization, with certain sample size requirement and choice of the regularization parameter, the following bound for $\widehat{\Theta}_\epsilon$ holds with probability at least $1 - 1/p_2^2$ for some $\tau > 2$:

$$\|\widehat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty \leq \{2(1 + 8\xi^{-1})\kappa_{H^*}\} \bar{\delta}_f(p_2^*, n), \quad (32)$$

where $\bar{\delta}(r, n)$ is defined as

$$\bar{\delta}(r, n) := 8(1 + 4\sigma^2) \max_i(\Sigma_{\epsilon, ii}^*) \sqrt{\frac{2 \log(4r)}{n}}. \quad (33)$$

The quantity $\bar{\delta}(p_2^*, n)$ that shows up in expression (32) is the bound for $\|S - \Sigma_\epsilon^*\|_\infty \equiv \|\widehat{\Sigma}_\epsilon - \Sigma_\epsilon^*\|_\infty$. In particular, in Lemma 8 (Ravikumar et al., 2011), they show that with probability at least $1 - 1/p_2^2$, $\tau > 2$, the following bound holds:

$$\|S - \Sigma_\epsilon^*\|_\infty \leq \bar{\delta}(p_2^*, n).$$

In our optimization problem (13), we are using \widehat{S} instead of S , hence a bound for $\|\widehat{S} - \Sigma_\epsilon^*\|_\infty$ is necessary, and the remaining argument in the proof of Theorem 1 (Ravikumar et al., 2011) will follow through.

Therefore in our theorem statement, we use $g(\nu/\beta)$ as a bound for $\|\widehat{S} - \Sigma_\epsilon^*\|_\infty$ then yield the bound for $\|\widehat{\Theta}_\epsilon - \Theta_\epsilon^*\|_\infty$, since we are using the surrogate error $\widehat{E} = Y - X\widehat{B}$ in the estimation, instead of the true error E . \square

Proof of Theorem 4. We first consider part (I) of the theorem. Note that by (5), $\widehat{\beta}^{(0)}$ can be equivalently written as

$$\widehat{\beta}^{(0)} \equiv \underset{\beta \in \mathbb{R}^{p_1 \times p_2}}{\text{argmin}} \{-2\beta\gamma^0 + \beta\Gamma^0\beta + \lambda_n^0 \|\beta\|_1\}, \quad (34)$$

where

$$\Gamma^{(0)} = \mathbf{I} \otimes \frac{X'X}{n}, \quad \gamma^{(0)} = (\mathbf{I} \otimes X') \text{vec} Y/n.$$

Consider the following events:

$$\mathbf{E1.} \left\{ \frac{X'X}{n} \sim RE(\varphi^*, \phi^*) \right\},$$

$$\mathbf{E2.} \quad \left\{ \frac{1}{n} \|X'E\|_\infty \leq c_2 [\Lambda_{\max}(\Sigma_X^*) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}} \right\}.$$

Note that $\mathbf{E1} \cap \mathbf{E2}$ implies the following events:

$$\Gamma^{(0)} \equiv \mathbf{I} \otimes \frac{X'X}{n} \sim RE(\varphi^*, \phi^*), \quad \text{where } \varphi^* = \Lambda_{\min}(\Sigma_X^*),$$

and

$$\|\gamma^{(0)} - \Gamma^{(0)}\beta^*\|_\infty = \frac{1}{n} \|X'E\|_\infty \leq c_2 [\Lambda_{\max}(\Sigma_X^*) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}. \quad (35)$$

Hence, by Proposition 4.1 of [Basu and Michaelidis \(2015\)](#), the bound [\(21\)](#) holds on $\mathbf{E1} \cap \mathbf{E2}$.

By Lemmas [1](#) and [2](#), $\mathbb{P}(\mathbf{E1})$ is at least $1 - 2 \exp(-c_3 n)$, for some $c_3 > 0$. By Lemma [3](#), $\mathbb{P}(\mathbf{E2})$ is at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$ for some $c_1 > 0$, $c_2 > 1$. Hence, with probability at least

$$\mathbb{P}(\mathbf{E1} \cap \mathbf{E2}) \geq 1 - \mathbb{P}(\mathbf{E1}^c) - \mathbb{P}(\mathbf{E2}^c),$$

the bound in [\(21\)](#) holds, which proves the first part of [\(1\)](#). In particular, we have $\|\hat{\beta}^0 - \beta^*\|_1 \leq \nu_\beta^{(0)} \sim O(\sqrt{\log(p_1 p_2)/n})$ on $\mathbf{E1} \cap \mathbf{E2}$.

To prove the second part of [\(1\)](#), note that by Theorem [3](#) the bound in [\(22\)](#) holds when $\mathbf{B1}$ - $\mathbf{B3}$ are satisfied. Now, from the argument above, $\mathbf{B1}$ holds on the event $\mathbf{E1} \cap \mathbf{E2}$. Also, from the proof of Proposition [3](#), $\mathbf{B2}$ is satisfied, i.e.,

$$\|\widehat{\Sigma}^{(0)} - \Sigma_\epsilon^*\|_\infty \leq g(\nu_\beta^{(0)}), \quad \text{where } \widehat{\Sigma}^{(0)} = \frac{1}{n} (Y - X\widehat{B}^{(0)})'(Y - X\widehat{B}^{(0)}), \quad (36)$$

on $\mathbf{E1} \cap \mathbf{E2} \cap \mathbf{E3} \cap \mathbf{E4}$, where the events $\mathbf{E3}$ and $\mathbf{E4}$ are given by:

$$\mathbf{E3.} \quad \left\{ \left\| \frac{E'E}{n} - \Sigma_\epsilon^* \right\|_\infty \leq \sqrt{\frac{\log(4+\tau) \log p_1}{c_\tau^2 n}} \right\} \text{ for some } \tau_2 > 2 \text{ and } c_\tau^* > 0 \text{ that depends on } \Sigma_\epsilon^*,$$

$$\mathbf{E4.} \quad \left\{ \left\| \frac{X'X}{n} - \Sigma_X^* \right\|_\infty \leq \sqrt{\frac{\log(4+\tau) \log p_1}{c_\tau^2 n}} \right\} \text{ for some } \tau_1 > 2 \text{ and } c_X^* > 0 \text{ that depends on } \Sigma_X^*.$$

Therefore, the probability of the bound for $\widehat{\Theta}_\epsilon^{(0)}$ in [\(22\)](#) to hold is at least

$$\mathbb{P}(\mathbf{E1} \cap \mathbf{E2} \cap \mathbf{E3} \cap \mathbf{E4}), \quad (37)$$

By Lemma [2](#), Lemma [3](#) and the proof of Proposition [3](#), the probability in [\(37\)](#) is lower bounded by:

$$1 - 2 \exp(-c_3 n) - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2}.$$

Consider the following two cases where the relative order of p_1 and p_2 differ. Case 1: $p_1 \prec p_2$, then $\nu_\Theta^{(0)} \sim O(\sqrt{\log p_2/n})$; case 2: $p_1 \gtrsim p_2$, then $\nu_\Theta^{(0)} \sim O(\log(p_1 p_2)/n)$. In either case, since we are assuming $\log(p_1 p_2)/n$ to be a small quantity and it follows that $\sqrt{\log(p_1 p_2)/n} \gtrsim \log(p_1 p_2)/n$, the following bound always holds:

$$\nu_\Theta^{(0)} \leq C\Theta \sqrt{\frac{\log(p_1 p_2)}{n}} \equiv M\Theta,$$

where $C\Theta$ is some large fixed constant that bounds the constant terms in front of $\sqrt{\log(p_1 p_2)/n}$. Now we consider part [\(II\)](#) of the theorem. Note that for each $k \geq 1$, $\widehat{\beta}^{(k)}$ and $\widehat{\Theta}_\epsilon^{(k)}$ are obtained via solving the following two optimizations:

$$\widehat{\beta}^{(k)} = \underset{\beta \in \mathbb{R}^{p_1 \times p_2}}{\operatorname{argmin}} \left\{ -2\beta' \widehat{\gamma}^{(k-1)} + \beta' \widehat{\Gamma}^{(k-1)} \beta + \lambda_n \|\beta\|_1 \right\}, \quad (38)$$

$$\widehat{\Theta}_\epsilon^{(k)} = \underset{\Theta_\epsilon \in \mathbb{S}_+^{p_2 \times p_2}}{\operatorname{argmin}} \left\{ \log \det \Theta_\epsilon - \operatorname{tr}(\widehat{\Sigma}^{(k)} \Theta_\epsilon) + p_n \|\Theta_\epsilon\|_{1,\text{off}} \right\}, \quad (39)$$

where

$$\widehat{\gamma}^{(k)} = \widehat{\Theta}^{(k)} \otimes \frac{X'Y}{n}, \quad \widehat{\Gamma}^{(k)} = \widehat{\Theta}^{(k)} \otimes \frac{X'X}{n}, \quad \widehat{\Sigma}^{(k)} = \frac{1}{n} (Y - X\widehat{B}^{(k)})'(Y - X\widehat{B}^{(k)}).$$

Consider the bound on $\widehat{\beta}^{(k)}$ for $k = 1$. The argument is similar to that of $\widehat{\beta}^{(0)}$, with appropriate modifications to account for the fact that the objective function now involves log likelihood instead of least squares. Formally, we consider the event $\mathbf{E1} \cap \mathbf{E2} \cap \mathbf{E3} \cap \mathbf{E4} \cap \mathbf{E5}$, where

$$\mathbf{E5.} \quad \left\{ \frac{1}{n} \|X'E\Theta_\epsilon^*\|_\infty \leq c_2 \left[\frac{\Lambda_{\max}(\Sigma_X^*)}{\Lambda_{\min}(\Sigma_\epsilon^*)} \right]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}} \right\}.$$

Note that $\{\|\widehat{\Theta}_\epsilon^{(0)} - \Theta_\epsilon^*\|_\infty \leq \nu_\Theta^{(0)}\}$ holds on this event. By Lemma [3](#), $\mathbb{P}(\mathbf{E5}) \geq 1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$. Combining this with the lower bound on [\(37\)](#) and the sample size requirement (note this sample size requirement can be relaxed to $n \gtrsim \log(p_1 p_2)$ if $p_1 \prec p_2$), we obtain that with probability at least

$$1 - 1/p_1^{\tau_1 - 2} - 1/p_2^{\tau_2 - 2} - 12c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)] - 2 \exp[-c_3 n],$$

the following three events hold simultaneously:

$$\mathbf{A1}^* \quad \|\widehat{\Theta}_\epsilon^{(0)} - \Theta_\epsilon^*\|_\infty \leq \nu_\Theta^{(0)} \lesssim O(\sqrt{\log(p_1 p_2)/n});$$

$$\mathbf{A2}^* \quad \widehat{\Gamma}^{(0)} \sim RE(\varphi^{(0)}, \phi^{(0)}) \text{ where}$$

$$\varphi^{(0)} \geq \frac{\Lambda_{\min}(\Sigma_X^*)}{2} (\min_i \psi^i - dM\Theta) \quad \text{and} \quad \phi^{(0)} \leq \frac{\log p_1}{n} \frac{\Lambda_{\min}(\Sigma_X^*)}{2} (\max_j \psi^j + dM\Theta);$$

$$\mathbf{A3}^* \quad \|\widehat{\gamma}^{(0)} - \widehat{\Gamma}^{(0)}\beta^*\|_\infty \leq \mathbb{Q}(\nu_\Theta^{(0)}) \sqrt{\frac{\log(p_1 p_2)}{n}} \quad \text{with the expression for } \mathbb{Q}(\cdot) \text{ given in } \text{a href="#">(16)}.$$

By Theorem [2](#), by choosing $\lambda_n \geq 4\mathbb{Q}(M\Theta) \sqrt{\frac{\log(p_1 p_2)}{n}}$, the following bound holds:

$$\|\widehat{\beta}^{(1)} - \beta^*\|_1 \leq 64s^{**} \lambda_n / \varphi^{(0)}. \quad (40)$$

The error bound for $\widehat{\Theta}_\epsilon^{(1)}$ can now be established using the same argument for $\widehat{\Theta}_\epsilon^{(0)}$, with the only difference that now we consider the event $\mathbf{E1} \cap \dots \cap \mathbf{E5}$ instead of $\mathbf{E1} \cap \dots \cap \mathbf{E4}$ and use [\(40\)](#) instead of [\(21\)](#).

Note that an upper bound for the leading term of the right hand side of (40) is at most of the order $O(\sqrt{\log(p_1 p_2)/n})$, and can be written as

$$C_\beta \left(s^{**} \sqrt{\frac{\log(p_1 p_2)}{n}} \right) \equiv M_\beta,$$

with C_β being some potentially large number that bounds the constant term. Notice that M_β is of the same order as $\nu_\beta^{(0)}$; thus, for $\widehat{\Theta}_\epsilon^{(1)}$, we can also achieve the following bound:

$$\|\widehat{\Theta}_\epsilon^{(1)} - \Theta_\epsilon^*\|_\infty \leq M_\Theta,$$

with high probability since we are assuming C_Θ to be some potentially large number.

Note that the events **E1**, ..., **E5** rely only on the parameters and not on the estimated quantities, and on their intersection we have uniform upper bounds on the errors of $\widehat{\beta}^{(k)}$ and $\widehat{\Theta}_\epsilon^k$ for $k = 0, 1$. Hence the error bounds for $k = 1$ can be used to invoke Theorems 2 and 3 inductively on realizations X and E from the set $\mathbf{E1} \cap \dots \cap \mathbf{E5}$ to provide high probability error bounds for all subsequent iterates as well. This leads to the uniform error bounds of part (II) with the desired probability. \square

Proof of Theorem 5. First, we note that with a Bonferroni correction, the family-wise type I error will be automatically controlled at level α . Hence, we will focus on the power of the screening step. Also, from Theorem 7 of Javanmard and Montanari (2014), it is easy to see that all the arguments below hold for a large set of random realizations of X , whose probability approaches 1 under the specified asymptotic regime when the eigenvalues of Σ_X are bounded away from 0 and infinity.

Let $B^* = [B_1^* \dots B_{p_2}^*]$ denote the true value of the regression coefficients and $\widehat{B}_j, j = 1, \dots, p_2$ denote the estimates given by the de-biased Lasso procedure in Javanmard and Montanari (2014). With the given level for sparsity, by Theorem 8 in Javanmard and Montanari (2014), each \widehat{B}_j satisfies the following:

$$\sqrt{n}(\widehat{B}_j - B_j^*) = Z + \Delta,$$

where $Z \sim \mathcal{N}(0, \sigma^2 M_j \widehat{\Sigma}_X M_j')$ and Δ vanishes asymptotically. Here $\widehat{\Sigma}_X$ is the sample covariance matrix of the predictors X , σ is the population noise level of the error term ϵ_j , and M_j is the matrix corresponding to the j th regression, produced by the procedure described in Javanmard and Montanari (2014)⁶. Let $\widehat{B}_{j,i}$ denote the i th coordinate of the j th regression coefficient vector \widehat{B}_j and $\widehat{\Sigma}_j$ be the covariance matrix of the estimator \widehat{B}_j , then

$$\widehat{\Sigma}_j = \frac{\sigma^2}{n} M_j \widehat{\Sigma}_X M_j',$$

and in particular, the variance of $\widehat{B}_{j,i}$ is $\widehat{\Sigma}_{j,ii} := \sigma_{\epsilon_i}^2$. Using these notations, for a prespecified level α , the test statistics for testing $H_0^i : B_{j,i}^* = 0$ vs. $H_A^i : B_{j,i}^* \neq 0$, for all $i = 1, \dots, p_2$ are

6. Details of the procedure is described in p.2871 in Javanmard and Montanari (2014), with M being an intermediate quantity obtained by solving an optimization problem.

$1, \dots, p_1; j = 1, \dots, p_2$ can be equivalently written as

$$\widehat{T}_{j,i} = \begin{cases} 1 & \text{if } |\widehat{B}_{j,i}|/\widehat{\sigma}_{ii}^j > z_{\alpha/(2p_1 p_2)}, \\ 0 & \text{otherwise.} \end{cases}$$

where z_α denotes the upper α quantiles of $\mathcal{N}(0, 1)$.

Define the ‘‘family-wise’’ power as follows:

$$\begin{aligned} \mathbb{P}(\text{all true alternatives are detected}) &= \mathbb{P}\left(\bigcap_{1 \leq j \leq p_2} \bigcap_{k \in S_j^*} \{\widehat{T}_{j,k} = 1\}\right) \\ &= 1 - \mathbb{P}\left(\bigcup_{1 \leq j \leq p_2} \bigcup_{k \in S_j^*} \{\widehat{T}_{j,k} = 0\}\right). \end{aligned}$$

Correspondingly, the family-wise type II error can be written as

$$\mathbb{P}\left(\bigcup_{1 \leq j \leq p_2} \bigcup_{k \in S_j^*} \{\widehat{T}_{j,k} = 0\}\right) \leq \sum_{j=1}^{p_2} \sum_{k \in S_j^*} \mathbb{P}(\widehat{T}_{j,k} = 0). \quad (41)$$

By Theorem 16 in Javanmard and Montanari (2014), asymptotically, $\forall k \in S_j, j = 1, \dots, p_2$,

$$\mathbb{P}(\widehat{T}_{j,k} = 0) \leq 1 - G\left(\frac{\alpha}{p_1 p_2}, \frac{\sqrt{n}\gamma}{\sigma[\widehat{\Sigma}_{k,k}^{-1}]^{1/2}}\right); \quad 0 < \gamma \leq \min |B_{j,k}^*|, \quad \forall k \in S_j, j = 1, \dots, p_2. \quad (42)$$

Here

$$G(\alpha, u) \equiv 2 - \mathbb{P}(\Phi < z_{\alpha/2} + u) - \mathbb{P}(\Phi < z_{\alpha/2} - u),$$

where we use Φ to denote the random variable following a standard Gaussian distribution and the choice of n in (42) doesn't depend on k . Hence, (42) can be rewritten as

$$\begin{aligned} \mathbb{P}(\widehat{T}_{j,k} = 0) &\leq 1 - G\left(\frac{\alpha}{p_1 p_2}, \frac{\sqrt{n}\gamma}{\sigma[\widehat{\Sigma}_{k,k}^{-1}]^{1/2}}\right) \\ &= \mathbb{P}\left(\Phi < z_{\alpha/(2p_1 p_2)} - \frac{\sqrt{n}\gamma}{\sigma[\widehat{\Sigma}_{k,k}^{-1}]^{1/2}}\right) - \mathbb{P}\left(\Phi > z_{\alpha/(2p_1 p_2)} + \frac{\sqrt{n}\gamma}{\sigma[\widehat{\Sigma}_{k,k}^{-1}]^{1/2}}\right) \\ &\leq \mathbb{P}\left(\Phi > \frac{\sqrt{n}\gamma}{\sigma[\widehat{\Sigma}_{k,k}^{-1}]^{1/2}} - z_{\alpha/(2p_1 p_2)}\right), \end{aligned} \quad (43)$$

where we use Φ to denote the random variable following a standard Gaussian distribution. Note that the following inequality holds for standard Normal percentiles:

$$2e^{-t^2} \leq \mathbb{P}(|\Phi| > t) \leq e^{-t^2/2},$$

and by taking the inverse function, the following inequality holds:

$$\sqrt{-\log \frac{y}{2}} \leq z_{y/2} \leq \sqrt{-2 \log y}.$$

Letting $y = \frac{\alpha}{p_1 p_2}$, it follows that

$$\left(-\log \frac{\alpha}{2p_1 p_2}\right)^{1/2} \leq z_{\alpha/(2p_1 p_2)} \leq \left(-2 \log \frac{\alpha}{p_1 p_2}\right)^{1/2},$$

hence

$$\mathbb{P}\left(\Phi > \frac{\sqrt{n}\gamma}{\sigma[\Sigma_{k,k}^{-1}]^{1/2}} - z_{\alpha/(2p_1 p_2)}\right) \leq \mathbb{P}\left(\Phi > \frac{\sqrt{n}\gamma}{\sigma[\Sigma_{k,k}^{-1}]^{1/2}} - \sqrt{-2 \log \frac{\alpha}{p_1 p_2}}\right).$$

Now given

$$\frac{\log(p_1 p_2)}{n} \rightarrow 0,$$

it follows that

$$\frac{\sqrt{2 \log \frac{p_1 p_2}{\alpha}}}{\sqrt{n}/\sigma[\Sigma_{k,k}^{-1}]^{1/2}} \rightarrow 0,$$

indicating that for sufficiently large n , the following lower bound holds for some constant $c_0 > 0$:

$$\left(\frac{\sqrt{n}\gamma}{\sigma[\Sigma_{k,k}^{-1}]^{1/2}} - \sqrt{-2 \log \frac{\alpha}{p_1 p_2}}\right) \geq c_0 \sqrt{n}.$$

Note that c_0 is universal for all choices of k , since this lower bound can be achieved by substituting $\Sigma_{k,k}^{-1}$ by $(1/\Lambda_{\min}(\Sigma_X))$, which is assumed to be bounded away from infinity.

Combined with the fact that $\mathbb{P}(\Phi > t) \leq e^{-t^2/2}$, the last expression in (43) can thus be bounded by

$$\mathbb{P}\left(\Phi > \frac{\sqrt{n}\gamma}{\sigma[\Sigma_{k,k}^{-1}]^{1/2}} - z_{\alpha/(2p_1 p_2)}\right) \leq \exp\left[-\frac{1}{2}\left(\frac{\sqrt{n}\gamma}{\sigma[\Sigma_{k,k}^{-1}]^{1/2}} - \sqrt{-2 \log \frac{\alpha}{p_1 p_2}}\right)^2\right] \leq e^{-c_1 n}, \quad (44)$$

for some universal constant $c_1 > 0$, and the bound in (44) holds uniformly for all $k \in S_j, \forall j$. Combine (41), (42) and (44), it follows that

$$\mathbb{P}\left(\bigcup_{1 \leq j \leq p_2} \bigcup_{k \in S_j^*} \{\hat{T}_{j,k} = 0\}\right) \leq s^* p_2 \exp(-c_1 n). \quad (45)$$

Now with $\log(p_1 p_2)/n = o(1)$ and the given sparsity level, that is, $s^* = o(\sqrt{n}/\log p_1)$, it follows that

$$s^* p_2 \exp(-c_1 n) = o(1),$$

and by (45), we have:

$$\mathbb{P}(\text{family-wise type II error}) \rightarrow 0, \quad \Leftrightarrow \quad \mathbb{P}(\text{family-wise power}) \rightarrow 1.$$

This is equivalent to establishing that, given $\log(p_1 p_2)/n \rightarrow 0$, the screening step recovers the true support sets S_j^* for all $j = 1, 2, \dots, p_2$ with high probability, while keeping the family-wise type I error rate under control. \square

Appendix B. Proofs for Propositions and Auxiliary Lemmas

In this subsection, we provide proofs for the propositions presented in Section 3, which requires several auxiliary lemmas, whose proofs are presented along the context.

To prove Proposition 1, we need the following two lemmas. Lemma 1 was originally provided as Lemma B.1 in Basu and Michailidis (2015), which states that if the sample covariance matrix of X satisfies the RE condition and Θ is diagonally dominant, then $(X'X/n) \otimes \Theta$ also satisfies the RE condition. Here we omit its proof and only state the main result. Lemma 2 verifies that with high probability, the sample covariance matrix of the design matrix X satisfies the RE condition.

Lemma 1. *If $X'X/n \sim RE(\varphi^*, \phi^*)$, and Θ is diagonally dominant, that is, $\psi^i := \sigma^{ii} - \sum_{j \neq i} \sigma^{ij} > 0$ for all $i = 1, 2, \dots, p_2$, where σ^{ij} is the ij th entry in Θ , then*

$$\Theta \otimes X'X/n \sim RE\left(\varphi^* \min_i \psi^i, \phi^* \max_i \psi^i\right).$$

Lemma 2. *With probability at least $1 - 2 \exp(-c_3 n)$, for a zero-mean sub-Gaussian random design matrix $X \in \mathbb{R}^{n \times p_1}$, its sample covariance matrix $\widehat{\Sigma}_X$ satisfies the RE condition with parameter φ^* and ϕ^* , i.e.,*

$$\widehat{\Sigma}_X \sim RE(\varphi^*, \phi^*), \quad (46)$$

where $\widehat{\Sigma}_X = X'X/n$, $\varphi^* = \Lambda_{\min}(\Sigma_X^*)/2$, $\phi^* = \varphi^* \log p_1/n$.

Proof. To prove this lemma, we first use Lemma 15 in Loh and Wainwright (2012), which states that if $X \in \mathbb{R}^{n \times p}$ is zero-mean sub-Gaussian with parameter (Σ, σ^2) , then there exists a universal constant $c > 0$ such that

$$\mathbb{P}\left(\sup_{v \in \mathbb{K}(2s)} \left| \frac{\|Xv\|_2^2}{n} - \mathbb{E}\left[\frac{\|Xv\|_2^2}{n}\right] \right| \geq t\right) \leq 2 \exp\left(-cn \min\left(\frac{t^2}{\sigma^4}, \frac{t}{\sigma^2}\right) + 2s \log p\right), \quad (47)$$

where $\mathbb{K}(2s)$ is a set of $2s$ sparse vectors, defined as

$$\mathbb{K}(2s) := \{v \in \mathbb{R}^p : \|v\| \leq 1, \|v\|_0 \leq 2s\}.$$

By taking $t = \frac{\Lambda_{\min}(\Sigma_X^*)}{54}$, with probability at least $1 - 2 \exp(-c'n + 2s \log p_1)$ for some $c' > 0$, the following bound holds:

$$|v'(\widehat{\Sigma}_X - \Sigma_X^*)v| \leq \frac{\Lambda_{\min}(\Sigma_X^*)}{54}, \quad \forall v \in \mathbb{K}(2s). \quad (48)$$

Then applying supplementary Lemma 13 in [Loh and Wainwright \(2012\)](#), for an estimator $\hat{\Sigma}_X$ of Σ_X^* satisfying the deviation condition in (48), the following RE condition holds:

$$v^* S_{v^*} v \geq \frac{\Lambda_{\min}(\hat{\Sigma}_X^*)}{2} \|v\|_2^2 - \frac{\Lambda_{\min}(\Sigma_X^*)}{2s} \|v\|_1^2.$$

Finally, set $s = c' n_i / 4 \log p_1$, then with probability at least $1 - 2 \exp(-c_3 n)$ ($c_3 > 0$), $\hat{\Sigma}_X \sim RE(\varphi^*, \phi^*)$ with $\varphi^* = \Lambda_{\min}(\Sigma_X^*)/2$, $\phi^* = \varphi^* \log p_1/n$. \square

With the above two lemmas, we are ready to prove [Proposition 1](#).

Proof of [Proposition 1](#). We first show that if Θ_ϵ^* is diagonally dominant, then $\hat{\Theta}_\epsilon$ is also diagonally dominant provided that the error of $\hat{\Theta}_\epsilon$ is of the given order and n is sufficiently large. Define

$$\tilde{\psi}^i = \hat{\sigma}_\epsilon^{ii} - \sum_{j \neq i} \hat{\sigma}_\epsilon^{ij},$$

where $\hat{\sigma}_\epsilon^{ij}$ is the ij th entry of $\hat{\Theta}_\epsilon$, then $\tilde{\psi}^i$ is the gap between the diagonal entry and the off-diagonal entries of row i in matrix $\hat{\Theta}_\epsilon$. We can decompose $\tilde{\psi}^i$ into the following:

$$\tilde{\psi}^i = \left[\sigma_\epsilon^{ii} - \sum_{j \neq i} \sigma_\epsilon^{ij} \right] + \left[(\hat{\sigma}_\epsilon^{ii} - \sigma_\epsilon^{ii}) + \sum_{j \neq i} (\sigma_\epsilon^{ij} - \hat{\sigma}_\epsilon^{ij}) \right]. \quad (49)$$

Recall that we define ψ_i as $\psi^i = \sigma_\epsilon^{ii} - \sum_{j \neq i} \sigma_\epsilon^{ij}$. Hence

$$\begin{aligned} \min_i \tilde{\psi}^i &\geq \min_i \psi^i - \left\| \hat{\Theta}_\epsilon - \Theta_\epsilon^* \right\|_\infty \geq \min_i (\sigma_\epsilon^{ii} - \sum_{j \neq i} \sigma_\epsilon^{ij}) - d\nu_\Theta = \min_i \psi^i - d\nu_\Theta, \\ \max_i \tilde{\psi}^i &\leq \max_i \psi^i + \left\| \hat{\Theta}_\epsilon - \Theta_\epsilon^* \right\|_\infty \leq \max_i (\sigma_\epsilon^{ii} - \sum_{j \neq i} \sigma_\epsilon^{ij}) + d\nu_\Theta = \max_i \psi^i + d\nu_\Theta. \end{aligned}$$

Now given $\nu_\Theta = \eta \epsilon \frac{\log p_2}{n} = O(\sqrt{\log p_2/n})$, with $n \gtrsim d^2 \log p_2$, $d\nu_\Theta = o(1)$, and it follows that

$$\min_i \tilde{\psi}^i - d\nu_\Theta \geq 0.$$

Now by [Lemma 2](#), $X'X/n \sim RE(\varphi^*, \phi^*)$ with high probability. Combine with [Lemma 1](#) and inequality (49), with probability at least $1 - 2 \exp(-c_3 n)$ for some $c_3 > 0$, $\hat{\Gamma}$ satisfies the following RE condition:

$$\hat{\Gamma} = \hat{\Theta}_\epsilon \otimes (X'X/n) \sim RE \left(\varphi^* (\min_i \psi^i - d\nu_\Theta), \phi^* \max_i (\psi^i + d\nu_\Theta) \right), \quad (50)$$

where $\varphi^* = \Lambda_{\min}(\Sigma_X^*)/2$, $\phi^* = \varphi^* \log p_1/n$. \square

To prove [Proposition 2](#), we first prove [Lemma 3](#).

Lemma 3. Let $X \in \mathbb{R}^{n \times p}$ be a zero-mean sub-Gaussian matrix with parameter (Σ_X, σ_X^2) and $E \in \mathbb{R}^{n \times p_2}$ be a zero-mean sub-Gaussian matrix with parameters $(\Sigma_\epsilon, \sigma_\epsilon^2)$. Moreover, X and E are independent. Let $\Theta_\epsilon := \Sigma_\epsilon^{-1}$, then if $n \gtrsim \log(p_1 p_2)$, the following two expressions hold with probability at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$ for some $c_1 > 0$, $c_2 > 1$, respectively:

$$\frac{1}{n} \|X'E\|_\infty \leq c_2 [\Lambda_{\max}(\Sigma_X) \Lambda_{\max}(\Sigma_\epsilon)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}, \quad (51)$$

and

$$\frac{1}{n} \|X'E\Theta_\epsilon\|_\infty \leq c_2 \left[\frac{\Lambda_{\max}(\Sigma_X)}{\Lambda_{\min}(\Sigma_\epsilon)} \right]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}. \quad (52)$$

Proof. The proof of this lemma uses [Lemma 14](#) in [Loh and Wainwright \(2012\)](#), in which they show that if $X \in \mathbb{R}^{n \times p_1}$ is a zero-mean sub-Gaussian matrix with parameters (Σ_X, σ_X^2) and $Y \in \mathbb{R}^{n \times p_2}$ is a zero-mean sub-Gaussian matrix with parameters (Σ_Y, σ_Y^2) , then if $n \gtrsim \log(p_1 p_2)$,

$$\mathbb{P} \left(\left\| \frac{Y'X}{n} - \text{cov}(y_i, x_i) \right\|_\infty \geq t \right) \leq 6p_1 p_2 \exp \left(-cn \min \left\{ \frac{t^2}{(\sigma_X \sigma_Y)^2}, \frac{t}{\sigma_X \sigma_Y} \right\} \right),$$

where X_i and Y_i are the i th row of X and Y , respectively.

Here, we replace Y by E , and since E and X are independent, $\text{cov}(X_i, E_i) = 0$. Let $t = c_2 \sigma_X \sigma_\epsilon \sqrt{\log(p_1 p_2)/n}$, $c_2 > 1$ we get

$$\mathbb{P} \left(\left\| \frac{X'E}{n} \right\|_\infty \geq c_2 \sigma_X \sigma_\epsilon \sqrt{\frac{\log(p_1 p_2)}{n}} \right) \leq 6c_1 (p_1 p_2)^{1-c_2^2} = 6c_1 \exp[-(c_2^2 - 2) \log(p_1 p_2)].$$

Note that the sub-Gaussian parameter satisfies $\sigma_X^2 \leq \max_i (\Sigma_{X,ii}) \leq \Lambda_{\max}(\Sigma_X)$. This directly gives the bound in (51).

To obtain the bound in (52), we note that if E is sub-Gaussian with parameters $(\Sigma_\epsilon, \sigma_\epsilon^2)$, then $E\Theta$ is sub-Gaussian with parameter $(\Theta, \theta_\epsilon^2)$, where

$$\theta_\epsilon^2 \leq \max_i (\Theta_{\epsilon,ii}) \leq \Lambda_{\max}(\Theta_\epsilon) = \frac{1}{\Lambda_{\min}(\Sigma_\epsilon)}.$$

Then we replace Y by $E\Theta$ and yield the bound in (52). \square

As a remark, here we note that the event in (51) and (52) may not be independent. However, the two events hold simultaneously with probability at least $1 - 2c_2 \exp[-c_2 \log(p_1 p_2)]$, with this crude bound for probability hold for sure.

Now we are ready to prove [Proposition 2](#).

Proof of [Proposition 2](#). First we note that

$$X'E\hat{\Theta}_\epsilon = X'E\Theta_\epsilon + X'E(\hat{\Theta}_\epsilon - \Theta_\epsilon^*),$$

which directly gives the following inequality:

$$\|\hat{\gamma} - \hat{\Gamma}\beta^*\|_\infty = \frac{1}{n} \|X'E\hat{\Theta}_\epsilon\|_\infty \leq \frac{1}{n} \|X'E\Theta_\epsilon\|_\infty + \frac{1}{n} \|X'E(\hat{\Theta}_\epsilon - \Theta_\epsilon^*)\|_\infty. \quad (53)$$

Now we would like to bound the two terms separately. The first term can be bounded by (52) in Lemma 3, that is,

$$\frac{1}{n} \|X'E\Theta_\epsilon^*\|_\infty \leq c_2 \left[\frac{\Lambda_{\max}(\Sigma_X)}{\Lambda_{\min}(\Sigma_\epsilon^*)} \right]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}.$$

w.p. at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$. For the second term, first we note that

$$\begin{aligned} \frac{1}{n} \|X'E(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*)\|_\infty &= \frac{1}{n} \max_{1 \leq i \leq p_1} \left| e_i' X'E(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*) e_j \right| \\ &\leq \frac{1}{n} \max_i \|e_i' X'E\|_\infty \max_j \|(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*) e_j\|_1, \end{aligned} \quad (54)$$

where we have $e_i \in \mathbb{R}^{p_1}$ and $e_j \in \mathbb{R}^{p_2}$, and the inequality comes from the fact that $|a'b| \leq \|a\|_\infty \|b\|_1$. Note that

$$\max_i \|e_i' X'E\|_\infty = \|X'E\|_\infty,$$

since $\|e_i' X'E\|_\infty$ gives the largest element (in absolute value) of the i th row of $X'E$, and taking the maximum over all i 's gives the largest element of $X'E$ over all entries. And for $\max_j \|(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*) e_j\|_1$, it holds that

$$\max_j \|(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*) e_j\|_1 = \| \widehat{\Theta}_\epsilon - \Theta_\epsilon^* \|_1 = \| \widehat{\Theta}_\epsilon - \Theta_\epsilon^* \|_\infty,$$

where $\|A\|_1 := \max_{|a_i|=1} \|Ax\|_1$ is the ℓ_1 -operator norm, and the last equality follows from the fact that $\|A\|_1 = \|A'\|_\infty$. As a result, (54) can be re-written as:

$$\frac{1}{n} \|X'E(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*)\|_\infty \leq \left(\frac{1}{n} \|X'E\|_\infty \right) \left(\| \widehat{\Theta}_\epsilon - \Theta_\epsilon^* \|_\infty \right). \quad (55)$$

Now, using (51), w.p. at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$, we have

$$\frac{1}{n} \|X'E\|_\infty \leq c_2 [\Lambda_{\max}(\Sigma_X) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}},$$

and since $\| \widehat{\Theta}_\epsilon - \Theta_\epsilon^* \|_\infty \leq \nu_\Theta$, it directly follows that $\| \widehat{\Theta}_\epsilon - \Theta_\epsilon^* \|_\infty \leq d\nu_\Theta$. Therefore, with probability at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$,

$$\frac{1}{n} \|X'E(\widehat{\Theta}_\epsilon - \Theta_\epsilon^*)\|_\infty \leq c_2 d\nu_\Theta [\Lambda_{\max}(\Sigma_X) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}. \quad (56)$$

Combine the two terms, we obtain the conclusion in Proposition 2. \square

Proof of Proposition 3. First we note the following decomposition:

$$\| \widehat{S} - \Sigma_\epsilon^* \|_\infty \leq \|S - \Sigma_\epsilon\|_\infty + \| \widehat{S} - S \|_\infty := \|W_1\|_\infty + \|W_2\|_\infty,$$

where S is the sample covariance matrix of the true errors E .

For W_1 , by Lemma 8 in Ravikumar et al. (2011), for sample size

$$n \geq 512(1 + 4\sigma_\epsilon^2)^4 \max_i (\Sigma_{\epsilon,ii}^*)^4 \log(4p_2^2),$$

the following bound holds w.p. at least $1 - 1/n_2^{\tau_2 - 2}$ ($\tau_2 > 2$),

$$\|W_1\|_\infty \leq \sqrt{\frac{\log 4 + \tau_2 \log p_2}{c_\epsilon^* n}}, \quad \text{where } c_\epsilon^* = \left[128(1 + 4\sigma_\epsilon^2)^2 \max_i (\Sigma_{\epsilon,ii}^*)^2 \right]^{-1}. \quad (57)$$

For W_2 , rewrite it as:

$$W_2 = \frac{2}{n} E' X(B^* - \widehat{B}) + (B^* - \widehat{B})' \left(\frac{X'X}{n} \right) (B^* - \widehat{B}). \quad (58)$$

The first term in (58) can be bounded as:

$$\left\| \frac{2}{n} E' X(B^* - \widehat{B}) \right\|_\infty \leq 2 \left\| B^* - \widehat{B} \right\|_1 \left\| \frac{1}{n} X'E \right\|_\infty \leq 2 \|\beta^* - \widehat{\beta}\|_1 \cdot \left\| \frac{1}{n} X'E \right\|_\infty. \quad (59)$$

By Lemma 3, with probability at least $1 - 6c_1 \exp[-(c_2^2 - 1) \log(p_1 p_2)]$, the following bound holds:

$$\left\| \frac{2}{n} E' X(B^* - \widehat{B}) \right\|_\infty \leq 2c_2 \nu_\beta [\Lambda_{\max}(\Sigma_X) \Lambda_{\max}(\Sigma_\epsilon^*)]^{1/2} \sqrt{\frac{\log(p_1 p_2)}{n}}, \quad (60)$$

with the sample size requirement being $n \gtrsim \log(p_1 p_2)$.

For the second term in (58), we consider the following bound:

$$\begin{aligned} \left\| (B^* - \widehat{B})' \left(\frac{X'X}{n} \right) (B^* - \widehat{B}) \right\|_\infty &\leq \left\| B^* - \widehat{B} \right\|_1 \left\| \left(\frac{X'X}{n} \right) (B^* - \widehat{B}) \right\|_\infty \\ &\leq \left\| B^* - \widehat{B} \right\|_1^2 \left\| \left(\frac{X'X}{n} \right) \right\|_\infty. \end{aligned} \quad (61)$$

Here, we apply Lemma 8 in Ravikumar et al. (2011) to the design matrix X , for sample size

$$n \geq 512(1 + 4\sigma_x^2)^4 \max_{i,j} (\Sigma_{X,ij})^4 \log(4p_1^2),$$

the following bound holds w.p. at least $1 - 1/p_1^{\tau_1 - 2}$ ($\tau_1 > 2$),

$$\left\| \left(\frac{X'X}{n} \right) - \Sigma_X \right\|_\infty \leq \sqrt{\frac{\log 4 + \tau_1 \log p_1}{c_X^* n}}, \quad \text{where } c_X^* = \left[128(1 + 4\sigma_x^2)^2 \max_{i,j} (\Sigma_{X,ij})^2 \right]^{-1}. \quad (62)$$

This indicates that with this choice of n , the following bound holds with probability at least $1 - 1/p_1^{\tau_1 - 2}$ ($\tau_1 > 2$),

$$\left\| \left(\frac{X'X}{n} \right) \right\|_{\infty} \leq \sqrt{\frac{\log 4 + \tau_1 \log p_1}{c_X^* n}} + \max_i (\Sigma_{X,ii}).$$

Combine with the bound in (61), with probability at least $1 - 1/p_1^{\tau_1 - 2}$ ($\tau_1 > 2$), the following bound holds:

$$\|(B^* - \widehat{B})' \left(\frac{X'X}{n} \right) (B^* - \widehat{B})\|_{\infty} \leq \nu_{\beta}^2 \left(\sqrt{\frac{\log 4 + \tau_1 \log p_1}{c_X^* n}} + \max_i (\Sigma_{X,ii}) \right). \quad (63)$$

Now combine (59), (60) and (63), we reach the conclusion of Proposition 3, with the leading term in the sample size requirement being $n \gtrsim \log(p_1 p_2)$. \square

Proof for Proposition 4. From the structural equations of a multi-layered graph introduced in Section 2.1, and setting $\epsilon^1 := X^1$, we can write

$$\begin{bmatrix} \epsilon^1 \\ \epsilon^2 \end{bmatrix} = \begin{bmatrix} I & 0 \\ -(B^{12})' & I \end{bmatrix} \begin{bmatrix} X^1 \\ X^2 \end{bmatrix}. \quad (64)$$

Define $P = [I, 0; -(B^{12})', I]$. Then, $P\tilde{X}$ is a centered Gaussian random vector with a block diagonal variance-covariance matrix $\text{diag}(\Sigma^1, \Sigma^2)$. Hence, the concentration matrix of \tilde{X} takes the form

$$\Theta_{\tilde{X}} = \Sigma_{\tilde{X}}^{-1} = \begin{bmatrix} I & -B^{12} \\ 0 & I \end{bmatrix} \begin{bmatrix} \Theta^1 & 0 \\ 0 & \Theta^2 \end{bmatrix} \begin{bmatrix} I & 0 \\ -(B^{12})' & 0 \end{bmatrix}.$$

This leads to an upper bound

$$\|\Theta_{\tilde{X}}\| \leq \|\Theta^1\| \|\Theta^2\| \|P\|^2.$$

The result then follows by using the matrix norm inequality $\|A\| \leq \sqrt{\|A\|_1 \|A\|_{\infty}}$ (Golub and Van Loan, 2012), where $\|A\|_1$ and $\|A\|_{\infty}$ denote the maximum absolute row and column sums of A , and the fact that $\Lambda_{\min}(\Sigma_{\tilde{X}}) = \|\Theta_{\tilde{X}}\|^{-1}$. \square

Appendix C. Numerical comparisons between different parametrizations.

In this subsection, we provide some numerical evidence to substantiate the point we made in Section 5, that the two parametrizations are not always equivalent. This is a point also mentioned in the original work on AMP graphs by Andersson et al. (2001), the framework adopted in this paper. The other parametrization which we referred to as the (Ω_{XY}, Ω_Y) -parametrization corresponds to the LWF framework (see Andersson et al., 2001, p.34-35). In the presence of sparsity penalization, a specific sparsity pattern for the (B, Θ_{ϵ}) -parametrization may not be recoverable through the (Ω_{XY}, Ω_Y) -parametrization and vice versa.

Consider the following two simulation settings, in which the data are generated from the AMP framework (B, Θ_{ϵ}) -parametrization and the LWF framework (Ω_{XY}, Ω_Y) -parametrization respectively.

- AMP framework. The data are generated according to the model $Y = XB^* + E$, similar to Model A described in Section 4; that is, each entry in B^* is nonzero with probability $5/p_1$, and off-diagonal entries for Θ_{ϵ}^* are nonzero with probability $5/p_2$. Nonzero entries of B^* and Θ_{ϵ}^* are generated from $\text{Unif}[-1, -0.5) \cup (0.5, 1]$, and diagonals of Θ_{ϵ}^* are set identical, such that the condition number of Θ_{ϵ}^* is p_2 . Table 11 shows the performance of estimated B using different methods that are designed for different parametrizations: the node-conditional method (mixed MRF) and the proposed method in this study (PML).

Table 11: Performance for \widehat{B} using different methods for different parametrizations

(p_1, p_2, n)	Method	SEN	SPC	MCC
(30, 60, 100)	mixed MRF (th)	0.86	0.71	0.45
	PML	0.96	0.99	0.93
(60, 30, 100)	mixed MRF (th)	0.96	0.76	0.70
	PML	0.99	0.99	0.93
(200, 200, 150)	mixed MRF (th)	0.80	0.99	0.70
	PML	0.99	0.99	0.88

- LWF framework. The data are generated based on the multivariate Gaussian specification:

$$\begin{pmatrix} X \\ Y \end{pmatrix} \sim \mathcal{N} \left(0, \begin{pmatrix} \Omega_X & \Omega_{XY} \\ \Omega_{YX} & \Omega_Y \end{pmatrix} \right),$$

Specifically, Ω_X is banded with 1 on the diagonal and 0.2 on the upper and lower first diagonal, Ω_Y is also banded with 1 on the diagonal and 0.3 on the upper and lower first diagonal. Each entry in Ω_{XY} is nonzero with probability $5/p_1$, and the nonzero entries are generated from $\text{Unif}[-1, -0.8) \cup (0.8, 1]$. Further, we bump up the diagonal of the joint precision matrix $\begin{bmatrix} \Omega_X & \Omega_{XY} \\ \Omega_{YX} & \Omega_Y \end{bmatrix}$ such that it is positive definite. Table 12 depicts the selection property of the estimated Ω_{XY} using different methods that are designed for different parametrizations.

Table 12: Performance for $\widehat{\Omega}_{XY}$ using different methods for different parametrizations

(p_1, p_2, n)	Method	SEN	SPC	MCC
(30, 60, 100)	mixed MRF	0.84	0.88	0.63
	PML-th	0.99	0.52	0.39
(60, 30, 100)	mixed MRF	0.847	0.95	0.70
	PML-th	1	0.80	0.52
(200, 200, 150)	mixed MRF	0.89	0.93	0.70
	PML-th	1	0.79	0.30

Note that to retrieve stable and meaningful results, for the AMP framework, the estimates using mixed MRF are thresholded at a proper level, and for the LWF framework, the estimates using PML are also thresholded.

It can be seen that the method compatible with the data generation mechanism exhibits superior performance, vis-a-vis its competitor that was designed for another parameterization. Further, the mixed MRF method suffers in terms of both sensitivity and specificity under the AMP parameterization, while the PML method suffers in terms of specificity only under the LWF parameterization.

Appendix D. An example for multi-layered network estimation.

As mentioned at the beginning of Section 2, the proposed methodology is designed for obtaining MLEs for multi-layer Gaussian networks, but the problem breaks down into a sequence of 2-layered estimation problems. Here we give an detailed example to illustrate how our proposed methodology proceeds for a 3-layered network.

Suppose there are p_1, p_2 and p_3 nodes in Layers 1, 2 and 3, respectively. This three-layered network is modeled as follows:

$$\begin{aligned} & - \mathbf{X} \sim \mathcal{N}(0, \Sigma_X), \mathbf{X} \in \mathbb{R}^{p_1}, \\ & - \text{For } j = 1, \dots, p_2: Y_j = \mathbf{X}' B_j^{x^{2y}} + \epsilon_j^y, B_j^{x^{2y}} \in \mathbb{R}^{p_1}, (\epsilon_1^y \dots \epsilon_{p_2}^y)' \sim \mathcal{N}(0, \Sigma_{\epsilon^y}), \\ & - \text{For } l = 1, 2, \dots, p_3: Z_l = \mathbf{X}' B_l^{x^{yz}} + \mathbf{Y}' B_l^{y^z} + \epsilon_l^z, B_l^{x^{yz}} \in \mathbb{R}^{p_1} \text{ and } B_l^{y^z} \in \mathbb{R}^{p_2}, \\ & \quad (\epsilon_1^z \dots \epsilon_{p_3}^z)' \sim \mathcal{N}(0, \Sigma_{\epsilon^z}). \end{aligned}$$

The parameters of interest are: $\Theta_{XY}, \Theta_{\epsilon^y}, \Theta_{\epsilon^z} := \Sigma_{\epsilon^y}^{-1}, \Theta_{\epsilon^z} := \Sigma_{\epsilon^z}^{-1}$, which denote the within-layer conditional dependencies, and

$$B_{XY} = [B_{1^{xy}}^{xy} \dots B_{p_2^{xy}}^{xy}], B_{XZ} = [B_{1^{xz}}^{xz} \dots B_{p_3^{xz}}^{xz}] \text{ and } B_{YZ} = [B_{1^{yz}}^{yz} \dots B_{p_3^{yz}}^{yz}],$$

which encode the across-layer dependencies.

Now given data $X \in \mathbb{R}^{n \times p_1}$, $Y \in \mathbb{R}^{n \times p_2}$ and $Z \in \mathbb{R}^{n \times p_3}$, all centered, the full log-likelihood can be written as:

$$\ell(Z, Y, X) = \ell(Z|Y, X; \Theta_{\epsilon^z}, B_{YZ}, B_{XZ}) + \ell(Y|X; \Theta_{\epsilon^y}, B_{XY}) + \ell(X; \Theta_X). \quad (65)$$

The separability of the log-likelihood enables us to ignore the inner structure of the combined layer $\tilde{X} := (X, Y)$ when trying to estimate the dependencies between Layer 1 and Layer 3, Layer 2 and Layer 3, as well as the conditional dependencies within Layer 3. As a consequence, the optimization problem minimizing the negative log-likelihood can be decomposed into three separate problems, i.e., solving for $\{\Theta_{\epsilon^z}, B_{XZ}, B_{YZ}\}$, $\{\Theta_{\epsilon^y}, B_{XY}\}$ and $\{\Theta_X\}$, respectively.

The estimation procedure described in Section 2.2 can thus be carried out in a recursive way in a sense of what follows. To obtain estimates for $\{B_{XZ}, B_{YZ}, \Theta_{\epsilon^z}\}$, based on the formulation in (2), we solve the following optimization problem:

$$\min_{\substack{\Theta_{\epsilon^z, Z} \in \mathbb{S}_{p_3}^{p_1 \times p_3} \\ B_{XZ}, B_{YZ}}} \left\{ \begin{aligned} & -\log \det \Theta_{\epsilon^z, Z} + \frac{1}{n} \sum_{j=1}^{p_3} \sigma_{Z_j}^2 (Z_j - X B_j^{xz} - Y B_j^{yz})^\top (Z_j - X B_j^{xz} - Y B_j^{yz}) \\ & + \lambda_n (\|B_{XZ}\|_1 + \|B_{YZ}\|_1) + \rho_n \|\Theta_{\epsilon^z, Z}\|_{1, \text{off}} \end{aligned} \right\},$$

which can be solved by treating the combined design matrix $\tilde{X} = (X, Y)$ as a single super layer and Z as the response layer, then apply each step described in Section 2.2. To obtain estimates for B_{XY} and Θ_{ϵ^y} , we can ignore the 3rd layer for now and apply the exact procedure all over again, by treating Y as the response layer and X as the design layer. The estimate for the precision matrix of the bottom layer Θ_X can be obtained by graphical lasso (Friedman et al., 2008) or the nodewise regression (Meinshausen and Bühlmann, 2006).

Abstract

Local network community detection is the task of finding a single community of nodes concentrated around few given seed nodes in a localized way. Conductance is a popular objective function used in many algorithms for local community detection. This paper studies a continuous relaxation of conductance. We show that continuous optimization of this objective still leads to discrete communities. We investigate the relation of conductance with weighted kernel k-means for a single community, which leads to the introduction of a new objective function, σ -conductance. Conductance is obtained by setting σ to 0. Two algorithms, EMC and PGDC, are proposed to locally optimize σ -conductance and automatically tune the parameter σ . They are based on expectation maximization and projected gradient descent, respectively. We prove locality and give performance guarantees for EMC and PGDC for a class of dense and well separated communities centered around the seeds. Experiments are conducted on networks with ground-truth communities, comparing to state-of-the-art graph diffusion algorithms for conductance optimization. On large graphs, results indicate that EMC and PGDC stay localized and produce communities most similar to the ground, while graph diffusion algorithms generate large communities of lower quality.¹

Keywords: community detection, conductance, k-means

1. Introduction

Imagine that you are trying to find a community of nodes in a network around a given set of nodes. A simple way to approach this problem is to consider this set as seed nodes, and then keep adding nodes in a local neighborhood of the seeds as long as this makes the community better in some sense. In contrast to global clustering, where the overall community structure of a network has to be found, local community detection aims to find only one community around the given seeds by relying on local computations involving only nodes relatively close to the seed. Local community detection by seed expansion is

especially beneficial in large networks, and is commonly used in real-life large scale network analysis (Gargi et al., 2011; Leskovec et al., 2010; Wu et al., 2012).

Several algorithms for local community detection operate by seed expansion. These methods have different expansion strategies, but what they have in common is their use of conductance as the objective to be optimized. Intuitively, conductance measures how strongly a set of nodes is connected to the rest of the graph; sets of nodes that are isolated from the graph have low conductance and make good communities.

The problem of finding a set of minimum conductance in a graph is computationally intractable (Chawla et al., 2005; Šima and Schaeffer, 2006). As a consequence, many heuristic and approximation algorithms for local community detection have been introduced (see references in the related work section). In particular, effective algorithms for this task are based on the local graph diffusion method. A graph diffusion vector \mathbf{f} is an infinite series $\mathbf{f} = \sum_{i=0}^{\infty} \alpha_i \mathbf{P}^i \mathbf{s}$, with diffusion coefficients $\sum_{i=0}^{\infty} \alpha_i = 1$, seed nodes \mathbf{s} , and random walk transition matrix \mathbf{P} . Types of graph diffusion, such as personalized Page Rank (Andersen and Lang, 2006) and Heat Kernel (Chung, 2007), are determined by the choice of the diffusion coefficients. In the diffusion method an approximation of \mathbf{f} is computed. After dividing each vector component by the degree of the corresponding node, the nodes are sorted in descending order by their values in this vector. Next, the conductance of each prefix of the sorted list is computed and either the set of smallest conductance is selected, e.g. in (Andersen and Lang, 2006) or a local optima of conductance along the prefix length dimension (Yang and Leskovec, 2012) is considered.

These algorithms optimize conductance along a single dimension, representing the order in which nodes are added by the algorithm. However this ordering is mainly related to the seed, and not directly to the objective that is being optimized. Algorithms for the direct optimization of conductance mainly operate in the discrete search space of communities, and locally optimize conductance by adding and/or removing one node. This amounts to fixing a specific neighborhood structure over communities where the neighbors of a community are only those communities which differ by the membership of a single node. This is just one possible choice of community neighbor. A natural way to avoid the problem of choosing a specific neighborhood structure is to use continuous rather than discrete optimization. To do this, we need a continuous relaxation of conductance, extending the notion of communities to allow for fractional membership. This paper investigates such a continuous relaxation, which leads to the following findings.

1.0.1 ON LOCAL OPTIMA

Although local optima of a continuous relaxation of conductance might at first glance have nodes with fractional memberships, somewhat surprisingly all strict local optima are discrete. This means that continuous optimization can directly be used to find communities without fractional memberships.

1.0.2 RELATION WITH WEIGHTED KERNEL K-MEANS

We unravel the relation between conductance and weighted kernel k-means objectives using the framework by Dhillion et al. (2007). Since the aim is to find only one community, we consider a slight variation with one mean, that is, with $k = 1$. This relation leads

¹ Source code of the algorithms used in the paper is available at <http://cs.ru.nl/~tvanlaarhoven/conductance2016>.

to the introduction of a new objective function for local community detection, called σ -conductance, which is the sum of conductance and a regularization term whose influence is controlled by a parameter σ . Interestingly, the choice of σ has a direct effect on the number of local optima of the function, where larger values of σ lead to more local optima. In particular, we prove that for $\sigma > 2$ all discrete communities are local optima. As a consequence, due to the seed expansion approach, local optimization of σ -conductance favors smaller communities for larger values of σ .

1.0.3 ALGORITHMS

Local optimization of σ -conductance can be easily performed using the projected gradient descent method. We develop an algorithm based on this method, called PGDC. Motivated by the relation between conductance and k-means clustering, we introduce an Expectation-Maximization (EM) algorithm for σ -conductance optimization, called EMC. We show that for $\sigma = 0$, this algorithm is almost identical to projected gradient descent with an infinite step size in each iteration. We then propose a heuristic procedure for choosing σ automatically in these algorithms.

1.0.4 RETRIEVING COMMUNITIES

We give a theoretic characterization of a class of communities, called dense and isolated communities, for which PGDC and EMC perform optimally. For this class of communities the algorithms exactly recover a community from the seeds. We investigate the relation between this class of communities and the notion of (α, β) -cluster proposed by (Mishra et al., 2008) for social networks analysis. And we show that, while all maximal cliques in a graph are (α, β) -clusters, they are not necessarily dense and isolated communities. We give a simple condition on the degree of the nodes of a community which guarantees that a dense and isolated community satisfying such condition is also an (α, β) -cluster.

1.0.5 EXPERIMENTAL PERFORMANCE

We use publicly available artificial and real-life network data with labeled ground-truth communities to assess the performance of PGDC and EMC. Results of the two methods are very similar, with PGDC performing slightly better, while EMC is slightly faster. These results are compared with those obtained by three state-of-the-art algorithms for conductance optimization based on the local graph diffusion: the popular Personalized Page Rank (PPR) diffusion algorithm by Andersen and Lang (2006), a more recent variant by Yang and Leskovec (2012) (here called YL), and the Heat Kernel (HK) diffusion algorithm by Kloster and Gleich (2014). On large networks PGDC and EMC stay localized and produce communities which are more faithful to the ground truth than those generated by the considered graph diffusion algorithms. PPR and HK produce much larger communities with a low conductance, while the YL strategy outputs very small communities with a higher conductance.

1.1 Related Work

The enormous growth of network data from diverse disciplines such as social and information science and biology has boosted research on network community detection (see for instance the overviews by Schaefer (2007) and Fortunato (2010)). Here we confine ourselves to literature we consider to be relevant to the present work, namely local community detection by seed expansion, and review related work on conductance as objective function and its local optimization. We also briefly review research on other objectives functions, and on properties of communities and of seeds.

1.1.1 CONDUCTANCE AND ITS LOCAL OPTIMIZATION

Conductance has been largely used for network community detection. For instance Leskovec et al. (2008) introduced the notion of network community profile plot to measure the quality of a ‘best’ community as a function of community size in a network. They used conductance to measure the quality of a community and analyze a large number of communities of different size scales in real-world social and information networks.

Direct conductance optimization was shown to favor communities which are quasi-cliques (Kang and Faloutsos, 2011) or communities of large size which include irrelevant subgraphs (Andersen and Lang, 2006; Whang et al., 2013).

Popular algorithms for local community detection employ the local graph diffusion method to find a community with small conductance.

Starting from the seminal work by Spielman and Teng (2004) various algorithms for local community detection by seed expansion based on this approach have been proposed (Andersen et al., 2006; Avron and Horesh, 2015; Chung, 2007; Kloster and Gleich, 2014; Zhu et al., 2013a). The theoretical analysis in these works is largely based on a mixing result which shows that a cut with small conductance can be found by simulating a random walk starting from a single node for sufficiently many steps (Lovász and Simonovits, 1990). This result is used to prove that if the seed is near to a set with small conductance then the result of the procedure is a community with a related conductance, which is returned in time proportional to the volume of the community (up to a logarithmic factor).

Mahoney et al. (2012) performed local community detection by modifying the spectral program used in standard global spectral clustering. Specifically the authors incorporated a bias towards a target region of seed nodes in the form of a constraint to force the solution to be well connected with or to lie near the seeds. The degree of connectedness was specified by setting a so-called correlation parameter. The authors showed that the optimal solution of the resulting constrained optimization problem is a generalization of Personalized PageRank (Andersen and Lang, 2006).

1.1.2 OTHER OBJECTIVES

Conductance is not the only objective function used in local community detection algorithms. Various other objective functions have been considered in the literature. For instance, Chen et al. (2009) proposed to use the ratio of the average internal and external degree of nodes in a community as objective function. Clauset (2005) proposed a local variant of modularity. Wu et al. (2015) modified the classical density objective, equal to the sum of edges in the community divided by its size, by replacing the denominator with the

sum of weights of the community nodes, where the weight of a node quantifies its proximity to the seeds and is computed using a graph diffusion method.

A comparative experimental analysis of objective functions with respect to their experimental and theoretical properties was performed e.g. in (Yang and Leskovec, 2012) and (Wu et al., 2015), respectively.

1.1.3 PROPERTIES OF COMMUNITIES

Instead of focusing on objective functions and methods for local community detection, other researchers investigated properties of communities. Mishra et al. (2008) focused on interesting classes of communities and algorithms for their exact retrieval. They defined the so called (α, β) -communities and developed algorithms capable of retrieving this type of communities starting from a seed connected to a large fraction of the members of the community. Zhu et al. (2013b) considered the class of well-connected communities, which have a better internal connectivity than conductance. Internal connectivity of a community is defined as the inverse of the mixing time for a random walk on the subgraph induced by the community. They showed that for well-connected communities, it is possible to provide an improved performance guarantee, in terms of conductance of the output, for local community detection algorithms based on the diffusion method. Gleich and Seshadhri (2012) investigated the utility of neighbors of the seed; in particular they showed empirically that such neighbors form a 'good' local community around the seed. Yang and Leskovec (2012) investigated properties of ground truth communities in social, information and technological networks.

Lancichinetti et al. (2011) addressed the problem of finding a significant local community from an initial group of nodes. They proposed a method which locally optimizes the statistical significance of a community, defined with respect to a global null model, by iteratively adding external significant nodes and removing internal nodes that are not statistically relevant. The resulting community is not guaranteed to contain the nodes of the initial community.

1.1.4 PROPERTIES OF SEEDS

Properties of seeds in relation to the performance of algorithms were investigated by e.g. Kloumann and Kleinberg (2014). They considered different types of algorithms, in particular a greedy seed expansion algorithm which at each step adds the node that yields the most negative change in conductance (Mislove et al., 2010). Whang et al. (2013) investigated various methods for choosing the seeds for a PageRank based algorithm for community detection. Chen et al. (2013) introduced the notion of local degree central node, whose degree is greater than or equal to the degree of its neighbor nodes. A new local community detection method is introduced based on the local degree central node. In this method, the local community is not discovered from the given starting node, but from the local degree central node that is associated with the given starting node.

1.2 Notation

We start by introducing the notation used in the rest of this paper. We denote by V the set of nodes in a network or graph G . A community, also called a cluster, $C \subseteq V$ will be a

subset of nodes, and its complement $\bar{C} = V \setminus C$ consists of all nodes not in C . Note that we consider any subset of nodes to be a community, and the goal of community detection is to find a *good* community.

Let A be the adjacency matrix of G , where a_{ij} denotes the weight of an edge between nodes i and j . In unweighted graphs a_{ij} is either 0 or 1, and in undirected graphs $a_{ij} = a_{ji}$. In this paper we work only with unweighted undirected graphs. We can generalize this notation to sets of nodes, and write $a_{xy} = \sum_{i \in x, j \in y} a_{ij}$. With this notation in hand we can write conductance as

$$\phi(C) = \frac{a_{C\bar{C}}}{a_{CV}} = 1 - \frac{a_{CC}}{a_{CV}}.$$

A common alternative definition is

$$\phi_{\text{alt}}(C) = \frac{a_{C\bar{C}}}{\min(a_{CV}, a_{\bar{C}V})},$$

which considers the community to be the smallest of C and \bar{C} . For instance Kloster and Gleich (2014) and Andersen and Lang (2006) use this alternative definition, while Yang and Leskovec (2012) use ϕ .

Note that ϕ has a trivial optimum when all nodes belong to the community, while ϕ_{alt} will usually have a global optimum with roughly half of the nodes belonging to the community. Neither of these optima are desirable for finding a single small community.

With a set X we associate an indicator vector $[X]$ of length $|V|$, such that $[X]_i = 1$ if $i \in X$ and $[X]_i = 0$ otherwise. We will usually call this vector \mathbf{x} .

2. Continuous Relaxation of Conductance

If we want to talk about directly optimizing conductance, then we need to define what (local) optima are. The notion of local optima depends on the topology of the input space, that is to say, on what communities we consider to be neighbors of other communities. We could, for instance, define the neighbors of a community to be all communities that can be created by adding or removing a single node. But this is an arbitrary choice, and we could equally well define the neighbors to be all communities reached by adding or removing up to two nodes. An alternative is to move to the continuous world, where we can use our knowledge of calculus to give us a notion of local optima.

To turn community finding into a continuous problem, instead of a set C we need to see the community as a vector \mathbf{c} of real numbers between 0 and 1, where c_i denotes the degree to which node i is a member of the community. Given a discrete community C , we have $\mathbf{c} = [C]$, but the inverse is not always possible, so the vectorial setting is more general.

The edge weight between sets of nodes can be easily generalized to the edge weight of membership vectors,

$$a_{\mathbf{x}\mathbf{y}} = \mathbf{x}^T \mathbf{A} \mathbf{y} = \sum_{i \in V} \sum_{j \in V} x_i a_{ij} y_j.$$

Now we can reinterpret the previous definition of conductance as a function of real vectors, which we could expand as

$$\phi(\mathbf{c}) = 1 - \frac{\sum_{i,j \in V} c_i a_{ij} c_j}{\sum_{i,j \in V} c_i a_{ij}}.$$

With this definition we can apply the vast literature on constrained optimization of differentiable functions. In particular, we can look for local optima of the conductance, subject to the constraint that $0 \leq c_i \leq 1$. These local optima will satisfy the Karush-Kuhn-Tucker conditions, which in this case amounts to, for all $i \in V$,

$$\begin{aligned} 0 &\leq c_i \leq 1 \\ \nabla \phi(\mathbf{c})_i &\geq 0 && \text{if } c_i = 0 \\ \nabla \phi(\mathbf{c})_i &= 0 && \text{if } 0 < c_i < 1, \\ \nabla \phi(\mathbf{c})_i &\leq 0 && \text{if } c_i = 1. \end{aligned}$$

To use the above optimization problem for finding communities from seeds, we add one additional constraint. Given a set S of seeds we require that $c_i \geq s_i$; in other words, that the seed nodes are members of the community. This is the only way in which the seeds are used, and the only way in which we can use the seeds without making extra assumptions.

2.1 A Look at the Local Optima

By allowing community memberships that are real numbers, uncountably many more communities are possible. One might expect that it is overwhelmingly likely that optima of the continuous relaxation of conductance are communities with fractional memberships. But this turns out not to be the case. In fact, the strict local optima will all represent discrete communities.

To see why this is the case, consider the objective in terms of the membership coefficient c_i for some node i . This takes the form of a quadratic rational function,

$$\phi(c_i) = \frac{\alpha_1 + \alpha_2 c_i + \alpha_3 c_i^2}{\alpha_4 + \alpha_5 c_i}.$$

The coefficients in the denominator are positive, which means that the denominator is also positive for $c_i > 0$. At an interior local minimum we must have $\phi'(c_i) = 0$, which implies that $\phi''(c_i) = 2\alpha_3/(\alpha_4 + \alpha_5 c_i)^3$. But $\alpha_3 \leq 0$, since it comes from the $c_i \alpha_i \alpha_i c_i$ term in the numerator of the conductance, so $\phi''(c_i) \leq 0$, and hence there are only local maxima or saddle points, not strict local minima.

It is still possible for there to be plateaus in the objective functions, where $\phi(\mathbf{c})$ is optimal regardless of the value of c_i for a certain node i .

2.2 The Relation to Weighted Kernel K-Means Clustering

Another view on conductance is by the connection to weighted kernel k -means clustering. The connection between weighted kernel k -means and objectives for graph partitioning has been thoroughly investigated in Dhillon et al. (2007). Here we extend that connection to the single cluster case.

Start with weighted k -means clustering, which, given a dataset $\{x_i\}_{i=1}^N$ and weights $\{w_i\}$ minimizes the following objective

$$\sum_{i=1}^N \sum_{j=1}^k w_i c_{ij} \|x_i - \mu_j\|_2^2$$

with respect to μ_j and c_{ij} , where c_{ij} indicates if point i belongs to cluster j , subject to the constraint that exactly one c_{ij} is 1 for every i .

Since our goal is to find a single cluster, a first guess would be to take $k = 2$, and to try to separate a foreground cluster from the background. But when using 2-means, there is no distinction between foreground and background, and so solutions will naturally have two clusters of roughly equal size. Instead, we can consider a one-cluster variant that distinguishes between points in a cluster and background points, which we call 1-mean clustering. This can be formulated as the minimization of

$$\sum_i w_i (c_i \|x_i - \mu\|_2^2 + (1 - c_i) \lambda_i)$$

with respect to a single μ and cluster membership indicators c_i (between 0 and 1). Here λ_i is a cost for node i being a member of the background.

We allow different λ_i for different nodes, as there is no reason to demand a single value. The condition for a node i to be part of the community is $\|x_i - \mu\|_2^2 < \lambda_i$. So different values for λ_i might be useful for two reasons. The first would be to allow incorporating prior knowledge, the second reason would be if the scale (of the clusters) is different, that is, nodes (in different clusters) have different distances from the mean. By adding a diagonal matrix to the kernel, the squared distance from all points to all other points is increased by that same amount. It makes sense to compensate for this in the condition for community membership. And since the diagonal terms we add to the kernel vary per node, the amount that these nodes move away from other points also varies, which is why we use different λ_i per node.

The minimizer for μ is the centroid of the points inside the cluster,

$$\mu = \frac{\sum_i w_i c_i x_i}{\sum_i w_i c_i},$$

while the minimizer for c_i is 1 if and only if $\|x_i - \mu\|_2^2 < \lambda_i$, and 0 otherwise.

The k -means and 1-mean objectives can be kernelized by writing distances in terms of inner products, and using a kernel $K(i, j) = \langle x_i, x_j \rangle$. The cluster mean is then a linear combination of points, $\mu = \sum_i \mu_i x_i$, giving

$$\|x_i - \mu\|_2^2 = K(i, i) - 2 \sum_j \mu_j K(i, j) + \sum_{j,k} \mu_j \mu_k K(j, k).$$

By filling in the optimal μ given above, the 1-mean objective then becomes

$$\begin{aligned} \phi_{W,K,\lambda}(\mathbf{c}) &= \sum_i w_i c_i (K(i, i) - \lambda_i) + \sum_i w_i \lambda_i \\ &\quad - \frac{\sum_{i,j} w_i c_i w_j c_j K(i, j)}{\sum_i w_i c_i}. \end{aligned}$$

The second term is constant, so we can drop it for the purposes of optimization.

We pick $\lambda_i = K(i, i)$. With this choice, the condition for a node i to be a member of the community is $\|x_i - \mu\|_2^2 < \|x_i - 0\|_2^2$. This can be seen as a 2-means cluster assignment

where the background cluster has the origin as the fixed mean. With this choice the first term also drops out.

By converting the graph into a kernel with

$$K = W^{-1}AW^{-1},$$

where W is a diagonal matrix with the weights w_i on the diagonal, we can obtain objectives like conductance and association ratio. However this K is not a legal kernel, because a kernel has to be positive definite. Without a positive definite kernel the distances $\|x_i - \mu\|$ from the original optimization problem can become negative. To make the kernel positive definite, we follow the same route as Dhillon et al., and add a diagonal matrix, obtaining

$$K = \sigma W^{-1} + W^{-1}AW^{-1}.$$

Since we are interested in conductance, we take as weights $w_i = a_{iV}$, the degree of node i , and we take $\lambda_i = K(i, i)$. This results (up to an additive constant) in the following objective which we call σ -conductance,

$$\phi_\sigma(\mathbf{c}) = 1 - \frac{\sum_{i,j} c_i c_j a_{ij}}{\sum_i c_i a_{iV}} - \sigma \frac{\sum_i c_i^2 a_{iV}}{\sum_i c_i a_{iV}}.$$

Observe that if \mathbf{c} is a discrete community, then $c_i^2 = c_i$, and the last term is constant. In that case optimization of this objective is exactly equivalent to optimizing conductance.

For the purposes of continuous optimization however, increasing the σ parameter has the effect of increasing the objective value of non-discrete communities. So different communities become more separated, and in the extreme case, every discrete community becomes a local optimum.

Theorem 1 *When $\sigma > 2$, all discrete communities \mathbf{c} are local minima of $\phi_\sigma(\mathbf{c})$ constrained to $0 \leq c_i \leq 1$.*

Proof The gradient of ϕ_σ is

$$\nabla \phi_\sigma(\mathbf{c})_i = a_{iV} \frac{a_{iC}}{a_{iV}^2} - 2 \frac{a_{iC}}{a_{iV}} + \sigma \left(a_{iV} \frac{c_i^2 a_{iV}}{a_{iV}^2} - 2c_i \frac{a_{iV}}{a_{iV}} \right).$$

When \mathbf{c} is discrete, then $\sum_j c_j^2 a_{jV} = a_{iV}$, so the gradient simplifies to

$$\nabla \phi_\sigma(\mathbf{c})_i = \frac{a_{iV}}{a_{iV}} \left(\frac{a_{iC}}{a_{iV}} + (1 - 2c_i) \sigma - 2 \frac{a_{iC}}{a_{iV}} \right).$$

Because $a_{iC} \leq a_{iV}$ and $a_{iC} \leq a_{iV}$ we can bound this by

$$\frac{a_{iV}}{a_{iV}} \left((1 - 2c_i) \sigma - 2 \right) \leq \nabla \phi_\sigma(\mathbf{c})_i \leq \frac{a_{iV}}{a_{iV}} \left((1 - 2c_i) \sigma + 1 \right).$$

So if $c_i = 0$, we get that $\nabla \phi_\sigma(\mathbf{c})_i > 0$ when $\sigma > 2$. And if $c_i = 1$, we get that $\nabla \phi_\sigma(\mathbf{c})_i < 0$ when $\sigma > 1$.

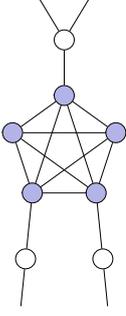

Figure 1: A simple subnetwork consisting of a clique with tails connecting it to the rest of the network. The clique (shaded nodes) is not a local optimum of conductance, but it is a local optimum of σ -conductance when $\sigma > 0.131$.

This means that when $\sigma > 2$ all discrete communities satisfy the KKT conditions, and from the sign of the gradient we can see that they are not local maxima. Furthermore, $\phi_\sigma(\mathbf{c})$ is a concave function, so it has no saddle points (see the proof of Theorem 2). This means that all discrete communities are local minima of ϕ_σ . ■

Conversely, the result from Section 2.1 generalizes to σ -conductance,

Theorem 2 *When $\sigma \geq 0$, all strict local minima \mathbf{c} of $\phi_\sigma(\mathbf{c})$ constrained to $0 \leq c_i \leq 1$ are discrete. Furthermore, if $\sigma > 0$ then all local minima are discrete.*

Proof By the argument from Section 2.1. When $\sigma > 0$ it is always the case that $\alpha_3 < 0$, so there are no saddle points or plateaus, and all local minima are discrete. ■

As an example application of σ -conductance, consider the network in Figure 1. In this network, the clique is not a local optimum of regular conductance. This is because the gradient for the adjacent nodes with degree 2 is always negative, regardless of the conductance of the community. However, for σ -conductance this gradient becomes positive when $\sigma > \phi_\sigma(\mathbf{c})$, in this case when $\sigma > 0.131$. In other words, with higher σ , adjacent nodes with low degree are no longer considered part of otherwise tightly connected communities such as cliques.

3. Algorithms

We now introduce two simple algorithms for the local optimization of conductance and σ -conductance, analyze their computational complexity and provide an exact performance guarantee for a class of communities. Then we look at a procedure for the automatic selection of a value for σ .

3.1 Projected Gradient Descent

Perhaps the simplest possible method for constrained continuous optimization problems is projected gradient descent. This is an iterative algorithm, where in each step the solution is moved in the direction of the negative gradient, and then this solution is projected so as to satisfy the constraints.

In our case, we start from an initial community containing only the seeds,

$$\mathbf{c}^{(0)} = \mathbf{s},$$

where $\mathbf{s} = [S]$ is a sparse vector indicating the seed node(s). Then in each subsequent iteration we get

$$\mathbf{c}^{(t+1)} = p(\mathbf{c}^{(t)} - \gamma^{(t)} \nabla \phi(\mathbf{c}^{(t)})).$$

This process is iterated until convergence. The step size $\gamma^{(t)}$ can be found with line search. The gradient $\nabla \phi$ is given by

$$\nabla \phi(\mathbf{c})_i = \frac{a_{AV} a_{cc}}{a_{cV}^2} - 2 \frac{a_{ic}}{a_{cV}}.$$

And the projection p onto the set of valid communities is defined by

$$p(\mathbf{c}) = \underset{\mathbf{c}', \text{ s.t. } 0 \leq c'_i \leq 1, s_i \leq c'_i}{\text{argmin}} \|\mathbf{c} - \mathbf{c}'\|_2^2,$$

which simply amounts to

$$p(\mathbf{c}) = \max(\mathbf{s}, \min(\mathbf{1}, \mathbf{c})).$$

This function clips values above 1 to 1, and values below s_i to s_i . Since $s_i \geq 0$ this also enforces that $c_i \geq 0$.

The complete algorithm is given in Algorithm 1. If a discrete community is desired, as a final step, we might threshold the vector \mathbf{c} . But as shown in Theorem 2 the found community is usually already discrete.

3.2 Expectation-Maximization

The connection to k -means clustering suggests that it might be possible to optimize conductance using an Expectation-Maximization algorithm similar to Lloyd's algorithm for k -means clustering. Intuitively, the algorithm would work as follows:

- **E step** assign each node i to the community if and only if its squared distance to the mean is less than λ_i .
- **M step** set the community mean to the weighted centroid of all nodes in the community.

These steps are alternated until convergence. Since both these steps do not increase the objective value, the algorithm is guaranteed to converge.

If the community after some iterations is C , then, as in the previous section, we can fill in the optimal mean into the E step, to obtain that a node i should be part of the community if

$$K(i, i) + \frac{a_{cC}/a_{cV} + \sigma}{a_{cV}} - 2 \frac{a_{iC}/a_{iV} + \sigma c_i}{a_{cV}} < \lambda_i.$$

When $\lambda_i = K(i, i)$, this condition is equivalent to

$$\nabla \phi_\sigma(C) < 0.$$

Algorithm 1 Projected Gradient Descent conductance optimization (PGDC)

Input: A set S of seeds of seeds, a graph G , a constant $\sigma \geq 0$.

- 1: $\mathbf{s} \leftarrow [S]$
- 2: $\mathbf{c}^{(0)} \leftarrow \mathbf{s}$
- 3: $t \leftarrow 0$
- 4: **repeat**
- 5: $\gamma^{(t)} \leftarrow \text{LineSearch}(\mathbf{c}^{(t)})$
- 6: $\mathbf{c}^{(t+1)} = p(\mathbf{c}^{(t)} - \gamma^{(t)} \nabla \phi_\sigma(\mathbf{c}^{(t)}))$
- 7: $t \leftarrow t + 1$
- 8: **until** $\mathbf{c}^{(t-1)} = \mathbf{c}^{(t)}$
- 9: $C \leftarrow \{i \in V \mid \mathbf{c}_i^{(t)} \geq 1/2\}$

function LineSearch(\mathbf{c})

- 1: $\gamma^* \leftarrow 0$, $\phi^* \leftarrow \phi_\sigma(\mathbf{c})$
 - 2: $\mathbf{g} \leftarrow \nabla \phi_\sigma(\mathbf{c})$
 - 3: $\gamma \leftarrow 1 / \max(|\mathbf{g}|)$
 - 4: **repeat**
 - 5: $\mathbf{c}' \leftarrow p(\mathbf{c} - \gamma \mathbf{g})$
 - 6: **if** $\phi_\sigma(\mathbf{c}') < \phi^*$ **then**
 - 7: $\gamma^* \leftarrow \gamma$, $\phi^* \leftarrow \phi_\sigma(\mathbf{c}')$
 - 8: **end if**
 - 9: $\gamma \leftarrow 2\gamma$
 - 10: **until** $\mathbf{c}'_i \in \{0, 1\}$ for all i with $g_i \neq 0$
 - 11: **return** γ^*
-

Algorithm 2 EM conductance optimization (EMC)

Input: A set S of seeds, a graph G , a constant $\sigma \geq 0$.

- 1: $C^{(0)} \leftarrow S$
 - 2: $t \leftarrow 0$
 - 3: **repeat**
 - 4: $C^{(t+1)} = \{i \mid \nabla \phi_\sigma(C^{(t)})_i < 0\} \cup S$
 - 5: $t \leftarrow t + 1$
 - 6: **while** $C^{(t)} < C^{(t-1)}$
-

This leads us to the EM community finding algorithm, Algorithm 2.

By taking $\sigma = 0$ we get that nodes are assigned to the community exactly if the gradient $\nabla\phi(C)_i$ is negative. So, this EM algorithm is very similar to projected gradient descent with an infinite step size in each iteration. The only difference is for nodes with $\nabla\phi(C)_i = 0$, which in the EMC algorithm are always assigned to the background, while in PGD their membership of the community is left unchanged compared to the previous iteration.

Of course, we have previously established that $\sigma = 0$ does not lead to a valid kernel (this doesn't preclude us from still using the EM algorithm). In the case that $\sigma > 0$ there is an extra barrier for adding nodes not currently in the community, and an extra barrier for removing nodes that are in the community. This is similar to the effect that increasing σ has on the gradient of ϕ .

3.3 Computational Complexity

Both methods require the computation of the gradient in each iteration. This computation can be done efficiently. The only nodes for which the gradient of the conductance is negative are the neighbors of nodes in the current community, and the only nodes for which a positive gradient can have an effect are those in the community. So the gradient doesn't need to be computed for other nodes. For the other nodes the gradient depends on the number of edges to the community, and on the node's degree. Assuming that the node degree can be queried in constant time, the total time per iteration is proportional to the size of the one-step-neighborhood of the community, which is of the order of the volume of the community. If the node degrees are not known, then the complexity increases to be proportional to the volume of the one-step-neighborhood of the community, though this is a one-time cost, not a per iteration cost.

As seen in Section 3.5, for dense and isolated communities, the number of iterations is bounded by the diameter of the community. In general we can not guarantee such a bound, but in practice the number of iterations is always on the order of the diameter of the recovered community.

For very large datasets, the computation of the gradient can still be expensive, even though it is a local operation. Therefore, we restrict the search to a set of 1000 nodes near the seed. This set N is formed by starting with the seed, and repeatedly adding all neighbors of nodes in N , until the set would contain more than 1000 nodes. In this last step we only add the nodes with the highest a_{iN}/a_{iV} so that the final set contains exactly 1000 nodes.

3.4 Choosing σ

In Section 2.2 we introduced the σ parameter, and we have shown that larger values of σ lead to more local optima. This leaves the question of choosing the value of σ .

One obvious choice is $\sigma = 0$, which means that ϕ_σ is exactly the classical conductance. Another choice would be to pick the smallest σ that leads to a positive definite kernel. But this is a global property of the network, that is furthermore very expensive to compute.

Instead, we try several different values of σ for each seed, and then pick the community with the highest density, that is, the community C with the largest $acc/|C|^2$.

3.5 Exactly Recoverable Communities

We now take a brief look at which kinds of communities can be exactly recovered with gradient descent and expectation-maximization. Suppose that we wish to recover a community C^* from a seeds set S , and assume that this community is connected. Denote by $d(i)$ the shortest path distance from a node $i \in C^*$ to any seed node, in the subnetwork induced by C^* .

First of all, since both algorithms grow the community from the seeds, we need to look at subcommunities $C \subseteq C^*$ centered around the seeds, by which we mean that $d(i) \leq d(j)$ for all nodes $i \in C$ and $j \in C^* \setminus C$.

Secondly, we need the community to be sufficiently densely connected to be considered a community in the first place; but at the same time the community needs to be separated from the rest of the network. Again, because the communities are grown, we require that this holds also for subcommunities that are grown from the seeds,

Definition 3 A community C^* is dense and isolated with threshold σ if for all subsets $C \subseteq C^*$ centered around the seeds S :

- $2a_{iC}/a_{iV} > acc/acv - \sigma$ for all nodes $i \in C$, and
- $2a_{iC}/a_{iV} \leq acc/acv - \sigma$ for all nodes $i \notin C^*$.

Some examples of communities that satisfy this property are cliques and quasi-cliques that are only connected to nodes of high degree.

Now denote by D_n the set of nodes i in C^* with $d(i) \leq n$. Clearly $D_0 = S$, and because the community is connected there is some n^* such that $D_{n^*} = C^*$.

We first look at the expectation-maximization algorithm.

Theorem 4 If C^* is dense and isolated, then the iterates of the EMC algorithm satisfy $C^{(t)} = D_t$.

Proof The proof proceeds by induction. For $t = 0$, the only nodes i with $d(i) = 0$ are the seeds, and $C^{(0)} = S$ by definition.

Now suppose that $C^{(t)} = D_t$. Then for any node i there are three possibilities.

- $i \in D_{t+1}$; then because C^* is dense and D_t is centered around the seeds, $2a_{iC^{(t)}}/a_{iV} > 1 - \phi_\sigma(C^{(t)})$. This implies that $\nabla\phi_\sigma(C^{(t)})_i < 0$.
- $i \in C^* \setminus D_{t+1}$; then there are no edges from D_t to i , since otherwise the shortest path distance from i to a seed would be $t + 1$. So $a_{iC^{(t)}} = 0$, which implies that $\nabla\phi_\sigma(C^{(t)})_i \geq 0$.
- $i \notin C^*$; then because C^* is isolated, $2a_{iC^{(t)}}/a_{iV} \leq 1 - \phi_\sigma(C^{(t)})$, which implies that $\nabla\phi_\sigma(C^{(t)})_i \geq 0$.

hence $\nabla\phi_\sigma(C^{(t)})_i < 0$ if $i \in D_{t+1}$, and $\nabla\phi_\sigma(C^{(t)})_i \geq 0$ otherwise. This means that $C^{(t+1)} = D_{t+1}$. ■

For the projected gradient descent algorithm from Section 3.1 we have an analogous theorem,

Theorem 5 *If C^* is dense and isolated, then the iterates of PGDC satisfy $\mathbf{c}^{(t)} = [D_t]$.*

Proof The proof proceeds by induction, and is analogous to the proof of Theorem 4. For $t = 0$, the only nodes i with $d(i) = 0$ are the seeds, and $\mathbf{c}^{(0)} = \mathbf{s} = [S]$ by definition.

Now suppose that $\mathbf{c}^{(t)} = [D_t]$. We have already shown that $\nabla\phi_\sigma(C^{(t)})_i < 0$ if and only if $i \in D_{t+1}$. This means that after projecting onto the set of valid communities, only the membership of nodes in D_{t+1} can increase. Since nodes in D_t already have membership 1, and nodes not in D_{t+1} already have membership 0, they are not affected.

Let $\gamma_{\max} = \max_{i \in D_{t+1}} -1/\nabla\phi_\sigma(\mathbf{c}^{(t)})_i$. Clearly if $\gamma^{(t)} \geq \gamma_{\max}$, then $c_i^{(t)} - \gamma^{(t)}\nabla\phi_\sigma(\mathbf{c}^{(t)})_i > 1$ for all nodes $i \in D_{t+1}$, and hence $p(\mathbf{c}^{(t)} - \gamma^{(t)}\nabla\phi_\sigma(\mathbf{c}^{(t)})) = [D_{t+1}]$. So to complete the proof, we only need to show that the optimal step size found with line search is indeed (at least) γ_{\max} .

Suppose that $\gamma^{(t)} < \gamma_{\max}$ leads to the optimal conductance. Then there is a node $i \in D_{t+1}$ with fractional membership, $0 < c_i^{(t+1)} < 1$. By repeated application of Theorem 2 we know that there is a discrete community C' with $\phi_\sigma(C') = \phi_\sigma(\mathbf{c}^{(t+1)})_i$, and furthermore $\phi_\sigma(C' \setminus \{i\}) = \phi_\sigma(C' \cup \{i\})$. The latter can only be the case if $\nabla\phi_\sigma(C')_i = 0$. Because the only nodes whose membership has changed compared to $\mathbf{c}^{(t)}$ are those in $D_{t+1} \setminus D_t$, it follows that C' contains all nodes with distance at most t to the seeds, as well as some nodes with distance $t+1$ to the seeds. This means that C' is centered around the seeds, and so $\nabla\phi_\sigma(C')_i > 0$. This is a contradiction, which means that $\gamma^{(t)} \geq \gamma_{\max}$ must be the optimum. ■

As a corollary, since $D_{n^*+1} = D_{n^*}$, both the EMC and the PGDC algorithm will halt, and exactly recover C^* .

The notion of dense and isolated community is weakly related to that of (α, β) -cluster (Mishra et al., 2008) (without the technical assumption that each node has a self-loop): C is an (α, β) -cluster, with $0 \leq \alpha < \beta \leq 1$ if $a_{iC} \geq \beta|C|$ for i in C , $a_{iC} \leq \alpha|C|$ for i outside C .

The definition of dense and isolated community depends on the degree of the nodes while that of (α, β) -cluster does not. As a consequence, not all maximal cliques of a graph are in general dense and isolated communities while they are (α, β) -clusters. For instance, a maximal clique linked to an external isolated node, that is, a node of degree 1, is not dense and isolated.

In general one can easily show that if C is dense and isolated and

$$\min_{i \in C} a_{iV} > \max_{i \notin C, a_{iC} > 0} a_{iV}$$

$$\beta = \frac{1 - \phi(C)}{2|C|} \min_{i \in C} a_{iV}$$

then C is an (α, β) -cluster with

$$\alpha = \frac{1 - \phi(C)}{2|C|} \max_{i \notin C, a_{iC} > 0} a_{iV}.$$

and

Table 1: Overview of the datasets used in the experiments. For each dataset we consider three different sets of communities.

4. Experiments

To test the proposed algorithms, we assess their performance on various networks. We also perform experiments on recent state-of-the-art algorithms based on the diffusion method which also optimize conductance.

4.1 Algorithms

Specifically, we perform a comparative empirical analysis of the following algorithms.

1. PGDC. The projected gradient descent algorithm for optimizing σ -conductance given in Algorithm 1. We show the results for two variants: PGDC-0 with $\sigma = 0$ and PGDC-d where σ is chosen to maximize the community's density as described in Section 3.4.
2. EMC. The Expectation Maximization algorithm for optimizing σ -conductance described in Section 2. We consider the variants EMC-0 with $\sigma = 0$ and EMC-d where σ is chosen automatically.

3. YL. The algorithm by Yang and Leskovec (2012) (with conductance as scoring function), based on the diffusion method. It computes an approximation of the personalized Page Rank graph diffusion vector (Andersen et al., 2006). The values in this

vector are divided by the degree of the corresponding nodes, and the nodes are sorted in descending order by their values. The ranking induces a one dimensional search space of communities C_k , called a sweep, defined by the sequence of prefixes of the sorted list, that is, the k top ranked nodes, for $k = 1, \dots, |V|$. The smallest k whose C_k is a 'local optimum' of conductance is computed and C_k is extracted. Local optima of conductance over the one dimensional space $C_1, C_2, \dots, C_{|V|}$ are computed using a heuristic. For increasing $k = 1, 2, \dots$ $\phi(C_k)$ is measured. When $\phi(C_k)$ stops decreasing at k^* this is a 'candidate point' for a local minimum. It becomes a selected local minimum if $\phi(C_k)$ keeps increasing after k^* and eventually becomes higher than $\alpha\phi(C_k)$, otherwise it is discarded. $\alpha = 1.2$ is shown to give good results and is also used in our experiments. Yang and Leskovec (2012) show that finding the local optima of the sweep curve instead of the global optimum gives a large improvement over previous local spectral clustering methods by Andersen and Lang (2006) and by Spielman and Teng (2004).

4. HK. The algorithm by Kloster and Gleich (2014), also based on the diffusion method. Here, instead of using the Personalized PageRank score, nodes are ranked based on a Heat Kernel diffusion score (Chung, 2007). We use the implementation made available by Kloster and Gleich (2014), which tries different values of the algorithm's parameters t and ϵ , and picks the community with the highest conductance among them. The details are in section 6.2 of (Kloster and Gleich, 2014). Code is available at <https://www.cs.purdue.edu/homes/dgleich/codes/hkgrow>.
5. PPR. The pprpush algorithm by Andersen and Lang (2006) based on the personalized Page Rank graph diffusion. Compared to YL instead of finding a local optimum of the sweep, the method looks for a global optimum, and hence often finds larger communities. We use the implementation included with the HK method.

4.2 Datasets

4.2.1 ARTIFICIAL DATASETS

The first set of experiments we performed is on artificially generated networks with a known community structure. We use the LFR benchmark (Lancichinetti et al., 2008). We used the parameter settings $\eta=5000$ $\mu=0.3$ $k=10$ $\maxk=50$ $t1=2$ $t2=1$ $\minc=20$ $\maxc=100$ $on=2500$, which means that the graph has 5000 nodes, and between 20 and 100 communities, each with between 10 and 50 nodes. Half of the nodes, 2500 are a member of multiple communities. We vary the overlap parameter (om), which determines how many communities these nodes are in. More overlap makes the problem harder.

4.2.2 SOCIAL AND INFORMATION NETWORK DATASETS WITH GROUND TRUTH

We use five social and information network datasets with ground-truth from the SNAP collection (Leskovec and Krevl, 2014). These datasets are summarized in Table 1. For each dataset we list the number of nodes, number of edges and the clustering coefficient. We consider all available ground truth communities with at least 3 nodes.

Yang and Leskovec (2012) also defined a set of top 5000 communities for each dataset. These are communities with a high combined score for several community goodness metrics,

among which is conductance. We therefore believe that communities in this set are biased to be more easy to recover by optimizing conductance, and therefore do not consider them here. Results with these top 5000 ground truth communities are available in tables 1–3 in the supplementary material².

In addition to the SNAP datasets we also include the Flickr social network dataset (Wang et al., 2012).

4.2.3 PROTEIN INTERACTION NETWORK DATASETS

We have also run experiments on protein interaction networks of yeast from the BioGRID database (Stark et al., 2006). This database curates networks from several different studies. We have constructed networks for Gavin et al. (2006), Krogan et al. (2006), Collins et al. (2007), Costanzo et al. (2010), Hoppins et al. (2011), as well as a network that is the union of all interaction networks confirmed by physical experiments.

As ground truth communities we take the CYC2008 catalog of protein complexes for each of the networks (Pu et al., 2009).

4.2.4 OTHER DATASETS

Additionally we used some classical datasets with known communities: Zachary's karate club Zachary (1977); Football: A network of American college football games (Girvan and Newman, 2002); Political books: A network of books about US politics (Krebs, 2004); and Political blogs: Hyperlinks between weblogs on US politics (Adamic and Glance, 2005). These datasets might not be very well suited for this problem, since they have very few communities.

4.3 Results

In all our experiments we use a single seed node, drawn uniformly at random from the community. We have also performed experiments with multiple seeds; the results of those experiments can be found in the supplementary material.

To keep the computation time manageable we have performed all experiments on a random sample of 1000 ground-truth communities. For datasets with fewer than 1000 communities, we include the same community multiple times with different seeds.

Since the datasets here considered have information about ground truth communities, a natural external validation criterion to assess the performance of algorithms on these datasets is to compare the community produced by an algorithm with the ground truth one. In general, that is, when ground truth information is not available, this task is more subtle, because it is not clear what is a good external validation metric to evaluate a community (Yang and Leskovec, 2015).

We measure quality performance with the F_1 score, which for community finding can be defined as

$$F_1(C, C^*) = 2 \frac{|C \cap C^*|}{|C| + |C^*|},$$

Table 2: Average F_1 score between recovered communities and ground-truth. The best result for each dataset is indicated in bold, as are the results not significantly worse according to a paired T-test (at significance level 0.01).

where C is the recovered community and C^* is the ground truth one. A higher F_1 score is better, with 1 indicating a perfect correspondence between the two communities.

Note that a seed node might be in multiple ground truth communities. In this case we only compare the recovered community to the true community that we started with. If a method finds another ground truth community this is not detected, and so it results in a low F_1 score.

We also analyze the output of these algorithms with respect to the conductance of produced communities and their size. Results on the run time of the algorithms are reported in the supplementary material (Table 4).

Figure 2 shows the F_1 scores as a function of the parameter σ . Table 2 shows the F_1 scores comparing the results of the methods to the true communities. Table 3 shows the mean size of the found communities, and Table 4 their conductance.

In general, results of these experiments indicate that on real-life networks, our methods based on continuous relaxation of conductance, PPR and HK produce communities with good conductance, but all are less faithful to the ground truth when the network contains many small communities. In PGDC, EMC the automatic choice of σ helps to achieve results closer to the ground truth, and the built-in tendency of YL to favor small communities helps

Table 3: Average size of the recovered communities.

as well. On the other hand, on networks with large communities our methods, PPR and HK work best. On the artificial LFR data continuous relaxation of conductance seems to work best. This result indicates that the LFR model of ‘what is a community’ is somehow in agreement with the notion of local community as local optimum of the continuous relaxation of conductance. However, as observed in recent works like (Jenb et al., 2015), the LFR model does not seem to represent the diverse characteristics of real-life communities.

We have included tables of the standard deviation in the supplementary material. Overall, the standard deviation in cluster size is of the same order of magnitude as the mean. The standard deviation of the conductance is around 0.1 for LFR datasets, 0.2 for the SNAP datasets and 0.3 for the CYC datasets. It is not surprising that the variance is this high, because the communities vary a lot in size and density.

Results on these datasets can be summarized as follows.

4.3.1 ARTIFICIAL LFR DATASETS

On these datasets, HK and PPR tend to find communities that are much too large, with small conductance but also with low F_1 scores. This happens because the LFR networks are small, and the methods are therefore able to consider a large part of the nodes in the network.

On the other hand, YL always starts its search at small communities, and it stops early, so the communities it finds are smaller than the ground truth ones on these networks.

Dataset	PGDC-0	PGDC-d	EMC-0	EMC-d	YL	HK	PPR

Table 4: Average conductance of the recovered communities.

The best F_1 results are achieved by PGDC with $\sigma = 0$, that is, when the continuous relaxation of conductance is used as the objective function. This method employs a more powerful optimizer than YL, so it is able to find a large community with a better conductance, but it still stops at the first local optimum. In the LFR datasets these optima are very clear, and correspond closely to the ground truth communities.

In all cases EMC shows similar or slightly worse performance compared to PGDC, so the gradient descend algorithm should be preferred.

The automatic choice of σ leads to communities which are of relatively small size. We believe that this happens because the nodes in LFR datasets all have exactly the same fraction of within community edges. Increasing σ suddenly makes the gradient for most of these nodes positive. In real networks there are often hubs that are more central to a community, with more connections to the community's nodes and to the seed. These hubs still can be found at higher values of σ .

4.3.2 SMALL REAL-LIFE SOCIAL NETWORKS WITH FEW COMMUNITIES (KARATE, FOOTBALL, BLOGS, BOOKS)

Our methods based on continuous relaxation of conductance yield the best F_1 results on the Football and Blog networks, while PPR performs best on the other two networks and achieves best overall conductance.

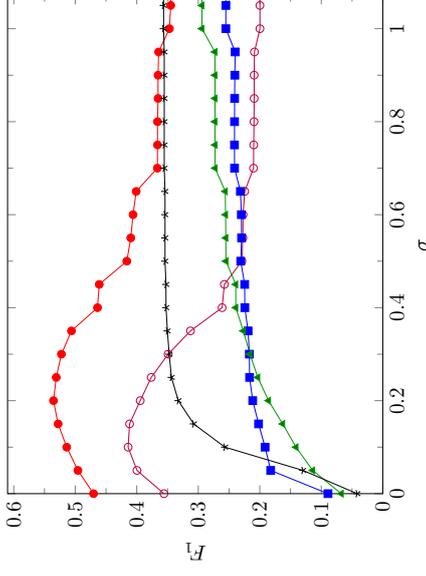

Figure 2: Average F_1 score as a function of the σ parameter on the SNAP datasets with the PGDC method.

4.3.3 LARGE SOCIAL NETWORK WITH BIG COMMUNITIES (FLICKR)

On this network, PPR achieves the best results both in terms of F_1 score as well as conductance. However the produced communities are about four times smaller than the ground truth communities, which have more than 4000 nodes. PGDC and EMC with $\sigma = 0$ yield communities of conductance similar to that of PPR communities, but their size is smaller (about 650 nodes). This happens because the algorithms are restricted to 1000 nodes around the seed, without this restriction larger communities would be found. Somewhat surprisingly HK produces communities of relatively small size (about 175 nodes). The automatic choice of σ yields to even smaller communities (about 64 nodes). The smallest size communities are produced by YL (about 13 nodes).

4.3.4 LARGE REAL-LIFE SNAP NETWORKS WITH MANY SMALL COMMUNITIES

On these networks the automatic choice of σ gives best results, consistently outperforming the other algorithms. In Figure 2, the F_1 score of PGDC and EMC as a function of σ is plotted. For some datasets a small value of σ works well, while for others a larger value of σ is better. Our procedure to choose σ produces results that are close to, but slightly below, the best a posteriori choice of σ . So on these networks the proposed procedure positively affects the performance of our algorithms. YL favors communities of small size less faithful to the ground truth. PGDC-0, EMC-0, PPR and HK 'explode', and produce very large communities. For our methods this 'explosion' is limited only because we limit the search to 1000 nodes near the seed. The ground-truth communities of these datasets have rather high conductance, and the networks have a very low clustering coefficient. In such a case,

communities have many links to nodes outside, hence conductance alone is clearly not suited to finding these type of local communities.

4.3.5 REAL-LIFE PROTEIN INTERACTION NETWORKS WITH VERY SMALL COMMUNITIES (CYC)

Also on these networks the automatic choice of σ gives best results. As expected, due to the very small size of the ground truth communities, YL also achieves very good results. The other algorithms tend to produce less realistic, large communities which have better conductance.

4.3.6 RUNNING TIME

The best performing algorithm with respect to running time is HK. PGDC and EMC are about four times slower with a fixed value of σ , and ten to twenty times slower when automatically determining σ . The running times are included in Table 4 of the supplementary material. All experiments were run on a 2.4GHz Intel XEON E7-4870 machine. Note that the different methods are implemented in different languages (our implementation is written in Octave, while HK and PPR are implemented in C++), so the running times only give an indication of the overall trend, and can not be compared directly.

4.3.7 TOP 5000 COMMUNITIES

Results with only the top 5000 ground truth communities available at the SNAP dataset collection are similar to the results with all communities. As expected, the F_1 score is much higher and the conductance of the recovered community is better. Because these ground truth communities have a better conductance, it is better to optimize conductance, that is to take $\sigma = 0$. As a consequence the performance of PGDC-0 and EMC-0 is better than that of PGDC-d and EMC-d for these communities. The full results are available in Tables 1-3 in the supplementary material.

5. Discussion

This paper investigated conductance as an objective function for local community detection from a set of seeds. By making a continuous relaxation of conductance we show how standard techniques such as projected gradient descent can be used to optimize it. Even though this is a continuous optimization problem, we show that the local optima are almost always discrete communities. We further showed how linking conductance with kernel weighted k -means clustering leads to the new σ -conductance objective function and to simple yet effective algorithms for local community detection by seed expansion.

We provided a formalization of a class of good local communities around a set of seeds and showed that the proposed algorithms can find them. We suspect that these communities can also be exactly retrieved using local community algorithms based on the diffusion method, but do not yet have a proof. The condition that such communities should be centered around the seeds raises the question of how to find such seeds. Although various works have studied seed selection for diffusion based algorithms, such as Kloumann and Kleinberg

(2014), this problem remains to be investigated in the context of local community detection by σ -conductance optimization using PGDC and EMC.

Our experimental results indicate the effectiveness of direct optimization of a continuous relaxation of σ -conductance using gradient descent and expectation maximization. In our algorithms we used community density as a criterion to choose σ . This resulted to be a good choice for the performance of our algorithms on the SNAP networks. It would be interesting to investigate also other criteria to choose σ . Conversely, the fact that maximum density is a good criterion for selecting σ implies that it might also be directly optimized as an objective for finding communities.

On some datasets, when optimizing normal conductance, that is, with $\sigma = 0$, our methods sometimes find very large communities. These communities will have a very good conductance, but they do not correspond well to the ground truth. In some sense the optimizer is ‘too good’, and conductance is not the best criterion to describe these communities. A better objective would perhaps take into account the size of the community more explicitly, but this needs to be investigated further.

In this paper we have used gradient descent, a first order optimization method which utilizes only the objective function’s gradient. More advanced optimization methods also use second derivatives or approximations of those. We believe that such methods will not bring a large advantage compared to gradient descent, because during the optimization many coordinates are at the boundary value 0 or 1, and second derivatives would not help to locate these boundary points. Other constrained optimizers such as interior point methods have the problem that they need to inspect a much larger part of the network, potentially all of it, because intermediate steps have nonzero membership for all nodes.

Abstract

Manifold Learning (ML) is a class of algorithms seeking a low-dimensional non-linear representation of high-dimensional data. Thus, ML algorithms are most applicable to high-dimensional data and require large sample sizes to accurately estimate the manifold. Despite this, most existing manifold learning implementations are not particularly scalable. Here we present a Python package that implements a variety of manifold learning algorithms in a modular and scalable fashion, using fast approximate neighbors searches and fast sparse eigendecompositions. The package incorporates theoretical advances in manifold learning, such as the unbiased Laplacian estimator introduced by Coifman and Lafon (2006) and the estimation of the embedding distortion by the Riemannian metric method introduced by Perrault-Joncas and Meilä (2013). In benchmarks, even on a single-core desktop computer, our code embeds millions of data points in minutes, and takes just 200 minutes to embed the main sample of galaxy spectra from the Sloan Digital Sky Survey—consisting of 0.6 million samples in 3750-dimensions—a task which has not previously been possible.

Keywords: manifold learning, dimension reduction, Riemannian metric, graph embedding, scalable methods, python

1. Motivation

We propose *megaman*, a new Python package for scalable manifold learning. This package is designed for performance, while inheriting the functionality of *scikit-learn*'s well-designed API (Buitinck et al., 2013).

2. Downloading and installation

megaman is publicly available at: <https://github.com/mmp2/megaman>. *megaman*'s required dependencies are *numpy*, *scipy*, and *scikit-learn*, but for optimal performance FLANN, *cython*, *pyang* and the C compiler *gcc* are also required. For unit tests and integration *megaman* depends on *nose*. The most recent *megaman* release can be installed along with its dependencies using the cross-platform `conda`¹ package manager:

```
$ conda install megaman --channel=conda-forge
```

Alternatively, *megaman* can be installed from source by downloading the source repository and running:

```
$ python setup.py install
```

With *nose* tests installed, unit tests can be run with:

```
$ make test
```

3. Logical structure and classes overview

embeddings The manifold learning algorithms are implemented in their own classes inheriting from a base class. Included are `SpectralEmbedding`, which implements *Laplacian Eigenmaps* (Belkin and Niyogi, 2002) and *Diffusion Maps* (Nadler et al., 2006), `L TSA` (Zhang and Zha, 2004), `LocallyLinearEmbedding` (Roweis and Saul, 2000), and `Isomap` (Bernstein et al., 2000). Geometric operations common to many or all embedding algorithms (such as computing distances, Laplacians) are implemented by the `Geometry` class. A `Geometry` object is passed or created inside every embedding class. In particular, `RiemannianMetric` produces the estimated Riemannian metric via the method of Perrault-Joncas and Meilä (2013). `eigendecomposition` (module) provides a unified (function) interface to the different eigendecomposition methods provided in *scipy*.

For background of manifold learning, as well as *megaman*'s design philosophy, please see McQueen et al. (2016).

4. Quick start

```
from megaman.geometry import Geometry
from megaman.embedding import SpectralEmbedding
from sklearn.datasets import make_swiss_roll
```

```
X = make_swiss_roll( 10000 ) # generate input data
radius = 1.1 # kernel bandwidth and for graph construction
# a Geometry object encapsulates generic geometric operations
geom = Geometry(
    adjacency_kwds = {'radius':3*radius}, # neighborhood radius
    adjacency_method = 'cyflann', # fast approximate neighbors
```

¹. Conda can be downloaded at <http://conda.pydata.org/miniconda.html>.

```

affinity_method = 'gaussian',          # Gaussian kernel
affinity_kwds = {'radius':radius},     # kernel bandwidth
laplacian_method = 'geometric')       # unbiased Laplacian
SE = SpectralEmbedding( # embedding algorithm & params
    n_components=2,                # embed into 2 dimensions
    eigen_solver='amg',           # eigensolver
    geom=geom)                    # pass the geometric information
Y = SE.fit_transform(X)           # perform embedding

```

The last two instructions are identical to their analogous instructions in `scikit-learn`. Full documentation is available from the `megaman` website at: <http://mmp2.github.io/megaman/>

5. Benchmarks

The one other popular comparable implementation of manifold learning algorithms is the `scikit-learn` package. To make the comparison as fair as possible, we choose the `SpectralEmbedding` method for the comparison, with radius-based neighborhoods and the *Locally-Optimized Block-Preconditioned Conjugate Gradient (lobpcg)* eigensolver. Note, too, that with the default settings, `scikit-learn` would perform slower than in our experiments.

We display total embedding time (including time to compute the graph G , the Laplacian matrix and the embedding 2) for `megaman` versus `scikit-learn`, as the number of samples N varies or the data dimension D varies (Figure 1). All benchmark computations were performed on a single desktop computer running Linux with 24.68GB RAM and a Quad-Core 3.07GHz Intel Xeon CPU. We use a relatively weak machine to demonstrate that our package can be reasonably used without high performance hardware. The experiments show that `megaman` scales considerably better than `scikit-learn`, even in the most favorable conditions for the latter: the memory footprint of `megaman` is smaller, even when `scikit-learn` uses sparse matrices internally. The advantages grow as the data size grows, whether it is w.r.t D or to N .

We also report run times on two real world data sets. The first is the `word2vec` data set ³ which contains feature vectors in 300 dimensions for about 3 million words and phrases, extracted from Google News. The vector representation was obtained via a multilayer neural network by Mikolov et al. (2013). The second data set contains galaxy spectra from the Sloan Digital Sky Survey ⁴ (Abazajian et al., 2009), preprocessed as described in Telford et al. (2016).

Dataset	Size N	Dimensions D	Distances	Embedding	R. metric	Total
Galaxies	0.7M	3750	190.5	8.9	0.1	199.5
Word2Vec	3M	300	107.9	44.8	0.6	153.3

Run time [min]

- For `megaman` we also compute the Riemannian metric estimate at each point; this time is negligible compared to the total time to obtain the embedding.
- The `word2vec` data used were from `GoogleNews-vectors-negative300.bin.gz` which can be downloaded from <https://code.google.com/archive/p/word2vec/>.
- The Sloan Digital Sky Survey data can be downloaded from www.sdss.org.

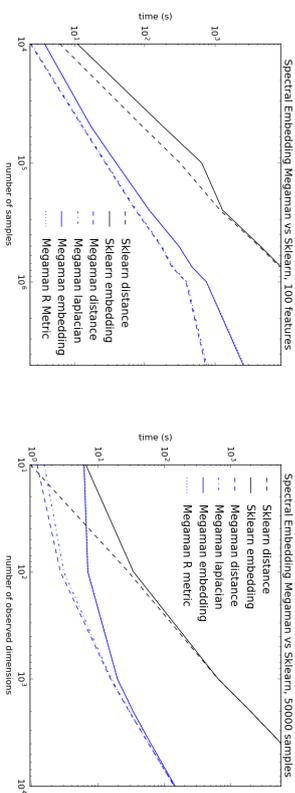

Figure 1: **Run time vs. data set size N** for fixed $D = 100$ (left) and **Run time vs. data set dimension D** for fixed $N = 50,000$ (right). The data is from a Swiss Roll (in 3 dimensions) with additional noise dimensions, embedded into $s = 2$ dimensions by the `SpectralEmbedding` algorithm. By $D = 10,000$ and $N = 1,000,000$ `scikit-learn` was unable to compute an embedding due to insufficient memory. All `megaman` run times (including time between distance and embedding) are faster than `scikit-learn`.

6. Conclusion

`megaman` puts in the hands of scientists and methodologists alike tools that enable them to apply state of the art manifold learning methods to data sets of realistic size. The package is extensible, modular, with an API familiar to `scikit-learn` users. Future development will be mainly in the direction of further scalability (Nystrom extension, parallelization) and expanding the data analytical tools (distance calculations, estimation of dimension, estimation of neighborhood radius, directed graph embedding).

We hope that by providing this package, non-linear dimension reduction will be benefit those who most need it: the practitioners exploring large scientific data sets.

Abstract

Multi-armed bandit problem is an important optimization game that requires an exploration-exploitation tradeoff to achieve optimal total reward. Motivated from industrial applications such as online advertising and clinical research, we consider a setting where the rewards of bandit machines are associated with covariates, and the accurate estimation of the corresponding mean reward functions plays an important role in the performance of allocation rules. Under a flexible problem setup, we establish asymptotic strong consistency and perform a finite-time regret analysis for a sequential randomized allocation strategy based on kernel estimation. In addition, since many nonparametric and parametric methods in supervised learning may be applied to estimating the mean reward functions but guidance on how to choose among them is generally unavailable, we propose a model combining allocation strategy for adaptive performance. Simulations and a real data evaluation are conducted to illustrate the performance of the proposed allocation strategy.

Keywords: contextual bandit problem, exploration-exploitation tradeoff, nonparametric regression, regret bound, upper confidence bound

1. Introduction

Following the seminal work by Robbins (1954), multi-armed bandit problems have been studied in multiple fields. The general bandit problem involves the following optimization game: A gambler is given l gambling machines, and each machine has an “arm” that the gambler can pull to receive the reward. The distribution of reward for each arm is unknown and the goal is to maximize the total reward over a given time horizon. If we define the regret to be the reward difference between the optimal arm and the pulled arm, the equivalent goal of the bandit problem is to minimize the total regret. Under a standard setting, it is assumed that the reward of each arm has fixed mean and variance throughout the time horizon of the game. Some of the representative work for standard bandit problem includes Lai and Robbins (1985), Berry and Fristedt (1985), Gittins (1989) and Auer et al. (2002).

See Cesa-Bianchi and Lugosi (2006) and Bubeck and Cesa-Bianchi (2012) for bibliographic remarks and recent overviews on bandit problems.

Different variants of the bandit problem motivated by real applications have been studied extensively in the past decade. One promising setting is to assume that the reward distribution of each bandit arm is associated with some common external covariate. More specifically, for an l -armed bandit problem, the game player is given a d -dimensional external covariate $x \in \mathbb{R}^d$ at each round of the game, and the expected reward of each bandit arm given x has a functional form $f_i(x)$, $i = 1 \dots l$. We call this variant **multi-armed bandit problem with covariates**, or MABC for its abbreviation (MABC is also referred to as CMAB for contextual multi-armed bandit problem in the literature). The consideration of external covariates is potentially important in applications such as personalized medicine. For example, before deciding which treatment arm to be assigned to a patient, we can observe the patient prognostic factors such as age, blood pressure or genetic information, and then use such information for adaptive treatment assignment for best outcome. It is worth noting that the consideration of external covariate is recently further generalized to partial monitoring by Bartók and Szepesvári (2012).

The MABC problems have been studied under both parametric and nonparametric frameworks with various types of algorithms. The first work in a parametric framework appears in Woodroofe (1979) under a somewhat restrictive setting. A linear response bandit problem in more flexible settings is recently studied under a minimax framework (Goldenshluger and Zeevi, 2009; Goldenshluger and Zeevi, 2013). Empirical studies are also reported for parametric UCB-type algorithms (e.g., Li et al., 2010). The regret analysis of a special linear setting is given in e.g., Auer (2002), Chu et al. (2011) and Agrawal and Goyal (2013), in which the linear parameters are assumed to be the same for all arms while the observed covariates can be different across different arms.

MABC problems with the nonparametric framework are first studied by Yang and Zhiu (2002). They show that with histogram or K -nearest neighbor estimation, the function estimation is uniformly strongly consistent, and consequently, the cumulative reward of their randomized allocation rule is asymptotically equivalent to the optimal cumulative reward. Their notion of reward strong consistency has been recently established for a Bayesian sampling method (May et al., 2012). Notably, under the Hölder smoothness condition and a margin condition, the recent work of Perchet and Rigollet (2013) establishes a regret upper bound by arm elimination algorithms with the same order as the minimax lower bound of a two-armed MABC problem (Rigollet and Zeevi, 2010). A different stream of work represented by, e.g., Langford and Zhang (2007) and Dudík et al. (2011) imposes neither linear nor any smoothness assumption on the mean reward function; instead, they consider a class of (finitely many) policies, and the cumulative reward of the proposed algorithms is compared to the best of the policies. Interested readers are also referred to Bubeck and Cesa-Bianchi (2012, Section 4) and its bibliography remarks for studies from numerous different perspectives.

Another important line of development in the bandit problem literature (closely related to, but different from the setting of MABC) is to consider the arm space as opposed to the covariate space in MABC. It is assumed that there are infinitely many arms, and at each round of the game, the player has the freedom to play one arm chosen from the arm space. Like MABC, the setting with the arm space can be studied from both parametric linear and

nonparametric frameworks. Examples of the linear parametric framework include Dani et al. (2008), Rusmevichentong and Tsiatis (2010) and Abbasi-Yadkori et al. (2011). Notable examples of the nonparametric framework (also known as the continuum-armed bandit problem) under the local or global Hölder and Lipschitz smoothness conditions are Kleinberg (2004), Auer et al. (2007), Kleinberg et al. (2007) and Brubeck et al. (2011). Abbasi-Yadkori (2009) studies a forced exploration algorithm over the arm space, which is applied to both parametric and nonparametric frameworks. Interestingly, Lu et al. (2010) and Slivkins (2011) consider both the arm space and the covariate space, and study the problem by imposing Lipschitz conditions on the joint space of arms and covariates.

Our work in this paper follows the nonparametric framework of MABC in Yang and Zhu (2002) and Rigollet and Zeevi (2010) with finitely many arms. One contribution in this work is to show that kernel methods enjoy estimation uniform strong consistency as well, which leads to strongly consistent allocation rules. Note that due to the dependence of the observations for each arm by the nature of the proposed randomized allocation strategy, it is difficult to apply the well-established kernel regression analysis results of i.i.d. or weak dependence settings (e.g., Devroye, 1978; Härdle and Uchmans, 1984; Hansen, 2008). New technical tools and arguments such as “chaining” are developed in this paper.

In addition, with the help of the Hölder smoothness condition, we provide a deeper understanding of the proposed randomized allocation strategy via a finite-time regret analysis. Compared with the result in Rigollet and Zeevi (2010) and Perchet and Rigollet (2013), our finite-time result remains sub-optimal in the minimax sense. Indeed, given Hölder smoothness parameter κ and total time horizon N , our expected cumulative regret upper bound is $O(N^{1-\frac{\kappa}{3+\kappa+d}})$ as compared to $O(N^{1-\frac{\kappa}{3+\kappa+d}})$ of Perchet and Rigollet (2013) (without the extra margin condition). The slightly sub-optimal rate can also be shown to apply to the histogram based randomized allocation strategy proposed in Yang and Zhu (2002). We tend to think that this rate is the best possible for these methods, reflecting to some extent the theoretical limitation of the randomized allocation strategy. In spite of this sub-optimality, our result explicitly shows both the bias-variance tradeoff and the exploration-exploitation tradeoff, which reflects the underlying nature of the proposed algorithm for the MABC problem. With a model combining strategy and dimension reduction technique to be introduced later, the kernel estimation based randomized allocation strategy can be quite flexible with wide potential practical use. Moreover, in Appendix A, we incorporate the kernel estimation into a UCB-type algorithm with randomization and show that its regret rate becomes minimax optimal up to a logarithmic factor.

One natural and interesting issue in the randomized allocation strategy in MABC is how to choose the modeling methods among numerous nonparametric and parametric estimators. The motivation of such a question shares the flavor of model aggregation/combining in statistical learning (see, e.g., Audibert, 2009; Rigollet and Tsybakov, 2012; Wang et al., 2014 and references therein). In the bandit problem literature, model combining is also quite relevant to the adversary bandit problem (e.g., Cesa-Bianchi and Lugosi, 2006; Auer et al., 2003). As a recent example, Mallard and Mimos (2011) study the history-dependent adversarial bandit to target the best among a pool of history class mapping strategies.

As an empirical solution to the difficulty in choosing the best estimation method for each arm in the randomized allocation strategy for MABC, we introduce a fully data-driven model combining technique motivated by the AFTER algorithm, which has shown success

both theoretically (Yang, 2004) and empirically (e.g., Zou and Yang, 2004; Wei and Yang, 2012). We integrate a model combining step by AFTER for reward function estimation into the randomized allocation strategy for MABC. Preliminary simulation results of combining various dimension reduction methods are reported in Qian and Yang (2012). However, no theoretical justification is given there. As another contribution of this paper, we present here new theoretical and numerical results on the proposed combining algorithm. In particular, the strong consistency of the model combining allocation strategy is established.

The rest of this paper is organized as follows. We present a general and flexible problem setup for MABC in Section 2. We describe the algorithm in Section 3 and study the strong consistency and the finite-time regret analysis of kernel estimation methods in Section 4. We also introduce a dimension reduction sub-procedure to handle the situation that the covariate dimension is high. The asymptotic results of the model combining allocation strategy is established in Section 5. We show in Section 6 and Section 7 the numerical performance of the proposed allocation strategy using simulations and a web-based news article recommendation data set, respectively. A brief conclusion is given in Section 8. The kernel estimation based UCB-type algorithm with randomization is described in Appendix A, all technical lemmas and proofs are given in Appendix B, and additional numerical results of the implemented algorithms are left in Appendix C.

2. Problem Setup

Suppose a bandit problem has l ($l \geq 2$) candidate arms to play. At each time point of the game, a d -dimensional covariate x is observed before we decide which arm to pull. Assume that the covariate x takes values in the hypercube $[0, 1]^d$. Also assume the (conditional) mean reward for arm i given x , denoted by $f_i(x)$, is uniformly upper bounded and unknown to game players. The observed reward is modeled as $f_i(x) + \epsilon_i$, where ϵ_i is a random error with mean 0.

Let $\{X_n, n \geq 1\}$ be a sequence of independent covariates generated from an underlying probability distribution P_X supported in $[0, 1]^d$. At each time $n \geq 1$, we need to apply a sequential allocation rule η to decide which arm to pull based on X_n and the previous observations. We denote the chosen arm by I_n and the observed reward of pulling the arm $I_n = i$ at time n by $Y_{i,n}$, $1 \leq i \leq l$. As a result, $Y_{n,n} = f_{I_n}(X_n) + \epsilon_n$, where ϵ_n is the random error with $E(\epsilon_n | X_n) = 0$. Different from Yang and Zhu (2002), the error ϵ_n may be dependent on the covariate X_n . Consider the simple scenario of online advertising where the response is binary (click: $Y = 1$; no click: $Y = 0$). Given an arm i and covariate $x \in [0, 1]$, suppose the mean reward function satisfies e.g., $f_i(x) = x$. Then it is easy to see that the distribution of the random error ϵ depends on x . In case of a continuous response, it is also well-known that heteroscedastic errors commonly occur.

By the previous definitions, we know that at time n , an allocation strategy chooses the arm I_n based on X_n and $(X_j, I_j, Y_{I_j,j})$, $1 \leq j \leq n-1$. To evaluate the performance of the allocation strategy, let $i^*(x) = \operatorname{argmax}_{1 \leq i \leq l} f_i(x)$ and $f^*(x) = f_{i^*(x)}(x)$ (any tie-breaking rule can be applied if there are ties). Without the knowledge of random error ϵ_j , the optimal performance occurs when $I_j = i^*(X_j)$, and the corresponding optimal cumulative reward given X_1, \dots, X_n can be represented as $\sum_{j=1}^n f^*(X_j)$. The cumulative mean reward of the applied allocation rule can be represented as $\sum_{j=1}^n f_{I_n}(X_j)$. Thus we can measure the

performance of an allocation rule η by the cumulative regret

$$R_n(\eta) = \sum_{j=1}^n (f^*(X_j) - f_{\eta_j}(X_j)).$$

We say the allocation rule η is strongly consistent if $R_n(\eta) = o(n)$ with probability one. Also, $R_n(\eta)$ is commonly used for finite-time regret analysis. In addition, define the per-round regret $r_n(\eta)$ by

$$r_n(\eta) = \frac{1}{n} \sum_{j=1}^n (f^*(X_j) - f_{\eta_j}(X_j)).$$

To maintain the readability for the rest of this paper, we use i only for bandit arms, j and n only for time points, r and s only for reward function estimation methods, and t and T only for the total number of times a specific arm is pulled.

3. Algorithm

In this section, we present the model-combining-based randomized allocation strategy. At each time $n \geq 1$, denote the set of past observations $\{(X_j, I_j, Y_{j,i}) : 1 \leq j \leq n-1\}$ by Z^n , and denote the arm i associated subset $\{(X_j, I_j, Y_{j,i}) : I_j = i, 1 \leq j \leq n-1\}$ by $Z^{i,n}$. For estimating the f_i 's, suppose we have m candidate regression estimation procedures (e.g., histogram, kernel estimation, etc.), and we denote the class of these candidate procedures by $\Delta = \{\delta_1, \dots, \delta_m\}$. Let $\hat{f}_{i,n,r}$ denote the regression estimate of procedure δ_r based on $Z^{i,n}$, and let $\hat{f}_{i,n}$ denote the weighted average of $\hat{f}_{i,n,r}$'s, $1 \leq r \leq m$, by the model combining algorithm to be given. Let $\{\pi_n, n \geq 1\}$ be a decreasing sequence of positive numbers approaching 0, and assume that $(l-1)\pi_n < 1$ for all $n \geq 1$. The model combining allocation strategy includes the following steps.

STEP 1. Initialize with forced arm selections. Give each arm a small number of applications. For example, we may pull each arm n_0 times at the beginning by taking $I_1 = 1$, $I_2 = 2, \dots, I_l = l, I_{l+1} = 1, \dots, I_{2l} = l, \dots, I_{(n_0-1)l+1} = 1, \dots, I_{n_0l} = l$.

STEP 2. Initialize the weights and the error variance estimates. For $n = n_0l + 1$, initialize the weights by

$$W_{i,n,r} = \frac{1}{m}, \quad 1 \leq i \leq l, 1 \leq r \leq m,$$

and initialize the error variance estimates by e.g.,

$$\hat{v}_{i,n,r} = 1, \hat{v}_{i,n} = 1, \quad 1 \leq i \leq l, 1 \leq r \leq m.$$

STEP 3. Estimate the individual functions f_i for $1 \leq i \leq l$. For $n = n_0l + 1$, based on the current data $Z^{i,n}$, obtain $\hat{f}_{i,n,r}$ using regression procedure δ_r , $1 \leq r \leq m$.

STEP 4. Combine the regression estimates and obtain the weighted average estimates

$$\hat{f}_{i,n} = \sum_{r=1}^m W_{i,n,r} \hat{f}_{i,n,r}, \quad 1 \leq i \leq l.$$

STEP 5. Estimate the best arm, select and pull. For the covariate X_n , define $\hat{i}_n = \operatorname{argmax}_{1 \leq i \leq l} \hat{f}_{i,n}(X_n)$ (If there is a tie, any tie-breaking rule may apply). Choose an arm, with probability $1 - (l-1)\pi_n$ for arm \hat{i}_n (the currently most promising choice) and with probability π_n for each of the remaining arms. That is,

$$I_n = \begin{cases} \hat{i}_n, & \text{with probability } 1 - (l-1)\pi_n, \\ i, & \text{with probability } \pi_n, i \neq \hat{i}_n, 1 \leq i \leq l. \end{cases}$$

Then pull the arm I_n to receive the reward $Y_{I_n,n}$.

STEP 6. Update the weights and the error variance estimates. For $1 \leq i \leq l$, if $i \neq I_n$, let $W_{i,n+1,r} = W_{i,n,r}$, $1 \leq r \leq m$, $\hat{v}_{i,n+1,r} = \hat{v}_{i,n,r}$, $1 \leq r \leq m$, and $\hat{v}_{i,n+1} = \hat{v}_{i,n}$. If $i = I_n$, update the weights and the error variance estimates by

$$W_{i,n+1,r} = \frac{W_{i,n,r} \exp\left(-\frac{(\hat{f}_{i,n,r}(X_n) - Y_{i,n})^2}{2\hat{v}_{i,n,r}}\right)}{\sum_{k=1}^m W_{i,n,k} \exp\left(-\frac{(\hat{f}_{i,n,k}(X_n) - Y_{i,n})^2}{2\hat{v}_{i,n,k}}\right)}, \quad 1 \leq r \leq m,$$

$$\hat{v}_{i,n+1,r} = \frac{\sum_{k=n_0l+1}^n (Y_{I_n,k} - \hat{f}_{i,n,k}(X_k))^2 I(I_k = i)}{\sum_{k=n_0l+1}^n 1} \vee \underline{v}, \quad 1 \leq r \leq m,$$

and

$$\hat{v}_{i,n+1} = \sum_{r=1}^m W_{i,n+1,r} \hat{v}_{i,n+1,r},$$

where $I(\cdot)$ is the indicator function and \underline{v} is a small positive constant (to ensure that $\hat{v}_{i,n+1,r}$ is nonzero). In practice, we set $\underline{v} = 10^{-16}$.

STEP 7. Repeat steps 3 - 6 for $n = n_0l + 2, n_0l + 3, \dots$, and so on.

In the allocation strategy above, step 1 and step 2 initialize the game and pull each arm the same number of times. Step 3 and step 4 estimate the reward function for each arm using several regression methods, and combine the estimates by a weighted average scheme. Clearly, the importance of these regression methods are differentiated by their corresponding weights. Step 5 performs an enforced randomization algorithm, which gives preference to the arm with the highest reward estimate. This type of arm randomization is also known as the ϵ -greedy algorithm. Step 6 is the key to the model combining algorithm, which updates the weights for the recently played arm. Its weight updating formula implies that if the estimated reward from a regression method turns out to be far away from the observed reward, we penalize this method by decreasing its weight, while if the estimated reward turns out to be accurate, we reward this method by increasing its weight. Note that our combining approach has few tuning parameters except for what is already included in the individual regression procedures.

4. Kernel Regression Procedures

In this section, we consider the special case that kernel estimation is used as the only modeling method. The primary goals include: 1) establishing the uniform strong consistency of kernel estimation under the proposed allocation strategy; 2) performing the finite-time regret analysis. To extend the applicability of kernel methods, a dimension reduction sub-procedure is described in Section 4.3.

4.1 Strong Consistency

We focus on the Nadaraya-Watson regression and study its strong consistency under the proposed allocation strategy. Given a regression method $\hat{y}_n \in \Delta$ and an arm i , we say it is strongly consistent in L_∞ norm for arm i if $\|\hat{f}_{i,n} - f_i\|_\infty \rightarrow 0$ a.s. as $n \rightarrow \infty$.

Assumption 0. *The errors satisfy a (conditional) moment condition that there exist positive constants v and c such that for all integers $k \geq 2$ and $n \geq 1$,*

$$E(|\varepsilon_n|^k | X_n) \leq \frac{k!}{2} v^2 c^{k-2}$$

almost surely.

Assumption 0 means that the error distributions, which could depend on the covariates, satisfy a moment condition known as refined Bernstein condition (e.g., Birgé and Massart, 1998, Lemma 8). Normal distribution, for instance, satisfies the condition. Bounded errors trivially meet the requirement. Therefore, Assumption 0 is met in a wide range of real applications, and will also be used in the next section for understanding strong consistency of model combining procedures. Note that heavy-tailed distributions are also possible for bandit problems (Bubeck et al., 2013).

Given a bandit arm $1 \leq i \leq l$, at each time point n , define $J_{i,n} = \{j : f_j = i, 1 \leq j \leq n-1\}$, the set of past time points at which arm i is pulled. Let $M_{i,n}$ denote the size of the set $J_{i,n}$. For each $u = (u_1, u_2, \dots, u_d) \in R^d$, define $\|u\|_\infty = \max\{|u_1|, |u_2|, \dots, |u_d|\}$. Consider two natural conditions on the mean reward functions and the covariate density as follows.

Assumption 1. *The functions f_i are continuous on $[0, 1]^d$ with $A =: \sup_{1 \leq i \leq l} \sup_{x \in [0, 1]^d} (f^*(x) - f_i(x)) < \infty$.*

Assumption 2. *The design distribution P_X is dominated by the Lebesgue measure with a continuous density $p(x)$ uniformly bounded above and away from 0 on $[0, 1]^d$; that is, $p(x)$ satisfies $\underline{c} \leq p(x) \leq \bar{c}$ for some positive constants $\underline{c} \leq \bar{c}$.*

In addition, consider a multivariate nonnegative kernel function $K(u) : R^d \rightarrow R$ that satisfies Lipschitz, boundedness and bounded support conditions.

Assumption 3. *For some constants $0 < \lambda < \infty$,*

$$|K(u) - K(u')| \leq \lambda \|u - u'\|_\infty$$

for all $u, u' \in R^d$.

Assumption 4. *There exist constants $L_1 \leq L$, $c_3 > 0$ and $c_4 \geq 1$ such that $K(u) = 0$ for $\|u\|_\infty > L$, $K(u) \geq c_3$ for $\|u\|_\infty \leq L_1$, and $K(u) \leq c_4$ for all $u \in R^d$.*

Let h_n denote the bandwidth, where $h_n \rightarrow 0$ as $n \rightarrow \infty$. The Nadaraya-Watson estimator of $f_i(x)$ is

$$\hat{f}_{i,n+1}(x) = \frac{\sum_{j \in J_{i,n+1}} Y_{j,i} K\left(\frac{x-X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x-X_j}{h_n}\right)}. \quad (1)$$

Theorem 1. *Suppose Assumptions 0-4 are satisfied. If the bandwidth sequence $\{h_n\}$ and the decreasing sequence $\{\pi_n\}$ are chosen to satisfy $h_n \rightarrow 0$, $\pi_n \rightarrow 0$ and*

$$\frac{nh_n^{2d}\pi_n^d}{\log n} \rightarrow \infty,$$

then the Nadaraya-Watson estimators defined in (1) are strongly consistent in L_∞ norm for the functions f_i .

Note that since checking L_∞ norm strong consistency of kernel methods is more challenging than that of histogram methods, new technical tools are necessarily developed to establish the strong consistency (as seen in the proof of Lemma 3 and Theorem 1 in Appendix B).

4.2 Finite-Time Regret Analysis

Next, we provide a finite-time regret analysis for the Nadaraya-Watson regression based randomized allocation strategy. To understand the regret cumulative rate, define a modulus of continuity $\omega(h; f_i)$ by

$$\omega(h; f_i) = \sup\{|f_i(x_1) - f_i(x_2)| : \|x_1 - x_2\|_\infty \leq h\}.$$

For technical convenience of guarding against the situation that the denominator of (1) is extremely small (which might occur with a non-negligible probability due to arm selection), in this subsection, we replace $K(\cdot)$ in (1) with the uniform kernel $I(\|u\|_\infty \leq L)$ when

$$\sum_{j \in J_{i,n+1}} K\left(\frac{x-X_j}{h_n}\right) < c_5 \sum_{j \in J_{i,n+1}} I(\|x-X_j\|_\infty \leq Lh_n) \quad (2)$$

for some small positive constant $0 < c_5 < 1$. Given $0 < \delta < 1$ and the total time horizon N , we define a special time point n_δ by

$$n_\delta = \min\left\{n > n_0^\delta : \sqrt{\frac{16v^2 \log(8LN^2/\delta)}{cn(2Lh_n)^d \pi_n}} \leq \frac{c_5 v^2}{c} \text{ and } \exp\left(-\frac{3cn(2Lh_n)^d \pi_n}{56}\right) \leq \frac{\delta}{4LN}\right\}. \quad (3)$$

Under the condition that $\lim_{n \rightarrow \infty} nh_n^d \pi_n / \log n = \infty$, we can see from (3) that $n_\delta/N \rightarrow 0$ as $N \rightarrow \infty$. As a result, if the total time horizon is long enough, we have $N > n_\delta$.

Theorem 2. *Suppose Assumptions 0-2 and 4 are satisfied and $\{\pi_n\}$ is a decreasing sequence. Assume $N > n_\delta$ and the kernel function is chosen as described in (2). Then with probability larger than $1 - 2\delta$, the cumulative regret satisfies*

$$R_N(\eta) < An_\delta + \sum_{n=n_\delta}^N \left(2 \max_{1 \leq i \leq l} \omega(Lh_n; f_i) + \frac{C_{N,\delta}}{\sqrt{nb_n^d \pi_n}} + (l-1)\pi_n \right) + A\sqrt{\frac{N}{2}} \log\left(\frac{1}{\delta}\right), \quad (4)$$

where $C_{N,\delta} = \sqrt{16c_d^2 v^2 \log(8lN^2/\delta)/c_d^2 \mathcal{L}(2L)^d}$.

It is interesting to see from the right hand side of (4) that the regret upper bound consists of several terms that make intuitive sense. The first term An_δ comes from the initial rough exploration. The second term has three essential components: $\max_{1 \leq i \leq l} \omega(Lh_n; f_i)$ is associated with the estimation bias, $C_{N,\delta}/\sqrt{nb_n^d \pi_n}$ conforms with the notion of estimation standard error, and $(l-1)\pi_n$ is the randomization error. The third term reflects the fluctuation of the randomization scheme. Such an upper bound explicitly illustrates both the bias-variance tradeoff and the exploration-exploitation tradeoff, which reflects the underlying nature of the proposed algorithm for the MABC problem.

Now we consider a smoothness assumption of the mean reward functions as follows.

Assumption 5. *There exist positive constants ρ and $\kappa \leq 1$ such that for each reward function f_i , the modulus of continuity satisfies*

$$\omega(h; f_i) \leq \rho h^\kappa.$$

Clearly, when $\kappa = 1$, Assumption 5 becomes Lipschitz continuity. As an immediate consequence of Theorem 2 and Assumption 5, we obtain the following result if we choose $h_n = \frac{1}{l} n^{-\frac{1}{3\kappa+d}}$ and $\pi_n = \frac{1}{l-1} n^{-\frac{1}{3\kappa+d/\kappa}}$.

Corollary 1. *Suppose the same conditions as in Theorem 2 are satisfied. Further assume Assumption 5 holds. Let $h_n = \frac{1}{l} n^{-\frac{1}{3\kappa+d}}$, $\pi_n = \frac{1}{l-1} n^{-\frac{1}{3\kappa+d/\kappa}}$ and $N > n_\delta$. Then with probability larger than $1 - 2\delta$, the cumulative regret satisfies*

$$R_N(\eta) < An_\delta + 2(2\rho + C_{N,\delta}^*) N^{1-\frac{1}{3\kappa+d/\kappa}} + A\sqrt{\frac{N}{2}} \log\left(\frac{1}{\delta}\right),$$

where $C_{N,\delta}^* = \sqrt{16c_d^2 v^2 (l-1) \log(8lN^2/\delta)/2^d c_d^2 \mathcal{L}}$.

In Corollary 1, the first term of the regret upper bound is dominated by the second term. Therefore, with high probability, the cumulative regret $R_N(\eta)$ increases at rate no faster than the order of $N^{1-\frac{1}{3\kappa+d/\kappa}} \log^{1/2} N$. This result can be seen more explicitly in Corollary 2, which gives an upper bound for the mean of $R_N(\eta)$. Note that by the definition of n_δ , the condition $N > n_\delta$ in Corollary 2 is satisfied if N is large enough.

Corollary 2. *Suppose the same conditions as in Theorem 2 are satisfied. Further assume Assumption 5 holds. Let $h_n = \frac{1}{l} n^{-\frac{1}{3\kappa+d}}$, $\pi_n = \frac{1}{l-1} n^{-\frac{1}{3\kappa+d/\kappa}}$ and $N > n_\delta$, where $\delta^* = N^{-\frac{1}{3\kappa+d/\kappa}}$. Then there exists a constant $C^* > 0$ (not dependent on N) such that the mean of cumulative regret satisfies*

$$ER_N(\eta) < C^* N^{1-\frac{1}{3\kappa+d/\kappa}} \log^{1/2} N.$$

As mentioned in Section 1, the derived regret cumulative rate in Corollary 2 is slightly slower than the minimax rate $N^{1-\frac{1}{3\kappa+d/\kappa}}$ obtained by Perchet and Rigollet (2013) (without assuming any extra margin condition). We tend to think this shows a limitation of the ϵ -greedy type approach. Nevertheless, with the help of the aforementioned model combining strategy along with the dimension reduction technique to be introduced in the next subsection, the kernel method based allocation can be quite flexible with potential practical use.

4.3 Dimension Reduction

When the covariate dimension is high, the Nadaraya-Watson estimation cannot be applied due to the curse of dimensionality. Next, we describe a dimension reduction sub-procedure to handle this situation, which is also discussed in Qian and Yang (2012). Different from the method there, a sparse dimension reduction technique will be included to handle cases with higher-dimensional covariates.

Recall that Z^n is the set of observations $\{(X_j, I_j, Y_{j,j}), 1 \leq j \leq n-1\}$, and $Z^{i,n}$ is the subset of Z^n where $I_j = i$. Then $M_{i,n}$ is the number of observations in $Z^{i,n}$. Let $X^{i,n}$ be the $M_{i,n} \times d$ design matrix consisting of all covariates in $Z^{i,n}$, and let $Y^{i,n} \in R^{M_{i,n}}$ be the observed reward vector corresponding to $X^{i,n}$. It is known that kernel methods do not perform well when the dimension of covariates is high. We want to apply some dimension reduction methods (see, e.g., Li, 1991; Chen et al., 2010) to $(X^{i,n}, Y^{i,n})$ first to obtain lower dimensional covariates before using kernel estimation.

Specifically, suppose for each arm i , there exists a reduction function $s_i : R^d \rightarrow R^{r_i}$ ($r_i < d$), such that $f_i(x) = g_i(s_i(x))$ for some function $g_i : R^{r_i} \rightarrow R$. Clearly, if the reduction function s_i is known, $s_i(x)$ can be treated like the new lower-dimensional covariate, with which the kernel methods can be applied to find the estimate of g_i , and hence f_i . However, s_i is generally unknown in practice, and it is necessary to first obtain the estimate of s_i . In addition, we assume that s_i is a linear reduction function in the sense that $s_i(x) = B_i^T x$, where $B_i \in R^{d \times r_i}$ is a dimension reduction matrix. It is worth mentioning that s_i is not unique, i.e., $s_i(x) = \tilde{A} B_i^T x$ is a valid reduction function for any full rank matrix $\tilde{A} \in R^{r_i \times r_i}$. Therefore, it suffices to estimate the dimension reduction subspace $\text{span}(B_i)$ spanned by the columns of B_i , and obtain $\hat{s}_{i,n}(x) = \hat{B}_{i,n}^T x$, where $\hat{B}_{i,n} \in R^{d \times r_i}$ is one basis matrix of the estimated subspace at time n , and $\hat{s}_{i,n}$ is the estimate of s_i .

Dimension reduction methods such as sliced inverse regression (also known as SIR, see Li, 1991) can be applied to $(X^{i,n}, Y^{i,n})$ to obtain $\hat{B}_{i,n}$. In practice, it is convenient to have $X^{i,n}$ work on the standardized scale (i.e., the sample mean is zero and the sample covariance matrix is the identity matrix; Li, 1991; Cook, 2007). Suppose the Nadaraya-Watson estimation is used with $K_j(u) : R^{r_i} \rightarrow R$ being a multivariate symmetric kernel function for arm i . Recall $J_{i,n} = \{j : I_j = i, 1 \leq j \leq n-1\}$ is the set of past time points at which arm i is pulled. Then, we can obtain $\hat{f}_{i,n}$ with the following steps.

Step 1. Transform $X^{i,n}$ to the standardized-scale matrix $X_*^{i,n}$: transform the original covariates X_j 's by $X_j^* = \hat{\Sigma}_{i,n}^{-1/2}(X_j - \bar{X}_{i,n})$ for every $j \in J_{i,n}$, where $\bar{X}_{i,n}$ and $\hat{\Sigma}_{i,n}$ are the sample mean vector and the sample covariance matrix of $X^{i,n}$, respectively.

Step 2. Apply a dimension reduction method to $(\hat{X}_{i,n}^{*T}, Y^{i,n})$ to obtain the estimated $d \times r_i$ dimension reduction matrix $B_{i,n}^*$, where $B_{i,n}^{*T} B_{i,n}^* = I_{r_i}$. For example, we can apply SIR (Li, 1991) to obtain $\hat{B}_{i,n}^*$ by using the MATLAB package LDR (Cook et al., 2011, available at <https://sites.google.com/site/11lianarforzani/ldr-package>)

Step 3. Given $x \in R^d$, let $x^* = \hat{\Sigma}_{i,n}^{-1/2}(x - \bar{X}_{i,n})$ be the transformed x at the standardized scale. The Nadaraya-Watson estimator of $f_i(x)$ is

$$\hat{f}_{i,n}(x) = \frac{\sum_{j \in I_{i,n}} Y_{i,j} K_i \left(\frac{\hat{B}_{i,n}^{*T} x^* - \hat{B}_{i,n}^{*T} X_j^*}{h_{n-1}} \right)}{\sum_{j \in I_{i,n}} K_i \left(\frac{\hat{B}_{i,n}^{*T} x^* - \hat{B}_{i,n}^{*T} X_j^*}{h_{n-1}} \right)}. \quad (5)$$

In addition to estimating the reward function for each arm, it is sometimes of interest to know which variables contribute to the reward for each arm, and some sparse dimension reduction techniques can be applied. In particular, Chen et al. (2010) propose the coordinate-independent sparse estimation (CISE) to give sparse dimension reduction matrix such that the estimated coefficients of some predictors are zero for all reduction directions (i.e., some row vectors in $\hat{B}_{i,n}^*$ become 0). When the SIR objective function is used, the corresponding CISE method is denoted by CIS-SIR. To obtain $\hat{B}_{i,n}^*$ in Step 2 above using CIS-SIR, we can apply the MATLAB package CISE (Chen et al., 2010, available at <http://www.stat.nyu.edu/~sgf-stackx/>).

The simulation example in Section 6 and the real data example in Section 7 both use the algorithms described here. The simulation example is implemented in MATLAB and the real data example is implemented in C++. The major source code illustrating the proposed algorithms is available upon request.

5. Strong Consistency in Model Combining Based Allocation

Next, we consider the general case that multiple function estimation methods are used for model combining. In general, it is technically difficult to verify strong consistency in L_∞ norm for a regression method. Also, practically, it is likely that some methods may give good estimation for only a subset of the arms, but performs poorly for the rest. Not knowing which methods work well for which arms, we proposed the combining algorithm in Section 3 to address this issue. We will show that even in the presence of bad-performing regression methods, the strong consistency of our allocation strategy still holds if for any given arm, there is at least one good regression method included for combining.

Given an arm i , let $N_t^{(i)} = \inf\{n : \sum_{j=n_0+1}^n I(U_j = i) \geq t\}$, $t \geq 1$, be the earliest time point where arm i is pulled exactly t times after the forced sampling period. For notation brevity, we use N_t instead of $N_t^{(i)}$ in the rest of this section. Consider the assumptions as follows.

Assumption A. Given any arm $1 \leq i \leq l$, the candidate regression procedures in Δ can be categorized into one of the two subsets denoted by Δ_{i1} (non-empty) and Δ_{i2} . All procedures

in Δ_{i1} are strongly consistent in L_∞ norm for arm i , while procedures in Δ_{i2} are less well-performing in the sense that for each procedure δ_s in Δ_{i2} , there exist a procedure δ_r in Δ_{i1} and some constants $b > 0.5$, $c_1 > 0$ such that

$$\liminf_{T \rightarrow \infty} \frac{\sum_{t=1}^T (\hat{f}_{i,N_t, s}(X_{N_t}) - f_i(X_{N_t}))^2 - \sum_{t=1}^T (\hat{f}_{i,N_t, r}(X_{N_t}) - f_i(X_{N_t}))^2}{\sqrt{T}(\log T)^b} > c_1$$

with probability one.

Assumption B. The mean functions satisfy $A = \sup_{1 \leq i \leq l} \sup_{x \in [0,1]^d} (f_i^*(x) - f_i(x)) < \infty$.

Assumption C. $\|\hat{f}_{i,n,r} - f_i\|_\infty$ is upper bounded by a constant c_2 for all $1 \leq i \leq l$, $n \geq n_0 l + 1$ and $1 \leq r \leq m$.

Assumption D. The variance estimates $\hat{v}_{i,n}$ are upper bounded by a positive constant q with probability one for all $1 \leq i \leq l$ and $n \geq n_0 l + 1$.

Assumption E. The sequence $\{\pi_n, n \geq 1\}$ satisfies that $\sum_{n=1}^\infty \pi_n$ diverges.

Note that Assumption A is automatically satisfied if all the regression methods happen to be strongly consistent (i.e., Δ_{i2} is empty). When a bad-performing method does exist, Assumption A requires that the difference of the mean square errors between a good-performing method and a bad-performing method decreases slower than the order of $(\log T)^b / \sqrt{T}$. If a parametric method δ_s in Δ is based on a wrong model, $\sum_{t=1}^T (\hat{f}_{i,N_t, s}(X_{N_t}) - f_i(X_{N_t}))^2$ is of order T , and then the requirement in Assumption A is met. For an inefficient nonparametric method, the enlargement of the mean square error by the order larger than $(\log T)^b / \sqrt{T}$ is natural to expect. Assumption B is a natural condition in the context of our bandit problem. Assumptions C and D are immediately satisfied if the response is bounded and the estimator is, e.g., a weighted average of some previous observations. Assumption E ensures that N_t is finite as shown in Lemma 5 in the Appendix. As implied in Lemma 5, if we are allowed to play the game infinitely many times, each arm will be pulled beyond any given integer. This guarantees that each ‘‘inferior’’ arm can be pulled reasonably often to ensure enough exploration.

Theorem 3. Under Assumption 0 and Assumptions A-E, the model combining allocation strategy is strongly consistent.

With Theorem 3, one is safe to explore different models or methods in estimating the mean reward functions that may or may not work well for some or all arms. The resulting per-round regret can be much improved if good methods (possibly different for different arms) are added in.

6. Simulations

In this section, we intend to illustrate the dimension reduction function estimation procedures described in Section 4.3 for bandit problem with multivariate covariates. Two

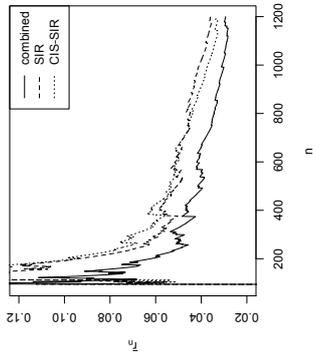

Figure 1: Averaged per-round regret from combining SIR and CIS-SIR.

readily available MATLAB packages for dimension reduction are used: LDR package (Cook et al., 2011) for SIR, and CJSE package (Chen et al., 2010) for CIS-SIR. The kernel used is the Gaussian kernel

$$K(t) = \exp\left(-\frac{\|t\|_2^2}{2}\right).$$

We consider a three-arm bandit model with $d = 10$. Assume that at each time n , the covariate is $X_n = (X_{n1}, X_{n2}, \dots, X_{nd})^T$, and X_{ni} 's ($i = 1, \dots, d$) are i.i.d random variables from $\text{uniform}(0,1)$. Assume the error $\epsilon_n \sim 0.5N(0,1)$. Consider the mean reward functions

$$\begin{aligned} f_1(X_n) &= 0.5(X_{n1} + X_{n2} + X_{n3}), \\ f_2(X_n) &= 0.4(X_{n3} + X_{n4})^2 + 1.5\sin(X_{n1} + 0.25X_{n4}), \\ f_3(X_n) &= \frac{2X_{n3}}{0.5 + (1.5 + X_{n3} + X_{n4})}. \end{aligned}$$

We set the reduction dimensions for the three arms by $r_1 = 1$, $r_2 = 2$ and $r_3 = 2$. Given the time horizon $N = 1200$, the first 90 rounds of the game are the forced sampling period. Let the ‘‘inferior’’ arm sampling probability be $\pi_n = \frac{1}{(\log_2 n)^2}$, and the kernel bandwidth for arm i be $h = n^{-1/(2+r_i)}$, $i = 1, 2, 3$. Dimension reduction methods SIR, CIS-SIR as well as their combining strategy are run separately, and their per-round regret r_n is summarized in Figure 1 (right panel), which shows that the combining strategy performs the best. Since the second arm ($i = 2$) is played the most (for SIR, 1022 times; for CIS-SIR, 1026 times), we show the estimated dimension reduction matrix for the second arm at the last time point $n = N$ in Table 1. As expected, CIS-SIR results in a sparse dimension reduction matrix with rows 1, 3 and 4 being non-zero.

It is worth mentioning that in the simulation above, we assume the reduction dimensions for all arms are already known. In cases where the reduction dimensions are unknown, we may apply model selection procedures to choose them, which will be investigated in the future.

Table 1: Comparing the estimated dimension reduction matrix $\hat{B}_{2,N}^*$ for the second arm between SIR and CIS-SIR.

	SIR	CIS-SIR
1	-0.658	-0.599
2	0.011	-0.091

7. Web-Based Personalized News Article Recommendation

In this section, we use the Yahoo! Front Page Today Module User Click Log data set (Yahoo! Academic Relations, 2011) to evaluate the proposed allocation strategy. The complete data set contains about 46 million web page visit interaction events collected during the first ten days in May 2009. Each of these events has four components: (1) five variables constructed from the Yahoo! front page visitor’s information; (2) a pool of about 10-14 editor-picked news articles; (3) one article actually displayed to the visitor (it is selected uniformly at random from the article pool); (4) the visitor’s response to the selected article (no click: 0, click: 1). Since different visitors may have different preferences for the same article, it is reasonable to believe that the displayed article should be selected based on the visitor associated variables. If we treat the articles in the pool as the bandit arms, and the visitor associated variables as the covariates, this data set provides the necessary platform to test a MABC algorithm.

One remaining issue before algorithm evaluation is that the complete data set is long-term in nature and the pool of articles is dynamic, i.e., some outdated articles are dropped out as people’s interest in these articles fades away, and some breaking-news articles can appear and be added to the pool. Our current problem setup, however, assumes stationary mean reward functions with a fixed set of arms. To avoid introducing biased evaluation results, we focus on short-term performance where people’s interest on a particular article does not change too much and the pool of articles remains stable. Therefore, we consider only one day’s data (May 1, 2009). Also, we choose four articles ($l = 4$) as the candidate bandit arms (article id 109511 - 109514), and keep only the events where the four articles are included in the article pool and one of the four articles is actually displayed to the visitor. A similar screening treatment of the data set is used in May et al. (2012) for MABC algorithm evaluation purposes. With the above, we obtain a reduced data set containing 452,189 interaction events for subsequent use.

Another challenge in evaluating a MABC algorithm comes from the intrinsic nature of bandit problem: for every visitor interaction event, only one article is displayed, and we only have this visitor’s response to the displayed article, while his/her response to other articles is not available, causing a difficulty if the actually displayed article does not match the article selected by a MABC algorithm. To overcome this issue caused by limited feedback, we apply the unbiased offline evaluation method proposed by Li et al. (2010). Briefly, for each encountered event, the MABC algorithm uses the previous “valid” data set (history) to estimate the mean reward functions and propose an arm to pull. If the proposed arm matches the actually displayed arm, this event is kept as a “valid” event, and the “valid” data set (history) is updated by adding this event. On the other hand, if the proposed arm does not match the displayed arm, this event is ignored, and the “valid” data set (history) is unchanged. This process is run sequentially over all the interaction events to generate the final “valid” data set, upon which a MABC algorithm can be evaluated by calculating the click-through rate (CTR, the proportion of times a click is made). Under the fact that in each interaction event, the displayed arm was selected uniformly at random from the pool, it can be argued that the final “valid” data set is like being obtained from running the MABC algorithm over a random sample of the underlying population.

