Editor: Mikhail Belkin

Abstract

Binary embeddings provide efficient and powerful ways to perform operations on large scale data. However binary embedding typically requires long codes in order to preserve the discriminative power of the input space. Thus binary coding methods traditionally suffer from high computation and storage costs in such a scenario. To address this problem, we propose Circulant Binary Embedding (CBE) which generates binary codes by projecting the data with a circulant matrix. The circulant structure allows us to use Fast Fourier Transform algorithms to speed up the computation. For obtaining k-bit binary codes from d-dimensional data, our method improves the time complexity from $\mathcal{O}(dk)$ to $\mathcal{O}(d \log d)$, and the space complexity from $\mathcal{O}(dk)$ to $\mathcal{O}(d)$.

We study two settings, which differ in the way we choose the parameters of the circulant matrix. In the first, the parameters are chosen randomly and in the second, the parameters are learned using the data. For randomized CBE, we give a theoretical analysis comparing it with binary embedding using an unstructured random projection matrix. The challenge here is to show that the dependencies in the entries of the circulant matrix do not lead to a loss in performance. In the second setting, we design a novel time-frequency alternating optimization to learn data-dependent circulant projections, which alternatively minimizes the objective in original and Fourier domains. In both the settings, we show by extensive experiments that the CBE approach gives much better performance than the state-of-the-art approaches if we fix a running time, and provides much faster computation with negligible performance degradation if we fix the number of bits in the embedding.

Keywords: structured matrix, circulant matrix, dimensionality reduction, binary embedding, FFT

1. Introduction

Sketching and dimensionality reduction have become powerful and ubiquitous tools in the analysis of large high-dimensional data sets, with applications ranging from computer vision, to biology, to finance. The celebrated Johnson-Lindenstrauss lemma says that projecting high dimensional points to a random $\mathcal{O}(\log N)$-dimensional space approximately preserves all the pairwise distances between a set of N points, making it a powerful tool for nearest neighbor search, clustering, etc. This started the paradigm of designing low dimensional *sketches* (or embeddings) of high dimensional data that can be used for efficiently solving various information retrieval problems.

More recently, *binary* embeddings (or embeddings into $\{0,1\}^k$ or $\{-1,1\}^k$) have been developed for problems in which we care about preserving the *angles* between high dimensional vectors (Li et al., 2011; Gong et al., 2013; Raginsky and Lazebnik, 2009; Gong et al., 2012b; Liu et al., 2011). The main appeal of binary embeddings stems from the fact that storing them is often much more efficient than storing real valued embeddings. Furthermore, operations such as computing the Hamming distance in binary space can be performed very efficiently either using table lookup, or hardware-implemented instructions on modern computer architectures.

In this paper, we study binary embeddings of high-dimensional data. Our goal is to address one of its main challenges: even though binary embeddings are easy to manipulate, it has been observed that obtaining high accuracy results *requires* the embeddings to be rather long when the data is high dimensional (Li et al., 2011; Gong et al., 2013; Sánchez and Perronnin, 2011). Thus in applications like computer vision, biology and finance (where high dimensional data is common), the task of computing the embedding is a bottleneck. The natural algorithms have time and space complexity $\mathcal{O}(dk)$ per input point in order to produce a k-bit embedding from a d-dimensional input. Our main contribution in this work is to improve these complexities to $\mathcal{O}(d \log d)$ for time and $\mathcal{O}(d)$ for space complexity.

Our results can be viewed as binary analogs of the recent work on *fast* Johnson-Lindenstrauss transform. Starting with the work of Ailon and Chazelle (Ailon and Chazelle, 2006), there has been a lot of beautiful work on fast algorithms for dimension reduction with the goal of preserving pairwise distances between points. Various aspects, such as exploiting sparsity, and using structured matrices to reduce the space and time complexity of dimension reduction, have been explored (Ailon and Chazelle, 2006; Matoušek, 2008; Liberty et al., 2008). But the key difference in our setting is that binary embeddings are *non-linear*. This makes the analysis tricky when the projection matrices do not have independent entries. Binary embeddings are also better suited to approximate the angles between vectors (as opposed to distances). Let us see why.

The general way to compute a binary embedding of a data point $\mathbf{x} \in \mathbb{R}^d$ is to first apply a linear transformation $\mathbf{Ax}$ (for a $k \times d$ matrix $\mathbf{A}$), and then apply a *binarization* step. We consider the natural binarization of taking the sign. Thus, for a point $\mathbf{x}$, the binary embedding into $\{-1,1\}^d$ we consider is

$$h(\mathbf{x}) = \text{sign}(\mathbf{Ax}), \tag{1}$$

where $\mathbf{A} \in \mathbb{R}^{k \times d}$ as above, and $\text{sign}(\cdot)$ is a binary map which returns element-wise sign[1]. How should one pick the matrix $\mathbf{A}$? One natural choice, in light of the Johnson-Lindenstrauss lemma, is to pick it randomly, i.e., each entry is sampled from an independent Gaussian. This *data oblivious* choice is well studied (Charikar, 2002; Raginsky and Lazebnik, 2009),

1. A few methods transform the linear projection via a nonlinear map before taking the sign (Weiss et al., 2008; Raginsky and Lazebnik, 2009).

and has the nice property that for two data vectors $\mathbf{x}, \mathbf{y}$, the ℓ_1 distance between their embeddings is proportional to the angle between $\mathbf{x}$ and $\mathbf{y}$, in expectation (over the random entries in $\mathbf{A}$). This is a consequence of the fact that for any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$, if $\mathbf{r}$ is drawn from $\mathcal{N}(0,1)^d$,

$$\Pr[\text{sign}\,\langle \mathbf{x}, \mathbf{r}\rangle = \text{sign}\,\langle \mathbf{y}, \mathbf{r}\rangle] = \frac{\angle(\mathbf{x}, \mathbf{y})}{\pi}. \tag{2}$$

Other data oblivious methods have also been studied in the literature, by choosing different distributions for the entries of $\mathbf{A}$. While these methods do reasonably well in practice, the natural question is if adapting the matrix to the data allows us to use shorter codes (i.e., have a smaller k) while achieving a similar error. A number of such data-dependent techniques have been proposed with different optimization criteria such as reconstruction error (Kulis and Darrell, 2009), data dissimilarity (Norouzi and Fleet, 2012; Weiss et al., 2008), ranking loss (Norouzi et al., 2012), quantization error after PCA (Gong et al., 2012a), and pairwise misclassification (Wang et al., 2010). As long as data is relatively low dimensional, these methods have been shown to be quite effective for learning compact codes.

However, the $\mathcal{O}(kd)$ barrier on the space and time complexity barrier prevents them from being applied with very high-dimensional data. For instance, to generate 10K-bit binary codes for data with 1M dimensions, a huge projection matrix will be required needing tens of GB of memory.[2]

In order to overcome these computational challenges, Gong et al. (2013) proposed a *bilinear projection* based coding method. The main idea here is to reshape the input vector $\mathbf{x}$ into a matrix $\mathbf{Z}$, and apply a bilinear projection to get the binary code:

$$h(\mathbf{x}) = \text{sign}(\mathbf{R}_1^T \mathbf{Z} \mathbf{R}_2). \tag{3}$$

When the shapes of $\mathbf{Z}, \mathbf{R}_1, \mathbf{R}_2$ are chosen appropriately[3], the method has time and space complexities $\mathcal{O}(d\sqrt{k})$ and $\mathcal{O}(\sqrt{dk})$ respectively. Bilinear codes make it feasible to work with data sets of very high dimensionality and have shown good results for a variety of tasks.

1.1 Our results

In this work, we propose a novel technique, called Circulant Binary Embedding (CBE), which is even faster than the bilinear coding. The main idea is to impose a *circulant* (described in detail in Section 3) structure on the projection matrix $\mathbf{A}$ in (1). This special structure allows us to compute the product $\mathbf{Ax}$ in time $\mathcal{O}(d \log d)$ using the Fast Fourier Transform (FFT), a tool of great significance in signal processing. The space complexity is also just $\mathcal{O}(d)$, making it efficient even for very high dimensional data. Table 1 compares the time and space complexity for the various methods outlined above.

Given the efficiency of computing the CBE, two natural questions arise: how good is the obtained embedding for various information retrieval tasks? and how should we pick the parameters of the circulant $\mathbf{A}$?

In Section 4, we study the first question for *random* CBE, i.e., when the parameters of the circulant are picked randomly (independent Gaussian, followed by its shifts). Specifically,

2. In the oblivious case, one can generate the random entries of the matrix on-the-fly (with fixed seeds) without needing to store the matrix, but this increases the computational time even further.
3. Specifically, $\mathbf{Z} \in \mathbb{R}^{\sqrt{d} \times \sqrt{d}}$, $\mathbf{R}_1, \mathbf{R}_2 \in \mathbb{R}^{\sqrt{k} \times \sqrt{d}}$.

Method	Time	Space	Time (optimization)
Unstructured	$\mathcal{O}(dk)$	$\mathcal{O}(dk)$	$\mathcal{O}(Nd^2k)$
Bilinear	$\mathcal{O}(d\sqrt{k})$	$\mathcal{O}(\sqrt{dk})$	$\mathcal{O}(Nd\sqrt{k})$
Circulant ($k \leq d$)	$\mathcal{O}(d \log d)$	$\mathcal{O}(d)$	$\mathcal{O}(Nd \log d)$
Circulant ($k > d$)	$\mathcal{O}(k \log d)$	$\mathcal{O}(k)$	$\mathcal{O}(Nk \log d)$

Table 1: Comparison of the time and space complexities. d is the input dimensionality, and k is the output dimensionality (number of bits). N is the number of instances used for learning data-dependent projection matrices. See Section 3.3 for discussions on $k < d$ and $k > d$.

we analyze the *angle estimating* property of binary embeddings (Eq.(1)), which is the basis for its use in applications. Under mild assumptions, we show that using a random circulant $\mathbf{A}$ has the same qualitative guarantees as using fully random $\mathbf{A}$. These results provide some of the few theoretical guarantees we are aware of, for non-linear circulant-based embeddings. We defer the formal statements of our results to Section 4, Theorems 3 and 4. We note that in independent and very recent work, Choromanska et al. (Choromanska et al., 2016) obtain a qualitatively similar analysis of CBE, however the bounds are incomparable to ours.

In Section 5, we study the second question, i.e., learning data-dependent circulant matrices. We propose a novel and efficient algorithm, which alternatively optimizes the objective in the original and frequency domains.

Finally in Section 7, we study the empirical performance of circulant embeddings via extensive experimentation. Compared to the state-of-the-art, our methods improve the performance dramatically for a fixed computation time. If we instead fix the number of bits in the embedding, we observe that the performance degradation is negligible, while speeding up the computation many-fold (see Section 7).

2. Background and related work

The lemma of Johnson and Lindenstrauss (Johnson and Lindenstrauss, 1984) is a fundamental tool in the area of sketching and dimension reduction. The lemma states that if we have N points in d-dimensional space, projecting them to an $\mathcal{O}(\log N)$ dimensional space (independent of d!) preserves all pairwise distances. One way of doing the projection is by a random Gaussian matrix. Formally,

Lemma 1 (Johnson Lindenstrass lemma) *Let S be a set of N points in $\mathbb{R}^d$. Let $\mathbf{A} \in \mathbb{R}^{k \times d}$ be a matrix whose entries are drawn i.i.d from $\mathcal{N}(0,1)$. Then with probability at least $1 - 2N^2 e^{-(\epsilon^2 - \epsilon^3)k/4}$*

$$(1-\epsilon)\|\mathbf{x}-\mathbf{y}\|_2 \leq \frac{1}{\sqrt{k}}\|\mathbf{A}(\mathbf{x}-\mathbf{y})\|_2 \leq (1+\epsilon)\|\mathbf{x}-\mathbf{y}\|_2 \tag{4}$$

for any $\mathbf{x}, \mathbf{y} \in S$.

When $k = \mathcal{O}(\log N/\epsilon^2)$, the probability above can be made arbitrarily close to 1. The result has also been shown to be optimal even if the projection can be chosen data-dependently (Larsen and Nelson, 2016). Due to the simplicity and theoretical support, random projection based dimensionality reduction has been applied in broad applications including approximate nearest neighbor research (Indyk and Motwani, 1998), dimensionality reduction in databases (Achlioptas, 2003), and bi-Lipschitz embeddings of graphs into normed spaces (Frankl and Maehara, 1988).

However a serious concern in a few applications is the dependence of k on the accuracy ($\mathcal{O}(1/\epsilon^2)$). The space and time complexity of dimension reduction are $\mathcal{O}(kd)$, if the computation is done in the natural way. Are there faster methods when k is reasonably large? As mentioned earlier, the line of work starting with (Ailon and Chazelle, 2006) aims to improve the time and space complexity of dimension reduction. This led to work showing Johnson-Lindenstruss-type guarantees with *structured* matrices (with some randomness), including Hadamard matrices along with a sparse random Gaussian matrix (Ailon and Chazelle, 2006), sparse matrices (Matoušek, 2008), and Lean Walsh Transformations (Liberty et al., 2008). The advantage of using structured matrices is that the space and computation cost can be dramatically reduced, yet the distance preserving property remains to be competitive.

In this context, randomized circulant matrices (which are also the main tool in our work) have been studied, starting with the works (Hinrichs and Vybíral, 2011; Vybíral, 2011). The dimension reduction comprises of random sign flips followed by multiplication by a randomized circulant matrix. For d-dimensional input, reducing the dimension to k for $k < d$ has time complexity $\mathcal{O}(d \log d)$ and space complexity $\mathcal{O}(d)$, independent of k. Proving bounds similar to Lemma 1 turns out to be much more challenging because the entries of the projection matrix are now highly dependent, and thus concentration bounds are hard to prove. The first analysis (Hinrichs and Vybíral, 2011) showed that reducing to $\mathcal{O}(\log^3 N/\epsilon^2)$ dimensions (compared to $\mathcal{O}(\log N/\epsilon^2)$ in Lemma 1) preserves all pairwise distances with high probability. This was improved to $\mathcal{O}(\log^2 N/\epsilon^2)$ in (Vybíral, 2011), and furthermore to $\mathcal{O}(\log^{(1+\delta)} N/\epsilon^2)$ in (Zhang and Cheng, 2013), using matrix-valued Bernstein inequalities. These works provide the motivation for our theoretical results, however the key difference for us is the *binarization* step, which is highly non-linear. Thus we need to develop new machinery for our analysis.

Binary embeddings. Recently, structured matrices used in the context of the fast JL transform (a combination of Hadamard and sparse random Gaussian matrices) have also been studied for binary embedding (Dasgupta et al., 2011), and more recently (Yi et al., 2015). In particular, Yi et al. (2015) showed that the method can achieve ϵ distance preserving error with $\mathcal{O}(\log N/\epsilon^2)$ bits and $\mathcal{O}(d \log d)$ computational complexity, for N points ($N \ll \epsilon\sqrt{d}$). In this work, we study the application of using the circulant matrix for binary embedding. The work extends and provides theoretical justification for our previous conference paper on this topic (Yu et al., 2014).

The idea of using structured matrices to speed up linear projection has also be exploited under the settings of deep neural networks (Cheng et al., 2015; Yang et al., 2015), and kernel approximation (Yu et al., 2015; Le et al., 2013) .

3. Circulant Binary Embedding

Let us start by describing our framework and setting up the notation that we use in the rest of the paper.

3.1 The Framework

We will now describe our algorithm for generating k-bit binary codes from d-dimensional real vectors. We start by discussing the case $k = d$ and move to the general case in Section 3.3. The key player is the circulant matrix, which is defined by a real vector $\mathbf{r} = (r_0, r_1, \cdots, r_{d-1})^T$ (Gray, 2006).

$$\mathcal{C}_{\mathbf{r}} := \begin{bmatrix} r_0 & r_{d-1} & \dots & r_2 & r_1 \\ r_1 & r_0 & r_{d-1} & & r_2 \\ \vdots & r_1 & r_0 & \ddots & \vdots \\ r_{d-2} & & \ddots & \ddots & r_{d-1} \\ r_{d-1} & r_{d-2} & \dots & r_1 & r_0 \end{bmatrix}. \tag{5}$$

Let $\mathbf{D}$ be a diagonal matrix with each diagonal entry σ_i, $i = 0, \cdots, d-1$, being a Rademacher variable (± 1 with probability $1/2$):

$$\mathbf{D} = \begin{bmatrix} \sigma_0 & & & & \\ & \sigma_1 & & & \\ & & \sigma_2 & & \\ & & & \ddots & \\ & & & & \sigma_{d-1} \end{bmatrix}. \tag{6}$$

For $\mathbf{x} \in \mathbb{R}^d$, its d-bit Circulant Binary Embedding (CBE) with $\mathbf{r} \in \mathbb{R}^d$ is defined as:

$$h(\mathbf{x}) = \text{sign}(\mathcal{C}_{\mathbf{r}}\mathbf{D}\mathbf{x}), \tag{7}$$

where $\mathcal{C}_{\mathbf{r}}$ is defined as above. Note that applying $\mathbf{D}$ to $\mathbf{x}$ is equivalent to applying a random sign flip to each coordinate of $\mathbf{x}$. The necessity of such an operation is discussed in the introduction of Section 4. Since sign flipping can be carried out as a preprocessing step for each input $\mathbf{x}$, here onwards for simplicity we will drop explicit mention of $\mathbf{D}$. Hence the binary code is given as $h(\mathbf{x}) = \text{sign}(\mathcal{C}_{\mathbf{r}}\mathbf{x})$.

3.2 Computational Complexity

The main advantage of a circulant based embedding is that it can be computed quickly using the Fast Fourier Transform (FFT). The following is a folklore result, whose proof we include for completeness.

Proposition 2 *For a d-dimensional vector $\mathbf{x}$ and any $\mathbf{r} \in \Re^d$, the d-bit CBE $\text{sign}(\mathcal{C}_r(\mathbf{D}\mathbf{x}))$ can be computed using $\mathcal{O}(d)$ space and $\mathcal{O}(d \log d)$ time.*

Proof The space complexity comes only from the storage of the vector $\mathbf{r}$ and the signs $\mathbf{D}$ (which amount to $\mathcal{O}(d)$). We never need to store the full matrix $\mathcal{C}_{\mathbf{r}}$ explicitly.

The main property of a circulant matrix is that for any vector $\mathbf{y} \in \mathbf{R}^d$, we can compute $\mathcal{C}_\mathbf{r}\mathbf{y}$ in time $\mathcal{O}(d \log d)$. This is because

$$\mathcal{C}_\mathbf{r} = \mathcal{F}_d^{-1} \text{ diag}(\mathcal{F}_d \mathbf{r}) \mathcal{F}_d, \tag{8}$$

where $\mathcal{F}_d$ is the matrix corresponding to the Discrete Fourier Transform (DFT) of periodicity N, i.e., whose (i, j)th entry is given by

$$\mathcal{F}_d(i, j) = \omega^{ij}, \tag{9}$$

where ω is the Nth root of unity $e^{-2\pi\iota/N}$. The celebrated Fast Fourier Transform algorithm (Oppenheim et al., 1999) says that for any $\mathbf{z} \in \mathbf{R}^d$, we can compute $\mathcal{F}_d\mathbf{z}$ and $\mathcal{F}_d^{-1}\mathbf{z}$ in time $\mathcal{O}(d \log d)$, using $\mathcal{O}(d)$ space. This immediately implies that we can compute $\mathcal{C}_\mathbf{r}\mathbf{y}$ within the same space and time complexity bounds. ■

3.3 Generalizing to $k \neq d$

The computation above assumed that number of bits we produce (k) is equal to the input dimension. Let us now consider the general case.

When $k < d$, we still use the circulant matrix $\mathbf{R} \in \mathbb{R}^{d\times d}$ with d parameters, but the output is set to be the first k elements in (7). This is equivalent to the operation

$$\Phi(\mathbf{x}) := \text{sign}(\mathcal{C}_{\mathbf{r},k}\mathbf{D}\mathbf{x}), \tag{10}$$

where $\mathcal{C}_{\mathbf{r},k}$ the so-called *partial circulant matrix*, which is $\mathcal{C}_\mathbf{r}$ truncated to k rows. We note that CBE with $k < d$ is not computationally more efficient than that with $k = d$.

When $k > d$, using a single $\mathbf{r}$ causes repetition of bits, so we propose using $\mathcal{C}_\mathbf{r}$ for multiple $\mathbf{r}$, and concatenating their output. This gives the computational complexity $\mathcal{O}(k \log d)$, and space complexity $\mathcal{O}(k)$. Note that as the focus of this paper is on binary embedding on high-dimensional data, from here onwards, we assume $k \leq d$. The $k > d$ case is useful in other applications such as neural network (Cheng et al., 2015) and kernel approximation (Yu et al., 2015).

3.4 Choosing the Parameters r

We have presented the general framework as well as its space and computation efficiency in this section. One critical question left unanswered is how to decide the parameter $\mathbf{r}$. As mentioned in the introduction, we consider two solutions. In Section 4, we study the randomized version, where each element of $\mathbf{r}$ is independently sampled from a unit Gaussian distribution. This is inspired by the popular Locality Sensitive Hashing (simhash) approach. Section 5 introduces an optimized version, where the parameters are optimized based on training data and an distance preserving objective function.

4. Randomized CBE – A Theoretical Analysis

We now analyze the angle preserving properties of CBE when the circulant matrix used is generated from a random d-dimensional vector. Formally, we consider the partial circulant

matrix $\mathcal{C}_{\mathbf{r},k}$, for $\mathbf{r} \sim \mathcal{N}(0, 1)^d$. The embedding we consider for an $\mathbf{x} \in \mathbb{R}^d$ is given by

$$\Phi(\mathbf{x}) := \text{sign}(\mathcal{C}_{\mathbf{r},k}\mathbf{D}\mathbf{x}). \tag{11}$$

As before, $\mathbf{D}$ is a diagonal matrix of signs. Hence the embedding uses $2d$ independent 'units' of randomness.

Now, for any two vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$, we have that

$$\mathbb{E}\left[\frac{1}{2k}\|\Phi(\mathbf{x}) - \Phi(\mathbf{y})\|_1\right] = \frac{\angle(\mathbf{x}, \mathbf{y})}{\pi}, \tag{12}$$

implying that the random variable $(1/2k)\|\Phi(\mathbf{x}) - \Phi(\mathbf{y})\|_1$ provides an estimate for θ/π, where $\theta := \angle(\mathbf{x}, \mathbf{y})$.

We present two main results. In the first, we bound the variance of the above angle estimate for given $\mathbf{x}, \mathbf{y}$. We compare with the variance in the *fully independent* case, i.e., when we consider the embedding $\text{sign}(\mathbf{A}\mathbf{x})$, where $\mathbf{A}$ is a $k \times d$ matrix with all entries being independent (and unit normal). In this case, the variance of the estimator in Eq. (12) is equal to $\frac{1}{k}\frac{\theta}{\pi}\left(1 - \frac{\theta}{\pi}\right)$.[4]

We show that using a circulant matrix instead of A above has a similar dependence on k, as long as the vectors are *well spread*. Formally,

Theorem 3 *Let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$, such that $\max\{\|\mathbf{x}\|_\infty/\|\mathbf{x}\|_2, \|\mathbf{y}\|_\infty/\|\mathbf{y}\|_2\} \leq \rho$, for some parameter $\rho < 1$, and set $\theta = \angle(\mathbf{x}, \mathbf{y})$. The variance of the averaged hamming distance of k-bit code generated by randomized CBE is*

$$var\left[\frac{1}{2k}\|\Phi_x - \Phi_y\|_1\right] \leq \frac{1}{k}\frac{\theta}{\pi}\left(1 - \frac{\theta}{\pi}\right) + 32\rho. \tag{13}$$

The variance above is over the choice of $\mathbf{r}$ and the random signs $\mathbf{D}$.

Remark. For typical vectors in $\mathbb{R}^d$, we have $\|\mathbf{x}\|_\infty/\|\mathbf{x}\|_2$ to be $O(\log d/\sqrt{d})$. Further, by using the idea from Ailon and Chazelle (Ailon and Chazelle, 2006), we can pre-process the data by multiplying it with a randomly signed Hadamard matrix, and guarantee such an ℓ_∞ bound with high probability.[5] Therefore the second term becomes negligible for large d. The above result suggests that the angle preservation performance of CBE (in term of the variance) is as good as LSH for high-dimensional data.

Our second theorem gives a large-deviation bound for the angle estimate, also assuming that the vectors are well-spread. This will then enable us to obtain a dimension reduction theorem which preserves all angles up to an additive error.

Theorem 4 *Let $\mathbf{x}, \mathbf{y} \in \mathbf{R}^d$ with $\angle(\mathbf{x}, \mathbf{y}) = \theta$, and suppose $\max\{\|\mathbf{x}\|_\infty/\|\mathbf{x}\|_2, \|\mathbf{y}\|_\infty/\|\mathbf{x}\|_2\} \leq \rho$, for some parameter ρ. Now consider the k-dimensional CBE Φ_x, Φ_y of $\mathbf{x}, \mathbf{y}$ respectively, for some $k < d$. Suppose $\rho \leq \frac{\theta^2}{16k\log(k/\delta)}$. For any $\delta > 0$, we have:*

$$\Pr\left[\left|\frac{1}{2k}\|\Phi_x - \Phi_y\|_1 - \frac{\theta}{\pi}\right| > \frac{4\log(k/\delta)}{\sqrt{k}}\right] < \delta. \tag{14}$$

4. We are computing the variance of an average of i.i.d. Bernoulli random variables which take value 1 with probability $p = \theta/\pi$.
5. However, applying this pre-processing leads to *dense* vectors, which may be memory intensive for some applications. In this case, dividing the co-ordinates into blocks of size $\sim k^2$ and performing the pre-processing on the blocks separately is better for small k.

Qualitatively, the condition on ρ is similar to the one we implicitly have in Theorem 3. Unless $\rho = o(\frac{1}{k}\frac{\theta}{\pi}(1-\frac{\theta}{\pi}))$, the additive term dominates, so for the bound to be interesting, we need this condition on ρ.

We observe that Theorem 4 implies a Johnson-Lindenstrauss type theorem.

Corollary 5 *Suppose we have N vectors $\mathbf{u}_0, \mathbf{u}_1, \ldots, \mathbf{u}_{N-1}$ in $\mathbf{R}^d$, and define*

$$\rho_{ij} = \max\{\|\mathbf{u}_i\|_\infty/\|\mathbf{u}_i\|_2, \|\mathbf{u}_j\|_\infty/\|\mathbf{u}_j\|_2\}, \quad \theta_{ij} = \angle(\mathbf{u}_i, \mathbf{u}_j). \tag{15}$$

Let $\epsilon > 0$ be a given accuracy parameter and let $k = C\log^2 n/\epsilon^2$. Then for all i, j such that $\rho_{ij} < \frac{\theta_{ij}^2}{16k\log(2kN^2)}$, we have

$$\left|\frac{1}{2k}\|\Phi_i - \Phi_j\|_1 - \frac{\theta_{ij}}{\pi}\right| < \epsilon, \tag{16}$$

with probability at least 3/4.

Proof We can set $\delta = 1/2N^2$ in Theorem 4 and then take a union bound over all $\binom{N}{2}$ choices of pairs i, j to obtain a failure probability $\leq 1/4$. Further, for our choice of k, setting $C = 144$ and assuming N is large enough that $k < N$, we have

$$\frac{4\log(k/\epsilon)}{\sqrt{k}} < \frac{12\delta\log N}{\sqrt{C}\cdot\log N} < \epsilon. \tag{17}$$

■

In the remainder of the section, we will prove the above theorems. We start with Theorem 3, whose proof will give a basic framework for that of Theorem 4.

4.1 Variance of the angle estimator

For a vector $\mathbf{x}$ and an index i, we denote by $s_{\to i}(\mathbf{x})$ the vector *shifted* by i positions: the jth entry of $s_{\to i}$ is the $((j-i)\text{mod } d)$'th entry of $\mathbf{x}$. Further, let us define

$$F_i = \frac{1 - \text{sign}(s_{\to i}(\mathbf{r})^T\mathbf{D}\mathbf{x})\,\text{sign}(s_{\to i}(\mathbf{r})^T\mathbf{D}\mathbf{y})}{2} - \frac{\theta}{\pi}. \tag{18}$$

where $s_{\to i}(\cdot)$ is defined as the operator circularly shifting a vector by i elements[6]. By definition, we have

$$var\left[\frac{1}{2k}\|\Phi_x - \Phi_y\|_1\right] = var\left[\frac{1}{k}\sum_{i=1}^{k} F_i\right]. \tag{19}$$

6. The above comes with a slight abuse of notation, where the first column (instead of row) of the projection matrix $\mathbf{R}$ is defined as $\mathbf{r}$.

Without loss of generality, we assume $\|\mathbf{x}\|_2, \|\mathbf{y}\|_2 = 1$ (since we only care about the angle). The mean of each F_i is zero, and thus $\mathbb{E}[\frac{1}{k}\sum_{i=1}^{k} F_i] = 0$. Thus the variance is equal to

$$\begin{aligned} var\left[\frac{1}{k}\sum_{i=0}^{k-1} F_i\right] &= \mathbb{E}\left[\frac{1}{k^2}\left(\sum_{i=0}^{k-1} F_i\right)^2\right] \qquad (20)\\ &= \mathbb{E}\left[\frac{\sum_{i=0}^{k-1} F_i^2 + \sum_{i\neq j} F_iF_j}{k^2}\right] \\ &= \frac{1}{k^2}\left(k\cdot\mathbb{E}F_1^2 + \sum_{i\neq j}\mathbb{E}(F_iF_j)\right) \\ &= \frac{1}{k}\frac{\theta}{\pi}\left(1-\frac{\theta}{\pi}\right) + \frac{1}{k^2}\sum_{i\neq j}\mathbb{E}(F_iF_j). \qquad (21)\end{aligned}$$

The last step is based on variance of the fully independent case: the variance of a Bernoulli random variable which takes value 1 with probability $p = \theta/\pi$ is $\frac{\theta}{\pi}\left(1-\frac{\theta}{\pi}\right)$.

To prove the theorem, it suffices to show that $\mathbb{E}(F_iF_j) \leq 32\rho$ for all $i \neq j$. Without loss of generality, we can assume that $i = 0$, and consider $\mathbb{E}(F_0F_j)$. By definition, it is equal to

$$\mathbb{E}\left[\left(\frac{1 - \text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{x})\,\text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{y})}{2} - \frac{\theta}{\pi}\right)\left(\frac{1 - \text{sign}(s_{\to j}(\mathbf{r})^T\mathbf{D}\mathbf{x})\,\text{sign}(s_{\to j}(\mathbf{r})^T\mathbf{D}\mathbf{y})}{2} - \frac{\theta}{\pi}\right)\right].$$

The trick now is to observe that

$$s_{\to j}(\mathbf{r})^T\mathbf{x} = \mathbf{r}^T s_{\to(d-j)}(\mathbf{x}). \tag{22}$$

Thus setting $t = d - j$, we can write the above as

$$\mathbb{E}\left[\left(\frac{1 - \text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{x})\,\text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{y})}{2} - \frac{\theta}{\pi}\right)\left(\frac{1 - \text{sign}(\mathbf{r}^T s_{\to t}(\mathbf{D}\mathbf{x}))\,\text{sign}(\mathbf{r}^T s_{\to t}(\mathbf{D}\mathbf{y}))}{2} - \frac{\theta}{\pi}\right)\right].$$

The key idea is that we expect the vector $s_{\to t}(\mathbf{D}\mathbf{x})$ to be nearly orthogonal to the space containing $\mathbf{D}\mathbf{x}, \mathbf{D}\mathbf{y}$. This is because $\mathbf{D}$ is a diagonal matrix of random signs, and $\mathbf{x}$ and $\mathbf{y}$ are vectors with small ℓ_∞ norm. We show this formally in Lemma 7.

Why does this help? Suppose for a moment that $\mathbf{u} := s_{\to t}(\mathbf{D}\mathbf{x})$ and $\mathbf{v} := s_{\to t}(\mathbf{D}\mathbf{y})$ are both orthogonal to $\text{span}\{\mathbf{D}\mathbf{x}, \mathbf{D}\mathbf{y}\}$. Then for a random Gaussian $\mathbf{r}$, the random variables $\text{sign}(\mathbf{r}^T\mathbf{u})\,\text{sign}(\mathbf{r}^T\mathbf{v})$ and $\text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{x})\,\text{sign}(\mathbf{r}^T\mathbf{D}\mathbf{y})$ are independent, because the former depends only on the projection of $\mathbf{r}$ onto $\text{span}\{\mathbf{u}, \mathbf{v}\}$, while the latter depends only on the projection of $\mathbf{r}$ onto $\text{span}\{\mathbf{D}\mathbf{x}, \mathbf{D}\mathbf{y}\}$. Now if these two spaces are orthogonal, the projections of a Gaussian vector onto these spaces are independent (this is a fundamental property of multidimensional Gaussians). This implies that the expectation of the product above is equal to the product of the expectations, which is zero (each expectation is zero).

The key lemma (see below) now says that even if $\mathbf{u}$ and $\mathbf{v}$ as defined above are *nearly* orthogonal to $\text{span}\{\mathbf{D}\mathbf{x}, \mathbf{D}\mathbf{y}\}$, we still get a good bound on the expectation above.

Lemma 6 *Let $\mathbf{a}, \mathbf{b}, \mathbf{u}, \mathbf{v}$ be unit vectors in $\mathbf{R}^d$ such that $\angle(\mathbf{a}, \mathbf{b}) = \angle(\mathbf{u}, \mathbf{v}) = \theta$, and let Π be the projector onto span$\{\mathbf{a}, \mathbf{b}\}$. Suppose $\max\{\|\Pi\mathbf{u}\|, \|\Pi\mathbf{v}\|\} = \delta < 1$. Then we have*

$$\mathbb{E}\left[\left(\frac{1 - \text{sign}(\mathbf{r}^T\mathbf{a})\,\text{sign}(\mathbf{r}^T\mathbf{b})}{2} - \frac{\theta}{\pi}\right)\left(\frac{1 - \text{sign}(\mathbf{r}^T\mathbf{u})\,\text{sign}(\mathbf{r}^T\mathbf{v})}{2} - \frac{\theta}{\pi}\right)\right] \leq 2\delta. \tag{23}$$

Here, the expectation is over the choice of $\mathbf{r}$.

The proof of the above lemma is moved to Appendix A.1.

We use the lemma with $\mathbf{a} = \mathbf{Dx}$ and $\mathbf{b} = \mathbf{Dy}$. To show Theorem 3, we have to prove that

$$\mathbb{E}\left[\max\{\|\Pi\mathbf{u}\|, \|\Pi\mathbf{v}\|\}\right] \leq 16\rho, \tag{24}$$

where $\Pi, \mathbf{u}, \mathbf{v}$ are defined as in the statement of Lemma 6. The expectation now is over the choice of $\mathbf{D}$. This leads us to our next lemma.

Lemma 7 *Let $\mathbf{p}, \mathbf{q} \in \mathbb{R}^d$ be vectors that satisfy $\|\mathbf{p}\|_2 = 1$ and $\|\mathbf{q}\|_\infty < \rho$ for some parameter ρ, and suppose $\mathbf{D} := diag(\sigma_0, \sigma_1, \ldots, \sigma_{d-1})$, where σ_i are random ± 1 signs. Then for any $0 < t < d$, we have*

$$\Pr[\langle \mathbf{Dp}, s_{\to t}(\mathbf{Dq})\rangle > \gamma] \leq e^{-\gamma^2/8\rho^2}. \tag{25}$$

Note that the probability is over the choice of $\mathbf{D}$.

The proof of the above lemma is moved to Appendix A.2. We remark that the lemma only assumes that $\mathbf{p}$ is a unit vector, it need not have a small ℓ_∞ norm.

We can now complete the proof of our theorem. As noted above, we need to show (24). To recall, Π is the projector onto span$\{\mathbf{Dx}, \mathbf{Dy}\}$, and we need to bound:

$$\mathbb{E}\left[\max\{\|\Pi\mathbf{u}\|, \|\Pi\mathbf{v}\|\}\right] \leq \mathbb{E}[\|\Pi\mathbf{u}\|] + \mathbb{E}[\|\Pi\mathbf{v}\|]. \tag{26}$$

Let $\mathbf{x}, \mathbf{z}$ be an orthonormal basis for span$\{\mathbf{x}, \mathbf{y}\}$; then it is easy to see that for any diagonal $\mathbf{D}$ with ± 1 entries on the diagonal, $\mathbf{Dx}, \mathbf{Dz}$ is an orthonormal basis for span$\{\mathbf{Dx}, \mathbf{Dy}\}$. Thus

$$\mathbb{E}[\|\Pi\mathbf{u}\|] \leq \mathbb{E}[|\langle \mathbf{u}, \mathbf{Dx}\rangle| + |\langle \mathbf{u}, \mathbf{Dz}\rangle|]. \tag{27}$$

Now by Lemma 7,

$$\Pr[|\langle \mathbf{u}, \mathbf{Dx}\rangle| > t\rho] \leq e^{-t^2/4}. \tag{28}$$

Integrating over t, we get $\mathbb{E}[|\langle \mathbf{u}, \mathbf{Dx}\rangle|] \leq 4\rho$. Thus we can bound the LHS of (26) by 16ρ, completing the proof of the theorem.

4.2 The Johnson-Lindenstrauss Type Result

Next, we turn to the proof of Theorem 4, where we wish to obtain a strong tail bound. At a high level, the argument consists of two steps:

- First, show that with probability $1 - \epsilon$ over the choice of $\mathbf{D}$, the k translates of $\mathbf{x}, \mathbf{y}$ satisfy certain orthogonality properties (this is in the same spirit as Lemma 7).
- Second, conditioned on orthogonality as above, with high probability over the choice of $\mathbf{r}$, we have the desired guarantee.

Next will will show the two steps respectively. Throughout this section, we denote by $X_0, X_1, \ldots, X_{k-1}$ the k shifts of $\mathbf{Dx}$, i.e., $X_i = s_{\to(i)}(\mathbf{Dx})$; define $Y_0, \ldots, Y_{k-1}$ analogously as shifts of $\mathbf{Dy}$. We will also assume that $\rho < \frac{\theta^2}{16k\log(k/\delta)}$.

The structure we require is formally the following.

Definition 8 ((γ, k)-orthogonality) *Two sequences of k unit vectors $X_0, X_1, \ldots, X_{k-1}$ and $Y_0, Y_1, \ldots, Y_{k-1}$ are said to be (γ, k)-orthogonal if there exists a decomposition (for every i)*

$$X_i = \mathbf{u}_i + \mathbf{e}_i\ ; \quad Y_i = \mathbf{v}_i + \mathbf{f}_i \tag{29}$$

satisfying the following properties:

1. *$\mathbf{u}_i$ and $\mathbf{v}_i$ are both orthogonal to span$\{\mathbf{u}_j, \mathbf{v}_j : j \neq i\}$.*
2. *$\max_i\{\|\mathbf{e}_i\|, \|\mathbf{f}_i\|\} < \gamma$.*

The lemma of the first step, as described earlier, is the following:

Lemma 9 *Let $\mathbf{x}, \mathbf{y}$ be unit vectors with $\|\mathbf{x}\|_\infty, \|\mathbf{y}\|_\infty \leq \rho$, and $\theta = \angle(\mathbf{x}, \mathbf{y})$, and let X_i, Y_i be rotations of $\mathbf{Dx}, \mathbf{Dy}$ respectively (as defined earlier). Then w.p. $1 - \delta$ over the choice of $\mathbf{D}$, the vectors $(X_i, Y_i)_{i=1}^k$ are (γ, k) orthogonal, for $\gamma = 4\sqrt{\rho}$.*

The proof of the lemma is quite technical, and is moved to Appendix A.3.

Now suppose we have that the shifts X_i, Y_i satisfy (γ, k)-orthogonality for some $\gamma > 0$. Suppose $\mathbf{u}_i, \mathbf{v}_i, \mathbf{e}_i, \mathbf{f}_i$ are as defined earlier. (γ, k)-orthogonality gives us that $\|\mathbf{e}_i\|, \|\mathbf{f}_i\| < \gamma$, which is $\ll 1$. Roughly speaking, we use this to say that *most of the time*, $\text{sign}(\langle \mathbf{r}, X_i\rangle = \langle \mathbf{r}, \mathbf{u}_i\rangle)$. Thus determining if $\text{sign}(\langle \mathbf{r}, X_i\rangle) = \text{sign}(\langle \mathbf{r}, Y_i\rangle)$ is essentially equivalent to determining if $\text{sign}(\langle \mathbf{r}, \mathbf{u}_i\rangle) = \text{sign}(\langle \mathbf{r}, \mathbf{v}_i\rangle)$. But the latter quantities, by orthogonality, are indepedent! (because the signs depend only on the projection of $\mathbf{r}$ onto the span of $\mathbf{u}_i, \mathbf{v}_i$, which is independent for different i).[7] The main lemma of the second step is the following:

Lemma 10 *Let $(X_i, Y_i)_{i=1}^k$ be a set of vectors satisfying (γ, k)-orthogonality and $\angle(X_i, Y_i) = \theta$ for all i. Then for any $\delta > 0$ and $k > \max\{1/\gamma, \log(4/\delta)\}$, we have*

$$\Pr\left[\left|\frac{1}{k}\sum_i (\text{sign}\,\langle \mathbf{r}, X_i\rangle \neq \text{sign}\,\langle \mathbf{r}, Y_i\rangle) - \frac{\theta}{\pi}\right| > \gamma \cdot (12\log(2k/\delta))\right] < 1 - \delta. \tag{30}$$

The probability here is over the choice of $\mathbf{r}$.

The proof is deferred to Appendix A.4.

We can now complete the proof of Theorem 4. It essentially follows using Lemma 9 and Lemma 10. Note that we can apply Lemma 10 because the angle between X_i and Y_i is also θ for each i (since they are shifts of $\mathbf{x}, \mathbf{y}$).

Formally, using the value of γ defined in Lemma 9, we have that the vectors X_i, Y_i are (γ, k) orthogonal with probability $1 - \delta$. Conditioned on this, the probability that the conclusion of Lemma 10 holds with probability $1 - \delta$. Thus the overall probability of success is at least $1 - 2\delta$. The theorem is thus easily proved by plugging in the value of γ from Lemma 9, together with $\rho < 1$. This completes the proof of the Theorem.

7. Again, using the property of multi-variate Gaussians that the projections onto orthogonal directions are orthogonal.

5. Optimized Binary Embedding

In the previous section, we showed the randomized CBE has LSH-like angle preserving properties, especially for high-dimensional data. One problem with the randomized CBE method is that it does not utilize the underlying data distribution while generating the matrix $\mathbf{R}$. In the next section, we propose to learn $\mathbf{R}$ in a data-dependent fashion, to minimize the distortions due to circulant projection and binarization.

The study in this section is closely related to data-dependent binary embeddings (Wang et al., 2010; Gong et al., 2012a, 2013). Different from the above works, the projection matrix has a circulant structure instead of being unstructured. The method is also related to data-dependent dimensionality reduction techniques such as PCA. Although it has been shown that the Johnson Lindenstrauss bound is tight even in the data-dependent setting (Larsen and Nelson, 2016), it is expected that optimization can improve the result of CBE: CBE differs from conventional dimensionality reduction by using the circulant structure and binarization; the data dependent bound is based on a worst case scenario of the data, whereas we study the empirical performance on real large-scale data sets.

We propose data-dependent CBE (CBE-opt), by optimizing the projection matrix with a novel time-frequency alternating optimization. We consider the following objective function in learning the d-bit CBE. The extension of learning $k < d$ bits will be shown in Section 5.2.

$$\begin{aligned} \underset{\mathbf{B},\mathbf{r}}{\text{argmin}} \quad & ||\mathbf{B} - \mathbf{X}\mathbf{R}^T||_F^2 + \lambda||\mathbf{R}\mathbf{R}^T - \mathbf{I}||_F^2 \\ \text{s.t.} \quad & \mathbf{R} = \text{circ}(\mathbf{r}), \end{aligned} \tag{31}$$

where $\mathbf{X} \in \mathbb{R}^{N\times d}$, is the data matrix containing n training points: $\mathbf{X} = [\mathbf{x}_0, \cdots, \mathbf{x}_{N-1}]^T$, and $\mathbf{B} \in \{-1, 1\}^{N\times d}$ is the corresponding binary code matrix.[8]

In the above optimization, the first term minimizes distortion due to binarization. The second term tries to make the projections (rows of $\mathbf{R}$, and hence the corresponding bits) as uncorrelated as possible. In other words, this helps to reduce the redundancy in the learned code. If $\mathbf{R}$ were to be an orthogonal matrix, the second term will vanish and the optimization would find the best rotation such that the distortion due to binarization is minimized. However, being a circulant matrix, $\mathbf{R}$, in general, will not be orthogonal[9]. A similar objective has been used in previous works including (Gong et al., 2012a, 2013) and (Wang et al., 2010).