With the reduced data set and the unbiased offline evaluation method, we evaluate the performance of the following algorithms.

random: an arm is selected uniformly at random.

ϵ -greedy: The randomized allocation strategy is run naively without consideration of covariates. A simple average is used to estimate the mean reward for each arm.

SIR-kernel: The randomized allocation strategy is run using SIR-kernel method to estimate the mean reward functions. Three sequences of bandwidth choices are considered: $h_{n1} = n^{-1/6}$, $h_{n2} = n^{-1/8}$ and $h_{n3} = n^{-1/10}$.

model combining: Model combining based randomized allocation strategy described in Section 3 is run with SIR-kernel method ($h_{n3} = n^{-1/10}$) and the naive simple average method (ϵ -greedy) as two candidate modeling methods.

The ϵ -greedy, SIR-kernel and model combining algorithms described above all take the first 1000 time points to be the forced sampling stage and use $\pi_n = n^{-1/4}/6$. Also, for any given arm, the SIR-kernel method limits the history time window for reward estimation to have maximum sample size of 10,000 (larger history sample size does not give us noticeable difference in performance). In addition, we consider the following parametric algorithm:

LinUCB: LinUCB employs Bayesian logistic regression to estimate the mean reward functions. The detailed implementation procedures are described in Algorithm 3 of Chapelle and Li (2011).

Each of the algorithms listed above is run 100 times over the reduced data set with the unbiased offline evaluation method. For each of the 100 runs, the algorithm starts at a position randomly chosen from the first 10,000 events of the reduced data set. The resulting CTRs are divided by the mean CTR of the random algorithm to give the normalized CTRs, and their boxplots are shown in Fig. 2.

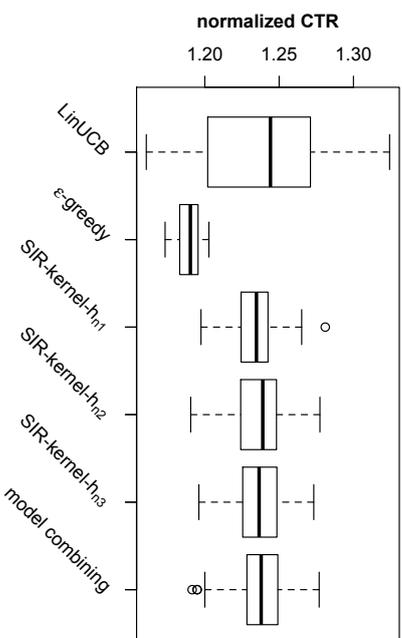

Figure 2: Boxplots of normalized CTRs of various algorithms on the news article recommendation data set. Algorithms include (from left to right): LinUCB, ϵ -greedy, SIR-kernel (h_{n1}), SIR-kernel (h_{n2}), SIR-kernel (h_{n3}), model combining with SIR-kernel (h_{n3}) and ϵ -greedy. CTRs are normalized with respect to the random algorithm.

It appears that the SIR-kernel methods with different candidate bandwidth sequences have very similar performance. The naive ϵ -greedy algorithm, however, clearly underperforms due to its failure to take advantage of the response-covariate association. When the naive simple average estimation (ϵ -greedy) is used together with SIR-kernel method (h_{n3}) in the model combining algorithm, the overall performance does not seem to deteriorate with the existence of this naive estimation method, showing once again that the model combining algorithm allows us to safely explore new modeling methods by automatically selecting the appropriate modeling candidate. Given that the covariates in the news article recommendation data set are constructed with logistic regression related methods (Li et al., 2010), it is satisfactory to observe that SIR-kernel algorithm can have similar performance with relatively small variation when compared with the LinUCB algorithm.

8. Conclusions

In this work, we study the kernel estimation based randomized allocation strategy in a flexible setting for MABC that works for both continuous and discrete response, and establish both the strong consistency and a finite-time regret upper bound. Allowing dependence of the covariate and the error, we rely on new technical tools to add kernel methods to the family of strongly consistent methods, which can potentially improve estimation efficiency for smooth reward functions. Although the finite-time regret upper bound is slightly sub-

optimal for the investigated randomized allocation strategy in the minimax sense (Perchet and Rigollet, 2013), the flexibility in estimation of the mean reward functions can be very useful in applications. In that regard, we integrate a model combination technique into the allocation strategy to share the strengths of different statistical learning methods for reward function estimation. It is shown that with the proposed data-driven combination of estimation methods, our allocation strategy can remain strongly consistent.

In Appendix A, we also show that by resorting to an alternative UCB-type criterion for arm comparison, the regret rate of the modified randomized allocation algorithm is improved to be minimax optimal up to a logarithmic factor. It remains to be seen if the UCB modification can be incorporated to construct a model combination algorithm with adaptive minimax rate. Moreover, as an important open question raised by a reviewer, it would be interesting to see whether the cumulative regret of the model combination strategy is comparable to that of the candidate model with the smallest regret in the sense of an oracle-type inequality similar to that of, e.g., Audibert (2009).

Acknowledgments

We would like to thank the Editor and two anonymous referees for their very constructive comments that help improving this manuscript significantly. This research was supported by the US NSF grant DMS-1106576

Appendix A. A Kernel Estimation Based UCB Algorithm

In this section, we modify the randomized allocation strategy to give a UCB-type algorithm that results in an improved rate of the cumulative regret. Similar to Section 4, we consider the Nadaraya-Watson estimation as the only modeling method, that is,

$$\hat{f}_{i,n}(x) = \frac{\sum_{j \in I_{i,n}} Y_{i,j} K\left(\frac{x-X_j}{h_{n-1}}\right)}{\sum_{j \in I_{i,n}} K\left(\frac{x-X_j}{h_{n-1}}\right)}. \quad (6)$$

We slightly revise step 5 of the proposed randomized allocation strategy:

STEP 5'. Estimate the best arm, select and pull. For the covariate X_n , define

$$\tilde{i}_n = \operatorname{argmax}_{1 \leq i \leq l} \hat{f}_{i,n}(X_n) + U_{i,n}(X_n),$$

where $U_{i,n}(x) = \sqrt{\frac{\tilde{c}(\log N) \sum_{j \in I_{i,n}} K^2\left(\frac{x-X_j}{h_{n-1}}\right)}{\sum_{j \in I_{i,n}} K\left(\frac{x-X_j}{h_{n-1}}\right)}}$ and \tilde{c} is some positive constant (if there is a tie, any tie-breaking rule may be applied). Choose an arm, with probability $1 - (l-1)\pi_n$ for arm \tilde{i}_n (the currently most promising choice) and with probability π_n for each of the remaining arms. That is,

$$I_n = \begin{cases} \tilde{i}_n, & \text{with probability } 1 - (l-1)\pi_n, \\ i, & \text{with probability } \pi_n, i \neq \tilde{i}_n, 1 \leq i \leq l. \end{cases}$$

Clearly, (6) shows a UCB-type algorithm that naturally extends from the UCB1 of Auer et al. (2002) and the UCBogram of Rigollet and Zeevi (2010). Indeed, given the uniform kernel $K(u) = I(\|u\|_\infty \leq 1)$, we have $U_{i,n}(x) = \tilde{c} \sqrt{\frac{\log N}{N_{i,n}(x)}}$, where $N_{i,n}(x)$ is the number of times arm i gets pulled inside the cube that centers at x with bin width $2h_{n-1}$. For presentation clarity, we assume $K(\cdot)$ is the uniform kernel, but the results can be generalized to kernel functions that satisfy Assumption 4. As shown in Theorem 4 below, the finite-time regret upper bound of the UCB-type algorithm achieves the minimax rate up to a logarithmic factor.

Theorem 4. *Suppose Assumptions 0-1 hold and the uniform kernel function is used. Then for the modified algorithm, if $n_0 = lN h^\kappa$, $\tilde{c} > \max\{2\sqrt{3}v, 12c\}$, $h = h_n = 1/\lceil(\frac{N}{\log N})^{\frac{1}{2\kappa+4}}\rceil$ and $\pi_n \leq \frac{1}{l} \wedge \frac{1}{\tilde{c}} \wedge \frac{1}{n} (\frac{\log N}{n})^{\frac{1}{2\kappa+4}}$, the mean of cumulative regret satisfies*

$$ER_N(\eta) < \tilde{C}^* N^{1-\frac{1}{2\kappa+4}} (\log N)^{\frac{1}{2\kappa+4}}. \quad (7)$$

It is worth noting that despite the seemingly minor algorithmic modification, the proof techniques used by Theorem 2 and Theorem 4 are quite different. The key difference is that: the UCB-type criterion enables us to provide upper bounds (with high probability) for the number of times the ‘‘inferior’’ arms are selected, and these bounds are dependent on the reward difference between the ‘‘optimal’’ and the ‘‘inferior’’ arms; for the algorithm before modification, we have to rely on studying the estimation errors of the reward functions and the UCB-type arguments do not apply. It is not settled yet as to whether the suboptimal rate of the ϵ -greedy type algorithm is intrinsic to the method or is the limitation of the proof techniques. But we tend to think that the rate given for the ϵ -greedy type algorithm is intrinsic to the method. Also, although the UCB-type algorithm leads to an improved regret rate, it is not yet clear how it could be used to construct a model combination algorithm.

Appendix B. Lemmas and Proofs

B.1 Proof of Theorem 1

Lemma 1. *Suppose $\{\mathcal{F}_j, j = 1, 2, \dots\}$ is an increasing filtration of σ -fields. For each $j \geq 1$, let ε_j be an \mathcal{F}_{j+1} -measurable random variable that satisfies $E(\varepsilon_j | \mathcal{F}_j) = 0$, and let T_j be an \mathcal{F}_j -measurable random variable that is upper bounded by a constant $C > 0$ in absolute value almost surely. If there exist positive constants v and c such that for all $k \geq 2$ and $j \geq 1$, $E(|\varepsilon_j|^k | \mathcal{F}_j) \leq kv^2 c^{k-2}/2$, then for every $\epsilon > 0$ and every integer $n \geq 1$,*

$$P\left(\sum_{j=1}^n T_j \varepsilon_j \geq n\epsilon\right) \leq \exp\left(-\frac{n\epsilon^2}{2C^2(v^2 + c\epsilon/C)}\right).$$

Proof of Lemma 1. Note that

$$\begin{aligned} P\left(\sum_{j=1}^n T_j \varepsilon_j \geq n\epsilon\right) &\leq e^{-tn\epsilon} E\left[\exp\left(t\sum_{j=1}^n T_j \varepsilon_j\right)\right] \\ &= e^{-tn\epsilon} E\left[E\left(\exp\left(t\sum_{j=1}^n T_j \varepsilon_j\right) \middle| \mathcal{F}_n\right)\right] \\ &= e^{-tn\epsilon} E\left[\exp\left(t\sum_{j=1}^{n-1} T_j \varepsilon_j\right) E(e^{tT_n \varepsilon_n} \middle| \mathcal{F}_n)\right]. \end{aligned}$$

By the moment condition on ε_n and Taylor expansion, we have

$$\begin{aligned} \log E(e^{tT_n \varepsilon_n} \middle| \mathcal{F}_n) &\leq E(e^{tT_n \varepsilon_n} \middle| \mathcal{F}_n) - 1 \\ &\leq tT_n E(\varepsilon_n \middle| \mathcal{F}_n) + \sum_{k=2}^{\infty} \frac{t^k |T_n|^k}{k!} E(|\varepsilon_n|^k \middle| \mathcal{F}_n) \\ &\leq \frac{v^2 C^2 t^2}{2} (1 + cCt + (cCt)^2 + \dots) \\ &= \frac{v^2 C^2 t^2}{2(1 - cCt)} \end{aligned}$$

for $t < 1/cC$. Thus, it follows by induction that

$$\begin{aligned} P\left(\sum_{j=1}^n T_j \varepsilon_j \geq n\epsilon\right) &\leq \exp\left(-tn\epsilon + \frac{nu^2 C^2 t^2}{2(1 - cCt)}\right) \\ &\leq \exp\left(-\frac{n\epsilon^2}{2C^2(v^2 + c\epsilon/C)}\right), \end{aligned}$$

where the last inequality is obtained by minimization over t . This completes the proof of Lemma 1. \square

Lemma 2. *Suppose $\{\mathcal{F}_j; j = 1, 2, \dots\}$ is an increasing filtration of σ -fields. For each $j \geq 1$, let W_j be an \mathcal{F}_j -measurable Bernoulli random variable whose conditional success probability satisfies*

$$P(W_j = 1 \middle| \mathcal{F}_{j-1}) \geq \beta_j$$

for some $0 \leq \beta_j \leq 1$. Then given $n \geq 1$,

$$P\left(\sum_{j=1}^n W_j \leq \sum_{j=1}^n \beta_j / 2\right) \leq \exp\left(-\frac{3\sum_{j=1}^n \beta_j}{28}\right).$$

Lemma 2 is known as an extended Bernstein inequality (see, e.g., Yang and Zhu (2002), Section A.4.). For completeness, we give a brief proof here.

Proof of Lemma 2. Suppose \tilde{W}_j , $1 \leq j \leq n$ are independent Bernoulli random variables with success probability β_j , and are assumed to be independent of \mathcal{F}_n . By Bernstein's inequality (e.g., Cesa-Bianchi and Lugosi, 2006, Corollary A.3),

$$P\left(\sum_{j=1}^n \tilde{W}_j \leq \left(\sum_{j=1}^n \beta_j\right) / 2\right) \leq \exp\left(-\frac{3\sum_{j=1}^n \beta_j}{28}\right).$$

Also, $\sum_{j=1}^n W_j$ is stochastically no smaller than $\sum_{j=1}^n \tilde{W}_j$, that is, for every t , $P(\sum_{j=1}^n W_j > t) \geq P(\sum_{j=1}^n \tilde{W}_j > t)$. Indeed, noting that $P(W_n > t \middle| \mathcal{F}_{n-1}) \geq P(\tilde{W}_n > t)$ for every t , we have

$$P(W_1 + \dots + W_n > t \middle| \mathcal{F}_{n-1}) \geq P(W_1 + \dots + W_{n-1} + \tilde{W}_n > t \middle| \mathcal{F}_{n-1}).$$

Similarly, by $P(W_{n-1} > t \middle| \mathcal{F}_{n-2}) \geq P(\tilde{W}_{n-1} > t)$ for every t and the independence of \tilde{W}_j 's,

$$P(W_1 + \dots + W_{n-1} + \tilde{W}_n > t \middle| \mathcal{F}_{n-2}, \tilde{W}_n) \geq P(W_1 + \dots + W_{n-2} + \tilde{W}_{n-1} + \tilde{W}_n > t \middle| \mathcal{F}_{n-2}, \tilde{W}_n).$$

Continuing the process above, we can see that $P(\sum_{j=1}^n W_j > t) \geq P(\sum_{j=1}^n \tilde{W}_j > t)$ holds. \square

Lemma 3. *Under the settings of the kernel estimation in Section 4.1, given arm i and a cube $A \subset [0, 1]^d$ with side width h , if Assumptions 0, 3 and 4 are satisfied, then for any $\epsilon > 0$,*

$$\begin{aligned} &P\left(\sup_{x \in A} \sum_{j \in J_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) > \frac{n\epsilon}{1 - 1/\sqrt{2}}\right) \\ &\leq \exp\left(-\frac{n\epsilon^2}{4c_2^2 v^2}\right) + \exp\left(-\frac{n\epsilon}{4c_4 c}\right) + \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{2^k n\epsilon^2}{\lambda^2 v^2}\right) + \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{2^{k/2} n\epsilon}{2\lambda c}\right). \end{aligned}$$

Proof of Lemma 3. At each time point j , let $W_j = 1$ if arm i is pulled (i.e., $I_j = i$), and $W_j = 0$ otherwise. Denote $G(x) = \sum_{j=1}^n \varepsilon_j W_j K\left(\frac{x - X_j}{h_n}\right)$. Then, to find an upper bound for $P(\sup_{x \in A} G(x) > n\epsilon/(1 - 1/\sqrt{2}))$, we use a ‘‘chaining’’ argument. For each $k \geq 0$, let $\gamma_k = h_n/2^k$, and we can partition the cube A into 2^{kd} bins with bin width γ_k . Let F_k denote the set consisting of the center points of these 2^{kd} bins. Clearly, $\text{card}(F_k) = 2^{kd}$, and F_k is a $\gamma_k/2$ -net of A in the sense that for every $x \in A$, we can find a $x' \in F_k$ such that $\|x - x'\|_{\infty} \leq \gamma_k/2$. Let $\tau_k(x) = \text{argmin}_{x' \in F_k} \|x - x'\|_{\infty}$ be the closest point to x in the net F_k . With the sequence F_0, F_1, F_2, \dots of $\gamma_0/2, \gamma_1/2, \gamma_2/2, \dots$ nets in A , it is easy to see that for every $x \in A$, $\|\tau_k(x) - \tau_{k-1}(x)\|_{\infty} \leq \gamma_k/2$ and $\lim_{k \rightarrow \infty} \tau_k(x) = x$. Thus, by the continuity of the kernel function, we have $\lim_{k \rightarrow \infty} G(\tau_k(x)) = G(x)$. It follows that

$$G(x) = G(\tau_0(x)) + \sum_{k=1}^{\infty} [G(\tau_k(x)) - G(\tau_{k-1}(x))].$$

Thus,

$$\begin{aligned}
& P\left(\sup_{x \in A} G(x) > \frac{n\epsilon}{1-1/\sqrt{2}}\right) \\
&= P\left(\sup_{x \in A} \{G(\tau_0(x)) + \sum_{k=1}^{\infty} [G(\tau_k(x)) - G(\tau_{k-1}(x))]\} > \sum_{k=0}^{\infty} \frac{n\epsilon}{2^{k/2}}\right) \\
&\leq P\left(\sup_{x \in A} G(\tau_0(x)) > n\epsilon\right) + \sum_{k=1}^{\infty} P\left(\sup_{x \in A} [G(\tau_k(x)) - G(\tau_{k-1}(x))] > \frac{n\epsilon}{2^{k/2}}\right) \\
&\leq P\left(\sup_{x \in F_0} G(x) > n\epsilon\right) + \sum_{k=1}^{\infty} P\left(\sup_{\substack{x_2 \in F_k, x_1 \in F_{k-1} \\ \|x_2 - x_1\|_{\infty} \leq \gamma_k/2}} [G(x_2) - G(x_1)] > \frac{n\epsilon}{2^{k/2}}\right) \\
&\leq \text{card}(F_0) \max_{x \in F_0} P(G(x) > n\epsilon) \\
&\quad + \sum_{k=1}^{\infty} 2^d \text{card}(F_{k-1}) \max_{\substack{x_2 \in F_k, x_1 \in F_{k-1} \\ \|x_2 - x_1\|_{\infty} \leq \gamma_k/2}} P\left(G(x_2) - G(x_1) > \frac{n\epsilon}{2^{k/2}}\right), \tag{8}
\end{aligned}$$

where the last inequality holds because for each $x_1 \in F_{k-1}$, there are only 2^d such points $x_2 \in F_k$ that can satisfy $\|x_2 - x_1\|_{\infty} \leq \gamma_k/2$. Given $x \in F_0$, since $|W_j K(\frac{x-X_j}{h})| \leq c_4$ almost surely for all $j \geq 1$, it follows by Lemma 1 that

$$P(G(x) > n\epsilon) \leq \exp\left(-\frac{n\epsilon^2}{2c_4^2(v^2 + \alpha\epsilon/c_4)}\right). \tag{9}$$

Similarly, given $x_2 \in F_k$, $x_1 \in F_{k-1}$ and $\|x_2 - x_1\|_{\infty} \leq \gamma_k$, since

$$\left|K\left(\frac{x_2 - X_j}{h_n}\right) - K\left(\frac{x_1 - X_j}{h_n}\right)\right| \leq \frac{\lambda \|x_2 - x_1\|_{\infty}}{2h_n} \leq \frac{\lambda \gamma_k}{2h_n} = \frac{\lambda}{2^{k+1}}$$

almost surely, it follows by Lemma 1 that

$$\begin{aligned}
P\left(G(x_2) - G(x_1) > \frac{n\epsilon}{2^{k/2}}\right) &= P\left(\sum_{j=1}^n \epsilon_j W_j \left[K\left(\frac{x_2 - X_j}{h}\right) - K\left(\frac{x_1 - X_j}{h}\right)\right] > \frac{n\epsilon}{2^{k/2}}\right) \\
&\leq \exp\left(-\frac{2^{k+2}n\epsilon^2}{2\lambda^2(v^2 + 2^{k/2+1}\alpha\epsilon/\lambda)}\right). \tag{10}
\end{aligned}$$

Thus, by (8), (9) and (10),

$$\begin{aligned}
& P\left(\sup_{x \in A} G(x) > \frac{n\epsilon}{1-1/\sqrt{2}}\right) \\
&\leq \exp\left(-\frac{n\epsilon^2}{2c_4^2(v^2 + \alpha\epsilon/c_4)}\right) + \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{2^{k+2}n\epsilon^2}{2\lambda^2(v^2 + 2^{k/2+1}\alpha\epsilon/\lambda)}\right) \\
&\leq \exp\left(-\frac{n\epsilon^2}{4c_4^2v^2}\right) + \exp\left(-\frac{n\epsilon}{4c_4\alpha}\right) + \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{2^{k/2}n\epsilon^2}{\lambda^2v^2}\right) + \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{2^{k/2}n\epsilon}{2\lambda\alpha}\right).
\end{aligned}$$

This completes the proof of Lemma 3. \square

Proof of Theorem 1. Recall that $M_{i,n} = |J_{i,n}|$, \underline{c} is the covariate density lower bound, and L, L_1, c_3 are constants defined in Assumption 4 for the kernel function $K(\cdot)$, and. Note that for each $x \in R^d$,

$$\begin{aligned}
& |\hat{f}_{i,n+1}(x) - f_i(x)| = \left| \frac{\sum_{j \in J_{i,n+1}} Y_{ij} K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} - f_i(x) \right| \\
&= \left| \frac{\sum_{j \in J_{i,n+1}} (f_i(X_j) + \epsilon_j) K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} - f_i(x) \right| \\
&= \left| \frac{\sum_{j \in J_{i,n+1}} (f_i(X_j) - f_i(x)) K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} + \frac{\sum_{j \in J_{i,n+1}} \epsilon_j K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} \right| \\
&\leq \sup_{\{x,y\}: \|x-y\|_{\infty} \leq Lh_n} |f_i(x) - f_i(y)| + \left| \frac{1}{M_{i,n+1}h_n^d} \frac{\sum_{j \in J_{i,n+1}} \epsilon_j K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} \right|, \tag{11}
\end{aligned}$$

where the last inequality follows from the bounded support assumption of kernel function $K(\cdot)$. By uniform continuity of the function f_i ,

$$\lim_{n \rightarrow \infty} \sup_{\{x,y\}: \|x-y\|_{\infty} \leq Lh_n} |f_i(x) - f_i(y)| = 0.$$

To show that $\|\hat{f}_{i,n} - f_i\|_{\infty} \rightarrow 0$ as $n \rightarrow \infty$, we only need

$$\sup_{x \in [0,1]^d} \left| \frac{1}{M_{i,n+1}h_n^d} \frac{\sum_{j \in J_{i,n+1}} \epsilon_j K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} \right| \rightarrow 0 \text{ as } n \rightarrow \infty. \tag{12}$$

First, we want to show

$$\inf_{x \in [0,1]^d} \frac{1}{M_{i,n+1}h_n^d} \sum_{j \in J_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) > \frac{c_3 \epsilon L_1^d n}{2}, \tag{13}$$

almost surely for large enough n . Indeed, for each $n \geq n_0l + 1$, we can partition the unit cube $[0,1]^d$ into \tilde{B} bins with bin width L_1h_n , such that $\tilde{B} \leq 1/(L_1h_n)^d$. We denote these

bins by $\tilde{A}_1, \tilde{A}_2, \dots, \tilde{A}_{\tilde{B}}$. Given an arm i and $1 \leq k \leq \tilde{B}$, for every $x \in \tilde{A}_k$, we have

$$\begin{aligned} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) &= \sum_{j=1}^n I(I_j = i) K\left(\frac{x - X_j}{h_n}\right) \\ &\geq \sum_{j=1}^n I(I_j = i, X_j \in \tilde{A}_k) K\left(\frac{x - X_j}{h_n}\right) \\ &\geq c_3 \sum_{j=1}^n I(I_j = i, X_j \in \tilde{A}_k), \end{aligned}$$

where the last inequality follows by Assumption 4. Consequently,

$$\begin{aligned} P\left(\inf_{x \in \tilde{A}_k} \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) \leq \frac{c_3 \mathcal{E} L_1^d \pi_n}{2}\right) \\ \leq P\left(\inf_{x \in \tilde{A}_k} \frac{1}{n h_n^d} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) \leq \frac{c_3 \mathcal{E} L_1^d \pi_n}{2}\right) \\ \leq P\left(\frac{c_3}{n h_n^d} \sum_{j=1}^n I(I_j = i, X_j \in \tilde{A}_k) \leq \frac{c_3 \mathcal{E} L_1^d \pi_n}{2}\right) \\ = P\left(\sum_{j=1}^n I(I_j = i, X_j \in \tilde{A}_k) \leq \frac{\mathcal{E} n (L_1 h_n)^d \pi_n}{2}\right). \end{aligned} \quad (14)$$

Noting that $P(I_j = i, X_j \in \tilde{A}_k | \mathcal{Z}^j) \geq \mathcal{E}(L_1 h_n)^d \pi_j$ for $1 \leq j \leq n$, we have by Lemma 2 that

$$P\left(\sum_{j=1}^n I(I_j = i, X_j \in \tilde{A}_k) \leq \frac{\mathcal{E} n (L_1 h_n)^d \pi_n}{2}\right) \leq \exp\left(-\frac{3\mathcal{E} n (L_1 h_n)^d \pi_n}{28}\right). \quad (15)$$

Therefore,

$$\begin{aligned} P\left(\inf_{x \in [0,1]^d} \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) \leq \frac{c_3 \mathcal{E} L_1^d \pi_n}{2}\right) \\ \leq \sum_{k=1}^{\tilde{B}} P\left(\inf_{x \in \tilde{A}_k} \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) \leq \frac{c_3 \mathcal{E} L_1^d \pi_n}{2}\right) \\ \leq \tilde{B} \exp\left(-\frac{3\mathcal{E} n (L_1 h_n)^d \pi_n}{28}\right), \end{aligned}$$

where the last inequality follows by (14) and (15). With the condition $n h_n^{2d} \pi_n^4 / \log n \rightarrow \infty$, we immediately obtain (13) by Borel-Cantelli lemma.

By (13), it follows that (12) holds if

$$\sup_{x \in [0,1]^d} \left| \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| = o(\pi_n). \quad (16)$$

In the rest of the proof, we want to show that (16) holds. For each $n \geq n_0 l + 1$, we can partition the unit cube $[0,1]^d$ into B bins with bin length h_n such that $B \leq 1/h_n^d$. At each time point j , let $W_j = 1$ if arm i is pulled (i.e., $I_j = i$), and $W_j = 0$ otherwise. Then given $\varepsilon > 0$,

$$\begin{aligned} P\left(\sup_{x \in [0,1]^d} \left| \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \pi_n \varepsilon\right) \\ \leq B \max_{1 \leq k \leq B} P\left(\sup_{x \in \tilde{A}_k} \left| \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \pi_n \varepsilon\right) \\ \leq B P\left(\frac{M_{i,n+1}}{n} \leq \frac{\pi_n}{2}\right) \\ + B \max_{1 \leq k \leq B} P\left(\sup_{x \in \tilde{A}_k} \left| \frac{1}{M_{i,n+1} h_n^d} \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \pi_n \varepsilon, \frac{M_{i,n+1}}{n} > \frac{\pi_n}{2}\right) \\ \leq B P\left(\frac{M_{i,n+1}}{n} \leq \frac{\pi_n}{2}\right) + B \max_{1 \leq k \leq B} P\left(\sup_{x \in \tilde{A}_k} \left| \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \frac{n \pi_n^2 h_n^d \varepsilon}{2}\right) \\ \leq B P\left(\frac{M_{i,n+1}}{n} \leq \frac{\pi_n}{2}\right) + B \max_{1 \leq k \leq B} P\left(\sup_{x \in \tilde{A}_k} \left| \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \frac{n \pi_n^2 h_n^d \varepsilon}{2}\right), \end{aligned} \quad (17)$$

where the last inequality follows by Lemma 2. Note that by Lemma 3,

$$\begin{aligned} P\left(\sup_{x \in \tilde{A}_k} \left| \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) \right| > \frac{n \pi_n^2 h_n^d \varepsilon}{2}\right) \\ \leq P\left(\sup_{x \in \tilde{A}_k} \sum_{j \in I_{i,n+1}} \varepsilon_j K\left(\frac{x - X_j}{h_n}\right) > \frac{n \pi_n^2 h_n^d \varepsilon}{2}\right) \\ + P\left(\sup_{x \in \tilde{A}_k} \sum_{j \in I_{i,n+1}} (-\varepsilon_j) K\left(\frac{x - X_j}{h_n}\right) > \frac{n \pi_n^2 h_n^d \varepsilon}{2}\right) \\ \leq 2 \exp\left(-\frac{(\sqrt{2}-1)^2 n \pi_n^4 h_n^{2d} \varepsilon^2}{32 c_4^2 v^2}\right) + 2 \exp\left(-\frac{(\sqrt{2}-1) n \pi_n^2 h_n^d \varepsilon}{8 \sqrt{2} c_4 v}\right) \\ + 2 \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{(\sqrt{2}-1)^{2k} n \pi_n^4 h_n^{2d} \varepsilon^2}{8 \lambda^2 v^2}\right) + 2 \sum_{k=1}^{\infty} 2^{kd} \exp\left(-\frac{(\sqrt{2}-1) 2^{k/2} n \pi_n^2 h_n^d \varepsilon}{4 \sqrt{2} \lambda v}\right). \end{aligned} \quad (18)$$

Thus, by (17), (18) and the condition that $n h_n^{2d} \pi_n^4 / \log n \rightarrow \infty$, (16) is an immediate consequence of Borel-Cantelli lemma. This completes the proof of Theorem 1. \square

B.2 Proofs of Theorem 2 and Corollary 2

Given $x \in [0,1]^d$, $1 \leq i \leq l$ and $n \geq n_0 l + 1$, define $G_{n+1}(x) = \{j : 1 \leq j \leq n, \|x - X_j\|_{\infty} \leq L h_n\}$ and $G_{i,n+1}(x) = \{j : 1 \leq j \leq n, I_j = i, \|x - X_j\|_{\infty} \leq L h_n\}$. Let $M_{n+1}(x)$ and $M_{i,n+1}(x)$ be the size of the sets $G_{n+1}(x)$ and $G_{i,n+1}(x)$, respectively. Then, the kernel method estimator $\hat{f}_{i,n+1}(x)$ satisfies the following lemma.

Lemma 4. *Suppose Assumptions 0, 1 and 4 are satisfied, and $\{\pi_n\}$ is a decreasing sequence. Given $x \in [0, 1]^d$, $1 \leq i \leq l$ and $n \geq n_{0l} + 1$, for every $\epsilon > \omega(Lh_n; f_i)$,*

$$\begin{aligned} P_{X^n}(|\hat{f}_{i,n+1}(x) - f_i(x)| \geq \epsilon) &\leq \exp\left(-\frac{3M_{n+1}(x)\pi_n}{28}\right) \\ &\quad + 4N \exp\left(-\frac{c_5^2 M_{n+1}(x)\pi_n(\epsilon - \omega(Lh_n; f_i))^2}{4c_4^2 v^2} + 4c_4 c(\epsilon - \omega(Lh_n; f_i))\right), \end{aligned} \quad (19)$$

where $P_{X^n}(\cdot)$ denotes the conditional probability given design points $X^n = (X_1, X_2, \dots, X_n)$.

Proof of Lemma 4. It is clear that if $M_{n+1}(x) = 0$, (19) trivially holds. Without loss of generality, assume $M_{n+1}(x) > 0$. Define the event $B_{i,n} = \left\{\frac{1}{M_{i,n+1}(x)} \sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right) \geq c_5\right\}$. Note that

$$\begin{aligned} &P_{X^n}(|\hat{f}_{i,n+1}(x) - f_i(x)| \geq \epsilon) \\ &\leq P_{X^n}\left(\frac{M_{i,n+1}(x)}{M_{n+1}(x)} \leq \frac{\pi_n}{2}\right) + P_{X^n}\left(|\hat{f}_{i,n+1}(x) - f_i(x)| \geq \epsilon, \frac{M_{i,n+1}(x)}{M_{n+1}(x)} > \frac{\pi_n}{2}\right) \\ &\leq \exp\left(-\frac{3M_{n+1}(x)\pi_n}{28}\right) + P_{X^n}\left(|\hat{f}_{i,n+1}(x) - f_i(x)| \geq \epsilon, \frac{M_{i,n+1}(x)}{M_{n+1}(x)} > \frac{\pi_n}{2}, B_{i,n}^c\right) \\ &\quad + P_{X^n}\left(|\hat{f}_{i,n+1}(x) - f_i(x)| \geq \epsilon, \frac{M_{i,n+1}(x)}{M_{n+1}(x)} > \frac{\pi_n}{2}, B_{i,n}^c\right), \\ &=: \exp\left(-\frac{3M_{n+1}(x)\pi_n}{28}\right) + A_1 + A_2, \end{aligned} \quad (20)$$

where the last inequality follows by Lemma 2. Under $B_{i,n}$, by Assumption 4, the definition of the modulus continuity and the same argument as (11), we have

$$\begin{aligned} |\hat{f}_{i,n+1}(x) - f_i(x)| &= \left| \frac{\sum_{j \in I_{i,n+1}} Y_{i,j} K\left(\frac{x - X_j}{h_n}\right)}{\sum_{j \in I_{i,n+1}} K\left(\frac{x - X_j}{h_n}\right)} \right| \\ &\leq \omega(Lh_n; f_i) + \frac{1}{c_5 M_{i,n+1}(x)} \left| \sum_{j \in G_{i,n+1}(x)} \epsilon_j K\left(\frac{x - X_j}{h_n}\right) \right|. \end{aligned}$$

Define $\tilde{\sigma}_t = \inf\{\tilde{n} : \sum_{j=1}^{\tilde{n}} I(I_j = i \text{ and } \|x - X_j\|_\infty \leq Lh_n) \geq t\}$, $t \geq 1$. Then, by the previous display, for every $\epsilon > \omega(Lh_n; f_i)$,

$$\begin{aligned} A_1 &\leq P_{X^n}\left(\left|\sum_{j \in G_{i,n+1}(x)} \epsilon_j K\left(\frac{x - X_j}{h_n}\right)\right| \geq c_5 M_{i,n+1}(x)(\epsilon - \omega(Lh_n; f_i)), \frac{M_{i,n+1}(x)}{M_{n+1}(x)} > \frac{\pi_n}{2}\right) \\ &\leq \sum_{\tilde{n}=0}^n P_{X^n}\left(\left|\sum_{t=1}^{\tilde{n}} \epsilon_t K\left(\frac{x - X_{\tilde{\sigma}_t}}{h_n}\right)\right| \geq c_5 \tilde{n}(\epsilon - \omega(Lh_n; f_i)), \frac{M_{i,n+1}(x)}{M_{n+1}(x)} > \frac{\pi_n}{2}, M_{i,n+1}(x) = \tilde{n}\right) \\ &\leq \sum_{\tilde{n}=\lfloor M_{n+1}(x)\pi_n/2 \rfloor}^n P_{X^n}\left(\left|\sum_{t=1}^{\tilde{n}} \epsilon_t K\left(\frac{x - X_{\tilde{\sigma}_t}}{h_n}\right)\right| \geq c_5 \tilde{n}(\epsilon - \omega(Lh_n; f_i))\right) \\ &\leq \sum_{\tilde{n}=\lfloor M_{n+1}(x)\pi_n/2 \rfloor}^n 2 \exp\left(-\frac{\tilde{n}c_5^2(\epsilon - \omega(Lh_n; f_i))^2}{2c_4^2 v^2} + 2c_4 c(\epsilon - \omega(Lh_n; f_i))\right) \\ &\leq 2N \exp\left(-\frac{c_5^2 M_{n+1}(x)\pi_n(\epsilon - \omega(Lh_n; f_i))^2}{4c_4^2 v^2} + 4c_4 c(\epsilon - \omega(Lh_n; f_i))\right), \end{aligned} \quad (21)$$

where the last to second inequality follows by Lemma 1 and the upper boundedness of the kernel function. By an argument similar to the previous two displays (using the uniform kernel), it is not hard to obtain that

$$A_2 \leq 2N \exp\left(-\frac{M_{n+1}(x)\pi_n(\epsilon - \omega(Lh_n; f_i))^2}{4v^2} + 4c(\epsilon - \omega(Lh_n; f_i))\right). \quad (22)$$

Combining (20), (21), (22) and the fact that $0 < c_5 \leq 1 \leq c_4$, we complete the proof of Lemma 4. \square

Proof of Theorem 2. Since $\hat{f}_{i^*(X_n),n}(X_n) \leq \hat{f}_{i_n,n}(X_n)$, the regret accumulated after the initial forced sampling period satisfies that

$$\begin{aligned} &\sum_{n=n_{0l}+1}^N (f^*(X_n) - f_{i_n}(X_n)) \\ &= \sum_{n=n_{0l}+1}^N (f_{i^*(X_n),n}(X_n) - \hat{f}_{i^*(X_n),n}(X_n) + \hat{f}_{i^*(X_n),n}(X_n) - f_{i_n}(X_n) + f_{i_n}(X_n) - f_{i_n}(X_n)) \\ &\leq \sum_{n=n_{0l}+1}^N (f_{i^*(X_n),n}(X_n) - \hat{f}_{i^*(X_n),n}(X_n) + \hat{f}_{i_n,n}(X_n) - f_{i_n}(X_n) + f_{i_n}(X_n) - f_{i_n}(X_n)) \\ &\leq \sum_{n=n_{0l}+1}^N \left(2 \sup_{1 \leq l \leq l} |f_{i_n}(X_n) - f_l(X_n)| + AI(I_n \neq \hat{i}_n)\right). \end{aligned} \quad (23)$$

It can be seen from (23) that the error upper bound consists of the estimation error regret and randomization error regret.

First, we find the upper bound of the estimation error regret. Given arm i , $n \geq n_{0l}$ and $\epsilon > \omega(Lh_n; f_i)$,

$$\begin{aligned} & P(|\hat{f}_{i,n+1}(X_{n+1}) - f_i(X_{n+1})| \geq \epsilon) \\ & \leq EP_{X_{n+1}}(M_{n+1}(X_{n+1}) \leq \frac{\epsilon n(2Lh_n)^d}{2}) \\ & \quad + EP_{X_{n+1}}(|\hat{f}_{i,n+1}(X_{n+1}) - f_i(X_{n+1})| \geq \epsilon, M_{n+1}(X_{n+1}) > \frac{\epsilon n(2Lh_n)^d}{2}). \end{aligned} \quad (24)$$

Since for every $x \in [0, 1]^d$, $P(\|x - X_j\|_\infty \leq Lh_n) \geq c_l(2Lh_n)^d$, $1 \leq j \leq n$, we have by the extended Bernstein's inequality that

$$P_{X_{n+1}}(M_{n+1}(X_{n+1}) \leq \frac{\epsilon n(2Lh_n)^d}{2}) \leq \exp\left(-\frac{3c_l \epsilon n(2Lh_n)^d}{28}\right). \quad (25)$$

By Lemma 4,

$$\begin{aligned} & P_{X_{n+1}}(|\hat{f}_{i,n+1}(X_{n+1}) - f_i(X_{n+1})| \geq \epsilon, M_{n+1}(X_{n+1}) > \frac{\epsilon n(2Lh_n)^d}{2}) \\ & \leq \exp\left(-\frac{3c_l \epsilon n(2Lh_n)^d \pi_n}{56}\right) + 4N \exp\left(-\frac{c_{\hat{f}_i}^2 \epsilon n(2Lh_n)^d \pi_n (\epsilon - \omega(Lh_n; f_i))^2}{8c_{\hat{f}_i}^2 \gamma^2 + 8c_{\hat{f}_i} c(\epsilon - \omega(Lh_n; f_i))}\right). \end{aligned} \quad (26)$$

Let

$$\tilde{\epsilon}_{i,n} = \omega(Lh_n; f_i) + \sqrt{\frac{16c_{\hat{f}_i}^2 \gamma^2 \log(8LN^2/\delta)}{c_{\hat{f}_i}^2 c(2L)^d n h_n^d \pi_n}}.$$

Then, by (24), (25) and the definition of n_δ in (3), it follows that for every $n \geq n_\delta$,

$$P(|\hat{f}_{i,n+1}(X_{n+1}) - f_i(X_{n+1})| \geq \tilde{\epsilon}_{i,n}) \leq \frac{\delta}{4N} + \frac{\delta}{4N} + \frac{\delta}{2N} = \frac{\delta}{N},$$

which implies that

$$P\left(\sum_{n=n_\delta+1}^N 2 \sup_{1 \leq i \leq l} |\hat{f}_{i,n}(X_n) - f_i(X_n)| \geq \sum_{n=n_\delta+1}^N 2 \max_{1 \leq i \leq l} \tilde{\epsilon}_{i,n-1}\right) \leq \delta. \quad (27)$$

Next, we want to bound the randomization error regret. Given $\epsilon > 0$, since $P(I_n \neq \hat{i}_n) = (l-1)\pi_n$, we have by Hoeffding's inequality that

$$P\left(A \left(\sum_{n=n_\delta+1}^N I(I_n \neq \hat{i}_n) - \sum_{n=n_\delta+1}^N (l-1)\pi_n\right) \geq \epsilon\right) \leq \exp\left(-\frac{2\epsilon^2}{N A^2}\right).$$

Taking $\epsilon = A\sqrt{N/2} \log(1/\delta)$, we immediately get

$$P\left(A \sum_{n=n_\delta+1}^N I(I_n \neq \hat{i}_n) \geq A \sum_{n=n_\delta+1}^N (l-1)\pi_n + A\sqrt{\frac{N}{2}} \log\left(\frac{1}{\delta}\right)\right) \leq \delta. \quad (28)$$

Then, (23), (27) and (28) together complete the proof of Theorem 2. \square

B.3 Proof of Theorem 3

Lemma 5. Under Assumption E and the proposed allocation strategy, for each arm i

$$N_t < \infty \quad \text{a.s. for all } t \geq 1.$$

Proof of Lemma 5. It suffices to check that

$$\sum_{j=n_{0l}+1}^{\infty} I(I_j = i) = \infty \quad \text{a.s.} \quad (29)$$

Indeed, let \mathcal{F}_n , $n \geq 1$ be the σ -field generated by (Z^n, X_n, I_n) . By the proposed allocation strategy, for all $j \geq n_{0l} + 1$,

$$P(I_j = i | \mathcal{F}_{j-1}) \geq \pi_j.$$

By Assumption E, $\sum_{j=n_{0l}+1}^{\infty} P(I_j = i | \mathcal{F}_{j-1}) = \infty$. Therefore, (29) is an immediate result of the Levy's extension of the Borel-Cantelli lemmas (Williams, 1991, pp.124). \square

Proof of Theorem 3. The key to the proof is to show $\|\hat{f}_{i,n} - f_i\|_\infty \rightarrow 0$ almost surely for $1 \leq i \leq l$ (Yang and Zhu, 2002; Theorem 1). Without loss of generality, assume Δ includes only two candidate procedures ($m = 2$). Given $1 \leq i \leq l$, assume that procedure $\delta_1 \in \Delta_1$ and procedure $\delta_2 \in \Delta_2$ (the case of $\delta_1, \delta_2 \in \Delta_1$ is trivial). Since

$$\begin{aligned} \|\hat{f}_{i,n} - f_i\|_\infty &= \|W_{i,n,1}(\hat{f}_{i,n,1} - f_i) + W_{i,n,2}(\hat{f}_{i,n,2} - f_i)\|_\infty \\ &\leq W_{i,n,1} \|\hat{f}_{i,n,1} - f_i\|_\infty + W_{i,n,2} \|\hat{f}_{i,n,2} - f_i\|_\infty, \end{aligned}$$

it suffices to prove that $\frac{W_{i,n,1}}{W_{i,n,2}} \rightarrow \infty$ almost surely as $n \rightarrow \infty$.

As defined before, $N_t = \inf\{n : \sum_{j=n_{0l}+1}^n I(I_j = i) \geq t\}$, and let \mathcal{F}_n be the σ -field generated by (Z^n, X_n, I_n) . Then for any $t \geq 1$, N_t is a stopping time relative to $\{\mathcal{F}_n, n \geq 1\}$. By Lemma 5, $N_t < \infty$ a.s. for all $t \geq 1$. Therefore, the weights $W_{i,N_t,1}$, $W_{i,N_t,2}$ and the variance estimates $\hat{v}_{i,N_t,1}$, $\hat{v}_{i,N_t,2}$ and \hat{v}_{i,N_t} for $t \geq 1$ are well-defined. By the allocation strategy, the weight associated with arm i is updated only after this arm is pulled. Consequently, we only need to show $\frac{W_{i,N_t,1}}{W_{i,N_t,2}} \rightarrow \infty$ almost surely as $t \rightarrow \infty$.

Note that for any $t \geq 1$,

$$\begin{aligned}
\frac{W_{i,N_{t+1,1}}}{W_{i,N_{t+1,2}}} &= \frac{W_{i,N_t,1}}{W_{i,N_t,2}} \times \frac{\hat{v}_{i,N_t,2}^{1/2}}{\hat{v}_{i,N_t,1}^{1/2}} \exp\left(-\frac{(\hat{f}_{i,N_t,1}(X_{N_t}) - Y_{i,N_t})^2 - (\hat{f}_{i,N_t,2}(X_{N_t}) - Y_{i,N_t})^2}{2\hat{v}_{i,N_t}}\right) \\
&= \frac{W_{i,N_t,1}}{W_{i,N_t,2}} \times \frac{\hat{v}_{i,N_t,2}^{1/2}}{\hat{v}_{i,N_t,1}^{1/2}} \times \frac{\hat{v}_{i,N_t,2}}{\hat{v}_{i,N_t,1}} \\
&\quad \times \exp\left(-\frac{(\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}) - \varepsilon_{N_t})^2 - (\hat{f}_{i,N_t,2}(X_{N_t}) - f_i(X_{N_t}) - \varepsilon_{N_t})^2}{2\hat{v}_{i,N_t}}\right) \\
&= \frac{W_{i,N_t,1}}{W_{i,N_t,2}} \times \frac{\hat{v}_{i,N_t,2}^{1/2}}{\hat{v}_{i,N_t,1}^{1/2}} \exp\left(\frac{(\hat{f}_{i,N_t,2}(X_{N_t}) - f_i(X_{N_t}))^2 - (\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}))^2}{2\hat{v}_{i,N_t}}\right) \\
&\quad \times \exp\left(\frac{\varepsilon_{N_t}(\hat{f}_{i,N_t,1}(X_{N_t}) - \hat{f}_{i,N_t,2}(X_{N_t}))}{\hat{v}_{i,N_t}}\right) \\
&= \frac{W_{i,N_t,1}}{W_{i,N_t,2}} \times \frac{\hat{v}_{i,N_t,2}^{1/2}}{\hat{v}_{i,N_t,1}^{1/2}} \exp(T_{1t} + T_{2t}),
\end{aligned}$$

where

$$T_{1t} = \frac{(\hat{f}_{i,N_t,2}(X_{N_t}) - f_i(X_{N_t}))^2 - (\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}))^2}{2\hat{v}_{i,N_t}},$$

and

$$T_{2t} = \frac{\varepsilon_{N_t}(\hat{f}_{i,N_t,1}(X_{N_t}) - \hat{f}_{i,N_t,2}(X_{N_t}))}{\hat{v}_{i,N_t}}.$$

Thus, for each $T \geq 1$,

$$\frac{W_{i,N_{T+1,1}}}{W_{i,N_{T+1,2}}} = \left(\prod_{t=1}^T \frac{\hat{v}_{i,N_t,2}^{1/2}}{\hat{v}_{i,N_t,1}^{1/2}}\right) \exp\left(\sum_{t=1}^T T_{1t} + \sum_{t=1}^T T_{2t}\right). \quad (30)$$

Then define $\xi_t = \varepsilon_{N_t}(\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}))$ and $\xi_t^* = \varepsilon_{N_t}(\hat{f}_{i,N_t,2}(X_{N_t}) - f_i(X_{N_t}))$. Since $E(\varepsilon_{N_t} | \mathcal{F}_{N_t}) = 0$, it follows by Assumption C, Assumption 0 and Lemma 1 that for every $\tau > 0$ and every $T \geq 1$,

$$P\left(\sum_{t=1}^T \xi_t > T\tau\right) < \exp\left(-\frac{T\tau^2}{2c_2^2(v^2 + c\tau/c_2)}\right).$$

Replacing τ by $\frac{(\log T)^b}{\sqrt{T}}\tau$, we obtain

$$\sum_{t=1}^T \xi_t = o(\sqrt{T}(\log T)^b) \quad (31)$$

almost surely by Borel-Cantelli lemma. By the same argument, $\sum_{t=1}^T \xi_t^* = o(\sqrt{T}(\log T)^b)$ almost surely. Note that for each $T \geq 1$,

$$\begin{aligned}
\hat{v}_{i,N_{T+1,1}} &= \frac{\sum_{t=1}^T (\hat{f}_{i,N_t,1}(X_{N_t}) - Y_{i,N_t})^2}{T} \\
&= \frac{\sum_{t=1}^T (\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}) - \varepsilon_{N_t})^2}{T} \\
&= \frac{\sum_{t=1}^T (\hat{f}_{i,N_t,1}(X_{N_t}) - f_i(X_{N_t}))^2}{T} + \frac{\sum_{t=1}^T \varepsilon_{N_t}^2}{T} - \frac{2\sum_{t=1}^T \xi_t}{T}.
\end{aligned}$$

Similarly, for each $T \geq 1$

$$\hat{v}_{i,N_{T+1,2}} = \frac{\sum_{t=1}^T (\hat{f}_{i,N_t,2}(X_{N_t}) - f_i(X_{N_t}))^2}{T} + \frac{\sum_{t=1}^T \varepsilon_{N_t}^2}{T} - \frac{2\sum_{t=1}^T \xi_t^*}{T}.$$

By Assumption A and the previous two equations, we obtain that

$$\hat{v}_{i,N_t,1} < \hat{v}_{i,N_t,2} \quad (32)$$

almost surely for large enough t .

The boundedness of $\{\hat{v}_{i,N_t}, t \geq 1\}$ as implied in Assumption D enables us to apply Lemma 1 again to obtain that

$$\sum_{t=1}^T T_{2t} = o(\sqrt{T}(\log T)^b), \quad (33)$$

almost surely. By (31), (32) and Assumption A, we conclude from (30) that

$$\frac{W_{i,N_{T+1,1}}}{W_{i,N_{T+1,2}}} \rightarrow \infty \quad \text{a.s. as } T \rightarrow \infty.$$

This completes the proof of Theorem 3. \square

B.4 Proof of Theorem 4

Proof of Theorem 4. First, note that

$$\begin{aligned}
R_N(\eta) &= \sum_{n=1}^N (f^*(X_n) - f_{I_n}(X_n)) I(I_n = \tilde{i}_n) + \sum_{n=1}^N (f^*(X_n) - f_{I_n}(X_n)) I(I_n \neq \tilde{i}_n) \\
&\leq \sum_{n=1}^N (f^*(X_n) - f_{I_n}(X_n)) I(I_n = \tilde{i}_n, \tilde{i}_n \neq i^*(X_n)) + \sum_{n=1}^N AI(I_n \neq \tilde{i}_n) \\
&= \sum_{i=1}^l \sum_{n=1}^N (f^*(X_n) - f_{I_n}(X_n)) I(I_n = i, \tilde{i}_n \neq i^*(X_n), \tilde{i}_n = i) + \sum_{n=1}^N AI(I_n \neq \tilde{i}_n) \\
&=: \sum_{i=1}^l \sum_{n=1}^N R_{i,n} + R_{N,2}.
\end{aligned} \quad (34)$$

Then we partition the domain into $1/h^d$ bins with bin width h and denote the set of these bins by \mathcal{B} .

Given bin $B \in \mathcal{B}$, define $R_{i,n,B} = \sum_{m=1}^N R_{i,n} I(X_n \in B)$. Let x_B be the center point in B . Define the (nearly) optimal arm $\bar{i} = \bar{i}_B = \operatorname{argmax}_{i \leq i \leq i} f_i(x_B)$ and $\Delta_{i,B} = f_{\bar{i}}(x_B) - f_i(x_B)$. Let $S_{i,B} = \{n : l_{n_0} + 1 \leq n \leq N, I_n = i, \bar{i}_n \neq i^*(X_n), \bar{i}_n = i, X_n \in B\}$. Define $N_{i,B} = \max S_{i,B}$ if $S_{i,B} \neq \emptyset$ and $N_{i,B} = 0$ if $S_{i,B} = \emptyset$. Given $N_{i,B} = \bar{n}$, let $\sigma_i = \sigma_{i,t,\bar{n}} = \min\{n : \sum_{j=1}^n I(I_j = i, K(\frac{X_j - X_{\bar{n}}}{h}) \neq 0) \geq t\}$ be the earliest time point where $\{I_j = i, K(\frac{X_j - X_{\bar{n}}}{h}) \neq 0\}$ happens t times. Define $\tau_i = \tau_{i,\bar{n}} = \max\{t : \sigma_{i,t,\bar{n}} < \bar{n}\}$, which is the number of times $\{I_j = i, K(\frac{X_j - X_{\bar{n}}}{h}) \neq 0\}$ happens before the time point \bar{n} . Similarly, for the (nearly) optimal arm \bar{i} , define $\eta_i = \min\{n : \sum_{j=1}^n I(I_j = \bar{i}, K(\frac{X_j - X_{\bar{n}}}{h}) \neq 0) \geq t\}$ and $\bar{\tau} = \max\{t : \eta_t < \bar{n}\}$. Then, if $N_{i,B} = \bar{n} \neq 0$ and $\tau_i \geq 1$, by the kernel-UCB algorithm, we have $f_{i,\bar{n}}(X_{\bar{n}}) + U_{i,\bar{n}}(X_{\bar{n}}) \geq f_{\bar{i},\bar{n}}(X_{\bar{n}}) + U_{\bar{i},\bar{n}}(X_{\bar{n}})$, that is,

$$\sum_{t=1}^{\tau_i} \frac{Y_{i,\sigma_t}}{\tau_i} + \tilde{c} \sqrt{\frac{\log N}{\log N}} \geq \sum_{t=1}^{\bar{\tau}} \frac{Y_{\bar{i},\eta_t}^2}{\bar{\tau}} + \tilde{c} \sqrt{\frac{\log N}{\bar{\tau}}}, \quad (34)$$

Note that (34) implies at least one of the following three events occurs:

$$\begin{aligned} G_B &=: \left\{ \sum_{t=1}^{\tau_i} \frac{Y_{i,\sigma_t}}{\tau_i} - \sum_{t=1}^{\bar{\tau}} \frac{f_{\bar{i}}(X_{\eta_t})}{\bar{\tau}} > \tilde{c} \sqrt{\frac{\log N}{\tau_i}} \right\}, \\ F_B &=: \left\{ \sum_{t=1}^{\bar{\tau}} \frac{Y_{\bar{i},\eta_t}}{\bar{\tau}} - \sum_{t=1}^{\bar{\tau}} \frac{f_{\bar{i}}(X_{\eta_t})}{\bar{\tau}} < -\tilde{c} \sqrt{\frac{\log N}{\bar{\tau}}} \right\}, \text{ or} \\ H_B &=: \left\{ \sum_{t=1}^{\tau_i} \frac{f_i(X_{\sigma_t})}{\tau_i} + 2\tilde{c} \sqrt{\frac{\log N}{\tau_i}} > \sum_{t=1}^{\bar{\tau}} \frac{f_{\bar{i}}(X_{\eta_t})}{\bar{\tau}} \right\}. \end{aligned}$$

Since $\|f_i(X_{\sigma_t}) - f_i(x_B)\|_\infty \leq \rho h^s$ and $\|f_{\bar{i}}(X_{\eta_t}) - f_{\bar{i}}(x_B)\|_\infty \leq \rho h^s$,

$$\begin{aligned} H_B &\Rightarrow f_i(x_B) + \rho h^s + 2\tilde{c} \sqrt{\frac{\log N}{\tau_i}} > f_{\bar{i}}(x_B) - \rho h^s \\ &\Rightarrow 2\tilde{c} \sqrt{\frac{\log N}{\tau_i}} > \Delta_{i,B} - 2\rho h^s \\ &\Rightarrow \{\Delta_{i,B} \leq 4\rho h^s\} \text{ or } \{\Delta_{i,B} > 4\rho h^s, \tau_i < \frac{16\tilde{c}^2}{\Delta_{i,B}^2} \log N\}. \end{aligned} \quad (35)$$

By Lemma 1,

$$\begin{aligned} P(G_B, N_{i,B} \neq 0, \tau_i > \log N) &\leq N^2 \exp\left(-\frac{\tilde{c}^2 \log N}{2(\rho^2 + \tilde{c}^2)}\right) \\ &\leq \frac{1}{N}, \end{aligned} \quad (36)$$

where the last inequality holds since $\tilde{c} > \max\{2\sqrt{3}\rho, 12\tilde{c}\}$.

Similarly, we can show that

$$P(F_B, N_{i,B} \neq 0, \tau_i > \log N) \leq \frac{1}{N}. \quad (37)$$

Note that

$$\begin{aligned} R_{i,n,B} &\leq R_{i,n,B} I(N_{i,B} = 0) + R_{i,n,B} I(\tau_i \leq \log N, N_{i,B} \neq 0) + \\ &\quad R_{i,n,B} I(\tau_i > \log N, N_{i,B} \neq 0, G_B) + R_{i,n,B} I(\tau_i > \log N, N_{i,B} \neq 0, F_B) + \\ &\quad R_{i,n,B} I(\tau_i > \log N, N_{i,B} \neq 0, H_B) \\ &\leq R_{i,n,B} I(N_{i,B} = 0) + A \log N + AN I(\tau_i > \log N, N_{i,B} \neq 0, G_B) + \\ &\quad AN I(\tau_i > \log N, N_{i,B} \neq 0, F_B) + 6\rho h^s \tau_{i,B} + \left(\frac{3}{2} \Delta_{i,B}\right) \left(\frac{16\tilde{c}^2}{\Delta_{i,B}^2} \log N\right) I(\Delta_{i,B} > 4\rho h^s), \end{aligned}$$

where the last inequality follows by (35), and $\tau_{i,B} = \sum_{n=1}^N I(I_n = i, X_n \in B)$. Then by (36), (37) and the definition of $N_{i,B}$,

$$\begin{aligned} E\left(\sum_{i=1}^L \sum_{n=1}^N R_{i,n}\right) &= \sum_{i=1}^L \sum_{B \in \mathcal{B}} E(R_{i,n,B}) \\ &\leq ALn_0 + ALh^{-d} \log N + 2A + 6\rho N h^s + \frac{6\tilde{c}^2 l}{\rho h^{s+d}} \log N. \end{aligned} \quad (38)$$

Also, taking $\delta = 1/N$, we have by (28) that

$$\begin{aligned} E(R_{N,2}) &\leq AN\delta + A \sum_{n=1}^N \pi_n + A \sqrt{\frac{N}{2}} \log \left(\frac{1}{\delta}\right) \\ &\leq A + A \sum_{n=1}^N \pi_n + A \sqrt{\frac{N}{2}} \log N. \end{aligned} \quad (39)$$

By (33), (38), (39) and our choice of n_0, h and π_n , we obtain (7). \square

Appendix C. Additional Numerical Results

Under the same settings of Section 7 with the Yahoo! data set, we implement additional algorithms as follows.

Simple-SIR-kernel : This algorithm is the same as the SIR-kernel algorithm described in Section 7 except that the dimension reduction matrix is estimated using only the data collected during the forced sampling stage. That is, for every $n > l_{n_0}$, the Nadaraya-Watson estimator of $f_i(x)$ shown in (5) is modified to be

$$\hat{f}_{i,n}(x) = \frac{\sum_{j \in I_{i,n}} Y_{i,j} K_i \left(\frac{\hat{B}_{i,l_{n_0}}^{*T} x^* - \hat{B}_{i,l_{n_0}}^{*T} X_j^*}{h_{n-1}} \right)}{\sum_{j \in I_{i,n}} K_i \left(\frac{\hat{B}_{i,l_{n_0}}^{*T} x^* - \hat{B}_{i,l_{n_0}}^{*T} X_j^*}{h_{n-1}} \right)}, \quad (40)$$

where the forced sampling size for each arm is $n_0 = 1000$ and the bandwidth is $h_n = n^{-1/10}$.

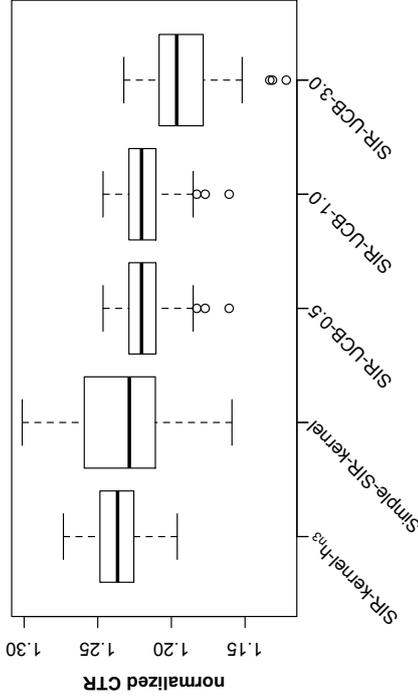

Figure 3: Boxplots of normalized CTRs of various algorithms on the news article recommendation data set. Algorithms include (from left to right): SIR-kernel ($h_{0.3}$), Simple-SIR-kernel, SIR-UCB ($\tilde{c}_0 = 0.5$), SIR-UCB ($\tilde{c}_0 = 1.0$) and SIR-UCB ($\tilde{c}_0 = 3.0$). CTRs are normalized with respect to the random algorithm.

SIR-UCB : This algorithm modifies the kernel estimation based UCB algorithm described in Appendix A to handle covariates with high dimensions. Rather than using the original covariates, we apply the SIR method to estimate the dimension reduction matrices and use them to transform covariates to lower dimensional. These transformed covariates are subsequently applied to compute the kernel estimation based UCB index. That is, at each time point n after the forced sampling stage, we pull the arm with the highest UCB index $\hat{f}_{i,n}(X_n) + U_{i,n}^*(X_n)$, where $\hat{f}_{i,n}(X_n)$ is defined in (5) and

$$U_{i,n}^*(x) = \frac{\tilde{c}_0 \sqrt{\sum_{j \in I_{i,n}} K^2 \left(\frac{\hat{B}_{i,n}^{*T} x^* - \hat{B}_{i,n-1}^{*T} X_n^*}{\sum_{j \in I_{i,n}} \hat{B}_{i,n}^{*T} x^* - \hat{B}_{i,n-1}^{*T} X_n^*} \right)}}{\sum_{j \in I_{i,n}} K \left(\frac{\hat{B}_{i,n}^{*T} x^* - \hat{B}_{i,n-1}^{*T} X_n^*}{h_{n-1}} \right)},$$

with $\hat{B}_{i,n}^*$, x^* and X_n^* defined in Section 4.3. We set $\tilde{c}_0 = 0.5, 1$ or 3 and $h_n = n^{-1/10}$.

The algorithms above are evaluated in the same manner as is described in Section 7, and the resulting normalized CTRs are summarized in the boxplots in Fig. 3. Although the averaged CTRs of the simple-SIR-kernel appears to be similar to SIR-kernel, the variation of the CTRs clearly enlarges as we use only the forced sampling stage to estimate the dimension reduction matrices. The SIR-UCB algorithm does not show significant improvement over the SIR-kernel algorithm either.

Remark 1. Because of the curse of dimensionality, the kernel estimation in Section 4.1 cannot be directly applied to the Yahoo! data set. As described in Section 4.3, one way to address this issue is to assume that for each arm i ($i = 1, 2, \dots, l$), there exists a dimension reduction matrix B_i and a function $g(\cdot)$ such that $\tilde{x}_i = B_i^T x$ becomes lower dimensional covariate and $f_i(x) = g(\tilde{x}_i)$. If B_i (or more precisely, $\text{span}(B_i)$) is known, we can simply work with the lower dimensional covariates (which can be different for different arms), and the kernel estimation algorithm in Section 4.1 still applies. Indeed, we note that if B_i is known, the consistency and finite-time regret analysis (with rate in accordance with the lower dimension) can still be established in a way similar to that of Theorem 1 and Corollary 2.

In practice, since the B_i is unknown, it is natural to estimate it by introducing a dimension reduction method like SIR. The theoretical implications of the dimension reduction procedure is not yet clear to us. To provide some numerical guidance on how to apply SIR, we explored two different ways of estimating B_i using the Yahoo! data. One is the SIR-kernel algorithm, where the estimator for B_i gets updated as more and more data is collected throughout the total time horizon. Alternatively, we considered here the Simple-SIR-kernel algorithm, where only data from the initial forced sampling stage is used to generate a consistent estimator for B_i (Zhu et al., 1996); Subsequently, with the lower-dimensional covariates from a fixed dimension reduction matrix, the kernel estimation can be applied to the remaining time period. Our numerical result favors the former way of applying SIR.

Abstract

A general asymptotic framework is developed for studying consistency properties of principal component analysis (PCA). Our framework includes several previously studied domains of asymptotics as special cases and allows one to investigate interesting connections and transitions among the various domains. More importantly, it enables us to investigate asymptotic scenarios that have not been considered before, and gain new insights into the consistency, subspace consistency and strong inconsistency regions of PCA and the boundaries among them. We also establish the corresponding convergence rate within each region. Under general spike covariance models, the dimension (or number of variables) discourages the consistency of PCA, while the sample size and spike information (the relative size of the population eigenvalues) encourage PCA consistency. Our framework nicely illustrates the relationship among these three types of information in terms of dimension, sample size and spike size, and rigorously characterizes how their relationships affect PCA consistency.

Keywords: High dimension low sample size, PCA, Random matrix, Spike model

1. Introduction

Principal Component Analysis (PCA) is an important visualization and dimension reduction tool which finds orthogonal directions reflecting maximal variation in the data. This allows the low dimensional representation of data, by projecting data onto these directions. PCA is usually obtained by an eigen decomposition of the sample variance-covariance matrix of the data. Properties of the sample eigenvalues and eigenvectors have been analyzed under several domains of asymptotics.

In this paper, we develop a *general asymptotic framework* to explore interesting transitions among the various asymptotic domains. The general framework includes the tradi-

tional asymptotic setups as special cases, and furthermore it allows a careful study of the connections among the various setups. More importantly, we investigate a wide range of interesting scenarios that have not been considered before, and offer new insights into the *consistency* (in the sense that the angle between estimated and population eigen directions tends to 0, or the inner product tends to 1) and *strong-inconsistency* (where the angle tends to $\pi/2$, i.e., the inner product tends to 0) properties of PCA, along with some technically challenging convergence rates.

Existing asymptotic studies of PCA roughly fall into four domains:

- (a) the **classical** domain of asymptotics, under which the sample size $n \rightarrow \infty$ and the dimension d is fixed (hence the ratio $n/d \rightarrow \infty$). For example, see Girshick (1939); Lawley (1956); Anderson (1963, 1984); Jackson (1991).
- (b) the **random matrix** theory domain, where both the sample size n and the dimension d increase to infinity, with the ratio $n/d \rightarrow c$, a constant mostly assumed to be within $(0, \infty)$. Representative work includes Bielei and Mietzner (1994); Watkin and Nadal (1994); Reimann et al. (1996); Hoyle and Rattray (2003) from the statistical physics literature, as well as Johnstone (2001); Baik et al. (2005); Baik and Silverstein (2006); Onatski (2012); Paul (2007); Nadler (2008); Johnstone and Lu (2009); Lee et al. (2010); Benaych-Georges and Nadakuditi (2011) from the statistics literature.
- (c) the **high dimension low sample size (HDLSS)** domain of asymptotics, which is based on the limit, as the dimension $d \rightarrow \infty$, with the sample size n being fixed (hence the ratio $n/d \rightarrow 0$). HDLSS asymptotics was originally studied by Casella and Hwang (1982), and rediscovered by Hall et al. (2005). PCA has been studied using the HDLSS asymptotics by Ahn et al. (2007); Jung and Marron (2009).
- (d) the **increasing signal strength** domain of asymptotics, where n, d are fixed and the signal strength tends to infinity. Such a setting is studied in Nadler (2008).

PCA consistency and (strong) inconsistency, defined in terms of angles, are important properties that have been studied before. A common technical device is the spike covariance model, initially introduced by Johnstone (2001). This model has been used in this context by, for example, Nadler (2008); Johnstone and Lu (2009); Jung and Marron (2009). Recently, Ma (2013) formulates sparse PCA (Zou et al., 2006) through iterative thresholding and studies its asymptotic properties under the spike model. An interesting, more general, model has been considered by Benaych-Georges and Nadakuditi (2011).

Under the spike model, the first few eigenvalues are much larger than the others. A *major message of the present paper* is that there are three critical features whose relationships drive the consistency properties of PCA, namely

- (1) the *sample size*: the sample size n *encourages* the consistency of the sample eigenvectors, meaning that more samples tend towards more frequent consistency;
- (2) the *dimension*: the dimension d *discourages* the consistency of the sample eigenvectors, meaning that higher d tends towards less frequent consistency;
- (3) the *spike signal*: the relative sizes of the several leading eigenvalues similarly encourage the consistency.

Our general framework considers increasing sample size n , increasing dimension d , and increasing spike signal. We clearly characterize how their relationships determine the regions of consistency and strong-inconsistency of PCA, along with the boundary in-between.

Note that the classical domain ((a) above) assumes increasing sample size n while fixing dimension d ; the random matrix domain ((b) above) assumes increasing sample size n and increasing dimension d , while fixing the spike signal; the HDLSS domain ((c) above) fixes the sample size, and increases the dimension and the spike signal; the increasing signal strength domain ((d) above) assumes increasing the spike signal, while fixing the sample size and the dimension; thus each of these three domains is a boundary case of our framework. Our theorems, when restricted to these existing domains of asymptotics, are consistent with known results.

In addition, our theorems go beyond these known results to demonstrate the transitions among the existing domains of asymptotics, and for the first time to the best of our knowledge, enable one to understand interesting connections among them. Finally, we also establish novel results on rates of convergence.

Sections 3 and 4 formally state very general theorems for multiple component spike models. For illustration purposes only, in this section we first consider Examples 1 and 2 under some strong assumptions, which provide intuitive insights regarding the much more general theory presented in Sections 3 and 4. In addition, we use Example 3 to show the application of our theoretical study to the factor model considered by Fan et al. (2013).

For Examples 1 and 2, to better demonstrate the connection with existing results, the three types of features (sample size, dimension, and spike signal) and their relationships are mathematically quantified by two indices, namely the *spike index* α and the *sample index* γ . Within the context of these examples, we point out the significant contributions of our results in comparison with existing results. The comparisons and connections are graphically illustrated in Figure 1 and discussed below.

Example 1 Single-component Spike Model Assume that X_1, \dots, X_n are sample vectors from a d -dimensional distribution with zero mean and covariance matrix Σ , where the entries of $\Sigma^{-\frac{1}{2}}X_i$ are i.i.d. random variables with zero mean, unit variance and finite fourth moment. (A special case: X_i is from the d -dimensional normal distribution $N(0, \Sigma)$). In addition, assume that the sample size $n = d^\gamma$ ($\gamma \geq 0$ is defined as the *sample index*), and the covariance matrix Σ has the following eigenvalues:

$$\lambda_1 = c_1 d^\alpha, \lambda_2 = \dots = \lambda_d = 1, \alpha \geq 0,$$

where the constant α is defined as the *spike index*.

Corollary B.2 in the supplementary materials, when applied to this example, shows that the maximal sample eigenvector is consistent when $\alpha + \gamma > 1$ (grey region in Figure 1(A)), and strongly inconsistent when $0 \leq \alpha + \gamma < 1$ (white triangle in Figure 1(A)). These very general new results nicely connect with many existing ones:

- **Previous Results I - the classical domain:**

Under the normal assumption, Theorem 1 of Anderson (1963) implied that for fixed dimension d and finite eigenvalues, when the sample size $n \rightarrow \infty$ (i.e. $\gamma \rightarrow \infty$, the limit on the vertical axis), the maximal sample eigenvector is consistent. This case is the upper left corner of Figure 1(A).

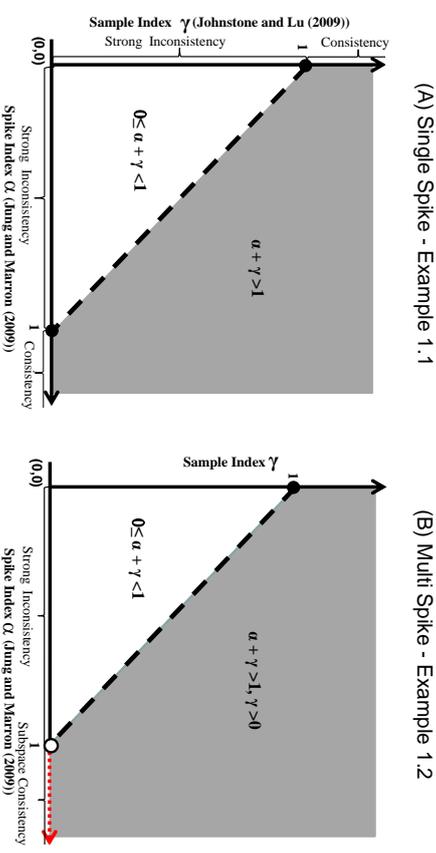

Figure 1: General consistency and strong inconsistency regions for PCA, as a function of the spike index α and the sample index γ . Panel (A) - single spike model in Example 1: PCA is consistent in the grey region ($\alpha + \gamma > 1$), and strongly inconsistent on the white triangle ($0 \leq \alpha + \gamma < 1$). Panel (B) - multiple spike model in Example 2: the first m sample PCs are consistent in the grey region ($\alpha + \gamma > 1, \gamma > 0$), subspace consistent on the dotted line ($\alpha > 1, \gamma = 0$) on the horizontal axis, and strongly inconsistent on the white triangle ($0 \leq \alpha + \gamma < 1$).

- **Previous Results II - the random matrix domain:**

(a) Assuming normality, the results of Johnstone and Lu (2009) appear on the vertical axis in Panel (A) where the spike index $\alpha = 0$ (as they fix the spike information): the first sample eigenvector is consistent when the sample index $\gamma > 1$ and strongly inconsistent when $\gamma < 1$.

(b) Again, under the normal assumption, Nadler (2008) explored the interesting boundary case of $\alpha = 0, \gamma = 1$ (i.e. $\frac{d}{n} \rightarrow c$ for a constant c) and showed that $\langle \hat{u}_1, u_1 \rangle \xrightarrow{a.s.} \frac{((\lambda_1 - 1)^2 - c)^+}{(\lambda_1 - 1)^2 + c(\lambda_1 - 1)^2}$, where \hat{u}_1 and u_1 are the first sample and population eigenvector. This result appears in Panel (A) as the single solid circle $\gamma = 1$ on the vertical axis. Our general framework doesn't cover this boundary case and this boundary result is a complement of our theoretical results.

- **Previous Results III - the HDLSS domain:**

(a) The theorems of Jung and Marron (2009) are represented on the horizontal axis in Panel (A) when the sample index $\gamma = 0$ (as they fix the sample size): the maximal sample eigenvector is consistent with the first population eigenvector when the spike index $\alpha > 1$ and strongly inconsistent when $\alpha < 1$.

(b) Under the normal assumption, Jung et al. (2012) deeply explored limiting behavior at the boundary $\alpha = 1, \gamma = 0$ (i.e. $\frac{d}{\lambda_1} \rightarrow c$ for a constant c) and showed that $\langle \hat{u}_1, u_1 \rangle > 2 \Rightarrow \frac{d}{\lambda_1 c} \rightarrow c$ means convergence in distribution and $A \sim \chi^2$, the chi-squared distribution with n degrees of freedom. This result appears in Panel (A) as the single solid circle $\alpha = 1$ on the horizontal axis. This boundary case is again a complement of our general framework.

- **Our Results** hence nicely connect existing domains of asymptotics, and give a much more complete characterization for the regions of PCA consistency, subspace consistency, and strong inconsistency. We also investigate asymptotic properties of the other sample eigenvectors and all the sample eigenvalues.

Example 2 Multiple-component Spike Model Assume that the covariance matrix Σ in Example 1 has the following eigenvalues:

$$\lambda_j = \begin{cases} c_j d^\alpha & \text{if } j \leq m, \\ 1 & \text{if } j > m, \end{cases} \quad \alpha \geq 0,$$

where m is a finite positive integer, the constants $c_j, j = 1, \dots, m$, are positive and satisfy that $c_j > c_{j+1} > 1, j = 1, \dots, m - 1$.

Corollary B.1 in the supplementary materials, when applied to this example, shows that the first m sample eigenvectors are individually consistent with corresponding population eigenvectors when $\alpha + \gamma > 1, \gamma > 0$ (the grey region in Figure 1(B)), instead of being subspace consistent (Jung and Marron, 2009), and strongly inconsistent when $\alpha + \gamma < 1$ (the white triangle in Panel (B)). This very general new result connects with many others in the existing literature:

- **Previous Results I - the classical domain.**

Assuming normality, Theorem 1 of Anderson (1963) implied that for fixed dimension d and finite eigenvalues, when the sample size $n \rightarrow \infty$ (i.e. $\gamma \rightarrow \infty$, the limit on the vertical axis), the first m sample eigenvectors are consistent, while the other sample eigenvectors are subspace consistent. This case is the upper left corner of Figure 1(B).

- **Previous Results II - the random matrix domain.**

The following results are under the normal assumption. Paul (2007) explored asymptotic properties of the first m eigenvectors and eigenvalues in the interesting boundary case of $\alpha = 0, \gamma = 1$, i.e., $\frac{d}{n} \rightarrow c$ with $c \in (0, 1)$ and showed that $\langle \hat{u}_j, u_j \rangle \xrightarrow{a.s.} \frac{((\lambda_j - 1)^2 - c)}{(\lambda_j - 1)^2 + c(\lambda_j - 1)}$ for $j = 1, \dots, m$. This result appears in Panel (B) as the solid circle $\gamma = 1$ on the vertical axis. This boundary case is a complement of our results for multiple spike models with distinct eigenvalues (Section B.1 of the supplementary materials). Paul and Johnstone (2012) considered a similar framework but from a minimax risk analysis perspective. Nadler (2008); Johnstone and Lu (2009) did not study multiple spike models.

- **Previous Results III - the HDLSS domain:**

The theorems of Jung and Marron (2009) are valid on the horizontal axis in Panel (B) where the sample index $\gamma = 0$. In particular, for this example, their results showed that the first m sample eigenvectors are not respectively consistent with the corresponding population eigenvectors when the spike index $\alpha > 1$ (the horizontal dotted red line segment), instead they are subspace consistent with their corresponding population eigenvectors, and are strongly inconsistent when the spike index $\alpha < 1$ (the horizontal solid line segment). They and Jung et al. (2012) did not study the asymptotic behavior on the boundary - the single open circle ($\alpha = 1, \gamma = 0$) on the horizontal axis.

- **Our Results** cover the classical domain, and are stronger than what Jung and Marron (2009) obtained: the increasing sample size enables us to separate out the first few leading eigenvectors and characterize individual consistency, while only subspace consistency was obtained by Jung and Marron (2009).

Example 3 The Factor Model of Fan et al. (2013) Consider the following model:

$$\mathbf{y}_t = \mathbf{B}\mathbf{f}_t + \mathbf{E}_t,$$

where $\mathbf{y}_t = (y_{t,1}, \dots, y_{t,d})^T$ is the d -dimensional response vector, $\mathbf{B} = (\mathbf{b}_1, \dots, \mathbf{b}_d)^T$ is the $d \times m$ (m is fixed) loading matrix, \mathbf{f}_t is the $m \times 1$ vector of common factors, and $\mathbf{E}_t = (e_{t,1}, \dots, e_{t,d})^T$ is the d -dimensional noise vector, $t = 1, \dots, T$. The noise vector \mathbf{E}_t is independent of \mathbf{f}_t . Then the population covariance matrix of \mathbf{y}_t is

$$\Sigma = \mathbf{B}\text{cov}(\mathbf{f}_t)\mathbf{B}^T + \Sigma_E,$$

where Σ_E is the covariance matrix of \mathbf{E}_t . Fan et al. (2013) assumes that the first m eigenvalues of $\mathbf{B}\text{cov}(\mathbf{f}_t)\mathbf{B}^T$ increase with d as $d \rightarrow \infty$, whereas all the eigenvalues of Σ_E are bounded. It then follows that $\lambda_m(\Sigma) \asymp \lambda_{m+1}(\Sigma) \asymp \dots \asymp \lambda_d(\Sigma) \asymp 1$, as $d \rightarrow \infty$. Then our theorems are applicable to this factor model when $\mathbf{f}_1, \dots, \mathbf{f}_T$ is i.i.d., and $\mathbf{E}_1, \dots, \mathbf{E}_T$ is i.i.d.

Under the above assumptions of the factor model, we have $d/(\mathbb{T}\lambda_m(\Sigma)) \rightarrow 0$. Then according to our Theorem 1 (together with the third comment after the theorem), the first m sample eigenvalues and eigenvectors are consistent. On the other hand, Fan et al. (2013) proposed the consistent principal orthogonal complement thresholding (POET) estimator for the covariance matrix Σ , which is obtained by keeping the first m sample eigenvalues and eigenvectors, and thresholding the residual sample matrix. Hence, our theorem offers another theoretical support on the consistency of their POET estimator.

The rest of the paper is organized as follows. Section 2 first introduces our notations and relevant consistency concepts. Section 3 studies the PCA asymptotics of spike models with increasing sample size n . We state the main results of our paper - Theorem 1 for multiple-component spike models where the dominating eigenvalues are inseparable. Theorem 2 in Section 4 then is about the HDLSS asymptotics of PCA, where the sample size n is fixed, for spike models with inseparable eigenvalues. Section 5 contains some discussions about the asymptotic properties of PCA when some eigenvalues equal to zero and the challenges to obtain non-asymptotic results. Section 7 contains the technical proofs of Theorem 1 and

the relevant lemmas. The supplementary materials contain the corresponding corollaries of Theorems 1 and 2, for multiple-spike models with distinct eigenvalues and single spike models, along with the proofs of Theorem 2 and all the corollaries.

2. Notations and Concepts

We now introduce some necessary notations, and define consistency concepts relevant for our asymptotic study.

2.1 Notation

Let the population covariance matrix be Σ , whose eigen decomposition is

$$\Sigma = U\Lambda U^T,$$

where Λ is the diagonal matrix of population eigenvalues $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_d$, and U is the matrix of the corresponding eigenvectors $U = [u_1, \dots, u_d]$.

As in Jung and Marron (2009), assume that X_1, \dots, X_n are i.i.d. d -dimensional random sample vectors and have the following representation

$$X_i = \sum_{j=1}^d \lambda_j^{\frac{1}{2}} z_{i,j} u_j, \quad (1)$$

where the $z_{i,j}$'s are i.i.d. random variables with zero mean, unit variance, and finite fourth moment. An important special case is that they follow the standard normal distribution.

Assumption 1 X_1, \dots, X_n are a random sample having the distribution of (1).

Jung and Marron (2009) assumes that

$$Z_i = (z_{i,1}, \dots, z_{i,d})^T, \quad i = 1, \dots, n, \quad (2)$$

are independent and the elements $z_{i,j}$ within Z_i are ρ -mixing. This assumption leads to the convergence in probability results under the HDLSS domain in Jung and Marron (2009). Here we assume that the elements $z_{i,j}$ within Z_i are also independent. This helps to get the almost sure convergence results under our general framework, which includes the HDLSS domain. Assumption 1 is necessary to satisfy the conditions of Lemma 1 - the Bai-Yin's law (Bai and Yin, 1993), which is important for our results, for example, Theorem 1.

Denote the sample covariance matrix by $\hat{\Sigma} = n^{-1} X X^T$, where $X = [X_1, \dots, X_n]$. Note that $\hat{\Sigma}$ can also be decomposed as

$$\hat{\Sigma} = \hat{U} \hat{\Lambda} \hat{U}^T, \quad (3)$$

where $\hat{\Lambda}$ is the diagonal matrix of sample eigenvalues $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \dots \geq \hat{\lambda}_d$, and \hat{U} is the matrix of corresponding sample eigenvectors where $\hat{U} = [\hat{u}_1, \dots, \hat{u}_d]$.

Below we introduce asymptotic notations that will be used in our theoretical studies. Let τ stand for either n or d , depending on the context. Assume that $\{\xi_\tau : \tau = 1, \dots, \infty\}$ is a sequence of random variables, and $\{a_\tau : \tau = 1, \dots, \infty\}$ is a sequence of constant values.

- Denote $\xi_\tau = o_{a.s.}(a_\tau)$ if $\lim_{\tau \rightarrow \infty} \frac{\xi_\tau}{a_\tau} = 0$ almost surely.
- Denote $\xi_\tau = O_{a.s.}(a_\tau)$ if $\overline{\lim}_{\tau \rightarrow \infty} \left| \frac{\xi_\tau}{a_\tau} \right| \leq M$, where M is a positive constant.
- Denote almost surely $\xi_\tau \asymp a_\tau$ if $c_2 \leq \underline{\lim}_{\tau \rightarrow \infty} \frac{\xi_\tau}{a_\tau} \leq \overline{\lim}_{\tau \rightarrow \infty} \frac{\xi_\tau}{a_\tau} \leq c_1$ almost surely, for two constants $c_1 \geq c_2 > 0$.

In addition, we introduce the following notions to help understand the assumptions on the population eigenvalues in our theorems and corollaries. Assume that $\{a_\tau : \tau = 1, \dots, \infty\}$ and $\{b_\tau : \tau = 1, \dots, \infty\}$ are two sequences of real valued numbers.

- Denote $a_\tau \gg b_\tau$ if $\lim_{\tau \rightarrow \infty} \frac{b_\tau}{a_\tau} = 0$.
- Denote $a_\tau \asymp b_\tau$ if $c_2 \leq \underline{\lim}_{\tau \rightarrow \infty} \frac{a_\tau}{b_\tau} \leq \overline{\lim}_{\tau \rightarrow \infty} \frac{a_\tau}{b_\tau} \leq c_1$ for two constants $c_1 \geq c_2 > 0$.

2.2 Concepts

We now list several concepts about consistency and strong inconsistency, some of which are modified from the related concepts in Jung and Marron (2009) and Shen et al. (2013).

Let H be an index set, e.g. $H = \{m+1, \dots, d\}$, and then denote $S = \text{span}\{u_k, k \in H\}$ as the linear span generated by $\{u_k, k \in H\}$. Define $\text{angle}(\hat{u}_j, S)$ as the angle between the estimator \hat{u}_j and the subspace S , which is the angle between the estimator and its projection onto the subspace (Jung and Marron, 2009). For further clarification, we provide a graphical illustration of the angle in Section B of the supplement (Shen et al., 2015). As pointed out earlier, let τ stand for either n or d , depending on the context.

- If as $\tau \rightarrow \infty$, $\text{angle}(\hat{u}_j, S) \xrightarrow{a.s.} 0$, then \hat{u}_j is **subspace consistent** with S . If H only includes one index j such that $S = \text{span}\{u_j\}$, then $\text{angle}(\hat{u}_j, S) \xrightarrow{a.s.} 0$ is equivalent to $|\langle \hat{u}_j, u_j \rangle| \xrightarrow{a.s.} 1$, and \hat{u}_j is **consistent** with u_j .
- If as $\tau \rightarrow \infty$, $|\langle \hat{u}_j, u_j \rangle| \xrightarrow{a.s.} 0$, then \hat{u}_j is **strongly inconsistent** with u_j .

3. Cases with increasing sample size n

We study spike models with increasing sample size $n \rightarrow \infty$ in this section. As such, the eigenvalues λ_j and the dimension d depend on the sample size n , and will be denoted as $\lambda_j^{(n)}$ and $d(n)$ throughout this section. They can be viewed as sequences of constant values indexed by n . This section considers multiple-component spike models with inseparable eigenvalues and presents the main theorem of our paper. Section B of the supplementary materials reports the corollaries for multiple component spike models with distinct eigenvalues and single spike models.

We consider multiple spike models with m (a finite integer) dominating eigenvalues. These m eigenvalues can be grouped into r tiers, where the eigenvalues within the same tier have the same limit. To fixed ideas, the first m eigenvalues are grouped into r tiers where there are $q_l (> 0)$ eigenvalues in the l th tier with $\sum_{l=1}^r q_l = m$. Define $q_0 = 0$,

$q_{r+1} = d(n) - \sum_{l=1}^r q_l$, and the index set of the eigenvalues in the l th tier as

$$H_l = \left\{ \sum_{k=0}^{l-1} q_k + 1, \sum_{k=0}^{l-1} q_k + 2, \dots, \sum_{k=0}^{l-1} q_k + q_l \right\}, \quad l = 1, \dots, r+1. \quad (4)$$

Assume the eigenvalues in the l th tier have the same limit $\delta_l^{(n)} (> 0)$, i.e.

Assumption 2 $\lim_{n \rightarrow \infty} \frac{\lambda_j^{(n)}}{\delta_l^{(n)}} = 1, j \in H_l, l = 1, \dots, r$.

According to the above assumption, the eigenvalues that are in the same tier will have the same limit as n goes to infinity. As a result, we can show that the corresponding sample eigenvectors can not be consistently estimated individually. This motivates us to consider subspace consistency. In addition, we assume that the first m population eigenvalues from different tiers are asymptotically different, and dominate the additional population eigenvalues beyond the first r tiers that have the same limit c_λ :

Assumption 3 as $n \rightarrow \infty, \delta_1^{(n)} > \dots > \delta_r^{(n)} > \lambda_{m+1}^{(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_\lambda > 0$.

For $i < j, \delta_i^{(n)} > \delta_j^{(n)}$ means that $\lim_{n \rightarrow \infty} \frac{\delta_i^{(n)}}{\delta_j^{(n)}} > 1$. This assumption allows $\delta_i^{(n)} \rightarrow \infty$ and $\delta_i^{(n)} \gg \delta_j^{(n)}$, which is not the case in Paul (2007). Regarding the constant c_λ , the second remark after Theorem 1 discusses what happens when $c_\lambda = 0$.

The above assumptions cover a general class of multiple spike models with tiered eigenvalues. A simple special case is the one where the eigenvalue matrix Λ is block diagonal: for $1 \leq h \leq r$, the h -th block of Λ is $\lambda_h^{(n)} I_{q_h}$ where I_{q_h} is the $q_h \times q_h$ identity matrix, with

$$\lambda_1^{(n)} > \lambda_2^{(n)} > \dots > \lambda_r^{(n)}, \quad q_1 + q_2 + \dots + q_r = m < d;$$

and the last block of Λ is $c_\lambda I_{d(n)-m}$ with $c_\lambda < \lambda_r^{(n)}$.

Under the above setup, Theorem 1 shows that the eigenvector estimates are either subspace consistent with the linear space spanned by the population eigenvectors, or strongly inconsistent. As discussed in the Introduction, Theorem 1 considers the delicate balance among the *sample size* n , the *spike signal* $\delta_l^{(n)}$, and the *dimension* $d(n)$, and characterize the various PCA consistency and strong-inconsistency regions. The three scenarios of Theorem 1 are arranged in the order of a decreasing amount of signal:

- Theorem 1(a): If the amount of signal dominates the amount of noise up to the r th tier, i.e. $\frac{d(n)}{n\delta_r^{(n)}} \rightarrow 0$, then the estimates for the eigenvectors in the first r tiers are subspace consistent, and the estimates for the higher order eigenvectors are also subspace consistent (but) at a different rate;
- Theorem 1(b): Otherwise, if the amount of signal dominates the amount of noise only up to the l th tier ($1 \leq h < r$), i.e. $\frac{d(n)}{n\delta_h^{(n)}} \rightarrow 0$ and $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$, then the estimates for the eigenvectors in the first h tiers are subspace consistent, and the estimates for the other eigenvectors are strongly-inconsistent;

- Theorem 1(c): Finally, if the amount of noise always dominates, i.e. $\frac{d(n)}{n\lambda_1^{(n)}} \rightarrow \infty$, then the sample eigenvalues are asymptotically indistinguishable, and the sample eigenvectors are strongly inconsistent.

Before stating Theorem 1, we first introduce several notations. Define the subspace $S_l = \text{span}\{u_k, k \in H_l\}$ for $l = 1, \dots, r+1$ and denote $\delta_0^{(n)} = \infty$ for every n .

Theorem 1 Under Assumptions 1, 2 and 3, as $n \rightarrow \infty$, the following results hold.

(a) If $\frac{d(n)}{n\delta_r^{(n)}} \rightarrow 0$, then $\frac{\lambda_j}{\lambda_1} \xrightarrow{\text{a.s.}} 1, j = 1, \dots, m$, and $\text{angle}(\hat{u}_j, S_l) = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right)$, $j \in H_l, l = 1, \dots, r-1$. In addition,

- If $\frac{d(n)}{n} \rightarrow 0$, then $\text{angle}(\hat{u}_j, S_l) = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{1}{\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right), j \in H_l$ for $l = r$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{1}{\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right)$ for $l = r+1$.

- If $\frac{d(n)}{n} \rightarrow c, 0 < c \leq \infty$, then $\text{angle}(\hat{u}_j, S_l) = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \right\}^{\frac{1}{2}} \right) \vee \text{O}_{\text{a.s.}} \left(\left\{ \frac{d(n)}{n\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right), j \in H_l$ for $l = r$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{d(n)}{n\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right)$ for $l = r+1$.

(b) If $\frac{d(n)}{n\delta_h^{(n)}} \rightarrow 0$ and $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$, where $1 \leq h < r$, then $\frac{\lambda_j}{\lambda_1} \xrightarrow{\text{a.s.}} 1, j \in H_l, l = 1, \dots, h$,

and the other non-zero $\frac{n\lambda_j}{d(n)} \xrightarrow{\text{a.s.}} c_\lambda$. In addition, $\text{angle}(\hat{u}_j, S_l) = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}^{\frac{1}{2}} \right)$,

$j \in H_l$ for $l = 1, \dots, h-1$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \right\}^{\frac{1}{2}} \right) \vee \text{O}_{\text{a.s.}} \left(\left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\}^{\frac{1}{2}} \right)$ for $l = h$. Finally, $|\langle \hat{u}_j, u_j \rangle| = \text{O}_{\text{a.s.}} \left(\left\{ \frac{n\lambda_j^{(n)}}{d(n)} \right\}^{\frac{1}{2}} \right), j \in H_l, l = h+1, \dots, r$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{n}{d(n)} \right\}^{\frac{1}{2}} \right), j > m$.

(c) If $\frac{d(n)}{n\delta_1^{(n)}} \rightarrow \infty$, then the non-zero $\frac{n\lambda_j}{d(n)} \xrightarrow{\text{a.s.}} c_\lambda$. In addition, $|\langle \hat{u}_j, u_j \rangle| = \text{O}_{\text{a.s.}} \left(\left\{ \frac{n\lambda_j^{(n)}}{d(n)} \right\}^{\frac{1}{2}} \right), j > m$.

The following comments can be made for the results of Theorem 1.

- Note that, for $j \in H_1$, the subspace consistency rate for \hat{u}_j is $\left\{ \frac{\delta_1^{(n)}}{\delta_1^{(n)}} \right\}^{\frac{1}{2}}$. By defining $\delta_0^{(n)} = \infty$, the consistency rate expression $\left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}^{\frac{1}{2}}$ remains valid for $l = 1$.

- If $c_\lambda = 0$ in Assumption 3, then that assumption can be rewritten as

$$\delta_1^{*(n)} > \dots > \delta_r^{*(n)} > \lambda_{m+1}^{*(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{*(n)} = 1,$$

where $\delta_j^{*(n)} = \frac{\delta_j^{(n)}}{\lambda_{d(n)}^{(n)}}$ and $\lambda_j^{*(n)} = \frac{\lambda_j^{(n)}}{\lambda_{d(n)}^{(n)}}$. We comment that the asymptotic properties of

\hat{u}_j then depend on the rescaled eigenvalues $\lambda_j^{*(n)}$, instead of the raw eigenvalues $\lambda_j^{(n)}$. In particular, with $c_\lambda = 0$, Theorem 1 can be slightly modified by replacing $\delta_j^{(n)}$ with

$$\delta_j^{*(n)}, \frac{n\hat{\lambda}_j^{(n)}}{d(n)} \xrightarrow{\text{a.s.}} c_\lambda \text{ " with " } \frac{n\hat{\lambda}_j^{(n)}}{d(n)\lambda_{d(n)}^{(n)}} \xrightarrow{\text{a.s.}} 1 \text{ " , and the strongly inconsistency rate } \left\{ \frac{n\lambda_{h-1}^{(n)}}{d(n)} \right\}^{\frac{1}{2}}$$

with $\left\{ \frac{n\lambda_j^{*(n)}}{d(n)} \right\}^{\frac{1}{2}}$, respectively.

- In Assumption 3, if there is a big gap between $\delta_r^{(n)}$ and $\lambda_{m+1}^{(n)}$ such that $\delta_r^{(n)} \gg \lambda_{m+1}^{(n)}$, then $\lambda_{m+1}^{(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_\lambda$ can be weakened to $\lambda_{m+1}^{(n)} \asymp \dots \asymp \lambda_{d(n)}^{(n)} \asymp 1$. It follows that the consistency results of the first r tiers of sample eigenvalues in Scenario (a) or the first h tiers in Scenario (b) remain the same, while all other results of the form “ $\xrightarrow{\text{a.s.}}$ ” for the sample eigenvalues should be replaced by almost surely “ \asymp ”. The results for the sample eigenvectors remain the same.

- One needs $\lambda_{m+1}^{(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_\lambda$, or $\lambda_{m+1}^{(n)} \asymp \dots \asymp \lambda_{d(n)}^{(n)} \asymp 1$, to obtain general convergence results for the non-spike sample eigenvalues $\hat{\lambda}_j$, $j > m$, under the wide range of scenarios: $\frac{d(n)}{n} \rightarrow 0$, $\frac{d(n)}{n} \rightarrow \infty$, or $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$ ($0 < c < \infty$). When one focusses only on the spike eigenvalues, a weaker assumption, such as the slowly decaying non-spike eigenvalues assumed by Bai and Yao (2012), is sufficient. Then, the spike condition $\delta_r^{(n)} \gg \lambda_{m+1}^{(n)}$ is enough to generate the consistency properties of $\hat{\lambda}_j$ and \hat{u}_j , $j \leq m$ in Scenario (a). In that case, the behaviors of the other sample eigenvalues and eigenvectors are scenario specific, depending on whether $\frac{d(n)}{n} \rightarrow 0$, $\frac{d(n)}{n} \rightarrow \infty$, or $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$ ($0 < c < \infty$).

- The cases covered by Theorem 1 are not studied in Paul (2007), where the eigenvalues are considered to be individually estimable.

- In Theorem 1, the dimension d can be fixed. In addition, suppose $\infty > \delta_1^{(n)} > \dots > \delta_r^{(n)} > \lambda_{m+1}^{(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_\lambda$, and the eigenvalues satisfy Assumption 2. Then, the results of Theorem 1(a) are consistent with the classical asymptotic subspace consistency results implied by Theorem 1 of Anderson (1963).

4. Cases with fixed n

This section studies spike models when the sample size n is fixed. Now the eigenvalues are denoted as $\lambda_j^{(d)}$, a sequence indexed by the dimension d . We first report here the theoretical results for spike models with inseparable eigenvalues. The corresponding results for models with distinct eigenvalues are presented in Section C of the supplementary materials.

Theorem 2 summarizes the results for spike models with tiered eigenvalues. In comparison with Jung and Marron (2009), we make more general assumptions on the population eigenvalues, and obtain the convergence rate results; furthermore, we obtain almost sure convergence, instead of convergence in probability.

Assume that as $d \rightarrow \infty$, the first m eigenvalues fall into r tiers, where the eigenvalues in the same tier are asymptotically equivalent, as stated in the following assumption:

Assumption 4 *for fixed n , as $d \rightarrow \infty$, $\lambda_j^{(d)} \asymp \delta_l^{(d)}$, $j \in H_l$, $l = 1, \dots, r$.*

Different from Assumption 2 for diverging sample size n , now with a fixed n , the eigenvalues within the same tier are assumed to be of the same order, rather than of the same limit when n increases to ∞ . As we will see below in Theorem 2, one can no longer separately estimate the eigenvalues of the same order when n is fixed, which is feasible with an increasing n as long as they do not have the same limit as shown in Theorem 1.

In addition, we assume that the population eigenvalues from different tiers are of different orders and dominate the higher-order eigenvalues which are asymptotically equivalent:

Assumption 5 *for fixed n , as $d \rightarrow \infty$, $\delta_1^{(d)} \gg \dots \gg \delta_r^{(d)} \gg \lambda_{m+1}^{(d)} \asymp \dots \asymp \lambda_{d(n)}^{(d)} \asymp 1$.*

Note that for fixed n and $d \rightarrow \infty$, the assumption $\delta_1^{(d)} > \delta_{h+1}^{(d)}$ can not guarantee asymptotic separation of the corresponding sample eigenvalues $\hat{\lambda}_j$ for $j \in H_l$ and $j \in H_{l+1}$. Thus, we need to replace Assumption 3 with Assumption 5 in order to asymptotically separate the first r subgroups of sample eigenvalues.

Before formally stating Theorem 2, we first introduce several notations. Denote $\delta_0^{(d)} = \infty$ for every d , which is used to describe the subspace consistent rates. Consider the z_{kj} in (1), and let

$$\tilde{Z}_j = (z_{1j}, \dots, z_{nj})^T, \quad j = 1, \dots, d. \quad (5)$$

Define

$$K = \lim_{d \rightarrow \infty} \frac{\sum_{j=m+1}^d \lambda_j^{(d)}}{d} \quad \text{and} \quad A_l^* = \frac{1}{n} \sum_{k \in H_l} \tilde{Z}_k \tilde{Z}_k^T, \quad l = 1, \dots, r, \quad (6)$$

which are used to describe the asymptotic properties of the sample eigenvalues.

Theorem 2 *Under Assumptions 1, 4 and 5, for fixed n , as $d \rightarrow \infty$, the following results hold.*

(a) *If $\frac{d}{n} \rightarrow 0$ and $\frac{d}{n} \rightarrow \infty$, where $1 \leq h \leq r$, then for $j \in H_l$, $l = 1, \dots, h$, almost surely*

$$\lambda_{\min}(A_l^*) \times \min_{k \in H_l} \lambda_k^{(d)} \leq \hat{\lambda}_j \leq \lambda_{\max}(A_l^*) \times \max_{k \in H_l} \lambda_k^{(d)}, \quad (7)$$

and the other non-zero $\hat{\lambda}_j$ satisfy $\frac{n\hat{\lambda}_j}{d} \xrightarrow{\text{a.s.}} K$. In addition, $\text{angle}(\hat{u}_j, S_l) = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\delta_l^{(d)}}{\delta_{l-1}^{(d)}} \vee \frac{\delta_{l+1}^{(d)}}{\delta_l^{(d)}} \right\}^{\frac{1}{2}} \right)$,

$j \in H_l$ for $l = 1, \dots, h-1$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{d}{\delta_{h-1}^{(d)}} \right\}^{\frac{1}{2}} \right) \vee \text{O}_{\text{a.s.}} \left(\left\{ \frac{d}{\delta_h^{(d)}} \right\}^{\frac{1}{2}} \right)$ for $l = h$. Finally,

$|\langle \hat{u}_j, u_j \rangle| = \text{O}_{\text{a.s.}} \left(\left\{ \frac{\lambda_j^{(d)}}{d} \right\}^{\frac{1}{2}} \right)$, $j \in H_l$, $l = h+1, \dots, r$, and $\text{O}_{\text{a.s.}} \left(\left\{ \frac{1}{d} \right\}^{\frac{1}{2}} \right)$, $j > m$.

the dual matrix Σ_D in Section 7.3. Finally, we derive the asymptotic properties of the sample eigenvectors of Σ in Section 7.4. Some intuitive ideas are provided in the supplement (Shen et al., 2015) to help understanding the proof.

7.2 Lemmas

We list four lemmas that are used in our proof. Lemma 1 studies asymptotic properties of the largest and smallest non-zero eigenvalues of a random matrix.

Lemma 1 Suppose $B = \frac{1}{q}VV^T$ where V is an $p \times q$ random matrix composed of i.i.d. random variables with zero mean, unit variance and finite fourth moment. As $q \rightarrow \infty$ and $\frac{p}{q} \rightarrow c \in [0, \infty)$, the largest and smallest non-zero eigenvalues of B converge almost surely to $(1 + \sqrt{c})^2$ and $(1 - \sqrt{c})^2$, respectively.

Remark 1 Lemma 1 is known as the Bai-Yin's law (Bai and Yin, 1993). As in Remark 1 of Bai and Yin (1993), the smallest non-zero eigenvalue is the $p - q + 1$ smallest eigenvalue of B for $c > 1$.

Lemma 2 is about the Weyl Inequality and the dual Weyl Inequality (Tao, 2010), which appear below as the right-hand-side inequality and the left-hand-side inequality, respectively.

Lemma 2 If A, B are $p \times p$ real symmetric matrices, then for all $j = 1, \dots, p$,

$$\begin{cases} \lambda_j(A) + \lambda_p(B) \\ \lambda_{j+1}(A) + \lambda_{p-1}(B) \\ \vdots \\ \lambda_p(A) + \lambda_j(B) \end{cases} \leq \lambda_j(A+B) \leq \begin{cases} \lambda_j(A) + \lambda_1(B) \\ \lambda_{j-1}(A) + \lambda_2(B) \\ \vdots \\ \lambda_1(A) + \lambda_j(B) \end{cases},$$

where $\lambda_j(\cdot)$ is the j -th largest eigenvalue of the matrix.

Lemma 3 As $n \rightarrow \infty$, the eigenvalues of the matrix A in (9) satisfy

$$\frac{\lambda_j(A)}{\lambda_j^{(n)}} \xrightarrow{\text{a.s.}} 1, \quad \text{for } j = 1, \dots, m.$$

Proof Define the m -dimensional random vectors $X_i^* = [m, 0_{m \times (d-m)}]$, X_i , $i = 1, \dots, n$. Then, X_i^* has mean zero and the following covariance matrix Σ^* :

$$\Sigma^* = \begin{pmatrix} \lambda_1^{(n)} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_m^{(n)} \end{pmatrix}.$$

Let A^* be the dual matrix of the matrix A . The sample covariance matrix of X_i^* is

$$\begin{aligned} A^* &= \frac{1}{n} \sum_{i=1}^n X_i^* X_i^{*T} \\ &= \lambda_1^{(n)} \times \begin{pmatrix} \frac{1}{n} \sum_{i=1}^n z_{i,1}^2 & \cdots & \left\{ \frac{\lambda_k^{(n)}}{\lambda_1^{(n)}} \right\}^{\frac{1}{2}} \frac{1}{n} \sum_{i=1}^n z_{i,1} z_{i,m} \\ \vdots & \ddots & \vdots \\ \left\{ \frac{\lambda_m^{(n)}}{\lambda_1^{(n)}} \right\}^{\frac{1}{2}} \frac{1}{n} \sum_{i=1}^n z_{i,1} z_{i,m} & \cdots & \frac{\lambda_m^{(n)}}{\lambda_1^{(n)}} \frac{1}{n} \sum_{i=1}^n z_{i,m}^2 \end{pmatrix}, \end{aligned} \quad (10)$$

where the $z_{i,j}$'s are defined in (1).

Since A^* is the dual matrix of A , then A and A^* share the same non-zero eigenvalues. Below we study the eigenvalues of A through the dual matrix A^* .

The i.i.d. and unit variance properties of the $z_{i,j}$'s yield that as $n \rightarrow \infty$,

$$\frac{1}{n} \sum_{i=1}^n z_{i,k} z_{i,l} \xrightarrow{\text{a.s.}} \begin{cases} 1 & 1 \leq k = l \leq m \\ 0 & 1 \leq k \neq l \leq m \end{cases}. \quad (11)$$

Denote $b_k = \lim_{n \rightarrow \infty} \frac{\lambda_k^{(n)}}{\lambda_1^{(n)}} \leq 1$, $k = 1, \dots, m$. Then it follows from (10) and (11) that as $n \rightarrow \infty$,

$$\frac{1}{\lambda_1^{(n)}} A^* \xrightarrow{\text{a.s.}} \begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & b_m \end{pmatrix},$$

which further yields

$$\frac{\lambda_1(A)}{\lambda_1^{(n)}} = \frac{\lambda_1(A^*)}{\lambda_1^{(n)}} \xrightarrow{\text{a.s.}} 1. \quad (12)$$

Similarly, for $k = 2, \dots, m$, we have that as $n \rightarrow \infty$,

$$\frac{\lambda_1\left(\frac{1}{n} \sum_{j=k}^m \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right)}{\lambda_k^{(n)}} \xrightarrow{\text{a.s.}} 1. \quad (13)$$

Next we derive the upper and lower bounds for $\lambda_k(A)$, $k = 2, \dots, m$. According to Lemma 2, we have the following inequality:

$$\lambda_k(A) = \lambda_k\left(\frac{1}{n} \sum_{j=1}^m \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right) \leq \lambda_1\left(\frac{1}{n} \sum_{j=k}^m \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right) + \lambda_k\left(\frac{1}{n} \sum_{j=1}^{k-1} \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right).$$

Since the rank of $\frac{1}{n} \sum_{j=1}^{k-1} \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T$ is at most $k-1$, then $\lambda_k\left(\frac{1}{n} \sum_{j=1}^{k-1} \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right) = 0$, which together with (13), yields that

$$\frac{\lambda_k(A)}{\lambda_k^{(n)}} \leq \frac{1}{\lambda_k^{(n)}} \times \lambda_1\left(\frac{1}{n} \sum_{j=k}^m \lambda_j^{(n)} \tilde{Z}_j \tilde{Z}_j^T\right). \quad (14)$$

For the lower bound, it follows from Equation (5.9) in Jung and Marron (2009) that

$$\lambda_1\left(\sum_{j=k+1}^n \frac{\lambda_k}{n} \tilde{Z}_k \tilde{Z}_k^T\right) + \lambda_n\left(\frac{1}{n} \sum_{j=k+1}^m \lambda_j \tilde{Z}_j \tilde{Z}_j^T\right) \leq \lambda_k(A). \quad (15)$$

Given that the rank of $\frac{1}{n} \sum_{j=k+1}^m \lambda_j \tilde{Z}_j \tilde{Z}_j^T$ is at most m with $m < n$, then $\lambda_n(\frac{1}{n} \sum_{j=k+1}^m \lambda_j \tilde{Z}_j \tilde{Z}_j^T) = 0$, which together with (15), yields that

$$\frac{\lambda_k(A)}{\lambda_k^{(n)}} \geq \frac{1}{\lambda_k^{(n)}} \times \lambda_1\left(\frac{\lambda_k}{n} \tilde{Z}_k \tilde{Z}_k^T\right). \quad (16)$$

Note that as $n \rightarrow \infty$,

$$\frac{1}{\lambda_k^{(n)}} \times \lambda_1\left(\frac{\lambda_k}{n} \tilde{Z}_k \tilde{Z}_k^T\right) = \frac{1}{n} \tilde{Z}_k^T \tilde{Z}_k \xrightarrow{\text{a.s.}} 1. \quad (17)$$

It follows from (13), (14), (16) and (17) that, for $k = 2, \dots, m$,

$$\frac{\lambda_k(A)}{\lambda_k^{(n)}} \xrightarrow{\text{a.s.}} 1, \quad \text{as } n \rightarrow \infty. \quad (18)$$

The combination of (12) and (18) proves Lemma 6.1. \blacksquare

Lemma 4 Assume that $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$, where $0 \leq c \leq \infty$, and let $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ be the largest and smallest non-zero eigenvalues of the matrix, respectively. As $n \rightarrow \infty$, $\lambda_{\max}(B)$ and $\lambda_{\min}(B)$, where B in (9), satisfy

$$\lambda_{\max}(B) \text{ and } \lambda_{\min}(B) \xrightarrow{\text{a.s.}} c_\lambda, \quad \text{for } c = 0, \quad (19)$$

$$\frac{n}{d(n)} \lambda_{\max}(B) \text{ and } \frac{n}{d(n)} \lambda_{\min}(B) \xrightarrow{\text{a.s.}} c_\lambda, \quad \text{for } c = \infty, \quad (20)$$

and

$$\lambda_{\max}(B) \xrightarrow{\text{a.s.}} c_\lambda(1 + \sqrt{c}^2) \quad \text{and} \quad \lambda_{\min}(B) \xrightarrow{\text{a.s.}} c_\lambda(1 - \sqrt{c}^2), \quad \text{for } 0 < c < \infty. \quad (21)$$

Remark 2 If $\lambda_{m+1}^{(n)} \rightarrow \dots \rightarrow \lambda_{d(n)}^{(n)}$ is relaxed to $\lambda_{m+1}^{(n)} \asymp \dots \asymp \lambda_{d(n)}^{(n)}$, then “ $\xrightarrow{\text{a.s.}}$ ” is replaced by almost surely “ \asymp ”.

Proof Define $B^* = \frac{1}{n} \sum_{j=m+1}^{d(n)} \tilde{Z}_j \tilde{Z}_j^T$. The proof uses the following inequalities for $k \geq 1$:

$$\lambda_{d(n)}^{(n)} \times \lambda_k(B^*) \leq \lambda_k(B) \leq \lambda_{m+1}^{(n)} \times \lambda_k(B^*). \quad (22)$$

We first prove the right inequality of (22). Note that $\lambda_{m+1}^{(n)} B^*$ can be rewritten as $\lambda_{m+1}^{(n)} B + B^*$, where $B_R^* = \frac{1}{n} \sum_{j=m+1}^{d(n)} (\lambda_m^{(n)} - \lambda_j^{(n)}) \tilde{Z}_j \tilde{Z}_j^T$ and is a non-negative matrix. It then follows from Lemma 2 that for $k \geq 1$,

$$\lambda_{m+1}^{(n)} \times \lambda_k(B^*) = \lambda_k(\lambda_{m+1}^{(n)} B^*) \geq \lambda_k(B) + \lambda_n(B_R^*) \geq \lambda_k(B),$$

which yields the right inequality of (22).

For the left inequality in (22), note that $B = \lambda_{d(n)}^{(n)} B^* + B_L^*$, where $B_L^* = \frac{1}{n} \sum_{j=m+1}^{d(n)} (\lambda_j^{(n)} - \lambda_{d(n)}^{(n)}) \tilde{Z}_j \tilde{Z}_j^T$ and is a non-negative matrix. Lemma 2 implies that for $k \geq 1$,

$$\lambda_k(B) \geq \lambda_k(\lambda_{d(n)}^{(n)} B^*) + \lambda_n(B_L^*) \geq \lambda_k(\lambda_{d(n)}^{(n)} B^*) = \lambda_{d(n)}^{(n)} \times \lambda_k(B^*),$$

which yields the left inequality of (22).

Note that B^* can be rewritten as $B^* = \frac{1}{n} V V^T$, where $V = [\tilde{Z}_{m+1}, \dots, \tilde{Z}_{d(n)}]$ is an $n \times (d(n) - m)$ matrix. If $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \lim_{n \rightarrow \infty} \frac{d(n) - m}{n} = \infty$, then according to Lemma 1, we have that

$$\frac{1}{d(n) - m} \lambda_{\max}(V V^T) \quad \text{and} \quad \frac{1}{d(n) - m} \lambda_{\min}(V V^T) \xrightarrow{\text{a.s.}} 1.$$

It then follows that $\frac{n}{d(n)} \lambda_{\max}(B^*)$ and $\frac{n}{d(n)} \lambda_{\min}(B^*) \xrightarrow{\text{a.s.}} 1$, which, together with (22) and $\lambda_{m+1}^{(n)} \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_r$, yields (20).

Now consider the case $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \lim_{n \rightarrow \infty} \frac{d(n) - m}{n} = c < \infty$. Since $B^* = \frac{1}{n} V V^T$ and $\frac{1}{n} V^T V$ share the non-zero eigenvalues, then we study the eigenvalues of B^* through $\frac{1}{n} V^T V$. Applying Lemma 1 to $\frac{1}{n} V^T V$ yields that

$$\lambda_{\max}\left(\frac{1}{n} V^T V\right) \xrightarrow{\text{a.s.}} (1 + \sqrt{c})^2 \quad \text{and} \quad \lambda_{\min}\left(\frac{1}{n} V^T V\right) \xrightarrow{\text{a.s.}} (1 - \sqrt{c})^2.$$

It then follows that $\lambda_{\max}(B^*) \xrightarrow{\text{a.s.}} (1 + \sqrt{c})^2$ and $\lambda_{\min}(B^*) \xrightarrow{\text{a.s.}} (1 - \sqrt{c})^2$. In addition, given that $\lambda_{m+1}^{(n)} \rightarrow \lambda_{d(n)}^{(n)} \rightarrow c_r$ and (22), then we have $\lambda_{\max}(B) \xrightarrow{\text{a.s.}} c_r(1 + \sqrt{c})^2$ and $\lambda_{\min}(B) \xrightarrow{\text{a.s.}} c_r(1 - \sqrt{c})^2$ for $0 \leq c < \infty$, which yields (19) ($c = 0$) and (21) ($0 < c < \infty$). \blacksquare

7.3 Asymptotic properties of the sample eigenvalues

We now study the asymptotic properties of the sample eigenvalues $\hat{\lambda}_j$ for $j = 1, \dots, [n \wedge d(n)]$, which are the same as those of the dual matrix $\tilde{\Sigma}_D$, denoted as $\lambda_j(\tilde{\Sigma}_D) = \lambda_j(A + B)$.

7.3.1 SCENARIO (a) IN THEOREM 1

Scenario (a) contains three different cases: $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = 0$, ∞ , or c ($0 < c < \infty$). The proofs are different for each case and are provided separately below.

Consider the first case: $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = 0$. According to Lemma 2, we have that

$$\frac{\lambda_j(A)}{\lambda_j^{(n)}} \leq \frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \leq \frac{\lambda_j(A)}{\lambda_j^{(n)}} + \frac{\lambda_1(B)}{\lambda_j^{(n)}}. \quad (23)$$

If $\lambda_m^{(n)} \rightarrow \infty$, it follows from (19) that $\frac{\lambda_1(B)}{\lambda_j^{(n)}} \xrightarrow{a.s.} 0$ for $j = 1, \dots, m$. Then the combination of Lemma 3 and (23) proves that, as $n \rightarrow \infty$,

$$\frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \xrightarrow{a.s.} 1, \quad j = 1, \dots, m. \quad (24)$$

If $\lambda_m^{(n)} < \infty$, according to Theorem 1 ($c = 0$) of Baik and Silverman (2006), we still have (24). In addition, according to Lemma 2, we have

$$\lambda_j(B) \leq \hat{\lambda}_j \leq \lambda_j(A) + \lambda_1(B). \quad (25)$$

Since the rank of A is at most m , then $\lambda_j(A) = 0$ for $j \geq m + 1$, which, together with (25), yields that for $j = m + 1, \dots, [n \wedge d(n) - m]$,

$$\lambda_{\min}(B) \leq \hat{\lambda}_j \leq \lambda_{\max}(B). \quad (26)$$

Thus it follows from (19) and (26) that as $n \rightarrow \infty$,

$$\hat{\lambda}_j \xrightarrow{a.s.} c_j, \quad j = m + 1, \dots, [n \wedge d(n) - m].$$

Now consider the second case: $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \infty$. Since $\frac{d(n)}{n\lambda_m^{(n)}} \rightarrow 0$, then $\lambda_m^{(n)} \rightarrow \infty$, which, together with (20), (23) and Lemma 3, yields (24). Since $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \infty$, then $[n \wedge d(n) - m] = [n \wedge d(n)] = n$ as $n \rightarrow \infty$. It follows from (20) and (26) that

$$\frac{n}{d(n)} \hat{\lambda}_j \xrightarrow{a.s.} c_j, \quad j = m + 1, \dots, [n \wedge d(n)].$$

Finally, consider the third case: $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$ ($0 < c < \infty$). Similarly, it follows from $\frac{d(n)}{n\lambda_m^{(n)}} \rightarrow 0$ that $\lambda_m^{(n)} \rightarrow \infty$, which, jointly with (21), (23) and Lemma 3, yields (24). In addition, note that (21) and (26), and then almost surely we have

$$c_j(1 - \sqrt{c})^2 \leq \underline{\lim}_{n \rightarrow \infty} \hat{\lambda}_j \leq \overline{\lim}_{n \rightarrow \infty} \hat{\lambda}_j \leq c_j(1 + \sqrt{c})^2, \quad j = m + 1, \dots, [n \wedge d(n) - m].$$

All together, we have proven the consistency of the first m sample eigenvalues under Scenario (a), as stated in (24).

7.3.2 SCENARIO (b) IN THEOREM 1

Given $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$ and (8), then $\frac{d(n)}{n} \rightarrow \infty$ and $\frac{d(n)}{n\lambda_j^{(n)}} \rightarrow 0$ for $j \in H_l, l = 1, \dots, h$. Thus, according to (20), we have that $\frac{\lambda_1(B)}{\lambda_j^{(n)}} = \left[\frac{\lambda_1(B)}{d(n)} \lambda_1(B) \right] \left[\frac{d(n)}{n\lambda_j^{(n)}} \right] \xrightarrow{a.s.} 0$ for $j \in H_l, l = 1, \dots, h$. Furthermore, it follows from Lemma 3 and (23) that as $n \rightarrow \infty$,

$$\frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \xrightarrow{a.s.} 1, \quad j \in H_l, l = 1, \dots, h. \quad (27)$$

Note that (25) can be rewritten as

$$\frac{n}{d(n)} \lambda_j(B) \leq \frac{n}{d(n)} \hat{\lambda}_j \leq \frac{n}{d(n)} \lambda_j(A) + \frac{n}{d(n)} \lambda_1(B), \quad (28)$$

which yields that for $j = j_h + 1, \dots, [n \wedge d(n) - m]$,

$$\frac{n}{d(n)} \lambda_{\min}(B) \leq \frac{n}{d(n)} \hat{\lambda}_j \leq \frac{n}{d(n)} \lambda_j(A) + \frac{n}{d(n)} \lambda_{\max}(B). \quad (29)$$

Note that for $j = j_h + 1, \dots, [n \wedge d(n) - m]$, we have

$$\frac{n}{d(n)} \lambda_j(A) \leq \frac{n}{d(n)} \lambda_{j_{h+1}}^{(n)}(A) = \left\{ \frac{n\delta_{h+1}^{(n)}}{d(n)} \right\} \left\{ \frac{\lambda_{j_{h+1}}^{(n)}(A)}{\delta_{h+1}^{(n)}} \right\}.$$

It then follows from $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$ and Lemma 3 that $\frac{d(n)}{d(n)} \lambda_j(A) \xrightarrow{a.s.} 0$. Since $\frac{d(n)}{n} \rightarrow \infty$, then $[n \wedge d(n) - m] = [n \wedge d(n)] = n$, as $n \rightarrow \infty$. Then it follows from (20) and (29) that as $n \rightarrow \infty$

$$\frac{n}{d(n)} \hat{\lambda}_j \xrightarrow{a.s.} c_j, \quad j = j_h + 1, \dots, [n \wedge d(n)]. \quad (30)$$

The combination of (27) and (30) yields the asymptotic properties of the non-zero sample eigenvalues in Scenario (b).

7.3.3 SCENARIO (c) IN THEOREM 1

Since $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$, then $\frac{d(n)}{n} \rightarrow \infty$. According to (28), we have that for $j = 1, \dots, [n \wedge d(n) - m]$,

$$\frac{n}{d(n)} \lambda_{\min}(B) \leq \frac{n}{d(n)} \hat{\lambda}_j \leq \frac{n}{d(n)} \lambda_1(A) + \frac{n}{d(n)} \lambda_{\max}(B). \quad (31)$$

Since $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$, it follows from (8) and Lemma 3 that

$$\frac{n}{d(n)} \lambda_1(A) = \left[\frac{n\delta_1^{(n)}}{d(n)} \right] \times \left[\frac{\lambda_1^{(n)}}{\delta_1^{(n)}} \right] \times \left[\frac{\lambda_1(A)}{\lambda_1^{(n)}} \right] \xrightarrow{a.s.} 0.$$

Again note that $[n \wedge d(n) - m] = [n \wedge d(n)] = n$, as $n \rightarrow \infty$. Then it follows from (20) and (31) that

$$\frac{n}{d(n)} \hat{\lambda}_j \xrightarrow{a.s.} c_j, \quad j = 1, \dots, [n \wedge d(n)].$$

7.4 Asymptotic properties of the sample eigenvectors

We first state two results that simplify the proof. As aforementioned, in light of the invariance property of the angle, we choose the population eigenvectors $u_j, j = 1, \dots, d(n)$, as the basis of the d -dimensional space. It then follows that $u_j = e_j$ where the j th component of e_j equals to 1 and all the other components equal to zero. This suggests that

$$|\langle \hat{u}_j, u_j \rangle|^2 = |\langle \hat{u}_j, e_j \rangle|^2 = \hat{u}_{j,j}^2, \quad (32)$$

and for any index set H ,

$$\cos[\text{angle}(\hat{u}_j, \text{span}\{u_k, k \in H\})] = \sum_{k \in H} \hat{u}_{k,j}^2. \quad (33)$$

As a reminder, the population eigenvalues are grouped into $r+1$ tiers and the index set of the eigenvalues in the l th tier H_l is defined in (4). Define

$$\tilde{U}_{k,l} = (\hat{u}_{i,j})_{i \in H_k, j \in H_l}, \quad 1 \leq k, l \leq r+1.$$

Then, the sample eigenvector matrix \tilde{U} can be rewritten as the following:

$$\tilde{U} = [\hat{u}_1, \hat{u}_2, \dots, \hat{u}_{d(n)}] = \begin{pmatrix} \tilde{U}_{1,1} & \tilde{U}_{1,2} & \dots & \tilde{U}_{1,r+1} \\ \tilde{U}_{2,1} & \tilde{U}_{2,2} & \dots & \tilde{U}_{2,r+1} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{U}_{r+1,1} & \tilde{U}_{r+1,2} & \dots & \tilde{U}_{r+1,r+1} \end{pmatrix}.$$

To derive the asymptotic properties of the sample eigenvectors \hat{u}_j , we consider the three scenarios of Theorem 1 separately.

7.4.1 SCENARIO (b) IN THEOREM 1

Under Scenario (b), there exists a constant $h \in [1, r]$, such that $\frac{d(n)}{n\delta_h^{(n)}} \rightarrow 0$ and $\frac{d(n)}{n\delta_{h+1}^{(n)}} \rightarrow \infty$. In order to obtain the the subspace consistency properties in Scenario (b), according to (33), we only need to show that as $n \rightarrow \infty$,

$$\sum_{k \in H_l} \hat{u}_{k,j}^2 = 1 + o_{\text{a.s.}} \left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}, \quad j \in H_l, \quad l = 1, \dots, h-1, \quad (34)$$

$$\sum_{k \in H_h} \hat{u}_{k,j}^2 = 1 + o_{\text{a.s.}} \left\{ \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \vee O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\} \right\}, \quad j \in H_h, \quad (35)$$

which are respectively equivalent to

$$\sum_{j \in H_l} \sum_{k \in H_l} \hat{u}_{k,j}^2 = |H_l| + o_{\text{a.s.}} \left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}, \quad l = 1, \dots, h-1, \quad (36)$$

$$\sum_{j \in H_h} \sum_{k \in H_h} \hat{u}_{k,j}^2 = |H_h| + o_{\text{a.s.}} \left\{ \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \vee O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\} \right\}, \quad (37)$$

where $|H_l|$ is the number of elements in H_l and less than m . Since $\sum_{j \in H_l} \sum_{k \in H_l} = \sum_{k \in H_l} \sum_{j \in H_l}$, then in order to obtain (36) and (37), we just need to prove that as $n \rightarrow \infty$,

$$\sum_{j \in H_l} \hat{u}_{k,j}^2 = 1 + o_{\text{a.s.}} \left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}, \quad k \in H_l, \quad l = 1, \dots, h-1, \quad (38)$$

$$\sum_{j \in H_h} \hat{u}_{k,j}^2 = 1 + o_{\text{a.s.}} \left\{ \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \vee O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\} \right\}, \quad k \in H_h. \quad (39)$$

Therefore the proof of the subspace consistency contains two steps (38) and (39). Here we first prove (39) and then (38).

The third step is to show the strong inconsistency in Scenario (b). Since $\hat{\lambda}_j = 0$ for $j > [n \wedge d(n)]$, then we only need to show the strong inconsistency of \hat{u}_j , $j < [n \wedge d(n)]$. Here we will prove that as $n \rightarrow \infty$,

$$\max_{j_h+1 \leq l \leq [n \wedge d(n)]} \left\{ \frac{d(n)}{n\lambda_j^{(n)}} \hat{u}_{j,j}^2 \right\} = O_{\text{a.s.}}(1). \quad (40)$$

The First Step: Proof of (39). Since

$$\sum_{j \in H_h} \hat{u}_{k,j}^2 = 1 - \sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 - \sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2, \quad (41)$$

then in order to obtain (39), we just need to show that as $n \rightarrow \infty$,

$$\sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 = O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\}, \quad k \in H_h, \quad (41)$$

$$\sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 = O_{\text{a.s.}} \left\{ \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \right\}, \quad k \in H_h. \quad (42)$$

We first prove (41). Since $\sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 \leq \sum_{k=1}^{j_h} \sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2$ for $k \in H_h$, then in order to generate (41), we need to show that as $n \rightarrow \infty$,

$$\sum_{k=1}^{j_h} \sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 = O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\}. \quad (43)$$

Since $\sum_{k=1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{j=1}^{d(n)} \hat{u}_{k,j}^2 = 1$, then we have

$$\begin{aligned} d(n) - j_l &= \sum_{j=j_l+1}^{d(n)} \sum_{k=1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{k=1}^{j_l} \sum_{j=j_l+1}^{d(n)} \hat{u}_{k,j}^2 + \sum_{k=j_l+1}^{d(n)} \sum_{j=j_l+1}^{d(n)} \hat{u}_{k,j}^2, \\ d(n) - j_l &= \sum_{k=j_l+1}^{d(n)} \sum_{j=1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{k=j_l+1}^{d(n)} \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 + \sum_{k=j_l+1}^{d(n)} \sum_{j=j_l+1}^{d(n)} \hat{u}_{k,j}^2, \end{aligned}$$

which yields

$$\sum_{k=1}^{j_l} \sum_{j=j_l+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{k=j_l+1}^{d(n)} \sum_{j=1}^{j_l} \hat{u}_{k,j}^2. \quad (44)$$

Let $l = h$ in (44) and then (43) can be obtained through showing

$$\sum_{k=j_h+1}^{d(n)} \sum_{j=1}^{j_h} \hat{u}_{k,j}^2 = O_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_h^{(n)}} \right\}. \quad (45)$$

Therefore, in order to show (41), we need to prove (45).

Before proving (45), we need some preparation. Denote $S = \Lambda^{-\frac{1}{2}} \hat{U} \hat{\Lambda}^{\frac{1}{2}}$ where \hat{U} is the sample eigenvector matrix and $\hat{\Lambda}$ is the sample eigenvalue matrix defined in (3). Define

$$Z = (Z_1, \dots, Z_m), \quad (46)$$

where Z_l is in (2). It follows from (1), (2) and (3) that $SS^T = \frac{1}{n}ZZ^T$. Since $s_{k,j} = \lambda_k^{(n)-\frac{1}{2}} \lambda_j^{\frac{1}{2}} \hat{u}_{k,j}$, then considering the k -th diagonal entry of the matrices $SS^T = \frac{1}{n}ZZ^T$ on the two sides leads to

$$\frac{1}{\lambda_k^{(n)}} \sum_{j=1}^d \lambda_j \hat{u}_{k,j}^2 = \sum_{j=1}^d s_{k,j}^2 = \frac{1}{n} \sum_{i=1}^n z_{i,k}^2 \quad k = 1, \dots, d(n). \quad (47)$$

In addition, the j -th diagonal entry of $S^T S$ is less than or equal to its largest eigenvalue, i.e. $\lambda_{\max}(S^T S) = \lambda_{\max}(\frac{1}{n}ZZ^T) = \lambda_{\max}(\frac{1}{n}Z^T Z)$, which yields

$$\hat{\lambda}_j \sum_{k=1}^{d(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 = \sum_{k=1}^{d(n)} s_{k,j}^2 \leq \lambda_{\max}(\frac{1}{n}Z^T Z), \quad j = 1, \dots, d(n). \quad (48)$$

According to (48), we have that for $l = 1, \dots, h$,

$$\begin{aligned} \hat{\lambda}_{j_l} \times \frac{1}{\lambda_{m+1}^{(n)}} \times \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 &\leq \sum_{j=1}^{j_l} \hat{\lambda}_j \sum_{k=m+1}^{d(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 \\ &\leq \sum_{j=1}^{j_l} \hat{\lambda}_j \sum_{k=1}^{d(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 \leq j_l \times \lambda_{\max}(\frac{1}{n}Z^T Z), \end{aligned}$$

which yields

$$\sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{j=1}^{j_l} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 \leq j_l \lambda_{m+1}^{(n)} \times \frac{\delta_{(n)}^{(n)}}{\lambda_{j_l}} \times \lambda_{\max}(\frac{1}{d(n)}Z^T Z) \times \frac{d(n)}{n \delta_l^{(n)}}. \quad (49)$$

Since $\frac{d(n)}{n} = \delta_{k+1}^{(n)} \times \frac{d(n)}{n \delta_{k+1}^{(n)}} \rightarrow \infty$, it follows from Lemma 3 that $\lambda_{\max}(\frac{1}{d(n)}Z^T Z) \xrightarrow{a.s} 1$.

According to (8) and (27), $\frac{\delta_{(n)}^{(n)}}{\lambda_{j_l}} = \frac{\delta_{(n)}^{(n)}}{\lambda_{j_l}} \times \frac{\lambda_{j_l}^{(n)}}{\lambda_{j_l}} \xrightarrow{a.s} 1$, $l = 1, \dots, h$. In addition, note that $j_l (< m)$ is finite and $\lambda_{m+1}^{(n)} \rightarrow c_Y$. Thus it follows from (49) that as $n \rightarrow \infty$,

$$\sum_{k=m+1}^{d(n)} \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 = O_{a.s} \left\{ \frac{d(n)}{n \delta_l^{(n)}} \right\}. \quad (50)$$

From (47), we have that for $l = 1, \dots, h$,

$$\begin{aligned} \frac{1}{\lambda_{j_h+1}^{(n)}} \times \hat{\lambda}_{j_l} \sum_{k=j_h+1}^m \hat{u}_{k,j}^2 &\leq \sum_{k=j_h+1}^m \frac{1}{\lambda_k^{(n)}} \sum_{j=1}^{j_l} \lambda_j \hat{u}_{k,j}^2 \\ &\leq \sum_{k=j_h+1}^m \frac{1}{\lambda_k^{(n)}} \sum_{j=1}^{d(n)} \lambda_j \hat{u}_{k,j}^2 = \sum_{k=j_h+1}^m \frac{1}{n} \sum_{i=1}^n z_{i,k}^2, \end{aligned}$$

which yields

$$\sum_{k=j_h+1}^m \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 \leq \frac{\lambda_{(n)}^{(n)}}{\delta_l^{(n)}} \times \frac{\delta_{(n)}^{(n)}}{\lambda_{j_l}} \times \sum_{k=j_h+1}^m \frac{1}{n} \sum_{i=1}^n z_{i,k}^2. \quad (51)$$

Since $\frac{\lambda_{j_h+1}^{(n)}}{\delta_{j_h+1}^{(n)}} \rightarrow 1$ and $\sum_{k=j_h+1}^m \frac{1}{n} \sum_{i=1}^n z_{i,k}^2 \xrightarrow{a.s} m - j_h$, it follows from (51) that as $n \rightarrow \infty$,

$$\sum_{k=j_h+1}^m \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 = O_{a.s} \left\{ \frac{\delta_{j_h+1}^{(n)}}{\delta_l^{(n)}} \right\}. \quad (52)$$

Since $\delta_{h+1}^{(n)} \ll \frac{d(n)}{n}$, it follows from (50) and (52) that as $n \rightarrow \infty$,

$$\sum_{k=j_h+1}^{d(n)} \sum_{j=1}^{j_l} \hat{u}_{k,j}^2 = O_{a.s} \left\{ \frac{d(n)}{n \delta_l^{(n)}} \right\}, \quad l = 1, \dots, h. \quad (53)$$

Letting $l = h$ in (53) results in (45).

Until now we have proven (41). In order to finish the first step proof, we need to show (42). Since $\frac{1}{n} \sum_{i=1}^n z_{i,k}^2 \xrightarrow{a.s} 1$, it follows from (47) that for $k \in H_n$,

$$\frac{1}{\lambda_k^{(n)}} \sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{\lambda}_j \hat{u}_{k,j}^2 + \frac{1}{\lambda_k^{(n)}} \sum_{j \in H_h} \hat{\lambda}_j \hat{u}_{k,j}^2 + \frac{1}{\lambda_k^{(n)}} \sum_{j=j_h+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 = \frac{1}{\lambda_k^{(n)}} \sum_{j=1}^{d(n)} \lambda_j \hat{u}_{k,j}^2 \xrightarrow{a.s} 1. \quad (54)$$

Since

$$\frac{\hat{\lambda}_j}{\lambda_k^{(n)}} \xrightarrow{a.s} \frac{\delta_{(n)}^{(n)}}{\delta_h^{(n)}}, \quad k \in H_n, j \in H_l, \quad (55)$$

and

$$\frac{1}{\lambda_k^{(n)}} \sum_{j=j_h+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 \leq \frac{\hat{\lambda}_{j_h+1}}{\lambda_k^{(n)}} \xrightarrow{a.s} \frac{\delta_{k+1}^{(n)}}{\delta_h^{(n)}} \rightarrow 0,$$

it follows from (54) that for $k \in H_n$,

$$\sum_{l=1}^{h-1} \frac{\delta_l^{(n)}}{\delta_h^{(n)}} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_h} \hat{u}_{k,j}^2 \xrightarrow{a.s} 1. \quad (56)$$

According to (43), we have $\sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 \leq \sum_{k=1}^{j_h} \sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 \xrightarrow{a.s} 0$, which together with

$$\sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_h} \hat{u}_{k,j}^2 + \sum_{j=j_h+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{j=1}^d \hat{u}_{k,j}^2 = 1,$$

yields that for $k \in H_n$,

$$\sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_h} \hat{u}_{k,j}^2 \xrightarrow{a.s} 1. \quad (57)$$

Since $\lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_h^{(n)}} > 1$ for $l < h$, it follows from (56) and (57) that $\sum_{j \in H_h} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1$ for $k \in H_h$, which together with (56), yields that for $k \in H_h$,

$$\sum_{l=1}^{h-1} \frac{\delta_l^{(n)}}{\delta_h^{(n)}} \sum_{j \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 0. \quad (58)$$

Since $\lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_h^{(n)}} \geq \lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_h^{(n)}}$ for $l \leq h-1$, it follows from (58) that as $n \rightarrow \infty$,

$$\sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\}, \quad k \in H_h,$$

which is (42).

The Second Step: Proof of (38). Below we illustrate how one can use (39) to prove (38) for $l = h-1$. Then through a similar procedure, the result for $l = h-1$ in (38) can be used to prove that (38) holds for $l = h-2$, which is then iterated until finishing the proof of (38).

Since

$$\sum_{j \in H_{h-1}} \hat{u}_{k,j}^2 = 1 - \sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{u}_{k,j}^2 - \sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2,$$

then in order to obtain (38) for $l = h-1$, we need to prove that as $n \rightarrow \infty$,

$$\sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\}, \quad k \in H_{h-1}, \quad (59)$$

$$\sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_{h-1}^{(n)} \\ \delta_{h-2}^{(n)} \end{matrix} \right\}, \quad k \in H_{h-1}. \quad (60)$$

Now we show the proof of (59). Since $j_h < m$ is finite and $\sum_{j=1}^{j_h-1} = \sum_{j=1}^{h-1} \sum_{j \in H_l}$, it follows from (42) that as $n \rightarrow \infty$,

$$\sum_{k=j_{h-1}+1}^{j_h} \sum_{j=1}^{j_h-1} \hat{u}_{k,j}^2 = \sum_{k=j_{h-1}+1}^{j_h} \left(\sum_{l=1}^{h-1} \sum_{j \in H_l} \hat{u}_{k,j}^2 \right) = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\}. \quad (61)$$

Let $l = h-1$ in (53) to obtain that $\sum_{k=j_h+1}^{d(n)} \sum_{j=1}^{j_h-1} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} d(n) \\ n \delta_{h-1}^{(n)} \end{matrix} \right\}$. Since $\delta_h^{(n)} \gg \frac{d(n)}{n}$, it follows from (61) that as $n \rightarrow \infty$,

$$\begin{aligned} \sum_{k=j_{h-1}+1}^{d(n)} \sum_{j=1}^{j_h-1} \hat{u}_{k,j}^2 &= \sum_{k=j_{h-1}+1}^{j_h} \sum_{j=1}^{j_h-1} \hat{u}_{k,j}^2 + \sum_{k=j_h+1}^{d(n)} \sum_{j=1}^{j_h-1} \hat{u}_{k,j}^2 \\ &= \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\} + \text{O}_{\text{a.s.}} \left\{ \begin{matrix} d(n) \\ n \delta_{h-1}^{(n)} \end{matrix} \right\} = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\}. \end{aligned} \quad (62)$$

Let $l = h-1$ in (44), which together with (62), proves that as $n \rightarrow \infty$,

$$\sum_{k=1}^{j_{h-1}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{k=j_{h-1}+1}^{j_{h-1}} \sum_{j=1}^{j_{h-1}} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-1}^{(n)} \end{matrix} \right\}. \quad (63)$$

Since $\sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2 \leq \sum_{k=1}^{j_{h-1}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2$ for $k \in H_{h-1}$, then (59) follows from (63).

Now we show the proof of (60) to finish the second step. Since $\frac{1}{n} \sum_{i=1}^n z_{i,k}^2 \xrightarrow{\text{a.s.}} 1$, it follows from (47) that for $k \in H_{h-1}$,

$$\frac{1}{\lambda_k^{(n)}} \sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{\lambda}_j \hat{u}_{k,j}^2 + \frac{1}{\lambda_k^{(n)}} \sum_{j \in H_{h-1}} \hat{\lambda}_j \hat{u}_{k,j}^2 + \frac{1}{\lambda_k^{(n)}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 = \frac{1}{\lambda_k^{(n)}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1. \quad (64)$$

Since $\frac{1}{\lambda_k^{(n)}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 \leq \frac{1}{\lambda_k^{(n)}} \hat{\lambda}_{j_{h-1}+1} \sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2$ and $\frac{\hat{\lambda}_{j_{h-1}+1}}{\lambda_k^{(n)}} \xrightarrow{\text{a.s.}} \lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} < 1$ for $k \in H_{h-1}$, it follows from (59) that

$$\frac{1}{\lambda_k^{(n)}} \sum_{j=j_{h-1}+1}^{d(n)} \hat{\lambda}_j \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 0,$$

which together with (55) and (64), yields

$$\sum_{l=1}^{h-2} \frac{\delta_l^{(n)}}{\delta_{h-1}^{(n)}} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_{h-1}} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1, \quad k \in H_{h-1}. \quad (65)$$

In addition, since

$$\sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_{h-1}} \hat{u}_{k,j}^2 = \sum_{j=j_{h-1}+1}^{d(n)} \hat{u}_{k,j}^2 = 1,$$

it follows from (59) that

$$\sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{u}_{k,j}^2 + \sum_{j \in H_{h-1}} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1, \quad k \in H_{h-1}. \quad (66)$$

Note that $\lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} > 1$ for $l < h-1$. Then the combination of (65) and (66) gives $\sum_{j \in H_{h-1}} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1$ for $k \in H_{h-1}$, which together with (65), yields

$$\sum_{l=1}^{h-2} \frac{\delta_l^{(n)}}{\delta_{h-1}^{(n)}} \sum_{j \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 0, \quad k \in H_{h-1}. \quad (67)$$

Since $\lim_{n \rightarrow \infty} \frac{\delta_h^{(n)}}{\delta_{h-1}^{(n)}} \geq \lim_{n \rightarrow \infty} \frac{\delta_{h-2}^{(n)}}{\delta_{h-1}^{(n)}}$ for $l \leq h-2$, it follows from (67) that as $n \rightarrow \infty$,

$$\sum_{l=1}^{h-2} \sum_{j \in H_l} \hat{u}_{k,j}^2 = \text{O}_{\text{a.s.}} \left\{ \begin{matrix} \delta_h^{(n)} \\ \delta_{h-2}^{(n)} \end{matrix} \right\}, \quad k \in H_h,$$

which is (60).

The Third Step: Proof of (40). According to (47), we have $\frac{1}{\lambda_j^{(n)}} \hat{\lambda}_j \hat{u}_{j,j}^2 \leq \frac{1}{n} \sum_{i=1}^n z_{i,j}^2$ for $j = 1, \dots, d(n)$, which yields

$$\begin{aligned} \hat{\lambda}_{j_{n \wedge d(n)}} \times \max_{j_n+1 \leq j \leq n \wedge d(n)} \left\{ \frac{1}{\lambda_j^{(n)}} \hat{u}_{j,j}^2 \right\} &\leq \max_{j_n+1 \leq j \leq n \wedge d(n)} \left\{ \frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \hat{u}_{j,j}^2 \right\} \\ &\leq \max_{1 \leq j \leq n \wedge d(n)} \left\{ \frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \hat{u}_{j,j}^2 \right\} \leq \max_{1 \leq j \leq n \wedge d(n)} \left\{ \frac{1}{n} \sum_{i=1}^n z_{i,j}^2 \right\}. \end{aligned} \quad (68)$$

Select the first $[n \wedge d(n)]$ rows of Z in (46) and denote the resulting random matrix as Z^* . Since $\frac{1}{n} \sum_{i=1}^n z_{i,j}^2$ is the j -th diagonal entry of $\frac{1}{n} Z^* Z^{*T}$ for $1 \leq j \leq [n \wedge d(n)]$, it follows that

$$\frac{1}{n} \sum_{i=1}^n z_{i,j}^2 \leq \lambda_{\max} \left(\frac{1}{n} Z^* Z^{*T} \right), \quad 1 \leq j \leq [n \wedge d(n)],$$

which yields

$$\max_{1 \leq j \leq [n \wedge d(n)]} \left\{ \frac{1}{n} \sum_{i=1}^n z_{i,j}^2 \right\} \leq \lambda_{\max} \left(\frac{1}{n} Z^* Z^{*T} \right).$$

Then from (68),

$$\left\{ \frac{n}{d(n)} \hat{\lambda}_{j_{n \wedge d(n)}} \right\} \times \max_{j_n+1 \leq j \leq n \wedge d(n)} \left\{ \frac{d(n)}{n \lambda_j^{(n)}} \hat{u}_{j,j}^2 \right\} \leq \lambda_{\max} \left(\frac{1}{n} Z^* Z^{*T} \right). \quad (69)$$

Since $\frac{d(n)}{n} \rightarrow \infty$ here, $[n \wedge d(n)] = n$. According to Lemma 1, we have $\lambda_{\max} \left(\frac{1}{n} Z^* Z^{*T} \right) \xrightarrow{\text{a.s.}} 4$, which together with (30) and (69), yields (40).

7.4.2 SCENARIO (a) IN THEOREM 1

Scenario (a) contains three different cases: $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = 0$, ∞ , or c ($0 < c < \infty$). The proofs are slightly different for each case and are provided separately below.

Consider the case $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \infty$. Since $\lambda_j^{(n)} \rightarrow c_j$ for $j \in H_{r+1}$, then $\frac{d(n)}{n \delta_r^{(n)}} \rightarrow 0$ and $\frac{d(n)}{n \lambda_j^{(n)}} \rightarrow \infty$ for $j \in H_{r+1}$. Thus h in (34) and (35) becomes r such that as $n \rightarrow \infty$,

$$\sum_{k \in H_l} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{\delta_l^{(n)}}{\delta_{l-1}^{(n)}} \vee \frac{\delta_{l+1}^{(n)}}{\delta_l^{(n)}} \right\}, \quad j \in H_l, \quad l = 1, \dots, r-1, \quad (70)$$

$$\sum_{k \in H_r} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{\delta_r^{(n)}}{\delta_{r-1}^{(n)}} \right\} \vee \mathbf{O}_{\text{as}} \left\{ \frac{d(n)}{n \delta_r^{(n)}} \right\}, \quad j \in H_r. \quad (71)$$

Since $j_r = m$, then (50) becomes that as $n \rightarrow \infty$,

$$\sum_{k=m+1, j=1}^{d(n)} \hat{u}_{k,j}^2 = \mathbf{O}_{\text{as}} \left\{ \frac{d(n)}{n \delta_r^{(n)}} \right\},$$

which together with (44), yields that

$$\sum_{k=1, j=m+1}^{d(n)} \hat{u}_{k,j}^2 = \mathbf{O}_{\text{as}} \left\{ \frac{d(n)}{n \delta_r^{(n)}} \right\}. \quad (72)$$

Since

$$1 \geq \sum_{k \in H_{r+1}} \hat{u}_{k,j}^2 = 1 - \sum_{k=1}^m \hat{u}_{k,j}^2 \geq 1 - \sum_{k=1, j=m+1}^m \hat{u}_{k,j}^2, \quad j > m, \quad (73)$$

it follows from (72) that

$$\sum_{k \in H_{r+1}} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{d(n)}{n \delta_r^{(n)}} \right\}, \quad j = m+1, \dots, [n \wedge d(n)]. \quad (74)$$

Now consider the second case $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$ ($0 < c < \infty$). Note that the subspace consistency of the sample eigenvectors in (70) only depends on the asymptotic properties of the sample eigenvalues $\hat{\lambda}_j$, $j = 1, \dots, m$. According to Section 7.3.1, the asymptotic properties of $\hat{\lambda}_j$, $j = 1, \dots, m$, only depends on $\frac{d(n)}{n \delta_r^{(n)}} \rightarrow 0$, and is the same as in the first case $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = \infty$. Thus (70) remains valid here.

However, the subspace consistency of the other eigenvectors also depends on $\hat{\lambda}_j$, $j > m$, whose properties are different from the first case. In fact (71) and (74) respectively become that as $n \rightarrow \infty$,

$$\sum_{k \in H_r} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{\delta_r^{(n)}}{\delta_{r-1}^{(n)}} \right\} \vee \mathbf{O}_{\text{as}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}, \quad j \in H_r, \quad (75)$$

$$\sum_{k \in H_{r+1}} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}, \quad j = m+1, \dots, [n \wedge d(n)]. \quad (76)$$

In order to obtain (75), following the first step proof procedure in Section 7.4.1, we only need to show that as $n \rightarrow \infty$,

$$\sum_{k=1, j=m+1}^m \hat{u}_{k,j}^2 = \mathbf{O}_{\text{as}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}. \quad (77)$$

Since $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = c$ ($0 < c < \infty$), then (72) becomes (77). In addition, it follows from (73) and (77) that (76) is established.

Note that we can combine the first and the second cases together as follows. If $\frac{d(n)}{n} \rightarrow c$, $0 < c \leq \infty$, then the combination of (71) and (75) provides

$$\sum_{k \in H_r} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{as}} \left\{ \frac{\delta_r^{(n)}}{\delta_{r-1}^{(n)}} \right\} \vee \mathbf{O}_{\text{as}} \left\{ \frac{d(n)}{n \delta_r^{(n)}} \right\}, \quad j \in H_r,$$

and the combination of (74) and (77) yields

$$\sum_{k \in H_{r+1}} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{a.s.}} \left\{ \frac{d(n)}{n\delta_r} \right\}, \quad j = m+1, \dots, [n \wedge d(n)].$$

In addition, (70) remains valid for both cases. Thus it follows from (33) that we have finished the proof of the second bullet point in Scenario (a).

Finally, consider the last case $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = 0$. It is clear that (70) still holds. According to (33), in order to finish the proof of the first bullet point in Scenario (a), we only need to show that as $n \rightarrow \infty$,

$$\sum_{k \in H_r} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{a.s.}} \left\{ \frac{\delta_r^{(n)}}{\delta_{r-1}^{(n)}} \vee \frac{1}{\delta_r^{(n)}} \right\}, \quad j \in H_r, \quad (78)$$

$$\sum_{k \in H_{r+1}} \hat{u}_{k,j}^2 = 1 + \mathbf{O}_{\text{a.s.}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}, \quad j = m+1, \dots, [n \wedge d(n)]. \quad (79)$$

In fact, in order to prove (78) and (79), we need to replace (77) by that as $n \rightarrow \infty$,

$$\sum_{k=1}^m \sum_{j=m+1}^{d(n)} \hat{u}_{k,j}^2 = \mathbf{O}_{\text{a.s.}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}. \quad (80)$$

It follows from (44) that

$$\sum_{k=1}^m \sum_{j=m+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{j=1}^m \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2.$$

We also have

$$\sum_{j=1}^m \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 = \sum_{l=1}^r \sum_{j \in H_l} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2.$$

Then in order to obtain (80), we only need to prove that as $n \rightarrow \infty$,

$$\sum_{j \in H_r} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 = \mathbf{O}_{\text{a.s.}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}, \quad (81)$$

$$\sum_{l=1}^{r-1} \sum_{j \in H_l} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 = \mathbf{O}_{\text{a.s.}} \left\{ \frac{1}{\delta_r^{(n)}} \right\}. \quad (82)$$

We now prove (81). Since the j -th diagonal entry of $S^T S$ is between its largest and smallest eigenvalue, then (48) becomes

$$\lambda_{\min} \left(\frac{1}{n} Z Z^T \right) \leq \hat{\lambda}_j \sum_{k=1}^{d(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 = \sum_{k=1}^{d(n)} s_{k,j}^2 \leq \lambda_{\max} \left(\frac{1}{n} Z Z^T \right), \quad j = 1, \dots, d(n). \quad (83)$$

Since $\lim_{n \rightarrow \infty} \frac{d(n)}{n} = 0$, it follows from Lemma 1 that $\lambda_{\min} \left(\frac{1}{n} Z Z^T \right)$ and $\lambda_{\max} \left(\frac{1}{n} Z Z^T \right) \xrightarrow{\text{a.s.}} 1$. In addition, since $\frac{\hat{\lambda}_j}{\lambda_j^{(n)}} \xrightarrow{\text{a.s.}} 1$ for $j = 1, \dots, m$ (Section 7.3.1), it follows from (83) that

$$\sum_{k=1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1, \quad j = 1, \dots, m. \quad (84)$$

Note that

$$\sum_{k=1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 = \sum_{l=1}^{r-1} \sum_{k \in H_l} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 + \sum_{k \in H_r} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2. \quad (85)$$

According to (70), we have that

$$\sum_{j \in H_l, k \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} |H_l|, \quad l = 1, \dots, r-1,$$

which leads to

$$\sum_{l=1}^{r-1} |H_l| = \sum_{j=1}^{d(n)} \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \geq \sum_{l=1}^{r-1} \sum_{j \in H_l^*} \sum_{k \in H_l} \hat{u}_{k,j}^2 \geq \sum_{l=1}^{r-1} \sum_{j \in H_l, k \in H_l} \sum_{l=1}^{r-1} |H_l|.$$

Then it follows that

$$\sum_{j \in H_r} \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \leq \sum_{j=1}^{d(n)} \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 - \sum_{l=1}^{r-1} \sum_{j \in H_l^*} \sum_{k \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 0. \quad (86)$$

According to (86), we have that

$$\sum_{l=1}^{r-1} \sum_{k \in H_l} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 \leq \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \leq \sum_{j \in H_r} \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 0, \quad j \in H_r. \quad (87)$$

Since $\frac{\lambda_j^{(n)}}{\lambda_k^{(n)}} \rightarrow 1$ for $k, j \in H_r$, it follows from (85) and (87) that

$$\sum_{k \in H_r} \hat{u}_{k,j}^2 + \sum_{k=m+1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1, \quad j \in H_r. \quad (88)$$

According to (86), we have that

$$\begin{aligned} 1 &\geq \sum_{k \in H_r} \hat{u}_{k,j}^2 + \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^2 = 1 - \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \\ &\geq 1 - \sum_{j \in H_r} \sum_{l=1}^{r-1} \sum_{k \in H_l} \hat{u}_{k,j}^2 \xrightarrow{\text{a.s.}} 1, \quad j \in H_r. \end{aligned}$$

Then it follows that

$$\sum_{k \in H_r} \hat{u}_{k,j}^{(n)2} + \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 1, \quad j \in H_r. \quad (89)$$

Since $\lim_{n \rightarrow \infty} \frac{\lambda_j^{(n)}}{\lambda_k^{(n)}} > 1$ for $j \in H_r$ and $k \geq m+1$, then combining (88) and (89) gives

$$\sum_{k \in H_r} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 1, \quad j \in H_r,$$

which together with (88), yields

$$\sum_{k=m+1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 0, \quad j \in H_r. \quad (90)$$

Since $\lambda_k^{(n)} \rightarrow c_k$ for $k \geq m+1$ and $\frac{\lambda_j^{(n)}}{c_k} \rightarrow 1$ for $j \in H_r$, it follows from (90) that as $n \rightarrow \infty$,

$$\sum_{j \in H_r} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^{(n)2} = O_{\text{a.s.}} \left\{ \frac{1}{\delta_l^{(n)}} \right\},$$

which is (81).

We now show the proof of (82). According to (84), we have that for $j \in H_l$, $l = 1, \dots, r-1$,

$$\sum_{k \in H_l} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} + \sum_{k=m+1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} \leq \sum_{k=1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 1. \quad (91)$$

Since $\lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \rightarrow 1$ for $k, j \in H_l$, it follows from (70) that

$$\sum_{k \in H_l} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} \rightarrow \sum_{k \in H_l} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 1, \quad k, j \in H_l,$$

which together with (91), yields

$$\sum_{k=m+1}^{d(n)} \lambda_j^{(n)} \frac{1}{\lambda_k^{(n)}} \hat{u}_{k,j}^{(n)2} \xrightarrow{\text{a.s.}} 0, \quad j \in H_l, \quad l = 1, \dots, r-1. \quad (92)$$

Since $\lambda_k^{(n)} \rightarrow c_k$ for $k \geq m+1$ and $\frac{\lambda_j^{(n)}}{c_l} \rightarrow 1$ for $j \in H_l$, it follows from (92) that as $n \rightarrow \infty$,

$$\sum_{j \in H_l} \sum_{k=m+1}^{d(n)} \hat{u}_{k,j}^{(n)2} = O_{\text{a.s.}} \left\{ \frac{1}{\delta_l^{(n)}} \right\}, \quad l = 1, \dots, r-1. \quad (93)$$

Since $\delta_l^{(n)} \leq \delta_l^{(n)}$ for $l = 1, \dots, r-1$, (82) then follows from (93).

7.4.3 SCENARIO (c) IN THEOREM 1

Finally, for Scenario (c) where $\frac{d(n)}{n \delta_1^{(n)}} \rightarrow \infty$, h in (40) equals to 0. Since $j_0 = 0$, then (40) becomes that as $n \rightarrow \infty$,

$$\max_{1 \leq j \leq \lfloor n \nu d(n) \rfloor} \left\{ \frac{d(n)}{n \lambda_j} \hat{u}_{j,j}^{(n)2} \right\} = O_{\text{a.s.}}(1),$$

which yields the strong inconsistency of the sample eigenvectors in Scenario (c).

Abstract

In this paper we analyze the relationship between faithfulness and the more recent condition of algorithmic Independence of Conditionals (IC) with respect to the Conditional Independencies (CIs) they allow. Both conditions have been extensively used for causal inference by refuting factorizations for which the condition does not hold. Violation of faithfulness happens when there are CIs that do not follow from the Markov condition. For those CIs, non-trivial constraints among some parameters of the Conditional Probability Distributions (CPDs) must hold. When such a constraint is defined over parameters of different CPDs, we prove that IC is also violated unless the parameters have a simple description. To understand which non-Markovian CIs are permitted we define a new condition closely related to IC: the Independence from Product Constraints (IPC). The condition reflects that CIs might be the result of specific parameterizations of individual CPDs but not from constraints on parameters of different CPDs. In that sense it is more restrictive than IC: parameters may have a simple description. On the other hand, IC also excludes other forms of algorithmic dependencies between CPDs. Finally, we prove that on top of the CIs permitted by the Markov condition (faithfulness), IPC allows non-minimality, deterministic relations and what we called proportional CPDs. These are the only cases in which a CI follows from a specific parameterization of a single CPD.

Keywords: faithfulness, causality, independence of conditionals, Kolmogorov complexity

1. Introduction

Algorithmic Independence of Conditionals (IC) has been put forward for causal inference and its relation with Faithfulness (FF) was analyzed by Lemeire and Janzing (2013). We showed that both conditions often lead to the same causal conclusions and are motivated by similar grounds: that the CPDs are independently chosen. But we argued that IC is more fundamental than FF: we can trust IC more whenever the conclusions are different from those of FF. Moreover, IC goes beyond FF. IC has led to successful causal inferences in cases that FF cannot decide on the causal orientations, see for instance Janzing and Schölkopf (2010); Janzing and Steudel (2010); Daniusis et al. (2010); Janzing et al. (2012); Chen et al. (2014). In this paper we establish the link between FF and IC regarding the Conditional Independencies (CIs) both conditions admit.

Faithfulness is based on the observed variables entailed by a system. Faithfulness assumes that all CIs come from the system's causal structure, described by a Directed Acyclic Graph (DAG), and hold for all parameterizations of the DAG. These CIs are defined by the Markov condition applied on the DAG and can be identified with the d -separation criterion. Lemeire and Janzing (2013) have shown that some CIs are rejected by causal faithfulness but have to be accepted

by the IC condition. This is true for deterministic relations for example, since a deterministically related variable becomes independent from all other variables when conditioned on its determiner, also those that are not d -separated.

FF is motivated by the Lebesgue measure zero argument, saying that if the system's parameters were randomly chosen, the probability of having a configuration following a specific constraint has Lebesgue measure zero (Meek, 1995). In the case of deterministic relations, all but one probability is zero for each input state. This is very unlikely to occur by chance, hence receives Lebesgue measure zero. IC follows a different reasoning. Its justification is based on Solomonoff's Universal Prior (Solomonoff, 1964) which assigns non-zero probability to those points in parameter space that have a finite description (Lemeire and Janzing, 2013). Points reflecting some regularity (allowing compression of the description) will receive a high probability. The Universal Prior favors simple CPDs, and therefore respects Occam's razor. The reasoning is that patterns or regularities are likely to occur; patterns have to be expected. Which is not the case if parameters are randomly chosen according to for instance a uniform distribution. On the other hand, IC follows FF by excluding 'non-generic' parameter configurations. IC assumes that CPDs correspond to independent mechanisms which were 'chosen' independently. While FF excludes all non-trivial constraints among some parameters of CPDs, IC will in general exclude CIs following from specific parameter matches between *different* conditionals. The latter will be expressed formally by the novel condition Independence from Product Constraints (IPC). The condition is introduced to analyze the relation between IC and FF. In this paper we analyze the relation between the 3 conditions.

We first recall the definitions. Then we discuss CIs that do not follow from the Markov condition and we introduce the new IPC criterion. Then, we analyze when CIs violate the IC condition. Section 5 establishes the link between IC/IPC and faithfulness. Next we prove the link between IC and IPC. Before concluding, we discuss the practical implications of these results.

2. Definitions

A Bayesian network consists of a Directed Acyclic Graph (DAG) and a set of Conditional Probability Distributions (CPDs) defined over variables X_1, \dots, X_n such that the joint probability distribution equals the following factorization:

$$P(X_1, \dots, X_n) = \prod_i P(X_i | \text{Parents}(X_i)) \quad (1)$$

with $\text{Parents}(X_i)$ the parent nodes of node X_i in the DAG. A Bayesian network is edge-minimal (MIN) in the sense that no edge can be removed from the DAG without violating the correctness of the factorization.

In a causal model represented by a Bayesian network, all edges correspond to direct causal relations and each CPD corresponds to an independent and autonomous mechanism of the system (Hausman and Woodward, 1999; Lemeire et al., 2011). Throughout the paper we assume that the CPD of each node X_j is described by a parameter vector $\lambda_j \in \mathbb{R}^{b_j}$. Although the finite dimension of the parameter space restricts the conditionals for continuous variables already, we believe that this is appropriate because inference from finite data requires strong assumptions or approximations anyway.

Conditional Independence (CI) is defined as

$$U \perp\!\!\!\perp W \mid Y \Leftrightarrow \forall v \in \mathcal{V}_{dom}, w \in \mathcal{W}_{dom} : P(U \mid v, w) = P(U \mid v) \text{ whenever } P(v, w) > 0. \quad (2)$$

where \mathcal{X}_{dom} is the domain of variable X . Single random variables are denoted by capital letters and sets of variables by boldface capital letters. Values of variables are denoted by lowercase letters. Note that the conditional distribution $P(U \mid v, w)$ is only defined in points where $P(v, w) > 0$.

The Markov condition gives all conditional independencies following from the above factorization (Hausman and Woodward, 1999, p. 532): Every variable is conditionally independent of its non-descendants (except for itself), given its parents. These Markovian independencies hold for all parameterizations of the CPDs. These independencies can be identified graphically by d -separation. A path¹ is said to be blocked by Z if it contains a collider $\rightarrow \cdot \leftarrow$ whose descendants are not in Z or a non-collider $\rightarrow \cdot \rightarrow$ or $\leftarrow \cdot \leftarrow$ that is in Z . X and Y are d -separated by Z if every path between X and Y is blocked by Z . d -separation is denoted by the ternary operator $\cdot \perp \cdot \mid \cdot$:

$$X \perp Y \mid Z.$$

A Bayesian network is said to be *faithful* if the Markovian CIs are the only independencies present in the joint probability distribution; in other words, there are no CIs not following from Markov. We call them *non-Markovian CIs*. Where the Markovian CIs occur for every parameterization of the CPDs, non-Markovian CIs only occur for specific parameterizations of the model. As we will see, specific parameter constraints should be met.

Next we provide the definition of the IC condition. It is based on Kolmogorov complexity or algorithmic information of a binary string s , denoted by $K(s)$: For a binary string $s \in \{0, 1\}^*$ the *algorithmic information* $K(s)$ (or ‘Kolmogorov complexity’) is defined as the length of the shortest program on a universal prefix-free Turing machine that generates s and then stops (Solomonoff, 1960; Kolmogorov, 1965; Chaitin, 1966, 1975). Prefix-free means that the program has to be given with respect to an encoding where no allowed program code is the prefix of another one. Thus, the program does not require an extra symbol indicating its end. Based on Kolmogorov complexity we can define algorithmic independence.

Definition 1 (Algorithmic Independence) Binary strings $s_1 \dots s_n$ are algorithmically independent if

$$K(s_1, \dots, s_n) \stackrel{\pm}{=} \sum_k^n K(s_k). \quad (3)$$

Note that here and throughout the paper we consider the number n of strings as a constant. Accordingly, in the following the number n of nodes will also be considered as a constant.

As usual in algorithmic information theory, \pm denotes equality up to a constant that is independent of the string s , but does depend on the Turing machine. For fixed strings, we have to interpret \pm in the sense of ‘equality up to a small number’ without further specifying what ‘small’ means. This arbitrariness in setting a threshold is similar to the freedom of choosing the significance level in a statistical dependence test.

1. A path is a set of consecutive edges (independent of the direction) that do not visit a vertex more than once.

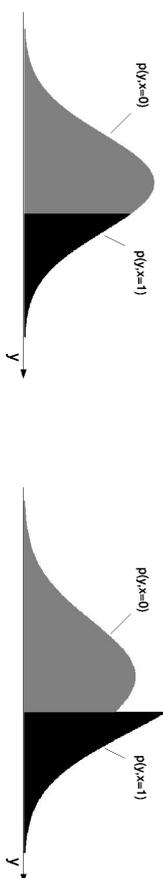

Figure 1: Binary variable X is determined by Gaussian variable Y by a thresholding mechanism, i.e., $X = 1$ for all $y > y_0$, and $X = 0$ otherwise. This is shown on the left. The causal hypothesis $Y \rightarrow X$ is plausible: the conditional $P(X|Y)$ corresponds to setting $X = 1$ for all Y above a certain threshold. On the other hand, $X \rightarrow Y$ is rejected by IC because $P(Y|X)$ and $P(X)$ share algorithmic information: given $P(Y|X)$, only specific choices of $P(X)$ reproduce the Gaussian $P(Y)$, whereas generic choices of $P(X)$ would yield ‘odd’ densities of the type on the right. The figures are taken from (Janzing et al., 2009).

Assumption 1 (CPDs have finite description length) We assume that each parameter vector $\lambda_j \in \mathbb{R}^{k_j}$ has finite description length. To be precise, there is a program that computes the l th component of λ_j up to the precision of d digits if it gets the input (i, j) .² Then, $K(\lambda_j)$ denotes the length of the shortest program of this type.

Now we are ready to define the IC condition (Lemeire and Janzing, 2013):

Definition 2 (Independence of Conditionals)

The conditional probability densities CPD_1, \dots, CPD_n corresponding to a DAG G with n nodes are said to satisfy the Algorithmic Independence of Conditionals, or Independence of Conditionals (IC) for short, if the corresponding parameter vectors λ_j satisfy

$$K(\lambda_1, \dots, \lambda_n) \stackrel{\pm}{=} \sum_{j=1}^n K(\lambda_j), \quad (4)$$

The uncomputability of Kolmogorov complexity hinders the applicability of these concepts. Applications rely on some approximative measure of algorithmic complexity or, as in the following example, on an approximative measure of ‘correlation’ between two distributions.

An example of the usage of the IC condition for causal inference is given by Fig. 1 (Janzing et al., 2009). Consider that Y causes X : $Y \rightarrow X$. Let Y be a Gaussian variable with zero mean and standard deviation 1 (i.e., described by a zero-dimensional parameter space). Let X be a binary variable deterministically determined by Y by a thresholding mechanism, i.e., $X = 1$ for all $y > y_0$ where $y_0 \in \mathbb{R}$ is some threshold, and $X = 0$ otherwise. Here, $P(X|Y)$ is described by 1 parameter, namely y_0 . We now describe the joint distribution $P(X, Y)$ in the wrong causal direction, i.e. with $P(X)$ and $P(Y|X)$. We observe that the set of possible $P(X)$ is not restricted, i.e., we have the one-dimensional parameter $\theta_1 = P(X = 0)$. The set of possible conditionals $P(Y|X)$ obtained by

2. Since the input consists of two strings and the output of k_j strings plus extra information specifying the position of the comma, we use some canonical bijection between $\{0, 1\}^*$ and $\{0, 1, \cdot\}^*$ for appropriate d for input and output.

the above model class is also determined by a one-dimensional parameter $\theta_2 = y_0$ that determines the cutoff. We then observe that θ_1 and θ_2 are related by

$$\theta_1 = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\theta_2} e^{-y^2/2} dy = \text{erf}(\theta_2).$$

Hence, IC is violated whenever $K(\theta_1) \not\geq K(\text{erf})$:

$$\begin{aligned} K(\lambda_X) + K(\lambda_Y) &\geq K(\theta_1) + K(\theta_2) \\ &> K(\text{erf}) + K(\theta_2) \\ &\pm K(\theta_1|\theta_2) + K(\theta_2) \\ &\geq K(\theta_1, \theta_2) \\ &\pm K(\lambda_X + \lambda_Y) \end{aligned}$$

Note that IC is not violated for $y_0 = 0$: then $K(\theta_1) = K(1/2) \pm 0$ and $K(\theta_2) = K(0) \pm 0$.

3. Non-Markovian conditional independencies

We start the investigation by analyzing the CIs that do not follow from the Markov condition. Non-trivial polynomial constraints must be satisfied for non-Markovian conditional independencies. This is shown for discrete Bayesian networks by Meek (1995) and the linear case for distributions over continuous variables by Spirtes et al. (1993).

For a given DAG G and an independence, we define the **Independence Parameter Subspace** as the set of all parameterizations λ of a DAG G for which the independence holds. For Markovian CIs this is the complete space $\mathcal{S} := \times_{j=1}^n \mathcal{S}_j$, where \mathcal{S}_j is the set of possible parameter vectors λ_j . For non-Markovian CIs this is a subspace of \mathcal{S} .

As already pointed out in the introduction and Lemeire and Janzing (2013), deterministic relations between some variables may induce conditional independencies that do not follow from the Markov condition. For $Y \perp\!\!\!\perp X$ in the example $X \rightarrow Y \rightarrow Z$, a sufficient condition is the function $Y = f(X)$. The independence parameter subspace for $Y \perp\!\!\!\perp Z|X$ can be represented by Fig. 2(a) in the case of deterministic relation $Y = f(X)$. If $\lambda_Y \subset \mathcal{R}_Y$ where \mathcal{R}_Y represents all functions, then we have the conditional independence in $P(X, Y, Z)$. λ_Y denotes the parameter vector of the CPD of variable Y , λ_Z that of Z , and so on.

As another example, consider the DAG in Fig. 3 and consider the case where A and D are independent because the influence via B compensates for the influence via C . Assume that all CPDs are given by linear structure equations:

$$\begin{aligned} B &= \alpha A + U_B, \\ C &= \beta A + U_C, \\ D &= \gamma B + \delta C + U_D, \end{aligned} \tag{5}$$

where U_B, U_C and U_D are unobserved disturbances or 'noise' terms that are jointly statistically independent and independent of A . Then the two influences of A on D cancel for

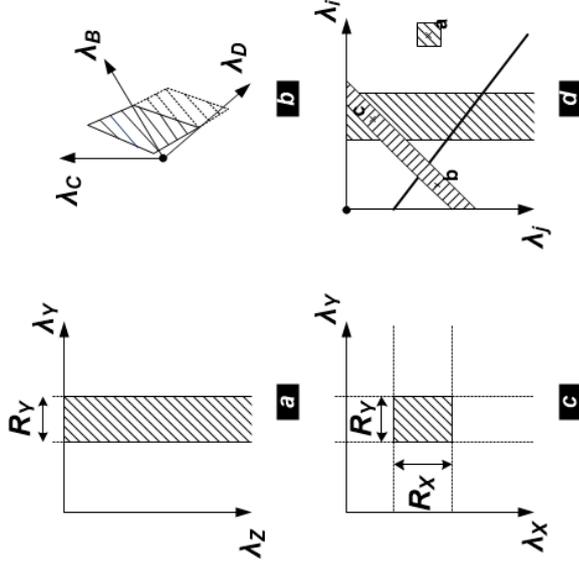

Figure 2: Independence parameter subspaces where each axis represents the possible parameter vectors of a single CPD. In (d) points c and a are permitted by IPC, while b is not.

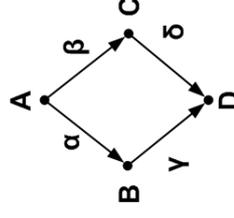

Figure 3: Causal model with linear influences described by parameters $\alpha, \beta, \gamma, \delta$.

such that $A \perp\!\!\!\perp D$. Obviously, FF rejects the causal DAG of Fig. 3 because A and D are not d -separated by the empty set and thus should not be independent. The independence parameter subspace for $A \perp\!\!\!\perp D$ can be represented by Fig. 2(b). Note that γ and δ are represented together by dimension λ_D .

As a third example, consider the causal model $W \rightarrow X \rightarrow Y \rightarrow Z$ with $X = g(W)$ and $Y = f(X)$. It follows that $Y \perp\!\!\!\perp Z|W$. Fig. 2(c) represents the parameter subspace for this CI: both λ_X and λ_Y are restricted for the CI to hold. But both restrictions do not depend on each other: the parameter subspace can be described by the product $\mathcal{R}_X \times \mathcal{R}_Y$. The forthcoming IPC criterion will reject the independence following from Eq. 5 but accepts the last example because the latter parameter subspace is a so-called product subspace.

To formalize the analysis of the independence parameter subspaces, we need the following postulate based on the results of (Meek, 1995) and (Spirtes et al., 1993).

Postulate 1 *There exists a complexity measure $C(\cdot)$ on polynomial equations such that for a given DAG the presence of any conditional independence can be identified by a unique minimal set of undecomposable polynomial constraints on the parameterization of the DAG. With ‘undecomposable’ we mean that a constraint c cannot be written as $(c_1$ or $c_2)$ (one of both constraints should be true) with $C(c) \geq C(c_1) + C(c_2)$. By ‘minimal’ we mean that there is no smaller such set.*

Note that Kolmogorov complexity is not appropriate as complexity measure since it attributes 0 complexity to polynomial functions with simple coefficients. A measure such as AIC or BIC is more appropriate to capture the complexities of polynomial equations. However, it would lead us too far to prove for a complexity measure that it leads to a unique decomposition for non-Markovian CIs. Hence the postulate.

The postulate implies that the parameter subspace of a CI can be described in a unique, ‘canonical’ way as a union of areas, where each of the areas reflects 1 basic polynomial constraint. Fig. 2(d) shows a general example of a parameter subspace. The subspace can be decomposed into 4 basic areas which cannot be further decomposed without increasing its descriptive complexity.

Some areas can be described by a product of parameter constraints and some areas can’t. The latter means that the CI does not follow from a product constraint on the parameters of different CPDs, but from a constraint that is defined over different CPDs. Those parameterizations will be referred: parameter configuration b in Fig. 2(d) is refuted while a and c are permitted. This is expressed by the Independence from Product Constraints (IPC) condition: a parameterization will be rejected if it gives rise to a CI which is part of an area in the parameter subspace which cannot be described by a product of subspaces.

Definition 3 (Independence from Product Constraints (IPC)) *Let a Bayesian network be described by the parameters $\lambda := (\lambda_1, \dots, \lambda_n)$. Then it is said to satisfy the Independence from Product Constraints Condition if for every independence that holds true for λ the parameterization satisfies a constraint of the minimal set of undecomposable constraints of the independence which is a product constraint. A product constraint is a constraint c that can be written as $(c_1$ and $c_2 \dots$ and $c_l)$ where each c_j is a constraint on exactly one λ_j .*

IC, however, will only reject non-product constraints if it results in a compression of the parameters. This is investigated in the next section.

4. Conditional independencies resulting in violations of IC

Although the IPC condition reflects the principle that ‘non-generic’ relations among CPDs are rejected, not all non-Markovian CIs are rejected by IC. To analyze this in detail, we have to recall the following theorem on the violation of IC (Lemeire and Janzing, 2013, Theorem 3):

Theorem 4 *For a given DAG G , let the set of possible CPDs $P(X_j|Parents(X_j))$ be parameterized by some parameter set $\lambda_j := \{\lambda_{j_1}^1, \dots, \lambda_{j_{k_j}}^{k_j}\}$ of parameters. Assume that the parameter values for some specific choice CPD_1, \dots, CPD_n of conditional probability densities satisfy a functional relation in the sense that $\theta_1 = f(\theta_2, \dots, \theta_k)$, where f is some function and $\theta_1, \dots, \theta_k$ are parameters taken from at least two different sets λ_j . Assume furthermore that θ_1 corresponds to CPD_1 (without loss of generality). Then the following condition implies violation of IC:*

$$K(f) \stackrel{\Delta}{\leq} K(\theta_1 | CPD_1^{(\theta_1, *)}), \quad (6)$$

where $CPD_1^{(\theta_1, *)}$ denotes the parameters of CPD_1 without θ_1 (recall that the asterisk denotes the shortest compression).

The theorem states that a constraint results in a violation of IC provided that the parameters are sufficiently complex compared to the complexity of the constraint.

Applied on the example of Fig. 3, the constraint defined by Eq. 5 leads to a violation of IC if α, β, γ and δ have complex values. Describing the JPD by separate descriptions of $P(A)$, $P(B|A)$, $P(C|A)$ and $P(D|B, C)$ is redundant because the parameter γ in $P(D|B, C)$ can be computed from the parameters of the other CPDs via Eq. 5. The constraint is an unlikely coincidence if all real-valued parameters are chosen independently (according to some continuous distribution on \mathbb{R}). Next, consider causal structure $X \rightarrow Y \leftarrow Z$ over binary variables X , Y and Z . $P(Z)$ is parameterized with $P(Z=0) = \alpha$ and $P(Z=1) = 1 - \alpha$, and $P(Y|X, Z)$ with 4 parameters:

$$\begin{array}{c|cc} P(Y=0|X, Z) & Z=0 & Z=1 \\ \hline X=0 & a & b \\ X=1 & c & d \end{array}$$

Then, non-Markovian independence $X \perp\!\!\!\perp Y$ holds when

$$\begin{aligned} P(Y=0|X=0) &= P(Y=0|X=1) \\ \Leftrightarrow P(Z=0).P(Y=0|X=0, Z=0) + P(Z=1).P(Y=0|X=0, Z=1) \\ &= P(Z=0).P(Y=0|X=1, Z=0) + P(Z=1).P(Y=0|X=1, Z=1) \\ \Leftrightarrow \alpha.a + (1-\alpha).b &= \alpha.c + (1-\alpha).d. \end{aligned}$$

Note that this constraint does not depend on the parameterization of $P(X)$. This equation can be rewritten in the following constraint between the parameters of $P(Z)$ and $P(Y|X, Z)$ with T a constant:

$$\frac{\alpha}{1-\alpha} = \frac{d-b}{a-c} = T \quad (7)$$

This equation holds for the following particular parameterization:

- $P(Z=0) = P(Z=1) = 0.5$
- $P(Y|X, Z)$ is a noisy exclusive or (with real-valued $E \in]0, 1[$ representing the noise):

$$\frac{P(Y|X, Z)}{\begin{array}{c|c} X=0 & E \\ X=1 & 1-E \end{array}} \Bigg| \begin{array}{c|c} Z=0 & Z=1 \\ \hline E & 1-E \end{array} = 1$$

It can easily be verified that Eq. 7 holds for all values of E and that $P(Y=1|X=x) = P(Y=1) = 0.5$ for all values of X . Although in this example the parameters of both CPDs are tightened by the constraint, one can hardly say that the parameter of one CPD helps the description of some parameter of the other CPD. $T = 1$ and therefore simple. Also α has constant complexity. Even if E is complex and $K(a)$ therefore too, $K(a|b, c, d)$ has low complexity. Eq. 6 of Theorem 4 does not hold: IC is not violated. It is only violated for complex values of T . Then α will have high Kolmogorov complexity but its description length has constant complexity with the help of a, b, c and d .

Concluding, factorizations having non-Markovian CIs will only be rejected for complex parameter values. The rationale is that we consider simple parameter settings to appear with a much greater probability than when they would be taken randomly from a uniform distribution over the parameter space. We prefer the Universal Prior (Solomonoff, 1964): the probability of a parameter configuration is high for simple parameters, where simple is defined by their Kolmogorov complexity. The probability decreases for increasing parameter complexities. As such we will refute only constraints leading to a compression. Simple parameters will occur and as such make it highly probable that a coincidental CI occurs. In our case, the uniform distribution for $P(Z)$ and xor configuration of $P(Y|X, Z)$ are simple and can be expected. As such, the CI can be expected and must not be excluded.

Finally, note that if a parameter is incompressible with respect to the other CPD parameters, then $K(\theta_1) = K(\theta_1|CPD_1^{\theta_1, \theta_2})$ and the constraint of Theorem 4 becomes simply:

$$K(f) \stackrel{+}{\leq} K(\theta_1). \quad (8)$$

As we will see, the polynomial constraints for non-Markovian CIs have simple coefficients which make that the functions have constant complexity. Thus, complex parameters lead to violations of IC and can be detected by an appropriate approximative measure of Kolmogorov complexity.

5. The IPC and IC conditions and Faithfulness.

Now we infer our most important result: the relation between IC and Faithfulness. We first establish the link between IPC and faithfulness, and then we show that the results also apply for IC when the parameters are sufficiently complex.

Faithfulness implies that variables that are d -connected are (conditionally) dependent: there are unblocked paths. We will prove that under IPC they yield dependence apart from 3 cases permitted by IPC. The theorem is constructed by decomposing the unblocked paths and proving dependency for each component. The basic components of the paths are adjacent variables and v -structures. These are considered first in 2 lemmas together with a lemma on conditioning variables that are not

on one of the paths. All proofs are given in the appendix. We prove it for discrete variables. We believe that a similar approach can be used to prove it for continuous variables.

For using IPC we need the following postulate:

Postulate 2 *The non-trivial polynomial constraints among different CPDs responsible for non-Markovian CIs cannot be decomposed into product constraints without increasing their complexity, i.e. $C(c) < C(c_1) + \dots + C(c_n)$ for any decomposition of non-product constraint c into product constraints c_1, \dots and c_n .*

Since the constraints apply on parameters of different CPDs it seems reasonable to believe that the constraints cannot be decomposed into constraints on individual parameters without increasing the descriptive complexity.

We first define formally what we mean by excluding deterministic relations.

Definition 5 (INDET) *A Bayesian network is said to satisfy INDET if there is no variable X_j that can be written as*

$$X_j = f(X_1, \dots, X_{j-1}, X_{j+1}, \dots, X_n).$$

The first lemma shows that 2 adjacent variables are dependent under IPC and edge-minimality (MIN).

Lemma 6 *Given a Bayesian network defined over discrete variables satisfying MIN and IPC, any two adjacent variables X and Y , where X is a parent of Y , are dependent conditioned on any subset of the other parents of Y .*

The next lemma states that conditionally dependent variables X and Y cannot get conditionally independent via extending the conditioning set by variables that are not on any path between X and Y unless deterministic variables are present.

Lemma 7 *Assume that MIN and IPC holds for some Bayesian network defined over discrete variables. Let $X_{\setminus \{X, Y\}} | \mathbf{Z}'$ where X, Y are arbitrary nodes and \mathbf{Z}' is a set of nodes. Let U denote the set of all variables on the non-blocked paths between X and Y , including X and Y . Then, for every set $\mathbf{Z}'' \subset \bar{\mathbf{Z}} \cup U$, when*

$$X \perp\!\!\!\perp Y | \mathbf{Z}', \mathbf{Z}'',$$

holds, there are deterministic relationships.

In the third lemma we deal with the case in which X and Y are connected via a v -structure $X \rightarrow Z \leftarrow Y$ and one conditions on Z or one of its descendants, such that X and Y are d -connected. It appears that there is a special parameterization in which X and Y are conditionally independent without violating IPC, which we call a *proportional conditional probability distribution*.

Definition 8 (proportional conditional probability distribution (pCPD))

Let Z, Y be variables and \mathbf{X} be a set of variables. The CPD $P(Z|Y, \mathbf{X})$ is said to have a proportional conditional probability distribution if Y can only attain two values y_1 and y_2 and we have

$$\frac{P(Z | y_1, \mathbf{x})}{P(Z | y_2, \mathbf{x})} = \alpha \quad \forall \mathbf{x} \in \mathbf{X}_{dom} \quad (9)$$

with α a constant only depending on Z and \mathbf{X}_{dom} , the domain of X .

The probability distribution of Table 1 shows an example of a PCPD for distributions over discrete variables, for which $\frac{P(z=1|y=1,x_1)}{P(z=1|y=0,x_1)} = 1.5$ and $X \perp\!\!\!\perp Y \mid Z$ holds, which is a non-Markovian CI.

X	$Y = 0$	$Y = 1$
0	0.3	0.45
1	0.6	0.9
2	0.4	0.6

Table 1: Conditional Probability Table of $P(z = 1 \mid X, Y)$ for which Eq. 9 holds and therefore $X \perp\!\!\!\perp Y \mid Z$.

An example for continuous variables in which Eq. 9 is satisfied is the following class of models

$$p(z|y, x_1, \dots, x_n) = e^{-\alpha(z)y - \sum_j \gamma_j(z)x_j},$$

where $c(z)$ and $\gamma_j(z)$ are arbitrary functions.

pCPDs imply non-Markovian CIs in v-structures as shown by the following lemma.

Lemma 9 *If MIN, INDET, IPC holds for a factorization of a joint probability distribution defined over discrete variables, then for any v-structure $X \rightarrow Z \leftarrow Y$ in the DAG and for all \mathbf{W} not containing X, Y or Z :*

$$\begin{aligned} X \perp\!\!\!\perp Y \mid Z, \mathbf{W} &\Leftrightarrow X \perp\!\!\!\perp Y \text{ and } P(Z \mid X, Y) \text{ is a proportional CPD} \\ \forall U \text{ descendants of } Z : X \&\&Y \mid U, \mathbf{W} \end{aligned}$$

The absence of pCPDs is denoted as the NOPCPD condition.

It can easily be verified that violation of MIN or INDET or the presence of a pCPD are permitted by IPC. These 3 cases define constraints on single CPDs. We have to exclude them on top of IPC for achieving faithfulness. The following theorem expresses the relation between IPC and faithfulness:

Theorem 10 *If for a given factorization of a JPD the conditions IPC, MIN, INDET and NOPCPD are met, then faithfulness holds:*

$$\forall \text{ disjoint subsets } X, Y, Z \subset V : X \perp\!\!\!\perp Y \mid Z \Leftrightarrow X \perp\!\!\!\perp Y \mid Z$$

with V the set of all variables under consideration.

In other words, there are only 3 cases in which a non-Markovian CI comes from a specific parameterization of a single CPD: deterministic relationships, non-minimality and proportional CPDs.

To identify the relation between FF and IC we have to define what we mean by sufficiently complex parameters.

Definition 11 (COMPLEX) *A parameterization of a Bayesian network is said to satisfy COMPLEX if for all parameters θ_i of all parameter vectors λ_j :*

$$K(\theta_i | CPD_j^{\setminus \theta_i, *}) \not\geq 0,$$

In the 3 previous lemmas and Theorem 10, the IPC condition can be replaced with IC and COMPLEX.

Theorem 12 *If for a given factorization of a JPD defined over discrete variables the conditions IC, COMPLEX, MIN, INDET and NOPCPD are met, then faithfulness holds:*

$$\forall \text{ disjoint subsets } X, Y, Z \subset V : X \perp\!\!\!\perp Y \mid Z \Leftrightarrow X \perp\!\!\!\perp Y \mid Z$$

with V the set of all variables under consideration.

6. The relation between IC and IPC.

IC and IPC partially overlap. IC rules out all atypical constraints on parameters between different CPDs. IPC only rules out the constraints leading to conditional independencies, while IC allows conditional independencies when matches are to be expected because of low complexity of the parameters.

The theorem on the relation between IC and IPC is based on the fact that non-trivial polynomial constraint must be satisfied for non-Markovian conditional independencies.

Theorem 13 *Given P a distribution over n variables and a DAG G with CPDs parameterized by $\theta_1, \dots, \theta_n$ describing a factorization of P .*

If the parameter vectors satisfy IPC, there exists a parameterization $\theta'_1, \dots, \theta'_n$ of the CPDs which has the same independencies as P and for which IC holds.

*For discrete Bayesian networks and the linear case for continuous distributions, if the factorization satisfies IC and COMPLEX (the parameters θ'_i of the parameter vectors $\theta_1, \dots, \theta_n$ have non-constant complexity: $K(\theta'_i | CPD_i^{\setminus \theta'_i, *}) \not\geq 0$), then IPC holds as well.*

The proof is given in the appendix. We believe that it is provable that under IPC, most parameterizations satisfy IC as well. The proof, however, need some quite technical details to be worked out.

7. Practical application

Despite the uncomputability of Kolmogorov complexity, several novel approaches to causal inference are based on the notion of IC, see for instance Janzing and Schölkopf (2010); Janzing and Stendel (2010); Danusis et al. (2010); Janzing et al. (2012); Chen et al. (2014). As more algorithms will pop up, a philosophical and theoretical underpinning is important. This paper tries to contribute to this endeavour.

Although we advocate that IC is more fundamental than FF (Lemeire and Janzing, 2013), independence-based learning remains a powerful approach. However, we believe that non-Markovian CIs should be taken into account and deserve an in-depth study. Accordingly, independence-based learning algorithms have been adopted in the past to incorporate the presence of deterministic relationships (Lemeire et al., 2012) and pCPDs (violations of orientation faithfulness) (Ramsey et al., 2006).

The theoretical results of this paper might help to understand the nature of the CIs. We showed that the appearance of CIs happens at different levels:

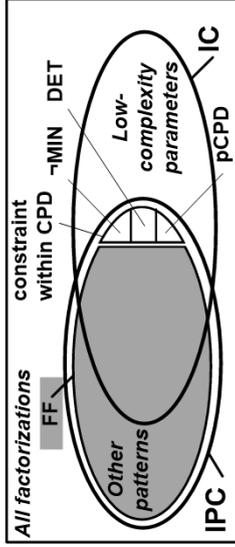

Figure 4: Relation between FF, the IC and IPC condition. It shows the factorizations for which FF, IC and/or IPC holds. The area in which FF holds is shown in gray.

1. some conditional independencies arise from the causal structure (given by the Markov condition),
2. some CIs arise from a specific parameterization of a single CPD,
3. some CIs arise from specific simple parameterizations of different CPDs,
4. some CIs arise from specific complex parameterizations of different CPDs.

Only level 1 is permitted by faithfulness. IPC also permits level 2, while the IC condition allows level 3 as well. Note that some examples of level 4 where given in Lemeire and Janzing (2013) (so-called metamechanisms).

8. Conclusions

Both Faithfulness (FF) and Independence of Conditionals (IC) express a condition on a factorization. They have been extensively used for learning a system’s causal structure from observational data. Non-causal factorizations are refuted when one of both conditions is violated. In this paper we investigated more deeply the relation between both conditions.

Although IC and FF sound like completely different inference principles, the common idea is to reject causal structures for which the CPDs satisfy ‘non-generic’ relations. The relation between the conditions is shown by Fig. 4. The sets represent the factorizations for which the conditions hold. We defined the Independence from Product Constraints (IPC) which allows non-Markovian CIs following from specific parameterizations of individual CPDs but not from constraints among parameterizations of different CPDs. We proved that those CIs come from non-minimality (\neg MIN), deterministic relationships (DET) or so-called proportional CPDs (pCPDs). They are allowed by IPC.

In contrast to IPC, IC is not violated for constraints on low-complexity parameters, since such constraints can be expected to appear by chance. As such, IC can only be applied for sufficiently complex parameters, e.g. when sufficient data is present. As IC goes beyond CIs, IC provides a way to select the causal structure in the Markov equivalence class (the set of DAGs having the same CIs) based on other patterns among the parameters of different CPDs. This has been shown by several recently developed algorithms.

Acknowledgments

I have to thank Dominik Janzing from the MPI for Intelligent Systems of Tübingen, Germany for his insightful comments and discussion. He came up with the IPC condition. He shows me true science. I am also grateful to the anonymous reviewers whose comments helped me to improve the quality of the paper.

Appendix A. Appendix: Proofs

Theorem 12, which is proven here, starts with a factorization and states that if 4 conditions are met, the DAG corresponding to the factorization is faithful to the joint probability distribution. We denote CPD_X as the CPD for X , given its parents, i.e., $P(X | Parents(X))$. To prove faithfulness we will write the down the left-hand side of Eq. 2 as function of the factors of the factorization. The IPC condition rules out independencies following from non-trivial constraints that relate parameters that correspond to different CPDs.

Recall that **conditional independence** is defined as

$$U \perp\!\!\!\perp W | V \Leftrightarrow \forall v \in V_{dom}, w \in W_{dom} : P(U | v, w) = P(U | v) \text{ whenever } P(v, w) > 0.$$

Note that the conditional distribution is only defined in points where $P(v, w) > 0$. Since the right hand side is independent of w , the left hand side must give the same result for all values of W . Hence:

$$U \perp\!\!\!\perp W | V \Leftrightarrow P(U | w_1, V) = P(U | w_2, V) \forall w_1, w_2 \in W_{dom} \quad (10)$$

This is the main equation that will be used throughout the proofs. Conditional dependence is therefore defined as $P(U | V, W) \neq P(U | V)$. It means that there is at least one value for U , V and W for which the negation holds. But since $P(U | V) = \sum_w P(U | V, w)P(w | V)$, there are at least two values of W for which $P(U | V, w) \neq P(U | V)$. This can be understood by noting that $P(U | V)$ is a weighted average of $P(U | V, W)$. If the probability for one value of W is higher than the average $P(U | V)$, there must be at least one value for which the probability is lower.

For completeness we restate the postulate which is necessary to use IPC.

Postulate 2 *The non-trivial polynomial constraints among different CPDs responsible for non-Markovian CIs cannot be decomposed into product constraints without increasing their complexity, i.e. $C(c) < C(c_1) + \dots + C(c_n)$ for any decomposition of non-product constraint c into product constraints c_1, \dots, c_n .*

Whenever we encounter a non-trivial constraint among different CPDs, we may assume that they are represented by a non-product constraint in the minimal decomposition (see definition of IPC). The parameterization could still satisfy a product constraint as well, but we will show that there are only 3 cases of such product constraints leading to CIs. They will be ruled out explicitly.

Lemma 6 *Given a Bayesian network defined over discrete variables satisfying MIN and IPC, any two adjacent variables X and Y , where X is a parent of Y , are dependent conditioned on any subset of the other parents of Y .*

Proof We will prove that $X \perp\!\!\!\perp Y \mid W$ with $W \subset \text{Parents}(Y) \setminus X$. We denote all other parents of Y by $U (= \text{Parents}(Y) \setminus X \setminus W)$. If U is empty, the dependency follows from MIN (otherwise the edge between X and Y can be removed without jeopardizing the factorization). Otherwise:

$$P(Y \mid X, W) = \sum_u P(u \mid X, W) P(Y \mid X, u, W)$$

Independence $X \perp\!\!\!\perp Y \mid W$ would imply (Eq. 10) that $\forall x_1, x_2$:

$$\begin{aligned} &P(u_1 \mid x_1, W) P(Y \mid x_1, u_1, W) + P(u_2 \mid x_1, W) P(Y \mid x_1, u_2, W) + \dots \\ &= P(u_1 \mid x_2, W) P(Y \mid x_2, u_1, W) + P(u_2 \mid x_2, W) P(Y \mid x_2, u_2, W) + \dots \end{aligned}$$

In this equation, $P(Y \mid x_i, u_j, W) \neq P(Y \mid x_i, u_j, W)$ for at least one set of indices i, j, k since, by MIN, $P(Y \mid \text{Parents}(Y)) \neq P(Y \mid \text{Parents}(Y) \setminus X)$. The equation would therefore only hold when there is a constraint satisfied between CPD_Y and the CPDs defining $P(U \mid X, W)$, which is ruled out by IPC. The latter follows from the postulate and the exclusion of non-minimality, the only case in which a product constraint can lead to independence $X \perp\!\!\!\perp Y$. ■

Lemma 7 Assume that MIN and IPC holds for some Bayesian network defined over discrete variables. Let $X \perp\!\!\!\perp Y \mid Z'$ where X, Y are arbitrary nodes and Z' is a set of nodes. Let U denote the set of all variables on the non-blocked paths between X and Y , including X and Y . Then, for every set $Z'' \subset Z' \cup U$, when

$$X \perp\!\!\!\perp Y \mid Z', Z''$$

holds, there are deterministic relationships.

Proof We have to check when $P(Y \mid X, Z', Z'') = P(Y \mid Z', Z'')$. Writing $P(Y \mid X, Z')$ in function of the factors of the factorization results in a function containing the CPD_{U_i} 's for all $U_i \in U$ and factors describing $P(\text{part}(U))$ with $\text{part}(U) \in \text{Parents}(U)$ for each U . Dependency $Y \perp\!\!\!\perp X \mid Z'$ means that the distribution $P(Y \mid X, Z')$ depends on X . Conditioning on $Z'' \in Z'$ results in a new distribution for every value of Z'' . We want to know when this can result in a distribution that becomes independent from X . We have to consider 3 different types of variables of Z'' by looking how they participate in the CPDs containing variables of U .

- (1) Consider that Z'' is a member of a $\text{Parents}(U)$ set but no other parent of that U is in U . Conditioning on Z'' will only change $P(U)$, which cannot affect the dependence between X and Y under IPC unless U is determined by Z'' which is discussed below.
- (2) Consider that Z'' is a member of a $\text{Parents}(U)$ and there is another parent of U in U . Then Z'' participates in a CPD of the form $P(U_1|U_2, Z'')$. Conditioning on Z'' results in a new CPD $P(U_1|U_2)$. This can only affect the dependence between X and Y if it makes U_1 independent from U_2 . This is ruled out by Lemma 6 and MIN.
- (3) If Z'' is a descendant of some U_i, X or Y , then we apply Bayes' theorem:

$$P(Y \mid X, Z', Z'') = P(Y \mid X, Z') \frac{P(Z'' \mid X, Y, Z')}{P(Z'' \mid X, Z')} \quad (11)$$

Z'' is not present in the first factor which depends on X . Therefore, for independence of X , a constraint between the three factors of Eq. 11 must be met. By construction, this will result in a constraint between the parameters of several CPDs, which is excluded by IPC or a deterministic relation must be present. This is proved in the following.

To get independence without a constraint among different CPDs, a factor of the form $P(K \mid L, M)$ must become equal to $P(K \mid M)$. This means that

$$P(K \mid l_1, M) = P(K \mid l_2, M) \quad \forall l_1, l_2 \in L_{\text{atom}}$$

The conditional distribution of the left hand side is undefined whenever $P(l, m) = 0$. If we rule out constraints leading to independence (IPC), independence can only happen when

$$P(l_1, m) = 0 \text{ or } P(l_2, m) = 0 \text{ whenever } P(K \mid l_1, m) \neq P(K \mid l_2, m). \quad (12)$$

The condition can only apply for one CPD (IPC), so it must be a condition on CPD_L or CPD_M which holds for all parameterizations of the other CPDs. Then Eq. 12 only holds if $P(l, m) \neq 0$ for exactly one value of l given m . It follows that $L = f(M)$. ■

Lemma 9 If MIN, INDET, IPC holds for a factorization of a joint probability distribution defined over discrete variables, then for any v-structure $X \rightarrow Z \leftarrow Y$ in the DAG and for all W not containing X, Y or Z :

$$\begin{aligned} X \perp\!\!\!\perp Y \mid Z, W &\Leftrightarrow X \perp\!\!\!\perp Y \text{ and } P(Z \mid X, Y) \text{ is a proportional CPD} \\ &\text{w/ descendants of } Z : X \perp\!\!\!\perp Y \mid U, W \end{aligned} \quad (13)$$

Proof Assume that Y is not an ancestor of X (otherwise swap X and Y in the following). (1) First we prove the first equation for an empty set W and $U \neq Z$.

$$\begin{aligned} P(Y \mid X, Z) &= \frac{P(Z \mid X, Y) \cdot P(Y \mid X)}{P(Z \mid X)} \\ &= \frac{P(Z \mid X, Y) \cdot P(Y \mid X)}{\sum_{y'} P(Z \mid y', X) P(y' \mid X)} \end{aligned}$$

It follows that (using $A/B = 1/(B/A)$)

$$P(y \mid X, Z) = \frac{1}{1 + \frac{\sum_{y' \neq y} P(Z|y', X) P(y'|X)}{P(Z|y, X) P(y|X)}} \quad \forall y$$

Then, for $X \perp\!\!\!\perp Y \mid Z$ Eq. 10 gives:

$$\frac{P(Z \mid y_1, x_1) \cdot P(y_1|z_1)}{\sum_{y' \neq y_1} P(Z \mid y', x_1) P(y'|z_1)} = \frac{P(Z \mid y_1, x_2) \cdot P(y_1|z_2)}{\sum_{y' \neq y_1} P(Z \mid y', x_2) P(y'|z_2)} \quad \forall x_1, x_2$$

This equation defines a constraint between $P(Z \mid X, Y)$ and $P(Y \mid X)$ unless $Y \perp\!\!\!\perp X$ and the domain of Y contains only two values, y_1 and y_2 . Then we have $P(Y \mid X) = P(Y)$ and $P(y_2) =$

$1 - P(y_1)$, which results in a constraint on $P(Z | X, Y)$:

$$\begin{aligned} \frac{P(Z | y_1, x_1).P(y_1)}{P(Z | y_2, x_1)(1 - P(y_1))} &= \frac{P(Z | y_1, x_2).P(y_1)}{P(Z | y_2, x_2)(1 - P(y_1))} \quad \forall x_1, x_2 \\ &\Rightarrow \\ \frac{P(Z | y_1, x_1)}{P(Z | y_2, x_1)} &= \frac{P(Z | y_1, x_2)}{P(Z | y_2, x_2)} = \dots = \frac{P(Z | y_1, x_n)}{P(Z | y_2, x_n)} \end{aligned} \quad (14)$$

Which is a relation only depending on the parameterization of $P(Z | X, Y)$. In function of CPD_Z it gives:

$$P(Z|x, y) = \sum_{\mathbf{o}} P(\mathbf{o}|x, y)P(Z|x, y, \mathbf{o}) \text{ with } \mathbf{o} \in \text{domain of Parents}(Z) \setminus X \setminus Y$$

Since Eq. 14 must hold independent of $P(\mathbf{o}|x, y)$ it follows that CPD_Z must be a *proportional CPT* (Eq. 9).

Next, we consider that the \mathbf{W} is not empty. (2) For the other parents of Z , $\mathbf{W}' \subset \mathbf{W}$ it leads in a similar way to a pCPD:

$$\frac{P(Z | y_1, x_1, \mathbf{W}')}{P(Z | y_2, x_1, \mathbf{W}')} = \frac{P(Z | y_1, x_2, \mathbf{W}')}{P(Z | y_2, x_2, \mathbf{W}')} = \dots = \frac{P(Z | y_1, x_n, \mathbf{W}')}{P(Z | y_2, x_n, \mathbf{W}')}.$$

- (3) Conditioning on some other variables $\mathbf{W}'' \subset \mathbf{W}$ cannot lead to independence by lemma 7.
- (4) For proving the second equation (Eq. 13), we first prove it for an empty set. We write the equation for $P(Y | X, U)$ in function of $P(Z | X, Y)$ with Bayes' theorem:

$$\begin{aligned} P(Y | X, U) &= \frac{P(U | X, Y).P(Y | X)}{P(U | X)} \\ P(Y | X, U) &= \frac{\sum_z P(U | z, X, Y).P(z | X, Y).P(Y | X)}{\sum_z P(U | z, X).P(z | X)} \end{aligned}$$

Since Y is not an ascendant of X , each of the equation's factors depends on different CPDs of the factorization. Independence of X cannot be obtained by a constraint on one CPD unless $Z = f(U)$ which is excluded by DET.

- (5) If $X \perp\!\!\!\perp Y | U$ holds unconditionally, conditioning on some other variables \mathbf{W} cannot lead to independence by lemma 7. ■

Theorem 10 *If for a given factorization of a JPD defined over discrete variables the conditions IPC, MIN, INDET and NOpCPD are met, then faithfulness holds:*

$$\forall \text{ disjoint subsets } \mathbf{X}, \mathbf{Y}, \mathbf{Z} \subset \mathbf{V} : \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z} \Leftrightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$$

with \mathbf{V} the set of all variables under consideration.

Proof We prove that $X \perp\!\!\!\perp Y | Z \Rightarrow X \perp\!\!\!\perp Y | Z$. The proof recursively cuts the non-blocked paths between X and Y into subpaths until we end up with a basic connection that follows under lemma 6 or lemma 9. With these lemmas it will be proven that the variables at the outer ends of each subpath

are dependent under the 4 conditions. Secondly, we will prove that combining subpaths results in a dependence. To illustrate this consider $X \rightarrow U \rightarrow Y$. The path between X and Y is cut by U . First, $X \perp\!\!\!\perp U$ and $U \perp\!\!\!\perp Y$ are proven and, secondly, that the concatenation of subpaths $X \rightarrow U$ and $U \rightarrow Y$ leads to a $X \perp\!\!\!\perp Y$.

Without loss of generality, we may consider that X is not a descendant of Y . If X and Y are adjacent, Lemma 6 proves the dependency. If X and Y are part of a v-structure $X \rightarrow Z \leftarrow Y$ of which Z or descendants of Z are in \mathbf{Z} , Lemma 9 proves the dependency. If they are part of several such v-structures, the same approach as in the proof of Lemma 9 can be used to prove dependency. Otherwise, take a minimal ordered cutset $\mathbf{U} \subset \mathbf{V} \setminus \{X, Y\}$ such that $X \perp\!\!\!\perp Y | \mathbf{Z}, \mathbf{U}$. Minimal means that omitting any element of the set would lead to a d -connection. Ordered means that $U_i \in \mathbf{U}$ is not a descendant (in the DAG corresponding to the factorization) of $U_j \in \mathbf{U}$ whenever $i < j$. From $X \perp\!\!\!\perp Y | \mathbf{Z}, \mathbf{U}$ follows $X \perp\!\!\!\perp Y | \mathbf{Z}, \mathbf{U}$, thus:

$$\begin{aligned} P(Y | X, \mathbf{Z}) &= \sum_{u_1} \dots \sum_{u_n} P(Y | \mathbf{Z}, u_1, \dots, u_n).P(u_1 \dots u_n | X, \mathbf{Z}) \\ &= \sum_{u_1} \dots \sum_{u_n} P(Y | \mathbf{Z}, u_1, \dots, u_n).P(u_1 | X, \mathbf{Z}) \prod_{i=2}^n P(u_i | X, \mathbf{Z}, u_1 \dots u_{i-1}) \end{aligned} \quad (15)$$

We will prove that (1) no u_i can be removed from the first factor ($Y \perp\!\!\!\perp U_i | \mathbf{Z}, \mathbf{U} \setminus U_i$) and that X cannot be removed from the following factors ($X \perp\!\!\!\perp U_i | \mathbf{Z}, U_{i+1} \dots U_n$ for all values of i). Under these dependencies we will prove (2) that the right hand side of the equation does not lead to a distribution which is independent of X .

(1) The dependencies are of the form $K \perp\!\!\!\perp L | M$. The d -connection of all dependencies, $K \perp\!\!\!\perp L | M$, follows from the minimality of the set \mathbf{U} . That the dependencies follow from the d -connections is proven in the same way as $X \perp\!\!\!\perp Y | \mathbf{Z}$. The non-blocked paths between K and L are cut into subpaths until the nodes K and L are adjacent or connected by a v-structure. In that case lemmas 6 and 9 apply and prove the dependency.

(2) Because of the dependencies, Eq. 15 cannot be reduced. The first factor depends on CPD_Y , the following on CPD_{U_i} . Therefore, independence of X and Y can only come from a specific parameterization of at least three CPDs. ■

Theorem 12 *If for a given factorization of a JPD defined over discrete variables the conditions IC, COMPLEX, MIN, INDET and NOpCPD are met, then faithfulness holds:*

$$\forall \text{ disjoint subsets } \mathbf{X}, \mathbf{Y}, \mathbf{Z} \subset \mathbf{V} : \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z} \Leftrightarrow \mathbf{X} \perp\!\!\!\perp \mathbf{Y} | \mathbf{Z}$$

with \mathbf{V} the set of all variables under consideration.

Proof In the previous proofs, constraints among parameters from different CPDs where ruled out by IPC and postulate 2. Conditions COMPLEX and IC will rule out the same constraints by Theorem 4. ■

Theorem 13 *Given P a distribution over n variables and a DAG G with CPDs parameterized by $\theta_1, \dots, \theta_n$ describing a factorization of P .*

If the parameter vectors satisfy IPC, there exists a parameterization $\theta_1^*, \dots, \theta_n^*$ of the CPDs which has the same independencies as P and for which IC holds.

For discrete Bayesian networks and the linear case for continuous distributions, if the factorization satisfies IC and COMPLEX (the parameters θ_i^* of the parameter vectors $\theta_1, \dots, \theta_n$ have non-constant complexity: $K(\theta_i^* | \text{CPD}_i^*) > 0$), then IPC holds as well.

Proof

The first statement: if the parameter vectors satisfy IPC, there exists a parameterization $\theta_1, \dots, \theta_n$ of the CPDs which has the same independencies as P and for which IC holds (IPC \rightarrow IC).

By IPC no constraint should hold among the parameters of different CPDs for the independencies of P . It could be that IC is violated for the given parameterization $\theta_1, \dots, \theta_n$, but it is not necessary for any of the conditional independencies in P to hold. By IPC, the parameter subspace of every independence in P can cover the complete subspace or be a product subspace of the form $R_1 \times \dots \times R_n$, where every R_i is an arbitrary subset of S_i , the set of possible parameter vectors θ_j . By Theorem 12 the subsets R_i have a generic form: some values of parameter vector θ_i are zero or similar (violation of MIN or presence of deterministic relationships) or determined by the other parameters (pCPD), but the remaining values of the CPDs are not constrained. Therefore we can choose the parameters independently in the subsets R_i such that the same independencies hold but IC is not violated.

Now the second statement: if the factorization satisfies IC and COMPLEX, then IPC holds as well (IC and COMPLEX \rightarrow IPC).

Non-Markovian CIs require non-trivial polynomial constraints (Spirtes et al., 1993; Meek, 1995) among some parameters, which can be either parameters of a single CPD or among parameters of different CPDs. The first case is not a problem for IPC, while the latter would imply a violation of IC if COMPLEX, since Theorem 4 applies: polynomial constraints correspond to holomorphic functions having zeroes for a finite number of values only. As such, they have a constant description length, while we assumed that all parameters of the CPDs have non-constant complexity. ■

Editor: Ingo Steinwart

We focus on the distribution regression problem: regressing to vector-valued outputs from probability measures. Many important machine learning and statistical tasks fit into this framework, including multi-instance learning and point estimation problems without analytical solution (such as hyperparameter or entropy estimation). Despite the large number of available heuristics in the literature, the inherent two-stage sampled nature of the problem makes the theoretical analysis quite challenging, since in practice only samples from sampled distributions are observable, and the estimates have to rely on similarities computed between sets of points. To the best of our knowledge, the only existing technique with consistency guarantees for distribution regression requires kernel density estimation as an intermediate step (which often performs poorly in practice), and the domain of the distributions to be compact Euclidean. In this paper, we study a simple, analytically computable, ridge regression-based alternative to distribution regression, where we embed the distributions to a reproducing kernel Hilbert space, and learn the regressor from the embeddings to the outputs. Our main contribution is to prove that this scheme is consistent in the two-stage sampled setup under mild conditions (on separable topological domains enriched with kernels): we present an exact computational-statistical efficiency trade-off analysis showing that our estimator is able to match the *one-stage* sampled minimax op-

*. Now at Applied Mathematics Department, Center for Applied Mathematics, École Polytechnique, University of Paris-Saclay, Route de Saclay, 91128 Palaiseau Cedex, France.

timal rate (Caponnetto and De Vito, 2007; Steinwart et al., 2009). This result answers a 17-year-old open question, establishing the consistency of the classical set kernel (Haussler, 1999; Gärtner et al., 2002) in regression. We also cover consistency for more recent kernels on distributions, including those due to Christmann and Steinwart (2010).

Keywords: Two-Stage Sampled Distribution Regression, Kernel Ridge Regression, Mean Embedding, Multi-Instance Learning, Minimax Optimality

1. Introduction

We address the learning problem of *distribution regression* in the two-stage sampled setting, where we only have bags of samples from the probability distributions: we regress from probability measures to real-valued (Póczos et al., 2013) responses, or more generally to vector-valued outputs (belonging to an arbitrary separable Hilbert space). Many classical problems in machine learning and statistics can be analysed in this framework. On the machine learning side, multiple instance learning (Dietterich et al., 1997; Ray and Page, 2001; Dooly et al., 2002) can be thought of in this way, where each instance in a labeled bag is an i.i.d. (independent identically distributed) sample from a distribution. On the statistical side, tasks might include point estimation of statistics on a distribution without closed form analytical expressions (e.g., its entropy or a hyperparameter).

Intuitive description of our goal: Let us start with a somewhat informal definition of the distribution regression problem and an intuitive phrasing of our goals. Suppose that our data consist of $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^l$, where x_i is a probability distribution, y_i is its label (in the simplest case $y_i \in \mathbb{R}$ or $y_i \in \mathbb{R}^d$) and each (x_i, y_i) pair is i.i.d. sampled from a meta distribution \mathcal{M} . However, we do not observe x_i directly; rather, we observe a sample $x_{i,1}, \dots, x_{i,N_i} \stackrel{i.i.d.}{\sim} x_i$. Thus the observed data are $\hat{\mathbf{z}} = \{(\{x_{i,n}\}_{n=1}^{N_i}, y_i)\}_{i=1}^l$. Since $x_{i,j}$ is sampled from x_i , and x_i is sampled from \mathcal{M} , we call this process two-stage sampling. Our goal is to predict a new y_{l+1} from a new batch of samples $x_{l+1,1}, \dots, x_{l+1,N_{l+1}}$ drawn from a new distribution $x_{l+1} \sim \mathcal{M}$. For example, in a medical application, the l^{th} patient might be identified with a probability distribution (x_i), which can be periodically assessed by blood tests $(\{x_{i,n}\}_{n=1}^{N_i})$. We are also given some health indicator of the patient (y_i), which might be inferred from his/her blood measurements. Based on the observations ($\hat{\mathbf{z}}$), we might wish to learn the mapping from the set of blood tests to the health indicator, and the hope is that by observing more patients (larger l) and performing a larger number of tests (larger N_i) the estimated mapping ($\hat{f} = \hat{f}(\hat{\mathbf{z}})$) becomes more “precise”. Briefly, we consider the following questions:

Can the distribution regression problem be solved consistently under mild conditions? What is the exact computational-statistical efficiency trade-off implied by the two-stage sampling?

In our work the estimated mapping (\hat{f}) is the analytical solution of a kernel ridge regression (KRR) problem.¹ The performance of \hat{f} depends on the assumed function class (\mathcal{H}), the

1. Beyond its simple analytical formula, kernel ridge regression also allows efficient distributed (Zhang et al., 2015; Richiárík and Tokáč, 2016), sketch (Alaoui and Mahoney, 2015; Yang et al., 2016) and Nyström based approximations (Rudi et al., 2015).

family of f candidates used in the ridge formulation. We shall focus on the analysis of two settings:

1. **Well-specified case** ($f_* \in \mathcal{H}$): In this case we assume that the regression function f_* belongs to \mathcal{H} . We focus on bounding the goodness of \hat{f} compared to f_* . In other words, if $\mathcal{R}[f_*]$ denotes the prediction error (expected risk) of f_* , then our goal is to derive a finite-sample bound for the excess risk, $\mathcal{E}(\hat{f}; f_*) = \mathcal{R}[\hat{f}] - \mathcal{R}[f_*]$ that holds with high probability. We make use of this bound to establish the consistency of the estimator (i.e., drive the excess risk to zero) and to derive the exact computational-statistical efficiency trade-off of the estimator as a function of the sample number (l , $N = N_i, V_i$) and the problem difficulty (see Theorem 5 and its corresponding remarks for more details).

2. **Misspecified case** ($f_* \in L^2(\mathcal{H})$): Since in practise it might be hard to check whether $f_* \in \mathcal{H}$, we also study the misspecified setting of $f_* \in L^2$, the relevant case is when $f_* \in L^2 \setminus \mathcal{H}$. In the misspecified setting the ‘richness’ of \mathcal{H} has crucial importance, in other words the size of $D_{\mathcal{H}}^2 = \inf_{f \in \mathcal{H}} \|f_* - f\|_2^2$, the approximation error from \mathcal{H} . Our main contributions consist of proving a finite-sample excess risk bound, using which we show that the proposed estimator can attain the ideal performance, i.e., $\mathcal{E}(\hat{f}; f_*) - D_{\mathcal{H}}^2$ can be driven to zero. Moreover, on smooth classes of f_* -s, we give a simple and explicit description for the computational-statistical efficiency trade-off of our estimator (see Theorem 9 and its corresponding remarks for more details).

There exist a vast number of heuristics to tackle learning problems on distributions; we will review them in Section 5. However, to the best of our knowledge, the only prior work addressing the *consistency* of regression on distributions requires kernel density estimation (Póczos et al., 2013; Oliva et al., 2014; Sutherland et al., 2016), which assumes that the response variable is scalar-valued,² and the covariates are nonparametric continuous distributions on \mathbb{R}^d . As in our setting, the exact forms of these distributions are unknown; they are available only through finite sample sets. Póczos et al. estimated these distributions through a kernel density estimator (assuming these distributions have a density) and then constructed a kernel regressor that acts on these kernel density estimates.³ Using the classical bias-variance decomposition analysis for kernel regressors, they showed the consistency of the constructed kernel regressor, and provided a polynomial upper bound on the rates, assuming the true regressor to be Hölder continuous, and the meta distribution that generates the covariates x_i to have finite doubling dimension (Kpotufe, 2011).⁴

One can define kernel learning algorithms on bags based on set kernels (Gärtner et al., 2002) by computing the similarity of the sets/bags of samples representing the input distributions; set kernels are also called multi-instance kernels or ensemble kernels, and are examples of convolution kernels (Haussler, 1999). In this case, the similarity of two sets

² Oliva et al. (2013, 2015) consider the case where the responses are also distributions or functions.
³ We would like to clarify that the kernels used in their work are classical smoothing kernels—extensively studied in non-parametric statistics (Györfi et al., 2002)—and not the reproducing kernels that appear throughout our paper.

⁴ Using a random kitchen sinks approach, with orthonormal basis projection estimators Oliva et al. (2014); Sutherland et al. (2016) propose distribution regression algorithms that can computationally handle large scale datasets; as with Póczos et al. (2013), these approaches are based on density estimation in \mathbb{R}^d .

is measured by the average pairwise point similarities between the sets. From a theoretical perspective, nothing is known about the consistency of set kernel based learning method since their introduction in 1999 (Haussler, 1999; Gärtner et al., 2002): i.e. in what sense (and with what rates) is the learning algorithm consistent, when the number of items per bag, and the number of bags, are allowed to increase?

It is possible, however, to view set kernels in a distribution setting, as they represent valid kernels between (mean) embeddings of empirical probability measures into a reproducing kernel Hilbert space (RKHS; Berlinet and Thomas-Agnan, 2004). The population limits are well-defined as being dot products between the embeddings of the generating distributions (Altmun and Smola, 2006), and for characteristic kernels the distance between embeddings defines a metric on probability measures (Sriperumbudur et al., 2011; Gretton et al., 2012). When bounded kernels are used, mean embeddings exist for all probability measures (Fukumizu et al., 2004). When we consider the distribution regression setting, however, there is no reason to limit ourselves to set kernels. Embeddings of probability measures to RKHS are used by Christmann and Steinwart (2010) in defining a yet larger class of easily computable kernels on distributions, via operations performed on the embeddings and their distances. Note that the relation between set kernels and kernels on distributions was also applied by MuanDET et al. (2012) for classification on distribution-valued inputs, however consistency was not studied in that work. We also note that motivated by the current paper, Lopez-Paz et al. (2015) have recently presented the first theoretical results about surrogate risk guarantees on a class (relying on uniformly bounded Lipschitz functionals) of soft distribution-classification problems.

Our **contribution** in this paper is to establish the learning theory of a simple, mean embedding based ridge regression (MERR) method for the distribution regression problem. This result applies both to the basic set kernels of Haussler (1999); Gärtner et al. (2002), the distribution kernels of Christmann and Steinwart (2010), and additional related kernels. We provide finite-sample excess risk bounds, prove consistency, and show how the two-stage sampled nature of the problem (bag size) governs the computational-statistical efficiency of the MERR estimator. More specifically, in the

1. **well-specified case:** We

- (a) derive finite-sample bounds on the excess risk: We construct $\mathcal{R}[\hat{f}] - \mathcal{R}[f_*] \leq r(l, N, \lambda)$ bounds holding with high probability, where λ is the regularization parameter in the ridge problem ($\lambda \rightarrow 0$, $l \rightarrow \infty$, $N = N_i \rightarrow \infty$).

- (b) establish consistency and computational-statistical efficiency trade-off of the MERR estimator on a general prior family $\mathcal{P}(b, c)$ as defined by Caporineto and De Vito (2007), where b captures the effective input dimension, and larger c means smoother f_* ($1 < b, c \in (1, 2]$). In particular, when the number of samples per bag is chosen as $N = n \log(l)$ and $a \geq \frac{b(c+1)}{bc+1}$, then the learning rate saturates at $l^{-\frac{1}{bc+1}}$, which is known to be one-stage sampled minimax optimal (Caporineto and De Vito, 2007). In other words, by choosing $a = \frac{b(c+1)}{bc+1} < 2$, we suffer *no loss in statistical performance* compared with the *best possible one-stage sampled estimator*.

Note: the advantage of considering the $\mathcal{P}(b, c)$ family is two-fold. It does not assume parametric distributions, yet certain complexity terms can be explicitly upper bounded in the family. This property will be exploited in our analysis. Moreover, (for special

input distributions) the parameter b can be related to the spectral decay of Gaussian Gram matrices, and existing analysis techniques (Steinwart and Christmann, 2008) may be used in interpreting these decay conditions.

2. misspecified case: We establish consistency and convergence rates even if $f_* \notin \mathcal{H}$. Particularly, by deriving finite-sample bounds on the excess risk we

- (a) prove that the MERR estimator can achieve the best possible approximation accuracy from \mathcal{H} , i.e. the $\mathcal{R}[f] - \mathcal{R}[f_*] - D_{\mathcal{H}}^2$ quantity can be driven to zero (recall that $D_{\mathcal{H}} = \inf_{f \in \mathcal{H}} \|f_* - f\|_2$). Specifically, this result implies that if \mathcal{H} is dense in L^2 ($D_{\mathcal{H}} = 0$), then the excess risk $\mathcal{R}[f] - \mathcal{R}[f_*]$ converges to zero.
- (b) analyse the computational-statistical efficiency trade-off: We show that by choosing the bag size as $N = \ell^{2a} \log(\ell)$ ($a > 0$) one can get rate $L^{-\frac{2sa}{s+1}}$ for $a \leq \frac{s+1}{s+2}$, and the rate saturates for $a \geq \frac{s+1}{s+2}$ at $L^{-\frac{2s}{s+2}}$, where the difficulty of the regression problem is captured by $s \in (0, 1]$ (a larger s means an easier problem). This means that easier tasks give rise to faster convergence (for $s = 1$, the rate is $L^{-\frac{2}{3}}$), the bag size N can again be *sub-quadratic* in ℓ ($2a \leq \frac{2(s+1)}{s+2} \leq \frac{4}{3} < 2$), and the rate at saturation is close to $\bar{r}(\ell) = L^{-\frac{2s}{2s+1}}$, which is the asymptotically optimal rate in the one-stage sampled setup, with real-valued output and stricter eigenvalue decay conditions (Steinwart et al., 2009).

Due to the differences in the assumptions made and the loss function used, a direct comparison of our theoretical result and that of Póczos et al. (2013) remains an open question, however we make three observations. First, our approach is more general, since we may regress from any probability measure defined on separable, topological domains endowed with kernels. Póczos et al.'s work is restricted to compact domains of finite dimensional Euclidean spaces, and requires the distributions to admit probability densities; distributions on strings, graphs, and other structured objects are disallowed. Second, in our analysis we will allow separable Hilbert space valued outputs, in contrast to the real-valued output considered by Póczos et al. (2013). Third, density estimates in high dimensional spaces suffer from slow convergence rates (Wasserman, 2006, Section 6.5). Our approach mitigates this problem, as it works directly on distribution embeddings, and does not make use of density estimation as an intermediate step.

The principal challenge in proving theoretical guarantees arises from the two-stage sampled nature of the inputs. In our analysis of the well-specified case, we make use of Caponnetto and De Vito (2007)'s results, which focus (only) on the one-stage sample setup. These results will make our analysis somewhat shorter (but still rather challenging) by giving upper bounds for some of the objective terms. Even the verification of these conditions requires care since the inputs in the ridge regression are themselves distribution embeddings (i.e., functions in a reproducing kernel Hilbert space).

In the misspecified case, RKHS methods alone are not sufficient to obtain excess risk bounds: one has to take into account the ‘‘richness’’ of the modelling RKHS class (\mathcal{H}) in the embedding L^2 space. The fundamental challenge is whether it is possible to achieve the best possible performance dictated by \mathcal{H} ; or in the special case when further smoothness conditions hold on f_* , what convergence rates can yet be attained, and what computational-statistical efficiency trade-off realized. The second smoothness property could be modelled

for example by range spaces of (fractional) powers of integral operators associated to \mathcal{H} . Indeed, there exist several results along these lines with KRR for the case of real-valued outputs: see for example (Sun and Wu, 2009a, Theorem 1.1), (Sun and Wu, 2009b, Corollary 3.2), (Mendelson and Neeman, 2010, Theorem 3.7 with Assumption 3.2). The question of optimal rates has also been addressed for the semi-supervised KRR setting (Caponnetto, 2006, Theorem 1), and for clipped KRR estimators (Steinwart et al., 2009) with integral operators of rapidly decaying spectrum. Our results apply more generally to the two-stage sampled setting and to vector valued outputs belonging to separable Hilbert spaces. Moreover, we obtain a general consistency result without range space assumptions, showing that the modelling power of \mathcal{H} can be fully exploited, and convergence to the best approximation available from \mathcal{H} can be realized.⁵

There are numerous areas in machine learning and statistics, where estimating vector-valued functions has crucial importance. Often in statistics, one is not only confronted with the estimation of a scalar parameter, but with a vector of parameters. On the machine learning side, multi-task learning (Evgeniou et al., 2005), functional response regression (Kadri et al., 2016), or structured output prediction (Brouard et al., 2011; Kadri et al., 2013) fall under the same umbrella: they can be naturally phrased as learning vector-valued functions (Micchelli and Pontil, 2005). The idea underlying all these tasks is simple and intuitive: if multiple prediction problems have to be solved simultaneously, it might be beneficial to exploit their dependencies. Imagine for example that the task is to predict the motion of a dancer: taking into account the interrelation of the actor's body parts is likely to lead to more accurate estimation, as opposed to predicting the individual parts one by one, independently. Successful real-world applications of a multi-task approach include for example preference modelling of users with similar demographics (Evgeniou et al., 2005), prediction of the daily precipitation profiles of weather stations (Kadri et al., 2010), acoustic-to-articulatory speech inversion (Kadri et al., 2016), identifying biomarkers capable of tracking the progress of Alzheimer's disease (Zhou et al., 2013), personalized human activity recognition based on iPod/iPhone accelerometer data (Sun et al., 2013), finger trajectory prediction in brain-computer interfaces (Kadri et al., 2012) or ecological inference (Flaxman et al., 2015); for a recent review on multi-output prediction methods see (Álvarez et al., 2011; Borchani et al., 2015). A mathematically sound way of encoding prior information about the relation of the outputs can be realized by operator-valued kernels and the associated vector-valued RKHSs (Pedrick, 1957; Micchelli and Pontil, 2005; Carmeli et al., 2006, 2010); this is the tool we use to allow vector-valued learning tasks.

Finally, we note that the current work extends our earlier conference paper (Szabó et al., 2015) in several important respects: we now show that the MERR method can attain the one-stage sampled minimax optimal rate; we generalize the analysis in the well-specified setting to allow outputs belonging to an arbitrary separable Hilbert spaces (in contrast to the original scalar-valued output domain); and we tackle the misspecified setting, obtaining finite sample guarantees, consistency, and computational-statistical efficiency trade-offs.

The paper is structured as follows: The distribution regression problem and the MERR technique are introduced in Section 2. Our assumptions are detailed in Section 3. We present our theoretical guarantees (finite-sample bounds on the excess risk, consistency,

⁵ Specializing our result, we get explicit rates and an exact computational-statistical efficiency description for MERR as a function of sample numbers and problem difficulty, for smooth regression functions.

computational-statistical efficiency trade-offs) in Section 4: the well-specified case is considered in Section 4.1, and the misspecified setting is the focus of Section 4.2. Section 5 is devoted to an overview of existing heuristics for learning on distributions. Conclusions are drawn in Section 6. Section 7 contains proof details. In Section 8 we discuss our assumptions with concrete examples.

2. The Distribution Regression Problem

Below we first introduce our notation (Section 2.1), then formally define the distribution regression task (Section 2.2).

2.1 Notation

We use the following notations throughout the paper:

- **Sets, topology, measure theory:** Let \mathcal{X} be a Hilbert space; $\text{cl}[Y]$ is the closure of a set $Y \subseteq \mathcal{X}$. $X_i \in I_i/S_i$ is the direct product of sets S_i . $f \circ g$ is the composition of function f and g . Let (\mathcal{X}, τ) be a topological space and let $\mathcal{B}(\mathcal{X}) := \mathcal{B}(\tau)$ be the Borel σ -algebra induced by the topology τ . If (\mathcal{X}, d) is a metric space, then $\mathcal{B} = \mathcal{B}(d)$ is the Borel σ -algebra generated by the open sets induced by metric d . $\mathcal{M}_1^+(\mathcal{X})$ denotes the set of Borel probability measures on the $(\mathcal{X}, \mathcal{B}(\mathcal{X}))$ measurable space. Given measurable spaces (U_1, \mathcal{S}_1) and (U_2, \mathcal{S}_2) , the $\mathcal{S}_1 \otimes \mathcal{S}_2$ product σ -algebra (Steinwart and Christmann, 2008, page 480) on the product space $U_1 \times U_2$ is the σ -algebra generated by the cylinder sets $U_1 \times S_2$, $S_1 \times U_2$ ($S_1 \in \mathcal{S}_1$, $S_2 \in \mathcal{S}_2$). The weak topology $(\tau_w = \tau_w(\mathcal{X}, \tau))$ on $\mathcal{M}_1^+(\mathcal{X})$ is defined as the weakest topology such that the $L_h : \mathcal{M}_1^+(\mathcal{X}, \tau_w) \rightarrow \mathbb{R}$, $L_h(x) = \int_{\mathcal{X}} h(u) d\tau(u)$ mapping is continuous for all $h \in C_b(\mathcal{X}) = \{\mathcal{X}, \tau\} \rightarrow \mathbb{R}$ bounded, continuous functions⁶.

- **Functional analysis:** Let $(N_1, \|\cdot\|_{N_1})$ and $(N_2, \|\cdot\|_{N_2})$ denote two normed spaces, then $\mathcal{L}(N_1, N_2)$ stands for the space of $N_1 \rightarrow N_2$ bounded linear operators; if $N_1 = N_2$, we will use the $\mathcal{L}(N_1) = \mathcal{L}(N_1, N_2)$ shorthand. For $M \in \mathcal{L}(N_1, N_2)$ the operator norm is defined as $\|M\|_{\mathcal{L}(N_1, N_2)} = \sup_{\|h\|_{N_2} \leq 1} \|Mh\|_{N_1}$. $\text{Im}(M) = \{Mn\}_{n \in N_1}$ denotes the range of M , $\text{Ker}(M) = \{n_1 \in N_1 : Mn_1 = 0\}$ is the null space of M . Let \mathcal{K} be a Hilbert space. The adjoint operator $M^* \in \mathcal{L}(\mathcal{K})$ of an operator $M \in \mathcal{L}(\mathcal{K})$ is the operator such that $\langle Ma, b \rangle_{\mathcal{K}} = \langle a, M^*b \rangle_{\mathcal{K}}$ for all a and b in \mathcal{K} . $M \in \mathcal{L}(\mathcal{K})$ is called positive if $\langle Ma, a \rangle_{\mathcal{K}} \geq 0$ ($\forall a \in \mathcal{K}$), self-adjoint if $M = M^*$, and trace class if $\sum_{j \in J} \langle M|e_j, e_j\rangle_{\mathcal{K}} < \infty$ for an $(e_j)_{j \in J}$ ONB (orthonormal basis) of \mathcal{K} ($|M| := (M^*M)^{\frac{1}{2}}$), in which case $\text{Tr}(M) := \sum_{j \in J} \langle M|e_j, e_j\rangle_{\mathcal{K}} < \infty$; compact if $\text{cl}[|M|a : a \in \mathcal{K}, \|a\|_{\mathcal{K}} \leq 1]$ is a compact set. Let \mathcal{K}_1 and \mathcal{K}_2 be Hilbert spaces. $M \in \mathcal{L}(\mathcal{K}_1, \mathcal{K}_2)$ is called Hilbert-Schmidt if $\|M\|_{\mathcal{L}_2(\mathcal{K}_1, \mathcal{K}_2)}^2 = \text{Tr}(M^*M) = \sum_{j \in J} \langle M|e_j, M|e_j\rangle_{\mathcal{K}_2} < \infty$ for some $(e_j)_{j \in J}$ ONB of \mathcal{K}_1 . The space of Hilbert-Schmidt operators is denoted by $\mathcal{L}_2(\mathcal{K}_1, \mathcal{K}_2) = \{M \in \mathcal{L}(\mathcal{K}_1, \mathcal{K}_2) : \|M\|_{\mathcal{L}_2(\mathcal{K}_1, \mathcal{K}_2)} < \infty\}$. We use the shorthand notation $\mathcal{L}_2(\mathcal{K}) = \mathcal{L}_2(\mathcal{K}, \mathcal{K})$ if $\mathcal{K} := \mathcal{K}_1 = \mathcal{K}_2$. $\mathcal{L}_2(\mathcal{K})$ is separable if and only if \mathcal{K} is separable (Steinwart and Christmann, 2008, page 506). Trace class and Hilbert-Schmidt operators over a \mathcal{K} Hilbert space are compact operators (Steinwart and Christmann, 2008, page 505-506); moreover,

$$\|A\|_{\mathcal{L}(\mathcal{K})} \leq \|A\|_{\mathcal{L}_2(\mathcal{K})}, \quad \forall A \in \mathcal{L}_2(\mathcal{K}), \quad (1)$$

$$\|AB\|_{\mathcal{L}_2(\mathcal{K})} \leq \|A\|_{\mathcal{L}_2(\mathcal{K})} \|B\|_{\mathcal{L}(\mathcal{K})}, \quad \forall A, B \in \mathcal{L}_2(\mathcal{K}). \quad (2)$$

I is the identity operator; $I_I \in \mathbb{R}^{K \times I}$ is the identity matrix.

- **RKHS, mean embedding:** Let $H = H(k)$ be an RKHS (Steinwart and Christmann, 2008) with $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ as the reproducing kernel. Denote by

$$X = \mu(\mathcal{M}_1^+(\mathcal{X})) = \{\mu_x : x \in \mathcal{M}_1^+(\mathcal{X}) \subseteq H, \quad \mu_x = \int_{\mathcal{X}} k(\cdot, u) dx(u) = \mathbb{E}_{u \sim x}[k(\cdot, u)] \in H$$

the set of mean embeddings (Berlinet and Thomas-Agnan, 2004) of the distributions to the space H .⁶ Let Y be a separable Hilbert space, where the inner product is denoted by $\langle \cdot, \cdot \rangle_Y$; the associated norm is $\|\cdot\|_Y$. $\mathcal{Y} = \mathcal{Y}(K)$ is the Y -valued RKHS (Pedrick, 1957; Micchelli and Pontil, 2005; Carmeli et al., 2006, 2010) of $X \rightarrow Y$ functions with $K : X \times X \rightarrow \mathcal{L}(Y)$ as the reproducing kernel (we will present some concrete examples of K in Section 3; see Table 1); $K_{\mu_x} \in \mathcal{L}(Y, \mathcal{Y})$ is defined as

$$K(\mu_x, \mu)(y) = (K_{\mu, y})(\mu_x), \quad (\forall \mu_x, \mu \in X), \quad \text{or } K(\cdot, \mu)(y) = K_{\mu, y}. \quad (3)$$

Further, $f(\mu_x) = K_{\mu_x}^* f$ ($\forall \mu_x \in X, f \in \mathcal{Y}$).

- **Regression function:** Let ρ be the μ -induced probability measure on the $Z = X \times Y$ product space, and let $\rho(\mu_x, y) = \rho(y|\mu_x)\rho_X(\mu_x)$ be the factorization of ρ into conditional and marginal distributions.⁷ The regression function of ρ with respect to the (μ_x, y) pair is denoted by

$$f_{\rho}(\mu_x) = \int_Y y d\rho(y|\mu_x) \quad (\mu_x \in X) \quad (4)$$

and for $f \in L_{\rho_X}^2$ let $\|f\|_{\rho} = \sqrt{\langle f, f \rangle_{\rho}} = \|f\|_{L_{\rho_X}^2} = \left[\int_X \|f(\mu_x)\|_Y^2 d\rho_X(\mu_x) \right]^{\frac{1}{2}}$. Let us assume that the operator-valued kernel $K : X \times X \rightarrow \mathcal{L}(Y)$ is a Mercer kernel (that is $\mathcal{Y} = \mathcal{Y}(K) \subseteq C(X, Y) = \{X \rightarrow Y \text{ continuous functions}\}$), is bounded ($\|BK\| < \infty$ such that $\|K(x, x)\|_{\mathcal{L}(Y)} \leq BK$), and is a compact operator for all $x \in X$. These requirements will be guaranteed by our assumptions; see Section 7.2.6. In this case, the inclusion $S_K^* : \mathcal{Y} \hookrightarrow L_{\rho_X}^2$ is bounded, and its adjoint $S_K : L_{\rho_X}^2 \rightarrow \mathcal{Y}$ is given by

$$(S_K g)(\mu_x) = \int_X K(\mu_x, \mu) g(\mu) d\rho_X(\mu). \quad (5)$$

We further define \tilde{T} as

$$\tilde{T} = S_K^* S_K : L_{\rho_X}^2 \rightarrow L_{\rho_X}^2; \quad (6)$$

in other words, the result of operation (5) belongs to \mathcal{Y} , which is embedded in $L_{\rho_X}^2$. \tilde{T} is a compact, positive, self-adjoint operator (Carmeli et al., 2010, Proposition 3), thus by the spectral theorem \tilde{T}^s exists, where $s \geq 0$.

6. The $x \rightarrow \mu_x$ mapping is defined for $\text{all } x \in \mathcal{M}_1^+(\mathcal{X})$ if k is bounded, i.e., $\sup_{u, v \in \mathcal{X}} k(u, v) < \infty$.

7. Our assumptions will guarantee the existence of ρ (see Section 3). Since Y is a Polish space (because it is separable Hilbert) the $\rho(y|\mu_x)$ conditional distribution ($y \in Y, \mu_x \in X$) is also well-defined (Steinwart and Christmann, 2008, Lemma A.3.16, page 487).

2.2 Distribution Regression

We now formally define the distribution regression task. Let us assume that $\mathcal{M}_1^+(\mathcal{X})$ is endowed with $S_1 = \mathcal{B}(\tau_w)$, the weak-topology generated σ -algebra; thus $(\mathcal{M}_1^+(\mathcal{X}), S_1)$ is a measurable space. In the *distribution regression* problem, we are given samples $\hat{\mathbf{z}} = \{(x_{i,n}, y_i)\}_{i=1}^l$ with $x_{i,1}, \dots, x_{i,N_i} \stackrel{i.i.d.}{\sim} x_i$ where $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^l$ with $x_i \in \mathcal{M}_1^+(\mathcal{X})$ and $y_i \in Y$ drawn i.i.d. from a joint meta distribution \mathcal{M} defined on the measurable space $(\mathcal{M}_1^+(\mathcal{X}) \times Y, S_1 \otimes \mathcal{B}(Y))$, the product space enriched with the product σ -algebra. Unlike in classical supervised learning problems, the problem at hand involves two levels of randomness, wherein first \mathbf{z} is drawn from \mathcal{M} , and then $\hat{\mathbf{z}}$ is generated by sampling points from x_i for all $i = 1, \dots, l$. The goal is to learn the relation between the random distribution x and response y based on the observed $\hat{\mathbf{z}}$. For notational simplicity, we will assume that $N = N_i$ ($\forall i$).

As in the classical regression problem ($\mathbb{R}^d \rightarrow \mathbb{R}$), distribution regression can be tackled via kernel ridge regression (using a squared loss as the discrepancy criterion). The kernel (say $K_{\mathcal{G}}$) is defined on $\mathcal{M}_1^+(\mathcal{X})$, and the regressor is then modelled by an element in the RKHS $\mathcal{G} = \mathcal{G}(K_{\mathcal{G}})$ of functions mapping from $\mathcal{M}_1^+(\mathcal{X})$ to Y . In this paper, we choose $K_{\mathcal{G}}(x, x') = K(\mu_x, \mu_{x'})$ where $x, x' \in \mathcal{M}_1^+(\mathcal{X})$ and so that the function (in 9) to describe the (x, y) random relation is constructed as a composition $f \circ \mu_x$, i.e.

$$\mathcal{M}_1^+(\mathcal{X}) \xrightarrow{\mu} X (\subseteq H = H(k)) \xrightarrow{f \in \mathcal{G} = \mathcal{G}(K)} Y. \quad (7)$$

In other words, the distribution $x \in \mathcal{M}_1^+(\mathcal{X})$ is first mapped to $X \subseteq H$ by the mean embedding μ , and the result is composed with f , an element of the RKHS \mathcal{G} .

Let the expected risk for a $\tilde{f}: X \rightarrow Y$ (measurable) function be defined as

$$\mathcal{R}[\tilde{f}] = \mathbb{E}_{(x,y) \sim \mathcal{M}} \|\tilde{f}(\mu_x) - y\|_Y^2,$$

which is minimized by the f_{ρ} regression function. The classical regularization approach is to optimize

$$f_{\mathbf{z}}^{\lambda} = \arg \min_{f \in \mathcal{G}} \frac{1}{l} \sum_{i=1}^l \|f(\mu_{x_i}) - y_i\|_Y^2 + \lambda \|f\|_{\mathcal{G}}^2 \quad (8)$$

instead of \mathcal{R} , based on samples \mathbf{z} . Since \mathbf{z} is not available, we consider the objective function defined by the observable quantity $\hat{\mathbf{z}}$,

$$f_{\hat{\mathbf{z}}}^{\lambda} = \arg \min_{f \in \mathcal{G}} \frac{1}{l} \sum_{i=1}^l \|f(\mu_{\hat{x}_i}) - y_i\|_Y^2 + \lambda \|f\|_{\mathcal{G}}^2, \quad (9)$$

where $\hat{x}_i = \frac{1}{N} \sum_{n=1}^N \delta_{x_{i,n}}$ is the empirical distribution determined by $\{x_{i,n}\}_{n=1}^N$. The ridge regression objective function has an analytical solution: given training samples $\hat{\mathbf{z}}$, the prediction for a new t test distribution is

$$(\hat{\mathbf{z}}^{\lambda} \circ \mu)(t) = \mathbf{k}(\mathbf{K} + t\lambda Y)^{-1} [y_1; \dots; y_l], \quad (10)$$

where $\mathbf{k} = [K(\mu_{\hat{x}_1}, \mu_t), \dots, K(\mu_{\hat{x}_l}, \mu_t)] \in \mathcal{L}(Y)^{l \times l}$, $\mathbf{K} = [K(\mu_{\hat{x}_i}, \mu_{\hat{x}_j})] \in \mathcal{L}(Y)^{l \times l}$, $[y_1; \dots; y_l] \in Y^l$.

Remark 1

- It is important to note that the algorithm has access to the sample points only via their mean embeddings $\{\mu_{\hat{x}_i}\}_{i=1}^l$ in Eq. (9).
- There is a two-stage sampling difficulty to tackle: The transition from f_{ρ} to $f_{\mathbf{z}}^{\lambda}$ represents the fact that we have only l distribution samples (\mathbf{z}); the transition from $f_{\mathbf{z}}^{\lambda}$ to $f_{\hat{\mathbf{z}}}^{\lambda}$ means that the x_i distributions can be accessed only via samples ($\hat{\mathbf{z}}$).
- While ridge regression can be performed using the kernel $K_{\mathcal{G}}$, the two-stage sampling makes it difficult to work with arbitrary $K_{\mathcal{G}}$. By contrast, our choice of $K_{\mathcal{G}}(x, x') = K(\mu_x, \mu_{x'})$ enables us to handle the two-stage sampling by estimating μ_x with an empirical estimator, and using it in the algorithm as shown above.
- In case of scalar output ($Y = \mathbb{R}$), $\mathcal{L}(Y) = \mathcal{L}(\mathbb{R}) = \mathbb{R}$ and (10) is a standard linear equation with $\mathbf{K} \in \mathbb{R}^{l \times l}$, $\mathbf{k} \in \mathbb{R}^{1 \times l}$. More generally, if $Y = \mathbb{R}^d$, then $\mathcal{L}(Y) = \mathcal{L}(\mathbb{R}^d) = \mathbb{R}^{d \times d}$ and (10) is still a finite-dimensional linear equation with $\mathbf{K} \in \mathbb{R}^{(dl) \times (dl)}$ and $\mathbf{k} \in \mathbb{R}^{d \times (dl)}$.
- One could also formulate the problem (and get guarantees) for more abstract $X \subseteq H \rightarrow Y$ regression tasks [see Eq. (7)] on a convex set X with H and Y being general, separable Hilbert spaces. Since distribution regression is probably the most accessible example where two-stage sampling appears, and in order to keep the presentation simple, we do not consider such extended formulations in this work.

Our main goals in this paper are as follows: first, to analyse the excess risk

$$\mathcal{E}(\hat{\mathbf{z}}^{\lambda}, f_{\rho}) := \mathcal{R}[f_{\hat{\mathbf{z}}}^{\lambda}] - \mathcal{R}[f_{\rho}],$$

both when $f_{\rho} \in \mathcal{H}$ (the well-specified case) and $f_{\rho} \in L_{\rho_X}^2 \setminus \mathcal{H}$ (the misspecified case); second, to establish consistency ($\mathcal{E}(f_{\hat{\mathbf{z}}}^{\lambda}, f_{\rho}) \rightarrow 0$, or in the misspecified case $\mathcal{E}(f_{\hat{\mathbf{z}}}^{\lambda}, f_{\rho}) - D_{\mathcal{H}}^2 \rightarrow 0$, where $D_{\mathcal{H}}^2 := \inf_{g \in \mathcal{H}} \|f_{\rho} - S_K g\|_{\rho}^2$ is the approximation error of f_{ρ} by a function in \mathcal{H}); and third, to derive an exact computational-statistical efficiency trade-off as a function of the (l, N, λ) triplet, and of the difficulty of the problem.

3. Assumptions

In this section, we detail our assumptions on the (\mathcal{X}, Y, k, K) quartet. Our analysis for the well-specified case uses existing ridge regression results (Caponnetto and De Vito, 2007) focusing on problem (8) where only a single-stage sampling is present, hence we have to verify the associated conditions. Though we make use of these results, the analysis still remains challenging: the available bounds can moderately shorten our proof. We must take particular care in verifying that Caponnetto and De Vito (2007)'s conditions are met, since they need to hold for the space of mean embeddings of the distributions ($X = \mu(\mathcal{M}_1^+(\mathcal{X}))$), whose properties as a function of \mathcal{X} and H must themselves be established.

Our **assumptions** are as follows:

1. (\mathcal{X}, τ) is a separable, topological space.

2. Y is a separable Hilbert space.
3. k is bounded, in other words $\exists B_k < \infty$ such that $\sup_{u,v \in X} k(u, v) \leq B_k$, and continuous.
4. The $\{K_{\mu_a}\}_{\mu_a \in X}$ operator family is uniformly bounded in Hilbert-Schmidt norm and Hölder continuous in operator norm. Formally, $\exists B_K < \infty$ such that

$$\|K_{\mu_a}\|_{\mathcal{L}(Y; \mathcal{Y})}^2 = \text{Tr} (K_{\mu_a}^* K_{\mu_a}) \leq B_K, \quad (\forall \mu_a \in X), \quad (11)$$

and $\exists L > 0, h \in (0, 1]$ such that the mapping $K(\cdot) : X \rightarrow \mathcal{L}(Y, \mathcal{Y})$ is Hölder continuous:

$$\|K_{\mu_a} - K_{\mu_b}\|_{\mathcal{L}(Y; \mathcal{Y})} \leq L \|\mu_a - \mu_b\|_H^h, \quad (\forall \mu_a, \mu_b) \in X \times X. \quad (12)$$

5. y is bounded: $\exists C < \infty$ such that $\|y\|_Y \leq C$ almost surely. These requirements hold under mild conditions: in Section 8, we provide insight into the consequences of our assumptions, with several concrete illustrations (e.g. regression with self- and RBF-type kernels).

4. Error Bounds, Consistency & Computational-Statistical Efficiency Trade-off

In this section, we present our analysis of the consistency of the mean embedding based ridge regression (MERR) method.

Given the estimator $(f_{\frac{\lambda}{2}}^\lambda)$ in Eq. (9), we derive finite-sample high probability upper bounds (see Theorems 2 and 7) for the excess risk $\mathcal{E}(f_{\frac{\lambda}{2}}^\lambda, f_\rho)$; and in the misspecified setting, for the excess risk compared to the best attainable value from \mathcal{F}_c , i.e., $\mathcal{E}(f_{\frac{\lambda}{2}}^\lambda, f_\rho) - D_{\mathcal{F}_c}^\lambda$. We illustrate the bounds for particular classes of prior distributions, and work through special cases to obtain consistency conditions and computational-statistical efficiency trade-offs (see Theorems 4, 9 and the 3rd bullet of Remark 8). The main challenge is how to turn the convergence rates of the mean embeddings into those for an error \mathcal{E} of the predictor. Although the main ideas of the proofs can be summarized relatively briefly, the full details are more demanding. High-level ideas with the sketches of the proofs and the obtained results are presented in Section 4.1 (well-specified case) and Section 4.2 (misspecified case). The derivations of some technical details of Theorems 2 and 7 are available in Section 7.

4.1 Results for the Well-specified Case

We first focus on the well-specified case ($f_\rho \in \mathcal{F}_c$) and present our first main result. We derive a high probability upper bound for the excess risk $\mathcal{E}(f_{\frac{\lambda}{2}}^\lambda, f_\rho)$ of the MERR method (Theorem 2). The upper bound is instantiated for a general class of prior distributions (Theorem 4), which leads to a simple computational-statistical efficiency description (Theorem 5); this shows (among others) conditions when the MERR technique is able to achieve the *one-stage* sampled minimax optimal rate. We first give a high-level sketch of our convergence analysis and an intuitive interpretation of the results. An outline of the main proof ideas is given below, with technical details in Section 7.

Let us define $\mathbf{x} = \{x_i\}_{i=1}^N$ and $\mathbf{X} = \{x_{i,n}\}_{i=1}^N$ as the ‘x-part’ of \mathbf{z} and $\hat{\mathbf{z}}$, respectively. One can express $f_{\frac{\lambda}{2}}^\lambda$ [Eq. (8)] (Caponnetto and De Vito, 2007), and similarly $f_{\frac{\lambda}{2}}^\lambda$ [Eq. (9)],

38

$$f_{\frac{\lambda}{2}}^\lambda = (T_{\mathbf{x}} + \lambda)^{-1} g_{\mathbf{x}}, \quad T_{\mathbf{x}} = \frac{1}{l} \sum_{i=1}^l T_{\mu_{x_i}}, \quad g_{\mathbf{x}} = \frac{1}{l} \sum_{i=1}^l K_{\mu_{x_i}} g_{i\mathbf{x}}, \quad (13)$$

$$f_{\frac{\lambda}{2}}^\lambda = (T_{\hat{\mathbf{x}}} + \lambda)^{-1} g_{\hat{\mathbf{x}}}, \quad T_{\hat{\mathbf{x}}} = \frac{1}{l} \sum_{i=1}^l T_{\mu_{\hat{x}_i}}, \quad g_{\hat{\mathbf{x}}} = \frac{1}{l} \sum_{i=1}^l K_{\mu_{\hat{x}_i}} g_{i\hat{\mathbf{x}}}, \quad (14)$$

where $T_{\mu_a} = K_{\mu_a} K_{\mu_a}^* \in \mathcal{L}(\mathcal{Y})$ ($\mu_a \in X$), $T_{\mathbf{x}}, T_{\hat{\mathbf{x}}} : \mathcal{Y} \rightarrow \mathcal{Y}$, $g_{\mathbf{x}}, g_{\hat{\mathbf{x}}} \in \mathcal{Y}$. By these explicit expressions, one can decompose the excess risk into 5 terms (Szabó et al., 2015, Section A.1.8):

$$\mathcal{E}(f_{\frac{\lambda}{2}}^\lambda, f_\rho) = \mathcal{R}[f_{\frac{\lambda}{2}}^\lambda] - \mathcal{R}[f_\rho] \leq 5[S_{-1} + S_0 + A(\lambda) + S_1 + S_2],$$

where

$$S_{-1} = S_{-1}(\lambda, \mathbf{z}, \hat{\mathbf{z}}) = \|\sqrt{T}(T_{\hat{\mathbf{x}}} + \lambda I)^{-1}(g_{\hat{\mathbf{x}}} - g_{\mathbf{x}})\|_{\mathcal{Y}}^2, \quad (15)$$

$$S_0 = S_0(\lambda, \mathbf{z}, \hat{\mathbf{z}}) = \|\sqrt{T}(T_{\hat{\mathbf{x}}} + \lambda I)^{-1}(T_{\hat{\mathbf{x}}} - T_{\mathbf{x}}) f_{\frac{\lambda}{2}}^\lambda\|_{\mathcal{Y}}^2, \quad (16)$$

$$A(\lambda) = \|\sqrt{T}(f_{\frac{\lambda}{2}}^\lambda - f_\rho)\|_{\mathcal{Y}}^2, \quad S_1 = S_1(\lambda, \mathbf{z}) = \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}(g_{\mathbf{x}} - T_{\mathbf{x}} f_\rho)\|_{\mathcal{Y}}^2,$$

$$S_2 = S_2(\lambda, \mathbf{z}) = \|\sqrt{T}(T_{\hat{\mathbf{x}}} + \lambda I)^{-1}(T_{\hat{\mathbf{x}}} - T_{\mathbf{x}})(f_{\frac{\lambda}{2}}^\lambda - f_\rho)\|_{\mathcal{Y}}^2,$$

$$f_{\frac{\lambda}{2}}^\lambda = \arg \min_{f \in \mathcal{F}_c} (\mathcal{R}[f] + \lambda \|f\|_{\mathcal{Y}}^2), \quad T = \int_X T_{\mu_a} d\rho_X(\mu_a) = S_K S_K^* : \mathcal{Y} \rightarrow \mathcal{Y}. \quad (17)$$

Three of the terms ($S_1, S_2, A(\lambda)$) are identical to the terms in Caponnetto and De Vito (2007), hence the earlier bounds can be applied. The two new terms (S_{-1}, S_0) resulting from two-stage sampling will be upper bounded by making use of the convergence of the empirical mean embeddings. These bounds will lead to the following results:

Theorem 2 (Finite-sample excess risk bounds; well-specified case) *Let*

$K(\cdot) : X \rightarrow \mathcal{L}(Y, \mathcal{Y})$ *be Hölder continuous with constants* L, h . *Let* $l \in \mathbb{Z}^+, N \in \mathbb{Z}^+, 0 < \lambda, 0 < \eta < 1, 0 < \delta$, $C_\eta = 32 \log^2(6/\eta)$, $\|y\|_Y \leq C$ (a.s.) *and* $A(\lambda)$ *be the residual as defined above. Define* $M = 2(C + \|f_\rho\|_{\mathcal{Y}} \sqrt{B_K})$, $\Sigma = \frac{M}{2}$, T *as in* (17), $\mathfrak{B}(\lambda) = \|f_{\frac{\lambda}{2}}^\lambda - f_\rho\|_{\mathcal{Y}}^2$ *as the reconstruction error, and* $\mathcal{N}(\lambda) = \text{Tr}((T + \lambda I)^{-1} T)$ *as the effective dimension. Then with probability at least* $1 - \eta - e^{-\delta}$, *the excess risk can be upper bounded as*

$$\begin{aligned} \mathcal{E}(f_{\frac{\lambda}{2}}^\lambda, f_\rho) &\leq 5 \left\{ \frac{4L^2 (1 + \sqrt{\log(l) + \delta})^{2h}}{\lambda N^h} (2B_K)^h \left[C^2 + 4B_K \times \right. \right. \\ &\quad \left. \left. \times \left(\log^2 \left(\frac{6}{\eta} \right) \left[\frac{64}{\lambda} \left[\frac{M^2 B_K}{l^2 \lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right] + \frac{24}{\lambda^2} \left[\frac{4B_K^2 \mathfrak{B}(\lambda)}{l^2} + \frac{B_K A(\lambda)}{l} \right] \right) + \mathfrak{B}(\lambda) + \|f_\rho\|_{\mathcal{Y}}^2 \right] \right. \\ &\quad \left. \left. + A(\lambda) + C_\eta \left[\frac{B_K^2 \mathfrak{B}(\lambda)}{l^2 \lambda} + \frac{B_K A(\lambda)}{4\lambda} + \frac{B_K M^2}{l^2 \lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right] \right\} \end{aligned}$$

if $l \geq 2C_\eta B_K \mathcal{N}(\lambda) \lambda$, $\lambda \leq \|T\|_{\mathcal{L}(Y; \mathcal{Y})}$ *and* $N \geq (1 + \sqrt{\log(l) + \delta})^2 2^{-\frac{h+\delta}{2}} B_K (B_K)^{\frac{1}{h}} L^{\frac{2}{h}} \lambda^{\frac{2}{h}}$.

Below we specialize our excess risk bound for a general prior class, which captures the difficulty of the regression problem as defined in Caponnetto and De Vito (2007). This $\mathcal{P}(b, c)$ class is described by two parameters b and c : larger b means faster decay of the eigenvalues of the covariance operator T [in Eq. (17)], hence smaller effective input dimension; larger c corresponds to a smoother regression function. Formally:

Definition of the $\mathcal{P}(b, c)$ class: Let us fix the positive constants R, α, β . Then given $1 < b, c \in (1, 2]$, the $\mathcal{P}(b, c)$ class is the set of probability distributions ρ on $Z = X \times Y$ such that

1. a range space assumption is satisfied: $\exists g \in \mathcal{H}$ s.t. $f_\rho = T^{\frac{c-1}{2}} g$ with $\|g\|_{\mathcal{H}}^2 \leq R$,
2. in the spectral decomposition of $T = \sum_{n=1}^{\infty} \lambda_n \langle \cdot, e_n \rangle_{\mathcal{H}} \langle \cdot, e_n \rangle_{\mathcal{H}}$, where $(e_n)_{n=1}^{\infty}$ is a basis of $\text{Ker}(T)^{\perp}$, the eigenvalues of T satisfy $\alpha \leq n^b \lambda_n \leq \beta$ ($\forall n \geq 1$).

Remark 3 We make few remarks about the $\mathcal{P}(b, c)$ class:

- Range space assumption on f_ρ : The smoothness of f_ρ is expressed as a range space assumption, which is slightly different from the standard smoothness conditions appearing in non-parametric function estimation. By the spectral decomposition of T given above $[\lambda_1 \geq \lambda_2 \geq \dots > 0, \lim_{n \rightarrow \infty} \lambda_n = 0]$, $T^r u = \sum_{n=1}^{\infty} (\lambda_n)^r \langle u, e_n \rangle_{\mathcal{H}} e_n$ ($r = \frac{c-1}{2} \geq 0, u \in \mathcal{H}$) and

$$\text{Im}(T^r) = \left\{ \sum_{n=1}^{\infty} c_n e_n : \sum_{n=1}^{\infty} c_n^2 \lambda_n^{2r} < \infty \right\}. \quad (18)$$

Specifically, in the limit as $r \rightarrow 0$, we obtain $f_\rho \in \text{Im}(T^0) = \text{Im}(I) = \mathcal{H}$ (no constraint); larger values of r give rise to faster decay of the $(c_n)_{n=1}^{\infty}$ Fourier coefficients. This is the concrete meaning of $f_\rho \in \text{Im}(T^r)$.

- Spectral decay condition: We can provide a simple illustration of when the spectral decay conditions hold, in the event that the distributions are normal with means m_i and identical variance ($x_i = N(m_i, \sigma^2 I)$). When Gaussian kernels (k) are used with linear K , then $K(\mu_{x_i}, \mu_{x_j}) = e^{-c \|m_i - m_j\|^2}$ (Muandet et al., 2012, Table 1, line 2) (Gaussian, with arguments equal to the difference in means). Thus, this Gram matrix will correspond to the Gram matrix using a Gaussian kernel between points m_i . The spectral decay of the Gram matrix will correspond to that of the Gaussian kernel, with points drawn from the meta-distribution over the m_i . Thus, the source conditions are analysed in the same manner as for Gaussian Gram matrices: see e.g. Steinwart and Christmann (2008) for a discussion of these spectral decay properties.

In the $\mathcal{P}(b, c)$ family, the behaviour of $\mathcal{A}(\lambda)$, $\mathcal{B}(\lambda)$ and $\mathcal{N}(\lambda)$ is known: $\mathcal{A}(\lambda) \leq R\lambda^c$, $\mathcal{B}(\lambda) \leq R\lambda^{c-1}$, $\mathcal{N}(\lambda) \leq \beta \frac{b}{b-1} \lambda^{-\frac{1}{b}}$. Specializing Theorem 2 and retaining its assumptions, we get:

Theorem 4 (Finite-sample excess risk bound for $\rho \in \mathcal{P}(b, c)$)

Suppose the conditions in Theorem 2 hold. Let $\rho \in \mathcal{P}(b, c)$, where $1 < b$ and $c \in (1, 2]$.

Then

$$\begin{aligned} \mathcal{E}(f_{\frac{\lambda}{2}}, f_\rho) &\leq 5 \left\{ \frac{4L^2 (1 + \sqrt{\log(l) + \delta})^{2h} (2B_k)^h}{\lambda N^h} C^2 + 4B_K \times \right. \\ &\quad \times \left. C_\eta \left\{ \frac{2}{\lambda} \left[\frac{M^2 B_K}{l^2 \lambda} + \frac{\Sigma^2 \beta b}{(b-1)\lambda^{\frac{1}{b}}} \right] + \frac{3}{4\lambda^2} \left[\frac{4B_K^2 R \lambda^{c-1}}{l^2} + \frac{B_K R \lambda^c}{l} \right] + R \lambda^{c-1} + \|f_\rho\|_{5\epsilon}^2 \right\} \right. \\ &\quad \left. + R \lambda^c + C_\eta \left[\frac{B_K^2 R \lambda^{c-2}}{l^2} + \frac{B_K R \lambda^{c-1}}{4l} + \frac{B_K M^2}{l^2 \lambda} + \frac{\Sigma^2 \beta b}{(b-1)\lambda^{\frac{1}{b}}} \right] \right\}. \end{aligned}$$

Discarding the constants in Theorem 4, the study of convergence of the excess risk $\mathcal{E}(f_{\frac{\lambda}{2}}, f_\rho)$ to 0 boils down to finding N and λ (as a function of l) where $N \rightarrow \infty$, $\lambda \rightarrow 0$ and

$$r(l, N, \lambda) = \frac{\log^h(l)}{N^h \lambda} \left(\frac{1}{\lambda^2 l^2} + 1 + \frac{1}{\lambda^{1+\frac{1}{b}}} \right) + \lambda^c + \frac{1}{l^2 \lambda} + \frac{1}{\lambda^{\frac{b+1}{b}}} \rightarrow 0, \text{ s.t. } l \lambda^{\frac{b+1}{b}} \geq 1, \frac{\log(l)}{\lambda^{\frac{b}{b-1}}} \leq N \quad (19)$$

as $l \rightarrow \infty$. Let us choose $N = l^{\frac{b}{b-1}} \log(l)$; in this case Eq. (19) reduces to

$$r(l, \lambda) = \frac{1}{l^{2+a} \lambda^3} + \frac{1}{l^a \lambda} + \frac{1}{l^{a+1} \lambda^{2+\frac{1}{b}}} + \lambda^c + \frac{1}{l^2 \lambda} + \frac{1}{\lambda^{\frac{b+1}{b}}} \rightarrow 0, \text{ s.t. } l \lambda^{\frac{b+1}{b}} \geq 1, l^a \lambda^2 \geq 1. \quad (20)$$

One can assume that $a > 0$, otherwise $r(l, \lambda) \rightarrow 0$ fails to hold; in other words, N should grow faster than $\log(l)$. Matching the ‘bias’ (λ^c) and ‘variance’ (other terms in $r(l, \lambda)$) to choose λ , and guaranteeing that the matched terms dominate and the constraints in Eq. (20) hold, one gets the following simple description for the computational-statistical efficiency trade-off:⁸

Theorem 5 (Computational-statistical efficiency trade-off; well-specified case; $\rho \in \mathcal{P}(b, c)$) Suppose the conditions in Theorem 2 hold. Let $\rho \in \mathcal{P}(b, c)$ and $N = l^{\frac{b}{b-1}} \log(l)$, where $0 < a, 1 < b, c \in (1, 2]$. If

- $a \leq \frac{b(c+1)}{bc+1}$, then $\mathcal{E}(f_{\frac{\lambda}{2}}, f_\rho) = \mathcal{O}_p\left(l^{-\frac{ac}{c+1}}\right)$ with $\lambda = l^{-\frac{a}{c+1}}$,
- $a \geq \frac{b(c+1)}{bc+1}$ then $\mathcal{E}(f_{\frac{\lambda}{2}}, f_\rho) = \mathcal{O}_p\left(l^{-\frac{bc}{bc+1}}\right)$ with $\lambda = l^{-\frac{b}{bc+1}}$.

Remark 6 Theorem 5 formulates an exact computational-statistical efficiency trade-off for the choice of the bag size (N) as a function of the number of distributions (l) and problem difficulty (b, c).

- a -dependence: A smaller bag size (smaller a ; $N = l^{\frac{b}{b-1}} \log(l)$) means computational savings, but reduced statistical efficiency. It is not worth increasing a above $\frac{b(c+1)}{bc+1}$ since from that point the rate becomes $r(l) = l^{-\frac{bc}{bc+1}}$; remarkably, this rate is minimax in the one-stage sampled setup (Caponnetto and De Vito, 2007). The sensible choice $a = \frac{b(c+1)}{bc+1} < 2$ means that the one-stage sampled minimax rate can be achieved in the two-stage sampled setting with bag size N sub-quadratic in l .

⁸ The derivations are available in the supplement of <http://arxiv.org/pdf/1411.2066>.

- h -dependence: *In accord with our ‘smoothness’ assumptions it is rewarding to use smoother K kernels (larger $h \in (0, 1]$) since this reduces the bag size $[N = \lfloor h \log(l) \rfloor]$.*
- c -dependence: *The strictly decreasing property of $c \mapsto \frac{h(c+1)}{c+1}$ implies that for ‘smoother’ problems (larger c) fewer samples (N) are sufficient.*

Below we elaborate on the sketched high-level idea and prove Theorem 2.

Proof of Theorem 2 (detailed derivations of each step can be found in Section 7.1)

1. **Decomposition of the excess risk:** We have the following upper bound for the excess risk

$$\mathcal{E}(f_{\mathcal{X}}^{\lambda}, f_D) = \mathcal{R}[f_{\mathcal{X}}^{\lambda}] - \mathcal{R}[f_D] \leq 5[S_{-1} + S_0 + \mathcal{A}(\lambda) + S_1 + S_2]. \quad (21)$$

2. **It is sufficient to upper bound S_{-1} and S_0 :** Caponnetto and De Vito (2007) have shown that for $\forall \eta > 0$ if $l \geq 2C_{\eta} B_K \mathcal{N}(\lambda)/\lambda$, $\lambda \leq \|T\|_{\mathcal{L}(\mathcal{G})}$, then $\mathbb{P}(\Theta(\lambda, \mathbf{z}) \leq 1/2) \geq 1 - \eta/3$, where

$$\Theta(\lambda, \mathbf{z}) = \|(T - T_{\mathcal{X}})(T + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})}, \quad (22)$$

using which upper bounds on S_1 and S_2 that hold with probability $1 - \eta$ are obtained. It is known that $\mathcal{A}(\lambda) \leq R\lambda^c$.

3. **Probabilistic bounds on $\|g_{\mathcal{X}} - g_{\mathcal{X}}\|_{\mathcal{G}}^2$:** $\|T_{\mathbf{x}} - T_{\mathcal{X}}\|_{\mathcal{L}(\mathcal{G})}^2$, $\|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})}^2$, $\|f_{\mathcal{X}}^{\lambda}\|_{\mathcal{G}}^2$: One can bound S_{-1} and S_0 as

$$S_{-1} \leq \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})}^2 \|g_{\mathcal{X}} - g_{\mathcal{X}}\|_{\mathcal{G}}^2$$

and

$$S_0 \leq \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})}^2 \|T_{\mathbf{x}} - T_{\mathcal{X}}\|_{\mathcal{L}(\mathcal{G})}^2 \|f_{\mathcal{X}}^{\lambda}\|_{\mathcal{G}}^2$$

For the terms on the r.h.s., we derive upper bounds [for the definition of α , see Eq. (24)]

$$\|g_{\mathcal{X}} - g_{\mathcal{X}}\|_{\mathcal{G}}^2 \leq L^2 C^2 \frac{(1 + \sqrt{\alpha})^{2h} (2B_K)^h}{N^h}, \quad \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})} \leq \frac{2}{\sqrt{\lambda}},$$

$$\|T_{\mathbf{x}} - T_{\mathcal{X}}\|_{\mathcal{L}(\mathcal{G})}^2 \leq \frac{(1 + \sqrt{\alpha})^{2h} (2B_K)^h B_K L^2}{N^h},$$

and

$$\|f_{\mathcal{X}}^{\lambda}\|_{\mathcal{G}}^2 \leq 6 \left(\frac{16}{\lambda} \log^2 \left(\frac{6}{\eta} \right) \left[\frac{M^2 B_K}{72\lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right] + \frac{4}{\lambda^2} \log^2 \left(\frac{6}{\eta} \right) \left[\frac{4B_K^2 \mathcal{B}(\lambda)}{l^2} + \frac{B_K \mathcal{A}(\lambda)}{l} \right] + \mathcal{B}(\lambda) + \|f_D\|_{\mathcal{G}}^2 \right). \quad (23)$$

The bounds hold under the following conditions:

- $\|g_{\mathcal{X}} - g_{\mathcal{X}}\|_{\mathcal{G}}^2$ (see Section 7.1.1): if the empirical mean embeddings are close to their population counterparts, i.e.,

$$\|\mu_{x_i} - \mu_{\mathcal{X}}\|_H \leq \frac{(1 + \sqrt{\alpha})\sqrt{2}B_K}{\sqrt{N}}, \quad (\forall i = 1, \dots, l). \quad (24)$$

This event has probability $1 - le^{-\alpha}$ over all $i = 1, \dots, l$ samples; see (Altmun and Smola, 2006) and (Szabó et al., 2015, Section A.1.10).

- $\|T_{\mathbf{x}} - T_{\mathcal{X}}\|_{\mathcal{L}(\mathcal{G})}^2$ (see Section 7.1.2): (24) is assumed.
- $\|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})}^2$ (Szabó et al., 2015, Section A.1.11): (24), $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$, and

$$\frac{(1 + \sqrt{\alpha})^2 2^{\frac{h+6}{h}} B_K (B_K)^{\frac{1}{h}} L^{\frac{6}{h}}}{\lambda^{\frac{6}{h}}} \leq N. \quad (25)$$

- $\|f_{\mathcal{X}}^{\lambda}\|_{\mathcal{G}}^2$: The bound is guaranteed to hold under the conditions of the bounds of S_1 and S_2 .⁸

4. **Union bound:** By applying an $\alpha = \log(l) + \delta$ reparameterization, and combining the received upper bounds with Caponnetto and De Vito (2007)’s results for S_1 and S_2 , Theorem 2 follows (Section 7.1.3) with a union bound.

Finally, we note that existing results/ideas were used at two points to simplify our analysis: bounding S_1 , S_2 , $\Theta(\lambda, \mathbf{z})$, $\|f_{\mathcal{X}}^{\lambda}\|_{\mathcal{G}}^2$ (Caponnetto and De Vito, 2007) and $\|\mu_{x_i} - \mu_{\mathcal{X}}\|_H$ (Altmun and Smola, 2006).⁹

4.2 Results for the Misspecified Case

In this section, we focus on the misspecified case ($f_D \in L_{\rho_{\mathcal{X}}}^2 \setminus \mathcal{F}$) and present our second main result, which was inspired by the proof technique of Stripunburd et al. (2014, Theorem 12). We derive a high probability upper bound for $\mathcal{E}(f_{\mathcal{X}}^{\lambda}, f_D)$, i.e., the excess risk of the MERR method (Theorem 7) which gives rise to consistency results (3rd bullet of Remark 8) and precise computational-statistical efficiency trade-off (Theorem 9). Theorem 7 consists of two finite-sample bounds:

1. The first, more general bound [Eq. (27)] will be used to show consistency in the misspecified case (see the 3rd bullet of Remark 8), in other words that $\mathcal{E}(f_{\mathcal{X}}^{\lambda}, f_D)$ can be driven to its smallest possible value determined by the ‘richness’ of \mathcal{F} :

$$D_{\mathcal{X}}^{\lambda} := \inf_{q \in \mathcal{F}} \|f_D - S_K^* q\|_{\rho}^2. \quad (26)$$

The value of $D_{\mathcal{X}}$ equals the approximation error of f_D by a function from \mathcal{F} . Specifically, if $\mathcal{F} = \{S_K^* q : q \in \mathcal{F}\} \subseteq L_{\rho_{\mathcal{X}}}^2$ is dense in $L_{\rho_{\mathcal{X}}}^2$, then $D_{\mathcal{X}} = 0$.

⁸ We also corrected some constants in the previous works (Altmun and Smola, 2006; Caponnetto and De Vito, 2007).

2. The second, specialized result [Eq. (28)] under additional smoothness assumptions on f_ρ will give rise to a precise computational-statistical efficiency trade-off in terms of the problem difficulty (s) and sample numbers (l, N); this result can be seen as the misspecified analogue of Theorem 5.

After stating our results, the main ideas of the proof follow; further technical details are available in Section 7.2. Our main theorem for bounding the excess risk is as follows:

Theorem 7 (Finite-sample excess risk bounds; misspecified case) Let $l \in \mathbb{Z}^+$, $N \in \mathbb{Z}^+$, $0 < \lambda, 0 < \eta < 1$, $0 < \delta$ and $C_\eta = \log\left(\frac{6}{\eta}\right)$. Assume that $\left(\frac{12B_K C_\eta}{\lambda}\right)^2 \leq l$ and $(1 + \sqrt{\log(l) + \delta})^2 2^{\frac{h+\delta}{\eta}} B_k (B_K)^{\frac{1}{2}} L^{\frac{2}{\eta}} / \lambda^{\frac{2}{\eta}} \leq N$.

1. Then for arbitrary $q \in \mathcal{H}$ with probability at least $1 - \eta - e^{-\delta}$

$$\begin{aligned} \sqrt{\mathcal{E}(f_{\frac{1}{2}}^\lambda, f_\rho)} &\leq \frac{2LC \left(1 + \sqrt{\log(l) + \delta}\right)^h (2B_k)^{\frac{1}{2}}}{\sqrt{\lambda N^{\frac{h}{2}}}} \left(1 + \frac{2\sqrt{B_K}}{\sqrt{\lambda}}\right) + \\ &\frac{2C_\eta}{\sqrt{\lambda}} \left\{ \left(\frac{2C\sqrt{B_K}}{l} + \frac{C\sqrt{B_K}}{\sqrt{l}}\right) + \left(\frac{2B_K}{l} + \frac{\sigma}{\sqrt{l}}\right) \frac{1}{\lambda\sqrt{\lambda}} \|f_\rho\|_\rho D_a(\lambda, q) \right\} + D_a(\lambda, q), \end{aligned} \quad (27)$$

where $D_a(\lambda, q) = \|f_\rho - S_K^* q\|_\rho + \max(1, \|\tilde{T}\|_{\mathcal{L}(L^2(\mathcal{H}))}) \lambda^{\frac{1}{2}} \|q\|_{\mathcal{H}}$.

2. In addition, suppose $f_\rho \in \text{Im}(\tilde{T}^s)$ for some $s > 0$, where \tilde{T} is defined in Eq. (6). Then with probability at least $1 - \eta - e^{-\delta}$, we have

$$\begin{aligned} \sqrt{\mathcal{E}(f_{\frac{1}{2}}^\lambda, f_\rho)} &\leq \frac{2LC \left(1 + \sqrt{\log(l) + \delta}\right)^h (2B_k)^{\frac{1}{2}}}{\sqrt{\lambda N^{\frac{h}{2}}}} \left(1 + \frac{2\sqrt{B_K}}{\sqrt{\lambda}}\right) + \\ &\frac{2C_\eta}{\sqrt{\lambda}} \left\{ \left(\frac{2C\sqrt{B_K}}{l} + \frac{C\sqrt{B_K}}{\sqrt{l}}\right) + \left(\frac{2B_K}{l} + \frac{\sigma}{\sqrt{l}}\right) \frac{1}{\lambda} \times \right. \\ &\left. \sqrt{\max\left(1, \|\tilde{T}\|_{\mathcal{L}(L^2(\mathcal{H}))}^s\right) \lambda} \|\tilde{T}^{-s} f_\rho\|_\rho D_b(\lambda, s) \right\} + D_b(\lambda, s), \end{aligned} \quad (28)$$

where $D_b(\lambda, s) = \max(1, \|\tilde{T}\|_{\mathcal{L}(L^2(\mathcal{H}))}^{s-1}) \lambda^{\min(1,s)} \|\tilde{T}^{-s} f_\rho\|_\rho$.

Remark 8 We give a short insight into the assumptions of Theorem 7, followed by consequences of the theorem.

- Range space assumption on f_ρ : The range space assumption for the compact, positive, self-adjoint operator, $\tilde{T} = \tilde{T}(K) : L_{\rho_X}^2 \rightarrow L_{\rho_X}^2$ in the 2nd part of Theorem 7 can be interpreted similarly to that on T ; see Eq. (18). One can also prove alternative descriptions for $\text{Im}(\tilde{T}^s)$ in terms of interpolation spaces (Steinwart and Scovel, 2012, Theorem 4.6, page 387), or the decay of the 2-approximation error function, $A_2(\lambda) = \inf_{f \in \mathcal{H}(K)} (\lambda \|f\|_{\mathcal{H}(K)}^2 + \mathcal{R}[f] - \mathcal{R}[f_\rho])$ (Smale and Zhou, 2003; Steinwart et al., 2009).

- $\sqrt{\mathcal{E}(f_{\frac{1}{2}}^\lambda, f_\rho)}$: Notice that in the bounds [(27), (28)], instead of the excess risk, its square root appears; this has technical reasons, as it is easier to have the $D_a(\lambda, q)$ quantity (without multiplicative constants) appear on the r.h.s. of Eq. (27) with this form.

- Consistency in the misspecified case: The consequence of Theorem 7(1) is as follows. Discarding the constants in Eq. (27), we obtain the upper bound (notice that the constant multiplier of $\|f_\rho - S_K^* q\|_\rho$ in the last term was one):

$$\sqrt{r(l, N, \lambda, q)} = \frac{\log^{\frac{h}{2}}(l)}{N^{\frac{h}{2}} \lambda} + \frac{1}{\sqrt{\lambda}} + \frac{\sqrt{\|f_\rho - S_K^* q\|_\rho + \sqrt{\lambda} \|q\|_{\mathcal{H}}}}{\lambda \sqrt{l}} + \|f_\rho - S_K^* q\|_\rho + \sqrt{\lambda} \|q\|_{\mathcal{H}}.$$

By choosing $N = l^{1/h} \log l$, $\sqrt{r(l, \lambda)}$ is bounded by

$$\inf_{q \in \mathcal{H}} \left\{ \|f_\rho - S_K^* q\|_\rho + \frac{\sqrt{\|f_\rho - S_K^* q\|_\rho + \sqrt{\lambda} \|q\|_{\mathcal{H}}}}{\lambda \sqrt{l}} + \sqrt{\lambda} \|q\|_{\mathcal{H}} \right\} + \mathcal{O}_p\left(\frac{1}{\sqrt{\lambda l}}\right).$$

Our goal is to investigate the behavior of the bound as $l \rightarrow \infty$, $\lambda \rightarrow 0$ and $\lambda \sqrt{l} \rightarrow \infty$. Define $K(\alpha, \beta, \gamma) := \inf_{q \in \mathcal{H}} \left\{ \|f_\rho - S_K^* q\|_\rho + \alpha \sqrt{\|f_\rho - S_K^* q\|_\rho + \beta \sqrt{\|q\|_{\mathcal{H}} + \gamma} \|q\|_{\mathcal{H}}} \right\}$. $K(\alpha, \beta, \gamma)$ is the pointwise infimum of affine functions, therefore it is upper semi-continuous and concave on $\mathbb{R}_{>0}^3$ (Aiprantis and Border, 2006, Lemmas 2.41 and 5.40); it is continuous on $\times_{s=1}^3 \mathbb{R}_{>0}$ (Rockafellar and Wets, 2008, Theorem 2.35). Moreover, by applying (Rockafellar and Wets, 2008, Corollary 2.37) it extends continuously to $\times_{s=1}^3 \mathbb{R}_{\geq 0}$; specifically it is continuous at $(\alpha, \beta, \gamma) = \mathbf{0}$. In other words, as $l \rightarrow \infty$, $\lambda \rightarrow 0$ and $\lambda \sqrt{l} \rightarrow \infty$, $K\left(\frac{1}{\lambda l}, \frac{1}{\lambda l \sqrt{l}}, \sqrt{\lambda}\right) \rightarrow D_{\mathcal{H}}$ and we get consistency in the misspecified case,¹⁰

$$\sqrt{r(N, l, \lambda)} \rightarrow D_{\mathcal{H}}.$$

Discarding the constants in Eq. (28) we get¹⁰

$$\sqrt{r(l, N, \lambda)} = \frac{\log^{\frac{h}{2}}(l)}{N^{\frac{h}{2}} \lambda} + \frac{1}{\sqrt{l\lambda}} + \frac{\sqrt{\lambda^{\min(1,s)}}}{\lambda \sqrt{l}} + \lambda^{\min(1,s)}, \text{ subject to } \frac{1}{\lambda^2} \leq l. \quad (29)$$

Our goal is to drive $r(l, N, \lambda)$ to zero with a suitable choice of the (l, N, λ) triplet under the stronger range space assumption. Since in Eq. (29) $\min(1, s)$ appears, one can assume without loss of generality that $s \in (0, 1]$; consequently $1 - \frac{s}{2} \in [\frac{1}{2}, 1)$ and $\frac{1}{l^{\frac{1}{2} - \frac{s}{2}}} \leq \frac{1}{\lambda^{1 - \frac{s}{2}}}$. Let us choose $N = l^{2s/h} \log(l)$; in this case using the previous dominance note, Eq. (29) reduces to the study of

$$\sqrt{r(l, \lambda)} = \frac{1}{l^{\alpha\lambda}} + \frac{1}{\lambda^{1 - \frac{s}{2} l^{\frac{1}{2}}}} + \lambda^s \rightarrow 0, \text{ s.t. } l\lambda^2 \geq 1. \quad (30)$$

One can assume that $\alpha > 0$, otherwise $r(l, \lambda) \rightarrow 0$ fails to hold: in other words, N should grow faster than $\log(l)$. Matching the ‘bias’ (λ^s) and ‘variance’ (other) terms in $r(l, \lambda)$ to choose λ , guaranteeing that the matched terms dominate and the constraint in Eq. (30) hold, one can arrive at the following computational-statistical efficiency trade-off.⁸

¹⁰ We have discarded the $\log(l)/\lambda^{\frac{s}{2}} \leq N$ constraint implied by the convergence of the first term in \sqrt{r} .

Theorem 9 (Computational-statistical efficiency trade-off; misspecified case, $f_\rho \in \text{Im}(T^s)$) Suppose that $f_\rho \in \text{Im}(T^s)$ and $N = l^{\frac{2a}{s}} \log(l)$, where $s \in (0, 1]$, $a > 0$. If

- $a \leq \frac{s+1}{s+2}$, then $\mathcal{E}(f_\frac{\lambda}{2}, f_\rho) = \mathcal{O}_p\left(l^{-\frac{2as}{s+1}}\right)$ with $\lambda = l^{-\frac{a}{s+1}}$,
- $a \geq \frac{s+1}{s+2}$, then $\mathcal{E}(f_\frac{\lambda}{2}, f_\rho) = \mathcal{O}_p\left(l^{-\frac{2a}{s+2}}\right)$ with $\lambda = l^{-\frac{1}{s+2}}$.

Remark 10 Theorem 9 provides a complete computational-statistical efficiency trade-off description for the choice of the bag size (N) as a number of the distributions (1).

- *a-dependence:* A smaller value of ‘ a ’ (smaller bags $N = \lceil 2a/h \log(l) \rceil$) leads to a computational advantage, but one loses in statistical efficiency. As ‘ a ’ reaches $\frac{s+1}{s+2}$, the rate becomes $r(l) = l^{-\frac{2a}{s+2}}$ and one does not gain from further increasing the value of a . The sensible choice of $a = \frac{s+1}{s+2} \leq \frac{2}{3}$ means that N can again be sub-quadratic ($2a < \frac{4}{3} < 2$) in l .
 - *h-dependence:* By using smoother K kernels (larger $h \in (0, 1]$) one can reduce the size of the bags: $h \mapsto 2a/h$ is decreasing in h . This is compatible with our smoothness requirement on f_ρ .
 - *s-dependence:* ‘Easier’ tasks (larger s) give rise to faster convergence. Indeed, in the $r(l) = l^{-\frac{2a}{s+2}}$ rate the $s \mapsto \frac{2a}{s+2}$ exponent is strictly increasing function of the problem difficulty (s). For example, for extremely non-smooth regression problems ($s \approx 0$) the convergence can be arbitrary slow ($\lim_{s \rightarrow 0} \frac{2a}{s+2} = 0$). In the smooth case ($s = 1$) $\lim_{s \rightarrow 1} \frac{2a}{s+2} = \frac{2}{3}$ and one can achieve the $r(l) = l^{-\frac{2}{3}}$ rate.
 - We may compare our $r(l) = l^{-\frac{2a}{s+2}}$ result with the $r_\rho(l) = l^{-\frac{2a}{2s+1}}$ (one-stage sampled) rate (Steinwart et al., 2009, $\beta/2 := s, q := 2, p := 1$ in Corollary 6), which was shown to be asymptotically optimal on $Y = \mathbb{R}$ for continuous k on compact metric \mathcal{X} . Steinwart et al.’s result is more general in terms of q ($\|f\|_{\mathcal{X}}^q$ based regularization) and p ($\|f\|_\infty \leq C \|f\|_{\mathcal{X}}^p \|f\|_\rho^{1-p}$, $\forall f \in \mathcal{H}$; in our case $p = 1$), although it imposes an additional eigenvalue constraint [(Steinwart et al., 2009, Eq. (6))] as well as $f_\rho \in \text{Im}(T^s)$. Moreover, one can observe that $r_\rho(l) \leq r(l)$ with a small gap, and that for $s \rightarrow 0$ and $s = 1$, $r_\rho(l) = r(l)$; see Fig. 1. We further remind the reader that our MERR analysis also holds for separable Hilbert output spaces Y , separable topological domains \mathcal{X} enriched with a bounded, continuous kernel k , and that we handle the two-stage sampled setting.
- The main steps of the proof of Theorem 7 are as follows:

Proof of Theorem 7 (the details of the derivation are available in Section 7.2) Steps 1-7 will be identical in both proofs,¹¹ and we present them jointly.

1. **Decomposition of the excess risk:** By the triangle inequality, we have

$$\sqrt{\mathcal{E}(f_\frac{\lambda}{2}, f_\rho)} = \|S_K^* f_\frac{\lambda}{2} - f_\rho\|_\rho \leq \|S_K^* (f_\frac{\lambda}{2} - f_\rho)\|_\rho + \|S_K^* f_\rho - f_\rho\|_\rho. \quad (31)$$

11. Importantly, with a slight modification of the more general, first part of Theorem 7, one can get the specialized second setting of the theorem (see Step 8).

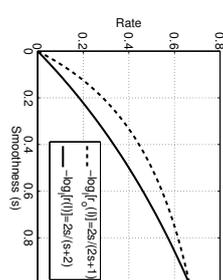

Figure 1: Comparison of the $r_\rho(l) = l^{-\frac{2a}{2s+1}}$ and $r(l) = l^{-\frac{2a}{s}}$ rates as function of the problem difficulty/smoothness (s).

2. **Bound on $\|S_K^*(f_\frac{\lambda}{2} - f_\rho)\|_\rho$:** Using¹² the fact that

$$\|S_K^* h\|_\rho^2 = \|\sqrt{T}h\|_{\mathcal{H}}^2 \quad (\forall h \in \mathcal{H}), \quad (32)$$

and the definitions of S_{-1} and S_0 [see Eqs. (15)-(16)], we obtain

$$\|S_K^*(f_\frac{\lambda}{2} - f_\rho)\|_\rho = \|\sqrt{T}(f_\frac{\lambda}{2} - f_\rho)\|_{\mathcal{H}} \leq \sqrt{S_{-1}} + \sqrt{S_0}, \quad (33)$$

through an application of triangle inequality. One can derive without a $\mathcal{P}(b, c)$ prior assumption (Section 7.2.1) the upper bound¹³

$$\sqrt{S_{-1}} + \sqrt{S_0} \leq \frac{2lC(1 + \sqrt{\alpha})^h (2B_k)^{\frac{h}{2}}}{\sqrt{\lambda} N^{\frac{h}{2}}} \left[1 + \frac{2\sqrt{BK}}{\sqrt{\lambda}} \right]$$

for the r.h.s. of Eq. (33) under the conditions that $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ (which holds with probability $1 - \eta$ if $[2BK \log(2/\eta)]/\lambda^2 \leq l$), and that Eqs. (24)-(25) hold.

3. **Decomposition of $\|S_K^* f_\frac{\lambda}{2} - f_\rho\|_\rho$:** By the triangle inequality and Eq. (32), we have

$$\begin{aligned} \|S_K^* f_\frac{\lambda}{2} - f_\rho\|_\rho &= \|S_K^*(f_\frac{\lambda}{2} - f^\lambda) + S_K^* f^\lambda - f_\rho\|_\rho \leq \|S_K^*(f_\frac{\lambda}{2} - f^\lambda)\|_\rho + \|S_K^* f^\lambda - f_\rho\|_\rho \\ &= \|\sqrt{T}(f_\frac{\lambda}{2} - f^\lambda)\|_{\mathcal{H}} + \|S_K^* f^\lambda - f_\rho\|_\rho. \end{aligned} \quad (34)$$

4. **Decomposition of $\|\sqrt{T}(f_\frac{\lambda}{2} - f^\lambda)\|_{\mathcal{H}}$:** Making use of the analytical expressions for $f_\frac{\lambda}{2}^\lambda$ and f^λ [see Eq. (13) and Eq. (17)], and the operator Woodbury formula (Ding and Zhou, 2008, Theorem 2.1, page 724) we arrive at the decomposition (see Section 7.2.2)

$$\begin{aligned} \|\sqrt{T}(f_\frac{\lambda}{2} - f^\lambda)\|_{\mathcal{H}} &\leq \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{H})} \left(\|g_{\mathbf{x}} - g_\rho\|_{\mathcal{H}} + \right. \\ &\quad \left. \|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H})} \lambda^{-1} \|S_K[f_\rho - (T + \lambda I)^{-1} S_K^* S_K f_\rho]\|_{\mathcal{H}} \right), \end{aligned}$$

where $g_\rho = S_K f_\rho$. As it is known (Caporineto and De Vito, 2007, page 348) $\|\sqrt{T}T_{\mathbf{x}} + \lambda I\|_{\mathcal{L}(\mathcal{H})} \leq 1/\sqrt{\lambda}$ provided that $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$.

12. See for example de Vito et al. (2006) on page 88 with the $(T, S, A, T) := (T, T_\rho^2, S_K^*, T)$ choice.

13. See the remark at the end of Section 7.2.1.

5. **Bound on $\|g_{\mathbf{z}} - g_{\rho}\|_{\mathcal{H}^c}$:** $\|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H}^c)}$: By concentration arguments the bounds

$$\|g_{\mathbf{z}} - g_{\rho}\|_{\mathcal{H}^c} \leq \left(\frac{4C\sqrt{B_K}}{l} + \frac{2C\sqrt{B_K}}{\sqrt{l}} \right) \log\left(\frac{2}{\eta}\right), \quad \|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H}^c)} \leq \left(\frac{4B_K}{l} + \frac{4\sigma}{\sqrt{l}} \right) \log\left(\frac{2}{\eta}\right)$$

hold with probability at least $1 - \eta$, each (see Section 7.2.3, 7.2.4).

6. **Decomposition of $\|S_K[f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\mathcal{H}^c}^2$:** Exploiting the analytical formula for f^{λ} , one can construct (Section 7.2.5) the upper bound

$$\|S_K[f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\mathcal{H}^c}^2 \leq \|\tilde{T}[f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\rho} \|S_K^* f^{\lambda} - f_{\rho}\|_{\rho}.$$

7. **Bound on $\|\tilde{T}[f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\rho}$:** Using our assumptions that $f_{\rho} \in \text{Im}(\tilde{T}^s)$ ($s \geq 0$)¹⁴ and exploiting the separability of $L_{\rho_X}^2$, by Lemma 7.3.2 ($\mathcal{K} = L_{\rho_X}^2$, $f = f_{\rho}$, $M = \tilde{T}$, $a = 1$) and $\tilde{T} = S_K^* S_K$ we obtain the upper bound

$$\begin{aligned} \|\tilde{T}[f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\rho} &= \|\tilde{T}[f_{\rho} - (\tilde{T} + \lambda I)^{-1} \tilde{T} f_{\rho}]\|_{\rho} \\ &\leq \max\left(1, \|\tilde{T}\|_{\mathcal{L}(L_{\rho_X}^2)}^s\right) \lambda^{\min(1, s+1)} \|\tilde{T}^{-s} f_{\rho}\|_{\rho} = \max\left(1, \|\tilde{T}\|_{\mathcal{L}(L_{\rho_X}^2)}^s\right) \lambda \|\tilde{T}^{-s} f_{\rho}\|_{\rho}, \end{aligned}$$

where we used at the last step that $\min(1, s+1) = 1$; this follows from $s \geq 0$.

8. **Bound on $\|S_K^* f^{\lambda} - f_{\rho}\|_{\rho}$:**

(a) **No range space assumption:** One can construct (Section 7.2.6) the bound

$$\|S_K^* f^{\lambda} - f_{\rho}\|_{\rho} \leq \|f_{\rho} - S_K^* q\|_{\rho} + \max\left(1, \|\tilde{T}\|_{\mathcal{L}(\mathcal{H}^c)}\right) \lambda^{\frac{1}{2}} \|q\|_{\mathcal{H}^c},$$

which holds for arbitrary $q \in \mathcal{H}$.

(b) **Range space assumption in $L_{\rho_X}^2$:** Using the $S_K^* f^{\lambda} = (\tilde{T} + \lambda I)^{-1} \tilde{T} f_{\rho}$ identity [see Eq. (43)], and Lemma 7.3.2 ($M = \tilde{T}$, $\mathcal{K} = L_{\rho_X}^2$, $a = 0$), we get

$$\|S_K^* f^{\lambda} - f_{\rho}\|_{\rho} = \|(\tilde{T} + \lambda I)^{-1} \tilde{T} f_{\rho} - f_{\rho}\|_{\rho} \leq \max\left(1, \|\tilde{T}\|_{\mathcal{L}(L_{\rho_X}^2)}^{s-1}\right) \lambda^{\min(1, s)} \|\tilde{T}^{-s} f_{\rho}\|_{\rho}.$$

9. **Union bound:** Applying an $\alpha = \log(l) + \delta$ reparameterization, changing η to $\frac{\eta}{l}$ and combining the derived results (in case of the first statement with $s = 0$) with a union bound, Theorem 7 follows.

Remark 11 *To contrast the derivation of the well- and the misspecified cases, we note that previous results [Section 4.1, or Caponnetto and De Vito (2007)'s bound] were used at two points:*

(a) *In Step 2 by using Eq. (32) and transforming the $L_{\rho_X}^2$ error $\|S_K^*(f_{\frac{\mathbf{z}}{2}} - f^{\lambda})\|_{\rho}$ to \mathcal{H} , we could rely on our previous bounds for S_{-1} and S_0 . However, we were required to use a different concentration argument to guarantee $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ since we no longer assume the $\mathcal{P}(b, c)$ prior class.*

¹⁴. Note that we choose $s = 0$ and $s > 0$ in the first and second theorem part, respectively.

(b) *In Step 4 the first term could be bounded by Caponnetto and De Vito (2007). Its $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ condition was guaranteed by Step 2; and see Section 7.2.1.*

We note that our misspecified proof method was inspired by Sriperumbudur et al. (2014, Theorem 12), where the authors focused on the consistency of an infinite-dimensional exponential family estimator.

5. Related Work

In this section we discuss existing approaches and heuristic techniques to tackle learning problems on distributions.

Methods based on parametric assumptions: A number of methods have been proposed to compute the similarity of distributions or bags of samples. As a first approach, one could fit a parametric model to the bags, and estimate the similarity of the bags based on the obtained parameters. It is then possible to define learning algorithms on the basis of these similarities, which often take analytical form. Typical examples with explicit formulas include Gaussians, finite mixtures of Gaussians, and distributions from the exponential family (with known log-normalizer function and zero carrier measure, see Kondor and Jebara, 2003; Jebara et al., 2004; Wang et al., 2009; Nielsen and Nock, 2012). A major limitation of these methods, however, is that they apply quite simple parametric assumptions, which may not be sufficient or verifiable in practise.

Methods based on parametric assumption in a RKHS: A heuristic related to the parametric approach is to assume that the training distributions are Gaussians in a reproducing kernel Hilbert space (see for example Jebara et al., 2004; Zhou and Chellappa, 2006, and references therein). This assumption is algorithmically appealing, as many divergence measures for Gaussians can be computed in closed form using only inner products, making them straightforward to kernelize. A fundamental shortfall of kernelized Gaussian divergences is the lack of their consistency analysis in specific learning algorithms.

Kernels based techniques: A more theoretically grounded approach to learning on distributions has been to define positive definite kernels on the basis of statistical divergence measures on distributions, or by metrics on non-negative numbers; these can then be used in kernel algorithms. This category includes work on semigroup kernels (Cuturi et al., 2005), non-extensive information theoretical kernel constructions (Martins et al., 2009), and kernels based on Hilbertian metrics (Hein and Bousquet, 2005). For example, the intuition of semigroup kernels (Cuturi et al., 2005) is as follows: if two measures or sets of points overlap, then their sum is expected to be more concentrated. The value of dispersion can be measured by entropy or inverse generalized variance. In the second type of approach (Hein and Bousquet, 2005), homogeneous Hilbert metrics on the non-negative real line are used to define the similarity of probability distributions. While these techniques guarantee to provide valid kernels on certain restricted domains of measures, the performance of learning algorithms based on finite-sample estimates of these kernels remains a challenging open question. One might also plug into learning algorithms (based on similarities of distributions) consistent Rényi and Tsallis divergence estimates (Póczos et al., 2011, 2012), but these similarity indices are *not* kernels, and their consistency in specific learning tasks remains an open question.

Multi-instance learning: An alternative paradigm in learning when the inputs are “bags of objects” is to simply treat each input as a *finite set*: this leads to the multi-instance learning task (MIL, see Dietterich et al., 1997; Ray and Page, 2001; Dooly et al., 2002). In MIL one is given a set of labelled bags, and the task of the learner is to find the mapping from the bags to the labels. Many important examples fit into the MIL framework: for example, different configurations of a given molecule can be handled as a bag of shapes, images can be considered as a set of patches or regions of interest, a video can be seen as a collection of images, a document might be described as a bag of words or paragraphs, a web page can be identified by its links, a group of people on a social network can be captured by their friendship graphs, in a biological experiment a subject can be identified by his/her time series trials, or a customer might be characterized by his/her shopping records. The MIL approach has been applied in several domains: see the reviews from Babenko (2004); Zhou (2004); Foulds and Frank (2010); Amores (2013).

“Bag-of-objects” methods (MIL, classification): Despite the large number of MIL applications and the spate of heuristic solution techniques, there exist few *theoretical results* in the area (Auer, 1998; Long and Tan, 1998; Blum and Kalai, 1998; Babenko et al., 2011; Zhang et al., 2013; Sabato and Tishby, 2012) and they focus on the multi-instance *classification* (MIC) task. In particular, let us first consider the standard MIC assumption (Dietterich et al., 1997), where a bag is declared to be positive (labelled with “1”) if at least one of its instances is positive (“1”); otherwise, the bag is negative (“0”).¹⁵ In other words, if the instances $(x_{i,n})$ in the i^{th} bag $\{x_{i,1}, \dots, x_{i,N}\}$ have hidden label $L(x_{i,n}) \in \{0, 1\}$, then the observed label of the bag is $y_i = h(x_{i,1}, \dots, x_{i,N}) = \max\{L(x_{i,1}), \dots, L(x_{i,N})\} \in \{0, 1\}$. In case of the original APR (axis-aligned rectangles; Dietterich et al., 1997) hypothesis class, function L is equal to the indicator of an unknown rectangle R ($L = \mathbb{1}_R$). In other words, a bag is declared to be positive if there exists at least one instance in the bag, which belongs to R .¹⁶ The goal is to learn R with high probability given the bags $(\{x_{i,1}, \dots, x_{i,N}\}$ -s) and their labels $(y_i$ -s). Long and Tan (1998) proved the PAC learnability (probably approximately correct; Valiant, 1984) of the APR hypothesis class, if all instances in each bag are i.i.d. and follow the same product distribution over the instance coordinates. On the other hand, for arbitrary distributions over bags, when the instances within a bag might be statistically dependent, APR learning under MIC is NP-hard (Auer, 1998); the same authors also showed that the product property (Long and Tan, 1998) on the coordinates is not required to obtain PAC results. Blum and Kalai (1998) extended PAC learnability of APRs to hypothesis classes learnable from one-sided classification noise. In contrast to the previous approaches (Long and Tan, 1998; Auer, 1998; Blum and Kalai, 1998), Babenko et al. (2011) modelled the bags as low-dimensional manifolds, and proved PAC bounds. By relaxing the standard MIC assumption, Sabato and Tishby (2012) showed PAC-learnability for general MIC hypothesis classes with extended “max” functions. Zhang et al. (2013) derived high-probability generalization bounds in the MIC setting, when local and global representations are combined. Our work falls outside this setting since the label and bag generation mechanisms we consider are different: we do not assume an exact form of the

labelling mechanism (function L and \max in h). Rather, the labelling is presumed to be stochastically determined by the underlying true distribution, not deterministically by the instance realizations in the bags (these are presumed i.i.d., and may be bag-specific).

“Bag-of-objects” methods (MIL, not classification): Beyond classification, there exist several *heuristics*—without consistency guarantees—for many other multi-instance problems in the literature, including regression (Ray and Page, 2001; Dooly et al., 2002; Zhou et al., 2009; Kwok and Cheung, 2007), clustering (Zhang and Zhou, 2009; Zhang et al., 2009, 2011; Chen and Wu, 2012), ranking (Bergeron et al., 2008; Hu et al., 2008; Bergeron et al., 2012), outlier detection (Wu et al., 2010), transfer learning (Raykar et al., 2008; Zhang and Si, 2009), and feature selection, -weighting and -extraction (also called dimensionality reduction, low-dimensional embedding, manifold learning; see Raykar et al., 2008; Pring et al., 2010; Sun et al., 2010; Carter et al., 2011; Zafra et al., 2013; Chai et al., 2014a,b, and references therein).

Approaches using set metrics: Adapting the bag viewpoint of MIL, one can come up with set metric based learning algorithms.¹⁷ Probably one of the most well-known set metrics is the Hausdorff metric (Edgar, 1995), which is defined for non-empty compact sets of metric spaces, specifically for sets containing finitely many points. There also exist other (semi)metric constructions on points sets (Eiter and Mannila, 1997; Ramon and Brynnoegle, 2001). Unfortunately, the classical Hausdorff metric is highly sensitive to outliers, seriously limiting its practical applicability. In order to mitigate this deficiency, several variants of the Hausdorff metric have been designed in the MIL literature, such as the maximal-, the minimal- and the ranked Hausdorff metrics, with successful applications in MIC (Wang and Zuecker, 2000) and multi-instance outlier detection (Wu et al., 2010); and the average Hausdorff metric (Zhang and Zhou, 2009) and contextual Hausdorff dissimilarity (Chen and Wu, 2012), which have been found useful in multi-instance clustering. Unfortunately, these methods lack any theoretical guarantee when applied in specific learning problems.

Functional data analysis techniques: Finally, the distribution regression task might also be interpreted as a functional data analysis problem (Ramsay and Silverman, 2002, 2005; Müller, 2005), by considering the probability measures π_i as functions. This is a highly non-standard setup, however, since these functions (π_i) are defined on σ -algebras and are non-negative, σ -additive.

6. Conclusion

We have established a learning theory of distribution regression, where the inputs are probability measures on separable, topological domains endowed with reproducing kernels, and the outputs are elements of a separable Hilbert space. We studied a ridge regression scheme defined on embeddings of the input distributions to a reproducing kernel Hilbert space, which has a simple analytical solution, as well as theoretically sound, efficient methods for approximation (Zhang et al., 2015; Richtárik and Takáč, 2016; Alaoui and Mahoney, 2015; Yang et al., 2016; Rudi et al., 2015). We derived explicit bounds on the excess risk as a function of the number of samples and problem difficulty. We tackled both the well-

15. The motivation of this assumption comes from drug discovery: if a molecule has at least one well-binding configuration, then it is considered to bind well.

16. In terms of drug binding prediction, this means that a molecule binds to a target iff at least one of its configurations falls within a fixed, but unknown rectangle.

17. Often these “metrics” are only semi-metrics, as they do not satisfy the triangle inequality.

specified case (when the regression function belongs to the assumed RKHS modelling class), and the more general misspecified setup. As a special case of our results, we proved the consistency of regression for set kernels (Haussler, 1999; Gärtner et al., 2002), which was a 17-year-old open problem, and for a recent kernel family (Christmann and Steinwart, 2010), which we have expanded upon (Table 1). We proved an exact computational-statistical efficiency trade-off for the MERR estimator: in the well-specified setting, we showed how to choose the bag size in the two-stage sampled setup to match the one-stage sampled min-max optimal rate (Caponnetto and De Vito, 2007); and in the misspecified setting, our rates approximate closely an asymptotically optimal estimator imposing stricter eigenvalue decay conditions (Steinwart et al., 2009). Several exciting open questions remain, including whether improved/optimal rates can be derived in the misspecified case, whether we can obtain consistency guarantees for non-point estimates, and how to handle non-ridge extensions.

Finally, we note that although the primary focus of the current paper was theoretical, we have applied the MERR method (Szabó et al., 2015, Section A.2) to supervised entropy learning and aerosol prediction based on multispectral satellite images.¹⁸ In future work, we will address applications with vector-valued outputs.

7. Proofs

We provide proofs for our results detailed in Section 4: Section 7.1 (*resp.* Section 7.2) focuses on the well-specified case (*resp.* misspecified setting). The used lemmas are enlisted in Section 7.3.

7.1 Proofs of the Well-specified Case

We give proof details concerning the excess risk in the well-specified case (Theorem 2).