5.1 The Time-Frequency Alternating Optimization

The above is a difficult non-convex combinatorial optimization problem. In this section we propose a novel approach to efficiently find a local solution. The idea is to alternatively optimize the objective by fixing $\mathbf{r}$, and $\mathbf{B}$, respectively. For a fixed $\mathbf{r}$, optimizing $\mathbf{B}$ can be easily performed in the input domain ("time" as opposed to "frequency"). For a fixed $\mathbf{B}$, the circulant structure of $\mathbf{R}$ makes it difficult to optimize the objective in the input domain.

8. If the data is ℓ_2 normalized, we can set $\mathbf{B} \in \{-1/\sqrt{d}, 1/\sqrt{d}\}^{N\times d}$ to make $\mathbf{B}$ and $\mathbf{X}\mathbf{R}^T$ more comparable. This does not empirically influence the performance.
9. We note that the rank of the circulant matrices can range from 1 (an all-1 matrix) to d (an identity matrix).

Hence we propose a novel method, by optimizing $\mathbf{r}$ in the frequency domain based on DFT. This leads to a very efficient procedure.

For a fixed r. The objective is independent on each element of $\mathbf{B}$. Denote B_{ij} as the element of the i-th row and j-th column of $\mathbf{B}$. It is easy to show that $\mathbf{B}$ can be updated as:

$$\begin{aligned} B_{ij} &= \begin{cases} 1 & \text{if } \mathbf{R}_j.\mathbf{x}_i \geq 0 \\ -1 & \text{if } \mathbf{R}_j.\mathbf{x}_i < 0 \end{cases}, \\ & i = 0, \cdots, N-1. \quad j = 0, \cdots, d-1. \end{aligned} \tag{32}$$

For a fixed B. Define $\tilde{\mathbf{r}}$ as the DFT of the circulant vector $\tilde{\mathbf{r}} := \mathcal{F}(\mathbf{r})$. Instead of solving $\mathbf{r}$ directly, we propose to solve $\tilde{\mathbf{r}}$, from which $\mathbf{r}$ can be recovered by IDFT.

Key to our derivation is the fact that DFT projects the signal to a set of orthogonal basis. Therefore the ℓ_2 norm can be preserved. Formally, according to Parseval's theorem, for any $\mathbf{t} \in \mathbb{C}^d$ (Oppenheim et al., 1999),

$$||\mathbf{t}||_2^2 = (1/d)||\mathcal{F}(\mathbf{t})||_2^2. \tag{33}$$

Denote $\text{diag}(\cdot)$ as the diagonal matrix formed by a vector. Denote $\Re(\cdot)$ and $\Im(\cdot)$ as the real and imaginary parts, respectively. We use $\mathbf{B}_{i\cdot}$ to denote the i-th row of $\mathbf{B}$. With complex arithmetic, the first term in (31) can be expressed in the frequency domain as:

$$\begin{aligned} &||\mathbf{B} - \mathbf{X}\mathbf{R}^T||_F^2 = \frac{1}{d}\sum_{i=0}^{N-1} ||\mathcal{F}(\mathbf{B}_{i\cdot}^T - \mathbf{R}\mathbf{x}_i)||_2^2 \\ =&\frac{1}{d}\sum_{i=0}^{N-1} ||\mathcal{F}(\mathbf{B}_{i\cdot}^T) - \tilde{\mathbf{r}} \circ \mathcal{F}(\mathbf{x}_i)||_2^2 = \frac{1}{d}\sum_{i=0}^{N-1} ||\mathcal{F}(\mathbf{B}_{i\cdot}^T) - \text{diag}(\mathcal{F}(\mathbf{x}_i))\tilde{\mathbf{r}}||_2^2 \\ =&\frac{1}{d}\sum_{i=0}^{N-1} \left(\mathcal{F}(\mathbf{B}_{i\cdot}^T) - \text{diag}(\mathcal{F}(\mathbf{x}_i))\tilde{\mathbf{r}}\right)^T \left(\mathcal{F}(\mathbf{B}_{i\cdot}^T) - \text{diag}(\mathcal{F}(\mathbf{x}_i))\tilde{\mathbf{r}}\right) \\ =&\frac{1}{d}\Big[\Re(\tilde{\mathbf{r}})^T\mathbf{M}\Re(\tilde{\mathbf{r}}) + \Im(\tilde{\mathbf{r}})^T\mathbf{M}\Im(\tilde{\mathbf{r}}) + \Re(\tilde{\mathbf{r}})^T\mathbf{h} + \Im(\tilde{\mathbf{r}})^T\mathbf{g}\Big] + ||\mathbf{B}||_F^2, \end{aligned} \tag{34}$$

where,

$$\mathbf{M} = \text{diag}\big(\sum_{i=0}^{N-1} \Re(\mathcal{F}(\mathbf{x}_i)) \circ \Re(\mathcal{F}(\mathbf{x}_i)) + \Im(\mathcal{F}(\mathbf{x}_i)) \circ \Im(\mathcal{F}(\mathbf{x}_i))\big), \tag{35}$$

$$\mathbf{h} = -2\sum_{i=0}^{N-1} \Re(\mathcal{F}(\mathbf{x}_i)) \circ \Re(\mathcal{F}(\mathbf{B}_{i\cdot}^T)) + \Im(\mathcal{F}(\mathbf{x}_i)) \circ \Im(\mathcal{F}(\mathbf{B}_{i\cdot}^T)), \tag{36}$$

$$\mathbf{g} = 2\sum_{i=0}^{N-1} \Im(\mathcal{F}(\mathbf{x}_i)) \circ \Re(\mathcal{F}(\mathbf{B}_{i\cdot}^T)) - \Re(\mathcal{F}(\mathbf{x}_i)) \circ \Im(\mathcal{F}(\mathbf{B}_{i\cdot}^T)). \tag{37}$$

The above can be derived based on the following fact. For any $\mathbf{Q} \in \mathbb{C}^{d\times d}$, $\mathbf{s}$, $\mathbf{t} \in \mathbb{C}^d$,

$$
\begin{aligned}
&||\mathbf{s}-\mathbf{Qt}||_2^2=(\mathbf{s}-\mathbf{Qt})^H(\mathbf{s}-\mathbf{Qt}) \qquad (38)\\
=&\mathbf{s}^H\mathbf{s}-\mathbf{s}^H\mathbf{Qt}-\mathbf{t}^H\mathbf{Q}^H\mathbf{s}+\mathbf{t}^H\mathbf{Q}^H\mathbf{Qt}\\
=&\Re(\mathbf{s})^T\Re(\mathbf{s})+\Im(\mathbf{s})^T\Im(\mathbf{s})-2\Re(\mathbf{t})^T(\Re(\mathbf{Q})^T\Re(\mathbf{s})+\Im(\mathbf{Q})^T\Im(\mathbf{s}))\\
&+2\Im(\mathbf{t})^T(\Im(\mathbf{Q})^T\Re(\mathbf{s})-\Re(\mathbf{Q})^T\Im(\mathbf{s}))+\Re(\mathbf{t})^T(\Re(\mathbf{Q})^T\Re(\mathbf{Q})+\Im(\mathbf{Q})^T\Im(\mathbf{Q}))\Re(\mathbf{t})\\
&+\Im(\mathbf{t})^T(\Re(\mathbf{Q})^T\Re(\mathbf{Q})+\Im(\mathbf{Q})^T\Im(\mathbf{Q}))\Im(\mathbf{t})+2\Re(\mathbf{t})^T(\Im(\mathbf{Q})^T\Re(\mathbf{Q})-\Re(\mathbf{Q})^T\Im(\mathbf{Q}))\Im(\mathbf{t}).
\end{aligned}
$$

For the second term in (31), we note that the circulant matrix can be diagonalized by DFT matrix $\mathbf{F}_d$ and its conjugate transpose $\mathbf{F}_d^H$. Formally, for $\mathbf{R}=\text{circ}(\mathbf{r})$, $\mathbf{r}\in\mathbb{R}^d$,

$$
\mathbf{R}=(1/d)\mathbf{F}_d^H\text{diag}(\mathcal{F}(\mathbf{r}))\mathbf{F}_d. \qquad (39)
$$

Let $\text{Tr}(\cdot)$ be the trace of a matrix. Therefore,

$$
\begin{aligned}
&||\mathbf{RR}^T-\mathbf{I}||_F^2=||\frac{1}{d}\mathbf{F}_d^H(\text{diag}(\tilde{\mathbf{r}})^H\text{diag}(\tilde{\mathbf{r}})-\mathbf{I})\mathbf{F}_d||_F^2 \qquad (40)\\
=&\,\text{Tr}\left[\frac{1}{d}\mathbf{F}_d^H(\text{diag}(\tilde{\mathbf{r}})^H\text{diag}(\tilde{\mathbf{r}})-\mathbf{I})^H(\text{diag}(\tilde{\mathbf{r}})^H\text{diag}(\tilde{\mathbf{r}})-\mathbf{I})\mathbf{F}_d\right]\\
=&\,\text{Tr}\left[(\text{diag}(\tilde{\mathbf{r}})^H\text{diag}(\tilde{\mathbf{r}})-\mathbf{I})^H(\text{diag}(\tilde{\mathbf{r}})^H\text{diag}(\tilde{\mathbf{r}})-\mathbf{I})\right]\\
=&||\tilde{\mathbf{r}}^H\circ\tilde{\mathbf{r}}-\mathbf{1}||_2^2=||\Re(\tilde{\mathbf{r}})^2+\Im(\tilde{\mathbf{r}})^2-\mathbf{1}||_2^2.
\end{aligned}
$$

Furthermore, as $\mathbf{r}$ is real-valued, additional constraints on $\tilde{\mathbf{r}}$ are needed. For any $u\in\mathbb{C}$, denote $\overline{u}$ as its complex conjugate. We have the following result (Oppenheim et al., 1999): For any real-valued vector $\mathbf{t}\in\mathbb{C}^d$, $\mathcal{F}(\mathbf{t})_0$ is real-valued, and

$$
\mathcal{F}(\mathbf{t})_{d-i}=\overline{\mathcal{F}(\mathbf{t})_i},\quad i=1,\cdots,\lfloor d/2\rfloor. \qquad (41)
$$

From (34) $-$ (41), the problem of optimizing $\tilde{\mathbf{r}}$ becomes

$$
\begin{aligned}
\underset{\tilde{\mathbf{r}}}{\text{argmin}}\quad & \Re(\tilde{\mathbf{r}})^T\mathbf{M}\Re(\tilde{\mathbf{r}})+\Im(\tilde{\mathbf{r}})^T\mathbf{M}\Im(\tilde{\mathbf{r}})+\Re(\tilde{\mathbf{r}})^T\mathbf{h}\\
&+\Im(\tilde{\mathbf{r}})^T\mathbf{g}+\lambda d||\Re(\tilde{\mathbf{r}})^2+\Im(\tilde{\mathbf{r}})^2-\mathbf{1}||_2^2 \qquad (42)\\
\text{s.t.}\quad & \Im(\tilde{r}_0)=0\\
& \Re(\tilde{r}_i)=\Re(\tilde{r}_{d-i}),i=1,\cdots,\lfloor d/2\rfloor\\
& \Im(\tilde{r}_i)=-\Im(\tilde{r}_{d-i}),i=1,\cdots,\lfloor d/2\rfloor.
\end{aligned}
$$

The above is non-convex. Fortunately, the objective function can be decomposed, such that we can solve two variables at a time. Denote the diagonal vector of the diagonal matrix $\mathbf{M}$ as $\mathbf{m}$. The above optimization can then be decomposed to the following sets of optimizations.

$$
\begin{aligned}
&\underset{\tilde{r}_0}{\text{argmin}}\quad m_0\tilde{r}_0^2+h_0\tilde{r}_0+\lambda d\left(\tilde{r}_0^2-1\right)^2,\ \text{s.t. }\tilde{r}_0=\overline{\tilde{r}_0}. \qquad (43)\\
&\underset{\tilde{r}_i}{\text{argmin}}\quad (m_i+m_{d-i})(\Re(\tilde{r}_i)^2+\Im(\tilde{r}_i)^2)+2\lambda d\left(\Re(\tilde{r}_i)^2+\Im(\tilde{r}_i)^2-1\right)^2\\
&\qquad\qquad +(h_i+h_{d-i})\Re(\tilde{r}_i)+(g_i-g_{d-i})\Im(\tilde{r}_i),\quad i=1,\cdots,\lfloor d/2\rfloor.
\end{aligned}
$$

In (43), we need to minimize a 4^{th} order polynomial with one variable, with the closed form solution readily available. In (44), we need to minimize a 4^{th} order polynomial with two variables. Though the closed form solution is hard to find (requiring solution of a cubic bivariate system), a local minimum can be found by gradient descent, which in practice has constant running time for such small-scale problems. The overall objective is guaranteed to be non-increasing in each step. In practice, we find that a good solution can be reached within just 5-10 iterations. Therefore in practice, the proposed time-frequency alternating optimization procedure has running time $\mathcal{O}(Nd\log d)$.

5.2 Learning with Dimensionality Reduction

In the case of learning $k<d$ bits, we need to solve the following optimization problem:

$$
\begin{aligned}
\underset{\mathbf{B},\mathbf{r}}{\text{argmin}}\quad & ||\mathbf{BP}_k-\mathbf{XP}_k^T\mathbf{R}^T||_F^2+\lambda||\mathbf{RP}_k\mathbf{P}_k^T\mathbf{R}^T-\mathbf{I}||_F^2 \qquad (44)\\
\text{s.t.}\quad & \mathbf{R}=\text{circ}(\mathbf{r}),
\end{aligned}
$$

in which $\mathbf{P}_k=\begin{bmatrix}\mathbf{I}_k & \mathbf{O}\\ \mathbf{O} & \mathbf{O}_{d-k}\end{bmatrix}$, $\mathbf{I}_k$ is a $k\times k$ identity matrix, and $\mathbf{O}_{d-k}$ is a $(d-k)\times(d-k)$ all-zero matrix.

In fact, the right multiplication of $\mathbf{P}_k$ can be understood as a "temporal cut-off", which is equivalent to a frequency domain convolution. This makes the optimization difficult, as the objective in frequency domain can no longer be decomposed. To address this issue, we propose a simple solution in which $B_{ij}=0$, $i=0,\cdots,N-1,j=k,\cdots,d-1$ in (31). Thus, the optimization procedure remains the same, and the cost is also $\mathcal{O}(Nd\log d)$. We will show in experiments that this heuristic provides good performance in practice.

6. Discussion

6.1 Limitations of the Theory for Long Codes

As was shown in earlier works (Li et al., 2011; Gong et al., 2013; Sánchez and Perronnin, 2011) and as we see in our experiments (Section 7), long codes are necessary for high-dimensional data for all binary embedding methods, either randomized or optimized.

However, when the code length is too large, our theoretical analysis is not optimal. For instance, consider our variance bound when $k>\sqrt{d}$. Here the ρ term always dominates, because for any vector, we have $\rho\geq 1/\sqrt{d}$ (at least one entry of a unit vector is at least $1/\sqrt{d}$). In numeric simulations, we see that the variance drops as $1/k$ for a larger range of k, roughly up to d. A similar behavior holds in Theorem 4, where the condition $\rho\leq\frac{\theta^2}{16k\log(k/\delta)}$ can hold only when $k<\mathcal{O}(\sqrt{d}/\log d)$. It is an interesting open question to analyze the variance and other concentration properties for larger k.

6.2 Semi-supervised Extension

In some applications, one can have access to a few labeled pairs of similar and dissimilar data points. Here we show how the CBE formulation can be extended to incorporate such

information in learning. This is achieved by adding an additional objective term $J(\mathbf{R})$.

$$\begin{aligned} \underset{\mathbf{B},\mathbf{r}}{\text{argmin}} \quad & ||\mathbf{B} - \mathbf{X}\mathbf{R}^T||_F^2 + \lambda||\mathbf{R}\mathbf{R}^T - \mathbf{I}||_F^2 + \mu J(\mathbf{R}) \\ \text{s.t.} \quad & \mathbf{R} = \text{circ}(\mathbf{r}), \end{aligned} \tag{45}$$

$$J(\mathbf{R}) = \sum_{i,j\in\mathcal{M}} ||\mathbf{R}\mathbf{x}_i - \mathbf{R}\mathbf{x}_j||_2^2 - \sum_{i,j\in\mathcal{D}} ||\mathbf{R}\mathbf{x}_i - \mathbf{R}\mathbf{x}_j||_2^2. \tag{46}$$

Here $\mathcal{M}$ and $\mathcal{D}$ are the set of "similar" and "dissimilar" instances, respectively. The intuition is to maximize the distances between the dissimilar pairs, and minimize the distances between the similar pairs. Such a term is commonly used in semi-supervised binary coding methods (Wang et al., 2010). We again use the time-frequency alternating optimization procedure of Section 5. For a fixed $\mathbf{r}$, the optimization procedure to update $\mathbf{B}$ is the same. For a fixed $\mathbf{B}$, optimizing $\mathbf{r}$ is done in frequency domain by expanding $J(\mathbf{R})$ as below, with similar techniques used in Section 5.

$$||\mathbf{R}\mathbf{x}_i - \mathbf{R}\mathbf{x}_j||_2^2 = (1/d)||\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j))\tilde{\mathbf{r}}||_2^2. \tag{47}$$

Therefore,

$$J(\mathbf{R}) = (1/d)(\Re(\tilde{\mathbf{r}})^T\mathbf{A}\Re(\tilde{\mathbf{r}}) + \Im(\tilde{\mathbf{r}})^T\mathbf{A}\Im(\tilde{\mathbf{r}})), \tag{48}$$

where $\mathbf{A} = \mathbf{A}_1 + \mathbf{A}_2 - \mathbf{A}_3 - \mathbf{A}_4$, and

$$\mathbf{A}_1 = \sum_{(i,j)\in\mathcal{M}} \Re(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j)))^T\Re(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j))), \tag{49}$$

$$\mathbf{A}_2 = \sum_{(i,j)\in\mathcal{M}} \Im(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j)))^T\Im(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j))), \tag{50}$$

$$\mathbf{A}_3 = \sum_{(i,j)\in\mathcal{D}} \Re(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j)))^T\Re(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j))), \tag{51}$$

$$\mathbf{A}_4 = \sum_{(i,j)\in\mathcal{D}} \Im(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j)))^T\Im(\text{diag}(\mathcal{F}(\mathbf{x}_i) - \mathcal{F}(\mathbf{x}_j))). \tag{52}$$

Hence, the optimization can be carried out as in Section 5, where $\mathbf{M}$ in (34) is simply replaced by $\mathbf{M}+\mu\mathbf{A}$. The semi-supervised extension improves over the non-semi-supervised version by 2% in terms of averaged AUC on the ImageNet-25600 data set.

7. Experiments

To compare the performance of the circulant binary embedding techniques, we conduct experiments on three real-world high-dimensional data sets used by the current state-of-the-art method for generating long binary codes (Gong et al., 2013). The Flickr-25600 data set contains 100K images sampled from a noisy Internet image collection. Each image is represented by a $25,600$ dimensional feature vector. To extract the feature vectors, we use

the publicly available SIFT features, which are densely extracted at three different scales. We cluster the features into 200 centers and then aggregate them into VLAD vectors (Jégou et al., 2010) of 128 200 = 25, 600 dimensions. The ImageNet-51200 contains 100k images sampled from 100 random classes from ImageNet (Deng et al., 2009), each represented by a $51,200$ dimensional VLAD vector generated by using 400 cluster centers. The third data set (ImageNet-25600) is another random subset of ImageNet containing 100K images in $25,600$ dimensional space. All the vectors are normalized to be of unit norm.

We compare the performance of the randomized (CBE-rand) and learned (CBE-opt) versions of our circulant embeddings with the current state-of-the-art for high-dimensional data, *i.e.*, bilinear embeddings. We use both the randomized (bilinear-rand) and learned (bilinear-opt) versions. Bilinear embeddings have been shown to perform similarly or better than another promising technique called Product Quantization (Jegou et al., 2011). Finally, we also compare against the binary codes produced by the baseline LSH method (Charikar, 2002), which is still applicable to 25,600 and 51,200 dimensional feature but with much longer running time and much more space. We also show an experiment with relatively low-dimensional feature (2048, with Flickr data) to compare against techniques that perform well for low-dimensional data but do not scale to high-dimensional scenario. Example techniques include ITQ (Gong et al., 2012a), SH (Weiss et al., 2008), SKLSH (Raginsky and Lazebnik, 2009), and AQBC (Gong et al., 2012b).

Following (Gong et al., 2013; Norouzi and Fleet, 2012; Gordo and Perronnin, 2011), we use 10,000 randomly sampled instances for training. We then randomly sample 500 instances, different from the training set as queries. The performance (recall@1-100) is evaluated by averaging the recalls of the query instances. The ground-truth of each query instance is defined as its 10 nearest neighbors based on ℓ_2 distance. For each data set, we conduct two sets of experiments: *fixed-time* where code generation time is fixed and *fixed-bits* where the number of bits is fixed across all techniques. We also show an experiment where the binary codes are used for classification.

The proposed CBE method is found robust to the choice of λ in (31). For example, in the retrieval experiments, the performance difference for $\lambda = 0.1$, 1, 10, is within 0.5%. Therefore, in all the experiments, we simply fix $\lambda = 1$. For the bilinear method, in order to get fast computation, the feature vector is reshaped to a near-square matrix, and the dimension of the two bilinear projection matrices are also chosen to be close to square. Parameters for other techniques are tuned to give the best results on these data sets.

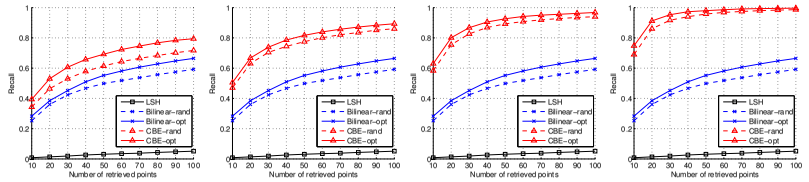
7.1 Computational Time

When generating k-bit code for d-dimensional data, the full projection, bilinear projection, and circulant projection methods have time complexity $O(kd)$, $O(\sqrt{k}d)$, and $O(d\log d)$, respectively. We compare the computational time in Table 2 on a fixed hardware. Based on our implementation, the computational time of the above three methods can be roughly characterized as $d^2 : d\sqrt{d} : 5d\log d$. Note that faster implementation of FFT algorithms will lead to better computational time for CBE by further reducing the constant factor. Due to the small storage requirement $\mathcal{O}(d)$, and the wide availability of highly optimized FFT libraries, CBE is also suitable for implementation on GPU. Our preliminary tests based on

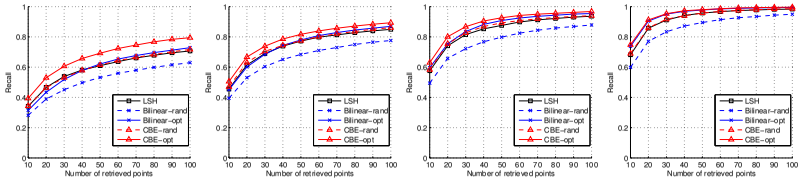
d	Full projection	Bilinear projection	Circulant projection
2^{15}	5.44×10^2	2.85	1.11
2^{17}	-	1.91×10^1	4.23
2^{20} (1M)	-	3.76×10^2	3.77×10^1
2^{24}	-	1.22×10^4	8.10×10^2
2^{27} (100M)	-	2.68×10^5	8.15×10^3

Table 2: Computational time (ms) of full projection (LSH, ITQ, SH *etc.*), bilinear projection (Bilinear), and circulant projection (CBE). The time is based on a single 2.9GHz CPU core. The error is within 10%. An empty cell indicates that the memory needed for that method is larger than the machine limit of 24GB.

GPU shows up to 20 times speedup compared with CPU. In this paper, for fair comparison, we use same CPU based implementation for all the methods.

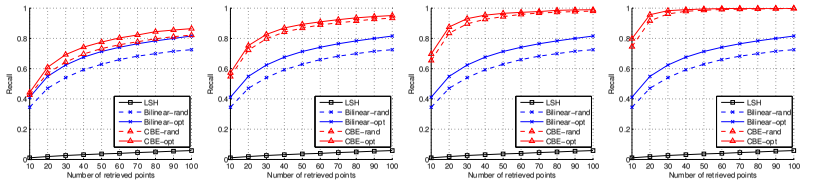


(a) #bit(CBE) = 3,200 (b) #bits(CBE) = 6,400 (c) #bits(CBE) = 12,800(d) #bits(CBE) = 25,600

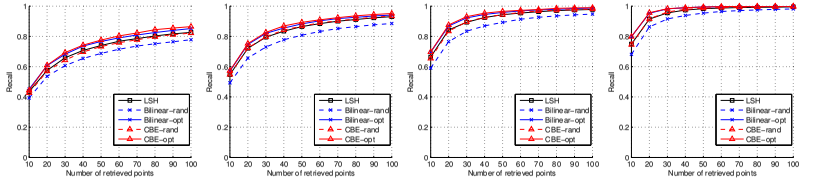


(e) # bits (all) = 3,200 (f) # bits (all) = 6,400 (g) # bits (all) = 12,800 (h) # bits (all) = 25,600

Figure 1: Recall on Flickr-25600. The standard deviation is within 1%. **First Row**: Fixed time. "# bits" is the number of bits of CBE. Other methods are using fewer bits to make their computational time identical to CBE. **Second Row**: Fixed number of bits. CBE-opt/CBE-rand are 2-3 times faster than Bilinear-opt/Bilinear-rand, and hundreds of times faster than LSH.



(a) #bits(CBE) = 3,200 (b) #bits(CBE) = 6,400 (c) #bits(CBE) = 12,800(d) #bits(CBE) = 25,600



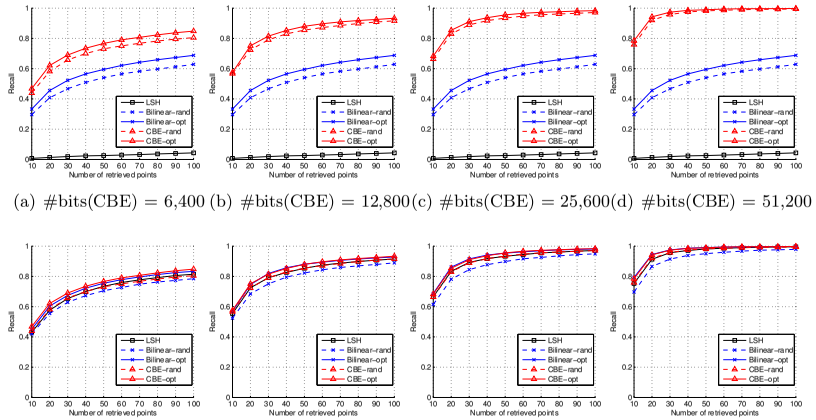
(e) # bits (all) = 3,200 (f) # bits (all) = 64,00 (g) # bits (all) = 12,800 (h) # bits (all) = 25,600

Figure 2: Recall on ImageNet-25600. The standard deviation is within 1%. **First Row**: Fixed time. "# bits" is the number of bits of CBE. Other methods are using fewer bits to make their computational time identical to CBE. **Second Row**: Fixed number of bits. CBE-opt/CBE-rand are 2-3 times faster than Bilinear-opt/Bilinear-rand, and hundreds of times faster than LSH.

7.2 Retrieval

The recalls of different methods are compared on the three data sets, shown in Figure 1 – 3. The top row in each figure shows the performance of different methods when the code generation time for all the methods is kept the same as that of CBE. For a fixed time, the proposed CBE yields much better recall than other methods. Even CBE-rand outperforms LSH and Bilinear code by a large margin. The second row compares the performance for different techniques with codes of same length. In this case, the performance of CBE-rand is almost identical to LSH even though it is hundreds of time faster. This is consistent with our analysis in Section 4. Moreover, CBE-opt/CBE-rand outperform Bilinear-opt/Bilinear-rand in addition to being 2-3 times faster.

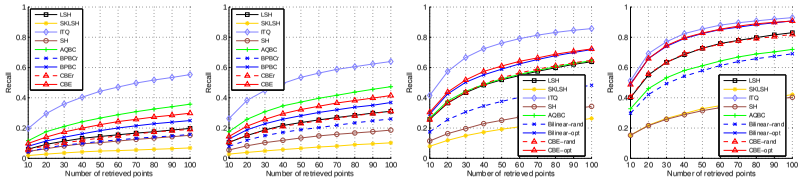
There exist several techniques that do not scale to high-dimensional case. To compare our method with those, we conduct experiments with fixed number of bits on a relatively low-dimensional data set (Flickr-2048), constructed by randomly sampling 2,048 dimensions of Flickr-25600. As shown in Figure 4, though CBE is not designed for such scenario, the CBE-opt performs better or equivalent to other techniques except ITQ which scales very poorly with d ($\mathcal{O}(d^3)$). Moreover, as the number of bits increases, the gap between ITQ and CBE becomes much smaller suggesting that the performance of ITQ is not expected to be better than CBE even if one could run ITQ on high-dimensional data.



(a) #bits(CBE) = 6,400 (b) #bits(CBE) = 12,800 (c) #bits(CBE) = 25,600 (d) #bits(CBE) = 51,200

(e) # bits (all) = 6,400 (f) # bits (all) = 12,800 (g) # bits (all) = 25,600 (h) # bits (all) = 51,200

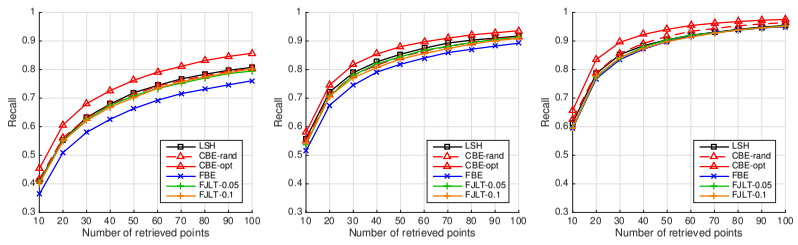
Figure 3: Recall on ImageNet-51200. The standard deviation is within 1%. **First Row**: Fixed time. "# bits" is the number of bits of CBE. Other methods are using fewer bits to make their computational time identical to CBE. **Second Row**: Fixed number of bits. CBE-opt/CBE-rand are 2-3 times faster than Bilinear-opt/Bilinear-rand, and hundreds of times faster than LSH.



(a) # bits = 256 (b) # bits = 512 (c) # bits = 1,024 (d) # bits = 2,048

Figure 4: Performance comparison on relatively low-dimensional data (Flickr-2048) with fixed number of bits. CBE gives comparable performance to the state-of-the-art even on low-dimensional data as the number of bits is increased. However, these other methods do not scale to very high-dimensional data setting which is the main focus of this work.

We also conduct additional experiments to compare CBE with the more recent Hadamard-based algorithms. The first algorithm we consider generates the binary code using the Fast



(a) # bits = 5,000 (b) # bits = 10,000 (c) # bits = 15,000

Figure 5: Recall on the Flickr-25600 data set. The methods compared are CBE-rand, CBE-opt, Fast Binary Embedding (FBE), Fast Johnson-Lindenstruss Transformation (FJLT) based methods and LSH. We follow the detailed setting of the FBE paper(Yi et al., 2015). In FJLT-p, p represents the percentage of nonzero elements in the sparse Gaussian matrix.

Johnson-Lindenstrss Transformation (FJLT). Similar to the circulant projection, FJLT has been used in dimensionality reduction (Ailon and Chazelle, 2006), deep neural networks (Yang et al., 2015), and kernel approximation (Le et al., 2013). Here, the binary code of $\mathbf{x} \in \mathbb{R}^d$ is generated as

$$h(\mathbf{x}) = \text{sign}(\mathbf{PHDx}), \tag{53}$$

where $\mathbf{P} \in \mathbb{R}^{k \times d}$ is a sparse matrix with the nonzeros entries generated iid from the standard distribution. $\mathbf{H} \in \mathbb{R}^{d \times d}$ is the Hadamard matrix, and $\mathbf{D} \in \mathbb{R}^{d \times d}$ is a diagonal matrix with random signs. Although the Hadamard transformation has computational complexity $\mathcal{O}(d \log d)$ (the multiplication with $\mathbf{H}$), this method is often slower than CBE due to the sparse Gaussian projection step (i.e., multiplication by $\mathbf{P}$).

The second method we compare with is Fast Binary Embedding (FBE). It is a theoretically sound method recently proposed in (Yi et al., 2015). FBE generates binary bits using a partial Walsh-Hadamard matrix and a set of partial Gaussian Toeplitz matrices. The method can achieve the optimal measurement complexity $\mathcal{O}(\frac{1}{\delta^2} \log N)$. Different from CBE, FBE uses multiple Toeplitz matrices each of which has more degrees of freedom than the circulant matrix ($2d$ vs. d), and their theory does not apply to the more structured CBE case. We follow the parameters settings in (Yi et al., 2015) (Flickr-25600 data set, with the number of bits 5,000, 10,000 and 15,000). Note that under the setting, FBE is at least a few times slower than CBE due to the use of multiple Toeplitz projections. Figure 5 shows the retrieval performance. Based on the experiments, in addition to being much faster than FBE and FJLT, CBE-rand provides comparable or even better performance. Another advantage of CBE is that the framework permits data-dependent optimization to further improve the performance. In all the experiments, CBE-opt achieves the highest recall by a large margin compared to other methods.

Original	LSH	Bilinear-opt	CBE-opt
25.59±0.33	23.49±0.24	24.02±0.35	24.55 ±0.30

Table 3: Multiclass classification accuracy (%) on binary coded ImageNet-25600. The binary codes of same dimensionality are 32 times more space efficient than the original features (single-float).

7.3 Classification

Besides retrieval, we also test the binary codes for classification. The advantage is to save on storage, allowing even large scale data sets to fit in memory (Li et al., 2011; Sánchez and Perronnin, 2011). We follow the asymmetric setting of (Sánchez and Perronnin, 2011) by training linear SVM on binary code sign($\mathbf{Rx}$), and testing on the original $\mathbf{Rx}$. Empirically, this has been shown to give better accuracy than the symmetric procedure. We use ImageNet-25600, with randomly sampled 100 images per category for training, 50 for validation and 50 for testing. The code dimension is set as 25,600. As shown in Table 3, CBE, which has much faster computation, does not show any performance degradation compared with LSH or bilinear codes in classification task.

8. Conclusion

We proposed a method of binary embedding for high-dimensional data. Central to our framework is to use a type of highly structured matrix, the circulant matrix, to perform the linear projection. The proposed method has time complexity $\mathcal{O}(d \log d)$ and space complexity $\mathcal{O}(d)$, while showing no performance degradation on real-world data compared with more expensive approaches ($\mathcal{O}(d^2)$ or $\mathcal{O}(d^{1.5})$). The parameters of the method can be randomly generated, where interesting theoretical analysis was carried out to show that the angle preserving quality can be as good as LSH. The parameters can also be learned based on training data with an efficient optimization algorithm.

Appendix A. Proofs of the Technical Lemmas

A.1 Proof of Lemma 6

For convenience, define $\mathbf{u}^\perp = \mathbf{u} - \Pi\mathbf{u}$, and similarly define $\mathbf{v}^\perp$. From our earlier observation about independence, we have that

$$\mathbb{E}\left[\left(\frac{1-\operatorname{sign}(\mathbf{r}^T\mathbf{a})\operatorname{sign}(\mathbf{r}^T\mathbf{b})}{2} - \frac{\theta}{\pi}\right)\left(\frac{1-\operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)\operatorname{sign}(\mathbf{r}^T\mathbf{v}^\perp)}{2} - \frac{\theta}{\pi}\right)\right] = 0. \tag{54}$$

Because the LHS is equal to the product of the expectations, and the first term is 0. Thus the quantity we wish to bound is

$$\mathbb{E}\left[\left(\frac{1-\operatorname{sign}(\mathbf{r}^T\mathbf{a})\operatorname{sign}(\mathbf{r}^T\mathbf{b})}{2} - \frac{\theta}{\pi}\right)\left(\frac{\operatorname{sign}(\mathbf{r}^T\mathbf{u})\operatorname{sign}(\mathbf{r}^T\mathbf{v}) - \operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)\operatorname{sign}(\mathbf{r}^T\mathbf{v}^\perp)}{2}\right)\right].$$

Now by using the fact that $\mathbb{E}[XY] \le \mathbb{E}[|X||Y|]$, together with the observation that the quantity $|(1-\operatorname{sign}(\mathbf{r}^T\mathbf{a})\operatorname{sign}(\mathbf{r}^T\mathbf{b}))/2 - \theta/\pi|$ is at most 2, we can bound the above by

$$\mathbb{E}\left[\left|\operatorname{sign}(\mathbf{r}^T\mathbf{u})\operatorname{sign}(\mathbf{r}^T\mathbf{v}) - \operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)\operatorname{sign}(\mathbf{r}^T\mathbf{v}^\perp)\right|\right]. \tag{55}$$

This is equal to

$$2\Pr[\operatorname{sign}(\mathbf{r}^T\mathbf{u})\operatorname{sign}(\mathbf{r}^T\mathbf{v}) \neq \operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)\operatorname{sign}(\mathbf{r}^T\mathbf{v}^\perp)], \tag{56}$$

since the term in the expectation is 2 if the product of signs is different, and 0 otherwise. To bound this, we first observe that for any two unit vectors $\mathbf{x}, \mathbf{y}$ with $\angle(\mathbf{x},\mathbf{y}) \le \epsilon$, we have $\Pr[\operatorname{sign}(\mathbf{r}^T\mathbf{x}) \neq \operatorname{sign}(\mathbf{r}^T\mathbf{y})] \le \epsilon/\pi$. We can use this to say that

$$\Pr[\operatorname{sign}(\mathbf{r}^T\mathbf{u}) \neq \operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)] = \frac{\angle(\mathbf{u},\mathbf{u}^\perp)}{\pi}. \tag{57}$$

This angle can be bounded in our case by $(\pi/2)\cdot\delta$ by basic geometry.[10] Thus by a union bound, we have that

$$\Pr[\big(\operatorname{sign}(\mathbf{r}^T\mathbf{u}) \neq \operatorname{sign}(\mathbf{r}^T\mathbf{u}^\perp)\big) \vee \big(\operatorname{sign}(\mathbf{r}^T\mathbf{v}) \neq \operatorname{sign}(\mathbf{r}^T\mathbf{v}^\perp)\big)] \le \delta. \tag{58}$$

This completes the proof.

A.2 Proof of Lemma 7

Denoting the ith entry of $\mathbf{p}$ by p_i (so also for $\mathbf{q}$), we have that

$$S := \langle \mathbf{Dp}, s_{\to t}(\mathbf{Dq})\rangle = \sum_{i=0}^{d-1} \sigma_i\sigma_{i+t}p_iq_{i+t}. \tag{59}$$

We note that $\mathbb{E}[S] = 0$, by linearity of expectation (as $t > 0$, $\mathbb{E}[\sigma_i\sigma_{i+t}] = 0$), thus the lemma is essentially a tail bound on S. While we can appeal to standard tail bounds for quadratic forms of sub-Gaussian random variables (e.g. Hansen-Wright (Rudelson and Vershynin, 2013)), we give below a simple argument. Let us define

$$f(\sigma_0,\sigma_1,\ldots,\sigma_{d-1}) = \sum_{i=0}^{d-1} p_iq_{i+t}\sigma_i\sigma_{i+t}. \tag{60}$$

We will view f as being obtained from a martingale as follows. Define

$$Q_i := f(\sigma_0,\sigma_1,\ldots,\sigma_i,0,\ldots,0) - f(\sigma_0,\sigma_1,\ldots,\sigma_{i-1},0,\ldots,0). \tag{61}$$

In this notation, we have $S = Q_0 + Q_1 + \cdots + Q_{d-1}$.

We have the martingale property that $\mathbb{E}[Q_i|Q_0,Q_1,\ldots,Q_{i-1}] = 0$ for all i, (because σ_i is ±1 with equal probability). Further, we have the *bounded difference* property, i.e., $|Q_i| \le |p_iq_{i+t}| + |p_{i-t}q_i|$. This implies that

$$|Q_i|^2 \le 2(p_i^2q_{i+t}^2 + p_{i-t}^2q_i^2). \tag{62}$$

10. $\mathbf{u}$ is a unit vector, and $\mathbf{u}^\perp + \Pi\mathbf{u} = \mathbf{u}$, and $\|\Pi\mathbf{u}\| \le \delta$, so the angle is at most $\sin^{-1}(\delta)$.

Thus we can use Azuma's inequality to conclude that for any $\gamma > 0$,

$$\Pr[|\sum_i Q_i - \mathbb{E}[\sum_i Q_i]| > \gamma] < e^{-\frac{\gamma^2}{2\cdot\sum_i 2(p_i^2 q_{i+t}^2 + p_{i-t}^2 q_i^2)}} = e^{-\frac{\gamma^2}{8\sum_i^2 p_i^2 q_{i+t}^2}}. \quad (63)$$

We can now use the fact that $\sum_i p_i^2 q_{i+t}^2 \leq \rho^2 \sum_i p_i^2 = \rho^2$ (since $\|\mathbf{p}\|_2 = 1$ and $\|\mathbf{q}\|_\infty \leq \rho$). This establishes the lemma.

A.3 Proof of Lemma 9

First, using Lemma 7 we have, for any $i \neq j$ and $c > 0$,

$$\Pr[|\langle X_i, Y_j\rangle| > c] < e^{-c^2/8\rho^2}. \quad (64)$$

We have a similar bound for $\Pr[|\langle X_i, X_j\rangle| > c]$. Thus by setting $c = 4\rho\sqrt{\log(k/\delta)}$ (δ as in the statement of the lemma), we can take a union bound over all k^2 choices of $i \neq j$ and conclude that w.p. at least $1 - \delta$, we have

$$\max_{i\neq j}\{|\langle X_i, X_j\rangle|, |\langle X_i, Y_j\rangle|\} < 4\rho\sqrt{\log(k/\delta)}. \quad (65)$$

We now prove that whenever Eq. (65) holds, we obtain (γ, k) orthogonality for the desired γ. Let us start with a basic fact in linear algebra.

Lemma 11 *Let A be an $d \times k$ matrix with $\sigma_k(A) \geq \tau$, for some parameter τ. Then any unit vector in the column span of A can be written as $\sum_i \alpha_i A_i$, with $\sum_i \alpha_i^2 \leq 1/\tau^2$.*

Proof By the definition of σ_k, we have that for any α_i, $\|\sum_i \alpha_i A_i\|_2^2 \geq \tau^2 \left(\sum_i \alpha_i^2\right)$. Thus for any unit vector $\sum_i \alpha_i A_i$, we have $\sum_i \alpha_i^2 \leq 1/\tau^2$. ■

Now let B be the $d \times 2k$ matrix whose columns are $X_1, Y_1, X_2, Y_2, \ldots, X_k, Y_k$ in that order. Consider the entries of $B^T B$. Since X_i, Y_i are unit vectors, the diagonals are all 1. The $(2i-1, 2i)$th and $(2i, 2i-1)$th entries are exactly $\cos\theta$, because the angle between X_i, Y_i is θ. The rest of the entries are of magnitude $< \eta := 4\rho\sqrt{\log(k/\delta)}$.

Thus if we consider $M = B^T B - I$ (diagonal removed from $B^T B$), we have $-(\cos\theta + k\eta)I \preceq M \preceq (\cos\theta + k\eta)I$ (diagonal dominance). Thus we conclude that $B^T B$ has all its eigenvalues $\geq 1 - \cos\theta - k\eta$. Since $\theta \in (0, \pi/2)$, we can use the standard inequality $\cos\theta < 1 - \theta^2/2$ to conclude that the eigenvalues are $\geq \theta^2/2 - k\eta$. Now by our assumption on ρ, we have that $k\eta < \theta^2/4$. This implies that all the eigenvalues are $\geq \theta^2/4$.

Thus we have $\sigma_{2k}^2(B) \geq \theta^2/4$. We prove now that this lets us obtain a decomposition that helps us prove (γ, k)-orthogonality. A crucial observation is the following.

Lemma 12 *The projection of X_i onto span$\{X_1, Y_1, X_2, Y_2, \ldots, X_{i-1}, Y_{i-1}\}$ has length at most $\frac{2\eta\sqrt{2k}}{\theta}$.*

Proof Let $\mathcal{S}$ denote span$\{X_1, Y_1, \ldots, X_{i-1}, Y_{i-1}\}$. By definition, the squared of the length of projection is equal to $\max\{\langle y, X_i\rangle^2 \mid y \in \mathcal{S} \text{ and } \|y\|_2 = 1\}$ (this is how the projection onto a subspace can be defined).