7.1.1 PROOF OF THE BOUND ON $\|g_{\mathbf{z}} - g_{\mathbf{z}}\|_{\mathcal{Y}}^2$

By (13), (14) we get $g_{\mathbf{z}} - g_{\mathbf{z}} = \frac{1}{l} \sum_{i=1}^l (K_{\mu_{x_i}} - K_{\mu_{x_i}}) y_i$; hence by applying the Hölder property of $K_{(\cdot)}$, the boundedness of y_i ($\|y_i\|_{\mathcal{Y}} \leq C$) and (24), we obtain

$$\begin{aligned} \|g_{\mathbf{z}} - g_{\mathbf{z}}\|_{\mathcal{Y}}^2 &\leq \frac{1}{l^2} \sum_{i=1}^l \|(K_{\mu_{x_i}} - K_{\mu_{x_i}}) y_i\|_{\mathcal{Y}}^2 \leq \frac{1}{l} \sum_{i=1}^l \|K_{\mu_{x_i}} - K_{\mu_{x_i}}\|_{L(\mathcal{Y}; \mathcal{Y})}^2 \|y_i\|_{\mathcal{Y}}^2 \\ &\leq \frac{L^2}{l} \sum_{i=1}^l \|y_i\|_{\mathcal{Y}}^2 \|\mu_{x_i} - \mu_{x_i}\|_H^2 \leq \frac{L^2 C^2}{l} \sum_{i=1}^l \left[\frac{(1 + \sqrt{\alpha}) \sqrt{2B_k}}{\sqrt{N}} \right]^{2h} = L^2 C^2 \frac{(1 + \sqrt{\alpha})^{2h} (2B_k)^h}{N^h} \end{aligned}$$

with probability at least $1 - le^{-\alpha}$, based on a union bound.

7.1.2 PROOF OF THE BOUND ON $\|T_{\mathbf{x}} - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{Y})}^2$

Using the definition of $T_{\mathbf{x}}$ and $T_{\mathbf{x}}$, and exploiting (with $\|\cdot\|_{\mathcal{L}(\mathcal{Y})}$) that in a normed space¹⁹ $(N, \|\cdot\|)$, $f_i \in N$, $(i = 1, \dots, n)$

$$\left\| \sum_{i=1}^n f_i \right\|^2 \leq n \sum_{i=1}^n \|f_i\|^2, \quad (35)$$

we get

$$\|T_{\mathbf{x}} - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{Y})}^2 \leq \frac{1}{l^2} \sum_{i=1}^l \|T_{\mu_{x_i}} - T_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y})}^2. \quad (36)$$

To upper bound $\|T_{\mu_{x_i}} - T_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y})}^2$, let us see how $T_{\mu_{x_i}} = K_{\mu_{x_i}} K_{\mu_{x_i}}^*$ acts. The existence of an $E \geq 0$ constant satisfying $\|(T_{\mu_{x_i}} - T_{\mu_{x_i}})(f)\|_{\mathcal{Y}} \leq E \|f\|_{\mathcal{Y}}$ implies $\|T_{\mu_{x_i}} - T_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y})} \leq E$. We continue with the l.h.s. of this equation using Eq. (35):

$$\begin{aligned} \|(T_{\mu_{x_i}} - T_{\mu_{x_i}})(f)\|_{\mathcal{Y}}^2 &= \|K_{\mu_{x_i}} K_{\mu_{x_i}}^*(f) - K_{\mu_{x_i}} K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 \\ &= \|K_{\mu_{x_i}} [K_{\mu_{x_i}}^*(f) - K_{\mu_{x_i}}^*(f)] + (K_{\mu_{x_i}} - K_{\mu_{x_i}}) K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 \\ &\leq 2 \left[\|K_{\mu_{x_i}} [K_{\mu_{x_i}}^*(f) - K_{\mu_{x_i}}^*(f)]\|_{\mathcal{Y}}^2 + \|(K_{\mu_{x_i}} - K_{\mu_{x_i}}) K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 \right]. \end{aligned}$$

By Eq. (45) and the Hölder continuity of $K_{(\cdot)}$, one arrives at

$$\begin{aligned} \|K_{\mu_{x_i}} [K_{\mu_{x_i}}^*(f) - K_{\mu_{x_i}}^*(f)]\|_{\mathcal{Y}}^2 &\leq \|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|K_{\mu_{x_i}}^*(f) - K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 \\ &\leq \|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|K_{\mu_{x_i}}^* - K_{\mu_{x_i}}^*\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|f\|_{\mathcal{Y}}^2 = \|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|(K_{\mu_{x_i}} - K_{\mu_{x_i}})^*\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|f\|_{\mathcal{Y}}^2 \\ &= \|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|K_{\mu_{x_i}} - K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|f\|_{\mathcal{Y}}^2 \leq B_K L^2 \|\mu_{x_i} - \mu_{x_i}\|_H^2 \|f\|_{\mathcal{Y}}^2, \\ \|(K_{\mu_{x_i}} - K_{\mu_{x_i}}) K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 &\leq \|K_{\mu_{x_i}} - K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|K_{\mu_{x_i}}^*(f)\|_{\mathcal{Y}}^2 \\ &\leq \|K_{\mu_{x_i}} - K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|K_{\mu_{x_i}}^*\|_{\mathcal{L}(\mathcal{Y}; \mathcal{Y})}^2 \|f\|_{\mathcal{Y}}^2 \leq B_K L^2 \|\mu_{x_i} - \mu_{x_i}\|_H^2 \|f\|_{\mathcal{Y}}^2. \end{aligned}$$

Hence $\|(T_{\mu_{x_i}} - T_{\mu_{x_i}})(f)\|_{\mathcal{Y}}^2 \leq 4B_K L^2 \|\mu_{x_i} - \mu_{x_i}\|_H^2 \|f\|_{\mathcal{Y}}^2 \Rightarrow E^2 = 4B_K L^2 \|\mu_{x_i} - \mu_{x_i}\|_H^2$. Exploiting this property in (36) with Eq. (24) we arrive to the bound

$$\begin{aligned} \|T_{\mathbf{x}} - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{Y})}^2 &\leq \frac{4B_K L^2}{l} \sum_{i=1}^l \|\mu_{x_i} - \mu_{x_i}\|_H^2 \leq \frac{4B_K L^2}{l} \sum_{i=1}^l \frac{(1 + \sqrt{\alpha})^{2h} (2B_k)^h}{N^h} \\ &= \frac{(1 + \sqrt{\alpha})^{2h} 2^{h+2} (B_k)^h B_K L^2}{N^h}. \end{aligned} \quad (37)$$

7.1.3 PROOF: FINAL UNION BOUND IN THEOREM 2

Until now, we obtained that if (i) the sample number N satisfies Eq. (25), (ii) (24) holds (which has probability at least $1 - le^{-\alpha} = 1 - e^{-[\alpha - \log(l)]} = 1 - e^{-\alpha}$ applying a union bound

19. Eq. (35) holds since $\|\cdot\|^2$ is convex function, thus $\|\frac{1}{n} \sum_{i=1}^n f_i\|^2 \leq \frac{1}{n} \sum_{i=1}^n \|f_i\|^2$.

18. For code, see <https://bitbucket.org/szozoli/ite/>.

argument; $\alpha = \log(l) + \delta$, and (iii) $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ is fulfilled [see Eq. (22)], then

$$\begin{aligned} S_{-1} + S_0 &\leq \frac{4}{\lambda} \left[L^2 C^2 (1 + \sqrt{\alpha})^{2h} (2B_K)^h + \frac{(1 + \sqrt{\alpha})^{2h} 2^{h+2} (B_K)^h B_K L^2}{N^h} \right. \\ &\quad \times \left. \left(\log^2 \left(\frac{6}{\eta} \right) \left\{ \frac{64}{\lambda} \left[\frac{M^2 B_K}{l^2 \lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right] + \frac{24}{\lambda^2} \left[\frac{4B_K^2 \mathcal{B}(\lambda)}{l^2} + \frac{B_K \mathcal{A}(\lambda)}{l} \right] \right\} + \mathcal{B}(\lambda) + \|f_\rho\|_{\mathcal{X}}^2 \right) \right] \\ &= \frac{4L^2 (1 + \sqrt{\alpha})^{2h} (2B_K)^h}{\lambda N^h} \left[C^2 + 4B_K \times \right. \\ &\quad \left. \times \left(\log^2 \left(\frac{6}{\eta} \right) \left\{ \frac{64}{\lambda} \left[\frac{M^2 B_K}{l^2 \lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right] + \frac{24}{\lambda^2} \left[\frac{4B_K^2 \mathcal{B}(\lambda)}{l^2} + \frac{B_K \mathcal{A}(\lambda)}{l} \right] \right\} + \mathcal{B}(\lambda) + \|f_\rho\|_{\mathcal{X}}^2 \right) \right]. \end{aligned}$$

By taking into account Caporinotto and De Vito (2007)'s bounds for S_1 and S_2 , $S_1 \leq 32 \log^2 \left(\frac{6}{\eta} \right) \left[\frac{B_K \lambda l^2}{l^2 \lambda} + \frac{\Sigma^2 \mathcal{N}(\lambda)}{l} \right]$, $S_2 \leq 8 \log^2 \left(\frac{6}{\eta} \right) \left[\frac{4B_K^2 \mathcal{B}(\lambda)}{l^2 \lambda} + \frac{B_K \mathcal{A}(\lambda)}{l \lambda} \right]$, plugging all the expressions to (21), we obtain Theorem 2 with a union bound.

7.2 Proofs of the Misspecified Case

We present the proof details concerning the excess risk in the misspecified case (Theorem 7).

7.2.1 PROOF OF THE BOUND ON $\sqrt{S_{-1}} + \sqrt{S_0}$ WITHOUT $\mathcal{P}(b, c)$

The upper bounds on S_{-1} and S_0 [which are defined in Eqs. (15), (16)] remain valid without modification provided that (i) $\Theta(\lambda, \mathbf{z}) = \|(T - T_{\mathbf{x}})(T + \lambda)^{-1}\|_{\mathcal{L}(\mathcal{G})} \leq \|(T - T_{\mathbf{x}})(T + \lambda)^{-1}\|_{\mathcal{L}_2(\mathcal{G})} \leq \frac{1}{2}$, where we used Eq. (1), (ii) Eq. (24) is satisfied (which has probability $1 - l e^{-\eta}$) and (iii) Eq. (25) holds. Our goal below is to guarantee the $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ condition with high probability *without* assuming that the prior belongs to $\mathcal{P}(b, c)$.

Requirement $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$: Let us define $\xi_i = T_{\mu_{\mathbf{x}_i}}(T + \lambda)^{-1} \in \mathcal{L}_2(\mathcal{G})$, $(i = 1, \dots, l)$. With this choice we get $\mathbb{E}[\xi_i] = T(T + \lambda)^{-1}$, $(T - T_{\mathbf{x}})(T + \lambda)^{-1} = \mathbb{E}[\xi_i] - \frac{1}{l} \sum_{i=1}^l \xi_i$ and

$$\|\xi_i\|_{\mathcal{L}_2(\mathcal{G})} \leq \|T_{\mu_{\mathbf{x}_i}}\|_{\mathcal{L}_2(\mathcal{G})} \|(T + \lambda)^{-1}\|_{\mathcal{L}(\mathcal{G})} \leq B_K / \lambda \Rightarrow \mathbb{E}[\|\xi_i\|_{\mathcal{L}_2(\mathcal{G})}^2] \leq (B_K)^2 / \lambda^2,$$

where we made use of (2), the $\|T_{\mu_{\mathbf{x}_i}}\|_{\mathcal{L}_2(\mathcal{G})} \leq B_K$ identity following from the boundedness of K (Caporinotto and De Vito, 2007, page 341, Eq. (13)), and the spectral theorem. Consequently, by the Bernstein's inequality (Lemma 7.3.1 with $\mathcal{X} = \mathcal{L}_2(\mathcal{G})$, $B = 2B_K / \lambda$, $\sigma = B_K / \lambda$) we obtain that for $\forall \eta \in (0, 1)$

$$\mathbb{P} \left(\|(T - T_{\mathbf{x}})(T + \lambda)^{-1}\|_{\mathcal{L}_2(\mathcal{G})} \leq 2 \left(\frac{2B_K}{\lambda l} + \frac{B_K}{\sqrt{l}\lambda} \right) \log \left(\frac{2}{\eta} \right) \right) \geq 1 - \eta.$$

Thus, for $\Theta(\lambda, \mathbf{z}) \leq \frac{1}{2}$ with probability $1 - \eta$ it is sufficient to have

$$2 \left(\frac{2B_K}{\lambda l} + \frac{B_K}{\sqrt{l}\lambda} \right) \log \left(\frac{2}{\eta} \right) \leq \frac{6B_K}{\sqrt{l}\lambda} \log \left(\frac{2}{\eta} \right) \leq \frac{1}{2} \Leftrightarrow \left[\frac{12B_K}{\lambda} \log \left(\frac{2}{\eta} \right) \right]^2 \leq l. \quad (38)$$

Under these conditions, we arrived at the upper bound

$$\begin{aligned} \sqrt{S_{-1}} + \sqrt{S_0} &\leq \sqrt{\frac{4L^2 C^2 (1 + \sqrt{\alpha})^{2h} (2B_K)^h}{\lambda N^h}} \left[\sqrt{1} + \sqrt{\frac{4B_K}{\lambda}} \right] \\ &= \frac{2LC(1 + \sqrt{\alpha})^h (2B_K)^{\frac{h}{2}}}{\sqrt{\lambda N^{\frac{h}{2}}}} \left[1 + \frac{2\sqrt{B_K}}{\sqrt{\lambda}} \right], \end{aligned}$$

where as opposed to Section 7.1.3 and Eq. (23) we used a slightly cruder $\|f_{\mathbf{z}}^{\lambda}\|_{\mathcal{X}}^2 \leq \frac{C^2}{\lambda}$ bound; it holds without the $\mathcal{P}(b, c)$ assumption by the definition of $f_{\mathbf{z}}^{\lambda}$ and the boundedness of y since $\lambda \|f_{\mathbf{z}}^{\lambda}\|_{\mathcal{X}}^2 \leq \frac{1}{l} \sum_{i=1}^l \|y_i\|_{\mathcal{Y}}^2 \leq C^2$.

Remark: Notice that the price we pay for not assuming that the prior belongs to the $\mathcal{P}(b, c)$ class ($b > 1$) is a slightly tighter $\frac{1}{\lambda^2} \leq l$ constraint [Eq. (38)] instead of $\frac{1}{\lambda^{1+\frac{1}{2}}} \leq l$ in Eq. (19), and a somewhat looser $\|f_{\mathbf{z}}^{\lambda}\|_{\mathcal{X}}^2$ bound.

7.2.2 PROOF OF THE DECOMPOSITION OF $\|\sqrt{T}(f_{\mathbf{z}}^{\lambda} - f^{\lambda})\|_{\mathcal{X}}$

Using the analytical formula of $f_{\mathbf{z}}^{\lambda}$ [see Eq. (13)] and that of f^{λ} [see Eq. (17)]

$$f^{\lambda} = (S_K S_K^* + \lambda I)^{-1} S_K f_\rho = (T + \lambda I)^{-1} S_K f_\rho \quad (39)$$

one gets $(T + \lambda I) f^{\lambda} = S_K f_\rho \Rightarrow \lambda f^{\lambda} = S_K f_\rho - T f^{\lambda}$ and

$$\begin{aligned} f_{\mathbf{z}}^{\lambda} - f^{\lambda} &= (T_{\mathbf{x}} + \lambda I)^{-1} g_{\mathbf{z}} - f^{\lambda} = (T_{\mathbf{x}} + \lambda I)^{-1} g_{\mathbf{z}} - (T_{\mathbf{x}} + \lambda I)^{-1} (T_{\mathbf{x}} + \lambda I) f^{\lambda} \\ &= (T_{\mathbf{x}} + \lambda I)^{-1} [g_{\mathbf{z}} - (T_{\mathbf{x}} + \lambda I) f^{\lambda}] = (T_{\mathbf{x}} + \lambda I)^{-1} (g_{\mathbf{z}} - T_{\mathbf{x}} f^{\lambda} - \lambda f^{\lambda}) \\ &= (T_{\mathbf{x}} + \lambda I)^{-1} (g_{\mathbf{z}} - T_{\mathbf{x}} f^{\lambda} - S_K f_\rho + T f^{\lambda}) \\ &= (T_{\mathbf{x}} + \lambda I)^{-1} (g_{\mathbf{z}} - S_K f_\rho) + (T_{\mathbf{x}} + \lambda I)^{-1} (T - T_{\mathbf{x}}) f^{\lambda} \\ &= (T_{\mathbf{x}} + \lambda I)^{-1} (g_{\mathbf{z}} - S_K f_\rho) + (T_{\mathbf{x}} + \lambda I)^{-1} (T - T_{\mathbf{x}}) (T + \lambda I)^{-1} S_K f_\rho. \end{aligned} \quad (40)$$

Let us rewrite $(T + \lambda I)^{-1}$ by the $(A + UV)^{-1} = A^{-1} - A^{-1} U (I + V A^{-1} U)^{-1} V A^{-1}$ operator Woodbury formula (Ding and Zhou, 2008, Theorem 2.1, page 724)

$$\begin{aligned} (T + \lambda I)^{-1} &= (\lambda I + S_K S_K^*)^{-1} = (\lambda^{-1} I) - (\lambda^{-1} I) S_K [I + S_K^* (\lambda^{-1} I) S_K]^{-1} S_K (\lambda^{-1} I) \\ &= (\lambda^{-1} I) - \lambda^{-1} S_K (\lambda I + \tilde{T})^{-1} S_K^*. \end{aligned}$$

By the derived expression for $(T + \lambda I)^{-1}$, we get $(T + \lambda I)^{-1} S_K f_\rho = \lambda^{-1} S_K f_\rho - \lambda^{-1} S_K (\lambda I + \tilde{T})^{-1} S_K^* S_K f_\rho = \lambda^{-1} S_K [f_\rho - (T + \lambda I)^{-1} S_K^* S_K f_\rho]$. Plugging this result to Eq. (40), introducing the $g_\rho = S_K f_\rho$ notation, using the triangle inequality we get

$$\begin{aligned} \|\sqrt{T}(f_{\mathbf{z}}^{\lambda} - f^{\lambda})\|_{\mathcal{X}} &= \\ &= \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1} \left\{ (g_{\mathbf{z}} - S_K f_\rho) + (T - T_{\mathbf{x}}) \lambda^{-1} S_K [f_\rho - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_\rho] \right\}\|_{\mathcal{X}} \\ &\leq \|\sqrt{T}(T_{\mathbf{x}} + \lambda I)^{-1}\|_{\mathcal{L}(\mathcal{G})} \left(\|g_{\mathbf{z}} - g_\rho\|_{\mathcal{X}} + \|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{G})} \lambda^{-1} \|S_K [f_\rho - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_\rho]\|_{\mathcal{X}} \right). \end{aligned}$$

7.2.3 PROOF OF THE BOUND ON $\|g_{\mathbf{x}} - g_{\rho}\|_{\mathcal{H}}$

As is known $g_{\mathbf{x}} = \frac{1}{l} \sum_{i=1}^l K_{\mu_{x_i}} y_i$ [see Eq. (13)] and $g_{\rho} = \int_{\mathcal{X}} K_{\mu_{\rho}} f_{\rho}(\mu_{\rho}) d\rho_{\mathcal{X}}(\mu_{\rho})$ (Caponnetto and De Vito, 2007, Eq. (23), page 344). Let $\xi_i = K_{\mu_{x_i}} y_i \in \mathcal{H}$ ($i = 1, \dots, l$). In this case $\mathbb{E}[\xi_i] = g_{\rho}$, $g_{\rho} - g_{\mathbf{x}} = \mathbb{E}[\xi_i] - \frac{1}{l} \sum_{i=1}^l \xi_i$, and $\|\xi_i\|_{\mathcal{H}}^2 = \|K_{\mu_{x_i}} y_i\|_{\mathcal{H}}^2 \leq \|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}, \mathcal{H})} \|y_i\|_{\mathcal{Y}}^2 \leq B_K C^2 \Rightarrow \|\xi_i\|_{\mathcal{H}} \leq C\sqrt{B_K} \Rightarrow \mathbb{E}[\|\xi_i\|_{\mathcal{H}}^2] \leq C^2 B_K$ using the boundedness of kernel K ($\|K_{\mu_{x_i}}\|_{\mathcal{L}(\mathcal{Y}, \mathcal{H})} \leq B_K$) and the boundedness of output y ($\|y\|_{\mathcal{Y}} \leq C$). Applying the Bernstein inequality (see Lemma 7.3.1 with $\mathcal{X} = \mathcal{H}$, $B = 2C\sqrt{B_K}$, $\sigma = C\sqrt{B_K}$) one gets that for any $\eta \in (0, 1)$

$$\mathbb{P}\left(\|g_{\mathbf{x}} - g_{\rho}\|_{\mathcal{H}} \leq 2\left(\frac{2C\sqrt{B_K}}{l} + \frac{C\sqrt{B_K}}{\sqrt{l}}\right) \log\left(\frac{2}{\eta}\right)\right) \geq 1 - \eta.$$

7.2.4 PROOF OF THE BOUND ON $\|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H})}$

Let $\xi_i = T_{\mu_{x_i}} \in \mathcal{L}_2(\mathcal{H})$ ($i = 1, \dots, l$), then $\mathbb{E}[\xi_i] = T$, $T - T_{\mathbf{x}} = T - \frac{1}{l} \sum_{i=1}^l T_{\mu_{x_i}}$, $\|\xi_i\|_{\mathcal{L}_2(\mathcal{H})} = \|T_{\mu_{x_i}}\|_{\mathcal{L}_2(\mathcal{H})} \leq B_K$, $\mathbb{E}[\|\xi_i\|_{\mathcal{L}_2(\mathcal{H})}^2] \leq B_K^2$. Applying the $\|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H})} \leq \|T - T_{\mathbf{x}}\|_{\mathcal{L}_2(\mathcal{H})}$ relation [see Eq. (1)] and the Bernstein inequality (see Lemma 7.3.1 with $\mathcal{X} = \mathcal{L}_2(\mathcal{H})$, $B = 2B_K$, $\sigma = B_K$), we obtain that for any $\eta \in (0, 1)$

$$\mathbb{P}\left(\|T - T_{\mathbf{x}}\|_{\mathcal{L}(\mathcal{H})} \leq 2\left(\frac{2B_K}{l} + \frac{\sigma}{\sqrt{l}}\right) \log\left(\frac{2}{\eta}\right)\right) \geq 1 - \eta.$$

7.2.5 PROOF OF THE DECOMPOSITION OF $\|S_K(f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho})\|_{\mathcal{H}}$

Since $\|S_K a\|_{\mathcal{H}}^2 = \langle S_K a, S_K a \rangle_{\mathcal{H}} = \langle S_K^* S_K a, a \rangle_{\rho} = \langle \tilde{T} a, a \rangle_{\rho}$ ($\forall a \in L_{\rho, \mathcal{X}}^2$) by the definition of the adjoint operator and $\tilde{T} = S_K^* S_K$ [see Eq. (6)], we can rewrite the target term as

$$\begin{aligned} & \|S_K [f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\mathcal{H}}^2 = \\ &= \langle \tilde{T} [f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}], f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho} \rangle_{\rho} \\ &\leq \|\tilde{T} [f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\rho} \|f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}\|_{\rho}, \end{aligned}$$

where the CBS (Cauchy-Bunyakovsky-Schwarz) inequality was applied. Since

$$\begin{aligned} (S_K^* S_K + \lambda I) S_K^* &= S_K^* (S_K S_K^* + \lambda I) & S_K^* (S_K S_K^* + \lambda I)^{-1} &= (S_K^* S_K + \lambda I)^{-1} S_K^* \\ S_K^* (S_K S_K^* + \lambda I)^{-1} S_K &= (S_K^* S_K + \lambda I)^{-1} S_K^* S_K & S_K^* (S_K S_K^* + \lambda I)^{-1} S_K &= S_K^* f^{\lambda} \\ S_K^* (T + \lambda I)^{-1} S_K &= (\tilde{T} + \lambda I)^{-1} \tilde{T} \end{aligned} \quad (41) \quad (42)$$

using Eq. (41) and the analytical expression for f^{λ} [see Eq. (39)] we have

$$\begin{aligned} (\tilde{T} + \lambda I)^{-1} \tilde{T} f_{\rho} &= (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho} = (S_K^* S_K + \lambda I)^{-1} S_K^* S_K f_{\rho} \\ &= S_K^* (S_K S_K^* + \lambda I)^{-1} S_K f_{\rho} = S_K^* f^{\lambda} \end{aligned} \quad (43)$$

and $\|S_K [f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\mathcal{H}}^2 \leq \|\tilde{T} [f_{\rho} - (\tilde{T} + \lambda I)^{-1} S_K^* S_K f_{\rho}]\|_{\rho} \|S_K^* f^{\lambda} - f_{\rho}\|_{\rho}$.

7.2.6 PROOF OF THE BOUND ON $\|S_K^* f^{\lambda} - f_{\rho}\|_{\rho}$

Let us apply (i) the $Af - f = Af - f - q' + q' = (A - I)(f - q') + Aq' - q'$ relation with $A = (\tilde{T} + \lambda I)^{-1} \tilde{T}$, $f = f_{\rho}$ and $q' = S_K^* q$, where $q \in \mathcal{H}$ is an arbitrary element from \mathcal{H} , (ii) Eq. (43) and (iii) the triangle inequality to arrive at

$$\begin{aligned} \|S_K^* f^{\lambda} - f_{\rho}\|_{\rho} &= \|(\tilde{T} + \lambda I)^{-1} \tilde{T} f_{\rho} - f_{\rho}\|_{\rho} \\ &= \|[(\tilde{T} + \lambda I)^{-1} \tilde{T} - I](f_{\rho} - S_K^* q) + (\tilde{T} + \lambda I)^{-1} \tilde{T} S_K^* q - S_K^* q\|_{\rho} \\ &\leq \|[(\tilde{T} + \lambda I)^{-1} \tilde{T} - I](f_{\rho} - S_K^* q)\|_{\rho} + \|(\tilde{T} + \lambda I)^{-1} \tilde{T} S_K^* q - S_K^* q\|_{\rho}. \end{aligned}$$

Below we give upper bounds on these two terms.

First, notice that $\mu_x \in X \mapsto \|K(\mu_x, \mu_x)\|_{\mathcal{L}(\mathcal{Y})} \leq B_K$. This boundedness with the strong continuity of $K(\cdot)$ imply (Carmeli et al., 2006, Proposition 12) that $\mathcal{H} \subseteq C(X, \mathcal{Y})$, i.e., K is a Mercer kernel. Since K_{μ_x} is a Hilbert-Schmidt operator for all $\mu_x \in X$ [see Eq. (11)], it is also a compact operator ($\forall \mu_x \in X$). The compactness of K_{μ_x} -s with the bounded and Mercer property of K guarantees the boundedness of S_K^* and that \tilde{T} is a compact, positive, self-adjoint operator (Carmeli et al., 2010, Proposition 3).

Bound on $\|[(\tilde{T} + \lambda I)^{-1} \tilde{T} - I](f_{\rho} - S_K^* q)\|_{\rho}$: Since \tilde{T} is a compact positive self-adjoint operator, by the spectral theorem (Steinwart and Christmann, 2008, Theorem 4.27, page 127) there exist an $(u_i)_{i \in I}$ countable ONB in $cl[Im(\tilde{T})]$, and $a_1 \geq a_2 \geq \dots > 0$ such that $\tilde{T} f = \sum_{i \in I} a_i \langle f, u_i \rangle_{\rho} u_i$ ($\forall f \in L_{\rho, \mathcal{X}}^2$) and let $(v_j)_{j \in J}$ (J is also countable by the separability²⁰ of $L_{\rho, \mathcal{X}}^2$) an ONB in $Ker(\tilde{T}^*) = Ker(\tilde{T})$; $L_{\rho, \mathcal{X}}^2 = cl[Im(\tilde{T})] \oplus Ker(\tilde{T})$. Thus,

$$\begin{aligned} \|(\tilde{T} + \lambda I)^{-1} \tilde{T} - I\|_{\rho} \|f_{\rho} - S_K^* q\|_{\rho} &= \sum_{i \in I} \left(\frac{a_i}{a_i + \lambda} - 1 \right)^2 \langle f_{\rho} - S_K^* q, u_i \rangle_{\rho}^2 + \sum_{j \in J} \langle f_{\rho} - S_K^* q, v_j \rangle_{\rho}^2 \\ &\leq \sum_{i \in I} \langle f_{\rho} - S_K^* q, u_i \rangle_{\rho}^2 + \sum_{j \in J} \langle f_{\rho} - S_K^* q, v_j \rangle_{\rho}^2 = \|f_{\rho} - S_K^* q\|_{\rho}^2 \end{aligned}$$

exploiting the Parseval's identity and that $\left(\frac{\lambda}{\lambda + \lambda} - 1\right)^2 \leq 1$.

Bound on $\|(\tilde{T} + \lambda I)^{-1} \tilde{T} S_K^* q - S_K^* q\|_{\rho}$: By using Eq. (42), Eq. (32), and Lemma 7.3.2 ($M = T = S_K^* S_K$, $\mathcal{X} = \mathcal{H}$, $f = q$, $a = \frac{1}{2}$), the target quantity can be bounded as

$$\begin{aligned} \|(\tilde{T} + \lambda I)^{-1} \tilde{T} S_K^* q - S_K^* q\|_{\rho} &= \|S_K^* (T + \lambda I)^{-1} S_K S_K^* q - S_K^* q\|_{\rho} \\ &= \|\sqrt{\tilde{T}} [(\tilde{T} + \lambda I)^{-1} S_K S_K^* q - q]\|_{\mathcal{H}} \\ &= \|\sqrt{\tilde{T}} [(T + \lambda I)^{-1} T q - q]\|_{\mathcal{H}} \leq \max(1, \|\tilde{T}\|_{\mathcal{L}(\mathcal{H})}) \lambda^{\frac{1}{2}} \|q\|_{\mathcal{H}}. \end{aligned}$$

Making use of the two derived bounds, we get $\|S_K^* f^{\lambda} - f_{\rho}\|_{\rho} \leq \|f_{\rho} - S_K^* q\|_{\rho} + \max(1, \|\tilde{T}\|_{\mathcal{L}(\mathcal{H})}) \lambda^{\frac{1}{2}} \|q\|_{\mathcal{H}}$.

²⁰ $L_{\rho, \mathcal{X}}^2 = L^2(X, \mathcal{B}(H))_{\mathcal{X}, \rho, \mathcal{X}; \mathbb{R}}$ is isomorphic to $L^2(X, \mathcal{B}(H))_{\mathcal{X}, \rho, \mathcal{X}; \mathbb{R}} \otimes Y$, where \otimes is the tensor product of Hilbert spaces. The separability follows from that of Y and $L^2(X, \mathcal{B}(H))_{\mathcal{X}, \rho, \mathcal{X}; \mathbb{R}}$; the latter holds (Cohn, 2013, Proposition 3.4.5) since $\mathcal{B}(H)_{\mathcal{X}}$ is countably generated since $X \subseteq H$ is separable.

7.3 Supplementary Lemmas

In this section, we list two lemmas used in the proofs.

7.3.1 BERNSTEIN'S INEQUALITY (CAPONNETTO AND DE VITO, 2007, Prop. 2, p. 345)

Let ξ_i ($i = 1, \dots, l$) be i.i.d. realizations of a random variable on a (Ω, \mathcal{A}, P) probability space with values in a separable Hilbert space \mathcal{X} . If there exist $B > 0$, $\sigma > 0$ constants such that $\|\xi_i(\omega)\|_{\mathcal{X}} \leq \frac{B}{\sigma}$ a.s., $\mathbb{E}[\|\xi_i\|_{\mathcal{X}}^2] \leq \sigma^2$, then for all $l \geq 1$ and $\eta \in (0, 1)$ we have

$$\mathbb{P}\left(\left\|\frac{1}{l}\sum_{i=1}^l \xi_i - \mathbb{E}[\xi_1]\right\|_{\mathcal{X}} \leq 2\left(\frac{B}{l} + \frac{\sigma}{\sqrt{l}}\right) \log\left(\frac{2}{\eta}\right)\right) \geq 1 - \eta.$$

7.3.2 LEMMA ON BOUNDED, SELF-ADJOINT COMPACT OPERATORS; SHPERUMBUDUR ET AL. (2014, PROPOSITION A.2, PAGE 39)

Let M be a bounded, self-adjoint compact operator on a separable Hilbert space \mathcal{X} . Let $a \geq 0$, $\lambda > 0$, and $s \geq 0$. Let $f \in \mathcal{X}$ such that $f \in \text{Im}(M^s)$. If $s + a > 0$, then

$$\|M^a [(M + \lambda I)^{-1} M f - f]\|_{\mathcal{X}} \leq \max\left(1, \|M\|_{\mathcal{L}(\mathcal{X})}^{\min(1, s+a)}\right) \|M^{-s} f\|_{\mathcal{X}}.$$

Note: specifically for $s = 0$ we have $\text{Im}(M^s) = \text{Im}(I) = \mathcal{X}$, in other words, there is no additional range space constraint.

8. Discussion of Our Assumptions

We give a short insight into the consequences of our assumptions (detailed in Section 3) and present some concrete examples.

- **Well-definedness of ρ :** The boundedness and continuity of k imply the measurability of $\mu : (\mathcal{M}_1^+(X), \mathcal{B}(\tau_w)) \rightarrow (H, \mathcal{B}(H))$. Let τ denote the open sets on $H = H(k)$, $\tau|_X = \{A \cap X : A \in \tau\}$ the subspace topology on X , and $\mathcal{B}(H)|_X = \{A \cap X : A \in \mathcal{B}(H)\}$ the subspace σ -algebra on X . By noting (Schwartz, 1998, Corollary 5.2.13) that $\mathcal{B}(\tau|_X) = \mathcal{B}(H)|_X = \{A \in \mathcal{B}(H) : A \subseteq X\} \subseteq \mathcal{B}(H)$, the H -measurability of μ guarantees the measurability of $\mu : (\mathcal{M}_1^+(X), \mathcal{B}(\tau_w)) \rightarrow (X, \mathcal{B}(H)|_X)$, and hence the well-definedness of ρ , the measure induced by \mathcal{M} on $X \times Y$; for further details see (Szabó et al., 2015, Section A.1.1).²¹
- **Separability of X :** separability of \mathcal{X} and the continuity of k implies the separability of $H = H(k)$ (Steinwart and Christmann, 2008, Lemma 4.33, page 130). Also, since $X \subseteq H$, X is separable.
- **Finiteness of B_k :** If X is compact, then the continuity of k implies $B_k < \infty$.
- **Finiteness of B_k , compact metrichness of X :** Let \mathcal{X} be a compact metric space. In this case $\mathcal{M}_1^+(X)$ is also compact metric (Parthasarathy, 1967, Theorem 6.4, page 55).

21. Note that the referred proof also holds for separable Hilbert Y , and by the simplified reasoning above the original $X \in \mathcal{B}(H)$ condition could be avoided.

Hence if $\mu : (\mathcal{M}_1^+(X), \tau_w) \rightarrow H(k)$ is continuous²² (not just measurable), then X is compact metric and thus by the Hölder property of $K(\cdot)$, it is continuous implying that $B_K < \infty$.

- **K properties:** It is known (Caponnetto and De Vito, 2007, page 339-340) that

$$K(\mu_a, \mu_b) = K_{\mu_a}^* K_{\mu_b}, \quad (\forall \mu_a, \mu_b \in X) \quad (44)$$

$$\|K_{\mu_a}\|_{\mathcal{L}(Y; Y)} = \|K_{\mu_a}^*\|_{\mathcal{L}(X; X)} \leq \sqrt{B_K}, \quad (\forall \mu_a \in X). \quad (45)$$

Remark: In terms of Eq. (44), the Eq. (11) assumption means that the $\{K(\mu_a, \mu_a)\}_{\mu_a \in X}$ operators are trace class, specifically they are compact operators.

- **Separability of \mathcal{Y} :** The separability of X and the continuity of K imply the separability of \mathcal{Y} . Indeed, since $\mu_a \mapsto K_{\mu_a}$ is Hölder continuous w.r.t. the Hilbert-Schmidt norm it is also continuous. As a result it is continuous w.r.t. the operator norm, and thus also w.r.t. the strong topology. Using this property with the finiteness of B_K the separability of \mathcal{Y} follows (Carmali et al., 2006, Proposition 5.1, Corollary 5.2).

- Our assumptions imply Caponnetto and De Vito (2007)'s conditions (not considering the $\mathcal{P}(b, c)$ prior requirement). Indeed
 1. Y is a separable Hilbert space by assumption; the same property also holds for \mathcal{Y} as we have seen.
 2. The measurability of $(\mu_x, \mu_t) \mapsto \langle K_{\mu_x} w, K_{\mu_t} v \rangle_{\mathcal{Y}}$ for $\forall w, v \in Y$ is guaranteed by the continuity of $K(\cdot)$ w.r.t. the strong topology.
 3. We have $\int_{X \times Y} \|y\|_{\mathcal{Y}}^2 d\rho_X(\mu_x; y) \leq \int_{X \times Y} C^2 d\rho_X(\mu_x; y) = C^2 < \infty$ due to the boundedness of y , and hence $\exists \Sigma > 0, \exists M > 0$ such that for ρ_X -almost $\mu_x \in X$

$$\int_Y \|y - f_{\rho}(\mu_x)\|_{\mathcal{Y}}^m d\rho(y|\mu_x) \leq \frac{m! \Sigma^2 M^{m-2}}{2} \quad (\forall m \geq 2). \quad (46)$$

Indeed, by (Caponnetto and De Vito, 2007, Eq. (33)) the Bernstein condition (46) holds if $\|y - f_{\rho}(\mu_x)\|_{\mathcal{Y}} \leq \frac{M}{\Sigma}$, $\int_Y \|y - f_{\rho}(\mu_x)\|_{\mathcal{Y}}^2 d\rho(y|\mu_x) \leq \Sigma^2$. In our case using the boundedness of y , the regression function is also bounded and the same holds for $\|y - f_{\rho}(\mu_x)\|_{\mathcal{Y}}$ by the triangle inequality: $\|y - f_{\rho}(\mu_x)\|_{\mathcal{Y}} \leq C + \|f_{\rho}\|_{\mathcal{Y}} \sqrt{B_K}$; thus, $M = 2(C + \|f_{\rho}\|_{\mathcal{Y}} \sqrt{B_K})$, $\Sigma = \frac{M}{\Sigma}$ is a suitable choice.

4. The Polishness of $X \times Y$ was used by Caponnetto and De Vito (2007) to assure the existence of $\rho(y|\mu_a)$; we guaranteed this existence under somewhat milder conditions (see footnote 7).

Real-valued outputs: We now consider the specific case of $Y = \mathbb{R}$, when the following simplifications and results hold. By noting that in this case $\text{Tr}(K_{\mu_a}^* K_{\mu_a}) = K(\mu_a, \mu_a)$, Eq. (11) simplifies to the boundedness of kernel K in the traditional sense

$$K(\mu_a, \mu_a) \leq B_K \quad (\forall \mu_a \in X). \quad (47)$$

22. For example, if k is universal, then μ metrizes the weak topology τ_w (Shperumbudur et al., 2010, Theorem 23, page 1552), hence μ is continuous.

K_G	K_e	K_C	K_t	K_i
$e^{-\frac{\ \mu_a - \mu_b\ _H^2}{2\theta^2}}$	$e^{-\frac{\ \mu_a - \mu_b\ _H}{2\theta^2}}$	$\left(1 + \frac{\ \mu_a - \mu_b\ _H^2}{\theta^2}\right)^{-1}$	$\left(1 + \frac{\ \mu_a - \mu_b\ _H}{\theta}\right)^{-1}$	$\left(\frac{\ \mu_a - \mu_b\ _H^2}{\theta^2} + \theta^2\right)^{-\frac{1}{2}}$
$h = 1$	$h = \frac{1}{2}$	$h = 1$	$h = \frac{\theta}{2}$ ($\theta \leq 2$)	$h = 1$

Table 1: Nonlinear kernels on mean embedded distributions: $K = K(\mu_a, \mu_b)$; $\theta > 0$. For the Hölder continuity of Ψ_K , we assume that \mathcal{X} is a compact metric space and μ is continuous.

Eq. (12) reduces to the Hölder continuity of the canonical feature map $\Psi_K(\mu_c) := K(\cdot, \mu_c) : X \rightarrow \mathcal{H}$, in other words $\exists L > 0$, $h \in (0, 1]$ such that $\|\Psi_K(\mu_a) - \Psi_K(\mu_b)\|_{\mathcal{H}} \leq L \|\mu_a - \mu_b\|_H^h$, $\forall (\mu_a, \mu_b) \in X \times X$. In case of a linear kernel, $K(\mu_a, \mu_b) = \langle \mu_a, \mu_b \rangle_H$, ($\mu_a, \mu_b \in X$), the Hölder continuity of Ψ_K holds with $L = 1$, $h = 1$, and $B_K = B_k$ is a suitable choice. Evaluating the kernel K at the empirical embeddings $\mu_{\hat{x}_i} = \int_X k(\cdot, u) d\hat{x}_i(u) = \frac{1}{N} \sum_{n=1}^N k(\cdot, x_{i,n}) \in H$ yields the standard set kernel

$$K(\mu_{\hat{x}_i}, \mu_{\hat{x}_j}) = \langle \mu_{\hat{x}_i}, \mu_{\hat{x}_j} \rangle_H = \left\langle \frac{1}{N} \sum_{n=1}^N k(\cdot, x_{i,n}), \frac{1}{N} \sum_{m=1}^N k(\cdot, x_{j,m}) \right\rangle_H = \frac{1}{N^2} \sum_{n,m=1}^N k(x_{i,n}, x_{j,m})$$

by the bilinearity of $\langle \cdot, \cdot \rangle_H$ and the reproducing property of k .

Remark: One can define many nonlinear kernels (see Table 1) on mean embedded distributions. These kernels are the natural extensions to distributions of the Gaussian (Christmann and Steinwart, 2010), exponential, Cauchy, generalized t-student and inverse multiquadratic kernels. If \mathcal{X} is a compact metric space and μ is continuous, then the Ψ_K canonical feature maps, associated to K -s in Table 1, can be shown to satisfy our Hölder continuity requirement [Eq. (12)]; for details, see (Szabó et al., 2015, Section A.1.5-A.1.6).

Acknowledgments

We would like to thank the anonymous reviewers for their highly valuable, constructive suggestions to improve the manuscript. This work was supported by the Gatsby Charitable Foundation, NSF grant 1247658, and DOE grant DE-SC001114. A part of the work was carried out while Bharath K. Sripunbudur was a research fellow in the Statistical Laboratory, Department of Pure Mathematics and Mathematical Statistics at the University of Cambridge, UK.

Abstract

We derive a second-order ordinary differential equation (ODE) which is the limit of Nesterov's accelerated gradient method. This ODE exhibits approximate equivalence to Nesterov's scheme and thus can serve as a tool for analysis. We show that the continuous time ODE allows for a better understanding of Nesterov's scheme. As a byproduct, we obtain a family of schemes with similar convergence rates. The ODE interpretation also suggests restarting Nesterov's scheme leading to an algorithm, which can be rigorously proven to converge at a linear rate whenever the objective is strongly convex.

Keywords: Nesterov's accelerated scheme, convex optimization, first-order methods, differential equation, restarting

1. Introduction

In many fields of machine learning, minimizing a convex function is at the core of efficient model estimation. In the simplest and most standard form, we are interested in solving

$$\text{minimize } f(x),$$

where f is a convex function, smooth or non-smooth, and $x \in \mathbb{R}^n$ is the variable. Since Newton, numerous algorithms and methods have been proposed to solve the minimization problem, notably gradient and subgradient descent, Newton's methods, trust region methods, conjugate gradient methods, and interior point methods (see e.g. Polyak, 1987; Boyd and Vandenberghe, 2004; Nocedal and Wright, 2006; Ruszczyński, 2006; Boyd et al., 2011; Shor, 2012; Beck, 2014, for expositions).

First-order methods have regained popularity as data sets and problems are ever increasing in size and, consequently, there has been much research on the theory and practice

of accelerated first-order schemes. Perhaps the earliest first-order method for minimizing a convex function f is the gradient method, which dates back to Euler and Lagrange. Thirty years ago, however, in a seminal paper Nesterov proposed an accelerated gradient method (Nesterov, 1983), which may take the following form: starting with x_0 and $y_0 = x_0$, inductively define

$$\begin{aligned} x_k &= y_{k-1} - s \nabla f(y_{k-1}) \\ y_k &= x_k + \frac{k-1}{k+2} (x_k - x_{k-1}). \end{aligned} \quad (1)$$

For any fixed step size $s \leq 1/L$, where L is the Lipschitz constant of ∇f , this scheme exhibits the convergence rate

$$f(x_k) - f^* \leq O\left(\frac{\|x_0 - x^*\|^2}{sk^2}\right). \quad (2)$$

Above, x^* is any minimizer of f and $f^* = f(x^*)$. It is well-known that this rate is optimal among all methods having only information about the gradient of f at consecutive iterates (Nesterov, 2004). This is in contrast to vanilla gradient descent methods, which have the same computational complexity but can only achieve a rate of $O(1/k)$. This improvement relies on the introduction of the momentum term $x_k - x_{k-1}$ as well as the particularly tuned coefficient $(k-1)/(k+2) \approx 1-3/k$. Since the introduction of Nesterov's scheme, there has been much work on the development of first-order accelerated methods, see Nesterov (2004, 2005, 2013) for theoretical developments, and Tseng (2008) for a unified analysis of these ideas. Notable applications can be found in sparse linear regression (Beck and Teboulle, 2009; Qin and Goldfarb, 2012), compressed sensing (Becker et al., 2011) and, deep and recurrent neural networks (Sutskever et al., 2013).

In a different direction, there is a long history relating ordinary differential equation (ODEs) to optimization, see Helmke and Moore (1996), Schropp and Singer (2000), and Fiori (2005) for example. The connection between ODEs and numerical optimization is often established via taking step sizes to be very small so that the trajectory or solution path converges to a curve modeled by an ODE. The conciseness and well-established theory of ODEs provide deeper insights into optimization, which has led to many interesting findings. Notable examples include linear regression via solving differential equations induced by linearized Bregman iteration algorithm (Osher et al., 2014), a continuous-time Nesterov-like algorithm in the context of control design (Dürri and Ebenbauer, 2012; Dürri et al., 2012), and modeling design iterative optimization algorithms as nonlinear dynamical systems (Lessard et al., 2014).

In this work, we derive a second-order ODE which is the exact limit of Nesterov's scheme by taking small step sizes in (1); to the best of our knowledge, this work is the first to use ODEs to model Nesterov's scheme or its variants in this limit. One surprising fact in connection with this subject is that a *first-order* scheme is modeled by a *second-order* ODE. This ODE takes the following form:

$$\ddot{X} + \frac{3}{t} \dot{X} + \nabla f(X) = 0 \quad (3)$$

for $t > 0$, with initial conditions $X(0) = x_0, \dot{X}(0) = 0$; here, x_0 is the starting point in Nesterov's scheme, $\dot{X} \equiv dX/dt$ denotes the time derivative or velocity and similarly

$\dot{X} \equiv d^2X/dt^2$ denotes the acceleration. The time parameter in this ODE is related to the step size in (1) via $t \approx k\sqrt{s}$. Expectedly, it also enjoys inverse quadratic convergence rate as its discrete analog,

$$f(X(t)) - f^* \leq O\left(\frac{\|x_0 - x^*\|^2}{t^2}\right).$$

Approximate equivalence between Nesterov's scheme and the ODE is established later in various perspectives, rigorous and intuitive. In the main body of this paper, examples and case studies are provided to demonstrate that the homogeneous and conceptually simpler ODE can serve as a tool for understanding, analyzing and generalizing Nesterov's scheme.

In the following, two insights of Nesterov's scheme are highlighted, the first one on oscillations in the trajectories of this scheme, and the second on the peculiar constant 3 appearing in the ODE.

1.1 From Overdamping to Underdamping

In general, Nesterov's scheme is not monotone in the objective function value due to the introduction of the momentum term. Oscillations or overshoots along the trajectory of iterates approaching the minimizer are often observed when running Nesterov's scheme. Figure 1 presents typical phenomena of this kind, where a two-dimensional convex function is minimized by Nesterov's scheme. Viewing the ODE as a damping system, we obtain interpretations as follows.

Small t . In the beginning, the damping ratio $3/t$ is large. This leads the ODE to be an overdamped system, returning to the equilibrium without oscillating.

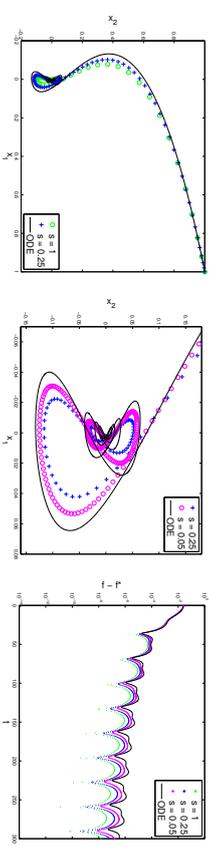

Large t . As t increases, the ODE with a small $3/t$ behaves like an underdamped system, oscillating with the amplitude gradually decreasing to zero.

As depicted in Figure 1a, in the beginning the ODE curve moves smoothly towards the origin, the minimizer x^* . The second interpretation "Large t " provides partial explanation for the oscillations observed in Nesterov's scheme at later stage. Although our analysis extends farther, it is similar in spirit to that carried in O'Donoghue and Candès (2013). In particular, the zoomed Figure 1b presents some butterfly-like oscillations for both the scheme and ODE. There, we see that the trajectory constantly moves away from the origin and returns back later. Each overshoot in Figure 1b causes a bump in the function values, as shown in Figure 1c. We observe also from Figure 1c that the periodicity captured by the bumps are very close to that of the ODE solution. In passing, it is worth mentioning that the solution to the ODE in this case can be expressed via Bessel functions, hence enabling quantitative characterizations of these overshoots and bumps, which are given in full detail in Section 3.

1.2 A Phase Transition

The constant 3, derived from $(k+2) - (k-1)$ in (3), is not haphazard. In fact, it is the smallest constant that guarantees $O(1/t^2)$ convergence rate. Specifically, parameterized by a constant r , the generalized ODE

$$\ddot{X} + \frac{r}{t}\dot{X} + \nabla f(X) = 0$$

(a) Trajectories.

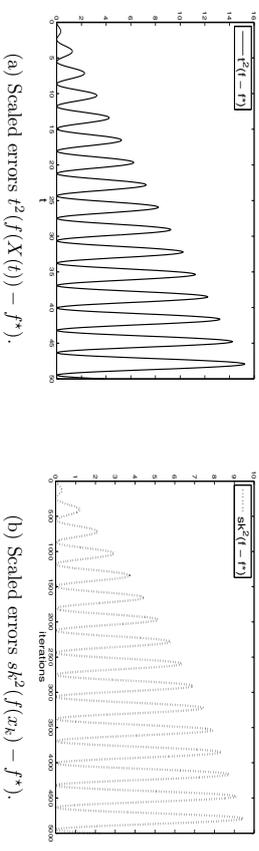

(b) Zoomed trajectories.

(c) Errors $f - f^*$.

Figure 1: Minimizing $f = 2 \times 10^{-2}x_1^2 + 5 \times 10^{-3}x_2^2$, starting from $x_0 = (1, 1)$. The black and solid curves correspond to the solution to the ODE. In (c), for the x-axis we use the identification between time and iterations, $t = k\sqrt{s}$.

can be translated into a generalized Nesterov's scheme that is the same as the original (1) except for $(k-1)/(k+2)$ being replaced by $(k-1)/(k+r-1)$. Surprisingly, for both generalized ODEs and schemes, the inverse quadratic convergence is guaranteed if and only if $r \geq 3$. This phase transition suggests there might be deep causes for acceleration among first-order methods. In particular, for $r \geq 3$, the worst case constant in this inverse quadratic convergence rate is minimized at $r = 3$.

Figure 2 illustrates the growth of $t^2(f(X(t)) - f^*)$ and $sk^2(f(x_k) - f^*)$, respectively, for the generalized ODE and scheme with $r = 1$, where the objective function is simply $f(x) = \frac{1}{2}x^2$. Inverse quadratic convergence fails to be observed in both Figures 2a and 2b, where the scaled errors grow with t or iterations, for both the generalized ODE and scheme.

(a) Scaled errors $t^2(f(X(t)) - f^*)$.

(b) Scaled errors $sk^2(f(x_k) - f^*)$.

Figure 2: Minimizing $f = \frac{1}{2}x^2$ by the generalized ODE and scheme with $r = 1$, starting from $x_0 = 1$. In (b), the step size $s = 10^{-4}$.

1.3 Outline and Notation

The rest of the paper is organized as follows. In Section 2, the ODE is rigorously derived from Nesterov's scheme, and a generalization to composite optimization, where f may be non-smooth, is also obtained. Connections between the ODE and the scheme, in terms of trajectory behaviors and convergence rates, are summarized in Section 3. In Section

4, we discuss the effect of replacing the constant 3 in (3) by an arbitrary constant on the convergence rate. A new restarting scheme is suggested in Section 5, with linear convergence rate established and empirically observed.

Some standard notations used throughout the paper are collected here. We denote by \mathcal{F}_L the class of convex functions f with L -Lipschitz continuous gradients defined on \mathbb{R}^n , i.e., f is convex, continuously differentiable, and satisfies

$$\|\nabla f(x) - \nabla f(y)\| \leq L\|x - y\|$$

for any $x, y \in \mathbb{R}^n$, where $\|\cdot\|$ is the standard Euclidean norm and $L > 0$ is the Lipschitz constant. Next, \mathcal{S}_μ denotes the class of μ -strongly convex functions f on \mathbb{R}^n with continuous gradients, i.e., f is continuously differentiable and $f(x) - \mu\|x\|^2/2$ is convex. We set $\mathcal{S}_{\mu,L} = \mathcal{F}_L \cap \mathcal{S}_\mu$.

2. Derivation

First, we sketch an informal derivation of the ODE (3). Assume $f \in \mathcal{F}_L$ for $L > 0$. Combining the two equations of (1) and applying a rescaling gives

$$\frac{x_{k+1} - x_k}{\sqrt{s}} = \frac{k-1}{k+2} \frac{x_k - x_{k-1}}{\sqrt{s}} - \sqrt{s} \nabla f(y_k). \quad (4)$$

Introduce the Ansatz $x_k \approx X(k\sqrt{s})$ for some smooth curve $X(t)$ defined for $t \geq 0$. Put $k = t/\sqrt{s}$. Then as the step size s goes to zero, $X(t) \approx x_{t/\sqrt{s}} = x_k$ and $X(t + \sqrt{s}) \approx x_{(t+\sqrt{s})/\sqrt{s}} = x_{k+1}$, and Taylor expansion gives

$$(x_{k+1} - x_k)/\sqrt{s} = \dot{X}(t) + \frac{1}{2} \ddot{X}(t)\sqrt{s} + o(\sqrt{s}), \quad (x_k - x_{k-1})/\sqrt{s} = \dot{X}(t) - \frac{1}{2} \ddot{X}(t)\sqrt{s} + o(\sqrt{s})$$

and $\sqrt{s} \nabla f(y_k) = \sqrt{s} \nabla f(X(t)) + o(\sqrt{s})$. Thus (4) can be written as

$$\begin{aligned} \dot{X}(t) + \frac{1}{2} \ddot{X}(t)\sqrt{s} + o(\sqrt{s}) \\ = \left(1 - \frac{3\sqrt{s}}{t}\right) \left(\dot{X}(t) - \frac{1}{2} \ddot{X}(t)\sqrt{s} + o(\sqrt{s})\right) - \sqrt{s} \nabla f(X(t)) + o(\sqrt{s}). \end{aligned} \quad (5)$$

By comparing the coefficients of \sqrt{s} in (5), we obtain

$$\ddot{X} + \frac{3}{t} \dot{X} + \nabla f(X) = 0.$$

The first initial condition is $X(0) = x_0$. Taking $k = 1$ in (4) yields

$$(x_2 - x_1)/\sqrt{s} = -\sqrt{s} \nabla f(y_1) = o(1).$$

Hence, the second initial condition is simply $\dot{X}(0) = 0$ (vanishing initial velocity).

One popular alternative momentum coefficient is $\theta_k(\theta_{k-1}^{-1} - 1)$, where θ_k are iteratively defined as $\theta_{k+1} = \left(\sqrt{\theta_k^4 + 4\theta_k^2 - \theta_k^2}\right)/2$, starting from $\theta_0 = 1$ (Nesterov, 1983; Beck and

Teboulle, 2009). Simple analysis reveals that $\theta_k(\theta_{k-1}^{-1} - 1)$ asymptotically equals $1 - 3/k + O(1/k^2)$, thus leading to the same ODE as (1).

Classical results in ODE theory do not directly imply the existence or uniqueness of the solution to this ODE because the coefficient $3/t$ is singular at $t = 0$. In addition, ∇f is typically not analytic at x_0 , which leads to the inapplicability of the power series method for studying singular ODEs. Nevertheless, the ODE is well posed: the strategy we employ for showing this constructs a series of ODEs approximating (3), and then chooses a convergent subsequence by some compactness arguments such as the Arzelà-Ascoli theorem. Below, $C^2((0, \infty); \mathbb{R}^n)$ denotes the class of twice continuously differentiable maps from $(0, \infty)$ to \mathbb{R}^n ; similarly, $C^1([0, \infty); \mathbb{R}^n)$ denotes the class of continuously differentiable maps from $[0, \infty)$ to \mathbb{R}^n .

Theorem 1 For any $f \in \mathcal{F}_\infty := \cup_{L>0} \mathcal{F}_L$ and any $x_0 \in \mathbb{R}^n$, the ODE (3) with initial conditions $X(0) = x_0, \dot{X}(0) = 0$ has a unique global solution $X \in C^2((0, \infty); \mathbb{R}^n) \cap C^1([0, \infty); \mathbb{R}^n)$.

The next theorem, in a rigorous way, guarantees the validity of the derivation of this ODE. The proofs of both theorems are deferred to the appendices.

Theorem 2 For any $f \in \mathcal{F}_\infty$, as the step size $s \rightarrow 0$, Nesterov's scheme (1) converges to the ODE (3) in the sense that for all fixed $T > 0$,

$$\lim_{s \rightarrow 0} \max_{0 \leq k \leq \frac{T}{\sqrt{s}}} \|x_k - X(k\sqrt{s})\| = 0.$$

2.1 Simple Properties

We collect some elementary properties that are helpful in understanding the ODE.

Time Invariance. If we adopt a linear time transformation, $\tilde{t} = ct$ for some $c > 0$, by the chain rule it follows that

$$\frac{dX}{d\tilde{t}} = \frac{1}{c} \frac{dX}{dt}, \quad \frac{d^2X}{d\tilde{t}^2} = \frac{1}{c^2} \frac{d^2X}{dt^2}.$$

This yields the ODE parameterized by \tilde{t} ,

$$\frac{d^2X}{d\tilde{t}^2} + \frac{3}{\tilde{t}} \frac{dX}{d\tilde{t}} + \nabla f(X)/c^2 = 0.$$

Also note that minimizing f/c^2 is equivalent to minimizing f . Hence, the ODE is invariant under the time change. In fact, it is easy to see that time invariance holds if and only if the coefficient of \dot{X} has the form C/t for some constant C .

Rotational Invariance. Nesterov's scheme and other gradient-based schemes are invariant under rotations. As expected, the ODE is also invariant under orthogonal transformation. To see this, let $Y = QX$ for some orthogonal matrix Q . This leads to $\dot{Y} = Q\dot{X}$, $\ddot{Y} = Q\ddot{X}$ and $\nabla_Y f = Q\nabla_X f$. Hence, denoting by Q^T the transpose of Q , the ODE in the new coordinate system reads $Q^T \ddot{Y} + \frac{3}{\tilde{t}} Q^T \dot{Y} + Q^T \nabla_Y f = 0$, which is of the same form as (3) once multiplying Q on both sides.

Initial Asymptotic. Assume sufficient smoothness of X such that $\lim_{t \rightarrow 0} \ddot{X}(t)$ exists. The mean value theorem guarantees the existence of some $\xi \in (0, t)$ that satisfies $\dot{X}(t)/t = (\dot{X}(t) - \dot{X}(0))/t = \ddot{X}(\xi)$. Hence, from the ODE we deduce $\dot{X}(t) + 3\dot{X}(\xi) + \nabla f(X(t)) = 0$.

Taking the limit $t \rightarrow 0$ gives $\dot{X}(0) = -\nabla f(x_0)/4$. Hence, for small t we have the asymptotic form:

$$X(t) = -\frac{\nabla f(x_0)t^2}{8} + x_0 + o(t^2).$$

This asymptotic expansion is consistent with the empirical observation that Nesterov's scheme moves slowly in the beginning.

2.2 ODE for Composite Optimization

It is interesting and important to generalize the ODE to minimizing f in the composite form $f(x) = g(x) + h(x)$, where the smooth part $g \in \mathcal{F}_L$ and the non-smooth part $h : \mathbb{R}^n \rightarrow (-\infty, \infty]$ is a structured general convex function. Both Nesterov (2013) and Beck and Teboulle (2009) obtain $O(1/k^2)$ convergence rate by employing the proximal structure of h . In analogy to the smooth case, an ODE for composite f is derived in the appendix.

3. Connections and Interpretations

In this section, we explore the approximate equivalence between the ODE and Nesterov's scheme, and provide evidence that the ODE can serve as an amenable tool for interpreting and analyzing Nesterov's scheme. The first subsection exhibits inverse quadratic convergence rate for the ODE solution, the next two address the oscillation phenomenon discussed in Section 1.1, and the last subsection is devoted to comparing Nesterov's scheme with gradient descent from a numerical perspective.

3.1 Analogous Convergence Rate

The original result from Nesterov (1983) states that, for any $f \in \mathcal{F}_L$, the sequence $\{x_k\}$ given by (1) with step size $s \leq 1/L$ satisfies

$$f(x_k) - f^* \leq \frac{2\|x_0 - x^*\|^2}{s(k+1)^2}. \quad (6)$$

Our next result indicates that the trajectory of (3) closely resembles the sequence $\{x_k\}$ in terms of the convergence rate to a minimizer x^* . Compared with the discrete case, this proof is shorter and simpler.

Theorem 3 *For any $f \in \mathcal{F}_\infty$, let $X(t)$ be the unique global solution to (3) with initial conditions $X(0) = x_0, \dot{X}(0) = 0$. Then, for any $t > 0$,*

$$f(X(t)) - f^* \leq \frac{2\|x_0 - x^*\|^2}{t^2}. \quad (7)$$

Our next result indicates that the trajectory of (3) closely resembles the sequence $\{x_k\}$ in terms of the convergence rate to a minimizer x^* . Compared with the discrete case, this proof is shorter and simpler.

$$\mathcal{E} = 2t(f(X) - f^*) + t^2 \langle \nabla f, \dot{X} \rangle + 4 \left\langle X + \frac{t}{2} \dot{X} - x^*, \frac{3}{2} \dot{X} + \frac{t}{2} \ddot{X} \right\rangle.$$

Proof Consider the energy functional¹ defined as $\mathcal{E}(t) = t^2(f(X(t)) - f^*) + 2\|X + t\dot{X}/2 - x^*\|^2$, whose time derivative is

$$\dot{\mathcal{E}} = 2t(f(X) - f^*) + t^2 \langle \nabla f, \dot{X} \rangle + 4 \left\langle X + \frac{t}{2} \dot{X} - x^*, \frac{3}{2} \dot{X} + \frac{t}{2} \ddot{X} \right\rangle.$$

1. We may also view this functional as the negative entropy. Similarly, for the gradient flow $\dot{X} + \nabla f(X) = 0$, an energy function of form $\mathcal{E}_{\text{gradient}}(t) = t(f(X(t)) - f^*) + \|X(t) - x^*\|^2/2$ can be used to derive the bound $f(X(t)) - f^* \leq \frac{\|x_0 - x^*\|^2}{2t}$.

Substituting $3\dot{X}/2 + t\ddot{X}/2$ with $-\nabla f(X)/2$, the above equation gives

$$\dot{\mathcal{E}} = 2t(f(X) - f^*) + 4\langle X - x^*, -\nabla f(X)/2 \rangle = 2t(f(X) - f^*) - 2t\langle X - x^*, \nabla f(X) \rangle \leq 0,$$

where the inequality follows from the convexity of f . Hence by monotonicity of \mathcal{E} and non-negativity of $2\|X + t\dot{X}/2 - x^*\|^2$, the gap satisfies

$$f(X(t)) - f^* \leq \frac{\mathcal{E}(t)}{t^2} \leq \frac{\mathcal{E}(0)}{t^2} = \frac{2\|x_0 - x^*\|^2}{t^2}. \quad \blacksquare$$

Making use of the approximation $t \approx k\sqrt{s}$, we observe that the convergence rate in (6) is essentially a discrete version of that in (7), providing yet another piece of evidence for the approximate equivalence between the ODE and the scheme.

We finish this subsection by showing that the number 2 appearing in the numerator of the error bound in (7) is optimal. Consider an arbitrary $f \in \mathcal{F}_\infty(\mathbb{R})$ such that $f(x) = x$ for $x \geq 0$. Starting from some $x_0 > 0$, the solution to (3) is $X(t) = x_0 - t^2/8$ before hitting the origin. Hence, $t^2(f(X(t)) - f^*) = t^2(x_0 - t^2/8)$ has a maximum $2x_0^2 = 2|x_0 - 0|^2$ achieved at $t = 2\sqrt{x_0}$. Therefore, we cannot replace 2 by any smaller number, and we can expect that this tightness also applies to the discrete analog (6).

3.2 Quadratic f and Bessel Functions

For quadratic f , the ODE (3) admits a solution in closed form. This closed form solution turns out to be very useful in understanding the issues raised in the introduction.

Let $f(x) = \frac{1}{2}\langle x, Ax \rangle + \langle b, x \rangle$, where $A \in \mathbb{R}^{n \times n}$ is a positive semidefinite matrix and b is in the column space of A because otherwise this function can attain $-\infty$. Then a simple translation in x can absorb the linear term $\langle b, x \rangle$ into the quadratic term. Since both the ODE and the scheme move within the affine space perpendicular to the kernel of A , without loss of generality, we assume that A is positive definite, admitting a spectral decomposition $A = Q^T \Lambda Q$, where Λ is a diagonal matrix formed by the eigenvalues. Replacing x with Qx , we assume $f = \frac{1}{2}\langle x, Ax \rangle$ from now on. Now, the ODE for this function admits a simple decomposition of form

$$\ddot{X}_i + \frac{3}{t} \dot{X}_i + \lambda_i X_i = 0, \quad i = 1, \dots, n$$

with $X_i(0) = x_{0,i}, \dot{X}_i(0) = 0$. Introduce $Y_i(u) = uX_i(u/\sqrt{\lambda_i})$, which satisfies

$$u^2 \ddot{Y}_i + u \dot{Y}_i + (u^2 - 1)Y_i = 0.$$

This is Bessel's differential equation of order one. Since Y_i vanishes at $u = 0$, we see that Y_i is a constant multiple of J_1 , the Bessel function of the first kind of order one.² It has an analytic expansion:

$$J_1(u) = \sum_{m=0}^{\infty} \frac{(-1)^m}{(2m)!(2m+2)!} u^{2m+1},$$

2. Up to a constant multiplier, J_1 is the unique solution to the Bessel's differential equation $u^2 \ddot{J}_1 + u \dot{J}_1 + (u^2 - 1)J_1 = 0$ that is finite at the origin. In the analytic expansion of J_1 , $m!!$ denotes the double factorial defined as $m!! = m \times (m-2) \times \dots \times 2$ for even m , or $m!! = m \times (m-2) \times \dots \times 1$ for odd m .

which gives the asymptotic expansion

$$J_1(u) = (1 + o(1)) \frac{u}{2}$$

when $u \rightarrow 0$. Requiring $X_i(0) = x_{0,i}$, hence, we obtain

$$X_i(t) = \frac{2x_{0,i}}{t\sqrt{\lambda_i}} J_1(t\sqrt{\lambda_i}). \quad (8)$$

For large t , the Bessel function has the following asymptotic form (see e.g. Watson, 1995):

$$J_1(t) = \sqrt{\frac{2}{\pi t}} \left(\cos(t - 3\pi/4) + O(1/t) \right). \quad (9)$$

This asymptotic expansion yields (note that $f^* = 0$)

$$f(X(t)) - f^* = f(X(t)) = \sum_{i=1}^n \frac{2x_{0,i}^2}{t^2} J_1^2(t\sqrt{\lambda_i})^2 = O\left(\frac{\|x_0 - x^*\|^2}{t^3 \sqrt{\min \lambda_i}}\right). \quad (10)$$

On the other hand, (9) and (10) give a lower bound:

$$\begin{aligned} \limsup_{t \rightarrow \infty} t^3 (f(X(t)) - f^*) &\geq \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t u^3 (f(X(u)) - f^*) du \\ &= \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \sum_{i=1}^n 2x_{0,i}^2 u J_1^2(u\sqrt{\lambda_i})^2 du \\ &= \sum_{i=1}^n \frac{2x_{0,i}^2}{\pi\sqrt{\lambda_i}} \geq \frac{2\|x_0 - x^*\|^2}{\pi\sqrt{L}}, \end{aligned} \quad (11)$$

where $L = \|A\|_2$ is the spectral norm of A . The first inequality follows by interpreting $\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t x^3 (f(X(u)) - f^*) du$ as the mean of $x^3 (f(X(u)) - f^*)$ on $(0, \infty)$ in certain sense.

In view of (10), Nesterov's scheme might possibly exhibit $O(1/k^3)$ convergence rate for strongly convex functions. This convergence rate is consistent with the second inequality in Theorem 6. In Section 4.3, we prove the $O(1/t^3)$ rate for a generalized version of (3). However, (11) rules out the possibility of a higher order convergence rate.

Recall that the function considered in Figure 1 is $f(x) = 0.02x_1^2 + 0.005x_2^2$, starting from $x_0 = (1, 1)$. As the step size s becomes smaller, the trajectory of Nesterov's scheme converges to the solid curve represented via the Bessel function. While approaching the minimizer x^* , each trajectory displays the oscillation pattern, as well-captured by the zoomed Figure 1b. This prevents Nesterov's scheme from achieving better convergence rate. The representation (8) offers excellent explanation as follows. Denote by T_1, T_2 , respectively, the approximate periodicities of the first component $|X_1|$ in absolute value and the second $|X_2|$. By (9), we get $T_1 = \pi/\sqrt{\lambda_1} = 5\pi$ and $T_2 = \pi/\sqrt{\lambda_2} = 10\pi$. Hence, as the amplitude gradually decreases to zero, the function $f = 2x_{0,1}^2 J_1(\sqrt{\lambda_1}t)^2/t^2 + 2x_{0,2}^2 J_1(\sqrt{\lambda_2}t)^2/t^2$ has a major cycle of 10π , the least common multiple of T_1 and T_2 . A careful look at Figure 1c reveals that within each major bump, roughly, there are $10\pi/T_1 = 2$ minor peaks.

3.3 Fluctuations of Strongly Convex f

The analysis carried out in the previous subsection only applies to convex quadratic functions. In this subsection, we extend the discussion to one-dimensional strongly convex functions. The Sturm-Picone theory (see e.g. Hinton, 2005) is extensively used all along the analysis.

Let $f \in \mathcal{S}_{\mu,L}(\mathbb{R})$. Without loss of generality, assume f attains minimum at $x^* = 0$. Then, by definition $\mu \leq f'(x)/x \leq L$ for any $x \neq 0$. Denoting by X the solution to the ODE (3), we consider the self-adjoint equation,

$$(t^3 Y')' + \frac{t^3 f'(X(t))}{X(t)} Y = 0, \quad (12)$$

which, apparently, admits a solution $Y(t) = X(t)$. To apply the Sturm-Picone comparison theorem, consider

$$(t^3 Y')' + \mu t^3 Y = 0$$

for a comparison. This equation admits a solution $\tilde{Y}(t) = J_1(\sqrt{\mu}t)/t$. Denote by $\tilde{t}_1 < \tilde{t}_2 < \dots$ all the positive roots of $J_1(t)$, which satisfy (see e.g. Watson, 1995)

$$3.8317 = \tilde{t}_1 - \tilde{t}_0 > \tilde{t}_2 - \tilde{t}_3 > \tilde{t}_3 - \tilde{t}_4 > \dots > \pi,$$

where $\tilde{t}_0 = 0$. Then, it follows that the positive roots of \tilde{Y} are $\tilde{t}_1/\sqrt{\mu}, \tilde{t}_2/\sqrt{\mu}, \dots$. Since $t^3 f'(X(t))/X(t) \geq \mu t^3$, the Sturm-Picone comparison theorem asserts that $X(t)$ has a root in each interval $[\tilde{t}_i/\sqrt{\mu}, \tilde{t}_{i+1}/\sqrt{\mu}]$.

To obtain a similar result in the opposite direction, consider

$$(t^3 Y')' + Lt^3 Y = 0. \quad (13)$$

Applying the Sturm-Picone comparison theorem to (12) and (13), we ensure that between any two consecutive positive roots of X , there is at least one \tilde{t}_i/\sqrt{L} . Now, we summarize our findings in the following. Roughly speaking, this result concludes that the oscillation frequency of the ODE solution is between $O(\sqrt{\mu})$ and $O(\sqrt{L})$.

Theorem 4 *Denote by $0 < t_1 < t_2 < \dots$ all the roots of $X(t) - x^*$. Then these roots satisfy, for all $i \geq 1$,*

$$t_1 < \frac{7.6635}{\sqrt{\mu}}, \quad t_{i+1} - t_i < \frac{7.6635}{\sqrt{\mu}}, \quad t_{i+2} - t_i > \frac{\pi}{\sqrt{L}}.$$

3.4 Nesterov's Scheme Compared with Gradient Descent

The ansatz $t \approx k\sqrt{s}$ in relating the ODE and Nesterov's scheme is formally confirmed in Theorem 2. Consequently, for any constant $t_c > 0$, this implies that x_k does not change much for a range of step sizes s if $k \approx t_c/\sqrt{s}$. To empirically support this claim, we present an example in Figure 3a, where the scheme minimizes $f(x) = \|y - Ax\|_2^2/2 + \|x\|_1$ with $y = (4, 2, 0)$ and $A(:, 1) = (0, 2, 4)$, $A(:, 2) = (1, 1, 1)$ starting from $x_0 = (2, 0)$ (here $A(:, j)$ is the j th column of A). From this figure, we are delighted to observe that x_k with the same t_c are very close to each other.

This interesting square-root scaling has the potential to shed light on the superiority of Nesterov's scheme over gradient descent. Roughly speaking, each iteration in Nesterov's scheme amounts to traveling \sqrt{s} in time along the integral curve of (3), whereas it is known that the simple gradient descent $x_{k+1} = x_k - s\nabla f(x_k)$ moves s along the integral curve of $\dot{X} + \nabla f(X) = 0$. We expect that for small s Nesterov's scheme moves more in each iteration since \sqrt{s} is much larger than s . Figure 3b illustrates and supports this claim, where the function minimized is $f = |x_1|^3 + 5|x_2|^3 + 0.001(x_1 + x_2)^2$ with step size $s = 0.05$ (The coordinates are appropriately rotated to allow x_0 and x^* lie on the same horizontal line). The circles are the iterates for $k = 1, 10, 20, 30, 45, 60, 90, 120, 150, 190, 250, 300$. For Nesterov's scheme, the seventh iterates for $k = 15$, while for gradient descent the last point has merely arrived at $t = 15$.

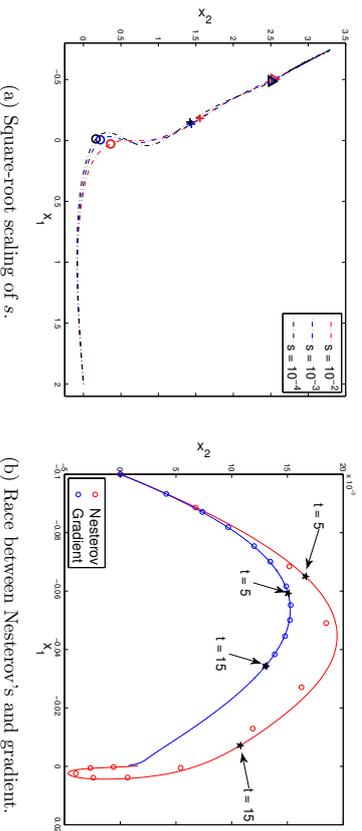

Figure 3: In (a), the circles, crosses and triangles are x_k evaluated at $k = \lceil 1/\sqrt{s} \rceil, \lceil 2/\sqrt{s} \rceil$ and $\lceil 3/\sqrt{s} \rceil$, respectively. In (b), the circles are iterations given by Nesterov's scheme or gradient descent, depending on the color, and the stars are $X(t)$ on the integral curves for $t = 5, 15$.

A second look at Figure 3b suggests that Nesterov's scheme allows a large deviation from its limit curve, as compared with gradient descent. This raises the question of the stable step size allowed for numerically solving the ODE (3) in the presence of accumulated errors. The finite difference approximation by the forward Euler method is

$$\frac{X(t + \Delta t) - 2X(t) + X(t - \Delta t)}{\Delta t^2} + \frac{3}{t} \frac{X(t) - X(t - \Delta t)}{\Delta t} + \nabla f(X(t)) = 0, \quad (14)$$

which is equivalent to

$$X(t + \Delta t) = \left(2 - \frac{3\Delta t}{t}\right)X(t) - \Delta t^2 \nabla f(X(t)) - \left(1 - \frac{3\Delta t}{t}\right)X(t - \Delta t). \quad (15)$$

Assuming f is sufficiently smooth, we have $\nabla f(x + \delta x) \approx \nabla f(x) + \nabla^2 f(x)\delta x$ for small perturbations δx , where $\nabla^2 f(x)$ is the Hessian of f evaluated at x . Identifying $k = t/\Delta t$,

the characteristic equation of this finite difference scheme is approximately

$$\det \left(\lambda^2 - \left(2 - \Delta t^2 \nabla^2 f - \frac{3\Delta t}{t}\right) \lambda + 1 - \frac{3\Delta t}{t} \right) = 0. \quad (16)$$

The numerical stability of (14) with respect to accumulated errors is equivalent to this: all the roots of (16) lie in the unit circle (see e.g. Leader, 2004). When $\nabla^2 f \leq L I_n$ (i.e. $L I_n - \nabla^2 f$ is positive semidefinite), if $\Delta t/t$ small and $\Delta t < 2/\sqrt{L}$, we see that all the roots of (16) lie in the unit circle. On the other hand, if $\Delta t > 2/\sqrt{L}$, (16) can possibly have a root λ outside the unit circle, causing numerical instability. Under our identification $s = \Delta t^2$, a step size of $s = 1/L$ in Nesterov's scheme (1) is approximately equivalent to a step size of $\Delta t = 1/\sqrt{L}$ in the forward Euler method, which is stable for numerically integrating (14). As a comparison, note that the finite difference scheme of the ODE $\dot{X}(t) + \nabla f(X(t)) = 0$, which models gradient descent with updates $x_{k+1} = x_k - s\nabla f(x_k)$, has the characteristic equation $\det(\lambda - (1 - \Delta t \nabla^2 f)) = 0$. Thus, to guarantee $-I_n \leq 1 - \Delta t \nabla^2 f \leq I_n$ in worst case analysis, one can only choose $\Delta t \leq 2/L$ for a fixed step size, which is much smaller than the step size $2/\sqrt{L}$ for (14) when ∇f is very variable, i.e., L is large.

4. The Magic Constant 3

Recall that the constant 3 appearing in the coefficient of \dot{X} in (3) originates from $(k+2) - (k-1) = 3$. This number leads to the momentum coefficient in (1) taking the form $(k-1)/(k+2) = 1 - 3/k + O(1/k^2)$. In this section, we demonstrate that 3 can be replaced by any larger number, while maintaining the $O(1/k^2)$ convergence rate. To begin with, let us consider the following ODE parameterized by a constant r :

$$\ddot{X} + \frac{r}{t} \dot{X} + \nabla f(X) = 0 \quad (17)$$

with initial conditions $X(0) = x_0, \dot{X}(0) = 0$. The proof of Theorem 1, which seamlessly applies here, guarantees the existence and uniqueness of the solution X to this ODE.

Interpreting the damping ratio r/t as a measure of friction³ in the damping system, our results say that more friction does not end the $O(1/t^2)$ and $O(1/k^2)$ convergence rate. On the other hand, in the lower friction setting, where r is smaller than 3, we can no longer expect inverse quadratic convergence rate, unless some additional structures of f are imposed. We believe that this striking phase transition at 3 deserves more attention as an interesting research challenge.

4.1 High Friction

Here, we study the convergence rate of (17) with $r > 3$ and $f \in \mathcal{F}_\infty$. Compared with (3), this new ODE as a damping suffers from higher friction. Following the strategy adopted in the proof of Theorem 3, we consider a new energy functional defined as

$$\mathcal{E}(t) = \frac{2t^2}{r-1} (f(X(t)) - f^*) + (r-1) \left\| X(t) + \frac{t}{r-1} \dot{X}(t) - x^* \right\|^2.$$

3. In physics and engineering, damping may be modeled as a force proportional to velocity but opposite in direction, i.e. resisting motion; for instance, this force may be used as an approximation to the friction caused by drag. In our model, this force would be proportional to $-t\dot{X}$ where \dot{X} is velocity and $\frac{r}{t}$ is the damping coefficient.

By studying the derivative of this functional, we get the following result.

Theorem 5 *The solution X to (17) satisfies*

$$f(X(t)) - f^* \leq \frac{(r-1)^2 \|x_0 - x^*\|^2}{2t^2}, \quad \int_0^\infty t(f(X(t)) - f^*) dt \leq \frac{(r-1)^2 \|x_0 - x^*\|^2}{2(r-3)}.$$

Proof Noting $r\dot{X} + t\ddot{X} = -t\nabla f(X)$, we get $\dot{\mathcal{E}}$ equal to

$$\begin{aligned} \frac{4t}{r-1}(f(X) - f^*) + \frac{2t^2}{r-1}\langle \nabla f, \dot{X} \rangle + 2\langle X + \frac{t}{r-1}\dot{X} - x^*, r\dot{X} + t\ddot{X} \rangle \\ = \frac{4t}{r-1}(f(X) - f^*) - 2t\langle X - x^*, \nabla f(X) \rangle \leq -\frac{2(r-3)t}{r-1}(f(X) - f^*), \end{aligned} \quad (18)$$

where the inequality follows from the convexity of f . Since $f(X) \geq f^*$, the last display implies that \mathcal{E} is non-increasing. Hence

$$\frac{2t^2}{r-1}(f(X(t)) - f^*) \leq \mathcal{E}(t) \leq \mathcal{E}(0) = (r-1)\|x_0 - x^*\|^2,$$

yielding the first inequality of this theorem. To complete the proof, from (18) it follows that

$$\int_0^\infty \frac{2(r-3)t}{r-1}(f(X) - f^*) dt \leq -\int_0^\infty \frac{d\mathcal{E}}{dt} dt = \mathcal{E}(0) - \mathcal{E}(\infty) \leq (r-1)\|x_0 - x^*\|^2,$$

as desired for establishing the second inequality. \blacksquare

The first inequality is the same as (7) for the ODE (3), except for a larger constant $(r-1)^2/2$. The second inequality measures the error $f(X(t)) - f^*$ in an average sense, and cannot be deduced from the first inequality.

Now, it is tempting to obtain such analogs for the discrete Nesterov's scheme as well. Following the formulation of Beck and Teboulle (2009), we wish to minimize f in the composite form $f(x) = g(x) + h(x)$, where $g \in \mathcal{F}_L$ for some $L > 0$ and h is convex on \mathbb{R}^n possibly assuming extended value ∞ . Define the proximal subgradient

$$G_s(x) \triangleq \frac{x - \operatorname{argmin}_z (\|z - (x - s\nabla g(x))\|^2 / (2s) + h(z))}{s}.$$

Parametrizing by a constant r , we propose the generalized Nesterov's scheme,

$$\begin{aligned} x_k &= y_{k-1} - sG_s(y_{k-1}) \\ y_k &= x_k + \frac{k-1}{k+r-1}(x_k - x_{k-1}), \end{aligned} \quad (19)$$

starting from $y_0 = x_0$. The discrete analog of Theorem 5 is below.

Theorem 6 *The sequence $\{x_k\}$ given by (19) with $0 < s \leq 1/L$ satisfies*

$$f(x_k) - f^* \leq \frac{(r-1)^2 \|x_0 - x^*\|^2}{2s(k+r-2)^2}, \quad \sum_{k=1}^\infty (k+r-1)(f(x_k) - f^*) \leq \frac{(r-1)^2 \|x_0 - x^*\|^2}{2s(r-3)}.$$

The first inequality suggests that the generalized Nesterov's schemes still achieve $O(1/k^2)$ convergence rate. However, if the error bound satisfies $f(x_{k'}) - f^* \geq c/k'^2$ for some arbitrarily small $c > 0$ and a dense subsequence $\{k'\}$, i.e., $\{k'\} \cap \{1, \dots, m\} \geq \alpha m$ for all $m \geq 1$ and some $\alpha > 0$, then the second inequality of the theorem would be violated. To see this, note that if it were the case, we would have $(k' + r - 1)(f(x_{k'}) - f^*) \geq \frac{\alpha}{k'}$; the sum of the harmonic series $\frac{1}{k'}$ over a dense subset of $\{1, 2, \dots\}$ is infinite. Hence, the second inequality is not trivial because it implies the error bound is, in some sense, $O(1/k^2)$ suboptimal.

Now we turn to the proof of this theorem. It is worth pointing out that, though based on the same idea, the proof below is much more complicated than that of Theorem 5. **Proof** Consider the discrete energy functional,

$$\mathcal{E}(k) = \frac{2(k+r-2)^2 s}{r-1}(f(x_k) - f^*) + (r-1)\|z_k - x^*\|^2,$$

where $z_k = (k+r-1)y_k/(r-1) - ky_k/(r-1)$. If we have

$$\mathcal{E}(k) + \frac{2s[(r-3)(k+r-2)+1]}{r-1}(f(x_{k-1}) - f^*) \leq \mathcal{E}(k-1), \quad (20)$$

then it would immediately yield the desired results by summing (20) over k . That is, by recursively applying (20), we see

$$\begin{aligned} \mathcal{E}(k) + \sum_{i=1}^k \frac{2s[(r-3)(i+r-2)+1]}{r-1}(f(x_{i-1}) - f^*) \\ \leq \mathcal{E}(0) = \frac{2(r-2)^2 s}{r-1}(f(x_0) - f^*) + (r-1)\|x_0 - x^*\|^2, \end{aligned}$$

which is equivalent to

$$\mathcal{E}(k) + \sum_{i=1}^{k-1} \frac{2s[(r-3)(i+r-1)+1]}{r-1}(f(x_i) - f^*) \leq (r-1)\|x_0 - x^*\|^2. \quad (21)$$

Noting that the left-hand side of (21) is lower bounded by $2s(k+r-2)^2(f(x_k) - f^*)/(r-1)$, we thus obtain the first inequality of the theorem. Since $\mathcal{E}(k) \geq 0$, the second inequality is verified via taking the limit $k \rightarrow \infty$ in (21) and replacing $(r-3)(i+r-1) + 1$ by $(r-3)(i+r-1)$.

We now establish (20). For $s \leq 1/L$, we have the basic inequality,

$$f(y - sG_s(y)) \leq f(x) + G_s(y)^T(y - x) - \frac{s}{2}\|G_s(y)\|^2, \quad (22)$$

for any x and y . Note that $y_{k-1} - sG_s(y_{k-1})$ actually coincides with x_k . Summing of $(k-1)/(k+r-2) \times (22)$ with $x = x_{k-1}, y = y_{k-1}$ and $(r-1)/(k+r-2) \times (22)$ with $x = x^*, y = y_{k-1}$ gives

$$\begin{aligned} f(x_k) &\leq \frac{k-1}{k+r-2}f(x_{k-1}) + \frac{r-1}{k+r-2}f^* \\ &\quad + \frac{r-1}{k+r-2}G_s(y_{k-1})^T \left(\frac{k+r-2}{r-1}y_{k-1} - \frac{k-1}{r-1}x_{k-1} - x^* \right) - \frac{s}{2}\|G_s(y_{k-1})\|^2 \\ &= \frac{k-1}{k+r-2}f(x_{k-1}) + \frac{r-1}{k+r-2}f^* + \frac{(r-1)^2}{2s(k+r-2)^2} (\|z_{k-1} - x^*\|^2 - \|z_k - x^*\|^2), \end{aligned}$$

where we use $z_{k-1} - s(k+r-2)G_s(y_{k-1})/(r-1) = z_k$. Rearranging the above inequality and multiplying by $2s(k+r-2)^2/(r-1)$ gives the desired (20). \blacksquare

In closing, we would like to point out this new scheme is equivalent to setting $\theta_k = (r-1)/(k+r-1)$ and letting $\theta_k(\theta_{k-1}^{-1}-1)$ replace the momentum coefficient $(k-1)/(k+r-1)$. Then, the equal sign “=” in the update $\theta_{k+1} = (\sqrt{\theta_k^4 + 4\theta_k^2} - \theta_k^2)/2$ has to be replaced by an inequality sign “ \geq ”. In examining the proof of Theorem 1(b) in Tseng (2010), we can get an alternative proof of Theorem 6.

4.2 Low Friction

Now we turn to the case $r < 3$. Then, unfortunately, the energy functional approach for proving Theorem 5 is no longer valid, since the left-hand side of (18) is positive in general. In fact, there are counterexamples that fail the desired $O(1/t^2)$ or $O(1/k^2)$ convergence rate. We present such examples in continuous time. Equally, these examples would also violate the $O(1/k^2)$ convergence rate in the discrete schemes, and we forego the details.

Let $f(x) = \frac{1}{2}\|x\|^2$ and X be the solution to (17). Then, $Y = t^{\frac{r-1}{2}}X$ satisfies

$$t^2\dot{Y} + (t^2 - (r-1)^2/4)Y = 0.$$

With the initial condition $Y(t) \approx t^{\frac{r-1}{2}}x_0$ for small t , the solution to the above Bessel equation in a vector form of order $(r-1)/2$ is $Y(t) = 2^{\frac{r-1}{2}}\Gamma((r+1)/2)J_{(r-1)/2}(t)x_0$. Thus,

$$X(t) = \frac{2^{\frac{r-1}{2}}\Gamma((r+1)/2)J_{(r-1)/2}(t)}{t^{\frac{r-1}{2}}}x_0.$$

For large t , the Bessel function $J_{(r-1)/2}(t) = \sqrt{2/(\pi t)}(\cos t - (r-1)\pi/4 - \pi/4) + O(1/t)$. Hence,

$$f(X(t)) - f^* = O(\|x_0 - x^*\|^2/t^r),$$

where the exponent r is tight. This rules out the possibility of inverse quadratic convergence of the generalized ODE and scheme for all $f \in \mathcal{F}_L$ if $r < 2$. An example with $r = 1$ is plotted in Figure 2.

Next, we consider the case $2 \leq r < 3$ and let $f(x) = |x|$ (this also applies to multivariate $f = \|x\|$).⁴ Starting from $x_0 > 0$, we get $X(t) = x_0 - \frac{t^2}{2(1+r)}$ for $t \leq \sqrt{2(1+r)x_0}$. Requiring continuity of X and \dot{X} at the change point 0, we get

$$X(t) = \frac{t^2}{2(1+r)} + \frac{2(2(1+r)x_0)^{\frac{r-1}{2}}}{(r^2-1)t^{r-1}} - \frac{r+3}{r-1}x_0$$

for $\sqrt{2(1+r)x_0} < t \leq \sqrt{2c^*(1+r)x_0}$, where c^* is the positive root other than 1 of $(r-1)c + 4c^{\frac{r-1}{2}} = r+3$. Repeating this process solves for X . Note that t^{1-r} is in the null

4. This function does not have a Lipschitz continuous gradient. However, a similar pattern as in Figure 2 can be also observed if we smooth $|x|$ at an arbitrarily small vicinity of 0.

space of $\dot{X} + r\dot{X}/t$ and satisfies $t^2 \times t^{1-r} \rightarrow \infty$ as $t \rightarrow \infty$. For illustration, Figure 4 plots $t^2(f(X(t)) - f^*)$ and $sk^2(f(x_k) - f^*)$ with $r = 2, 2.5$, and $r = 4$ for comparison⁵. It is clearly that inverse quadratic convergence does not hold for $r = 2, 2.5$, that is, (2) does not hold for $r < 3$. Interestingly, in Figures 4a and 4d, the scaled errors at peaks grow linearly, whereas for $r = 2.5$, the growth rate, though positive as well, seems sublinear.

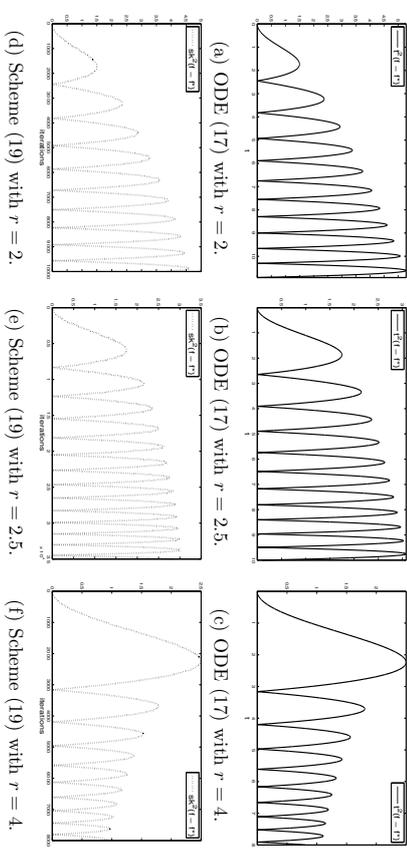

Figure 4: Scaled errors $t^2(f(X(t)) - f^*)$ and $sk^2(f(x_k) - f^*)$ of generalized ODEs and schemes for minimizing $f = |x|$. In (d), the step size $s = 10^{-6}$, in (e), $s = 10^{-7}$, and in (f), $s = 10^{-6}$.

However, if f possesses some additional property, inverse quadratic convergence is still guaranteed, as stated below. In that theorem, f is assumed to be a continuously differentiable convex function.

Theorem 7 Suppose $1 < r < 3$ and let X be a solution to the ODE (17). If $(f - f^*)^{\frac{r-1}{2}}$ is also convex, then

$$f(X(t)) - f^* \leq \frac{(r-1)^2\|x_0 - x^*\|^2}{2t^2}.$$

Proof Since $(f - f^*)^{\frac{r-1}{2}}$ is convex, we obtain

$$(f(X(t)) - f^*)^{\frac{r-1}{2}} \leq \langle X - x^*, \nabla(f(X) - f^*)^{\frac{r-1}{2}} \rangle = \frac{r-1}{2}(f(X) - f^*)^{\frac{r-3}{2}} \langle X - x^*, \nabla f(X) \rangle,$$

which can be simplified to $\frac{r-2}{r-1}(f(X) - f^*) \leq \langle X - x^*, \nabla f(X) \rangle$. This inequality combined with (18) leads to the monotonically decreasing of $\mathcal{E}(t)$ defined for Theorem 5. This completes the proof by noting $f(X) - f^* \leq (r-1)\mathcal{E}(t)/(2t^2) \leq (r-1)\mathcal{E}(0)/(2t^2) = (r-1)^2\|x_0 - x^*\|^2/(2t^2)$. \blacksquare

5. For Figures 4d, 4e and 4f, if running generalized Nesterov's schemes with too many iterations (e.g. 10^5), the deviations from the ODE will grow. Taking a sufficiently small s can solve this issue.

4.3 Strongly Convex f

Strong convexity is a desirable property for optimization. Making use of this property carefully suggests a generalized Nesterov's scheme that achieves optimal linear convergence (Nesterov, 2004). In that case, even vanilla gradient descent has a linear convergence rate. Unfortunately, the example given in the previous subsection simply rules out such possibility for (1) and its generalizations (19). However, from a different perspective, this example suggests that $O(t^{-r})$ convergence rate can be expected for (17). In the next theorem, we prove a slightly weaker statement of this kind, that is, a provable $O(t^{-\frac{2r}{3}})$ convergence rate is established for strongly convex functions. Bridging this gap may require new tools and more careful analysis.

Let $f \in \mathcal{S}_{\mu,L}(\mathbb{R}^n)$ and consider a new energy functional for $\alpha > 2$ defined as

$$\mathcal{E}(t; \alpha) = t^\alpha (f(X(t)) - f^*) + \frac{(2r - \alpha)^2 t^{\alpha-2}}{8} \|X(t) + \frac{2t}{2r - \alpha} \dot{X} - x^*\|^2.$$

When clear from the context, $\mathcal{E}(t; \alpha)$ is simply denoted as $\mathcal{E}(t)$. For $r > 3$, taking $\alpha = 2r/3$ in the theorem stated below gives $f(X(t)) - f^* \lesssim \|x_0 - x^*\|^2/t^{\frac{2r}{3}}$.

Theorem 8 For any $f \in \mathcal{S}_{\mu,L}(\mathbb{R}^n)$, if $2 \leq \alpha \leq 2r/3$ we get

$$f(X(t)) - f^* \leq \frac{C \|x_0 - x^*\|^2}{\mu^{\frac{\alpha-2}{2}} t^\alpha}$$

for any $t > 0$. Above, the constant C only depends on α and r .

Proof Note that $\dot{\mathcal{E}}(t; \alpha)$ equals

$$\begin{aligned} \alpha t^{\alpha-1} (f(X) - f^*) - \frac{(2r - \alpha)t^{\alpha-1}}{2} \langle X - x^*, \nabla f(X) \rangle + \frac{(\alpha - 2)(2r - \alpha)^2 t^{\alpha-3}}{8} \|X - x^*\|^2 \\ + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{4} \langle \dot{X}, X - x^* \rangle. \end{aligned} \quad (23)$$

By the strong convexity of f , the second term of the right-hand side of (23) is bounded below as

$$\frac{(2r - \alpha)t^{\alpha-1}}{2} \langle X - x^*, \nabla f(X) \rangle \geq \frac{(2r - \alpha)t^{\alpha-1}}{2} (f(X) - f^*) + \frac{\mu(2r - \alpha)t^{\alpha-1}}{4} \|X - x^*\|^2.$$

Substituting the last display into (23) with the awareness of $r \geq 3\alpha/2$ yields

$$\dot{\mathcal{E}} \leq -\frac{(2\mu(2r - \alpha)t^2 - (\alpha - 2)(2r - \alpha)^2)t^{\alpha-3}}{8} \|X - x^*\|^2 + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{8} d \|X - x^*\|^2.$$

Hence, if $t \geq t_\alpha := \sqrt{(\alpha - 2)(2r - \alpha)/(2\mu)}$, we obtain

$$\dot{\mathcal{E}}(t) \leq \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{8} d \|X - x^*\|^2.$$

Integrating the last inequality on the interval (t_α, t) gives

$$\begin{aligned} \mathcal{E}(t) &\leq \mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{8} \|X(t) - x^*\|^2 - \frac{(\alpha - 2)(2r - \alpha)t_\alpha^{\alpha-2}}{8} \|X(t_\alpha) - x^*\|^2 \\ &\quad - \frac{1}{8} \int_{t_\alpha}^t (\alpha - 2)^2 (2r - \alpha) t^{\alpha-3} \|X(u) - x^*\|^2 du \leq \mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{8} \|X(t) - x^*\|^2 \\ &\leq \mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2}}{4\mu} (f(X(t)) - f^*). \end{aligned} \quad (24)$$

Making use of (24), we apply induction on α to finish the proof. First, consider $2 < \alpha \leq 4$. Applying Theorem 5, from (24) we get that $\mathcal{E}(t)$ is upper bounded by

$$\mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(r - 1)^2 (2r - \alpha) \|x_0 - x^*\|^2}{8\mu t_\alpha^{4-\alpha}} \leq \mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(r - 1)^2 (2r - \alpha) \|x_0 - x^*\|^2}{8\mu t_\alpha^{4-\alpha}}. \quad (25)$$

Then, we bound $\mathcal{E}(t_\alpha)$ as follows.

$$\begin{aligned} \mathcal{E}(t_\alpha) &\leq t_\alpha^\alpha (f(X(t_\alpha)) - f^*) + \frac{(2r - \alpha)^2 t_\alpha^{\alpha-2}}{4} \| \frac{2r-2}{2r-\alpha} X(t_\alpha) + \frac{2t_\alpha}{2r-\alpha} \dot{X}(t_\alpha) - \frac{2r-2}{2r-\alpha} x^* \|^2 \\ &\quad + \frac{(2r - \alpha)^2 t_\alpha^{\alpha-2}}{4} \| \frac{\alpha-2}{2r-\alpha} X(t_\alpha) - \frac{\alpha-2}{2r-\alpha} x^* \|^2 \\ &\leq (r - 1)^2 t_\alpha^{\alpha-2} \|x_0 - x^*\|^2 + \frac{(\alpha - 2)^2 (r - 1)^2 \|x_0 - x^*\|^2}{4\mu t_\alpha^{4-\alpha}}, \end{aligned} \quad (26)$$

where in the second inequality we use the decreasing property of the energy functional defined for Theorem 5. Combining (25) and (26), we have

$$\mathcal{E}(t) \leq (r - 1)^2 t_\alpha^{\alpha-2} \|x_0 - x^*\|^2 + \frac{(\alpha - 2)(r - 1)^2 (2r + \alpha - 4) \|x_0 - x^*\|^2}{8\mu t_\alpha^{4-\alpha}} = O\left(\frac{\|x_0 - x^*\|^2}{\mu^{\frac{\alpha-2}{2}} t^\alpha}\right).$$

For $t \geq t_\alpha$, it suffices to apply $f(X(t)) - f^* \leq \mathcal{E}(t)/t^\alpha$ to the last display. For $t < t_\alpha$, by Theorem 5, $f(X(t)) - f^*$ is upper bounded by

$$\begin{aligned} \frac{(r - 1)^2 \|x_0 - x^*\|^2}{2t^2} &\leq \frac{(r - 1)^2 t^{\frac{\alpha-2}{2}} [(\alpha - 2)(2r - \alpha)/(2\mu)]^{\frac{\alpha-2}{2}} \|x_0 - x^*\|^2}{2} \\ &\quad = O\left(\frac{\|x_0 - x^*\|^2}{\mu^{\frac{\alpha-2}{2}} t^\alpha}\right). \end{aligned} \quad (27)$$

Next, suppose that the theorem is valid for some $\tilde{\alpha} > 2$. We show below that this theorem is still valid for $\alpha := \tilde{\alpha} + 1$ if still $r \geq 3\alpha/2$. By the assumption, (24) further induces

$$\mathcal{E}(t) \leq \mathcal{E}(t_\alpha) + \frac{(\alpha - 2)(2r - \alpha)t^{\alpha-2} \tilde{C} \|x_0 - x^*\|^2}{4\mu} \leq \mathcal{E}(t_\alpha) + \frac{\tilde{C}(\alpha - 2)(2r - \alpha) \|x_0 - x^*\|^2}{4\mu^{\frac{\alpha-1}{2}} t_\alpha}$$

for some constant \tilde{C} only depending on $\bar{\alpha}$ and r . This inequality with (26) implies

$$\begin{aligned} \mathcal{E}(t) &\leq (r-1)^2 t_\alpha^{\alpha-2} \|x_0 - x^*\|^2 + \frac{(\alpha-2)^2 (r-1)^2 \|x_0 - x^*\|^2}{4\mu t_\alpha^4 - \alpha} \tilde{C}(\alpha-2)(2r-\alpha) \|x_0 - x^*\|^2 \\ &\quad + O\left(\|x_0 - x^*\|^2 / \mu^{\frac{\alpha-2}{2}}\right), \end{aligned}$$

which verify the induction for $t \geq t_\alpha$. As for $t < t_\alpha$, the validity of the induction follows from Theorem 5, similarly to (27). Thus, combining the base and induction steps, the proof is completed. \blacksquare

It should be pointed out that the constant C in the statement of Theorem 8 grows with the parameter r . Hence, simply increasing r does not guarantee to give a better error bound. While it is desirable to expect a discrete analogy of Theorem 8, i.e., $O(1/k^s)$ convergence rate for (19), a complete proof can be notoriously complicated. That said, we mimic the proof of Theorem 8 for $\alpha = 3$ and succeed in obtaining a $O(1/k^3)$ convergence rate for the generalized Nesterov's schemes, as summarized in the theorem below.

Theorem 9 *Suppose f is written as $f = g+h$, where $g \in S_{\mu,L}$ and h is convex with possible extended value ∞ . Then, the generalized Nesterov's scheme (19) with $r \geq 9/2$ and $s = 1/L$ satisfies*

$$f(x_k) - f^* \leq \frac{CL\|x_0 - x^*\|^2 \sqrt{L/\mu}}{k^2},$$

where C only depends on r .

This theorem states that the discrete scheme (19) enjoys the error bound $O(1/k^3)$ without any knowledge of the condition number L/μ . In particular, this bound is much better than that given in Theorem 6 if $k \gg \sqrt{L/\mu}$. The strategy of the proof is fully inspired by that of Theorem 8, though it is much more complicated and thus deferred to the Appendix. The relevant energy functional $\mathcal{E}(k)$ for this Theorem 9 is equal to

$$\frac{s(2k+3r-5)(2k+2r-5)(4k+4r-9)}{16} (f(x_k) - f^*) + \frac{2k+3r-5}{16} \|2(k+r-1)yk - (2k+1)x_k - (2r-3)x^*\|^2. \quad (28)$$

4.4 Numerical Examples

We study six synthetic examples to compare (19) with the step sizes are fixed to be $1/L$, as illustrated in Figure 5. The error rates exhibit similar patterns for all r , namely, decreasing while suffering from local bumps. A smaller r introduces less friction, thus allowing x_k moves towards x^* faster in the beginning. However, when sufficiently close to x^* , more friction is preferred in order to reduce overshoot. This point of view explains what we observe in these examples. That is, across these six examples, (19) with a smaller r performs slightly better in the beginning, but a larger r has advantage when k is large. It is an interesting question how to choose a good r for different problems in practice.

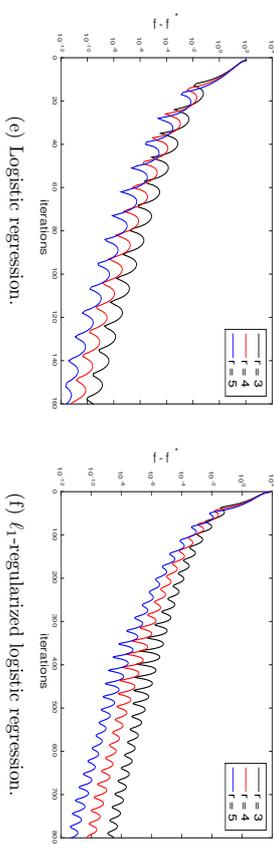

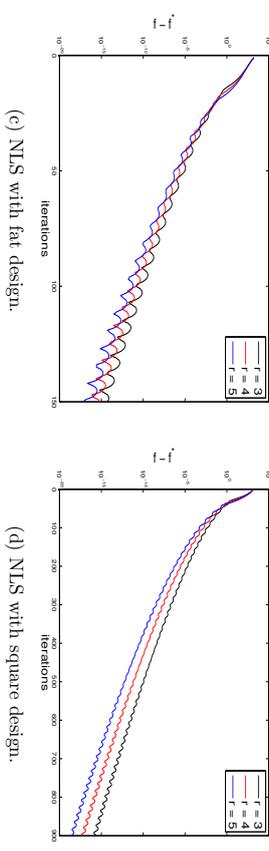

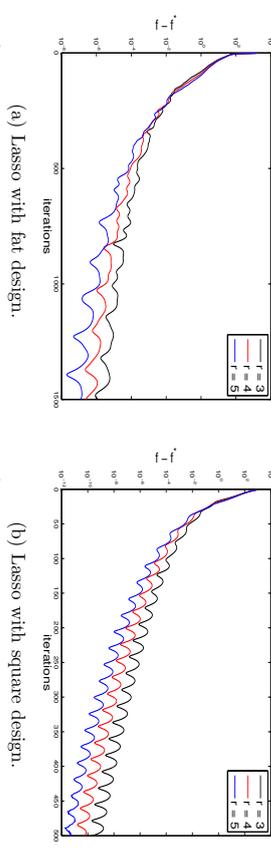

Figure 5: Comparisons of generalized Nesterov's schemes with different r .

Lasso with fat design. Minimize $f(x) = \frac{1}{2}\|Ax - b\|^2 + \lambda\|x\|_1$, in which A a 100×500 random matrix with i.i.d. standard Gaussian $\mathcal{N}(0, 1)$ entries, b generated independently has i.i.d. $\mathcal{N}(0, 25)$ entries, and the penalty $\lambda = 4$. The plot is Figure 5a.

Lasso with square design. Minimize $f(x) = \frac{1}{2}\|Ax - b\|^2 + \lambda\|x\|$, where A a 500×500 random matrix with i.i.d. standard Gaussian entries, b generated independently has i.i.d. $\mathcal{N}(0, 9)$ entries, and the penalty $\lambda = 4$. The plot is Figure 5b.

Nonnegative least squares (NLS) with fat design. Minimize $f(x) = \|Ax - b\|^2$ subject to $x \succeq 0$, with the same design A and b as in Figure 5a. The plot is Figure 5c.

Nonnegative least squares with sparse design. Minimize $f(x) = \|Ax - b\|^2$ subject to $x \geq 0$, in which A is a 1000×10000 sparse matrix with nonzero probability 10% for each entry and b is given as $b = Ax^0 + \mathcal{N}(0, I_{1000})$. The nonzero entries of A are independently Gaussian distributed before column normalization, and x^0 has 100 nonzero entries that are all equal to 4. The plot is Figure 5d.

Logistic regression. Minimize $\sum_{i=1}^n -y_i a_i^T x + \log(1 + e^{a_i^T x})$, in which $A = (a_1, \dots, a_n)^T$ is a 500×100 matrix with i.i.d. $\mathcal{N}(0, 1)$ entries. The labels $y_i \in \{0, 1\}$ are generated by the logistic model: $\mathbb{P}(Y_i = 1) = 1/(1 + e^{-a_i^T x^0})$, where x^0 is a realization of i.i.d. $\mathcal{N}(0, 1/100)$. The plot is Figure 5c.

ℓ_1 -regularized logistic regression. Minimize $\sum_{i=1}^n -y_i a_i^T x + \log(1 + e^{a_i^T x}) + \lambda \|x\|_1$, in which $A = (a_1, \dots, a_n)^T$ is a 200×1000 matrix with i.i.d. $\mathcal{N}(0, 1)$ entries and $\lambda = 5$. The labels y_i are generated similarly as in the previous example, except for the ground truth x^0 here having 10 nonzero components given as i.i.d. $\mathcal{N}(0, 225)$. The plot is Figure 5f.

5. Restarting

The example discussed in Section 4.2 demonstrates that Nesterov's scheme and its generalizations (19) are not capable of fully exploiting strong convexity. That is, this example suggests evidence that $O(1/\text{poly}(k))$ is the best rate achievable under strong convexity. In contrast, the vanilla gradient method achieves linear convergence $O((1 - \mu/L)^k)$. This drawback results from too much momentum introduced when the objective function is strongly convex. The derivative of a strongly convex function is generally more reliable than that of non-strongly convex functions. In the language of ODEs, at later stage a too small $3/t$ in (3) leads to a lack of friction, resulting in unnecessary overshoot along the trajectory. Incorporating the optimal momentum coefficient $\frac{\sqrt{L - \sqrt{\mu}}}{\sqrt{T + \sqrt{\mu}}}$ (This is less than $(k - 1)/(k + 2)$ when k is large), Nesterov's scheme has convergence rate of $O((1 - \sqrt{\mu/L})^k)$ (Nesterov, 2004), which, however, requires knowledge of the condition number μ/L . While it is relatively easy to bound the Lipschitz constant L by the use of backtracking, estimating the strong convexity parameter μ , if not impossible, is very challenging.

Among many approaches to gain acceleration via adaptively estimating μ/L (see Nesterov, 2013; O'Donoghue and Candès (2013) proposes a procedure termed as gradient restarting for Nesterov's scheme in which (1) is restarted with $x_0 = y_0 := x_k$ whenever $f(x_{k+1}) > f(x_k)$). In the language of ODEs, this restarting essentially keeps $\langle \nabla f, \dot{X} \rangle$ negative, and resets $3/t$ each time to prevent this coefficient from steadily decreasing along the trajectory. Although it has been empirically observed that this method significantly boosts convergence, there is no general theory characterizing the convergence rate.

In this section, we propose a new restarting scheme we call the speed restarting scheme. The underlying motivation is to maintain a relatively high velocity \dot{X} along the trajectory, similar in spirit to the gradient restarting. Specifically, our main result, Theorem 10, ensures linear convergence of the continuous version of the speed restarting. More generally, our contribution here is merely to provide a framework for analyzing restarting schemes rather than competing with other schemes; it is beyond the scope of this paper to get optimal constants in these results. Throughout this section, we assume $f \in \mathcal{S}_{\mu,L}$ for some $0 < \mu \leq L$. Recall that function $f \in \mathcal{S}_{\mu,L}$ if $f \in \mathcal{F}_L$ and $f(x) - \mu \|x\|^2/2$ is convex.

5.1 A New Restarting Scheme

We first define the speed restarting time. For the ODE (3), we call

$$T = T(x_0; f) = \sup \left\{ t > 0 : \forall u \in (0, t), \frac{d\|\dot{X}(u)\|^2}{du} > 0 \right\}$$

the speed restarting time. In words, T is the first time the velocity $\|\dot{X}\|$ decreases. Back to the discrete scheme, it is the first time when we observe $\|x_{k+1} - x_k\| < \|x_k - x_{k-1}\|$. This definition itself does not directly imply that $0 < T < \infty$, which is proven later in Lemmas 13 and 25. Indeed, $f(X(t))$ is a decreasing function before time T ; for $t \leq T$,

$$\frac{df(X(t))}{dt} = \langle \nabla f(X), \dot{X} \rangle = -\frac{3}{t} \|\dot{X}\|^2 - \frac{1}{2} \frac{d\|\dot{X}\|^2}{dt} \leq 0.$$

The speed restarted ODE is thus

$$\ddot{X}(t) + \frac{3}{t_{\text{sr}}} \dot{X}(t) + \nabla f(X(t)) = 0, \quad (29)$$

where t_{sr} is set to zero whenever $\langle \dot{X}, \ddot{X} \rangle = 0$ and between two consecutive restarts, t_{sr} grows just as t . That is, $t_{\text{sr}} = t - \tau$, where τ is the latest restart time. In particular, $t_{\text{sr}} = 0$ at $t = 0$. Letting X^{sr} be the solution to (29), we have the following observations.

- $X^{\text{sr}}(t)$ is continuous for $t \geq 0$, with $X^{\text{sr}}(0) = x_0$;
- $X^{\text{sr}}(t)$ satisfies (3) for $0 < t < T_1 := T(x_0; f)$;
- Recursively define $T_{i+1} = T(X^{\text{sr}}(\sum_{j=1}^i T_j); f)$ for $i \geq 1$, and $\tilde{X}(t) := X^{\text{sr}}(\sum_{j=1}^i T_j + t)$ satisfies the ODE (3), with $\tilde{X}(0) = X^{\text{sr}}(\sum_{j=1}^i T_j)$, for $0 < t < T_{i+1}$.

The theorem below guarantees linear convergence of X^{sr} . This is a new result in the literature (O'Donoghue and Candès, 2013; Monteiro et al., 2012). The proof of Theorem 10 is based on Lemmas 12 and 13, where the first guarantees the rate $f(X^{\text{sr}}) - f^*$ decays by a constant factor for each restarting, and the second confirms that restartings are adequate. In these lemmas we all make a convention that the uninteresting case $x_0 = x^*$ is excluded.

Theorem 10 *There exist positive constants c_1 and c_2 , which only depend on the condition number L/μ , such that for any $f \in \mathcal{S}_{\mu,L}$, we have*

$$f(X^{\text{sr}}(t)) - f^* \leq \frac{c_1 L \|x_0 - x^*\|^2}{2} e^{-c_2 t \sqrt{L}}.$$

Before turning to the proof, we make a remark that this linear convergence of X^{sr} remains to hold for the generalized ODE (17) with $r > 3$. Only minor modifications in the proof below are needed, such as replacing u^3 by u^r in the definition of $I(t)$ in Lemma 25.

5.2 Proof of Linear Convergence

First, we collect some useful estimates. Denote by $M(t)$ the supremum of $\|\dot{X}(u)\|/u$ over $u \in (0, t]$ and let

$$I(t) := \int_0^t u^3 (\nabla f(X(u)) - \nabla f(x_0)) du.$$

It is guaranteed that M defined above is finite, for example, see the proof of Lemma 18. The definition of M gives a bound on the gradient of f ,

$$\|\nabla f(X(t)) - \nabla f(x_0)\| \leq L \left\| \int_0^t \dot{X}(u) du \right\| \leq L \int_0^t u \frac{\|\dot{X}(u)\|}{u} du \leq \frac{LM(t)t^2}{2}.$$

Hence, it is easy to see that I can also be bounded via M ,

$$\|I(t)\| \leq \int_0^t u^3 \|\nabla f(X(u)) - \nabla f(x_0)\| du \leq \int_0^t \frac{LM(u)u^5}{2} du \leq \frac{LM(t)t^6}{12}.$$

To fully facilitate these estimates, we need the following lemma that gives an upper bound of M , whose proof is deferred to the appendix.

Lemma 11 For $t < \sqrt{12/L}$, we have

$$M(t) \leq \frac{\|\nabla f(x_0)\|}{4(1 - Lt^2/12)}.$$

Next we give a lemma which claims that the objective function decays by a constant through each speed restarting.

Lemma 12 There is a universal constant $C > 0$ such that

$$f(X(T)) - f^* \leq \left(1 - \frac{C\mu}{L}\right) (f(x_0) - f^*).$$

Proof By Lemma 11, for $t < \sqrt{12/L}$ we have

$$\left\| \dot{X}(t) + \frac{t}{4} \nabla f(x_0) \right\| = \frac{1}{t^3} \|I(t)\| \leq \frac{LM(t)t^3}{12} \leq \frac{L\|\nabla f(x_0)\|t^3}{48(1 - Lt^2/12)},$$

which yields

$$0 \leq \frac{t}{4} \|\nabla f(x_0)\| - \frac{L\|\nabla f(x_0)\|t^3}{48(1 - Lt^2/12)} \leq \|\dot{X}(t)\| \leq \frac{t}{4} \|\nabla f(x_0)\| + \frac{L\|\nabla f(x_0)\|t^3}{48(1 - Lt^2/12)}. \quad (30)$$

Hence, for $0 < t < 4/(5\sqrt{L})$ we get

$$\begin{aligned} \frac{df(X)}{dt} &= -\frac{3}{t} \|\dot{X}\|^2 - \frac{1}{2} \frac{d}{dt} \|\dot{X}\|^2 \leq -\frac{3}{t} \|\dot{X}\|^2 \\ &\leq -\frac{3}{t} \left(\frac{t}{4} \|\nabla f(x_0)\| - \frac{L\|\nabla f(x_0)\|t^3}{48(1 - Lt^2/12)} \right)^2 \leq -C_1 t \|\nabla f(x_0)\|^2, \end{aligned}$$

where $C_1 > 0$ is an absolute constant and the second inequality follows from Lemma 25 in the appendix. Consequently,

$$f\left(X(4/(5\sqrt{L}))\right) - f(x_0) \leq \int_0^{4/(5\sqrt{L})} -C_1 u \|\nabla f(x_0)\|^2 du \leq -\frac{C\mu}{L} (f(x_0) - f^*),$$

where $C = 16C_1/25$ and in the last inequality we use the μ -strong convexity of f . Thus we have

$$f\left(X\left(\frac{4}{5\sqrt{L}}\right)\right) - f^* \leq \left(1 - \frac{C\mu}{L}\right) (f(x_0) - f^*).$$

To complete the proof, note that $f(X(T)) \leq f(X(4/(5\sqrt{L})))$ by Lemma 25. ■

With each restarting reducing the error $f - f^*$ by a constant a factor, we still need the following lemma to ensure sufficiently many restartings.

Lemma 13 There is a universal constant \tilde{C} such that

$$T \leq \frac{4 \exp(\tilde{C}L/\mu)}{5\sqrt{L}}.$$

Proof For $4/(5\sqrt{L}) \leq t \leq T$, we have $\frac{df(X)}{dt} \leq -\frac{3}{t} \|\dot{X}(t)\|^2 \leq -\frac{3}{t} \|\dot{X}(4/(5\sqrt{L}))\|^2$, which implies

$$f(X(T)) - f(x_0) \leq -\int_{4/(5\sqrt{L})}^T \frac{3}{t} \|\dot{X}(4/(5\sqrt{L}))\|^2 dt = -3 \|\dot{X}(4/(5\sqrt{L}))\|^2 \log \frac{5T\sqrt{L}}{4}.$$

Hence, we get an upper bound for T ,

$$T \leq \frac{4}{5\sqrt{L}} \exp\left(\frac{f(x_0) - f(X(T))}{3\|\dot{X}(4/(5\sqrt{L}))\|^2}\right) \leq \frac{4}{5\sqrt{L}} \exp\left(\frac{f(x_0) - f^*}{3\|\dot{X}(4/(5\sqrt{L}))\|^2}\right).$$

Plugging $t = 4/(5\sqrt{L})$ into (30) gives $\|\dot{X}(4/(5\sqrt{L}))\| \geq \frac{C\mu}{2L} \|\nabla f(x_0)\|$ for some universal constant $C_1 > 0$. Hence, from the last display we get

$$T \leq \frac{4}{5\sqrt{L}} \exp\left(\frac{L(f(x_0) - f^*)}{3C_1^2 \|\nabla f(x_0)\|^2}\right) \leq \frac{4}{5\sqrt{L}} \exp\frac{L}{6C_1^2 \mu}.$$

■

Now, we are ready to prove Theorem 10 by applying Lemmas 12 and 13.

Proof Note that Lemma 13 asserts, by time t at least $m := \lfloor 5t\sqrt{L}e^{-C_1L/\mu}/4 \rfloor$ restartings have occurred for X^{sr} . Hence, recursively applying Lemma 12, we have

$$\begin{aligned} f(X^{\text{sr}}(t)) - f^* &\leq f(X^{\text{sr}}(T_1 + \dots + T_m)) - f^* \\ &\leq (1 - C\mu/L) (f(X^{\text{sr}}(T_1 + \dots + T_{m-1})) - f^*) \\ &\leq \dots \leq \dots \\ &\leq (1 - C\mu/L)^m (f(x_0) - f^*) \leq e^{-C\mu m/L} (f(x_0) - f^*) \\ &\leq c_1 e^{-c_2 \sqrt{L}t} (f(x_0) - f^*) \leq \frac{c_1 L \|x_0 - x^*\|^2}{2} e^{-c_2 \sqrt{L}t}, \end{aligned}$$

where $c_1 = \exp(C\mu/L)$ and $c_2 = 5C\mu e^{-C\mu/L}/(4L)$. ■

In closing, we remark that we believe that estimate in Lemma 12 is tight, while not for Lemma 13. Thus we conjecture that for a large class of $f \in \mathcal{S}_{\mu,L}$, if not all, $T = O(\sqrt{L}/\mu)$. If this is true, the exponent constant c_2 in Theorem 10 can be significantly improved.

5.3 Numerical Examples

Below we present a discrete analog to the restarted scheme. There, k_{\min} is introduced to avoid having consecutive restarts that are too close. To compare the performance of the restarted scheme with the original (1), we conduct four simulation studies, including both smooth and non-smooth objective functions. Note that the computational costs of the restarted and non-restarted schemes are the same.

Algorithm 1 Speed Restarting Nesterov's Scheme

input: $x_0 \in \mathbb{R}^n, y_0 = x_0, x_{-1} = x_0, 0 < s \leq 1/L, k_{\max} \in \mathbb{N}^+$ and $k_{\min} \in \mathbb{N}^+$
 $j \leftarrow 1$
for $k = 1$ to k_{\max} **do**
 $x_k \leftarrow \operatorname{argmin}_x (\frac{1}{2s} \|x - y_{k-1} + s\nabla g(y_{k-1})\|^2 + h(x))$
 $y_k \leftarrow x_k + \frac{j-1}{j+2}(x_k - x_{k-1})$

 $j \leftarrow j + 1$
end if
end for

Quadratic. $f(x) = \frac{1}{2}x^T Ax + b^T x$ is a strongly convex function, in which A is a 500×500 random positive definite matrix and b a random vector. The eigenvalues of A are between 0.001 and 1. The vector b is generated as i.i.d. Gaussian random variables with mean 0 and variance 25.

Log-sum-exp.

$$f(x) = \rho \log \left[\sum_{i=1}^m \exp((a_i^T x - b_i)/\rho) \right],$$

where $n = 50, m = 200, \rho = 20$. The matrix $A = (a_{ij})$ is a random matrix with i.i.d. standard Gaussian entries, and $b = (b_i)$ has i.i.d. Gaussian entries with mean 0 and variance 2. This function is not strongly convex.

Matrix completion. $f(X) = \frac{1}{2} \|X_{\text{obs}} - M_{\text{obs}}\|_F^2 + \lambda \|X\|_*$, in which the ground truth M is a rank-5 random matrix of size 300×300 . The regularization parameter is set to $\lambda = 0.05$. The 5 singular values of M are $1, \dots, 5$. The observed set is independently sampled among the 300×300 entries so that 10% of the entries are actually observed.

Lasso in ℓ_1 -constrained form with large sparse design. $f(x) = \frac{1}{2} \|Ax - b\|^2$ s.t. $\|x\|_1 \leq \delta$, where A is a 5000×5000 random sparse matrix with nonzero probability 0.5% for each

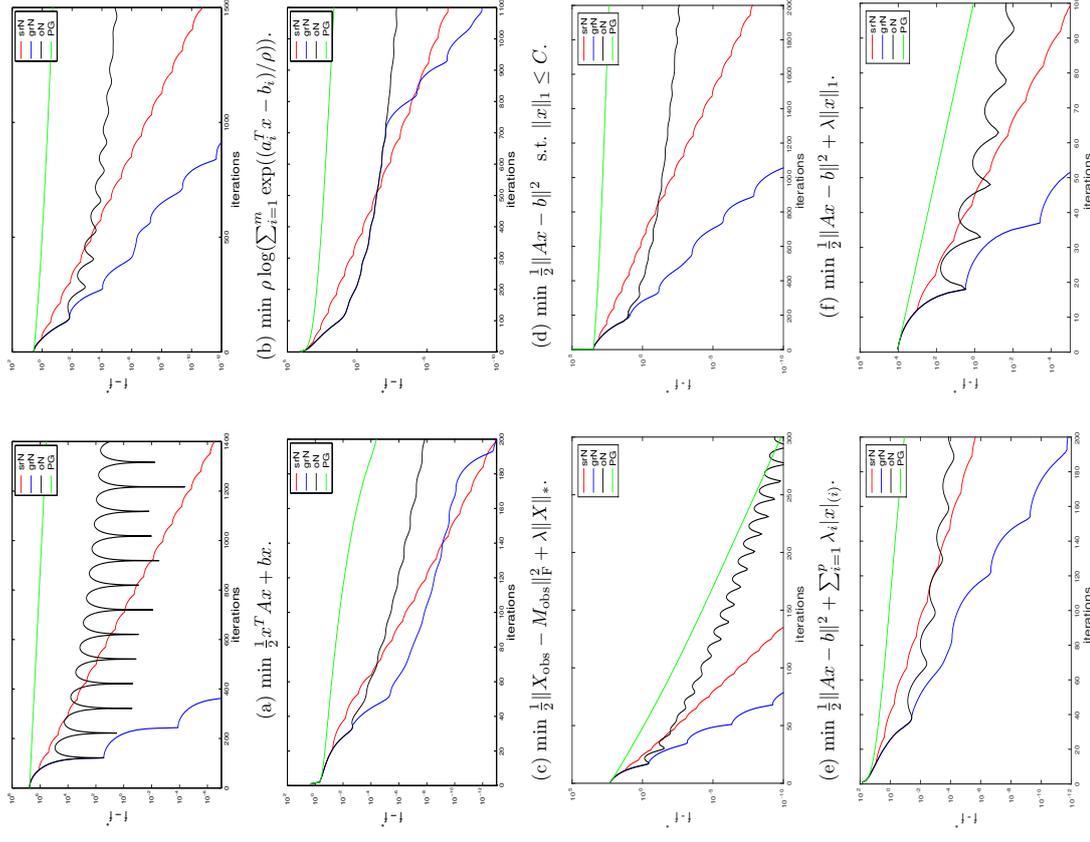

Figure 6: Numerical performance of speed restarting (srN), gradient restarting (grN), the original Nesterov's scheme (oN) and the proximal gradient (PG).

entry and b is generated as $b = Ax^0 + z$. The nonzero entries of A independently follow the Gaussian distribution with mean 0 and variance 0.04. The signal x^0 is a vector with 250 nonzeros and z is i.i.d. standard Gaussian noise. The parameter δ is set to $\|x^0\|_1$.

Sorted l_1 penalized estimation. $f(x) = \frac{1}{2}\|Ax - b\|^2 + \sum_{i=1}^p \lambda_i |x|_{(i)}$, where $|x|_{(i)} \geq \dots \geq |x|_{(p)}$ are the order statistics of $|x|$. This is a recently introduced testing and estimation procedure (Bogdan et al., 2015). The design A is a 1000×10000 Gaussian random matrix, and b is generated as $b = Ax^0 + z$ for 20-sparse x^0 and Gaussian noise z . The penalty sequence is set to $\lambda_i = 1.1\Phi^{-1}(1 - 0.05i/(2p))$.

Lasso. $f(x) = \frac{1}{2}\|Ax - b\|^2 + \lambda\|x\|_1$, where A is a 1000×500 random matrix and b is given as $b = Ax^0 + z$ for 20-sparse x^0 and Gaussian noise z . We set $\lambda = 1.5\sqrt{2\log p}$.

l_1 -regularized logistic regression. $f(x) = \sum_{i=1}^n -y_i a_i^T x + \log(1 + e^{a_i^T x}) + \lambda\|x\|_1$, where the setting is the same as in Figure 5f. The results are presented in Figure 6g.

Logistic regression with large sparse design. $f(x) = \sum_{i=1}^n -y_i a_i^T x + \log(1 + e^{a_i^T x})$, in which $A = (a_1, \dots, a_n)^T$ is a $10^7 \times 20000$ sparse random matrix with nonzero probability 0.1% for each entry, so there are roughly 2×10^8 nonzero entries in total. To generate the labels y_i , we set x^0 to be i.i.d. $\mathcal{N}(0, 1/4)$. The plot is Figure 6h.

In these examples, k_{\min} is set to be 10 and the step sizes are fixed to be $1/L$. If the objective is in composite form, the Lipschitz bound applies to the smooth part. Figure 6 presents the performance of the speed restarting scheme, the gradient restarting scheme, the original Nesterov's scheme and the proximal gradient method. The objective functions include strongly convex, non-strongly convex and non-smooth functions, violating the assumptions in Theorem 10. Among all the examples, it is interesting to note that both speed restarting scheme empirically exhibit linear convergence by significantly reducing bumps in the objective values. This leaves us an open problem of whether there exists provable linear convergence rate for the gradient restarting scheme as in Theorem 10. It is also worth pointing out that compared with gradient restarting, the speed restarting scheme empirically exhibits more stable linear convergence rate.

6. Discussion

This paper introduces a second-order ODE and accompanying tools for characterizing Nesterov's accelerated gradient method. This ODE is applied to study variants of Nesterov's scheme and is capable of interpreting some empirically observed phenomena, such as oscillations along the trajectories. Our approach suggests (1) a large family of generalized Nesterov's schemes that are all guaranteed to converge at the rate $O(1/k^2)$, and (2) a restarting scheme provably achieving a linear convergence rate whenever f is strongly convex.

In this paper, we often utilize ideas from continuous-time ODEs, and then apply these ideas to discrete schemes. The translation, however, involves parameter tuning and tedious calculations. This is the reason why a general theory mapping properties of ODEs into corresponding properties for discrete updates would be a welcome advance. Indeed, this would allow researchers to only study the simpler and more user-friendly ODEs.

As evidenced by many examples, the viewpoint of regarding the ODE as a surrogate for Nesterov's scheme would allow a new perspective for studying accelerated methods in optimization. The discrete scheme and the ODE are closely connected by the exact

mapping between the coefficients of momentum (e.g. $(k-1)/(k+2)$) and velocity (e.g. $3/t$). The derivations of generalized Nesterov's schemes and the speed restarting scheme are both motivated by trying a different velocity coefficient, in which the surprising phase transition at 3 is observed. Clearly, such alternatives are endless, and we expect this will lead to findings of many discrete accelerated schemes. In a different direction, a better understanding of the trajectory of the ODEs, such as curvature, has the potential to be helpful in deriving appropriate stopping criteria for termination, and choosing step size by backtracking.

Appendix A. Proof of Theorem 1

The proof is divided into two parts, namely, existence and uniqueness.

Lemma 14 For any $f \in \mathcal{F}_\infty$ and any $x_0 \in \mathbb{R}^n$, the ODE (3) has at least one solution X in $C^2(0, \infty) \cap C^1[0, \infty)$.

Below, some preparatory lemmas are given before turning to the proof of this lemma. To begin with, for any $\delta > 0$ consider the smoothed ODE

$$\ddot{X} + \frac{3}{\max(\delta, t)} \dot{X} + \nabla f(X) = 0 \quad (31)$$

with $X(0) = x_0, \dot{X}(0) = 0$. Denoting by $Z = \dot{X}$, then (31) is equivalent to

$$\frac{d}{dt} \begin{pmatrix} X \\ Z \end{pmatrix} = \begin{pmatrix} Z \\ -\frac{3}{\max(\delta, t)} Z - \nabla f(X) \end{pmatrix}$$

with $X(0) = x_0, Z(0) = 0$. As functions of (X, Z) , both Z and $-3Z/\max(\delta, t) - \nabla f(X)$ are $\max(1, L) + 3/\delta$ -Lipschitz continuous. Hence by standard ODE theory, (31) has a unique global solution in $C^2(0, \infty)$ denoted by X_δ . Note that X_δ is also well defined at $t = 0$.

Next, introduce $M_\delta(t)$ to be the supremum of $\|\dot{X}_\delta(u)\|/u$ over $u \in (0, t]$. It is easy to see that $M_\delta(t)$ is finite because $\|\dot{X}_\delta(u)\|/u = (\|\dot{X}_\delta(u) - \dot{X}_\delta(0)\|)/u = \|\dot{X}_\delta(0)\| + o(1)$ for small u . We give an upper bound for $M_\delta(t)$ in the following lemma.

Lemma 15 For $\delta < \sqrt{6/L}$, we have

$$M_\delta(t) \leq \frac{\|\nabla f(x_0)\|}{1 - L\delta^2/6}.$$

The proof of Lemma 15 relies on a simple lemma.

Lemma 16 For any $u > 0$, the following inequality holds

$$\|\nabla f(\dot{X}_\delta(u)) - \nabla f(x_0)\| \leq \frac{1}{2} LM_\delta(u) u^2.$$

Proof By Lipschitz continuity,

$$\|\nabla f(\dot{X}_\delta(u)) - \nabla f(x_0)\| \leq L \|\dot{X}_\delta(u) - x_0\| = \left\| \int_0^u \dot{X}_\delta(v) dv \right\| \leq \int_0^u \frac{\|\dot{X}_\delta(v)\|}{v} dv \leq \frac{1}{2} LM_\delta(u) u^2. \quad \blacksquare$$

Next, we prove Lemma 15.

Proof For $0 < t \leq \delta$, the smoothed ODE takes the form

$$\ddot{X}_\delta + \frac{3}{\delta} \dot{X}_\delta + \nabla f(\dot{X}_\delta) = 0,$$

which yields

$$\dot{X}_\delta e^{3t/\delta} = - \int_0^t \nabla f(\dot{X}_\delta(u)) e^{3u/\delta} du = - \nabla f(x_0) \int_0^t e^{3u/\delta} du - \int_0^t (\nabla f(\dot{X}_\delta(u)) - \nabla f(x_0)) e^{3u/\delta} du.$$

Hence, by Lemma 16

$$\begin{aligned} \frac{\|\dot{X}_\delta(t)\|}{t} &\leq \frac{1}{t} e^{-3t/\delta} \|\nabla f(x_0)\| \int_0^t e^{3u/\delta} du + \frac{1}{t} e^{-3t/\delta} \int_0^t \frac{1}{2} LM_\delta(u) u^2 e^{3u/\delta} du \\ &\leq \|\nabla f(x_0)\| + \frac{LM_\delta(\delta) \delta^2}{6}. \end{aligned}$$

Taking the supremum of $\|\dot{X}_\delta(t)\|/t$ over $0 < t \leq \delta$ and rearranging the inequality give the desired result. \blacksquare

Next, we give an upper bound for $M_\delta(t)$ when $t > \delta$.

Lemma 17 For $\delta < \sqrt{6/L}$ and $\delta < t < \sqrt{12/L}$, we have

$$M_\delta(t) \leq \frac{(5 - L\delta^2/6) \|\nabla f(x_0)\|}{4(1 - L\delta^2/6)(1 - Lt^2/12)}.$$

Proof For $t > \delta$, the smoothed ODE takes the form

$$\ddot{X}_\delta + \frac{3}{t} \dot{X}_\delta + \nabla f(\dot{X}_\delta) = 0,$$

which is equivalent to

$$\frac{dt^3 \dot{X}_\delta(t)}{dt} = -t^3 \nabla f(\dot{X}_\delta(t)).$$

Hence, by integration, $t^3 \dot{X}_\delta(t)$ is equal to

$$- \int_\delta^t u^3 \nabla f(\dot{X}_\delta(u)) du + \delta^3 \dot{X}_\delta(\delta) = - \int_\delta^t u^3 \nabla f(x_0) du - \int_\delta^t u^3 (\nabla f(\dot{X}_\delta(u)) - \nabla f(x_0)) du + \delta^3 \dot{X}_\delta(\delta).$$

Therefore by Lemmas 16 and 15, we get

$$\begin{aligned} \frac{\|\dot{X}_\delta(t)\|}{t} &\leq \frac{t^4 - \delta^4}{4t^4} \|\nabla f(x_0)\| + \frac{1}{t^4} \int_\delta^t \frac{1}{2} LM_\delta(u) u^5 du + \frac{\delta^4 \|\dot{X}_\delta(\delta)\|}{t^4} \\ &\leq \frac{1}{4} \|\nabla f(x_0)\| + \frac{1}{12} LM_\delta(t) t^2 + \frac{\|\nabla f(\dot{X}_0)\|}{1 - L\delta^2/6}, \end{aligned}$$

where the last expression is an increasing function of t . So for any $\delta < t' < t$, it follows that

$$\frac{\|\dot{X}_\delta(t')\|}{t'} \leq \frac{1}{4} \|\nabla f(x_0)\| + \frac{1}{12} LM_\delta(t) t^2 + \frac{\|\nabla f(x_0)\|}{1 - L\delta^2/6},$$

which also holds for $t' \leq \delta$. Taking the supremum over $t' \in (0, t)$ gives

$$M_\delta(t) \leq \frac{1}{4} \|\nabla f(x_0)\| + \frac{1}{12} LM_\delta(t) t^2 + \frac{\|\nabla f(\dot{X}_0)\|}{1 - L\delta^2/6}.$$

The desired result follows from rearranging the inequality. \blacksquare

Lemma 18 The function class $\mathcal{F} = \{X_\delta : [0, \sqrt{6/L}] \rightarrow \mathbb{R}^n \mid \delta = \sqrt{3/L}/2^m, m = 0, 1, \dots\}$ is uniformly bounded and equicontinuous.

Proof By Lemmas 15 and 17, for any $t \in [0, \sqrt{6/L}]$, $\delta \in (0, \sqrt{3/L})$ the gradient is uniformly bounded as

$$\|\dot{X}_\delta(t)\| \leq \sqrt{6/L} M_\delta(\sqrt{6/L}) \leq \sqrt{6/L} \max \left\{ \frac{\|\nabla f(x_0)\|}{1 - \frac{1}{2}}, \frac{5 \|\nabla f(x_0)\|}{4(1 - \frac{1}{2})(1 - \frac{1}{2})} \right\} = 5\sqrt{6/L} \|\nabla f(x_0)\|.$$

Thus it immediately implies that \mathcal{F} is equicontinuous. To establish the uniform boundedness, note that

$$\|X_\delta(t)\| \leq \|X_\delta(0)\| + \int_0^t \|\dot{X}_\delta(u)\| du \leq \|x_0\| + 30 \|\nabla f(x_0)\| / L. \quad \blacksquare$$

We are now ready for the proof of Lemma 14.

Proof By the Arzelà-Ascoli theorem and Lemma 18, \mathcal{F} contains a subsequence converging uniformly on $[0, \sqrt{6/L}]$. Denote by $\{X_{\delta_{m_i}}\}_{i \in \mathbb{N}}$ the convergent subsequence and \check{X} the limit. Above, $\delta_{m_i} = \sqrt{3/L}/2^{m_i}$ decreases as i increases. We will prove that \check{X} satisfies (3) and the initial conditions $\check{X}(0) = x_0, \check{X}'(0) = 0$.

Fix an arbitrary $t_0 \in (0, \sqrt{6/L})$. Since $\|\dot{X}_{\delta_{m_i}}(t_0)\|$ is bounded, we can pick a subsequence of $\dot{X}_{\delta_{m_i}}(t_0)$ which converges to a limit, denoted by $\dot{X}_{t_0}^D$. Without loss of generality, assume the subsequence is the original sequence. Denote by \tilde{X} the local solution to (3) with $X(t_0) = \tilde{X}(t_0)$ and $\dot{X}(t_0) = \dot{X}_{t_0}^D$. Now recall that $X_{\delta_{m_i}}$ is the solution to (3) with $X(t_0) = X_{\delta_{m_i}}(t_0)$ and $\dot{X}(t_0) = \dot{X}_{\delta_{m_i}}(t_0)$ when $\delta_{m_i} < t_0$. Since both $X_{\delta_{m_i}}(t_0)$ and $\dot{X}_{\delta_{m_i}}(t_0)$ approach $\tilde{X}(t_0)$ and $\dot{X}_{t_0}^D$, respectively, there exists $\epsilon_0 > 0$ such that

$$\sup_{t_0 - \epsilon_0 < t < t_0 + \epsilon_0} \|\dot{X}_{\delta_{m_i}}(t) - \tilde{X}(t)\| \rightarrow 0$$

as $i \rightarrow \infty$. However, by definition we have

$$\sup_{t_0 - \epsilon_0 < t < t_0 + \epsilon_0} \|\dot{X}_{\delta_{m_i}}(t) - \tilde{X}(t)\| \rightarrow 0.$$

Therefore \tilde{X} and \tilde{X} have to be identical on $(t_0 - \epsilon_0, t_0 + \epsilon_0)$. So \tilde{X} satisfies (3) at t_0 . Since t_0 is arbitrary, we conclude that \tilde{X} is a solution to (3) on $(0, \sqrt{6/L})$. By extension, \tilde{X} can be a global solution to (3) on $(0, \infty)$. It only leaves to verify the initial conditions to complete the proof.

The first condition $\tilde{X}(0) = x_0$ is a direct consequence of $\dot{X}_{\delta_{m_i}}(0) = x_0$. To check the second, pick a small $t > 0$ and note that

$$\begin{aligned} \frac{\|\tilde{X}(t) - \tilde{X}(0)\|}{t} &= \lim_{t \rightarrow \infty} \frac{\|\dot{X}_{\delta_{m_i}}(t) - \dot{X}_{\delta_{m_i}}(0)\|}{t} = \lim_{t \rightarrow \infty} \|\dot{X}_{\delta_{m_i}}(\xi_t)\| \\ &\leq \limsup_{t \rightarrow \infty} t M_{\delta_{m_i}}(t) \leq 5t \sqrt{6/L} \|\nabla f(x_0)\|, \end{aligned}$$

where $\xi_t \in (0, t)$ is given by the mean value theorem. The desired result follows from taking $t \rightarrow 0$. ■

Next, we aim to prove the uniqueness of the solution to (3).

Lemma 19 *For any $f \in \mathcal{F}_\infty$, the ODE (3) has at most one local solution in a neighborhood of $t = 0$.*

Suppose on the contrary that there are two solutions, namely: X and Y , both defined on $(0, \alpha)$ for some $\alpha > 0$. Define $\tilde{M}(t)$ to be the supremum of $\|\dot{X}(u) - \dot{Y}(u)\|$ over $u \in [0, t)$. To proceed, we need a simple auxiliary lemma.

Lemma 20 *For any $t \in (0, \alpha)$, we have*

$$\|\nabla f(X(t)) - \nabla f(Y(t))\| \leq Lt \tilde{M}(t).$$

Proof By Lipschitz continuity of the gradient, one has

$$\begin{aligned} \|\nabla f(X(t)) - \nabla f(Y(t))\| &\leq L \|X(t) - Y(t)\| = L \left\| \int_0^t \dot{X}(u) - \dot{Y}(u) du + X(0) - Y(0) \right\| \\ &\leq L \int_0^t \|\dot{X}(u) - \dot{Y}(u)\| du \leq Lt \tilde{M}(t). \end{aligned}$$

Now we prove Lemma 19.

Proof Similar to the proof of Lemma 17, we get

$$t^3 \|\dot{X}(t) - \dot{Y}(t)\| = - \int_0^t u^3 (\nabla f(X(u)) - \nabla f(Y(u))) du.$$

Applying Lemma 20 gives

$$t^3 \|\dot{X}(t) - \dot{Y}(t)\| \leq \int_0^t L u^4 \tilde{M}(u) du \leq \frac{1}{5} L t^5 \tilde{M}(t),$$

which can be simplified as $\|\dot{X}(t) - \dot{Y}(t)\| \leq L t^2 \tilde{M}(t)/5$. Thus, for any $t' \leq t$ it is true that $\|\dot{X}(t') - \dot{Y}(t')\| \leq L t'^2 \tilde{M}(t)/5$. Taking the supremum of $\|\dot{X}(t') - \dot{Y}(t')\|$ over $t' \in (0, t)$ gives $\tilde{M}(t) \leq L t^2 \tilde{M}(t)/5$. Therefore $\tilde{M}(t) = 0$ for $t < \min(\alpha, \sqrt{5/L})$, which is equivalent to saying $X = Y$ on $[0, \min(\alpha, \sqrt{5/L})]$. With the same initial value $X(0) = Y(0) = x_0$ and the same gradient, we conclude that X and Y are identical on $(0, \min(\alpha, \sqrt{5/L}))$, a contradiction. ■

Given all of the aforementioned lemmas, Theorem 1 follows from a combination of Lemmas 14 and 19.

Appendix B. Proof of Theorem 2

Identifying $\sqrt{s} = \Delta t$, the comparison between (4) and (15) reveals that Nesterov's scheme is a discrete scheme for numerically integrating the ODE (3). However, its singularity of the damping coefficient at $t = 0$ leads to the nonexistence of off-the-shelf ODE theory for proving Theorem 2. To address this difficulty, we use the smoothed ODE (31) to approximate the original one; then bound the difference between Nesterov's scheme and the forward Euler scheme of (31), which may take the following form:

$$\begin{aligned} X_{k+1}^{\delta} &= X_k^{\delta} + \Delta t Z_k^{\delta} \\ Z_{k+1}^{\delta} &= \left(1 - \frac{3\Delta t}{\max\{\delta, k\Delta t\}} \right) Z_k^{\delta} - \Delta t \nabla f(X_k^{\delta}) \end{aligned} \quad (32)$$

with $X_0^{\delta} = x_0$ and $Z_0^{\delta} = 0$.

Lemma 21 *With step size $\Delta t = \sqrt{s}$, for any $T > 0$ we have*

$$\max_{1 \leq k \leq \frac{T}{\sqrt{s}}} \|X_k^{\delta} - x_k\| \leq C \delta^2 + o_{\delta}(1)$$

for some constant C .

Proof Let $z_k = (x_{k+1} - x_k)/\sqrt{s}$. Then Nesterov's scheme is equivalent to

$$\begin{aligned} x_{k+1} &= x_k + \sqrt{s} z_k \\ z_{k+1} &= \left(1 - \frac{3}{k+3} \right) z_k - \sqrt{s} \nabla f \left(x_k + \frac{2k+3}{k+3} \sqrt{s} z_k \right). \end{aligned} \quad (33)$$

Denote by $a_k = \|X_k^\delta - x_k\|$, $b_k = \|Z_k^\delta - z_k\|$, whose initial values are $a_0 = 0$ and $b_0 = \|\nabla f(x_0)\|/\sqrt{s}$. The idea of this proof is to bound a_k via simultaneously estimating a_k and b_k . By comparing (32) and (33), we get the iterative relationship for a_k : $a_{k+1} \leq a_k + \sqrt{s}b_k$. Denoting by $S_k = b_0 + b_1 + \dots + b_k$, this yields

$$a_k \leq \sqrt{s}S_{k-1}. \quad (34)$$

Similarly, for sufficiently small s we get

$$\begin{aligned} b_{k+1} &\leq \left| 1 - \frac{3}{\max\{\delta/\sqrt{s}, k\}} b_k + L\sqrt{s}a_k + \left(\frac{3}{k+3} - \frac{3}{\max\{\delta/\sqrt{s}, k\}} + 2Ls \right) \|z_k\| \right| \\ &\leq b_k + L\sqrt{s}a_k + \left(\frac{3}{k+3} - \frac{3}{\max\{\delta/\sqrt{s}, k\}} + 2Ls \right) \|z_k\|. \end{aligned}$$

To upper bound $\|z_k\|$, denoting by C_1 the supremum of $\sqrt{2L}(f(y_k) - f^*)$ over all k and s , we have

$$\|z_k\| \leq \frac{k-1}{k+2} \|z_{k-1}\| + \sqrt{s} \|\nabla f(y_k)\| \leq \|z_{k-1}\| + C_1\sqrt{s},$$

which gives $\|z_k\| \leq C_1(k+1)\sqrt{s}$. Hence,

$$\begin{aligned} \left(\frac{3}{k+3} - \frac{3}{\max\{\delta/\sqrt{s}, k\}} + 2Ls \right) \|z_k\| &\leq \begin{cases} C_2\sqrt{s}, & k \leq \frac{\delta}{\sqrt{s}} \\ \frac{C_2\sqrt{s}}{k} < \frac{C_2s}{\theta}, & k > \frac{\delta}{\sqrt{s}}. \end{cases} \end{aligned} \quad (35)$$

Making use of (34) gives

$$b_{k+1} \leq \begin{cases} b_k + LsS_{k-1} + C_2\sqrt{s}, & k \leq \delta/\sqrt{s} \\ b_k + LsS_{k-1} + \frac{C_2s}{\theta}, & k > \delta/\sqrt{s}. \end{cases}$$

By induction on k , for $k \leq \delta/\sqrt{s}$ it holds that

$$b_k \leq \frac{C_1Ls + C_2 + (C_1 + C_2)\sqrt{Ls}}{2\sqrt{L}} (1 + \sqrt{Ls})^{k-1} - \frac{C_1Ls + C_2 - (C_1 + C_2)\sqrt{Ls}}{2\sqrt{L}} (1 - \sqrt{Ls})^{k-1}.$$

Hence,

$$S_k \leq \frac{C_1Ls + C_2 + (C_1 + C_2)\sqrt{Ls}}{2L\sqrt{s}} (1 + \sqrt{Ls})^k + \frac{C_1Ls + C_2 - (C_1 + C_2)\sqrt{Ls}}{2L\sqrt{s}} (1 - \sqrt{Ls})^k - \frac{C_2}{L\sqrt{s}}.$$

Letting $k^* = \lceil \delta/\sqrt{s} \rceil$, we get

$$\limsup_{s \rightarrow 0} \sqrt{s}S_{k^*-1} \leq \frac{C_2e^{\delta\sqrt{L}} + C_2e^{-\delta\sqrt{L}} - 2C_2}{2L} = O(\delta^2),$$

which allows us to conclude that

$$a_k \leq \sqrt{s}S_{k-1} = O(\delta^2) + o_s(1) \quad (36)$$

for all $k \leq \delta/\sqrt{s}$.

Next, we bound b_k for $k > k^* = \lceil \delta/\sqrt{s} \rceil$. To this end, we consider the worst case of (35), that is,

$$b_{k+1} = b_k + LsS_{k-1} + \frac{C_2s}{\theta}$$

for $k > k^*$ and $S_{k^*} = S_{k^*+1} = C_3\delta^2/\sqrt{s} + o_s(1/\sqrt{s})$ for some sufficiently large C_3 . In this case, $C_2s/\theta < sS_{k-1}$ for sufficiently small s . Hence, the last display gives

$$b_{k+1} \leq b_k + (L+1)sS_{k-1}.$$

By induction, we get

$$S_k \leq \frac{C_3\delta^2/\sqrt{s} + o_s(1/\sqrt{s})}{2} \left((1 + \sqrt{(L+1)s})^{k-k^*} + (1 - \sqrt{(L+1)s})^{k-k^*} \right).$$

Letting $k^\circ = \lceil T/\sqrt{s} \rceil$, we further get

$$\limsup_{s \rightarrow 0} \sqrt{s}S_{k^\circ} \leq \frac{C_3\delta^2(e^{(T-\delta)\sqrt{L+1}} + e^{-(T-\delta)\sqrt{L+1}})}{2} = O(\delta^2),$$

which yields

$$a_k \leq \sqrt{s}S_{k-1} = O(\delta^2) + o_s(1)$$

for $k^* < k \leq k^\circ$. Last, combining (36) and the last display, we get the desired result. \blacksquare

Now we turn to the proof of Theorem 2.

Proof. Note the triangular inequality

$$\|x_k - X(k\sqrt{s})\| \leq \|x_k - X_k^\delta\| + \|X_k^\delta - X_\delta(k\sqrt{s})\| + \|X_\delta(k\sqrt{s}) - X(k\sqrt{s})\|,$$

where $X_\delta(\cdot)$ is the solution to the smoothed ODE (31). The proof of Lemma 14 implies that, we can choose a sequence $\delta_m \rightarrow 0$ such that

$$\sup_{0 \leq t \leq T} \|X_{\delta_m}(t) - X(t)\| \rightarrow 0.$$

The second term $\|X_k^{\delta_m} - X_{\delta_m}(k\sqrt{s})\|$ will uniformly vanish as $s \rightarrow 0$ and so does the first term $\|x_k - X_k^{\delta_m}\|$ if first $s \rightarrow 0$ and then $\delta_m \rightarrow 0$. This completes the proof. \blacksquare

Appendix C. ODE for Composite Optimization

In analogy to (3) for smooth f in Section 2, we develop an ODE for composite optimization,

$$\text{minimize } f(x) = g(x) + h(x), \quad (37)$$

where $g \in \mathcal{F}_L$ and h is a general convex function possibly taking on the value $+\infty$. Provided it is easy to evaluate the proximal of h , Beck and Teboulle (2009) propose a proximal

gradient version of Nesterov's scheme for solving (37). It is to repeat the following recursion for $k \geq 1$,

$$\begin{aligned} x_k &= y_{k-1} - sG_k(y_{k-1}) \\ y_k &= x_k + \frac{k-1}{k+2}(x_k - x_{k-1}), \end{aligned}$$

where the proximal subgradient G_s has been defined in Section 4.1. If the constant step size $s \leq 1/L$, it is guaranteed that (Beck and Teboulle, 2009)

$$f(x_k) - f^* \leq \frac{2\|x_0 - x^*\|^2}{s(k+1)^2},$$

which in fact is a special case of Theorem 6.

Compared to the smooth case, it is not as clear to define the driving force as ∇f in (3). At first, it might be a good try to define

$$G(x) = \lim_{s \rightarrow 0} G_s(x) = \lim_{s \rightarrow 0} \frac{x - \operatorname{argmin}_z (\|z - (x - s\nabla g(x))\|^2 / (2s) + h(z))}{s},$$

if it exists. However, as implied in the proof of Theorem 24 stated below, this definition fails to capture the *directional* aspect of the subgradient. To this end, we define the subgradients through the following lemma.