To bound this, consider any unit vector $y \in \mathcal{S}$, and suppose we write it as $\sum_{j<i} \alpha_j X_j + \beta_j Y_j$. Let B' be the matrix that has columns X_j, Y_j, $j < i$. Then it is straightforward to see that $\sigma_{2(i-1)}(B') \geq \sigma_{2k}(B) \geq \theta/2$. Thus Claim 11 implies that $\sum_{j<i} \alpha_j^2 + \beta_j^2 \leq 4/\theta^2$. This means that

$$\langle X_i, y\rangle^2 = \big(\sum_{j<i} \alpha_j \langle X_j, X_i\rangle + \beta_j \langle Y_j, X_i\rangle\big)^2 \quad (66)$$

$$\leq \big(\sum_{j<i} \alpha_j^2 + \beta_j^2\big)\big(\sum_{j<i} \langle X_j, X_i\rangle^2 + \langle Y_j, X_i\rangle^2\big) \quad (67)$$

$$\leq \frac{4}{\theta^2} \cdot (2i-2)\eta^2. \quad (68)$$

(In the first step, we used Cauchy-Schwartz.) Taking square roots now gives the claim. ■

Now we perform the following procedure on the vectors (it is essentially Gram-Schmidt orthonormalization, with the slight twist that we deal with X_i, Y_i together):

1. Initialize: $\mathbf{u}_1 = X_1, \quad \mathbf{e}_1 = 0, \quad \mathbf{v}_1 = Y_1, \quad \mathbf{f}_1 = 0$.
2. For $i = 2, \ldots, k$, we set $\mathbf{u}_i, \mathbf{v}_i$ to be the projections of X_i, Y_i (respectively) orthogonal to span$\{X_1, Y_1, \ldots, X_{i-1}, Y_{i-1}\}$. Set $\mathbf{e}_i = X_i - \mathbf{u}_i$ and $\mathbf{f}_i = Y_i - \mathbf{v}_i$.

The important observation is that for any i, we have

$$\text{span}\{\mathbf{u}_j, \mathbf{v}_j : j < i\} = \text{span}\{\mathbf{u}_j, \mathbf{v}_j, \mathbf{e}_j, \mathbf{f}_j : j < i\} = \text{span}\{X_j, Y_j : j < i\}. \quad (69)$$

This is because by definition, $\mathbf{e}_i, \mathbf{f}_i \in \text{span}\{X_j, Y_j : j < i\}$ for all i. Thus we have that $\mathbf{u}_i$ and $\mathbf{v}_i$ satisfy the first condition in Definition 8. It just remains to analyze the lengths. Now we can use Claim 12 to conclude that

$$\|\mathbf{e}_i\|_2^2, \|\mathbf{f}_i\|_2^2 < \frac{8k\eta^2}{\theta^2} = \frac{128 \cdot k\rho^2 \log(k/\delta)}{\theta^2}. \quad (70)$$

Once again, we use the bound on ρ to conclude that this quantity is at most 16ρ. This completes the proof of Lemma 9, with $\gamma = 4\sqrt{\rho}$.

A.4 Proof of Lemma 10

We start with a simple claim about the angle between $\mathbf{u}_i$ and $\mathbf{v}_i$.

Lemma 13 *For all i, we have $\angle(\mathbf{u}_i, \mathbf{v}_i) \in (\theta - \pi\gamma, \theta + \pi\gamma)$.*

Proof The angle between X_i and $\mathbf{u}_i$ is at most $\sin^{-1}(\gamma) < (\pi/2)\gamma$. So also, the angle between Y_i and $\mathbf{v}_i$ is at most $(\pi/2)\gamma$. Thus the angle between $\mathbf{u}_i, \mathbf{v}_i$ is in the interval $(\theta - \pi\gamma, \theta + \pi\gamma)$ (by triangle inequality for the geodesic distance). ■

Let $\eta > 0$ be a parameter we will fix later (it will be a constant times $\gamma\sqrt{\log(k/\delta)}$). For all i, we define the following events:

$$E_i: \quad \min\{\langle \mathbf{r}, \mathbf{u}_i\rangle, \langle \mathbf{r}, \mathbf{v}_i\rangle\} < \eta \quad (71)$$

$$F_i: \quad \neg E_i \text{ and } \text{sign}\langle \mathbf{r}, \mathbf{u}_i\rangle \neq \text{sign}\langle \mathbf{r}, \mathbf{v}_i\rangle \quad (72)$$

The following claim now follows easily.

Lemma 14 *For any i, we have*

$$\Pr[E_i] \leq 2\eta, \tag{73}$$

$$\Pr[F_i] \in \left(\frac{\theta}{\pi} - \pi\gamma - 2\eta, \frac{\theta}{\pi}\right) \tag{74}$$

Proof The first inequality follows from the small ball probability of a univariate Gaussian (since $\langle \mathbf{r}, \mathbf{u}_i \rangle$ is a Gaussian of unit variance), and the second follows from Claim 13 and (73). ■

We will set η to be larger than $\pi\gamma$, so the RHS in (74) can be replaced with $(\theta/\pi - 3\eta, \theta/\pi)$. Furthermore, the events above for a given i depend *only* on the projection of $\mathbf{r}$ to $\text{span}\{\mathbf{u}_i, \mathbf{v}_i\}$; thus they are independent for different i. Let us abuse notation slightly and denote by E_i also the indicator random variable for the event E_i (so also F_i). Then by standard Chernoff bounds, we have for any $\tau > 0$,

$$\Pr\left[\sum_i E_i \geq 2k\eta + k\tau\right] < e^{-\frac{k\tau^2}{4\eta+\tau}}, \tag{75}$$

$$\Pr\left[\sum_i F_i \notin \left(\frac{k\theta}{\pi} - 3k\eta - k\tau, \frac{k\theta}{\pi} + k\tau\right)\right] < 2e^{-\frac{k\tau^2}{\theta+\tau}}. \tag{76}$$

Finally let H denote the event:

$$\max_i \{|\langle \mathbf{r}, \mathbf{e}_i \rangle|, |\langle \mathbf{r}, \mathbf{f}_i \rangle|\} \geq \eta. \tag{77}$$

For any i, since $\|\mathbf{e}_i\| < \gamma$, we have $\Pr[|\langle \mathbf{r}, \mathbf{e}_i \rangle| > t\gamma] \leq e^{-t^2/2}$. We can use the same bound with $\mathbf{f}_i$, and take a union bound over all i, to conclude that $\Pr[H] \leq 2k \cdot e^{-\eta^2/2\gamma^2}$.

Let us call a choice of $\mathbf{r}$ *good* if neither of the events in (75)-(76) above occur, and additionally H does not occur. Clearly, the probability of an $\mathbf{r}$ being good is at least $1 - \delta$, provided τ and η are chosen such that the RHS of the tail bounds above are all made $\leq \delta/4$.

Before setting these values, we note that for a good $\mathbf{r}$,

$$\frac{1}{k}\sum_i \mathbf{1}\{\text{sign}\,\langle \mathbf{r}, X_i \rangle \neq \text{sign}\,\langle \mathbf{r}, Y_i \rangle\} \in \left(\frac{\theta}{\pi} - 3\eta - \tau, \frac{\theta}{\pi} + 2\eta + 2\tau\right). \tag{78}$$

This is because whenever $F_i \wedge \neg H$ occurs, we have $\text{sign}\,\langle \mathbf{r}, X_i \rangle \neq \text{sign}\,\langle \mathbf{r}, Y_i \rangle$, and thus the LHS above is at least $\frac{\theta}{\pi} - 3\eta - \tau$. Also if we have $\neg H$, then the only way we can have $\text{sign}\,\langle \mathbf{r}, X_i \rangle \neq \text{sign}\,\langle \mathbf{r}, Y_i \rangle$ is if either F_i occurs, or if E_i occurs (in the latter case, it is not necessary that the signs are unequal). Thus we can upper bound the LHS by $\frac{\theta}{\pi} + 2\eta + 2\tau$.

Let us now set the values of η and τ. From the above, we need to ensure:

$$\frac{k\tau^2}{4\eta+\tau} \geq \log(4/\delta), \quad \frac{k\tau^2}{\theta+\tau} \geq \log(8/\delta), \quad \text{and} \quad \frac{\eta^2}{2\gamma^2} \geq \log(4k/\delta). \tag{79}$$

Thus we set $\eta = 2\gamma\sqrt{\log(4k/\delta)}$, and

$$\tau \geq \max\left\{\frac{2\log(8/\delta)}{k}, \sqrt{\frac{2\theta\log(8/\delta)}{k}}, \sqrt{\frac{8\eta\log(4/\delta)}{k}}\right\}. \tag{80}$$

For the above inequality to hold, it suffices to set

$$\tau \geq \frac{8\log(1/\delta)}{\sqrt{k}}. \tag{81}$$

This gives the desired bound on the deviation in the angle.

Abstract

This work brings together two powerful concepts in Gaussian processes: the variational approach to sparse approximation and the spectral representation of Gaussian processes. This gives rise to an approximation that inherits the benefits of the variational approach but with the representational power and computational scalability of spectral representations. The work hinges on a key result that there exist spectral features related to a finite domain of the Gaussian process which exhibit almost-independent covariances. We derive these expressions for Matérn kernels in one dimension, and generalize to more dimensions using kernels with specific structures. Under the assumption of additive Gaussian noise, our method requires only a single pass through the data set, making for very fast and accurate computation. We fit a model to 4 million training points in just a few minutes on a standard laptop. With non-conjugate likelihoods, our MCMC scheme reduces the cost of computation from $\mathcal{O}(NM^2)$ (for a sparse Gaussian process) to $\mathcal{O}(NM)$ per iteration, where N is the number of data and M is the number of features.

Keywords: Gaussian processes, Fourier features, variational inference

1. Introduction

Efficient computation in Gaussian process (GP) models is of broad interest across machine learning and statistics, with applications in the fields of spatial epidemiology (Diggle, 2013; Banerjee et al., 2014), robotics and control (Deisenroth et al., 2015), signal processing (e.g. Särkkä et al., 2013), Bayesian optimization and probabilistic numerics, (e.g. Osborne, 2010; Briol et al., 2016; Hennig et al., 2015), and many others.

Computation is challenging for several reasons. First, the computational complexity usually scales cubically with the number of data N, as one must decompose a $N \times N$ dense covariance matrix. Second, the posterior is both high-dimensional and non-Gaussian if the data likelihood is not conjugate. Third, GP models have a hierarchical structure, with the latent values of the function being conditioned on parameters of the covariance function.

In this work, we adopt a variational Bayesian framework for dealing with these issues. By this we mean that we minimize the Kullback-Leibler (KL) divergence $\mathrm{KL}[q||p]$, where q denotes an approximation to the posterior, and p is the posterior itself. Many authors have applied this framework to GP problems before: perhaps the earliest example is Csató et al. (2002). Seeger (2003) also made use of this KL criterion in the context of Gaussian processes. Particularly influentuial works include Titsias (2009), who developed the first sparse GP using the KL divergence, and Opper and Archambeau (2009), who made a case for this approximation in the non-conjugate (but not sparse) case.

The variational framework for Gaussian processes has several advantages. First, the three challenges mentioned above can be tackled by a single unified objective. Second, the accuracy of the approximation can easily be shown to increase monotonically with increasing complexity of the proposed approximating family (i.e. more inducing points is always better). Third, the framework provides an evidence lower bound (or ELBO), which can be evaluated to compare different approximations.

In this work, we combine the variational approach with Fourier features; we refer to our method as Variational Fourier Features (VFF). Whilst most sparse Gaussian process approximations rely on *inducing* or *pseudo* inputs, which lie in the same domain as the inputs to the GP, Fourier features lie in the spectral domain of the process. As inducing-point approximations build up the posterior through kernel functions, Fourier features build up the approximate posterior through sinusoids. Our approach differs from existing works which use random frequencies (Rahimi and Recht, 2008, 2009) or optimized frequencies (Lázaro-Gredilla et al., 2010), in that we use frequencies placed on a regular grid (cf. Solin and Särkkä, 2014), which is key in our derivation of a computationally convenient matrix structure.

Naive combination of Fourier features with sparse GP approaches is not feasible because the standard Fourier transform of a stochastic process does not converge, meaning that these features are associated with random variables of infinite variance. Matthews et al. (2016) have shown that valid inducing features for the variational approach require finite, deterministic projections of the process. To combat this, Figueiras-Vidal and Lázaro-Gredilla (2009) used a windowing technique, which made the integrals converge to valid inducing features (for the squared-exponential kernel), but lost perhaps the most important aspect of a Fourier approach: that the features should be independent. In this work, we combine a finite window with a Reproducing Kernel Hilbert Space (RKHS) projection to construct features that are *almost* independent, having covariance structures that are easily decomposed. This gives rise to a complexity of $\mathcal{O}(NM)$, comparing favourably with the $\mathcal{O}(NM^2)$ complexity of other variational approaches, where M denotes the number of features.

The contributions of this paper are the following:

- We introduce a novel approximation scheme for representing a GP using a Fourier decomposition. We limit our interest to the widely used Matérn family of stationary kernels, for which our proposed decomposition exhibits an almost-independent structure.

∗. This work was partially completed whilst JH was affiliated to the Centre for Health Information, Computation, and Statistcs (CHICAS), Faculty of Health and Medicine, Lancaster University, UK.

†. This work was partially completed whilst ND was affiliated to Institut Fayol–LIMOS, Mines Saint-Étienne, 158 cours Fauriel, Saint-Étienne, France.

- We combine our approximation scheme with the variational Bayesian framework for Gaussian processes, and present how the methodology generalizes to GP inference problems with general likelihoods.

Consequently, this paper aims to provide an approximate Gaussian process inference scheme which is theoretically sound, has strong representative power, is extremely fast, and—most importantly—works well in practice.

The rest of this paper is structured as follows. Section 2 reviews the relevant background related to Gaussian process inference and previous work in sparse and spectral approximations to GP models. In Section 3 the core methodology for Variational Fourier Features is presented for the one-dimensional case. In Section 4 this is extended to multidimensional cases with additive and product structures. Implementation details and computational complexity of the method are covered in Section 5. Section 6 is dedicated to a set of illustrative toy examples and a number of empirical experiments, where practical aspects of Variational Fourier Feature inference are demonstrated. Finally, we conclude the paper with a discussion in Section 7.

2. Background

In this section, we first set up the family of Gaussian process models that we will consider, which allows us to establish some notation. Next, we review some basic results regarding the spectrum of stationary Gaussian processes, and recall how Fourier features approximate the kernel. We relate sparse Gaussian process approximations and Fourier approximations by explicating them as alternative models (Quiñonero-Candela and Rasmussen, 2005). We then recap the variational approximation to Gaussian processes, including expressions for sparse approximations and approximations for non-conjugate likelihoods. The two final subsections in this section discuss decomposition of Gaussian processes: we first link decomposition and conditioning and then discuss inter-domain decomposition.

2.1 Gaussian process models

Gaussian processes are distributions over functions, defined by a mean function and a covariance function (see Williams and Rasmussen, 2006, for an introduction). In this section we consider GPs over the real line, $x \in \mathbb{R}$. Making the standard assumption that the mean function is zero, we write

$$f(x) \sim \mathcal{GP}\left(0,\, k(x, x')\right) . \tag{1}$$

The data $\mathbf{y} = [y_n]_{n=1}^N$ at locations $\mathbf{X} = [x_n]_{n=1}^N$ are conditioned on the function evaluations $\mathbf{f} = [f(x_n)]_{n=1}^N$ through some factorising likelihood

$$p(\mathbf{y} \,|\, f(x)) = p(\mathbf{y} \,|\, \mathbf{f}) = \prod_n p(y_n \,|\, f(x_n)) \,, \tag{2}$$

which we do not in general assume to be Gaussian. A defining property of Gaussian processes is that any finite number of function evaluations follow a multivariate normal distribution, so

$$p(\mathbf{f}) = \mathcal{N}(\mathbf{0},\, \mathbf{K_{ff}}) \,, \tag{3}$$

and the process conditioned on these values is given by a conditional Gaussian process:

$$f(x) \,|\, \mathbf{f} \sim \mathcal{GP}\left(\mathbf{k_f}(x)^\top \mathbf{K_{ff}^{-1}} \mathbf{f},\; k(x,x') - \mathbf{k_f}(x)^\top \mathbf{K_{ff}^{-1}} \mathbf{k_f}(x')\right) . \tag{4}$$

To compute the posterior over functions given the data $f(x) \,|\, \mathbf{y}$, it is possible to compute the posterior only for the finite set $p(\mathbf{f} \,|\, \mathbf{y})$ using standard methodologies like Markov Chain Monte Carlo (MCMC) (e.g. Murray et al., 2010; Filippone et al., 2013) or variational Bayes (e.g. Opper and Archambeau, 2009; Khan et al., 2012, 2013). Evaluating the function at a test point means averaging equation (4) over this posterior $p(\mathbf{f} \,|\, \mathbf{y})$.

In our notation, the matrix $\mathbf{K_{ff}}$ is given by evaluating the covariance function at all pairs of data points $\mathbf{K_{ff}}[i,j] = k(x_i, x_j)$. The vector valued function $\mathbf{k_f}(x)$ is given similarly, $\mathbf{k_f}(x) = [k(x_1, x), k(x_2, x), \ldots, k(x_n, x)]^\top$. We omit dependence on covariance function parameters for clarity.

2.2 Spectral representations of stationary covariances

Stationary Gaussian processes are those with a covariance function that can be written as a function of the distance between observations, $k(x,x') = k(|x - x'|) = k(r)$. Of particular interest in this work will be the Matérn family with half-integer orders, the first three of which are

$$\begin{aligned} k_{\frac{1}{2}}(r) &= \sigma^2 \exp(-r/\ell) \,, \\ k_{\frac{3}{2}}(r) &= \sigma^2 (1 + \sqrt{3} r/\ell) \exp(-\sqrt{3} r/\ell) \,, \\ k_{\frac{5}{2}}(r) &= \sigma^2 (1 + \sqrt{5} r/\ell + \tfrac{5}{3} r^2/\ell^2) \exp(-\sqrt{5} r/\ell) \,, \end{aligned} \tag{5}$$

where σ^2 and ℓ are variance and lengthscale parameters respectively.

Bochner's theorem (Akhiezer and Glazman, 1993) tells us that any continuous positive definite function, such as a covariance function, can be represented as the Fourier transform of a positive measure. If the measure has a density, it is known as the spectral density $s(\omega)$ of the covariance function. This gives rise to the Fourier duality of spectral densities and covariance functions, known as the Wiener-Khintchin theorem. It gives the following relations:

$$s(\omega) = \mathcal{F}\{k(r)\} \quad = \int_{-\infty}^{\infty} k(r) e^{-i\omega r} \,\mathrm{d}r \,, \tag{6}$$

$$k(r) = \mathcal{F}^{-1}\{s(\omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} s(\omega) e^{i\omega r} \,\mathrm{d}\omega \,. \tag{7}$$

Since kernels are symmetric real functions, the spectrum of the process is also a symmetric real function. The spectra corresponding to the Matérn covariances are

$$s_{\frac{1}{2}}(\omega) = 2\sigma^2 \lambda (\lambda^2 + \omega^2)^{-1}, \qquad \lambda = \ell^{-1}, \tag{8}$$

$$s_{\frac{3}{2}}(\omega) = 4\sigma^2 \lambda^3 (\lambda^2 + \omega^2)^{-2}, \qquad \lambda = \sqrt{3}\ell^{-1}, \tag{9}$$

$$s_{\frac{5}{2}}(\omega) = \tfrac{16}{3}\sigma^2 \lambda^5 (\lambda^2 + \omega^2)^{-3}, \qquad \lambda = \sqrt{5}\ell^{-1} \,. \tag{10}$$

2.3 Model approximations

In order to overcome the cubic computational scaling of Gaussian process methods, many approximations have been proposed. Here we briefly review two types of approximations, those based on the spectrum of the process and others referred to as 'sparse' approximations.

2.3.1 Random Fourier features

Random Fourier Features (RFF) is a method for approximating kernels. The essential element of the RFF approach (Rahimi and Recht, 2008, 2009) is the realization that the Wiener-Khintchin integral (7) can be approximated by a Monte Carlo sum

$$k(r) \approx \tilde{k}(r) = \frac{\sigma^2}{M} \sum_{m=1}^{M} \cos(\omega_m r), \tag{11}$$

where the frequencies ω_m are drawn randomly from the distribution proportional to $s(\omega)$. Note that the imaginary part is zero because $s(\omega r)$ is even and $i \sin(\omega r)$ is odd.

This approximate kernel has a finite basis function expansion as

$$\boldsymbol{\phi}(x) = [\cos(\omega_1 x), \cos(\omega_2 x), \ldots, \cos(\omega_M x), \sin(\omega_1 x), \sin(\omega_2 x), \ldots, \sin(\omega_M x)]^\top, \tag{12}$$

and we can write the approximate Gaussian process as

$$f(x) \sim \mathcal{GP}\left(0, \tilde{k}(x - x')\right) \qquad \text{or} \qquad f(x) \sim \mathcal{GP}\left(0, \frac{\sigma^2}{M} \boldsymbol{\phi}(x)^\top \boldsymbol{\phi}(x')\right) \tag{13}$$

or equivalently as a parametric model, in the form

$$f(x) = \boldsymbol{\phi}(x)^\top \mathbf{w}, \tag{14}$$

$$\mathbf{w} \sim \mathcal{N}\left(\mathbf{0}, \frac{\sigma^2}{M} \mathbf{I}\right). \tag{15}$$

2.3.2 Optimized Fourier features

In order to have a representative sample of the spectrum, the RFF methodology typically requires the number of spectral sample points to be large. In Lázaro-Gredilla et al. (2010), this was addressed by the attractive choice of optimizing the spectral locations along with the hyperparameters (the 'Sparse Spectrum GP'). However, as argued by those authors, this option does not converge to the full GP and can suffer from overfitting to the training data. We confirm this empirically in a simple experiment in Section 6.

Noting that this method was prone to overfitting, Gal and Turner (2015) sought to improve the model by integrating out, rather than optimizing the frequencies. Gal and Turner derived a variational approximation that made use of a tractable integral over the frequency space. The result is an algorithm that suffers less overfitting than the Sparse Spectrum GP, yet remains flexible. We emphasize the difference to the approach in this work: Gal and Turner proposed variational inference in a sparse spectrum model that is derived from a GP model; our work aims to directly approximate the posterior of the true models using a variational representation.

2.3.3 Regular Fourier features

Another way to approximate the integral in (7) is with a regularly spaced set of frequencies ω. We refer to this method as *regular* Fourier features. While the Random Fourier Features approach could be interpreted as a Monte Carlo approximation to the Wiener-Khintchin integral, the regular Fourier features approach can be seen as a quadrature approximation of the same integral. Therefore the regular methods are not *sparse* in spectral sense, but *dense* and deterministic given the domain of interest (Solin and Särkkä, 2014).

The approximation to the original covariance function takes the form of a finite sum

$$k(r) \approx \tilde{k}(r) = \sum_m s(\omega_m) \cos(\omega_m r) \qquad \omega_m = m\Delta, \tag{16}$$

where Δ is a small number which defines the grid spacing. Similarly to Random Fourier features, the resulting approximate Gaussian process can be written as a parametric model:

$$f(x) = \boldsymbol{\phi}(x)^\top \mathbf{w}, \tag{17}$$

$$\mathbf{w} \sim \mathcal{N}(\mathbf{0}, \mathbf{S}) \qquad \mathbf{S} = \operatorname{diag}(s(\omega_1), \ldots, s(\omega_M), s(\omega_1), \ldots, s(\omega_M)). \tag{18}$$

Like in the Random Fourier Features approximation (15), regular Fourier features are independent (the matrix $\mathbf{S}$ is diagonal), and if the inputs are spaced on a regular grid, fast Fourier transform (FFT) methods can speed up the computations to $\mathcal{O}(N \log N)$ (see e.g. Paciorek, 2007; Fritz et al., 2009).

2.3.4 Sparse Gaussian process models

In the above we reviewed how spectral approximations result in parametric models. In their review paper, Quiñonero-Candela and Rasmussen (2005) also presented a view of sparse Gaussian processes where the result is an approximate, parametric model.

The terminology 'sparse' originally referred to methods which restricted computation to a subset of the data points (e.g. Csató and Opper, 2002; Williams and Seeger, 2001), until Snelson and Ghahramani (2005) relaxed this assumption with the idea of pseudo inputs. The pseudo-inputs (or 'inducing points') $\mathbf{Z} = [z_m]_{m=1}^M$ lie in the same domain as $\mathbf{X}$, but with $M < N$. The values of the process associated with these points are denoted $\mathbf{u} = [f(z_m)]_{m=1}^M$. The simplest form of sparse Gaussian process model using these variables is the Deterministic Training Conditional (DTC) model, written

$$f(x) = \mathbf{k}_{\mathbf{u}}(x)^\top \mathbf{K}_{\mathbf{uu}}^{-1} \mathbf{u}, \tag{19}$$

$$\mathbf{u} \sim \mathcal{N}(\mathbf{0}, \mathbf{K}_{\mathbf{uu}}). \tag{20}$$

This kind of 'projected process' approximation has also been discussed by e.g. Banerjee et al. (2008). The literature contains many parametric models that approximate Gaussian process behaviours; for example Bui and Turner (2014) included tree-structures in the approximation for extra scalability, and Moore and Russell (2015) combined local Gaussian processes with Gaussian random fields.

2.4 Variational Gaussian process approximations

We have seen how Fourier approximations and sparse Gaussian processes can be written as approximate parametric models. The variational approximation to Gaussian processes provides a more elegant, flexible and extensible solution in that the *posterior distribution* of the original model is approximated, rather than the model itself. In existing work, the variational approach has been used alongside ideas from the sparse GP literature: the remit of this work is to combine the variational methodology with Fourier based approximations. We provide a short review of the variational methodology here, for a more detailed discussion see Matthews (2016).

In variational Bayes (see e.g. Blei et al., 2016, for a contemporary review) the idea is to approximate the posterior of a model by selecting the optimal distribution from a fixed family. Optimality is usually defined through the Kullback-Leibler divergence

$$\mathrm{KL}[q(f(x)) \,\|\, p(f(x)\,|\,\mathbf{y})] = \mathbb{E}_{q(f(x))}\left[\log q(f(x)) - \log p(f(x)\,|\,\mathbf{y})\right] . \tag{21}$$

This equation is a slight abuse of notation, since it is not legitimate to write $p(f(x))$. Nonetheless, the intuition is good, and our overview has the same result as given by a more technical derivation (Matthews et al., 2016).

2.4.1 The approximating stochastic process

We are tasked with defining a family of variational distributions q. Similarly to the sparse GP models, we introduce a set of pseudo inputs (or 'inducing points') $\mathbf{Z} = [z_m]_{m=1}^M$, which lie in the same domain as $\mathbf{X}$, but with $M < N$. Note that $\mathbf{Z}$ do not form part of the model, but only the variational approximating distribution $q(f(x))$: we may choose them freely, and we assume here that $\mathbf{X}$ and $\mathbf{Z}$ do not intersect. We collect the values of the function at $\mathbf{Z}$ into a vector $\mathbf{u} = [f(z_m)]_{m=1}^M$, and write the process conditioned on these values as

$$f(x)\,|\,\mathbf{u} \sim \mathcal{GP}\left(\mathbf{k_u}(x)^\top \mathbf{K_{uu}^{-1}}\mathbf{u},\; k(x,x') - \mathbf{k_u}(x)^\top \mathbf{K_{uu}^{-1}}\mathbf{k_u}(x')\right) , \tag{22}$$

echoing the true posterior of the process, equation (4). We emphasize that we have *selected* this particular form of distribution for $q(f(x)\,|\,\mathbf{u})$, and the joint approximation for the posterior is $q(\mathbf{u})q(f(x)\,|\,\mathbf{u})$. Whilst most of the flexibility of the approximation comes from $q(\mathbf{u})$, using this form of conditional GP for $q(f(x)\,|\,\mathbf{u})$ means that the approximation cannot be written as a parametric model, and does not suffer the degenerate behaviour associated with the DTC approximation (20).

We must also choose some approximate posterior distribution $q(\mathbf{u})$, whose exact form will depend on the likelihood $p(\mathbf{y}\,|\,f(x))$ as we shall discuss momentarily.

2.4.2 The ELBO

Variational Bayes proceeds by maximizing the Evidence Lower Bound (ELBO), which indirectly *minimizes* the Kullback-Leibler objective. By expanding the true posterior using Bayes' rule, and substituting this into equation (21), we have

$$\begin{aligned}\mathrm{KL}\left[q(f(x)) \,\|\, p(f(x)\,|\,\mathbf{y})\right] &= -\mathbb{E}_{q(f(x))}\left[\log \frac{p(\mathbf{y}\,|\,f(x))\,p(f(x))}{q(f(x))}\right] + \log p(\mathbf{y}) \\ &\triangleq -\mathrm{ELBO} + \log p(\mathbf{y}) .\end{aligned} \tag{23}$$

To obtain a tractable ELBO for Gaussian processes, we factor both prior and approximate posterior processes into conditional GPs, conditioning on: the inducing input points and values $(\mathbf{Z}, \mathbf{u})$; the data pairs $(\mathbf{X}, \mathbf{f})$; the remainder of the process $f(x)$. The prior distribution on the process $p(f(x))$ can be written $p(\mathbf{u})p(\mathbf{f}\,|\,\mathbf{u})p(f\,|\,\mathbf{f},\mathbf{u})$, with

$$\begin{aligned} p(\mathbf{u}) &= \mathcal{N}(\mathbf{0},\, \mathbf{K_{uu}}) \\ p(\mathbf{f}\,|\,\mathbf{u}) &= \mathcal{N}\left(\mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{u},\, \mathbf{K_{ff}} - \mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{K_{fu}^\top}\right) \\ p(f(x)\,|\,\mathbf{f},\mathbf{u}) &= \mathcal{GP}\left(m^\star(x),\, k^\star(x,x')\right) . \end{aligned} \tag{24}$$

where $m^\star(x)$ and $k^\star(x,x')$ are the usual Gaussian process conditional mean and variance, conditioned on both $\mathbf{f}$ and $\mathbf{u}$. The approximate posterior process can be factored similarly:

$$\begin{aligned} q(\mathbf{f}\,|\,\mathbf{u}) &= \mathcal{N}\left(\mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{u},\, \mathbf{K_{ff}} - \mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{K_{fu}^\top}\right) , \\ q(f(x)\,|\,\mathbf{f},\mathbf{u}) &= \mathcal{GP}\left(m^\star(x),\, k^\star(x,x')\right) . \end{aligned} \tag{25}$$

Noting that the two processes are the same, aside for $p(\mathbf{u})$ and $q(\mathbf{u})$, substituting into equation (23) significantly simplifies the ELBO:

$$\mathrm{ELBO} = \mathbb{E}_{q(\mathbf{u})q(\mathbf{f}\,|\,\mathbf{u})}\left[\log p(\mathbf{y}\,|\,\mathbf{f})\right] - \mathbb{E}_{q(\mathbf{u})}\left[\log \frac{q(\mathbf{u})}{p(\mathbf{u})}\right] . \tag{26}$$

2.4.3 The optimal approximation

It is possible to show that the distribution $\hat{q}(\mathbf{u})$ that maximizes the ELBO is given by

$$\log \hat{q}(\mathbf{u}) = \mathbb{E}_{q(\mathbf{f}\,|\,\mathbf{u})}\left[\log p(\mathbf{y}\,|\,\mathbf{f})\right] + \log p(\mathbf{u}) + \textit{const.} \tag{27}$$

This distribution is intractable for general likelihoods, but can be well approximated using MCMC methods. Parameters of the covariance function can be incorporated into the MCMC scheme in a straightforward manner, see Hensman et al. (2015a) for details.

2.4.4 Gaussian approximations

A computationally cheaper method than sampling $\hat{q}(\mathbf{u})$ is to approximate it using a Gaussian distribution, and to optimize the ELBO with respect to the mean and covariance of the approximating distribution, in order to minimize the KL divergence (Hensman et al., 2015b). If the approximating Gaussian distribution $q(\mathbf{u})$ has mean $\mathbf{m}$ and covariance $\mathbf{\Sigma}$, then the entire approximating process is a GP, with

$$\begin{aligned} q(f(x)) &= \int q(\mathbf{u})q(f(x)\,|\,\mathbf{u})\,\mathrm{d}\mathbf{u} \\ &= \mathcal{GP}\left(\mathbf{k_u}(x)^\top \mathbf{K_{uu}^{-1}}\mathbf{m},\; k(x,x') + \mathbf{k_u}(x)^\top(\mathbf{K_{uu}^{-1}}\mathbf{\Sigma}\mathbf{K_{uu}^{-1}} - \mathbf{K_{uu}^{-1}})\mathbf{k_u}(x')\right) . \end{aligned} \tag{28}$$

The covariance function parameters can be estimated by optimization of the ELBO alongside the variational parameters, which leads to approximate maximum likelihood estimation. This may lead to some bias in the estimation of the parameters (Turner and Sahani, 2011), but the method is reported to work well in practice (Chai, 2012; Hensman et al., 2015b; Lloyd et al., 2015; Dezfouli and Bonilla, 2015).

2.4.5 Gaussian likelihood

For the special case where the data-likelihood $p(y_n \,|\, f(x_n))$ is Gaussian with noise-variance σ_n^2, the optimal distribution for q is given by

$$\hat{q}(\mathbf{u}) = \mathcal{N}\left(\hat{\mathbf{m}},\, \hat{\mathbf{\Sigma}}\right), \quad \text{with} \quad \begin{aligned} \hat{\mathbf{\Sigma}} &= [\mathbf{K}_{\mathbf{uu}}^{-1} + \sigma_n^{-2}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{uf}}\mathbf{K}_{\mathbf{uf}}^{\top}\mathbf{K}_{\mathbf{uu}}^{-1}]^{-1}\,, \\ \hat{\mathbf{m}} &= \sigma_n^{-2}\hat{\mathbf{\Sigma}}\mathbf{K}_{\mathbf{uf}}\mathbf{y}\,, \end{aligned} \tag{29}$$

and the ELBO at this optimal point is

$$\text{ELBO}\,(\hat{q}) = \log \mathcal{N}\left(\mathbf{y} \,|\, 0,\, \mathbf{K}_{\mathbf{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{uf}} + \sigma_n^2\mathbf{I}\right) - \tfrac{1}{2}\sigma_n^{-2}\text{tr}\big(\mathbf{K}_{\mathbf{ff}} - \mathbf{K}_{\mathbf{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{uf}}\big)\,. \tag{30}$$

This expression might give the misleading impression that this approximation resembles the DTC method (described by Quiñonero-Candela and Rasmussen, 2005) if one interprets the matrix $\mathbf{K}_{\mathbf{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{uf}}$ as an approximate prior. However, prediction in the variational approximation does not suffer the same degenerate behaviour as DTC (Titsias, 2009; Hensman et al., 2013).

2.4.6 Prediction

Prediction in the variational approximation to Gaussian processes differs from the view given in Quiñonero-Candela and Rasmussen (2005), and it is here that the elegance of the method is apparent. It is not necessary to make any additional approximations at predict-time, since the whole process has already been approximated. For Gaussian posteriors (and Gaussian approximate posteriors), one simply evaluates the GP (equation (28)). For non Gaussian approximations to $q(\mathbf{u})$, one must average the conditional equation (22) under $q(\mathbf{u})$.

2.5 Linking conditioning and decomposition

The sparse-variational methodology that we have presented involved factoring the Gaussian process as $p(f(x)) = p(f(x) \,|\, \mathbf{u})p(\mathbf{u})$. A related and useful concept is decomposition of the process: we will make use of such a decomposition in sebsequent sections to derive Variational Fourier Features.

Let $f(x) \sim \mathcal{GP}\big(0, k(x, x')\big)$. We can decompose f as the sum of two independent Gaussian processes:

$$g(x) \sim \mathcal{GP}\big(0,\, \mathbf{k}_{\mathbf{u}}(x)^{\top}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{k}_{\mathbf{u}}(x')\big)\,, \tag{31}$$

$$h(x) \sim \mathcal{GP}\big(0,\, k(x, x') - \mathbf{k}_{\mathbf{u}}(x)^{\top}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{k}_{\mathbf{u}}(x')\big)\,, \tag{32}$$

$$f(x) = g(x) + h(x). \tag{33}$$

It is clear from the additivity of the covariance functions that this sum recovers the correct covariance for $f(x)$. Note that the covariance of $h(x)$ is the same as for $p(f(x) \,|\, \mathbf{u})$. We say that $g(x)$ is the projection of $f(x)$ onto $\mathbf{u}$, and $h(x)$ is the orthogonal complement of $g(x)$.

Figure 1 shows the decomposition of a Gaussian process using inducing points and also with the Fourier features that we shall derive in this document.

In the variational approximation, the posterior is controlled through the variables $\mathbf{u}$, and the conditional $p(f(x) \,|\, \mathbf{u})$ remains the same in the approximate posterior as in the

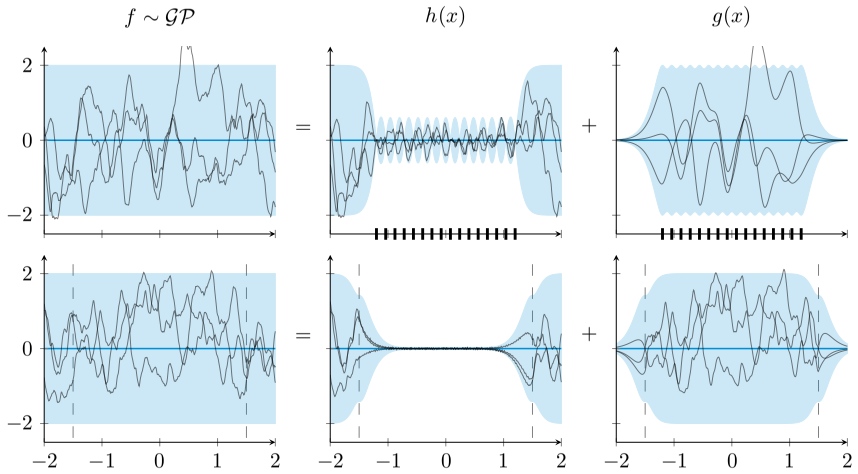

Figure 1: Decomposition of a Gaussian process with a Matérn-$\frac{3}{2}$ covariance function ($\sigma = 1, \ell = 0.2$) using inducing points (top) and Variational Fourier Features (bottom). The shaded region represents two standard deviations, and samples from the processes are shown as black lines. In the top row, the positions of the 16 inducing points are marked in black; on the bottom row 31 frequencies (hence 63 inducing variables) are used and vertical lines denote the boundary of the projection $[a, b]$. Note the variance of $h(x)$ is zero wherever there is an inducing point (top). In the bottom row, the variance is close to zero for a continuous stretch (where the data should live); in this region $h(x)$ contains only high-frequency functions that we have failed to capture with the Fourier features. The variance increases towards the boundaries: since all Fourier basis functions have the same value at a and b, they cannot fit functions with different values in a and b and this is left as a residual. Instead of adding more basis functions, such as a linear one, to account for this, we advocate for choosing an interval $[a, b]$ larger than the data.

prior. In terms of the projection, we see that the process $g(x)$ is completely controlled by the variables $\mathbf{u}$ and the process $h(x)$ is completely independent of $\mathbf{u}$. This is borne out by the independence relations of the processes, formally:

$$g(x) \,|\, \mathbf{u} = \mathcal{GP}\left(\mathbf{k_u}(x)^\top \mathbf{K_{uu}}^{-1}\mathbf{u},\, 0\right), \tag{34}$$

$$h(x) \,|\, \mathbf{u} = h(x)\,. \tag{35}$$

The assumption of the sparse variational framework is that the posterior process can be captured by the random variables $\mathbf{u}$, or equivalently by the process $g(x)$. The power of the framework lies in the fact that the ELBO can be used to evaluate whether the projection is sufficient, and that the orthogonal part $h(x)$ is not discarded but taken into account in the ELBO computation and incorporated fully at predict time. The ELBO encapsulates the degree to which the posterior can be captured by $g(x)$ (or equivalently $\mathbf{u}$).

2.6 Inter-domain approaches

The most common method for efficient approximation of Gaussian processes is based on the idea of inducing variables, denoted $u_m = f(z_m)$ in the above. A powerful idea is to generalize this, allowing a different decomposition of the process by constructing linear combinations of the process values as projections, instead of simple evaluations.

Previous work that has considered inter-domain approaches has suggested that the corresponding features have better ability to represent complicated functions (Figueiras-Vidal and Lázaro-Gredilla, 2009) than the inducing points approach, and have promise for applications in multiple-output settings (Alvarez and Lawrence, 2009).

In inter-domain Gaussian process approximations, the idea is to change

$$u_m = f(z_m) \tag{36}$$

to a projection

$$u_m = \int f(x)\,\mathrm{d}\mu_m(x)\,, \tag{37}$$

so that the variable u_m is more informative about the process, and in turn the projection onto $\mathbf{u}$ is able to capture more information about the posterior.

The utility of the variable u_m depends mostly on its covariance with the remainder of the process, which is encapsulated in the vector-valued function $\mathbf{k_u}(x)$. This vector plays a similar role in the variational method to the feature vector $\boldsymbol{\phi}(x)$ in the Fourier-based approximate models of Sections 2.3.1 and 2.3.2. The remit of this work is to construct inducing variables $\mathbf{u}$ such that $\mathbf{k_u}(x)$ contains sinusoidal functions as is $\boldsymbol{\phi}(x)$, which we will do by using Fourier projections of the process.

The central challenge is that the Fourier transform of the process does not make a valid inducing variable because its variance would be infinite. To make valid and useful inducing variables, Matthews et al. (2016) have shown that the inducing variables u_m must be "deterministic, conditioned on the whole latent function". In the following section, we construct valid inducing variables and examine their properties.

3. Variational Fourier Features

Our goal is to combine the variational sparse GP idea with Fourier features, so that the approximating process in (22) contains a mean function which is built from sinusoids, like the $\boldsymbol{\phi}(x)$ features in the Fourier-features approximate model (15).

This is more tricky than it first appears. An initial idea would be to define u_m as the Fourier transform of the process, so that $\mathbf{k_u}(x) = \mathrm{cov}(\mathbf{u}, x) \propto \boldsymbol{\phi}(x)$. The question is, what would the $\mathbf{K_{uu}}$ matrix be? One might hope for a diagonal matrix related to the spectral content of the kernel $s(\omega)$, but as we discuss in Section 3.1, the Fourier transform of a stationary GP has diverging variance, i.e. this matrix is not defined.

To proceed, we need to make two alterations to the initial idea, which we outline in Sections 3.2 and 3.3. First we must window the domain, in order to obtain variables with finite variance (Section 3.2). Second, since these variables do not have an elegant form, we switch from an L^2 integral to one under the RKHS norm (Section 3.3). Subsequently, we show that our approach has covariance structures that make for efficient computations (Section 3.4), and conclude this section by explaining the behaviour of our approximation outside the windowing box (Section 3.5).

3.1 The trouble with Fourier features

In the variational sparse GP (Section 2.4) we made use of the random variables $u_m = f(z_m)$. To obtain a Fourier-based approximation, we might consider the inter-domain variables $u_m = \int_{-\infty}^{\infty} f(t)e^{-i\omega_m t}\,\mathrm{d}t$. It is straightforward to show that such variables have zero mean and infinite variance, and so will not be useful in the variational framework; nonetheless the properties of the variables are interesting as we now demonstrate.