Lemma 22 (Rockafellar, 1997) *For any convex function f and any $x, p \in \mathbb{R}^n$, the directional derivative $\lim_{t \rightarrow 0^+} (f(x+sp) - f(x))/s$ exists, and can be evaluated as*

$$\lim_{s \rightarrow 0^+} \frac{f(x+sp) - f(x)}{s} = \sup_{\xi \in \partial f(x)} \langle \xi, p \rangle.$$

Note that the directional derivative is semilinear in p because

$$\sup_{\xi \in \partial f(x)} \langle \xi, cp \rangle = c \sup_{\xi \in \partial f(x)} \langle \xi, p \rangle$$

for any $c > 0$.

Definition 23 *A Borel measurable function $G(x, p; f)$ defined on $\mathbb{R}^n \times \mathbb{R}^n$ is said to be a directional subgradient of f if*

$$\begin{aligned} G(x, p) &\in \partial f(x), \\ \langle G(x, p), p \rangle &= \sup_{\xi \in \partial f(x)} \langle \xi, p \rangle \end{aligned}$$

for all x, p .

Convex functions are naturally locally Lipschitz, so $\partial f(x)$ is compact for any x . Consequently there exists $\xi \in \partial f(x)$ which maximizes $\langle \xi, p \rangle$. So Lemma 22 guarantees the existence of a directional subgradient. The function G is essentially a function defined on $\mathbb{R}^n \times \mathbb{S}^{n-1}$ in that we can define

$$G(x, p) = G(x, p/\|p\|),$$

and $G(x, 0)$ to be any element in $\partial f(x)$. Now we give the main theorem. However, note that we do not guarantee the existence of solution to (38).

Theorem 24 *Given a convex function $f(x)$ with directional subgradient $G(x, p; f)$, assume that the second order ODE*

$$\ddot{X} + \frac{3}{t}\dot{X} + G(X, \dot{X}) = 0, \quad X(0) = x_0, \dot{X}(0) = 0 \quad (38)$$

admits a solution $X(t)$ on $[0, \alpha)$ for some $\alpha > 0$. Then for any $0 < t < \alpha$, we have

$$f(X(t)) - f^* \leq \frac{2\|x_0 - x^*\|_2^2}{t^2}.$$

Proof It suffices to establish that \mathcal{E} , first defined in the proof of Theorem 3, is monotonically decreasing. The difficulty comes from that \mathcal{E} may not be differentiable in this setting. Instead, we study $(\mathcal{E}(t + \Delta t) - \mathcal{E}(t))/\Delta t$ for small $\Delta t > 0$. In \mathcal{E} , the second term $2\|X + t\dot{X}/2 - x^*\|^2$ is differentiable, with derivative $4\langle X + \frac{t}{2}\dot{X} - x^*, \frac{t}{2}\dot{X} + \frac{t}{2}\ddot{X} \rangle$. Hence,

$$\begin{aligned} & 2\|X(t + \Delta t) + \frac{t}{2}\dot{X}(t + \Delta t) - x^*\|^2 - 2\|X(t) + \frac{t}{2}\dot{X}(t) - x^*\|^2 \\ &= 4\langle X + \frac{t}{2}\dot{X} - x^*, \frac{3}{2}\dot{X} + \frac{t}{2}\ddot{X} \rangle \Delta t + o(\Delta t) \\ &= -t^2 \langle \dot{X}, G(X, \dot{X}) \rangle \Delta t - 2t \langle X - x^*, G(X, \dot{X}) \rangle \Delta t + o(\Delta t). \end{aligned} \quad (39)$$

For the first term, note that

$$(t + \Delta t)^2 (f(X(t + \Delta t)) - f^*) - t^2 (f(X(t)) - f^*) = 2t(f(X(t + \Delta t)) - f^*) \Delta t + t^2 (f(X(t + \Delta t)) - f(X(t))) + o(\Delta t).$$

Since f is locally Lipschitz, $o(\Delta t)$ term does not affect the function in the limit,

$$f(X(t + \Delta t)) = f(X + \Delta t \dot{X} + o(\Delta t)) = f(X + \Delta t \dot{X}) + o(\Delta t). \quad (40)$$

By Lemma 22, we have the approximation

$$f(X + \Delta t \dot{X}) = f(X) + \langle \dot{X}, G(X, \dot{X}) \rangle \Delta t + o(\Delta t). \quad (41)$$

Combining all of (39), (40) and (41), we obtain

$$\begin{aligned} \mathcal{E}(t + \Delta t) - \mathcal{E}(t) &= 2t(f(X(t + \Delta t)) - f^*) \Delta t + t^2 \langle \dot{X}, G(X, \dot{X}) \rangle \Delta t - t^2 \langle \dot{X}, G(X, \dot{X}) \rangle \Delta t \\ &\quad - 2t \langle X - x^*, G(X, \dot{X}) \rangle \Delta t + o(\Delta t) \\ &= 2t(f(X) - f^*) \Delta t - 2t \langle X - x^*, G(X, \dot{X}) \rangle \Delta t + o(\Delta t) \leq o(\Delta t), \end{aligned}$$

where the last inequality follows from the convexity of f . Thus,

$$\limsup_{\Delta t \rightarrow 0^+} \frac{\mathcal{E}(t + \Delta t) - \mathcal{E}(t)}{\Delta t} \leq 0,$$

which along with the continuity of \mathcal{E} , concludes that $\mathcal{E}(t)$ is a non-increasing function of t . \blacksquare

We give a simple example as follows. Consider the Lasso problem

$$\text{minimize } \frac{1}{2}\|y - Ax\|^2 + \lambda\|x\|_1.$$

Any directional subgradients admits the form $G(x, p) = -A^T(y - Ax) + \lambda \text{sgn}(x, p)$, where

$$\text{sgn}(x, p)_i = \begin{cases} \text{sgn}(x_i), & x_i \neq 0 \\ \text{sgn}(p_i), & x_i = 0, p_i \neq 0 \\ \in [-1, 1], & x_i = 0, p_i = 0. \end{cases}$$

To encourage sparsity, for any index i with $x_i = 0, p_i = 0$, we let

$$G(x, p)_i = \text{sgn}(A_i^T(Ax - y)) (|A_i^T(Ax - y)| - \lambda)_+.$$

Appendix D. Proof of Theorem 9

Proof Let g be μ -strongly convex and h be convex. For $f = g + h$, we show that (22) can be strengthened to

$$f(y - sG_s(y)) \leq f(x) + G_s(y)^T(y - x) - \frac{s}{2}\|G_s(y)\|^2 - \frac{\mu}{2}\|y - x\|^2. \quad (42)$$

Summing $(4k-3) \times (42)$ with $x = x_{k-1}, y = y_{k-1}$ and $(4r-6) \times (42)$ with $x = x^*, y = y_{k-1}$ yields

$$\begin{aligned} (4k+4r-9)f(x_k) &\leq (4k-3)f(x_{k-1}) + (4r-6)f^* \\ &\quad + G_s(y_{k-1})^T[(4k+4r-9)y_{k-1} - (4k-3)x_{k-1} - (4r-6)x^*] \\ &\quad - \frac{s(4k+4r-9)}{2}\|G_s(y_{k-1})\|^2 - \frac{\mu(4k-3)}{2}\|y_{k-1} - x_{k-1}\|^2 - \mu(2r-3)\|y_{k-1} - x^*\|^2 \\ &\leq (4k-3)f(x_{k-1}) + (4r-6)f^* - \mu(2r-3)\|y_{k-1} - x^*\|^2 \\ &\quad + G_s(y_{k-1})^T[(4k+4r-9)(y_{k-1} - x^*) - (4k-3)(x_{k-1} - x^*)], \quad (43) \end{aligned}$$

which gives a lower bound on $G_s(y_{k-1})^T[(4k+4r-9)y_{k-1} - (4k-3)x_{k-1} - (4r-6)x^*]$. Denote by Δ_k the second term of $\mathcal{E}(k)$ in (28), namely,

$$\Delta_k \triangleq \frac{k+d}{8}\|(2k+2r-2)(y_k - x^*) - (2k+1)(x_k - x^*)\|^2,$$

where $d := 3r/2 - 5/2$. Then by (43), we get

$$\begin{aligned} \Delta_k - \Delta_{k-1} &= -\frac{k+d}{8}\left\langle s(2r+2k-5)G_s(y_{k-1}) + \frac{k-2}{k+r-2}(x_{k-1} - x_{k-2}), (4k+4r-9)(y_{k-1} - x^*) \right. \\ &\quad \left. - (4k-3)(x_{k-1} - x^*) \right\rangle + \frac{1}{8}\|(2k+2r-4)(y_{k-1} - x^*) - (2k-1)(x_{k-1} - x^*)\|^2 \\ &\leq -\frac{s(k+d)(2k+2r-5)}{8}[(4k+4r-9)(f(x_k) - f^*) \\ &\quad - (4k-3)(f(x_{k-1}) - f^*) + \mu(2r-3)\|y_{k-1} - x^*\|^2] \\ &\quad - \frac{(k+d)(k-2)}{8(k+r-2)}\langle x_{k-1} - x_{k-2}, (4k+4r-9)(y_{k-1} - x^*) - (4k-3)(x_{k-1} - x^*) \rangle \\ &\quad + \frac{1}{8}\|2(k+r-2)(y_{k-1} - x^*) - (2k-1)(x_{k-1} - x^*)\|^2. \end{aligned}$$

Hence,

$$\begin{aligned} \Delta_k + \frac{s(k+d)(2k+2r-5)(4k+4r-9)}{8}(f(x_k) - f^*) \\ \leq \Delta_{k-1} + \frac{s(k+d)(2k+2r-5)(4k-3)}{8}(f(x_{k-1}) - f^*) \\ - \frac{s\mu(2r-3)(k+d)(2k+2r-5)}{8}\|y_{k-1} - x^*\|^2 + \Pi_1 + \Pi_2, \quad (44) \end{aligned}$$

where

$$\Pi_1 \triangleq -\frac{(k+d)(k-2)}{8(k+r-2)}\langle x_{k-1} - x_{k-2}, (4k+4r-9)(y_{k-1} - x^*) - (4k-3)(x_{k-1} - x^*) \rangle,$$

$$\Pi_2 \triangleq \frac{1}{8}\|2(k+r-2)(y_{k-1} - x^*) - (2k-1)(x_{k-1} - x^*)\|^2.$$

By the iterations defined in (19), one can show that

$$\begin{aligned} \Pi_1 &= -\frac{(2r-3)(k+d)(k-2)}{8(k+r-2)}\frac{\|x_{k-1} - x^*\|^2 - \|x_{k-2} - x^*\|^2}{8(k+r-2)^2} \\ &\quad - \frac{(k-2)^2(4k+4r-9)(k+d) + (2r-3)(k-2)(k+r-2)(k+d)}{8(k+r-2)^2}\|x_{k-1} - x_{k-2}\|^2, \\ \Pi_2 &= \frac{(2r-3)^2}{8}\|y_{k-1} - x^*\|^2 + \frac{(2r-3)(2k-1)(k-2)}{8(k+r-2)}(\|x_{k-1} - x^*\|^2 - \|x_{k-2} - x^*\|^2) \\ &\quad + \frac{(k-2)^2(2k-1)(2k+4r-7) + (2r-3)(2k-1)(k-2)(k+r-2)}{8(k+r-2)^2}\|x_{k-1} - x_{k-2}\|^2. \end{aligned}$$

Although this is a little tedious, it is straightforward to check that $(k-2)^2(4k+4r-9)(k+d) + (2r-3)(k-2)(k+r-2)(k+d) \geq (k-2)^2(2k-1)(2k+4r-7) + (2r-3)(2k-1)(k-2)(k+r-2)$ for any k . Therefore, $\Pi_1 + \Pi_2$ is bounded as

$$\Pi_1 + \Pi_2 \leq \frac{(2r-3)^2}{8}\|y_{k-1} - x^*\|^2 + \frac{(2r-3)(k-d-1)(k-2)}{8(k+r-2)}(\|x_{k-1} - x^*\|^2 - \|x_{k-2} - x^*\|^2),$$

which, together with the fact that $s\mu(2r-3)(k+d)(2k+2r-5) \geq (2r-3)^2$ when $k \geq \sqrt{(2r-3)/(2s\mu)}$, reduces (44) to

$$\begin{aligned} \Delta_k &+ \frac{s(k+d)(2k+2r-5)(4k+4r-9)}{8} (f(x_k) - f^*) \\ &\leq \Delta_{k-1} + \frac{s(k+d)(2k+2r-5)(4k-3)}{8} (f(x_{k-1}) - f^*) \\ &\quad + \frac{(2r-3)(k-d-1)(k-2)}{8(k+r-2)} (\|x_{k-1} - x^*\|^2 - \|x_{k-2} - x^*\|^2). \end{aligned}$$

This can be further simplified as

$$\tilde{\mathcal{E}}(k) + A_k(f(x_{k-1}) - f^*) \leq \tilde{\mathcal{E}}(k-1) + B_k(\|x_{k-1} - x^*\|^2 - \|x_{k-2} - x^*\|^2) \quad (45)$$

for $k \geq \sqrt{(2r-3)/(2s\mu)}$, where $A_k = (8r-36)k^2 + (20r^2 - 126r + 200)k + 12r^3 - 100r^2 + 288r - 281 > 0$ since $r \geq 9/2$ and $B_k = (2r-3)(k-d-1)(k-2)/(8(k+r-2))$. Denote by $k^* = \lceil \max\{\sqrt{(2r-3)/(2s\mu)}, 3r/2 - 3/2\} \rceil \asymp 1/\sqrt{s\mu}$. Then B_k is a positive increasing sequence if $k > k^*$. Summing (45) from k to k^*+1 , we obtain

$$\begin{aligned} \mathcal{E}(k) &+ \sum_{i=k^*+1}^k A_i(f(x_{i-1}) - f^*) \leq \mathcal{E}(k^*) + \sum_{i=k^*+1}^k B_i(\|x_{i-1} - x^*\|^2 - \|x_{i-2} - x^*\|^2) \\ &= \mathcal{E}(k^*) + B_k\|x_{k-1} - x^*\|^2 - B_{k^*+1}\|x_{k^*-1} - x^*\|^2 + \sum_{i=k^*+1}^{k-1} (B_j - B_{j+1})\|x_{j-1} - x^*\|^2 \\ &\leq \mathcal{E}(k^*) + B_k\|x_{k-1} - x^*\|^2. \end{aligned}$$

Similarly, as in the proof of Theorem 8, we can bound $\mathcal{E}(k^*)$ via another energy functional defined from Theorem 5,

$$\begin{aligned} \mathcal{E}(k^*) &\leq \frac{s(2k^*+3r-5)(k^*+r-2)^2}{2} (f(x_{k^*}) - f^*) \\ &\quad + \frac{2k^*+3r-5}{16} \|2(k^*+r-1)yk^* - 2k^*x_{k^*} - 2(r-1)x^* - (x_{k^*} - x^*)\|^2 \\ &\quad \leq \frac{s(2k^*+3r-5)(k^*+r-2)^2}{2} (f(x_{k^*}) - f^*) \\ &\quad + \frac{2k^*+3r-5}{8} \|2(k^*+r-1)yk^* - 2k^*x_{k^*} - 2(r-1)x^*\|^2 \\ &\quad + \frac{2k^*+3r-5}{8} \|x_{k^*} - x^*\|^2 \leq \frac{(r-1)^2(2k^*+3r-5)}{2} \|x_0 - x^*\|^2 \\ &\quad + \frac{(r-1)^2(2k^*+3r-5)}{8s\mu(k^*+r-2)^2} \|x_0 - x^*\|^2 \lesssim \frac{\|x_0 - x^*\|^2}{\sqrt{s\mu}}. \quad (46) \end{aligned}$$

For the second term, it follows from Theorem 6 that

$$\begin{aligned} B_k\|x_{k-1} - x^*\|^2 &\leq \frac{(2r-3)(2k-3r+3)(k-2)}{8\mu(k+r-2)} (f(x_{k-1}) - x^*) \\ &\leq \frac{(2r-3)(2k-3r+3)(k-2)}{8\mu(k+r-2)} \frac{(r-1)^2\|x_0 - x^*\|^2}{2s(k+r-3)^2} \\ &\leq \frac{(2r-3)(r-1)^2(2k^*-3r+3)(k^*-2)}{16s\mu(k^*+r-2)(k^*+r-3)^2} \|x_0 - x^*\|^2 \lesssim \frac{\|x_0 - x^*\|^2}{\sqrt{s\mu}}. \end{aligned} \quad (47)$$

For $k > k^*$, (46) together with (47) this gives

$$\begin{aligned} f(x_k) - f^* &\leq \frac{16\mathcal{E}(k)}{s(2k+3r-5)(2k+2r-5)(4k+4r-9)} \\ &\leq \frac{16(\mathcal{E}(k^*) + B_k\|x_{k-1} - x^*\|^2)}{s(2k+3r-5)(2k+2r-5)(4k+4r-9)} \lesssim \frac{\|x_0 - x^*\|^2}{s^{\frac{3}{2}}\mu^{\frac{1}{2}}k^3}. \end{aligned}$$

To conclusion, note that by Theorem 6 the gap $f(x_k) - f^*$ for $k \leq k^*$ is bounded by

$$\frac{(r-1)^2\|x_0 - x^*\|^2}{2s(k+r-2)^2} = \frac{(r-1)^2\sqrt{s\mu}k^3\|x_0 - x^*\|^2}{2(k+r-2)^2} \lesssim \sqrt{s\mu}k^* \frac{\|x_0 - x^*\|^2}{s^{\frac{3}{2}}\mu^{\frac{1}{2}}k^3} \lesssim \frac{\|x_0 - x^*\|^2}{s^{\frac{3}{2}}\mu^{\frac{1}{2}}k^3}. \quad \blacksquare$$

Appendix E. Proof of Lemmas in Section 5

First, we prove Lemma 11.

Proof To begin with, note that the ODE (3) is equivalent to $d(t^{\frac{r}{2}}\dot{X}(t))/dt = -\partial^2\nabla f(\dot{X}(t))$, which by integration leads to

$$t^{\frac{3}{2}}\dot{X}(t) = -\frac{t^4}{4}\nabla f(x_0) - \int_0^t v^3(\nabla f(\dot{X}(u)) - \nabla f(x_0))du = -\frac{t^4}{4}\nabla f(x_0) - I(t). \quad (48)$$

Dividing (48) by t^4 and applying the bound on $I(t)$, we obtain

$$\frac{\|\dot{X}(t)\|}{t} \leq \frac{\|\nabla f(x_0)\|}{4} + \frac{\|I(t)\|}{t^4} \leq \frac{\|\nabla f(x_0)\|}{4} + \frac{LM(t)t^2}{12}.$$

Note that the right-hand side of the last display is monotonically increasing in t . Hence, by taking the supremum of the left-hand side over $(0, t]$, we get

$$M(t) \leq \frac{\|\nabla f(x_0)\|}{4} + \frac{LM(t)t^2}{12},$$

which completes the proof by rearrangement. \blacksquare

Next, we prove the lemma used in the proof of Lemma 12.

Lemma 25 *The speed restarting time T satisfies*

$$T(x_0, f) \geq \frac{4}{5\sqrt{L}}.$$

Proof The proof is based on studying $\langle \dot{X}(t), \ddot{X}(t) \rangle$. Dividing (48) by t^3 , we get an expression for \ddot{X} ,

$$\ddot{X}(t) = -\frac{t}{4}\nabla f(x_0) - \frac{1}{t^3} \int_0^t u^3(\nabla f(X(u)) - \nabla f(x_0))du. \quad (49)$$

Differentiating the above, we also obtain an expression for \ddot{X} :

$$\ddot{X}(t) = -\nabla f(\dot{X}(t)) + \frac{3}{4}\nabla f(x_0) + \frac{3}{t^4} \int_0^t u^3(\nabla f(X(u)) - \nabla f(x_0))du. \quad (50)$$

Using the two equations we can show that $d\|\dot{X}\|^2/dt = 2\langle \dot{X}(t), \ddot{X}(t) \rangle > 0$ for $0 < t < 4/(5\sqrt{L})$. Continue by observing that (49) and (50) yield

$$\begin{aligned} \langle \dot{X}(t), \ddot{X}(t) \rangle &= \left\langle -\frac{t}{4}\nabla f(x_0) - \frac{1}{t^3}I(t), -\nabla f(X(t)) + \frac{3}{4}\nabla f(x_0) + \frac{3}{t^4}I(t) \right\rangle \\ &\geq \frac{t}{4}\langle \nabla f(x_0), \nabla f(X(t)) \rangle - \frac{3t}{16}\|\nabla f(x_0)\|^2 - \frac{1}{t^3}\|I(t)\| \left(\|\nabla f(X(t))\| + \frac{3}{2}\|\nabla f(x_0)\| \right) - \frac{3}{t^7}\|I(t)\|^2 \\ &\geq \frac{t}{4}\|\nabla f(x_0)\|^2 - \frac{t}{4}\|\nabla f(x_0)\|\|\nabla f(X(t)) - \nabla f(x_0)\| - \frac{3t}{16}\|\nabla f(x_0)\|^2 \\ &\quad - \frac{LM(t)t^2}{12} \left(\|\nabla f(X(t)) - \nabla f(x_0)\| + \frac{5}{2}\|\nabla f(x_0)\| \right) - \frac{L^2M(t)t^5}{48} \\ &\geq \frac{t}{16}\|\nabla f(x_0)\|^2 - \frac{LM(t)t^2\|\nabla f(x_0)\|}{8} - \frac{LM(t)t^3}{2} \left(\frac{LM(t)t^2}{2} + \frac{5}{2}\|\nabla f(x_0)\| \right) - \frac{L^2M(t)t^5}{48} \\ &= \frac{t}{16}\|\nabla f(x_0)\|^2 - \frac{LM(t)t^3}{3}\|\nabla f(x_0)\| - \frac{L^2M(t)t^5}{16}. \end{aligned}$$

To complete the proof, applying Lemma 11, the last inequality yields

$$\langle \dot{X}(t), \ddot{X}(t) \rangle \geq \left(\frac{1}{16} - \frac{Lt^2}{12(1-Lt^2/12)} - \frac{L^2t^4}{256(1-Lt^2/12)^2} \right) \|\nabla f(x_0)\|^2 t \geq 0$$

for $t < \min\{\sqrt{12/L}, 4/(5\sqrt{L})\} = 4/(5\sqrt{L})$, where the positivity follows from

$$\frac{1}{16} - \frac{Lt^2}{12(1-Lt^2/12)} - \frac{L^2t^4}{256(1-Lt^2/12)^2} > 0,$$

which is valid for $0 < t \leq 4/(5\sqrt{L})$. ■

Abstract

We propose a sample-efficient alternative for importance weighting for situations where one only has sample access to the probability distribution that generates the observations. Our new method, called Geometric Resampling (GR), is described and analyzed in the context of online combinatorial optimization under semi-bandit feedback, where a learner sequentially selects its actions from a combinatorial decision set so as to minimize its cumulative loss. In particular, we show that the well-known Follow-the-Perturbed-Leader (FPL) prediction method coupled with Geometric Resampling yields the first computationally efficient reduction from offline to online optimization in this setting. We provide a thorough theoretical analysis for the resulting algorithm, showing that its performance is on par with previous, inefficient solutions. Our main contribution is showing that, despite the relatively large variance induced by the GR procedure, our performance guarantees hold with high probability rather than only in expectation. As a side result, we also improve the best known regret bounds for FPL in online combinatorial optimization with full feedback, closing the perceived performance gap between FPL and exponential weights in this setting.

Keywords: online learning, combinatorial optimization, bandit problems, semi-bandit feedback, follow the perturbed leader, importance weighting

1. Introduction

Importance weighting is a crucially important tool used in many areas of machine learning, and specifically online learning with partial feedback. While most work assumes that importance weights are readily available or can be computed with little effort during runtime, this is often not the case in many practical settings, even when one has cheap sample access to the distribution generating the observations. Among other cases, such situations may arise when observations are generated by complex hierarchical sampling schemes, probabilistic programs, or, more generally, black-box generative models. In this paper, we propose a simple and efficient sampling scheme called *Geometric Resampling (GR)* to compute reliable estimates of importance weights *using only sample access*.

Our main motivation is studying a specific online learning algorithm whose practical applicability in partial-feedback settings had long been hindered by the problem outlined above. Specifically, we consider the well-known *Follow-the-Perturbed-Leader (FPL)* prediction method that maintains implicit sampling distributions that usually cannot be expressed in closed form. In this paper, we endow FPL with our Geometric Resampling scheme to construct the first known computationally efficient reduction from offline to online combinatorial optimization under an important partial-

Parameters: set of decision vectors $\mathcal{S} \subseteq \{0, 1\}^d$, number of rounds T ;
For all $t = 1, 2, \dots, T$, **repeat**

1. The learner chooses a probability distribution p_t over \mathcal{S} .
2. The learner draws action V_t randomly according to p_t .
3. The environment chooses loss vector ℓ_t .
4. The learner suffers loss $V_t^\top \ell_t$.
5. The learner observes some feedback based on ℓ_t and V_t .

Figure 1: The protocol of online combinatorial optimization.

information scheme known as *semi-bandit feedback*. In the rest of this section, we describe our precise setting, present related work and outline our main results.

1.1 Online Combinatorial Optimization

We consider a special case of online linear optimization known as online combinatorial optimization (see Figure 1). In every round $t = 1, 2, \dots, T$ of this sequential decision problem, the learner chooses an *action* V_t from the finite action set $\mathcal{S} \subseteq \{0, 1\}^d$, where $\|v\|_1 \leq m$ holds for all $v \in \mathcal{S}$. At the same time, the environment fixes a loss vector $\ell_t \in [0, 1]^d$ and the learner suffers loss $V_t^\top \ell_t$. The goal of the learner is to minimize the cumulative loss $\sum_{t=1}^T V_t^\top \ell_t$. As usual in the literature of online optimization (Cesa-Bianchi and Lugosi, 2006), we measure the performance of the learner in terms of the *regret* defined as

$$R_T = \max_{v \in \mathcal{S}} \sum_{t=1}^T (V_t - v)^\top \ell_t = \sum_{t=1}^T V_t^\top \ell_t - \min_{v \in \mathcal{S}} \sum_{t=1}^T v^\top \ell_t, \quad (1)$$

that is, the gap between the total loss of the learning algorithm and the best fixed decision in hindsight. In the current paper, we focus on the case of *non-oblivious* (or *adaptive*) environments, where we allow the loss vector ℓ_t to depend on the previous decisions V_1, \dots, V_{t-1} in an arbitrary fashion. Since it is well-known that no deterministic algorithm can achieve sublinear regret under such weak assumptions, we will consider learning algorithms that choose their decisions in a randomized way.

For such learners, another performance measure that we will study is the *expected regret* defined as

$$\widehat{R}_T = \max_{v \in \mathcal{S}} \sum_{t=1}^T \mathbb{E} [(V_t - v)^\top \ell_t] = \mathbb{E} \left[\sum_{t=1}^T V_t^\top \ell_t \right] - \min_{v \in \mathcal{S}} \mathbb{E} \left[\sum_{t=1}^T v^\top \ell_t \right].$$

The framework described above is general enough to accommodate a number of interesting problem instances such as path planning, ranking and matching problems, finding minimum-weight spanning trees and cut sets. Accordingly, different versions of this general learning problem have drawn considerable attention in the past few years. These versions differ in the amount of information made available to the learner after each round t . In the simplest setting, called the *full-information* setting, it is assumed that the learner gets to observe the loss vector ℓ_t , regardless of the choice of V_t . As this assumption does not hold for many practical applications, it is more interesting to study the problem under *partial-information* constraints, meaning that the learner only gets some limited feedback based on its own decision. In the current paper, we focus on a more realistic partial-information scheme known as *semi-bandit feedback* (Audibert, Bubeck, and Lugosi, 2014) where the

learner only observes the components $\ell_{t,i}$ of the loss vector for which $V_{t,i} = 1$, that is, the losses associated with the components selected by the learner.¹

1.2 Related Work

The most well-known instance of our problem is the *multi-armed bandit* problem considered in the seminal paper of Auer, Cesa-Bianchi, Freund, and Schapire (2002): in each round of this problem, the learner has to select one of N arms and minimize regret against the best fixed arm while only observing the losses of the chosen arms. In our framework, this setting corresponds to setting $d = N$ and $m = 1$. Among other contributions concerning this problem, Auer et al. propose an algorithm called **Exp3** (Exploration and Exploitation using Exponential weights) based on constructing loss estimates $\hat{\ell}_{t,i}$ for each component of the loss vector and playing arm i with probability proportional to $\exp(-\eta \sum_{s=1}^{t-1} \hat{\ell}_{s,i})$ at time t , where $\eta > 0$ is a parameter of the algorithm, usually called the learning rate². This algorithm is essentially a variant of the Exponentially Weighted Average (EWA) forecaster (a variant of weighted majority algorithm of Littlestone and Warmuth, 1994, and aggregating strategies of Vovk, 1990, also known as Hedge by Freund and Schapire, 1997). Besides proving that the *expected* regret of **Exp3** is $O(\sqrt{NT \log N})$, Auer et al. also provide a general lower bound of $\Omega(\sqrt{NT})$ on the regret of any learning algorithm on this particular problem. This lower bound was later matched by a variant of the Implicitly Normalized Forecaster (INF) of Audibert and Bubeck (2010) by using the same loss estimates in a more refined way. Audibert and Bubeck also show bounds of $O(\sqrt{NT/\log N} \log(N/\delta))$ on the regret that hold with probability at least $1 - \delta$, uniformly for any $\delta > 0$.

The most popular example of online learning problems with actual combinatorial structure is the shortest path problem first considered by Takimoto and Warmuth (2003) in the full information scheme. The same problem was considered by Györfy, Lindner, Lugosi and Ottucsák (2007), who proposed an algorithm that works with semi-bandit information. Since then, we have come a long way in understanding the ‘‘price of information’’ in online combinatorial optimization—see Audibert, Bubeck, and Lugosi (2014) for a complete overview of results concerning all of the information schemes considered in the current paper. The first algorithm directly targeting general online combinatorial optimization problems is due to Koolen, Warmuth, and Kivinen (2010): their method named **Component Hedge** guarantees an optimal regret of $O(m\sqrt{T \log(d/m)})$ in the full information setting. As later shown by Audibert, Bubeck, and Lugosi (2014), this algorithm is an instance of a more general algorithm class known as Online Stochastic Mirror Descent (OSMD). Taking the idea one step further, Audibert, Bubeck, and Lugosi (2014) also show that OSMD-based methods can also be shown to provide expected regret bounds of $O(\sqrt{m d T})$ for the semi-bandit setting, which is also used to coincide with the minimax regret in this setting. For completeness, we note that the EWA forecaster is known to attain an expected regret of $O(m^{3/2} \sqrt{T \log(d/m)})$ in the full information case and $O(m \sqrt{d T \log(d/m)})$ in the semi-bandit case.

While the results outlined above might suggest that there is absolutely no work left to be done in the full information and semi-bandit schemes, we get a different picture if we restrict our attention to *computationally efficient* algorithms. First, note that methods based on exponential weighting of each decision vector can only be efficiently implemented for a handful of decision sets S —see Koolen et al. (2010) and Cesa-Bianchi and Lugosi (2012) for some examples. Furthermore, as noted by Audibert et al. (2014), OSMD-type methods can be efficiently implemented by convex programming if the convex hull of the decision set can be described by a polynomial number of constraints. Details of such an efficient implementation are worked out by Suehiro, Hataano, Kijima, Takimoto, and Nngano (2012), whose algorithm runs in $O(d^{\delta})$ time, which can still be prohibitive in practical applications.

¹ Here, $V_{t,i}$ and $\ell_{t,i}$ are the i th components of the vectors V_t and ℓ_t , respectively.

² In fact, Auer et al. mix the resulting distribution with a uniform distribution over the arms with probability ηN . However, this modification is not needed when one is concerned with the total expected regret, see, e.g., Bubeck and Cesa-Bianchi (2012, Section 3.1).

While Koolen et al. (2010) list some further examples where OSMD can be implemented efficiently, we conclude that there is no general efficient algorithm with near-optimal performance guarantees for learning in combinatorial semi-bandits.

The Follow-the-Perturbed-Leader (FPL) prediction method (first proposed by Hannan, 1957 and later rediscovered by Kalai and Vempala, 2005) offers a computationally efficient solution for the online combinatorial optimization problem given that the *static* combinatorial optimization problem minimizes $v^T \ell$ admits computationally efficient solutions for any $\ell \in \mathbb{R}^d$. The idea underlying FPL is very simple: in every round t , the learner draws some random perturbations $Z_t \in \mathbb{R}^d$ and selects the action that minimizes the perturbed total losses:

$$V_t = \arg \min_{v \in S} v^T \left(\sum_{s=1}^{t-1} \ell_s - Z_t \right).$$

Despite its conceptual simplicity and computational efficiency, FPL have been relatively overlooked until very recently; due to two main reasons:

- The best known bound for FPL in the full information setting is $O(m\sqrt{dT})$, which is worse than the bounds for both EWA and OSMD that scale only logarithmically with d .
- Considering bandit information, no efficient FPL-style algorithm is known to achieve a regret of $O(\sqrt{T})$. On one hand, it is relatively straightforward to prove $O(T^{2/3})$ bounds on the expected regret for an efficient FPL-variant (see, e.g., Averbuch and Kleinberg, 2004 and McMahan and Blum, 2004). Poland (2005) proved bounds of $O(\sqrt{NT \log N})$ in the N -armed bandit setting, however, the proposed algorithm requires $O(T^2)$ numerical operations per round.

The main obstacle for constructing a computationally efficient FPL-variant that works with partial information is precisely the lack of closed-form expressions for importance weights. In the current paper, we address the above two issues and show that an efficient FPL-based algorithm using independent exponentially distributed perturbations can achieve as good performance guarantees as EWA in online combinatorial optimization.

Our work contributes to a new wave of positive results concerning FPL. Besides the reservations towards FPL mentioned above, the reputation of FPL has been also suffering from the fact that the nature of regularization arising from perturbations is not as well-understood as the explicit regularization schemes underlying OSMD or EWA. Very recently, Abernethy et al. (2014) have shown that FPL implements a form of strongly convex regularization over the convex hull of the decision space. Furthermore, Rakhtin et al. (2012) showed that FPL run with a specific perturbation scheme can be regarded as a relaxation of the minimax algorithm. Another recently initiated line of work shows that intuitive *parameter-free* variants of FPL can achieve excellent performance in full-information settings (Devroye et al., 2013 and Van Erven et al., 2014).

1.3 Our Results

In this paper, we propose a loss-estimation scheme called Geometric Resampling to efficiently compute importance weights for the observed components of the loss vector. Building on this technique and the FPL principle, resulting in an *efficient algorithm for regret minimization under semi-bandit feedback*. Besides this contribution, our techniques also enable us to improve the best known regret bounds of FPL in the full information case. We prove the following results concerning variants of our algorithm:

- a bound of $O(m \sqrt{d T \log(d/m)})$ on the expected regret under semi-bandit feedback (Theorem 1),
- a bound of $O(m \sqrt{d T \log(d/m)} + \sqrt{m d T} \log(1/\delta))$ on the regret that holds with probability at least $1 - \delta$, uniformly for all $\delta \in (0, 1)$ under semi-bandit feedback (Theorem 2),

- a bound of $O(m^{3/2}\sqrt{T\log(d/m)})$ on the expected regret under full information (Theorem 13).

We also show that both of our semi-bandit algorithms access the optimization oracle $O(dT)$ times over T rounds with high probability, increasing the running time only by a factor of d compared to the full-information variant. Notably, our results close the gaps between the performance bounds of FPL and EWA under both full information and semi-bandit feedback. Table 1 puts our newly proven regret bounds into context.

	FPL	EWA	OSMD
Full info regret bound	$m^{3/2}\sqrt{T\log\frac{d}{m}}$	$m^{3/2}\sqrt{T\log\frac{d}{m}}$	$m\sqrt{T\log\frac{d}{m}}$

Computationally efficient?	always	sometimes	sometimes

Table 1: Upper bounds on the regret of various algorithms for online combinatorial optimization, up to constant factors. The third row roughly describes the computational efficiency of each algorithm—see the text for details. New results are presented in boldface.

2. Geometric Resampling

In this section, we introduce the main idea underlying Geometric Resampling in the specific context of N -armed bandits where $d = N$, $m = 1$ and the learner has access to the basis vectors $\{\mathbf{e}_i\}_{i=1}^d$ as its decision set \mathcal{S} . In this setting, components of the decision vector are referred to as *arms*. For ease of notation, define I_t as the unique arm such that $V_{t,I_t} = 1$ and \mathcal{F}_{t-1} as the sigma-algebra induced by the learner’s actions and observations up to the end of round $t - 1$. Using this notation, we define $P_{t,i} = \mathbb{P}[I_t = i | \mathcal{F}_{t-1}]$.

Most bandit algorithms rely on feeding some loss estimates to a sequential prediction algorithm. It is commonplace to consider *importance-weighted* loss estimates of the form

$$\widehat{\ell}_{t,i}^* = \frac{\mathbb{1}_{\{I_t=i\}} \ell_{t,i}}{P_{t,i}} \quad (2)$$

for all t, i such that $P_{t,i} > 0$. It is straightforward to show that $\widehat{\ell}_{t,i}^*$ is an unbiased estimate of the loss $\ell_{t,i}$ for all such t, i . Otherwise, when $P_{t,i} = 0$, we set $\widehat{\ell}_{t,i}^* = 0$, which gives $\mathbb{E}[\widehat{\ell}_{t,i}^* | \mathcal{F}_{t-1}] = 0 \leq \ell_{t,i}$.

To our knowledge, all existing bandit algorithms operating in the non-stochastic setting utilize some version of the importance-weighted loss estimates described above. This is a very natural choice for algorithms that operate by first computing the probabilities $P_{t,i}$ and then sampling I_t from the resulting distributions. While many algorithms fall into this class (including the Exp3 algorithm of Auer et al. (2002), the Green algorithm of Allenberg et al. (2006) and the INF algorithm of Audibert and Bubeck (2010), one can think of many other algorithms where the distribution \mathbf{p}_t is specified implicitly and thus importance weights are not readily available. Arguably, FPL is the most important online prediction algorithm that operates with implicit distributions that are notoriously difficult to compute in closed form. To overcome this difficulty, we propose a different loss estimate that can be efficiently computed *even when \mathbf{p}_t is not available for the learner*.

Our estimation procedure dubbed Geometric Resampling (GR) is based on the simple observation that, even though $P_{t,i}$ might not be computable in closed form, one can simply generate a geometric random variable with expectation $1/P_{t,i}$ by repeated sampling from \mathbf{p}_t . Specifically, we propose the following procedure to be executed in round t :

Geometric Resampling for multi-armed bandits

1. The learner draws $I_t \sim \mathbf{p}_t$.
2. For $k = 1, 2, \dots$
 - (a) Draw $I'_t(k) \sim \mathbf{p}_t$.
 - (b) If $I'_t(k) = I_t$, break.
3. Let $K_t = k$.

Observe that K_t generated this way is a geometrically distributed random variable given I_t and \mathcal{F}_{t-1} . Consequently, we have $\mathbb{E}[K_t | \mathcal{F}_{t-1}, I_t] = 1/P_{t,I_t}$. We use this property to construct the estimates

$$\widehat{\ell}_{t,i} = K_{t,i} \mathbb{1}_{\{I_t=i\}} \ell_{t,i} \quad (3)$$

for all arms i . We can easily show that the above estimate is unbiased whenever $P_{t,i} > 0$:

$$\begin{aligned} \mathbb{E}[\widehat{\ell}_{t,i} | \mathcal{F}_{t-1}] &= \sum_j P_{t,j} \mathbb{E}[\widehat{\ell}_{t,i} | \mathcal{F}_{t-1}, I_t = j] \\ &= P_{t,i} \mathbb{E}[\ell_{t,i} K_t | \mathcal{F}_{t-1}, I_t = i] \\ &= P_{t,i} \ell_{t,i} \mathbb{E}[K_t | \mathcal{F}_{t-1}, I_t = i] \\ &= \ell_{t,i}. \end{aligned}$$

Notice that the above procedure produces $\widehat{\ell}_{t,i} = 0$ almost surely whenever $P_{t,i} = 0$, giving $\mathbb{E}[\widehat{\ell}_{t,i} | \mathcal{F}_{t-1}] = 0$ for such t, i .

One practical concern with the above sampling procedure is that its worst-case running time is unbounded: while the expected number of necessary samples K_t is clearly N , the actual number of samples might be much larger. In the next section, we offer a remedy to this problem, as well as generalize the approach to work in the combinatorial semi-bandit case.

3. An Efficient Algorithm for Combinatorial Semi-Bandits

In this section, we present our main result: an efficient reduction from offline to online combinatorial optimization under semi-bandit feedback. The most critical element in our technique is extending the Geometric Resampling idea to the case of combinatorial action sets. For defining the procedure, let us assume that we are running a randomized algorithm mapping histories to probability distributions over the action set \mathcal{S} : letting \mathcal{F}_{t-1} denote the sigma-algebra induced by the history of interaction between the learner and the environment, the algorithm picks action $\mathbf{v} \in \mathcal{S}$ with probability $P_t(\mathbf{v}) = \mathbb{P}[V_t = \mathbf{v} | \mathcal{F}_{t-1}]$. Also introducing $q_{t,i} = \mathbb{E}[V_{t,i} | \mathcal{F}_{t-1}]$, we can define the counterpart of the standard importance-weighted loss estimates of Equation 2 as the vector $\widehat{\ell}_t^*$ with components

$$\widehat{\ell}_{t,i}^* = \frac{V_{t,i} \ell_{t,i}}{q_{t,i}} \quad (4)$$

Again, the problem with these estimates is that for many algorithms of practical interest, the importance weights $q_{t,i}$ cannot be computed in closed form. We now extend the Geometric Resampling procedure defined in the previous section to estimate the importance weights in an efficient manner. One adjustment we make to the procedure presented in the previous section is capping off the number of samples at some finite $M > 0$. While this capping obviously introduces some bias, we will show later that for appropriate values of M , this bias does not hurt the performance of

the overall learning algorithm too much. Thus, we define the Geometric Resampling procedure for combinatorial semi-bands as follows:

Geometric Resampling for combinatorial semi-bands

1. The learner draws $V_t \sim p_t$.
2. For $k = 1, 2, \dots, M$, draw $V_t^i(k) \sim p_t$.
3. For $i = 1, 2, \dots, d$,

$$K_{t,i} = \min\{k : V_t^i(k) = 1\} \cup \{M\}.$$

Based on the random variables output by the GR procedure, we construct our loss-estimate vector $\hat{\ell}_t \in \mathbb{R}^d$ with components

$$\hat{\ell}_{t,i} = K_{t,i} V_{t,i} \ell_{t,i} \quad (5)$$

for all $i = 1, 2, \dots, d$. Since $V_{t,i}$ are nonzero only for coordinates for which $\ell_{t,i}$ is observed, these estimates are well-defined. It also follows that the sampling procedure can be terminated once for every i with $V_{t,i} = 1$, there is a copy $V_t^i(k)$ such that $V_t^i(k) = 1$.

Now everything is ready to define our algorithm: FPL+GR, standing for Follow-the-Perturbed-Leader with Geometric Resampling. Defining $\tilde{L}_t = \sum_{s=1}^t \hat{\ell}_s$, at time step t FPL+GR draws the components of the perturbation vector Z_t independently from a standard exponential distribution and selects action³

$$V_t = \arg \min_{v \in S} v^\top (\eta \tilde{L}_{t-1} - Z_t), \quad (6)$$

where $\eta > 0$ is a parameter of the algorithm. As we mentioned earlier, the distribution p_t , while implicitly specified by Z_t and the estimated cumulative losses L_{t-1} , cannot usually be expressed in closed form for FPL.⁴ However, sampling the actions $V_t^i(\cdot)$ can be carried out by drawing additional perturbation vectors $Z_t^i(\cdot)$ independently from the same distribution as Z_t and then solving a linear optimization task. We emphasize that the above additional actions are *never actually played by the algorithm*, but are only necessary for constructing the loss estimates. The power of FPL+GR is that, unlike other algorithms for combinatorial semi-bands, its implementation only requires access to a linear optimization oracle over S . We point the reader to Section 3.2 for a more detailed discussion of the running time of FPL+GR. Pseudocode for FPL+GR is shown on as Algorithm 1.

As we will show shortly, FPL+GR as defined above comes with strong performance guarantees that hold *in expectation*. One can think of several possible ways to robustify FPL+GR so that it provides bounds that hold with high probability. One possible path is to follow Aber et al. (2002) and define the loss-estimate vector $\hat{\ell}_t^*$ with components

$$\hat{\ell}_{t,i}^* = \hat{\ell}_{t,i} - \frac{\beta}{q_{t,i}}$$

for some $\beta > 0$. The obvious problem with this definition is that it requires perfect knowledge of the importance weights $q_{t,i}$ for all i . While it is possible to extend Geometric Resampling developed in the previous sections to construct a reliable proxy to the above loss estimate, there are several downsides to this approach. First, observe that one would need to obtain estimates of $1/q_{t,i}$ for every single i —even for the ones for which $V_{t,i} = 0$. Due to this necessity, there is no hope to terminate

³ By the definition of the perturbation distribution, the minimum is unique almost surely.

⁴ One notable exception is when the perturbations are drawn independently from standard Gumbel distributions, and the decision set is the d -dimensional simplex: in this case, FPL is known to be equivalent with ERM—see, e.g., Abernethy et al. (2014) for further discussion.

Algorithm 1: FPL+GR implemented with a waiting list. The notation $\mathbf{a} \circ \mathbf{b}$ stands for elementwise product of vectors \mathbf{a} and \mathbf{b} : $(\mathbf{a} \circ \mathbf{b})_i = a_i b_i$ for all i .

```

Input:  $S \subseteq \{0, 1\}^d$ ,  $\eta \in \mathbb{R}^+$ ,  $M \in \mathbb{Z}^+$ ;
Initialization:  $\hat{L} = \mathbf{0} \in \mathbb{R}^d$ ;
for  $t = 1, \dots, T$  do
  Draw  $Z_t \in \mathbb{R}^d$  with independent components  $Z_{t,i} \sim \text{Exp}(1)$ ;
  Choose action  $V = \arg \min_{v \in S} \{v^\top (\eta \hat{L} - Z)\}$ ; /* Follow the perturbed leader */
  for  $k = 1, \dots, M$  do /* Initialize waiting list and counters */
     $K = K + \mathbf{r}$ ; /* Geometric Resampling */
    /* Increment counter */
  Draw  $Z_t^i \in \mathbb{R}^d$  with independent components  $Z_{t,i}^i \sim \text{Exp}(1)$ ; /* Sample a copy of  $V$  */
   $V^i = \arg \min_{v \in S} \{v^\top (\eta \hat{L} - Z^i)\}$ ; /* Update waiting list */
   $\mathbf{r} = \mathbf{r} \circ V^i$ ; /* All indices recurred */
  if  $\mathbf{r} = \mathbf{0}$  then break;
   $\hat{L} = \hat{L} + K \circ V \circ \ell$ ; /* Update cumulative loss estimates */
end

```

the sampling procedure in reasonable time. Second, reliable estimation requires multiple samples of $K_{t,i}$, where the sample size has to explicitly depend on the desired confidence level.

Thus, we follow a different path: Motivated by the work of Audibert and Bubeck (2010), we propose to use a loss-estimate vector $\tilde{\ell}_t$ with components of the form

$$\tilde{\ell}_{t,i} = \frac{1}{\beta} \log \left(1 + \beta \hat{\ell}_{t,i} \right) \quad (7)$$

with an appropriately chosen $\beta > 0$. Then, defining $\tilde{L}_{t-1} = \sum_{s=1}^{t-1} \tilde{\ell}_s$, we propose a variant of FPL+GR that simply replaces \tilde{L}_{t-1} by \tilde{L}_{t-1} in the rule (6) for choosing V_t . We refer to this variant of FPL+GR as FPL+GR, P. In the next section, we provide performance guarantees for both algorithms.

3.1 Performance Guarantees

Now we are ready to state our main results. Proofs will be presented in Section 4. First, we present a performance guarantee for FPL+GR in terms of the *expected regret*:

Theorem 1 *The expected regret of FPL+GR satisfies*

$$\hat{R}_T \leq \frac{m(\log(d/m) + 1)}{\eta} + 2mndT + \frac{dT}{cM}$$

under semi-bandit information. In particular, with

$$\eta = \sqrt{\frac{\log(d/m) + 1}{2dT}} \quad \text{and} \quad M = \left\lceil \frac{\sqrt{dT}}{cm\sqrt{2(\log(d/m) + 1)}} \right\rceil,$$

the expected regret of FPL+GR is bounded as

$$\hat{R}_T \leq 3m\sqrt{2dT \left(\log \frac{d}{m} + 1 \right)}.$$

Our second main contribution is the following bound on the regret of FPL+GR . \mathcal{P} .

Theorem 2 Fix an arbitrary $\delta > 0$. With probability at least $1 - \delta$, the regret of FPL+GR . \mathcal{P} satisfies

$$\begin{aligned} R_T \leq & \frac{m(\log(d/m) + 1)}{\eta} + \eta \left(Mm\sqrt{2T \log \frac{5}{\delta}} + 2md\sqrt{T \log \frac{5}{\delta}} + 2mdT \right) + \frac{dT}{eM} \\ & + \beta \left(M\sqrt{2mT \log \frac{5}{\delta}} + 2d\sqrt{T \log \frac{5}{\delta}} + 2dT \right) + \frac{m \log(5d/\delta)}{\beta} \\ & + m\sqrt{2(e-2)T \log \frac{5}{\delta}} + \sqrt{8T \log \frac{5}{\delta}} + \sqrt{2(e-2)T}. \end{aligned}$$

In particular, with

$$M = \left\lceil \sqrt{\frac{dT}{m}} \right\rceil, \quad \beta = \sqrt{\frac{m}{dT}}, \quad \text{and} \quad \eta = \sqrt{\frac{\log(d/m) + 1}{dT}},$$

the regret of FPL+GR . \mathcal{P} is bounded as

$$\begin{aligned} R_T \leq & 3m\sqrt{dT \left(\log \frac{d}{m} + 1 \right)} + \sqrt{mdT} \left(\log \frac{5d}{\delta} + 2 \right) + \sqrt{2mT \log \frac{5}{\delta}} \left(\sqrt{\log \frac{d}{m}} + 1 + 1 \right) \\ & + 1.2m\sqrt{T \log \frac{5}{\delta}} + \sqrt{T} \left(\sqrt{8 \log \frac{5}{\delta}} + 1.2 \right) + 2\sqrt{d \log \frac{5}{\delta}} \left(m\sqrt{\log \frac{d}{m}} + 1 + \sqrt{m} \right) \end{aligned}$$

with probability at least $1 - \delta$.

3.2 Running Time

Let us now turn our attention to computational issues. First, we note that the efficiency of FPL -type algorithms crucially depends on the availability of an efficient oracle that solves the static combinatorial optimization problem of finding $\arg \min_{v \in \mathcal{S}} v^T \ell$. Computing the running time of the full-information variant of FPL is straightforward: assuming that the oracle computes the solution to the static problem in $O(f(S))$ time, FPL returns its prediction in $O(f(S) + d)$ time (with the d overhead coming from the time necessary to generate the perturbations). Naturally, our loss estimation scheme multiplies these computations by the number of samples taken in each round. While terminating the estimation procedure after M samples helps in controlling the running time with high probability, observe that the naive bound of MT on the number of samples becomes way too large when setting M as suggested by Theorems 1 and 2. The next proposition shows that the amortized running time of Geometric Resampling remains as low as $O(d)$ even for large values of M .

Proposition 3 Let S_t denote the number of sample actions taken by GR in round t . Then, $\mathbb{E}[S_t] \leq d$. Also, for any $\delta > 0$,

$$\sum_{t=1}^T S_t \leq (e-1)dT + M \log \frac{1}{\delta}$$

holds with probability at least $1 - \delta$.

Proof For proving the first statement, let us fix a time step t and notice that

$$S_t = \max_{j: V_{t,j}=1} K_{t,j} = \max_{j=1,2,\dots,d} V_{t,j} K_{t,j} \leq \sum_{j=1}^d V_{t,j} K_{t,j}.$$

Now, observe that $\mathbb{E}[K_{t,j} | \mathcal{F}_{t-1}, V_{t,j}] \leq 1/\mathbb{E}[V_{t,j} | \mathcal{F}_{t-1}]$, which gives $\mathbb{E}[S_t] \leq d$, thus proving the first statement. For the second part, notice that $X_t = (S_t - \mathbb{E}[S_t | \mathcal{F}_{t-1}])$ is a martingale-difference sequence with respect to (\mathcal{F}_t) with $X_t \leq M$ and with conditional variance

$$\begin{aligned} \text{Var}[X_t | \mathcal{F}_{t-1}] &= \mathbb{E} \left[(S_t - \mathbb{E}[S_t | \mathcal{F}_{t-1}])^2 | \mathcal{F}_{t-1} \right] \leq \mathbb{E} \left[S_t^2 | \mathcal{F}_{t-1} \right] \\ &= \mathbb{E} \left[\max_j (V_{t,j} K_{t,j})^2 | \mathcal{F}_{t-1} \right] \leq \mathbb{E} \left[\sum_{j=1}^d V_{t,j} K_{t,j}^2 | \mathcal{F}_{t-1} \right] \\ &\leq \sum_{j=1}^d \min \left\{ \frac{2}{q_{t,j}}, M \right\} \leq dM, \end{aligned}$$

where we used $\mathbb{E}[K_{t,i}^2 | \mathcal{F}_{t-1}] = \frac{2-q_{t,i}}{q_{t,i}}$. Then, the second statement follows from applying a version of Freedman's inequality due to Beygelzimer et al. (2011) (stated as Lemma 16 in the appendix) with $B = M$ and $\Sigma_T \leq dMT$. \blacksquare

Notice that choosing $M = O(\sqrt{dT})$ as suggested by Theorems 1 and 2, the above result guarantees that the amortized running time of FPL+GR is $O((d + \sqrt{dT}) \cdot (f(S) + d))$ with high probability.

4. Analysis

This section presents the proofs of Theorems 1 and 2. In a didactic attempt, we present statements concerning the loss-estimation procedure and the learning algorithm separately: Section 4.1 presents various important properties of the loss estimates produced by Geometric Resampling, Section 4.2 presents general tools for analyzing Follow-the-Perturbed-Leader methods. Finally, Sections 4.3 and 4.4 put these results together to prove Theorems 1 and 2, respectively.

4.1 Properties of Geometric Resampling

The basic idea underlying Geometric Resampling is replacing the importance weights $1/q_{t,i}$ by appropriately defined random variables $K_{t,i}$. As we have seen earlier (Section 2), running GR with $M = \infty$ amounts to sampling each $K_{t,i}$ from a geometric distribution with expectation $1/q_{t,i}$, yielding an unbiased loss estimate. In practice, one would want to set M to a finite value to ensure that the running time of the sampling procedure is bounded. Note however that early termination of GR introduces a bias in the loss estimates. This section is mainly concerned with the nature of this bias. We emphasize that the statements presented in this section remain valid no matter what randomized algorithm generates the actions \tilde{V}_t . Our first lemma gives an explicit expression on the expectation of the loss estimates generated by GR .

Lemma 4 For all j and t such that $q_{t,j} > 0$, the loss estimates (5) satisfy

$$\mathbb{E} \left[\hat{\ell}_{t,j} | \mathcal{F}_{t-1} \right] = (1 - (1 - q_{t,j})^M) \ell_{t,j}.$$

Proof Fix any j, t satisfying the condition of the lemma. Setting $q = q_{t,j}$ for simplicity, we write

$$\begin{aligned} \mathbb{E}[K_{t,j} | \mathcal{F}_{t-1}] &= \sum_{k=1}^{\infty} k(1-q)^{k-1} q - \sum_{k=M}^{\infty} (k-M)(1-q)^{k-1} q \\ &= \sum_{k=1}^{\infty} k(1-q)^{k-1} q - (1-q)^M \sum_{k=M}^{\infty} (k-M)(1-q)^{k-M-1} q \\ &= (1 - (1-q)^M) \sum_{k=1}^{\infty} k(1-q)^{k-1} q = \frac{1 - (1-q)^M}{q}. \end{aligned}$$

The proof is concluded by combining the above with $\mathbb{E} \left[\widehat{\ell}_{k,j} \middle| \mathcal{F}_{t-1} \right] = q_{t,j} \ell_{t,j} \mathbb{E} [K_{t,j} \middle| \mathcal{F}_{t-1}]$. \blacksquare

The following lemma shows two important properties of the GR loss estimates (5). Roughly speaking, the first of these properties ensure that any learning algorithm relying on these estimates will be *optimistic* in the sense that the loss of any fixed decision will be underestimated in expectation. The second property ensures that the learner will not be *overly optimistic* concerning its own performance.

Lemma 5 For all $\mathbf{v} \in \mathcal{S}$ and t , the loss estimates (5) satisfy the following two properties:

$$\mathbb{E} \left[\mathbf{v}^\top \widehat{\ell}_t \middle| \mathcal{F}_{t-1} \right] \leq \mathbf{v}^\top \ell_t, \quad (8)$$

$$\mathbb{E} \left[\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \widehat{\ell}_t \right) \middle| \mathcal{F}_{t-1} \right] \geq \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \ell_t \right) - \frac{d}{cM}. \quad (9)$$

Proof Fix any $\mathbf{v} \in \mathcal{S}$ and t . The first property is an immediate consequence of Lemma 4: we have that $\mathbb{E} \left[\widehat{\ell}_{t,k} \middle| \mathcal{F}_{t-1} \right] \leq \ell_{t,k}$ for all k , and thus $\mathbb{E} \left[\mathbf{v}^\top \widehat{\ell}_t \middle| \mathcal{F}_{t-1} \right] \leq \mathbf{v}^\top \ell_t$. For the second statement, observe that

$$\mathbb{E} \left[\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \widehat{\ell}_t \right) \middle| \mathcal{F}_{t-1} \right] = \sum_{i=1}^d q_{t,i} \mathbb{E} \left[\widehat{\ell}_{t,i} \middle| \mathcal{F}_{t-1} \right] = \sum_{i=1}^d q_{t,i} \left(1 - (1 - q_{t,i})^M \right) \ell_{t,i}$$

also holds by Lemma 4. To control the bias term $\sum_i q_{t,i} (1 - q_{t,i})^M$, note that $q_{t,i} (1 - q_{t,i})^M \leq q_{t,i} e^{-Mq_{t,i}}$. By elementary calculations, one can show that $f(q) = qe^{-Mq}$ takes its maximum at $q = \frac{1}{M}$ and thus $\sum_{i=1}^d q_{t,i} (1 - q_{t,i})^M \leq \frac{d}{cM}$. \blacksquare

Our last lemma concerning the loss estimates (5) bounds the conditional variance of the estimated loss of the learner. This term plays a key role in the performance analysis of Exp3-style algorithms (see, e.g., Auer et al. (2002); Uchiya et al. (2010); Audibert et al. (2014)), as well as in the analysis presented in the current paper:

Lemma 6 For all t , the loss estimates (5) satisfy

$$\mathbb{E} \left[\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \widehat{\ell}_t \right)^2 \middle| \mathcal{F}_{t-1} \right] \leq 2md.$$

Before proving the statement, we remark that the conditional variance can be bounded as md for the standard (although usually infeasible) loss estimates (4). That is, the above lemma shows that, somewhat surprisingly, the variance of our estimates is only twice as large as the variance of the standard estimates.

Proof Fix an arbitrary t . For simplifying notation below, let us introduce $\widetilde{\mathbf{V}}$ as an independent copy of \mathbf{V}_t such that $\mathbb{P} \left[\widetilde{\mathbf{V}} = \mathbf{v} \middle| \mathcal{F}_{t-1} \right] = p_t(\mathbf{v})$ holds for all $\mathbf{v} \in \mathcal{S}$. To begin, observe that for any i

$$\mathbb{E} \left[K_{t,i}^2 \middle| \mathcal{F}_{t-1} \right] \leq \frac{2 - q_{t,i}}{q_{t,i}^2} \leq \frac{2}{q_{t,i}^2} \quad (10)$$

holds, as $K_{t,i}$ has a truncated geometric law. The statement is proven as

$$\begin{aligned} & \mathbb{E} \left[\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \widehat{\ell}_t \right)^2 \middle| \mathcal{F}_{t-1} \right] = \mathbb{E} \left[\sum_{i=1}^d \sum_{j=1}^d \left(\widetilde{V}_i \widehat{\ell}_{t,i} \right) \left(\widetilde{V}_j \widehat{\ell}_{t,j} \right) \middle| \mathcal{F}_{t-1} \right] \\ &= \mathbb{E} \left[\sum_{i=1}^d \sum_{j=1}^d \left(\widetilde{V}_i K_{t,i} V_{t,i} \ell_{t,i} \right) \left(\widetilde{V}_j K_{t,j} V_{t,j} \ell_{t,j} \right) \middle| \mathcal{F}_{t-1} \right] \\ & \quad \text{(using the definition of } \widehat{\ell}_t \text{)} \\ & \leq \mathbb{E} \left[\sum_{i=1}^d \sum_{j=1}^d \frac{K_{t,i}^2 + K_{t,j}^2}{2} \left(\widetilde{V}_i V_{t,i} \ell_{t,i} \right) \left(\widetilde{V}_j V_{t,j} \ell_{t,j} \right) \middle| \mathcal{F}_{t-1} \right] \\ & \quad \text{(using } 2AB \leq A^2 + B^2 \text{)} \\ & \leq 2\mathbb{E} \left[\sum_{i=1}^d \frac{1}{q_{t,i}^2} \left(\widetilde{V}_i V_{t,i} \ell_{t,i} \right) \sum_{j=1}^d V_{t,j} \ell_{t,j} \middle| \mathcal{F}_{t-1} \right] \\ & \quad \text{(using symmetry, Eq. (10) and } \widetilde{V}_j \leq 1 \text{)} \\ & \leq 2m\mathbb{E} \left[\sum_{j=1}^d \ell_{t,j} \middle| \mathcal{F}_{t-1} \right] \leq 2md, \end{aligned}$$

where the last line follows from using $\|\mathbf{V}_t\|_1 \leq m$, $\|\ell_t\|_\infty \leq 1$, and $\mathbb{E} [V_{t,i} \middle| \mathcal{F}_{t-1}] = \mathbb{E} [\widetilde{V}_i \middle| \mathcal{F}_{t-1}] = q_{t,i}$. \blacksquare

4.2 General Tools for Analyzing FPL

In this section, we present the key tools for analyzing the FPL-component of our learning algorithm. In some respect, our analysis is a synthesis of previous work on FPL-style methods: we borrow several ideas from Poland (2005) and the proof of Corollary 4.5 in Cesa-Bianchi and Lugosi (2006). Nevertheless, our analysis is the first to directly target combinatorial settings and yields the tightest known bounds for FPL in this domain. Indeed, the tools developed in this section also permit an improvement for FPL in the full-information setting, closing the presumed performance gap between FPL and EMA in both the full-information and the semi-bandit settings. The statements we present in this section are not specific to the loss-estimate vectors used by FPL+GR.

Like most other known work, we study the performance of the learning algorithm through a *virtual algorithm* that (i) uses a time-independent perturbation vector and (ii) is allowed to peek one step into the future. Specifically, letting $\widetilde{\mathbf{Z}}$ be a perturbation vector drawn independently from the same distribution as \mathbf{Z}_t , the virtual algorithm picks its t^{th} action as

$$\widetilde{\mathbf{V}}_t = \arg \min_{\mathbf{v} \in \mathcal{S}} \left\{ \mathbf{v}^\top \left(\eta \widetilde{\mathbf{L}}_t - \widetilde{\mathbf{Z}} \right) \right\}. \quad (11)$$

In what follows, we will crucially use that $\widetilde{\mathbf{V}}_t$ and \mathbf{V}_{t+1} are conditionally independent and identically distributed given \mathcal{F}_t . In particular, introducing the notations

$$\begin{aligned} q_{t,i} &= \mathbb{E} [V_{t,i} \middle| \mathcal{F}_{t-1}] & \widetilde{q}_{t,i} &= \mathbb{E} \left[\widetilde{V}_{t,i} \middle| \mathcal{F}_t \right] \\ p_t(\mathbf{v}) &= \mathbb{P} [V_t = \mathbf{v} \middle| \mathcal{F}_{t-1}] & \widetilde{p}_t(\mathbf{v}) &= \mathbb{P} [\widetilde{V}_t = \mathbf{v} \middle| \mathcal{F}_t], \end{aligned}$$

we will exploit the above property by using $q_{t,i} = \tilde{q}_{t-1,i}$ and $p_t(\mathbf{v}) = \tilde{p}_{t-1}(\mathbf{v})$ numerous times in the proofs below.

First, we show a regret bound on the virtual algorithm that plays the action sequence $\tilde{\mathbf{V}}_1, \tilde{\mathbf{V}}_2, \dots, \tilde{\mathbf{V}}_T$.

Lemma 7 For any $\mathbf{v} \in \mathcal{S}$,

$$\sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} \tilde{p}_t(\mathbf{u}) \left((\mathbf{u} - \mathbf{v})^\top \hat{\boldsymbol{\ell}}_t \right) \leq \frac{m(\log(d/m) + 1)}{\eta}. \quad (12)$$

Although the proof of this statement is rather standard, we include it for completeness. We also note that the lemma slightly improves other known results by replacing the usual $\log d$ term by $\log(d/m)$.

Proof Fix any $\mathbf{v} \in \mathcal{S}$. Using Lemma 3.1 of Cesa-Bianchi and Lugosi (2006) (sometimes referred to as the “follow-the-leader/be-the-leader” lemma) for the sequence $(\eta \hat{\boldsymbol{\ell}}_1 - \tilde{\mathbf{Z}}, \eta \hat{\boldsymbol{\ell}}_2, \dots, \eta \hat{\boldsymbol{\ell}}_T)$, we obtain

$$\sum_{t=1}^T \tilde{\mathbf{V}}_t^\top \hat{\boldsymbol{\ell}}_t - \tilde{\mathbf{V}}_1^\top \tilde{\mathbf{Z}} \leq \eta \sum_{t=1}^T \mathbf{v}^\top \hat{\boldsymbol{\ell}}_t - \mathbf{v}^\top \tilde{\mathbf{Z}}.$$

Reordering and integrating both sides with respect to the distribution of $\tilde{\mathbf{Z}}$ gives

$$\sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} \tilde{p}_t(\mathbf{u}) \left((\mathbf{u} - \mathbf{v})^\top \hat{\boldsymbol{\ell}}_t \right) \leq \mathbb{E} \left[\left(\tilde{\mathbf{V}}_1 - \mathbf{v} \right)^\top \tilde{\mathbf{Z}} \right]. \quad (13)$$

The statement follows from using $\mathbb{E} \left[\tilde{\mathbf{V}}_1^\top \tilde{\mathbf{Z}} \right] \leq m(\log(d/m) + 1)$, which is proven in Appendix A as Lemma 14, noting that $\tilde{\mathbf{V}}_1^\top \tilde{\mathbf{Z}}$ is upper-bounded by the sum of the m largest components of $\tilde{\mathbf{Z}}$. ■

The next lemma relates the performance of the virtual algorithm to the actual performance of FPL. The lemma relies on a “sparse-loss” trick similar to the trick used in the proof Corollary 4.5 in Cesa-Bianchi and Lugosi (2006), and is also related to the “unit rule” discussed by Koolen et al. (2010).

Lemma 8 For all $t = 1, 2, \dots, T$, assume that $\hat{\boldsymbol{\ell}}_{t,k} \geq 0$ for all $k \in \{1, 2, \dots, d\}$. Then,

$$\sum_{\mathbf{u} \in \mathcal{S}} (p_t(\mathbf{u}) - \tilde{p}_t(\mathbf{u})) \left(\mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right) \leq \eta \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right)^2.$$

Proof Fix an arbitrary t and $\mathbf{u} \in \mathcal{S}$, and define the “sparse loss vector” $\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})$ with components $\hat{\ell}_{t,k}^-(\mathbf{u}) = u_k \hat{\ell}_{t,k}$ and

$$\mathbf{V}_t^-(\mathbf{u}) = \arg \min_{\mathbf{v} \in \mathcal{S}} \left\{ \mathbf{v}^\top \left(\eta \hat{\boldsymbol{\ell}}_{t-1} + \eta \hat{\boldsymbol{\ell}}_t^-(\mathbf{u}) - \tilde{\mathbf{Z}} \right) \right\}.$$

Using the notation $p_t^-(\mathbf{u}) = \mathbb{P} \left[\mathbf{V}_t^-(\mathbf{u}) = \mathbf{u} \mid \mathcal{F}_t \right]$, we show in Lemma 15 (stated and proved in Appendix A) that $p_t^-(\mathbf{u}) \leq \tilde{p}_t(\mathbf{u})$. Also, define

$$\mathbf{U}(\mathbf{z}) = \arg \min_{\mathbf{v} \in \mathcal{S}} \left\{ \mathbf{v}^\top \left(\eta \hat{\boldsymbol{\ell}}_{t-1} - \mathbf{z} \right) \right\}.$$

Letting $f(\mathbf{z}) = e^{-\|\mathbf{z}\|_1}$, ($\mathbf{z} \in \mathbb{R}_+^d$) be the density of the perturbations, we have

$$\begin{aligned} p_t(\mathbf{u}) &= \int_{\mathbf{z} \in [0, \infty]^d} \mathbb{I}_{\{\mathbf{U}(\mathbf{z}) = \mathbf{u}\}} f(\mathbf{z}) \, d\mathbf{z} \\ &= e^{\eta \|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1} \int_{\mathbf{z} \in [0, \infty]^d} \mathbb{I}_{\{\mathbf{U}(\mathbf{z}) = \mathbf{u}\}} f(\mathbf{z} + \eta \hat{\boldsymbol{\ell}}_t^-(\mathbf{u})) \, d\mathbf{z} \\ &= e^{\eta \|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1} \int \dots \int_{\mathbf{z}_t \in (\hat{\ell}_{t,1}^-(\mathbf{u}), \infty)} \mathbb{I}_{\{\mathbf{U}(\mathbf{z} - \eta \hat{\boldsymbol{\ell}}_t^-(\mathbf{u})) = \mathbf{u}\}} f(\mathbf{z}) \, d\mathbf{z} \\ &\leq e^{\eta \|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1} \int_{\mathbf{z} \in [0, \infty]^d} \mathbb{I}_{\{\mathbf{U}(\mathbf{z} - \eta \hat{\boldsymbol{\ell}}_t^-(\mathbf{u})) = \mathbf{u}\}} f(\mathbf{z}) \, d\mathbf{z} \\ &\leq e^{\eta \|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1} p_t^-(\mathbf{u}) \leq e^{\eta \|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1} \tilde{p}_t(\mathbf{u}). \end{aligned}$$

Now notice that $\|\hat{\boldsymbol{\ell}}_t^-(\mathbf{u})\|_1 = \mathbf{u}^\top \hat{\boldsymbol{\ell}}_t^-(\mathbf{u}) = \mathbf{u}^\top \hat{\boldsymbol{\ell}}_t$, which gives

$$\tilde{p}_t(\mathbf{u}) \geq p_t(\mathbf{u}) e^{-\eta \mathbf{u}^\top \hat{\boldsymbol{\ell}}_t} \geq p_t(\mathbf{u}) \left(1 - \eta \mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right).$$

The proof is concluded by repeating the same argument for all $\mathbf{u} \in \mathcal{S}$, reordering and summing the terms as

$$\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right) \leq \sum_{\mathbf{u} \in \mathcal{S}} \tilde{p}_t(\mathbf{u}) \left(\mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right) + \eta \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \hat{\boldsymbol{\ell}}_t \right)^2. \quad (14)$$

4.3 Proof of Theorem 1

Now, everything is ready to prove the bound on the expected regret of FPL+GR. Let us fix an arbitrary $\mathbf{v} \in \mathcal{S}$. By putting together Lemmas 6, 7 and 8, we immediately obtain

$$\mathbb{E} \left[\sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left((\mathbf{u} - \mathbf{v})^\top \hat{\boldsymbol{\ell}}_t \right) \right] \leq \frac{m(\log(d/m) + 1)}{\eta} + 2\eta m d T, \quad (15)$$

leaving us with the problem of upper bounding the expected regret in terms of the left-hand side of the above inequality. This can be done by using the properties of the loss estimates (5) stated in Lemma 5:

$$\mathbb{E} \left[\sum_{t=1}^T (\mathbf{V}_t - \mathbf{v})^\top \boldsymbol{\ell}_t \right] \leq \mathbb{E} \left[\sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left((\mathbf{u} - \mathbf{v})^\top \hat{\boldsymbol{\ell}}_t \right) \right] + \frac{dT}{\epsilon M}.$$

Putting the two inequalities together proves the theorem.

4.4 Proof of Theorem 2

We now turn to prove a bound on the regret of FPL+GR. P that holds with high probability. We begin by noting that the conditions of Lemmas 7 and 8 continue to hold for the new loss estimates, so we can obtain the central terms in the regret:

$$\sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left((\mathbf{u} - \mathbf{v})^\top \tilde{\boldsymbol{\ell}}_t \right) \leq \frac{m(\log(d/m) + 1)}{\eta} + \eta \sum_{t=1}^T \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \tilde{\boldsymbol{\ell}}_t \right)^2.$$

The first challenge posed by the above expression is relating the left-hand side to the true regret with high probability. Once this is done, the remaining challenge is to bound the second term on the right-hand side, as well as the other terms arising from the first step. We first show that the loss estimates used by FPL+GR, \mathbf{P} consistently underestimate the true losses with high probability.

Lemma 9 Fix any $\delta' > 0$. For any $\mathbf{v} \in S$,

$$v^* (\tilde{\mathbf{L}}_T - \mathbf{L}_T) \leq \frac{m \log(d/\delta')}{\beta}$$

holds with probability at least $1 - \delta'$.

The simple proof is directly inspired by Appendix C.9 of Audibert and Bubeck (2010).

Proof Fix any t and i . Then,

$$\mathbb{E} \left[\exp(\beta \tilde{\ell}_{t,i}) \middle| \mathcal{F}_{t-1} \right] = \mathbb{E} \left[\exp \left(\log \left(1 + \beta \tilde{\ell}_{t,i} \right) \right) \middle| \mathcal{F}_{t-1} \right] \leq 1 + \beta \ell_{t,i} \leq \exp(\beta \ell_{t,i}),$$

where we used Lemma 4 in the first inequality and $1 + z \leq e^z$ that holds for all $z \in \mathbb{R}$. As a result, the process $W_t = \exp(\beta(\tilde{\mathbf{L}}_{t,i} - L_{t,i}))$ is a supermartingale with respect to (\mathcal{F}_t) : $\mathbb{E}[W_t | \mathcal{F}_{t-1}] \leq W_{t-1}$. Observe that, since $W_0 = 1$, this implies $\mathbb{E}[W_t] \leq \mathbb{E}[W_{t-1}] \leq \dots \leq 1$. Applying Markov's inequality gives that

$$\begin{aligned} \mathbb{P}[\tilde{L}_{T,i} > L_{T,i} + \epsilon] &= \mathbb{P}[\tilde{L}_{T,i} - L_{T,i} > \epsilon] \\ &\leq \mathbb{E} \left[\exp \left(\beta (\tilde{L}_{T,i} - L_{T,i}) \right) \right] \exp(-\beta \epsilon) \leq \exp(-\beta \epsilon) \end{aligned}$$

holds for any $\epsilon > 0$. The statement of the lemma follows after using $\|\mathbf{v}\|_1 \leq m$, applying the union bound for all i , and solving for ϵ . \blacksquare

The following lemma states another key property of the loss estimates.

Lemma 10 For any t ,

$$\sum_{i=1}^d q_{t,i} \hat{\ell}_{t,i} \leq \sum_{i=1}^d q_{t,i} \tilde{\ell}_{t,i} + \frac{\beta}{2} \sum_{i=1}^d q_{t,i} \tilde{\ell}_{t,i}^2.$$

Proof The statement follows trivially from the inequality $\log(1+z) \geq z - \frac{z^2}{2}$ that holds for all $z \geq 0$. In particular, for any fixed t and i , we have

$$\log \left(1 + \beta \tilde{\ell}_{t,i} \right) \geq \beta \tilde{\ell}_{t,i} - \frac{\beta^2}{2} \tilde{\ell}_{t,i}^2.$$

Multiplying both sides by $q_{t,i}/\beta$ and summing for all i proves the statement. \blacksquare

The next lemma relates the total loss of the learner to its total estimated losses.

Lemma 11 Fix any $\delta' > 0$. With probability at least $1 - 2\delta'$,

$$\sum_{i=1}^T V_t^r \ell_i \leq \sum_{i=1}^T \sum_{\mathbf{w} \in S} p_i(\mathbf{w}) \left(\mathbf{w}^T \hat{\ell}_i \right) + \frac{dT}{cM} + \sqrt{2(e-2)T} \left(m \log \frac{1}{\delta'} + 1 \right) + \sqrt{87T \log \frac{1}{\delta'}}$$

Proof We start by rewriting

$$\sum_{\mathbf{w} \in S} p_i(\mathbf{w}) \left(\mathbf{w}^T \hat{\ell}_i \right) = \sum_{i=1}^d q_{t,i} K_{t,i} V_{t,i} \ell_{t,i}.$$

Now let $k_{t,i} = \mathbb{E}[K_{t,i} | \mathcal{F}_{t-1}]$ for all i and notice that

$$X_t = \sum_{i=1}^d q_{t,i} V_{t,i} \ell_{t,i} (k_{t,i} - K_{t,i})$$

is a martingale-difference sequence with respect to (\mathcal{F}_t) with elements upper-bounded by m (as Lemma 4 implies $k_{t,i}, q_{t,i} \leq 1$ and $\|V_t\|_1 \leq m$). Furthermore, the conditional variance of the increments is bounded as

$$\text{Var}[X_t | \mathcal{F}_{t-1}] \leq \mathbb{E} \left[\left(\sum_{i=1}^d q_{t,i} V_{t,i} K_{t,i} \right)^2 \middle| \mathcal{F}_{t-1} \right] \leq \mathbb{E} \left[\sum_{j=1}^d V_{t,j} \left(\sum_{i=1}^d q_{t,i}^2 K_{t,i}^2 \right) \middle| \mathcal{F}_{t-1} \right] \leq 2m,$$

where the second inequality is Cauchy-Schwarz and the third one follows from $\mathbb{E}[K_{t,i}^2 | \mathcal{F}_{t-1}] \leq 2/q_{t,i}^2$ and $\|V_t\|_1 \leq m$. Thus, applying Lemma 16 with $B = m$ and $\Sigma_T \leq 2mT$ we get that for any $S \geq m \sqrt{\log \frac{1}{\delta'}} / (e-2)$,

$$\sum_{t=1}^T \sum_{i=1}^d q_{t,i} \ell_{t,i} V_{t,i} (k_{t,i} - K_{t,i}) \leq \sqrt{(e-2) \log \frac{1}{\delta'}} \left(\frac{2mT}{S} + S \right)$$

holds with probability at least $1 - \delta'$, where we have used $\|V_t\|_1 \leq m$. After setting $S = m \sqrt{2T \log \frac{1}{\delta'}}$, we obtain that

$$\sum_{t=1}^T \sum_{i=1}^d q_{t,i} \ell_{t,i} V_{t,i} (k_{t,i} - K_{t,i}) \leq \sqrt{2(e-2)T} \left(m \log \frac{1}{\delta'} + 1 \right) \quad (16)$$

holds with probability at least $1 - \delta'$.

To proceed, observe that $q_{t,i} k_{t,i} = 1 - (1 - q_{t,i})^M$ holds by Lemma 4, implying

$$\sum_{i=1}^d q_{t,i} V_{t,i} \ell_{t,i} k_{t,i} \geq V_t^T \ell_t - \sum_{i=1}^d V_{t,i} (1 - q_{t,i})^M.$$

Together with Eq. (16), this gives

$$\sum_{i=1}^T V_t^r \ell_i \leq \sum_{i=1}^T \sum_{\mathbf{w} \in S} p_i(\mathbf{w}) \left(\mathbf{w}^T \hat{\ell}_i \right) + \sqrt{2(e-2)T} \left(m \log \frac{1}{\delta'} + 1 \right) + \sum_{t=1}^T \sum_{i=1}^d V_{t,i} (1 - q_{t,i})^M.$$

Finally, we use that, by Lemma 5, $(1 - q_{t,i})^M \leq 1/(eM)$, and

$$Y_t = \sum_{i=1}^d (V_{t,i} - q_{t,i}) (1 - q_{t,i})^M$$

is a martingale-difference sequence with respect to (\mathcal{F}_t) with increments bounded in $[-1, 1]$. Then, by an application of Hoeffding–Azuma inequality, we have

$$\sum_{i=1}^T \sum_{i=1}^d V_{t,i} (1 - q_{t,i})^M \leq \frac{dT}{cM} + \sqrt{87T \log \frac{1}{\delta'}}$$

with probability at least $1 - \delta'$, thus proving the lemma. \blacksquare

Finally, our last lemma in this section bounds the second-order terms arising from Lemmas 8 and 10.

Lemma 12 Fix any $\delta' > 0$. With probability at least $1 - 2\delta'$, the following hold simultaneously:

$$\begin{aligned} \sum_{t=1}^T \sum_{\mathbf{v} \in \mathcal{S}} p_t(\mathbf{v}) \left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 &\leq Mm \sqrt{2T \log \frac{1}{\delta'}} + 2md \sqrt{T \log \frac{1}{\delta'}} + 2mdT \\ \sum_{t=1}^T \sum_{i=1}^d q_{t,i} \hat{\rho}_{t,i}^2 &\leq M \sqrt{2mT \log \frac{1}{\delta'}} + 2d \sqrt{T \log \frac{1}{\delta'}} + 2dT. \end{aligned}$$

Proof First, recall that

$$\mathbb{E} \left[\sum_{\mathbf{v} \in \mathcal{S}} p_t(\mathbf{v}) \left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 \middle| \mathcal{F}_{t-1} \right] \leq 2md$$

holds by Lemma 8. Now, observe that

$$X_t = \sum_{\mathbf{v} \in \mathcal{S}} p_t(\mathbf{v}) \left(\left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 - \mathbb{E} \left[\left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 \middle| \mathcal{F}_{t-1} \right] \right)$$

is a martingale-difference sequence with increments in $[-2md, mM]$. An application of the Hoeffding-Azuma inequality gives that

$$\sum_{t=1}^T \sum_{\mathbf{v} \in \mathcal{S}} p_t(\mathbf{v}) \left(\left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 - \mathbb{E} \left[\left(\mathbf{v}^\top \hat{\boldsymbol{\ell}}_t \right)^2 \middle| \mathcal{F}_{t-1} \right] \right) \leq Mm \sqrt{2T \log \frac{1}{\delta'}} + 2md \sqrt{T \log \frac{1}{\delta'}}$$

holds with probability at least $1 - \delta'$. Reordering the terms completes the proof of the first statement. The second statement is proven analogously, building on the bound

$$\mathbb{E} \left[\sum_{t=1}^d \sum_{i=1}^d q_{t,i} \hat{\rho}_{t,i}^2 \middle| \mathcal{F}_{t-1} \right] \leq \mathbb{E} \left[\sum_{t=1}^d \sum_{i=1}^d q_{t,i} V_{t,i} K_{t,i}^2 \middle| \mathcal{F}_{t-1} \right] \leq 2d.$$

Theorem 2 follows from combining Lemmas 9 through 12 and applying the union bound. \blacksquare

5. Improved Bounds for Learning With Full Information

Our proof techniques presented in Section 4.2 also enable us to tighten the guarantees for FPL in the full information setting. In particular, consider the algorithm choosing action

$$\mathbf{V}_t = \arg \min_{\mathbf{v} \in \mathcal{S}} \langle \eta \mathbf{L}_{t-1} - \mathbf{Z}_t, \mathbf{v} \rangle,$$

where $\mathbf{L}_t = \sum_{s=1}^t \boldsymbol{\ell}_s$ and the components of \mathbf{Z}_t are drawn independently from a standard exponential distribution. We state our improved regret bounds concerning this algorithm in the following theorem.

Theorem 13 For any $\mathbf{v} \in \mathcal{S}$, the total expected regret of FPL satisfies

$$\hat{R}_T \leq \frac{m \left(\log(d/m) + 1 \right)}{\eta} + \eta m \sum_{t=1}^T \mathbb{E} [\mathbf{V}_t^\top \boldsymbol{\ell}_t]$$

under full information. In particular, defining $L_T^* = \min_{\mathbf{v} \in \mathcal{S}} \mathbf{v}^\top L_T$ and setting

$$\eta = \min \left\{ \sqrt{\frac{\log(d/m) + 1}{L_T^*}}, \frac{1}{2} \right\},$$

the regret of FPL satisfies

$$R_T \leq 4m \max \left\{ \sqrt{L_T^* \left(\log \left(\frac{d}{m} \right) + 1 \right)}, (m^2 + 1) \left(\log \frac{d}{m} + 1 \right) \right\}.$$

In the worst case, the above bound becomes $2m^{3/2} \sqrt{T \log(d/m) + 1}$, which improves the best known bound for FPL of Kalai and Vempala (2005) by a factor of $\sqrt{d/m}$.

Proof The first statement follows from combining Lemmas 7 and 8, and bounding

$$\sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \boldsymbol{\ell}_t \right)^2 \leq m \sum_{\mathbf{u} \in \mathcal{S}} p_t(\mathbf{u}) \left(\mathbf{u}^\top \boldsymbol{\ell}_t \right),$$

while the second one follows from standard algebraic manipulations. \blacksquare

6. Conclusions and Open Problems

In this paper, we have described the first *general and efficient* algorithm for online combinatorial optimization under semi-bandit feedback. We have proved that the regret of this algorithm is $O(m\sqrt{dT} \log(d/m))$ in this setting, and have also shown that FPL can achieve $O(m^{3/2} \sqrt{T \log(d/m)})$ in the full information case when tuned properly. While these bounds are off by a factor of $\sqrt{m \log(d/m)}$ and \sqrt{m} from the respective minimax results, they exactly match the best known regret bounds for the well-studied Exponentially Weighted Forecaster (EWA). Whether the remaining gaps can be closed for FPL-style algorithms (e.g., by using more intricate perturbation schemes or a more refined analysis) remains an important open question. Nevertheless, we regard our contribution as a significant step towards understanding the inherent trade-offs between computational efficiency and performance guarantees in online combinatorial optimization and, more generally, in online optimization.

The efficiency of our method rests on a novel loss estimation method called Geometric Resampling (GR). This estimation method is not specific to the proposed learning algorithm. While GR has no immediate benefits for OSMD-type algorithms where the ideal importance weights are readily available, it is possible to think about problem instances where EWA can be efficiently implemented while importance weights are difficult to compute.

The most important open problem left is the case of efficient online linear optimization with *full bandit feedback* where the learner only observes the inner product $\mathbf{V}_t^\top \boldsymbol{\ell}_t$ in round t . Learning algorithms for this problem usually require that the (pseudo-)inverse of the covariance matrix $P_t = \mathbb{E}[\mathbf{V}_t \mathbf{V}_t^\top | \mathcal{F}_{t-1}]$ is readily available for the learner at each time step (see, e.g., McMahan and Blum (2004); Dani et al. (2008); Cesa-Bianchi and Lugosi (2012); Buback et al. (2012)). Computing this matrix, however, is at least as challenging as computing the individual importance weights $1/q_{t,i}$. That said, our Geometric Resampling technique can be directly generalized to this setting by observing that the matrix geometric series $\sum_{n=1}^{\infty} (I - P_t)^n$ converges to P_t^{-1} under certain conditions. This sum can then be efficiently estimated by sampling independent copies of \mathbf{V}_t , which paves the path for constructing low-bias estimates of the loss vectors. While it seems straightforward to go ahead and use these estimates in tandem with FPL, we have to note that the analysis presented in this paper does not carry through directly in this case. The main limitation is that our techniques only apply for loss vectors with *non-negative* elements (cf. Lemma 8). Nevertheless, we believe that Geometric Resampling should be a crucial component for constructing truly effective learning algorithms for this important problem.

Appendix A. Further Proofs and Technical Tools

Lemma 14 Let Z_1, \dots, Z_d be i.i.d. exponentially distributed random variables with unit expectation and let Z_1^*, \dots, Z_d^* be their permutation such that $Z_1^* \geq Z_2^* \geq \dots \geq Z_d^*$. Then, for any $1 \leq m \leq d$,

$$\mathbb{E} \left[\sum_{i=1}^m Z_i^* \right] \leq m \left(\log \left(\frac{d}{m} \right) + 1 \right).$$

Proof Let us define $Y = \sum_{i=1}^m Z_i^*$. Then, as Y is nonnegative, we have for any $A \geq 0$ that

$$\begin{aligned} \mathbb{E}[Y] &= \int_0^\infty \mathbb{P}[Y > y] dy \\ &\leq A + \int_A^\infty \mathbb{P} \left[\sum_{i=1}^m Z_i^* > y \right] dy \\ &\leq A + \int_A^\infty \mathbb{P} \left[Z_1^* > \frac{y}{m} \right] dy \\ &\leq A + d \int_A^\infty \mathbb{P} \left[Z_1 > \frac{y}{m} \right] dy \\ &= A + de^{-A/m} \\ &\leq m \log \left(\frac{d}{m} \right) + m, \end{aligned}$$

where in the last step, we used that $A = \log \left(\frac{d}{m} \right)$ minimizes $A + de^{-A/m}$ over the real line. ■

Lemma 15 Fix any $\mathbf{v} \in S$ and any vectors $\mathbf{L} \in \mathbb{R}^d$ and $\boldsymbol{\ell} \in [0, \infty)^d$. Define the vector $\boldsymbol{\ell}'$ with components $\ell'_k = v_k \ell_k$. Then, for any perturbation vector \mathbf{Z} with independent components,

$$\begin{aligned} \mathbb{P}[\mathbf{v}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \leq \mathbf{u}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \mid \forall \mathbf{u} \in S] \\ \leq \mathbb{P}[\mathbf{v}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \leq \mathbf{u}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \mid \forall \mathbf{u} \in S]. \end{aligned}$$

Proof Fix any $\mathbf{u} \in S \setminus \{\mathbf{v}\}$ and define the vector $\boldsymbol{\ell}'' = \boldsymbol{\ell} - \boldsymbol{\ell}'$. Define the events

$$A(\mathbf{u}) = \{\mathbf{v}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \leq \mathbf{u}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z})\}$$

and

$$A(\mathbf{u}) = \{\mathbf{v}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z}) \leq \mathbf{u}^\top (\mathbf{L} + \boldsymbol{\ell}' - \mathbf{Z})\}.$$

We have

$$\begin{aligned} A(\mathbf{u}) &= \{(\mathbf{v} - \mathbf{u})^\top \mathbf{Z} \geq (\mathbf{v} - \mathbf{u})^\top (\mathbf{L} + \boldsymbol{\ell}')\} \\ &\subseteq \{(\mathbf{v} - \mathbf{u})^\top \mathbf{Z} \geq (\mathbf{v} - \mathbf{u})^\top (\mathbf{L} + \boldsymbol{\ell}') - \mathbf{u}^\top \boldsymbol{\ell}''\} \\ &= \{(\mathbf{v} - \mathbf{u})^\top \mathbf{Z} \geq (\mathbf{v} - \mathbf{u})^\top (\mathbf{L} + \boldsymbol{\ell}') - A(\mathbf{u})\}, \end{aligned}$$

where we used $\mathbf{v}^\top \boldsymbol{\ell}'' = 0$ and $\mathbf{u}^\top \boldsymbol{\ell}'' \geq 0$. Now, since $A(\mathbf{u}) \subseteq A(\mathbf{u})$, we have $\mathbb{P}_{\mathbf{u} \in S} A(\mathbf{u}) \subseteq \mathbb{P}_{\mathbf{u} \in S} A(\mathbf{u})$, thus proving $\mathbb{P}[\mathbb{P}_{\mathbf{u} \in S} A(\mathbf{u})] \leq \mathbb{P}[\mathbb{P}_{\mathbf{u} \in S} A(\mathbf{u})]$ as claimed in the lemma. ■

Lemma 16 (cf. Theorem 1 in Beygelzimer et al. (2011)) Assume X_1, X_2, \dots, X_T is a martingale-difference sequence with respect to the filtration (\mathcal{F}_t) with $X_t \leq B$ for $1 \leq t \leq T$. Let $\sigma_t^2 = \text{Var}[X_t \mid \mathcal{F}_{t-1}]$ and $\Sigma_t^2 = \sum_{s=1}^t \sigma_s^2$. Then, for any $\delta > 0$,

$$\mathbb{P} \left[\sum_{t=1}^T \mathbf{X}_t > B \log \frac{1}{\delta} + (e-2) \frac{\Sigma_T^2}{B} \right] \leq \delta.$$

Furthermore, for any $S > B \sqrt{\log(1/\delta)}(e-2)$,

$$\mathbb{P} \left[\sum_{t=1}^T \mathbf{X}_t > \sqrt{(e-2) \log \frac{1}{\delta}} \left(\frac{\Sigma_T^2}{S} + S \right) \right] \leq \delta.$$

Abstract

We study a regularizer which is defined as a parameterized infimum of quadratics, and which we call the box-norm. We show that the k -support norm, a regularizer proposed by Argyriou et al. (2012) for sparse vector prediction problems, belongs to this family, and the box-norm can be generated as a perturbation of the former. We derive an improved algorithm to compute the proximity operator of the squared box-norm, and we provide a method to compute the norm. We extend the norms to matrices, introducing the spectral k -support norm and spectral box-norm. We note that the spectral box-norm is essentially equivalent to the cluster norm, a multitask learning regularizer introduced by Jacob et al. (2009a), and which in turn can be interpreted as a perturbation of the spectral k -support norm. Centering the norm is important for multitask learning and we also provide a method to use centered versions of the norms as regularizers. Numerical experiments indicate that the spectral k -support and box-norms and their centered variants provide state of the art performance in matrix completion and multitask learning problems respectively.

Keywords: Convex optimization, matrix completion, multitask learning, spectral regularization, structured sparsity.

1. Introduction

We continue the study of a family of norms which are obtained by taking the infimum of a class of quadratic functions. These norms can be used as a regularizer in linear regression learning problems, where the parameter set can be tailored to assumptions on the underlying regression model. This family of norms is sufficiently rich to encompass regularizers such as the ℓ_p norms, the group Lasso with overlap (Jacob et al., 2009b) and the norm of Micchelli et al. (2013). In this paper we focus on a particular norm in this framework—the box-norm—

in which the parameter set involves box constraints and a linear constraint. We study the norm in detail and show that it can be generated as a perturbation of the k -support norm introduced by Argyriou et al. (2012) for sparse vector estimation, which hence can be seen as a special case of the box-norm. Furthermore, our variational framework allows us to study efficient algorithms to compute the norms and the proximity operator of the square of the norms.

Another main goal of this paper is to extend the k -support and box-norms to a matrix setting. We observe that both norms are symmetric gauge functions, hence by applying them to the spectrum of a matrix we obtain two orthogonally invariant matrix norms. In addition, we observe that the spectral box-norm is essentially equivalent to the cluster norm introduced by Jacob et al. (2009a) for multitask clustering, which in turn can be interpreted as a perturbation of the spectral k -support norm.

The characteristic properties of the vector norms translate in a natural manner to matrices. In particular, the unit ball of spectral k -support norm is the convex hull of the set of matrices of rank no greater than k , and Frobenius norm bounded by one. In numerical experiments we present empirical evidence on the strong performance of the spectral k -support norm in low rank matrix completion and multitask learning problems.

Moreover, our computation of the vector box-norm and its proximity operator extends naturally to the spectral case, which allows us to use proximal gradient methods to solve regularization problems using the cluster norm. Finally, we provide a method to use the centered versions of the penalties, which are important in applications (see e.g. Evgeniou et al., 2007; Jacob et al., 2009a).

1.1 Related Work

Our work builds upon a recent line of papers which considered convex regularizers defined as an infimum problem over a parametric family of quadratics, as well as related infimal convolution problems (see Jacob et al., 2009b; Bach et al., 2011; Maurer and Pontil, 2012; Micchelli and Pontil, 2005; Obozinski and Bach, 2012, and references therein). Related variational formulations for the Lasso have also been discussed in (Grandvalet, 1998) and further studied in (Szafranski et al., 2007).

To our knowledge, the box-norm was first suggested by Jacob et al. (2009a) and used as a symmetric gauge function in matrix learning problems. The induced orthogonally invariant matrix norm is named the *cluster norm* in (Jacob et al., 2009a) and was motivated as a convex relaxation of a multitask clustering problem. Here we formally prove that the cluster norm is indeed an orthogonal invariant norm. More importantly, we explicitly compute the norm and its proximity operator.

A key observation of this paper is the link between the box-norm and the k -support norm and in turn the link between the cluster norm and the spectral k -support norm. The k -support norm was proposed in (Argyriou et al., 2012) for sparse vector prediction and was shown to empirically outperform the Lasso (Tibshirani, 1996) and Elastic Net (Zou and Hastie, 2005) penalties. See also Gkirtzou et al. (2013) for further empirical results.

In recent years there has been a great deal of interest in the problem of learning a low rank matrix from a set of linear measurements. A widely studied and successful instance of this problem arises in the context of matrix completion or collaborative filtering, in which

we want to recover a low rank (or approximately low rank) matrix from a small sample of its entries, see e.g. Srebro et al. (2005); Abernethy et al. (2009) and references therein. One prominent method of solving this problem is trace norm regularization: we look for a matrix which closely fits the observed entries and has a small trace norm (sum of singular values) (Jaggi and Sulovsky, 2010; Toh and Yun, 2011; Mazumder et al., 2010). In our numerical experiments we consider the spectral k -support norm and spectral box-norm as alternatives to the trace norm and compare their performance.

Another application of matrix learning is multitask learning. In this framework a number of tasks, such as classifiers or regressors, are learned by taking advantage of commonalities between them. This can improve upon learning the tasks separately, for instance when insufficient data is available to solve each task in isolation (see e.g. Evgeniou et al., 2005; Argyriou et al., 2007, 2008; Jacob et al., 2009a; Cavallanti et al., 2010; Maurer, 2006; Maurer and Pontil, 2008). An approach which has been successful is the use of spectral regularizers such as the trace norm to learn a matrix where the columns represent the individual tasks, and in this paper we compare the performance of the spectral k -support and box-norms as penalties in multitask learning problems.

Finally, we note that this is a longer version of the conference paper (McDonald et al., 2014) and includes new theoretical and experimental results.

1.2 Contributions

We summarise the main contributions of this paper.

- We show that the vector k -support norm is a special case of the more general *box-norm*, which in turn can be seen as a perturbation of the former. The box-norm can be written as a parameterized infimum of quadratics, and this framework is instrumental in deriving a fast algorithm to compute the norm and the proximity operator of the squared norm in $\mathcal{O}(d \log d)$ time. Apart from improving on the $\mathcal{O}(d(k + \log d))$ algorithm for the proximity operator in Argyriou et al. (2012), this method allows one to use optimal first order optimization algorithms (Nesterov, 2007) for the box-norm.¹
- We extend the k -support and box-norms to orthogonally invariant matrix norms. We note that the spectral box-norm is essentially equivalent to the cluster norm, which in turn can be interpreted as a perturbation of the spectral k -support norm in the sense of the Moreau envelope. Our computation of the vector box-norm and its proximity operator also extends naturally to the spectral case. This allows us to use proximal gradient methods for the cluster norm. Furthermore, we provide a method to apply the centered versions of the penalties, which are important in applications.

- We present extensive numerical experiments on both synthetic and real matrix learning data sets. Our findings indicate that regularization with the spectral k -support and box-norms produces state-of-the-art results on a number of popular matrix completion benchmarks and centered variants of the norms show a significant improvement

¹ We note that recently Chatterjee et al. (2014) showed that the proximity operator of the vector k -support norm can be computed in $\mathcal{O}(d \log d)$. Here we directly follow Argyriou et al. (2012) and consider the squared k -support norm.

in performance over the centered trace norm and the matrix elastic net on multitask learning benchmarks.

1.3 Notation

We use \mathbb{N}_n for the set of integers from 1 up to and including n . We let \mathbb{R}^d be the d dimensional real vector space, whose elements are denoted by lower case letters. We let \mathbb{R}_+^d and \mathbb{R}_{++}^d be the subsets of vectors with nonnegative and strictly positive components, respectively. We denote by Δ^d the unit d -simplex, $\Delta^d = \{\lambda \in \mathbb{R}^{d+1} : \sum_{i=1}^{d+1} \lambda_i = 1\}$. For any vector $w \in \mathbb{R}^d$, its *support* is defined as $\text{supp}(w) = \{i : w_i \neq 0\} \subseteq \mathbb{N}_d$. We use 1 to denote either the scalar or a vector of all ones, whose dimension is determined by its context. Given a subset g of \mathbb{N}_d , the d -dimensional vector 1_g has ones on the support g , and zeros elsewhere. We let $\mathbb{R}^{d \times T}$ be the space of $d \times T$ real matrices and write $W = [w_1, \dots, w_T]$ to denote the matrix whose columns are formed by the vectors $w_1, \dots, w_T \in \mathbb{R}^d$. For a vector $\sigma \in \mathbb{R}^d$, we denote by $\text{diag}(\sigma)$ the $d \times d$ diagonal matrix having elements σ_i on the diagonal. We say matrix $W \in \mathbb{R}^{d \times T}$ is diagonal if $W_{ij} = 0$ whenever $i \neq j$. We denote the trace of a matrix W by $\text{tr}(W)$, and its rank by $\text{rank}(W)$. We let $\sigma(W) \in \mathbb{R}_+^T$ be the vector formed by the singular values of W , where $r = \min(d, T)$, and where we assume that the singular values are ordered nonincreasing, i.e. $\sigma_1(W) \geq \dots \geq \sigma_r(W) \geq 0$. We use \mathbf{S}^d to denote the set of real $d \times d$ symmetric matrices, and \mathbf{S}_+^d to denote the subset of positive semidefinite matrices. We use \succeq to denote the positive semidefinite ordering on \mathbf{S}^d . The notation (\cdot, \cdot) denotes the standard inner products on \mathbb{R}^d and $\mathbb{R}^{d \times T}$, that is $(x, y) = \sum_{i=1}^d x_i y_i$ for $x, y \in \mathbb{R}^d$, and $(X, Y) = \text{tr}(X^T Y)$, for $X, Y \in \mathbb{R}^{d \times T}$. Given a norm $\|\cdot\|$ on \mathbb{R}^d or $\mathbb{R}^{d \times T}$, $\|\cdot\|_*$ denotes the corresponding dual norm, given by $\|u\|_* = \sup\{u, w\} : \|w\| \leq 1\}$. On \mathbb{R}^d we denote by $\|\cdot\|_2$ the Euclidean norm, and on $\mathbb{R}^{d \times T}$ we denote by $\|\cdot\|_F$ the Frobenius norm and by $\|\cdot\|_{\text{tr}}$ the trace norm, that is the sum of singular values.

1.4 Organization

The paper is organized as follows. In Section 2, we review a general class of norms and characterize their unit ball. In Section 3, we specialize these norms to the box-norm, which we show is a perturbation of the k -support norm. We study the properties of the norms and we describe the geometry of the unit balls. In Section 4, we compute the box-norm and we provide an efficient method to compute the proximity operator of the squared norm. In Section 5, we extend the norms to orthogonally invariant matrix norms—the spectral k -support and spectral box-norms—and we show that these exhibit a number of properties which relate to the vector properties in a natural manner. In Section 6, we review the clustered multitask learning setting, we recall the cluster norm introduced by Jacob et al. (2009a) and we show that the cluster norm corresponds to the spectral box-norm. We also provide a method for solving the resulting matrix regularization problem using “centered” norms. In Section 7, we apply the norms to matrix learning problems on a number of simulated and real data sets and report on their performance. In Section 8, we discuss extensions to the framework and suggest directions for future research. Finally, in Section 9, we conclude.

2. Preliminaries

In this section we review a family of norms parameterized by a set Θ , and which we call the Θ -norms. They are closely related to the norms considered in Micchelli et al. (2010, 2013). Similar norms are also discussed in Bach et al. (2011, Sect. 1.4.2) where they are called H -norms. We first recall the definition of the norm.

Definition 1 Let Θ be a convex bounded subset of the open positive orthant. For $w \in \mathbb{R}^d$ the Θ -norm is defined as

$$\|w\|_{\Theta} = \sqrt{\inf_{\theta \in \Theta} \sum_{i=1}^d \frac{w_i^2}{\theta_i}}. \quad (1)$$

Note that the function $(w, \theta) \mapsto \sum_{i=1}^d \frac{w_i^2}{\theta_i}$ is strictly convex on $\mathbb{R}^d \times \mathbb{R}_{++}^d$, hence every minimizing sequence converges to the same point. The infimum is, however, not attained in general because a minimizing sequence may converge to a point on the boundary of Θ . For instance, if $\Theta = \{\theta \in \mathbb{R}_{++}^d : \sum_{i=1}^d \theta_i \leq 1\}$, then $\|w\|_{\Theta} = \|w\|_1$ and the minimizing sequence converges to the point $(\frac{w_1}{\|w\|_1}, \dots, \frac{w_d}{\|w\|_1})$, which belongs to Θ only if all the components of w are different from zero.

Proposition 2 The Θ -norm is well defined and the dual norm is given, for $u \in \mathbb{R}^d$, by

$$\|u\|_{*\Theta} = \sqrt{\sup_{\theta \in \Theta} \sum_{i=1}^d \theta_i u_i^2}. \quad (2)$$

Proof Consider the expression for the dual norm. The function $\|\cdot\|_{*\Theta}$ is a norm since it is a supremum of norms. Recall that the Fenchel conjugate h^* of a function $h: \mathbb{R}^d \rightarrow \mathbb{R}$ is defined for every $u \in \mathbb{R}^d$ as $h^*(u) = \sup \{\langle u, w \rangle - h(w) : w \in \mathbb{R}^d\}$. It is a standard result from convex analysis that for any norm $\|\cdot\|$, the Fenchel conjugate of the function $h := \frac{1}{2} \|\cdot\|^2$ satisfies $h^* = \frac{1}{2} \|\cdot\|_*^2$, where $\|\cdot\|_*$ is the corresponding dual norm (see, e.g. Lewis, 1995). By the same result, for any norm the biconjugate is equal to the norm, that is $(\|\cdot\|_*)^* = \|\cdot\|$. Applying this to the dual norm we have, for every $w \in \mathbb{R}^d$, that

$$h(w) = \sup_{u \in \mathbb{R}^d} \{\langle w, u \rangle - h^*(u)\} = \sup_{u \in \mathbb{R}^d} \inf_{\theta \in \Theta} \left\{ \sum_{i=1}^d \left(w_i u_i - \frac{1}{2} \theta_i u_i^2 \right) \right\}.$$

This is a minimax problem in the sense of von Neumann (see e.g. Prop. 2.6.3 in Bertsekas et al., 2003), and we can exchange the order of the inf and the sup, and solve the latter (which is in fact a maximum) componentwise. The gradient with respect to u_i is zero for $u_i = \frac{w_i}{\theta_i}$, and substituting this into the objective function we obtain $h(w) = \frac{1}{2} \|w\|_{\Theta}^2$. It follows that the expression in (1) defines a norm, and its dual norm is defined by (2), as required. ■

The Θ -norm (1) encompasses a number of well known norms. For instance, for $p \in [1, \infty)$ the ℓ_p norm is defined, for every $w \in \mathbb{R}^d$, as $\|w\|_p = (\sum_{i=1}^d |w_i|^p)^{\frac{1}{p}}$, if $p \in [1, \infty)$ and

$\|w\|_{\infty} = \max_{i=1}^d |w_i|$. For $p \in [1, 2)$, one can show (Micchelli and Pontil, 2005, Lemma 26), that $\|w\|_p = \|w\|_{\Theta_p}$, where we have defined $\Theta_p = \{\theta \in \mathbb{R}_{++}^d : \sum_{i=1}^d \theta_i^{\frac{2}{2-p}} \leq 1\}$. For $p = 1$ this confirms the set Θ corresponding to the ℓ_1 norm as claimed above. Similarly, for $p \in (2, \infty]$ we have that $\|w\|_p = \|w\|_{*\Theta_p}$, where $\frac{1}{p} + \frac{1}{q} = 1$. The ℓ_2 -norm is obtained as both a primal and dual Θ -norm in the limit as p tends to 2. See also Aflalo et al. (2011) who considered the case of $p > 2$.

Other norms which belong to the family (1) are presented in (Micchelli et al., 2013) and correspond to choosing $\Theta = \{\theta \in \Lambda : \sum_{i=1}^d \theta_i \leq 1\}$, where $\Lambda \subseteq \mathbb{R}_{++}^d$ is a convex cone. A specific example described therein is the wedge penalty, which corresponds to choosing $\Lambda = \{\theta \in \mathbb{R}_{++}^d, \theta_1 \geq \dots \geq \theta_d\}$.

We now describe the unit ball of the Θ -norm when the set Θ is a polyhedron and we characterize the unit ball of the norm. This setting applies to a number of norms of practical interest, including the group lasso with overlap, the wedge norm mentioned above and, as we shall see, the k -support norm. To describe our observation, for every vector $\gamma \in \mathbb{R}_{++}^d$, we define the seminorm

$$\|w\|_{\gamma} = \sqrt{\sum_{i:\gamma_i>0} \frac{w_i^2}{\gamma_i}}.$$

Proposition 3 Let $\gamma^1, \dots, \gamma^m \in \mathbb{R}_{++}^d$ such that $\sum_{\ell=1}^m \gamma^{\ell} \in \mathbb{R}_{++}^d$ and let $\Theta = \{\theta \in \mathbb{R}_{++}^d : \theta = \sum_{\ell=1}^m \lambda \gamma^{\ell}, \lambda \in \Delta^{m-1}\}$.

Then we have, for every $w \in \mathbb{R}^d$, that

$$\|w\|_{\Theta} = \inf \left\{ \sum_{\ell=1}^m \|v_{\ell}\|_{\gamma^{\ell}} : v_{\ell} \in \mathbb{R}^d, \text{supp}(v_{\ell}) \subseteq \text{supp}(\gamma^{\ell}), \ell \in \mathbb{N}_m, \sum_{\ell=1}^m v_{\ell} = w \right\}. \quad (3)$$

Moreover, the unit ball of the norm is given by the convex hull of the set

$$\bigcup_{\ell=1}^m \left\{ w \in \mathbb{R}^d : \text{supp}(w) \subseteq \text{supp}(\gamma^{\ell}), \|w\|_{\gamma^{\ell}} \leq 1 \right\}. \quad (4)$$

The proof of this result is presented in the appendix. It is based on observing that the Minkowski functional (see e.g. Rudin, 1991) of the convex hull of the set (4) is a norm and it is given by the right hand side of equation (3); we then prove that this norm coincides with $\|\cdot\|_{\Theta}$ by noting that both norms share the same dual norm. To illustrate an application of the proposition, we specialize it to the group Lasso with overlap (Jacob et al., 2009b).

Corollary 4 If \mathcal{G} is a collection of subsets of \mathbb{N}_d such that $\bigcup_{g \in \mathcal{G}} g = \mathbb{N}_d$ and Θ is the interior of the set $\text{co}\{1_g : g \in \mathcal{G}\}$, then we have, for every $w \in \mathbb{R}^d$, that

$$\|w\|_{\Theta} = \inf \left\{ \sum_{g \in \mathcal{G}} \|v_g\|_2 : v_g \in \mathbb{R}^d, \text{supp}(v_g) \subseteq g, \sum_{g \in \mathcal{G}} v_g = w \right\}. \quad (5)$$

Moreover, the unit ball of the norm is given by the convex hull of the set

$$\bigcup_{g \in \mathcal{G}} \left\{ w \in \mathbb{R}^d : \text{supp}(w) \subseteq g, \|w\|_2 \leq 1 \right\}. \quad (6)$$

We do not claim any originality in the above corollary and proposition, although we cannot find a specific reference. The utility of the result is that it links seemingly different norms such as the group Lasso with overlap and the Θ -norms, which provide a more compact representation, involving only d additional variables. This formulation is especially useful whenever the optimization problem (1) can be solved in closed form. One such example is provided by the wedge norm described above. In the next section we discuss one more important case, the box-norm, which plays a central role in this paper.

3. The Box-Norm and the k -Support Norm

We now specialize our analysis to the case that

$$\Theta = \left\{ \theta \in \mathbb{R}^d : a \leq \theta_i \leq b, \sum_{i=1}^d \theta_i \leq c \right\} \quad (7)$$

where $0 < a \leq b$ and $c \in [ad, bd]$. We call the norm defined by (1) the *box-norm* and we denote it by $\|\cdot\|_{\text{box}}$.

The structure of set Θ for the box-norm will be fundamental in computing the norm and deriving the proximity operator in Section 4. Furthermore, we note that the constraints are invariant with respect to permutations of the components of Θ and, as we shall see in Section 5, this property is key to extending the norm to matrices. Finally, while a restriction of the general family, the box-norm nevertheless encompasses a number of norms including the ℓ_1 and ℓ_2 norms, as well as the k -support norm, which we now recall.

For every $k \in \mathbb{N}_d$, the k -support norm $\|\cdot\|_{(k)}$ (Argyriou et al., 2012) is defined as the norm whose unit ball is the convex hull of the set of vectors of cardinality at most k and ℓ_2 -norm no greater than one. The authors show that the k -support norm can be written as the infimal convolution (see Rockafellar, 1970, p. 34)

$$\|w\|_{(k)} = \inf \left\{ \sum_{g \in G_k} \|v_g\|_2 : v_g \in \mathbb{R}^d, \text{supp}(v_g) \subseteq g, \sum_{g \in G_k} v_g = w \right\}, \quad w \in \mathbb{R}^d, \quad (8)$$

where G_k is the collection of all subsets of \mathbb{N}_d containing at most k elements. The k -support norm is a special case of the group lasso with overlap (Jacob et al., 2009b), where the cardinality of the support sets is at most k . When used as a regularizer, the norm encourages vectors w to be a sum of a limited number of vectors with small support. Note that while definition (8) involves a combinatorial number of variables, Argryiou et al. (2012) observed that the norm can be computed in $\mathcal{O}(d \log d)$, a point we return to in Section 4.

Comparing equation (8) with Corollary 4 it is evident that the k -support norm is a Θ -norm where $\Theta = \{\theta \in \mathbb{R}_+^d : \theta = \sum_{g \in G_k} \lambda_g 1_g, \lambda \in \Delta^{(|G_k|-1)}\}$, which by symmetry can be expressed as $\Theta = \{\theta : 0 < \theta_i \leq 1, \sum_{i=1}^d \theta_i \leq k\}$. Hence, we see that the k -support norm is a special case of the box-norm.

Despite the complicated form of (8), Argryiou et al. (2012) observe that the dual norm has a simple formulation, namely the ℓ_2 -norm of the k largest components,

$$\|u\|_{*(k)} = \sqrt{\sum_{i=1}^k (u_i^\dagger)^2}, \quad u \in \mathbb{R}^d, \quad (9)$$

where $|u|^\dagger$ is the vector obtained from u by reordering its components so that they are non-increasing in absolute value. Note from equation (9) that for $k = 1$ and $k = d$, the dual norm is equal to the ℓ_∞ -norm and ℓ_2 -norm, respectively. It follows that the k -support norm includes the ℓ_1 -norm and ℓ_2 -norm as special cases.

We now provide a different argument illustrating that the k -support norm belongs to the family of box-norms using the dual norm. We first derive the dual box-norm.

Proposition 5 *The dual box-norm is given by*

$$\|u\|_{*\text{box}}^2 = a\|u\|_2^2 + (b-a) \left(\|u\|_{*(k)}^2 + (\rho - k)(|u|_{k+1}^\dagger)^2 \right), \quad (10)$$

where $\rho = \frac{c-da}{b-a}$ and k is the largest integer not exceeding ρ .

Proof We need to solve problem (2). We make the change of variable $\phi_i = \frac{\theta_i - a}{b-a}$ and observe that the constraints on θ induce the constraint set $\{\phi \in (0, 1]^d, \sum_{i=1}^d \phi_i \leq \rho\}$, where $\rho = \frac{c-da}{b-a}$. Furthermore $\sum_{i=1}^d \theta_i a_i^2 = a\|u\|_2^2 + (b-a) \sum_{i=1}^d \phi_i u_i^2$. The result then follows by taking the supremum over ϕ . ■

We see from equation (10) that the dual norm decomposes into a weighted combination of the ℓ_2 -norm, the k -support norm and a residual term, which vanishes if $\rho = k \in \mathbb{N}_d$. For the rest of this paper we assume this holds, which loses little generality. This choice is equivalent to requiring that $c = (b-a)k + da$, which is the case considered by Jacob et al. (2009a) in the context of multitask clustering, where $k+1$ is interpreted as the number of clusters and d as the number of tasks. We return to this case in Section 6, where we explain in detail the link between the spectral k -support norm and the cluster norm.

Observe that if $a = 0$, $b = 1$, and $\rho = k$, the dual box-norm (10) coincides with dual k -support norm in equation (9). We conclude that if

$$\Theta = \left\{ \theta \in \mathbb{R}^d : 0 < \theta_i \leq 1, \sum_{i=1}^d \theta_i \leq k \right\}$$

then the Θ -norm coincides with the k -support norm.

3.1 Properties of the Norms

In this section we illustrate a number of properties of the box-norm and the connection to the k -support norm. The first result follows as a special case of Proposition 3.

Corollary 6 *If $0 < a < b$ and $c = (b-a)k + da$, for $k \in \mathbb{N}_d$, then it holds that*

$$\|w\|_{\text{box}} = \inf \left\{ \sum_{g \in G_k} \sqrt{\frac{v_{g,i}^2}{b} + \sum_{i \notin g} \frac{v_{g,i}^2}{a}} : v_g \in \mathbb{R}^d, \sum_{g \in G_k} v_g = w \right\}, \quad w \in \mathbb{R}^d.$$

Furthermore, the unit ball of the norm is given by the convex hull of the set

$$\bigcup_{g \in G_k} \left\{ w \in \mathbb{R}^d : \sum_{i \in g} \frac{w_i^2}{b} + \sum_{i \notin g} \frac{w_i^2}{a} \leq 1 \right\}. \quad (11)$$

Notice in Equation (11) that if $b = 1$, then as a tends to zero, we obtain the expression of the k -support norm (8), recovering in particular the support constraints. If a is small and positive, the support constraints are not imposed, however most of the weight for each v_g tends to be concentrated on $\text{supp}(g)$. Hence, Corollary 6 suggests that if $a \ll b$ then the box-norm regularizer will encourage vectors w whose dominant components are a subset of a union of a small number of groups $g \in \mathcal{G}_k$.

Our next result links two Θ -norms whose parameter sets are related by a linear transformation with positive coefficients.

Lemma 7 *Let Θ be a convex bounded subset of the positive orthant in \mathbb{R}^d , and let $\Phi = \{\phi \in \mathbb{R}^d : \phi_i = \alpha + \beta\theta_i, \theta \in \Theta\}$, where $\alpha, \beta > 0$. Then*

$$\|w\|_{\Phi}^2 = \min_{z \in \mathbb{R}^d} \left\{ \frac{1}{\alpha} \|w - z\|_2^2 + \frac{1}{\beta} \|z\|_{\Theta}^2 \right\}.$$

Proof We consider the definition of the norm $\|\cdot\|_{\Phi}$ in (1). We have

$$\|w\|_{\Phi}^2 = \inf_{\phi \in \Phi} \sum_{i=1}^d \frac{w_i^2}{\phi_i} = \inf_{\theta \in \Theta} \sum_{i=1}^d \frac{w_i^2}{\alpha + \beta\theta_i}, \quad (12)$$

where we have made the change of variable $\phi_i = \alpha + \beta\theta_i$. Next we observe that

$$\min_{z \in \mathbb{R}^d} \left\{ \frac{1}{\alpha} \|w - z\|_2^2 + \frac{1}{\beta} \|z\|_{\Theta}^2 \right\} = \min_{z \in \mathbb{R}^d} \inf_{\theta \in \Theta} \left\{ \sum_{i=1}^d \frac{(w_i - z_i)^2}{\alpha} + \frac{z_i^2}{\beta\theta_i} \right\} = \inf_{\theta \in \Theta} \sum_{i=1}^d \frac{w_i^2}{\alpha + \beta\theta_i}, \quad (13)$$

where we interchanged the order of the minimum and the infimum and solved for z componentwise, setting $z_i = \frac{\beta\theta_i w_i}{\alpha + \beta\theta_i}$. The result now follows by combining equations (12) and (13). ■

In Section 3 we characterized the k -support norm as a special case of the box-norm. Conversely, Lemma 7 allows us to interpret the box-norm as a perturbation of the k -support norm with a quadratic regularization term.

Proposition 8 *Let $\|\cdot\|_{\text{box}}$ be the box-norm on \mathbb{R}^d with parameters $0 < a < b$ and $c = k(b - a) + da$, for $k \in \mathbb{N}_d^+$, then*

$$\|w\|_{\text{box}}^2 = \min_{z \in \mathbb{R}^d} \left\{ \frac{1}{a} \|w - z\|_2^2 + \frac{1}{b - a} \|z\|_{\tau(k)}^2 \right\}. \quad (14)$$

Proof The result directly follows from Lemma 7 for $\Theta = \{\theta \in \mathbb{R}^d : 0 < \theta_i \leq 1, \sum_{i=1}^d \theta_i \leq k\}$, $\alpha = a$ and $\beta = b - a$. ■

Lemma 7 and Proposition 8 can further be interpreted using the Moreau envelope from convex optimization, which we now recall (Rockafellar and Wets, 2009, Ch. 1 §G).

Definition 9 *Let $f : \mathbb{R}^d \rightarrow (-\infty, \infty]$ be proper, lower semi-continuous and let $\rho > 0$. The Moreau envelope of f with parameter ρ is defined as*

$$e_{\rho}f(w) = \inf_{z \in \mathbb{R}^d} \left\{ f(z) + \frac{1}{2\rho} \|w - z\|_2^2 \right\}.$$

Note that $e_{\rho}f$ minorizes f and is convex and smooth (Bauschke and Combettes, 2010, see e.g.). It acts as a parameterized smooth approximation to f from below, which motivates its use in variational analysis (see e.g. Rockafellar and Wets, 2009, for further discussion). Lemma 7 therefore says that $\beta\|\cdot\|_{\Theta}^2$ is a Moreau-envelope of $\|\cdot\|_{\Theta}^2$ with parameter $\rho = \frac{2}{\beta}$ whenever Φ is defined as $\Phi = \alpha + \beta\Theta$, $\alpha, \beta > 0$. In particular we see from (14) that the squared box-norm, scaled by a factor of $(b - a)$, is a Moreau envelope of the squared k -support norm as we have

$$(b - a)\|w\|_{\text{box}}^2 = \min_{z \in \mathbb{R}^d} \left\{ \|z\|_{\tau(k)}^2 + \frac{1}{2\rho} \|w - z\|_2^2 \right\} =: e_{\rho}f(w), \quad (15)$$

where $f(w) = \|w\|_{\tau(k)}^2$ and $\rho = \frac{1}{2(b-a)}$.

Proposition 8 further allows us to decompose the solution to a vector learning problem using the squared box-norm into two components with particular structure. Specifically, consider the regularization problem

$$\min_{w \in \mathbb{R}^d} \|Xw - y\|_2^2 + \lambda\|w\|_{\text{box}}^2 \quad (16)$$

with data $X \in \mathbb{R}^{n \times d}$ and response $y \in \mathbb{R}^n$. Using Proposition 8 and setting $w = u + z$, we see that (16) is equivalent to

$$\min_{u, z \in \mathbb{R}^d} \left\{ \|X(u + z) - y\|_2^2 - \frac{\lambda}{a} \|u\|_2^2 + \frac{\lambda}{b - a} \|z\|_{\tau(k)}^2 \right\}. \quad (17)$$

Furthermore, if (\hat{u}, \hat{z}) solves problem (17) then $\hat{w} = \hat{u} + \hat{z}$ solves problem (16). The solution \hat{w} can therefore be interpreted as the superposition of a vector which has small ℓ_2 norm, and a vector which has small k -support norm, with the parameter a regulating these two components. Specifically, as a tends to zero, in order to prevent the objective from blowing up, \hat{u} must also tend to zero and we recover k -support norm regularization. Similarly, as a tends to b , \hat{z} vanishes and we have a simple ridge regression problem.

A further consequence of Proposition 8 is the differentiability of the squared box-norm.

Proposition 10 *If $a > 0$ the squared box-norm is differentiable on \mathbb{R}^d and its gradient*

$$\nabla(\|\cdot\|_{\text{box}}^2) = \frac{2}{a} \left(\text{Id} - \text{prox}_{\rho\|\cdot\|_{\tau(k)}} \right)$$

is Lipschitz continuous with parameter $\frac{2}{a}$.

Proof Letting $f(w) = \|w\|_{\tau(k)}^2$, $\rho = \frac{1}{2(b-a)}$, by (15) we have $e_{\rho}f(w) = (b - a)\|w\|_{\text{box}}^2$. The result follows directly from Bauschke and Combettes (2010, Prop. 12.29), as f is convex and continuous on \mathbb{R}^d and the gradient is given as $\nabla(e_{\rho}f) = \frac{1}{\rho}(\text{Id} - \text{prox}_{\rho f})$. ■

Proposition 10 establishes that the square of the box-norm is differentiable and its smoothness is controlled by the parameter a . Furthermore, the gradient can be determined from the proximity operator, which we compute in Section 4.

3.2 Geometry of the Norms

In this section, we briefly investigate the geometry of the box-norm. Figure 1 depicts the unit balls for the k -support norm in \mathbb{R}^3 for various parameter values, setting $b = 1$ throughout. For $k = 1$ and $k = 3$ we recognize the ℓ_1 and ℓ_2 balls respectively. For $k = 2$ the unit ball retains characteristics of both norms, and in particular we note the discontinuities along each of x , y and z planes, as in the case of the ℓ_1 norm.

Figure 2 depicts the unit balls for the box-norm for a range of values of a and k , with $c = (b - a)k + da$. We see that in general the balls increase in volume with each of a and k , holding the other parameter fixed. Comparing the k -support norm ($k = 1$), that is the ℓ_1 norm, and the box-norm ($k = 1, a = 0.15$), we see that the parameter a smooths out the sharp edges of the ℓ_1 norm. This is also visible when comparing the k -support ($k = 2$) and the box ($k = 2, a = 0.15$). This illustrates the smoothing effect of the parameter a , as suggested by Proposition 10.

We can gain further insight into the shape of the unit balls of the box-norm from Corollary 6. Equation (11) shows that the primal unit ball is the convex hull of ellipsoids in \mathbb{R}^d , where for each group g the semi-principle axis along dimension i has length \sqrt{b} if $i \in g$, and length \sqrt{a} if $i \notin g$. Similarly, the unit ball of the dual box-norm is the intersection of ellipsoids in \mathbb{R}^d where for each group g the semi-principle axis in dimension i has length $1/\sqrt{b}$ if $i \in g$, and length $1/\sqrt{a}$ if $i \notin g$ (see also Equation 37 in the appendix). It is instructive to further consider the effect of the parameter a on the unit balls for fixed k . To this end, recall that since $c = (b - a)k + da$, when $k = d$ we have $c = bd$. In this case, for all values of a in $(0, b]$, the objective in (1) is attained by setting $\theta_i = b$ for all i , and we recover the ℓ_2 -norm, scaled by $1/\sqrt{b}$, for the primal box-norm. Similarly in (2), the dual norm gives rise to the ℓ_2 -norm, scaled by \sqrt{b} . In the remainder of this section we therefore only consider the cases $k \in \{1, 2\}$ in \mathbb{R}^3 .

For $k = 1$, $\mathcal{G}_k = \{\{1\}, \{2\}, \{3\}\}$. The unit ball of the primal box-norm is the convex hull of the ellipsoids defined by

$$\frac{w_1^2}{b} + \frac{w_2^2}{a} + \frac{w_3^2}{a} = 1, \quad \frac{w_1^2}{a} + \frac{w_2^2}{b} + \frac{w_3^2}{a} = 1, \quad \text{and} \quad \frac{w_1^2}{a} + \frac{w_2^2}{a} + \frac{w_3^2}{b} = 1, \quad (18)$$

and the unit ball of the dual box-norm is the intersection of the ellipsoids defined by

$$\frac{w_1^2}{b-1} + \frac{w_2^2}{a-1} + \frac{w_3^2}{a-1} = 1, \quad \frac{w_1^2}{a-1} + \frac{w_2^2}{b-1} + \frac{w_3^2}{a-1} = 1, \quad \text{and} \quad \frac{w_1^2}{a-1} + \frac{w_2^2}{a-1} + \frac{w_3^2}{b-1} = 1. \quad (19)$$

For $k = 2$, $\mathcal{G}_k = \{\{1\}, \{2\}, \{3\}, \{1, 2\}, \{2, 3\}, \{1, 3\}\}$. The unit ball of the primal box-norm is the convex hull of the ellipsoids defined by (18) in addition to the following

$$\frac{w_1^2}{b} + \frac{w_2^2}{b} + \frac{w_3^2}{a} = 1, \quad \frac{w_1^2}{a} + \frac{w_2^2}{b} + \frac{w_3^2}{b} = 1, \quad \text{and} \quad \frac{w_1^2}{b} + \frac{w_2^2}{a} + \frac{w_3^2}{b} = 1, \quad (20)$$

and the unit ball of the dual box-norm is the intersection of the ellipsoids defined by (19) in addition to the following

$$\frac{w_1^2}{b-1} + \frac{w_2^2}{b-1} + \frac{w_3^2}{a-1} = 1, \quad \frac{w_1^2}{a-1} + \frac{w_2^2}{b-1} + \frac{w_3^2}{a-1} = 1, \quad \text{and} \quad \frac{w_1^2}{b-1} + \frac{w_2^2}{a-1} + \frac{w_3^2}{b-1} = 1. \quad (21)$$

For the primal norm, note that since $b > a$, each of the ellipsoids in (18) is entirely contained within one of those defined by (20), hence when taking the convex hull we need only consider the latter set. Similarly for the dual norm, since $\frac{1}{b} < \frac{1}{a}$, each of the ellipsoids in (19) is contained within one of those defined by (21), hence when taking the intersection we need only consider the latter set.

Figures 3 and 4 depict the constituent ellipses for various parameter values for the primal and dual norms. As a tends to zero the ellipses become degenerate. For $k = 1$, taking the convex hull we recover the ℓ_1 unit ball in the primal norm, and taking the intersection we recover the ℓ_∞ unit ball in the dual norm. As a tends to 1 we recover the ℓ_2 norm in both the primal and the dual.

4. Computation of the Norm and the Proximity Operator

In this section, we compute the norm and the proximity operator of the squared box-norm by explicitly solving the optimization problem (1). We also specialize our results to the k -support norm and comment on the improvement with respect to the method by Argyron et al. (2012). Recall that, for every vector $w \in \mathbb{R}^d$, $|w|^\dagger$ denotes the vector obtained from w by reordering its components so that they are non-increasing in absolute value.

Theorem 11 For every $w \in \mathbb{R}^d$ it holds that

$$\|w\|_{\text{box}}^2 = \frac{1}{b}\|w_Q\|_2^2 + \frac{1}{a}\|w_I\|_2^2 + \frac{1}{a}\|w_L\|_2^2, \quad (22)$$

where $w_Q = (|w|_1^\dagger, \dots, |w|_\ell^\dagger)$, $w_I = (|w|_{q+1}^\dagger, \dots, |w|_{d-\ell}^\dagger)$, $w_L = (|w|_{d-\ell+1}^\dagger, \dots, |w|_d^\dagger)$, q and ℓ are the unique integers in $\{0, \dots, d\}$ that satisfy $q + \ell \leq d$,

$$\frac{|w|_q|}{b} \geq \frac{1}{p} \sum_{i=q+1}^{d-\ell} |w_i| > \frac{|w_{q+1}|}{b}, \quad \frac{|w_{d-\ell}|}{a} \geq \frac{1}{p} \sum_{i=q+1}^{d-\ell} |w_i| > \frac{|w_{d-\ell+1}|}{a}, \quad (23)$$

$p = c - qb - la$ and we have defined $|w_0| = \infty$ and $|w_{d+1}| = 0$. Furthermore, the minimizer θ has the form

$$\theta_i = \begin{cases} b, & \text{if } i \in \{1, \dots, q\}, \\ p \frac{\sum_{j=q+1}^d |w_j|}{\sum_{j=q+1}^d |w_j|}, & \text{if } i \in \{q+1, \dots, d-\ell\}, \\ a, & \text{otherwise.} \end{cases}$$

Proof We solve the constrained optimization problem

$$\inf \left\{ \sum_{i=1}^d \frac{w_i^2}{\theta_i} : a \leq \theta_i \leq b, \sum_{i=1}^d \theta_i \leq c \right\}. \quad (24)$$

To simplify the notation we assume without loss of generality that w_i are positive and ordered nonincreasing, and note that the optimal θ_i are ordered non increasing. To see this, let $\theta^* = \arg\min_{\theta \in \Theta} \sum_{i=1}^d \frac{w_i^2}{\theta_i}$. Now suppose that $\theta_i^* < \theta_j^*$ for some $i < j$ and define $\hat{\theta}$ to

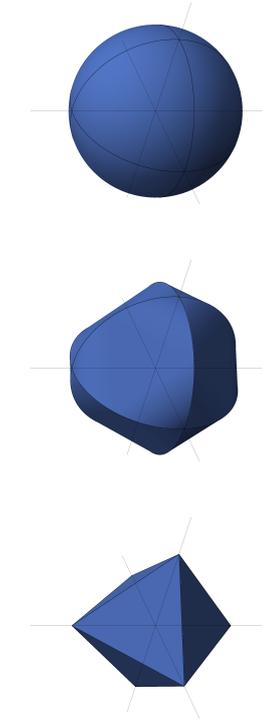

Figure 1: Unit balls of the k -support norm for $k \in \{1, 2, 3\}$.

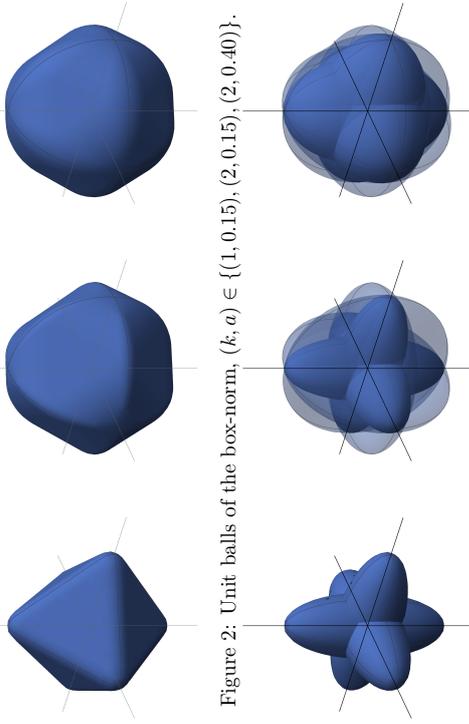

Figure 2: Unit balls of the box-norm, $(k, a) \in \{(1, 0.15), (2, 0.15), (2, 0.40)\}$.

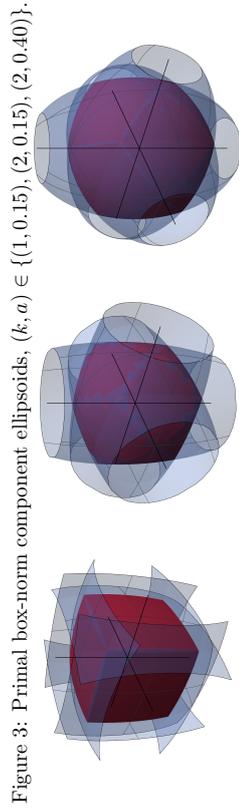

Figure 3: Primal box-norm component ellipsoids, $(k, a) \in \{(1, 0.15), (2, 0.15), (2, 0.40)\}$.

Figure 4: Dual box-norm unit balls and ellipsoids, $(k, a) \in \{(1, 0.15), (2, 0.15), (2, 0.40)\}$. For $k = 2$, only 3 tightest ellipsoids are shown.

be identical to θ^* , except with the i and j elements exchanged. The difference in objective values is

$$\sum_{i=1}^d \frac{w_i^2}{\theta_i^*} - \sum_{i=1}^d \frac{w_i^2}{\theta_i^*} = (w_i^2 - w_j^2) \left(\frac{1}{\theta_j^*} - \frac{1}{\theta_i^*} \right),$$

which is negative so θ^* cannot be a minimizer.

We further assume without loss of generality that $w_i \neq 0$ for all i , and $c \leq db$ (see Remark 12 below). The objective is continuous and we take the infimum over a closed bounded set, so a solution exists and it is unique by strict convexity. Furthermore, since $c \leq db$, the sum constraint will be tight at the optimum. Consider the Lagrangian function

$$L(\theta, \alpha) = \sum_{i=1}^d \frac{w_i^2}{\theta_i} + \frac{1}{\alpha^2} \left(\sum_{i=1}^d \theta_i - c \right), \tag{25}$$

where $1/\alpha^2$ is a strictly positive multiplier, and α is to be chosen to make the sum constraint tight, call this value α^* . Let θ^* be the minimizer of $L(\theta, \alpha^*)$ over θ subject to $a \leq \theta_i \leq b$.

We claim that θ^* solves equation (24). Indeed, for any $\theta \in [a, b]^d$, $L(\theta^*, \alpha^*) \leq L(\theta, \alpha^*)$, which implies that

$$\sum_{i=1}^d \frac{w_i^2}{\theta_i^*} \leq \sum_{i=1}^d \frac{w_i^2}{\theta_i} + \frac{1}{(\alpha^*)^2} \left(\sum_{i=1}^d \theta_i - c \right).$$

If in addition we impose the constraint $\sum_{i=1}^d \theta_i \leq c$, the second term on the right hand side is at most zero, so we have for all such θ that

$$\sum_{i=1}^d \frac{w_i^2}{\theta_i^*} \leq \sum_{i=1}^d \frac{w_i^2}{\theta_i},$$

whence it follows that θ^* is the minimizer of (24).

We can therefore solve the original problem by minimizing the Lagrangian (25) over the box constraint. Due to the coupling effect of the multiplier, the problem is separable, and we can solve the simplified problem componentwise (see Michelli et al., 2013, Theorem 3.1). For completeness we repeat the argument here. For every $w_i \in \mathbb{R}$ and $\alpha > 0$, the unique solution to the problem $\min\{\frac{w_i^2}{\theta} + \frac{\theta}{\alpha^2} : a \leq \theta \leq b\}$ is given by

$$\theta = \begin{cases} b, & \text{if } \alpha|w_i| > b, \\ \alpha|w_i|, & \text{if } b \geq \alpha|w_i| \geq a, \\ a, & \text{if } a > \alpha|w_i|. \end{cases} \tag{26}$$

Indeed, for fixed w_i , the objective function is strictly convex on \mathbb{R}_{++}^d , and has a unique minimum on $(0, \infty)$ (see Figure 1.b in Michelli et al. (2013) for an illustration). The derivative of the objective function is zero for $\theta = \theta^* := \alpha|w_i|$, strictly positive below θ^* and strictly increasing above θ^* . Considering these three cases the result follows and θ is determined by (26) where α satisfies $\sum_{i=1}^d \theta_i(\alpha) = c$.

The minimizer then has the form

$$\theta = (\underbrace{b, \dots, b}_q, \theta_{q+1}, \dots, \theta_{d-\ell}, \underbrace{a, \dots, a}_\ell, d),$$

where $q, \ell \in \{0, \dots, d\}$ are determined by the value of α which satisfies

$$S(\alpha) = \sum_{i=1}^d \theta_i(\alpha) = qb + \sum_{i=q+1}^{d-\ell} \alpha |w_i| + \ell a = c,$$

i.e. $\alpha = p / \left(\sum_{i=q+1}^{d-\ell} |w_i| \right)$, where $p = c - qb - \ell a$.

The value of the norm follows by substituting θ into the objective and we get

$$\|w\|_{\text{box}}^2 = \sum_{i=1}^q \frac{|w_i|^2}{b} + \frac{1}{p} \left(\sum_{i=q+1}^{d-\ell} |w_i| \right)^2 + \sum_{i=d-\ell+1}^d \frac{|w_i|^2}{a} = \frac{1}{b} \|w_Q\|_2^2 + \frac{1}{p} \|w_I\|_1^2 + \frac{1}{a} \|w_A\|_2^2,$$

as required. We can further characterize q and ℓ by considering the form of θ . By construction we have $\theta_q \geq b > \theta_{q+1}$ and $\theta_{d-\ell} > a \geq \theta_{d-\ell+1}$, or equivalently

$$\frac{|w_q|}{b} \geq \frac{1}{p} \sum_{i=q+1}^{d-\ell} |w_i| > \frac{|w_{q+1}|}{b} \quad \text{and} \quad \frac{|w_{d-\ell}|}{a} \geq \frac{1}{p} \sum_{i=q+1}^{d-\ell} |w_i| > \frac{|w_{d-\ell+1}|}{a}.$$

The proof is completed. \blacksquare

Remark 12 *The case where some w_i are zero follows from the case that we have considered in the theorem. If $w_i = 0$ for $n < i \leq d$, then clearly we must have $\theta_i = a$ for all such i . We then consider the n -dimensional problem of finding $(\theta_1, \dots, \theta_n)$ that minimizes $\sum_{i=1}^n \frac{w_i^2}{\theta_i}$, subject to $a \leq \theta_i \leq b$, and $\sum_{i=1}^n \theta_i \leq c'$, where $c' = c - (d - n)a$. As $c \geq da$ by assumption, we also have $c' \geq na$, so a solution exists to the n -dimensional problem. If $c' \geq bn$, then a solution is trivially given by $\theta_i = b$ for all $i = 1, \dots, n$. In general, $c' < bn$, and we proceed as per the proof of the theorem. Finally, a vector that solves the original d -dimensional problem will be given by $(\theta_1, \dots, \theta_n, a, \dots, a)$.*

Theorem 11 suggests two methods for computing the box-norm. First, we can find α such that $S(\alpha) = c$; this value uniquely determines θ in (26), and the norm follows by substitution into the objective in (25). Alternatively, we identify q and ℓ that jointly satisfy (23) and we compute the norm using (22). Taking advantage of the structure of θ in the former method leads to a computation time that is $\mathcal{O}(d \log d)$.

Theorem 13 *The computation of the box-norm can be completed in $\mathcal{O}(d \log d)$ time.*

Proof Following Theorem 11, we need to determine α^* to satisfy the coupling constraint $S(\alpha^*) = c$. Each component θ_i is a piecewise linear function in the form of a step function with a constant positive slope between the values $a/|w_i|$ and $b/|w_i|$. Let $\{\alpha^i\}_{i=1}^{2d}$ be the

set of the $2d$ critical points, where the α^i are ordered nondecreasing. The function $S(\alpha)$ is a nondecreasing piecewise linear function with at most $2d$ critical points. We can find α^* by first sorting the points $\{\alpha^i\}$, finding α^i and α^{i+1} such that

$$S(\alpha^i) \leq c \leq S(\alpha^{i+1})$$

by binary search, and then interpolating α^* between the two points. Sorting takes $\mathcal{O}(d \log d)$. Computing $S(\alpha^i)$ at each step of the binary search is $\mathcal{O}(d)$, so $\mathcal{O}(d \log d)$ overall. Given α^i and α^{i+1} , interpolating α^* is $\mathcal{O}(1)$, so the overall algorithm is $\mathcal{O}(d \log d)$ as claimed. \blacksquare

The k -support norm is a special case of the box-norm, and as a direct corollary of Theorem 11 and Theorem 13, we recover (Argyriou et al., 2012; Proposition 2.1):

Corollary 14 *For $w \in \mathbb{R}^d$, and $k \leq d$,*

$$\|w\|_{(k)} = \left(\sum_{j=1}^q (|w_j|^2)^2 + \frac{1}{k-q} \left(\sum_{j=q+1}^d |w_j|^2 \right)^2 \right)^{\frac{1}{2}},$$

where q is the unique integer in $\{0, k-1\}$ satisfying

$$|w_q| \geq \frac{1}{k-q} \sum_{j=q+1}^d |w_j| > |w_{q+1}|, \quad (27)$$

and we have defined $w_0 = \infty$. Furthermore, the norm can be computed in $\mathcal{O}(d \log d)$ time.

4.1 Proximity Operator

Proximal gradient methods can be used to solve optimization problems of the form

$$\min_w f(w) + \lambda g(w), \quad w \in \mathbb{R}^d,$$

where f is a convex loss function with Lipschitz continuous gradient, $\lambda > 0$ is a regularization parameter, and g is a convex function for which the proximity operator can be computed efficiently, see Nesterov (2007); Combettes and Pesquet (2011); Beck and Teboulle (2009) and references therein. The proximity operator of g with parameter $\rho > 0$ is defined as

$$\text{prox}_{\rho g}(w) = \arg \min \left\{ \frac{1}{2} \|x - w\|^2 + \rho g(x) : x \in \mathbb{R}^d \right\}.$$

We now use the infimum formulation of the box-norm to derive the proximity operator of the squared norm.

Theorem 15 *The proximity operator of the square of the box-norm at point $w \in \mathbb{R}^d$ with parameter $\frac{\lambda}{2}$ is given by $\text{prox}_{\frac{\lambda}{2} \|\cdot\|_{\text{box}}^2}(w) = (\frac{\theta_1 w_1}{\theta_1 + \lambda}, \dots, \frac{\theta_n w_n}{\theta_n + \lambda})$, where*

$$\theta_i = \begin{cases} b, & \text{if } \alpha |w_i| - \lambda > b, \\ \alpha |w_i| - \lambda, & \text{if } b \geq \alpha |w_i| - \lambda \geq a, \\ a, & \text{if } a > \alpha |w_i| - \lambda, \end{cases}$$

and α is chosen such that $S(\alpha) := \sum_{i=1}^d \theta_i(\alpha) = c$. Furthermore, the computation of the proximity operator can be completed in $\mathcal{O}(d \log d)$ time.

Proof Using the infimum formulation of the norm, we solve

$$\min_{x \in \mathbb{R}^d} \inf_{\theta \in \Theta} \left\{ \frac{1}{2} \sum_{i=1}^d (x_i - w_i)^2 + \lambda \sum_{i=1}^d \frac{x_i^2}{\theta_i} \right\}.$$

We can exchange the order of the optimization and solve for x first. The problem is separable and a direct computation yields that $x_i = \frac{\theta_i w_i}{\theta_i + \lambda}$. Discarding a multiplicative factor of $\lambda/2$, and noting that the infimum is attained, the problem in θ becomes

$$\min_{\theta} \left\{ \sum_{i=1}^d \frac{w_i^2}{\theta_i + \lambda} : a \leq \theta_i \leq b, \sum_{i=1}^d \theta_i \leq c \right\}.$$

Note that this is the same as computing a box-norm in accordance with Proposition 8. Specifically, this is exactly like problem (24) after the change of variable $\theta'_i = \theta_i + \lambda$. The remaining part of the proof then follows in a similar manner to the proof of Theorem 11. ■

Algorithm 1 illustrates the computation of the proximity operator for the squared box-norm in $\mathcal{O}(d \log d)$ time. This includes the k -support as a special case, where we let a tend to zero, and set $b = 1$ and $c = k$, which improves upon the complexity of the $\mathcal{O}(d(k + \log d))$ computation provided in Argyriou et al. (2012), and we illustrate the improvement empirically in Table 1. We summarize this in the following corollary.

Corollary 16 *The proximity operator of the square of the k -support norm at point w with parameter $\frac{\lambda}{2}$ is given by $\text{prox}_{\frac{\lambda}{2} \|\cdot\|_k^2}(w) = x$, where $x_i = \frac{\theta_i w_i}{\theta_i + \lambda}$, and*

$$\theta_i = \begin{cases} 1, & \text{if } \alpha |w_i| > \lambda + 1, \\ \alpha |w_i| - \lambda, & \text{if } \lambda + 1 \geq \alpha |w_i| \geq \lambda \\ 0, & \text{if } \lambda > \alpha |w_i|, \end{cases}$$

where α is chosen such that $S(\alpha) = k$. Furthermore, the proximity operator can be computed in $\mathcal{O}(d \log d)$ time.

5. Spectral Norms

We now turn our focus to the matrix norms. For this purpose, we recall that a norm $\|\cdot\|$ on $\mathbb{R}^{d \times T}$ is called orthogonally invariant if $\|W\| = \|UWV\|$, for any orthogonal matrices $U \in \mathbb{R}^{d \times d}$ and $V \in \mathbb{R}^{T \times T}$. A classical result by Von Neumann (1937) establishes that a norm is orthogonally invariant if and only if it is of the form $\|W\| = g(\sigma(W))$, where $\sigma(W)$ is the vector formed by the singular values of W in nonincreasing order, and g is a symmetric gauge function, that is a norm which is invariant under permutations and sign changes of the vector components.

Algorithm 1 Computation of $x = \text{prox}_{\frac{\lambda}{2} \|\cdot\|_{\Theta, \text{box}}}(w)$.

Require: parameters a, b, c, λ .

1. Sort points $\{\alpha^i\}_{i=1}^{2d} = \left\{ \frac{a+\lambda}{|w_j|}, \frac{b+\lambda}{|w_j|} \right\}_{j=1}^d$ such that $\alpha^i \leq \alpha^{i+1}$;
2. Identify points α^i and α^{i+1} such that $S(\alpha^i) \leq c$ and $S(\alpha^{i+1}) \geq c$ by binary search;
3. Find α^* between α^i and α^{i+1} such that $S(\alpha^*) = c$ by linear interpolation;
4. Compute $\theta_i(\alpha^*)$ for $i = 1, \dots, d$;
5. Return $x_i = \frac{\theta_i w_i}{\theta_i + \lambda}$ for $i = 1, \dots, d$.

Lemma 17 *If Θ is a convex bounded subset of the strictly positive orthant in \mathbb{R}^d which is invariant under permutations, then $\|\cdot\|_{\Theta}$ is a symmetric gauge function.*

Proof Let $g(w) = \|w\|_{\Theta}$. We need to show that g is a norm which is invariant under permutations and sign changes. By Proposition 2, g is a norm, so it remains to show that $g(w) = g(Pw)$ for every permutation matrix P , and $g(Jw) = g(w)$ for every diagonal matrix J with entries ± 1 . The former property follows since the set Θ is permutation invariant. The latter property is true because the objective function in (1) involves the squares of the components of w . ■

In particular, this readily applies to both the k -support norm and the box-norm. We can therefore extend both norms to orthogonally invariant norms, which we term the spectral k -support norm and the spectral box-norm respectively, and which we write (with some abuse of notation) as $\|W\|_{(k)} = \|\sigma(W)\|_{(k)}$ and $\|W\|_{\text{box}} = \|\sigma(W)\|_{\text{box}}$. We note that since the k -support norm subsumes the ℓ_1 and ℓ_2 -norms for $k = 1$ and $k = d$ respectively, the corresponding spectral k -support norms are equal to the trace and Frobenius norms respectively.

A number of properties of the vector norms translate in the natural manner to the matrix norms. We first characterize the unit ball of the spectral k -support norm.

Proposition 18 *The unit ball of the spectral k -support norm is the convex hull of the set of matrices of rank at most k and Frobenius norm no greater than one.*

Proof For any $W \in \mathbb{R}^{d \times T}$, define the following sets

$$\bar{T}_k = \{W \in \mathbb{R}^{d \times T} : \text{rank}(W) \leq k, \|W\|_F \leq 1\}, \quad A_k = \text{co}(T_k),$$

and consider the following functional

$$\lambda(W) = \inf\{\lambda > 0 : W \in \lambda A_k\}, \quad W \in \mathbb{R}^{d \times T}. \quad (28)$$

We will apply Lemma 23 in the appendix to the set A_k . To do this, we need to show that the set A_k is bounded, convex, symmetric and absorbing. The first three are clearly satisfied. To see that it is absorbing, let $W \in \mathbb{R}^{d \times T}$ have singular value decomposition $U\Sigma V^T$, and let $r = \min(d, T)$. If W is zero then clearly $W \in A_k$, so assume it is non zero.

For $i \in \mathbb{N}_r$, let $S_i \in \mathbb{R}^{d \times T}$ have entry (i, j) equal to 1, and all remaining entries zero. We then have

$$W = U \Sigma V^T = U \left(\sum_{i=1}^r \sigma_i S_i \right) V^T = \left(\sum_{i=1}^d \sigma_i \right) \sum_{i=1}^r \frac{\sigma_i}{\sum_{j=1}^r \sigma_j} (U S_i V^T) =: \lambda \sum_{i=1}^r \beta_i Z_i.$$

Now for each i , $\|Z_i\|_F = \|S_i\|_F = 1$, and $\text{rank}(Z_i) = \text{rank}(S_i) = 1$, so $Z_i \in T_k$ for any $k \geq 1$. Furthermore $\beta_i \in [0, 1]$ and $\sum_{i=1}^r \beta_i = 1$, that is $(\beta_1, \dots, \beta_r) \in \Delta^{r-1}$, so $\frac{1}{\lambda} W$ is a convex combination of Z_i , in other words $W \in \lambda A_k$, and we have shown that A_k is absorbing. It follows that A_k satisfies the hypotheses of Lemma 23, where we let $C = A_k$, hence λ defines a norm on $\mathbb{R}^{d \times T}$ with unit ball equal to A_k .

Since the constraints in T_k involve spectral functions, the sets T_k and A_k are invariant to left and right multiplication by orthogonal matrices. It follows that λ is a spectral function, that is $\lambda(W)$ is defined in terms of the singular values of W . By von Neumann’s Theorem (Von Neumann, 1937) the norm it defines is orthogonally invariant and we have

$$\lambda(W) = \inf\{\lambda > 0 : W \in \lambda A_k\} = \inf\{\lambda > 0 : \sigma(W) \in \lambda C_k\} = \|\sigma(W)\|_{(k)}$$

where we have used Corollary 24, which states that C_k is the unit ball of the k -support norm. It follows that the norm defined by (28) is the spectral k -support norm with unit ball given by A_k . ■

Referring to the unit ball characterization of the k -support norm, we note that the restriction on the cardinality of the vectors which define the extreme points of the unit ball naturally extends to a restriction on the rank operator in the matrix setting. Furthermore, as noted by Argyrion et al. (2012), regularization using the k -support norm encourages vectors to be sparse, but less so than the l_1 -norm. In matrix regularization problems, Proposition 18 suggests that the spectral k -support norm for $k > 1$ encourages matrices to have low rank, but less so than the trace norm. This is intuitive as the extreme points of the unit ball have rank at most k .

As in the case of the vector norm (Proposition 8), the spectral box-norm (or cluster norm—see below) can be written as a perturbation of the spectral k -support norm with a quadratic term.

Proposition 19 *Let $\|\cdot\|_{\text{box}}$ be a matrix box-norm with parameters a, b, c and let $k = \frac{c-d}{b-a}$. Then*

$$\|W\|_{\text{box}}^2 = \min_{Z \in \mathbb{R}^{d \times T}} \left\{ \frac{1}{a} \|W - Z\|_F^2 + \frac{1}{b-a} \|Z\|_{(k)}^2 \right\}.$$

Proof By von Neumann’s trace inequality (Theorem 25 in the appendix) we have

$$\begin{aligned} \frac{1}{a} \|W - Z\|_F^2 + \frac{1}{b-a} \|Z\|_{(k)}^2 &= \frac{1}{a} (\|W\|_F^2 + \|Z\|_F^2 - 2\langle W, Z \rangle) + \frac{1}{b-a} \|Z\|_{(k)}^2 \\ &\geq \frac{1}{a} (\|\sigma(W)\|_2^2 + \|\sigma(Z)\|_2^2 - 2\langle \sigma(W), \sigma(Z) \rangle) + \frac{1}{b-a} \|\sigma(Z)\|_{(k)}^2 \\ &= \frac{1}{a} \|\sigma(W) - \sigma(Z)\|_2^2 + \frac{1}{b-a} \|\sigma(Z)\|_{(k)}^2. \end{aligned}$$

Furthermore the inequality is tight if W and Z have the same ordered set of singular vectors. Hence

$$\min_{Z \in \mathbb{R}^{d \times T}} \left\{ \frac{1}{a} \|W - Z\|_F^2 + \frac{1}{b-a} \|Z\|_{(k)}^2 \right\} = \min_{z \in \mathbb{R}^d} \left\{ \frac{1}{a} \|\sigma(W) - z\|_2^2 + \frac{1}{b-a} \|z\|_{(k)}^2 \right\} = \|\sigma(W)\|_{\text{box}}^2,$$

where the last equality follows by Proposition 8. ■

In other words, this result shows that the (scaled) squared spectral box-norm can be seen as the Moreau envelope of a squared spectral k -support norm.

5.1 Proximity Operator for Orthogonally Invariant Norms

The computational considerations outlined in Section 4 can be naturally extended to the matrix setting by using von Neumann’s trace inequality stated in the appendix. Here we comment on the computation of the proximity operator, which is important for our numerical experiments in Section 7. The proximity operator of an orthogonally invariant norm $\|\cdot\| = g(\sigma(\cdot))$ is given by

$$\text{prox}_{\|\cdot\|}(W) = U \text{diag}(\text{prox}_g(\sigma(W))) V^T, \quad W \in \mathbb{R}^{m \times T},$$

where U and V are the matrices formed by the left and right singular vectors of W (see e.g. Argyrion et al., 2011, Prop. 3.1). Using this result we can employ proximal gradient methods to solve matrix regularization problems using the square of the spectral k -support and box-norms.

6. Multitask Learning

In this section, we address multitask learning, a framework in which spectral regularizers have successfully been used to learn a set of regression or binary classification tasks. Within this setting each column of the matrix W represents one of the task weight vectors. By leveraging the commonalities between the tasks, learning can often be improved compared to solving each task in isolation (see e.g. Evgeniou et al., 2005; Argyrion et al., 2007, 2008; Jacob et al., 2009a; Cavallanti et al., 2010, and references therein). A natural assumption that arises in applications is that the tasks are clustered. The cluster norm was introduced by Jacob et al. (2009b) as a means to favour this structure. We show that this norm is equivalent to the spectral box-norm and then address the issue of centering the norm.

6.1 Clustering the Tasks

A general approach to multitask learning is based on the regularization problem

$$\min_{W \in \mathbb{R}^{d \times T}} \mathcal{L}(W) + \lambda \Omega(W)$$

where $W = [w_1, \dots, w_T]$ is the $d \times T$ matrix whose columns represent the task vectors, Ω is a regularizer which incorporates prior knowledge of sharing between tasks and \mathcal{L} is the compound empirical error. That is, $\mathcal{L}(W) = \frac{1}{Tn} \sum_{t=1}^T \sum_{i=1}^n \ell(y_i^t, \langle w_t, x_i^t \rangle)$ where

$(x_1^t, y_1^t), \dots, (x_n^t, y_n^t) \in \mathbb{R}^d \times \mathbb{R}$ are the training points for task t (for simplicity we assume that each task has the same number n of training points) and ℓ is a convex loss function.

Jacob et al. (2009a) consider a composite penalty which encourages the tasks to be clustered into $Q < T$ groups. To introduce their setting we require some more notation. Let $\mathcal{J}_q \subseteq \mathbb{N}_T$ be the set of tasks in cluster $q \in \mathbb{N}_Q$ and let $T_q = |\mathcal{J}_q| \geq 0$ be the number of tasks in cluster q , so that $\sum_{q=1}^Q T_q = T$. The clustering uniquely defines the $T \times T$ normalized connectivity matrix M where $M_{st} = \frac{1}{T_q}$ if $s, t \in \mathcal{J}_q$ and $M_{st} = 0$ otherwise. We let $\bar{w} = \frac{1}{T} \sum_{t=1}^T w_t$ be the mean weight vector, $\bar{w}_q = \frac{1}{T_q} \sum_{t \in \mathcal{J}_q} w_t$ be the mean weight vector of tasks in cluster q and define the $T \times T$ orthogonal projection matrices $U = \mathbb{1}^T / T$ and $\Pi = I - U$. Note that $W\Pi = [w_1 - \bar{w}, \dots, w_T - \bar{w}]$. Finally, let $r = \min(d, T)$.

Using this notation, we introduce the three seminorms

$$\begin{aligned} \Omega_m(W) &= T \|\bar{w}\|^2 = \text{tr}(WUW^\top) \\ \Omega_b(W) &= \sum_{q=1}^Q T_q \|\bar{w}_q - \bar{w}\|^2 = \text{tr}(W(M - U)W^\top) \\ \Omega_w(W) &= \sum_{q=1}^Q \sum_{t \in \mathcal{J}_q} \|w_t - \bar{w}_q\|^2 = \text{tr}(W(I - M)W^\top), \end{aligned}$$

each of which captures a different aspect of the clustering: Ω_m penalizes the total *mean* of the weight vectors, Ω_b measures how close to each other the clusters are (*between* cluster variance), and Ω_w measures the compactness of the clusters (*within* cluster variance). Scaling the three penalties by positive parameters ϵ_b , ϵ_b and ϵ_w respectively, we obtain the composite penalty $\epsilon_b \Omega_m + \epsilon_b \Omega_b + \epsilon_w \Omega_w$. The first term Ω_m does not depend on the connectivity matrix M , and it can be included in the error term. The remaining two terms depend on M , which in general may not be known *a-priori*. Jacob et al. (2009a) propose to learn the clustering by minimizing with respect to matrix M , under the assumption that $\epsilon_w \geq \epsilon_b$; this assumption is reasonable as we care more about enforcing a small variance of parameters within the clusters than between them. Using the elementary properties that $M - U = M\Pi = \Pi M\Pi$ and $I - M = (I - M)\Pi = \Pi(I - M)\Pi$ and letting $\tilde{M} = M\Pi$, we rewrite

$$\epsilon_b \Omega_b(W) + \epsilon_w \Omega_w(W) = \text{tr} \left(W\Pi(\epsilon_b \tilde{M} + \epsilon_w(I - \tilde{M}))\Pi W^\top \right) = \text{tr}(W\Pi\Sigma^{-1}\Pi W^\top) \quad (29)$$

where we have defined $\Sigma^{-1} = \epsilon_b \tilde{M} + \epsilon_w(I - \tilde{M})$. Since \tilde{M} is an orthogonal projection, the matrix Σ is well defined and we have

$$\Sigma = (\epsilon_b^{-1} - \epsilon_w^{-1})\tilde{M} + \epsilon_w^{-1}I. \quad (30)$$

The expression in the right hand side of equation (29) is jointly convex in W and Σ (see e.g. Boyd and Vandenberghe, 2004), however the set of matrices Σ defined by equation (30), generated by letting $\tilde{M} = M\Pi$ vary, is nonconvex, because M takes values on a nonconvex set. To address this, Jacob et al. (2009a) relax the constraint on matrix \tilde{M} to the set $\{0 \preceq \tilde{M} \preceq I, \text{tr} \tilde{M} \leq Q - 1\}$. This in turn induces the convex constraint set for Σ

$$\mathcal{S}_{Q,T} = \{\Sigma \in \mathbb{R}^{T \times T} : \Sigma = \Sigma^\top, \epsilon_w^{-1}I \preceq \Sigma \preceq \epsilon_b^{-1}I, \text{tr} \Sigma \leq (\epsilon_b^{-1} - \epsilon_w^{-1})(Q - 1) + \epsilon_w^{-1}T\}.$$

In summary Jacob et al. (2009a) arrive at the optimization problem

$$\min_{W \in \mathbb{R}^{d \times T}} \tilde{\mathcal{L}}(W) + \lambda \|W\Pi\|_c^2 \quad (31)$$

where $\tilde{\mathcal{L}}(W) = \mathcal{L}(W) + \lambda \epsilon_m \text{tr}(WUW^\top)$ and $\|\cdot\|_c$ is the *cluster norm* defined by the equation

$$\|W\|_c = \sqrt{\inf_{\Sigma \in \mathcal{S}_{Q,T}} \text{tr}(\Sigma^{-1}W^\top W)}. \quad (32)$$

6.2 The Cluster Norm and the Spectral Box-Norm

We now discuss the cluster norm in the context of the spectral box-norm. Jacob et al. (2009a) state that the cluster norm of W equals what we in this paper have termed the spectral box-norm, with parameters $a = \epsilon_w^{-1}$, $b = \epsilon_b^{-1}$ and $c = (T - Q + 1)\epsilon_w^{-1} + (Q - 1)\epsilon_b^{-1}$. Here we prove this fact. Denote by $\lambda_i(\cdot)$ the eigenvalues of a matrix which we write in non increasing order $\lambda_1(\cdot) \geq \lambda_2(\cdot) \geq \dots \geq \lambda_d(\cdot)$. Note that if θ_i are the eigenvalues of Σ then $\theta_i = \lambda_{d-i+1}(\Sigma^{-1})$. We have that

$$\text{tr}(\Sigma^{-1}W^\top W) \geq \sum_{i=1}^r \lambda_{d-i+1}(\Sigma^{-1}) \lambda_i(W^\top W) = \sum_{i=1}^r \frac{\sigma_i^2(W)}{\theta_i}$$

where the inequality follows by Lemma 26 (stated in the appendix) for $A = \Sigma^{-1}$ and $B = W^\top W \succeq 0$. Since this inequality is attained whenever $\Sigma = U \text{diag}(\theta) U$, where U are the eigenvectors of $W^\top W$, we see that the cluster norm coincides with the spectral box-norm, that is $\|W\|_c = \|\sigma(W)\|_\Theta$ for $\Theta = \{\theta \in [a, b]^r : \sum_{i=1}^r \theta_i \leq c\}$. In light of our observations in Section 5, we also see that the spectral k -support norm is a special case of the cluster norm, where we let a tend to zero, $b = 1$ and $c = k$, where $k = Q - 1$. More importantly the cluster norm is a perturbation of the spectral k -support norm. Moreover, the methods to compute the norm and its proximity operator (cf. Theorems 11 and 15) can directly be applied to the cluster norm using von Neumann's trace inequality (see Theorem 25 in the appendix).

6.3 Optimization with Centered Spectral Θ -Norms

Centering a matrix has been shown to improve learning in other multitask learning problems, for example Evgeniou et al. (2005) reported improved results using the trace norm. It is therefore valuable to address the problem of how to solve a regularization problem of the type

$$\min_{W \in \mathbb{R}^{d \times T}} \tilde{\mathcal{L}}(W) + \lambda \|W\Pi\|_\Theta^2 \quad (33)$$

in which the regularizer is applied to the matrix $W\Pi = [w_1 - \bar{w}, \dots, w_T - \bar{w}]$. To this end, let Θ be a bounded and convex subset of \mathbb{R}_{++}^r which is invariant under permutation. We have already noted that the function defined, for every $W \in \mathbb{R}^{d \times T}$, as

$$\|W\|_\Theta := \|\sigma(W)\|_\Theta,$$

is an orthogonally invariant norm. In particular, problem (33) includes regularization with the centered cluster norm outlined above.

Note that right multiplication by the centering operator Π , is invariant to a translation of the columns of the matrix by a fixed vector, that is, for every $z \in \mathbb{R}^d$, we have $[w_1 + z, \dots, w_T + z]\Pi = W\Pi$. The quadratic term $\epsilon_m \text{tr}(WUW^T)$, which is included in the error, implements square norm regularization of the mean of the tasks, which can help to prevent overfitting. However, in the remainder of this section this term plays no role in the analysis, which equally applies to the case that $\epsilon_m = 0$.

In order to solve the problem (33) with a centered regularizer the following lemma is key.

Lemma 20 *Let $r = \min(d, T)$ and let Θ be a bounded and convex subset of \mathbb{R}^r_{++} which is invariant under permutation. For every $W = [w_1, \dots, w_T] \in \mathbb{R}^{d \times T}$, it holds that*

$$\|W\Pi\|_{\Theta} = \min_{z \in \mathbb{R}^d} \|[w_1 - z, \dots, w_T - z]\|_{\Theta}.$$

Proof Given the set Θ we define the set $\Theta^{(T)} = \{\Sigma \in \mathbf{S}^T_{++}, \lambda(\Sigma) \in \Theta\}$ and $\Theta^{(d)} = \{D \in \mathbf{S}^{d}_{++} : \lambda(D) \in \Theta\}$. It follows from Lemma 26 that

$$\|W\|_{\Theta}^2 = \|\sigma(W)\|_{\Theta}^2 = \inf_{\Sigma \in \Theta^{(T)}} \text{tr}(\Sigma^{-1}W^TW) = \inf_{D \in \Theta^{(d)}} \text{tr}(D^{-1}W^TW).$$

Using the second identity and recalling that $W\Pi = [w_1 - \bar{w}, \dots, w_T - \bar{w}]$, we have that

$$\begin{aligned} \|W\Pi\|_{\Theta}^2 &= \inf_{D \in \Theta^{(d)}} \text{tr}((W\Pi)^TD^{-1}(W\Pi)) \\ &= \inf_{D \in \Theta^{(d)}} \sum_{t=1}^T (w_t - \bar{w})^TD^{-1}(w_t - \bar{w}) = \inf_{D \in \Theta^{(d)}} \min_{z \in \mathbb{R}^d} \sum_{t=1}^T (w_t - z)^TD^{-1}(w_t - z) \end{aligned}$$

where in the last step we used the fact that the quadratic form $\sum_{t=1}^T (w_t - z)^TD^{-1}(w_t - z)$ is minimized at $z = \bar{w}$. The result now follows by interchanging the infimum and the minimum in the last expression and using the definition of the Θ -norm. ■

Using this lemma, we rewrite problem (31) as

$$\begin{aligned} \min_{W \in \mathbb{R}^{d \times T}} \min_{z \in \mathbb{R}^d} \tilde{\mathcal{L}}(W) + \lambda \|[w_1 - z, \dots, w_T - z]\|_{\Theta}. \\ \min_{(V, z) \in \mathbb{R}^{d \times T} \times \mathbb{R}^d} \tilde{\mathcal{L}}(V + z\mathbf{1}^T) + \lambda \|V\|_{\Theta}. \end{aligned} \quad (34)$$

Letting $v_t = w_t - z$, and $V = [v_1, \dots, v_T]$, we obtain the equivalent problem

This problem is of the form $f(V, z) + \lambda g(V, z)$, where $g(V, z) = \|V\|_{\Theta}$. Using this formulation, we can directly apply the proximal gradient method using the proximity operator computation for the vector norm, since $\text{prox}_{g, \|\cdot\|_{\Theta}}(V_0, z_0) = (\text{prox}_{\|\cdot\|_{\Theta}}(V_0), z_0)$. This observation establishes that, whenever the proximity operator of the spectral Θ -norm is available, we can use proximal gradient methods with minimal additional effort to perform optimization with the corresponding centered spectral Θ -norm. For example, this is the case with the trace norm, the spectral k -support norm and the spectral box-norm or cluster norm.

7. Numerical Experiments

Argyriou et al. (2012) demonstrated the good estimation properties of the vector k -support norm compared to the Lasso and the elastic net. In this section, we investigate the matrix norms and report on their statistical performance in matrix completion and multitask learning experiments on simulated as well as benchmark real data sets. We also offer an interpretation of the role of the parameters in the box-norm and we empirically verify the improved performance of the proximity operator computation of Algorithm 1 (see Table 1).

We compare the spectral k -support norm (k -sup) and the spectral box-norm (box) to the baseline trace norm (*trace*) (see e.g. Argyriou et al., 2007; Mazumder et al., 2010; Srebro et al., 2005; Toh and Yun, 2011), matrix elastic net (*elnet*) (Li et al., 2012) and, in the case of multitask learning, the Frobenius norm (fr), which we recall is equivalent to the spectral k -support norm when $k = d$. As we highlighted in Section 6.3, centering a matrix can lead to improvements in learning. For data sets which we expect to exhibit clustering we therefore also apply centered versions of the norms, c -fr, c -trace, c -elnet, c - k -sup, c -box.²

We report test error and standard deviation, matrix rank (r) and optimal parameter values for k and α , which are determined by validation. We used a t -test to determine the statistical significance of the difference in performance between the regularizers, at a level of $p < 0.001$.

To solve the optimization problem we used an accelerated proximal gradient method (FISTA), (see e.g. Beck and Teboulle, 2009; Nesterov, 2007), using the percentage change in the objective as convergence criterion, with a tolerance of 10^{-5} (10^{-3} for real matrix completion experiments).

As is typical with spectral regularizers such as the trace norm, we found that the spectrum of the learned matrix exhibited a rapid decay to zero. In order to explicitly impose a low rank on the final matrix, we included a thresholding step at the end of the optimization. For the matrix completion experiments, the thresholding level was chosen by validation. Matlab code used in the experiments is available at <http://www0.cs.ucl.ac.uk/staff/M.Pontil/software.html>.

7.1. Simulated Data

Matrix Completion. We applied the norms to matrix completion on noisy observations of low rank matrices. Each $d \times d$ matrix was generated as $W = AB^T + E$, where $A, B \in \mathbb{R}^{d \times r}$, $r \ll d$, and the entries of A, B and E were set to be i.i.d. standard Gaussian. We set $d = 100$, $r \in \{5, 10\}$ and we sampled uniformly a percentage $\rho \in \{10\%, 20\%, 30\%\}$ of the entries for training, and used a fixed 10% for validation. Following Mazumder et al.

2. As we described in Section 6.2, the cluster norm regularization problem from Jacob et al. (2009a) is equivalent to regularization using the box-norm with a squared ℓ_2 norm of the mean column vector included in the loss function. The centering operator is invariant to constant shifts of the columns, which allows the matrix to have unbounded Frobenius norm when using a centered regularizer. The additional quadratic term regulates this effect and can prevent against overfitting. We tested the effect of the quadratic term on the centered norms, however the impact on performance was only incremental, and it introduced a further parameter requiring validation. On the real data sets in particular, the impact was not significant compared to simple centering, so we do not report on the method below.

Table 1: Comparison of proximity operator algorithms for the k -support norm (time in seconds), $k = 0.05d$. Algorithm 1 is our method, Algorithm 2 is the method in Argyriou et al. (2012).

(2010) the error was measured as

$$\text{error} = \frac{\|w_{\text{true}} - w_{\text{predicted}}\|^2}{\|w_{\text{true}}\|^2},$$

and averaged over 100 trials. The results are summarized in Table 2. With thresholding, all methods recovered the rank of the true noiseless matrix. The spectral box-norm generated the lowest test errors in all regimes, with the spectral k -support norm a close second, and both were significantly better than trace and elastic net.

Figure 6: Impact of matrix rank on value of k .

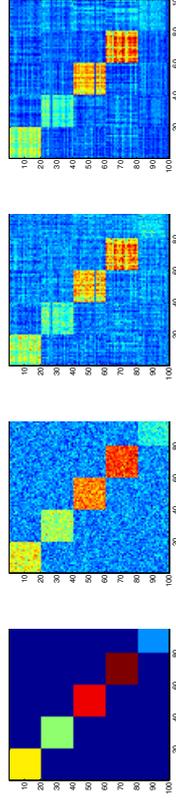

Figure 7: Clustered matrix and recovered solutions. From left to right: true, noisy, trace norm, box-norm.

Role of Parameters. In the same setting we investigated the role of the parameters in the box-norm. As previously discussed, parameter b can be set to 1 without loss of generality. Figure 5 shows the optimal value of parameter a chosen by validation for varying signal to noise ratios (SNR), keeping k fixed. We see that for greater noise levels (smaller SNR), the optimal value for a increases, which further suggests that the noise is filtered out by higher values of the parameter. Figure 6 shows the optimal value of k chosen by validation for matrices with increasing rank, keeping a fixed, and using the relation $k = \frac{a-d}{b-a}$. We note that as the rank of the matrix increases, the optimal k value increases, which is expected since it is an upper bound on the sum of the singular values.

Clustered Learning. We tested the centered norms on a synthetic data set which exhibited a clustered structure. We generated a 100×100 , rank 5, block diagonal matrix, where the entries of each 20×20 block were set to a random integer chosen uniformly in $\{1, \dots, 10\}$, with additive noise. Table 3 illustrates the results averaged over 100 runs. Within each group of norms, the box-norm and the k -support norm outperformed the trace norm and elastic net, and centering improved performance for all norms. Figure 7 illustrates a sample matrix along with the solution found using the box and trace norms.

7.2 Real Data

Matrix Completion (MovieLens and Jester). In this section we report on the performance of the norms on real data sets. We observe a subset of the (user, rating) entries of a matrix and the task is to predict the unobserved ratings, with the assumption that the true matrix is low rank (or approximately low rank). In the first instance we considered the MovieLens data sets³. These consist of user ratings of movies, the ratings are integers from 1 to 5, and all users have rated a minimum number of 20 films. Specifically we considered the following data sets:

- *MovieLens 100k*: 943 users and 1,682 movies, with a total of 100,000 ratings;
- *MovieLens 1M*: 6,040 users and 3,900 movies, with a total of 1,000,209 ratings.

We also considered the Jester⁴ data sets, which consist of user ratings of jokes, where the ratings are real values from -10 to 10 :

- *Jester 1*: 24,983 users and 100 jokes, all users have rated a minimum of 36 jokes;
- *Jester 2*: 23,500 users and 100 jokes, all users have rated a minimum of 36 jokes;
- *Jester 3*: 24,938 users and 100 jokes, all users have rated between 15 and 35 jokes.

Following Toh and Yun (2011), for MovieLens we uniformly sampled $\rho = 50\%$ of the available entries for each user for training, and for Jester 1, Jester 2 and Jester 3 we sampled

3. MovieLens data sets are available at <http://grouplens.org/datasets/movielens/>.

4. Jester data sets are available at <http://goldberg.berkeley.edu/jester-data/>.

Table 4: Matrix completion on real data sets, without (left) and with (right) thresholding.

20, 20 and 8 ratings per user respectively, and we again used 10% for validation. The error was measured as normalized mean absolute error,

$$\text{NMAE} = \frac{\|w_{\text{true}} - w_{\text{predicted}}\|_2}{\#\text{observations}/(r_{\text{max}} - r_{\text{min}})},$$

where r_{max} and r_{min} are upper and lower bounds for the ratings (Toh and Yun, 2011), averaged over 50 runs. The results are outlined in Table 4. In the thresholding case, the spectral box-norm and the spectral k -support norm showed the best performance, and in the absence of thresholding, the spectral k -support norm showed slightly improved performance. Comparing to the synthetic data sets, this suggests that the parameter a did not provide any benefit in the absence of noise. We also note that without thresholding our results for trace norm regularization on MovieLens 100k agreed with those in Jaggi and Sultowsky (2010).

Multitask Learning (Lentk and Animals with Attributes). In our final set of experiments we considered two multitask learning data sets, where we expected the data to exhibit clustering. The *Lentk personal computer* data set (Lentk et al., 1996) consists of 180 ratings of 20 profiles of computers characterized by 14 features (including a bias term). The clustering is suggested by the assumption that users are motivated by similar groups of features. We used the root mean square error of true vs. predicted ratings, normalised over the tasks, averaged over 100 runs. We also report on the Frobenius norm, which in the multitask

Table 5: Multitask learning clustering on Lenk data set.

learning framework corresponds to independent task learning. The results are outlined in Table 5. The centered versions of the spectral k -support norm and spectral box-norm outperformed the other penalties in all regimes. Furthermore, the results clearly indicate the importance of centering, as discussed for the trace norm in Evgeniou et al. (2007).

The *Animals with Attributes* data set (Lampert et al., 2009) consists of 30,475 images of animals from 50 classes. Along with the images, the data set includes pre-extracted features for each image. The data set has been analyzed in the context of multitask learning. We followed the experimental protocol from (Kang et al., 2011), however we used an updated feature set, and we considered all 50 classes. Specifically, we used the DeCAF feature set provided by Lampert et al. (2009) rather than the SIFT bag of word descriptors. These updated features were obtained through a deep convolutional network and represent each image by a 4,096-dimensional vector (Donahue et al., 2014). As the smallest class size is 92 we selected the first $n = 92$ examples of each of the $T = 50$ classes, used PCA (with centering) on the resulting data matrix to reduce dimensionality ($d = 1, 718$) retaining a variance of 95%, and obtained a data set of size $4,600 \times 1, 718$. For each class the examples were split into training, validation and testing data sets, with a split of 50%, 25%, 25% respectively, and we averaged the performance over 50 runs.

We used the logistic loss, yielding the error term

$$\mathcal{L}(W) = \sum_{t=1}^T \sum_{i=1}^{Tn} \log(1 + \exp(-y_{t,i}(w_t, x_i)))$$

where $W = [w_1, \dots, w_T]$, x_1, \dots, x_{Tn} are the inputs and $y_{t,i} = 1$ if x_i is in class t , and $y_{t,i} = -1$ otherwise.

The predicted class for testing example x was $\operatorname{argmax}_{t=1}^T \langle w_t, x \rangle$ and the accuracy was measured as the percentage of correctly classified examples, also known as multi-class error. The results without centering are outlined in Table 6. The corresponding results with centering showed the same relative performance, but worse overall accuracy, which is reasonable as the data is not expected to be clustered, and we omit the results here.

The spectral k -support and box-norms gave the best results, outperforming the Frobenius norm and the matrix elastic net, which in turn outperformed the trace norm. We highlight that in contrast to the Lenk experiments, the Frobenius norm, corresponding to

norm	test error	k	a

independent task learning, was competitive. Furthermore, the optimal values of k for the spectral k -support norm and spectral box-norm were high (38 and 33, respectively) relative to the maximum rank of 50, corresponding to a relatively high rank solution. The spectral k -support norm and spectral box-norm nonetheless outperformed the other regularizers. Notice also that the spectral k -support norm requires the same number of parameters to be tuned as the matrix elastic net, which suggests that it somehow captures the underlying structure of the data in a more appropriate manner.

We finally note as an aside that using the SIFT bag of words descriptors provided by Lampert et al. (2009), which represent the images as a 2,000-dimensional histogram of local features, we replicated the results for independent task learning (Frobenius norm regularization) and single-group learning (trace norm regularization) of Kang et al. (2011) for the subset of 20 classes considered in their paper.

8. Extensions

In this section we outline a number of extensions to topics in this paper.

8.1 k -Support p -Norms

A natural extension of the k -support norm follows by applying a p -norm, rather than the Euclidean norm, in the infimum convolution definition of the k -support norm. In the dual norm, we then obtain the corresponding q -norm, where $\frac{1}{p} + \frac{1}{q} = 1$.

Definition 21 The k -support p -norm is defined for $w \in \mathbb{R}^d$ as

$$\|w\|_{(k,p)} = \inf \left\{ \sum_{g \in \mathcal{G}_k} \|v_g\|_p : \operatorname{supp}(v_g) \subseteq g, \sum_{g \in \mathcal{G}_k} v_g = w \right\}. \quad (35)$$

The following corollary follows along the same lines as the proof of Proposition 3 in the appendix.

Corollary 22 The (p, k) -support norm is well defined and its unit ball is the convex hull of the set $\{w \in \mathbb{R}^d : \|w\|_p \leq 1, \operatorname{card}(w) \leq k\}$. Furthermore, its dual norm is given by

$$\|u\|_{*(k,q)} = \left(\sum_{i=1}^k (|u_i|^q) \right)^{\frac{1}{q}}, \quad u \in \mathbb{R}^d.$$

We discuss the special cases $p \in \{1, 2, \infty\}$. The case $p = 2$ is the k -support norm of Agrignon et al. (2012) discussed above. For $p = 1$ we have $\|u\|_{*(k,q)} = \|u\|_\infty$, hence the $(k, 1)$ -support norm coincides with the ℓ_1 norm for every $k \in \mathbb{N}_d$. The case $p = \infty$ is more interesting; specifically the dual norm is the well-known Ky-Fan norm (see e.g. Bhatia, 1997).

$$\|u\|_{*(k,\infty)} = \sum_{i=1}^k |u_i|.$$

Using the fact that the primal norm is the dual of the dual, we obtain by a direct computation that

$$\|u\|_{(k,\infty)} = \max \left(\|u\|_\infty, \frac{1}{k} \|u\| \right).$$

It is clear that the (p, k) -support norm is a symmetric gauge function. Hence we can define the spectral (p, k) -support norm as $\|W\|_{(k,p)} = \|\sigma(W)\|_{(k,p)}$, for $W \in \mathbb{R}^{d \times T}$. Since the dual of any orthogonally invariant norm is given by $\|\cdot\|_* = \|\sigma(\cdot)\|_*$ (see e.g. Lewis, 1995), we conclude that the dual spectral (k, p) -support norm is given by $\|U\|_{*(k,p)} = \|\sigma(U)\|_{*(k,p)}$, for every $U \in \mathbb{R}^{d \times T}$. Furthermore, the unit ball of the spectral (p, k) -support norm is equal to the convex hull of the set $\{W \in \mathbb{R}^{d \times T} : \text{rank}(W) \leq k, \|\sigma(W)\|_p \leq 1\}$.

8.2 Kernels

The ideas discussed in this paper can be used in the context of multiple kernel learning in a natural way (see e.g. Micchelli and Pontil, 2007, and references therein). Let $K_j, j \in \mathbb{N}_s$, be prescribed reproducing kernels on a set X , and H_j the corresponding reproducing kernel Hilbert spaces with norms $\|\cdot\|_j$. We consider the problem

$$\min \left\{ \sum_{i=1}^n \ell \left(\psi_i, \sum_{\ell=1}^s f_\ell(x_i) \right) + \lambda \left(\|f_1\|_1, \dots, \|f_s\|_s \right) \middle| \Theta : f_1 \in H_1, \dots, f_s \in H_s \right\}.$$

The choice $\Theta = \{\theta \in \mathbb{R}^d : 0 < \theta_i \leq 1, \sum_{i=1}^d \theta_i \leq k\}$, when $k \leq s$, is particularly interesting. It gives rise to a version of multiple kernel learning in which at least k kernels are employed.

8.3 Rademacher Complexity

We briefly comment on the Rademacher complexity of the spectral k -support norm, namely

$$\mathbb{E} \sup_{\|a\|_0 \leq 1} \frac{1}{Tn} \sum_{t=1}^T \sum_{i=1}^n \epsilon_t^i \langle w_t, x_t^i \rangle$$

where the expectations is taken with respect to i.i.d. Rademacher random variables $\epsilon_t^i, i \in \mathbb{N}_n, t \in \mathbb{N}_T$ and the x_t^i are either prescribed or random datapoints associated with the different regression tasks. The Rademacher complexity can be used to derive uniform bounds on the estimation error and excess risk bounds (see Bartlett and Mendelson, 2002; Koltchinskii and Panchenko, 2002, for a discussion). Although a complete analysis is beyond

the scope of the present paper, we remark that the Rademacher complexity of the unit ball of the spectral k -support is a factor of \sqrt{k} larger than the Rademacher complexity bound for the trace norm provided in (Proposition 6 Maurer and Pontil, 2013). This follows from the fact that the dual spectral k -support norm is bounded by \sqrt{k} times the operator norm. Of course the unit ball of the spectral k -support norm contains the unit ball of the trace norm, so the associated excess risk bounds need to be compared with care.

9. Conclusion

We studied the family of box-norms, and showed that the k -support norm belongs to this family. We noted that these can be naturally extended from the vector to the matrix setting. We also provided a connection between the k -support norm and the cluster norm, which essentially coincides with the spectral box-norm. We further observed that the cluster norm is a perturbation of the spectral k -support norm, and we were able to compute the norm and the proximity operator of the squared norm. We also provided a method to solve regularization problems using centered versions of the norms and we considered a number of extensions to the box-norm framework.

Our experiments indicate that the spectral box-norm and k -support norm consistently outperform the trace norm and the matrix elastic net on various matrix completion problems. Furthermore, we studied the application of centering to clustering problems in multi-task learning, and found that this improved performance. With a single parameter, compared to two for the spectral box-norm, and three for the cluster norm, our results suggest that the spectral k -support norm represents a powerful yet straightforward alternative to the trace norm for low rank matrix learning. In future work we would like to complete the analysis of the Rademacher complexity for the norms in this paper, and derive associated statistical oracle inequalities. We would also like to investigate the family of Θ -norms for more general parameter sets.

Acknowledgments

We would like to thank Andreas Maurer, Charles Micchelli and especially Andreas Agrignon for useful discussions. This work was supported in part by EPSRC Grant EP/H027203/1.

Appendix A.

In this appendix, we discuss some auxiliary results which are used in the main body of the paper.

Let X be a finite dimensional vector space. Recall that a subset C of X is called *balanced* if $\alpha C \subseteq C$ whenever $|\alpha| \leq 1$. Furthermore, C is called *absorbing* if for any $x \in X, x \in \lambda C$ for some $\lambda > 0$.

Lemma 23 *Let $C \subseteq X$ be a bounded, convex, balanced, and absorbing set. The Minkowski functional μ_C of C , defined for every $w \in X$, as*

$$\mu_C(w) = \inf \left\{ \lambda : \lambda > 0, \frac{1}{\lambda} w \in C \right\}$$

is a norm on X .

Proof We give a direct proof that μ_C satisfies the properties of a norm. See also e.g. (Rudin, 1991, §1.35) for further details. Clearly $\mu_C(w) \geq 0$ for all w , and $\mu_C(0) = 0$. Moreover, as C is bounded, $\mu_C(w) > 0$ whenever $w \neq 0$.

Next we show that μ_C is one-homogeneous. For every $\alpha \in \mathbb{R}$, $\alpha \neq 0$, let $\sigma = \text{sign}(\alpha)$ and note that

$$\begin{aligned} \mu_C(\alpha w) &= \inf \left\{ \lambda > 0 : \frac{1}{\lambda} \alpha w \in C \right\} \\ &= \inf \left\{ \lambda > 0 : \frac{|\alpha|}{\lambda} \sigma w \in C \right\} \\ &= |\alpha| \inf \left\{ \lambda > 0 : \frac{1}{\lambda} w \in \sigma C \right\} \\ &= |\alpha| \inf \left\{ \lambda > 0 : \frac{1}{\lambda} w \in C \right\} = |\alpha| \mu_C(w), \end{aligned}$$

where we have made a change of variable and used the fact that $\sigma C = C$.

Finally, we prove the triangle inequality. For every $v, w \in X$, if $v/\lambda \in C$ and $w/\mu \in C$ then setting $\gamma = \lambda/(\lambda + \mu)$, we have

$$\frac{v+w}{\lambda+\mu} = \gamma \frac{v}{\lambda} + (1-\gamma) \frac{w}{\mu}$$

and since C is convex, then $\frac{v+w}{\lambda+\mu} \in C$. We conclude that $\mu_C(v+w) \leq \mu_C(v) + \mu_C(w)$. The proof is completed. \blacksquare

Note that for such set C , the unit ball of the induced norm μ_C is C . Furthermore, if $\|\cdot\|$ is a norm then its unit ball satisfies the hypotheses of Lemma 23.

Using this lemma we can prove Proposition 3.

Proof of Proposition 3 Let $A_\ell = \{w \in \mathbb{R}^d : \|w\|_{\gamma^\ell} \leq 1, \text{supp}(w) \subseteq \text{supp}(\gamma^\ell)\}$, and define

$$C = \text{co} \bigcup_{\ell=1}^m A_\ell.$$

Note that C is bounded and balanced, since each set A_ℓ is so. Furthermore, the hypothesis that $\sum_{\ell=1}^m \gamma^\ell > 0$ ensures that C is absorbing. Hence, by Lemma 23 the Minkowski functional μ_C defines a norm. We rewrite $\mu_C(w)$ as

$$\mu_C(w) = \inf \left\{ \lambda : \lambda > 0, w = \lambda \sum_{\ell=1}^m \alpha_\ell z_\ell, z_\ell \in A_\ell, \alpha \in \Delta^{m-1} \right\}$$

where the infimum is over λ , the vectors $z_\ell \in \mathbb{R}^d$ and the vector $\alpha = (\alpha_1, \dots, \alpha_m)$, and recall Δ^{m-1} denotes the unit simplex in \mathbb{R}^m .

The rest of the proof is structured as follows. We first show that $\mu_C(w)$ coincides with the right hand side of equation (3), which we denote by $\nu(w)$. Then we show that $\|w\|_\Theta = \mu_C(w)$ by observing that both norms have the same dual norm.

Choose any vectors $v_1, \dots, v_m \in \mathbb{R}^d$ which satisfies the constraint set in the right hand side of (3) and set $\alpha_\ell = \|v_\ell\|_{\gamma^\ell} / (\sum_{k=1}^m \|v_k\|_{\gamma^k})$ and $z_\ell = v_\ell / \|v_\ell\|_{\gamma^\ell}$. We have

$$w = \sum_{\ell=1}^m v_\ell = \left(\sum_{k=1}^m \|v_k\|_{\gamma^k} \right) \sum_{\ell=1}^m \alpha_\ell z_\ell.$$

This implies that $\mu_C(w) \leq \nu(w)$. Conversely, if $w = \lambda \sum_{\ell=1}^m \alpha_\ell z_\ell$ for some $z_\ell \in A_\ell$ and $\alpha \in \Delta^{m-1}$, then letting $v_\ell = \lambda \alpha_\ell z_\ell$ we have

$$\sum_{\ell=1}^m \|v_\ell\|_{\gamma^\ell} = \sum_{\ell=1}^m \|\lambda \alpha_\ell z_\ell\|_{\gamma^\ell} = \lambda \sum_{\ell=1}^m \alpha_\ell \|z_\ell\|_{\gamma^\ell} \leq \lambda.$$

Next, we show that both norms have the same dual norm. We noted in Proposition 2 that the dual norm of $\|\cdot\|_\Theta$ takes the form (2). When Θ is the interior of $\text{co}\{\gamma^1, \dots, \gamma^m\}$, this can be written as

$$\|u\|_{*\Theta} = \sup_{\theta \in \Theta} \sqrt{\sum_{i=1}^d \theta_i u_i^2} = \max_{\ell=1}^m \sqrt{\sum_{i=1}^d \gamma_i^\ell u_i^2}.$$

We now compute the dual of the norm μ_C ,

$$\max_{w \in C} \langle w, u \rangle = \max \{ \langle w, u \rangle : w \in \bigcup_{\ell=1}^m A_\ell \} = \max_{\ell=1}^m \max_{w \in A_\ell} \langle w, u \rangle = \max_{\ell=1}^m \sqrt{\sum_{i=1}^d \gamma_i^\ell u_i^2}. \quad (36)$$

It follows that the norms share the same dual norm, hence $\mu_C(\cdot)$ coincides with $\|\cdot\|_\Theta$. \blacksquare

The above proof reveals that the unit ball of the dual norm of $\|\cdot\|_\Theta$ is given by an intersection of ellipsoids in \mathbb{R}^d . Indeed equation (36) provides that

$$\begin{aligned} \left\{ u \in \mathbb{R}^d : \|u\|_{*\Theta} \leq 1 \right\} &= \left\{ u \in \mathbb{R}^d : \max_{\ell=1}^m \sum_{i=1}^d \gamma_i^\ell u_i^2 \leq 1 \right\} \\ &= \left\{ u \in \mathbb{R}^d : \sum_{i=1}^d \gamma_i^\ell u_i^2 \leq 1, \forall \ell \in \mathbb{N}_m \right\} \\ &= \bigcap_{\ell \in \mathbb{N}_m} \left\{ u \in \mathbb{R}^d : \sum_{i=1}^d \gamma_i^\ell u_i^2 \leq 1 \right\}. \end{aligned} \quad (37)$$

Notice that for each $\ell \in \mathbb{N}_m$, the set $\left\{ u \in \mathbb{R}^d : \sum_{i=1}^d \gamma_i^\ell u_i^2 \leq 1 \right\}$ defines a (possibly degenerate) ellipsoid in X , where the i -th semi-principal axis has length $1/\sqrt{\gamma_i^\ell}$ (which is infinite if $\gamma_i^\ell = 0$) and the unit ball of the dual Θ -norm is given by the intersection of m such ellipsoids.

The following result, which is discussed in (Argyriou et al., 2012, Section 2) is key for the proof of Proposition 18.

Corollary 24 *The unit ball of the vector k -support norm is equal to the convex hull of the set $\{w \in \mathbb{R}^d : \text{card}(w) \leq k, \|w\|_2 \leq 1\}$.*

Proof The result follows directly by Corollary 4 for $\mathcal{G} = \mathcal{G}_k$ observing that in this case $\bigcup_{g \in \mathcal{G}_k} \{w \in \mathbb{R}^d : \text{supp}(w) \subseteq g, \|w\|_2 \leq 1\} = \{w \in \mathbb{R}^d : \text{card}(w) \leq k, \|w\|_2 \leq 1\}$. ■

The next result is due to Von Neumann (1937); see also Lewis (1995).

Theorem 25 (Von Neumann's trace inequality) *For any $d \times m$ matrices X and Y ,*

$$\text{tr}(XY^T) \leq \langle \sigma(X), \sigma(Y) \rangle$$

and equality holds if and only if X and Y admit a simultaneous singular value decomposition, that is, $X = U \text{diag}(\sigma(X)) V^T$, $Y = U \text{diag}(\sigma(Y)) V^T$, where $U \in \mathbb{R}^{d \times d}$ and $V \in \mathbb{R}^{m \times m}$ are orthogonal matrices.

The following inequality is given in Marshall and Olkin (1979, Sec. 9 H.1.b).

Lemma 26 *If $A, B \in \mathbf{S}_+^d$, then it holds*

$$\text{tr}(AB) = \sum_{i=1}^d \lambda_i(AB) \geq \sum_{i=1}^d \lambda_i(A) \lambda_{d-i+1}(B).$$

Abstract

Associating distinct groups of objects (clusters) with contiguous regions of high probability density (high-density clusters), is central to many statistical and machine learning approaches to the classification of unlabelled data. We propose a novel hyperplane classifier for clustering and semi-supervised classification which is motivated by this objective. The proposed *minimum density hyperplane* minimises the integral of the empirical probability density function along it, thereby avoiding intersection with high density clusters. We show that the minimum density and the maximum margin hyperplanes are asymptotically equivalent, thus linking this approach to maximum margin clustering and semi-supervised support vector classifiers. We propose a projection pursuit formulation of the associated optimisation problem which allows us to find minimum density hyperplanes efficiently in practice, and evaluate its performance on a range of benchmark data sets. The proposed approach is found to be very competitive with state of the art methods for clustering and semi-supervised classification.

Keywords: low-density separation, high-density clusters, clustering, semi-supervised classification, projection pursuit

1. Introduction

We study the fundamental learning problem: *Given a random sample from an unknown probability distribution with no, or partial label information, identify a separating hyperplane that avoids splitting any of the distinct groups (clusters) present in the sample.* We adopt the cluster definition given by Hartigan (1975, chap. 11), in which a *high-density cluster* is defined as a maximally connected component of the level set of the probability density function, $p(\mathbf{x})$, at level $c \geq 0$,

$$\text{lev}_c p(\mathbf{x}) = \left\{ \mathbf{x} \in \mathbb{R}^d \mid p(\mathbf{x}) > c \right\}.$$

An important advantage of this approach over other methods is that it is well founded from a statistical perspective, in the sense that a well-defined population quantity is being estimated.

However, since $p(\mathbf{x})$ is typically unknown, detecting high-density clusters necessarily involves estimates of this function, and standard approaches to nonparametric density estimation are reliable only in low dimensions. A number of existing *density clustering* algorithms approximate the level sets of the empirical density through a union of spheres around points whose estimated density exceeds a user-defined threshold (Walker, 1997; Cuevas et al., 2000, 2001; Rinaldo and Wasserman, 2010). The choice of this threshold affects both the shape and number of detected clusters, while an appropriate threshold is typically not known in advance. The performance of these methods deteriorates sharply as dimensionality increases, unless the clusters are assumed to be clearly discernible (Rinaldo and Wasserman, 2010). An alternative is to consider the more specific problem of allocating observations to clusters, which shifts the focus to local properties of the density, rather than its global approximation. The central idea underlying such methods is that if a pair of observations belong to the same cluster they must be connected through a path traversing only high-density regions. Graph theory is a natural choice to address this type of problem. Azzalini and Torelli (2007); Stuetzle and Nugent (2010) and Menardi and Azzalini (2014) have recently proposed algorithms based on this approach. Even these approaches however are limited to problems of low dimensionality by the standards of current applications (Menardi and Azzalini, 2014).

An equivalent formulation of the density clustering problem is to assume that clusters are separated through contiguous regions of low probability density, known as the *low-density separation* assumption. In both clustering and semi-supervised classification, identifying the hyperplane with the maximum margin is considered a direct implementation of the low-density separation approach. Motivated by the success of support vector machines (SVMs) in classification, maximum margin clustering (MMC) (Xu et al., 2004), seeks the maximum margin hyperplane to perform a binary partition (bi-partition) of unlabelled data. MMC can be equivalently viewed as seeking the binary labelling of the data sample that will maximise the margin of an SVM estimated using the assigned labels.

In a plethora of applications data can be collected cheaply and automatically, while labelling observations is a manual task that can be performed for a small proportion of the data only. Semi-supervised classifiers attempt to exploit the abundant unlabelled data to improve the generalisation error over using only the scarce labelled examples. Unlabelled data provide additional information about the marginal density, $p(\mathbf{x})$, but this is beneficial only insofar as it improves the inference of the class conditional density, $p(\mathbf{x}|y)$. Semi-supervised classification relies on the assumption that a relationship between $p(\mathbf{x})$ and $p(\mathbf{x}|y)$ exists. The most frequently assumed relationship is that high-density clusters are associated with a single class (cluster assumption), or equivalently that class boundaries pass through low-density regions (low-density separation assumption). The most widely used semi-supervised classifier based on the low-density separation assumption is the semi-supervised support vector machine (S²SVM) (Vapnik and Sterin, 1977; Joachims, 1999; Chapelle and Zien, 2005). S²SVMs implement the low-density separation assumption by partitioning the data according to the maximum margin hyperplane with respect to both labelled and unlabelled data.

Encouraging theoretical results for semi-supervised classification have been obtained under the cluster assumption. If $p(\mathbf{x})$ is a mixture of class conditional distributions, Castelli and Cover (1995, 1996) have shown that the generalisation error will be reduced exponentially in the number of labelled examples if the mixture is identifiable. More recently, Singh et al. (2009) showed that the mixture components can be identified if $p(\mathbf{x})$ is a mixture of a finite number of smooth density functions, and the separation between mixture components is large. Rigollet (2007) considers the cluster assumption in a nonparametric setting, that is in terms of density level sets, and shows that the generalisation error of a semi-supervised classifier decreases exponentially given a sufficiently large number of unlabelled data. However, the cluster assumption is difficult to verify with a limited number of labelled examples. Furthermore, the algorithms proposed by Rigollet (2007) and Singh et al. (2009) are difficult to implement efficiently even if the cluster assumption holds. This renders them impractical for real-world problems (Ji et al., 2012).

Although intuitive, the claim that maximising the margin over (labelled and) unlabelled data is equivalent to identifying the hyperplane that goes through regions with the lowest possible probability density has received surprisingly little attention. The work of Ben-David et al. (2009) is the only attempt we are aware of to theoretically investigate this claim. Ben-David et al. (2009) quantify the notion of a low-density separator by defining the *density on a hyperplane*, as the integral of the probability density function along the hyperplane. They study the existence of universally consistent algorithms to compute the hyperplane with minimum density. The maximum hard margin classifier is shown to be consistent only in one dimensional problems. In higher dimensions only a soft-margin algorithm is a consistent estimator of the minimum density hyperplane. Ben-David et al. (2009) do not provide an algorithm to compute low density hyperplanes.

This paper introduces a novel approach to clustering and semi-supervised classification which directly identifies low-density hyperplanes in the finite sample setting. In this approach the density on a hyperplane criterion proposed by Ben-David et al. (2009) is directly minimised with respect to a kernel density estimator that employs isotropic Gaussian kernels. The density on a hyperplane provides a uniform upper bound on the value of the empirical density at points that belong to the hyperplane. This bound is tight and proportional to the density on the hyperplane. Therefore, the smallest upper bound on the value of the empirical density on a hyperplane is achieved by hyperplanes that minimise the density on a hyperplane criterion. An important feature of the proposed approach is that the density on a hyperplane can be evaluated exactly through a one-dimensional kernel density estimator, constructed from the projections of the data sample onto the vector normal to the hyperplane. This renders the computation of minimum density hyperplanes tractable even in high dimensional applications.

We establish a connection between the minimum density hyperplane and the maximum margin hyperplane in the finite sample setting. In particular, as the bandwidth of the kernel density estimator is reduced towards zero, the minimum density hyperplane converges to the maximum margin hyperplane. An intermediate result establishes that there exists a positive bandwidth such that the partition of the data sample induced by the minimum density hyperplane is identical to that of the maximum margin hyperplane.

The remaining paper is organised as follows: The formulation of the minimum density hyperplane problem as well as basic properties are presented in Section 2. Section 3

establishes the connection between minimum density hyperplanes and maximum margin hyperplanes. Section 4 discusses the estimation of minimum density hyperplanes and the computational complexity of the resulting algorithm. Experimental results are presented in Section 5, followed by concluding remarks and future research directions in Section 6.

2. Problem Formulation

We study the problem of estimating a hyperplane to partition a finite data set, $\mathcal{X} = \{\mathbf{x}_i\}_{i=1}^n \subset \mathbb{R}^d$, without splitting any of the high-density clusters present. We assume that \mathcal{X} is an i.i.d. sample of a random variable \mathbf{X} on \mathbb{R}^d , with unknown probability density function $p : \mathbb{R}^d \rightarrow \mathbb{R}^+$. A hyperplane is defined as $H(\mathbf{v}, b) := \{\mathbf{x} \in \mathbb{R}^d \mid \mathbf{v} \cdot \mathbf{x} = b\}$, where without loss of generality we restrict attention to hyperplanes with unit normal vector, i.e., those parameterised by $(\mathbf{v}, b) \in S^{d-1} \times \mathbb{R}$, where $S^{d-1} = \{\mathbf{v} \in \mathbb{R}^d \mid \|\mathbf{v}\| = 1\}$. Following Ben-David et al. (2009) we define the *density on the hyperplane* $H(\mathbf{v}, b)$ as the integral of the probability density function along the hyperplane,

$$I(\mathbf{v}, b) := \int_{H(\mathbf{v}, b)} p(\mathbf{x}) d\mathbf{x}. \quad (1)$$

We approximate $p(\mathbf{x})$ through a kernel density estimator with isotropic Gaussian kernels,

$$\hat{p}(\mathbf{x} \mid \mathcal{X}, h^2 I) = \frac{1}{n(2\pi h^2)^{d/2}} \sum_{i=1}^n \exp \left\{ -\frac{\|\mathbf{x} - \mathbf{x}_i\|^2}{2h^2} \right\}. \quad (2)$$

This class of kernel density estimators has the useful property that the integral in Equation (1) can be evaluated exactly by projecting \mathcal{X} onto \mathbf{v} ; constructing a one-dimensional density estimator with Gaussian kernels and bandwidth h ; and evaluating the density at b ,

$$\begin{aligned} \hat{I}(\mathbf{v}, b, \mathcal{X}, h^2 I) &:= \int_{H(\mathbf{v}, b)} \hat{p}(\mathbf{x} \mid \mathcal{X}, h^2 I) d\mathbf{x} \\ &= \frac{1}{n\sqrt{2\pi}h^2} \sum_{i=1}^n \exp \left\{ -\frac{(b - \mathbf{v} \cdot \mathbf{x}_i)^2}{2h^2} \right\} = \hat{p}(b \mid \{\mathbf{v} \cdot \mathbf{x}_i\}_{i=1}^n, h^2). \end{aligned} \quad (3)$$

The univariate kernel estimator $\hat{p}(\cdot \mid \{\mathbf{v} \cdot \mathbf{x}_i\}_{i=1}^n, h^2)$ approximates the *projected density* on \mathbf{v} , that is, the density function of the random variable, $X_{\mathbf{v}} = \mathbf{X} \cdot \mathbf{v}$. Henceforth we use $\hat{I}(\mathbf{v}, b)$ to approximate $I(\mathbf{v}, b)$. To simplify terminology we refer to $\hat{I}(\mathbf{v}, b)$ as the *density on $H(\mathbf{v}, b)$* , or the *density integral on $H(\mathbf{v}, b)$* , rather than the empirical density, or the empirical density integral, respectively. For notational convenience we write $I(\mathbf{v}, b)$ for $\hat{I}(\mathbf{v}, b, \mathcal{X}, h^2 I)$, where \mathcal{X} and h are apparent from context.

The following Lemma, adapted from Tasoulis et al., 2010, Lemma 3, shows that $\hat{I}(\mathbf{v}, b)$ provides an upper bound for the maximum value of the empirical density at any point that belongs to the hyperplane.

Lemma 1 *Let $\mathcal{X} = \{\mathbf{x}_i\}_{i=1}^n \subset \mathbb{R}^d$, and $\hat{p}(\mathbf{x} \mid \mathcal{X}, h^2 I)$ be a kernel density estimator with isotropic Gaussian kernels. Then, for any $(\mathbf{v}, b) \in S^{d-1} \times \mathbb{R}$,*

$$\max_{\mathbf{x} \in H(\mathbf{v}, b)} \hat{p}(\mathbf{x} \mid \mathcal{X}, h^2 I) \leq (2\pi h^2)^{\frac{1-d}{2}} \hat{I}(\mathbf{v}, b), \quad \text{for all } \mathbf{x} \in H(\mathbf{v}, b). \quad (4)$$

This lemma shows that a hyperplane, $H(\mathbf{v}, b)$, cannot intersect level sets of the empirical density with level higher than $(2\pi h^2)^{\frac{1-d}{2}} \hat{I}(\mathbf{v}, b)$. The proof of the lemma relies on the fact that projection contracts distances, and follows from simple algebra. In Equation (4) equality holds if and only if there exists $\mathbf{x} \in H(\mathbf{v}, b)$ and $\mathbf{c} \in \mathbb{R}^n$ such that all $\mathbf{x}_i \in \mathcal{X}$, can be written as $\mathbf{x}_i = \mathbf{x} + c_i \mathbf{v}$. It is therefore not possible to obtain a uniform upper bound on the value of the empirical density at points that belong to $H(\mathbf{v}, b)$ that is lower than $(2\pi h^2)^{\frac{1-d}{2}} \hat{I}(\mathbf{v}, b)$ using only one-dimensional projections. Since the upper bound of Lemma 1 is tight and proportional to $\hat{I}(\mathbf{v}, b)$, minimising the density on the hyperplane leads to the lowest upper bound on the maximum value of the empirical density along the hyperplane separator.

To obtain hyperplane separators that are meaningful for clustering and semi-supervised classification, it is necessary to constrain the set of feasible solutions, because the density on a hyperplane can be made arbitrarily low by considering a hyperplane that intersects only the tail of the density. In other words, for any \mathbf{v} , $I(\mathbf{v}, b)$ can be made arbitrarily low for sufficiently large $|b|$. In both problems the constraints restrict the feasible set to a subset of the hyperplanes that intersect the interior of the convex hull of \mathcal{X} . In detail, let $\text{conv } \mathcal{X}$ denote the convex hull of \mathcal{X} , and assume $\text{Int}(\text{conv } \mathcal{X}) \neq \emptyset$. Define C to be the set of hyperplanes that intersect $\text{Int}(\text{conv } \mathcal{X})$,

$$C = \left\{ H(\mathbf{v}, b) \mid (\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R}, \exists \mathbf{z} \in \text{Int}(\text{conv } \mathcal{X}) \text{ s.t. } \mathbf{v} \cdot \mathbf{z} = b \right\}. \quad (5)$$

Then denote by F the set of feasible hyperplanes, where $F \subset C$. We define the *minimum density hyperplane* (MDH), $H(\mathbf{v}^*, b^*) \in F$ to satisfy,

$$\hat{I}(\mathbf{v}^*, b^*) = \min_{(\mathbf{v}, b) \in F} \hat{I}(\mathbf{v}, b). \quad (6)$$

In the following subsections we discuss the specific formulations for clustering and semi-supervised classification in turn.

2.1 Clustering

Since high-density clusters are formed around the modes of $p(\mathbf{x})$, the convex hull of these modes would be a natural choice to define the set of feasible hyperplanes. Unfortunately, this convex hull is unknown and difficult to estimate. We instead propose to constrain the distance of hyperplanes to the origin, b . Such a constraint is inevitable as for any $\mathbf{v} \in \mathcal{S}^{d-1}$, $\hat{I}(\mathbf{v}, b)$ can become arbitrarily close to zero for sufficiently large $|b|$. Obviously, such hyperplanes are inappropriate for the purposes of bi-partitioning as they assign all the data to the same partition. Rather than fixing b to a constant, we constrain it in the interval,

$$F(\mathbf{v}) = [\mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}}, \mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}}], \quad (7)$$

where $\mu_{\mathbf{v}}$ and $\sigma_{\mathbf{v}}$ denote the mean and standard deviation, respectively, of the projections $\{\mathbf{v} \cdot \mathbf{x}_i\}_{i=1}^n$. The parameter $\alpha \geq 0$, controls the width of the interval, and has a probabilistic interpretation from Chebyshev's inequality. Smaller values of α favour more balanced partitions of the data at the risk of excluding low density hyperplanes that separate clusters more effectively. On the other hand, increasing α increases the risk of separating out only a

few outlying observations. We discuss in detail how to set this parameter in the experimental results section. If $\text{Int}(\text{conv } \mathcal{X}) \neq \emptyset$, then there exists $\alpha > 0$ such that the set of feasible hyperplanes for clustering, F_{CL} , satisfies,

$$F_{\text{CL}} = \left\{ H(\mathbf{v}, b) \mid (\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R}, b \in F(\mathbf{v}) \right\} \subset C, \quad (8)$$

where C is the set of hyperplanes that intersect $\text{Int}(\text{conv } \mathcal{X})$, as defined in Equation (5).

The minimum density hyperplane for clustering is the solution to the following constrained optimisation problem,

$$\min_{(\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R}} \hat{I}(\mathbf{v}, b), \quad (9a)$$

$$\text{subject to: } b - \mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}} \geq 0, \quad (9b)$$

$$\mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}} - b \geq 0. \quad (9c)$$

Since the objective function and the constraints are continuously differentiable, MDHs can be estimated through constrained optimisation methods like sequential quadratic programming (SQP). Unfortunately the problem of local minima due to the nonconvexity of the objective function seriously hinders the effectiveness of this approach.

To mitigate this we propose a parameterised optimisation formulation, which gives rise to a projection pursuit approach. Projection pursuit methods optimise a measure of ‘‘interestingness’’ of a linear projection of a data sample, known as the projection index. For our problem the natural choice of projection index for \mathbf{v} is the minimum value of the projected density within the feasible region, $\min_{b \in F(\mathbf{v})} \hat{I}(\mathbf{v}, b)$. This index gives the minimum density integral of feasible hyperplanes with normal vector \mathbf{v} . To ensure the differentiability of the projection index we incorporate a penalty term into the objective function. We define the penalised density integral as,

$$f_{\text{CL}}(\mathbf{v}, b) = \hat{I}(\mathbf{v}, b) + \frac{L}{\eta} \max\{0, \mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}} - b, b - \mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}}\}^{1+\epsilon}, \quad (10)$$

where, $L = (e^{1/2} h^2 \sqrt{2\pi})^{-1} \geq \sup_{b \in \mathbb{R}} \left| \frac{\partial \hat{I}(\mathbf{v}, b)}{\partial b} \right|$, $\epsilon \in (0, 1)$ is a constant term that ensures that the penalty function is everywhere continuously differentiable, and $\eta \in (0, 1)$. Other penalty functions are possible, but we only consider the above due to its simplicity, and the fact that its parameters offer a direct interpretation: L in terms of the derivative of the projected density on \mathbf{v} ; and η in terms of the desired accuracy of the minimisers of $f_{\text{CL}}(\mathbf{v}, b)$ relative to the minimisers of Equation (9), as discussed in the following proposition.

Proposition 2 For $\mathbf{v} \in \mathcal{S}^{d-1}$, define, the set of minimisers,

$$B(\mathbf{v}) = \arg \min_{b \in F(\mathbf{v})} \hat{I}(\mathbf{v}, b), \quad (11)$$

$$B_C(\mathbf{v}) = \arg \min_{b \in \mathbb{R}} f_{\text{CL}}(\mathbf{v}, b) \quad (12)$$

For every $b^* \in B(\mathbf{v})$ there exists $b_C^* \in B_C(\mathbf{v})$ such that $|b^* - b_C^*| \leq \eta$. Moreover, there are no minimisers of $f_{\text{CL}}(\mathbf{v}, b)$ outside the interval $[\mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}} - \eta, \mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}} + \eta]$,

$$B_C(\mathbf{v}) \cap \mathbb{R} \setminus [\mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}} - \eta, \mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}} + \eta] = \emptyset.$$

Proof

Any minimiser in the interior of the feasible region, $b^* \in B(\mathbf{v}) \cap \text{Int}(F(\mathbf{v}))$, also minimises the penalised function, since $f_{\text{CL}}(\mathbf{v}, b) = \hat{I}(\mathbf{v}, b)$ for all $b \in \text{Int}(F(\mathbf{v}))$, hence $b^* \in B_C(\mathbf{v})$.

Next we consider the case when either or both of the boundary points of $F(\mathbf{v})$, $b^- = \mu_0 - \sigma\sigma_{\mathbf{v}}$ and $b^+ = \mu_0 + \sigma\sigma_{\mathbf{v}}$, are contained in $B(\mathbf{v})$. It suffices to show that, $f_{\text{CL}}(\mathbf{v}, b) > \hat{I}(\mathbf{v}, b^-)$ for all $b < b^- - \eta$, and $f_{\text{CL}}(\mathbf{v}, b) > \hat{I}(\mathbf{v}, b^+)$ for all $b > b^+ + \eta$. We discuss only the case $b > b^+ + \eta$ as the treatment of $b < b^- - \eta$ is identical. Assume that $\hat{I}(\mathbf{v}, b) < \hat{I}(\mathbf{v}, b^+)$ (since in the opposite case the result follows immediately: $f_{\text{CL}}(\mathbf{v}, b) > \hat{I}(\mathbf{v}, b) > \hat{I}(\mathbf{v}, b^+)$). From the mean value theorem there exists $\xi \in (b^+, b)$ such that,

$$\begin{aligned} \hat{I}(\mathbf{v}, b^+) &= \hat{I}(\mathbf{v}, b) - (b - b^+) \frac{\partial \hat{I}(\mathbf{v}, b)}{\partial b} \Big|_{b=\xi} \\ &\leq \hat{I}(\mathbf{v}, b) + (b - b^+)L \\ &< \hat{I}(\mathbf{v}, b) + \frac{L(b - b^+)1+\epsilon}{\eta^\epsilon} = f_{\text{CL}}(\mathbf{v}, b), \end{aligned}$$

In the above we used the following facts: $\frac{\partial \hat{I}(\mathbf{v}, b)}{\partial b} \Big|_{b=\xi} < 0$, $L \geq \sup_{b \in \mathbb{R}} \left| \frac{\partial \hat{I}(\mathbf{v}, b)}{\partial b} \right|$, and $\frac{b - b^+}{\eta} > 1$. ■

We define the projection index for the clustering problem as the minimum of the penalised density integral,

$$\phi_{\text{CL}}(\mathbf{v}) = \min_{b \in \mathbb{R}} f_{\text{CL}}(\mathbf{v}, b). \quad (13)$$

Since the optimisation problem of Equation (13) is one-dimensional it is simple to compute the set of global minimisers $B_C(\mathbf{v})$. As we discuss in Section 4, this is necessary to compute directional derivatives of the projection index, as well as, to determine whether ϕ_{CL} is differentiable. We call the optimisation of ϕ_{CL} , *minimum density projection pursuit* (MDP²). For each \mathbf{v} , MDP² considers only the optimal choice of b . This enables it to avoid local minima of $\hat{I}(\mathbf{v}, \cdot)$. Most importantly MDP² is able to accommodate a discontinuous change in the location of the global minimiser(s), $\arg \min_{b \in \mathbb{R}} f_{\text{CL}}(\mathbf{v}, b)$, as \mathbf{v} changes. Neither of the above can be achieved when the optimisation is jointly over (\mathbf{v}, b) as in the original constrained optimisation problem, Equation (9). The projection index ϕ_{CL} is continuous, but it is not guaranteed to be everywhere differentiable when $B_C(\mathbf{v})$ is not a singleton. The resulting optimisation problem is therefore nonsmooth and nonconvex.

To illustrate the effectiveness of MDP² to estimate MDHs, we compare this approach with a direct optimisation of the constrained problem given in Equation (9) using SQP. To enable visualisation we consider the two-dimensional S1 data set (Franti and Virmajoki, 2006), constructed by sampling from a Gaussian mixture distribution with fifteen components, where each component corresponds to a cluster. Figure 1 depicts the MDHs obtained over 100 random initialisations of SQP and MDP². It is evident that SQP frequently yields hyperplanes that intersect regions with high probability density thus splitting clusters. As SQP always converged in these experiments the poor performance is solely due to convergence to local minima. In contrast, MDP² converges to three different solutions over the 100 experiments, all of which induce high quality partitions, and none intersects a high-density

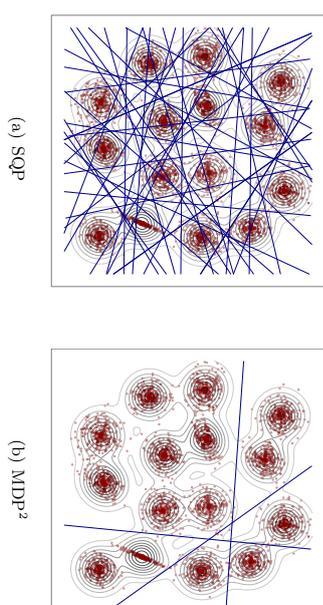

Figure 1: Binary partitions induced by 100 MDHs estimated through SQP and MDP²

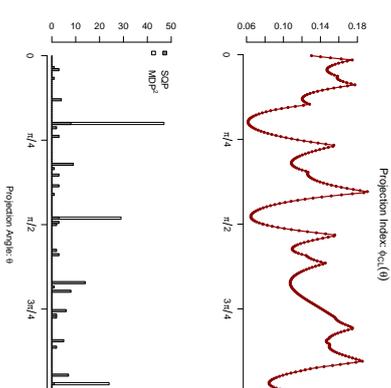

Figure 2: Projection index for S1 data set and solutions obtained through SQP and MDP²

cluster. In polar coordinates any $\mathbf{v} \in S^1$ can be parameterised through a single projection angle. Using this parameterisation, the upper plot of Figure 2 depicts the value of the projection index, $\phi_{\text{CL}}(\mathbf{v}(\theta))$, for $\theta \in [0, \pi]$. The lower plot of the figure provides histograms of the distribution of the solutions (locally optimal projection angles) obtained over the 100 experiments with SQP (grey) and MDP² (white). The figure shows that $\phi_{\text{CL}}(\mathbf{v})$ is continuous but not everywhere differentiable. The solution most frequently obtained through MDP² corresponds to the global optimum, while the only other two solutions identified are the local minimisers with the next two lowest function values. In contrast SQP converges to a much wider range of solutions. Note that this method is not guaranteed to identify the

optimal value of b for any $\mathbf{v}(\theta)$ and this indeed occurs in this example. Therefore the value of $\phi_{\text{CL}}(\mathbf{v})$ is a lower bound for the function values of the minimisers identified through SQP.

2.2 Semi-Supervised Classification

In semi-supervised classification labels are available for a subset of the data sample. The resulting classifier needs to predict as accurately as possible the labelled examples, while avoiding intersection with high-density regions of the empirical density. The MDH formulation can readily accommodate partially labelled data by incorporating the linear constraints associated with the labelled data into the clustering formulation. Without loss of generality assume that the first ℓ examples are labelled by $\mathbf{y} = (y_1, \dots, y_\ell)^\top \in \{-1, 1\}^\ell$. The MDH for semi-supervised classification is the solution to the problem,

$$\min_{(\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R}} \hat{I}(\mathbf{v}, b), \quad (14a)$$

$$\text{subject to: } y_i(\mathbf{v} \cdot \mathbf{x}_i - b) \geq 0, \quad \forall i = 1, \dots, \ell, \quad (14b)$$

$$b - \mu_{\mathbf{v}} + \alpha\sigma_{\mathbf{v}} \geq 0, \quad (14c)$$

$$\mu_{\mathbf{v}} + \alpha\sigma_{\mathbf{v}} - b \geq 0, \quad (14d)$$

where $\hat{I}(\mathbf{v}, b)$, $\mu_{\mathbf{v}}$, and $\sigma_{\mathbf{v}}$ are computed over the entire data set. If the labelled examples are linearly separable the constraints in Equation (14) define a nonempty feasible set of hyperplanes,

$$F_{\text{LB}} = \left\{ H(\mathbf{v}, b) \mid (\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R}, b \in F(\mathbf{v}), y_i(\mathbf{v} \cdot \mathbf{x}_i - b) \geq 0, \forall i \in \{1, \dots, \ell\} \right\} \subset C. \quad (15)$$

Equations (14c) and (14d) act as a *balancing constraint* which discourages MDHs that classify the vast majority of unlabelled data to a single class. Balancing constraints are included in the estimation of S3VMs for the same reason (Joachims, 1999; Chapelle and Zien, 2005).

As in the case of clustering, the direct minimisation of Equation (14) frequently leads to locally optimal solutions. To mitigate this we again propose a projection pursuit formulation. We define the penalised density integral for semi-supervised classification as,

$$f_{\text{SSC}}(\mathbf{v}, b) = f_{\text{CL}}(\mathbf{v}, b) + \gamma \sum_{i=1}^{\ell} \max\{0, -y_i(\mathbf{v} \cdot \mathbf{x}_i - b)\}^{1+\epsilon} \quad (16)$$

where, $\gamma > 0$ is a user-defined constant, which controls the trade-off between reducing the density on the hyperplane, and misclassifying the labelled examples. The projection index is then defined as the minimum of the penalised density integral,

$$\phi_{\text{SSC}}(\mathbf{v}) = \min_{b \in \mathbb{R}} f_{\text{SSC}}(\mathbf{v}, b). \quad (17)$$

3. Connection to Maximum Margin Hyperplanes

In this section we discuss the connection between MDHs and maximum (hard) margin hyperplane separators. The margin of a hyperplane $H(\mathbf{v}, b)$ with respect to a data set \mathcal{X} is

defined as the minimum Euclidean distance between the hyperplane and its nearest datum, margin $H(\mathbf{v}, b) = \min_{\mathbf{x} \in \mathcal{X}} |\mathbf{v} \cdot \mathbf{x} - b|$. (18)

The points whose distance to the hyperplane $H(\mathbf{v}, b)$ is equal to the margin of the hyperplane, that is, $\arg \min_{\mathbf{x} \in \mathcal{X}} |\mathbf{v} \cdot \mathbf{x} - b|$, are called the *support points* of $H(\mathbf{v}, b)$. Let F denote the set of feasible hyperplanes; then the *maximum margin hyperplane* (MMH), $H(\mathbf{v}^m, b^m) \in F$ satisfies,

$$\text{margin } H(\mathbf{v}^m, b^m) = \max_{(\mathbf{v}, b) \mid H(\mathbf{v}, b) \in F} \text{margin } H(\mathbf{v}, b). \quad (19)$$

The main result of this section is Theorem 5, which states that as the bandwidth parameter, h , is reduced to zero the MDH converges to the MMH. An intermediate result, Lemma 4, shows that there exists a positive bandwidth, $h' > 0$ such that, for all $h \in (0, h')$, the partition of the data set induced by the MDH is identical to that of the MMH.

We first discuss some assumptions which allow us to present the theoretical results of this section. As before we assume a fixed and finite data set $\mathcal{X} \subset \mathbb{R}^d$, and approximate its (assumed) underlying probability density function via a kernel density estimator using Gaussian kernels with isotropic bandwidth matrix $h^2 I$. We assume that the interior of the convex hull of the data, $\text{Int}(\text{conv } \mathcal{X})$, is non-empty, and define C as the set of hyperplanes that intersect $\text{Int}(\text{conv } \mathcal{X})$, as in Equation (5). The set of feasible hyperplanes, F , for either clustering or the semi-supervised classification satisfies $F \subset C$. By construction every $H(\mathbf{v}, b) \in F$ defines a hyperplane which partitions \mathcal{X} into two non-empty subsets. Observe that if for each $\mathbf{v} \in \mathcal{S}^{d-1}$ the set $\{b \in \mathbb{R} \mid H(\mathbf{v}, b) \in F\}$ is compact, then by the compactness of \mathcal{S}^{d-1} a maximum margin hyperplane in F exists. For both the clustering and semi-supervised classification problems this compactness holds by construction.

For any $h > 0$, let $(\mathbf{v}_h^*, b_h^*) \in \mathcal{S}^{d-1} \times \mathbb{R}$ parameterise a hyperplane which achieves the minimal density integral over all hyperplanes in F , for bandwidth matrix $h^2 I$. That is,

$$\hat{I}(\mathbf{v}_h^*, b_h^*) = \min_{(\mathbf{v}, b) \mid H(\mathbf{v}, b) \in F} \hat{I}(\mathbf{v}, b). \quad (20)$$

Following the approach of Tong and Koller (2000) we first show that as the bandwidth, h , is reduced towards zero, the density on a hyperplane is dominated by its nearest point. This is achieved by establishing that for all sufficiently small values of h , a hyperplane with non-zero margin has lower density integral than any other hyperplane with smaller margin.

Lemma 3 *Take $H(\mathbf{v}, b) \in F$ with non-zero margin and $0 < \delta < \text{margin } H(\mathbf{v}, b) := M_{\mathbf{v}, b}$. Then $\exists h' > 0$ such that $h \in (0, h')$ and $M_{\mathbf{w}, c} := \text{margin } H(\mathbf{w}, c) \leq M_{\mathbf{v}, b} - \delta$ implies $\hat{I}(\mathbf{v}, b) < \hat{I}(\mathbf{w}, c)$.*

Proof

Using Equation (3) it is easy to see that,

$$\hat{I}(\mathbf{v}, b) \leq \frac{1}{h\sqrt{2\pi}} \exp\left\{-\frac{M_{\mathbf{v}, b}^2}{2h^2}\right\},$$

$$\inf\left\{\hat{I}(\mathbf{w}, c) \mid M_{\mathbf{w}, c} \leq M_{\mathbf{v}, b} - \delta\right\} \geq \frac{1}{nh\sqrt{2\pi}} \exp\left\{-\frac{(M_{\mathbf{v}, b} - \delta)^2}{2h^2}\right\}.$$

Therefore,

$$0 \leq \lim_{h \rightarrow 0^+} \frac{\hat{I}(\mathbf{v}, b)}{\inf_{M_{\mathbf{w},c} \leq M_{\mathbf{v},b} - \delta} \hat{I}(\mathbf{w}, c)} \leq \lim_{h \rightarrow 0^+} \frac{n \exp \left\{ \begin{array}{l} M_{\mathbf{v},b}^2 \\ -\frac{2M_{\mathbf{v},b}^2}{h^2} \end{array} \right\}}{\exp \left\{ \begin{array}{l} -(M_{\mathbf{v},b} - \delta)^2 \\ \frac{2(M_{\mathbf{v},b} - \delta)^2}{h^2} \end{array} \right\}} = 0.$$

Therefore, $\exists h' > 0$ such that $h \in (0, h') \Rightarrow \frac{\hat{I}(\mathbf{v}, b)}{\inf_{M_{\mathbf{w},c} \leq M_{\mathbf{v},b} - \delta} \hat{I}(\mathbf{w}, c)} < 1$. \blacksquare

An immediate corollary of Lemma 3 is that as h tends to zero the margin of the MDH tends to the maximum margin. However, this does not necessarily ensure the stronger result that the sequence of MDHs converges to the MMH. To establish this we require two technical results, which describe some algebraic properties of the MMH, and are provided as part of the proof of Theorem 5 which is given in Appendix A.

The next lemma uses the previous result to show that there exists a positive bandwidth, $h' > 0$, such that an MDH estimated using $h \in (0, h')$ induces the same partition of \mathcal{X} as the MMH. The result assumes that the MMH is unique. Notice that if \mathcal{X} is a sample of realisations of a continuous random variable then this uniqueness holds with probability 1.

Lemma 4 *Suppose there is a unique hyperplane in F with maximum margin, which can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$. Then $\exists h' > 0$ s.t. $h \in (0, h') \Rightarrow H(\mathbf{v}_h^*, b_h^*)$ induces the same partition of \mathcal{X} as $H(\mathbf{v}^m, b^m)$.*

Proof

Let $M = \text{margin } H(\mathbf{v}^m, b^m)$, and let P be the collection of hyperplanes that induce the same partition of \mathcal{X} as that induced by $H(\mathbf{v}^m, b^m)$. Since \mathcal{X} is finite and $H(\mathbf{v}^m, b^m)$ is unique, $\exists \delta > 0$ s.t. $H(w, c) \notin P \Rightarrow \text{margin } H(w, c) \leq M - \delta$. By Lemma 3, $\exists h' > 0$ s.t.,

$$h \in (0, h') \Rightarrow H(\mathbf{v}_h^*, b_h^*) \notin \{H(\mathbf{w}, c) \mid \text{margin } H(\mathbf{w}, c) \leq M - \delta\},$$

therefore $H(\mathbf{v}_h^*, b_h^*) \in P$. \blacksquare

The next theorem is the main result of this section, and states that the MDH converges to the MMH as the bandwidth parameter is reduced to zero. Notice that by the non-unique representation of hyperplanes, the maximum margin hyperplane has two parameterisations in C , namely (\mathbf{v}^m, b^m) and $(-\mathbf{v}^m, -b^m)$. Convergence to the maximum margin hyperplane is therefore equivalent to showing that,

$$\min \{ \|(\mathbf{v}_h^*, b_h^*) - (\mathbf{v}^m, b^m) \|, \| (\mathbf{v}_h^*, b_h^*) + (\mathbf{v}^m, b^m) \| \} \rightarrow 0 \text{ as } h \rightarrow 0^+.$$

Theorem 5 *Suppose there is a unique hyperplane in F with maximum margin, which can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$. Then,*

$$\lim_{h \rightarrow 0^+} \min \{ \|(\mathbf{v}_h^*, b_h^*) - (\mathbf{v}^m, b^m) \|, \| (\mathbf{v}_h^*, b_h^*) + (\mathbf{v}^m, b^m) \| \} = 0.$$

The set F used in Theorem 5 is generic so it can capture the constraints associated with both clustering and semi-supervised classification, Equations (9) and (14) respectively. In the case of semi-supervised classification we must also assume that the labelled data are linearly separable. Theorem 5 is not directly applicable to the MDP² formulations as in this case the function being minimised is not the density on a hyperplane. The next two subsections establish this result for the MDP² formulation of the clustering and semi-supervised classification problem.

3.1 MDP² for Clustering

We have shown that for the constrained optimisation formulation the MDH converges to the MMH within the feasible set, $F_{\text{CL}} \subset C$. In addition, for a fixed \mathbf{v} , Proposition 2 bounds the distance between minimisers of the penalised function f_{CL} , $\arg \min_{\mathbf{v} \in \mathbb{R}} f_{\text{CL}}(\mathbf{v}, b)$, and the optimal b of the constrained problem, $\arg \min_{b \in F(\mathbf{v})} \hat{I}(\mathbf{v}, b)$. Combining these we can show that the optimal solution to the penalised MDP² formulation converges to the maximum margin hyperplane in F_{CL} , provided the parameters within the penalty term suitably depend on the bandwidth parameter, h . While the general case can be shown, for ease of exposition we make the simplifying assumption that the maximum margin hyperplane is strictly feasible, i.e., if (\mathbf{v}^m, b^m) parameterises the maximum margin hyperplane then $b^m \in (h\mathbf{v}^m - \alpha\sigma\mathbf{v}^m, h\mathbf{v}^m + \alpha\sigma\mathbf{v}^m)$.

For $h, \eta, L > 0$ define $(\mathbf{v}_{h,\eta,L}^*, b_{h,\eta,L}^*)$ to be any global minimiser of f_{CL} , i.e.,

$$f_{\text{CL}}(\mathbf{v}_{h,\eta,L}^*, b_{h,\eta,L}^*) = \min_{(\mathbf{v},b) \in \mathcal{S}^{d-1} \times \mathbb{R}} f_{\text{CL}}(\mathbf{v}, b).$$

Lemma 6 *Suppose there is a unique hyperplane in F_{CL} with maximum margin, which can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$. Suppose further that $b^m \in (h\mathbf{v}^m - \alpha\sigma\mathbf{v}^m, h\mathbf{v}^m + \alpha\sigma\mathbf{v}^m)$. For $h > 0$, let $L(h) = (e^{1/2}h^2\sqrt{2\pi})^{-1}$, and $0 < \eta(h) \leq h$. Then,*

$$\lim_{h \rightarrow 0^+} \min \{ \|(\mathbf{v}_{h,\eta(h),L(h)}^*, b_{h,\eta(h),L(h)}^*) - (\mathbf{v}^m, b^m) \|, \| (\mathbf{v}_{h,\eta(h),L(h)}^*, b_{h,\eta(h),L(h)}^*) + (\mathbf{v}^m, b^m) \| \} = 0.$$

Proof

Let $M = \text{margin } H(\mathbf{v}^m, b^m)$ and as in the proof of Lemma 4, let $\delta > 0$ be such that any hyperplane inducing a different partition from $H(\mathbf{v}^m, b^m)$ has margin at most $M - \delta$. Consider the set $F_{\text{CL}}^\delta := \{(\mathbf{v}, b) \in \mathcal{S}^{d-1} \times \mathbb{R} \mid b \in \mathbb{B}_{\delta/2}(F(\mathbf{v}))\}$, where we used the notation $\mathbb{B}_{\delta/2}(F(\mathbf{v}))$ to denote the neighbourhood of $F(\mathbf{v})$ given by $\{r \in \mathbb{R} \mid |d(r, F(\mathbf{v}))| < \delta/2\}$. The set F_{CL}^δ increases the feasible set of hyperplanes by allowing b to range in $b \in \mathbb{B}_{\delta/2}(F(\mathbf{v}))$. For any fixed \mathbf{v} , the maximum margin of all hyperplanes with normal vector \mathbf{v} can increase by at most $\delta/2$. Thus, any hyperplane inducing a different partition compared to $H(\mathbf{v}^m, b^m)$ has a margin at most $M - \delta/2$. Since $H(\mathbf{v}_{h,\eta}^m, b_{h,\eta}^m)$ is strictly feasible it therefore remains the unique maximum margin hyperplane in F_{CL}^δ . Observe now that for $0 < h < \delta/2$ we have $H(\mathbf{v}_{h,\eta(h),L(h)}^*, b_{h,\eta(h),L(h)}^*) \in F_{\text{CL}}^\delta$, by Proposition 2. In addition, by Theorem 5, we know that the minimisers of $\hat{I}(\mathbf{v}, b)$ over F_{CL}^δ , say $H(\mathbf{v}_{h,\eta}^\delta, b_h^\delta)$, satisfy

$$\lim_{h \rightarrow 0^+} \min \{ \|(\mathbf{v}_{h,\eta}^\delta, b_h^\delta) - (\mathbf{v}^m, b^m) \|, \| (\mathbf{v}_{h,\eta}^\delta, b_h^\delta) + (\mathbf{v}^m, b^m) \| \} = 0.$$

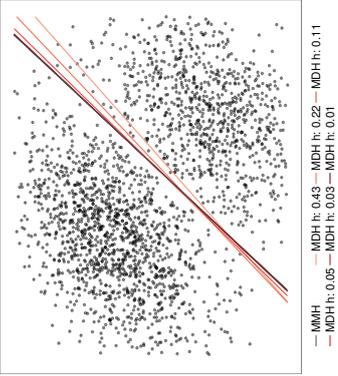

Figure 3: Convergence of the MDH to the maximum margin hyperplane for a decreasing sequence of bandwidth parameters, h .

Now, since $H(\mathbf{v}^m, b^m)$ is strictly feasible $\exists \epsilon' > 0$ s.t. $(\mathbf{v}, b) \in \mathbb{B}_\epsilon(\{(\mathbf{v}^m, b^m), -(\mathbf{v}^m, b^m)\}) \Rightarrow H(\mathbf{v}, b) \in F_{\text{CL}}$. Then for any $0 < \epsilon < \epsilon'$ there exists $h' > 0$ s.t. for $0 < h < h'$ both $(\mathbf{v}_h^*, b_h^*) \in \mathbb{B}_\epsilon(\{(\mathbf{v}^m, b^m), -(\mathbf{v}^m, b^m)\}) \Rightarrow H(\mathbf{v}_h^*, b_h^*) \in F_{\text{CL}}$ and $H(\mathbf{v}_{h, \eta(h), L(h)}^*, b_{h, \eta(h), L(h)}^*) \in F_{\text{CL}}^{\delta}$. Now for $H(\mathbf{v}, b) \in F_{\text{CL}}^{\delta} \setminus F_{\text{CL}}$ we know that $\hat{I}(\mathbf{v}, b) < f_{\text{CL}}(\mathbf{v}, b)$, whereas for $H(\mathbf{v}, b) \in F_{\text{CL}}$, $\hat{I}(\mathbf{v}, b) = f_{\text{CL}}(\mathbf{v}, b)$ and therefore the minimiser of $f_{\text{CL}}(\mathbf{v}, b)$ must lie in the neighbourhood $\mathbb{B}_\epsilon(\{(\mathbf{v}^m, b^m), -(\mathbf{v}^m, b^m)\})$, and the result follows. ■

To illustrate the convergence of the MDH to the MMH we use the two-dimensional data set shown in Figure 3. The data is sampled from a mixture of two Gaussian distributions with equal covariance matrix. The MDH with respect to the true underlying density is $H((1, -1), 0)$. A large margin separator is artificially introduced by removing a few observations in a narrow margin around a hyperplane different from $H((1, -1), 0)$. The margin is intentionally small to ensure that identifying the MMH is non-trivial. Figure 3 illustrates the MDH solutions arising from the MDP2 method for a decreasing sequence of bandwidths, h . Initially the MDH approximately coincides with the optimal MDH with respect to the true density of the Gaussian mixture. As h decreases, the MDH approaches the MMH and for the smallest values of h the two are indistinguishable.

3.2 MDP² for Semi-Supervised Classification

Denote the set of hyperplanes which correctly classify the labelled data by F_{LB} . Under the assumption that $\exists H(\mathbf{v}, b) \in F_{\text{LB}} \cap F_{\text{CL}}$ with non-zero margin, we can show that, provided the parameter γ does not shrink too quickly with h , the hyperplane that minimises f_{SSC} converges to the MMH contained in $F_{\text{LB}} \cap F_{\text{CL}}$, where as before we assume that such an MMH is strictly feasible. To establish this result it is sufficient to show that there exists $h' > 0$ such

that for all $h \in (0, h')$, the optimal hyperplane $H(\mathbf{v}_{h, \eta, L, \gamma}^*, b_{h, \eta, L, \gamma}^*)$ correctly classifies all the labelled examples. If this holds, then $f_{\text{SSC}}(\mathbf{v}_{h, \eta, L, \gamma}^*, b_{h, \eta, L, \gamma}^*) = f_{\text{CL}}(\mathbf{v}_{h, \eta, L, \gamma}^*, b_{h, \eta, L, \gamma}^*)$ for all sufficiently small h , and hence Lemma 6 can be applied to establish the result. The proof relies on the fact that the penalty terms associated with the known labels in Equation (16) are polynomials in b . Provided that γ is bounded below by a polynomial in h , the value of the penalty terms for hyperplanes that do not correctly classify the labelled data dominate the value of the density integral as h approaches zero. Therefore the optimal hyperplane must correctly classify the labelled data for small values of h .

Lemma 7 Define $F_{\text{LB}} = \{H(\mathbf{v}, b) | y_i(\mathbf{v} \cdot \mathbf{x}_i - b) > 0, \forall i = 1, \dots, \ell\}$ and $F_{\text{CL}} = \{H(\mathbf{v}, b) | \mu_{\mathbf{v}} - \alpha \sigma_{\mathbf{v}} \leq b \leq \mu_{\mathbf{v}} + \alpha \sigma_{\mathbf{v}}\}$ and assume that $F_{\text{SSC}} = F_{\text{LB}} \cap F_{\text{CL}} \neq \emptyset$ and that $\exists H(\mathbf{v}, b) \in F_{\text{SSC}}$ with non-zero margin. For $h > 0$, let $L(h) = (e^{1/2} h^2 \sqrt{2\pi})^{-1}$, $0 < \eta(h) \leq h$ and $\gamma(h) \geq h^r$ for some $r > 0$. Then $\exists h' > 0$ s.t. $h \in (0, h') \Rightarrow H(\mathbf{v}_{h, \eta(h), L(h), \gamma(h)}^*, b_{h, \eta(h), L(h), \gamma(h)}^*) \in F_{\text{LB}}$.

Proof

Consider $H(\mathbf{v}, b) \notin F_{\text{LB}}$. Then,

$$f_{\text{SSC}}(\mathbf{v}, b) \geq \frac{1}{n\sqrt{2\pi}h} \exp(-\nu_*^2/2h^2) + \gamma(h)\nu_*^{1+\epsilon} > \gamma(h)\nu_*^{1+\epsilon},$$

where $\nu_* > 0$ minimises $\frac{1}{n\sqrt{2\pi}h} \exp(-\nu^2/2h^2) + \gamma(h)\nu^{1+\epsilon}$. Therefore, ν_* is the unique positive number satisfying,

$$\begin{aligned} \frac{1}{n\sqrt{2\pi}h} \exp\left(-\frac{\nu_*^2}{2h^2}\right) \left(-\frac{\nu_*}{h^2}\right) + (1+\epsilon)\gamma(h)\nu_*^\epsilon &= 0 \\ \Rightarrow \nu_*^{1-\epsilon} &= (1+\epsilon)\gamma(h)n\sqrt{2\pi}h^3 \exp\left(\frac{\nu_*^2}{2h^2}\right) \\ \Rightarrow \nu_* &\geq \left((1+\epsilon)\gamma(h)n\sqrt{2\pi}h^3\right)^{1/1-\epsilon}. \end{aligned}$$

We therefore have,

$$\begin{aligned} f_{\text{SSC}}(\mathbf{v}, b) &> \gamma(h) \left((1+\epsilon)\gamma(h)n\sqrt{2\pi}h^3 \right)^{\frac{1+\epsilon}{1-\epsilon}} \\ &= K\gamma(h)^{\frac{2}{1-\epsilon}} h^{\frac{3(1+\epsilon)}{1-\epsilon}} \\ &\geq K h^{\frac{2+3(1+\epsilon)}{1-\epsilon}}, \end{aligned}$$

where K is a constant which can be chosen independent of (\mathbf{v}, b) . Finally, for any $H(\mathbf{v}', b') \in F_{\text{SSC}}$ with non-zero margin, $\exists h' > 0$ s.t.

$$h \in (0, h') \Rightarrow f_{\text{SSC}}(\mathbf{v}', b') = \hat{I}(\mathbf{v}', b') < K h^{\frac{2+3(1+\epsilon)}{1-\epsilon}} < f_{\text{SSC}}(\mathbf{v}, b).$$

Since K is independent of (\mathbf{v}, b) , the result follows. The final set of inequalities holds since the hyperplane $H(\mathbf{v}', b')$ is assumed to have non-zero margin, say $M_{\mathbf{v}', b'} > 0$, and hence $\hat{I}(\mathbf{v}', b') \leq \frac{1}{n\sqrt{2\pi}} \exp\{-M_{\mathbf{v}', b'}/2h'^2\}$, which tends to zero faster than any polynomial in h . ■

4. Estimation of Minimum Density Hyperplanes

In this section we discuss the computation of MDHs. We first investigate the continuity and differentiability properties required to optimise the projection indices $\phi_{\text{CL}}(\mathbf{v})$ and $\phi_{\text{SSC}}(\mathbf{v})$. Since the domain of both projection indices, $\phi_{\text{CL}}(\mathbf{v})$ and $\phi_{\text{SSC}}(\mathbf{v})$, is the boundary of the unit-sphere in \mathbb{R}^d it is more convenient to express \mathbf{v} in terms of spherical coordinates,

$$v_i(\theta) = \begin{cases} \cos(\theta_i) \prod_{j=1}^{i-1} \sin(\theta_j), & i = 1, \dots, d-1 \\ \prod_{j=1}^{d-1} \sin(\theta_j), & i = d, \end{cases} \quad (21)$$

where $\theta \in \Theta = [0, \pi]^{d-2} \times [0, 2\pi]$ is called the *projection angle*. Using spherical coordinates renders the domain, Θ , convex and compact, and reduces dimensionality by one.

As the following discussion applies to both $\phi_{\text{CL}}(\mathbf{v})$ and $\phi_{\text{SSC}}(\mathbf{v})$ we denote a generic projection index $\phi : \Theta \rightarrow \mathbb{R}$, and the associated set of minimisers, as,

$$\phi(\theta) = \min_{b \in A} f(\mathbf{v}(\theta), b), \quad (22)$$

$$B(\theta) = \{b \in A \mid f(\mathbf{v}(\theta), b) = \phi(\theta)\}, \quad (23)$$

where $f(\mathbf{v}(\theta), b)$ is continuously differentiable, $A \subset \mathbb{R}$ is compact and convex, and the correspondence $B(\theta)$ gives the set of global minimisers of $f(\mathbf{v}(\theta), b)$ for each θ . The definition of A is not critical in our formulation. Setting,

$$A \supset \left[\min_{\mathbf{v} \in S^{d-1}} \{\mu_{\mathbf{v}}\} - \alpha \sigma_{\text{PC}_1} - \eta, \max_{\mathbf{v} \in S^{d-1}} \{\mu_{\mathbf{v}}\} + \alpha \sigma_{\text{PC}_1} + \eta \right], \quad (24)$$

where $\sigma_{\text{PC}_1}^2$ is the variance of the projections along the first principal component, ensures that the set of hyperplanes that satisfy the constraint of Equation (7) will be a subset of A for all \mathbf{v} .

Berge's maximum theorem (Berge, 1963; Polak, 1987), establishes the continuity of $\phi(\theta)$ and the upper-semicontinuity (i.s.c.) of the correspondence $B(\theta)$. Theorem 3.1 in (Polak, 1987) enables us to establish that $\phi(\theta)$ is locally Lipschitz continuous. Using Theorem 4.13 of Bonnans and Shapiro (2000) we can further show that $\phi(\theta)$ is directionally differentiable everywhere. The directional derivative at θ in the direction ν is given by,

$$d\phi(\theta; \nu) = \min_{b \in B(\theta)} D_b f(\mathbf{v}(\theta), b) \cdot \nu, \quad (25)$$

where D_b denotes the derivative with respect to θ . It is clear from Equation (25) that $\phi(\theta)$ is differentiable if $D_b f(\mathbf{v}(\theta), b)$ is the same for all $b \in B(\theta)$. If $B(\theta)$ is a singleton then this condition is trivially satisfied and $\phi(\theta)$ is continuously differentiable at θ .

It is possible to construct examples in which $B(\theta)$ is not a singleton. However, with the exception of contrived examples, our experience with real and simulated data sets indicates that when h is set through standard bandwidth selection rules $B(\theta)$ is almost always a singleton over the optimisation path.

Proposition 8 *Suppose $B(\theta)$ is a singleton for almost all $\theta \in \Theta$. Then $\phi(\theta)$ is continuously differentiable almost everywhere.*

Proof The result follows immediately from the fact that if $B(\theta) = \{b\}$ is a singleton, then the derivative $D\phi(\theta) = D_b f(\mathbf{v}(\theta), b)$, which is continuous. ■

Wolfe (1972) has provided early examples of how standard gradient-based methods can fail to converge to a local optimum when used to minimise nonsmooth functions. In the last decade a new class of nonsmooth optimisation algorithms has been developed based on gradient sampling (Burke et al., 2006). Gradient sampling methods use generalised gradient descent to find local minima. At each iteration points are randomly sampled in a radius ε of the current candidate solution, and the gradient at each point is computed. The convex hull of these gradients serves as an approximation of the ε -Clarke generalised gradient (Burke et al., 2002). The minimum element in the convex hull of these gradients is a descent direction. The gradient sampling algorithm progressively reduces the sampling radius so that the convex hull approximates the Clarke generalised gradient. When the origin is contained in the Clarke generalised gradient there is no direction of descent, and hence the current candidate solution is a local minimum. Gradient sampling achieves almost sure global convergence for functions that are locally Lipschitz continuous and almost everywhere continuously differentiable. It is also well documented that it is an effective optimisation method for functions that are only locally Lipschitz continuous.

4.1 Computational Complexity

In this subsection we analyse the computational complexity of MDP². At each iteration the algorithm projects the data sample onto $\mathbf{v}(\theta)$ which involves $\mathcal{O}(nd)$ operations. To compute the projection index, $\phi(\theta)$, we need to minimise the penalised density integral, $f(\mathbf{v}(\theta), b)$. This can be achieved by first evaluating $f(\mathbf{v}(\theta), b)$ on a grid of m points, to bracket the location of the minimiser, and then applying bisection to compute the minimiser(s) within the desired accuracy. The main computational cost of this procedure is due to the first step which involves m evaluations of a kernel density estimator with n kernels. Using the improved fast Gauss transform (Morariu et al., 2008) this can be performed in $\mathcal{O}(m+n)$ operations, instead of $\mathcal{O}(mn)$. Bisection requires $\mathcal{O}(-\log_2 \varepsilon)$ iterations to locate the minimiser with accuracy ε .

If the minimiser of the penalised density integral $b^* = \arg \min_{b \in A} f(\mathbf{v}(\theta), b)$, is unique the projection index is continuously differentiable at θ . To obtain the derivative of the projection index it is convenient to define the projection function, $F(\mathbf{v}) = (\mathbf{x}_1 \cdot \mathbf{v}, \dots, \mathbf{x}_n \cdot \mathbf{v})^\top$. An application of the chain rule yields,

$$d_b \phi = D_b f(\mathbf{v}(\theta), b^*) = D_P f(\mathbf{v}(\theta), b^*) D_{\mathbf{v}} P D_b \mathbf{v} \quad (26)$$

where the derivative of the projections of the data sample with respect to \mathbf{v} is equal to the data matrix, $D_{\mathbf{v}} P = (\mathbf{x}_1, \dots, \mathbf{x}_n)^\top$; and $D_P \mathbf{v}$ is the derivative of \mathbf{v} with respect to the projection angle, which yields a $d \times (d-1)$ matrix. The computation of the derivative therefore requires $\mathcal{O}(d(n+d))$ operations.

The original GS algorithm requires $\mathcal{O}(d)$ gradient evaluations at each iteration which is costly. Curtis and Que (2013) have developed an adaptive gradient sampling algorithm that requires $\mathcal{O}(1)$ gradient evaluations in each iteration. More recently, Lewis and Overton (2013) have strongly advocated that for the minimisation of nonsmooth, nonconvex, locally

Lipschitz functions, a simple BFGS method using inexact line searches is much more efficient in practice than gradient sampling, although no convergence guarantees have been established for this method. BFGS requires a single gradient evaluation at each iteration and a matrix vector operation to update the Hessian matrix approximation. In our experiments we use the BFGS algorithm.

5. Experimental Results

In this section we assess the empirical performance of MDHs for clustering and semi-supervised classification. We compare performance with existing state-of-the-art methods for both problems on the following 14 benchmark data sets: Banknote authentication (banknote), Breast Cancer Wisconsin original (br. cancer), Forest type mapping (forest), Ionosphere, Optical recognition of handwritten digits (optdigits), Pen-based recognition of hand-written digits (pendigits), Seeds, Smartphone-Based Segmentation of Human Activities and Postural Transitions (smartphone), Statlog Image Segmentation (image seg.), Statlog Landsat Satellite (satellite), Synthetic control chart time series (synth control), Congressional voting records (voting), Wine, and Yeast cell cycle analysis (yeast). Details of these data sets, in terms of their size, n , dimensionality, d and number of clusters, c , can be seen in Table 1.

5.1 Clustering

Since an MDH yields a bi-partition of a data set rather than a complete clustering, we propose two measures to assess the quality of a binary partition of a data set containing an

arbitrary number of clusters. Both take values in $[0, 1]$ with larger values indicating a better partition. These measures are motivated by the fact that a good binary partition should (a) avoid dividing clusters between elements of the partition, and (b) be able to discriminate at least one cluster from the rest of the data. To capture this we modify the cluster labels of the data by assigning each cluster to the element of the binary partition which contains the majority of its members. In the case of a tie the cluster is assigned to the smaller of the two partitions. We thus merge the true clusters into two aggregate clusters, C_1 and C_2 .

The first measure we use is the binary V-measure which is simply the V-measure (Rosenberg and Hirschberg, 2007) computed on C_1, C_2 with respect to the binary partition, which we denote Π_1, Π_2 . The V-measure is the harmonic mean of homogeneity and completeness. For a data set containing clusters C_1, \dots, C_c , partitioned as Π_1, \dots, Π_k , homogeneity is defined as the conditional entropy of the cluster distribution within each partition, Π_i . Completeness is symmetric to homogeneity and measures the conditional entropy of each partition within each cluster, C_j . An important characteristic of the V-measure for evaluating binary partitions is that if the distribution of clusters within each partition is equal to the overall cluster distribution in the data set then the V-measure is equal to zero (Rosenberg and Hirschberg, 2007). This means that if an algorithm fails to distinguish the majority of any of the clusters from the remainder of the data, the binary V-measure returns zero performance. Other evaluation metrics for clustering, such as purity and the Rand index, can assign a high value to such partitions.

To define the second performance measure we first determine the number of correctly and incorrectly classified samples. The error of a binary partition, $E(\Pi_1, \Pi_2)$, given in Equation (27), is defined as the number of elements of each aggregate cluster which are not in the same partition as the majority of their original clusters. In contrast, the success of a partition, $S(\Pi_1, \Pi_2)$, Equation (28), measures the number of samples which are in the same partition as the majority of their original clusters. The Success Ratio, $SR(\Pi_1, \Pi_2)$, Equation (29), captures the extent to which the majority of at least one cluster is well-distinguished from the rest of the data.

$$E(\Pi_1, \Pi_2) = \min \{ |\Pi_1 \cap C_1| + |\Pi_2 \cap C_2|, |\Pi_1 \cap C_2| + |\Pi_2 \cap C_1| \}, \quad (27)$$

$$S(\Pi_1, \Pi_2) = \min \{ \max \{ |\Pi_1 \cap C_1|, |\Pi_1 \cap C_2| \}, \max \{ |\Pi_2 \cap C_1|, |\Pi_2 \cap C_2| \} \}, \quad (28)$$

$$SR(\Pi_1, \Pi_2) = \frac{S(\Pi_1, \Pi_2)}{S(\Pi_1, \Pi_2) + E(\Pi_1, \Pi_2)}. \quad (29)$$

The Success Ratio takes the value zero if an algorithm fails to distinguish the majority of any cluster from the remainder of the data.

5.1.1 PARAMETER SETTINGS FOR MDP²

The two most important settings for the performance of the proposed approach are the initial projection direction, and the choice of α , which controls the width of the interval $F(\mathbf{v})$ within which the optimal hyperplane falls. Despite the ability of the MDP² formulation to mitigate the effect of local minima of the projected density, the problem remains non-convex and local minima in the projection index can still lead to suboptimal performance. We have found that this effect is amplified in general when either or both the number of dimensions, and the number of high density clusters in the data set is large. To better handle the effect

of local optima, we use multiple initialisations and select the MDH that maximises the *relative depth* criterion, defined in Equation (30). The relative depth of an MDH, $H(\mathbf{v}, b)$, is defined as the smaller of the relative differences in the density on the MDH and its two adjacent modes in the projected density,

$$\text{RelativeDepth}(\mathbf{v}, b) = \frac{\min \left\{ \hat{f}(\mathbf{v}, m_l), \hat{f}(\mathbf{v}, m_r) \right\} - \hat{f}(\mathbf{v}, b)}{\hat{f}(\mathbf{v}, b)} \quad (30)$$

where m_l and m_r are the two adjacent modes in the projected density on \mathbf{v} . If an MDH does not separate the modes of the projected density, then its relative depth is set to zero, signalling a failure of MDP2 to identify a meaningful bi-partition. The relative depth is appealing because it captures the fact that a high quality separating hyperplane should have a low density integral, and separate well the modes of the projected density. Note also that the relative depth is equivalent to the inverse of a measure used to define cluster overlap in the context of Gaussian mixtures (Althouiri et al., 2000). In all the reported experiments we initialise MDP2 to the first and second principal component and select the MDH with the largest relative depth. For the data sets listed above it was never the case that both initialisations led to MDHs with zero relative depth.

The choice of α determines the trade-off between a balanced bi-partition and the ability to discover lower density hyperplanes. The difficulties associated with choosing this parameter are illustrated in Figure 4. In each sub-figure the horizontal axis is the candidate projection vector, \mathbf{v} , while the right vertical axis is the direction of maximum variability orthogonal to \mathbf{v} . Points correspond to projections of the data sample onto this two-dimensional space, while colour indicates cluster membership. The solid line depicts the projected density on \mathbf{v} , while the dotted line depicts the penalised function, $f_{CL}(\mathbf{v}, \cdot)$. The scale of both functions is depicted on the left vertical axis. The solid vertical line indicates the MDH along \mathbf{v} . Setting α to a large value can cause MDP2 to focus on hyperplanes that have low density because they partition only a small subset of the data set as shown in Figure 4(a). In contrast smaller values of α may cause the algorithm to disregard valid lower density hyperplane separators (see Figure 4(b)), or for the separating hyperplane to not be a local minimiser of the projected density (see Figure 4(c)).

Rather than selecting a single value for α we recommend solving MDP2 repeatedly for an increasing sequence of values in the range $\{\alpha_{\min}, \alpha_{\max}\}$, where each implementation beyond the first is initialised using the solution to the previous. Setting α_{\min} close to zero forces MDP2 to seek low density hyperplanes that induce a balanced data partition. This tends to find projections which display strong multimodal structure, yet prevents convergence to hyperplanes that have low density because they partition a few observations, as in the case shown in Figure 4(a). Increasing α progressively fine-tunes the location of the MDH. To avoid sensitivity to the value of α_{\max} (set to 0.9) the output of the algorithm is the last hyperplane that corresponds to a minimiser of the projected density. Figure 5 illustrates this approach using the optical recognition of handwritten digits data set from the UCI machine learning repository (Lichman, 2013). Figure 5(a) depicts the projected density on the initial projection direction, which in this case is the second principal component. As shown, the density is unimodal and the clusters are not well separated along this vector. Although not shown, if a large value of α is used from the outset, MDP2 will identify a vector

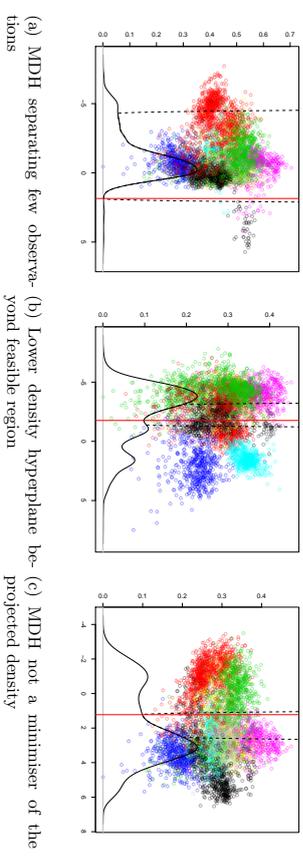

Figure 4: Impact of choice of α on minimum density hyperplane.

along which the projected density is unimodal and skewed. Figure 5(b) shows that after five iterations with $\alpha = 10^{-2}$ MDP2 has identified a projection vector with bimodal density. In subsequent iterations the two modes become more clearly separated, Figure 5(c), while increasing α enables MDP2 to locate an MDH that corresponds to a minimiser of $\hat{f}(\mathbf{v}, b)$, as illustrated in Figure 5(d).

In all experiments we set the bandwidth parameter to $h = 0.9\hat{\sigma}_{p_{C_1}} n^{-1/5}$, where $\hat{\sigma}_{p_{C_1}}$ is the estimated standard deviation of the data projected onto the first principal component. This bandwidth selection rule is recommended when the density being approximated is assumed to be multimodal (Silverman, 1986). The parameter η controls the distance between the minimisers of $\arg \min_{b \in \mathbb{R}} f_{CL}(\mathbf{v}, b)$ and $\arg \min_{b \in F(\mathbf{v})} \hat{f}(\mathbf{v}, b)$, while larger values of ϵ increase the smoothness of the penalised function f_{CL} . Values of η close to zero affect the numerical stability of the one-dimensional optimisation problem, due to the term $\frac{\epsilon}{\eta}$ in f_{CL} becoming very large. We used $\eta = 10^{-2}$ and $\epsilon = 1 - 10^{-6}$ to avoid numerical instability. Beyond these numerical problems the values of η and ϵ do not affect the solutions obtained through MDP2.

5.1.2 PERFORMANCE EVALUATION

We compare the performance of MDP2 for clustering with the following methods:

1. k -means++ (Arthur and Vassilvitskii, 2007), a version of k -means that is guaranteed to be $O(\log k)$ -competitive to the optimal k -means clustering.
2. The adaptive linear discriminant analysis guided k -means (LDA- k m) (Ding and Li, 2007). LDA- k m attempts to discover the most discriminative linear subspace for clustering by iteratively using k -means, to assign labels to observations, and LDA to identify the most discriminative subspace.
3. The principal direction divisive partitioning (PDDP) (Boley, 1998), and the density-enhanced PDDP (dePDDP) (Tasoulis et al., 2010). Both methods project the data onto the first principal component. PDDP splits at the mean of the projections, while dePDDP splits at the lowest local minimum of the one-dimensional density estimator.

space. For the 2-means and LDA-2m algorithm the hyperplane separator bisects the line segment joining the two centroids. iSVR-L directly seeks the maximum margin hyperplane in the original space, while iSVR-G seeks the maximum margin hyperplane in the feature space defined by the Gaussian kernel. PDDP and dePDDP use a hyperplane whose normal vector is the first principal component. PDDP uses a fixed split point while dePDDP uses the hyperplane with minimum density along the fixed projection direction.

Table 2 reports the performance of the considered methods with respect to the success ratio (SR) and the binary V-measure (V-m) on the fourteen data sets. In addition Figures 6(a) and 6(b) provide summaries of the overall performance on all data sets using boxplots of the raw performance measures as well as the associated *regret*. The regret of an algorithm on a given data set is defined as the difference between the best performance attained on this data set and the performance of this algorithm. By comparing against the best performing clustering algorithm regret accommodates for differences in difficulty between clustering problems, while also making use of the magnitude of performance differences between algorithms. The distribution of performance with respect to both SR and V-m is negatively skewed for most methods, and as a result the median is higher than the mean (indicated with a red dot).

It is clear from Table 2 that no single method is consistently superior to all others, although MDP² achieves the highest or tied highest performance on seven data sets (more than any other method). More importantly MDP² is among the best performing methods in almost all cases. This fact is better captured by the regret distributions in Figure 6(b). Here we see that the average, median, and maximum regret of MDP² is substantially lower than any of the competing methods. In addition MDP² achieves the highest mean and median performance with respect to both SR and V-m, while also having much lower variability in performance when compared with most other methods.

Pairwise comparisons between MDP² and other methods reveal some less obvious facts. SCn achieves higher performance than MDP² in more examples (six) than any other competing method, however it is much less consistent in its performance, obtaining very poor performance on five of the data sets. The iSVR maximum margin clustering approach is arguably the closest competitor to MDP². iSVR-L and iSVR-G achieve the second and third highest average performance with respect to V-m and SR respectively. The PDDP algorithm is the second best performing method on average with respect to SR, but performs poorly with respect to V-m. The density enhanced variant, dePDDP, performs on average much worse than MDP². This approach is similarly motivated by obtaining hyperplanes with low density integral, and its low average performance indicates the usefulness of searching for high quality projections as opposed to always using the first principal component. Finally, neither of the k -means variants appears to be competitive with MDP² in general.

5.2 Semi-Supervised Classification

In this section we evaluate MDHs for semi-supervised classification. We compare MDHs against three state-of-the-art semi-supervised classification methods: Laplacian Regularised Support Vector Machines (LapSVM) (Belkin et al., 2006), Simple Semi-Supervised Learning (SSSL) (Ji et al., 2012), and Correlated Nystrom Views (XNV) (McWilliams et al., 2013). For all methods the inner product kernel was used to render the resulting classifiers linear,

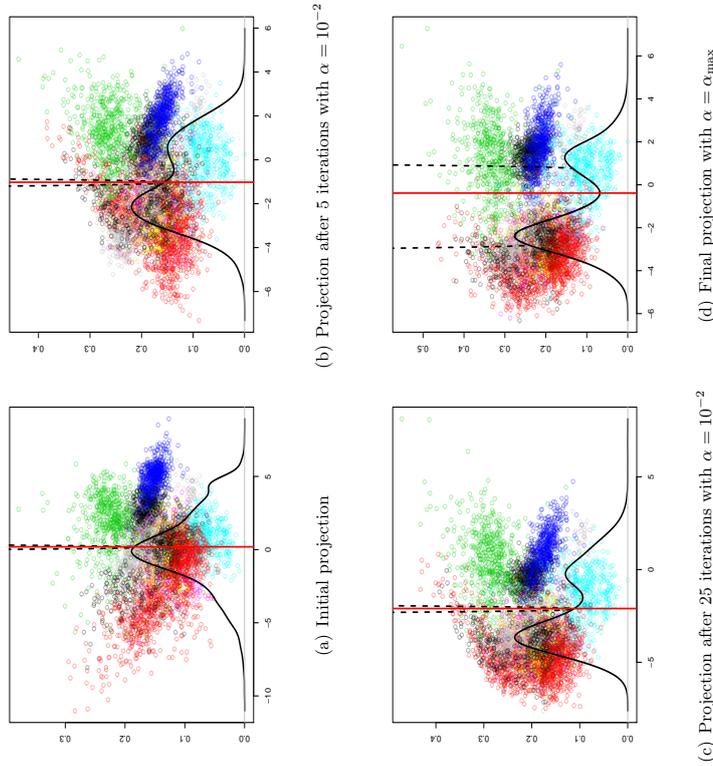

Figure 5: Evolution of the minimum density hyperplane through consecutive iterations.

4. The iterative support vector regression algorithm for MMC (Zhang et al., 2009) using the inner product and Gaussian kernel, iSVR-L and iSVR-G respectively. Both are initialised with the output of 2-means++.
5. Normalised cut spectral clustering (SCn) (Ng et al., 2002) using the Gaussian affinity function, and the automatic bandwidth selection method of Zelnik-Manor and Perona (2004). This choice of kernel and bandwidth produced substantially better performance than alternative choices considered. For data sets that are too large for the eigen decomposition of the Gram matrix to be feasible we employed the Nystrom method (Fowlkes et al., 2004).

We also considered the density-based clustering algorithm PdfCluster (Menardi and Azzalini, 2014), but this algorithm could not be executed on the larger data sets and so its performance is not reported in this paper. With the exception of SCn and iSVR-G, the methods considered bi-partition the data through a hyperplane in the original feature

and thereby comparable to our method. As the MDH is asymptotically equivalent to a linear S³VM we also considered the continuous formulation for the estimation of a S³VM proposed by Chapelle and Zien (2005). These results are omitted as this method was not competitive on any of the considered data sets.

5.2.1 PARAMETER SETTINGS FOR MDP²

The existence of a few labelled examples enables an informed initialisation of MDP². We consider the first and second principal components as well as the weight vector of a linear SVM trained on the labelled examples only, and initialise MDP² with the vector that minimises the value of the projection index, ϕ_{SVC} . The penalty parameter γ is first set to 0.1 and with this setting α is progressively increased in the same way as for clustering. After this, α is kept at α_{max} and γ is increased to 1 and then 10. Thus the emphasis is initially on finding a low density hyperplane with respect to the marginal density $\hat{p}(\mathbf{x})$. As the algorithm progresses the emphasis on correctly classifying the labelled examples increases, so as to obtain a hyperplane with low training error within the region of low density already determined.

5.2.2 PERFORMANCE EVALUATION

To assess the effect on performance of the number of labelled examples, ℓ , we consider a range of values. We compare the methods using the subset of data sets used in the previous section in which the size of the smallest class exceeds 100. In total eight data sets are used. For each value of ℓ , 30 random partitions into labelled and unlabelled data are considered. As classes are balanced in the data sets considered, performance is measured only in terms of classification error on the unlabelled data. For data sets with more than two classes all pairwise combinations of classes are considered and aggregate performance is reported.

Figure 7 provides plots of the median and interquartile range of the classification error for values of ℓ between 5 and 100 for the four data sets with two classes. Overall MDP² appears to be most competitive when the number of labelled examples is small. In addition, MDP² is comparable with the best performing method in almost every case. The only exception is the ionosphere data set where LapSVM outperforms MDP² for all values of ℓ . Figure 8 provides plots of the median and interquartile range of the aggregate classification error on data sets containing more than two classes. As these data sets are larger we consider up to 300 labelled examples. Note that the interquartile range for XNV is not depicted for the satellite data set. The variability of performance of XNV on this data set was so high that including the interquartile range would obscure all other information in the figure. MDP² exhibits the best performance overall, and obtains the lowest median classification error, or tied lowest, for all data sets and values of ℓ .

5.3 Summary of Experimental Results

We evaluated the performance of the MDP² formulation for finding MDHs for both clustering and semi-supervised classification, on a large collection of benchmark data sets, and in comparison with state-of-the-art methods for both problems.

For clustering, we found that no single method was consistently superior to all others. This is a result of the vastly differing nature of the data sets in terms of size, dimensionality, number and shape of clusters, etc. MDP² achieved the best performance on more data sets than any of the competing methods, and importantly was competitive with the best performing method in almost every data set considered. All other methods performed poorly in at least as many examples. Boxplots of both the raw performance and performance regret, which measures the difference between each method and the best performing method on each

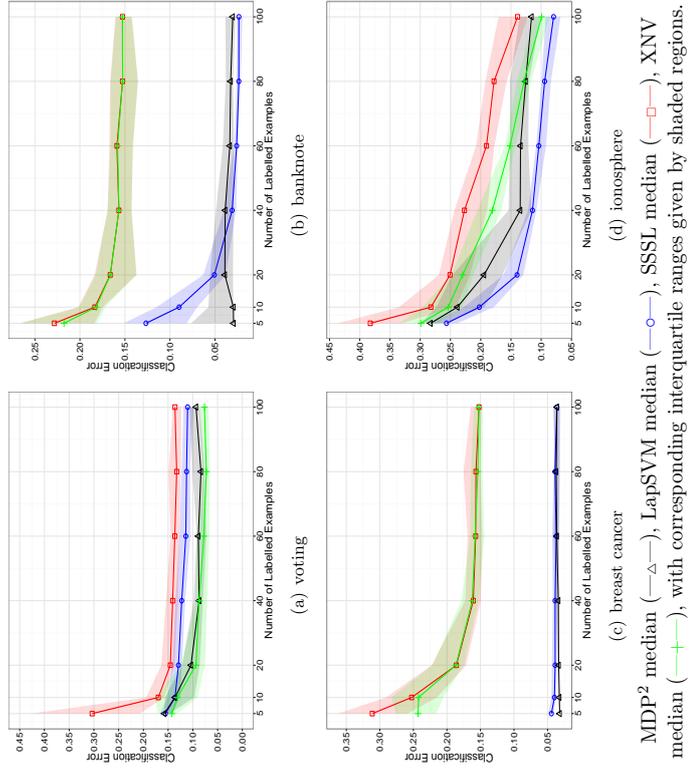

Figure 7: Classification error for different number of labelled examples for data sets with two clusters.

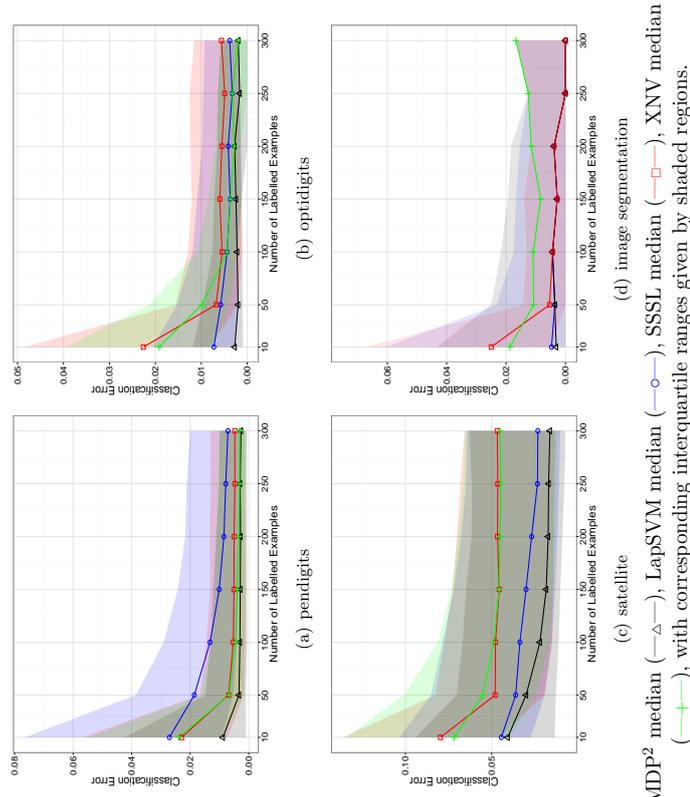

Figure 8: Classification error for different numbers of labelled examples over all pairwise combinations of classes.

data set, allowed us to summarise the comparative performance of the different methods across data sets. The mean and median raw performance of MDP² is substantially higher than the next best performing method, and the regret is also substantially lower.

In the case of semi-supervised classification it was apparent that MDP² is extremely competitive when the number of labelled examples is (very) small, but that in some cases its performance does not improve as much as that of the other methods considered, when the labelled examples become more abundant. Our experiments suggest that overall MDP² is very competitive with the state-of-the-art for semi-supervised classification problems.

6. Conclusions

We proposed a new hyperplane classifier for clustering and semi-supervised classification. The proposed approach is motivated by determining low density linear separators of the high-density clusters within a data set. This is achieved by minimising the integral of the empirical density along the hyperplane, which is computed through kernel density estimation. To the best of our knowledge this is the first direct implementation of the low density separation assumption that underlies high-density clustering and numerous influential semi-supervised classification methods. We show that the minimum density hyperplane is asymptotically connected with maximum margin hyperplane, thereby establishing an important link between the proposed approach, maximum margin clustering, and semi-supervised support vector machines.

The proposed formulation allows us to evaluate the integral of the density on a hyperplane by projecting the data onto the vector normal to the hyperplane, and estimating a univariate kernel density estimator. This enables us to apply our method effectively and efficiently on data sets of much higher dimensionality than is generally possible for density based clustering methods. To mitigate the problem of convergence to locally optimal solutions we proposed a projection pursuit formulation.

We evaluated the minimum density hyperplane approach on a large collection of benchmark data sets. The experimental results obtained indicate that the method is competitive with state-of-the-art methods for clustering and semi-supervised classification. Importantly the performance of the proposed approach displays low variability across a variety of data sets, and is robust to differences in data size, dimensionality, and number of clusters. In the context of semi-supervised classification, the proposed approach shows especially good performance when the number of labelled data is small.

Acknowledgments

We would like to thank the reviewers for their insightful comments which substantially improved this paper. We also thank Prof. David Leslie, and Dr. Teemu Roos for valuable comments and suggestions on this work. Nicos Pavlidis would like to thank the Isaac Newton Institute for Mathematical Sciences, Cambridge, for support and hospitality during the programme ‘Inference for Change-Point and Related Processes’, where part of the work on this paper was undertaken. David Hoemeyer gratefully acknowledges the support of the EPSRC funded EP/H023151/1 STOR-i centre for doctoral training, as well as the Openheimer

Memorial Trust. The underlying code and data are openly available from Lancaster University data repository at <http://dx.doi.org/10.17635/lancaster/researchdata/97>.

Appendix A. Proof of Theorem 5

Before proving Theorem 5 we require the following two technical lemmata, which establish some algebraic properties of the maximum margin hyperplane. The following lemma shows that any hyperplane orthogonal to the maximum margin hyperplane results in a different partition of the support points of the maximum margin hyperplane. The proof relies on the fact that if this statement does not hold then a hyperplane with larger margin exists which is a contradiction. Figure 9 provides an illustration of why this result holds. (a) Any hyperplane orthogonal to MMH generates a different partition of the support points of MMH, e.g., the point highlighted in red in (b) is grouped with the lower three by the dotted line but with the upper two by the solid line, the MMH. If an orthogonal hyperplane can generate the same partition (c), then a larger margin hyperplane than the proposed MMH exists (d).

Lemma 9 *Suppose there is a unique hyperplane in F with maximum margin, which can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$. Let $M = \text{margin } H(\mathbf{v}^m, b^m)$, $C^+ = \{\mathbf{x} \in \mathcal{X} \mid \mathbf{v}^m \cdot \mathbf{x} - b^m = M\}$ and $C^- = \{\mathbf{x} \in \mathcal{X} \mid b^m - \mathbf{v}^m \cdot \mathbf{x} = M\}$. Then, $\forall \mathbf{w} \in \text{Null}(\mathbf{v}^m)$, $c \in \mathbb{R}$ either $\min\{\mathbf{w} \cdot \mathbf{x} - c \mid \mathbf{x} \in C^+\} \leq 0$, or $\max\{\mathbf{w} \cdot \mathbf{x} - c \mid \mathbf{x} \in C^-\} \geq 0$.*

Proof

Suppose the result does not hold, then $\exists(\mathbf{w}, c)$ with $\|\mathbf{w}\| = 1, \mathbf{w} \cdot \mathbf{v}^m = 0$ and $\min\{\mathbf{w} \cdot \mathbf{x} - c | \mathbf{x} \in C^+\} > 0$ and $\max\{\mathbf{w} \cdot \mathbf{x} - c | \mathbf{x} \in C^-\} < 0$. Let $m = \min\{\mathbf{w} \cdot \mathbf{x} - c | \mathbf{x} \in C^+ \cup C^-\}$. Define $\lambda = \frac{m}{2M} < 1$. Define $\mathbf{u} = \frac{1}{\sqrt{\lambda^2 + (1-\lambda)^2}}(\lambda \mathbf{w} + (1-\lambda)\mathbf{v}^m)$ and $d = \frac{\lambda c + (1-\lambda)b^m}{\sqrt{\lambda^2 + (1-\lambda)^2}}$. By construction $\|\mathbf{u}\| = 1$. For any $\mathbf{x}_+ \in C^+$ we have,

$$\begin{aligned} \mathbf{u} \cdot \mathbf{x}_+ - d &= \frac{\lambda(\mathbf{w} \cdot \mathbf{x}_+ - c) + (1-\lambda)(\mathbf{v}^m \cdot \mathbf{x}_+ - b^m)}{\sqrt{\lambda^2 + (1-\lambda)^2}} \\ &\geq \frac{\lambda m + (1-\lambda)M}{\sqrt{\lambda^2 + (1-\lambda)^2}} \\ &= \frac{m^2 + 2M^2 - Mm}{\sqrt{m^2 + (2M - m)^2}} \\ &> M. \end{aligned}$$

Similarly one can show that $d - \mathbf{u} \cdot \mathbf{x}_- > M$ for any $\mathbf{x}_- \in C^-$, meaning that (\mathbf{u}, d) achieves a larger margin on C^+ and C^- than (\mathbf{v}^m, b^m) , a contradiction. \blacksquare

The next lemma uses the above result to provide an upper bound on the distance between pairs of support points projected onto any vector, in terms of the angle between that vector and \mathbf{v}^m .

Lemma 10 *Suppose there is a unique hyperplane in F with maximum margin, which can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$. Define $M = \text{margin } H(\mathbf{v}^m, b^m)$, $C^+ = \{\mathbf{x} \in \mathcal{X} | \mathbf{v}^m \cdot \mathbf{x} - b^m = M\}$, and $C^- = \{\mathbf{x} \in \mathcal{X} | b^m - \mathbf{v}^m \cdot \mathbf{x} = M\}$. There is no vector $\mathbf{w} \in \mathbb{R}^d$ for which $\mathbf{w} \cdot \mathbf{x}_+ - \mathbf{w} \cdot \mathbf{x}_- > 2M\mathbf{v}^m \cdot \mathbf{w}$ for all pairs $\mathbf{x}_+ \in C^+, \mathbf{x}_- \in C^-$.*

Proof

Suppose such a vector exists. Define $\mathbf{w}' = \mathbf{w} - (\mathbf{v}^m \cdot \mathbf{w})\mathbf{v}^m$. By construction $\mathbf{w}' \in \text{Null}(\mathbf{v}^m)$. For any pair $\mathbf{x}_+ \in C^+, \mathbf{x}_- \in C^-$ we have

$$\begin{aligned} \mathbf{w}' \cdot \mathbf{x}_+ - \mathbf{w}' \cdot \mathbf{x}_- &= \mathbf{w} \cdot \mathbf{x}_+ - (\mathbf{v}^m \cdot \mathbf{w})\mathbf{v}^m \cdot \mathbf{x}_+ - \mathbf{w} \cdot \mathbf{x}_- + (\mathbf{v}^m \cdot \mathbf{w})\mathbf{v}^m \cdot \mathbf{x}_- \\ &> \mathbf{v}^m \cdot \mathbf{w}(2M - \mathbf{v}^m \cdot \mathbf{x}_+ + b^m - b^m + \mathbf{v}^m \cdot \mathbf{x}_-) \\ &= 0. \end{aligned}$$

Define $c := \frac{1}{2}(\min\{\mathbf{w}' \cdot \mathbf{x}_+ | \mathbf{x}_+ \in C^+\} + \max\{\mathbf{w}' \cdot \mathbf{x}_- | \mathbf{x}_- \in C^-\})$. Then $\min\{\mathbf{w}' \cdot \mathbf{x}_+ - c | \mathbf{x}_+ \in C^+\} > 0$ and $\max\{\mathbf{w}' \cdot \mathbf{x}_- - c | \mathbf{x}_- \in C^-\} < 0$, a contradiction. \blacksquare

We are now in a position to provide the main proof of this appendix. The theorem states that if the maximum margin hyperplane is unique, and can be parameterised by $(\mathbf{v}^m, b^m) \in \mathcal{S}^{d-1} \times \mathbb{R}$, then

$$\lim_{h \rightarrow 0^+} \min\{\|(\mathbf{v}_h^*, b_h^*) - (\mathbf{v}^m, b^m)\|, \|(\mathbf{v}_h^*, b_h^*) - (\mathbf{v}^m, b^m)\|\} = 0,$$

where $\{H(\mathbf{v}_h^*, b_h^*)\}_h$ is any collection of minimum density hyperplanes indexed by their bandwidth $h > 0$.

Proof of Theorem 5

Define $M = \text{margin } H(\mathbf{v}^m, b^m)$, $C^+ = \{\mathbf{x} \in \mathcal{X} | \mathbf{v}^m \cdot \mathbf{x} - b^m = M\}$ and $C^- = \{\mathbf{x} \in \mathcal{X} | b^m - \mathbf{v}^m \cdot \mathbf{x} = M\}$. Let $B = \max\{\|\mathbf{x}\| | \mathbf{x} \in \mathcal{X}\}$. Take any $\epsilon > 0$ and set $0 < \delta$ to satisfy $\frac{2\delta}{M}(1+B^2) + 2B\delta^{3/2}\sqrt{\frac{2}{M}} + \delta^2 = \epsilon^2$. Now, suppose $(\mathbf{w}, c) \in \mathcal{S}^{d-1} \times \mathbb{R}$ satisfies,

$$\mathbf{w} \cdot \mathbf{x}_+ - c > M - \delta, \forall \mathbf{x}_+ \in C^+ \text{ and } c - \mathbf{w} \cdot \mathbf{x}_- > M - \delta, \forall \mathbf{x}_- \in C^-.$$

By Lemma 10 we know that $\exists \mathbf{x}_+ \in C^+, \mathbf{x}_- \in C^-$ s.t. $\mathbf{w} \cdot \mathbf{x}_+ - \mathbf{w} \cdot \mathbf{x}_- \leq 2M\mathbf{v}^m \cdot \mathbf{w}$. Thus

$$\begin{aligned} \mathbf{v}^m \cdot \mathbf{w} &\geq \frac{\mathbf{w} \cdot \mathbf{x}_+ - \mathbf{w} \cdot \mathbf{x}_-}{2M} \\ &= \frac{2M}{\mathbf{w} \cdot \mathbf{x}_+ - c + c - \mathbf{w} \cdot \mathbf{x}_-} \\ &> \frac{2M - 2\delta}{2M} = 1 - \frac{\delta}{M}. \end{aligned}$$

Thus $\|\mathbf{v}^m - \mathbf{w}\|^2 < \frac{2\delta}{M}$. Now, for each $\mathbf{x}_+ \in C^+, \mathbf{v}^m \cdot \mathbf{x}_+ - b = M$ and for each $\mathbf{x}_- \in C^-, b - \mathbf{v}^m \cdot \mathbf{x}_- = M$. Thus for any such $\mathbf{x}_+, \mathbf{x}_-$ we have,

$$\begin{aligned} M - \delta + \mathbf{w} \cdot \mathbf{x}_- &< c < \mathbf{w} \cdot \mathbf{x}_+ - M + \delta, \\ b^m - \mathbf{v}^m \cdot \mathbf{x}_- - \delta + \mathbf{w} \cdot \mathbf{x}_- &< c < \mathbf{w} \cdot \mathbf{x}_+ - \mathbf{v}^m \cdot \mathbf{x}_+ + b^m + \delta, \\ b^m - \delta - (\mathbf{v}^m - \mathbf{w}) \cdot \mathbf{x}_- &< c < b^m + \delta + (\mathbf{w} - \mathbf{v}^m) \cdot \mathbf{x}_+, \\ b^m - \delta - B\|\mathbf{v}^m - \mathbf{w}\| &< c < b^m + \delta + B\|\mathbf{w} - \mathbf{v}^m\|, \\ |c - b^m| &< |\delta + B\|\mathbf{w} - \mathbf{v}^m\||. \end{aligned}$$

We can now bound the distance between (\mathbf{w}, c) and (\mathbf{v}^m, b^m) ,

$$\begin{aligned} \|(\mathbf{v}^m, b^m) - (\mathbf{w}, c)\|^2 &= \|\mathbf{v}^m - \mathbf{w}\|^2 + |b^m - c|^2 \\ &< \|\mathbf{v}^m - \mathbf{w}\|^2(1+B^2) + 2B\delta\|\mathbf{v}^m - \mathbf{w}\| + \delta^2 \\ &< \frac{2\delta}{M}(1+B^2) + 2B\delta\sqrt{\frac{2\delta}{M}} + \delta^2 \\ &= \epsilon^2. \end{aligned}$$

We have shown that for any hyperplane $H(\mathbf{w}, c)$ that achieves a margin larger than $M - \delta$ on the support points of the maximum margin hyperplane, $\mathbf{x} \in C^+ \cup C^-$, the distance between (\mathbf{w}, c) and (\mathbf{v}^m, b^m) is less than ϵ . Equivalently, any hyperplane $H(\mathbf{w}, c)$ such that $\|(\mathbf{w}, c) - (\mathbf{v}^m, b^m)\| > \epsilon$ has a margin less than $M - \delta$, as $\min\{\mathbf{w} \cdot \mathbf{x} - c | \mathbf{x} \in C^+ \cup C^-\} < M - \delta$. By symmetry, the same holds for any (\mathbf{w}, c) within distance ϵ of $(-\mathbf{v}^m, -b^m)$.

By Lemma 4 $\exists h_1 > 0$ such that for all $h \in (0, h_1)$, the minimum density hyperplane for h , $H(\mathbf{v}_h^*, b_h^*)$, induces the same partition of \mathcal{X} as the maximum margin hyperplane, $H(\mathbf{v}^m, b^m)$. By Lemma 3 $\exists h_2 > 0$ such that for all $h \in (0, h_2)$, $\text{margin } H(\mathbf{v}_h^*, b_h^*) > M - \delta$. Therefore for $h \in (0, \min\{h_1, h_2\})$, $\min\{\|(\mathbf{v}_h^*, b_h^*) - (\mathbf{v}^m, b^m)\|, \|(\mathbf{v}_h^*, b_h^*) - (-\mathbf{v}^m, -b^m)\|\} < \epsilon$. Since $\epsilon > 0$ was arbitrarily chosen, this gives the result. \blacksquare

Abstract

Slow feature analysis (SFA) is an unsupervised learning algorithm that extracts slowly varying features from a multi-dimensional time series. Graph-based SFA (GSFA) is an extension to SFA for supervised learning that can be used to successfully solve regression problems if combined with a simple supervised post-processing step on a small number of slow features. The objective function of GSFA minimizes the squared output differences between pairs of samples specified by the edges of a structure called training graph. The edges of current training graphs, however, are derived only from the relative order of the labels. Exploiting the exact numerical value of the labels enables further improvements in label estimation accuracy.

In this article, we propose the exact label learning (ELL) method to create a more precise training graph that encodes the desired labels explicitly and allows GSFA to extract a normalized version of them directly (i.e., without supervised post-processing). The ELL method is used for three tasks: (1) We estimate gender from artificial images of human faces (regression) and show the advantage of coding additional labels, particularly skin color. (2) We analyze two existing graphs for regression. (3) We extract *compact* discriminative features to classify traffic sign images. When the number of output features is limited, such compact features provide a higher classification rate compared to a graph that generates features equivalent to those of nonlinear Fisher discriminant analysis. The method is versatile, directly supports multiple labels, and provides higher accuracy compared to current graphs for the problems considered.

Keywords: slow feature analysis, nonlinear regression, image analysis, pattern recognition, many classes

1. Introduction

The slowness principle is one of the learning paradigms that might explain the self-organization of neurons in the brain to extract invariant representations (e.g. Franzius et al., 2007). This principle operates on an abstract level of information processing and postulates that perceived information relevant to a subject typically changes much slower than individual sensory components—e.g., the position of a moth changes slower than the quickly changing neural activations in the retina of a frog observing it.

The slowness principle was probably first formulated by Hinton (1989), and early online learning rules were developed by Földiák (1991) and Mitchison (1991). The first closed-form algorithm is referred to as slow feature analysis (SFA, Wiskott, 1998; Wiskott and Sejnowski, 2002). Given a multi-dimensional time series (i.e., a sequence of samples), SFA finds an instantaneous mapping from the input samples to output features that change as slowly as possible within a given feature space. The objective function of SFA requires the minimization of the average squared differences of consecutive output values. Thus, SFA is especially useful for extracting slowly changing hidden parameters of the data.

Although SFA is unsupervised, it has also been used to solve supervised learning tasks, where it operates as a dimensionality reduction algorithm that is complemented by a supervised algorithm on a small number of slow features. This is motivated by the idea that samples originating at a similar time (e.g., consecutive samples) are likely to have similar labels due to physical and biological constraints on the subject and the environment. Thus, the temporal arrangement of the samples provides a weak form of supervised information.

Recently, an extension of SFA for classification and regression, called graph-based SFA (GSFA, Escalante-B. and Wiskott, 2013), has been proposed, which explicitly exploits the available labels. The training data of GSFA are organized in a graph structure called training graph, in which the vertices are the samples and the edge weights represent similarities between the corresponding labels, where each sample typically has several connections. The objective function of GSFA is similar to that of SFA, except that the pairs of samples need not be temporally consecutive, are weighted, and are indicated by the edges of the graph.

Typically, GSFA is more effective than SFA at extracting a set of features that tend to concentrate the label information, allowing accurate prediction of the labels from a few features, and implicitly solving the supervised learning problem. The resulting (low-dimensional) output features can then be easily post-processed by standard supervised algorithms, such as a regression method based on a Gaussian classifier (Escalante-B. and Wiskott, 2012) or ordinary least squares, to generate the final label estimation.

The main type of application addressed in this article is the solution of regression problems on high-dimensional data with hierarchical GSFA (HGSFA, see Section 2). Regression problems can be solved with GSFA using pre-defined graphs (e.g., a serial graph explained in Section 5.1). However, the structure of pre-defined graphs only takes into account the rank of the labels and not their exact value, a simplification that might decrease the estimation accuracy.

In this article, we focus on the analysis and design of training graphs. We develop a new approach, called exact label learning (ELL), for solving regression problems with GSFA based on the construction of a special training graph, in which the slowest feature extracted is already a label estimation, up to an affine transformation (Figure 1.c). The resulting system learns a nonlinear mapping from the input data (e.g., the pixels or features) to label estimations, where the features extracted by the layers of the GSFA network increase in complexity, abstraction level, and invariance as the data is propagated from the bottom to the top layer.

To develop the ELL method, we first study the slowest possible features that can be extracted by GSFA from a given graph when the feature space is unrestricted. Such features are called optimal free responses. After we express the optimal free responses of GSFA in a closed form, we develop a theoretical method for the converse operation: from a set of free

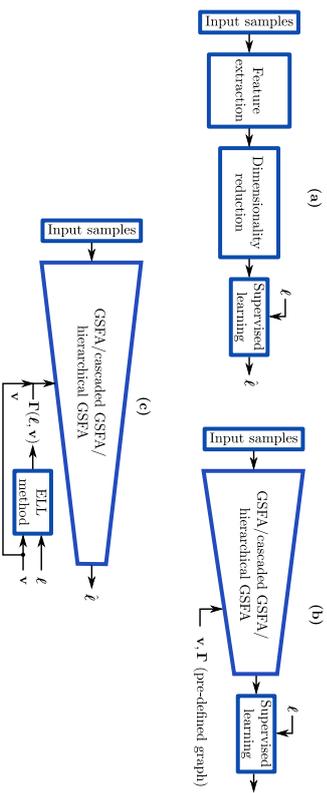

Figure 1: Three approaches for solving supervised learning problems. (a) A classic approach. (b) Previous approach using GSFA with a pre-defined training graph, which is defined by the input samples, node weights \mathbf{v} , and edge weights Γ . The samples are assumed to be ordered by increasing label. (c) Our proposal, which consists of a single GSFA architecture that is trained with a specially constructed graph $\Gamma(\ell, \mathbf{v})$. The first slow feature (with a global sign adjustment) directly provides the label estimation. If the label ℓ does not have weighted zero mean and weighted unit variance, a final affine transformation (scaling and offset) should be included.

responses we design the corresponding training graph. The method allows the creation of a graph in which the slowest possible feature is the label to be learned. Moreover, one can learn *multiple labels* simultaneously (e.g., object position, average color, shape, and size), and balance their importance by setting the value of certain parameters.

We show analytically that the serial graph is similar to the ELL graph in terms of the first optimal free responses, and that when only one label is learned the former may substitute the latter reasonably well with faster training time. In addition, we outline in the discussion a few extensions to the ELL method towards improving its efficiency and allowing the combination of training graphs.

The remainder of the article is organized as follows: In the next section, we describe the context of the ELL method and review previous work. In Section 3, we review GSFA. In Section 4, we propose the ELL method. In Section 5, we provide 3 applications: (1) We solve a regression problem on gender estimation from artificial images, validating the method. (2) We analyze efficient pre-defined training graphs for regression. (3) We use the ELL method in a non-conventional way to design a training graph for the extraction of compact features for classification, yielding improved performance when the number of features preserved is between $\log_2(C)$ and $C - 2$, where C is the number of classes. For applications (1) and (3) the accuracy is evaluated experimentally; the first one uses HGSA and the latter one uses direct (i.e., non-hierarchical) GSFA. Section 6 closes the article with a discussion.

2. Related Work

There are several approaches to solve regression problems on high-dimensional data and reduce the expensive computational requirements typically associated with this type of problems. A classic approach consists of feature extraction, (unsupervised) dimensionality reduction (DR), and an explicit supervised step (Figure 1.a). A different approach first uses GSFA for *supervised* DR. Supervised DR might result in higher accuracy than unsupervised DR. A small number of slow features extracted by GSFA are post-processed with a conventional classification or regression algorithm (Escalante-B. and Wiskott, 2013), see Figure 1.b. In such an approach, the supervised learning problem is mostly solved by GSFA implicitly, because it identifies and concentrates the label-predictive information in a few features.

For high-dimensional data, the direct application of SFA and GSFA is computationally too expensive, but one can resort to hierarchical processing (e.g., Franzini et al., 2011), which is an efficient divide-and-conquer strategy for the extraction of slow features¹ (e.g., Figure 2). For example, if the input dimension I is large, one can divide input data spatially into k lower-dimensional signals $\mathbf{x}^{(1)}(t), \dots, \mathbf{x}^{(k)}(t)$ of dimensionality $I' \stackrel{\text{def}}{=} I/k$. Then, one can extract slow features $\mathbf{y}^{(1)}, \dots, \mathbf{y}^{(k)}$ from each lower-dimensional signal: $\mathbf{y}^{(1)}(t) \stackrel{\text{def}}{=} \text{SFA}^{(1)}(\mathbf{x}^{(1)}(t)), \mathbf{y}^{(2)}(t) \stackrel{\text{def}}{=} \text{SFA}^{(2)}(\mathbf{x}^{(2)}(t)), \dots, \mathbf{y}^{(k)}(t) \stackrel{\text{def}}{=} \text{SFA}^{(k)}(\mathbf{x}^{(k)}(t))$. A concrete instance of SFA trained with a particular subset of the training data is denoted as $\text{SFA}^{(\cdot)}$. Different SFA instances are also referred to as SFA nodes, especially in the context of hierarchical SFA networks structured as directed graphs. The nodes above are called local because their input is only a local subset of the original input. Each of them extracts J' slow features. Afterwards, another SFA node $\text{SFA}^{(\text{top})}$ in an additional layer extracts global slow features from the concatenation of the local slow features computed previously: $\mathbf{y}^{(\text{top})}(t) \stackrel{\text{def}}{=} \text{SFA}^{(\text{top})}(\mathbf{y}^{(1)}(t) \dots \mathbf{y}^{(k)}(t))$, where \cdot is the concatenation operation in space (not in time). A proper choice of J' and k ensures that the computation of $\mathbf{y}^{(\text{top})}(t)$ is feasible.

If the input dimensionality I' of the local nodes $\text{SFA}^{(1)}, \dots, \text{SFA}^{(k)}$ is still too large, one can repeat the strategy above to each of these nodes. Following such an approach recursively results in a multi-layer hierarchical network. Due to information loss before the top node and the change of the feature space, hierarchical SFA does not guarantee globally optimal slow features anymore. However, it has been shown to be effective in many practical experiments, in part because low-level features are spatially localized in most real-world data. Hierarchical GSFA (HGSA) offers an excellent computational complexity compared to direct GSFA that can be as good as linear w.r.t. the number of samples and the input dimensionality, depending on the network architecture (Escalante-B. and Wiskott, 2016).

The ELL method allows the creation of graphs useful to train direct, cascaded, and hierarchical GSFA. Cascaded GSFA refers to the application of several consecutive passes of GSFA (thus, it is equivalent to HGSA with only one GSFA node per layer) and is a useful approach when the features obtained through direct GSFA are not slow enough for a

1. Even linear SFA becomes infeasible if I is sufficiently large. Therefore, the usefulness of hierarchical processing is not limited to nonlinear SFA.

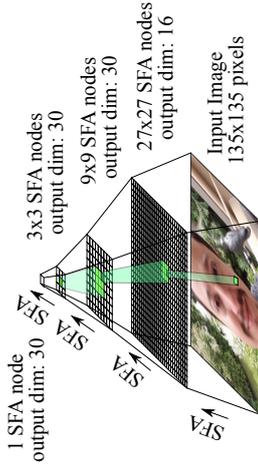

Figure 2: An example hierarchical SFA network for 2D data with 4 layers and no receptive field overlap that has been used for gender and age estimation from artificial face images (Escalante-B. and Wiskott, 2010). The SFA nodes can be easily replaced by GSFA nodes to construct an HG-SFA network. The input to one node in layers 1, 2 and 3 is highlighted.

particular application. The main advantage of cascaded over direct GSFA is that the feature space of the cascade may be more complex without making the individual nodes/layers/steps more complex. The theoretical part of this article concentrates on GSFA for simplicity, but we implicitly assume that it will be implemented in practice as HGSFA and applied to high-dimensional data.

There is a close relation between GSFA, generalized SFA (genSFA, Sprekeler, 2011; also see Rehn and Sprekeler, 2014) and locality preserving projections (LPP, He and Niyogi, 2003), sharing very similar objective functions and constraints, even though they originate from different backgrounds and were developed with different goals and applications in mind. Two differences are that in GSFA the vertex weights are independent of the edge weights and that GSFA is invariant to the scale of the weights, providing a normalized objective function $0 \leq \Delta \leq 4$ (for consistent graphs with non-negative edge weights). There are also differences in the similarity matrices used in practice for these algorithms. LPP originates from the field of manifold learning and its similarity matrices have been frequently computed using nearest neighbors of the input samples, reflecting input similarities. genSFA has mostly been used for classification and its similarity matrices are typically computed using input similarity information (nearest neighbors) with transitions restricted to samples of the same class. One can consider genSFA as LPP applied on the nonlinearly expanded data. GSFA originates from unsupervised learning and learning of invariances but is motivated by supervised learning, and training graphs for classification and regression have been used. Such graphs are computed using only the label information. The goal is to provide sensitivity to the label information and invariance to any other factor. Therefore, GSFA does not intend to preserve the manifold structure of the input data. It is possible to use GSFA to compute LPP features, and vice versa. The results of this article might thus also be relevant for researchers using LPP and genSFA.

Various efficient training graphs for classification (clustered graph) and regression (e.g., serial, mixed, sliding window graphs) have been proposed (Escalante-B. and Wiskott, 2013). These graphs have been pre-defined with efficiency in mind; although the number of edges contained in them is $\mathcal{O}(N^2)$, where N is the number of samples, their structure makes the training complexity linear w.r.t. N . This is possible due to algebraic simplifications in the training method that avoid the explicit representation of the graph as an $N \times N$ matrix.

Wiskott (2003) has studied the optimal free responses of SFA, i.e., the slowest possible features that can be extracted by SFA when there is no restriction regarding the training data or feature space. For SFA, he has computed the optimal free responses in continuous time by using variational calculus (also see Franzius et al., 2007). In this article, we use a different method for GSFA based on linear algebra to cope with the discrete nature of the index n that takes the place of time.

Due to the close connection between GSFA and LPP, the method proposed in Section 4.1 for computing the free responses of GSFA is closely connected to Laplacian eigenmaps (LE, Belkin and Niyogi, 2003). LE can be interpreted as a relaxation of LPP where the output features belong to an unrestricted feature space instead of being linear transformations of the inputs. Equivalently, LPP is a linearization of LE (Zhang et al., 2009).

Most regression methods have the shortcoming of a prohibitive computational cost if the data is high dimensional. Unsupervised DR can be useful to reduce the complexity, but the final accuracy may be suboptimal. Instead of direct regression, one could attempt to do hierarchical regression by training several regression nodes on low-dimensional data chunks and then combining their outputs on higher layers, similarly as HG-SFA is built to create a network of GSFA nodes. However, it is likely that the labels are not extractable at the lowest levels of the network (except with a noticeable error). Therefore, most information would be lost after the first layer, making the next layers unable to recover the labels accurately. GSFA extracts several slow features that do not need to be related to the labels in any simple way, allowing more label information to reach the top layers in HG-SFA, even if the labels cannot be extracted in the first layers.

The features extracted by GSFA nodes in an HG-SFA network have smaller receptive fields in the first layers that increase in size, as well as in complexity and selectivity, as one approaches the top of the network. This property is also present in other neural networks, such as the highly successful convolutional neural networks (CNNs). However, HG-SFA and CNNs differ considerably: the training method of HG-SFA is bottom-up, uses other types of nonlinearities, is not convolutional (although one can make some layers convolutional via weight sharing), and uses neither backpropagation nor max pooling. Moreover, in HG-SFA the features of each node fulfill a local optimality criterion (i.e., slowness).

3. Review of Graph-Based SFA (GSFA)

In this section, we recall the GSFA optimization problem and the GSFA algorithm. For a more detailed presentation of GSFA we refer to Escalante-B. and Wiskott (2013).

3.1 Training Graphs and the GSFA Problem

GSFA is trained with a so-called training graph, in which the vertices are the samples and the edges between two samples may represent or be related to the similarity of their labels.

In mathematical terms, the training data is represented as a training graph $G = (\mathbf{V}, \mathbf{E})$ (illustrated in Figure 3.a) with a set $\mathbf{V} = \{\mathbf{x}(n)\}_n$ of vertices, each vertex being a sample (i.e., a vector of length L), and a set \mathbf{E} of edges $(\mathbf{x}(n), \mathbf{x}(n'))$, which are pairs of samples, with $1 \leq n, n' \leq N$. The index n (or n') replaces the time variable t used by SFA. The edges are directed but typically have symmetric weights $\mathbf{\Gamma}^T = \mathbf{\Gamma} = \{\gamma_{n,n'}\}_{n',n}$; weights $v_n > 0$ are associated with the vertices $\mathbf{x}(n)$ and can be used to reflect their importance, frequency, or reliability. This representation includes the standard time series of SFA as a special case in which the graph has a linear structure (see Figure 3.b).

In order to solve classification problems with GSFA features, one should use training graphs that favor connections between samples from the same class by means of larger edge weights compared to those of different classes. When one is interested in regression problems, the training graphs should favor connections between samples with similar labels.

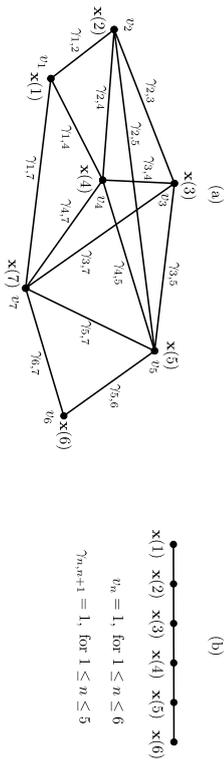

Figure 3: (a) Example of a training graph with $N = 7$ vertices. (b) A regular sample sequence (time series), which can be used to train SFA. This sequence is represented here as a linear graph that can be used with GSFA. If labels are available and the samples have been reordered by increasing/decreasing label (e.g., instead of having been ordered by time), the graph is called *sample reordering* graph. (Figure from Escalante-B. and Wiskott, 2013).

The concept of slowness has been originally defined for sequences of samples, but it has been generalized for GSFA to training graphs. The general goal of GSFA is to extract features that fulfill certain normalization restrictions and minimize the sum of the weighted squared output differences of all connected samples. More formally, the GSFA optimization problem (Escalante-B. and Wiskott, 2013) can be stated as follows: For $1 \leq j \leq J$, where J is the number of output features, find features $y_j(n) \stackrel{\text{def}}{=} g_j(\mathbf{x}(n))$, where $1 \leq n \leq N$, N is the number of samples, and g_j is a function belonging to a feature space \mathcal{F} (frequent choices for \mathcal{F} are all linear or quadratic transformations of the inputs), such that the objective function (weighted data value)

$$\Delta_j \stackrel{\text{def}}{=} \frac{1}{R} \sum_{n,n'} \gamma_{n,n'} (y_j(n') - y_j(n))^2 \text{ is minimal} \quad (1)$$

under the constraints

$$\frac{1}{Q} \sum_n v_n y_j(n) = 0, \quad (2)$$

$$\frac{1}{Q} \sum_n v_n (y_j(n))^2 = 1, \quad \text{and} \quad (3)$$

$$\frac{1}{Q} \sum_n v_n y_j(n) y_{j'}(n) = 0, \quad \text{for } j' < j, \quad (4)$$

$$\text{with } Q \stackrel{\text{def}}{=} \sum_n v_n \quad \text{and} \quad R \stackrel{\text{def}}{=} \sum_{n,n'} \gamma_{n,n'}. \quad (5)$$

The objective function penalizes the squared output differences between arbitrary pairs of samples using the edge weights as weighting factors. The feature $y_1(n)$, for $1 \leq n \leq N$, is the slowest one, $y_2(n)$ is the second slowest, and so on. Constraints (2)–(4) are called weighted zero mean, weighted unit variance, and weighted decorrelation, respectively. They are similar to the normalization constraints of SFA, except for the inclusion of vertex weights. The factors $1/R$ and $1/Q$ are not essential for the optimization problem, but they provide invariance to the scale of the edge weights as well as to the scale of the vertex weights, and serve a normalization purpose.