In order to use u_m as an inducing variable, we would require both $\mathrm{cov}(u_m, f(x))$ and $\mathrm{cov}(u_m, u_{m'})$ which make up the entries in $\mathbf{k_u}(x)$ and $\mathbf{K_{uu}}$ respectively. If f is drawn from a GP with zero mean and covariance $k(x, x')$, then formally we may write

$$\mathrm{cov}(u_m, f(x)) = \mathbb{E}\left[u_m f(x)\right] = \int_{-\infty}^{\infty} \mathbb{E}[f(t)f(x)]e^{-i\omega_m t}\,\mathrm{d}t = \int_{-\infty}^{\infty} k(t,x)e^{-i\omega_m t}\,\mathrm{d}t\,. \tag{38}$$

To solve this integral, we can first plug in the definition of the kernel function in terms of the spectrum (7), and then change the order of integration, giving

$$\mathrm{cov}(u_m, f(x)) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} s(\omega)e^{i\omega(t-x)}\,\mathrm{d}\omega\, e^{-i\omega_m t}\,\mathrm{d}t = s(\omega_m)e^{-i\omega_m x}\,. \tag{39}$$

This initially appears promising: the covariance function is a sinusoid rescaled by the relevant spectrum and the elements of $\mathbf{k_u}(x)$ have the desired form. The corresponding elements of $\mathbf{K_{uu}}$ are given by the (co)variance of u_m. It is here that problems arise. Denoting the complex conjugate of u_m as $\bar{u}_m$,

$$\mathrm{cov}(u_m, u_{m'}) = \mathbb{E}\left[u_m \bar{u}_{m'}\right] = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} k(t,t')e^{-i\omega_m t}\,\mathrm{d}t\, e^{i\omega_{m'}t'}\,\mathrm{d}t' = s(\omega_m)\delta(\omega_m - \omega_{m'})\,, \tag{40}$$

where $\delta(\cdot)$ is Dirac's delta. This implies that the matrix $\mathbf{K_{uu}}$ is diagonal, but with undefined entries on the diagonal. This result shows that it is simply not possible to use the Fourier transform of the whole GP as a valid inducing variable.

One approach to address this issue might be to take a power-averaged Fourier transform of the form

$$u_m = \lim_{a\to\infty} \frac{1}{a}\int_{-a/2}^{a/2} f(t)e^{-i\omega_m t}\,\mathrm{d}t\,. \tag{41}$$

Unfortunately, this still does not yield useful features, because the variables $\mathbf{u}_m$ are now independent of the function at any particular value. Writing formally:

$$\mathrm{cov}(u_m, f(x)) = \mathbb{E}[u_m f(x)] = \lim_{a\to\infty} \frac{1}{a}\int_{-a/2}^{a/2} k(x,t)e^{-i\omega_m r}\,\mathrm{d}t = 0\,. \tag{42}$$

As recognised by Figueiras-Vidal and Lázaro-Gredilla (2009), the only way to obtain valid features is to specify an input density (cf. Williams and Seeger, 2000). We proceed by considering a uniform input density on the interval $[a, b]$.

3.2 L_2 Fourier features on $[a, b]$

The reason that the Fourier transform of a GP behaves so strangely is that it must explain the behaviour over the whole real line. One might interpret the Fourier transform at a particular frequency as a sum of all the random variables in the GP (i.e. integrating over the real line) multiplied by a sinusoidal weight. The result is a Gaussian random variable, but unless the weight decays to zero at infinity, the result has infinite variance.

Our solution to this diverging integral is to window the integral. Figueiras-Vidal and Lázaro-Gredilla (2009) also use a window to ensure convergence of the integral, but their choice of a Gaussian windowing function means that the result is tractable only for Gaussian (squared exponential) covariance functions, and does not admit a diagonal form for $\mathbf{K_{uu}}$.

We will apply a square window, effectively changing the integration limits to a and b:

$$u_m = \int_a^b f(t)e^{-i\omega_m(t-a)}\,\mathrm{d}t\,. \tag{43}$$

In addition, we will assume that the frequency ω_m is harmonic on the interval $[a, b]$; that is

$$\omega_m = \frac{2\pi m}{b-a}\,. \tag{44}$$

For $x \in [a, b]$, the covariance between such inducing variables and the GP at x is

$$\mathrm{cov}(u_m, f(x)) = \mathbb{E}\left[u_m f(x)\right] = \int_a^b \mathbb{E}[f(t)f(x)]e^{-i\omega_m(t-a)}\,\mathrm{d}t = \int_a^b k(t,x)e^{-i\omega_m(t-a)}\,\mathrm{d}t\,. \tag{45}$$

These integrals are tractable for Matérn kernels. As detailed in Appendix A, we obtain the following results for Matérn-$\frac{1}{2}$ kernels:

$$\mathrm{cov}(u_m, f(x)) = s_{1/2}(\omega_m)e^{i\omega_m(x-a)} + s_{1/2}(\omega_m)\frac{1}{2\lambda}\left(\lambda[-e^{a-x} - e^{x-b}] + i\omega_m[e^{a-x} - e^{x-b}]\right)\,. \tag{46}$$

Similarly, the covariance between two inducing variables also has a closed form expression. A complete derivation is given in Appendix A for the Matérn-$\frac{1}{2}$ case. These inter-domain inducing variables have two desirable properties: they have finite variance and their associated covariance matrix $\mathbf{K_{uu}}$ can be written as a diagonal matrix plus some rank one matrices (two in the Matérn-$\frac{1}{2}$ case).

Figure 2 illustrates entries of the feature vector $\mathbf{k_u}(x) = \mathrm{cov}(u_m, f(x))$, and compares them to the RKHS features that we shall derive in the next section. We see from the Figure that the covariance function $\mathrm{cov}(u_m, f(x))$ is almost sinusoidal in x for a region sufficiently far from the boundaries a and b. The 'edge effects' depend on the involved frequency as well as the lengthscale parameter of the kernel.

We have constructed inducing variables that are valid (in the sense that they have finite variance), but the result is somewhat inelegant: the expressions for $\mathrm{cov}(u_m, f(x)$ and $\mathrm{cov}(u_m, u_{m'})$ are long for the Matérn-$\frac{1}{2}$ kernel and become trickier (but still tractable) for higher orders. We abandon them at this stage in preference of the RKHS-based inducing variables that we derive in the next section. These have preferable edge effects and an elegant expressions for the required covariances.

3.3 RKHS Fourier features on $[a, b]$

In the previous section we saw that choosing inducing variables of the form $u_i = \langle f, \cos(\omega(xa)\rangle_{L^2}$ or $u_i = \langle f, \sin(\omega(xa)\rangle_{L^2}$ resulted in features that are very distinct from cosine and sine functions. In this section, we replace the L^2 inner product by the RKHS inner product $u_i = \langle f, \cos(\omega(xa)\rangle_{\mathcal{H}}$ in order to guarantee that the features are exactly the sine and cosine functions. As we will discuss later, a direct asset of this approach is that the simple expression of the features makes the computation of the covariances between inducing variables much easier.

We start with a truncated Fourier basis defined similarly to (12)

$$\boldsymbol{\phi}(x) = [1, \cos(\omega_1(x-a)), \ldots, \cos(\omega_M(x-a)), \sin(\omega_1(x-a)), \ldots, \sin(\omega_M(x-a))]^\top\,, \tag{47}$$

where we include the constant basis function, $\phi_0(x) = 1$, accounting for $\omega_m = 0$, and define $\omega_m = \frac{2\pi m}{b-a}$ as previously.

A key RKHS result (see Berlinet and Thomas-Agnan, 2004, Theorem 11), is that if $\mathcal{F} = \mathrm{span}(\boldsymbol{\phi})$ is a subspace of a RKHS $\mathcal{H}$, then $\mathcal{F}$ has the kernel

$$k_{\mathcal{F}}(x, x') = \boldsymbol{\phi}(x)^\top \mathbf{K}_{\phi\phi}^{-1}\boldsymbol{\phi}(x')\,, \tag{48}$$

where $\mathbf{K}_{\phi\phi}[m, m'] = \langle \phi_m, \phi_{m'}\rangle_{\mathcal{H}}$ is the Gram matrix of $\boldsymbol{\phi}$ in $\mathcal{H}$. By this, we mean that for any function $f \in \mathcal{F}$, $\langle f, k_{\mathcal{F}}(\cdot, x)\rangle_{\mathcal{H}} = f(x)$. Furthermore, the coordinate of the projection of a function $h \in \mathcal{H}$ onto ϕ_m is defined as

$$\mathcal{P}_{\phi_m}(h) = \langle h, \phi_m\rangle_{\mathcal{H}}\,. \tag{49}$$

Since $\mathcal{F} \subset \mathcal{H}$, $k(x, x') - k_{\mathcal{F}}(x, x')$ is a positive definite function corresponding to the kernel of $\mathcal{F}^\perp$, and we can decompose the GP in a similar way to (33) which gives

$$g(x) \sim \mathcal{GP}(0,\, \boldsymbol{\phi}(x)^\top \mathbf{K}_{\phi\phi}^{-1}\boldsymbol{\phi}(x'))\,, \tag{50}$$

$$h(x) \sim \mathcal{GP}(0,\, k(x, x') - \boldsymbol{\phi}(x)^\top \mathbf{K}_{\phi\phi}^{-1}\boldsymbol{\phi}(x'))\,, \tag{51}$$

$$f(x) = g(x) + h(x)\,. \tag{52}$$

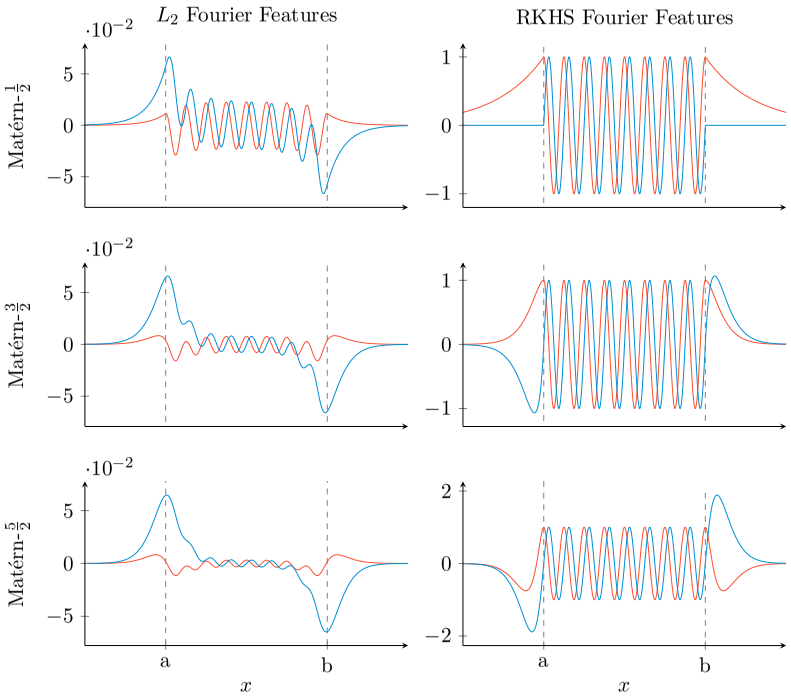

Figure 2: The covariance $\mathrm{cov}(u_m, f(x))$ as a function of x for the Matérn-$\frac{1}{2}$ (top), Matérn-$\frac{3}{2}$ (middle) and Matérn-$\frac{5}{2}$ (bottom) kernels, using L_2 Fourier features (left column) and RKHS Fourier features (right column). The red and blue lines represent the real and imaginary parts of the covariance. The boundaries of the projection $[a, b]$ are marked by vertical dashed lines. The L_2 features are wiggly with overwhelming edge effects, whereas the RKHS features are exactly sinusoids for $x \in [a, b]$. Beyond the boundaries, the covariance reverts to zero in a way which depends on the smoothness of the kernel and the lengthscale parameter. We have used $\omega_m = 16\pi/(b-a)$, and a lengthscale of $\ell = (b-a)/10$.

For this to be valid we need two things: $\mathcal{F}$ must be included in $\mathcal{H}$ and the matrix $\mathbf{K}_{\phi\phi}$ must be invertible. The first is not true in general (Matérn RKHS over $\mathbb{R}$ or the RBF and Brownian RKHS on $[0, 1]$ are counter examples) but has been proved to be true for Matérn kernels over $[a, b]$ (Durrande et al., 2016). The second is a direct conclusion of the linear independence between the elements of $\boldsymbol{\phi}$. Furthermore, Durrande et al. (2016) also detail the closed-form expressions of the inner products for the Matérn-$\frac{1}{2}$, Matérn-$\frac{3}{2}$ and Matérn-$\frac{5}{2}$ RKHSs. These expressions, which are repeated in Appendix B, are of particular interest here since they allow us to compute the entries of the $\mathbf{K}_{\phi\phi}$ matrix. Although we refer to the above reference for the constructive proof of these expressions, it is easy to check that the reproducing property is satisfied. For example, the expression given in the appendix for a Matérn-$\frac{1}{2}$ RKHS over $[a, b]$ is

$$\langle g, h\rangle_{\mathcal{H}_{1/2}} = \frac{1}{2\lambda\sigma^2}\int_a^b \big(\lambda g(t) + g'(t)\big)\big(\lambda h(t) + h'(t)\big)\,\mathrm{d}t + \frac{1}{\sigma^2} g(a)\,h(a)\,, \tag{53}$$

so we can write for any function g that is continuous and (weakly) differentiable

$$\left\langle g, k_{\frac{1}{2}}(x,\cdot)\right\rangle_{\mathcal{H}_{1/2}} = \frac{1}{2\lambda\sigma^2}\left(\int_a^x \big(\lambda g(t) + g'(t)\big)\,2\lambda\sigma^2 e^{\lambda(t-x)}\,\mathrm{d}t + \int_x^b 0\,\mathrm{d}t\right) + g(a)e^{\lambda(a-x)} \tag{54}$$

$$= \int_a^x \lambda g(t) e^{\lambda(t-x)}\,\mathrm{d}t + \Big[g(t)e^{\lambda(t-x)}\Big]_a^x - \int_a^x g(t)\lambda e^{\lambda(t-x)}\,\mathrm{d}t + g(a)e^{\lambda(a-x)} \tag{55}$$

$$= g(x) - g(a)e^{\lambda(a-x)} + g(a)e^{\lambda(a-x)} \tag{56}$$

$$= g(x)\,. \tag{57}$$

Another property of this inner product is that the Gram matrix $\mathbf{K}_{\phi\phi}$ has a particular structure which allows to reduce drastically the computational burden of computing and inverting $\mathbf{K}_{\phi\phi}$. This will be addressed in Section 3.4.

3.3.1 The corresponding random variables

To interpret these results from a Gaussian process point of view, we need to find the inducing variables $\mathbf{u}$ that would lead to the exact same decomposition.

We would like to use the RKHS inner product between the sinusoids and the GP sample path in place of the L_2 inner product (43), but since GP samples do not belong the RKHS (Driscoll, 1973), it is a priori not possible to apply $\mathcal{P}_{\phi_m}$ to f and define $u_m = \langle \phi_m, f\rangle_{\mathcal{H}}$. For example, the Matérn-$\frac{1}{2}$ inner product involves derivatives whereas the Matérn-$\frac{1}{2}$ samples are not differentiable anywhere. However, using the fact that the functions from $\boldsymbol{\phi}$ are very regular, it is possible to extend the operators $\mathcal{P}_{\phi_m} : h \mapsto \langle \phi_m, h\rangle_{\mathcal{H}}$ to square integrable functions using integration by parts. For the Matérn-$\frac{1}{2}$ kernel, integrating (53) results in

$$\mathcal{P}_{\phi_m}(h) = \frac{1}{2\lambda\sigma^2}\left(\int_a^b h(\lambda^2\phi_m - \phi_m'')\,\mathrm{d}t + h(b)\big(\lambda\phi_m(b) + \phi_m'(b)\big) + h(a)\big(\lambda\phi_m(a) - \phi_m'(a)\big)\right). \tag{58}$$

Note that the function h does not need to be differentiated, and so it is possible to apply this functional to a sample from the GP. Similar results apply for the Matérn-$\frac{3}{2}$ and Matérn-$\frac{5}{2}$ kernels. It is now possible to apply these operators to the Gaussian process in order to construct the inducing variables,

$$u_m = \mathcal{P}_{\phi_m}(f)\,. \tag{59}$$

The covariance of the inducing variables with the function values is given by

$$\mathrm{cov}(u_m, f(x)) = \mathbb{E}[u_m f(x)] = \mathbb{E}[\mathcal{P}_{\phi_m}(f) f(x)] = \mathcal{P}_{\phi_m}\left(k(x,\cdot)\right) = \phi_m(x) \tag{60}$$

which is valid for $a \leq x \leq b$. This means that $\mathbf{k_u}(x) = \boldsymbol{\phi}(x)$ when $x \in [a,b]$. Similarly the covariance of the features is given by

$$\mathrm{cov}(u_m, u_{m'}) = \mathbb{E}[u_m u_{m'}] = \mathbb{E}[\mathcal{P}_{\phi_m}(f)\mathcal{P}_{\phi_{m'}}(f)] = \mathcal{P}_{\phi_m}(\phi_{m'}) = \langle \phi_m, \phi_{m'} \rangle_{\mathcal{H}}\,, \tag{61}$$

and so we have $\mathbf{K_{uu}} = \mathbf{K}_{\phi\phi}$.

3.4 Covariance structures for RKHS Fourier features

To compute the covariance matrix $\mathbf{K_{uu}}$, we return again to the closed-form expressions for the inner product provided by Durrande et al. (2016), substituting the basis functions ϕ_m and $\phi_{m'}$ appropriately. The solutions are tractable, and we detail in the appendix the expressions of $\mathbf{K_{uu}}$ for the first three half-integer Matérn kernels. One striking property of the resulting $\mathbf{K_{uu}}$ is that they can be written as a diagonal matrix plus a few rank one matrices. For example in the Matérn-$\frac{1}{2}$ case we find that $\mathbf{K_{uu}}$ is equal to a diagonal matrix plus a rank one matrix,

$$\mathbf{K_{uu}} = \mathrm{diag}(\boldsymbol{\alpha}) + \boldsymbol{\beta}\boldsymbol{\beta}^\top\,, \tag{62}$$

with

$$\boldsymbol{\alpha} = \frac{b-a}{2}\left[2s(0)^{-1}, s(\omega_1)^{-1}, \ldots, s(\omega_M)^{-1}, s(\omega_1)^{-1}, \ldots, s(\omega_M)^{-1}\right]^\top, \tag{63}$$

$$\boldsymbol{\beta} = \left[\sigma^{-1}\ , \sigma^{-1}\ , \ldots, \sigma^{-1}\ , 0\ , \ldots, 0\ \right]^\top. \tag{64}$$

As shown in the appendix, $\mathbf{K_{uu}}$ still has a similar structure for higher order Matérn kernels: in the Matérn-$\frac{3}{2}$ case, it is the sum of a diagonal matrix and two rank one matrices and in the Matérn-$\frac{5}{2}$ case, it is the sum of a diagonal matrix and three rank one matrices.

Since $\mathbf{K_{uu}}$ has a low-rank plus diagonal form, one of the usual computational bottlenecks in the variational framework, solving $\mathbf{K_{uu}^{-1}K_{uf}}$, can be done in $\mathcal{O}(NM)$ operations, rather than the standard $\mathcal{O}(NM^2)$, by a straightforward application of the Woodbury matrix identity.

This low-rank plus diagonal structure was not published previously in Durrande et al. (2016); we believe that we are the first to make use of this result for computational efficiency and we expect it to provide similar superior computational benefits as the pure diagonal structure in Solin and Särkkä (2014).

$\phi_m(x)$, $x \in [a,b]$	Matérn-$\frac{1}{2}$	Matérn-$\frac{3}{2}$	Matérn-$\frac{5}{2}$
$\cos(\omega_m(x-a))$	$e^{-\lambda r}$	$(1+\lambda r)e^{-\lambda r}$	$(1+\lambda r+\frac{1}{2}(\lambda^2-\omega_m^2)r^2)e^{-\lambda r}$
$\sin(\omega_m(x-a))$	0	$sr\omega_m e^{-\lambda r}$	$sr\omega_m(1+\lambda r)e^{-\lambda r}$

Table 1: The covariance $\mathrm{cov}(u_m, f(x))$ for x outside the interval $[a,b]$. Here, we define r as the absolute distance to the closest edge (a or b), and s to be 1 for $x < a$ and -1 for $x > b$.

3.5 Predicting outside the interval $[a,b]$

In the preceding sections, we have defined our inducing variables and how they covary with the function; we have assumed throughout that we wish to examine a point on the latent function in the pre-defined interval $[a,b]$. This does not pose a problem at training time, since we can easily define $[a,b]$ to contain all the data. For prediction we may need to predict outside this interval. For a point on the function $f(x)$ outside the interval $[a,b]$, the covariance with the inducing variables is still well defined, though the form is slightly more complicated than the simple sinusoids inside the interval.

To obtain the expressions for the covariance beyond $[a,b]$, we apply the closed-form expression for the covariance (58), this time for $\mathrm{cov}(u_m, f(x)) = \mathrm{cov}(\mathcal{P}_{\phi_m}(f), f(x))$ with $x > b$ and $x < a$. After some fairly elementary simplifications, the results are shown in Table 1, and illustrated in Figure 2. The result is that the covariance function $\mathrm{cov}(u_m, f(x))$ returns to zero beyond the boundary, with smoothness that depends on the order of the kernel.

4. Extending the applicable kernel family

In the above we have focused on the Matérn family of kernels in one dimension. In this section we will expand the approach to higher-dimensional inputs using sums and products of kernels.

4.1 Additive kernels

A straightforward way to produce a Gaussian process prior on multiple inputs (say D) is to use a sum of independent Gaussian processes, one for each input:

$$f(\mathbf{x}) = \sum_{d=1}^{D} f_d(x_d)\,, \qquad f_d \sim \mathcal{GP}\left(0,\, k_d(x_d, x_d')\right)\,, \tag{65}$$

where x_d is the dth element in $\mathbf{x}$ and $k_d(\cdot,\cdot)$ is a kernel defined on a scalar input space. This construction leads to a Gaussian process with an additive kernel, that is we can write

$$f(\mathbf{x}) \sim \mathcal{GP}\left(0,\, \sum_{d=1}^{D} k_d(x_d, x_d')\right)\,. \tag{66}$$

Additive kernel structures have been explored by Durrande et al. (2012) and Duvenaud et al. (2011), who have shown that these kernels are well suited to high-dimensional problems. To use our Variational Fourier Features approach with an additive kernel, we assume that each function $f_d(x_d)$ has a Matérn covariance function, and decompose each of these GPs. We construct a matrix of features, with elements

$$u_{m,d} = \mathcal{P}_{\phi_m}(f_d)\,. \tag{67}$$

The result is that we have DM features. By construction, we see that features from different GPs are independent, $\mathrm{cov}(u_{m,d}, u_{m,d'}) = 0$, and that the covariance between features for the same dimension follows the construction for a single dimension. It is straightforward to exploit these independence structures for computational scalability during inference.

4.2 Separable kernels

A kernel is said to be separable if it can be written as a product of kernels with no shared inputs. This means that for any D-dimensional input $\mathbf{x}$, we can write

$$k(\mathbf{x}, \mathbf{x}') = \prod_{d=1}^{D} k_d(x_d, x_d')\,. \tag{68}$$

We can construct Variational Fourier Features for such a product kernel if each sub-kernel is in the Matérn family.

This formulation of separability has been extensively used in speeding up GP inference (see, e.g., Saatçi, 2012; Stegle et al., 2011) by writing the covariance matrix as a Kronecker product of the individual covariance matrices. These speed-ups usually require the data to be aligned with a regular or rectilinear grids (see, e.g., Solin et al., 2016), though some approaches exist to extend to observations beyond the grid (Wilson et al., 2014; Nickson et al., 2015), requiring additional approximations.

In contrast, our approach of decomposing the kernel naturally leads to a Kronecker structure, even for irregularly spaced data. Let $f(x) \sim \mathcal{GP}\left(0, \prod_d k_d(x_d, x_d')\right)$, and define a vector of features as the Kronecker product of features over each dimension,

$$\boldsymbol{\phi}(\mathbf{x}) = \bigotimes_{d=1}^{D} \left[\phi_1(x_d), \ldots, \phi_M(x_d)\right]^\top\,, \tag{69}$$

so that each of the M^D elements of $\boldsymbol{\phi}(\mathbf{x})$ is a product of one-dimensional functions $\prod_d \phi_i^{(d)}(x_d)$. We define a hyper-rectangular boundary given by $\prod_d [a_d, b_d]$, and define the inducing variables $\mathbf{u}$ using a projection similar to the one-dimensional case

$$u_m = \mathcal{P}_{\phi_m}(f)\,, \tag{70}$$

where we use the norm of the Hilbert space associated with the product kernel. The covariance between an inducing point u_m and the function is then given by

$$\mathrm{cov}(u_m, f(\mathbf{x})) = \mathbb{E}[\mathcal{P}_{\phi_m}(f) f(x)] = \mathcal{P}_{\phi_m}(k(\mathbf{x}, \cdot)) = \prod_{d=1}^{D} \phi_m^{(d)}(x_d) = \boldsymbol{\phi}_m(\mathbf{x})\,. \tag{71}$$

Extending the covariance function beyond the boundary follows similarly to the one-dimensional case above. The covariance between inducing variables is given by

$$\mathrm{cov}(u_m, u_m') = \prod_d \left\langle \phi_m^{(d)}, \phi_{m'}^{(d)} \right\rangle_{\mathcal{H}_d}\,. \tag{72}$$

This means that the covariance matrix $\mathbf{K_{uu}}$ has a Kronecker structure, $\mathbf{K_{uu}} = \bigotimes_{d=1}^{D} \mathbf{K}_{\mathbf{uu}}^{(d)}$, where each sub-matrix $\mathbf{K}_{\mathbf{uu}}^{(d)}$ has the same structure as for the one-dimensional case (62).

5. Implementation details and computational complexity

In this section we give some details of our implementation of the methods proposed, and consider the theoretical computational complexity of each. To make use of the RKHS Fourier features that we have derived, the expressions given for $\mathbf{K_{uu}}$ and $\mathbf{k_u}(x)$ can simply be plugged in to the variational framework described in Section 2.4.

5.1 Implementation

All of the methods in this paper and all of the code to replicate the experiments in Section 6 are available at `http://github.com/jameshensman/VFF`. We made use of TensorFlow (Abadi et al., 2015) and GPflow (Matthews et al., 2017) to construct model classes in Python. Some simple matrix classes in Python assisted with computing efficient solutions to low-rank matrix problems (e.g. solving $\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}$). Using TensorFlow's automatic differentiation made application of gradient based optimization straightforward.

5.2 The one-dimensional case

Consider first problems with only one input dimension. The sparse variational framework discussed in Section 2.4 gives three methods: if the likelihood is Gaussian, then it is possible to compute the optimal posterior in closed form (as per Titsias, 2009), if the likelihood is not Gaussian we can approximate the posterior with a Gaussian or use MCMC on the optimal distribution.

For the Gaussian case, we see that the computation of the optimal posterior (equation (29)) is dominated by the matrix multiplication $\mathbf{K_{uf}}\mathbf{K_{fu}}$, which costs $\mathcal{O}(NM^2)$ operations. In our case, since $\mathbf{K_{fu}}$ does not depend on the kernel parameters, this multiplication only needs to be computed once before optimizing (or sampling) the covariance function parameters. To compute the posterior mean and covariance, we must invert an $M \times M$ matrix, so the cost per iteration is $\mathcal{O}(M^3)$, after the initial cost of $\mathcal{O}(NM^2)$.

For the non-Gaussian case with a Gaussian approximation we must compute the marginals of $q(\mathbf{f})$, in order to evaluate the ELBO (equation (26)) for optimization. We parameterize the Gaussian covariance using a lower-triangular matrix $\mathbf{L}$, so $\boldsymbol{\Sigma} = \mathbf{L}\mathbf{L}^\top$, and the computational cost is dominated by the matrix multiplication $\mathbf{K_{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{L}$. Even though the matrix $\mathbf{K_{uu}}$ has computationally-convenient structure, we cannot avoid a dense matrix multiplication in this case. It may be possible that by assuming some structure for the approximate covariance, computation could be reduced, but we leave investigation of that line for future research.

We note however that the Gaussian approximation does lend itself to stochastic optimization, where the data are randomly sub-sampled (Hensman et al., 2013). In this case the computational complexity is $\mathcal{O}(\tilde{N}M^2)$, where $\tilde{N}$ is the size of the minibatch.

For the MCMC approach, evaluating the unnormalised distribution (27) and its derivative costs $\mathcal{O}(NM)$ per iteration, since again the cost is dominated by the computation of the marginals of $q(\mathbf{f}\,|\,\mathbf{u})$, which requires only the product $\mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}$, and the low-rank structure of $\mathbf{K_{uu}}$ enables this to be computed efficiently.

5.3 The additive case

If we consider the kernel to be a sum of kernels over D input dimensions (Section 4.1), then we again have access to the three methods provided by the sparse GP framework. In this case, the number of inducing variables is $2MD+1$, since we have M frequencies per dimension, with sine and cosine terms.

For the method with a Gaussian likelihood, the cost is $\mathcal{O}(D^3M^3)$ per iteration, with an initial cost of $\mathcal{O}(NM^2D^2)$, following the arguments above. When the likelihood is non-Gaussian, with a Gaussian approximation to the posterior, the cost is $\mathcal{O}(NM^2D^2)$. However, if we assume that the posterior factorizes over the dimensions, then the cost can be reduced to $\mathcal{O}(NM^2D)$ (Adam et al., 2016).

For an MCMC approach, the cost is again dominated by the computation of $\mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}$, which must be done once for each dimension and so the cost is $\mathcal{O}(NMD)$. We note that these operations can be effectively distributed on multiple machines (in our implementation this can be done by TensorFlow), since $\mathbf{K_{uu}}$ is a block-diagonal matrix.

5.4 The Kronecker case

If we use a separable kernel made from a product of kernels over the D dimensions as discussed in Section 4.2, then the number of inducing variables grows exponentially with the input dimension to $(2M)^D$. This gives the potential for a very detailed representation, with many basis functions, and the Kronecker structure can be exploited for efficiency in some cases. However, this approximation will be unsuitable for large D.

For the case with Gaussian noise, it is not straightforward to avoid computing the inverse of the $M^D \times M^D$ matrix, and so the cost is $\mathcal{O}(M^{3D})$. It may be possible, however, that some efficient methods for solving linear systems might be applicable (e.g. Filippone and Engler, 2015), though we leave that avenue for future work.

For the case with a Gaussian approximation to $q(\mathbf{u})$, we can exploit the Kronecker structure of the model. We note the relationship to the work of Nickson et al. (2015), which used the inducing-point approach, with the points confined to a regular lattice. In their work, the covariance structure of the approximation was constrained to also have a Kronecker structure, which appeared to work well in the cases considered. However, our experiments suggest (Section 6.3) that this approximation may not be sufficient in all cases. Our proposal is to use a sum of two Kronecker structured matrices:

$$q(\mathbf{u}) = \mathcal{N}(\mathbf{m}, \mathbf{S}), \qquad \text{where } \mathbf{S} = \bigotimes_{d=1}^{D} \mathbf{L}_d\mathbf{L}_d^\top + \bigotimes_{d=1}^{D} \mathbf{J}_d\mathbf{J}_d^\top. \tag{73}$$

Noting that we can compute the determinant of such a matrix structure in $\mathcal{O}(DM^3)$ (see e.g. Rakitsch et al., 2013), the computational cost of the method is then dominated by the cost of computing the mean and marginal variances of $q(\mathbf{f})$. For the mean, we first compute $\mathbf{K_{uu}^{-1}}\mathbf{m}$ which costs $\mathcal{O}(M^D)$ (making use of the low-rank structure of $\mathbf{K_{uu}}$), and then $\mathbf{K_{fu}}(\mathbf{K_{uu}^{-1}}\mathbf{m})$, which costs $\mathcal{O}(NM^D)$. In computing the marginal variances of $q(\mathbf{f})$, the additive structure of $\mathbf{S}$ poses no problem, and the Kronecker structures mean that $\mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{S}$ can be computed in $\mathcal{O}(NM^{2D})$. Again, it is possible to make use of stochastic optimization to reduce the cost per iteration.

In the MCMC case, the cost is once again dominated by computing the marginals of $q(\mathbf{f}\,|\,\mathbf{u})$, which costs $\mathcal{O}(NM^D)$.

5.5 Centring of variables for MCMC

For an effective MCMC scheme, it is necessary to re-centre the variables $\mathbf{u}$ using a square-root of $\mathbf{K_{uu}}$ (Christensen et al., 2006; Vanhatalo and Vehtari, 2007; Murray and Adams, 2010; Filippone et al., 2013; Hensman et al., 2015a) such that

$$\mathbf{v} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}), \tag{74}$$

$$\mathbf{u} = \mathbf{K_{uu}^{1/2}}\mathbf{v}, \tag{75}$$

which gives $\mathbf{u} \sim \mathcal{N}(\mathbf{0}, \mathbf{K_{uu}})$. For dense $\mathbf{K_{uu}}$ matrices, the square root $\mathbf{K_{uu}^{1/2}}$ is often chosen to be the Cholesky factor, but the structured $\mathbf{K_{uu}}$ described above has a more convenient square root, given by concatenating the two parts into

$$\mathbf{R} = \left[\mathrm{diag}(\boldsymbol{\alpha})^{\frac{1}{2}}, \boldsymbol{\beta}\right] \tag{76}$$

so that $\mathbf{R}\mathbf{R}^\top = \mathrm{diag}(\boldsymbol{\alpha}) + \boldsymbol{\beta}\boldsymbol{\beta}^\top = \mathbf{K_{uu}}$. Since $\mathbf{R}$ has an extra column (or two or three extra columns for Matérn-$\frac{3}{2}$ and Matérn-$\frac{5}{2}$ respectively) we require an extra variable(s) in the vector $\mathbf{v}$.

6. Experiments

This Section provides empirical evidence and examples of how the Variational Fourier Features method works in practice. We first cover some illustrative toy examples, which underline the accuracy of the approximation and the influence of the approximation parameters. After this we address three standard test examples for GP regression (for high- and low-dimensional inputs) and classification, where we show the method provides accurate predictions, and does so extremely fast. Finally, we examine how the approximation approaches the posterior in the MCMC case by examining a simple log Gaussian Cox process data set.

6.1 Illustrative examples

Our Variational Fourier Features (VFF) method has two tuning parameters which affect the approximation: the number of Fourier features M, and the choice of the bounds a and b. In this Section the effects related to tuning these parameters are demonstrated.

6.1.1 Regression

To perform GP regression with Variational Fourier Features, one simply takes the expressions given for standard GP approximations (equations (28) and (29)) and substitutes $\mathbf{K_{uu}}$, $\mathbf{K_{uf}}$ and $\mathbf{k_u}(x)$ appropriately. Figure 3 compares the VFF approximation with Random Fourier Features on a trivial but illuminating regression experiment.

We started by fitting a 'full' GP model (i.e. with inversion of the dense covariance matrix), maximising the likelihood with respect to the kernel's variance parameter, lengthscale parameter and the noise variance. We then used these fitted values to compare variational and Random Fourier Features.

The Random Fourier Features method has some attractive convergence properties (Rahimi and Recht, 2008), as well as being simple to implement. Here we show empirically that the VFF method approaches the true posterior much faster, in terms of the number of basis functions used.

This experiment uses a Matérn-$\frac{1}{2}$ kernel. The corresponding spectral density is proportional to a Cauchy distribution, which has heavy tails. The frequencies in Random Fourier Features are drawn from this heavy-tailed distribution. We see from Figure 3 that this leads to a poor Monte Carlo estimate of equation (7). With 20 random features, the fit of the model is poor, whilst with 20 variational features, the approximation is qualitatively better. With 100 features, the random features approach still cannot replicate the full GP, whilst the variational method is already exact since the ELBO is tight to the likelihood to within numerical precision. Even with 500 features, the RFF method cannot approximate the model well.

This demonstration is exacerbated by the choice of kernel function. For other kernels in the Matérn series, with spectra that behave more like a Gaussian, the problem is less severe. Nonetheless, this demonstrates the power of Variational Fourier Features for these models.

6.1.2 Setting a, b, and M

To use Variational Fourier Features, we must select the projection interval $[a, b]$, as well as the frequencies used. In all our experiments, we use the first M frequencies that are harmonic on the interval, that is $\omega = [\frac{2\pi m}{(b-a)}]_{m=1}^{M}$.

Figure 4 compares the effect of changing the interval size and the number of inducing frequencies, for a simple Gaussian regression problem. We drew data from a Gaussian process with a Matérn-$\frac{3}{2}$ kernel ($\sigma^2 = 1$, $\ell = 0.2$) and added Gaussian noise ($\sigma_n^2 = 0.05$). We used these known parameters for the series of regression fits shown, varying $[a, b]$ and M. The true marginal likelihood was computed to be -15.99.

The top row has the interval set too narrow, within the region of the training data (this is valid but not recommended!). Accordingly, the ELBO (marked in the upper left corner of each plot) is low, no matter how many frequencies are used. In the next row, the boundary is still too close to the data: some edge effects are visible. The low value of the ELBO reflects the low quality oif the approximation.

In the third row, the boundary $[a, b]$ is sufficiently far from the data. No edge effects are visible, but we notice extra wiggles in the approximation when insufficient frequencies

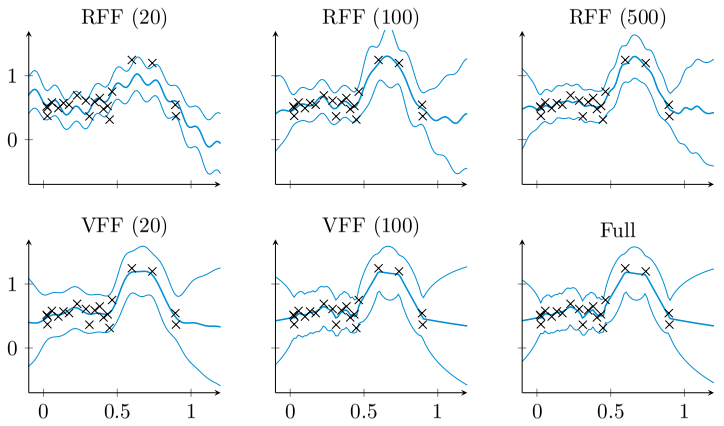

Figure 3: A comparison of our Variational Fourier Features (VFF) with Random Fourier Features (RFF). Top row: Random Fourier Features with 20, 100, and 500 frequencies. Bottom row: Variational Fourier Features with 20 and 100 frequencies, and the full-GP fit. The kernel is a Matérn-$\frac{1}{2}$, with variance, lengthscale and noise variance set by maximum likelihood according to the full GP. The bounds of the problem are set to $[-1, 2]$ for the VFF.

are used. For sufficient frequencies, and this sensible setting of the interval, the ELBO is close to the marginal likelihood.

The fourth row of Figure 4 shows the effect of choosing an interval that is too large. Because we have set the frequencies to be dependent on $(b-a)$, making this quantity large makes the frequencies too low. Sinusoidal behaviour is visible with $M = 8$ or $M = 16$, although a sensible solution is recovered once $M = 32$. Again, the ELBO reflects the quality of the approximation.

The purpose of this experiment was to illustrate how the properties of the approximation parameters (a, b, and M) affect the approximation. We have emphasized how the ELBO can be examined to ensure that two key considerations are met. First, that a and b are sufficiently far from the edges of the data. Second, that a sufficient number of frequencies are used. We emphasize again the monotonic nature of the approximation inherited from the variational framework: adding more features (increasing M) necessarily improves the approximation in the KL sense.

6.1.3 Comparison with Sparse GP for various input dimensions

The computational complexity of the VFF approach increases with the dimension of the input space. For additive kernels, we have shown that the complexity increases linearly with input dimension, and for models with a product kernel, the computation increases

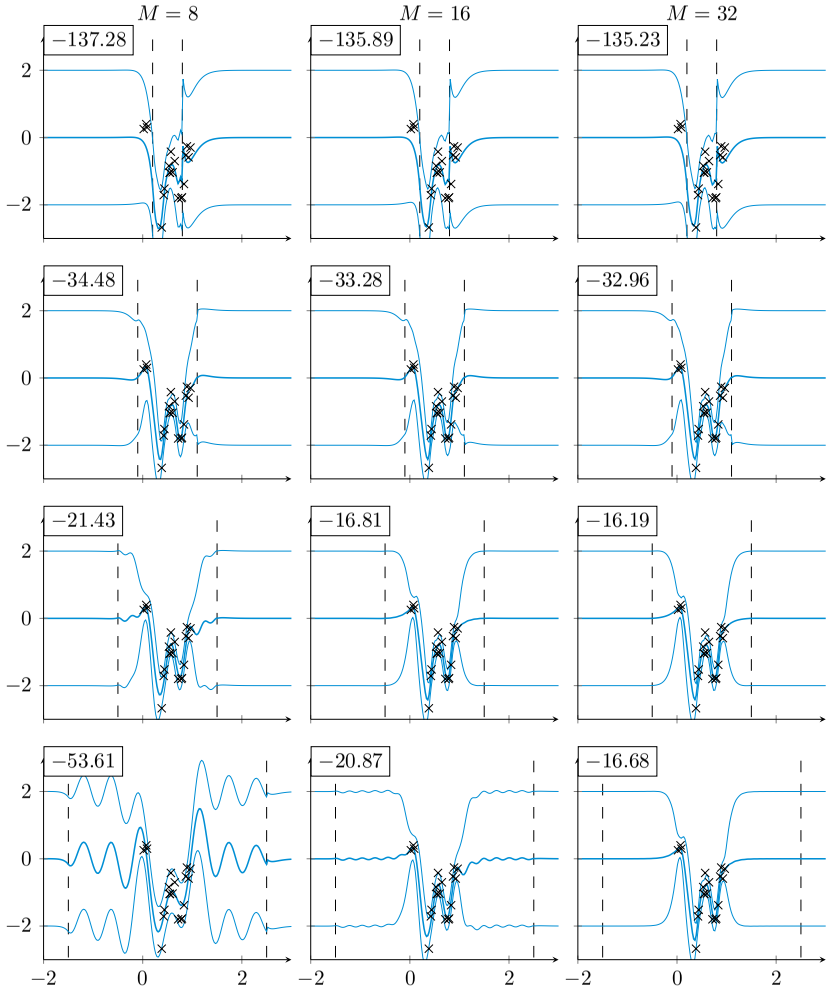

Figure 4: Demonstration of the effect of changing the interval size $[a, b]$ and the number of frequencies used. Each column has an increasing number of frequencies ($M = 8, M = 16, M = 32$), and each row has an increasing interval size, marked by vertical dashed lines. The data are drawn from a Matérn-$\frac{3}{2}$ kernel with Gaussian noise, and inference is performed with the kernel parameters set to the known values. The ELBO is shown in the top left of each plot. For reference, the true marginal likelihood in this problem is -15.99.

exponentially. In this section we explore the quality of our approximation in the product-kernel case, and compare with the sparse (inducing input) approach. We measure the time/accuracy tradeoff as a function of the input dimension and the number of inducing variables.

We consider toy data sets with input dimension $d = 1 \dots 4$, with input locations drawn uniformly over $[0, 1]^d$. The response data are given by GP samples with products of Matérn-$\frac{3}{2}$ kernels, with additive Gaussian observation noise:

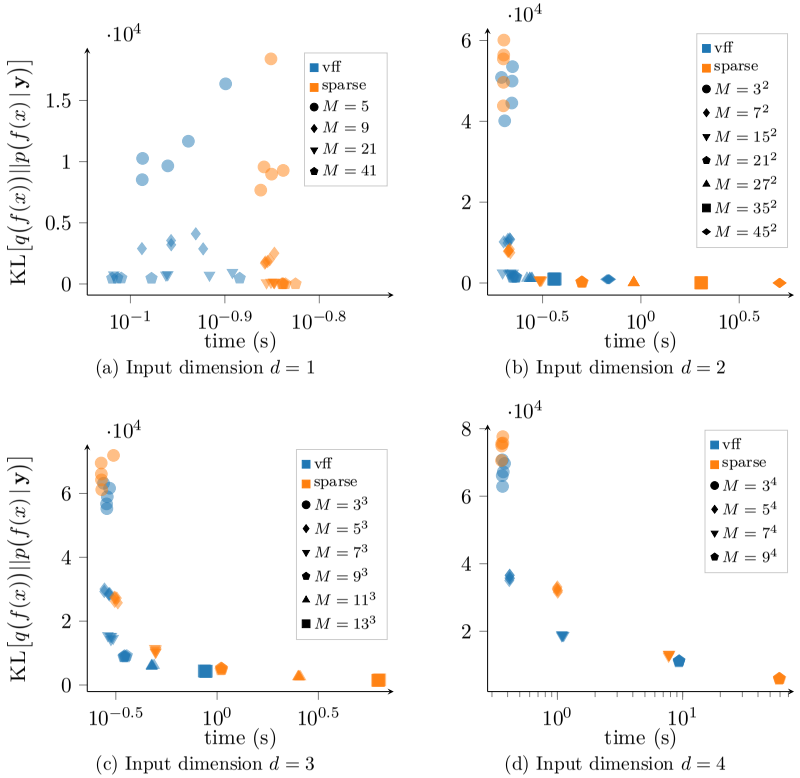
$$\begin{aligned} x_{i,j} &\sim \mathcal{U}(0,1) && \text{for } 1 \le i \le 10^4 \text{ and } 1 \le j \le d\,, \\ \mathbf{f} &\sim \mathcal{N}\Big(\mathbf{0}, \prod_{j=1}^{d} k_{3/2}(\mathbf{X}_j, \mathbf{X}_j)\Big)\,, \\ \mathbf{y} &\sim \mathcal{N}\big(\mathbf{f},\, 0.1 \times \mathbf{I}\big)\,. \end{aligned} \tag{77}$$

Given these data, we compare two approximations: one sparse GP with $M = m^d$ inducing inputs located on a regular grid with minimal and maximal values equal to 0 and 1 for each coordinate and a VFF approximation based on a Kronecker structure with $M = (m-1)/2$ frequencies for each input dimension which also leads to m^d inducing variables. For both approximations, the parameters of the covariance function were fixed to the known values used to generate the data (lengthscales $\ell = 0.2$, variance $\sigma^2 = 1$). The domain boundaries $[a, b]$ that are specific to the VFF model were fixed to $[-0.3, 1.3]$, which seemed to be a reasonable trade-off for the various dimensions after testing a few other values. We then compute the KL divergence between each approximation and the truth, by comparing the ELBO to the marginal likelihood from a 'full' GP regression model. We recorded the time required to compute the ELBO, and repeated the whole experiment five times.

The results are reported in Figure 5. In one dimension, both methods have a similar accuracy in term of KL for a given number of inducing variables but VFF appears to be faster than sparse GPs. However the low complexity of this one dimensional model does not allow us to measure the time accurately enough to distinguish the influence of the number of inducing variables on the execution time. More interesting conclusions can be drawn when the input space is greater than one: for the same number of inducing variables, VFF is significantly faster than the sparse GP (one fewer Cholesky decomposition is required) but the quality of the approximation is not as good as the sparse GP for the same number of basis functions.

For a given computational time, both methods have an equivalent accuracy but with a different number of inducing variables. The VFF basis functions appear to have less representational power, but their structure allows faster computations. Our understanding is that this smaller representational power of VFF can be explained by the fact that the inducing functions need to account for variations on $[a, b]^d$ whereas the sparse GP basis functions only need account for that on $[0, 1]^d$: a much smaller volume, especially in high dimensions. Note that the accuracy of the sparse GP can be improved by optimization of the location of the inducing inputs but that would result in computation times many times larger.

We have shown empirically that in the worst case, VFF is comparable to the sparse GP in terms of the available computate-time/accuracy tradeoff. For other models including



(a) Input dimension $d = 1$

(b) Input dimension $d = 2$

(c) Input dimension $d = 3$

(d) Input dimension $d = 4$

Figure 5: KL divergence versus wall clock time for sparse GPs and VFF with various number M of inducing inputs. The data is obtained by sampling a GP with Matérn-$\frac{3}{2}$ kernel ($\sigma^2 = 1$, $\ell = 0.2$) at 10^4 uniformly distributed input locations and $\mathcal{N}(0, 0.1)$ observation noise. The KL is computed with respect to the full GP regression model with known parameters for all models. The experiments are replicated five times with different draws of $\mathbf{X}$ and $\mathbf{y}$.

additive models, we expect much stronger performance from the VFF approximation, as the following sections demonstrate.

6.2 Additive modelling of airline delays

We demonstrate the feasibility of the variational spectral approximation in a high-dimensional GP regression example for predicting airline delays. The US flight delay prediction example (see Hensman et al., 2013, for the original example) has reached the status of a standard test data set in Gaussian process regression, partly because of its large-scale non-stationary nature and partly because of the massive size of the data set with nearly 6 million records.

This example has recently been used by Deisenroth and Ng (2015), where it was solved using distributed Gaussian processes. Samo and Roberts (2016) use this example for demonstrating the computational efficiency of string Gaussian processes. Furthermore, Adam et al. (2016) bring this problem forward as an example of a data set, where the model can be formed by the addition of multiple underlying components.

The data set consists of flight arrival and departure times for every commercial flight in the USA for the year 2008. Each record is complemented with details on the flight and the aircraft. The eight covariates $\mathbf{x}$ are the same as in Hensman et al. (2013), namely the age of the aircraft (number of years since deployment), route distance, airtime, departure time, arrival time, day of the week, day of the month, and month. We predict the delay of the aircraft at landing (in minutes), y.

Following the proposed solution by Adam et al. (2016) for this estimation problem, we use a Gaussian process regression model with a prior covariance structure given as a sum of Matérn-$\frac{3}{2}$ covariance functions for each input dimension, and assume the observations to be corrupted by independent Gaussian noise, $\varepsilon_i \sim \mathcal{N}(0, \sigma_n^2)$. The model is

$$f(\mathbf{x}) \sim \mathcal{GP}\left(0, \sum_{d=1}^{8} k(x_d, x'_d)\right), \tag{78}$$

$$y_i = f(\mathbf{x}_i) + \varepsilon_i, \tag{79}$$

for $i = 1, 2, \ldots, N$. For the Variational Fourier Feature method (VFF), we used $M = 30$ frequencies per input dimension.

We consider the entire data set of 5.93 million records. To provide comparable predictions, we follow the test setup in the paper by Samo and Roberts (2016), where results were calculated using String GPs (their method), the Bayesian committee machine (BCM, Tresp, 2000), the robust Bayesian committee machine (rBCM, Deisenroth and Ng, 2015), and stochastic variational GP inference (SVIGP, Hensman et al., 2013). The SVIGP used a squared-exponential kernel with one lengthscale per dimension. We repeated the SVIGP experiments of Samo and Roberts (2016) to complete the table for larger data sets and predictive densities.

Predictions are made for several subset sizes of the data, each selected uniformly at random: 10,000, 100,000, 1,000,000, and 5,929,413 (all data). In each case, two thirds of the data is used for training and one third for testing. For each subset size, the training is repeated ten times, and for each run, the outputs are normalized by subtracting the training sample mean from the outputs and dividing the result by the sample standard deviation. In the VFF method, the inputs were normalized to $[0, 1]$ and the domain size was set to $[-2, 3]$, i.e. the boundary is at a distance of two times the range of the data for each dimension.

N	10,000		100,000		1,000,000		5,929,413	
	MSE	NLPD	MSE	NLPD	MSE	NLPD	MSE	NLPD

Full-RBF	0.89 ± 0.16	1.349 ± 0.098	N/A	N/A	N/A	N/A	N/A	N/A
Full-additive	0.89 ± 0.16	1.362 ± 0.096	N/A	N/A	N/A	N/A	N/A	N/A
SVIGP	0.89 ± 0.16	1.354 ± 0.096	0.79 ± 0.05	1.299 ± 0.033	0.79 ± 0.01	1.301 ± 0.009	0.791 ± 0.005	1.300 ± 0.003
String GP†	1.03 ± 0.10	N/A	0.93 ± 0.03	N/A	0.93 ± 0.01	N/A	0.90 ± 0.01	N/A
rBCM†	1.06 ± 0.10	N/A	1.04 ± 0.04	N/A	N/A	N/A	N/A	N/A

Table 2: Predictive mean squared errors (MSEs) and negative log predictive densities (NLPDs) with one standard deviation on the airline arrival delays experiment. †MSE results as reported by Samo and Roberts (2016), who also list results for the BCM and rBCM methods.

Table 2 shows the predictive mean squared errors (MSEs) and the negative log predictive densities (NLPDs) with one standard deviation on the airline arrival delays experiment. In this form the MSEs over the normalized data can be interpreted as a fraction of the sample variance of airline arrival delays. Thus a MSE of 1.00 is an accuracy equivalent to using the training mean as predictor. The results for the String GP method are included for reference only and they are given as reported by Samo and Roberts (2016). They also list results for the rBCM method, which performed worse than the String GP.

Running the VFF experiment with all 5.93 million data using our Python implementation took 265 ± 6 seconds (626 ± 11 s CPU time) on a two-core MacBook Pro laptop (with all calculation done on the CPU). The results for 10,000 data were calculated in 21 ± 2 seconds (27 ± 4 s CPU time). For comparison, according to Samo and Roberts (2016), running the String GP experiment took 91.0 hours total CPU time (or 15 h of wall-clock time on an 8-core machine). Even the SVIGP method required 5.1 ± 0.1 hours of computing (27.0 ± 0.8 h CPU time) on a cluster.

For comparison, we have also included the results for the naive full GP solution for 10,000 data. These results were computed on a computing cluster and the computation time was several hours per repetition. We show results both for a squared-exponential kernel with one lengthscale per dimension, and also with an additive kernel similar to the one defined for the VFF method. As one might expect, the RBF model had a slightly lower average MSE (0.8898) than the additive model (0.89274). The difference is small: only 3 seconds of RMSE in the original units of flight-delay. The VFF result (0.8934) for the same data is close to the full GP solution (the difference being only about 0.66 s in terms of non-normalized RMSE). In terms of NLPD the results agree as well; the full RBF model is able to capture the phenomenon slightly better than the full additive model, and the VFF model approximates well the full additive model. The variability in the data is large, and including more data in the GP training gives the model more power for prediction. The SVIGP model (with a squared-exponential kernel) is the most flexible one and reaches the lowest RMSE and NLPD in the experiments.

Figure 6 shows the component-wise predictions for each of the covariates, thus summarizing the underlying structure of the delay prediction model. As one might expect, the effect of the month, day of month, and day of week are small. The only interpretable effects are seen in slightly higher delays in the summer months and around the holiday season

towards the end of the year, as well as some effects for the weekend traffic on Friday and Sunday. The age of the aircraft has a barely noticeable effect. The four remaining inputs (e–h) explain most of the delay. The effects of airtime and travel distance are strongly correlated. Strong correlation can also be seen in departure and arrival time effects, both of which show peaks during the night. The model also catches the periodic nature of the departure and arrival time effects. These results are in line with the analysis of Adam et al. (2016).

6.3 Classification with a Gaussian approximation

To perform variational classification using Variational Fourier Features, we can use a Gaussian approximation to the posterior $q(\mathbf{u})$ and optimize the ELBO with respect to the mean and variance of the approximation, as described in Section 2.4.4. To illustrate, we replicate the experiment on the banana data set from Hensman et al. (2015b). In that work, the authors showed that a variational inducing point method performed better than competing alternatives because the positions of the inducing points could be effectively optimized using the ELBO as the objective. In this work, we have selected the frequencies of the Variational Fourier Features to be placed on a regular grid: the only aspect of the Fourier features to be tuned is M, controlling the number of features used.

Since the variational framework provides a guarantee that more inducing variables must be monotonically better (Titsias, 2009), we expect that increasing the number of Variational Fourier Features will provide improved approximations. However, if we restrict the form of the Gaussian approximation by requiring a structured covariance, this may no longer be true. In practice, we have found that a freely-structured covariance matrix works well in one dimension and for additive models, but for Kronecker-structured models, optimization over an exponentially large matrix is intolerably slow. A suggestion for a related method provided by Nickson et al. (2015) is to force the Gaussian approximation to have a Kronecker-structured covariance matrix. This reduces the number of variables over which we have to optimize, but removes the guarantee that more inducing variables is always better. We find in practice that this structure does not work well: Figure 7 shows the ELBO as a function of the number of inducing variables M, for both a trained covariance and a Kronecker–structured one. We see that for the Kronecker structure, the ELBO decreases as M increases, implying that more inducing variables are actually making the approximation worse in this case.

Our suggestion is to use a sum of two Kronecker-structured matrices. The right-most plot of Figure 7 shows that the ELBO increases monotonically with M when we use this structure. We provide no guarantee that the sum of two Kronecker matrices is optimal, and suggest that future work might consider generalizing the form of this approximation.

To compare our method with the inducing-point method, we refer to Figure 8, which shows the results of fitting a Gaussian process classifier to the banana data set using increasing numbers of inducing points (IP) and increasing numbers of Fourier features (VFF). We observe the effect noted in Hensman et al. (2015b) that the inducing points move toward the decision boundary, though some slight differences from that experiment exist because of our choice of the product of Matérn-$\frac{5}{2}$ kernels, instead of the squared exponential kernel. The Figure also shows that the number of frequencies required to obtain a good approximation

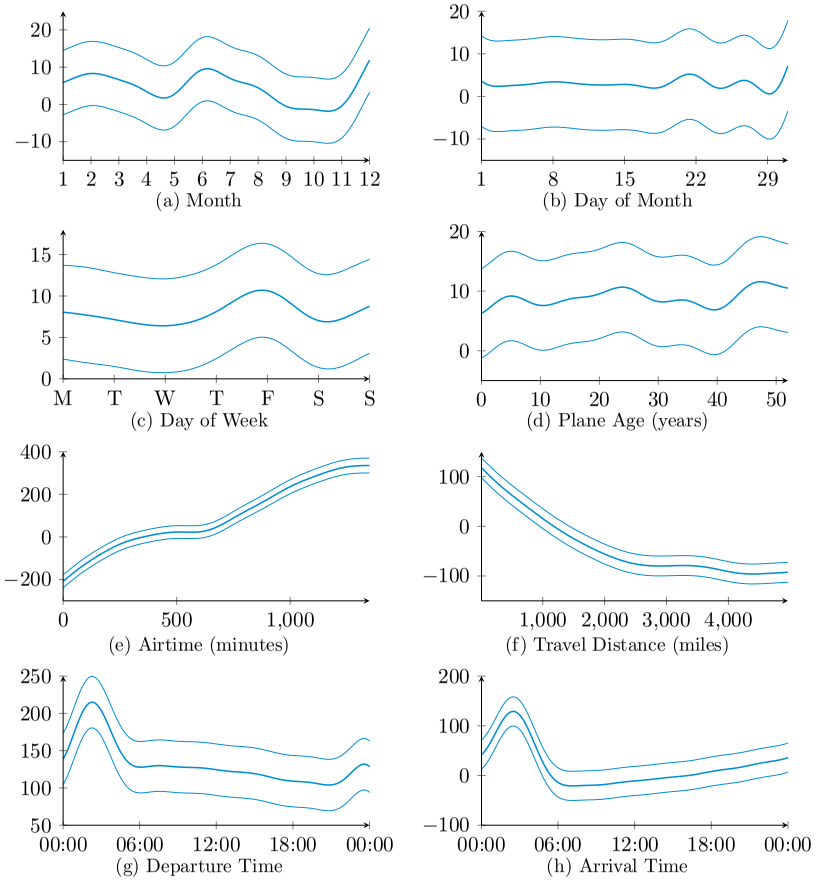

Figure 6: The posterior mean and two posterior standard deviations in the airline delay prediction experiment estimated from 5.93 million data. Each panel show the posterior over the effect from one covariate under an additive model. The vertical axis represents delay in minutes in each case.

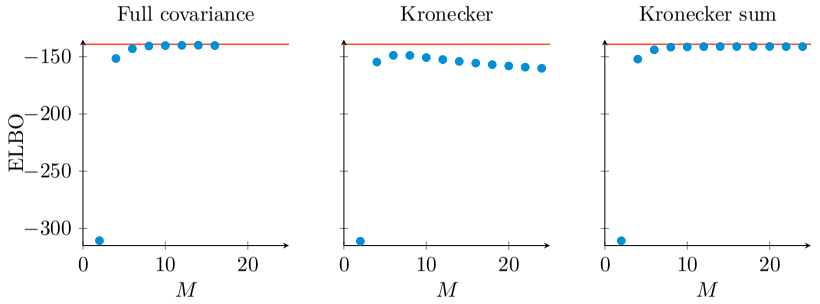

Figure 7: The increasing ELBO for the banana data set with increasing numbers of frequencies M, and a Gaussian approximation to the posterior. Left: $q(\mathbf{u})$ has an unconstrained covariance matrix. Middle: $q(\mathbf{u})$ has a Kronecker-structured covariance matrix. Right: $q(\mathbf{u})$ has a covariance matrix with a sum of two Kronecker-structured matrices. In each case the ELBO achieved using a full matrix decomposition is shown as a horizontal red line.

is reasonable, though it is not straightforward to compare directly between the VFF and IP methods. The total number of basis functions used in the Fourier features is twice the number of frequencies (M) listed, squared (since we have real and imaginary components, and take the Kronecker product). Still, the VFF method requires fewer computations per frequency than the IIP method does per inducing point, since the $\mathbf{K_{uu}}$ matrix is easily decomposed.

6.4 Solar irradiance

An alternative, but related idea to our proposed Variational Fourier Features approach is presented by Gal and Turner (2015). In that work, the authors used a Random Fourier Features model (as in equation (15)), but additionally performed a variational-Bayesian treatment of the frequencies. We repeat an experiment from that work on solar irradiance data (Lean, 2004), shown in Figure 9. In this experiment, the time series was normalized and segments of the data were removed; in Figure 9, removed data are shown in red, and vertical dashed lines denote the removed sections. The remaining data are shown in black, and we show the predicted mean (heavy blue line) and 95% confidence intervals (light blue lines). We fitted five models (or model approximations) to the remaining data, using 50 inducing points (or frequencies) except in the case of the Random Fourier Features, where we used 500 (following Gal and Turner, 2015). In each case, we used a Matérn-$\frac{5}{2}$ kernel initialized with a lengthscale of 10, and optimized the parameters with respect to the marginal likelihood (or ELBO, accordingly).

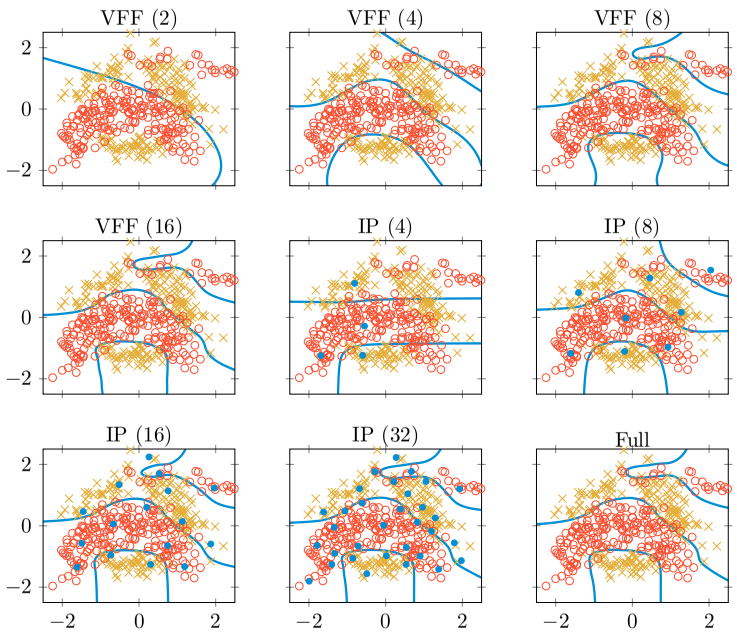

Figure 8: Classification of the banana data set with increasing number of Variational Fourier Features (VFF) and Inducing Points (IP). The two classes of data are shown as red circles and yellow crosses, and the decision boundary is shown as a solid blue line. An approximation with a full inversion of the covariance matrix is shown in the last plot. The blue dots show optimized positions of the inducing points. The Variational Fourier Features approach the true posterior more rapidly than the inducing point method.

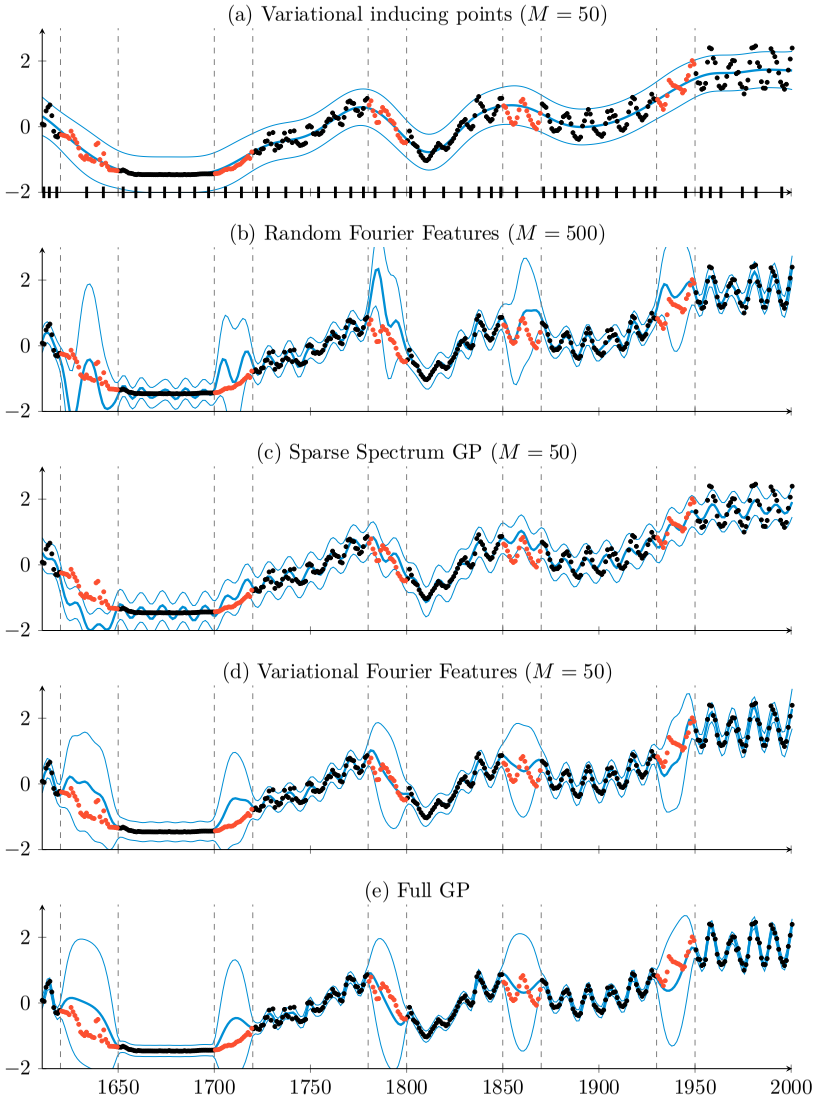

Figure 9: Replicating the experiment on solar irradiance data from Gal and Turner (2015).

Figure 9(a) shows the results of an inducing point method (still within the variational framework, based on Titsias, 2009). The positions of the inducing points z are shown as black marks on the horizontal axis. In this case, there are insufficient points to capture the complexity of the data, and the model reverts to a long lengthscale. This is an interesting case of underfitting, where the variational approximation to the function values gives rise to a bias in the estimate of the lengthscale parameter. This bias occurs because when maximising the ELBO with respect to the parameters, the KL divergence is smaller for longer lengthscales, biasing the parameter estimation in that direction. Turner and Sahani (2011) give an excellent discussion of this issue.

Figure 9(b) shows the results of the Random Fourier Features method. This method is given 500 frequencies; we concur with the findings of Gal and Turner (2015) that using only 50 frequencies gives very poor performance. Where the data are missing, the error bars provided by the model are large, similarly to the full GP (Figure 9(e)). The approximation is unable to recover the correct mean function, however, and is somewhat subject to overfitting: the model emphasises the high-frequency content in the data. In some sense, this is a desirable property as the model is more flexible than the original GP. For example, Yang et al. (2015) exploited this property to fit complex GP models. However, we advocate the variational method precisely because of the asymptotic convergence (in M) to the true posterior distribution of the original model.

Figure 9(c) shows the result of fitting the Sparse Spectrum GP approximation (Lázaro-Gredilla et al., 2010). This model is similar to the Random Fourier Features model, except that the frequencies are optimized. Here the overfitting is more severe: the model focusses entirely on the high-frequency content of the data. Although this gives good predictions in some cases (the segment around 1930 for example), the predictions are wild in others (e.g. around 1630, where none of the held-out data fall within the 95% intervals).

Figure 9(d) and (e) show the Variational Fourier Features method and the full GP method. The VFF approximation strives to approach the true posterior, and it is clear that the method is superior to the inducing points method in (a) in that the lengthscale is well estimated and the confidence intervals match the behaviour of the full GP. Some small discrepancies exist, but we note that these disappear completely at 100 inducing frequencies.

In summary, this experiment emphasises again how the variational approach attempts to approximate the posterior of the model, whereas previous approximations have *changed* the model, giving different behaviours. Within the variational methods, the Variational Fourier Features outperform the inducing point approach in this case, since our orthogonal basis functions are capable of capturing the posterior more effectively.

6.5 MCMC approximations

Above we have used the Gaussian approximation to the posterior process. Hensman et al. (2015a) propose a methodology which combines the variational approach with MCMC by sampling from the optimal approximating distribution, as we described in equation (27). The advantages of this approach are that the posterior need not be assumed Gaussian, and that the covariance parameters can also be treated in a Bayesian fashion. The VFF framework that we have described fits well into this scheme, and as we have already described,

the computational cost per iteration is linear in the number of data and in the number of required frequencies.

Here we replicate an experiment from Hensman et al. (2015a) (therein based on inducing point representations) in estimating the rate of a two-dimensional log Gaussian Cox process. In this experiment, we aim to emphasise the convergent properties of Variational Fourier Features, and show how they might be used in practice within the MCMC framework.

The data consist of a series of 127 points collected in a square area, denoting the location of pine saplings. This simple illustration was also used by Møller et al. (e.g. 1998). The model is

$$f(\mathbf{s}) \sim \mathcal{GP}\big(0, k(\mathbf{s}, \mathbf{s}')\big)\,, \tag{80}$$

$$\log \lambda(\mathbf{s}) = f(\mathbf{s}) + c\,, \tag{81}$$

$$\mathbf{y} \sim \mathcal{PP}(\lambda)\,, \tag{82}$$

where $\mathcal{PP}$ denotes an inhomogeneous Poisson process with intensity λ, $\mathbf{y}$ are spatial locations representing a draw from that Poisson process, k is a product of Matérn-$\frac{3}{2}$ covariance functions of the two-dimensional space indexed by $\mathbf{s}$, and c is a parameter to be inferred alongside the covariance function parameters. The model contains a doubly-intractable likelihood, which can be approximated by gridding the space and assuming that the intensity is constant across the bin size. The resulting approximation to the likelihood is

$$p(\mathbf{y} \mid \mathbf{f}) = \prod_{i=1}^{G} \mathcal{P}(N_i \mid \lambda(\mathbf{s}_i)\Delta)\,, \tag{83}$$

where G is the number of grid cells, $\mathbf{s}_i$ represent the centres of those cells, N_i is the number of data in the i^{th} cell, Δ is the area of a grid cell and $\mathcal{P}$ represents the Poisson distribution. To perform inference in this model, we decompose the GP with Variational Fourier features, use the rotation described in Section 5.5 to centre the $\mathbf{u}$ variables and run Hamiltonian Monte Carlo (HMC) to jointly sample the centred variables alongside the covariance function parameters and c.

To illustrate how the VFF method approaches the posterior in the MCMC case, we ran the HMC algorithm using $M = 14, 16, \ldots, 30$ frequencies. We selected the boundaries of the decomposition $[a, b]$ to be $[-1, 2]^2$, whilst the data were normalized to the unit square $[0, 1]^2$. The posterior mean intensity of the process on the unit square, along with the data, are shown in Figure 10. The figure shows that as M increases, the behaviour of the method stabilizes: there is little to distinguish $M = 30$ from $M = 28$. If M is too low, then there is a bias towards longer lengthscales, but this is alleviated as M increases. Since more inducing variables must always move the approximation toward the posterior in the KL sense (Titsias, 2009), once the optimal posterior (for each fixed M) remains unchanging with an increase in M, we must be approximating the posterior closely. A practical approach then, is to use some reasonable number for M (say, 100) and then ensure that the sampled distribution is unmoving with increased M. Since our experiments suggest that the lengthscale parameter is particularly sensitive to bias due to M being too low, we suggest examining the convergent behaviour of the lengthscale posterior. Figure 11 shows how the posterior distribution of the lengthscales converges as M increases.

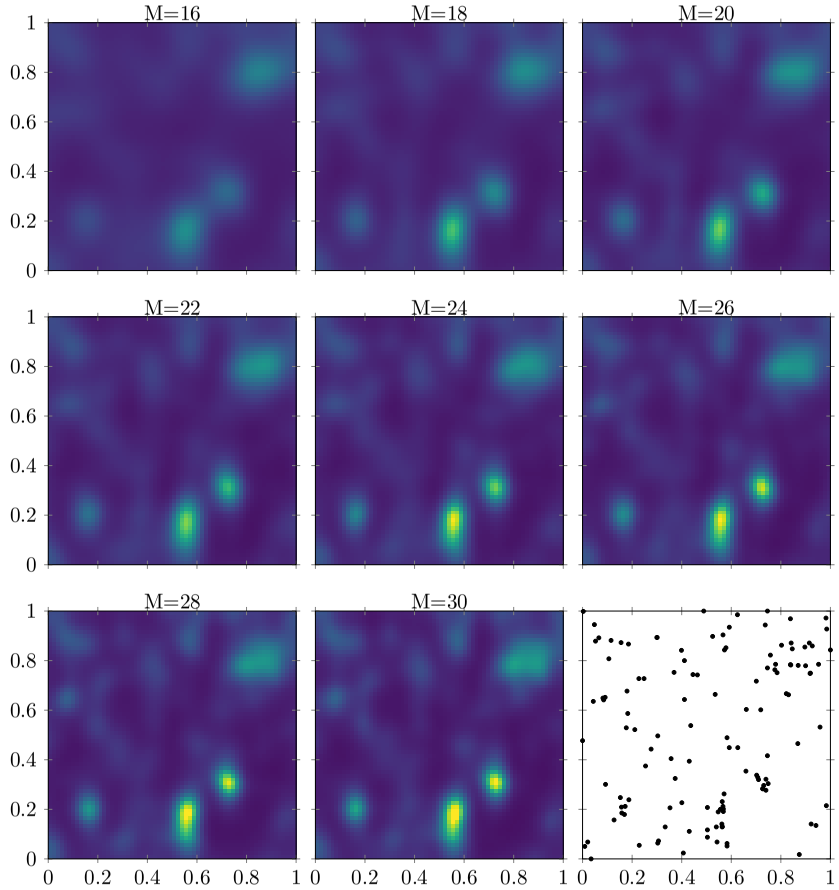

Figure 10: The posterior mean of the process intensity with increasing M (denoted above each figure). The spatial locations of the data are shown in the last pane. As M increases, the behaviour of the method stabilizes: we conclude that at $M = 30$ there is no benefit from increasing M further. If M is too low, the method is biased towards a longer lengthscale (see also Figure 11).

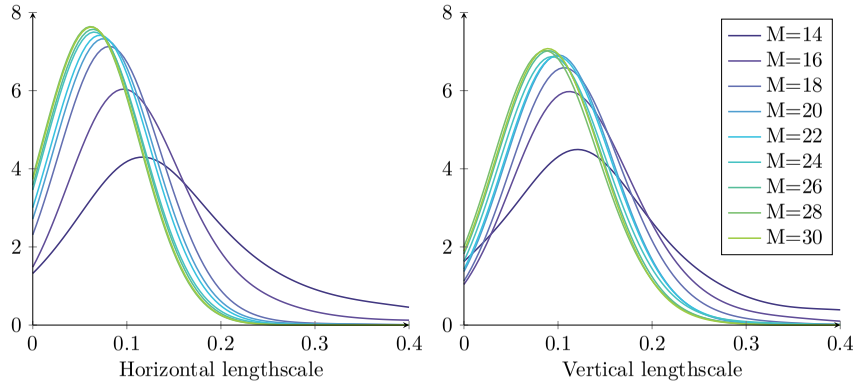

Figure 11: The posterior distribution of the two lengthscale parameters for the pines problem (see also Figure 10), estimated using kernel density smoothing on the MCMC trace. As more frequencies are used, the posterior distribution converges.

We note that the regular-lattice nature of this problem means that it can also be efficiently solved using fast Fourier transform (FFT) methods (e.g. Taylor and Diggle, 2014). However, our approach offers several advantages. First, in our method the number of frequencies used is a variational parameter: we have discussed how to select M above. Since the dimension of the vector which is subject to MCMC depends on the number of frequencies, it is desirable to decouple it from the grid density: fine grids are desired to resolve the spatial nature of the process, whilst the length of the vector $\mathbf{u}$ is desired to be short for computational reasons. Second, our approach does not require the embedding of the kernel matrix into a circulant matrix which can occasionally suffer from non-positive-definiteness. Third and most importantly, our method is not restricted to problems on a regular grid.

7. Discussion and future directions

In this paper we have presented a method which we refer to as the Variational Fourier Features (VFF) approach to Gaussian process modelling. It combines the variational approach to sparse approximations in Gaussian processes with a representation based on the spectrum of the process. This approach inherits its appealing approximative construction from the variational approach, but with the representative power and computational scalability of spectral representations.

We generalized the method to several dimensions in cases where the kernel exhibits special structure in the form of additive or separable (product) covariance functions. This choice made it possible to apply the scheme to higher-dimensional test problems in the experiments, for which we demonstrate good performance both in terms of computational speed and predictive power.

Our example application of predicting airline delays suggested that the additive structure worked well for that problem: for data subsets where the full model could be fitted, there was little performance difference between the additive and isotropic case, and indeed the VFF method was competitive with both, suggesting that the posterior was very well approximated. It seems implausible that this structure could work well for all problems, and clearly it will not work well where interesting interactions occur between covariates.

The method is capable of modelling interactions between covariates using separable kernel structures. As was noted in the text, the computational scalability in this case limits the method to low-dimensional problems, because the number of inducing frequencies scales exponentially with the input dimension. In this sense this approach is not a sparse approximation, but rather based on a 'dense' basis function projection. Like related approximation schemes (Solin and Särkkä, 2014; Wilson and Nickisch, 2015; Nickson et al., 2015), VFF scales well as the number of data increases, with the drawback of difficulty in dealing with high-dimensional problems out-of-the-box.

To further improve the computational scaling in high-dimensional problems, there are several approaches which could apply. Wilson et al. (2015) presents a projection approach (based on the ideas in Wilson and Nickisch, 2015). These ideas could be expanded to our approach as well, and we might expect the variational properties of the approximation to be useful in this case. Alternatively, replacing the dense grid spectrum with a set of sparsely well-chosen spectral points is an option that can — at least for models or data with suitable structure — provide computational remedy in high input dimensions. Future work might incorporate some ideas from the sparse spectrum method (Lázaro-Gredilla et al., 2010) where the frequencies are optimized, though we might hope that the variational formulation could prevent over-fitting.

We note that one of the key computations in our method, the multiplication $\mathbf{K_{uf}y}$, is precisely a non-uniform FFT (NUFFT, see Dutt and Rokhlin, 1993; Greengard and Lee, 2004; Bernstein et al., 2004), which can be approximated in $\mathcal{O}(N \log N)$ operations. Although we have so far avoided using this technology in our implementations, some initial experiments suggest that further speed-up is possible at the cost of a very small loss in accuracy. In the special case where the data lie on a regular grid, it is possible to compute the product $\mathbf{K_{uf}y}$ exactly in $\mathcal{O}(N \log N)$ operations using an FFT. Again we have not exploited this in our presentation so far, and future work may consider the relations between VFF and FFT methods based on the circulant embedding trick (Taylor and Diggle, 2014; Turner, 2010).

A further limitation of our current presentation is that we have only considered Matérn covariance functions with half-integer orders. A productive future direction will be to expand the number of kernels which can be decomposed using Variational Fourier Features. An interesting class of kernels may be the spectral mixture kernel (Wilson and Adams, 2013). Although that work was based on frequency-shifted versions of the RBF covariance, we anticipate that frequency-shifted Matérn kernels would work just as well, and may be more amenable to the VFF framework.

In our derivations, we have considered uniform input densities on some bounded interval $[a, b]$. Instead of considering such compact bounded subsets of $\mathbb{R}$, it might be possible to extend our methodology to more general input densities (cf. Williams and Seeger, 2000). In special cases this can lead to convenient approximations for the eigen-decomposition of the

kernel. For example, for a RBF covariance function and a Gaussian input density, the eigenfunctions can be given in closed-form in terms of Hermite polynomials (see Williams and Rasmussen, 2006, Ch. 4.3). There is a connection between harmonic Fourier approximations like ours and the covariance operator defined through the covariance function and the input density. The connection goes back to Sturm-Liouville theory and is further discussed in Solin and Särkkä (2014).

Finally, we note that VFF may be particularly well-suited to machine learning methods where Gaussian processes are embedded in some further model structure, such as the Gaussian process latent variable model (GPLVM, Lawrence, 2005) and its variational-Bayesian variant (Titsias and Lawrence, 2010), as well as deep Gaussian processes (Damianou and Lawrence, 2013). As described by Damianou et al. (2016), variational inference in these models involves propagating uncertainty by convolving the $\mathbf{K_{uf}}$ matrix with Gaussian approximations to the input distribution. Since the VFF method has precisely sinusoidal $\mathbf{K_{uf}}$ matrices, this convolution will take a simple form, and we envisage that combining the VFF framework with variational uncertainty propagation will lead to substantial improvements in inference for these models.

Part of this research was conducted during the invitation of J. Hensman at Mines Saint-Étienne. This visit was funded by the Chair in Applied Mathematics OQUAIDO, which gather partners in technological research (BRGM, CEA, IFPEN, IRSN, Safran, Storengy) and academia (Ecole Centrale de Lyon, Mines Saint-Étienne, University of Grenoble, University of Nice, University of Toulouse) on the topic of advanced methods for computer experiments. J. Hensman gratefully acknowledges a fellowship from the Medical Research Council UK. A. Solin acknowledges the Academy of Finland grant 308640. We acknowledge the computational resources provided by the Aalto Science-IT project. J. Hensman would like to thank T. Smith for insightful discussions. The authors would like to thank T. Bui, A. Vehtari, S.T. John and the anonymous reviewers who helped to improve this manuscript.

Appendix A. L_2 Projection on Fourier Features for Matérn-$\frac{1}{2}$

In this Appendix we derive expressions for Fourier features using the L_2 norm.

A.1 Covariance between inducing variable and GP

$$\operatorname{cov}(u_m, f(x)) = \mathbb{E}\left[u_m f(x)\right] = \int_a^b \mathbb{E}[f(t)f(x)]e^{-i\omega_m(t-a)}\,\mathrm{d}t = \int_a^b k(t,x)e^{-i\omega_m(t-a)}\,\mathrm{d}t \quad (84)$$

$$= e^{-i\omega_m a}\sigma^2\left(\int_a^x e^{\lambda(t-x)+i\omega_m t}\,\mathrm{d}t + \int_x^b e^{\lambda(x-t)+i\omega_m t}\,\mathrm{d}t\right) \quad (85)$$

$$= e^{-i\omega_m a}\sigma^2\left(\left[\frac{e^{\lambda(t-x)+i\omega_m t}}{i\omega_m+\lambda}\right]_a^x + \left[\frac{e^{\lambda(x-b)+i\omega_m t}}{i\omega_m-\lambda}\right]_x^b\right) \quad (86)$$

$$= e^{-i\omega_m a}\sigma^2\left(\frac{e^{i\omega_m x}-e^{\lambda(a-x)+i\omega_m a}}{i\omega_m+\lambda} + \frac{e^{\lambda(x-b)+i\omega_m b}-e^{i\omega_m x}}{i\omega_m-\lambda}\right) \quad (87)$$

$$= \sigma^2\left(\frac{e^{i\omega_m(x-a)}-e^{\lambda(a-x)}}{i\omega_m+\lambda} + \frac{e^{\lambda(x-b)}-e^{i\omega_m(x-a)}}{i\omega_m-\lambda}\right) \quad (88)$$

$$= \frac{2\sigma^2\lambda}{\lambda^2+\omega_m^2}e^{i\omega_m(x-a)} + \frac{\sigma^2}{\lambda^2+\omega_m^2}\left(\lambda[-e^{a-x}-e^{x-b}] + i\omega_m[e^{a-x}-e^{x-b}]\right) \quad (89)$$

$$= s_{1/2}(\omega_m)e^{i\omega_m(x-a)} + s_{1/2}(\omega_m)\frac{1}{2\lambda}\left(\lambda[-e^{a-x}-e^{x-b}] + i\omega_m[e^{a-x}-e^{x-b}]\right). \quad (90)$$

A.2 Covariance between inducing variables

For the L_2 Fourier features, the covariance between two features u_m and $u_{m'}$ depends on the basis functions being sines or cosines. We will thus detail the two cases considering either the real or imaginary part of $\mathbf{u}$. The following integrals, which can be computed using $\cos(\omega x) = \mathcal{R}\mathrm{e}(e^{i\omega x})$, will be of particular interest:

$$\int_x^y e^{\lambda s}\cos(\omega s)\,\mathrm{d}s = \frac{1}{\lambda^2+\omega^2}\left[e^{\lambda x}(-\lambda\cos(\omega x)-\omega\sin(\omega x)) + e^{\lambda y}(\lambda\cos(\omega y)+\omega\sin(\omega y))\right], \quad (91)$$

$$\int_x^y e^{\lambda s}\sin(\omega s)\,\mathrm{d}s = \frac{1}{\lambda^2+\omega^2}\left[e^{\lambda x}(\omega\cos(\omega x)-\lambda\sin(\omega x)) + e^{\lambda y}(-\omega\cos(\omega y)+\lambda\sin(\omega y))\right]. \quad (92)$$

case 1: $i, j \le M$ (cosine block)

$$\operatorname{cov}[u_m, u_{m'}] = \mathbb{E}\left[\int_a^b f(s)\cos(-\omega_m(s-a))\,\mathrm{d}s\int_a^b f(t)\cos(-\omega_{m'}(t-a))\,\mathrm{d}t\right] \quad (93)$$

$$= \int_a^b\int_a^b k(s,t)\cos(-\omega_m(s-a))\cos(-\omega_{m'}(t-a))\,\mathrm{d}s\,\mathrm{d}t \quad (94)$$

$$= \int_0^{a-b}\int_0^{b-a} k(s,t)\cos(\omega_m s)\cos(\omega_{m'}t)\,\mathrm{d}s\,\mathrm{d}t \quad (95)$$

$$= \frac{1}{\lambda^2+\omega_m^2}\int_0^{b-a}\left[2\lambda\cos(\omega_m t) - \lambda(e^{-\lambda t}+e^{\lambda(t+a-b)})\right]\cos(\omega_{m'}t)\,\mathrm{d}t \quad (96)$$

$$= \frac{2\lambda}{\lambda^2+\omega_m^2}\int_a^b\left[\cos(\omega_m t) - e^{-\lambda t}\right]\cos(\omega_{m'}t)\,\mathrm{d}t\,. \quad (97)$$

case 1a: $m \neq m'$

$$\operatorname{cov}[u_m, u_{m'}] = \frac{-2\lambda}{\lambda^2+\omega_m^2}\int_0^{b-a} e^{-\lambda t}\cos(\omega_{m'}t)\,\mathrm{d}t \quad (98)$$

$$= \frac{-2\lambda^2}{(\lambda^2+\omega_m^2)(\lambda^2+\omega_{m'}^2)}\left[1-e^{\lambda(a-b)}\right]. \quad (99)$$

case 1b: $m = m' \neq 0$

$$\operatorname{cov}[u_m, u_{m'}] = \frac{-2\lambda^2}{(\lambda^2+\omega_m^2)(\lambda^2+\omega_{m'}^2)}\left[1-e^{\lambda(a-b)}\right] + (b-a)\frac{\lambda}{\lambda^2+\omega_m^2}\,. \quad (100)$$

case 1c: $m = m' = 0$

$$\operatorname{cov}[u_m, u_{m'}] = \frac{-2\lambda^2}{(\lambda^2+\omega_m^2)(\lambda^2+\omega_{m'}^2)}\left[1-e^{\lambda(a-b)}\right] + 2(b-a)\frac{\lambda}{\lambda^2+\omega_m^2}\,. \quad (101)$$

case 2: m, $m' > M$ (sine block)

$$\operatorname{cov}[u_m, u_{m'}] = \int_0^{b-a}\int_0^{b-a} k(s,t)\sin(\omega_m s)\sin(\omega_{m'}t)\,\mathrm{d}s\;\,\mathrm{d}t \quad (102)$$

$$= \frac{2}{\lambda^2+\omega_m^2}\int_0^{b-a}\left[\lambda\sin(\omega_m t) + \omega_m e^{-\lambda t}\right]\sin(\omega_{m'}t)\,\mathrm{d}t\,. \quad (103)$$

case 2a: $m \neq m'$

$$\operatorname{cov}[u_m, u_{m'}] = \frac{2\omega_m}{\lambda^2+\omega_m^2}\int_0^{b-a} e^{-\lambda t}\sin(\omega_{m'}t)\,\mathrm{d}t \quad (104)$$

$$= \frac{2\omega_m\omega_{m'}}{(\lambda^2+\omega_m^2)(\lambda^2+\omega_{m'}^2)}\left[1-e^{\lambda(a-b)}\right]. \quad (105)$$

case 2b: $m = m'$

$$\operatorname{cov}[u_m, u_{m'}] = \frac{2\omega_{m'}^2}{(\lambda^2+\omega_m^2)(\lambda^2+\omega_{m'}^2)}\left[1-e^{\lambda(a-b)}\right] + (b-a)\frac{\lambda}{\lambda^2+\omega_m^2}\,. \quad (106)$$

Appendix B. Matérn inner products

The expressions of inner products for Matérn RKHS on $[a, b]$ can be found in Durrande et al. (2016). We adopt here the following notations to obtain compact expressions: for any function $h \in \mathcal{H}$, $\mathcal{I} : \ h \to h$ is the identity operator and $\mathcal{D} : \ g \to g'$ is the differentiation operator. As a consequence, $(\lambda\mathcal{I} + \mathcal{D})^2(h)$ is a shorthand for $\lambda^2 h + 2\lambda h' + h''$.

$$\text{Matérn-}\tfrac{1}{2}\text{: } \langle g, h\rangle_{\mathcal{H}_{1/2}} = \frac{1}{2\lambda\sigma^2}\int_a^b (\lambda\mathcal{I}+\mathcal{D})(g)(\lambda\mathcal{I}+\mathcal{D})(h)\,\mathrm{d}t + \frac{1}{\sigma^2}g(a)h(a)\,, \tag{107}$$

$$\begin{aligned}\text{Matérn-}\tfrac{3}{2}\text{: } \langle g, h\rangle_{\mathcal{H}_{3/2}} &= \frac{1}{4\lambda^3\sigma^2}\int_a^b (\lambda\mathcal{I}+\mathcal{D})^2(g)(\lambda\mathcal{I}+\mathcal{D})^2(h)\,\mathrm{d}t \\ &\quad + \frac{1}{\sigma^2}g(a)h(a) + \frac{1}{\lambda^2\sigma^2}g'(a)h'(a)\,,\end{aligned} \tag{108}$$

$$\begin{aligned}\text{Matérn-}\tfrac{5}{2}\text{: } \langle g, h\rangle_{\mathcal{H}_{5/2}} &= \frac{3}{16\lambda^5\sigma^2}\int_a^b (\lambda\mathcal{I}+\mathcal{D})^3(g)(\lambda\mathcal{I}+\mathcal{D})^3(h)\,\mathrm{d}t \\ &\quad + \frac{9}{8\sigma^2}g(a)h(a) + \frac{9}{8\lambda^4\sigma^2}g(a)''h''(a) \\ &\quad + \frac{3}{\lambda^2\sigma^2}\left(g'(a)h'(a) + \frac{1}{8}g''(a)h(a) + \frac{1}{8}g(a)h''(a)\right)\,.\end{aligned} \tag{109}$$

B.1 Gram matrix between Fourier features for the exponential kernel

We detail here the computations of $\mathbf{K_{uu}}[i, j] = \langle\phi_i, \phi_j\rangle_{\mathcal{H}}$ for the exponential kernel. We recall that $\phi_0 = 1$ and that $\phi_i = \cos(\omega_i(x-a))$ and $\phi_{i+M} = \sin(\omega_i(x-a))$ for $i \in \{1, \dots, M\}$. Furthermore, the frequencies ω_i are harmonic on $[a, b]$.

case 1 : $i, j \le M$ (cosine block)

$$\mathbf{K_{uu}}[i, j] = \frac{1}{2\sigma^2\lambda}\int_0^{b-a}(\lambda\cos(\omega_i s) - \omega_i\sin(\omega_i s))(\lambda\cos(\omega_j s) - \omega_j\sin(\omega_j s))\,\mathrm{d}s + \frac{1}{\sigma^2}\,. \tag{110}$$

The integral is zero for all non-diagonal terms ($i \neq j$). As a consequence, the block of $\mathbf{K_{uu}}$ associated with the cosine basis functions are $\mathrm{diag}(\alpha_{cos}) + \sigma^{-2}$, where

$$\alpha_{cos}[i] = \frac{1}{2\sigma^2\lambda}\int_0^{b-a}\lambda^2\cos(\omega_i s)^2 + \omega_i^2\sin(\omega_i s)^2\,\mathrm{d}s = \begin{cases}\dfrac{\lambda(b-a)}{2\sigma^2} & \text{if } i = 0\,,\\ \dfrac{b-a}{4\sigma^2\lambda}(\lambda^2+\omega_i^2) & \text{if } i \neq 0\,,\end{cases} \tag{111}$$

which leads to $\alpha_{cos} = \frac{1}{2}(b-a)\left[2s(0)^{-1}, s(\omega_1)^{-1}, \dots, s(\omega_M)^{-1}\right]$.

case 2 : $i, j > M$ (sine block)

$$\mathbf{K_{uu}}[i, j] = \frac{1}{2\sigma^2\lambda}\int_0^{b-a}(\lambda\sin(\omega_i s) - \omega_i\cos(\omega_i s))(\lambda\sin(\omega_j s) - \omega_j\cos(\omega_j s))\,\mathrm{d}s\,. \tag{112}$$

The $\mathbf{K_{uu}}$ block associated to the sine basis functions is exactly a diagonal matrix with:

$$\mathbf{K_{uu}}[i, i] = \frac{1}{2\sigma^2\lambda}\int_0^{b-a}(\lambda^2\sin(\omega_i s)^2 + \omega_i^2\cos(\omega_i s))\,\mathrm{d}s = \frac{b-a}{4\sigma^2\lambda}(\lambda^2+\omega_i^2)\,. \tag{113}$$

Similarly to the cosine block, we can write the sine block as $\mathrm{diag}(\alpha_{sin})$ with $\alpha_{sin} = \frac{1}{2}(b-a)\left[s(\omega_1)^{-1}, \dots, s(\omega_M)^{-1}\right]$.

case 3 : $i \le 2M + 1 < j$ (off-diagonal block) leads to $\mathbf{K}_{\phi\phi}[i, j] = 0$.