We write vectors and matrices in bold type. For instance, \mathbf{y}_j is the j -th feature vector of size N , $y_j(n)$ is the j -th feature of sample n , and $\mathbf{x}(n)$ is the n -th input sample of size L .

3.2 Linear GSFA Algorithm

The linear GSFA algorithm is similar to standard SFA (Wiskott and Sejnowski, 2002) and only differs in the computation of the matrices \mathbf{C} and $\hat{\mathbf{C}}$, which in GSFA takes into account the neighborhood structure specified by the training graph (samples, edges, and weights). The sample covariance matrix $\mathbf{C}_{\mathbf{G}}$ is defined as:

$$\mathbf{C}_{\mathbf{G}} \stackrel{\text{def}}{=} \frac{1}{Q} \sum_n v_n (\mathbf{x}(n) - \bar{\mathbf{x}})(\mathbf{x}(n) - \bar{\mathbf{x}})^T,$$

where $\mathbf{x}(n)$ and v_n denote an input sample and its weight, respectively, and

$$\bar{\mathbf{x}} \stackrel{\text{def}}{=} \frac{1}{Q} \sum_n v_n \mathbf{x}(n)$$

is the weighted average of all samples. The derivative second-moment matrix $\hat{\mathbf{C}}_{\mathbf{G}}$ is defined as:

$$\hat{\mathbf{C}}_{\mathbf{G}} \stackrel{\text{def}}{=} \frac{1}{R} \sum_{n,n'} \gamma_{n,n'} (\mathbf{x}(n') - \mathbf{x}(n))(\mathbf{x}(n') - \mathbf{x}(n))^T, \quad (6)$$

where edge weights $\gamma_{n,n'}$ are defined as 0 if the graph does not have an edge $(\mathbf{x}(n), \mathbf{x}(n'))$. Given these matrices, a sphering matrix \mathbf{S} and a rotation matrix \mathbf{R} are computed with

$$\mathbf{S}^T \mathbf{C}_{\mathbf{G}} \mathbf{S} = \mathbf{I}, \quad \text{and} \\ \mathbf{R}^T \mathbf{S}^T \hat{\mathbf{C}}_{\mathbf{G}} \mathbf{S} \mathbf{R} = \mathbf{A},$$

where \mathbf{A} is a diagonal matrix with diagonal elements $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_J$. Finally the algorithm returns $\Delta(y_1, \dots, \Delta(y_J), \mathbf{W}$ and $\mathbf{y}(n)$, where

$$\begin{aligned} \mathbf{W} &= \mathbf{S}\mathbf{R}, \text{ and} \\ \mathbf{y}(n) &= \mathbf{W}^T(\mathbf{x}(n) - \hat{\mathbf{x}}). \end{aligned} \quad (7)$$

It has been shown that the GSFA algorithm presented above indeed solves the optimization problem (1)–(4) in the linear function space. The proof is similar to the corresponding proof of standard linear SFA (Wiskott and Sejnowski, 2002).

The choice of the training graph $\mathbf{\Gamma}$ is important because it defines the types of features to be extracted. Figure 5 shows a serial graph useful for regression, whereas Figure 9 shows a clustered graph useful for classification.

3.3 Probabilistic interpretation of a graph

Interestingly, if the graph is connected and the following *consistency* restriction is fulfilled

$$\forall n : v_n/Q = \sum_{n'} \gamma_{n,n'}/R, \quad (8)$$

then GSFA yields the same features as standard SFA trained on a sequence generated by using the graph as a Markov chain with transition probabilities $\gamma_{n,n'}/R$ (see Klampff and Maass, 2010; Escalante-B. and Wiskott, 2013). Thus, one can use SFA to emulate GSFA. However, depending on the training graph chosen, emulating GSFA with SFA may be more expensive computationally.

3.4 GSFA Optimization Problem in Matrix Notation

In order to apply linear algebra methods to analyze GSFA, we use matrix notation. In what follows we assume that the edge weights are symmetric² ($\mathbf{\Gamma} = \mathbf{\Gamma}^T$) and that the consistency restriction (8) is fulfilled. This restriction can also be written as

$$\mathbf{v} \stackrel{(8)}{=} \frac{Q}{R} \mathbf{\Gamma} \mathbf{1}, \quad (9)$$

where $\mathbf{1}$ is a vector of ones of length N .

If \mathbf{y} is a feasible solution (i.e., satisfying (2) and (3)) and the graph fulfills the consistency restriction (8), the weighted delta value (1) can be simplified as follows,

$$\begin{aligned} \Delta \mathbf{y} &\stackrel{(1)}{=} \frac{1}{R} \sum_{n,n'} \gamma_{n,n'} (y(n') - y(n))^2 \\ &= \frac{1}{R} \left(\sum_{n'} (y(n'))^2 \sum_n \gamma_{n,n'} + \sum_n (y(n))^2 \sum_{n'} \gamma_{n,n'} - 2 \sum_{n,n'} \gamma_{n,n'} y(n') y(n) \right) \\ &\stackrel{(8)}{=} \frac{1}{R} \left(\sum_{n'} (y(n'))^2 \frac{R}{Q} v(n') + \sum_n (y(n))^2 \frac{R}{Q} v(n) - 2 \mathbf{y}^T \mathbf{\Gamma} \mathbf{y} \right) \\ &\stackrel{(3)}{=} 2 - \frac{2}{R} \mathbf{y}^T \mathbf{\Gamma} \mathbf{y}. \end{aligned} \quad (10)$$

2. An asymmetric edge-weight matrix $\mathbf{\Gamma}$ can be converted into a symmetric one $\mathbf{\Gamma}' \stackrel{\text{def}}{=} \frac{\mathbf{\Gamma} + \mathbf{\Gamma}^T}{2}$ without altering the solution to the optimization problem.

The optimization problem can then be stated as follows: For $1 \leq j \leq J$, find vectors \mathbf{y}_j of length N , with $y_j(n) \stackrel{\text{def}}{=} g_j(\mathbf{x}(n))$ and $g_j \in \mathcal{F}$, minimizing

$$\Delta_j \stackrel{(1,3,8)}{=} 2 - \frac{2}{R} \mathbf{y}_j^T \mathbf{\Gamma} \mathbf{y}_j \quad (11)$$

subject to:

$$\mathbf{v}^T \mathbf{y}_j \stackrel{(2)}{=} 0 \quad (12)$$

$$\mathbf{y}_j^T \text{Diag}(\mathbf{v}) \mathbf{y}_j \stackrel{(3)}{=} Q \quad (13)$$

$$\mathbf{y}_j^T \text{Diag}(\mathbf{v}) \mathbf{y}_{j'} \stackrel{(4)}{=} 0, \text{ for } j' < j, \quad (14)$$

where

$$Q \stackrel{(5,a)}{=} \mathbf{1}^T \mathbf{v}, \quad (15)$$

$$R \stackrel{(5,b)}{=} \mathbf{1}^T \mathbf{\Gamma} \mathbf{1}, \quad (16)$$

and $\text{Diag}(\mathbf{v})$ denotes a diagonal matrix with diagonal \mathbf{v} .

The use of matrix notation will facilitate the study of GSFA and the development of the ELL method in the next section.

4. Explicit Label Learning for Regression Problems

In this section, we propose the ELL method. First, we compute the optimal free responses of GSFA given any training graph. Then, we show how to construct a graph useful to learn any particular label or multiple labels. Afterwards, we show how to convert graphs with negative edge weights into graphs with non-negative weights only (such a method is useful to allow the probabilistic interpretation of the graph and to guarantee that the Δ values of all features lie between 0 and 4). Then, we motivate the use of auxiliary labels to improve learning. Finally, we analyze the computational complexity of the ELL method.

4.1 Optimal Free Responses of GSFA

In this section, we calculate the slowest possible solutions (optimal free responses) to the GSFA problem (11)–(14) that one could find if the feature space were unlimited. As we will see, the optimal free responses together with their corresponding Δ values, provide an alternative representation of the training graph and are a useful tool to understand its structure.

We use the Lagrange multiplier method to find critical points \mathbf{y} that are candidates for the optimal free responses. For the moment, we ignore the weighted decorrelation constraint (14) to solve for the first optimal free response, but we consider the remaining responses later. The method of Wiskott (2003) and Franzius et al. (2007) for computing optimal free responses of SFA relies on a continuous time variable t and cannot be applied to GSFA due to the discrete index n . Due to the close relationship between GSFA and LPP, the approach below is strongly related to Laplacian Eigenmaps (Belkin and Niyogi, 2003). Let

$$L \stackrel{\text{def}}{=} \left(2 - \frac{2}{R} \mathbf{y}^T \mathbf{\Gamma} \mathbf{y} \right) + \alpha \mathbf{v}^T \mathbf{y} + \beta \left(\mathbf{y}^T \text{Diag}(\mathbf{v}) \mathbf{y} - Q \right) \quad (17)$$

be a Lagrangian corresponding to the objective function (11), under the constraints (12) and (13). A signal \mathbf{y} is a critical point if the partial derivatives of L with respect to α, β , and $y_i(n)$, for $1 \leq n \leq N$, are simultaneously zero:

$$\partial L / \partial \alpha \stackrel{(17)}{=} \mathbf{v}^T \mathbf{y} \stackrel{!}{=} 0, \quad (18)$$

$$\partial L / \partial \beta \stackrel{(17)}{=} \mathbf{y}^T \text{Diag}(\mathbf{v}) \mathbf{y} - Q \stackrel{!}{=} 0, \quad \text{and} \quad (19)$$

$$\partial L / \partial \mathbf{y} \stackrel{(17)}{=} -\frac{4}{R} \mathbf{\Gamma} \mathbf{y} + \alpha \mathbf{v} + 2\beta \text{Diag}(\mathbf{v}) \mathbf{y} \stackrel{!}{=} \mathbf{0}, \quad (20)$$

where $\mathbf{0}$ is a vector of zeros.

Equations (18) and (19) merely require that the output \mathbf{y} has weighted zero mean and weighted unit variance, respectively. Multiplying (20) with $\mathbf{1}^T$ from the left and taking into account that $\mathbf{1}^T \text{Diag}(\mathbf{v}) = \mathbf{v}^T$, $\mathbf{1}^T \mathbf{v} \stackrel{(15)}{=} Q$, $\mathbf{1}^T \mathbf{\Gamma} \stackrel{(9)}{=} R \mathbf{v}^T$, and $Q > 0$ results in

$$-\frac{4}{R} \left(\frac{R}{Q} \mathbf{v}^T \right) \mathbf{y} + \alpha Q + 2\beta \mathbf{v}^T \mathbf{y} = 0,$$

implying $\alpha = 0$ due to (18). Therefore, (20) can be simplified to:

$$\left(-\frac{4}{R} \mathbf{\Gamma} + 2\beta \text{Diag}(\mathbf{v}) \right) \mathbf{y} = \mathbf{0},$$

$$\Leftrightarrow \text{Diag}(\mathbf{v}^{-1/2}) \left(\frac{4}{R} \mathbf{\Gamma} - 2\beta \text{Diag}(\mathbf{v}) \right) \text{Diag}(\mathbf{v}^{-1/2}) \text{Diag}(\mathbf{v}^{1/2}) \mathbf{y} = \mathbf{0},$$

$$\Leftrightarrow \left(\frac{4}{R} \text{Diag}(\mathbf{v}^{-1/2}) \mathbf{\Gamma} \text{Diag}(\mathbf{v}^{-1/2}) - 2\beta \mathbf{I} \right) \left(\text{Diag}(\mathbf{v}^{1/2}) \mathbf{y} \right) = \mathbf{0},$$

$$\Leftrightarrow \left(\text{Diag}(\mathbf{v}^{-1/2}) \mathbf{\Gamma} \text{Diag}(\mathbf{v}^{-1/2}) - \frac{R\beta}{2} \mathbf{I} \right) \left(\text{Diag}(\mathbf{v}^{1/2}) \mathbf{y} \right) = \mathbf{0}, \quad (21)$$

where $\mathbf{v}^{-1/2}$ is defined as the element-wise square root of the elements of \mathbf{v} , and $\mathbf{v}^{-1/2}$ is defined similarly (as usual, weights v_j are required to be strictly positive).

In a few words, \mathbf{y} is a critical point if it fulfills the weighted normalization constraints and the vector $\text{Diag}(\mathbf{v}^{1/2}) \mathbf{y}$ is an eigenvector of the matrix \mathbf{M} defined as

$$\mathbf{M} \stackrel{\text{def}}{=} \text{Diag}(\mathbf{v}^{-1/2}) \mathbf{\Gamma} \text{Diag}(\mathbf{v}^{-1/2}). \quad (22)$$

The corresponding eigenvalue is denoted

$$\lambda = \frac{R\beta}{2}. \quad (23)$$

We denote the (orthogonal) eigenvectors of matrix \mathbf{M} as \mathbf{u}_j with $\mathbf{u}_j^T \mathbf{u}_j = 1$. Each eigenvector \mathbf{u}_j gives rise to a critical point $\mathbf{y}_j \stackrel{\text{def}}{=} Q^{1/2} \text{Diag}(\mathbf{v}^{-1/2}) \mathbf{u}_j$, as long as also the weighted normalization constraints (12) and (13) are satisfied by \mathbf{y}_j . The slowest possible solution is the critical point \mathbf{y}_j with the smallest Δ -value. As we show below, the Δ -value of a critical point \mathbf{y}_j is directly related to the eigenvalue λ_j of the eigenvector $\mathbf{u}_j = Q^{-1/2} \text{Diag}(\mathbf{v}^{1/2}) \mathbf{y}_j$ of \mathbf{M} and can be computed as follows.

$$\Delta_{\mathbf{y}_j} \stackrel{(11)}{=} 2 - \frac{2}{R} (\mathbf{y}_j)^T \mathbf{\Gamma} \mathbf{y}_j$$

$$\stackrel{(22)}{=} 2 - \frac{2}{R} (\mathbf{y}_j)^T \text{Diag}(\mathbf{v}^{1/2}) \mathbf{M} \left(\text{Diag}(\mathbf{v}^{1/2}) \mathbf{y}_j \right)$$

$$\stackrel{(23)}{=} 2 - \frac{2}{R} (\mathbf{y}_j)^T \text{Diag}(\mathbf{v}^{1/2}) \lambda_j \text{Diag}(\mathbf{v}^{1/2}) \mathbf{y}_j$$

$$\stackrel{(13)}{=} 2 - \frac{2Q}{R} \lambda_j. \quad (24)$$

Thus, the slowest solution is the critical point \mathbf{y}_j with the largest eigenvalue λ_j . The remaining optimal free responses can now be addressed. They are given by the remaining critical points, where their corresponding eigenvalue defines their order, from largest to smallest. The weighted decorrelation condition (14) is fulfilled automatically due to the orthogonality of the eigenvectors: $\mathbf{u}_j^T \mathbf{u}_{j'} = 0 \Leftrightarrow \frac{1}{Q} \mathbf{y}_j^T \text{Diag}(\mathbf{v}) \mathbf{y}_{j'} = 0$ (follows from the definition of \mathbf{y}_j above).

One special case is when an eigenvalue has multiplicities. This means that two or more optimal free responses have the same Δ value, which is in fact the same Δ value of any rotation of such free responses. Therefore, optimal free responses with the same Δ value are not uniquely defined and any rotation of them is equivalent.

4.2 Design of a Training Graph for Learning One or Multiple Labels

Given a set of samples $\{\mathbf{x}(1), \dots, \mathbf{x}(N)\}$ with label $\ell = (\ell_1, \dots, \ell_N)$, we show how to generate a training graph, such that the slowest feature that could be extracted by GSFA is equal to a normalized version of the label. Notice that this problem (determining the structure of a training graph, or more concretely, its edge-weight matrix $\mathbf{\Gamma}$, having a particular optimal solution) differs considerably from the original GSFA problem of finding an optimal solution given a training graph and a feature space. The approach can be extended to multiple labels per sample. To distinguish them, we introduce an index $1 \leq j \leq L$, making ℓ_j denote the j -th label. The L labels can then be expressed as an affine transformation of the first L free responses, as described below.

Vertex-weights v_n indicate *a priori* likelihood information about the samples, and are thus assumed to be given and strictly positive. If this information is absent, one may set the vertex weights constant, e.g. $\mathbf{v} = \frac{1}{N} \mathbf{1}$.

Due to the normalization constraints, the outputs generated by GSFA must have weighted zero mean (12) and weighted unit variance (13). Therefore, to learn a single label ℓ we normalize it as follows: Let $\mu_\ell = \frac{1}{Q} \mathbf{v}^T \ell$ be the weighted label average and $\sigma_\ell^2 = \frac{1}{Q} (\ell - \mu_\ell \mathbf{1})^T \text{Diag}(\mathbf{v}) (\ell - \mu_\ell \mathbf{1})$ be the weighted label variance. Then, the normalized label is computed as

$$\tilde{\ell} = \frac{1}{\sigma_\ell} (\ell - \mu_\ell \mathbf{1}). \quad (25)$$

Hence, it is trivial to convert a normalized label into a non-normalized label and *vice versa*.

In order for the construction to work when samples have multiple labels, we must weight decorrelate them first. To decorrelate two labels $\ell_{j'}$ and ℓ_j , with $j' > j$, one can project ℓ_j out of $\ell_{j'}$: $\ell_{j'}^{\text{dec}}(n) = \ell_{j'}(n) - \frac{1}{Q} (\ell_j^T \text{Diag}(\mathbf{v}) \ell_j) \ell_j(n)$, which is an invertible linear operation.

From now on, we assume that the labels ℓ_1, \dots, ℓ_L have been decorrelated and normalized. We show how to compute edge weights $\gamma_{n,n'}$ such that the j -th optimal free response is equal to ℓ_j (with arbitrary polarity).

Define

$$\mathbf{\Gamma}^{\text{ELL}} \stackrel{\text{def}}{=} \text{Diag}(\mathbf{v}^{1/2}) \mathbf{M}^{\text{ELL}} \text{Diag}(\mathbf{v}^{1/2}), \quad (26)$$

where

$$\mathbf{M}^{\text{ELL}} \stackrel{\text{def}}{=} \sum_{j=0}^{N-1} \lambda_j \mathbf{u}_j^{\text{ELL}} (\mathbf{u}_j^{\text{ELL}})^T. \quad (27)$$

If $L < N - 1$ one can set $\lambda_{j>L} = 0$. The matrix $\mathbf{\Gamma}^{\text{ELL}}$ is symmetric by construction. The eigenvectors and eigenvalues of \mathbf{M}^{ELL} , which are explicit in its eigenvector decomposition (27), directly define the matrix $\mathbf{\Gamma}^{\text{ELL}}$, and determine the optimal free responses of the resulting graph. Concretely, for each $j \geq 1$ one sets $\mathbf{u}_j^{\text{ELL}}$ according to the desired label ℓ_j (ignore $\mathbf{u}_0^{\text{ELL}}$ and λ_0 for the time being).

$$\mathbf{u}_j^{\text{ELL}} = Q^{-1/2} \text{Diag}(\mathbf{v}^{1/2}) \ell_j, \text{ for } j \geq 1 \quad (28)$$

Notice that the weighted decorrelation of the labels translates directly into the orthogonality of the corresponding eigenvectors, that is

$$\frac{1}{Q} (\ell_j)^T \text{Diag}(\mathbf{v}) \ell_{j'} \stackrel{(14)}{=} 0 \quad \Leftrightarrow \quad (\mathbf{u}_j^{\text{ELL}})^T \mathbf{u}_{j'}^{\text{ELL}} = 0 \quad (29)$$

Once the eigenvectors are computed we must decide which eigenvalues we want to give them. Alternatively, we can decide which Δ values we give to the labels, because $\Delta \ell_j$ and λ_j are directly related: $\lambda_j \stackrel{(24)}{=} \frac{R}{2Q} (2 - \Delta \ell_j)$.

Larger eigenvalues (equivalent to smaller Δ values) might result in higher accuracy for the corresponding label. We give some intuition on how to choose the eigenvalues of the eigenvectors. a) In general, important labels should have larger eigenvalues than less important ones. b) The global scale of the eigenvalues $\lambda_{j>0}$ is irrelevant, only their relative scales matter. For convenience one can scale them so that $\sum \lambda_{j>0} = 1$. c) If two labels are similarly important, their eigenvalues should be also similar.

For example, if one only wants to learn a single label ℓ_1 with a delta value $\Delta \ell_1 = 0$, one can set $\mathbf{u}_1^{\text{ELL}} = Q^{-1/2} \text{Diag}(\mathbf{v}^{1/2}) \ell_1$, $\lambda_1 = 1$, and the eigenvalues $\lambda_{j>1}$ to zero. If ℓ_1 takes only two possible values (e.g., -1 and 1), the resulting graph will be disconnected and contain two clusters. Otherwise, the resulting graph will be connected, and the condition $\Delta \ell_1 = 0$ necessarily implies that some of the resulting edge weights will be negative, a condition that we deal with in Section 4.3.

The analysis of Section 4.1, which is used by the ELL method requires that the graph fulfills the consistency restriction (9). We set the remaining eigenvector

$$\mathbf{u}_0^{\text{ELL}} = Q^{-1/2} \mathbf{v}^{1/2}, \quad (30)$$

with eigenvalue $\lambda_0 = R/Q$. This ensures that $(\mathbf{u}_0^{\text{ELL}})^T \mathbf{u}_0^{\text{ELL}} = 1$ and (9) is fulfilled, as follows.

$$\begin{aligned} \mathbf{\Gamma}^{\text{ELL}} \mathbf{1} &\stackrel{(26,27)}{=} \text{Diag}(\mathbf{v}^{1/2}) \left(\sum \lambda_j \mathbf{u}_j^{\text{ELL}} (\mathbf{u}_j^{\text{ELL}})^T \right) \text{Diag}(\mathbf{v}^{1/2}) \mathbf{1} \\ &\stackrel{(30)}{=} \text{Diag}(\mathbf{v}^{1/2}) \left(\sum \lambda_j \mathbf{u}_j^{\text{ELL}} (\mathbf{u}_j^{\text{ELL}})^T \right) \mathbf{u}_0^{\text{ELL}} Q^{1/2} \\ &\stackrel{(30)}{=} \text{Diag}(\mathbf{v}^{1/2}) \lambda_0 \mathbf{u}_0^{\text{ELL}} Q^{1/2} \\ &= (R/Q) \mathbf{v}. \end{aligned} \quad (31)$$

The assignment of $\mathbf{u}_0^{\text{ELL}}$ and λ_0 above also ensures that $\mathbf{1}^T \mathbf{\Gamma}^{\text{ELL}} \mathbf{1} \stackrel{(15,31)}{=} R$. The free pseudo-response $\ell_0 \stackrel{(28)}{=} \mathbf{1}$ corresponding to $\mathbf{u}_0^{\text{ELL}}$ fulfills equations (13) and (14) but not (12). Therefore, ℓ_0 is not a feasible solution, but it has similar properties to the optimal free responses. The introduction of $\mathbf{u}_0^{\text{ELL}}$ does not reduce the generality of the labels $\ell_{j>0}$ that can be learned; orthogonality between $\mathbf{u}_0^{\text{ELL}}$ and $\mathbf{u}_{j>0}^{\text{ELL}}$ is equivalent to (12), i.e., the weighted zero mean of $\ell_{j>0}$, a condition that is required anyway for any feasible solution: $(\mathbf{u}_0^{\text{ELL}})^T \mathbf{u}_{j>0}^{\text{ELL}} = 0 \stackrel{(28)}{\Leftrightarrow} (Q^{-1/2} \mathbf{v}^{1/2})^T Q^{-1/2} \text{Diag}(\mathbf{v}^{1/2}) \ell_{j>0} = Q^{-1} \mathbf{v}^T \ell_{j>0} = 0$.

Although only L free responses are explicitly defined, $N - L - 1$ additional optimal free responses are defined implicitly with an eigenvalue of 0, corresponding to $\Delta = 2.0$. This Δ value has a particular meaning, because as we prove in the next paragraph, it is the Δ value of unit-variance zero-mean i.i.d. noise for certain graphs.

4.2.1 EXPECTED WEIGHTED Δ VALUE OF A NOISE FEATURE

Let \mathbf{y} be a noise feature randomly sampled from a zero-mean unit-variance distribution \mathcal{D} , i.e., $y(n) \leftarrow \mathcal{D}(0, 1)$. On average, \mathbf{y} fulfills the weighted normalization constraints (12) and (13), as can be seen as follows.

$$\langle \mathbf{v}^T \mathbf{y} \rangle_{\mathcal{D}} = \mathbf{v}^T \langle \mathbf{y} \rangle_{\mathcal{D}} = 0, \quad (32)$$

$$\langle \mathbf{y}^T \text{Diag}(\mathbf{v}) \mathbf{y} \rangle_{\mathcal{D}} = \langle \sum_n v_n y(n)^2 \rangle_{\mathcal{D}} = \sum_n v_n \langle y(n)^2 \rangle_{\mathcal{D}} = Q, \quad (33)$$

where $\langle \cdot \rangle_{\mathcal{D}}$ denotes expected value when sampling over \mathcal{D} . The expected delta value can be computed as

$$\begin{aligned} \langle \Delta \rangle_{\mathcal{D}} &\stackrel{(1)}{=} \frac{1}{R} \sum_{n,n'} \gamma_{n,n'} \langle (y(n') - y(n))^2 \rangle_{\mathcal{D}} \\ &= \frac{1}{R} \left(\sum_{n,n',n \neq n'} \gamma_{n,n'} \langle (y(n') - y(n))^2 \rangle_{\mathcal{D}} + \sum_n \gamma_{n,n} \langle (y(n) - y(n))^2 \rangle_{\mathcal{D}} \right) \\ &= \frac{1}{R} \left(\sum_{n,n',n \neq n'} \gamma_{n,n'} \langle (y(n')^2)_{\mathcal{D}} + (y(n)^2)_{\mathcal{D}} - 2 \langle y(n') y(n) \rangle_{\mathcal{D}} \rangle_{\mathcal{D}} + 0 \right) \\ &= \frac{1}{R} \sum_{n,n',n \neq n'} \gamma_{n,n'} (1 + 1 - 0) \\ &= \frac{2}{R} \left(\sum_{n,n',n \neq n'} \gamma_{n,n'} - \sum_n \gamma_{n,n} \right) \stackrel{(5)}{=} \frac{2(R - \sum_n \gamma_{n,n})}{R}. \end{aligned} \quad (34)$$

Therefore, if the graph has no self-loops (i.e., $\forall n : \gamma_{n,n} = 0$), the expected Δ value $(\Delta_y)_p$ of a noise feature \mathbf{y} is 2.0. The self-loops of a graph (e.g., one constructed using the ELL method) can be removed (i.e., their weight be set to zero). This does not change the free responses, only the scale of the Δ values is modified due to the change in R . The consistency restriction might be broken, though.

4.3 Elimination of Negative Edge Weights

From the objective function (1), it is obvious that a positive edge weight connecting two samples expresses that those samples should be mapped close to each other in feature space. In contrast, a negative edge weight expresses that two samples should be mapped as far apart as possible, thus encoding output dissimilarities. Nevertheless, the weighted unit variance constraint still applies, so the solutions are not unbounded.

If the edge weights are non-negative, the smallest possible Δ value is $\Delta = 0$. However, if negative edge weights are allowed, some feasible features might have $\Delta < 0$. A feature with $\Delta < 0$ would appear to be “slower” than the infeasible constant feature $\mathbf{y} = \mathbf{1}$ with $\Delta = 0$, contradicting the intuitive interpretation of slowness. Moreover, negative edge weights hinder the probabilistic interpretation of the graph (see Section 3.2), because some of the transition probabilities $\gamma_{n,n}/R$ of the resulting Markov chain would be negative.

Training graphs constructed using the ELL method might include negative edge weights, which would result in the disadvantages described above. Therefore, in this section, we add an additional step to the ELL method to ensure that the training graph has non-negative edge weights. More concretely, we show how to transform a training graph with strictly positive vertex weights v_n and arbitrary edge weights $\mathbf{\Gamma}$ (positive and negative) into a graph with the same vertex weights and only non-negative edge weights $\mathbf{\Gamma}'$. The optimization problem defined by $\mathbf{\Gamma}'$ is equivalent to the original optimization problem in terms of its solutions and their order. Only the value of the objective function is linearly changed (or, more precisely, changed by an affine function).

Assume that $\forall n : v_n > 0$, and that there is at least one element $\gamma_{n,n'} < 0$. Let

$$c \stackrel{\text{def}}{=} \max_{n,n'} \frac{-\gamma_{n,n'}}{v_n v_{n'}}. \quad (35)$$

The new edge weights $\mathbf{\Gamma}'$ are defined as

$$\mathbf{\Gamma}' \stackrel{\text{def}}{=} \frac{1}{1 + cQ^2/R} (\mathbf{\Gamma} + c\mathbf{v}\mathbf{v}^T). \quad (36)$$

Now, we show the properties of $\mathbf{\Gamma}'$ compared to those of $\mathbf{\Gamma}$:

1. All elements of $\mathbf{\Gamma}'$ are greater or equal to zero, as desired. (Follows from (35), which implies $\gamma_{n,n'} + cv_n v_{n'} \geq 0$.)
2. Symmetry is preserved by (36). Clearly $\mathbf{\Gamma}'$ is symmetric if and only if $\mathbf{\Gamma}$ is symmetric.
3. The sum of edge-weights is preserved:

$$R' \stackrel{(16)}{=} \mathbf{1}^T \mathbf{\Gamma}' \mathbf{1} \stackrel{(36)}{=} \frac{R + cQ^2}{1 + cQ^2/R} = R. \quad (37)$$

4. Fulfillment of the graph consistency restriction (9) is preserved:

$$\begin{aligned} \mathbf{1}^T \mathbf{\Gamma} \stackrel{(9)}{=} R/Q\mathbf{v}^T &\Rightarrow \mathbf{1}^T \mathbf{\Gamma}' \stackrel{(36)}{=} \frac{1}{1 + cQ^2/R} (\mathbf{1}^T \mathbf{\Gamma} + c\mathbf{1}^T \mathbf{v}\mathbf{v}^T) \\ &\stackrel{(9)}{=} \frac{R/Q}{1 + cQ^2/R} (R/Q\mathbf{v}^T + cQ\mathbf{v}^T) \\ &= \frac{R/Q}{1 + cQ^2/R} (1 + cQ^2/R)\mathbf{v}^T \\ &= R/Q\mathbf{v}^T. \end{aligned}$$

5. $\mathbf{\Gamma}$ and $\mathbf{\Gamma}'$ define equivalent optimization problems. Let \mathbf{y} be a feasible solution. The constraints of the optimization problem are independent of $\mathbf{\Gamma}'$, and only the objective function is modified as follows:

$$\begin{aligned} \Delta_y &\stackrel{(10)}{=} 2 - \frac{2}{R} \mathbf{y}^T \mathbf{\Gamma}' \mathbf{y} \\ &\stackrel{(36,37)}{=} 2 - \frac{2}{R(1 + cQ^2/R)} (\mathbf{y}^T \mathbf{\Gamma} \mathbf{y} + c\mathbf{y}^T \mathbf{v}\mathbf{v}^T \mathbf{y}) \\ &\stackrel{(12)}{=} 2 - \frac{2}{R(1 + cQ^2/R)} \mathbf{y}^T \mathbf{\Gamma} \mathbf{y} \\ &\stackrel{(10)}{=} 2 - \frac{R}{R(1 + cQ^2/R)} \frac{2}{2} (2 - \Delta_y) \\ &= \frac{1}{(1 + cQ^2/R)} \left(\Delta_y + \frac{2cQ^2}{R} \right). \end{aligned} \quad (38) \quad (39)$$

Therefore, the objective function is only modified by a positive scaling factor and a constant positive offset, proving that the optimal free solutions to the training graph remain stable, as well as their order.

6. In particular, a feature \mathbf{y} with $\Delta_y = 2$ preserves its delta value, i.e. $\Delta_y = 2 \stackrel{(38)}{\Leftrightarrow} \Delta_y' = 2$.

4.4 Auxiliary Labels for Boosting Estimation Accuracy

It is possible to provide additional *auxiliary* labels derived from the original one ℓ_1 to improve the estimation accuracy when GSFA is applied repeatedly (e.g., cascaded or in a convergent hierarchical GSFA network). Consider two GSFA nodes, one stacked on top of the other. If the first GSFA node is not be able to extract ℓ_1 accurately, it might still be capable of approximating labels $\ell_k = f_k(\ell_1)$, for $2 \leq k \leq K$, where the functions $f_k(\cdot)$ are nonlinear. Since these features are derived from the original label ℓ_1 , they contain a certain amount of information about it. In this case, the output features are likely to contain linear combinations of the labels ℓ_1, \dots, ℓ_k providing a redundant coding of ℓ_1 . These features are likely to be easier to disentangle by the second node to better approximate the original label ℓ_1 . Therefore, we suggest to explicitly promote the appearance of these features by learning also auxiliary labels.

The functions f_k can be defined arbitrarily; we suggest to use

$$\ell_k(n) = \cos \left(\frac{\ell_1(n) - \min(\ell_1)}{\max(\ell_1) - \min(\ell_1)} \pi k \right), \quad \text{for } 2 \leq k \leq K, \quad (40)$$

where $\max(\ell_1)$ is the largest label value, and $\min(\ell_1)$ is the smallest one. As usual, we assume the labels ℓ_1 to ℓ_K are weight decorrelated and normalized before the ELL method is applied.

The eigenvalues corresponding to the auxiliary labels must be set smaller than those of the original label. Otherwise, the slowest features might be more similar to the auxiliary labels than to the original one. From now on, the term *target* labels will be used to refer to the original and auxiliary labels, if present.

The use of auxiliary samples can be justified from information theory. Assume that the samples have been ordered by increasing label ℓ_1 . This implies that for ℓ_k the argument of the cosine function ranges from 0 to $k\pi$. Thus ℓ_2 describes 1 oscillation, ℓ_3 describes 1.5 oscillations, etc. In this sense, the auxiliary labels are “higher-frequency” versions of ℓ_1 . Notice that ℓ_2 contains almost all the information about ℓ_1 except for 1 bit. That is, $I(\ell_1, \ell_2) = H(\ell_1) - 1$, where I is mutual information and H is entropy. Similarly, ℓ_4 loses 2 bits of information about ℓ_1 , ℓ_8 loses 3 bits, and so on. Thus, auxiliary labels contain a large amount of information about ℓ_1 .

Moreover, the use of auxiliary labels supports the goal that samples $\mathbf{x}(n)$ and $\mathbf{x}(n')$ with similar labels $\ell_1(n)$ and $\ell_1(n')$ should have similar output features $y_j(n)$ and $y_j(n')$ on average, for $1 \leq j \leq J$, and not only the slowest features $y_1(n)$ and $y_1(n')$. This is a result of the “smoothness” of the auxiliary labels in terms of ℓ_1 (i.e., how fast they change w.r.t. ℓ_1). Notice that $\ell_1, \ell_2, \dots, \ell_J$ would be ordered by decreasing smoothness.

Interestingly, in regular SFA (or GSFA trained with the reordering graph) the inclusion of auxiliary labels occurs automatically. The slowest free response is a half period of a cosine function, and the subsequent free responses are the higher-frequency harmonics of the first one (see Section 5.2, particularly Figure 7).

4.5 Computational Complexity of Explicit Label Learning

The main drawback of ELL is its computational efficiency compared to efficient pre-defined training graphs, which is more marked for large N . We analyze the efficiency of explicit label learning by considering its two main parts: The construction of the training graph and training GSFA with it.

The graph construction requires $\mathcal{O}(L^2N + LN^2)$ operations. The term L^2N is due to the transformation of L target labels into eigenvectors, which might require a decorrelation step on L N -dimensional vectors. The term LN^2 is due to the computation of \mathbf{M} , which involves L vector multiplications $\mathbf{u}_j \mathbf{u}_j^T$.

When GSFA is trained, three computations are particularly expensive. (1) The computation of \mathbf{C}_G , which takes $\mathcal{O}(NI^2)$ operations. (2) The computation of $\hat{\mathbf{C}}_G$, which can be expressed as $\hat{\mathbf{C}}_G = \frac{2}{\sigma} \mathbf{X} \text{Diag}(\mathbf{v}) \mathbf{X}^T - \frac{2}{\sigma} \mathbf{X} \mathbf{I} \mathbf{X}^T$, where $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_N)$, taking $\mathcal{O}(N^2I + NI^2)$ operations. (3) The solution to the generalized eigenvalue problem, which requires $\mathcal{O}(I^3)$ operations. Therefore, in general, training GSFA requires $\mathcal{O}(N^2 + N^2I + I^3)$ operations. Typically $N > I$ to avoid overfitting, so the computation of $\hat{\mathbf{C}}_G$ is the most expensive part.

However, when an efficient pre-defined graph (e.g., the serial graph) is used instead of an ELL graph, it is possible to avoid the explicit graph construction and compute \mathbf{C}_G with optimized algorithms that take into account the regular structure of the graph. In this way,

efficient pre-defined graphs allow the computation of $\hat{\mathbf{C}}_G$ in $\mathcal{O}(NI^2)$ operations, which is equivalent to the complexity of standard SFA on N I -dimensional samples. Moreover, if the number of edges $N_e \leq N(N+1)/2$ is small, one can use (6) to compute $\hat{\mathbf{C}}_G$ in $\mathcal{O}(N_e I^2)$ operations. Therefore, for these two special cases, training GSFA takes $\mathcal{O}(NI^2 + I^3)$ and $\mathcal{O}(N_e + N)I^2 + I^3$ operations, respectively. In Section 6.4 we further discuss the complexity of the ELL method and in Section 6.5 we propose a few approaches to improve it.

5. Applications of Explicit Label Learning

This section we present three applications of the proposed method. The first one illustrates how to solve a regression problem with GSFA explicitly, learning a direct mapping from images to labels (see Figure 1.c). The second application shows the analysis of two pre-defined graphs by computing their optimal free responses. In the third application, the ELL method is used in a new way to learn compact discriminative labels for classification.

5.1 Explicit Estimation of Gender with GSFA

We consider the problem of gender estimation from artificial face images, which is treated here as a regression problem, because the gender parameter is defined as a real value by the face modeling software (FaceGen SDK, Singular Inversions Inc., 2008).

Input data. The input data are 12,000 64×64 grayscale images. Each image is generated using a new subject identity, where the gender is explicitly specified, and the rest of the parameters of the faces (e.g., age, racial composition) are random. The average pixel intensity of each image is normalized by multiplying the pixel values by an appropriate factor to eliminate skin color as a cue for gender estimation. The resulting images show subjects with a fixed pose, no hair or accessories, and the illumination is fixed, as well as the average pixel intensity and the background color (black). See Figure 4 for some sample images. To specify the gender parameter, 60 different values are used $(-3, -2.9, \dots, 2.9)$.

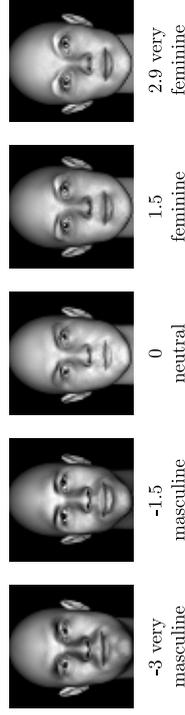

Figure 4: Example of the normalized images used, showing different values of the gender parameter.

The images are randomly split into a training and a test set. The training set consists of 10,800 images, 180 images for each gender value, whereas the test set consists of 1,200 images, 20 images for each gender value.

Besides the gender label, also a second “color” label is considered, which is the average pixel intensity of the image *before* normalization. Due to normalization, this label cannot be

the final clipping step LR was clearly more accurate than affine mapping (experiment not shown), but both methods have similar accuracy if clipping is enabled. For all graphs, the explicitly supervised soft GC method provided better accuracy than the affine mapping, although the difference is smaller than one might have expected.

L	Graph ELL^{g-c-L}			Graph ELL^{g-c-L}		
	scaling (1F)	LR (1F)	soft GC (3F)	scaling (1F)	LR (1F)	soft GC (3F)
1	0.376	0.380	0.364	0.365	0.298	0.289
10	0.364	0.365	0.353	0.356	0.349	0.350
20	0.372	0.374	0.356	0.357	0.423	0.426
30	0.367	0.368	0.350	0.349	0.473	0.478
40	0.368	0.367	0.346	0.345	0.508	0.514
50	0.376	0.375	0.351	0.350	0.535	0.543

Table 2: *Gender* estimation errors (RMSE) using various graphs and either one (1F) or three (3F) features. For the linear regression (LR) mapping, the label is estimated as $\hat{\ell}_1 = ay_1 + b$, with a and b fitted to the training data. Chance level (RMSE) is 1.731 if one uses the constant estimation $\hat{\ell}_1 = -0.05$. All errors computed on test data and averaged over 10 runs. (Left) Estimation errors using training graphs for gender estimation only. (Right) Estimation errors using training graphs for the experiment on simultaneous estimation of gender and color.

For comparison, the serial graph results in RMSEs of 0.351 (soft GC, 1F) and 0.349 (soft GC, 3F), whereas the reordering graph results in RMSEs of 0.353 (soft GC, 1F) and 0.347 (soft GC, 3F). The accuracy of these two graphs appears to be similar; however, in more complex experiments the serial graph has typically been more accurate. The ELL^{g-c-L} graph is, therefore, slightly more accurate than the serial and reordering graphs but 25 times slower, taking about 250 min for training instead of about 10 min (single thread).

Simultaneous learning of gender and color. We construct a graph that encodes gender and color simultaneously, learning labels ℓ_1, \dots, ℓ_L , where ℓ_1 is the gender label, ℓ_2 is the color label, $\ell_3, \dots, \ell_{L-1}$ are derived from ℓ_1 , and $\ell_4, \ell_6, \dots, \ell_L$ are derived from ℓ_2 . Each set of labels is computed using (40) similarly to the auxiliary labels for gender only but starting from either the original gender or color labels. The chosen eigenvalues decrease linearly and add to one. The resulting graphs are denoted ELL^{g-c-L} , where L is the total number of target labels, with $L = 2 \times d$, for $d \in \{1, 5, 10, 15, 20, 25\}$, and $2(d-1)$ is the number of auxiliary labels used for gender and color.

The effect of coding gender and color simultaneously on gender estimation is shown in Table 2, right (compare to Table 2, left). The ELL^{g-c-L} graphs yield significantly higher accuracy than the ELL^{g-L} graphs (an MAE as small as 0.277 vs. 0.345). The results on color estimation using the ELL^{g-c-L} graphs are shown in Table 3, right (compare to Table 3, left). The slowest extracted feature represents mostly gender. However, it must also contain color information since it allows color estimation better than chance level. When 3 features are preserved, the ELL^{g-c-L} graphs yield higher accuracy than the ELL^c-L graphs. Similar

L	Graph ELL^c-L			Graph ELL^{g-c-L}

experimental results have been reported, e.g. by Guo and Mu (2014), who have shown that age estimation improves when gender and race labels are also considered.

Learning label transformations. We verify that the method can learn other labels that are implicitly described by the data. More precisely, we use GSFA to learn labels $(\ell_1)^2$ and $(\ell_1)^3$, which are distorted versions of the original gender label ℓ_1 . The graphs constructed for this purpose are denoted $\text{ELL}^{g-40(\ell_1)^2}$ and $\text{ELL}^{g-40(\ell_1)^3}$, respectively. Both of them include 39 auxiliary labels besides the main distorted label. To better approximate the target labels, more complex nonlinearities are used in some of the nodes of the hierarchical networks. The $(\ell_1)^2$ network is identical to the ℓ_1 network, except that in the top node the quadratic expansion is used instead of the 0.8Expo expansion. Similarly, the $(\ell_1)^3$ network uses the quadratic expansion in the 7th layer, and the 6th-degree polynomial expansion in the top node. In both networks, the output dimension of the node in the 7th layer is set to 3 to avoid overfitting due to the expansion in the 8th layer.

The corresponding label estimations are shown in Figure 6. For comparison, also the ELL^{g-40} graph is included. The results prove that the ELL method can also be used to learn distortions of the main label. Admittedly, the accuracy of the estimations (expressed as a fraction of the respective chance levels) decreases even though we increased the complexity of the feature space.

5.2 Analysis of Pre-Defined Training Graphs

In this section, we use the method of Section 4.1 to extract the optimal free responses of three graphs (reordering, serial and ELL^c-L). The optimal free responses and their Δ values (alternatively, the eigenvectors \mathbf{u}_j and eigenvalues λ_j) fully characterize the properties of a training graph, and provide another representation of it that might be more useful in some contexts.

We compute optimal free responses using (21)–(23) and their delta values using (24). Therefore, these results have been obtained analytically. We plot them in Figure 7, which shows an arbitrary label to be learned (top), and three different graphs that can be used

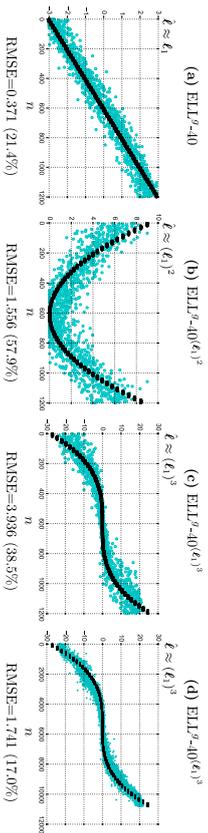

Figure 6: Plots (a) to (c) show the label estimations on test data (a single run) when different distorted versions of ℓ_1 are learned. The affine mapping is used. Therefore, the estimations are only generated from the slowest feature. Ground-truth values are shown in thicker black. The RMSE is expressed in parenthesis as a percentage of the chance level. Plot (d) is analogous to (c) but shows *training* data.

for this purpose. Only $N = 30$ samples (ordered by increasing label) are used to ease visualization, but the plots behave similarly for larger N . The following three graphs are employed. 1) A reordering graph (Figure 3.b) that has been extended with two edge weights $\gamma_{0,0} = 1$ and $\gamma_{N-1,N-1} = 1$ to fulfill the consistency restriction (8), which is required by the method. These weights introduce a constant scaling $N/(N+2)$ of the delta values, without any further consequence. 2) A serial graph (Section 5.1) with $K = 15$ groups of 2 samples each. 3) An ELL-4 graph (Sections 4.2-4.4) that is constructed with the original labels $\ell_1(n) = \ell(n)$, and 3 auxiliary labels computed using (40).

Figure 7 shows also that the most remarkable difference between these graphs is the number of optimal free responses with $\Delta < 2.0$, which is 14 for the reordering graph, 6 for the serial graph, and 4 for the ELL-4 graph, for the parameters above. For arbitrary parameters, the reordering, serial and ELL- L graphs have $\lfloor (N-1)/2 \rfloor$, $\lfloor (K-1)/2 \rfloor$, and, depending on the eigenvalues, up to $L \leq N-1$ optimal free responses with $\Delta < 2.0$, respectively.

Although the graphs differ considerably in their connectivity, their first four to five optimal free responses have a somewhat similar shape. Since in all graphs the slowest free response \mathbf{y}_1 is increasing, a monotonic mapping would be enough to approximate the label for any of these graphs. However, the slowest response of the serial graph is constant within each group, which might lower accuracy due to a discretization error. In contrast, the ELL-4 graph has been tailored to learn a particular label, and therefore \mathbf{y}_1 is exactly ℓ_1 (the original label) except for an offset and scaling.

The analysis makes clear that the serial and ELL-4 graphs are *more selective* than the reordering graph regarding the features that they consider slow. To illustrate why this might be an advantage, consider a scaled and noisy version \mathbf{y}_1 of ℓ_1 . More concretely, $\hat{y}_1(n) = \frac{\sqrt{2}}{2}\ell_1(n) + \frac{\sqrt{2}}{2}e(n)$, where $e(n)$ is an i.i.d. zero-mean unit-variance noise signal. When the reordering graph is used, the feature \mathbf{y}_1 has an average Δ -value of about 1 (i.e. $\langle \Delta_{\mathbf{y}_1} \rangle \approx 1$), and therefore such a feature would appear to be faster than an auxiliary (40) feature $\mathbf{y}_6 = \ell_6$, because $\Delta_{\ell_6} \approx 0.38$. Hence, a GSFA node trained with the reordering

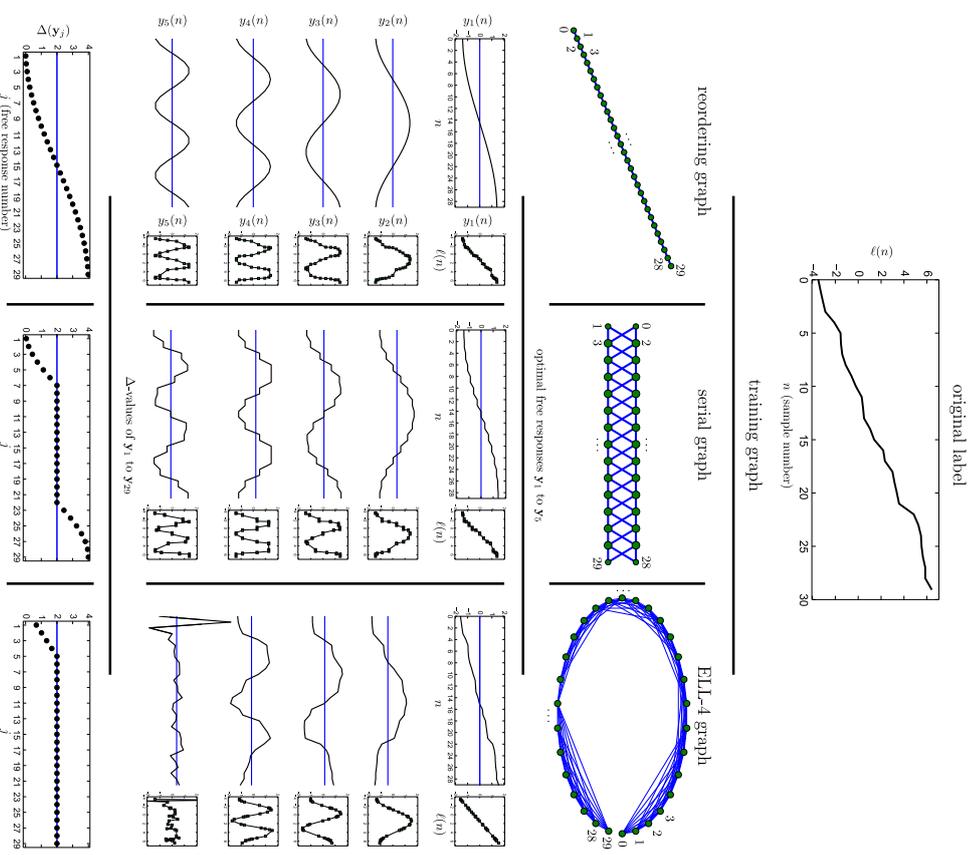

Figure 7: An arbitrary label $\ell(n)$ (top) and three graphs that can be used to learn it. The five slowest optimal free responses \mathbf{y}_1 to \mathbf{y}_5 of each graph are plotted, as well as the delta values of all optimal free responses. The ELL-4 graph is almost fully connected, but here only the strongest 30% of the connections are displayed. Samples have an index n from 0 to 29, and free responses have an index j from 1 to 29. The free responses are also plotted against the original label (smaller square plots). The polarity of the free responses was adjusted once to make them negative for the first sample.

graph would favor the extraction of \mathbf{y}_6 over $\hat{\mathbf{y}}_1$, even though $\hat{\mathbf{y}}_1$ is more similar to the label. In contrast, the serial and ELL-4 graphs might favor the extraction of $\hat{\mathbf{y}}_1$, because for these graphs $\Delta_{\mathcal{L}_6}$ is larger and close to 2.0.

5.3 Compact Discriminative Features for Classification

A well-known algorithm for supervised dimensionality reduction for classification is Fisher discriminant analysis (FDA). According to the theory of FDA, if there are C classes, $C - 1$ features define a $C - 1$ dimensional subspace that best separates the classes. In practice, one typically uses all these $C - 1$ features, because all of them contain discriminative information and contribute to classification accuracy. The same holds for GSFA if the clustered training graph is used (GSFA+clustered), because in this case the features learned are equivalent to those of FDA (see Klampfl and Maass, 2010; Escalante-B. and Wiskott, 2013).

One can take advantage of hierarchical processing to do classification using the clustered graph (HGSFA+clustered). However, when the number of classes C is large (e.g. $C \geq 100$) it might become expensive to preserve $C - 1$ features in each node, because the size of the input to subsequent nodes would be a multiple of $C - 1$. Such a large dimensionality would be further increased by the expansion function, resulting in a large training complexity. For instance, consider a 2-layer nonlinear network for classification with two GSFA nodes in the first layer and one in the top layer. Suppose the first two nodes have output dimensionality $C - 1 = 99$, making the input of the top node 198-dimensional, and suppose that the top node applies a quadratic expansion to its input data before linear GSFA. The expanded data would have dimensionality $I' = 19,701$. The combination of a large sample dimensionality I' and a large number of samples N (with $N \gg I'$ to avoid overfitting) would result in considerable computational and memory costs. Therefore, if we could encode the class information in the first layer more compactly, we could reduce the output dimensionality of the first-layer nodes and reduce overfitting, aiming at increasing classification accuracy.

In this section, we use the theory of explicit learning of multiple labels to compute compact features for classification using GSFA. We classify images of $C = 32$ traffic signs from the German traffic sign recognition benchmark database (Houben et al., 2013).

The images are represented as 48×48 -pixel color (RGB) images (see Figure 8). We use only 32 out of 43 traffic signs with the most samples, so that the number of classes is a power of 2 and the number of samples is maximized. For the training data, we use the same number of samples for each class (traffic sign), namely 2,160 of them, making a total of 69,120 images. To reach 2,160 samples per class, images of some classes are used up to 6 times (since the database is unbalanced). The images used for training are distorted by a random rotation r of $-3.15 \leq r \leq 3.15$ degrees, horizontal and vertical translations Δ_x, Δ_y with $-1.73 \leq \Delta_x, \Delta_y \leq 1.73$ pixels, and a scaling factor s with $0.91 \leq s \leq 1.09$. The purpose of these distortions is to improve generalization and provide invariances to small misalignments. We use the official test data, which ensures that the test images originate from signs physically different from the ones used for training. The test data consists of 9,030 undistorted images.

We used a simple (non-hierarchical) GSFA architecture, in which PCA is applied first to reduce the dimensionality to 120 principal components. Afterwards, quadratic GSFA is

Figure 8: The 32 traffic signs learned, one image per class.

applied using different training graphs, described below. Finally, since this is a classification problem, a nearest centroid classifier is used instead of the affine mapping.

The ELL method is used to construct two training graphs with binary target labels (i.e., label values are either 1 or -1). The first one has 5 labels (compact+5) and the second one has 31 (compact+31). The target labels are defined in Table 4. Notice that the first 5 labels (for both graphs) suffice, in principle, to fully encode the class information, because they can be viewed as a binary representation of the class number.

For the compact+5 graph, identical eigenvalues $(\lambda_1^1 = \lambda_2^1 = \lambda_3^1 = \lambda_4^1 = \lambda_5^1 = 0.2)$ are used to express equal importance of the target labels. The compact+31 graph has been included to show the effect of auxiliary labels $\ell_6, \ell_7, \dots, \ell_{31}$. For this graph, the first five eigenvalues $(\lambda_1^2, \lambda_2^2, \dots, \lambda_5^2) = (0.056, 0.056, \dots, 0.056)$ are identical, but the rest decrease linearly: $(\lambda_6^2, \lambda_7^2, \dots, \lambda_{31}^2) = (0.053, 0.051, \dots, 0.004, 0.002)$, where only three decimal places are shown. Thus, the importance given to the auxiliary labels decreases from ℓ_6 to ℓ_{31} . For both graphs, we scale the eigenvalues to make their sum equal to 1.

We choose $C = 2^5$ classes, because powers of two make it simple to obtain binary labels with a weighted zero mean, weighted unit variance, and weighted decorrelation, as follows. The first five original labels can be computed as $\ell_j(c) = 2 \lfloor \frac{c-1}{2^j} \rfloor \bmod 2 - 1$, where $1 \leq c \leq C$ is the class number, the division is integer division and “mod” is the modulo operation (i.e., an image n of class c is assigned a label $\ell_j(c)$). The auxiliary labels are computed as the product of two or more labels ℓ_1 to ℓ_5 , possibly multiplied by a factor -1 to make the label assigned to the first class negative. More concretely, ℓ_6 is the product of all original labels, ℓ_7 to ℓ_{11} are all products of four of them, ℓ_{12} to ℓ_{21} are all products of three, and ℓ_{22} to ℓ_{31} are all products of two (e.g., $\ell_6 = \ell_1 \ell_2 \ell_3 \ell_4 \ell_5$, $\ell_7 = -\ell_1 \ell_2 \ell_3 \ell_4$, $\ell_8 = -\ell_1 \ell_2 \ell_3 \ell_5$, $\ell_{30} = -\ell_3 \ell_5$, $\ell_{31} = -\ell_4 \ell_5$).

For both graphs, we set $\mathbf{v} = \mathbf{1}$. The corresponding eigenvectors are $\mathbf{u}_j \stackrel{(28)}{=} Q^{-1/2} \ell_j$, where $Q \stackrel{(9)}{=} N \cdot \mathbf{1} = 69,120$ (N is the number of training images). These eigenvectors are also binary and allow for a fast computation of the covariance matrix in $\mathcal{O}(LN I^2 + I^3)$ operations, where L is the number of target labels.

$c \rightarrow$	1	2	3	4	5	6	7	8	9	...	16	17	...	30	31	32

Table 4: Target labels used to encode the class information, compactly expressed as a function of the class number c . The compact+5 graph is constructed with labels ℓ_1 to ℓ_5 , whereas the compact+31 graph with ℓ_1 to ℓ_{31} . The first five labels can be seen as the original ones and the rest as auxiliary.

Clustered training graph. For comparison purposes, we also consider the clustered graph (Escalante-B. and Wiskott, 2013), an efficient pre-defined graph that generates features useful for classification, see Figure 9. The optimization problem associated with this graph explicitly demands that samples from the same class should typically be mapped to similar outputs.

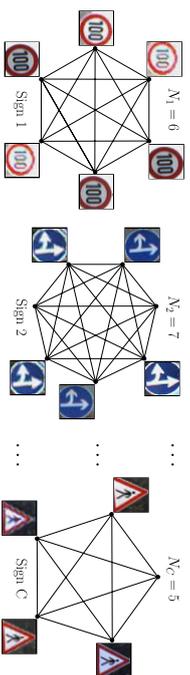

Figure 9: Illustration of a clustered training graph for classification with C classes (traffic signs). Each vertex represents a sample, and edges represent transitions. The N_c samples belonging to a class $c \in \{1, \dots, C\}$ are connected, constituting a fully connected subgraph. Samples of different classes are not connected. Vertex weights are identical and equal to one, whereas edge weights depend on the cluster size as $\gamma_{n,n'} = 1/(N_c - 1)$, where $\mathbf{x}(n)$ and $\mathbf{x}(n')$ belong to class c and $n \neq n'$. For traffic sign recognition, we use $C = 32$ signs and $N_c = 2, 160$ images per sign.

The features learned by GSFA on this graph are equivalent to those learned by Fisher discriminant analysis (FDA, see Klampff and Mass 2010 and also compare Berkes 2005a and Berkes 2005b). This type of problem can be analyzed theoretically when the function space of SFA is unrestricted. Consistent with FDA, the first $C - 1$ slow features extracted (optimal

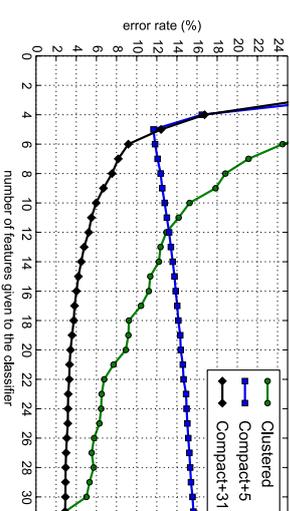

Figure 10: Classification error when GSFA is trained with the compact+5, compact+31 and clustered graph (FDA). This error is a function of the graph and the number of slow features d passed to the classifier. For the clustered graph, dropping even a single feature might increase the error rate significantly. For instance, the error rate of using 30 features computed with the clustered graph is worse than the error rate of 13 features computed with the compact+31 graph. Performance on 9,030 test samples, averaged over 10 runs. For $d \geq 4$ the standard error or the mean is at most 0.38%.

free responses) are orthogonal step functions, and are piece-wise constant for samples from the same class (Berkes, 2005a).

The classification error is plotted in Figure 10, where the number of slow features d given to a nearest centroid classifier ranges from 4 to 31. For comparison, the clustered graph is also evaluated. For $d = 5$ features, the compact+5 graph results in the best accuracy with an error rate of 11.67%, against 12.42% (compact+31) and 29.74% (clustered). However, the error rate of the compact+5 graph increases if one preserves more than 5 features, indicating that additional features contain little or no discriminative information. For $6 \leq d \leq 30$, the compact+31 graph yields clearly better accuracy than the other graphs. Interestingly, for $d = 31 = C - 1$ features, the compact+31 and clustered graph give identical error rates of 2.89%, which is their top performance. In this case, the features extracted are *different* but contain the *same information* since they can be mapped to each other linearly. In other words, the first 31 free responses of both graphs describe the same subspace. Any *single* optimal free response from the compact+31 graph contains 1 bit of discriminative information (which might be redundant to the others). In contrast, the first features extracted by the clustered graph might sacrifice discriminative information to minimize within-class variance (e.g., a feature $\mathbf{Y}(c) = ((\frac{C}{2})^{1/2}, -(\frac{C}{2})^{1/2}, 0, \dots, 0)$ has minimal (zero) within-class variance but provides little discriminative information (less than 1 bit if $C \geq 9$), because most of the time the feature takes the value 0 and otherwise only the first two classes can be identified from it). Using $d > 31$ features does not improve accuracy in any case. For comparison, the highest performance obtained for this database during the official competition is a 0.54% error rate for all 43 signs by Cirisan et al. (2012).

The method of compact discriminative classes provides more accurate label estimations if the feature space is complex enough to allow the extraction of features that approximate the binary labels. If the feature space is poor, the compact graphs might not bring any advantage over the clustered one.

6. Discussion

In this article, we propose exact label learning (ELL) for the construction of training graphs. When GSFA is trained with an ELL graph, the final label estimation is just an affine transformation of the slowest extracted feature. Thus, the method allows the direct solution of regression problems with GSFA, without having to resort to a supervised post-processing step. In other words, given a new input sample (e.g., an input image) the first feature computed using an ELL graph directly provides an approximation of the label (or an affine transformation of it). In practice, even better results may be achieved using more than one feature and supervised post-processing.

Supervised learning problems on high-dimensional data are of great practical importance, but they frequently result in systems with large computational demands. A common approach is to apply feature extraction, dimensionality reduction, and a supervised learning algorithm. A promising alternative approach is hierarchical GSFA (HGSFA), because its complexity scales in some cases even linearly w.r.t. the input dimensionality and the number of samples. In this context, it is especially useful to train HGSFA with an ELL graph since the resulting architecture is simple and homogeneous, as shown in Figure 1.c.

We have proposed a method to compute the optimal free responses of a training graph analytically. This method allows us to understand the type of features that can be extracted from a training graph independently of the feature space. Moreover, it has allowed us to propose the ELL method, where the labels are explicitly considered to create the training graph. In the resulting ELL graph, the optimal free responses are equal to a normalized version of the labels, and if the feature space is complex enough, HGSFA will learn features that approximate (or span) the original labels.

Graphs with negative edge weights would result in negative transition probabilities, violating the probabilistic interpretation of the graph, and might yield features with negative Δ value, contradicting the notion of slowness. Therefore, we also show how to transform a graph to make the edge weights non-negative without altering the extracted features.

We have proved the usefulness of the ELL method by showing three types of applications that are relevant in practice: ELL regression with multiple labels, analysis of training graphs, and classification with compact discriminative features.

It is crucial to emphasize that GSFA optimizes feature slowness, which depends on the particular training graph used, and not label estimation accuracy. However, when the ELL method is used, the training graphs define a slowness objective that requires optimizing an output similarity function where the similarities are intimately related to the desired label similarities. As a consequence, the feature slowness objective and estimation accuracy objective become equivalent when the feature space \mathcal{F} is unlimited. That is, the slowest possible features that can be extracted (i.e. optimal free responses) are equal to a normalized version of the label(s). In practice, \mathcal{F} is finite to allow generalization from training to test data and, if the features extracted are slow enough (i.e. close to the optimal free responses),

they are also good solutions to the original regression problem. If the slowest feature extracted is not sufficiently similar to the label, one can enhance the mapping from features to labels by mapping more than one output feature, and one can boost feature slowness by including auxiliary labels in the graph construction, as explained in Section 6.1.

We would like to underline that the ELL method is not equivalent to linear regression from the data to the (weight-decorrelated and normalized) target labels ℓ_1, \dots, ℓ_L . Any feasible feature vector $\tilde{\mathbf{y}}$ can be decomposed in terms of the optimal free responses $\mathbf{y}_1, \dots, \mathbf{y}_{N-1}$ as $\tilde{\mathbf{y}} = \sum_{j=1}^{N-1} \alpha_j \mathbf{y}_j$, with $\alpha^T \boldsymbol{\alpha} = 1$ to ensure weighted unit variance. The ELL method ensures that the first L optimal free responses $\mathbf{y}_1, \dots, \mathbf{y}_L$ are equal to the target labels ℓ_1, \dots, ℓ_L and have Δ values $\Delta_1, \dots, \Delta_L$. The remaining free responses are defined implicitly and have $\Delta_{L < j < N} = 2$. The Δ value of $\tilde{\mathbf{y}}$ can be expressed as $\Delta_{\tilde{\mathbf{y}}} = \sum_{j=1}^{N-1} (\alpha_j)^2 \Delta_j$. Let $\tilde{\mathbf{y}}_1, \dots, \tilde{\mathbf{y}}_J$ be concrete output features of GSFA for particular data using an ELL graph. We remark that the features $\tilde{\mathbf{y}}_1, \dots, \tilde{\mathbf{y}}_J$ are ordered by slowness, and $\tilde{\mathbf{y}}_j$ does not necessarily approximate \mathbf{y}_j . In particular, $\tilde{\mathbf{y}}_1$ is the slowest possible feature in the feature space, and it may be a linear combination of the free responses that is uncorrelated with $\mathbf{y}_1 = \ell_1$ if \mathbf{y}_1 cannot be approximated in the feature space (although this extreme case is less likely). In contrast, if one used linear regression, each one of the target labels would be approximated separately (i.e., $\tilde{\mathbf{y}}_j$ would approximate \mathbf{y}_j) regardless of the quality of the approximation. This would be mostly disadvantageous when used hierarchically. For instance, if a node in a network has output dimensionality $J < L$ (this scenario is frequent in the lower layers of the network), it is preferable to preserve the J slowest extractable features than the (eventually poor) linear approximations of ℓ_1, \dots, ℓ_J .

6.1 Multiple and Auxiliary Labels

ELL allows learning multiple labels simultaneously, for instance to encode different aspects of the input at once (e.g. object color, size, shape, orientation). The use of multiple labels has been inspired by biological systems, where complementary information channels have been observed and appear to improve feature robustness, for example, under incomplete information (Krüger et al., 2013). Learning gender and color simultaneously yielded clearly smaller estimation errors than when these labels were estimated separately (Section 5.1). This shows that multiple label learning is not only theoretically possible, but that coding complementary information channels might boost accuracy in practice. For instance, an automatic system for face image processing might benefit from the simultaneous extraction of the subject's identity, age, gender, race, pose, and expression.

One application of multiple labels is learning auxiliary labels derived from the original one (e.g. "higher-frequency" transformations of it). The results show that encoding auxiliary labels improves accuracy (Section 5.1). Such a technique is particularly relevant for cascaded or convergent hierarchical GSFA networks, where the outputs of some GSFA nodes feed other nodes. The use of auxiliary labels has been justified based on the fact that these labels contain substantial information about the original label (Section 4.4). For instance, as explained before, the first auxiliary label ℓ_2 only lacks one bit of information about the original label ℓ_1 . Therefore, even if ℓ_1 does not belong to the feature space of a node, the auxiliary labels might be (approximately) extracted, preserving information about ℓ_1 . A GSFA node (or any supervised learning algorithm) higher in the hierarchy may then be

able to approximate ℓ_1 more accurately by making use of the information carried by the auxiliary labels. Additionally, auxiliary labels have also been justified by a smoothness heuristic, where samples n and n' having similar labels $\ell_1(n)$ and $\ell_1(n')$ should have similar output features $y_j(n)$ and $y_j(n')$, for $1 \leq j \leq J$. Without auxiliary labels only the first output feature would have this property, and the remaining features might vary quickly w.r.t. the original label.

6.2 Application of the ELL Method

The experiments on gender (and skin-color) estimation from artificial face images demonstrate that the ELL method also works in practice when used hierarchically.

The experiments of Section 5.1 and the analytical results of Section 5.2 show the strength of the serial graph when only a single label is available. In this case, the ELL graph provided marginally better estimations than the serial graph (an RMSE of 0.345 with the ELL $_{\mathcal{G},40}$ graph vs. 0.349 with the serial graph, in both cases using 3 features, the soft GC post-processing method, and averaging over 10 runs), but the computation time was 25 times longer. We verified that the difference is statistically significant.

Although the shape of the slowest feature extracted with the serial graph may be less similar to the label, a monotonic transformation of the slowest feature learned by a nonlinear supervised step (e.g. soft GC) may suffice to approximate it.

However, the results suggest that if two or more (intrinsically connected) labels are available, the accuracy of using ELL graphs further increases. Efficient pre-defined graphs are not available in this case. In the gender estimation experiment, the RMSE was improved to 0.277 by jointly learning gender and skin (ELL $_{\mathcal{G},\mathcal{C}}(2 \times 5)$ graph, 3 features, soft GC). This is much better than the serial graph. Hence, a particularly promising application for the ELL method is multiple label learning.

Various methods for mapping the slowest feature to a label were tested. The affine mapping method is interesting from a theoretical point of view. However, as one would expect, the soft GC method, which is nonlinear and supervised, provides better accuracy on test data. Therefore, the latter might be preferred in practical applications. Moreover, in this scenario, supervised post-processing methods might be computationally inexpensive, because their input is frequently low-dimensional (e.g., we only used 1 to 3 slow features for gender estimation).

6.3 Classification with ELL

Although ELL was originally designed for regression, we have shown that it can also be useful for classification when particular labels are learned. The experiment on traffic sign classification shows the benefit of using compact discriminative features, implemented here by learning multiple binary labels. The resulting system has a much smaller classification error than the clustered graph (equivalent to nonlinear FDA) when the number of output dimensions is less than $C-1$, where C is the number of classes. The compactness of the feature set can be useful to do classification with many classes. This is particularly beneficial for hierarchical GSFA because less features have to be propagated by the network, which might also reduce overfitting. Although ideally $\log_2(C)$ binary target labels suffice for

perfect classification, the experiments show that additional target labels via auxiliary labels improve classification accuracy in practice.

Interestingly, the clustered graph for C classes (equivalent to FDA) and the compact+ $(C-1)$ graph are equivalent if the latter is constructed with constant positive eigenvalues $\lambda_1 = \dots = \lambda_{C-1} = 1/(C-1)$. The reason for this equivalence is that this compact+ $(C-1)$ graph would only have within-class transitions, because transitions between different classes cancel out each other. Therefore, the clustered graph can be seen as a special case of the compact+ $(C-1)$ graph, with maximum label redundancy ($C-1$ target labels) and giving equal importance (eigenvalues) to all of them.

For simplicity we used binary target labels, but it is also possible to use C -valued labels. For instance, the first label can be the class number, and additional labels can be random permutations of this assignment (label decorrelation and normalization still apply). Ideally, these labels might result in an even more compact representation, because a single optimal free response encodes the class information.

Contrary to many approaches for classification based on LPP, the goal of the ELL method is strictly focused on learning the label information while being invariant to any other aspect of the data. Since we do not intend to learn the input manifold, we do not use nearest neighbors to compute the training graph. However, as shown by the (regression) experiments on simultaneous gender and color estimation, learning specific additional labels can also be useful to better disentangle the discriminative information.

6.4 Efficiency of ELL

The complexity of training a single GSFA node with an ELL graph is $\mathcal{O}(IN^2 + I^2N + I^3)$ operations, where I is the input dimensionality (possibly after a nonlinear expansion), and $N > I$ is the number of samples. For comparison, the serial graph has a complexity of $\mathcal{O}(I^2N + I^3)$. Thus, the main limitation of using ELL graphs is the training complexity when N is large. However, this might not be a big disadvantage for the following reasons: (1) The complexity of the ELL method is comparable to the complexity of LPP. Similarity matrices in LPP are typically computed using nearest neighbors. In practice, the complexity of computing these matrices is similar to $\mathcal{O}(IN^2)$ (He, 2005), and the remaining steps of LPP have complexity $\mathcal{O}(I^2N + I^3)$ if the number of edges is linear w.r.t. N .

(2) The experiment on the estimation of gender shows that it is feasible to apply the ELL method to 10,800 64×64 images in 250 min (*single thread*, Intel Core i7-870 2.93GHz, 16 GByte RAM). This might be fast enough for some real-life applications.

(3) The ELL method is of theoretical interest in any case, allowing the analysis of training graphs and providing insights for the design of better hand-crafted graphs.

In case better efficiency is still necessary, we outline a few extensions to the ELL method in Section 6.5, two of them trading accuracy for speed.

6.5 Extensions of ELL

We have devised the following possible extensions (which may be combined):

(1) **Graph trimming.** One might compute sparse approximations of the ELL graphs with significantly less than $\mathcal{O}(N^2)$ edges. For example, one might delete a fraction of the edges having the smallest weights or a random selection of all the edges.

(2) **Sample grouping.** Another method first groups the input samples according to their labels, resulting in K groups of N/K samples each. The ELL method is then applied to the average labels of the groups to compute a reduced graph with K vertices and $\mathcal{O}(K^2)$ edges. If the largest number of labels L is used, i.e. $L = I$, the reduced graph can be constructed in $\mathcal{O}(IK^2 + I^2K)$ operations. Afterwards, one can derive a specialized method to train GSFA using the reduced graph. Such a method considers the transitions between all pairs of samples of two connected groups, in the same way as the serial graph. This avoids the explicit computation of the full edge-weight matrix of size $N \times N$. The training complexity would then be $\mathcal{O}(I^2N + I^2K^2 + I^3)$ using $\mathcal{O}(I^2K + NI)$ memory. An interesting value for K is $K = \sqrt{N}$, which divides the training data in \sqrt{N} groups of \sqrt{N} samples each, resulting in $\mathcal{O}(I^2N + I^3)$ operations. The term I^2K in the memory complexity might be large, but one can sacrifice some performance to reduce memory usage, resulting in $\mathcal{O}(I^2N + I^2KN + I^3)$ operations and $\mathcal{O}(I^2 + NI)$ memory.

(3) **Combination of graphs.** Under some conditions, we show how to combine training graphs meaningfully. Consider two training graphs that fulfill the consistency restriction (9) and share the same vertices (samples) $\mathbf{x}(n)$ and vertex weights $v(n)$. Let $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$ be the corresponding edge weight matrices, and $0 < \alpha < 1$ be a weighting factor. The combined graph has the same vertices and node weights, but a combined edge weight matrix $\mathbf{\Gamma}_c \stackrel{\text{def}}{=} \alpha\mathbf{\Gamma}_1 + (1 - \alpha)\mathbf{\Gamma}_2$. Assume that $\mathbf{1}^T\mathbf{\Gamma}_1\mathbf{1} = \mathbf{1}^T\mathbf{\Gamma}_2\mathbf{1} = R$ (otherwise the edge weights of one graph can be scaled). Since the vertices and vertex weights are identical, a feature \mathbf{y} that is feasible for one of the graphs is also feasible for the other two. Let $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_1}$ and $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_2}$ be the Δ value of \mathbf{y} for the original graphs. Then, $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_c} \stackrel{(10)}{=} \alpha\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_1} + (1 - \alpha)\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_2}$. This implies that if a feature \mathbf{y} has a Δ -value smaller than an arbitrary constant β (i.e., $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_1} < \beta$) and it is not larger than β in the second one (i.e., $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_2} \leq \beta$), it can be warranted that it will be also smaller than β in the combined graph (i.e., $\Delta_{\mathbf{y}}^{\mathbf{\Gamma}_c} < \beta$) for any $0 < \alpha < 1$. This property may be useful to create graphs with optimal free responses that span various labels.

The third extension can be used to combine ELL and/or pre-defined graphs without distinction. In an upcoming work, Escalante-B. and Wiskott (2016) combine three efficient pre-defined graphs for face image analysis: two clustered graphs for classification of race and gender, and a serial graph for the estimation of age. The accuracy for age estimation on the MORPH-II database using the combined graph (and an improved version of HGSFA) is a mean average error (MAE) of 3.50 years, which is more accurate than the current state-of-the-art systems for this database (Yi et al., 2015 with an MAE of 3.63 years and Guo and Mu, 2014 with an MAE of 3.92).

6.6 Future Work

In future work, we would like to explore the extensions above. For example, it seems reasonable to combine the serial and the reordering graph. The first one has a large number of edges, which provides good generalization, whereas the second one does not incur in the quantization error of the serial graph caused by its grouping of samples. Thus, the combination might improve accuracy.

Although the ELL method supports multiple labels, it might be less effective if the number of target labels L is large. However, in this case the labels are frequently categorical

and sparse. Therefore, we would like to investigate methods that concentrate the label information (e.g., by computing a compressed representation of the labels) to reduce the number of effective labels.

We have proposed a method to set the auxiliary labels, and have explained why it is meaningful to use them. However, one could choose them according to some optimization criterion, e.g., to explicitly maximize estimation accuracy. Also the assignment of the eigenvalues could be optimized. Apparently it is difficult to determine optimal auxiliary labels and their eigenvalues analytically. For classification with $C = 32$ classes, *linearly* decreasing eigenvalues (for the auxiliary labels) provided great results, but other eigenvalues might be better if C is very large.

In the ELL method, several eigenvalues were set to zero and the corresponding eigenvectors remained unspecified. As suggested by a reviewer, one could use these eigenvectors and eigenvalues to construct graphs with special structural constraints, such as a minimum and maximum number of edges per vertex.

6.7 Conclusion

Hierarchical processing and the slowness principle are two powerful brain-inspired learning principles. The strength of SFA originates from its theoretical foundations in the field of learning of invariances and the generality of the slowness principle. For practical supervised learning applications, HGSFA provides good accuracy and efficiency and still profits from strong theoretical foundations. An advantage of relying on such general principles is that the resulting algorithms are application independent and not confined to a particular problem or input feature representation. Of course, fine tuning the network parameters and the integration of problem-specific knowledge are always possible for additional performance. The proposed ELL method explores the limits of HGSFA and is valuable as a theoretical tool for the analysis and design of training graphs. However, the results show that with certain adaptations (e.g., the use of supervised post-processing) it is also sufficiently robust to be applied to practical computer vision and machine learning tasks.

Abstract

The Restricted Boltzmann Machine (RBM) has proved to be a powerful tool in machine learning, both on its own and as the building block for Deep Belief Networks (multi-layer generative graphical models). The RBM and Deep Belief Network have been shown to be universal approximators for probability distributions on binary vectors. In this paper we prove several similar universal approximation results for two variations of the Restricted Boltzmann Machine with time dependence, the Temporal Restricted Boltzmann Machine (TRBM) and the Recurrent Temporal Restricted Boltzmann Machine (RTRBM). We show that the TRBM is a universal approximator for Markov chains and generalize the theorem to sequences with longer time dependence. We then prove that the RTRBM is a universal approximator for stochastic processes with finite time dependence. We conclude with a discussion on efficiency and how the constructions developed could explain some previous experimental results.

Keywords: TRBM, RTRBM, machine learning, universal approximation

1. Introduction

Modeling temporal sequences has been an important problem in machine learning because of the natural time dependence in many data sets. The Restricted Boltzmann Machine (RBM), a type of probabilistic neural network, has become popular as a result of the use of an efficient learning algorithm called contrastive divergence (Hinton, 2002). In particular, its use in the construction of Deep Belief Networks (Hinton and Osindero, 2006) has led to widespread use in a number of machine learning tasks. One major drawback of the basic model, however, is the difficulty in using these models to capture temporal dependence in a data set. Several refinements of the model have attempted to combine the efficient statistical modeling of RBMs with the dynamic properties of Recurrent Neural Networks (Hinton and Osindero, 2006)(Taylor et al., 2006)(Le Roux and Bengio, 2008). These include the Temporal Restricted Boltzmann Machine (TRBM), the Recurrent Temporal Restricted Boltzmann Machine (RTRBM), and the Conditional Restricted Boltzmann Machine (CRBM). Boltzmann machines, and RBMs have been shown to be universal approximators for probability distributions on binary vectors (Freund and Haussler, 1991)(Younes, 1996)(Le Roux and

Bengio, 2008). Furthermore the related Deep Belief Networks have also been shown to be universal approximators even when each hidden layer is restricted to a relatively small number of hidden nodes (Sutskever and Hinton, 2010)(Le Roux and Bengio, 2010)(Montufar and Ay, 2011). The universal approximation of CRBMs follows immediately from that of Boltzmann machines (Montufar et al., 2014). The question we wish to address here is the universal approximation of stochastic processes by TRBMs and RTRBMs.

1.1 The Restricted Boltzmann Machine

An RBM defines a probability distribution over a set of binary vectors $x \in \{0, 1\}^n = X$ as follows

$$P(v, h) = \exp(v^\top W h + c^\top v + b^\top h) / Z$$

where the set of binary vectors X is partitioned into visible and hidden units $X = V \times H$ and Z is the normalization factor, in other words $Z = \sum_{v,h} \exp(v^\top W h + c^\top v + b^\top h)$. This distribution is entirely defined by (W, b, c) and is referred to as a Boltzmann Distribution. We are generally concerned with the marginal distribution of the visible units. When we refer to the distribution of an RBM we are referring to the marginal distribution of its visible units. The marginal distribution of a single visible node is given by

$$P(v_i = 1|h) = \sigma \left(\sum_j w_{ij} h_j + c_i \right)$$

where $\sigma(x) = \frac{1}{1 + \exp(-x)}$. A similar equation holds for the hidden units. Variations of the RBM which use real-valued visible and hidden units (or mixes of the two) exist but will not be considered here.

1.2 Approximation

In order to measure how well one distribution approximates another we use the Kullback-Leibler divergence, which for discrete probability distributions is given by

$$KL(R||P) = \sum_v R(v) \log \left(\frac{R(v)}{P(v)} \right),$$

where v ranges over the sample space of R and P . It can be shown that for any $\epsilon > 0$, given a probability distribution R on V there is a Boltzmann Distribution given by an RBM P such that $KL(R||P) < \epsilon$ (Le Roux and Bengio, 2008)(Freund and Haussler, 1991). Our goal now is to prove the same result where R satisfies certain temporal dependency conditions and P is a TRBM.

2. Universal Approximation Results for the TRBM

A TRBM defines a probability distribution on a sequence $x^T = (x^{(0)}, \dots, x^{(T-1)})$, $x^{(t)} \in \{0, 1\}^n$, $x^{(t)} = (v^{(t)}, h^{(t)})$, given by

$$P(v^{(t)}, h^{(t)} | h^{(t-1)}) = \frac{\exp(v^{(t)T} W h^{(t)} + c^T v^{(t)} + b^T h^{(t)} + h^{(t)T} W' h^{(t-1)})}{Z(h^{(t-1)})},$$

$$P(v^T, h^T) = \left(\prod_{k=1}^{T-1} P(v^{(k)}, h^{(k)} | h^{(k-1)}) \right) R_0(v^{(0)}, h^{(0)}).$$

This distribution is defined by the same parameters as the RBM along with the additional parameters W' . The TRBM can be seen as an RBM with a dynamic hidden bias determined by $W' h^{(t-1)}$. The initial distribution, $P_0(v^{(0)}, h^{(0)})$, is the same as $P(v^{(t)}, h^{(t)} | h^{(t-1)})$ with $h^{(0)T} b_{\text{init}}$ replacing $h^{(t)T} W' h^{(t-1)}$ for some initial hidden bias b_{init} . Note that W' is not symmetric in general. We call the connections between $h^{(t-1)}$ and $h^{(t)}$ with weights in W' temporal connections.

2.1 Universal Approximation Results for the Basic TRBM

Our approximation results will deal with distributions which are time-homogeneous and have finite time dependence. These distributions can be written in the form

$$R(v^T) = \left(\prod_{k=m}^{T-1} R_1(v^{(k)} | v^{(k-1)}, \dots, v^{(k-m)}) \right) R_0(v^{(0)}, \dots, v^{(m-1)})$$

where R_1 is the transition probability and R_0 is the initial distribution. We first show that a TRBM can approximate a Markov chain (distributions of the above form with $m = 1$) for a finite number of time steps to arbitrary precision. We begin by proving a lemma. Here P_t is the marginal distribution of P over $(v^{(0)}, \dots, v^{(t)})$. Similarly $R_{0,t}$ is the marginal distribution of R_0 over $(v^{(0)}, \dots, v^{(t)})$.

Lemma 1: *Let R be a distribution on a finite sequence of length T of n -dimensional binary vectors that is time homogeneous with finite time dependence. Given a set of distributions \mathbf{P} on the same sequences, if for every $\epsilon > 0$ we can find a distribution $P \in \mathbf{P}$ such that for every v^T ,*

$$KL(R_1(\cdot | v^{(t-1)}, \dots, v^{(t-m)}) || P_t(\cdot | v^{(t-1)}, \dots, v^{(t-m)})) < \epsilon \text{ for } m \leq t < T - 1,$$

$$KL(R_{0,t}(\cdot | v^{(t-1)}, \dots, v^{(0)}) || P_0(\cdot | v^{(t-1)}, \dots, v^{(0)})) < \epsilon \text{ for } 0 < t < m,$$

and $KL(R_{0,0}(\cdot) || R_0(\cdot)) < \epsilon$, then we can find distributions $P \in \mathbf{P}$ to approximate R to arbitrary precision.

Proof: The proof is given in the appendix.

Now we use this lemma to prove our first universal approximation theorem. In this case \mathbf{P} is the set of distributions given by a TRBM. Note that throughout this paper P will often be used to refer to a TRBM. When we say P is a TRBM we are referring to the distribution associated with a set of parameters defining the TRBM.

Theorem 1: *Let R be a distribution over a sequence of length T of binary vectors of length n that is time homogeneous and satisfies the Markov property. For any $\epsilon > 0$ there exists a TRBM defined on sequences of length T of binary vectors of length n with distribution P such that $KL(R || P) < \epsilon$.*

Proof: By the previous lemma we will be looking for a TRBM that can approximate the transition probabilities of R along with its initial distribution. The proof will rely on the universal approximation properties of RBMs. The idea is that given one of the 2^n configurations of the visible units, v , there is an RBM with distribution P_v approximating $R_1(\cdot | v^{(t-1)} = v)$ to a certain precision. The universal approximation results for RBMs tell us that this approximation can be made arbitrarily precise for an RBM with enough hidden units. Furthermore, this approximation can be done with visible biases set to 0 (Le Roux and Bengio, 2008). We thus set all visible biases of our TRBM to 0 and include each of the approximating RBMs without difficulty. We label these RBMs H_1, \dots, H_{2^n} . Given a specific configuration of the visible nodes v , H_v refers to the RBM chosen to approximate $R_1(\cdot | v^{(t-1)} = v)$.

The challenge then is to signal the TRBM which of the 2^n RBMs should be active at the next time step. To do this we include 2^n additional hidden nodes which we will call *control nodes*, each corresponding to a particular configuration of the visible units. Thus we add 2^n control nodes, $h_{c,1}, \dots, h_{c,2^n}$ corresponding to the hidden nodes H_1, \dots, H_{2^n} . Again, given a particular visible configuration v , we denote the corresponding control node by $h_{c,v}$. The set of all control nodes will be denoted H_c . Note that (c, v) is the label of $h_{c,v}$ and weights involving $h_{c,v}$ will be denoted $w_{c,v}^{(c,v)}$ or $w_{j_i}^{(c,v)}$. The control nodes will signal which of the H_i 's should be active at the next time step. To accomplish this we will choose parameters such that when v is observed at time $t - 1$, $h_{c,v}$ will be on at time $t - 1$ with a probability close to 1 and every other control node will be off at time $t - 1$ with probability close to 0. Each $h_{c,v}$ will have strong negative temporal connections to every $H_{v'}$ with $v' \neq v$, in essence turning off every RBM corresponding to $R_1(\cdot | v^{(t-1)} = v')$, and leaving the RBM corresponding to $R_1(\cdot | v^{(t-1)} = v)$ active (see Fig. 1). We will break the proof down into four parts and we must be able to choose parameters that satisfy all four conditions.

First, we must be able to choose parameters so that given $v^{(t-1)} = v$, the probability that $h_{c,v}^{(t-1)} = 1$ can be made arbitrarily close to 1 and the probability that $h_{c,v'}^{(t-1)} = 1$ can be made arbitrarily close to 0. Second, we must have that the control nodes have no impact on the visible distribution at the same time step so the transition probabilities of the TRBM will still approximate $R_1(\cdot | v^{(t-1)} = v)$. Third, we must be able to choose parameters so that given $h_{c,v}^{(t-1)} = 1$ and $h_{c,v'}^{(t-1)} = 0$, the probability that any nodes in $H_{v'}$ are on at time t can be made arbitrarily close to 0 for $v' \neq v$. Finally, we must be able to approximate the initial distribution R_0 .

Note in the TRBM temporal data cannot flow directly from the visible nodes to the hidden nodes at the next time step. In contrast, by using the visible nodes at time t as input and the visible nodes at time $t + 1$ as output, in the CRBM there is a direct relationship between the visible nodes at time t and the hidden nodes at time $t + 1$. The CRBM is known to be a universal approximator (Montufar et al., 2014). The main challenge for the TRBM is to

encode the visible state in the control unit so that information can be passed to the hidden nodes at the next time step without the encoding changing the visible distribution. This is covered in Steps 1 and 2. Step 3 verifies that the correct distribution can be recovered from the encoding and Step 4 shows we can simulate the initial distribution without changing the rest of the machine.

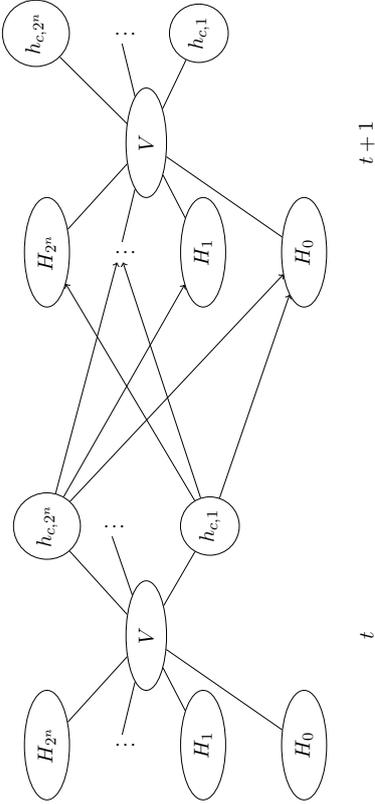

Figure 1: Interactions between sets of nodes within and between time steps: each $h_{c,v}$ turns off every $H_{v'} : v \neq v'$ in the subsequent time step. $h_{c,v}$ will only be on if v is observed at time t and collectively the control nodes H_c have negligible effect on the visible distribution. H_0 is an additional set of hidden units that will be used to model the initial distribution.

To choose temporal connections, define $w'_{j,(c,v)}$ to be $-\alpha$ if $h_j \in H_{v'}$ where $v' \neq v$ and 0 otherwise. Let every other $w'_{i,j} = 0$. In particular, remembering that W' is not necessarily symmetric, we have $w'_{(c,v),j} = 0$ for all h_j . The only parameters left to define are the biases and visible-hidden connections of H_c . Let $b_{(c,v)} = -(k - 0.5)\beta$ where k is the number of visible nodes on in v . Finally, define the connections from the visible units to $h_{c,v}$ by $w_{i,(c,v)} = \beta$ if v_i is on in the configuration v and $-\beta$ otherwise. Here the parameters of the control nodes are completely determined by α and β . We will proceed by showing that all necessary conditions are satisfied when α and β are large enough.

A note on notation. Throughout the proof H will denote the set of hidden nodes and $H^{(t)}$ will denote the set of configurations of hidden nodes at time t . Similarly $H_v^{(t)}$ will denote the set of configurations of the hidden nodes in which $h_i^{(t)} = 0$ if $h_i \notin H_v$. Similar conventions are used for H_c . $(H \setminus H_c)^{(t)}$ then denotes the set of configurations of non-control nodes. This is used in scenarios where we want to sum over a certain subset of hidden nodes and ignore the others, which is equivalent to simply setting all other nodes to 0. $H_{c,v}^{(t)}$ denotes the set of configurations of $h^{(t)}$ with $h_{c,v}^{(t)} = 1$ and $h_{c,v'}^{(t)} = 0$ for $v \neq v'$. $\bar{H}_{c,v}^{(t)}$ denotes the set of configurations $H^{(t)} \setminus H_{c,v}^{(t)}$. See Appendix A for a partial list of relevant notation.

Step 1:

For this step we show that as $\beta \rightarrow \infty$ we have $P(H_{c,v}^{(t)} | v^{(t)}, \dots, v^{(0)}) \rightarrow 1$. Note that given the visible state at time t , the state of the control nodes at time t is conditionally independent of all other previous states. With this in mind, we can write the probability of a control node being on at time t as

$$P(h_{c,v}^{(t)} = 1 | v^{(t)}, \dots, v^{(0)}) = \sigma \left(\sum_i v_i^{(t)} w_{i,(c,v)} + b_{(c,v)} \right),$$

where σ is the logistic function. Note that for all $v^{(t)} \in \{0, 1\}^n$ and $v \in \{0, 1\}^n$, $\sum_i v_i^{(t)} w_{i,(c,v)} = a\beta - b\beta$ where a is the number of nodes on in both v and $v^{(t)}$ and b is the number of nodes on in $v^{(t)}$ but off in v . Since $b_{(c,v)} = -(k - 0.5)\beta$ if $v \neq v^{(t)}$, then either $a < k$, in which case $\sum_i v_i^{(t)} w_{i,(c,v)} + b_{(c,v)} \leq -0.5\beta$, or $a = k$ and $b \geq 1$, which again implies $\sum_i v_i^{(t)} w_{i,(c,v)} + b_{(c,v)} \leq -0.5\beta$. If $v = v^{(t)}$ then $a\beta - b\beta + b_{(c,v)} = k\beta - (k - 0.5)\beta = 0.5\beta$. Thus if $v = v^{(t)}$,

$$\sigma \left(\sum_i v_i^{(t)} w_{i,(c,v)} + b_{(c,v)} \right) = \sigma(0.5\beta).$$

Otherwise

$$\sigma \left(\sum_i v_i^{(t)} w_{i,(c,v)} + b_{(c,v)} \right) \leq \sigma(-0.5\beta).$$

So as $\beta \rightarrow \infty$, $P(H_{c,v}^{(t)} | v^{(t)}, \dots, v^{(0)}) \rightarrow 1$. In other words, for all $v^{(t)}, \dots, v^{(0)}$ and all $\epsilon_0 > 0$ there exists some β_0 such that $\beta > \beta_0$ implies $|1 - P(H_{c,v}^{(t)} | v^{(t)}, \dots, v^{(0)})| = P(\bar{H}_{c,v}^{(t)} | v^{(t)}, \dots, v^{(0)}) < \epsilon_0$.

Step 2:

Here we show that by making β large enough we can make the effect of the control nodes on the visible distribution at the same time step negligible. Take any $v^{(t)}$, for all $h^{(t-1)}$, we have

$$\begin{aligned} P(v^{(t)} | h^{(t-1)}) &= \frac{P(v^{(t)} | h^{(t-1)})}{\sum_{v^{(t)}} P(v^{(t)} | h^{(t-1)})} \\ &= \frac{\sum_{h^{(t)} \in \bar{H}_{c,v}^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)}) + \sum_{h^{(t)} \in H_{c,v}^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})}{\sum_{v^{(t)}} \sum_{h^{(t)} \in \bar{H}_{c,v}^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)}) + \sum_{v^{(t)}} \sum_{h^{(t)} \in H_{c,v}^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})}. \end{aligned} \quad (1)$$

We also have that $P(v^{(t)}, h^{(t)} | h^{(t-1)}) = P(h^{(t)} | v^{(t)}, h^{(t-1)}) P(v^{(t)} | h^{(t-1)})$ for all $h^{(t)}, v^{(t)}$ and by definition

$$\sum_{h^{(t)} \in \bar{H}_{c,v}^{(t)}} P(h^{(t)} | v^{(t)}, h^{(t-1)}) P(v^{(t)} | h^{(t-1)}) = P(\bar{H}_{c,v}^{(t)} | v^{(t)}, h^{(t-1)}) P(v^{(t)} | h^{(t-1)}).$$

By Step 1, there exists a β_0 such that for any $\beta > \beta_0$ we have $P(\bar{H}_{c,\alpha^{(t)}}^{(t)} | v^{(t)}, \dots, v^{(0)}) < \epsilon_0$ for all $v^{(t)}, \dots, v^{(t-1)}$. Since the only connections going to a control node are from the visible units, given $v^{(t)}$, the state of the control nodes are conditionally independent of $v^{(t-1)}, \dots, v^{(0)}$ and $h^{(t-1)}$. Since $P(v^{(t)} | h^{(t-1)}) < 1$, we have that $\beta > \beta_0$ implies that $P(\bar{H}_{c,\alpha^{(t)}}^{(t)} | v^{(t)}, h^{(t-1)}) P(v^{(t)} | h^{(t-1)}) < \epsilon_0$, giving us that for $\beta > \beta_0$ and all $v^{(t)}$,

$$\sum_{h^{(t)} \in H^{(t)}} \sum_{c,\alpha^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)}) < \epsilon_0. \quad (2)$$

Note that this inequality is independent of α . Increasing α has no effect on $P(\bar{H}_{c,\alpha^{(t)}}^{(t)} | v^{(t)}, h^{(t-1)})$ and $P(v^{(t)} | h^{(t-1)})$ is bounded above by 1 so even after increasing α arbitrarily the inequality will hold with the same choice of β . Looking back to equation (1), as $\beta \rightarrow \infty$ the right hand terms in both the numerator and denominator go to 0. Consider $\sum_{h^{(t)} \in H^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})$. For all $v^{(t)}$, this is bounded above by 1 and since we are

summing over $h^{(t)} \in H^{(t)}$, Step 1 tells us this is strictly increasing in β . This tells us that limit of the numerator and denominator of (1) are both finite and non-zero giving us that

$$\lim_{\beta \rightarrow \infty} P(v^{(t)} | h^{(t-1)}) = \lim_{\beta \rightarrow \infty} \frac{\sum_{h^{(t)} \in H^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})}{\sum_{v^{(t)} \in H^{(t)}} \sum_{c,\alpha^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})}.$$

Define

$$\begin{aligned} \tilde{P}(v^{(t)} | h^{(t-1)}) &:= \frac{\sum_{h^{(t)} \in H^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})}{\sum_{v^{(t)} \in H^{(t)}} \sum_{c,\alpha^{(t)}} P(v^{(t)}, h^{(t)} | h^{(t-1)})} \\ &= \sum_{h^{(t)} \in H^{(t)}} \exp \left(\sum_{i,j,h_j \in (H \setminus H_c)} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_{j,h_j \in (H \setminus H_c)} b_j h_j^{(t)} + 0.5\beta + \sum_{i,j} h_i^{(t)} h_j^{(t-1)} w'_{i,j} \right) \\ &= \sum_{v^{(t)} \in H^{(t)}} \sum_{c,\alpha^{(t)}} \exp \left(\sum_{i,j,h_j \in (H \setminus H_c)} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_{j,h_j \in (H \setminus H_c)} b_j h_j^{(t)} + \sum_{i,j} h_i^{(t)} h_j^{(t-1)} w'_{i,j} \right) \\ &= \frac{\sum_{h^{(t)} \in H^{(t)}} \exp \left(\sum_{i,j,h_j \in (H \setminus H_c)} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_{j,h_j \in (H \setminus H_c)} b_j h_j^{(t)} + \sum_{i,j} h_i^{(t)} h_j^{(t-1)} w'_{i,j} \right)}{\sum_{v^{(t)} \in H^{(t)}} \sum_{c,\alpha^{(t)}} \exp \left(\sum_{i,j,h_j \in (H \setminus H_c)} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_{j,h_j \in (H \setminus H_c)} b_j h_j^{(t)} + \sum_{i,j} h_i^{(t)} h_j^{(t-1)} w'_{i,j} \right)}, \end{aligned}$$

but this is just the probability of $v^{(t)}$ when we remove the control nodes. Thus for any $v^{(t)}$ and $\epsilon_1 > 0$ there exists a β_0 such that $\beta > \beta_0$ implies that for all $h^{(t-1)}$, $|P(v^{(t)} | h^{(t-1)}) - \tilde{P}(v^{(t)} | h^{(t-1)})| < \epsilon_1$. Furthermore, this is unchanged by increasing α .

Step 3:

In this step, remembering that P_v is the distribution of the RBM corresponding to $R_{h_1} \cdot (v^{(t-1)} = v)$, we show that as α and β are increased to infinity, if $h^{(t-1)} \in H_{c,v}^{(t-1)}$ then $P(v^{(t)} | h^{(t-1)}) \rightarrow P_v(v^{(t)})$ for all $v^{(t)}$. First note that since the states of any two hidden nodes at time t are independent, $P(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)}) = \tilde{P}(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)})$. Here \tilde{P} is the system without control nodes, defined in the previous step. Take any $v^{(t)}$ and consider some configuration $h^{(t-1)} \in H_{c,v}^{(t-1)}$. We have $h_{c,v}^{(t-1)} = 0$ for all $v' \neq v$ and $w_{j(c,v)} = 0$ for $h_j \in H_v$, giving us

$$\tilde{P}(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)}) = \sigma \left(\sum_i v_i^{(t)} w_{i,j} + b_j \right).$$

This is $P_v(h_j^{(t)} = 1 | v^{(t)})$. Now take a hidden unit $h_j \in H_{v'}$ with $v' \neq v$. Since $v' \neq v$ and $h^{(t-1)} \in H_{c,v}^{(t-1)}$, then $h_{c,v}^{(t-1)} = 1$ and $w_{j(c,v)} = -\alpha$. This gives us

$$\tilde{P}(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)}) = \sigma \left(\sum_i v_i^{(t)} w_{i,j} + b_j - \alpha \right).$$

Since h_j is not a control node, $w_{i,j}$ is fixed for all v_i . Thus as $\alpha \rightarrow \infty$, $\tilde{P}(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)}) \rightarrow 0$. So for any $\epsilon_0 > 0$ there exists α_0 such that $\alpha > \alpha_0$ implies that if $h_j \in H_{v'}$ with $v' \neq v$, $|\tilde{P}(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)})| < \epsilon_0$. Now we have

$$\begin{aligned} \tilde{P}(v^{(t)} | h^{(t-1)}) &= \sum_{h^{(t)} \in (H \setminus H_c)^{(t)}} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)}) \\ &= \sum_{h^{(t)} \in H_c^{(t)}} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)}) + \sum_{h^{(t)} \in ((H \setminus H_c)^{(t)} \setminus H_c^{(t)})} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)}). \end{aligned} \quad (3)$$

Note that $\tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)}) = \tilde{P}(h^{(t)} | v^{(t)}, h^{(t-1)}) \tilde{P}(v^{(t)} | h^{(t-1)}, h_j^{(t)})$ and $h_j^{(t)}$ are independent for all i, j , and $\tilde{P}(v^{(t)} | h^{(t-1)}) < 1$. Thus we have that $\alpha > \alpha_0$ implies that if $h^{(t)} \in (H \setminus H_c)^{(t)} \setminus H_c^{(t)}$, then $\tilde{P}(h^{(t)} | v^{(t)}, h^{(t-1)}) \tilde{P}(v^{(t)} | h^{(t-1)}) < \epsilon_0$. So as $\alpha \rightarrow \infty$, the right hand term of (3) goes to 0. So for any ϵ_1 there exists an α_1 such that $\alpha > \alpha_1$ implies $|\tilde{P}(v^{(t)} | h^{(t-1)}) - \sum_{h^{(t)} \in H_c^{(t)}} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)})| < \epsilon_1$. Note that since there are a finite number

of configurations, $v^{(t)}$, we can take α large enough so that this is true for all $v^{(t)}$. So for any ϵ_1 we can choose $\alpha > \alpha_1$ so that

$$\left| \tilde{P}(v^{(t)} | h^{(t-1)}) - \frac{\sum_{h^{(t)} \in H_c^{(t)}} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)})}{\sum_{v^{(t)}, h^{(t)} \in H_c^{(t)}} \tilde{P}(v^{(t)}, h^{(t)} | h^{(t-1)})} \right| < \epsilon_1,$$

but we have

$$\begin{aligned} \frac{\sum_{h^{(t)} \in H_v^{(t)}} \tilde{P}(v^{(t)}, h^{(t)}) |h^{(t-1)}|}{\sum_{v^{(t)}, h^{(t)} \in H_v^{(t)}} \tilde{P}(v^{(t)}, h^{(t)}) |h^{(t-1)}|} &= \frac{\sum_{h^{(t)} \in H_v^{(t)}} \exp\left(\sum_{i,j} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_j b_j h_j^{(t)}\right)}{\sum_{v^{(t)}, h^{(t)} \in H_v^{(t)}} \exp\left(\sum_{i,j} v_i^{(t)} h_j^{(t)} w_{i,j} + \sum_j b_j h_j^{(t)}\right)} \\ &= P_v(v^{(t)}). \end{aligned}$$

To summarize, Step 3 tells us that for any given $v^{(t)}$ and all $h^{(t-1)} \in H_{c,v}^{(t-1)}$ and any $\epsilon_1 > 0$, there exists α_1 such that $\alpha > \alpha_1$ implies that $|\tilde{P}(v^{(t)}) |h^{(t-1)}| - P_v(v^{(t)})| < \epsilon_1$.

Step 4:

Finally, we must also be able to approximate the initial distribution R_0 to arbitrary precision. We know there is an RBM H_0 with visible biases 0 whose Boltzmann distribution can approximate R_0 to a certain precision. Include this machine in our TRBM. Now we define the initial biases. Let $b_{i,init} = \gamma$ for every $h_i \in H_0$ and $b_{c,v,init} = 0$ for all (c, v) . Set $b_{i,init} = -\gamma$ for all other hidden nodes. Add $-\gamma$ to the biases of H_0 . Call the distribution of this modified machine \tilde{P} . By Step 2, for any $v^{(t)}$, and any $\epsilon_0 > 0$, there exists β_0 such that $\beta > \beta_0$ implies $|\tilde{P}_0(v^{(t)}, h^{(0)}) - \tilde{P}_0(v^{(t)}, h^{(0)})| < \epsilon_0$. If $h_k \in H_v$ for some v , we have

$$\tilde{P}_0(h_k^{(0)}) = 1|v^{(0)}| = \sigma\left(\sum_i v_i^{(0)} w_{i,k} + b_k - \gamma\right),$$

and for $h_j \in H_0$ we have

$$\tilde{P}_0(h_j^{(0)}) = 1|v^{(0)}| = \sigma\left(\sum_i v_i^{(0)} w_{i,j} + b_j\right).$$

Note that \tilde{P}_0 does not depend on α or β . Following the same logic as in Step 3, for any $\epsilon_0 > 0$, there exists γ_0 such that $\gamma > \gamma_0$ implies $\tilde{P}_0(v^{(0)}, h^{(0)}) < \epsilon_0$ if $h^{(0)} \in (H \setminus H_c)^{(t)} \setminus H_0^{(t)}$ for some H_v . So for all $v^{(t)}$, $\tilde{P}_0(v^{(0)})$ can be made arbitrarily close to the probability of $v^{(0)}$ in the Boltzmann distribution of H_0 , which by construction approximates R_0 . At subsequent time steps, for each $h_j \in H_0$ we have $P(h_j^{(t)}) = 1|h^{(t-1)}, v^{(t)}| = \sigma(\sum_i w_{i,j} v_i^{(t)} + b_j - \gamma)$. This can be made arbitrarily close to 0 by making γ arbitrarily large, so $P(h_j^{(t)}) = 1, v^{(t)} |h^{(t-1)}$ can be made arbitrarily close to 0. Thus for any $\epsilon_0 > 0$ there exists γ_1 such that $\gamma > \gamma_1$ implies

$$|\tilde{P}(v^{(t)}) |h^{(t-1)}| - \sum_{h^{(t)} \notin H_0^{(t)}} \tilde{P}(v^{(t)}, h^{(t)}) |h^{(t-1)}| < \epsilon_0. \quad (4)$$

But since γ does not appear anywhere else for $t > 0$, $\sum_{h^{(t)} \notin H_0^{(t)}} \tilde{P}(v^{(t)}, h^{(t)}) |h^{(t-1)}| = P(v^{(t)}) |h^{(t-1)}$.

Note that this construction allows the control nodes to be active in the first time step and to transmit temporal data without disturbing the initial distribution.

Now we put the four steps together. Given an arbitrary $0 < t < T$, we can write each $P(v^{(t)}) |v^{(t-1)}, \dots, v^{(0)}$ as

$$\begin{aligned} &\sum_{h^{(t-1)}} P(v^{(t)}, h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)} \\ &= \sum_{h^{(t-1)}} P(v^{(t)}) |h^{(t-1)}, v^{(t-1)}, \dots, v^{(0)} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)} \\ &= \sum_{h^{(t-1)}} P(v^{(t)}) |h^{(t-1)} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}. \end{aligned}$$

Step 1 tells us that if $h^{(t-1)} \notin H_{c,v}^{(t-1)}$, then $\lim_{\beta \rightarrow \infty} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| = 0$. Step 2 tells us that $\lim_{\beta \rightarrow \infty} P(v^{(t)}) |h^{(t-1)}| = \tilde{P}(v^{(t)}) |h^{(t-1)}|$. Since P is continuous in terms of β , for any ϵ_1 , there exists β_0 such that $\beta > \beta_0$ implies

$$\begin{aligned} &|\sum_{h^{(t-1)}} P(v^{(t)}) |h^{(t-1)} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| \\ &= \sum_{h^{(t-1)} \in H_{c,v}^{(t-1)}} \tilde{P}(v^{(t)}) |h^{(t-1)} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| < \epsilon_1. \end{aligned} \quad (5)$$

Step 3 tells us that for any $\epsilon_0 > 0$, there exists an α_0 such that for all $h^{(t-1)} \in H_{c,v}^{(t-1)}$, if $\alpha > \alpha_0$ we have $|\tilde{P}(v^{(t)}) |h^{(t-1)}| - P_v(v^{(t)}) |v^{(t-1)}| < \epsilon_0$. So for any ϵ_1 , there exists an α_0 such that $\alpha > \alpha_0$ implies

$$\begin{aligned} &|\sum_{h^{(t-1)} \in H_{c,v}^{(t-1)}} \tilde{P}(v^{(t)}) |h^{(t-1)} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| \\ &= P_v(v^{(t-1)}) |v^{(t)}| \sum_{h^{(t-1)} \in H_{c,v}^{(t-1)}} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| < \epsilon_1. \end{aligned} \quad (6)$$

Again by Step 1, as β goes to infinity, $\sum_{h^{(t-1)} \in H_{c,v}^{(t-1)}} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| \rightarrow 1$, so for any ϵ_1 there exists β_1 such that $\beta > \beta_1$ implies that

$$|P_v(v^{(t-1)}) |v^{(t)}| \sum_{h^{(t-1)} \in H_{c,v}^{(t-1)}} P(h^{(t-1)}) |v^{(t-1)}, \dots, v^{(0)}| - P_v(v^{(t-1)}) |v^{(t)}| < \epsilon_1. \quad (7)$$

Now take any $\epsilon_2 > 0$ and take $\epsilon_1 < \epsilon_2/4$ with corresponding $\beta_0, \beta_1, \alpha_0$ so that the inequalities in (5), (6) and (7) hold. Then from Step 4 there exist γ_0, β_2 such that $\gamma > \gamma_0$ and $\beta > \beta_2$ implies that (4) holds. Then taking $\beta > \max(\beta_0, \beta_1, \beta_2)$, $\alpha > \alpha_0$, $\gamma > \gamma_0$ and applying the triangle inequality to (4), (5), (6), and (7) we have that $|\tilde{P}(v^{(t)}) |v^{(t-1)}, \dots, v^{(0)}| - P_v(v^{(t-1)}) |v^{(t)}| < \epsilon_2$. Since there are a finite number of configurations $v^{(t)}, v^{(t-1)}, \dots, v^{(0)}$, we can choose α, β, γ so that this holds for all $v^{(t)}, v^{(t-1)}, \dots, v^{(0)}$ and by construction, $KL(R(\cdot |v^{(t-1)})) |P_{v^{(t-1)}}| < \epsilon$

for some arbitrarily chosen ϵ . Since the KL -divergence as a function of α , β , and γ is continuous, for any $\epsilon' > 0$ we can find $\alpha_1, \beta_2, \gamma_1$ such that $\alpha > \alpha_1$, $\beta > \beta_2$, $\gamma > \gamma_1$ implies that $|KL(R(\cdot|v^{(t-1)}))|P(\cdot|v^{(t-1)}, \dots, v^{(0)}) - KL(R(\cdot|v^{(t-1)}))|P_{\epsilon'}(\cdot|v^{(t-1)})| < \epsilon'$. And $KL(R(\cdot|v^{(t-1)}))|P_{\epsilon'}(\cdot|v^{(t-1)})| < \epsilon$ for some arbitrarily chosen ϵ . So we can choose parameters such that $KL(R(\cdot|v^{(t-1)}))|P(\cdot|v^{(t-1)}, \dots, v^{(0)})| < \epsilon$. By the same argument, Step 4 tells us that we can choose parameters so that $KL(R_0||P_0) < \epsilon$. Thus by Lemma 1 the result holds. ■

Note that following the remark after the proof of Lemma 1, if we have a TRBM which approximates R over T time steps to a certain precision, it also approximates R over $t < T$ time steps to at least the same precision since the construction satisfies the conditions of Lemma 1.

2.2 The Generalized TRBM

The TRBM used in the previous section is a restricted instance of a more generalized model described by Sutskever et al. (2006). In the full model we allow explicit long-term hidden-hidden connections as well as long-term visible-visible connections. In this paper we will not consider models with visible-visible temporal interaction. From a practical standpoint any learning algorithm operating on a class of models with visible-visible interactions would be able to make those connections arbitrarily small if it helped, so in practice the class of models with visible-visible temporal connections is bigger than the one without any. The generalized TRBM is given by

$$P(v^{(t)}, h^{(t)}|h^{(t-1)}, \dots, h^{(0)}) \\ = \frac{\exp(v^{(t)\top} W h^{(t)} + c^\top v^{(t)} + b^\top h^{(t)} + h^{(t)\top} W^{(1)} h^{(t-1)} + \dots + h^{(t)\top} W^{(m)} h^{(t-m)})}{Z(h^{(t-1)}, \dots, h^{(0)})},$$

$$P(v^{(t)}, h^{(t)}|h^{(t-1)}, \dots, h^{(0)}) \\ \times P_0(v^{(0)}, h^{(0)}),$$

$$P(v^{(t)}, h^{(t)}|h^{(t-1)}, \dots, h^{(t-m)}) \\ = \left(\prod_{i=m}^{t-1} P(v^{(i)}, h^{(i)}|h^{(i-1)}, \dots, h^{(t-m)}) \right) \left(\prod_{i=1}^{m-1} P(v^{(i)}, h^{(i)}|h^{(i-1)}, \dots, h^{(0)}) \right)$$

where we have a finite number of weight matrices $W^{(i)}$ used to determine the bias at time t . We replace $W^{(k)} h^{(t-k)}$ with an initial bias $b_{init}^{(k)}$ if $k > t$. The distribution $P(v^{(t)}, h^{(t)})$ is then given by

$$P(v^{(t)}, h^{(t)}|h^{(t-1)}, \dots, h^{(0)}) \\ \times P_0(v^{(0)}, h^{(0)}),$$

If we drop the restriction that R be a Markov chain we can generalize the previous theorem so that R is any distribution homogeneous in time with a finite time dependence.

Theorem 2: *Let R be a distribution over a sequence of length T of binary vectors of length n that is time homogeneous and has finite time dependence. For any $\epsilon > 0$ there exists a generalized TRBM, P , such that $KL(R||P) < \epsilon$.*

Proof: The initial part of the proof is identical to the proof of Theorem 1. Let m be the time dependence of R . Then for each visible sequence $v^{(t-1)}, \dots, v^{(t-m)}$ we construct a TRBM P by adding sets of hidden units $H_{v^{(t-1)}, \dots, v^{(t-m)}}$ with parameters chosen to approximate $R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)})$. Note that although the indices here are written as $v^{(t-1)}, \dots, v^{(t-m)}$,

they do not depend on the time step t . Rather, there is one set of hidden nodes added for each configuration of an m -length sequence of visible nodes. The superscripts are added to distinguish different vectors in the sequence as well as emphasize how the connections should be made.

For each visible configuration v we add a control unit $h_{c,v}$ with the same bias and visible-hidden connections (determined by a parameter β) as in the construction for Theorem 1. If $i \leq m$, define the i -step temporal connections as $w_{(c,v)j}^{(i)} = -\alpha$, if $h_j \in H_{v^{(t-1)}, \dots, v^{(t-m)}}$ with $v^{(t-i)} \neq v$ and 0 otherwise. All other temporal connections are set to 0. Then repeating Step 1, Step 2, and Step 3 in Theorem 1, by making α and β sufficiently large we can make $KL(R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)}))|P(\cdot|v^{(t-1)}, \dots, v^{(0)})|$ arbitrarily small for all $v^{(t)}$.

To finish the proof we must modify the machine to approximate the m initial distributions as well. In practice, one could train an RBM with the first m time steps as input in order to simulate the initial distribution. In this case the remainder of the proof is identical to step 4 of Theorem 1. The proof for the general TRBM as defined above is more intricate. In order to simulate the initial distributions with the general TRBM, first set $b_{init}^{(k)}$ to $-\gamma$ for each node $h \in H_{v^{(t-1)}, \dots, v^{(t-m)}}$ and all k , and set $b_{init}^{(k)}$ to 0 for every control node. Now for each sequence $v^{(t-1)}, \dots, v^{(0)}$ with $i < m$ add a set of hidden units $H_{v^{(t-1)}, \dots, v^{(0)}}$ to approximate $R_{0,i}(\cdot|v^{(t-1)}, \dots, v^{(0)})$ to a certain precision. For each i , call the set of all of these hidden units $H_{(i)}$. Connect each of these sets to the control nodes in the same way as done previously. In other words if $h_j \in H_{v^{(t-1)}, \dots, v^{(0)}}$ then $w_{j(c,v)}^{(l)} = -\alpha$ if $v^{(t-l)} \neq v$ and 0 otherwise. Add $-\gamma$ to the bias of each h_j if $h_j \in H_{(i)}$ for some i . For each $h_j \in H_{(i)}$ let $b_{init}^{(l)} = -\gamma$ for $l \neq i$ and $b_{init}^{(i)} = (m - i + 2)\gamma$.

Start by choosing β so that $|P(v^{(i)}|v^{(i-1)}, \dots, v^{(0)}) - \tilde{P}(v^{(i)}|v^{(i-1)}, \dots, v^{(0)})| < \epsilon_0$. This can be done for any $\epsilon_0 > 0$ by the argument in Theorem 1 Step 2. Now for time $l < m$, for any non-control node $h_j \notin H_{(i)}$, and all $h^{(l-1)}, \dots, h^{(0)}$, $\tilde{P}(h_j^{(l)} = 1|v^{(l-1)}, \dots, h^{(0)}) \leq \sigma \sum w_{i,j} v_i^{(l)} + b_j - \gamma$. This tends to 0 as $\gamma \rightarrow \infty$. So for any $\epsilon_1 > 0$, the argument in Theorem 1 Step 3 tells us we can choose γ large enough so that

$$|P(v^{(l)}|v^{(l-1)}, \dots, v^{(0)}) - \sum_{h^{(0)} \in H_{(i)}^{(0)}} \tilde{P}(v^{(l)}|v^{(l-1)}, \dots, v^{(0)})| < \epsilon_1. \quad (8)$$

Furthermore if $h_j \in H_{(i)}$ then

$$\tilde{P}(h_j^{(l)} = 1|v^{(l-1)}, \dots, h^{(0)})$$

$$= \sigma \left(\sum_i w_{i,j} v_i^{(l)} + b_j + (m - i + 2)\gamma - (m - i + 2)\gamma + \sum_i w_{i,j}^{(1)} h_i^{(l-1)} + \dots + \sum_i w_{i,j}^{(l)} h_i^{(0)} \right) \\ = \sigma \left(\sum_i w_{i,j} v_i^{(l)} + b_j + \sum_i w_{i,j}^{(1)} h_i^{(l-1)} + \dots + \sum_i w_{i,j}^{(l)} h_i^{(0)} \right).$$

So $\sum_{h^{(l)} \in H^{(l)}} \tilde{P}(v^{(l)}, h^{(l)} | v^{(l-1)}, \dots, v^{(0)})$ does not depend on γ . Using the same argument as in Step 3 of Theorem 1, for all $\epsilon_1 > 0$ there exists α_0 so that $\alpha > \alpha_0$ implies that

$$| \sum_{h^{(l)} \in H^{(l)}} \tilde{P}(v^{(l)}, h^{(l)} | v^{(l-1)}, \dots, v^{(0)}) - \sum_{h^{(l)} \in H_{\epsilon} \setminus H_{(0)}} \tilde{P}(v^{(l)}, h^{(l)} | v^{(l-1)}, \dots, v^{(0)}) | < \epsilon_1.$$

But the second term is just the probability of $v^{(l)}$ under the Boltzmann distribution of $H_{v^{(l-1)}, \dots, v^{(0)}}$, so using continuity of the KL-divergence along with the triangle inequality gives us the second and third condition for Lemma 1. Finally note that for $t \geq m$, if $h_j \in H^{(t)}$ for any l and all $h^{(l-1)}, \dots, h^{(l-m)}$, $P(h_j^{(t)} = 1 | v^{(t)}, h^{(t-1)}, \dots, h^{(l-m)}) \leq \sigma(\sum w_{i,j} v_i^{(t)} + b_j - \gamma)$. So for any ϵ_1 , we can take γ large enough such that

$$| \tilde{P}(v^{(t)} | v^{(t-1)}, \dots, v^{(0)}) - \sum_{h^{(l)} \in (H \setminus H_{\epsilon}) \setminus H_{(0)}} \tilde{P}(v^{(t)}, h^{(l)} | v^{(t-1)}, \dots, v^{(0)}) | < \epsilon_1. \quad (9)$$

Since for $t \geq m$, γ does not appear anywhere in the second term, this leaves us with the machine described in the first part of the proof, thus the first condition for Lemma 1 also holds. ■

3. Universal Approximation Results for the Recurrent Temporal Restricted Boltzmann Machines

The TRBM gives a nice way of using a Boltzmann Machine to define a probability distribution that captures time dependence in data, but it turns out to be difficult to train in practice (Sutskever et al., 2008). To fix this, a slight variation of the model, the RTRBM, was introduced. The key difference between the TRBM and the RTRBM is the use of deterministic real values denoted $h^{(t)}$. We will denote the probabilistic binary hidden units at time t by $h^{(t)}$. The distribution defined by an RTRBM, Q , is

$$Q(v^T, h^T) = \left(\prod_{k=1}^{T-1} Q(v^{(k)}, h^{(k)} | h^{(k-1)}) \right) Q_0(v^{(0)}, h^{(0)}).$$

Here $Q(v^{(t)}, h^{(t)} | h^{(t-1)})$ is defined as

$$Q(v^{(t)}, h^{(t)} | h^{(t-1)}) = \frac{\exp(v^{(t)\top} W h^{(t)} + c^\top v^{(t)} + b^\top h^{(t)} + h^{(t)\top} W' h^{(t-1)})}{Z(h^{(t-1)})},$$

and h^T is a sequence of real-valued vectors defined by

$$\begin{aligned} h^{(0)} &= \sigma(W v^{(0)} + W' h^{(0)} + b), \\ h^{(0)} &= \sigma(W v^{(0)} + b_{\text{init}} + b), \end{aligned} \quad (10)$$

where σ is the logistic function and b_{init} is an initial bias. Q_0 is once again an initial distribution defined as a Boltzmann Distribution with bias $b + b_{\text{init}}$. The difference between

the RTRBM and the TRBM is the use of the sequence of real valued vectors h^T for the temporal connections. At each time step each hidden node h_i takes on two values, a deterministic $h_i^{(t)}$ and a probabilistic $h_i^{(t)}$. The fact that the temporal parameters are calculated deterministically makes learning more tractable in these machines (Sutskever et al., 2008).

Theorem 3: *Let R be a distribution over a sequence of length T of binary vectors of length n that is time homogeneous and has finite time dependence. For any ϵ there exists an RTRBM, Q , such that $KL(R||Q) < \epsilon$.*

Proof: As in Theorem 2, for each configuration $v^{(t-1)}, \dots, v^{(l-m)}$, include hidden units $H_{v^{(t-1)}, \dots, v^{(l-m)}}$ with parameters so that the KL distance between the visible distribution of the Boltzmann machine given by $H_{v^{(t-1)}, \dots, v^{(l-m)}}$ with these parameters and the distribution $R_1(\cdot | v^{(t-1)}, \dots, v^{(l-m)})$ is less than ϵ' . Now for each possible visible configuration v add the control node $h_{c,v}$ with the same biases and visible-hidden weights as in Theorems 1 and 2 (determined entirely by parameter β). In Theorem 2, $h_{c,v}$ had i -step temporal connections from $h_{c,v}$ to every $H_{v^{(t-1)}, \dots, v^{(l-m)}}$ with $v^{(l-t)} \neq v$. The proof will proceed by showing that each of these i -step temporal connections can instead be given by a chain of nodes in the RTRBM. We wish to show that we can add i hidden units connecting $h_{c,v}$ to every hidden node in $H_{v^{(t-1)}, \dots, v^{(l-m)}}$ such that if $h_{c,v}$ is on at time $t-i$, it will have the same effect on the distribution of a node in $H_{v^{(t-1)}, \dots, v^{(l-m)}}$ as it does in the general TRBM, and the i additional hidden units do not effect the visible distribution. If we can achieve this then the same proof will hold for the RTRBM. This will be done as follows.

For each $h_{c,v}$ and each $1 \leq k < m$, add an additional hidden unit with 0 bias and no visible-hidden connections. For each $h_{c,v}$, label these $m-1$ hidden units $g_{(v,1)}, \dots, g_{(v,m-1)}$. Since these nodes have no visible-hidden connections they have no effect on the visible distribution at the current time step. For $1 < k < m-1$, let $w'_{(v,k),(v,k+1)} = 1$. Let $w'_{(c,v),(v,1)} = 1$ and $w'_{(v,k),j} = -\alpha$ if $h_j \in H_{v^{(t-1)}, \dots, v^{(t-k-1)}, \dots, v^{(l-m)}}$ with $v^{(t-k-1)} \neq v$, and $w'_{(v,k),j} = 0$ otherwise (see Fig. 2). Given a sequence $v^{(t-1)}, \dots, v^{(l-m)}$, consider the probability that $h_j^{(t)} = 1$ for some hidden unit $h_j \in H_{v^{(t-1)}, \dots, v^{(l-m)}}$ where $v^{(t-k)} \neq v^{(t-k)}$ for some k . Then by construction there is some hidden node g_{k-1} with $w'_{(v,k-1),j} = -\alpha$. The value of $g_{k-1}^{(t-1)}$ is calculated recursively by $g_{k-1}^{(t-1)} = \sigma(g_{k-2}^{(t-2)}) = \sigma^{k-1}(h_{c,v}^{(t-k)}) = \sigma^k(0.5\beta)$. Since k is bounded, by making β arbitrarily large we make g_{k-1} arbitrarily close to 1 and thus make $h_j^{(t)}$ $w'_{(v,k-1),j} g_{k-1}^{(t-1)}$ arbitrarily close to $-\alpha$.

Now suppose we have $h_j^{(t')} = 1$ for some hidden unit in $H_{v^{(t-1)}, \dots, v^{(l-m)}}$. Then every temporal connection is $-\alpha$, and $g_{(v,k)}^{(t-1)} = \sigma^k(-0.5\beta)$ for every $g_{(v,k)}$, so again by making β arbitrarily large we make the temporal terms arbitrarily close to 0. Thus as $\beta \rightarrow \infty$, the temporal terms from $h_{c,v}^{(t')}$ are either $-\alpha$ or 0 as needed.

We know from Theorem 2 that we can construct a TRBM with distribution P such that for $t \geq m$ and all $v^{(t)}$, $|P(v^{(t)} | v^{(t-1)}, \dots, v^{(0)}) - R(v^{(t)} | v^{(t-1)}, \dots, v^{(l-m)})| < \epsilon$ for any $\epsilon > 0$. The above argument shows that we can construct an RTRBM by replacing the connections $w_{(c,v),j}^{(t)}$ in the TRBM with the chain described above so that for any $\epsilon' > 0$

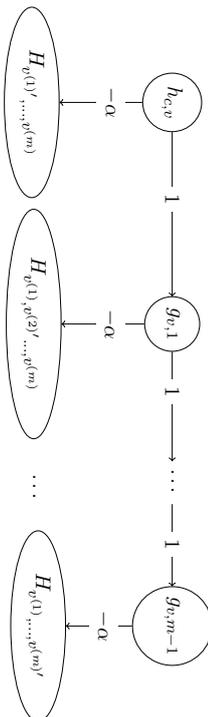

Figure 2: The temporal connections of a control node. Each $g_{c,i}$ connects to every $H_{v^{(i)}, \dots, v^{(m)}}$ with $v^{(i+1)} \neq v$ and $h_{c,v}$ connects to every $H_{v^{(1)}, v^{(2)}, \dots, v^{(m)}}$ with $v^{(1)} \neq v$.

there exist α_0, β_0 such that $\alpha > \alpha_0$ and $\beta > \beta_0$ imply that for all $v^{(t)}$ with $t \geq m$, $|\bar{Q}(v^{(t)}|v^{(t-1)}, \dots, v^{(0)}) - P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})| < \epsilon'$. Note that since the chains are of length m , Q only depends on the previous m visible configurations. Then, once again applying the triangle inequality and continuity of the KL-divergence we can satisfy the first condition of Lemma 1.

To finish the proof our machine must also be able to approximate the initial m distributions. Again this could be easily done should we choose to use an RBM to approximate the distribution of the first m time step. Instead we provide a construction to simulate the first m distributions in the RTRBM using the definition given above. As before we will use the construction of Theorem 2 and replace the long-term temporal connections with a chain. To begin, add each $H^{(i)}$ described in Theorem 2 with the temporal connections again replaced by the chains described in the above step. Now we just need to replace the m initial biases. First add $-\gamma$ to the bias of each node in $H^{(i)}$. Add hidden units l_0, \dots, l_{m-1} with connections between them $w^{(i,j)}(l_{i+1}) = \delta$ and biases $-\delta$ for l_0, l_1 and -0.5δ for l_2, \dots, l_{m-1} . For every $i > 0$, define the temporal connections to be 2γ from l_i to every node in $H^{(i)}$ and -2γ to every node in $H_{v^{(i-1)}, \dots, v^{(i-m)}}$ for all $v^{(i-1)}, \dots, v^{(i-m)}$. Now set the initial biases for every l_i to be 0 except for l_0 . Set this initial bias to be 2δ . Define the initial bias for every other non-control node to be $-\delta$ with the exception of $H^{(0)}$ whose initial bias is 0 (see Fig 3).

First we calculate the values $l_i^{(t)}$. Since l_0 has bias of $-\delta$ and initial bias of 2δ , we have $l_0^{(0)} = \sigma(\delta)$, and $l_1^{(1)} = \sigma(\delta\sigma(\delta) - \delta)$. Taking the limit as $\delta \rightarrow \infty$ we have $l_0^{(0)} = 1$ and

$$\lim_{\delta \rightarrow \infty} l_1^{(1)} = \lim_{\delta \rightarrow \infty} \sigma(\delta(\sigma(\delta) - 1)) = \lim_{\delta \rightarrow \infty} \sigma\left(\frac{-\delta}{1 + \exp(\delta)}\right) = \sigma(0) = 0.5.$$

Next we calculate the limit of $l_2^{(2)}$ as $\delta \rightarrow \infty$:

$$\lim_{\delta \rightarrow \infty} l_2^{(2)} = \lim_{\delta \rightarrow \infty} \sigma(\delta l_1^{(1)} - 0.5\delta) = \lim_{\delta \rightarrow \infty} \sigma\left(\frac{\delta}{l_1^{(1)} - 0.5}\right) = \lim_{\delta \rightarrow \infty} \sigma\left(\frac{-(l_1^{(1)} - 0.5)^2}{\frac{\delta}{l_1^{(1)}}}\right).$$

Note that $\frac{\delta}{l_1^{(1)}}$ is finite and non-zero, so evaluating the limit we get $\lim_{\delta \rightarrow \infty} l_2^{(2)} = \sigma(0) = 0.5$. Then by induction $l_j^{(j)} = 0.5$ for $i > 1$. Now we look at the case where $j \neq i$. For $j > 0$

we have $l_0^{(j)} = \sigma(-\delta)$, $l_1^{(j+1)} = \sigma(l_0^{(j)} - \delta)$ and $l_k^{(j+k)} = \sigma(l_{k-1}^{(j+k-1)} - 0.5\delta)$ for $k > 1$. So for $j > i$ we have in the limit that $l_j^{(j)} = 0$. For $j < i$, we know $l_{j-i}^{(0)} \leq (-0.5\delta)$ so $l_{j-i+1}^{(1)} = \sigma(l_{j-i}^{(0)} - 0.5\delta)$, etc., so that in the limit we have $l_j^{(j)} = 0$. We conclude that for any $\epsilon > 0$, there exists δ_0 such that $\delta > \delta_0$ implies that for all $i > 0$ and all $j \neq i$, $|l_0^{(j)} - 1| < \epsilon$, $|l_i^{(j)} - 0.5| < \epsilon$, and $|l_k^{(j)}| < \epsilon$.

When $l_0^{(0)} = 0$, $l_i^{(i)} = 0.5$, and $l_j^{(j)} = 0$, we have that for $t < m$, if $h_j \in H_{v^{(t-1)}, \dots, v^{(t-m)}}$ or $h_j \in H^{(i)}$ with $i \neq t$ then the bias is at most $b_j - \gamma$ and if $h_j \in H^{(i)}$ then the temporal connections from l_1, \dots, l_{m-1} are γ , which cancels the γ subtracted initially so the added bias is 0. For $t \geq m$ the temporal connections from l_i, \dots, l_{m-1} to all $H_{v^{(t-1)}, \dots, v^{(t-m)}}$ are 0 and the added bias to each node in $H^{(i)}$ is $-\gamma$. This is exactly the machine described in the second part of Theorem 2.

Putting this together, we first note that since each l_i has no visible connections we can ignore their binary values much in the same way that we can ignore the chains in the first part of the proof. Now for $t \neq 0$ and any $\epsilon > 0$ and any $v^{(t)}$, first we choose $\beta > \beta_0$ so that $|\bar{Q}(v^{(t)}|v^{(t-1)}, \dots, v^{(0)}) - \bar{Q}(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})| < \epsilon'$, then we choose $\delta > \delta_0$ so that $|\bar{Q}(v^{(t)}|v^{(t-1)}, \dots, v^{(0)}) - \bar{Q}(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})| < \epsilon'$ where \bar{Q} is the distribution obtained by replacing $l_0^{(0)}$ with 1, $l_i^{(i)}$ with 0.5 for $i > 0$, and $l_j^{(j)}$ with 0. As noted above this distribution is exactly the construction from the second part of Theorem 2. Finally, by the reasoning of Theorem 1 Step 4, by making δ large we make the initial distribution arbitrarily close to $H^{(0)}$ allowing us to approximate the distribution for the first time step. So the first, second and third conditions of the lemma are satisfied by the same argument used in Theorem 2. ■

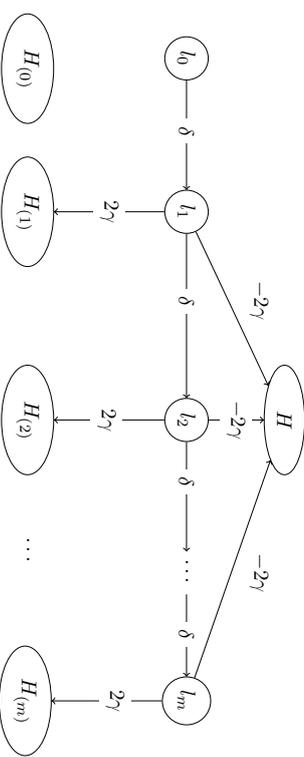

Figure 3: The temporal connections of the initial chain. H is the machine defined in the first part of the proof. Each connection from an l_i to H or $H^{(i)}$ only goes to non-control nodes in the set (control nodes include the chains $g_{v^{(i)}, \dots, v^{(i-m)}}$). The l_i 's have no visible connections.

4. Conclusion

The proofs above have shown that generalized TRBMs and RTRBMs both satisfy the same universal approximation condition. In the proof of universal approximation for the RTRBM we take the weights large enough so that the real-valued hidden sequence becomes approximately binary. This suggests that the same proof could be adapted to the basic TRBM. However, the TRBM seems to have difficulty modeling distributions with long term time dependence. After an RTRBM was trained on videos of bouncing balls the machine was able to model the movement correctly and the hidden units contained chains of length two as described in the above proof (Sutskever et al., 2008). On the other hand the TRBM did not have this structure and modeled the motion of balls as a random walk which is what one might expect for a machine that is unable to use velocity data by modeling two-step time dependencies. Given the likely equivalence in representational power of the two models, this discrepancy of results is best explained by the efficiency of the learning algorithm for the RTRBM in comparison to the TRBM.

At first glance the constructions used here seem quite inefficient. For Theorem 1 we require $2^n(G(n)+1)$ hidden nodes where G is the number of hidden nodes required to approximate an arbitrary distribution on n nodes with a Restricted Boltzmann Machine. It is important to note that the number of nodes required here, although large, depends only on the number of visible units and the process we wish to approximate, not the number of time steps for which we wish to approximate R . If the required number of hidden nodes had depended on the number of time steps then the TRBM and RTRBM would be essentially pointless as the RBM can do the same for any finite number of time steps. In contrast, the CRBM has a comparatively small lower bound on the number of hidden units required to approximate a set of conditional distributions (Montufar et al., 2014). Nonetheless, the above proofs are constructive and give only an upper bound on the required number of hidden units. Furthermore, we made no assumptions about $KL(R_1(\cdot|v^{(t-1)}))\|R_1(\cdot|v^{(t-1)'})$. Even if $v^{(t-1)}$ and $v^{(t-1)'}$ are similar vectors, the resulting distributions may be quite different, so to guarantee the result in full generality we could need a whole new set of hidden units to approximate R_1 for each pattern $v^{(t-1)}$. With this in mind, we might expect $2^n(G(n))$ to be a reasonable lower bound. In practice, similar vectors in the previous time step should produce similar distributions for the current time step. For example, looking at consecutive frames in video data, we expect that two similar frames at a certain time step will lead to similar frames in the next time step. To formalize this we could impose the restriction $KL(R_1(\cdot|v^{(t-1)}))\|R_1(\cdot|v^{(t-1)'}) < f(d(v^{(t-1)}, v^{(t-1)'})$, where f is a bounded function and d is a metric on $\{0, 1\}^n$. With this condition we could hope to find a more efficient TRBM to approximate R than the one given in the proof.

Without making this additional assumption, the most obvious way to increase efficiency is to obtain a better upper bound on G . We know that the bounds given by Le Roux et al. (2008) are not the lowest possible upper bounds for G (Montufar and Ay, 2011). In practice, multiple layers of RBMs are often stacked, leading to a Deep Belief Network. Several papers have investigated the universal approximation properties of Deep Belief Networks (Sutskever and Hinton, 2010)(Le Roux and Bengio, 2010)(Montufar and Ay, 2011). Re-

calling the constructions used in the previous proofs, by replacing the RBMs modeling the transition probabilities with Deep Belief Networks we end up with a column structure in which certain control nodes in a column send negative feedback to the other columns. This structure bears an interesting resemblance to the structure of the visual cortex (Goodhill and Carreira-Perpinán, 2006) suggesting that perhaps the two are computationally similar.

Appendix A.

The following table lists notations used for the labels and states for the nodes in the previous proofs

H_0	a set of hidden nodes whose distribution approximates R_0
$H^{(t)}$	a set of hidden nodes used to approximate the distribution at time t
H_v	Hidden nodes whose distribution approximates $R_1(\cdot v^{(t-1)}) = v$
$h_{c,v}$	the control node corresponding to the configuration v of the visible units
H_c	the set of all control nodes
$H_{c,v}^{(t)}$	the set of configurations of the hidden nodes at time t with $h_{c,v}^{(t)} = 1$ and $h_{c,v'}^{(t)} = 0$
$\bar{H}_{c,v}^{(t)}$	the set of configurations of hidden nodes at time t not in $H_{c,v}^{(t)}$
$g_{c,v^{(t)}}$	the i^{th} node in a chain connecting $h_{c,v}$ to the visible nodes
l_i	the i^{th} node in the initial chain connecting l_0 with the rest of the H

Appendix B.

In this appendix we provide a proof for Lemma 1

Proof: For an arbitrary $\epsilon > 0$, we need to find a $P \in \mathbf{P}$ such that $KL(R\|P) < \epsilon$, where the KL-divergence is

$$KL(R\|P) = \sum_{v^T} R(v^T) \log \left(\frac{R(v^T)}{P(v^T)} \right).$$

We can write $P(v^T)$ as

$$\left(\prod_{t=1}^{T-1} P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)}) \right) P(v^{(0)}),$$

and by assumption

$$R(v^T) = \left(\prod_{t=m}^{T-1} R_1(v^{(t)}|v^{(t-1)}, \dots, v^{(t-m)}) \right) \prod_{i=1}^{m-1} R_0(v^{(i)}|v^{(i-1)}, \dots, v^{(0)}).$$

Then expanding out the log in the KL-divergence gives us

$$\begin{aligned} KL(R\|P) &= \sum_{v^T} \sum_{t=m}^{T-1} R(v^T) \log \left(\frac{R_1(v^{(t)}|v^{(t-1)}, \dots, v^{(t-m)})}{P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})} \right) \\ &\quad + \sum_{v^T} \sum_{t=1}^{m-1} R(v^T) \log \left(\frac{R_0(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})}{P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})} \right) + \sum_{v^T} R(v^T) \log \left(\frac{R_0(v^{(0)})}{P(v^{(0)})} \right). \end{aligned}$$

We can decompose $R(v^T)$ into $R(v^{(T-1)}, \dots, v^{(t)}|v^{(t-1)}, \dots, v^{(0)})R(v^{(t-1)}, \dots, v^{(0)})$ so for a given t we can write

$$\sum_{v^T} R(v^T) \log \left(\frac{R_1(v^{(t)}|v^{(t-1)}, \dots, v^{(t-m)})}{P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})} \right)$$

$$= \sum_{v^{(t-1)}, \dots, v^{(0)}} R(v^{(t-1)}, \dots, v^{(0)})$$

$$\begin{aligned} &\times \left(\sum_{v^{(t)}} \sum_{v^{(t-1)}, \dots, v^{(t+1)}} R(v^{(T-1)}, \dots, v^{(t)}|v^{(t-1)}, \dots, v^{(0)}) \log \left(\frac{R_1(v^{(t)}|v^{(t-1)}, \dots, v^{(t-m)})}{P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})} \right) \right) \\ &= \sum_{v^{(t-1)}, \dots, v^{(0)}} R(v^{(t-1)}, \dots, v^{(0)}) KL(R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)}) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)})). \end{aligned}$$

Since $R(v^{(t-1)}, \dots, v^{(0)}) < 1$ for all $v^{(t-1)}, \dots, v^{(0)}$ we have

$$\begin{aligned} &\sum_{v^T} R(v^T) \log \left(\frac{R_1(v^{(t)}|v^{(t-1)}, \dots, v^{(t-m)})}{P(v^{(t)}|v^{(t-1)}, \dots, v^{(0)})} \right) \\ &\leq 2^{tn} \sum_{v^t} KL(R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)}) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)})). \end{aligned}$$

The same logic applies for the cases with $t < m$.

By hypothesis there exists $P \in \mathbf{P}$ such that for every v^T and every ϵ' ,

$$\begin{aligned} KL(R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)}) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)})) &< \epsilon' \text{ for } t \geq m, \\ KL(R_0, \delta(\cdot|v^{(t-1)}, \dots, v^{(0)})) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)}) &< \epsilon' \text{ for every } 0 < t < m \text{ and} \\ KL(R_0 \| P_0) &< \epsilon'. \end{aligned}$$

This gives us

$$\begin{aligned} KL(R\|P) &\leq \sum_{t=m}^{T-1} 2^{tn} \sum_{v^t} KL(R_1(\cdot|v^{(t-1)}, \dots, v^{(t-m)}) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)})) \\ &\quad + \sum_{t=1}^{m-1} 2^{tn} \sum_{v^t} KL(R_0(\cdot|v^{(t-1)}, \dots, v^{(0)})) \| P_1(\cdot|v^{(t-1)}, \dots, v^{(0)}) \\ &\quad + KL(R_0 \| P_0) \\ &< \sum_{t=m}^{T-1} 4^{tn} \epsilon' + \sum_{t=0}^{m-1} 4^{tn} \epsilon'. \end{aligned}$$

Then we merely choose an ϵ' so that this expression is less than ϵ and choose a corresponding $P \in \mathbf{P}$. \blacksquare

Notice in the proof that T was chosen arbitrarily and in the last line of the proof we see that decreasing T provides a tighter bound on the KL-divergence so any distribution which approximates R with a certain upper bound on the KL-divergence for T time steps will approximate R with at most the same upper bound on the KL-divergence for $t < T$ time steps.

Abstract

Applying standard Markov chain Monte Carlo (MCMC) algorithms to large data sets is computationally infeasible. The recently proposed stochastic gradient Langevin dynamics (SGLD) method circumvents this problem in three ways: it generates proposed moves using only a subset of the data, it skips the Metropolis-Hastings accept-reject step, and it uses sequences of decreasing step sizes. In Teh et al. (2014), we provided the mathematical foundations for the decreasing step size SGLD, including consistency and a central limit theorem. However, in practice the SGLD is run for a relatively small number of iterations, and its step size is not decreased to zero. The present article investigates the behaviour of the SGLD with fixed step size. In particular, we characterise the asymptotic bias explicitly, along with its dependence on the step size and the variance of the stochastic gradient. On that basis a modified SGLD which removes the asymptotic bias due to the variance of the stochastic gradients up to first order in the step size is derived. Moreover, we are able to obtain bounds on the finite-time bias, variance and mean squared error (MSE). The theory is illustrated with a Gaussian toy model for which the bias and the MSE for the estimation of moments can be obtained explicitly. For this toy model we study the gain of the SGLD over the standard Euler method in the limit of large data sets.

Keywords: Markov Chain Monte Carlo, Langevin dynamics, big data, fixed step size.

1. Introduction

A standard approach to estimating expectations under a given target density $\pi(\theta)$ is to construct and simulate from Markov chains whose equilibrium distributions are designed to be π Brooks et al. (2011). A well-studied approach, for example in molecular dynamics Leimkuhler and Matthews (2013); Nawaf and Vanden-Eijnden (2010) and throughout Bayesian statistics Millstein and Tretyakov (2007); Neal (2011), is to use Markov chains constructed as numerical schemes which approximate the time dynamics of stochastic differential equations (SDEs). In this paper we will focus on the case of first order Langevin dynamics, which has the form

$$d\theta(t) = \frac{1}{2} \nabla \log \pi(\theta(t)) dt + dW_t, \quad (1)$$

^{*}. vollmer@stats.ox.ac.uk

[†]. kzygalak@ed.ac.uk

[‡]. y.w.teh@stats.ox.ac.uk

where $t \in \mathbb{R}_+$, $\theta \in \mathbb{R}^d$ and W_t is a d -dimensional standard Brownian motion. Under appropriate assumptions on $\pi(\theta)$, it is possible to show that the dynamics generated by Equation (1) are ergodic with respect to $\pi(\theta)$.

The simplest possible numerical scheme for approximating Equation (1) is the Euler-Maruyama method. Let $h > 0$ be a step size. Abusing notation, the diffusion $\theta(k \cdot h)$ at time $k \cdot h$ is approximated by θ_k , which is obtained using the following recursion equation

$$\theta_{k+1} = \theta_k + \frac{h}{2} \nabla \log \pi(\theta_k) + \sqrt{h} \xi_k, \quad (2)$$

where ξ_k is a standard Gaussian random variable on \mathbb{R}^d . One can use the numerical trajectories generated by this scheme for the construction of an empirical measure $\pi_h(\theta)$ either by averaging over one single long trajectory or by averaging over many realisations in order to obtain a finite ensemble average (see for example Milstein and Tretyakov (2007)). However, as discussed in Roberts and Tweedie (1996), one needs to be careful when doing this as it could be the case that the discrete Markov chain generated by Equation (2) is not ergodic. But even if the resulting Markov Chain is ergodic, $\pi_h(\theta)$ will not be equal to $\pi(\theta)$. Mattingly et al. (2010); Abdulle et al. (2014) which thus implies that the resulting sample average is biased. An alternative strategy that avoids this discretization bias and the ergodicity of the numerical procedure, is to use Equation (2) as a proposal for a Metropolis-Hastings (MH) MCMC algorithm Brooks et al. (2011), with an additional accept-reject step which corrects the discretization error.

In this paper we are interested in situations where π arises as the posterior in a Bayesian inference problem with prior density $\pi_0(\theta)$ and a large number $N \gg 1$ of i.i.d. observations X_i with likelihoods $\pi(X_i|\theta)$. In this case, we can write

$$\pi(\theta) \propto \pi_0(\theta) \prod_{i=1}^N \pi(X_i|\theta), \quad (3)$$

and we have the following gradient,

$$\nabla \log \pi(\theta) = \nabla \log \pi_0(\theta) + \sum_{i=1}^N \nabla \log \pi(X_i|\theta). \quad (4)$$

In these situations each update (2) has an impractically high computational cost of $\mathcal{O}(N)$ since it involves computations on all N items in the data set. Likewise, each MH accept-reject step is impractically expensive.

In contrast, the recently proposed stochastic gradient Langevin dynamics (SGLD) algorithm Welling and Teh (2011) circumvents this problem by generating proposals which are only based on a subset of the data, by skipping the accept-reject step and by using a decreasing step-size sequence (h_k) $_{k \geq 0}$. In particular one has

$$\theta_{k+1} = \theta_k + \frac{h_k}{2} \nabla \log \pi(\theta_k) + \sqrt{h_k} \xi_k, \quad (5)$$

$$\widehat{\nabla \log \pi}(\theta_k) = \nabla \log \pi_0(\theta_k) + \frac{1}{n} \sum_{i=1}^n \nabla \log \pi(X_{\tau_{n,i}}|\theta_k) \quad (6)$$

where ξ_k are independent standard Gaussian random variables on \mathbb{R}^d , and $\tau_k = (\tau_{k,1}, \dots, \tau_{k,n})$ is a random subset of $[N] := \{1, \dots, N\}$ of size n , generated, for example, by sampling with or without replacement from $[N]$. The idea behind this algorithm is that, since the stochastic gradient appearing in Equation (5) is an unbiased estimator of the true gradient $\nabla \log \pi(\theta)$, the additional perturbation due to the gradient stochasticity is of order h , smaller than the \sqrt{h} order of the injected noise, and so the limiting dynamics ($k \rightarrow \infty$) of Equation (5) should behave similarly to the case $n = N$. In Teh et al. (2014) it was shown that in this case that the K -step size weighted sample average is consistent and satisfies a CLT with rate depending on the decay of h_k . The optimal rate is limited to $K^{-\frac{1}{3}}$ and achieved by an asymptotic step size decay of $\asymp K^{-\frac{1}{3}}$.

The problem with decaying step sizes is that the efficiency of the algorithm slows the longer it is run for. A common practice for the SGLD and its extensions, the Stochastic Gradient Hamiltonian Monte Carlo Chen et al. (2014) and the Stochastic Gradient Thermostat Monte Carlo algorithm Ding et al. (2014), is to use step sizes that are only decreasing up to a point. The primary aim of this paper is to analyse the behaviour of SGLD with fixed step sizes of $h_k = h$. We provide two complementary analyses in this setting, one asymptotic in nature and one finite time. Let $\phi : \mathbb{R}^d \rightarrow \mathbb{R}$ be a test function whose expectation we are interested in estimating. Using simulations of the dynamics governed by Equation (5), we can estimate the expectation using

$$\mathbb{E}_\pi[\phi(\theta)] \approx \frac{1}{K} \sum_{k=1}^K \phi(\theta_k) \quad (7)$$

for some large number of steps K . Our analyses shed light on the behaviour of this estimator.

In the first analysis, we are interested in the asymptotic bias of the estimator (7) as $K \rightarrow \infty$,

$$\lim_{K \rightarrow \infty} \frac{1}{K} \sum_{k=1}^K \phi(\theta_k) - \mathbb{E}_\pi[\phi(\theta)]. \quad (8)$$

Assuming for the moment that the dynamics governed by Equation (5) is ergodic, with invariant measure $\pi_h(\theta; n)$, the above asymptotic bias simply becomes $\mathbb{E}_{\pi_h(\cdot; n)}[\phi(\theta)] - \mathbb{E}_\pi[\phi(\theta)]$. In the case of Euler-Maruyama, where $n = N$ and the gradient is computed exactly, the asymptotic behaviour of the dynamics is well understood, in particular its asymptotic bias is $\mathcal{O}(h)$ Mattingly et al. (2010). When $n < N$, using the recent generalisations Abdulle et al. (2014); Sato and Nakagawa (2014) of the approach by Talay and Tubaro (1990) reviewed in Section 3, we are able to derive an expansion of the asymptotic bias in powers of the step size h . This allows us to explicitly identify the effect, on the leading order term in the asymptotic bias, of replacing the true gradient (4) with the unbiased estimator (6). In particular, we show in Section 4 that, relative to Euler-Maruyama, the leading term contains an additional factor related to the covariance of the subsampled gradient estimators (6).

Based on this result, in Section 4.2, we propose a modification of the SGLD (referred to simply as mSGLD) which has the same asymptotic bias as the Euler-Maruyama method up to first order in h . The mSGLD is given by

$$\theta_{k+1} = \theta_k + \frac{h}{2} \widehat{\nabla \log \pi}(\theta_k) + \sqrt{h} \left(I - \frac{h}{2} \text{Cov} \left[\widehat{\nabla \log \pi}(\theta_k) \right] \right) \xi; \quad (9)$$

where $\text{Cov} \left[\widehat{\nabla \log \pi}(\theta_k) \right]$ is the covariance of the gradient estimator. When the covariance is unknown, it can in turn be estimated by subsampling as well. This modification is different from the Stochastic Gradient Fisher Scoring S. Ahn and Welling (2012), a modification of the injected noise in order to better match the Bernstein von Mises posterior. In contrast, the mSGLD is a local modification based on the estimated variance of the stochastic gradient.