B.2 Gram matrix associated to Fourier features for the Matérn-$\frac{3}{2}$ kernel

case 1 : $i, j \le M$ (cosine block)

$$\begin{aligned}\mathbf{K}_{\phi\phi}[i, j] &= \frac{1}{4\sigma^2\lambda^3}\int_0^{b-a}(\lambda^2\cos(\omega_i s) - 2\lambda\omega_i\sin(\omega_i s) - \omega_i^2\cos(\omega_i s))\times \\ &\qquad (\lambda^2\cos(\omega_j s) - 2\lambda\omega_j\sin(\omega_j s) - \omega_j^2\cos(\omega_j s))\,\mathrm{d}s \\ &\quad + \frac{1}{\sigma^2}\cos(\omega_i a)\cos(\omega_j a) + \frac{1}{\lambda^2\sigma^2}\omega_i\omega_j\sin(\omega_i a)\sin(\omega_j a) \\ &= \begin{cases}\dfrac{1}{\sigma^2} & \text{if } i \neq j\,,\\ \dfrac{1}{4\sigma^2\lambda^3}\displaystyle\int_0^{b-a}\lambda^4\cos^2(\omega_i s) + \omega_i^4\cos^2(\omega_i s) & \\ \qquad -2\lambda^2\omega^2\cos^2(\omega_i s) + 4\lambda^2\omega_i^2\sin^2(\omega_i s)ds + \dfrac{1}{\sigma^2} & \text{if } i = j\,,\end{cases} \\ &= \begin{cases}\dfrac{1}{\sigma^2} & \text{if } i \neq j\,,\\ \dfrac{b-a}{8\sigma^2\lambda^3}(\lambda^2+\omega_i^2)^2 + \dfrac{1}{\sigma^2} & \text{if } i = j \neq 0\,,\\ \dfrac{\lambda(b-a)}{4\sigma^2} + \dfrac{1}{\sigma^2} & \text{if } i = j = 0\,.\end{cases}\end{aligned} \tag{114}$$

case 2 : $i, j > M$ (sine block)

$$\begin{aligned}\mathbf{K}_{\phi\phi}[i, j] &= \frac{1}{4\sigma^2\lambda^3}\int_0^{b-a}(\lambda^2\sin(\omega_i s) + 2\lambda\omega_i\cos(\omega_i s) - \omega_i^2\sin(\omega_i s))\times \\ &\qquad (\lambda^2\sin(\omega_j s) + 2\lambda\omega_j\cos(\omega_j s) - \omega_j^2\sin(\omega_j s))\,\mathrm{d}s \\ &\quad + \frac{1}{\sigma^2}\sin(\omega_i a)\sin(\omega_j a) + \frac{1}{\lambda^2\sigma^2}\omega_i\omega_j\cos(\omega_i a)\cos(\omega_j a) \\ &= \begin{cases}\dfrac{\omega_i\omega_j}{\lambda^2\sigma^2} & \text{if } i \neq j\,,\\ \dfrac{1}{4\sigma^2\lambda^3}\displaystyle\int_0^{b-a}\lambda^4\sin^2(\omega_i s) + \omega_i^4\sin^2(\omega_i s) & \\ \qquad -2\lambda^2\omega^2\sin^2(\omega_i s) + 4\lambda^2\omega_i^2\cos^2(\omega_i s)ds + \dfrac{\omega_i\omega_j}{\lambda^2\sigma^2} & \text{if } i = j\,,\end{cases} \\ &= \begin{cases}\dfrac{\omega_i\omega_j}{\lambda^2\sigma^2} & \text{if } i \neq j\,,\\ \dfrac{b-a}{8\sigma^2\lambda^3}(\lambda^2+\omega_i^2)^2 + \dfrac{\omega_i\omega_j}{\lambda^2\sigma^2} & \text{if } i = j\,.\end{cases}\end{aligned} \tag{115}$$

case 3: $i \leq M < j$ (off-diagonal block)

$$\begin{aligned}\mathbf{K}_{\phi\phi}[i,j] &= \frac{1}{4\sigma^2\lambda^3}\int_0^{b-a} (\lambda^2\cos(\omega_i s) - 2\lambda\omega_i\sin(\omega_i s) - \omega_i^2\cos(\omega_i s))\times \\ &\qquad (\lambda^2\sin(\omega_j s) + 2\lambda\omega_j\cos(\omega_j s) - \omega_j^2\sin(\omega_j s))\,\mathrm{d}s \\ &\quad + \frac{1}{\sigma^2}\cos(\omega_i a)\sin(\omega_j a) - \frac{1}{\lambda^2\sigma^2}\omega_i\omega_j\sin(\omega_i a)\cos(\omega_j a) \\ &= \begin{cases} 0 & \text{if } i \neq j\,, \\ \frac{1}{4\sigma^2\lambda^3}\int_0^{b-a} 2\lambda^3\omega_i\cos^2(\omega_i s) - 2\lambda\omega_i^3\cos^2(\omega_i s) & \\ \qquad -2\lambda^3\omega_i\sin^2(\omega_i s) + 2\lambda\omega_i^3\sin^2(\omega_i s)\,\mathrm{d}s & \text{if } i = j\,, \end{cases} \\ &= 0\end{aligned} \tag{116}$$

B.3 Gram matrix of Fourier features for the Matérn-$\frac{5}{2}$ kernel

$$\langle g, h\rangle_{\mathcal{H}_{5/2}} = \frac{3}{16\lambda^5\sigma^2}\int_0^{b-a} L_t(g)L_t(h)\,\mathrm{d}t + G(a)\,, \tag{117}$$

$$\begin{aligned}\text{where } L_t(g) &= \left(\lambda^3 g(t) + 3\lambda^2 g'(t) + 3\lambda g''(t) + g'''(t)\right)\,, \\ G(a) &= \frac{9}{8\sigma^2}g(a)h(a) + \frac{9}{8\lambda^4\sigma^2}g(a)''h''(a) \\ &\quad + \frac{3}{\lambda^2\sigma^2}\left(g'(a)h'(a) + \frac{1}{8}g''(a)h(a) + \frac{1}{8}g(a)h''(a)\right)\,.\end{aligned} \tag{118}$$

case 1: $i, j \leq M$ (cosine block)

$$\begin{aligned}L_x(\cos(\omega_i .)) &= \lambda^3\cos(\omega_i x) - 3\omega_i\lambda^2\sin(\omega_i x) - 3\lambda\omega_i^2\cos(\omega_i x) + \omega_i^3\sin(\omega_i x) \\ &= (\lambda^3 - 3\lambda\omega_i^2)\cos(\omega_i x) + (\omega_i^3 - 3\omega_i\lambda^2)\sin(\omega_i x) \\ G(a) &= \frac{9}{8\sigma^2} + \frac{9}{8\lambda^4\sigma^2}\omega_i^2\omega_j^2 - \frac{3}{8\lambda^2\sigma^2}(\omega_i^2 + \omega_j^2) \\ &= \frac{1}{\sigma^2} + \frac{1}{8\sigma^2}\left(\frac{3\omega_i^2}{\lambda^2} - 1\right)\left(\frac{3\omega_j^2}{\lambda^2} - 1\right)\,.\end{aligned} \tag{119}$$

$$\mathbf{K}_{\phi\phi}[i,j] = \begin{cases} G(a) & \text{if } i \neq j\,, \\ \frac{3(b-a)}{32\lambda^5\sigma^2}(\lambda^6 - 6\lambda^4\omega_i^2 + 9\lambda^2\omega_i^4 + \omega_i^6 - 6\lambda^2\omega_i^4 + 9\omega_i^2\lambda^4) + G(a) & \text{if } i = j \neq 0\,, \\ \frac{3(b-a)}{16\lambda^5\sigma^2}(\lambda^6 - 6\lambda^4\omega_i^2 + 9\lambda^2\omega_i^4) + G(a) & \text{if } i = j = 0\,, \end{cases} \tag{120}$$

which boils down to

$$\mathbf{K}_{\phi\phi}[i,j] = \begin{cases} G(a) & \text{if } i \neq j\,, \\ \frac{3(b-a)}{32\lambda^5\sigma^2}(\lambda^2 + \omega_i^2)^3 + G(a) & \text{if } i = j \neq 0\,, \\ \frac{3\lambda(b-a)}{16\sigma^2} + G(a) & \text{if } i = j = 0\,. \end{cases} \tag{121}$$

case 2: $i, j > M$ (sine block)

$$\begin{aligned}L_x(\sin(\omega_i .)) &= \lambda^3\sin(\omega_i x) + 3\omega_i\lambda^2\cos(\omega_i x) - 3\lambda\omega_i^2\sin(\omega_i x) - \omega_i^3\cos(\omega_i x) \\ &= (\lambda^3 - 3\lambda\omega_i^2)\sin(\omega_i x) - (\omega_i^3 - 3\omega_i\lambda^2)\cos(\omega_i x)\,, \\ G(a) &= \frac{3\omega_i\omega_j}{\lambda^2\sigma^2}\,,\end{aligned} \tag{122}$$

$$\mathbf{K}_{\phi\phi}[i,j] = \begin{cases} G(a) & \text{if } i \neq j\,, \\ \frac{3(b-a)}{32\lambda^5\sigma^2}(\lambda^2 + \omega_i^2)^3 + G(a) & \text{if } i = j \neq 0\,. \end{cases} \tag{123}$$

case 3: $i \leq M < j$ (off-diagonal block). As previously, calculations give $\mathbf{K}_{\phi\phi}[i,j] = 0$.

Abstract

Dimensionality reduction algorithms have played a foundational role in facilitating the deep understanding of complex high-dimensional data. One particularly useful application of dimensionality reduction techniques is in data visualization. Low-dimensional visualizations can help practitioners understand where machine learning algorithms might leverage the geometric properties of a dataset to improve performance. Another challenge is to generalize insights across datasets [e.g. data from multiple modalities describing the same system (Haxby et al., 2011), artwork or photographs of similar content in different styles (Zhu et al., 2017), etc.]. Several recently developed techniques (e.g. Haxby et al., 2011; Chen et al., 2015) use the procrustean transformation (Schönemann, 1966) to align the geometries of two or more spaces so that data with different axes may be plotted in a common space. We propose that each of these techniques (dimensionality reduction, alignment, and visualization) applied in sequence should be cast as a single conceptual *hyperplot* operation for gaining geometric insights into high-dimensional data. Our Python toolbox enables this operation in a single (highly flexible) function call.

Keywords: visualization, high-dimensional, dimensionality reduction, procrustes, time-series data

1. Introduction

A major focus of machine learning research is finding patterns in, and making predictions from, complex data that might be otherwise inscrutable to a human viewer. Paradoxically, designing effective algorithms for discovering, characterizing, and leveraging structure in many complex datasets often requires the practitioner to have some initial intuitions about the structure of the data. One commonly used approach for discovering structure in high-dimensional data is to use dimensionality reduction algorithms (e.g. Pearson, 1901; Tipping and Bishop, 1999; Jutten and Herault, 1991; Comon et al., 1991; Torgerson, 1958; van der Maaten and Hinton, 2008) to visualize high-dimensional data in two or three dimensions, thereby providing insights into geometric patterns that pervade the data (Uddenberg et al., 2016). Despite the so-called "curse of dimensionality," whereby high-dimensional data can behave differently from low-dimensional data, visualizing data via low-dimensional projections can provide a glimpse (though imperfect) into what the dataset "looks like." By leveraging different dimensionality reduction algorithms, or by viewing the data through different projections (or as an animation), one can begin to form intuitions that generalize beyond the specific imperfections of a given dimensionality reduction tool or projection. We highlight several examples of how low-dimensional projections may be used to understand the geometry of high-dimensional data in Figure 1. Complete details may be found here, and sample IPython notebooks may be found here.

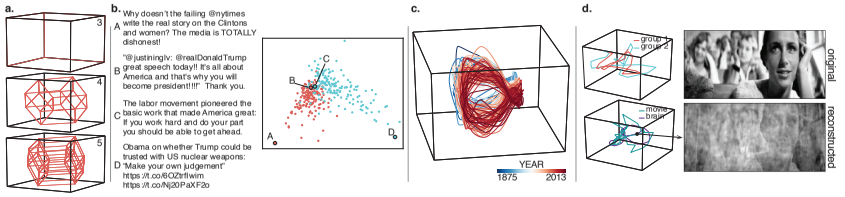

Figure 1: **Data visualization examples. a.** Hypercubes of increasing dimensionality (3, 4 and 5 dimensions). The cubes provide some insights into which aspects of high-dimensional data are preserved (or distorted) when projected onto 3 dimensions. **b.** Topic modeling (Blei et al., 2003) of political Twitter data: 2D projections of topic vectors of Hillary Clinton's (blue) and Donald Trump's (red) tweets during their 2016 presidential campaigns (link to data). The 'V' shape highlights that Trump and Clinton tweets are largely about fundamentally different topics. The highlighted examples include (A) a Trump tweet that is especially "Trump-like," (B) a Trump tweet that is Clinton-like, (C) a Clinton tweet that is Trump-like, and (D) a Clinton tweet that is especially Clinton-like. **c.** Changing temperatures across the Earth's surface from 1875—2013 (link to data). The visualization highlights the cyclical (seasonal) nature of global temperatures that occurs alongside a gradual increase in global temperatures over time. **d.** Brain/movie trajectories during movie viewing (link to data). (Top left) Group-averaged trajectories of brain activity from the ventral visual cortex, split into two randomly-selected groups of subjects (group 1: $n = 6$, group 2: $n = 5$) watching *Raiders of the Lost Ark* (Haxby et al., 2011). (Bottom left) Group-averaged trajectory of brain activity from ventral visual cortex and trajectory of the movie frames (pixel intensities over time), hyperaligned to a common space. (Right) Movie frame reconstructed from the group-averaged brain activity that was aligned to movie space. The example illustrates geometric commonalities across brains, and between the movie frames and the brain responses to those frames.

Although dimensionality reduction algorithms provide a useful means of visualizing high-dimensional data, they cannot (by themselves) solve the problem of identifying geometric similarities across different types of data. For example, as highlighted in Figure 1d, different people's brains might exhibit similar (but not identical) activity patterns while watching a movie, and those brain patterns might exhibit a similar temporal covariance structure to

the movie itself. However, if one were to project brain data and movie data onto a three dimensional space, although the overall "shapes" of those datasets might be similar, there would be no inherent reason for the datasets to align. Algorithms inspired by the procrustean transformation (Schönemann, 1966), including Hyperalignment (Haxby et al., 2011) and the Shared Response Model (Chen et al., 2015) compute the affine transformations of two or more datasets that bring the data into a common alignment. This can reveal similarities (or differences) between the underlying geometries of otherwise incompatible data. Further, because the transformation is invertible, one can map between any point in that common space (e.g. a shared movie-brain space) and the original data spaces (e.g. the movie frames; the lower right panel of Fig. 1d shows a movie frame corresponding to a brain pattern recorded during one time in the movie, and the upper panel shows the original movie frame viewed at that moment).

The `HyperTools` toolbox (current version: 0.4.2) provides a powerful set of Python functions for projecting high dimensional data onto lower-dimensional spaces, aligning data of different types, and visualizing the results in publication-quality figures and movies. A central goal of the toolbox is to cast dimensionality reduction, alignment, and visualization as a single highly flexible "hyperplot" command:

```
import hypertools as hyp                                              (1)
hyp.plot(list_of_arrays, reduce='TSNE', align='hyper', ndims=3)       (2)
```

This example function call projects the high-dimensional data onto 3 dimensions using the t-SNE algorithm, aligns the data matrices in the given list of arrays into a common space using hyperalignment, and produces a 3D plot analogous to those shown in Figure 1. These hyperplot visualizations provide an intuitive means of understanding how different observations relate to each other or how those observations change over time. These insights can guide algorithm design decisions, or help practitioners to understand which aspects of the data may be easy (or difficult) to model or measure.

2. Overview of the Toolbox

`HyperTools` is open-source, installable from GitHub or pip (`pip install hypertools`), and is distributed with the MIT License. The toolbox depends on the following open-source software packages: `Matplotlib` (Hunter, 2007) for plotting functionality, `Seaborn` (Waskom et al., 2016) for plot styling, `Scikit-learn` (Pedregosa et al., 2011) for data analysis (dimensionality reduction, clustering, etc.), and `PPCA` for inferring missing data (Tipping and Bishop, 1999). The toolbox also includes a port of the hyperalignment algorithm (Haxby et al., 2011) from the `PyMVPA` library, as well as the shared response model from the `BrainIAK` toolbox (Capota et al., 2017), as an alternative data alignment technique. At the time of writing this manuscript, the toolbox incorporates two general classes of algorithms: *dimensionality reduction* (PCA, incremental PCA, sparse PCA, kernel PCA, probabilistic PCA, t-SNE, MDS, ICA, factor analysis, truncated SVD, dictionary learning, mini-batch dictionary learning, isomap, spectral embedding, and local linear embedding) and *alignment* (hyperalignment, shared response model, and procrustean transformation). `HyperTools` provides a simple interface to these functions, with support for a variety of convenient data formats including `NumPy` arrays (van der Walt et al., 2011), `Pandas` dataframes (McKinney, 2010), or

mixed lists of arrays and dataframes. [Each to-be-analyzed (or to-be visualized) dataset must be formated as a number-of-observations (S) by number-of-features (F) array or dataframe.] `HyperTools` also adds a number of custom arguments to facilitate data visualization and manipulation of high-dimensional data. Nearly all of the `HyperTools` functions may be accessed through the `plot` function (Ex. 2). This design enables complex data analysis and plotting to be carried out in a single function call. The same function call also returns the analyzed data (and the transformations applied to it) for potential follow-up analyses. There are two general types of plots supported by the toolbox: *static plots* and *animated plots*.

2.1 Static Plots

By default, the `plot` function will perform dimensionality reduction (using incremental PCA), converting the $S \times F$ data matrix (or matrices) into an $S \times 3$ matrix (or matrices), and then create an interactive 3D line plot that can be explored by using the mouse to rotate the plot. If there are `NaNs` present in the dataset, these missing values will be automatically interpolated using PPCA (Tipping and Bishop, 1999) (preserving the dimensionality of the original data) prior to reducing the dimensionality of the data using the user-specified algorithm. The `plot` function also accepts format strings to specify line styling (following `Matplotlib` conventions):

```
hyp.plot(data)                                                        (3)
hyp.plot([data1, data2, data3], '.')                                  (4)
```

2.2 Animated Trajectory Plots

Animated 3D plots (created using the `animate` flag) are useful for visualizing high-dimensional timeseries data:

```
hyp.plot(data, animate=True).                                         (5)
```

This function call creates a 3D trajectory animated over the rows of the `data` matrix. Each frame of the animation displays a portion of the total data trajectory enclosed in a cube. In successive frames, the displayed portion of the data trajectory incrementally advances, and the camera angle rotates around the cube, providing visual access to different aspects of the data as the animation progresses.

2.3 Align

Two or more datasets may share geometric structure, but reside in different coordinate systems. The `align` function accepts a list of arrays as input and returns a hyperaligned list of arrays in a common geometric space:

```
hyp.plot([array1, array2, array3], align='hyper')                     (6)
hyperaligned_list = hyp.align([array1, array2, array3])               (7)
```

2.4 Reduce

Users can access a variety of dimensionality reduction algorithms by passing the `reduce` keyword argument to the `plot` function. We also provide API access to the `reduce`

function that underlies these transformations. At its core, the `reduce` function wraps many of `scikit-learn`'s dimensionality reduction algorithms, along with the `PPCA` library. `HyperTools` extends the functionality of these tools by providing a streamlined syntax that accepts data matrices in a larger variety of formats (e.g. `NumPy` arrays and `Pandas` dataframes, or lists of arrays and dataframes, may all be analyzed using the same syntax). The function may be used as follows:

```
hyp.plot(data, reduce='MDS')                                    (8)
reduced_data = hyp.reduce(data, reduce='TSNE', ndims=5)         (9)
```

3. Concluding Remarks

The `HyperTools` toolbox is designed to provide geometric insights into high-dimensional datasets with a single function call. We also provide a convenient syntax to access a variety of dimensionality reduction and data alignment algorithms. The above overview of the toolbox highlights its primary features; additional functionality and a detailed description of the API may be found here.

Acknowledgments

We are grateful to Luke J. Chang and Matthijs van der Meer for useful discussions, and to J. Swaroop Guntapalli for help implementing our `align` function. We also thank Ryan Arredondo, Aly Sivji and Steph Wright for their code contributions during the Mozilla Global Sprint in June 2017, and we thank Mozilla for organizing the Global Sprint. We also thank Chase Williams for contributing code. Our work was supported in part by NSF EPSCoR Award Number 1632738. Abstract

Derivatives, mostly in the form of gradients and Hessians, are ubiquitous in machine learning. Automatic differentiation (AD), also called algorithmic differentiation or simply "autodiff", is a family of techniques similar to but more general than backpropagation for efficiently and accurately evaluating derivatives of numeric functions expressed as computer programs. AD is a small but established field with applications in areas including computational fluid dynamics, atmospheric sciences, and engineering design optimization. Until very recently, the fields of machine learning and AD have largely been unaware of each other and, in some cases, have independently discovered each other's results. Despite its relevance, general-purpose AD has been missing from the machine learning toolbox, a situation slowly changing with its ongoing adoption under the names "dynamic computational graphs" and "differentiable programming". We survey the intersection of AD and machine learning, cover applications where AD has direct relevance, and address the main implementation techniques. By precisely defining the main differentiation techniques and their interrelationships, we aim to bring clarity to the usage of the terms "autodiff", "automatic differentiation", and "symbolic differentiation" as these are encountered more and more in machine learning settings.

Keywords: Backpropagation, Differentiable Programming

1. Introduction

Methods for the computation of derivatives in computer programs can be classified into four categories: (1) manually working out derivatives and coding them; (2) *numerical differentiation* using finite difference approximations; (3) *symbolic differentiation* using expression manipulation in computer algebra systems such as Mathematica, Maxima, and Maple; and (4) *automatic differentiation*, also called *algorithmic differentiation*, which is the subject matter of this paper.

Conventionally, many methods in machine learning have required the evaluation of derivatives and most of the traditional learning algorithms have relied on the computation of gradients and Hessians of an objective function (Sra et al., 2011). When introducing new models, machine learning researchers have spent considerable effort on the manual derivation of analytical derivatives to subsequently plug these into standard optimization procedures such as L-BFGS (Zhu et al., 1997) or stochastic gradient descent (Bottou, 1998). Manual differentiation is time consuming and prone to error. Of the other alternatives, numerical differentiation is simple to implement but can be highly inaccurate due to round-off and truncation errors (Jerrell, 1997); more importantly, it scales poorly for gradients, rendering it inappropriate for machine learning where gradients with respect to millions of parameters are commonly needed. Symbolic differentiation addresses the weaknesses of both the manual and numerical methods, but often results in complex and cryptic expressions plagued with the problem of "expression swell" (Corliss, 1988). Furthermore, manual and symbolic methods require models to be defined as closed-form expressions, ruling out or severely limiting algorithmic control flow and expressivity.

We are concerned with the powerful fourth technique, automatic differentiation (AD). AD performs a non-standard interpretation of a given computer program by replacing the domain of the variables to incorporate derivative values and redefining the semantics of the operators to propagate derivatives per the chain rule of differential calculus. Despite its widespread use in other fields, general-purpose AD has been underused by the machine learning community until very recently.[1] Following the emergence of deep learning (LeCun et al., 2015; Goodfellow et al., 2016) as the state-of-the-art in many machine learning tasks and the modern workflow based on rapid prototyping and code reuse in frameworks such as Theano (Bastien et al., 2012), Torch (Collobert et al., 2011), and TensorFlow (Abadi et al., 2016), the situation is slowly changing where projects such as autograd[2] (Maclaurin, 2016), Chainer[3] (Tokui et al., 2015), and PyTorch[4] (Paszke et al., 2017) are leading the way in bringing general-purpose AD to the mainstream.

The term "automatic" in AD can be a source of confusion, causing machine learning practitioners to put the label "automatic differentiation", or just "autodiff", on any method or tool that does not involve manual differentiation, without giving due attention to the underlying mechanism. We would like to stress that AD as a technical term refers to a specific family of techniques that compute derivatives through accumulation of values during code execution to generate numerical derivative evaluations rather than derivative

4. http://pytorch.org/

expressions. This allows accurate evaluation of derivatives at machine precision with only a small constant factor of overhead and ideal asymptotic efficiency. In contrast with the effort involved in arranging code as closed-form expressions under the syntactic and semantic constraints of symbolic differentiation, AD can be applied to regular code with minimal change, allowing branching, loops, and recursion. Because of this generality, AD has been applied to computer simulations in industry and academia and found applications in fields including engineering design optimization (Forth and Evans, 2002; Casanova et al., 2002), computational fluid dynamics (Müller and Cusdin, 2005; Thomas et al., 2006; Bischof et al., 2006), physical modeling (Ekström et al., 2010), optimal control (Walther, 2007), structural mechanics (Haase et al., 2002), atmospheric sciences (Carmichael and Sandu, 1997; Charpentier and Ghemires, 2000), and computational finance (Bischof et al., 2002; Capriotti, 2011).

In machine learning, a specialized counterpart of AD known as the backpropagation algorithm has been the mainstay for training neural networks, with a colorful history of having been reinvented at various times by independent researchers (Griewank, 2012; Schmidhuber, 2015). It has been one of the most studied and used training algorithms since the day it became popular mainly through the work of Rumelhart et al. (1986). In simplest terms, backpropagation models learning as gradient descent in neural network weight space, looking for the minima of an objective function. The required gradient is obtained by the backward propagation of the sensitivity of the objective value at the output (Figure 1), utilizing the chain rule to compute partial derivatives of the objective with respect to each weight. The resulting algorithm is essentially equivalent to transforming the network evaluation function composed with the objective function under reverse mode AD, which, as we shall see, actually generalizes the backpropagation idea. Thus, a modest understanding of the mathematics underlying backpropagation provides one with sufficient background for grasping AD techniques.

In this paper we review AD from a machine learning perspective, covering its origins, applications in machine learning, and methods of implementation. Along the way, we also aim to dispel some misconceptions that we believe have impeded wider recognition of AD by the machine learning community. In Section 2 we start by explicating how AD differs from numerical and symbolic differentiation. Section 3 gives an introduction to the AD technique and its forward and reverse accumulation modes. Section 4 discusses the role of derivatives in machine learning and examines cases where AD has relevance. Section 5 covers various implementation approaches and general-purpose AD tools, followed by Section 6 where we discuss future directions.

2. What AD Is Not

Without proper introduction, one might assume that AD is either a type of numerical or symbolic differentiation. Confusion can arise because AD does in fact provide numerical values of derivatives (as opposed to derivative expressions) and it does so by using symbolic rules of differentiation (but keeping track of derivative values as opposed to the resulting expressions), giving it a two-sided nature that is partly symbolic and partly numerical (Griewank, 2003). We start by emphasizing how AD is different from, and in several aspects superior to, these two commonly encountered techniques of computing derivatives.

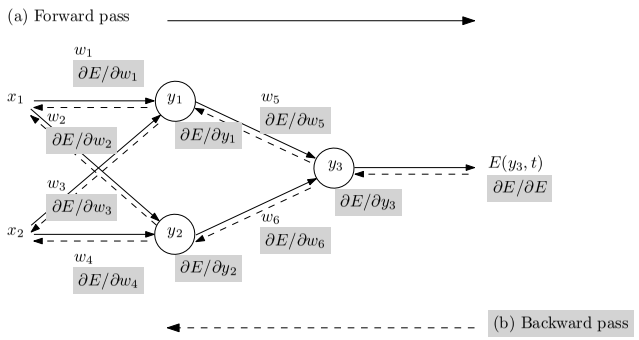

Figure 1: Overview of backpropagation. (a) Training inputs x_i are fed forward, generating corresponding activations y_i. An error E between the actual output y_3 and the target output t is computed. (b) The error adjoint is propagated backward, giving the gradient with respect to the weights $\nabla_{w_i} E = \left(\frac{\partial E}{\partial w_1}, \ldots, \frac{\partial E}{\partial w_6}\right)$, which is subsequently used in a gradient-descent procedure. The gradient with respect to inputs $\nabla_{x_i} E$ can be also computed in the same backward pass.

2.1 AD Is Not Numerical Differentiation

Numerical differentiation is the finite difference approximation of derivatives using values of the original function evaluated at some sample points (Burden and Faires, 2001) (Figure 2, lower right). In its simplest form, it is based on the limit definition of a derivative. For example, for a multivariate function $f : \mathbb{R}^n \to \mathbb{R}$, one can approximate the gradient $\nabla f = \left(\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}\right)$ using

$$\frac{\partial f(\mathbf{x})}{\partial x_i} \approx \frac{f(\mathbf{x} + h\mathbf{e}_i) - f(\mathbf{x})}{h} , \tag{1}$$

where $\mathbf{e}_i$ is the i-th unit vector and $h > 0$ is a small step size. This has the advantage of being uncomplicated to implement, but the disadvantages of performing $O(n)$ evaluations of f for a gradient in n dimensions and requiring careful consideration in selecting the step size h.

Numerical approximations of derivatives are inherently ill-conditioned and unstable,[5] with the exception of complex variable methods that are applicable to a limited set of holomorphic functions (Fornberg, 1981). This is due to the introduction of truncation[6] and

5. Using the limit definition of the derivative for finite difference approximation commits both cardinal sins of numerical analysis: *"thou shalt not add small numbers to big numbers"*, and *"thou shalt not subtract numbers which are approximately equal"*.
6. Truncation error is the error of approximation, or inaccuracy, one gets from h not actually being zero. It is proportional to a power of h.

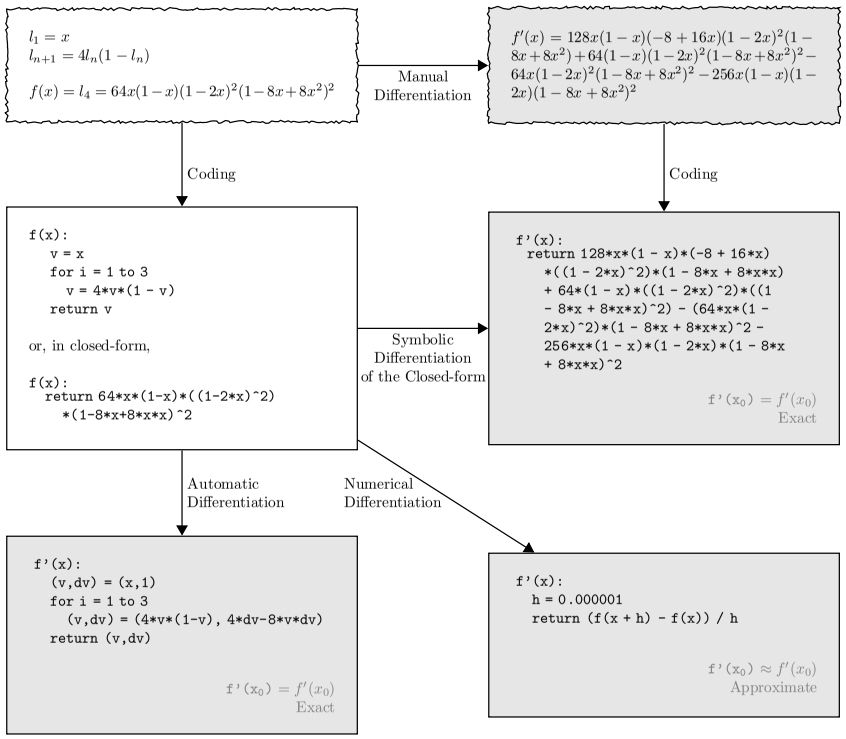

Figure 2: The range of approaches for differentiating mathematical expressions and computer code, looking at the example of a truncated logistic map (upper left). Symbolic differentiation (center right) gives exact results but requires closed-form input and suffers from expression swell; numerical differentiation (lower right) has problems of accuracy due to round-off and truncation errors; automatic differentiation (lower left) is as accurate as symbolic differentiation with only a constant factor of overhead and support for control flow.

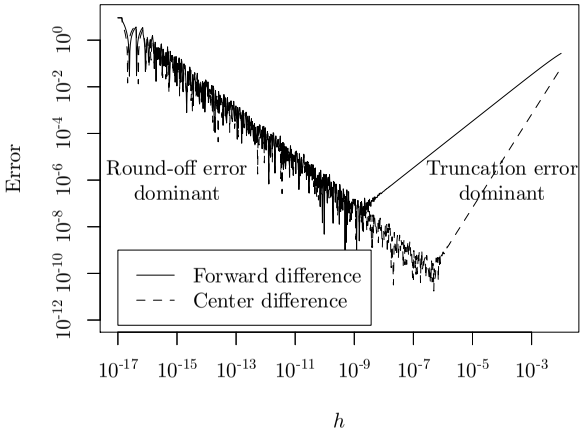

Figure 3: Error in the forward (Eq. 1) and center difference (Eq. 2) approximations as a function of step size h, for the derivative of the truncated logistic map $f(x) = 64x(1-x)(1-2x)^2(1-8x+8x^2)^2$. Plotted errors are computed using $E_{\text{forward}}(h, x_0) = \left|\frac{f(x_0+h)-f(x_0)}{h} - \frac{d}{dx}f(x)\big|_{x_0}\right|$ and $E_{\text{center}}(h, x_0) = \left|\frac{f(x_0+h)-f(x_0-h)}{2h} - \frac{d}{dx}f(x)\big|_{x_0}\right|$ at $x_0 = 0.2$.

round-off[7] errors inflicted by the limited precision of computations and the chosen value of the step size h. Truncation error tends to zero as $h \to 0$. However, as h is decreased, round-off error increases and becomes dominant (Figure 3).

Various techniques have been developed to mitigate approximation errors in numerical differentiation, such as using a center difference approximation

$$\frac{\partial f(\mathbf{x})}{\partial x_i} = \frac{f(\mathbf{x} + h\mathbf{e}_i) - f(\mathbf{x} - h\mathbf{e}_i)}{2h} + O(h^2) \,, \tag{2}$$

where the first-order errors cancel and one effectively moves the truncation error from first-order to second-order in h.[8] For the one-dimensional case, it is just as costly to compute the forward difference (Eq. 1) and the center difference (Eq. 2), requiring only two evaluations of f. However, with increasing dimensionality, a trade-off between accuracy and performance is faced, where computing a Jacobian matrix of a function $f : \mathbb{R}^n \to \mathbb{R}^m$ requires $2mn$ evaluations.

7. Round-off error is the inaccuracy one gets from valuable low-order bits of the final answer having to compete for machine-word space with high-order bits of $f(\mathbf{x}+h\mathbf{e}_i)$ and $f(\mathbf{x})$ (Eq. 1), which the computer has to store just until they cancel in the subtraction at the end. Round-off error is inversely proportional to a power of h.
8. This does not avoid either of the cardinal sins, and is still highly inaccurate due to truncation.

Other techniques for improving numerical differentiation, including higher-order finite differences, Richardson extrapolation to the limit (Brezinski and Zaglia, 1991), and differential quadrature methods using weighted sums (Bert and Malik, 1996), have increased computational complexity, do not completely eliminate approximation errors, and remain highly susceptible to floating point truncation.

The $O(n)$ complexity of numerical differentiation for a gradient in n dimensions is the main obstacle to its usefulness in machine learning, where n can be as large as millions or billions in state-of-the-art deep learning models (Shazeer et al., 2017). In contrast, approximation errors would be tolerated in a deep learning setting thanks to the well-documented error resiliency of neural network architectures (Gupta et al., 2015).

2.2 AD Is Not Symbolic Differentiation

Symbolic differentiation is the automatic manipulation of expressions for obtaining derivative expressions (Grabmeier and Kaltofen, 2003) (Figure 2, center right), carried out by applying transformations representing rules of differentiation such as

$$\begin{aligned} \frac{d}{dx}\left(f(x)+g(x)\right) &\rightsquigarrow \frac{d}{dx}f(x)+\frac{d}{dx}g(x) \\ \frac{d}{dx}\left(f(x)\,g(x)\right) &\rightsquigarrow \left(\frac{d}{dx}f(x)\right)g(x)+f(x)\left(\frac{d}{dx}g(x)\right)\ . \end{aligned} \tag{3}$$

When formulae are represented as data structures, symbolically differentiating an expression tree is a perfectly mechanistic process, considered subject to mechanical automation even at the very inception of calculus (Leibniz, 1685). This is realized in modern computer algebra systems such as Mathematica, Maxima, and Maple and machine learning frameworks such as Theano.

In optimization, symbolic derivatives can give valuable insight into the structure of the problem domain and, in some cases, produce analytical solutions of extrema (e.g., solving for $\frac{d}{dx}f(x)=0$) that can eliminate the need for derivative calculation altogether. On the other hand, symbolic derivatives do not lend themselves to efficient runtime calculation of derivative values, as they can get exponentially larger than the expression whose derivative they represent.

Consider a function $h(x)=f(x)g(x)$ and the multiplication rule in Eq. 3. Since h is a product, $h(x)$ and $\frac{d}{dx}h(x)$ have some common components, namely $f(x)$ and $g(x)$. Note also that on the right hand side, $f(x)$ and $\frac{d}{dx}f(x)$ appear separately. If we just proceeded to symbolically differentiate $f(x)$ and plugged its derivative into the appropriate place, we would have nested duplications of any computation that appears in common between $f(x)$ and $\frac{d}{dx}f(x)$. Hence, careless symbolic differentiation can easily produce exponentially large symbolic expressions which take correspondingly long to evaluate. This problem is known as *expression swell* (Table 1).

When we are concerned with the accurate numerical evaluation of derivatives and not so much with their actual symbolic form, it is in principle possible to significantly simplify computations by storing only the values of intermediate sub-expressions in memory. Moreover, for further efficiency, we can interleave as much as possible the differentiation and simplification steps. This interleaving idea forms the basis of AD and provides an account

Table 1: Iterations of the logistic map $l_{n+1}=4l_n(1-l_n)$, $l_1=x$ and the corresponding derivatives of l_n with respect to x, illustrating expression swell.

n	l_n	$\frac{d}{dx}l_n$	$\frac{d}{dx}l_n$ (Simplified form)
1	x	1	1
2	$4x(1-x)$	$4(1-x)-4x$	$4-8x$
3	$16x(1-x)(1-2x)^2$	$16(1-x)(1-2x)^2-16x(1-2x)^2-64x(1-x)(1-2x)$	$16(1-10x+24x^2-16x^3)$
4	$64x(1-x)(1-2x)^2(1-8x+8x^2)^2$	$128x(1-x)(-8+16x)(1-2x)^2(1-8x+8x^2)+64(1-x)(1-2x)^2(1-8x+8x^2)^2-64x(1-2x)^2(1-8x+8x^2)^2-256x(1-x)(1-2x)(1-8x+8x^2)^2$	$64(1-42x+504x^2-2640x^3+7040x^4-9984x^5+7168x^6-2048x^7)$

of its simplest form: *apply symbolic differentiation at the elementary operation level and keep intermediate numerical results, in lockstep with the evaluation of the main function.* This is AD in the forward accumulation mode, which we shall introduce in the following section.

3. AD and Its Main Modes

AD can be thought of as performing a non-standard interpretation of a computer program where this interpretation involves augmenting the standard computation with the calculation of various derivatives. All numerical computations are ultimately compositions of a finite set of elementary operations for which derivatives are known (Verma, 2000; Griewank and Walther, 2008), and combining the derivatives of the constituent operations through the chain rule gives the derivative of the overall composition. Usually these elementary operations include the binary arithmetic operations, the unary sign switch, and transcendental functions such as the exponential, the logarithm, and the trigonometric functions.

On the left hand side of Table 2 we see the representation of the computation $y=f(x_1,x_2)=\ln(x_1)+x_1x_2-\sin(x_2)$ as an *evaluation trace* of elementary operations—also called a Wengert list (Wengert, 1964). We adopt the three-part notation used by Griewank and Walther (2008), where a function $f:\mathbb{R}^n\to\mathbb{R}^m$ is constructed using intermediate variables v_i such that

- variables $v_{i-n}=x_i,\ i=1,\ldots,n$ are the input variables,
- variables $v_i\ i=1,\ldots,l$ are the working (intermediate) variables, and
- variables $y_{m-i}=v_{l-i},\ i=m-1,\ldots,0$ are the output variables.

Figure 4 shows the given trace of elementary operations represented as a computational graph (Bauer, 1974), useful in visualizing dependency relations between intermediate variables.

Evaluation traces form the basis of the AD techniques. An important point to note here is that AD can differentiate not only closed-form expressions in the classical sense, but also algorithms making use of control flow such as branching, loops, recursion, and procedure

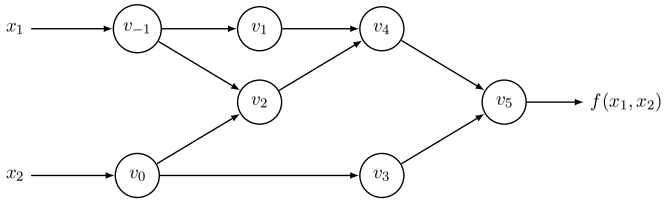

Figure 4: Computational graph of the example $f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$. See the primal trace in Tables 2 or 3 for the definitions of the intermediate variables $v_{-1} \dots v_5$.

calls, giving it an important advantage over symbolic differentiation which severely limits such expressivity. This is thanks to the fact that any numeric code will eventually result in a numeric evaluation trace with particular values of the input, intermediate, and output variables, which are the only things one needs to know for computing derivatives using chain rule composition, regardless of the specific control flow path that was taken during execution. Another way of expressing this is that AD is blind with respect to any operation, including control flow statements, which do not directly alter numeric values.

3.1 Forward Mode

AD in forward accumulation mode[9] is the conceptually most simple type. Consider the evaluation trace of the function $f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$ given on the left-hand side in Table 2 and in graph form in Figure 4. For computing the derivative of f with respect to x_1, we start by associating with each intermediate variable v_i a derivative

$$\dot{v}_i = \frac{\partial v_i}{\partial x_1} .$$

Applying the chain rule to each elementary operation in the forward primal trace, we generate the corresponding tangent (derivative) trace, given on the right-hand side in Table 2. Evaluating the primals v_i in lockstep with their corresponding tangents $\dot{v}_i$ gives us the required derivative in the final variable $\dot{v}_5 = \frac{\partial y}{\partial x_1}$.

This generalizes naturally to computing the Jacobian of a function $f : \mathbb{R}^n \to \mathbb{R}^m$ with n independent (input) variables x_i and m dependent (output) variables y_j. In this case, each forward pass of AD is initialized by setting only one of the variables $\dot{x}_i = 1$ and setting the rest to zero (in other words, setting $\dot{\mathbf{x}} = \mathbf{e}_i$, where $\mathbf{e}_i$ is the i-th unit vector). A run of the code with specific input values $\mathbf{x} = \mathbf{a}$ then computes

$$\dot{y}_j = \left.\frac{\partial y_j}{\partial x_i}\right|_{\mathbf{x}=\mathbf{a}} , \; j = 1, \dots, m ,$$

9. Also called *tangent linear* mode.

Table 2: Forward mode AD example, with $y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$ evaluated at $(x_1, x_2) = (2, 5)$ and setting $\dot{x}_1 = 1$ to compute $\frac{\partial y}{\partial x_1}$. The original forward evaluation of the primals on the left is augmented by the tangent operations on the right, where each line complements the original directly to its left.

Forward Primal Trace			Forward Tangent (Derivative) Trace		
v_{-1}	$= x_1$	$= 2$	$\dot{v}_{-1}$	$= \dot{x}_1$	$= 1$
v_0	$= x_2$	$= 5$	$\dot{v}_0$	$= \dot{x}_2$	$= 0$
v_1	$= \ln v_{-1}$	$= \ln 2$	$\dot{v}_1$	$= \dot{v}_{-1}/v_{-1}$	$= 1/2$
v_2	$= v_{-1} \times v_0$	$= 2 \times 5$	$\dot{v}_2$	$= \dot{v}_{-1} \times v_0 + \dot{v}_0 \times v_{-1}$	$= 1 \times 5 + 0 \times 2$
v_3	$= \sin v_0$	$= \sin 5$	$\dot{v}_3$	$= \dot{v}_0 \times \cos v_0$	$= 0 \times \cos 5$
v_4	$= v_1 + v_2$	$= 0.693 + 10$	$\dot{v}_4$	$= \dot{v}_1 + \dot{v}_2$	$= 0.5 + 5$
v_5	$= v_4 - v_3$	$= 10.693 + 0.959$	$\dot{v}_5$	$= \dot{v}_4 - \dot{v}_3$	$= 5.5 - 0$
y	$= v_5$	$= 11.652$	$\dot{y}$	$= \dot{v}_5$	$= 5.5$

giving us one column of the Jacobian matrix

$$\mathbf{J}_f = \left.\begin{bmatrix} \frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial y_m}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_n} \end{bmatrix}\right|_{\mathbf{x}=\mathbf{a}}$$

evaluated at point $\mathbf{a}$. Thus, the full Jacobian can be computed in n evaluations.

Furthermore, forward mode AD provides a very efficient and matrix-free way of computing Jacobian–vector products

$$\mathbf{J}_f \mathbf{r} = \begin{bmatrix} \frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial y_m}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_n} \end{bmatrix} \begin{bmatrix} r_1 \\ \vdots \\ r_n \end{bmatrix} , \tag{4}$$

simply by initializing with $\dot{\mathbf{x}} = \mathbf{r}$. Thus, we can compute the Jacobian–vector product in just one forward pass. As a special case, when $f : \mathbb{R}^n \to \mathbb{R}$, we can obtain the directional derivative along a given vector $\mathbf{r}$ as a linear combination of the partial derivatives

$$\nabla f \cdot \mathbf{r}$$

by starting the AD computation with the values $\dot{\mathbf{x}} = \mathbf{r}$.

Forward mode AD is efficient and straightforward for functions $f : \mathbb{R} \to \mathbb{R}^m$, as all the derivatives $\frac{dy_i}{dx}$ can be computed with just one forward pass. Conversely, in the other extreme of $f : \mathbb{R}^n \to \mathbb{R}$, forward mode AD requires n evaluations to compute the gradient

$$\nabla f = \left(\frac{\partial y}{\partial x_1}, \dots, \frac{\partial y}{\partial x_n} \right) ,$$

which also corresponds to a $1 \times n$ Jacobian matrix that is built one column at a time with the forward mode in n evaluations.

In general, for cases $f : \mathbb{R}^n \to \mathbb{R}^m$ where $n \gg m$, a different technique is often preferred. We will describe AD in *reverse accumulation mode* in Section 3.2.

3.1.1 Dual Numbers

Mathematically, forward mode AD (represented by the left- and right-hand sides in Table 2) can be viewed as evaluating a function using dual numbers,[10] which can be defined as truncated Taylor series of the form

$$v + \dot{v}\epsilon \,,$$

where $v, \dot{v} \in \mathbb{R}$ and ϵ is a nilpotent number such that $\epsilon^2 = 0$ and $\epsilon \neq 0$. Observe, for example, that

$$\begin{aligned}(v + \dot{v}\epsilon) + (u + \dot{u}\epsilon) &= (v + u) + (\dot{v} + \dot{u})\epsilon \\ (v + \dot{v}\epsilon)(u + \dot{u}\epsilon) &= (vu) + (v\dot{u} + \dot{v}u)\epsilon \,,\end{aligned}$$

in which the coefficients of ϵ conveniently mirror symbolic differentiation rules (e.g., Eq. 3). We can utilize this by setting up a regime where

$$f(v + \dot{v}\epsilon) = f(v) + f'(v)\dot{v}\epsilon \tag{5}$$

and using dual numbers as data structures for carrying the tangent value together with the primal.[11] The chain rule works as expected on this representation: two applications of Eq. 5 give

$$\begin{aligned}f(g(v + \dot{v}\epsilon)) &= f(g(v) + g'(v)\dot{v}\epsilon) \\ &= f(g(v)) + f'(g(v))g'(v)\dot{v}\epsilon \,.\end{aligned}$$

The coefficient of ϵ on the right-hand side is exactly the derivative of the composition of f and g. This means that since we implement elementary operations to respect the invariant Eq. 5, all compositions of them will also do so. This, in turn, means that we can extract the derivative of a function by interpreting any non-dual number v as $v + 0\epsilon$ and evaluating the function in this non-standard way on an initial input with a coefficient 1 for ϵ:

$$\left.\frac{df(x)}{dx}\right|_{x=v} = \text{epsilon-coefficient}(\text{dual-version}(f)(v + 1\epsilon)) \,.$$

This also extends to arbitrary program constructs, since dual numbers, as data types, can be contained in any data structure. As long as a dual number remains in a data structure with no arithmetic operations being performed on it, it will just remain a dual number; and if it is taken out of the data structure and operated on again, then the differentiation will continue.

In practice, a function f coded in a programming language of choice would be fed into an AD tool, which would then augment it with corresponding extra code to handle the dual operations so that the function and its derivative are simultaneously computed. This can be implemented through calls to a specific library, in the form of source code transformation where a given source code will be automatically modified, or through operator overloading, making the process transparent to the user. We discuss these implementation techniques in Section 5.

10. First introduced by Clifford (1873), with important uses in linear algebra and physics.
11. Just as the complex number written $x + yi$ is represented in the computer as a pair in memory (x, y) whose two slots are reals, the dual number written $x + \dot{x}\epsilon$ is represented as the pair $(x, \dot{x})$. Such pairs are sometimes called Argand pairs (Hamilton, 1837, p107 Eqs. (157) and (158)).

3.2 Reverse Mode

AD in the reverse accumulation mode[12] corresponds to a generalized backpropagation algorithm, in that it propagates derivatives backward from a given output. This is done by complementing each intermediate variable v_i with an adjoint

$$\bar{v}_i = \frac{\partial y_j}{\partial v_i} \,,$$

which represents the sensitivity of a considered output y_j with respect to changes in v_i. In the case of backpropagation, y would be a scalar corresponding to the error E (Figure 1).

In reverse mode AD, derivatives are computed in the second phase of a two-phase process. In the first phase, the original function code is run *forward*, populating intermediate variables v_i and recording the dependencies in the computational graph through a bookkeeping procedure. In the second phase, derivatives are calculated by propagating adjoints $\bar{v}_i$ in *reverse*, from the outputs to the inputs.

Returning to the example $y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$, in Table 3 we see the adjoint statements on the right-hand side, corresponding to each original elementary operation on the left-hand side. In simple terms, we are interested in computing the contribution $\bar{v}_i = \frac{\partial y}{\partial v_i}$ of the change in each variable v_i to the change in the output y. Taking the variable v_0 as an example, we see in Figure 4 that the only way it can affect y is through affecting v_2 and v_3, so its contribution to the change in y is given by

$$\frac{\partial y}{\partial v_0} = \frac{\partial y}{\partial v_2}\frac{\partial v_2}{\partial v_0} + \frac{\partial y}{\partial v_3}\frac{\partial v_3}{\partial v_0} \qquad \text{or} \qquad \bar{v}_0 = \bar{v}_2\frac{\partial v_2}{\partial v_0} + \bar{v}_3\frac{\partial v_3}{\partial v_0} \,.$$

In Table 3, this contribution is computed in two incremental steps

$$\bar{v}_0 = \bar{v}_3\frac{\partial v_3}{\partial v_0} \qquad \text{and} \qquad \bar{v}_0 = \bar{v}_0 + \bar{v}_2\frac{\partial v_2}{\partial v_0} \,,$$

lined up with the lines in the forward trace from which these expressions originate.

After the forward pass on the left-hand side, we run the reverse pass of the adjoints on the right-hand side, starting with $\bar{v}_5 = \bar{y} = \frac{\partial y}{\partial y} = 1$. In the end we get the derivatives $\frac{\partial y}{\partial x_1} = \bar{x}_1$ and $\frac{\partial y}{\partial x_2} = \bar{x}_2$ in just one reverse pass.

Compared with the straightforwardness of forward accumulation mode, reverse mode AD can, at first, appear somewhat "mysterious" (Dennis and Schnabel, 1996). Griewank and Walther (2008) argue that this is in part because of the common acquaintance with the chain rule as a mechanistic procedure propagating derivatives forward.

An important advantage of the reverse mode is that it is significantly less costly to evaluate (in terms of operation count) than the forward mode for functions with a large number of inputs. In the extreme case of $f : \mathbb{R}^n \to \mathbb{R}$, only one application of the reverse mode is sufficient to compute the full gradient $\nabla f = \left(\frac{\partial y}{\partial x_1}, \ldots, \frac{\partial y}{\partial x_n}\right)$, compared with the n passes of the forward mode needed for populating the same. Because machine learning practice principally involves the gradient of a scalar-valued objective with respect to a large number of parameters, this establishes the reverse mode, as opposed to the forward mode, as the mainstay technique in the form of the backpropagation algorithm.

12. Also called *adjoint* or *cotangent linear* mode.

Table 3: Reverse mode AD example, with $y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$ evaluated at $(x_1, x_2) = (2, 5)$. After the forward evaluation of the primals on the left, the adjoint operations on the right are evaluated in reverse (cf. Figure 1). Note that both $\frac{\partial y}{\partial x_1}$ and $\frac{\partial y}{\partial x_2}$ are computed in the same reverse pass, starting from the adjoint $\bar{v}_5 = \bar{y} = \frac{\partial y}{\partial y} = 1$.

Forward Primal Trace		Reverse Adjoint (Derivative) Trace		
$v_{-1} = x_1$	$= 2$	$\bar{\boldsymbol{x}}_{\mathbf{1}} = \bar{\boldsymbol{v}}_{\mathbf{-1}}$		$\mathbf{= 5.5}$
$v_0 = x_2$	$= 5$	$\bar{\boldsymbol{x}}_{\mathbf{2}} = \bar{\boldsymbol{v}}_{\mathbf{0}}$		$\mathbf{= 1.716}$
$v_1 = \ln v_{-1}$	$= \ln 2$	$\bar{v}_{-1} = \bar{v}_{-1} + \bar{v}_1 \frac{\partial v_1}{\partial v_{-1}}$	$= \bar{v}_{-1} + \bar{v}_1 / v_{-1}$	$= 5.5$
$v_2 = v_{-1} \times v_0$	$= 2 \times 5$	$\bar{v}_0 = \bar{v}_0 + \bar{v}_2 \frac{\partial v_2}{\partial v_0}$	$= \bar{v}_0 + \bar{v}_2 \times v_{-1}$	$= 1.716$
		$\bar{v}_{-1} = \bar{v}_2 \frac{\partial v_2}{\partial v_{-1}}$	$= \bar{v}_2 \times v_0$	$= 5$
$v_3 = \sin v_0$	$= \sin 5$	$\bar{v}_0 = \bar{v}_3 \frac{\partial v_3}{\partial v_0}$	$= \bar{v}_3 \times \cos v_0$	$= -0.284$
$v_4 = v_1 + v_2$	$= 0.693 + 10$	$\bar{v}_2 = \bar{v}_4 \frac{\partial v_4}{\partial v_2}$	$= \bar{v}_4 \times 1$	$= 1$
		$\bar{v}_1 = \bar{v}_4 \frac{\partial v_4}{\partial v_1}$	$= \bar{v}_4 \times 1$	$= 1$
$v_5 = v_4 - v_3$	$= 10.693 + 0.959$	$\bar{v}_3 = \bar{v}_5 \frac{\partial v_5}{\partial v_3}$	$= \bar{v}_5 \times (-1)$	$= -1$
		$\bar{v}_4 = \bar{v}_5 \frac{\partial v_5}{\partial v_4}$	$= \bar{v}_5 \times 1$	$= 1$
$y = v_5$	$= 11.652$	$\bar{v}_5 = \bar{y}$	$= 1$	

In general, for a function $f : \mathbb{R}^n \to \mathbb{R}^m$, if we denote the operation count to evaluate the original function by $\mathrm{ops}(f)$, the time it takes to calculate the $m \times n$ Jacobian by the forward mode is $n\, c\, \mathrm{ops}(f)$, whereas the same computation can be done via reverse mode in $m\, c\, \mathrm{ops}(f)$, where c is a constant guaranteed to be $c < 6$ and typically $c \sim [2, 3]$ (Griewank and Walther, 2008). That is to say, reverse mode AD performs better when $m \ll n$.

Similar to the matrix-free computation of Jacobian–vector products with forward mode (Eq. 4), reverse mode can be used for computing the transposed Jacobian–vector product

$$\mathbf{J}_f^\intercal \mathbf{r} = \begin{bmatrix} \frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_1} \\ \vdots & \ddots & \vdots \\ \frac{\partial y_1}{\partial x_n} & \cdots & \frac{\partial y_m}{\partial x_n} \end{bmatrix} \begin{bmatrix} r_1 \\ \vdots \\ r_m \end{bmatrix},$$

by initializing the reverse phase with $\bar{\mathbf{y}} = \mathbf{r}$.

The advantages of reverse mode AD, however, come with the cost of increased storage requirements growing (in the worst case) in proportion to the number of operations in the evaluated function. It is an active area of research to improve storage requirements in implementations by using advanced methods such as checkpointing strategies and data-flow analysis (Dauvergne and Hascoët, 2006; Siskind and Pearlmutter, 2017).

3.3 Origins of AD and Backpropagation

Ideas underlying AD date back to the 1950s (Nolan, 1953; Beda et al., 1959). Forward mode AD as a general method for evaluating partial derivatives was essentially discovered

by Wengert (1964). It was followed by a period of relatively low activity, until interest in the field was revived in the 1980s mostly through the work of Griewank (1989), also supported by improvements in modern programming languages and the feasibility of an efficient reverse mode AD.

Reverse mode AD and backpropagation have an intertwined history. The essence of the reverse mode, cast in a continuous-time formalism, is the Pontryagin maximum principle (Rozonoer, 1959; Boltyanskii et al., 1960). This method was understood in the control theory community (Bryson and Denham, 1962; Bryson and Ho, 1969) and cast in more formal terms with discrete-time variables topologically sorted in terms of dependency by Werbos (1974). Prior to Werbos, the work by Linnainmaa (1970, 1976) is often cited as the first published description of the reverse mode. Speelpenning (1980) subsequently introduced reverse mode AD as we know it, in the sense that he gave the first implementation that was actually automatic, accepting a specification of a computational process written in a general-purpose programming language and automatically performing the reverse mode transformation.

Incidentally, Hecht-Nielsen (1989) cites the work of Bryson and Ho (1969) and Werbos (1974) as the two earliest known instances of backpropagation. Within the machine learning community, the method has been reinvented several times, such as by Parker (1985), until it was eventually brought to fame by Rumelhart et al. (1986) and the Parallel Distributed Processing (PDP) group. The PDP group became aware of Parker's work only after their own discovery; similarly, Werbos' work was not appreciated until it was found by Parker (Hecht-Nielsen, 1989). This tells us an interesting story of two highly interconnected research communities that have somehow also managed to stay detached during this foundational period.

For a thorough review of the development of AD, we advise readers to refer to Rall (2006). Interested readers are highly recommended to read Griewank (2012) for an investigation of the origins of the reverse mode and Schmidhuber (2015) for the same for backpropagation.

4. AD and Machine Learning

In the following, we examine the main uses of derivatives in machine learning and report on a selection of works where general-purpose AD, as opposed to just backpropagation, has been successfully applied in a machine learning context. Areas where AD has seen use include optimization, neural networks, computer vision, natural language processing, and probabilistic inference.

4.1 Gradient-Based Optimization

Gradient-based optimization is one of the pillars of machine learning (Bottou et al., 2016). Given an objective function $f : \mathbb{R}^n \to \mathbb{R}$, classical gradient descent has the goal of finding (local) minima $\mathbf{w}^* = \arg\min_{\mathbf{w}} f(\mathbf{w})$ via updates of the form $\Delta\mathbf{w} = -\eta \nabla f$, where $\eta > 0$ is a step size. Gradient-based methods make use of the fact that f decreases steepest if one goes in the direction of the negative gradient. The convergence rate of gradient-based methods is usually improved by adaptive step-size techniques that adjust the step size η on every iteration (Duchi et al., 2011; Schaul et al., 2013; Kingma and Ba, 2015).

Table 4: Evaluation times of the Helmholtz free energy function and its gradient (Figure 5). Times are given relative to that of the original function with both (1) $n = 1$ and (2) n corresponding to each column. (For instance, reverse mode AD with $n = 43$ takes approximately twice the time to evaluate relative to the original function with $n = 43$.) Times are measured by averaging a thousand runs on a machine with Intel Core i7-4785T 2.20 GHz CPU and 16 GB RAM, using DiffSharp 0.5.7. The evaluation time for the original function with $n = 1$ is 0.0023 ms.

	n, number of variables							
	1	8	15	22	29	36	43	50
f, original								
Relative $n = 1$	1	5.12	14.51	29.11	52.58	84.00	127.33	174.44
∇f, numerical diff.								
Relative $n = 1$	1.08	35.55	176.79	499.43	1045.29	1986.70	3269.36	4995.96
Relative n in column	1.08	6.93	12.17	17.15	19.87	23.64	25.67	28.63
∇f, forward AD								
Relative $n = 1$	1.34	13.69	51.54	132.33	251.32	469.84	815.55	1342.07
Relative n in column	1.34	2.66	3.55	4.54	4.77	5.59	6.40	7.69
∇f, reverse AD								
Relative $n = 1$	1.52	11.12	31.37	67.27	113.99	174.62	254.15	342.33
Relative n in column	1.52	2.16	2.16	2.31	2.16	2.07	1.99	1.96

As we have seen, for large n, reverse mode AD provides a highly efficient method for computing gradients.[13] Figure 5 and Table 4 demonstrate how gradient computation scales differently for forward and reverse mode AD and numerical differentiation, looking at the Helmholtz free energy function that has been used in AD literature for benchmarking gradient calculations (Griewank, 1989; Griewank and Walther, 2008; Griewank et al., 2012).

Second-order methods based on Newton's method make use of both the gradient ∇f and the Hessian $\mathbf{H}_f$, working via updates of the form $\Delta\mathbf{w} = -\eta\,\mathbf{H}_f^{-1}\nabla f$ and providing significantly faster convergence (Press et al., 2007). AD provides a way of automatically computing the exact Hessian, enabling succinct and convenient general-purpose implementations.[14] Newton's method converges in fewer iterations, but this comes at the cost of having to compute $\mathbf{H}_f$ in each iteration. In large-scale problems, the Hessian is usually replaced by a numerical approximation using first-order updates from gradient evaluations, giving rise to quasi-Newton methods. A highly popular such method is the BFGS[15] algorithm, together with its limited-memory variant L-BFGS (Dennis and Schnabel, 1996). On the other hand, Hessians arising in large-scale applications are typically sparse. This spar-

13. See `http://DiffSharp.github.io/DiffSharp/examples-gradientdescent.html` for an example of a general-purpose AD-based gradient descent routine using DiffSharp.
14. See `http://DiffSharp.github.io/DiffSharp/examples-newtonsmethod.html` for an implementation of Newton's method with the full Hessian.
15. After Broyden–Fletcher–Goldfarb–Shanno, who independently discovered the method in the 1970s.

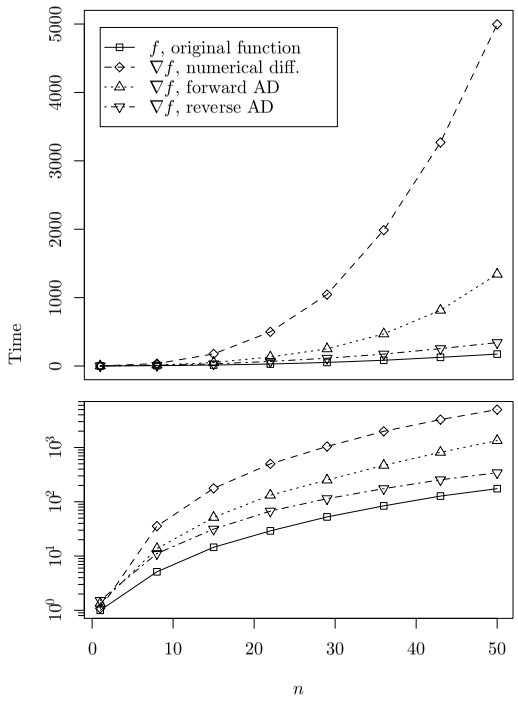

Figure 5: Evaluation time of the Helmholtz free energy function of a mixed fluid, based on the Peng-Robinson equation of state (Peng and Robinson, 1976), $f(\mathbf{x}) = RT\sum_{i=0}^{n}\log\frac{x_i}{1-\mathbf{b^T x}} - \frac{\mathbf{x^T A x}}{\sqrt{8}\mathbf{b^T x}}\log\frac{1+(1+\sqrt{2})\mathbf{b^T x}}{1+(1-\sqrt{2})\mathbf{b^T x}}$, where R is the universal gas constant, T is the absolute temperature, $\mathbf{b} \in \mathbb{R}^n$ is a vector of constants, $\mathbf{A} \in \mathbb{R}^{n\times n}$ is a symmetric matrix of constants, and $\mathbf{x} \in \mathbb{R}^n$ is the vector of independent variables describing the system. The plots show the evaluation time of f and the gradient ∇f with numerical differentiation (central difference), forward mode AD, and reverse mode AD, as a function of the number of variables n. Reported times are relative to the evaluation time of f with $n = 1$. The lower plot uses logarithmic scale for illustrating the behavior for small n. Numerical results are given in Table 4. (Code: `http://DiffSharp.github.io/DiffSharp/misc/Benchmarks-h-grad-v0.5.7.fsx`)

sity along with symmetry can be readily exploited by AD techniques such as computational graph elimination (Dixon, 1991), partial separability (Gay, 1996), and matrix coloring and compression (Gebremedhin et al., 2009).

In many cases one does not need the full Hessian but only a Hessian–vector product $\mathbf{Hv}$, which can be computed efficiently using a reverse-on-forward configuration of AD by applying the reverse mode to take the gradient of code produced by the forward mode.[16] Given the function $f : \mathbb{R}^n \to \mathbb{R}$, the evaluation point $\mathbf{x}$, and the vector $\mathbf{v}$, one can accomplish this by first computing the directional derivative $\nabla f \cdot \mathbf{v}$ through the forward mode via setting $\dot{\mathbf{x}} = \mathbf{v}$ and then applying the reverse mode on this result to get $\nabla^2 f \cdot \mathbf{v} = \mathbf{H}_f \mathbf{v}$ (Pearlmutter, 1994). This computes $\mathbf{Hv}$ with $O(n)$ complexity, even though $\mathbf{H}$ is a $n \times n$ matrix. Availability of robust AD tools may make more sophisticated optimization methods applicable to large-scale machine-learning problems. For instance, when fast stochastic Hessian–vector products are available, these can be used as the basis of stochastic Newton's methods (Agarwal et al., 2016), which have the potential to endow stochastic optimization with quadratic convergence.

Another approach for improving the rate of convergence of gradient-based methods is to use gain adaptation methods such as stochastic meta-descent (SMD) (Schraudolph, 1999), where stochastic sampling is introduced to avoid local minima and reduce the computational expense. An example using SMD with AD Hessian–vector products is given by Vishwanathan et al. (2006) on conditional random fields (CRF). Similarly, Schraudolph and Graepel (2003) use Hessian–vector products in their model combining conjugate gradient techniques with stochastic gradient descent.

4.2 Neural Networks, Deep Learning, Differentiable Programming

Training of a neural network is an optimization problem with respect to its set of weights, which can in principle be addressed by using any method ranging from evolutionary algorithms (Such et al., 2017) to gradient-based methods such as BFGS (Apostolopoulou et al., 2009) or the mainstay stochastic gradient descent (Bottou, 2010) and its many variants (Kingma and Ba, 2015; Tieleman and Hinton, 2012; Duchi et al., 2011). As we have seen, the backpropagation algorithm is only a special case of AD: by applying reverse mode AD to an objective function evaluating a network's error as a function of its weights, we can readily compute the partial derivatives needed for performing weight updates.[17]

The LUSH system (Bottou and LeCun, 2002), and its predecessor SN (Bottou and LeCun, 1988), were the first production systems that targeted efficient neural network simulation while incorporating both a general-purpose programming language and AD. Modern deep learning frameworks provide differentiation capability in one way or another, but the underlying mechanism is not always made clear and confusion abounds regarding the use of the terms "autodiff", "automatic differentiation", and "symbolic differentiation", which

16. Christianson (2012) demonstrates that the second derivative can be computed with the same arithmetic operation sequence using forward-on-reverse, reverse-on-forward, and reverse-on-reverse. The taping overheads of these methods may differ in implementation-dependent ways.
17. See `http://DiffSharp.github.io/DiffSharp/examples-neuralnetworks.html` for an implementation of backpropagation with reverse mode AD.

are sometimes even used interchangeably. In mainstream frameworks including Theano[18] (Bastien et al., 2012), TensorFlow (Abadi et al., 2016), Caffe (Jia et al., 2014), and CNTK (Seide and Agarwal, 2016) the user first constructs a model as a computational graph using a domain-specific mini language, which then gets interpreted by the framework during execution. This approach has the advantage of enabling optimizations of the computational graph structure (e.g., as in Theano), but the disadvantages of having limited and unintuitive control flow and being difficult to debug. In contrast, the lineage of recent frameworks led by autograd (Maclaurin, 2016), Chainer (Tokui et al., 2015), and PyTorch (Paszke et al., 2017) provide truly general-purpose reverse mode AD of the type we outline in Section 3, where the user directly uses the host programming language to define the model as a regular program of the forward computation. This eliminates the need for an interpreter, allows arbitrary control flow statements, and makes debugging simple and intuitive.

Simultaneously with the ongoing adoption of general-purpose AD in machine learning, we are witnessing a modeling-centric terminology emerge within the deep learning community. The terms *define-and-run* and *static computational graph* refer to Theano-like systems where a model is constructed, before execution, as a computational graph structure, which later gets executed with different inputs while remaining fixed. In contrast, the terms *define-by-run* and *dynamic computational graph* refer to the general-purpose AD capability available in newer PyTorch-like systems where a model is a regular program in the host programming language, whose execution dynamically constructs a computational graph on-the-fly that can freely change in each iteration.[19]

Differentiable programming[20] is another emerging term referring to the realization that deep learning models are essentially differentiable program templates of potential solutions to a problem. These templates are constructed as differentiable directed graphs assembled from functional blocks, and their parameters are learned using gradient-based optimization of an objective describing the task. Expressed in this paradigm, neural networks are just a class of parameterized differentiable programs composed of building blocks such as feed-forward, convolutional, and recurrent elements. We are increasingly seeing these traditional building blocks freely composed in arbitrary algorithmic structures using control flow, as well as the introduction of novel differentiable architectures such as the neural Turing machine (Graves et al., 2014), a range of controller–interface abstractions (Graves et al., 2016; Zaremba et al., 2016; Joulin and Mikolov, 2015; Sukhbaatar et al., 2015), and differentiable versions of data structures such as stacks, queues, deques (Grefenstette et al., 2015). Availability of general-purpose AD greatly simplifies the implementation of such architectures by enabling their expression as regular programs that rely on the differentiation infrastructure. Although the differentiable programming perspective on deep learning is new, we note that

18. Theano is a computational graph optimizer and compiler with GPU support and it currently handles derivatives in a highly optimized form of symbolic differentiation. The result can be interpreted as a hybrid of symbolic differentiation and reverse mode AD, but Theano does not use the general-purpose reverse accumulation as we describe in this paper. (Personal communication with the authors.)
19. Note that the terms "static" and "dynamic" here are used in the sense of having a fixed versus non-fixed computational graph topology and not in the sense of data flow architectures.
20. A term advocated by Christopher Olah (`http://colah.github.io/posts/2015-09-NN-Types-FP/`), David Dalrymple (`https://www.edge.org/response-detail/26794`), and Yann LeCun (`https://www.facebook.com/yann.lecun/posts/10155003011462143`) from a deep learning point of view. Note the difference from *differential* dynamic programming (Mayne and Jacobson, 1970) in optimal control.

programming with differentiable functions and having differentiation as a language infrastructure has been the main research subject of the AD community for many decades and realized in a wide range of systems and languages as we shall see in Section 5.

There are instances in neural network literature—albeit few—where explicit reference has been made to AD for computing error gradients, such as Eriksson et al. (1998) using AD for large-scale feed-forward networks, and the work by Yang et al. (2008), where the authors use AD to train a neural-network-based proportional-integral-derivative (PID) controller. Similarly, Rollins (2009) uses reverse mode AD in conjunction with neural networks for the problem of optimal feedback control. Another example is given for continuous time recurrent neural networks (CTRNN) by Al Seyab and Cao (2008), where the authors apply AD for the training of CTRNNs predicting dynamic behavior of nonlinear processes in real time and report significantly reduced training time compared with other methods.

4.3 Computer Vision

Since the influential work by Krizhevsky et al. (2012), computer vision has been dominated by deep learning, specifically, variations of convolutional neural networks (LeCun et al., 1998). These models are trained end-to-end, meaning that a mapping from raw input data to corresponding outputs is learned, automatically discovering the representations needed for feature detection in a process called representation learning (Bengio et al., 2013).

Besides deep learning, an interesting area where AD can be applied to computer vision problems is inverse graphics (Horn, 1977; Hinton and Ghahramani, 1997)—or analysis-by-synthesis (Yildirim et al., 2015)—where vision is seen as the inference of parameters for a generative model of a scene. Using gradient-based optimization in inverse graphics requires propagating derivatives through whole image synthesis pipelines including the renderer. Eslami et al. (2016) use numerical differentiation for this purpose. Loper and Black (2014) implement the Open Differentiable Renderer (OpenDR), which is a scene renderer that also supplies derivatives of the image pixels with respect to scene parameters, and demonstrate it in the task of fitting an articulated and deformable 3D model of the human body to image and range data from a Kinect device. Similarly, Kulkarni et al. (2015) implement a differentiable approximate renderer for the task of inference in probabilistic programs describing scenes.

Srajer et al. (2016) investigate the use of AD for three tasks in computer vision and machine learning, namely bundle adjustment (Triggs et al., 1999), Gaussian mixture model fitting, and hand tracking (Taylor et al., 2014), and provide a comprehensive benchmark of various AD tools for the computation of derivatives in these tasks.

Pock et al. (2007) make use of AD in addressing the problems of denoising, segmentation, and recovery of information from stereoscopic image pairs, and note the usefulness of AD in identifying sparsity patterns in large Jacobian and Hessian matrices. In another study, Grabner et al. (2008) use reverse mode AD for GPU-accelerated medical 2D/3D registration, a task involving the alignment of data from different sources such as X-ray images or computed tomography. The authors report a six-fold increase in speed compared with numerical differentiation using center difference (cf. our benchmark with the Helmholtz function, Figure 5 and Table 4).

Barrett and Siskind (2013) present a use of general-purpose AD for the task of video event detection using hidden Markov models (HMMs) and Dalal and Triggs (2005) object detectors, performing training on a corpus of pre-tracked video using an adaptive step size gradient descent with reverse mode AD. Initially implemented with the R6RS-AD package[21] which provides forward and reverse mode AD in Scheme, the resulting gradient code was later ported to C and highly optimized.[22]

4.4 Natural Language Processing

Natural language processing (NLP) constitutes one of the areas where rapid progress is being made by applying deep learning techniques (Goldberg, 2016), with applications in tasks including machine translation (Bahdanau et al., 2014), language modeling (Mikolov et al., 2010), dependency parsing (Chen and Manning, 2014), and question answering (Kumar et al., 2016). Besides deep learning approaches, statistical models in NLP are commonly trained using general purpose or specialized gradient-based methods and mostly remain expensive to train. Improvements in training time can be realized by using online or distributed training algorithms (Gimpel et al., 2010). An example using stochastic gradient descent for NLP is given by Finkel et al. (2008) optimizing conditional random field parsers through an objective function. Related with the work on video event detection in the previous section, Yu and Siskind (2013) report their work on sentence tracking, representing an instance of grounded language learning paired with computer vision, where the system learns word meanings from short video clips paired with descriptive sentences. The method uses HMMs to represent changes in video frames and meanings of different parts of speech. This work is implemented in C and computes the required gradients using AD through the ADOL-C tool.[23]

4.5 Probabilistic Modeling and Inference

Inference in probabilistic models can be static, such as compiling a given model to Bayesian networks and using algorithms such as belief propagation for inference; or they can be dynamic, executing a model forward many times and computing statistics on observed values to infer posterior distributions. Markov chain Monte Carlo (MCMC) (Neal, 1993) methods are often used for dynamic inference, such as the Metropolis–Hastings algorithm based on random sampling (Chib and Greenberg, 1995). Meyer et al. (2003) give an example of how AD can be used to speed up Bayesian posterior inference in MCMC, with an application in stochastic volatility. Amortized inference (Gershman and Goodman, 2014; Stuhlmüller et al., 2013) techniques based on deep learning (Le et al., 2017; Ritchie et al., 2016) work by training neural networks for performing approximate inference in generative models defined as probabilistic programs (Gordon et al., 2014).

When model parameters are continuous, the Hamiltonian—or, hybrid—Monte Carlo (HMC) algorithm provides improved convergence characteristics avoiding the slow explo-

ration of random sampling, by simulating Hamiltonian dynamics through auxiliary "momentum variables" (Duane et al., 1987). The advantages of HMC come at the cost of requiring gradient evaluations of complicated probability models. AD is highly suitable here for complementing probabilistic modeling, because it relieves the user from the manual derivation of gradients for each model.[24] For instance, the probabilistic programming language Stan (Carpenter et al., 2016) implements automatic Bayesian inference based on HMC and the No-U-Turn sampler (NUTS) (Hoffman and Gelman, 2014) and uses reverse mode AD for the calculation of gradients for both HMC and NUTS (Carpenter et al., 2015). Similarly, Wingate et al. (2011) demonstrate the use of AD as a non-standard interpretation of probabilistic programs enabling efficient inference algorithms. Kucukelbir et al. (2017) present an AD-based method for deriving variational inference (VI) algorithms.

PyMC3 (Salvatier et al., 2016) allows fitting of Bayesian models using MCMC and VI, for which it uses gradients supplied by Theano. Edward (Tran et al., 2016) is a library for deep probabilistic modeling, inference, and criticism (Tran et al., 2017) that supports VI using TensorFlow. Availability of general-purpose AD in this area has enabled new libraries such as Pyro[25] and ProbTorch (Siddharth et al., 2017) for deep *universal* probabilistic programming with support for recursion and control flow, relying, in both instances, on VI using gradients supplied by PyTorch's reverse mode AD infrastructure.

When working with probabilistic models, one often needs to backpropagate derivatives through sampling operations of random variables in order to achieve stochastic optimization of model parameters. The score-function estimator, or REINFORCE (Williams, 1992), method provides a generally applicable unbiased gradient estimate, albeit with high variance. When working with continuous random variables, one can substitute a random variable by a deterministic and differentiable transformation of a simpler random variable, a method known as the "reparameterization trick" (Williams, 1992; Kingma and Welling, 2014; Rezende et al., 2014). For discrete variables, the REBAR (Tucker et al., 2017) method provides a lower-variance unbiased gradient estimator by using continuous relaxation. A generalization of REBAR called RELAX (Grathwohl et al., 2017) works by learning a free-form control variate parameterized by a neural network and is applicable in both discrete and continuous settings.

5. Implementations

It is useful to have an understanding of the different ways in which AD can be implemented. Here we cover major implementation strategies and provide a survey of existing tools.

A principal consideration in any AD implementation is the performance overhead introduced by the AD arithmetic and bookkeeping. In terms of computational complexity, AD guarantees that the amount of arithmetic goes up by no more than a small constant factor (Griewank and Walther, 2008). On the other hand, managing this arithmetic can introduce a significant overhead if done carelessly. For instance, naïvely allocating data structures for holding dual numbers will involve memory access and allocation for every arithmetic operation, which are usually more expensive than arithmetic operations on modern computers.[26] Likewise, using operator overloading may introduce method dispatches with attendant costs, which, compared to raw numerical computation of the original function, can easily amount to a slowdown of an order of magnitude.[27]

Another major issue is the risk of hitting a class of bugs called "perturbation confusion" (Siskind and Pearlmutter, 2005; Manzyuk et al., 2012). This essentially means that if two ongoing differentiations affect the same piece of code, the two formal epsilons they introduce (Section 3.1.1) need to be kept distinct. It is very easy to have bugs—particularly in performance-oriented AD implementations—that confuse these in various ways. Such situations can also arise when AD is nested, that is, derivatives are computed for functions that internally compute derivatives.

Translation of mathematics into computer code often requires attention to numeric issues. For instance, the mathematical expressions $\log(1+x)$ or $\sqrt{x^2+y^2+z^2}$ or $\tan^{-1}(y/x)$ should not be naïvely translated, but rather expressed as `log1p(x)`, `hypot(x,hypot(y,z))`, and `atan2(y,x)`. In machine learning, the most prominent example of this is probably the so-called log-sum-exp trick to improve the numerics of calculations of the form $\log \sum_i \exp x_i$. AD is not immune to such numeric considerations. For example, code calculating $E = \sum_i E_i$, processed by AD, will calculate $\nabla_w E = \sum_i \nabla_w E_i$. If the system is seeking a local minimum of E then $\nabla_w E = \sum_i \nabla_w E_i \to_t 0$, and naïvely adding a set of large numbers whose sum is near zero is numerically fraught. This is to say that AD is not immune to the perils of floating point arithmetic, and can sometimes introduce numeric issues which were not present in the primal calculation. Issues of numeric analysis are outside our present scope, but there is a robust literature on the numerics of AD (e.g., Griewank et al. (2012)) involving using subgradients to allow optimization to proceed despite non-differentiability of the objective, appropriate subgradients and approximations for functions like $|\cdot|$ and $\|\cdot\|_2$ and $\sqrt{\cdot}$ near zero, and a spate of related issues.

One should also be cautious about approximated functions and AD (Sirkes and Tziperman, 1997). In this case, if one has a procedure *approximating* an ideal function, AD always gives the derivative of the procedure that was actually programmed, which may not be a good approximation of the derivative of the ideal function that the procedure was approximating. For instance, consider e^x computed by a piecewise-rational approximation routine. Using AD on this routine would produce an approximated derivative in which each piece of the piecewise formula will get differentiated. Even if this would remain an approximation of the derivative of e^x, we know that $\frac{de^x}{dx} = e^x$ and the original approximation itself was already a better approximation for the derivative of e^x.[28] Users of AD implementations must be therefore cautious to *approximate the derivative, not differentiate the approximation.* This would require explicitly approximating a known derivative, in cases where a mathe-

24. See `http://diffsharp.github.io/DiffSharp/examples-hamiltonianmontecarlo.html` for an implementation of HMC with reverse mode AD.
25. `http://pyro.ai/`
26. The implementation of forward mode in Julia (Revels et al., 2016b) attempts to avoid this, and some current compilers can avoid this expense by unboxing dual numbers (Leroy, 1997; Jones et al., 1993b; Jones and Launchbury, 1991; Siskind and Pearlmutter, 2016). This method is also used to reduce the memory-access overhead in the implementations of forward mode in Stalingrad and the Haskell *ad* library.
27. Flow analysis (Shivers, 1991) and/or partial evaluation (Jones et al., 1993a), together with tag stripping (Appel, 1989; Peterson, 1989), can remove this method dispatch. These, together with unboxing, can often make it possible to completely eliminate the memory access, memory allocation, memory reclamation, and method dispatch overhead of dual numbers (Siskind and Pearlmutter, 2016).
28. In modern systems this is not an issue, because e^x is a primitive implemented in hardware.

matical function can only be computed approximately but has a well-defined mathematical derivative.