The second contribution provides a complementary finite time analysis. In the finite time case both the bias and the variance of the estimator are non-negligible, and our analysis accounts for both by focussing on bounding the mean squared error (MSE) of the estimator (7). Our results, presented in Section 5, show that,

$$\mathbb{E} \left[\left(\frac{1}{K} \sum_{k=0}^{K-1} \phi(\theta_k) - \pi(\phi) \right)^2 \right] \leq C(n) \left(h^2 + \frac{1}{Kh} \right), \quad (10)$$

where the RHS only depends on n through the constant $C(n)$, the h^2 term is a contribution of the (square of the) bias while the $1/Kh$ term is a contribution of the variance. We see that there is a bias-variance trade-off, with bias increasing and variance decreasing monotonically with h . Intuitively, with larger h the Markov chain can converge faster (lower variance) with the same number of steps, but this incurs higher discretization error. Our result is achieved by extending the work of Mattingly et al. (2010) from \mathbb{T}^d to \mathbb{R}^d . The main difficulty in achieving this relates to combining the results of Pardoux and Veretennikov (2001) and Teh et al. (2014), in order to establish the existence of nice, well controlled solutions to the corresponding Poisson equation Mattingly et al. (2010). We can minimise Equation (10) over h , finding that the minimizing h is on the order of $K^{-\frac{1}{3}}$, and yields an MSE of order $K^{-\frac{2}{3}}$. This agrees, surprisingly, with the scaling of $K^{-\frac{1}{3}}$ for the central limit theorem established for the case of decreasing step sizes, for the Euler-Maruyama scheme in Lambertson and Pages (2002) and for SGLD in Teh et al. (2014). This unexpected result, that the decreasing step size and fixed step size discretisations have, up to a constant, the same efficiency seems to be missing from the literature.

Our theoretical findings are confirmed by numerical simulations. More precisely, we start by studying a one dimensional Gaussian toy model both in terms of the asymptotic bias and the MSE of time averages in Section 2. The simplicity of this model allows us to obtain explicit expressions for these quantities and thus illustrate in a clear way the connection with the theory. More precisely, we confirm that the scaling of the step size and the number of steps for a prescribed MSE obtained from the upper bound in Equation (10) matches the scaling derived from the analytic expression for the MSE for this toy model. More importantly, this simplicity allows us to make significant analytic progress in the study of the asymptotic bias and MSE of time averages in the limit of large data sets $N \rightarrow \infty$. In particular, we are able to show that the SGLD reduces the computational complexity by one order of magnitude in N , for the estimation of the second moment in comparison with the Euler method if the error is quantified through the MSE.

In summary, this paper is organised as follows. We present our first explorations of the SGLD applied to a one-dimensional Gaussian toy model in Section 2. For this model we obtain an analytic characterisation of its bias and variance. This serves as intuition and benchmark for the two analyses developed in Sections 3 to 5. In Section 3 we review

some known results about the effect of the numerical discretisation of Equation (1) in terms of the finite time weak error as well as in terms of the invariant measure approximation. In Section 4 we apply these results to analyse the finite and long time properties of the SGLD, as well as to construct the modified SGLD algorithm which, asymptotically in h , behaves exactly as the Euler-Maruyama method ($n = N$) while still sub-sampling the data set at each step. Furthermore, in Section 5 we discuss the properties of the finite time sample averages, include its MSE. In Section 6 we revisit the Gaussian toy model to obtain a more precise understanding of the behaviour of SGLD in a large data and high accuracy regime. This is achieved using analytic expressions of the expectations of the sample average which are obtained using the Mathematics[®] notebook that is available upon request from the first author described in detail in Appendix 10. Finally, in Section 7 we demonstrate the observed performance of SGLD for a Bayesian logistic regression model which matches the theory, while, we conclude this paper in Section 8 with a discussion on some possible extensions of this work.

2. Exploring a one-dimensional Gaussian Toy Model

In this section, we develop results for a simple toy model, which will serve as a benchmark for the theory developed in Sections 3 to 5. In particular, we obtain analytic expressions for the bias and the variance of the sample average of the SGLD, allowing us to characterise its performance in detail.

We consider a one-dimensional linear Gaussian model,

$$\begin{aligned} \theta &\sim \mathcal{N}(0, \sigma_\theta^2), \\ X_i | \theta &\stackrel{i.i.d.}{\sim} \mathcal{N}(\theta, \sigma_x^2) \quad \text{for } i = 1, \dots, N. \end{aligned} \quad (11)$$

The posterior is given by

$$\pi = \mathcal{N}(\mu_p, \sigma_p^2) = \mathcal{N}\left(\frac{\sum_{i=1}^N X_i}{\frac{\sigma_x^2}{\sigma_\theta^2} + N}, \left(\frac{1}{\sigma_\theta^2} + \frac{N}{\sigma_x^2}\right)^{-1}\right). \quad (12)$$

For this choice of π , the Langevin diffusion (1) becomes,

$$d\theta(t) = -\frac{1}{2} \left(\frac{\theta(t) - \mu_p}{\sigma_p^2} \right) dt + dW_t, \quad (13)$$

and its numerical discretisation by the SGLD with step size h reads as follows,

$$\theta_{k+1} = (1 - Ah)\theta_k + B_k h + \sqrt{h}\xi_k, \quad (14)$$

where $\xi_k \stackrel{i.i.d.}{\sim} \mathcal{N}(0, 1)$ and

$$\begin{aligned} A &= \frac{1}{2} \left(\frac{1}{\sigma_\theta^2} + \frac{N}{\sigma_x^2} \right), \\ B_k &= \frac{N}{n} \sum_{j=1}^n X_{\tau_{k,j}} - \frac{2\sigma_p^2}{\sigma_x^2}, \end{aligned} \quad (15)$$

where $\tau_k = (\tau_{k,1}, \dots, \tau_{k,n})$ denote a random subset of $[N] = \{1, \dots, N\}$ generated, for example, by sampling with or without replacement from $[N]$, independently for each k . We note that the updates (14) will be stable only if $0 \leq 1 - Ah < 1$, that is, $0 < h < 1/A$. In the following we will also consider parameterising the step size as $h = r/A$ where $0 < r < 1$.

We denote $B = (B_k)_{k \geq 0}$. At the risk of obfuscating the notation, we will denote by $\text{Var}(B)$ the common variance of B_k for all k . For sampling with replacement, we have

$$\text{Var}(B) = \frac{1}{4\sigma_x^4} \frac{N}{n} \sum_{j=1}^n \left(X_j - \frac{1}{N} \sum_{i=1}^N X_i \right)^2 = \frac{1}{4\sigma_x^4} \frac{N(N-1)}{n} \text{Var}(X),$$

where $\text{Var}(X)$ is the typical unbiased empirical estimate of the variance of $\{X_1, \dots, X_N\}$. For sampling without replacement we have,

$$\text{Var}(B) = \frac{1}{4\sigma_x^4} \frac{N(N-n)}{n(N-1)} \sum_{i=1}^N \left(X_i - \frac{1}{N} \sum_{i=1}^N X_i \right)^2 = \frac{1}{4\sigma_x^4} \frac{N(N-n)}{n} \text{Var}(X). \quad (16)$$

2.1 Analysis of the Asymptotic Bias

We start by inspecting the estimate of the posterior mean. In particular, using Equation (14) and taking expectations with respect to ξ_k , we have

$$\mathbb{E}(\theta_{k+1}|B) = (1 - Ah)\mathbb{E}(\theta_k|B) + B_k h \quad (17)$$

which can be solved in order to obtain

$$\mathbb{E}(\theta_M|B) = (1 - Ah)^M \mathbb{E}(\theta_0) + \sum_{k=0}^{M-1} h(1 - Ah)^k B_{M-k-1}.$$

If we now take the expectation with respect to the random subsets B_k , using the fact that $\mathbb{E}(B_k) = \mathbb{E}(B)$ and take the limit of $M \rightarrow \infty$, we have

$$\mathbb{E}(\theta_\infty) = \sum_{k=0}^{\infty} (1 - Ah)^k h \mathbb{E}(B) = h/(1 - (1 - Ah)\mathbb{E}(B)) = \frac{\mathbb{E}(B)}{A} = \frac{\sum_{i=1}^N X_i}{\frac{\sigma_x^2}{\sigma_\theta^2} + N}.$$

We thus see that the SGLD is capturing the correct limiting mean of the posterior independently of the choice of the step size h . In other words, for the test function $\phi(\theta) = \theta$, the asymptotic bias is nil.

We now investigate the behaviour of the limiting variance under the SGLD. Starting with the law of total variance,

$$\text{Var}[\theta_{k+1}] = \mathbb{E}(\text{Var}[\theta_{k+1} | B]) + \text{Var}(\mathbb{E}[\theta_{k+1} | B]),$$

a simple calculation now shows that

$$\text{Var}[\theta_{k+1} | B] = (1 - Ah)^2 \text{Var}[\theta_k | B] + h$$

1. Note that the posterior variance is $\asymp 1/A$, so that steps of size $\asymp 1/A$ are $1/\sqrt{A}$ smaller than the width of the posterior. However the injected noise has variance $\asymp 1/A$ which matches the posterior variance.

and

$$\text{Var}(\mathbb{E}[\theta_{k+1} | B]) = (1 - Ah)^2 \text{Var}(\mathbb{E}[\theta_k | B]) + h^2 \text{Var}(B_k).$$

Combining these two results, we see that

$$\text{Var}(\theta_{k+1}) = (1 - Ah)^2 \text{Var}(\theta_k) + h + h^2 \text{Var}(B_k).$$

If we now take the limit of $k \rightarrow \infty$, we have that

$$\text{Var}(\theta_\infty) = \frac{1}{2A - A^2h} + \frac{h \text{Var}(B)}{2A - A^2h}. \quad (18)$$

where $\text{Var}(B)$ is the common value of $\text{Var}(B_k)$ for all $k \geq 0$. We note here that in the case of the Euler-Maruyama method (from here on we will simply refer to this as the Euler method) where $n = N$ and $\text{Var}(B) = 0$, only the first term remains. In other words, the first term is an (over-)estimate of the posterior variance $\sigma_p^2 = 1/2A$ obtained by the Euler-Maruyama discretisation at step size h . Our result here coincides with Zygalkakis (2011). On the other hand, the second term is an additional bias term due to the variability of the stochastic gradients. Further, using a Taylor expansion in h of the second summand, we see that the SGLD has an excess bias, relative to the Euler method, with first order term equal to

$$h \frac{\text{Var}(B)}{2A}. \quad (19)$$

Using the fact that $\text{Var}(\theta_\infty) = \mathbb{E}[\theta_\infty^2] - \mathbb{E}[\theta_\infty]^2$, and that the asymptotic bias of estimating $\mathbb{E}[\theta]$ is nil in this simple model, we see that the above gives the asymptotic biases of the Euler method and SGLD in the case of the test function $\phi(\theta) = \theta^2$.

We now consider the modified SGLD given in Equation (9) and to be discussed in Section 4.2. In this case the numerical discretisation of Equation (13) becomes

$$\theta_{k+1} = \theta_k - Ah\theta_k + B_k h + \sqrt{h} \left(1 - \frac{h}{2} \text{Var}(B)\right) \xi_k \quad (20)$$

A similar calculation as for the SGLD shows that

$$\begin{aligned} \mathbb{E}(\theta_\infty) &= \frac{\sum_{i=1}^N X_i}{\frac{\sigma_p^2}{\sigma_\theta^2} + N} \\ \text{Var}(\theta_\infty) &= \frac{1}{2A - A^2h} + \frac{h^2 \text{Var}^2(B)}{4(2A - A^2h)}. \end{aligned} \quad (21)$$

with the last term being the excess asymptotic bias. A Taylor expansion of the excess bias term shows that the term of order h vanishes and the leading term has order h^2 . Hence, for small h , the excess bias is negligible compared to the asymptotic bias of the Euler method, and we can say that, up to first order and in this simple example, the mSGLD has the same asymptotic bias as for the Euler method. In Section 4.2, we will show that these results hold more generally.

It is useful to visualise the above analytic results for the asymptotic biases of the Euler method, SGLD and mSGLD. In Figure 1 we show this for a data set of 1000 points drawn

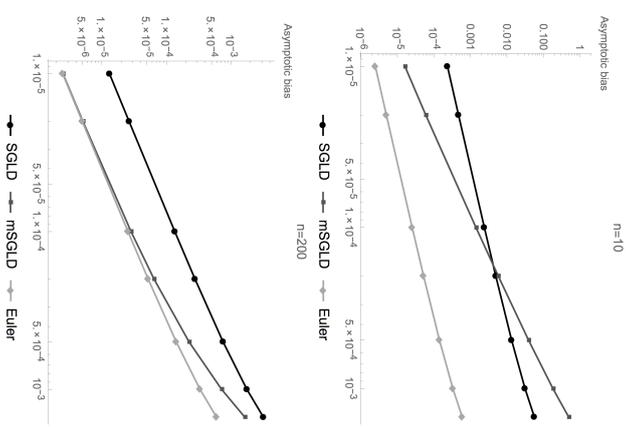

Figure 1: Comparison of the asymptotic biases for the SGLD, the mSGLD and the Euler method for the test function $\phi(\theta) = \theta^2$. For all simulations, we have used $N = 10^3$. We used $n = 10$ on the LHS and $n = 200$ on the RHS.

according to the model. In particular, after choosing the data set, then we calculate analytically $\text{Var}(B)$ for each choice of n using (16), and then use (18), (21) to evaluate the asymptotic bias for each of the methods. The first observation is that the Euler method has lowest asymptotic bias among all three methods (although of course it is also the most computationally expensive; see Section 6). We observe that if we choose $n = 10$ points for each gradient evaluation, for large values of the step size h , the SGLD is superior to the mSGLD. However, as h is reduced, this is no longer the case. Furthermore, if we use a more accurate gradient estimation with $n = 200$ data points, we see that mSGLD outperforms SGLD for all the step sizes used, but more importantly its asymptotic bias is now directly comparable with the Euler method where all the data points are used for evaluating the gradient.

2.2 Finite Time Analysis

In the previous subsection we analysed the behaviours of the three algorithms in terms of their biases in the asymptotic regime. In practice, we can only run our algorithms for a finite number of steps, say K , and it would be interesting to understand the behaviours of the algorithms in this scenario. With a finite number of samples, in addition to bias we also have to account for variance due to the Monte Carlo estimation.

A sensible analysis accounting for both bias and variance is to study the behaviour of the mean squared error (MSE), say in the Monte Carlo estimation for the second moment,

$$\text{MSE}_2 := \mathbb{E} \left(\frac{1}{K} \sum_{k=0}^{K-1} \theta_k^2 - (\mu_p^2 + \sigma_p^2) \right)^2. \quad (22)$$

We can expand the quadratic, and express MSE_2 as a linear combination of terms of the form $\mathbb{E}[\theta_k^p]$ for $p = 1, 2, 3, 4$. Each of terms can be calculated analytically, depending on the data set X , the total number of steps K , the subset size n , as well as the scaled step size parameter $r = hA$. We provide these calculations in Appendix 10.1 and a Mathematica® file in the supplementary materials.

In Figure 2 we visualise the behaviour of the resulting MSE_2 for a fixed data set with $N = 1000$ items, and with scaled step size $r = 1/20$. For the same number of steps M , the left figure shows that SGLD and mSGLD behaves similarly, decreasing initially then asymptoting at their asymptotic biases studied in the previous subsection. At $r = 1/20$ mSGLD has lower asymptotic biases than SGLD. Further, both MSE_2 's decrease with increasing subset size n , and are higher than that for the Euler method at $n = 1000$. Since SGLD and mSGLD computational costs per step are linear in n , the right figure instead plots the same MSE_2 's against the (effective) number of passes through the data set, that is, number of steps times n/N . This quantity is now proportional to the computational budget. Now we see that smaller subset sizes produce initial gains, but asymptote at higher biases.

These analytical results for a simple Gaussian model demonstrate the more general theory which forms the core contributions of this paper. Sections 3 and 4 develop a method to study the asymptotic bias as a Taylor expansion in h , while Section 5 provides a finite time analysis in terms of the mean squared error. Both analyses are based on the behaviour of the algorithms for small step sizes, and in this regime we see that mSGLD has better performance than SGLD. In Section 6 we will return to the simple Gaussian model to study the behaviour of the algorithms using different measures of performance and in different regimes. In particular, we will see that for larger step sizes SGLD has better performance than mSGLD.

3. Review of Weak Order Results

In this section we review some existing results regarding the ergodicity and accuracy of numerical approximations of SDEs. We start in Section 3.1 by introducing the framework and notation, the Fokker-Planck and backward Kolmogorov equations, and with some preliminary results on local weak errors of numerical one-step integrators. Section 3.2 presents assumptions necessary for ergodicity, and extends the results to a global error expansion of

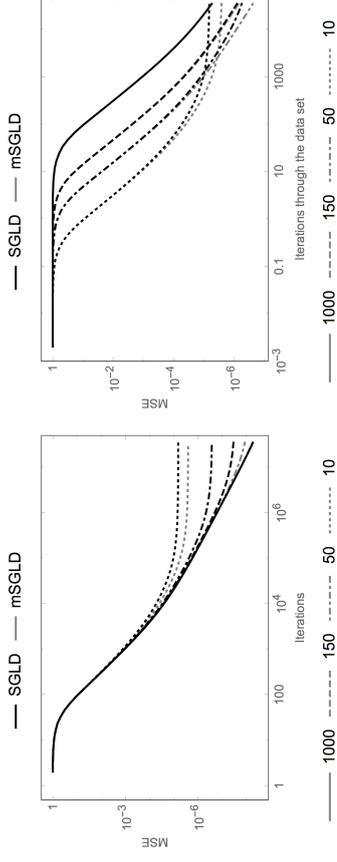

Figure 2: MSE₂ of the sample average for the SGLD and the mSGLD for the second moment of the posterior.

the weak error as well as the error in the approximation of the invariant measure. Finally, in Section 3.3 we apply our results to explicitly calculate the leading order error term of the numerical approximation of an Ornstein-Uhlenbeck solved by the Euler method.

3.1 One-step Numerical Approximations of Langevin Diffusions

Let us denote by $\rho(y, t)$ the probability density of $\theta(t)$ defined by the Langevin diffusion (1) with initial condition $\theta(0) = \theta$ and target density $\pi(y)$. Then $\rho(y, t)$ is the solution of the Fokker-Planck equation,

$$\frac{\partial \rho}{\partial t} = \mathcal{L}^* \rho, \quad (23)$$

with initial condition $\rho(y, 0) = \delta(y - \theta)$, a Dirac mass for the deterministic initial condition, and the operator \mathcal{L}^* given by

$$\mathcal{L}^* \rho = -\frac{1}{2} \nabla_{\theta} \cdot (\nabla \log \pi(\theta) \rho) + \frac{1}{2} \nabla_{\theta} \cdot \nabla_{\theta} \rho. \quad (24)$$

This operator is the L^2 -adjoint of the generator of the Markov process $(\theta(t))_{t \geq 0}$ given by (1),

$$\mathcal{L} = \frac{1}{2} \nabla_{\theta} \log \pi(\theta) \cdot \nabla_{\theta} + \frac{1}{2} \Delta_{\theta}, \quad (25)$$

Given a test function ϕ , define $u(\theta, t)$ to be the expectation,

$$u(\theta, t) = \mathbb{E}(\phi(\theta(t)) | \theta(0) = \theta), \quad (26)$$

with respect to the diffusion at time t when started with initial condition $\theta(0) = \theta$. We note that $u(\theta, t)$ is the solution of the backward Kolmogorov equation

$$\begin{aligned} \frac{\partial u}{\partial t} &= \mathcal{L}u, \\ u(\theta, 0) &= \phi(\theta). \end{aligned} \quad (27)$$

A formal Taylor series expansion for u in terms of the generator \mathcal{L} was derived in Zygalkakis (2011) and made rigorous by Debussche and Raou (2012) for the case where the state space is $\theta \in \mathbb{T}^d$. The Taylor series is of the following form,

$$u(\theta, h) = \phi(\theta) + \sum_{j=1}^l \frac{h^j}{j!} \mathcal{L}^j \phi(\theta) + h^{l+1} r_l(\theta), \quad (28)$$

for all positive integers l , with the remainder satisfying a bound of the form $|r_l(\theta)| \leq c_l(1 + |\theta|^{r_l})$ for some constants c_l, r_l depending on π and ϕ .

Remark 1 Another way to turn $u(\theta, h) = \phi(\theta) + h\mathcal{L}\phi + \frac{h^2}{2}\mathcal{L}^2\phi + \dots$ into a rigorous expansion, see Equation (28), is to follow the approach in (Taday and Tubaro, 1990, Lemma 2) and to assume that $\log \pi$ is C^∞ with bounded derivatives of any order (and this is the approach we follow here). This fact, together with the assumption that

$$|\phi(\theta)| \leq C(1 + |\theta|^s) \quad (29)$$

for some positive integer s is enough to prove that the solution u of Equation (27) has derivatives of any order that have a polynomial growth of the form of Equation (29), with other constants C, s that are independent of $t \in [0, T]$. In turn, these regularity bounds establish that Equation (28) holds. We mention here that the regularity conditions were relaxed in recent work in Kopec (2014) for the elliptic case and in Kopec (2015) for the hypoelliptic case.

Now assume that one solves Equation (1) numerically with a one step integrator, which we shall denote by,

$$\theta_{n+1} = \Psi(\theta_n, h, \xi_n), \quad (30)$$

where $\theta_0 = \theta(0)$, h denotes the step size, ξ_n are iid $\mathcal{N}(0, 1)$, and θ_n denotes the numerical approximation of $\theta(nh)$ for each $n \in \mathbb{N}$. For example in the case of the Euler method for equation (1) one has

$$\Psi(\theta, h, \xi) = \theta + \frac{h}{2} \nabla \log \pi(\theta) + \sqrt{h} \xi$$

Now, using this formulation we can define

$$U(\theta, h) = \mathbb{E}[\phi(\theta_1)|\theta_0 = \theta], \quad (31)$$

for the expectation of the test function after one step of the numerical integrator starting with the initial condition $\theta_0 = \theta$. We will make the following (easily satisfied) regularity and consistency assumptions about the integrator:

Assumption 2 We assume that the following hold:

- $\nabla \log \pi$ is C^∞ with bounded derivatives of all orders.
- For all deterministic initial conditions θ_0 , we have

$$|\mathbb{E}[\theta_1 - \theta_0]| \leq C(1 + |\theta_0|)h, \quad \text{and} \quad |\theta_1 - \theta_0| \leq M(1 + |\theta_0|)\sqrt{h}, \quad (32)$$

where C is a constant independent of h , for h small enough and M is a random variable that has bounded moments of all orders independent of h and θ_0 .

- Equation (31) has a weak Taylor series expansion of the form

$$U(\theta, h) = \phi(\theta) + hA_0(\pi)\phi(\theta) + h^2A_1(\pi)\phi(\theta) + \dots, \quad (33)$$

where $A_i(\pi)$, $i = 0, 1, 2, \dots$ are linear differential operators with coefficients depending smoothly on the drift function $\nabla \log \pi(\theta)$ and its derivatives (depending on the choice of the integrator).

- $A_0(\pi)$ coincides with the generator \mathcal{L} , in other words, the numerical method has weak order at least one.

Remark 3 Equation (33) holds for almost any Taylor based method applied to (1) but also to general SDEs with multiplicative noise. This is discussed further in Abulle et al. (2012), which also contains examples numerical methods, other than the Euler-Maryama method, for which (33) holds.

Assumptions 2 immediately imply the existence of a rigorous expansion

$$U(\theta, h) = \phi(\theta) + \sum_{i=0}^l h^{i+1} A_i(\pi)\phi(\theta) + h^{l+2} R_l(\theta) \quad (34)$$

for all positive integers l , with a remainder satisfying $|R_l(\theta)| \leq C_l(1 + |\theta|^{r_l})$ for some constants C_l, r_l . We say that the numerical solution has local weak order p if the first p terms in the expansion (33) of the numerical approximation agrees with that (28) for the exact diffusion. In this case, it is easy to see that the following local error formula holds,

$$\mathbb{E}[\phi(\theta(h))|\theta(0) = \theta] - \mathbb{E}[\phi(\theta_1)|\theta_0 = \theta] = h^{p+1} \left(\frac{\mathcal{L}^{p+1}}{(p+1)!} - A_p \right) \phi(\theta) + \mathcal{O}(h^{p+2}). \quad (35)$$

3.2 Global Weak Error Expansion

In this subsection, we will extend the local weak error expansion to a global one. Specifically, after M steps of the numerical integrator with step size h , we are interested in the difference between θ_M and the exact diffusion $\theta(T)$ where $T = Mh$, as evaluated by the difference between the corresponding expectations of ϕ ,

$$E(\phi, h, T) = \mathbb{E}[\phi(\theta(T))|\theta(0) = \theta] - \mathbb{E}[\phi(\theta_M)|\theta_0 = \theta], \quad (36)$$

In order for this study to make sense (when considering the limit $T \rightarrow \infty$), we will require that the SDE and its numerical approximation are both ergodic. We make standard assumptions in order for the Langevin diffusion $(\theta(t))_{t \geq 0}$ as given by (1) to be ergodic (see Hasminskii (1980)):

Assumption 4 We assume that the following hold for the Langevin diffusion $(\theta(t))_{t \geq 0}$:

- $\nabla \log \pi$ is C^∞ with bounded derivatives of all orders.
- there exists $\beta > 0$ and a compact set $K \subset \mathbb{R}^d$ such that $\forall \theta \in \mathbb{R}^d \setminus K$,

$$(\theta, \nabla \log \pi(\theta)) \leq -\beta \|\theta\|_2^2.$$

The question of the ergodicity of the numerical approximation (θ_n) is considerably more intricate in general. There exist cases where the underlying Langevin diffusion is ergodic, but its numerical approximation is not ergodic, or does not converge exponentially fast (Roberts and Tweedie (1996)). This relates mainly to the properties of the drift coefficient and its behaviour at infinity. For the Euler-Maruyama and the Milstein scheme this has been investigated in Talay and Tubaro (1990). In what follows we will simply assume that the Markov chain (θ_n) defined by the numerical approximation is indeed ergodic. Under this assumption the following theorem, which combines results derived by Talay and Tubaro (1990) and Milstein (1986), can be shown (see Abdulle et al. (2014) for a proof):

Theorem 5 Suppose that the state space is \mathbb{R}^d , that Assumptions 2 and 4 hold, and that the Markov chain $(\theta_n)_{n \geq 0}$ defined by the one step integrator (30) is ergodic. If the numerical approximation has local weak order p , that is, Equation (35) holds, then we have the following expansion of the global error (36), for all $\phi \in C_P^{2p+4}(\mathbb{R}^d, \mathbb{R})$,

$$E(\phi, h, T) = h^p \int_0^T \mathbb{E}(e(\theta(s), s)) ds + \mathcal{O}(h^{p+1}), \quad (37)$$

where $e(\theta, t)$ is given by

$$e(\theta, t) = \left(\frac{1}{(p+1)!} \mathcal{L}^{p+1} - A_p \right) v(\theta, t), \quad (38)$$

with $v(\theta, t) = \mathbb{E}(\phi(\theta(T)) | \theta(t) = \theta)$ satisfying

$$\begin{aligned} \frac{\partial v}{\partial t} &= -\mathcal{L}v, \\ v(\theta, T) &= \phi(\theta). \end{aligned} \quad (39)$$

The expression (37) was proved by Talay and Tubaro (1990) for specific methods (e.g. the Euler-Maruyama or the Milstein methods), while the general procedure to infer the global weak order from the local weak order is due to Milstein (1986) (see also (Milstein and Tretyakov, 2004, Chapter 2.2)). However, the formulation of the error function (38) here is in terms of the generator \mathcal{L} and the operators A_i in Assumption 2, and does not contain any time derivatives as in Talay and Tubaro (1990); Milstein (1986). This formulation will be particularly useful for obtaining our main results.

Using Theorem 5, one can obtain a similar expansion to that in Equation (37) for the difference between the true and the numerical ergodic averages:

Theorem 6 Suppose that Assumption 4 holds, that our numerical method with deterministic initial condition is ergodic and of weak order p , and that $\phi : \mathbb{R}^d \rightarrow \mathbb{R}$ is a smooth function satisfying Equation (29). Then,

$$\lim_{K \rightarrow \infty} \frac{1}{K} \sum_{n=0}^{K-1} \phi(\theta_n) - \int_{\mathbb{R}^d} \phi(y) \pi(y) dy = -\lambda_p h^p + \mathcal{O}(h^{p+1}) \quad (40)$$

where λ_p is defined as

$$\lambda_p = \int_{\mathbb{R}^d} \int_0^\infty \left(\frac{1}{(p+1)!} \mathcal{L}^{p+1} - A_p \right) u(y, t) \pi(y) dt dy, \quad (41)$$

and $u(y, t)$ satisfies Equation (27).

The proof is given in Abdulle et al. (2014), and is similar to that in (Talay and Tubaro, 1990, Theorem 4) with the main difference being that Equation (37) is used as the starting point, instead of the specific formula for the Euler-Maruyama method used in Talay and Tubaro (1990).

Theorem 6 provides an explicit expression for the leading order term of the asymptotic bias of the numerical method. It will thus be the key result in our analysis of the asymptotic behaviour of SGLD later. Intuitively Equation (41) says that if we want to calculate the error between the numerical and the true ergodic averages, we need to take into account the long time ($t \rightarrow \infty$) discrepancy between the true and the numerical solution given by

$$\left(\frac{1}{(p+1)!} \mathcal{L}^{p+1} - A_p \right) u(y, t),$$

and then average over all possible initial conditions y with respect to invariant measure $\pi(y)$.

3.3 An Illustrative Example

We illustrate the weak order results above in the case of the Euler-Maruyama scheme applied to the Ornstein-Uhlenbeck process. For ease of notation, let $f(x) = \frac{1}{2} \nabla \log \pi(\theta)$. The Euler-Maruyama update steps are,

$$\theta_{n+1} = \theta_n + hf(\theta_n) + \sqrt{h} \xi_n. \quad (42)$$

A straightforward calculation Zygalkakis (2011) yields that the differential operator A_1 in (33) is given by

$$A_1 \psi = \frac{1}{2} f^T \nabla^2 \psi + \frac{1}{2} \sum_{i=1}^d \psi^{(i)}(e_i, e_i, f) + \frac{1}{8} \sum_{i,j=1}^d \psi^{(4)}(e_i, e_i, e_j, e_j) \quad (43)$$

where e_1, \dots, e_d denotes the canonical basis of \mathbb{R}^d and $\psi^{(i)}(\cdot, \cdot, \cdot)$ and $\psi^{(4)}(\cdot, \cdot, \cdot, \cdot)$, are the derivatives of ψ , which are trilinear and quadrilinear forms, respectively. In dimension $d = 1$, it reduces to

$$A_1 \psi = \frac{1}{2} f^2 \psi'' + \frac{1}{2} \psi''' + \frac{1}{8} \psi^{(4)}$$

In the case where $\theta \in \mathbb{R}$ and $\pi(\theta) = e^{-(\theta-\mu)^2/2\sigma^2}$, the Langevin diffusion (1) corresponds to the one dimensional Ornstein-Uhlenbeck process,

$$d\theta(t) = -\frac{1}{2} \left(\frac{\theta(t) - \mu}{\sigma^2} \right) dt + dW_t \quad (44)$$

For the test function $\phi(\theta) = \theta^2$, a simple calculation reveals that the solution of Equation (27) is

$$u(\theta, t) = \sigma^2 \left(1 - e^{-t/\sigma^2} \right) + \theta^2 e^{-t/\sigma^2} + \frac{\mu\theta}{\sigma^2} \left(1 - e^{-t/2\sigma^2} \right) e^{-t/2\sigma^2} + \frac{\mu^2}{4\sigma^4} \left(1 - e^{-t/2\sigma^2} \right)^2. \quad (45)$$

The Euler-Maruyama scheme has weak order $p = 1$, and (see Zygalakis (2011) for more details),

$$\frac{1}{2} \mathcal{L}^2 - A_1 = \frac{1}{8\sigma^4} (\theta - \mu) \frac{d}{d\theta} - \frac{1}{4\sigma^2} \frac{d^2}{d\theta^2}.$$

Using this together with Equation (45) for $u(\theta, t)$, we find

$$\left(\frac{1}{2} \mathcal{L}^2 - A_1 \right) u(\theta, t) = \frac{e^{-t/\sigma^2}}{2\sigma^2} - \frac{e^{-t/2\sigma^2}}{4\sigma^4} (\mu - \theta) \left(\left(1 - e^{-t/2\sigma^2} \right) \mu + e^{-t/2\sigma^2} \theta \right)$$

Formula (41) now gives

$$\begin{aligned} \lambda_1 &= - \int_0^\infty \int_{-\infty}^{+\infty} \left(\frac{e^{-t/\sigma^2}}{2\sigma^2} - \frac{e^{-t/2\sigma^2}}{4\sigma^4} (\mu - \theta) \left(\left(1 - e^{-t/2\sigma^2} \right) \mu + e^{-t/2\sigma^2} \theta \right) \right) \frac{e^{-(\theta-\mu)^2/2\sigma^2}}{\sqrt{2\pi}\sigma} d\theta dt \\ &= \frac{1}{4}. \end{aligned} \quad (46)$$

This is in agreement with known results on the stationary distribution of the Euler-Maruyama approximation to the Ornstein-Uhlenbeck process, see Zygalakis (2011):

$$\pi_h \sim N(\mu, \sigma_h^2) \quad \text{where} \quad \sigma_h^2 = \frac{\sigma^2}{1 - \frac{h}{4}\sigma^{-2}} = \sigma^2 + \frac{1}{4}h + \mathcal{O}(h^2).$$

4. Weak Convergence Analysis

We study the weak convergence properties of the SGLD method in the light of Theorems 5 and 6. The analysis in Section 4.1 implies that at leading order there is a cost associated with not calculating the likelihood over all points. Thus, we introduce in Section 4.2 a modification of the original algorithm which has an error that is asymptotically in h , identical to the error of the Euler method, when all data points are taken into account in the calculation of each likelihood gradient.

4.1 Stochastic Gradient Langevin Dynamics

Theorems 5 and 6 imply that in order to characterise the leading order error term both for the weak convergence and the invariant measure, we need to calculate the corresponding

differential operators A_0, A_1, \dots in Equation (33). To simplify the presentation and to illustrate the main ideas, we present the calculations only in the case where $\theta(t)$ is one dimensional. We start our calculations by rewriting the SGLD method in the following form

$$\theta_{j+1} = \theta_j + h \hat{f}_j(\theta_j) + \sqrt{h} \xi_j, \quad (47)$$

where

$$\hat{f}_j(\theta) = \frac{1}{2} \left(\nabla \log \pi_0(\theta) + \frac{1}{n} \sum_{i=1}^n \nabla \log \pi(X_{\tau_{j+1}}^i | \theta) \right),$$

τ_j is the subset (possibly with repetition) chosen at step j and,

$$\mathbb{E}_{\tau_j} \hat{f}_j(\theta) = f(\theta) := \frac{1}{2} \nabla \log \pi(\theta), \quad \forall n \leq N. \quad (48)$$

Expanding $\phi(\theta_{j+1})$ in powers of h and then taking expectations with respect to the injected random noise ξ_j ,

$$\begin{aligned} \mathbb{E}_{\xi_j} (\phi(\theta_{j+1}) | \theta_j) &= \phi(\theta_j) + h \left(\hat{f}_j(\theta_j) \phi'(\theta_j) + \frac{1}{2} \phi''(\theta_j) \right) \\ &\quad + \frac{h^2}{2} \left(\hat{f}_j^2(\theta_j) \phi''(\theta_j) + \hat{f}_j(\theta_j) \phi^{(3)}(\theta_j) + \frac{1}{4} \phi^{(4)}(\theta_j) \right) + \mathcal{O}(h^3). \end{aligned}$$

If we now take expectations with respect to τ_j ,

$$\mathbb{E} \phi(\theta_{j+1}) | \theta_j = \phi(\theta_j) + h \mathcal{L} \phi(\theta_j) + \frac{h^2}{2} \left(\mathbb{E}_{\tau_j} (\hat{f}_j^2(\theta_j)) \phi''(\theta_j) + f'(\theta_j) \phi^{(3)}(\theta_j) + \frac{1}{4} \phi^{(4)}(\theta_j) \right) + \mathcal{O}(h^3), \quad (49)$$

where \mathcal{L} is the generator (25) of Equation (1). We thus see that the SGLD method is a first order weak method and, dropping the indexing by j for notational convenience from now on,

$$A_1(\pi) \phi = \frac{1}{2} \left(\mathbb{E}_\pi (\hat{f}^2(\theta)) \phi'' + f'(\theta) \phi^{(3)} + \frac{1}{4} \phi^{(4)} \right).$$

The asymptotic bias in Equation (41) has an expansion based on the differential operator,

$$\begin{aligned} \frac{1}{2} \mathcal{L}^2 - A_1 &= \frac{1}{2} \left(f(\theta) f'(\theta) + \frac{1}{2} f''(\theta) \right) \frac{d}{d\theta} + \frac{1}{2} \left(f'(\theta) + f^2(\theta) - \mathbb{E}_\pi (\hat{f}^2(\theta)) \right) \frac{d^2}{d\theta^2} \\ &= \frac{1}{2} \left(f(\theta) f'(\theta) + \frac{1}{2} f''(\theta) \right) \frac{d}{d\theta} + \frac{1}{2} \left(f'(\theta) - \text{Var} \hat{f}(\theta) \right) \frac{d^2}{d\theta^2} \end{aligned} \quad (50)$$

We thus see that in the case of SGLD the leading order error term contains an extra factor of $-\frac{1}{2} \text{Var} \hat{f}(\theta) \nabla^2$ when compared to the Euler method ($n = N$), in which case $\text{Var} \hat{f}(\theta) = 0$. This can be understood as the penalty associated with not using all the available points for calculating the likelihood at every time step. It results in an extra term in the corresponding error expressions given in Theorems 5 and 6 when compared with the Euler method. More precisely, for $n \ll N$ the term $-\frac{1}{2} \text{Var}(\hat{f}(\theta))$ is of size $\mathcal{O}(N^{-2})$ thus making the leading order error term $\mathcal{O}(hN^{-2})$ in Equation (37).

Example 1 We illustrate the above findings on the toy model discussed in Section 2. In particular, using the expression for $u(\theta, t)$ from Section 3.3 (replacing μ and σ by μ_p and σ_p respectively), and that $\text{Var}(\hat{f}(\theta)) = \text{Var}(B)$ for this simple model, the extra term in Equation (50) when compared with the Euler method is now given by

$$-\frac{1}{2} \text{Var}(B) \partial_\theta^2 u(\theta, t) = -\text{Var}(B) e^{-t/\sigma_p}.$$

A simple integration of this term according to the formula (41) gives that the overall contribution of the extra term, which is,

$$\sigma_p \text{Var}(B) = \frac{\text{Var}(B)}{2A},$$

and thus agreeing with Equation (19) derived in Section 2.1.

4.2 Modified SGLD

As we have seen in the previous section, the SGLD method introduces an extra term $-\frac{1}{2} \text{Var}(f(\theta)) \nabla_\theta^2$ in the leading order error term related to the weak error (Theorem 5) and to the ergodic averages (Theorem 6). When $n \ll N$, this term is of order $\mathcal{O}(hN^2)$. In this section we will explore a modification of SGLD (mSGLD) for which this term is removed, so that the leading order term is exactly the same as for the Euler-Maruyama scheme. Specifically, the mSGLD updates are,

$$\theta_{j+1} = \theta_j + h\hat{f}(\theta_j) + \sqrt{h} \left(1 - \frac{h}{2} \text{Var}(\hat{f}(\theta_j)) \right) \xi_j. \quad (51)$$

We can again derive the weak order expansion as in the previous subsection. Our first step is to expand $\phi(\theta_{j+1})$ in powers of h and then take expectations with respect to the random variable ξ_j . In particular, we obtain

$$\begin{aligned} \mathbb{E}_{\xi_j}(\phi(\theta_{j+1})) &= \phi(\theta_j) + h \left(\hat{f}_j(\theta_j) \phi'(\theta_j) + \frac{1}{2} \phi''(\theta_j) \right) \\ &\quad + \frac{h^2}{2} \left(\hat{f}_j^2(\theta_j) - \text{Var}(\hat{f}(\theta_j)) \right) \phi''(\theta_j) + \hat{f}_j(\theta_j) \phi^{(3)}(\theta_j) + \frac{1}{4} \phi^{(4)}(\theta_j) + \mathcal{O}(h^3). \end{aligned}$$

Taking expectations with respect to the random sampling and using Equation (48), we obtain

$$\begin{aligned} \mathbb{E}(\phi(\theta_{j+1})) &= \phi(\theta_j) + h\mathcal{L}\phi(\theta_j) \\ &\quad + \frac{h^2}{2} \left(\mathbb{E}_{\tau_j}(\hat{f}_j^2(\theta_j)) - \text{Var}(\hat{f}(\theta_j)) \right) \phi''(\theta_j) + f(\theta_j) \phi^{(3)}(\theta_j) + \frac{1}{4} \phi^{(4)}(\theta_j) + \mathcal{O}(h^3), \end{aligned} \quad (52)$$

where \mathcal{L} is the generator of Equation (1). We thus see that the mSGLD is a first order weak method and

$$A_1(\pi)\phi = \frac{1}{2} \left(\mathbb{E}_{\tau_j}(\hat{f}_j^2(\theta)) - \text{Var}(\hat{f}(\theta)) \right) \phi'' + f(\theta) \phi^{(3)} + \frac{1}{4} \phi^{(4)}$$

Using the expression for \mathcal{L}^2 as in the case of SGLD, we have that,

$$\begin{aligned} \frac{1}{2} \mathcal{L}^2 - A_1 &= \frac{1}{2} \left(f(\theta) f'(\theta) + \frac{1}{2} f''(\theta) \right) \frac{d}{d\theta} + \frac{1}{2} \left(f'(\theta) + f^2(\theta) - \mathbb{E}_{\tau_j}(f^2(\theta)) + \text{Var}(\hat{f}(\theta)) \right) \frac{d^2}{d\theta^2} \\ &= \frac{1}{2} \left(f(\theta) f'(\theta) + \frac{1}{2} f''(\theta) \right) \frac{d}{d\theta} + \frac{1}{2} f'(\theta) \frac{d^2}{d\theta^2} \end{aligned} \quad (53)$$

We see that the leading order term in the weak error and the error for the ergodic averages is the same as for the Euler method, which uses all data at every step. In higher dimensions, a similar calculation gives the mSGLD updates,

$$\theta_{j+1} = \theta_j + h\hat{f}_j(\theta_j) + \sqrt{h} \left(I - \frac{h}{2} \text{Cov}(\hat{f}(\theta_j)) \right) \xi_j \quad (54)$$

where

$$\text{Cov}(\hat{f}(\theta)) = \mathbb{E} \left[\left(\hat{f}(\theta) - \mathbb{E}(\hat{f}(\theta)) \right) \left(\hat{f}(\theta) - \mathbb{E}(\hat{f}(\theta)) \right)^\top \right]$$

and ξ_j is a d -dimensional standard normal random variable.

Remark 7 Except for special cases, $\text{Var}(\hat{f}(\theta_j))$ does not have a closed form. The simplest possible way to proceed without it is to replace it by an unbiased estimator, for example in case of sampling without replacement,

$$\widehat{\text{Var}}(\hat{f}(\theta)) := \frac{N(N-n)}{n(n-1)} \sum_{i=1}^n \left(\nabla \log \pi(x_{\tau_i} | \theta) - \frac{\hat{f}_j(\theta)}{N} \right)^2.$$

This replacement does not change Equation (53) because the smallest order contribution to Equation (49) is of the form

$$-h^2 \mathbb{E} \left[\widehat{\text{Var}}(\hat{f}(\theta_j)) \xi_j^2 \right] = -h^2 \text{Var}(\hat{f}(\theta_j)).$$

However, estimating the variance of the stochastic gradient will affect higher order terms in h . For fixed h these terms may have larger contribution to the overall error depending on the choice of n and N . In fact, this is true even if we use the exact variance for the toy model in Section 2.1. More precisely, we compare the bias of the mSGLD and the SGLD in Equation (70) notice that h^2 term might be larger depending on the choice of n and N .

5. Finite Time Sample Averages

Having focused on the SGLD in the asymptotic regime, we will now provide non-asymptotic analysis of the mean squared error (MSE) of the finite time sample averages of the SGLD. In particular, we will decompose the MSE into bias and variance. The main result of this section will be of the form

$$\begin{aligned} \text{Bias:} & \quad \left| \mathbb{E} \frac{1}{K} \sum_{i=0}^{K-1} \phi(\theta_i) - \int \phi(x) \pi(x) dx \right| = \mathcal{O} \left(\frac{1}{h + \frac{1}{Kh}} \right) \\ \text{MSE:} & \quad \mathbb{E} \left(\frac{1}{K} \sum_{i=0}^{K-1} \phi(\theta_i) - \int \phi(x) \pi(x) dx \right)^2 = \mathcal{O} \left(h^2 + \frac{1}{Kh} \right) \end{aligned} \quad (55)$$

Remark 8 In Teh et al. (2014), a central limit theorem was provided for the decreasing step size SGLD which shows a convergence rate of $O(K^{-\frac{5}{3}})$. At first sight, the bound in Equation (55) seems better because of the $\frac{1}{\sqrt{K}}$ term in the upper bound. However, due to the bias, an additional term of order $O(h^2)$ appears. In order to compare (55) with the previous result of Teh et al. (2014), we optimise the sum of both terms over the step size h . This results in a bound on the MSE of the SGLD of order $O(K^{-\frac{5}{3}})$ and agrees with the rate achieved by the decreasing step size SGLD. This agreement between decreasing step size discretisation and fixed step size discretisation is, to our knowledge, not a widely-known observation in the literature. In contrast, for standard MCMC algorithms the MSE is bounded by order $O(K^{-1})$ due to the Metropolis-Hastings correction that removes the bias. Nevertheless, experimental results in the literature demonstrate that the SGLD might be advantageous in the initial transient phase of learning, see e.g. Patterson and Teh (2013); Chen et al. (2014)

In Section 5.2 we will focus on establishing the bound in Equation (55) which is an extension of the work by Mattingly et al. (2010). The authors obtained similar results for finite time sample averages of discretisations of diffusions of the form

$$d\theta_t = f(\theta_t) + g(\theta_t) dW_t \quad (56)$$

on the torus which we review subsequently in Section 5.1.

5.1 Preliminaries on the Poisson Equation and Time Averages

In the following a connection between time averages of the diffusion and the corresponding Poisson equation will be presented. For a more elaborate description of this technique we point the reader to Section 4.2 of Mattingly et al. (2010) and references therein.

The Poisson equation is an elliptic PDE on the basis of the generator associated with Equation (56). The generator of Equation (56) is

$$\mathcal{L}\psi = \nabla\psi \cdot \nabla f + \frac{1}{2}g(\theta)^\top \nabla^2\psi g(\theta),$$

while the Poisson equation is given by

$$\mathcal{L}\psi = \phi - \bar{\phi} \quad \text{on } \mathbb{R}^d \quad (57)$$

where ϕ is a test function and $\bar{\phi} := \int \phi(x)\pi(dx)$ with π being the invariant distribution of (56). For applications in Bayesian statistics π represents the posterior and the quantity $\bar{\phi}$ the posterior expectation of interest. The posterior expectation ϕ is estimated by the time average $\frac{1}{T} \int_0^T \phi(\theta(s)) ds$ of the Langevin dynamics. The difference between the two can be expressed explicitly by using Itô's formula on the solution ψ of the Poisson equation

$$\begin{aligned} \psi(\theta(t)) - \psi(\theta(0)) &= \int_0^t \phi(\theta(s)) - \bar{\phi} ds + \int_0^t \nabla\psi(\theta(s)) \cdot g(\theta(s)) dW_s, \\ \frac{1}{T} \int_0^T \phi(\theta(s)) ds - \bar{\phi} &= \frac{1}{T} (\psi(\theta(T)) - \psi(\theta(0))) - \frac{1}{T} \int_0^T \nabla\psi(\theta(s)) \cdot g(\theta(s)) dW_s. \end{aligned}$$

If the first term and the variance of the second term (the martingale term) on the right hand side can be bounded, an error bound for the time average is obtained.

In this article, we are interested in the time average of the Euler discretisation and the SGLD. We can build on the ideas of Section 5 in Mattingly et al. (2010) which considers time discretisations of Equation (56) of the following form

$$\theta_{k+1} = \theta_k + h f(\theta_k, h) + \sqrt{hg}(\theta_k, h) \eta_k, \quad \eta_k \sim \mathcal{N}(0, I).$$

In Mattingly et al. (2010) a Taylor expansion is used to express

$$\Delta\psi(\theta_{k+1}) := \psi(\theta_{k+1}) - \psi(\theta_k) = h(A_0\psi)'(\theta_k) + R_k$$

where R_k is the remainder term. The term A_0 was introduced in Equation (33) in Section 3.1.

Using that $\mathcal{L}\psi = \phi - \bar{\phi}$, summing over k and dividing by hK yields

$$\hat{\phi}_K := \frac{1}{K} \sum_{k=0}^{K-1} \phi(\theta_k) = \bar{\phi} + \frac{1}{Kh} (\psi(\theta_K) - \psi(\theta_0)) - \frac{1}{hK} \sum_{k=0}^{K-1} h(A_0 - \mathcal{L})\psi(\theta_k) - \frac{1}{Kh} \sum_{k=0}^{K-1} R_k.$$

Controlling $A_0 - \mathcal{L}$ and the remainder gives rise to Theorem 5.1 and 5.2 in Mattingly et al. (2010) stating that

$$\begin{aligned} \left| \mathbb{E} \hat{\phi}_K - \bar{\phi} \right| &\leq C \left(h + \frac{1}{h \cdot K} \right) \\ \mathbb{E} \left(\hat{\phi}_K - \bar{\phi} \right)^2 &\leq C \left(h^2 + \frac{1}{h \cdot K} \right). \end{aligned} \quad (58)$$

In particular, these results were derived for discretisations of SDEs on the torus. This simplifies the presentation because the derivatives of ψ are bounded on a compact set. However, the same arguments hold if the following assumption is imposed instead

$$\sup_k \mathbb{E} \left\| \psi^{(i)}(\theta_k) \right\| < \infty \quad \text{for } i = 1, \dots, 4, \quad (59)$$

verifying this condition will allow us to work on \mathbb{R}^d .

5.2 The Bias and the MSE of Finite Time SGLD Averages

We consider the SDE

$$d\theta_t = f(\theta_t) dt + g(\theta_t) dW_t, \quad (60)$$

with $g = I$ being the identity matrix but we keep g in order to make the presentation clearer. Based on this setup the recursion of the corresponding SGLD reads as follows

$$\Delta_{k+1} = \theta_{k+1} - \theta_k = \hat{f}_k h + h^{\frac{1}{2}} g_k \xi_{k+1}$$

where \hat{f}_k is an unbiased estimate of f . The focus of this section is to establish results similar to Equation (58) for the SGLD. They will be formulated in Theorem 9.

For the readability of the subsequent calculation we use the following notations

$$\Delta_{k+1} = \theta_{k+1} - \theta_k, \quad \phi_k = \phi(\theta_k),$$

$\hat{f}_k = \hat{f}(\theta_k, \tau_k, h)$ for the estimate of the drift, $g_k = g(\theta_k, h) = I$, $\psi_k = \psi(\theta_k)$, $V_k = V(\theta_k)$ and $D^k \psi_k = D^k \psi(\theta_k)$. The term A_0 , as introduced in Equation (33) in Section 3.1, satisfies $A_0 = \mathcal{L} = \mathcal{L}$ but we keep A_0 for clarity. Thus, we have

$$A_0 \psi_k = \nabla \psi \cdot \mathbb{E}_\tau \hat{f}(\theta_k, \tau, h) + \frac{1}{2} \text{trace} \left(S(\theta_k)^t \nabla^2 \psi(\theta_k) \right)$$

where $S(\theta) = g(\theta)g(\theta)^T = I$.

We use the following third order Taylor expansion on $\psi(\theta_{k+1}) - \psi(\theta_k)$ in order to obtain a bound on $\frac{1}{K} \sum_{k=0}^{K-1} (\phi_k - \bar{\phi})$

$$\begin{aligned} \psi_{k+1} &= \psi_k + \nabla \psi_k \cdot \Delta_{k+1} + \frac{1}{2} \Delta_{k+1}^T \nabla^2 \psi_k \Delta_{k+1} + \frac{1}{6} \psi_k^{(3)}(\Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}) + R_{k+1} \\ R_{k+1} &= \frac{1}{6} \int_0^1 s^3 \psi_k^{(4)}(s\theta_k + (1-s)\theta_{k+1})(\Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}) ds. \end{aligned}$$

Here $\psi^{(3)}$ and $\psi^{(4)}$ are the third and fourth order derivative in the form of a trilinear and a quadrilinear form, respectively. In this setting, a third order expansion is required in order to obtain the h^2 term in the $h^2 + \frac{1}{T}$ bound in the MSE (see Equation (58) or Theorem 9). More precisely, the remainder of this expansion is fourth order which together with the term $\sqrt{h} \xi_m$ in Equation (5) contributes to the h^2 error term. In order to make the connection to the Poisson equation, we write the expansion above in terms of A_0 . This yields

$$\begin{aligned} \psi_{k+1} &= \psi_k + h A_0 \psi_k + h^{\frac{1}{2}} \nabla \psi_k \cdot \underbrace{\left(\hat{f}_k - \mathbb{E}_\tau \hat{f}(\theta_k, \tau, h) \right)}_{H_k} + h^{\frac{3}{2}} (g_k \xi_{k+1})^T \nabla^2 \psi_k \hat{f}_k \\ &\quad + \frac{1}{2} \hat{f}_k^T h^2 \nabla^2 \psi_k \hat{f}_k + \frac{1}{6} \psi_k^{(3)}(\Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}) + r_{k+1} + R_{k+1} \end{aligned}$$

where $r_{k+1} = h^{\frac{1}{2}} \left((g_k \xi_{k+1})^T \nabla^2 \psi_k (g_k \xi_{k+1}) - S(x, h) \right)$.

Notice that $\frac{1}{hK} \sum_{k=0}^{K-1} h A_0 \psi_k = \frac{1}{K} \sum_{k=0}^{K-1} (\phi_k - \bar{\phi})$ is the error of interest. In order to control this error, we sum the expression for ψ_{k+1} for $k = 0, \dots, K-1$ and divide by

$T = hK$. Grouping the terms for subsequent inspection gives

$$\begin{aligned} \frac{\psi_K - \psi_0}{Kh} &= \frac{1}{K} \sum_{k=0}^{K-1} (\phi_k - \bar{\phi}) + \underbrace{\sum_{k=0}^{K-1} (\mathcal{L} - A_0) \psi_k}_0 \\ &\quad + \underbrace{\frac{1}{T} \sum_{k=0}^{K-1} r_{k+1}}_{M_{1,K}} + \underbrace{\frac{1}{T} h^{\frac{1}{2}} \sum_{k=0}^{K-1} \nabla \psi_k (g_k \xi_{k+1})}_{M_{2,K}} + \underbrace{\frac{1}{T} h^{\frac{3}{2}} \sum_{k=0}^{K-1} \hat{f}_k^T \nabla^2 \psi_k (g_k \xi_{k+1})}_{M_{3,K}} \\ &\quad + \underbrace{\frac{1}{T} h \sum_{k=0}^{K-1} \nabla \psi_k \cdot \left(\hat{f}_k - \mathbb{E}_\tau \hat{f}(\theta_k, \tau, h) \right)}_{M_{4,K}} + \underbrace{\frac{1}{T} \frac{1}{2} \sum_{k=0}^{K-1} h^2 \hat{f}_k^T \nabla^2 \psi_k \hat{f}_k}_{S_{1,K}} \\ &\quad + \underbrace{\frac{1}{T} \sum_{k=0}^{K-1} R_{k+1}}_{S_{2,K}} + \underbrace{\frac{1}{T} \frac{1}{6} \sum_{k=0}^{K-1} \psi_k^{(3)}(\Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1})}_{S_{3,K}}. \end{aligned} \quad (61)$$

where the $M_{i,k}$ indicate the martingale terms and the $S_{i,k}$ other remainder terms. We split

$$S_{3,K} = M_{0,K} + \tilde{M}_{0,K} + \tilde{S}_{0,K} + \tilde{S}_{0,K}$$

in terms of

$$\begin{aligned} M_{0,K} &= \frac{1}{6} h^{\frac{3}{2}} \sum_{k=0}^{K-1} \left(\psi_k^{(3)} \left((g_k \eta_{k+1}), (g_k \eta_{k+1}), (g_k \eta_{k+1}) \right) \right) \\ \tilde{M}_{0,K} &= \frac{1}{2} \sum_{k=0}^{K-1} h^{\frac{5}{2}} \psi_k^{(3)} \left(\hat{f}_k, \hat{f}_k, g_k \eta_{k+1} \right) \\ S_{0,K} &= \frac{1}{6} \sum_{k=0}^{K-1} 3h^2 \psi_k^{(3)} \left(g_k \eta_{k+1}, g_k \eta_{k+1}, \hat{f}_k \right) \\ \tilde{S}_{0,K} &= \frac{1}{6} \sum_{k=0}^{K-1} h^3 \psi_k^{(3)} \left(\hat{f}_k, \hat{f}_k, \hat{f}_k \right). \end{aligned}$$

Rearranging Equation (61) for $\frac{1}{K} \sum_{k=0}^{K-1} (\phi_k - \bar{\phi})$ and controlling the resulting right hand side of Equation (61) gives rise to the following theorem.

Theorem 9 *Suppose that there exists a function V such that the following three assumptions hold:*

1. *There are $p_{\psi,1}, \dots, p_{\psi,4} \in (0, \infty)$ such that the derivatives of the solution ψ to the Poisson equation satisfy the following bound*

$$\|\psi^{(k)}\| \lesssim V^{p_{\psi,k}}, \quad \text{for } k = 0, \dots, 4. \quad (62)$$

2. The drift f and the error from the estimate $H := f(\theta, \tau) - f(\theta)$ satisfy

$$\mathbb{E}_x H(\theta, \tau)^{2p} \lesssim V(\theta)^p \quad \forall p \leq p^* \quad (63)$$

$$\|f\|^2 \lesssim V.$$

for $p^* = \max\{2p_{\psi,2} + 2, 2p_{\psi,4} + 4, 2p_{\psi,3} + 1, 2p_{\psi,3} + 3\}$. Moreover, we suppose that the $\mathbb{E}V^p(\theta_k)$ is bounded from above and that this bound is independent of k , that is

$$\sup_k \mathbb{E}V^p(\theta_k) < \infty, \quad \forall p \leq p^*. \quad (64)$$

3. V satisfies

$$\sup_s V(s\theta_1 + (1-s)\theta_2)^p \lesssim V(\theta_1)^p + V(\theta_2)^p, \quad \text{for all } \theta_1, \theta_2, p \leq p^*. \quad (65)$$

Under these assumptions there exists $h_0 > 0$ and constant C such that for all $h < h_0$

$$\text{Bias}(\hat{\phi}_K) = \left| \mathbb{E}\hat{\phi}_K - \bar{\phi} \right| \leq C \left(h + \frac{1}{Kh} \right) \quad (66)$$

$$\mathbb{E} \left(\hat{\phi}_K - \bar{\phi} \right)^2 \leq C \left(h^2 + \frac{1}{Kh} \right) \quad (67)$$

where

$$\hat{\phi}_K = \frac{1}{K} \sum_{k=0}^{K-1} \phi(\theta_k) \quad \text{and} \quad \bar{\phi} = \mathbb{E}\pi\phi.$$

Proof For each term we bound the term inside the sum by a power of V^p and then obtain an overall bound using $\sup_i \mathbb{E}V_i^p < \infty$. For example, $\frac{1}{K}\mathbb{E}S_{1,K}$ can be bounded as follows

$$\begin{aligned} \frac{1}{T} \mathbb{E}S_{1,K} &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 V_k^{p_{\psi,2}} \mathbb{E}\tau_k \|\hat{f}_k\|^2 \\ &\lesssim \frac{1}{T} \sum_{k=0}^{K-1} h^2 \sup_i \mathbb{E}V_i^{p_{\psi,2}+1} \lesssim \frac{1}{T} h^2 K \lesssim h. \end{aligned}$$

The details of this computation are contained in Appendix 9. \blacksquare

Theorem 9 and the results for the decreasing step size SGLD Teh et al. (2014) hold under assumptions formulated in terms of the solution ψ of the Poisson equation. More precisely, the crucial step is to establish a bound of the form

$$\sup_k \mathbb{E} \left\| \psi_{k+1}^{(i)}(\theta_k) \right\| < \infty \quad \text{for } k = 1, \dots, 4.$$

This bound is established using Equations (62) and (64)

$$\sup_k \mathbb{E} \left\| D^{(i)} \psi(\theta_k) \right\| \lesssim \sup_k \mathbb{E} \|V\|^{p_{\psi,i}} < \infty \quad \text{for } i = 1, \dots, 4.$$

Thus, we are left with finding an appropriate Lyapunov function V such that Equations (62) and (64) hold. In Appendix 9.1, we formulate strong sufficient conditions on π that ensure that these assumptions are satisfied and that Theorem 9 is applicable.

6. An Analytic Investigation of the Toy Model

We now extend our analysis of the one-dimensional Gaussian toy model introduced in Section 2 beyond the general results of the previous two sections. More precisely, in Section 6.1, we compare the Euler method, the SGLD and the mSGLD by comparing the computational cost for fixed level accuracy specified in terms of the mean square error in estimating the second moment (MSE₂), optimising over the step size h , the subsample size n and the number of steps M . A numerical solution to the resulting optimisation problem demonstrates that the SGLD is advantageous in the lower accuracy regime while it degenerates to $n = N$ in the high accuracy regime. On the other hand the mSGLD does not degenerate and seems to maintain a constant speed up compared to the Euler method. In Section 6.2 we then consider the MSE₂ and use an analytic expression to study the behaviour of these algorithms for growing N . This allows us to extend the analysis of Sections 2 and 4 (in which we only consider the case limit $h \rightarrow 0$) and study the asymptotic bias of the SGLD and the mSGLD by scaling both n and h in N .

In Section 6.3 we finally adopt a different viewpoint by considering a fixed value of our parameter θ , denoted by θ^* , while we take expectations with respect to the realisation of the data $\{X_i\}$. This enables us to study how $\mathbb{E}_X(\text{MSE}_2)$ behaves in the limit of $N \rightarrow \infty$. In particular, we find that for the case of the SGLD, the computational cost in order for $\mathbb{E}_X(\text{MSE}_2) \rightarrow 0$ is reduced by a factor of N when compared to the Euler method. A similar analysis for the expected relative error in estimating the posterior variance (ERE)

$$\text{ERE} = \mathbb{E}_{\{\theta_i\}} \left[\frac{\frac{1}{K} \sum_{i=0}^{K-1} \theta_i^2 - \left(\frac{1}{K} \sum_{i=0}^{K-1} \theta_i \right)^2}{\sigma_\theta^2} \right] - 1. \quad (68)$$

reveals that under the constraint $\mathbb{E}_X(\text{ERE}) \rightarrow 0$ the Euler method and the SGLD have the same computational cost on the algebraic scale in N .

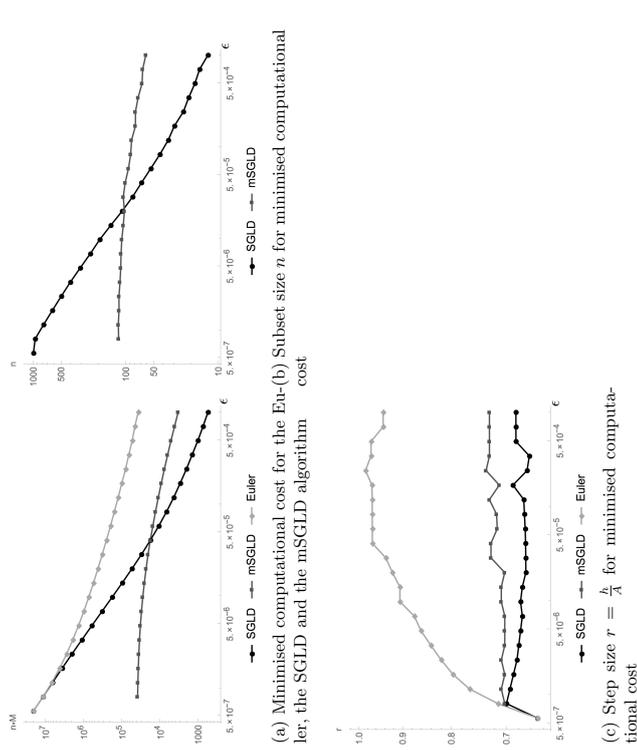

6.1 Minimising Computational Effort for Constrained MSE₂

In Section 2.2 we compared the Euler method, the SGLD and the mSGLD for the same choice of $r = \frac{r}{4}$. In the following we numerically minimise the computational effort with respect to the condition $\text{MSE}_2 \leq \epsilon^2$. We assume that the computational cost is proportional to $M \cdot n$ which leads to the problem of solving

$$\begin{aligned} \min_p \quad & M \cdot n \\ \text{subject to} \quad & \text{MSE}_2(r, M, n) \leq \epsilon^2 \\ \text{w.r.t.} \quad & r < 1, M, n. \end{aligned} \quad (69)$$

Even though we have analytic expressions for the MSE₂, the solution to the optimisation problem does not have a closed form. To conclude our analysis, we illustrate the numerical solution to this problem for $N = 1000$ for the Euler method, the SGLD and the mSGLD. The results, depicted in Figure 3, can be summarised as follows:

1. as ϵ becomes smaller, the gain of the SGLD over the Euler method in terms of computational effort decreases (due to the fact that n increases);

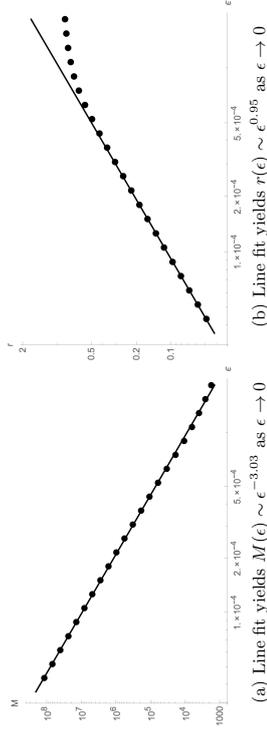

Figure 3: Minimisation of computational cost $\propto M \cdot n$ subject to $MSE \leq \epsilon^2$

- as ϵ becomes smaller, the mSGLD gains efficiency over the SGLD (the reason being that n seems to asymptote as ϵ decreases).

The upper bound obtained in Equation (67) suggests a scaling of $M \sim \epsilon^{-3}$ and $r \sim \epsilon$ to obtain an MSE of order ϵ^2 with minimal computational effort. The numerical minimisation of M with respect to r and M subject to the condition $MSE(r, M) \leq \epsilon^2$ confirms this scaling empirically, see Figure 4.

6.2 The MSE₂ for fixed and increasing N

We now consider the behaviour for growing data size N where a new data set X is generated in each instance. Figure 5 depicts the MSE₂ for $N = 10^i$ with $i = 1, \dots, 4$ for the subset choices $n = N^{0.1}, N^{0.5}$ and $N^{0.9}$; each compared to the Euler method corresponding to $n = N$. In this plot we notice that the SGLD outperforms the mSGLD for $n = N^{0.1}$ and $n = N^{0.5}$. The behaviour in Figure 5 suggests that the mSGLD has a larger bias than the SGLD which seems to contradict the findings of Section 2 and 4. Previously, we have just considered the asymptotic of $h \rightarrow 0$. In contrast, we scale both $h = r \frac{1}{\lambda(N)}$ and $n = N^p$ in

Figure 4: Scaling of $r(\epsilon)$ and $M(\epsilon)$ for minimal computational cost subject to the $MSE_2(r(\epsilon), M(\epsilon)) \leq \epsilon^2$

terms of N in Figure 5. In the following we investigate this relationship further by using the explicit formula for the asymptotic bias which has been made available in Section 2.

For simplicity we consider sampling without replacement, using the expression in Equation (16). Similar conclusions hold for sampling with replacement. First we consider the mSGLD. From Equation (21) and using the parameterisation $h = r/A$ of the step size, the excess asymptotic bias becomes

$$h^2 \frac{\text{Var}(B)^2}{4(2A - A^2h)} = \frac{(r/A)^2 \left(\frac{N-n}{n}\right)^2 N^2 \text{Var}(X)^2}{4(2 - r)A}.$$

Because $A \sim N$, we see that the excess bias stays bounded for large N if and only if $n \gtrsim N^{\frac{1}{2}}$. In contrast, the same consideration for the SGLD shows that the excess bias due to subsampling vanishes so long as $n \rightarrow \infty$ when $N \rightarrow \infty$.

We can also identify the regime in which the mSGLD has a smaller asymptotic bias than the SGLD. From Equations (18) and (21) we see that this is the case when

$$\frac{h^2 \text{Var}^2(B)}{4(2A - A^2h)} \leq \frac{h \text{Var}(B)}{2A - A^2h}. \quad (70)$$

Using Equation (16), the above can be rearranged to

$$1 \geq \frac{h}{4} \frac{1}{16\sigma_x^2} \frac{N(N-n)}{N} \text{Var}(X).$$

Let $c = \frac{N}{N-n}$ be the relative size of the subsampling. Using $h = r/A$ where A is given in Equation (15), we get

$$c \geq \frac{2rN\text{Var}X}{16\sigma_x^2 \left(\frac{1}{\sigma_\theta^2} + \frac{N}{\sigma_x^2}\right) + 2rN\text{Var}X}$$

which in the limit of large data sets $N \rightarrow \infty$ yields

$$c \geq \frac{2r\text{Var}X}{16 + 2r\text{Var}X} > 0.$$

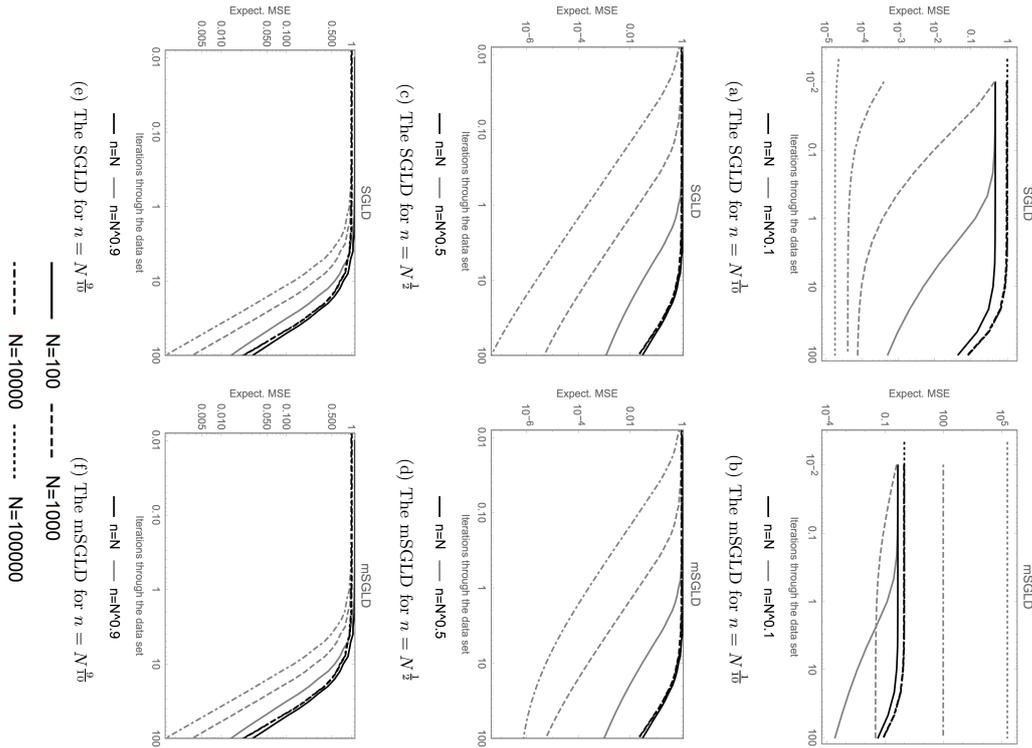

Figure 5: MSE_2 of the time average for the SGLD and the mSGLD for the second moment of the posterior as $N \rightarrow \infty$. Notice that Figures (c) and (d) and (e) and (f) have the same scaling respectively. Moreover, figures (a) and (b) have separate scaling because of the instability of the mSGLD.

In conclusion, for a fixed step size given by r/A , the mSGLD has a smaller bias than the SGLD if the above holds. In other words, the subsampling size has to be linear in the size of the data set for a fixed choice of r .

6.3 Limit of the MSE and ERE for well-specified Data as $N \rightarrow \infty$

In order to investigate the limit of $N \rightarrow \infty$, we need to specify the behaviour of the data as well. We study this in the well-specified case; in other words, we assume that the data is generated by the model for $\theta^* = 1$. Previously, we have obtained an analytic expression for the expectation of the MSE_2 with respect to the realisation of the noise driving the algorithm. In contrast, we take expectations with respect to the realisation of the data X and the noise driving the algorithm in the following results. These results are formulated in analytic expressions² for the MSE_2 and the ERE depending only on M, n, r and N . We then choose M, n and r as functions of N and study the limit $N \rightarrow \infty$ and how this affects the computational cost and the behaviour of the ERE and the MSE_2 as $N \rightarrow \infty$ for the different algorithms.

For the Euler method ($n = N$) we need to take $h < \frac{1}{4} \asymp \frac{1}{N}$ in order to make Equation (17) stable. Moreover, we need the number of steps M to be of order N to approximate the diffusion to a time of order $\mathcal{O}(1)$. Because we evaluate N data points per step, this heuristic argument suggests that the complexity is of order $\mathcal{O}(N^2)$. Furthermore, we verify (using Mathematica[®]), that for the Euler method ($n = N$)

$$\lim_{N \rightarrow \infty} \mathbb{E}_X \text{MSE} = 0, \quad \lim_{N \rightarrow \infty} \mathbb{E}_X \text{ERE} = 0 \quad (71)$$

for the choices $M = N^{1+2\epsilon}$ and $r = N^{-\epsilon}$ for any $\epsilon > 0$. The computational cost for fixed N is $M \cdot n = N^{2+2\epsilon}$. Thus, this confirms the heuristics we used for the Euler method in Section 6.2.

A natural next question to ask in terms of the SGLD is if one can have Equation (71) to hold but for smaller computational complexity than the Euler method. Using Mathematica[®], we obtain the following theorem for the MSE

Theorem 10 For any $\epsilon > 0$ and the choices $h = N^{-1-\epsilon}$, $M = N^{1+2\epsilon}$ and $n = 1$, the SGLD satisfies

$$\lim_{N \rightarrow \infty} \mathbb{E}_{\theta_{1:1}, X} \left(\frac{1}{M} \sum_{k=0}^{M-1} \theta_k^2 - (\mu_p^2 + \sigma_p^2) \right)^2 = 0.$$

This constitutes a substantial gain compared to the Euler method because it reduces the computational complexity in the data size N from being almost quadratic to almost linear.

We now draw our attention to the expected relative error in estimating the posterior variance, abbreviated by

$$\text{ERE} := \mathbb{E}_{(\theta_1)} \frac{\frac{1}{K} \sum_{i=0}^{K-1} \theta_i^2 - \left(\frac{1}{K} \sum_{i=0}^{K-1} \theta_i \right)^2}{\sigma_p^2} - 1. \quad (72)$$

² see Appendix 10.2 for a sketch of the derivation for the MSE_2 (the derivation for ERE is similar)

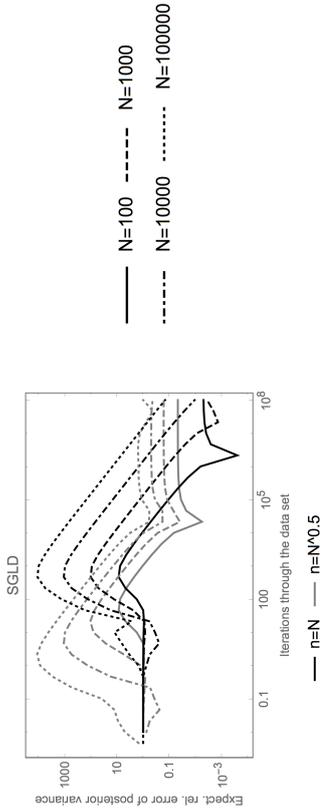

Figure 6: Expected relative error of the estimate of the variance of the posterior based on the SGLD.

Because the posterior variance goes to zero as $N \Rightarrow \infty$, it is conceivable that it requires more computational effort to ensure that $\lim_{N \rightarrow \infty} \mathbb{E}_X \text{ERE} = 0$. In order to illustrate the behaviour of the ERE, we first consider the behaviour for a fixed data set and repeat the experiment of Figure 5 in Figure 6. The latter demonstrates that the asymptotic bias for the choice $n = N^{\frac{1}{2}}$ (the asymptotes for the grey lines) have an increasing value in N . We used $h = \frac{1}{20A} \sim \frac{1}{N}$ which decreases with N . However, we show below that is requirement cancels exactly the gain from $n \ll N$ at least on the algebraic scale in N .

In particular, we now choose $r = N^{-\alpha}$, $n = N^\beta$ and $M = N^\gamma$. Hence the computational cost is $N^{\beta+\gamma}$. The step size $h = \frac{1}{N}$ satisfies $h \sim N^{-1-\alpha}$ because $A \sim N$. Since the algorithm performs $M = N^\gamma$ steps, we expect it to approximate the diffusion on the time interval $h \cdot M = N^{-1-\alpha+\gamma}$. Therefore it is reasonable to require that $\gamma > 1 + \alpha$. Under this assumption and with the help of Mathematica[®], we reduced the limit above to

$$\lim_{N \rightarrow \infty} \mathbb{E}_X \text{ERE} = \lim_{N \rightarrow \infty} \left(\frac{2 \cdot N^{-\alpha-\beta+3}}{(N+1)^2 (N^{-\alpha}-2)^2} - \frac{N^{-2\alpha-\beta+3}}{(N+1)^2 (N^{-\alpha}-2)^2} \right) = \begin{cases} 0 & \text{if } \alpha + \beta > 1 \\ \infty & \text{if } \alpha + \beta < 1. \end{cases}$$

Thus for $\lim_{N \rightarrow \infty} \mathbb{E}_X \text{ERE} = 0$ it is necessary that $\alpha + \beta \geq 1$. This condition in turn implies that the computational complexity satisfies

$$\underbrace{N^\gamma}_{\text{steps}} \times \underbrace{N^\beta}_{\text{cost per step}} = N^{1+\alpha} N^\beta = N^{1+\alpha+\beta} \gtrsim N^2.$$

Thus, there is no computational gain for the ERE in the limit $N \rightarrow \infty$ on the algebraic scale in N . We note that picking $\theta^* = \frac{1}{N}$ instead of $\theta^* = 1$ does not change the results. Thus, a closer initialisation does not change the result for the ERE.

7. Logistic Regression

In the following we present numerical simulations for a Bayesian logistic regression model. The data items are given by covariates $x_i \in \mathbb{R}^d$ that are labeled by $y_i \in \{-1, 1\}$. We assume the data $y_i \in \{-1, 1\}$ is modelled by

$$p(y_i | x_i, \beta) = \sigma(y_i \beta^T x_i) \quad (73)$$

where $\sigma(z) = \frac{1}{1 + \exp(-z)} \in [0, 1]$. The model poses the assumption that y_i depends on x_i through the linear relationship $\beta^T x_i$. Nevertheless, logistic regression is commonly used after a preprocessing has taken place and is therefore used here for numerical illustration.

We put a Gaussian prior $\mathcal{N}(0, C_0)$ on β , for simplicity we use $C_0 = I$ subsequently. By Bayes' rule the posterior π satisfies

$$\pi(\beta) \propto \exp\left(-\frac{1}{2} \|\beta\|_{C_0}^2\right) \prod_{i=1}^N \sigma(y_i \beta^T x_i).$$

We consider $d = 3$ and $N = 1000$ data points and choose the covariate to be

$$x = \begin{pmatrix} x_{1,1} & x_{1,2} & 1 \\ x_{2,1} & x_{2,2} & 1 \\ \vdots & \vdots & \vdots \\ x_{1000,1} & x_{1000,2} & 1 \end{pmatrix}$$

for a fixed sample of $x_{i,j} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, 1)$ for $i = 1, \dots, 1000$ and $j = 1, 2$. We use a long run of the Random-Walk-Metropolis algorithm to estimate the posterior mean.

On that basis we estimate the MSE of the SGLD based mean estimate using 100 runs of the algorithm with step size $h = 0.002$ for various subset sizes. Figure 7 depicts the MSE as function of the iterations and effective iterations through the data set. Notice that for this example the variance of the stochastic gradient $f(\theta)$ depends on both θ and all the data items. For this reason we replace $\text{Var } f(\theta)$ by an estimate $\text{Var } \hat{f}(\theta)$, see also Remark 7. We note that the mSGLD is superior for $n = 150$, inferior for $n = 50$ and for $n = 10$ the MSE of the mSGLD does not drop below 1.

8. Conclusion

This article presents the mathematical foundations that are necessary for posterior sampling for stochastic gradient methods with fixed step sizes. We derived an error expansion of the asymptotic bias in terms of powers of the step size and identified how the constant in the leading order term depends on the unbiased estimator of the gradient. We construct a modified SGLD to match the Euler method in this asymptotic expansion. These asymptotic results are complemented by upper bounds on the bias and the MSE over a finite time horizon. Minimising the MSE with respect to the step size yields a decay of the error at the same rate as the decreasing step size SGLD, see Remark 8. These theoretical findings are completed with extensive analytic investigations of a one dimensional toy model that allows the derivation of analytic expressions for the sample average and its moments. Finally, this

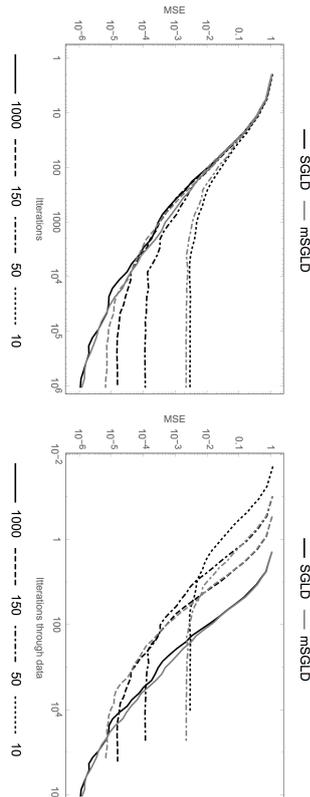

Figure 7: Expected MSE of time average for the SGLD and the mSGLD for the mean of the posterior

yields an exact quantification of expected errors. The results of this investigation can be summarised as follows:

- In the high accuracy regime the SGLD deteriorates to the Euler method while the mSGLD prevails.
- For small data batches the bias of the mSGLD is larger than for the SGLD.
- In the limit as the number of data items goes to infinity the SGLD reduces computational complexity of estimating the second moment with vanishing MSE by one power of the number of data items.

This recommends the construction of new and a study of existing modifications of the SGLD such as the Stochastic Gradient Hamiltonian Monte Carlo Chen et al. (2014) and the Stochastic Gradient Thermostat Monte Carlo Ding et al. (2014) algorithms.

9. Appendix A: Finite time Ergodic Average based Poisson Equation

Proof [Proof of Theorem 9] Rearranging Equation (61) for $\frac{1}{K} \sum_{k=0}^{K-1} (\phi_k - \bar{\phi})$, the bias and the MSE can be controlled as follows:

$$\mathbb{E} \frac{1}{K} (\psi_K - \psi_0) \lesssim \frac{1}{T} \sup_i \mathbb{E} V_i^{p_{\psi,0}} \lesssim \frac{1}{T}.$$

Because $A_0 = \mathcal{L}$ for the SGLD it is left to bound to bound $\mathbb{E} \frac{1}{T} S_{i,K}$ for $i = 0 \dots 4$. First we consider $i = 1$ and use Equation (A.6)

$$\begin{aligned} \frac{1}{T} \mathbb{E} S_{1,K} &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 V_k^{p_{\psi,2}} \mathbb{E}_{\tau_k} \|\hat{f}_k\|^2 \\ &\lesssim \frac{1}{T} \sum_{k=0}^{K-1} h^2 \sup_i \mathbb{E} V_i^{p_{\psi,2}+1} \lesssim \frac{1}{T} h^2 K \lesssim h. \end{aligned}$$

This procedure will be used over and over again. It can be summarised as follows:

1. bounding the terms in the sum by a power of V^p , using Equation (A.6) and the assumption on derivatives of ψ ;
2. then derive the bound using $\sup_i \mathbb{E} V_i^p < \infty$.

For $i = 2$ we additionally use that Equation (65) implies

$$\int_0^1 s^3 \psi^{(4)}(s\theta_k + (1-s)\theta_{k+1}) (\Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}, \Delta_{k+1}) ds \lesssim (V_k^{p_{\psi,4}} + V_{k+1}^{p_{\psi,4}}) \|\Delta_k\|^4,$$

which allows us to follow the general procedure

$$\begin{aligned} \frac{1}{T} \mathbb{E} S_{2,K} &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} R_{k+1} \\ &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 (V_k^{p_{\psi,4}} + V_{k+1}^{p_{\psi,4}}) \mathbb{E}_{\tau} \|\Delta_{k+1}\|^4 \\ &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 \sup_i \mathbb{E} V_i^{p_{\psi,4}+2}(\theta_i) \lesssim \frac{1}{T} h^2 \lesssim h. \end{aligned}$$

We apply the general procedure to $\mathbb{E} S_{0,K}$

$$\begin{aligned} \frac{1}{T} \mathbb{E} S_{0,K} &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 V_k^{p_{\psi,3}} \mathbb{E}_{\tau} \|g_k \eta_{k+1}\|^2 \|\hat{f}_k\| \\ &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^2 \sup_i \mathbb{E} V_i^{p_{\psi,3}+\frac{1}{2}}(\theta_i) \\ &\lesssim \frac{1}{T} h^2 \lesssim h. \\ \frac{1}{T} \mathbb{E} \tilde{S}_{0,K} &\lesssim \frac{1}{T} \mathbb{E} \sum_{k=0}^{K-1} h^3 V_k^{p_{\psi,3}} \mathbb{E}_{\tau} \|\hat{f}_k\|^3 \\ &\lesssim \frac{1}{T} \sum_{k=0}^{K-1} h^3 \sup_i \mathbb{E} V_i^{p_{\psi,3}+\frac{3}{2}}(\theta_i) \lesssim \frac{1}{T} K h^3 \lesssim h^2. \end{aligned}$$

Thus, we have established the bound on the bias given by Equation (A.3).

In order to establish the bound one the MSE in Equation (67) we note that Equation (61) yields

$$\begin{aligned} \mathbb{E} \left(\frac{1}{K} \sum_{k=0}^{K-1} (\phi - \bar{\phi}) \right)^2 &\lesssim \mathbb{E} \frac{(\psi_K - \psi)^2}{T^2} \\ &+ \frac{1}{T^2} \sum_{i=0}^2 \mathbb{E} S_{i,K}^2 + \frac{1}{T^2} \sum_{i=0}^2 \mathbb{E} M_{i,K}^2 \end{aligned}$$

First we note that

$$\mathbb{E} \frac{(\psi_K - \psi)^2}{T^2} \lesssim \frac{1}{T^2} \sup_i \mathbb{E} V_i^{2p_{\psi,0}} \lesssim \frac{1}{T^2}.$$

The $S_{i,K}^2$ terms can be bound in similar way as above with the additional use of Cauchy-Schwartz inequality to break the correlation between V_i^p and V_j^p .

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} S_{1,K}^2 &\lesssim \frac{1}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} h^4 \nabla^2 \psi_i [f_i, f_i] \nabla^2 \psi_j [f_j, f_j] \\ &\lesssim \frac{1}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} h^4 \|\nabla^2 \psi_i\| \|\mathbb{E}_\tau [f_i]\|^2 \|\nabla^2 \psi_j\| \|\mathbb{E}_\tau [f_j]\|^2 \\ &\lesssim \frac{1}{T^2} \sum_{i,j=0}^{K-1} h^4 \mathbb{E} V_i^{2p_{\psi,2}+1} V_j^{2p_{\psi,2}+1} \\ &\lesssim \frac{1}{T^2} \sum_{i,j=0}^{K-1} h^4 \left(\mathbb{E} V_i^{2p_{\psi,2}+2} \right)^{\frac{1}{2}} \left(\mathbb{E} V_j^{2p_{\psi,2}+2} \right)^{\frac{1}{2}} \\ &\lesssim \frac{1}{T^2} \sum_{i,j=0}^{K-1} h^4 \left(\sup_i \mathbb{E} V_i^{2p_{\psi,2}+2} \right) \lesssim \frac{K^2 h^4}{T^2} \lesssim h^2 \end{aligned}$$

Similarly, we bound

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} M_{1,K}^2 &= \frac{1}{T^2} \sum_{i=0}^{K-1} \left(\mathbb{E} D_{lm}^2 \psi_i \left(g_i^{l,a} \eta_{i+1}^{m,b} \eta_{i+1}^{k,l} - g_i^{k,l} g_i^{m,b} \right) \right)^2 \\ &\lesssim \frac{1}{T^2} \sum_{i=0}^{K-1} \sup_i \mathbb{E} V_i^{2p_{\psi,2}}. \end{aligned}$$

The following term is the crucial Martingale term as it yields the $\mathcal{O}(\frac{1}{T})$ contribution

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} M_{2,K}^2 &\lesssim \frac{1}{T^2} h \sum_{k=0}^{K-1} \mathbb{E} \|\nabla \psi_k\|^2 \|g_k \xi_{k+1}\|^2 \\ &\lesssim \frac{1}{T^2} h \sum_{k=0}^{K-1} \mathbb{E} V_k^{2p_{\psi,1}} \lesssim \frac{1}{T}. \end{aligned}$$

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} S_{2,K}^2 &\lesssim \frac{1}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} R_{i+1} R_{j+1} \\ &\lesssim \frac{1}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} (V_i^{2p_{\psi,4}} + V_{i+1}^{2p_{\psi,4}}) (V_j^{2p_{\psi,4}} + V_{j+1}^{2p_{\psi,4}}) \mathbb{E}_\tau \|\Delta_{i+1}\|^4 \mathbb{E}_\tau \|\Delta_{j+1}\|^4 \\ &\lesssim \frac{h^4}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} (V_i^{2p_{\psi,4}} + V_{i+1}^{2p_{\psi,4}}) (V_j^{2p_{\psi,4}} + V_{j+1}^{2p_{\psi,4}}) V_i^2 V_j^2 \\ &\lesssim \frac{h^4}{T^2} \mathbb{E} \sum_{i,j=0}^{K-1} (V_i^{2p_{\psi,4}} + V_{i+1}^{2p_{\psi,4}}) (V_j^{2p_{\psi,4}} + V_{j+1}^{2p_{\psi,4}}) V_i^2 V_j^2 \\ &\lesssim \frac{h^4}{T^2} \sum_{i,j=0}^{K-1} \left(\sup_i \mathbb{E} V_i^{2p_{\psi,4}+4} \right) \lesssim \frac{K^2 h^4}{T^2} \lesssim h^2. \end{aligned}$$

Similar bounds can also be obtained for $\frac{1}{T^2} \mathbb{E} S_{0,K}^2$ and $\frac{1}{T^2} \mathbb{E} \tilde{S}_{0,K}^2$

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} S_{0,K}^2 &\lesssim \frac{h^4}{T^2} \sum_{i,j=0}^{K-1} \mathbb{E} V_i^{2p_{\psi,3}} \|f_i\| V_j^{2p_{\psi,3}} \|f_j\| \\ &\lesssim \frac{h^4 K^2}{T^2} \sup_i \mathbb{E} V_i^{2p_{\psi,3}+1} \lesssim h^2 \\ \frac{1}{T^2} \mathbb{E} \tilde{S}_{0,K}^2 &\lesssim \frac{h^6}{T^2} \sum_{i,j=0}^{K-1} \mathbb{E} V_i^{2p_{\psi,3}} \|f_i\|^3 V_j^{2p_{\psi,3}} \|f_j\|^3 \\ &\lesssim \frac{h^6 K^2}{T^2} \sup_i \mathbb{E} V_i^{2p_{\psi,3}+2} \lesssim h^4 \end{aligned}$$

For Martingale terms the cross terms vanish which allows us to obtain the following bounds

Similarly, we estimate

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} M_{3,K}^2 &\lesssim \frac{1}{T^2} h^3 \sum_{k=0}^{K-1} \mathbb{E} \|\nabla^2 \psi_k\|^2 \|f_k\|^2 \|g_k \xi_{k+1}\|^2 \\ &\lesssim \frac{1}{T^2} h^3 \sum_{k=0}^{K-1} \mathbb{E} V_k^{2p_{\psi,2}+1} \lesssim \frac{h^2}{T}. \end{aligned}$$

The terms $\frac{1}{T^2} \mathbb{E} \bar{M}_{0,K}^2$ and $\frac{1}{T^2} \mathbb{E} \bar{M}_{0,K}^2$ can be bounded in the same way

$$\begin{aligned} \frac{1}{T^2} \mathbb{E} M_{0,K}^2 &\lesssim \frac{h^3}{T^2} \sum_{k=0}^{K-1} \mathbb{E} V_k^{2p_{\psi,3}} \lesssim \frac{h^3 K}{T^2} \leq \frac{h^2}{T} \\ \frac{1}{T^2} \mathbb{E} \bar{M}_{0,K}^2 &\lesssim \frac{h^5}{T^2} \sum_{k=0}^{K-1} \mathbb{E} V_k^{2p_{\psi,3}+2} \lesssim \frac{h^5 K}{T^2} \leq \frac{h^4}{T} \end{aligned}$$

The additional part for the SGLD is the term corresponding to the Martingale $M_{4,K}$

$$\begin{aligned} \frac{1}{T^2} M_{4,K}^2 &\lesssim \frac{1}{T^2} \mathbb{E} h^2 \sum_{k=0}^{K-1} (\nabla \psi_k(H_k))^2 \\ &\lesssim \frac{1}{T^2} \mathbb{E} h^2 \sum_{k=0}^{K-1} V_k^{2p_{\psi,1}} \mathbb{E}_\tau \|H_k\|^2 \\ &\lesssim \frac{1}{T^2} h^2 \sum_{k=0}^{K-1} \mathbb{E} V_k^{2p_{\psi,1}+1} \lesssim \frac{h}{T} \end{aligned}$$

For all these calculations to go through need $\sup_i E V_i^{p^*}$ to be bounded. Collecting the orders present, we see that

$$p^* = \max \{2p_{\psi,2} + 2, 2p_{\psi,4} + 4, 2p_{\psi,3} + 1, 2p_{\psi,3} + 3\}$$

is sufficient. \blacksquare

9.1 Sufficient Conditions on π Ensuring Finite Time Bounds on Bias and MSE

We formulate a sufficient condition on π that ensure that Theorem 9 is applicable. This hinges on deriving a sufficient condition for Equations (62), (64) and (65). The aim of this section is to establish and motivate the sufficient condition formulated in the following theorem.

Theorem 11 *Suppose the following condition holds*

$$\langle \theta, \nabla \log \pi_0(\theta) \rangle \leq -\alpha \|\theta\|^2 + \beta \tag{A.1}$$

$$\langle \theta, \nabla \log \pi(X_i | \theta) \rangle \leq -\alpha \|\theta\|^2 + \beta \text{ for } i = 1, \dots, N. \tag{A.2}$$

then Theorem 9 is applicable for polynomially bounded and continuous ϕ , that is

$$\begin{aligned} \text{Bias}(\hat{\phi}_K) &= \left| \mathbb{E} \hat{\phi}_K - \bar{\phi} \right| \leq C \left(h + \frac{1}{Kh} \right) \\ \mathbb{E} \left(\hat{\phi}_K - \bar{\phi} \right)^2 &\leq C \left(h^2 + \frac{1}{Kh} \right) \end{aligned}$$

Proof This result follows from Theorem 5.2 and results quoted below. \blacksquare

First we appeal to a sufficient condition for Equation (64) before summarising a regularity results of Pardoux and Veretennikov (2001) which allows us to establish Equation (62). We believe that the sufficient conditions above can be weakened, but this requires improving the results of Pardoux and Veretennikov (2001) which is out of the scope of this article.

The condition $\sup_k \mathbb{E} V^p(\theta_k) < \infty$ (that is Equation (64)) is established for all $p \leq p^*$ by Lemma 5 in Teh et al. (2014) if p^* satisfies the following assumption.

Assumption 12 *The drift term $\theta \mapsto \frac{1}{2} \nabla \log \pi(\theta)$ is continuous. The function $V : \mathbb{R}^d \rightarrow [1, \infty)$ tends to infinity as $\|\theta\| \rightarrow \infty$, is twice differentiable with bounded second derivatives and satisfies the following conditions:*

1. V is a Lyapunov function for the Langevin dynamics, i.e. there are constants $\alpha, \beta > 0$ such that for every $\theta \in \mathbb{R}^d$ we have

$$\left\langle \nabla V(\theta), \frac{1}{2} \nabla \log \pi(\theta) \right\rangle \leq -\alpha V(\theta) + \beta. \tag{A.3}$$

2. The following bounds hold

- There exists an exponent $p_H \geq 2$ such that
$$\mathbb{E} \|H(\theta, \mathcal{U})\|^{2p_H} \lesssim V^{p_H}(\theta). \tag{A.4}$$

Moreover, this implies that $\mathbb{E} \|H(\theta, \mathcal{U})\|^{2p} \lesssim V^p(\theta)$ for any exponent $0 \leq p \leq p_H$.

- For every $\theta \in \mathbb{R}^d$ we have

$$\|\nabla V(\theta)\|^2 + \|\nabla \log \pi(\theta)\|^2 \lesssim V(\theta). \tag{A.5}$$

Notice that for \hat{f} based on subsampling we obtain that $p_H = \infty$ if

$$\|\nabla \log \pi(x|\theta)\|^2 \leq C(x) V(\theta).$$

Notice that Assumption 12 also implies

$$\begin{aligned} \mathbb{E} \|\theta_{k+1} - \theta_k\|^{2p} &\leq V_k^p \\ \mathbb{E} \|\hat{f}_k\|^{2p} &\leq V_k^p \end{aligned} \tag{A.6}$$

if for $p \leq p_H$. Equation (65) could now simply be formulated as an additional assumption, however currently we need even stronger assumptions to verify Equation (62). Subsequently, we show how the results of Pardoux and Veretennikov (2001) can be used to establish Equation (62) if Equations (A.3) and (A.5) hold for $V = \|\theta\|^2 + 1$.

Theorem 1 and 2 of Pardoux and Veretennikov (2001) characterise the smoothness and growth of the solution to the Poisson equation associated with Equation (60). This is important for our results because the key ingredient for the proof of Theorem 9 is

$$\sup_k \mathbb{E} \left\| \psi^{(i)}(\theta_k) \right\| < \infty \text{ for } k = 1, \dots, 4.$$

Because we have already established in Section 4 that $\sup_i \mathbb{E} V^p(\theta_i) < \infty$ it is left to verify

$$\left\| \psi^{(k)} \right\| \lesssim V^{p_{\psi,k}}, \quad \text{for } k = 0, \dots, 4 \quad (62)$$

The assumptions needed to apply the Theorem 9 results are

$$\left\langle f(\theta), \frac{\theta}{\|\theta\|} \right\rangle \leq -r \|\theta\|, \quad \|\theta\| \geq M_0 \quad (A.7)$$

$$0 < \lambda_- \leq \left\langle g(\theta) g^*(\theta) \frac{\theta}{\|\theta\|}, \frac{\theta}{\|\theta\|} \right\rangle \leq \lambda_+ < \infty. \quad (A.8)$$

This holds if Assumption 12 is satisfied with $V(\theta) = \|\theta\|^2 + 1$.

Theorem 13 *Pardoux and Veretennikov (2001)* Let $\bar{f} = 0$ and Equations (A.7) and (A.8) are satisfied. Then there exists a solution $\psi \in W_{loc}^2$ to the Poisson equation

$$\mathcal{L}\psi = \phi - \bar{\phi}$$

1. If there is a C such that

$$|\phi(\theta)| \leq C(1 + \|\theta\|)^\beta$$

for some $\beta < 0$, then ψ is bounded. Moreover,

$$\sup_{\theta} |\psi(\theta)| \leq C \sup_{\theta} |f|(1 + \|\theta\|)^{-\beta}$$

and

$$\|\nabla\psi\| \leq C$$

2. if there exists a constant C and some $\beta > 0$ such that

$$|\phi(\theta)| \leq C(1 + \|\theta\|)^\beta$$

then there exist a constant such that

$$|\psi(\theta)| \leq C'(1 + \|\theta\|)^\beta.$$

Finally there exists C such that

$$\|\nabla\psi\| \leq C(1 + \|\theta\|^\beta).$$

Remark 14 *We believe that assumption Theorem 13 can be weakened to be of the form of Equation (A.3) but it is out of the scope of this article to explore this direction.*

In order to iterate Theorem 13 we note that the derivatives ψ can be expressed as solution to Poisson equations with different RHSs.

$$\mathcal{L}\psi = \phi - \bar{\phi} \quad (A.9)$$

$$A\partial_i\psi = \partial_i\phi - \frac{1}{2}\nabla\psi \cdot \partial_i\psi \quad (A.10)$$

$$A\partial_{ij}\psi = \partial_{ij}\phi - \frac{1}{2}\nabla\partial_j\psi \cdot \partial_i\psi - \frac{1}{2}\nabla\psi \cdot \partial_{ij}\psi - \frac{1}{2}\nabla\psi \cdot \partial_j\psi \cdot \partial_i\psi \quad (A.11)$$

$$A\partial_{ijk}\psi = \partial_{ijk}\phi - \frac{1}{2}\nabla\partial_k\psi \cdot \partial_{ij}\psi - \frac{1}{2}\nabla\partial_j\psi \cdot \partial_{ik}\psi - \frac{1}{2}\nabla\partial_i\psi \cdot \partial_{jk}\psi - \frac{1}{2}\nabla\psi \cdot \partial_{ijk}\psi - \frac{1}{2}\nabla\psi \cdot \partial_{ij}\psi \cdot \partial_k\psi - \frac{1}{2}\nabla\psi \cdot \partial_{jk}\psi \cdot \partial_i\psi - \frac{1}{2}\nabla\psi \cdot \partial_{ik}\psi \cdot \partial_j\psi \quad (A.12)$$

We will denote by $\beta_{\psi,i}$ numbers that satisfy

$$\sup_{|\alpha|=i} \|\theta^\alpha \psi\| \lesssim (1 + \|\theta\|^{\beta_{\psi,i}}) \quad (A.13)$$

where we used multi-index notation for derivatives. We use a similar notation for the derivatives of f , that is $\beta_{f,i}$ and assume that these bounds are a priori given.

Using Theorem 13 we can obtain $p_{\psi,i}$ to satisfy Equation (62) in terms of the β 's which we formulate as the following lemma.

Lemma 15 *Suppose that ϕ and its derivatives are bounded and Assumption 12 and Equations (A.7) and (A.8) hold. Then the choice*

$$\begin{aligned} p_{\psi,0} &= 0 \\ p_{\psi,1} &= 0 \\ p_{\psi,2} &= \frac{\beta_{f,1}}{2} \\ p_{\psi,3} &= \beta_{f,1} \vee \frac{\beta_{f,2}}{2} \\ p_{\psi,4} &= \frac{1}{2} (3\beta_{f,1} \vee (\beta_{f,1} + \beta_{f,2}) \vee \beta_{f,3}) \end{aligned}$$

satisfies Equation (62).

Proof Assumption 12 yields that $\beta_{f,0} = 1$ is a valid choice. Applying Theorem 13 to Equation (A.9) implies that $\beta_{\psi,0} := \beta_{\psi,1} = 0$ satisfies Equation (A.13). Applying Theorem 13 to Equation (A.10) yields that

$$\beta_{\psi,2} \leq \beta_{f,1}.$$

Applying Theorem 13 to Equation (A.11) yields that

$$\beta_{\psi,3} \leq 2\beta_{f,1} \vee \beta_{f,2}.$$

Applying Theorem 13 to Equation (A.12) yields that

$$\begin{aligned} \beta_{\psi,4} &\leq (\beta_{f,1} + (2\beta_{f,1} \vee \beta_{f,2})) \vee (\beta_{f,1} + \beta_{f,2}) \vee \beta_{f,3} \\ &\leq 3\beta_{f,1} \vee (\beta_{f,1} + \beta_{f,2}) \vee \beta_{f,3}. \end{aligned}$$

Thus we have established Equation (62). \blacksquare

10. Analytic expressions for the Gaussian Toy Model

We sketch the derivation of the analytic expression of the MSE are used for the plots in Section 6.

10.1 Expected MSE for fixed Data Sets

We outline how an analytic expression for the MSE of the sample average can be derived. The following method generalises to any polynomial test function but we concentrate on the sample average for the second moment of the posterior given by $S_2 = \frac{1}{M} \sum_{j=0}^{M-1} \theta_j^2$. Its MSE can be expressed using Equation (12)

$$MSE = \mathbb{E} \left(\frac{1}{M} \sum_{k=0}^{M-1} \theta_j^2 - (\mu_j^2 + \sigma_j^2) \right)^2 = \mathbb{E} S_2^2 - 2\mathbb{E} S_2 (\mu_j^2 + \sigma_j^2) + (\mu_j^2 + \sigma_j^2)^2. \quad (\text{C.1})$$

In order to express $\mathbb{E} S_2^2$ in Equation (C.1) we derive the recurrence equations for $\mathbb{E} \theta_j^i$ for $i = 1, \dots, 4$ by taking the expectations of

$$\theta_{j+1} = (1 - Ah)\theta_j + hB_j + \sqrt{h}\eta_j$$

$$\theta_{j+1}^2 = (1 - Ah)^2 \theta_j^2 + h^2 B_j^2 + h\eta_j^2 + 2(1 - Ah)\theta_j h B_j + 2(1 - Ah)\theta_j \sqrt{h}\eta_j + 2hB_j \sqrt{h}\eta_j \quad (\text{C.2})$$

$$\begin{aligned} \theta_{j+1}^3 &= \left((1 - Ah)\theta_j + hB_j + \sqrt{h}\eta_j \right)^3 \\ &= (1 - Ah)^3 \theta_j^3 + 3(1 - Ah)^2 \theta_j^2 h B_j + 3(1 - Ah)\theta_j h^2 B_j^2 + h^3 B_j^3 \\ &\quad + 3\sqrt{h}\eta_j (\dots) + 3\eta_j^2 h ((1 - Ah)\theta_j + hB_j) + \eta_j^3 h^{\frac{3}{2}} \end{aligned}$$

$$\theta_{j+1}^4 = (1 - Ah)^4 \theta_j^4 + 4(1 - Ah)^3 \theta_j^3 h B_j + 6(1 - Ah)^2 \theta_j^2 h^2 B_j^2 \quad (\text{C.3})$$

$$+ 4(1 - Ah)\theta_j h^3 B_j^3 + h^4 B_j^4 + 4\eta_j (\dots) + 4\eta_j^3 (\dots) \quad (\text{C.4})$$

$$+ 6h\eta_j^2 ((1 - Ah)^2 \theta_j^2 + 2(1 - Ah)\theta_j h B_j + h^2 B_j^2) + \eta_j^4 h^2. \quad (\text{C.5})$$

The recurrent equation for $\mathbb{E} \theta_j$ is linear and first order and can therefore be solved explicitly. Plugging the result into the equation for $\mathbb{E} \theta_j^2$ turns it into a first order linear equation as well. Repeating this processes yields explicit expressions for $\mathbb{E} \theta_j^i$ $i = 1, \dots, 4$. The sums can be carried out explicitly because the terms are of the form of a geometric sum or a geometric term with a polynomial factor. This allows us to obtain an analytic expression for $\mathbb{E} S_2^2$ by reducing it to $\mathbb{E} \theta_j^i$ as follows

$$\mathbb{E} S_2^2 = \frac{1}{M^2} \mathbb{E} \left(\sum_{i=0}^{M-1} \theta_i^4 + 2 \sum_{i=0}^{M-1} \theta_i^2 \sum_{j=i+1}^{M-1} \theta_j^2 \right). \quad (\text{C.6})$$

The cross terms can be removed using Equation (C.2) so that

$$\begin{aligned} \theta_j^2 &= (1 - Ah)^{2(j-i)} \theta_i^2 + \sum_{k=0}^{j-1-i} (1 - Ah)^{2k} \\ &\quad [h^2 B_{j-1-k}^2 + h^2 \eta_{j-1-k}^2 + 2(1 - Ah) B_{j-1-k} h \theta_{j-1-k} + \\ &\quad + 2(1 - Ah) \eta_{j-1-k} \theta_{j-1-k} \sqrt{h} + 2h^{\frac{3}{2}} B_{j-1-k} \eta_{j-1-k}]. \end{aligned} \quad (\text{C.7})$$

Plugging this into Equation (C.6) yields

$$\begin{aligned} \mathbb{E} S_2^2 &= \mathbb{E} \frac{1}{M^2} \sum_{i=0}^{M-1} \theta_i^4 \left(1 + 2 \sum_{j=i+1}^{M-1} (1 - Ah)^{2(j-i)} \right) \\ &\quad + \mathbb{E} \frac{1}{M^2} \sum_{i=0}^{M-1} \theta_i^2 \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1 - Ah)^{2k} \\ &\quad [h^2 B_{j-1-k}^2 + h\eta_{j-1-k}^2 + h\eta_{j-1-k}^2 \sqrt{h} + 2(1 - Ah) B_{j-1-k} h \theta_{j-1-k} \\ &\quad + 2(1 - Ah) \eta_{j-1-k} \sqrt{h} + 2h^{\frac{3}{2}} B_{j-1-k} \eta_{j-1-k}]. \end{aligned}$$

Using the recurrence Equation to express θ_{j-1-k} in terms of θ_i we conclude that $\mathbb{E} S_2^2$ is equal to

$$\begin{aligned} &\frac{1}{M^2} \sum_{i=0}^{M-1} \mathbb{E} \theta_i^4 \left(1 + 2 \sum_{j=i+1}^{M-1} (1 - Ah)^{j-i} \right) \\ &\quad + \frac{1}{M^2} \sum_{i=0}^{M-1} \mathbb{E} \theta_i^2 \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1 - Ah)^{2k} [h^2 \mathbb{E} B^2 + h]. \\ &\quad + \mathbb{E} \frac{1}{M^2} \sum_{i=0}^{M-1} \theta_i^2 \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1 - Ah)^{2k} 2(1 - Ah) B_{j-1-k} h \\ &\quad \left((1 - Ah)^{(j-1-k)-i} \theta_i + \sum_{l=0}^{(j-1-k)-i-1} (1 - Ah)^l (h B_{j-1-k-l-1} + \sqrt{h} \eta_{j-1-k-l-1}) \right) \end{aligned}$$

Taking the expectations into the sum yields

$$\begin{aligned} \mathbb{E}S_2^2 &= \frac{1}{M^2} \sum_{i=0}^{M-1} \mathbb{E}\theta_i^4 \left(1 + 2 \sum_{j=i+1}^{M-1} (1-Ah)^{j-i} \right) \\ &\quad + \frac{1}{M^2} \sum_{i=0}^{M-1} \mathbb{E}\theta_i^2 \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1-Ah)^{2k} [h^2 \mathbb{E}B^2 + h]. \\ &\quad + \mathbb{E} \frac{1}{M^2} \sum_{i=0}^{M-1} \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1-Ah)^{2k} 2(1-Ah) \mathbb{E}Bh(1-Ah)^{j-1-k-i} \\ &\quad + \frac{1}{M^2} \sum_{i=0}^{M-1} \mathbb{E}\theta_i^2 \sum_{j=i+1}^{M-1} \sum_{k=0}^{j-1-i} (1-Ah)^{2k} 2(1-Ah) \mathbb{E}Bh \sum_{l=0}^{j-1-k-i-1} (1-Ah)^l h \mathbb{E}B. \end{aligned}$$

We have an expressions for $\mathbb{E}B$ but in the following we derive the expressions for $\mathbb{E}B^2$ required to express $\mathbb{E}S_2^2$. The terms $\mathbb{E}B^3$ and $\mathbb{E}B^4$ are needed for the derivation of $\mathbb{E}\theta_j^4$. In order to derive expressions for $\mathbb{E}B^p$, we introduce the power sums

$$p_k = \sum_{i=1}^N X_i^k$$

and the elementary symmetric polynomials

$$e_0 = 1, e_1 = \sum_{i=1}^N X_i, e_2 = \sum_{1 \leq i < j \leq N} X_i X_j, \dots, e_N = \prod_{i=1}^N X_i. \quad (\text{C.8})$$

Computing e_i naively has complexity of order $\mathcal{O}(N^i)$ for $i \ll N$. Using Newton's identities

$$e_1 = p_1, e_2 = \frac{1}{2}(e_1 p_1 - p_2), e_3 = \frac{1}{3}(-e_1 p_2 + e_2 p_1 + p_3), e_4 = \frac{1}{4}(e_1 p_3 - e_2 p_2 + e_3 p_1 - p_4)$$

e_i can be expressed in terms of p_k , $k \leq i$ each of which can be computed with complexity of order $\mathcal{O}(N)$.

We consider the term $B = \frac{N}{n} \sum_{\tau_i}^{X_{\tau_i}}$ where τ_i are sampled with replacement from a fixed data set $\{1, \dots, N\}$. The second moment can be calculated as follows

$$\begin{aligned} \mathbb{E}B^2 &= \left(\frac{N}{n^2 \sigma_x^2} \right)^2 \sum_{i,j} \mathbb{E}X_{\tau_i} X_{\tau_j} \\ &= \left(\frac{N}{n^2 \sigma_x^2} \right)^2 \left(n(n-1) \underbrace{\mathbb{E}X_{\tau_1} X_{\tau_2}}_{\text{Mom}_{2,1}} + n \underbrace{\mathbb{E}X_{\tau_1}^2}_{\text{Mom}_{2,2}} \right). \end{aligned}$$

We use Newton's identities to express $\text{Mom}_{2,1}$ and $\text{Mom}_{2,2}$

$$\text{Mom}_{2,1} = \frac{2e_2}{N(N-1)} \quad \text{Mom}_{2,2} = \frac{p_2}{N}.$$

Similarly, we obtain

$$\begin{aligned} \mathbb{E}B^3 &= \left(\frac{N}{n^2 \sigma_x^2} \right)^3 \sum_{i,j,k} \mathbb{E}X_{\tau_i} X_{\tau_j} X_{\tau_k} \\ &= \left(\frac{N}{n^2 \sigma_x^2} \right)^3 \left(n(n-1)(n-2) \underbrace{\mathbb{E}X_{\tau_1} X_{\tau_2} X_{\tau_3}}_{\text{Mom}_{3,1}} + 3n(n-1) \underbrace{\mathbb{E}X_{\tau_1} X_{\tau_2}^2}_{\text{Mom}_{3,2}} + n \underbrace{\mathbb{E}X_{\tau_1}^3}_{\text{Mom}_{3,3}} \right) \\ \text{Mom}_{3,1} &= \frac{\sum_{i \neq j \neq k} X_i X_j X_k}{N(N-1)(N-2)} = \frac{6e_3}{N(N-1)(N-2)} \\ \text{Mom}_{3,2} &= \frac{p_1 p_2 - p_3}{N(N-1)}, \quad \text{Mom}_{3,3} = \frac{p_3}{N}. \end{aligned}$$

A similar calculation yields a representation of $\mathbb{E}B^4$ in terms of p_1, \dots, p_4 .

10.2 Expected MSE for Random Data

We sketch the derivation of the MSE

$$\mathbb{E}_{\theta, X} \left(\frac{1}{M} \sum_{k=0}^{M-1} \theta_j^2 - (\mu_p^2 + \sigma_p^2) \right)^2$$

where we take expectation with respect to $X_i \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(\theta^i, \sigma_x^2)$ for $i = 1, \dots, N$ and the randomness in the recursion for θ_j . We obtain an analytic expression for the MSE by deriving expressions for $\mathbb{E}_{X, \theta} \theta_j^p$. We illustrate the computation for $p = 2$, noting that we assume $\theta_0 = 0$ a.s.. We know that

$$\begin{aligned} \theta_j^2 &= \sum_{k=0}^{j-1} (1-Ah)^{2k} \left[h^2 B_{j-1-k}^2 + h \eta_{j-1-k}^2 + 2(1-Ah) \eta_{j-1-k} \theta_{j-1-k} \sqrt{h} \right] \\ &\quad + 2h^{\frac{3}{2}} B_{j-1-k} \eta_{j-1-k} + 2(1-Ah) B_{j-1-k} h \theta_{j-1-k} \\ &= \sum_{k=0}^{j-1} (1-Ah)^{2k} \left[h^2 B_{j-1-k}^2 + 2(1-Ah) \eta_{j-1-k} \theta_{j-1-k} \sqrt{h} + 2h^{\frac{3}{2}} B_{j-1-k} \eta_{j-1-k} \right. \\ &\quad \left. + 2h B_{j-1-k-2-l} + \sqrt{h} \eta_{j-k-2-l} \right] \sum_{l=0}^{j-1-k-1} (1-Ah)^l \left(h B_{j-k-2-l} + \sqrt{h} \eta_{j-k-2-l} \right). \end{aligned} \quad (\text{C.9})$$

The expectation $\mathbb{E}_{X, \theta} \theta_j$ therefore boils down to calculating $\mathbb{E}B^2$, $\mathbb{E}B'$ and $\mathbb{E}B$ where B and B' are independent samples of Equation (15). We start by calculating

$$\begin{aligned} \mathbb{E}BB' &= \frac{N^2}{n^2 4\sigma_x^4} \sum_{i=1}^n \sum_{j=1}^n \mathbb{E}X_{\tau_i} X_{\tau_j} \\ &= \frac{N^2}{n^2 4\sigma_x^4} \sum_{i=1}^n \sum_{j=1}^n \left(\frac{1}{N} \mathbb{E}X^2 + \frac{N-1}{N} \mathbb{E}X\bar{X} \right) \\ &= \frac{N^2}{n^2 4\sigma_x^4} \left(\sum_{i=1}^n \sum_{j=1}^n \frac{1}{N} (\theta^{i^2} + \sigma_x^2) + \frac{N-1}{N} \theta^{i^2} \right). \end{aligned}$$

Similarly, we obtain

$$\mathbb{E}B^2 = \frac{N^2}{n^2 4\sigma_x^4} \frac{n(\theta^{i^2} + \sigma_\theta^2) + n(n-1)\theta^{i^2}}{1}.$$

Deriving $\mathbb{E}B_j^p$ for $p = 1, 2, 3, 4$ requires the calculation of $\mathbb{E}B_1^{\alpha_1} B_3^{\alpha_2} B_4^{\alpha_3} B_4^{\alpha_4}$ where B_i are i.i.d. following the distribution of Equation (15) for $\alpha_i \geq 0$ and $\sum_i \alpha_i \leq 4$. The arguments so far allow us to derive T_1 and T_3 in

$$\begin{aligned} MSE &= \mathbb{E} \left(S_2^2 - 2S_2(\mu_p^2 + \sigma_p^2) + (\mu_p^2 + \sigma_p^2)^2 \right) \\ &= \underbrace{\mathbb{E}S_2^2}_{T_1} - 2 \underbrace{\mathbb{E}S_2 \mu_p^2}_{T_2} - 2 \underbrace{\mathbb{E}S_2 \sigma_p^2}_{T_3} + \underbrace{\mathbb{E}(\mu_p^4 + 2\mu_p^2 \sigma_p^2 + \sigma_p^4)}_{T_4}. \end{aligned}$$

Recall that the posterior for this toy model is given by

$$\mathcal{N}(\mu_p, \sigma_p^2) = \mathcal{N} \left(\frac{\sum_{i=1}^N X_i}{\sigma_\theta^2 + N}, \left(\frac{1}{\sigma_\theta^2} + \frac{N}{\sigma_x^2} \right)^{-1} \right)$$

and hence T_1 can be computed explicitly. The summands of T_2 can be derived similarly to Equation (C.9) in terms of the quantities $\mathbb{E}B_j \mu_p^2$, $\mathbb{E}B_j^2 \mu_p^2$ and $\mathbb{E}BB_j \mu_p^2$. The explicit expression can be obtained from the supplemented Mathematica® file.

1. Introduction

Many real-world optimization problems involve finding a global minimizer of a black-box objective function subject to a set of black-box constraints all being simultaneously satisfied. For example, consider the problem of optimizing the performance of a speech recognition system, subject to the requirement that it operates within a specified time limit. The system may be implemented as a neural network with hyper-parameters such as the number of hidden units, learning rates, regularization constants, etc. These hyper-parameters have to be tuned to minimize the recognition error on some validation data under a constraint on the maximum runtime of the resulting system. Another example is the discovery of new materials. Here, we aim to find new molecular compounds with optimal properties such as the power conversion efficiency in photovoltaic devices. Constraints arise from our ability (or inability) to synthesize various molecules. In this case, the estimation of the properties of the molecule and its synthesizability can be achieved by running expensive simulations on a computer.

More formally, we are interested in finding the global minimum \mathbf{x}_* of a scalar objective function $f(\mathbf{x})$ over some bounded domain, typically $\mathcal{X} \subset \mathbb{R}^D$, subject to the non-negativity of a set of constraint functions c_1, \dots, c_K . We write this as

$$\min_{\mathbf{x} \in \mathcal{X}} f(\mathbf{x}) \quad \text{s.t.} \quad c_1(\mathbf{x}) \geq 0, \dots, c_K(\mathbf{x}) \geq 0. \quad (1)$$

However, f and c_1, \dots, c_K are unknown and can only be evaluated pointwise via expensive queries to “black boxes” that may provide noise-corrupted values. Note that we are assuming that f and each of the constraints c_k are defined over the entire space \mathcal{X} . We seek to find a solution to Eq. (1) with as few queries as possible.

For solving unconstrained problems, Bayesian optimization (BO) is a successful approach to the efficient optimization of black-box functions (Mockus et al., 1978). BO methods work by applying a Bayesian model to the previous evaluations of the function, with the aim of reasoning about the global structure of the objective function. The Bayesian model is then used to compute an *acquisition function* (i.e., expected utility function) that represents how promising each possible $\mathbf{x} \in \mathcal{X}$ is if it were to be evaluated next. Maximizing the acquisition function produces a *suggestion* which is then used as the next evaluation location. When the evaluation of the objective at the suggested point is complete, the Bayesian model is updated with the newly collected function observation and the process repeats. The optimization ends after a maximum number of function evaluations is reached, a time threshold is exceeded, or some other stopping criterion is met. When this occurs, a *recommendation* of the solution is given to the user. This is achieved for example by optimizing the predictive mean of the Bayesian model, or by choosing the best observed point among the evaluations. The Bayesian model is typically a Gaussian process (GP); an in-depth treatment of GPs is given by Rasmussen and Williams (2006). A commonly-used acquisition function is the expected improvement (EI) criterion (Jones et al., 1998), which measures the expected amount by which we will improve over some *incumbent* or current best solution, typically given by the expected value of the objective at the current best recommendation. Other acquisition functions aim to approximate the expected information gain or expected reduction in the posterior entropy of the global minimizer of the objective

Abstract

We present an information-theoretic framework for solving global black-box optimization problems that also have black-box constraints. Of particular interest to us is to efficiently solve problems with *decoupled* constraints, in which subsets of the objective and constraint functions may be evaluated independently. For example, when the objective is evaluated on a CPU and the constraints are evaluated independently on a GPU. These problems require an acquisition function that can be separated into the contributions of the individual function evaluations. We develop one such acquisition function and call it Predictive Entropy Search with Constraints (PESC). PESC is an approximation to the expected information gain criterion and it compares favorably to alternative approaches based on improvement in several synthetic and real-world problems. In addition to this, we consider problems with a mix of functions that are fast and slow to evaluate. These problems require balancing the amount of time spent in the meta-computation of PESC and in the actual evaluation of the target objective. We take a bounded rationality approach and develop a partial update for PESC which trades off accuracy against speed. We then propose a method for adaptively switching between the partial and full updates for PESC. This allows us to interpolate between versions of PESC that are efficient in terms of function evaluations and those that are efficient in terms of wall-clock time. Overall, we demonstrate that PESC is an effective algorithm that provides a promising direction towards a unified solution for constrained Bayesian optimization.

(Villemonteix et al., 2009; Hennig and Schuler, 2012; Hernández-Lobato et al., 2014). For more information on BO, we refer to the tutorial by Brochu et al. (2010).

There have been several attempts to extend BO methods to address the constrained optimization problem in Eq. (1). The proposed techniques use GPs and variants of the EI heuristic (Schonlau et al., 1998; Parr, 2013; Snoek, 2013; Gelbart et al., 2014; Gardner et al., 2014; Gramacy et al., 2016; Gramacy and Lee, 2011; Picheny, 2014). Some of these methods lack generality since they were designed to work in specific contexts, such as when the constraints are noiseless or the objective is known. Furthermore, because they are based on EI, computing their acquisition function requires the current best feasible solution or incumbent: a location in the search space with low expected objective value and high probability of satisfying the constraints. However, the best feasible solution does not exist when no point in the search space satisfies the constraints with high probability (for example, because of lack of data). Finally and more importantly, these methods run into problems when the objective and the constraint functions are *decoupled*, meaning that the functions f, c_1, \dots, c_r in Eq. (1) can be evaluated independently. In particular, the acquisition functions used by these methods usually consider joint evaluations of the objective and constraints and cannot produce an optimal suggestion when only subsets of these functions are being evaluated.

In this work, we propose a general approach for constrained BO that does not have the problems mentioned above. Our approach to constraints is based on an extension of Predictive Entropy Search (PES) (Hernández-Lobato et al., 2014), an information-theoretic method for unconstrained BO problems. The resulting technique is called Predictive Entropy Search with Constraints (PESC) and its acquisition function approximates the expected information gain with regard to the solution of Eq. (1), which we call \mathbf{x}_* . At each iteration, PESC collects data at the location that is the most informative about \mathbf{x}_* , in expectation. One important property of PESC is that its acquisition function naturally separates the contributions of the individual function evaluations when those functions are modeled independently. That is, the amount of information that we approximately gain by jointly evaluating a set of independent functions is equal to the sum of the gains of information that we approximately obtain by the individual evaluation of each of the functions. This additive property in its acquisition function allows PESC to efficiently solve the general constrained BO problem, including those with decoupled evaluation, something that no other existing technique can achieve, to the best of our knowledge.

An initial description of PESC is given by Hernández-Lobato et al. (2015). That work considers PESC only in the coupled evaluation scenario, where all the functions are jointly evaluated at the same input value. This is the standard setting considered by most prior approaches for constrained BO. Here, we further extend that initial work on PESC as follows:

1. We present a taxonomy of constrained BO problems. We consider problems in which the objective and constraints can be split into subsets of functions or *tasks* that require coupled evaluation, but where different tasks can be evaluated in a decoupled way. These different tasks may or may not compete for a limited set of resources. We propose a general algorithm for solving this type of problems and then show how PESC can be used for the practical implementation of this algorithm.

2. We analyze PESC in the decoupled scenario. We evaluate the accuracy of PESC when the different functions (objective or constraint) are evaluated independently. We show how PESC efficiently solves decoupled problems with an objective and constraints that compete for the same computational resource.

3. We intelligently balance the computational overhead of the Bayesian optimization method relative to the cost of evaluating the black-boxes. To achieve this, we develop a partial update to the PESC approximation that is less accurate but faster to compute. We then automatically switch between partial and full updates so that we can balance the amount of time spent in the Bayesian optimization subroutines and in the actual collection of data. This allows us to efficiently solve problems with a mix of decoupled functions where some are fast and others slow to evaluate.

The rest of the paper is structured as follows. Section 2 reviews prior work on constrained BO and considers these methods in the context of decoupled functions. In Section 3 we present a general framework for describing BO problems with decoupled functions, which contains as special cases the standard coupled framework considered in most prior work as well as the notion of decoupling introduced by Gelbart et al. (2014). This section also describes a general algorithm for BO problems with decoupled functions. In Section 4 we show how to extend Predictive Entropy Search (PES) (Hernández-Lobato et al., 2014) to solve Eq. (1) in the context of decoupling, an approach that we call Predictive Entropy Search with Constraints (PESC). We also show how PESC can be used to implement the general algorithm from Section 3. In Section 5 we modify the PESC algorithm to be more efficient in terms of wall-clock time by adaptively using an approximate but faster version of the method. In Sections 6 and 7 we perform empirical evaluations of PESC on coupled and decoupled optimization problems, respectively. Finally, we conclude in Section 8.

2. Related Work

Below we discuss previous approaches to Bayesian optimization with black-box constraints, many of which are variants of the expected improvement (EI) heuristic (Jones et al., 1998). In the unconstrained setting, EI measures the expected amount by which observing the objective f at \mathbf{x} leads to improvement over the current best recommendation or *incumbent*, the objective value of which is denoted by η (thus, η has the units of f , not \mathbf{x}). The incumbent η is usually defined as the lowest expected value for the objective over the optimization domain. The EI acquisition function is then given by

$$e_{\text{EI}}(\mathbf{x}) = \int \max(0, \eta - f(\mathbf{x}))p(f(\mathbf{x})|\mathcal{D})df(\mathbf{x}) = \sigma f(\mathbf{x})(z_f(\mathbf{x})\Phi(z_f(\mathbf{x})) + \phi(z_f(\mathbf{x}))), \quad (2)$$

where \mathcal{D} represents the collected data (previous function evaluations) and $p(f(\mathbf{x})|\mathcal{D})$ is the predictive distribution for the objective made by a Gaussian process (GP), $\mu_f(\mathbf{x})$ and $\sigma_f^2(\mathbf{x})$ are the GP predictive mean and variance for $f(\mathbf{x})$, $z_f(\mathbf{x}) \equiv (\eta - \mu_f(\mathbf{x}))/\sigma_f(\mathbf{x})$, and Φ and ϕ are the standard Gaussian CDF and PDF, respectively.

2.1 Expected Improvement with Constraints

An intuitive extension of EI in the presence of constraints is to define improvement as only occurring when the constraints are satisfied. Because we are uncertain about the values of the constraints, we must weight the original EI value by the probability of the constraints being satisfied. This results in what we call Expected Improvement with Constraints (EIC):

$$\alpha_{\text{EIC}}(\mathbf{x}) = \alpha_{\text{EI}}(\mathbf{x}) \prod_{k=1}^K \Pr(c_k(\mathbf{x}) \geq 0 | \mathcal{D}) = \alpha_{\text{EI}}(\mathbf{x}) \prod_{k=1}^K \Phi\left(\frac{\mu_k(\mathbf{x})}{\sigma_k(\mathbf{x})}\right), \quad (3)$$

The constraint satisfaction probability factorizes because f and c_1, \dots, c_K are modeled by independent GPs. In this expression μ_k and σ_k^2 are the posterior predictive mean and variance for $c_k(\mathbf{x})$. EIC was initially proposed by Schonlau et al. (1998) and has been revisited by Parr (2013), Snoek (2013), Gardner et al. (2014) and Gelbart et al. (2014).

In the constrained setting, the incumbent η can be defined as the minimum expected objective value subject to all the constraints being satisfied at the corresponding location. However, we can never guarantee that all the constraints will be satisfied when they are only observed through noisy evaluations. To circumvent this problem, Gelbart et al. (2014) define η as the lowest expected objective value subject to all the constraints being satisfied with posterior probability larger than the threshold $1 - \delta$, where δ is a small number such as 0.05. However, this value for η still cannot be computed when there is no point in the search space that satisfies the constraints with posterior probability higher than $1 - \delta$. For example, because of lack of data for the constraints. In this case, Gelbart et al. change the original acquisition function given by Eq. (3) and ignore the factor $\alpha_{\text{EI}}(\mathbf{x})$ in that expression. This allows them to search only for a feasible location, ignoring the objective f entirely and just optimizing the constraint satisfaction probability. However, this can lead to inefficient optimization in practice because the data collected for the objective f is not used to make optimal decisions.

2.2 Integrated Expected Conditional Improvement

Gramacy and Lee (2011) propose an acquisition function called the integrated expected conditional improvement (IECI), defined as

$$\alpha_{\text{IECI}}(\mathbf{x}) = \int_{\mathcal{X}} [\alpha_{\text{EI}}(\mathbf{x}') - \alpha_{\text{EI}}(\mathbf{x} | \mathbf{x})] h(\mathbf{x}') d\mathbf{x}'. \quad (4)$$

Here, $\alpha_{\text{EI}}(\mathbf{x}')$ is the expected improvement at \mathbf{x}' , $\alpha_{\text{EI}}(\mathbf{x} | \mathbf{x})$ is the expected improvement at \mathbf{x}' given that the objective has been observed at \mathbf{x} (but without making any assumptions about the observed value), and $h(\mathbf{x}')$ is an arbitrary density over \mathbf{x}' . The IECI at \mathbf{x} is the expected reduction in EI at \mathbf{x}' , under the density $h(\mathbf{x}')$, caused by observing the objective at \mathbf{x} . Gramacy and Lee use IECI for constrained BO by setting $h(\mathbf{x}')$ to the probability of the constraints being satisfied at \mathbf{x}' . They define the incumbent η as the lowest posterior mean for the objective f over the whole optimization domain, ignoring the fact that the lowest posterior mean for the objective may be achieved in an infeasible location.

The motivation for IECI is that collecting data at an infeasible location may also provide useful information. EIC strongly discourages this, because Eq. (3) always takes very low

values when the constraints are unlikely to be satisfied. This is not the case with IECI because Eq. (4) considers the EI over the whole optimization domain instead of focusing only on the EI at the current evaluation location, which may be infeasible with high probability. Gelbart et al. (2014) compare IECI with EIC for optimizing the hyper-parameters of a topic model with constraints on the entropy of the per-topic word distribution and show that EIC outperforms IECI on this problem.

2.3 Expected Volume Minimization

An alternative approach is given by Picheny (2014), who proposes to sequentially explore the location that most decreases the expected volume (EV) of the feasible region below the best feasible objective value η found so far. This quantity is computed by integrating the product of the probability of improvement and the probability of feasibility. That is,

$$\alpha_{\text{EV}}(\mathbf{x}) = \int p[f(\mathbf{x}') \leq \eta] h(\mathbf{x}') d\mathbf{x}' - \int p[f(\mathbf{x}') \leq \min(\eta, f(\mathbf{x}))] h(\mathbf{x}') d\mathbf{x}', \quad (5)$$

where, as in IECI, $h(\mathbf{x}')$ is the probability that the constraints are satisfied at \mathbf{x}' . Picheny considers noiseless evaluations for the objective and constraint functions and defines η as the best feasible objective value seen so far or $+\infty$ when no feasible location has been found.

A disadvantage of Picheny's method is that it requires the integral in Eq. (5) to be computed over the entire search domain \mathcal{X} , which is done numerically over a grid on \mathbf{x}' . The resulting acquisition function must then be globally optimized. This is often performed by first evaluating the acquisition function on a grid on \mathbf{x} . The best point in this second grid is then used as the starting point of a numerical optimizer for the acquisition function. This nesting of grid operations limits the application of this method to small input dimension D . This is also the case for IECI whose acquisition function in Eq. (4) also includes an integral over \mathcal{X} . Our method PESC requires a similar integral in the form of an expectation with respect to the posterior distribution of the global feasible minimizer \mathbf{x}_* . Nevertheless, this expectation can be efficiently approximated by averaging over samples of \mathbf{x}_* drawn using the approach proposed by Hernández-Lobato et al. (2014). This approach is further described in Appendix B.3. Note that the integrals in Eq. (5) could in principle be also approximated by using Markov chain Monte Carlo (MCMC) to sample from the unnormalized density $h(\mathbf{x}')$. However, this was not proposed by Picheny and he only described the grid based method.

2.4 Modeling an Augmented Lagrangian

Gramacy et al. (2016) propose to use a combination of EI and the augmented Lagrangian (AL) method: an algorithm which turns an optimization problem with constraints into a sequence of unconstrained optimization problems. Gramacy et al. use BO techniques based on EI to solve the unconstrained *inner* loop of the AL problem. When f and c_1, \dots, c_K are known the unconstrained AL objective is defined as

$$L_A(\mathbf{x} | \lambda_1, \dots, \lambda_K, p) = f(\mathbf{x}) + \sum_{k=1}^K \left[\frac{1}{2p} \min(0, c_k(\mathbf{x}))^2 - \lambda_k c_k(\mathbf{x}) \right], \quad (6)$$

where $p > 0$ is a penalty parameter and $\lambda_1 \geq 0, \dots, \lambda_K \geq 0$ serve as Lagrange multipliers. The AL method iteratively minimizes Eq. (6) with different values for p and $\lambda_1, \dots, \lambda_K$ at each iteration. Let $\mathbf{x}_k^{(n)}$ be the minimizer of Eq. (6) at iteration n using parameter values $p^{(n)}$ and $\lambda_1^{(n)}, \dots, \lambda_K^{(n)}$. The next parameter values are $\lambda_k^{(n+1)} = \max(0, \lambda_k^{(n)} - c_k(\mathbf{x}_k^{(n)})/p^{(n)})$ for $k = 1, \dots, K$ and $p^{(n+1)} = p^{(n)}$ if $\mathbf{x}_k^{(n)}$ is feasible and $p^{(n+1)} = p^{(n)}/2$ otherwise. When f and c_1, \dots, c_K are unknown we cannot directly minimize Eq. (6). However, if we have observations for f and c_1, \dots, c_K , we can then map such data into observations for the AL objective. Gramacy et al. fit a GP model to the AL observations and then select the next evaluation location using the EI heuristic. After collecting the data, the AL parameters are updated as above using the new values for the constraints and the whole process repeats.

A disadvantage of this approach is that it assumes that the constraints c_1, \dots, c_K are noiseless to guarantee that that p and $\lambda_1, \dots, \lambda_K$ can be correctly updated. Furthermore, Gramacy et al. (2016) focus only on the case in which the objective f is known, although they provide suggestions for extending their method to unknown f . In section 6.3 we show that PESC and EIC perform better than the AL approach on the synthetic benchmark problem considered by Gramacy et al., even when the AL method has access to the true objective function and PESC and EIC do not.

2.5 Existing Methods for Decoupled Evaluations

The methods described above can be used to solve constrained BO problems with *coupled* evaluations. These are problems in which all the functions (objective and constraints) are always evaluated jointly at the same input. Gelbart et al. (2014) consider extending the EIC method from Section 2.1 to the *decoupled* setting, where the different functions can be independently evaluated at different input locations. However, they identify a problem with EIC in the decoupled scenario. In particular, the EIC utility function requires two conditions to produce positive values. First, the evaluation for the objective must achieve a lower value than the best feasible solution so far and, second, the evaluations for the constraints must produce non-negative values. When we evaluate only one function (objective or constraint), the conjunction of these two conditions cannot be satisfied by a single observation under a myopic search policy. Thus, the new evaluation location can never become the new incumbent and the EIC is zero everywhere. Therefore, standard EIC fails in the decoupled setting.

Gelbart et al. (2014) circumvent the problem mentioned above by treating decoupling as a special case and using a two-stage acquisition function: first, the next evaluation location \mathbf{x} is chosen with EIC, and then, given \mathbf{x} , the task (whether to evaluate the objective or one of the constraints) is chosen according to the expected reduction in the entropy of the global feasible minimizer \mathbf{x}_* , where the entropy computation is approximated using Monte Carlo sampling as proposed by Villemonteix et al. (2009). We call the resulting method EIC-D. Note that the two-stage decision process used by EIC-D is sub-optimal and a joint selection of \mathbf{x} and the task should produce better results. As discussed in the sections that follow, our method, PESC, does not suffer from this disadvantage and furthermore, can be extended to a wider range of decoupled problems than EIC-D can.

3. Decoupled Function Evaluations and Resource Allocation

We present a framework for describing constrained BO problems. We say that a set of functions (objective or constraints) are *coupled* when they always require joint evaluation at the same input location. We say that they are *decoupled* when they can be evaluated independently at different inputs. In practice, a particular problem may exhibit coupled or decoupled functions or a combination of both. An example of a problem with coupled functions is given by a financial simulator that generates many samples from the distribution of possible financial outcomes. If the objective function is the expected profit and the constraint is a maximum tolerable probability of default, then these two functions are computed jointly by the same simulation and are thus coupled to each other. An example of a problem with decoupled functions is the optimization of the predictive accuracy of a neural network speech recognition system subject to prediction time constraints. In this case different neural network architectures may produce different predictive accuracies and different prediction times. Assessing the prediction time may not require training the neural network and could be done using arbitrary network weights. Thus, we can evaluate the timing constraint without evaluating the accuracy objective.

When problems exhibit a combination of coupled and decoupled functions, we can then partition the different functions into subsets of functions that require coupled evaluation. We call these subsets of coupled functions *tasks*. In the financial simulator example, the objective and the constraint form the only task. In the speech recognition system there are two tasks, one for the objective and one for the constraint. Functions within different tasks are decoupled and can be evaluated independently. These tasks may or may not compete for a limited set of *resources*. For example, two tasks that both require the performance of expensive computations may have to compete for using a single available CPU. An example with no competition is given by two tasks, one which performs computations in a GPU and another one which performs computations in a GPU. Finally, two competitive tasks may also have different evaluation costs and this should be taken into account when deciding which one is going to be evaluated next.

In the previous section we showed that most existing methods for constrained BO can only address problems with coupled functions. Furthermore, the extension of these methods to the decoupled setting is difficult because most of them are based on the EI heuristic and, as illustrated in Section 2.5, improvement can be impossible with decoupled evaluations. A decoupled problem can, of course, be coupled artificially and then solved as a coupled problem with existing methods. We examine this approach here with a thought experiment and with empirical evaluations in Section 7. Returning to our time-limited speech recognition system, let us consider the cost of evaluating each of the tasks. Evaluating the objective requires training the neural network, which is a very expensive process. On the other hand, evaluating the constraint (run time) requires only to time the predictions made by the neural network and this could be done without training, using arbitrary network weights. Therefore, evaluating the constraint is in this case much faster than evaluating the objective. In a decoupled framework, one could first measure the run time at several evaluation locations, gaining a sense of the constraint surface. Only then would we incur the significant expense of evaluating the objective task, heavily biasing our search towards locations that are considered to be feasible with high probability. Put another way, arti-

cially coupling the tasks becomes increasingly inefficient as the cost differential is increased; for example, one might spend a week examining one aspect of a design that could have been ruled out within seconds by examining another aspect.

In the following sections we present a formalization of constrained Bayesian optimization problems that encompasses all of the cases described above. We then show that our method, PESC (Section 4), is an effective practical solution to these problems because it naturally separates the contributions of the different function evaluations in its acquisition function.

3.1 Competitive Versus Non-competitive Decoupling and Parallel BO

We divide the class of problems with decoupled functions into two sub-classes, which we call *competitive decoupling* (CD) and *non-competitive decoupling* (NCD). CD is the form of decoupling considered by Gelbart et al. (2014), in which two or more tasks compete for the same resource. This happens when there is only one CPU available and the optimization problem includes two tasks with each of them requiring a CPU to perform some expensive simulations. In contrast, NCD refers to the case in which tasks require the use of different resources and can therefore be evaluated independently, in parallel. This occurs, for example, when one of the two tasks uses a CPU and the other task uses a GPU.

Note that NCD is very related to *parallel* Bayesian optimization (see e.g., Ginsbourger et al., 2011; Snoek et al., 2012). In both parallel BO and NCD we perform multiple task evaluations concurrently, where each new evaluation location is selected optimally according to the available data and the locations of all the currently pending evaluations. The difference between parallel BO and NCD is that in NCD the tasks whose evaluations are currently pending may be different from the task that will be evaluated next, while in parallel BO there is only a single task. Parallel BO conveniently fits into the general framework described below.

3.2 Formalization of Constrained Bayesian Optimization Problems

We now present a framework for describing constrained BO problems of the form given by Eq. (1). Our framework can be used to represent general problems within any of the categories previously described, including coupled and decoupled functions that may or may not compete for a limited number of resources, each of which may be replicated multiple times. Let \mathcal{F} be the set of functions $\{f, c_1, \dots, c_K\}$ and let the set of tasks \mathcal{T} be a partition of \mathcal{F} indicating which functions are coupled and must be jointly evaluated. Let $\mathcal{R} = \{r_1, \dots, r_{|\mathcal{R}|}\}$ be the set of resources available to solve this problem. We encode the relationship between tasks and resources with a bipartite graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with vertices $\mathcal{V} = \mathcal{T} \cup \mathcal{R}$ and edges $\{t \sim r\} \in \mathcal{E}$ such that $t \in \mathcal{T}$ and $r \in \mathcal{R}$. The interpretation of an edge $\{t \sim r\}$ is that task t can be performed on resource r . (We do not address the case in which a task requires multiple resources to be executed; we leave this as future work.) We also introduce a *capacity* ω_{\max} for each resource r . The capacity $\omega_{\max}(r) \in \mathbb{N}$ represents how many tasks may be simultaneously executed on resource r ; for example, if r represents a cluster of CPUs, $\omega_{\max}(r)$ would be the number of CPUs in the cluster. Introducing the notion of capacity is simply a matter of convenience since it is equivalent to setting all capacities to one and replicating each resource node in \mathcal{G} according to its capacity.

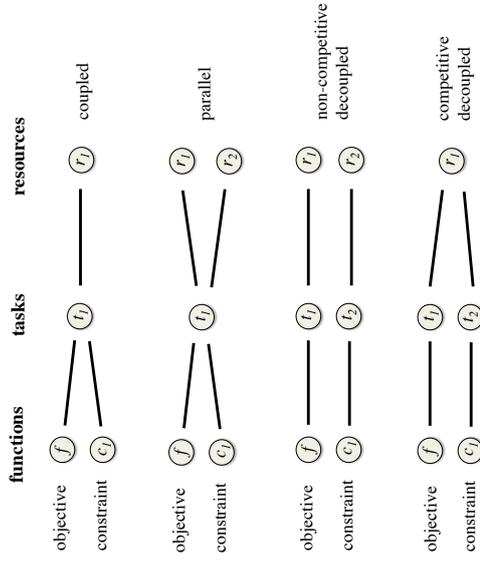

Figure 1: Schematic comparing the coupled, parallel, non-competitive decoupled (NCD), and competitive decoupled (CD) scenarios for a problem with a single constraint c_1 . In each case, the mapping between tasks and resources (the right-hand portion of the figure) is the bipartite graph \mathcal{G} .

We can now formally describe problems with coupled evaluations as well as NCD and CD. In particular, coupling occurs when two functions g_1 and g_2 belong to the same task t . If this task can be evaluated on multiple resources (or one resource with $\omega_{\max} > 1$), then this is parallel Bayesian optimization. NCD occurs when two functions g_1 and g_2 belong to different tasks t_1 and t_2 , which themselves require different resources r_1 and r_2 , (that is, $t_1 \sim r_1, t_2 \sim r_2$ and $r_1 \neq r_2$). CD occurs when two functions g_1 and g_2 belong to *different* tasks t_1 and t_2 (decoupled) that require the *same* resource r (competitive). These definitions are visually illustrated in Fig. 1. The definitions can be trivially extended to cases with more than two functions. The most general case is an arbitrary task-resource graph \mathcal{G} encoding a combination of coupling, NCD, CD and parallel Bayesian optimization.

3.3 A General Algorithm for Constrained Bayesian Optimization

In this section we present a general algorithm for solving constrained Bayesian optimization problems specified according to the formalization from the previous section. Our approach relies on an acquisition function that can measure the expected utility of evaluating any arbitrary subset of functions, that is, of any possible task. When an acquisition function satisfies this requirement we say that it is *separable*. As discussed in Section 4.1, our

Algorithm 1 A general method for constrained Bayesian optimization.

- 1: **Input:** $\mathcal{F}, \mathcal{G} = (\mathcal{T} \cup \mathcal{R}, \mathcal{E}), \alpha_t$ for $t \in \mathcal{T}, \mathcal{K}, \mathcal{M}, \mathcal{D}, \omega, \omega_{\max}$ and δ .
 - 2: **repeat**
 - 3: **for** $r \in \mathcal{R}$ such that $\omega(r) < \omega_{\max}(r)$ **do**
 - 4: Update \mathcal{M} with any new data in \mathcal{D}
 - 5: **for** $t \in \mathcal{T}$ such that $\{t \sim r\} \in \mathcal{E}$ **do**
 - 6: $\mathbf{x}_t^* \leftarrow \arg \max_{\mathbf{x} \in \mathcal{X}} \alpha_t(\mathbf{x} | \mathcal{M})$
 - 7: $\alpha_t^* \leftarrow \alpha_t(\mathbf{x}_t^* | \mathcal{M})$
 - 8: **end for**
 - 9: $t^* \leftarrow \arg \max_r \alpha_t^*$
 - 10: Submit task t^* at input \mathbf{x}_t^* to resource r
 - 11: Update \mathcal{M} with the new pending evaluation
 - 12: **end for**
 - 13: **until** termination condition is met
 - 14: **Output:** $\arg \min_{\mathbf{x} \in \mathcal{X}} \mathbb{E}_{\mathcal{M}}[f(\mathbf{x})]$ s.t. $p(c_1(\mathbf{x}) \geq 0, \dots, c_K(\mathbf{x}) \geq 0 | \mathcal{M}) \geq 1 - \delta$
-

method PESG has this property; when the functions are modeled as independent. This property makes PESG an effective solution for the practical implementation of our general algorithm. By contrast, the EIG-D method of Gelbart et al. (2014) is not separable and cannot be applied in the general case presented here.

Algorithm 1 provides a general procedure for solving constrained Bayesian optimization problems. The inputs to the algorithm are the set of functions \mathcal{F} , the set of tasks \mathcal{T} , the set of resources \mathcal{R} , the task-resource graph $\mathcal{G} = (\mathcal{T} \cup \mathcal{R}, \mathcal{E})$, an acquisition function for each task, that is, α_t for $t \in \mathcal{T}$, the search space \mathcal{X} , a Bayesian model \mathcal{M} , the initial data set \mathcal{D} , the resource query functions ω and ω_{\max} and a confidence level δ for making a final recommendation. Recall that ω_{\max} indicates how many tasks can be simultaneously executed on a particular resource. The function ω is introduced here to indicate how many tasks are currently being evaluated in a resource. The acquisition function α_t measures the utility of evaluating task t at the location \mathbf{x} . This acquisition function depends on the predictions of the Bayesian model \mathcal{M} . The separability property of the original acquisition function guarantees that we can compute an α_t for each $t \in \mathcal{T}$.

Algorithm 1 works as follows. First, in line 3, we iterate over the resources, checking if they are available. Resource r is available if its number of currently running jobs $\omega(r)$ is less than its capacity $\omega_{\max}(r)$. Whenever resource r is available, we check in line 4 if any new function observations have been collected. If this is the case, we then update the Bayesian model \mathcal{M} with the new data (in most cases we will have new data since the resource r probably became available due to the completion of a previous task). Next, we iterate in line 5 over the tasks t that can be evaluated in the new available resource r as dictated by \mathcal{G} . In line 6 we find the evaluation location \mathbf{x}_t^* that maximizes the utility obtained by the evaluation of task t , as indicated by the task-specific acquisition function α_t . In line 7 we obtain the corresponding maximum task utility α_t^* . In line 9, we then maximize over tasks, selecting the task t^* with highest maximum task utility α_t^* (this is the “competition” in CD). Upon doing so, the pair $(t^*, \mathbf{x}_{t^*}^*)$ forms the next *suggestion*. This pair represents the experiment with the highest acquisition function value over all possible

(t, \mathbf{x}) pairs in $\mathcal{T} \times \mathcal{X}$ that can be run on resource r . In line 10, we evaluate the selected task at resource r and in line 11 we update the Bayesian model \mathcal{M} to take into account that we are expecting to collect data for task t^* at input $\mathbf{x}_{t^*}^*$. This can be done for example by drawing virtual data from \mathcal{M} 's predictive distribution and then averaging across the predictions made when each virtual data point is assumed to be the data actually collected by the pending evaluation (Schonlau et al., 1998; Snoek et al., 2012). In line 13 the whole process repeats until a termination condition is met. Finally, in line 14, we give to the user a final *recommendation* of the solution to the optimization problem. This is the input that attains the lowest expected objective value subject to all the constraints being satisfied with posterior probability larger than $1 - \delta$, where δ is maximum allowable probability of the recommendation being infeasible according to \mathcal{M} .

Algorithm 1 can solve problems that exhibit any combination of coupling, parallelism, NCD, and CD.

3.4 Incorporating Cost Information

Algorithm 1 always selects, among a group of competitive tasks, the one whose evaluation produces the highest utility value. However, other cost factors may render the evaluation of one task more desirable than another. The most salient of these costs is the run time or duration of the task’s evaluation, which could depend on the evaluation location \mathbf{x} . For example, in the neural network speech recognition system, one of the variables to be optimized may be the number of hidden units in the neural network. In this case, the run time of an evaluation of the predictive accuracy of the system is a function of \mathbf{x} since the training time for the network scales with its size. Snoek et al. (2012) consider this issue by automatically measuring the duration of function evaluations. They model the duration as a function of \mathbf{x} with an additional Gaussian process (GP). Swersky et al. (2013) extend this concept over multiple optimization tasks so that an independent GP is used to model the unknown duration of each task. This approach can be applied in Algorithm 1 by penalizing the acquisition function for task t with the expected cost of evaluating that task. In particular, we can change lines 6 and 7 in Algorithm 1 to

- 6: $\mathbf{x}_t^* \leftarrow \arg \max_{\mathbf{x} \in \mathcal{X}} \alpha_t(\mathbf{x} | \mathcal{M}) / \zeta_t(\mathbf{x})$
- 7: $\alpha_t^* \leftarrow \alpha_t(\mathbf{x}_t^* | \mathcal{M}) / \zeta_t(\mathbf{x}_t^*)$

where $\zeta_t(\mathbf{x})$ is the expected cost associated with the evaluation of task t at \mathbf{x} : as estimated by a model of the collected cost data. When taking into account task costs modeled by Gaussian processes, the total number of GP models used by Algorithm 1 is equal to the number of functions in the constrained BO problem plus the number of tasks, that is, $|\mathcal{T}| + |\mathcal{T}|$. Alternatively, one could fix the cost functions $\zeta_t(\mathbf{x})$ *a priori* instead of learning them from collected data.

4. Predictive Entropy Search with Constraints (PESG)

To implement Algorithm 1 in practice we need to compute an acquisition function that is separable and can measure the utility of evaluating an arbitrary subset of functions. In this section we describe how to achieve this.

Our acquisition function approximates the expected gain of information about the solution to the constrained optimization problem, which is denoted by \mathbf{x}_* . Importantly, our approximation is additive. For example, let \mathcal{A} be a set of functions and let $I(\mathcal{A})$ be the amount of information that we approximately gain in expectation by jointly evaluating the functions in \mathcal{A} . Then $I(\mathcal{A}) = \sum_{a \in \mathcal{A}} I(\{a\})$. Although our acquisition function is additive, the exact expected gain of information is not. Additivity is the result of a factorization assumption in our approximation (see Section 4.2 for further details). The good results obtained in our experiments seem to support that this is a reasonable assumption. Because of this additive property, we can compute an acquisition function for any possible subset of f, c_1, \dots, c_K using the individual acquisition functions for these functions as building blocks.

We follow MacKay (1992) and measure information about \mathbf{x}_* by the differential entropy of $p(\mathbf{x}_*|\mathcal{D})$, where \mathcal{D} is the data collected so far. The distribution $p(\mathbf{x}_*|\mathcal{D})$ is formally defined in the unconstrained case by Hennig and Schuler (2012). In the constrained case $p(\mathbf{x}_*|\mathcal{D})$ can be understood as the probability distribution determined by the following sampling process. First, we draw f, c_1, \dots, c_K from their posterior distributions given \mathcal{D} and second, we minimize the sampled f subject to the sampled c_1, \dots, c_K being non-negative, that is, we solve Eq. (1) for the sampled functions. The solution to Eq. (1) obtained by this procedure represents then a sample from $p(\mathbf{x}_*|\mathcal{D})$.