We note that there are similarities as well as differences between machine learning workloads and those studied in the traditional AD literature (Baydin et al., 2016b). Deep learning systems are generally compute-bound and spend a considerable amount of computation time in highly-optimized numerical kernels for matrix operations (Hadjis et al., 2015; Chetlur et al., 2014). This is a situation which is arguably amenable to operator-overloading-based AD implementations on high-level operations, as is commonly found in current machine learning frameworks. In contrast, numerical simulation workloads in traditional AD applications can be bandwidth-bound, making source code transformation and compiler optimization approaches more relevant. Another difference worth noting is that whereas high numerical precision is desirable in traditional application domains of AD such as computational fluid dynamics (Cohen and Molemaker, 2009), in deep learning lower-precision is sufficient and even desirable in improving computational efficiency, thanks to the error resiliency of neural networks (Gupta et al., 2015; Courbariaux et al., 2015).

There are instances in recent literature where implementation-related experience from the AD field has been put to use in machine learning settings. One particular area of recent interest is implicit and iterative AD techniques (Griewank and Walther, 2008), which has found use in work incorporating constrained optimization within deep learning (Amos and Kolter, 2017) and probabilistic graphical models and neural networks (Johnson et al., 2016). Another example is checkpointing strategies (Dauvergne and Hascoët, 2006; Siskind and Pearlmutter, 2017), which allow balancing of application-specific trade-offs between time and space complexities of reverse mode AD by not storing the full tape of intermediate variables in memory and reconstructing these as needed by re-running parts of the forward computation from intermediate checkpoints. This is highly relevant in deep learning workloads running on GPUs with limited memory budgets. A recent example in this area is the work by Gruslys et al. (2016), where the authors construct a checkpointing variety of the backpropagation through time (BPTT) algorithm for recurrent neural networks and demonstrate it saving up to 95% memory usage at the cost of a 33% increase in computation time in one instance.

In Table 5 we present a review of notable general-purpose AD implementations.[29] A thorough taxonomy of implementation techniques was introduced by Juedes (1991), which was later revisited by Bischof et al. (2008) and simplified into *elemental*, *operator overloading*, *compiler-based*, and *hybrid* methods. We adopt a similar classification for the following part of this section.

5.1 Elemental Libraries

These implementations form the most basic category and work by replacing mathematical operations with calls to an AD-enabled library. Methods exposed by the library are then used in function definitions, meaning that the decomposition of any function into elementary operations is done manually when writing the code.

The approach has been utilized since the early days of AD, with prototypical examples being the WCOMP and UCOMP packages of Lawson (1971), the APL package of Neidinger

29. Also see the website `http://www.autodiff.org/` for a list of tools maintained by the AD community.

Table 5: Survey of AD implementations. Tools developed primarily for machine learning are highlighted in bold.

(1989), and the work by Hinkins (1994). Likewise, Rich and Hill (1992) formulate their implementation of AD in MATLAB using elemental methods.

Elemental libraries still constitute the simplest strategy to implement AD for languages without operator overloading.

5.2 Compilers and Source Code Transformation

These implementations provide extensions to programming languages that automate the decomposition of algorithms into AD-enabled elementary operations. They are typically executed as preprocessors[30] to transform the input in the extended language into the original language.

Classical instances of source code transformation include the Fortran preprocessors GRESS (Horwedel et al., 1988) and PADRE2 (Kubo and Iri, 1990), which transform AD-enabled variants of Fortran into standard Fortran 77 before compiling. Similarly, the ADIFOR tool (Bischof et al., 1996), given a Fortran source code, generates an augmented code in which all specified partial derivatives are computed in addition to the original result. For procedures coded in ANSI C, the ADIC tool (Bischof et al., 1997) implements AD as a source code transformation after the specification of dependent and independent variables. A recent and popular tool also utilizing this approach is Tapenade (Pascual and Hascoët, 2008; Hascoët and Pascual, 2013), implementing forward and reverse mode AD for Fortran and C programs. Tapenade itself is implemented in Java and can be run locally or as an online service.[31]

In addition to language extensions through source code transformation, there are implementations introducing new languages with tightly integrated AD capabilities through special-purpose compilers or interpreters. Some of the earliest AD tools such as SLANG (Adamson and Winant, 1969) and PROSE (Pfeiffer, 1987) belong to this category. The NAGWare Fortran 95 compiler (Naumann and Riehme, 2005) is a more recent example, where the use of AD-related extensions triggers automatic generation of derivative code at compile time.

As an example of interpreter-based implementation, the algebraic modeling language AMPL (Fourer et al., 2002) enables objectives and constraints to be expressed in mathematical notation, from which the system deduces active variables and arranges the necessary AD computations. Other examples in this category include the FM/FAD package (Mazourik, 1991), based on the Algol-like DIFALG language, and the object-oriented COSY language (Berz et al., 1996) similar to Pascal.

The Stalingrad compiler (Pearlmutter and Siskind, 2008; Siskind and Pearlmutter, 2008a), working on the Scheme-based AD-aware VLAD language, also falls under this category. The newer DVL compiler[32] is based on Stalingrad and uses a reimplementation of portions of the VLAD language.

Motivated by machine learning applications, the Tangent library (van Merriënboer et al., 2017) implements AD using source code transformation, and accepts numeric functions written in a syntactic subset of Python and Numpy.

30. Preprocessors transform program source code before it is given as an input to a compiler.

5.3 Operator Overloading

In modern programming languages with polymorphic features, operator overloading provides the most straightforward way of implementing AD, exploiting the capability of redefining elementary operation semantics.

A popular tool implemented with operator overloading in C++ is ADOL-C (Walther and Griewank, 2012). ADOL-C requires the use of AD-enabled types for variables, and records arithmetic operations on variables in tape data structures, which can subsequently be "played back" during reverse mode AD computations. The Mxyzptlk package (Michelotti, 1990) is another example for C++ capable of computing arbitrary-order partial derivatives via forward propagation. The FADBAD++ library (Bendtsen and Stauning, 1996) implements AD for C++ using templates and operator overloading. For Python, the *ad* package[33] uses operator overloading to compute first- and second-order derivatives, while the newer autograd package[34] provides forward and reverse mode AD with support for higher-order derivatives.

For functional languages, examples include R6RS-AD[35] and the AD routines within the Scmutils library[36] for Scheme, the *ad* library[37] for Haskell, and DiffSharp[38] for F# and C#.

6. Conclusions

Backpropagation and gradient-based optimization are behind virtually all recent successes in machine learning, yielding state-of-the-art results in computer vision, speech recognition and synthesis, and machine translation. We expect these techniques to remain at the core of machine learning for the foreseeable future. Research in the field involves a rapid prototyping and development cycle for testing new models and ideas, using a collection of increasingly higher-quality machine learning frameworks. These frameworks are in the process of transition from coarse-grained (module level) backpropagation towards fine-grained, general-purpose AD, allowing models to be implemented as regular programs in general-purpose programming languages with differentiation as an integral part of the infrastructure. We strongly believe that general-purpose AD is the future of gradient-based machine learning and we expect it to become an indispensable tool in the machine learning toolbox.

It is an exciting time for working at the intersection of AD and machine learning, and there are many opportunities for bringing advanced techniques and expertise from AD literature to bear on machine learning problems. Techniques that have been developed by the AD community such as tape reduction and elimination (Naumann, 2004), fixed-point iterations (Christianson, 1994), utilizing sparsity by matrix coloring (Gebremedhin et al., 2009, 2013), and reverse AD checkpointing (Dauvergne and Hascoët, 2006) are just a few examples that can find potential use in machine learning for increasing performance, improving convergence of optimization, using hardware more efficiently, and even enabling

new types of machine learning models to be implemented. Similarly, exciting new AD modes like direct propagation of the inverse Jacobian (Srinivasan and Todorov, 2015) have emerged from the machine learning community, but have yet to be examined and formalized by the AD community.

An important direction for future work is to make use of nested AD techniques in machine learning, allowing differentiation to be nested arbitrarily deep with referential transparency (Siskind and Pearlmutter, 2008b; Pearlmutter and Siskind, 2008). Nested AD is highly relevant in hyperparameter optimization as it can effortlessly provide exact hypergradients, that is, derivatives of a training objective with respect to the hyperparameters of an optimization routine (Maclaurin et al., 2015; Baydin et al., 2018). Potential applications include Bayesian model selection (Rasmussen and Williams, 2006) and gradient-based tuning of Hamiltonian Monte Carlo step sizes and mass matrices (Salimans et al., 2015). Besides hyperparameters, models internally using higher-order derivatives constitute a straightforward usage case for nested AD. The Riemannian manifold Langevin and Hamiltonian Monte Carlo methods (Girolami and Calderhead, 2011) use higher-order derivative information to more closely track the information geometry of the sampled distribution for faster convergence and exploration. In neural networks, it is very natural to use nested derivatives in defining objective functions that take input transformations into account, such as the Tangent Prop method (Simard et al., 1998) for imposing invariance under a set of chosen transformations.

Abstract

Consider the problem of sampling sequentially from a finite number of $N \geqslant 2$ populations, specified by random variables X_k^i, $i = 1,\ldots,N$, and $k = 1,2,\ldots$; where X_k^i denotes the outcome from population i the k^{th} time it is sampled. It is assumed that for each fixed i, $\{X_k^i\}_{k\geqslant 1}$ is a sequence of i.i.d. normal random variables, with unknown mean μ_i and unknown variance σ_i^2. The objective is to have a policy π for deciding from which of the N populations to sample from at any time $t = 1,2,\ldots$ so as to maximize the expected sum of outcomes of n total samples or equivalently to minimize the regret due to lack on information of the parameters μ_i and σ_i^2. In this paper, we present a simple inflated sample mean (ISM) index policy that is asymptotically optimal in the sense of Theorem 4 below. This resolves a standing open problem from Burnetas and Katehakis (1996b). Additionally, finite horizon regret bounds are given.

Keywords: Inflated Sample Means, UCB policies, Multi-armed Bandits, Sequential Allocation

1. Introduction and Summary

Consider the problem of a controller sampling sequentially from a finite number of $N \geqslant 2$ populations or 'bandits', where the measurements from population i are specified by a sequence of i.i.d. random variables $\{X_k^i\}_{k\geqslant 1}$, taken to be normal with finite mean μ_i and finite variance σ_i^2. The means $\{\mu_i\}$ and variances $\{\sigma_i^2\}$ are taken to be unknown to the controller. It is convenient to define the maximum mean, $\mu^* = \max_i\{\mu_i\}$, and the bandit discrepancies $\{\Delta_i\}$ where $\Delta_i = \mu^* - \mu_i \geqslant 0$. It is additionally convenient to define σ_*^2 as the minimal variance of any bandit that achieves μ^*, that is $\sigma_*^2 = \min_{i:\mu_i=\mu^*}\sigma_i^2$.

In this paper, given k samples from population i we will take the estimators: $\bar{X}_k^i = \sum_{t=1}^k X_t^i/k$ and $S_i^2(k) = \sum_{t=1}^k \left(X_t^i - \bar{X}_k^i\right)^2/k$ for μ_i and σ_i^2 respectively. Note that the use of the biased estimator for the variance, with the $1/k$ factor in place of $1/(k-1)$, is largely for aesthetic purposes - the results presented here adapt to the use of the unbiased estimator as well.

For any adaptive, non-anticipatory policy π, $\pi(t) = i$ indicates that the controller samples bandit i at time t. Define $T_\pi^i(n) = \sum_{t=1}^n \mathbb{1}\{\pi(t) = i\}$, denoting the number of times bandit i has been sampled during the periods $t = 1,\ldots,n$ under policy π; we take, as a convenience, $T_\pi^i(0) = 0$ for all i,π. The *value* of a policy π is the expected sum of the first n outcomes under π, which we define to be the function $V_\pi(n)$:

$$V_\pi(n) = \mathbb{E}\left[\sum_{i=1}^N \sum_{k=1}^{T_\pi^i(n)} X_k^i\right] = \sum_{i=1}^N \mu_i \mathbb{E}\left[T_\pi^i(n)\right], \tag{1}$$

where for simplicity the dependence of $V_\pi(n)$ on the true, unknown, values of the parameters $\underline{\mu} = (\mu_1,\ldots,\mu_N)$ and $\underline{\sigma}^2 = (\sigma_1^2,\ldots,\sigma_N^2)$, is supressed. The *pseudo-regret*, or simply *regret*, of a policy is taken to be the expected loss due to ignorance of the parameters $\underline{\mu}$ and $\underline{\sigma}^2$ by the controller. Had the controller complete information, she would at every round activate some bandit i^* such that $\mu_{i^*} = \mu^* = \max_i\{\mu_i\}$. For a given policy π, we define the expected regret of that policy at time n as

$$R_\pi(n) = n\mu^* - V_\pi(n) = \sum_{i=1}^n \Delta_i \mathbb{E}\left[T_\pi^i(n)\right]. \tag{2}$$

It follows from Eqs. (1) and (2) that maximization of $V_\pi(n)$ with respect to π is equivalent to minimization of $R_\pi(n)$. This type of loss due to ignorance of the means (regret) was first introduced in the context of an $N = 2$ problem by Robbins (1952) as the 'loss per trial' $L_\pi(n)/n = \mu^* - \sum_{i=1}^N \sum_{k=1}^{T_\pi^i(n)} X_k^i/n$ (for which $R_\pi(n) = \mathbb{E}[L_\pi(n)]$). Robbins constructed a modified (along two sparse sequences) 'play the winner' policy, π_R, such that for all choices of bandit parameters, $L_{\pi_R}(n) = o(n)$ (a.s.) and $R_{\pi_R}(n) = o(n)$, using for his derivation only the assumption of the Strong Law of Large Numbers. Following Burnetas and Katehakis (1996b) when $n \to \infty$, if π is such that $R_\pi(n) = o(n)$ for all choices of bandit parameters, we say policy π is ***uniformly convergent*** (UC) (since then $\lim_{n\to\infty} V_\pi(n)/n = \mu^*$). However, if under a policy π, $R_\pi(n)$ grew at a slower pace, such as $R_\pi(n) = o(n^{1/2})$, or better $R_\pi(n) = o(n^{1/100})$ etc., then the controller would be assured that π is making an effective trade-off between exploration and exploitation. It turns out that it is possible to construct ***'uniformly fast convergent'*** (UFC) policies, also known as *consistent* or *strongly consistent*, defined

as the policies π for which:

$$R_\pi(n) = o(n^\alpha), \text{ for all } \alpha > 0 \text{ for all } (\underline{\mu}, \underline{\sigma}^2).$$

For clarification, it is worth noting here that while a naive policy such as 'always activate bandit 1' will have 0 regret for some choices of $(\underline{\mu}, \underline{\sigma}^2)$ (in particular, those for which $\mu_1 = \mu^*$), such a policy will have linear regret for any other choice of $(\underline{\mu}, \underline{\sigma}^2)$ and hence cannot be a UFC policy.

The existence of UFC policies in the case considered here is well established, e.g., Auer et al. (2002) (Fig. 4 therein) presented the following UFC policy π_{ACF}:

Policy π_{ACF} (UCB1-NORMAL). At each $n = 1, 2, \ldots$:

i) Sample from any bandit i for which $T^i_{\pi_{\text{ACF}}}(n) < \lceil 8 \ln n \rceil$.

ii) If $T^i_{\pi_{\text{ACF}}}(n) > \lceil 8 \ln n \rceil$, for all $i = 1, \ldots, N$, sample from bandit $\pi_{\text{ACF}}(n+1)$ with

$$\pi_{\text{ACF}}(n+1) = \arg\max_i \left\{ \bar{X}^i_{T^i_\pi(n)} + 4 \cdot S_i(T^i_\pi(n)) \sqrt{\frac{\ln n}{T^i_\pi(n)}} \right\}. \quad (3)$$

(Taking, in this case, $S_i^2(k)$ as the unbiased estimator.)

Additionally, Auer et al. (2002) (in Theorem 4 therein) gave the following bound:

$$R_{\pi_{\text{ACF}}}(n) \leqslant M_{\text{ACF}}(\underline{\mu}, \underline{\sigma}^2) \ln n + C_{\text{ACF}}(\underline{\mu}), \text{ for all } n \text{ and all } (\underline{\mu}, \underline{\sigma}^2), \quad (4)$$

with

$$M_{\text{ACF}}(\underline{\mu}, \underline{\sigma}^2) = 256 \sum_{i:\mu_i \neq \mu^*} \frac{\sigma_i^2}{\Delta_i} + 8 \sum_{i=1}^N \Delta_i, \quad (5)$$

$$C_{\text{ACF}}(\underline{\mu}) = (1 + \frac{\pi^2}{2}) \sum_{i=1}^N \Delta_i. \quad (6)$$

Ineq. (4) readily implies that $R_{\pi_{\text{ACF}}}(n) \leqslant M_{\text{ACF}}(\underline{\mu}, \underline{\sigma}^2) \ln n + o(\ln n)$. Thus, since $\ln n = o(n^\alpha)$ for all $\alpha > 0$ and $R_{\pi_{\text{ACF}}}(n) \geqslant 0$, it follows that π_{ACF} is uniformly fast convergent.

Given that UFC policies exist, the question immediately follows: just how fast can they be? The primary motivation of this paper is the following general result, from Burnetas and Katehakis (1996b), which leveraged the UFC property to establish an asymptotic lower bound on the growth of regret for any such policy π, as well as determining a constant associated with that growth, i.e, that for any UFC policy π, the following holds:

$$\liminf_{n\to\infty} \frac{R_\pi(n)}{\ln n} \geqslant \mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2), \text{ for all } (\underline{\mu}, \underline{\sigma}^2), \quad (7)$$

where the bound itself $\mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2)$ is determined by the specific distributions of the populations, in this case

$$\mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2) = \sum_{i:\mu_i \neq \mu^*} \frac{2\Delta_i}{\ln\left(1 + \frac{\Delta_i^2}{\sigma_i^2}\right)}. \quad (8)$$

For comparison, depending on the specifics of the bandit distributions, there can be considerable distance between the logarithmic term of the upper bound of Eq. (4) and the lower bound implied by Ineq. (7).

The derivation of Ineq. (7) implies that in order to guarantee that a policy is uniformly fast convergent, sub-optimal populations have to be sampled at least a logarithmic number of times. The above bound is a special case of a more general result derived in Burnetas and Katehakis (1996b) (part 1 of Theorem 1 therein) for distributions with multi-parameters $\underline{\theta}$ being unknown:

$$\mathbb{M}_{\text{BK}}(\underline{\theta}) = \sum_{i:\mu_i \neq \mu^*} \frac{\Delta_i}{\mathbb{K}(\underline{\theta}^i, \mu^*)}, \quad (9)$$

where

$$\mathbb{K}(\underline{\theta}, \mu^*) = \inf_{\underline{\theta}'} \{ \mathbb{I}(f_{\underline{\theta}}; f_{\underline{\theta}'}) : \mu(\underline{\theta}') > \mu^* \}, \quad (10)$$

taking $\mathbb{I}(f; g)$ to represent the Kullback-Leibler divergence between densities f and g. For the case of normal distributions with unknown means and variances, the derivation of Eq. (8) from Eq. (9) is given as Proposition 7 in the Appendix.

Previously, Lai and Robbins (1985) had obtained a lower bound for distributions with one-parameter (such as in the current problem of Normal populations with unknown mean but known variance), policies that achieved the lower bound were called ***asymptotically efficient*** or ***asymptotically optimal***.

Ineq. (7) motivates the definition of a uniformly fast convergent policy π as having a ***uniformly maximal convergence rate*** (UM) or simply being *asymptotically optimal*, within the class of uniformly fast convergent policies, if $\lim_{n\to\infty} R_\pi(n)/\ln n = \mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2)$, since then $V_\pi(n) = n\mu^* - \mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2) \ln n + o(\ln n)$.

Burnetas and Katehakis (1996b) proposed the following index policy π_{BK} as one that could achieve this lower bound:

Policy π_{BK} (ISM-NORMAL^0)

i) For $n = 1, 2, \ldots, 2N$ sample each bandit twice, and

ii) for $n \geqslant 2N$, sample from bandit $\pi_{\text{BK}}(n+1)$ with

$$\pi_{\text{BK}}(n+1) = \arg\max_i \left\{ \bar{X}^i_{T^i_\pi(n)} + S_i(T^i_\pi(n)) \sqrt{n^{\frac{2}{T^i_\pi(n)}} - 1} \right\}. \quad (11)$$

Burnetas and Katehakis (1996b) were not able to establish the asymptotic optimality of the π_{BK} policy because they were not able to establish a sufficient condition (*Condition* A3 therein), which we express here as the following equivalent conjecture (the referenced open question in the Abstract).

Conjecture 1 *For each i, for every $\varepsilon > 0$, and for $k \to \infty$, the following is true:*

$$\mathbb{P}\left(\bar{X}^i_j + S_i(j)\sqrt{k^{2/j}-1} < \mu_i - \varepsilon \text{ for some } 2 \leqslant j \leqslant k\right) = o(1/k). \tag{12}$$

We show that the above conjecture is *false*, cf. Proposition 9 in the Appendix. In addition, it will follow as a result of Theorem 2 that $R_{\pi_{\text{BK}}} \geqslant O(\sqrt{n})$, i.e., π_{BK} fails to be asymptotically optimal.

One of the central results of this paper is to establish that with a small change (though with large effect), the policy π_{BK} may be modified to one that is provably asymptotically optimal. We introduce in this paper the policy π_{CHK} defined as follows

Policy π_{CHK} (ISM-NORMAL^2)

i) For $n = 1, 2, \ldots, 3N$ sample each bandit three times, and

ii) for $n \geqslant 3N$, sample from bandit $\pi_{\text{CHK}}(n+1)$ with

$$\pi_{\text{CHK}}(n+1) = \arg\max_i \left\{ \bar{X}^i_{T^i_\pi(n)} + S_i(T^i_\pi(n))\sqrt{n^{\frac{2}{T^i_\pi(n)-2}}-1} \right\}. \tag{13}$$

Note that the policy π_{CHK} is only a slight modification of π_{BK}, introducing a -2 in the power of n under the radical. This change is seemingly asymptotically negligible, as in practice, $T^i_{\pi_{\text{BK}}}(n) \to \infty$ (a.s.) with n. It will be shown that not only is π_{CHK} asymptotically optimal (Theorem 5 below), but also:

Theorem 2 *Consider a policy $\pi_{(a,b)}$, with $a > b$, that initially samples each bandit a times, then successively activates bandits according to the maximal index* $\arg\max_i u_i(n, T^i_{\pi_{(a,b)}}(n))$ *where*

$$u_i(n,k) = \bar{X}^i_k + S_i(k)\sqrt{n^{\frac{2}{k-b}}-1}. \tag{14}$$

Then, if the optimal bandit is unique, for $b < 1$,

$$R_{\pi_{(a,b)}} \geqslant O(n^{\frac{1-b}{a-b}}). \tag{15}$$

The proof is given in the Appendix.

Remark 1. 1) We note that the indices of policy π_{CHK} are a significant modification of those of the optimal allocation policy $\pi_{\underline{\sigma}^2}$ for the case of normal bandits with *known* variances,

cf. Burnetas and Katehakis (1996b) and Katehakis and Robbins (1995), which are:

$$\pi_{\underline{\sigma}^2}(n+1) = \arg\max_i \left\{ \bar{X}^i_{T^i_\pi(n)} + \sigma_i\sqrt{\frac{2\ln n}{T^i_\pi(n)}} \right\}$$

the difference being replacing the term $\sigma_i\sqrt{\frac{2\ln n}{T^i_\pi(n)}}$ in $\pi_{\underline{\sigma}^2}$ by $S_i(T^i_\pi(n))\sqrt{n^{\frac{2}{T^i_\pi(n)-2}}-1}$ in π_{CHK}. However, the upper confidence bounds used in policy π_{ACF} are a minor modification of the optimal policy $\pi_{\underline{\sigma}^2}$ the difference being replacing the term $\sigma_i\sqrt{\frac{2\ln n}{T^i_\pi(n)}}$ in $\pi_{\underline{\sigma}^2}$ by $S_i(T^i_\pi(n))\sqrt{\frac{16\ln n}{T^i_\pi(n)}}$ in π_{ACF}.

2) The π_{BK} and $\pi_{\underline{\sigma}^2}$ policies can be seen as connected in the following way, however, observing that $2\ln n/T^i_\pi(n)$ is a first-order approximation of $n^{2/T^i_\pi(n)} - 1 = e^{2\ln n/T^i_\pi(n)} - 1$.

Following Robbins (1952), and additionally Gittins (1979), Lai and Robbins (1985) and Weber (1992) there is a large literature on versions of this problem, cf. Burnetas and Katehakis (2003), Burnetas and Katehakis (1997b) and references therein. For recent work in this area we refer to Audibert et al. (2009), Auer and Ortner (2010), Gittins et al. (2011), Bubeck and Slivkins (2012), Cappé et al. (2013), Kaufmann (2015), Li et al. (2014), Cowan and Katehakis (2015b), Cowan and Katehakis (2015c), and references therein. For more general dynamic programming extensions we refer to Burnetas and Katehakis (1997a), Butenko et al. (2003), Tewari and Bartlett (2008), Audibert et al. (2009), Littman (2012), Abbasi et al. (2013),Feinberg et al. (2014) and references therein. Other related work in this area includes: Burnetas and Katehakis (1993), Burnetas and Katehakis (1996a), Lagoudakis and Parr (2003), Bartlett and Tewari (2009), Tekin and Liu (2012), Jouini et al. (2009), Dayanik et al. (2013), Filippi et al. (2010), Osband and Van Roy (2014), Denardo et al. (2013).

To our knowledge, outside the work in Lai and Robbins (1985), Burnetas and Katehakis (1996b) and Burnetas and Katehakis (1997a), asymptotically optimal policies have only been developed in in Honda and Takemura (2011), and in Honda and Takemura (2010) for the problem of finite known support where optimal policies, cyclic and randomized, that are simpler to implement than those consider in Burnetas and Katehakis (1996b) were constructed. Recently in Cowan and Katehakis (2015a), an asymptotically optimal policy for uniform bandits of unknown support was constructed. The question of whether asymptotically optimal policies exist in the case discussed herein of normal bandits with unknown means and unknown variances was recently resolved in the positive by Honda and Takemura (2013) who demonstrated that a form of Thompson sampling with certain priors on $(\underline{\mu}, \underline{\sigma}^2)$ achieves the asymptotic lower bound $\mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2)$.

The structure of the rest of the paper is as follows. In Section 2, Theorem 4 establishes a finite horizon bound on the regret of π_{CHK}. From this bound, it follows that π_{CHK} is asymptotically optimal (Theorem 5), and we provide a bound on the remainder term (Theorem 6).

Additionally, in Section 3, the Thompson sampling policy of Honda and Takemura (2013) and π_{CHK} are compared and discussed, as both achieve asymptotic optimality.

2. The Optimality Theorem and Finite Time Bounds

The main results of this paper, that Conjecture 1 is false (cf. Proposition 9 in the Appendix), the asymptotic optimality, and the bounds on the behavior of π_{CHK}, all depend on the following probability bounds; we note that tighter bounds seem possible, but these are sufficient for the proof of the main Theorem.

Proposition 3 *Let Z, U be independent random variables, $Z \sim N(0,1)$ a standard normal, and $U \sim \chi^2_d$ a chi-squared distribution with d degrees of freedom, where $d \geqslant 2$.*

For $\delta > 0$, $p > 0$, the following holds for all $k \geqslant 1$:

$$\frac{1}{2}\mathbb{P}\left(\frac{1}{4}Z^2 \geqslant U \geqslant \delta^2\right) k^{-d/p} \leqslant \mathbb{P}\left(\delta + \sqrt{U}\sqrt{k^{2/p}-1} < Z\right) \leqslant \frac{e^{-(1+\delta^2)/2} p}{2\delta^2\sqrt{d}} \frac{k^{(1-d)/p}}{\ln k}. \quad (16)$$

The proof is given in the Appendix. The bounds provided by this proposition are hardly intuitive, and it is not clear that they are of any particular interest in their own right. However, the order results for the dependence on k, p, and d allow the analysis of this paper to go through.

Theorem 4 *For policy π_{CHK} as defined above, under any choice of bandit parameters, the following bounds hold for all $n \geqslant 3N$ and all $\varepsilon \in (0,1)$:*

$$R_{\pi_{CHK}}(n) \leqslant \sum_{i:\mu_i \neq \mu^*} \left(\frac{2\ln n}{\ln\left(1 + \frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + \sqrt{\frac{\pi}{2e}}\frac{8\sigma_*^3}{\Delta_i^3\varepsilon^3}\ln\ln n + \frac{8}{\varepsilon^2} + \frac{8\sigma_i^2}{\Delta_i^2\varepsilon^2} + 3 \right) \Delta_i. \quad (17)$$

Before giving the proof of this bound, we present two results, the first demonstrating the asymptotic optimality of π_{CHK}, the second giving an ε-free version of the above bound, which gives a bound on the sub-logarithmic remainder term. It is worth noting the following: the bounds of Theorem 4 can actually be improved, through the use of a modified version of Proposition 3, to eliminate the $\ln\ln n$ dependence, so the only dependence on n is through the initial $\ln n$ term. The cost of this, however, is a dependence on a larger power of $1/\varepsilon$. The particular form of the bound given in Eq. (17) was chosen to simplify the following two results, cf. Remark 5 in the proof of Proposition 3.

Theorem 5 *For a policy π_{CHK} as defined above, π_{CHK} is asymptotically optimal in the sense that for any choice of bandit parameters,*

$$\lim_{n\to\infty} \frac{R_{\pi_{CHK}}(n)}{\ln n} = \mathbb{M}_{BK}(\underline{\mu}, \underline{\sigma}^2). \quad (18)$$

Proof For any ε such that $0 < \varepsilon < 1$, we have from Theorem 4 that the following holds:

$$\limsup_{n\to\infty} \frac{R_{\pi_{\text{CHK}}}(n)}{\ln n} \leqslant \sum_{i:\mu_i\neq\mu^*} \frac{2\Delta_i}{\ln\left(1 + \frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)}. \quad (19)$$

Taking the infimum over all such ε,

$$\limsup_{n\to\infty} \frac{R_{\pi_{\text{CHK}}}(n)}{\ln n} \leqslant \sum_{i:\mu_i\neq\mu^*} \frac{2\Delta_i}{\ln\left(1 + \frac{\Delta_i^2}{\sigma_i^2}\right)} = \mathbb{M}_{\text{BK}}(\underline{\mu}, \underline{\sigma}^2), \quad (20)$$

and observing the lower bound of Ineq. (7) completes the result. ■

Having established the primary growth order of the regret under policy π_{CHK}, in the following theorem we give a bound on the growth of the remainder term. The utility of this bound depends to some extent on the specific bandit parameters, but we view this particular form of the remainder term as an artifact of the analysis given here, rather than an inherent property of the policy itself. Alternative analyses might yield tighter bounds, we simply establish a convenient bound on the growth order of the remainder.

Theorem 6 *For a policy π_{CHK} as defined above, $R_{\pi_{CHK}}(n) \leqslant \mathbb{M}_{BK}(\underline{\mu}, \underline{\sigma}^2)\ln n + O((\ln n)^{3/4}\ln\ln n)$, and more concretely*

$$\begin{aligned} R_{\pi_{CHK}}(n) \leqslant\ & M^0_{CHK}(\underline{\mu}, \underline{\sigma}^2)\ln n + M^1_{CHK}(\underline{\mu}, \underline{\sigma}^2)(\ln n)^{3/4}\ln\ln n \\ & + M^2_{CHK}(\underline{\mu}, \underline{\sigma}^2)(\ln n)^{3/4} \\ & + M^3_{CHK}(\underline{\mu}, \underline{\sigma}^2)(\ln n)^{1/2} \\ & + M^4_{CHK}(\underline{\mu}, \underline{\sigma}^2), \end{aligned} \quad (21)$$

where

$$\begin{aligned} M^0_{CHK}(\underline{\mu}, \underline{\sigma}^2) &= \mathbb{M}_{BK}(\underline{\mu}, \underline{\sigma}^2) \\ M^1_{CHK}(\underline{\mu}, \underline{\sigma}^2) &= 64\sqrt{\frac{\pi}{2e}} \sum_{i:\mu_i\neq\mu^*} \left(\frac{\sigma_*^3}{\Delta_i^2}\right) \\ M^2_{CHK}(\underline{\mu}, \underline{\sigma}^2) &= 10 \sum_{i:\mu_i\neq\mu^*} \left(\frac{\Delta_i^3}{\left(\sigma_i^2 + \Delta_i^2\right)\left(\ln\left(1 + \frac{\Delta_i^2}{\sigma_i^2}\right)\right)^2} \right) \\ M^3_{CHK}(\underline{\mu}, \underline{\sigma}^2) &= 32 \sum_{i:\mu_i\neq\mu^*} \left(\Delta_i + \frac{\sigma_i^2}{\Delta_i}\right) \\ M^4_{CHK}(\underline{\mu}, \underline{\sigma}^2) &= 3 \sum_{i:\mu_i\neq\mu^*} \Delta_i. \end{aligned} \quad (22)$$

While the above bound admittedly has a more complex form than such a bound as in Eq. (4), it demonstrates the asymptotic optimality of the dominating term, and bounds the sub-logarithmic remainder term.

Proof The bound follows directly from Theorem 4, taking $\varepsilon = \frac{1}{2}(\ln n)^{-1/4}$ for $n \geqslant 3$, and observing the following bound, that for ε such that $0 < \varepsilon < 1/2$,

$$\frac{1}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{1+\varepsilon}\right)} \leqslant \frac{1}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\right)} + \frac{10\Delta_i^2}{\left(\sigma_i^2+\Delta_i^2\right)\left(\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\right)\right)^2}\varepsilon. \tag{23}$$

This inequality is proven separately as Proposition 10 in the Appendix. ■

We make no claim that the results of Theorems 4, 6 are the best achievable for this policy π_{CHK}. At several points in the proofs, choices of convenience were made in the bounding of terms, and different techniques may yield tighter bounds still. But they are sufficient to demonstrate the asymptotic optimality of π_{CHK}, and give useful bounds on the growth of $R_{\pi_{\text{CHK}}}(n)$.

Proof [of Theorem 3] In this proof, we take $\pi = \pi_{\text{CHK}}$ as defined above. For notational convenience, we define the index function

$$u_i(k,j) = \bar{X}_j^i + S_i(j)\sqrt{k^{\frac{2}{j-2}} - 1}. \tag{24}$$

The structure of this proof will be to bound the expected value of $T_\pi^i(n)$ for all sub-optimal bandits i, and use this to bound the regret $R_\pi(n)$. The basic techniques follow those in Katehakis and Robbins (1995) for the known variance case, modified accordingly here for the unknown variance case and assisted by the probability bound of Proposition 3. For any i such that $\mu_i \neq \mu^*$, we define the following quantities: Let $1 > \varepsilon > 0$ and define $\tilde{\varepsilon} = \Delta_i\varepsilon/2$. For $n \geqslant 3N$,

$$\begin{aligned}
n_1^i(n,\varepsilon) &= \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i, u_i(t, T_\pi^i(t)) \geqslant \mu^* - \tilde{\varepsilon}, \bar{X}^i_{T_\pi^i(t)} \leqslant \mu_i + \tilde{\varepsilon}, S_i^2(T_\pi^i(t)) \leqslant \sigma_i^2(1+\varepsilon)\} \\
n_2^i(n,\varepsilon) &= \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i, u_i(t, T_\pi^i(t)) \geqslant \mu^* - \tilde{\varepsilon}, \bar{X}^i_{T_\pi^i(t)} \leqslant \mu_i + \tilde{\varepsilon}, S_i^2(T_\pi^i(t)) > \sigma_i^2(1+\varepsilon)\} \\
n_3^i(n,\varepsilon) &= \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i, u_i(t, T_\pi^i(t)) \geqslant \mu^* - \tilde{\varepsilon}, \bar{X}^i_{T_\pi^i(t)} > \mu_i + \tilde{\varepsilon}\} \\
n_4^i(n,\varepsilon) &= \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i, u_i(t, T_\pi^i(t)) < \mu^* - \tilde{\varepsilon}\}.
\end{aligned} \tag{25}$$

Hence, we have the following relationship for $n \geqslant 3N$, that

$$T_\pi^i(n+1) = 3 + \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i\} = 3 + n_1^i(n,\varepsilon) + n_2^i(n,\varepsilon) + n_3^i(n,\varepsilon) + n_4^i(n,\varepsilon). \tag{26}$$

The proof proceeds by bounding, in expectation, each of the four terms.

Observe that, by the structure of the index function u_i,

$$\begin{aligned}
n_1^i(n,\varepsilon) &\leqslant \sum_{t=3N}^{n} \mathbb{1}\left\{\pi(t+1) = i, (\mu_i + \tilde{\varepsilon}) + \sigma_i\sqrt{1+\varepsilon}\sqrt{t^{\frac{2}{T_\pi^i(t)-2}} - 1} \geqslant \mu^* - \tilde{\varepsilon}\right\} \\
&= \sum_{t=3N}^{n} \mathbb{1}\left\{\pi(t+1) = i, T_\pi^i(t) \leqslant \frac{2\ln t}{\ln\left(1+\frac{1}{\sigma_i^2}\frac{(\Delta_i - 2\tilde{\varepsilon})^2}{(1+\varepsilon)}\right)} + 2\right\} \\
&= \sum_{t=3N}^{n} \mathbb{1}\left\{\pi(t+1) = i, T_\pi^i(t) \leqslant \frac{2\ln t}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + 2\right\} \\
&\leqslant \sum_{t=3N}^{n} \mathbb{1}\left\{\pi(t+1) = i, T_\pi^i(t) \leqslant \frac{2\ln n}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + 2\right\} \\
&\leqslant \frac{2\ln n}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + 2 + 1 - 3 \\
&= \frac{2\ln n}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)}.
\end{aligned} \tag{27}$$

The last inequality follows, observing that $T_\pi^i(n)$ may be expressed as the sum of $\pi(t) = i$ indicators, and seeing that the additional condition bounds the number of non-zero terms in this sum. The additional $+1$ term accounts for the potential $\pi(n+1) = i$ term beyond the condition on $T_\pi^i(t)$, and the -3 accounts for the initial three activations of bandit i, which are not counted within the bounds of the sum. Note, this bound holds surely, over all outcomes.

For the second term,

$$\begin{aligned}
n_2^i(n,\varepsilon) &\leqslant \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1) = i, S_i^2(T_\pi^i(t)) > \sigma_i^2(1+\varepsilon)\} \\
&= \sum_{t=3N}^{n} \sum_{k=3}^{t} \mathbb{1}\{\pi(t+1) = i, S_i^2(k) > \sigma_i^2(1+\varepsilon), T_\pi^i(t) = k\} \\
&= \sum_{t=3N}^{n} \sum_{k=3}^{t} \mathbb{1}\{\pi(t+1) = i, T_\pi^i(t) = k\}\mathbb{1}\{S_i^2(k) > \sigma_i^2(1+\varepsilon)\} \\
&\leqslant \sum_{k=3}^{n} \mathbb{1}\{S_i^2(k) > \sigma_i^2(1+\varepsilon)\} \sum_{t=k}^{n} \mathbb{1}\{\pi(t+1) = i, T_\pi^i(t) = k\} \\
&\leqslant \sum_{k=3}^{n} \mathbb{1}\{S_i^2(k) > \sigma_i^2(1+\varepsilon)\}.
\end{aligned} \tag{28}$$

The last inequality follows as, for fixed k, $\{\pi(t+1)=i, T_\pi^i(t)=k\}$ may be true for at most one value of t. Recall that $kS_i^2(k)/\sigma_i^2$ has the distribution of a χ^2_{k-1} random variable. Letting $U_k \sim \chi^2_k$, from the above we have

$$\begin{aligned}
\mathbb{E}\left[n_2^i(n,\varepsilon)\right] &\leqslant \sum_{k=3}^{n} \mathbb{P}\left(S_i^2(k) > \sigma_i^2(1+\varepsilon)\right) \\
&= \sum_{k=3}^{\infty} \mathbb{P}\left(U_{k-1}/k > (1+\varepsilon)\right) \\
&\leqslant \sum_{k=3}^{\infty} \mathbb{P}\left(U_{k-1}/(k-1) > (1+\varepsilon)\right) \\
&\leqslant \sum_{k=1}^{\infty} \mathbb{P}\left(U_k > k(1+\varepsilon)\right) \\
&\leqslant \frac{1}{\sqrt{\frac{e^\varepsilon}{1+\varepsilon}-1}} \leqslant \frac{8}{\varepsilon^2} < \infty.
\end{aligned} \tag{29}$$

The penultimate step is a Chernoff bound on the terms, $\mathbb{P}\left(U_k > k(1+\varepsilon)\right) \leqslant (e^{-\varepsilon}(1+\varepsilon))^{k/2}$. As this bound is not common, it is verified in the Appendix as Proposition 8.

To bound the third term, a similar rearrangement to Eq. (28) (using the sample mean instead of the sample variance) yields:

$$n_3^i(n,\varepsilon) \leqslant \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1)=i, \bar{X}^i_{T_\pi^i(t)} > \mu_i + \tilde{\varepsilon}\} \leqslant \sum_{k=3}^{n} \mathbb{1}\{\bar{X}_k^i > \mu_i + \tilde{\varepsilon}\}. \tag{30}$$

Recalling that $\bar{X}_k^i - \mu_i \sim Z\sigma_i/\sqrt{k}$ for Z a standard normal,

$$\mathbb{E}\left[n_3^i(n,\varepsilon)\right] \leqslant \sum_{k=3}^{n} \mathbb{P}\left(\bar{X}_k^i > \mu_i + \tilde{\varepsilon}\right) \leqslant \sum_{k=1}^{\infty} \mathbb{P}\left(Z\sigma_i/\sqrt{k} > \tilde{\varepsilon}\right) \leqslant \frac{1}{e^{\frac{\tilde{\varepsilon}^2}{2\sigma_i^2}}-1} \leqslant \frac{2\sigma_i^2}{\tilde{\varepsilon}^2} < \infty. \tag{31}$$

The penultimate step is the standard Chernoff bound on the terms, $\mathbb{P}\left(Z > \delta\sqrt{k}\right) \leqslant e^{-k\delta^2/2}$.

To bound the n_4^i term, observe that in the event $\pi(t+1)=i$, from the structure of the policy it must be true that $u_i(t, T_\pi^i(t)) = \max_j u_j(t, T_\pi^j(t))$. Thus, if i^* is some bandit such that $\mu_{i^*} = \mu^*$, $u_{i^*}(t, T_\pi^{i^*}(t)) \leqslant u_i(t, T_\pi^i(t))$. In particular, we take i^* to be a bandit that not only achieves the maximal mean μ^*, but also the minimal variance among optimal bandits, $\sigma_{i^*}^2 = \sigma_*^2$. We have the following bound,

$$\begin{aligned}
n_4^i(n,\varepsilon) &\leqslant \sum_{t=3N}^{n} \mathbb{1}\{\pi(t+1)=i, u_{i^*}(t, T_\pi^{i^*}(t)) < \mu^* - \tilde{\varepsilon}\} \\
&\leqslant \sum_{t=3N}^{n} \mathbb{1}\{u_{i^*}(t, T_\pi^{i^*}(t)) < \mu^* - \tilde{\varepsilon}\} \\
&\leqslant \sum_{t=3N}^{n} \mathbb{1}\{u_{i^*}(t,s) < \mu^* - \tilde{\varepsilon} \text{ for some } 3 \leqslant s \leqslant t\}.
\end{aligned} \tag{32}$$

The last step follows as for t in this range, $3 \leqslant T_\pi^{i^*}(t) \leqslant t$. Hence

$$\mathbb{E}\left[n_4^i(n,\varepsilon)\right] \leqslant \sum_{t=3N}^{n} \mathbb{P}\left(u_{i^*}(t,s) < \mu^* - \tilde{\varepsilon} \text{ for some } 3 \leqslant s \leqslant t\right). \tag{33}$$

As an aside, this is essentially the point at which the conjectured Eq. (12) would have come into play for the proof of the optimality of π_{BK}, bounding the growth of the corresponding term for that policy. We will essentially prove a successful version of that conjecture here. Define the events $A^*_{s,t,\tilde{\varepsilon}} = \{u_{i^*}(t,s) < \mu^* - \tilde{\varepsilon}\}$. Observing that $\sqrt{s}(\bar{X}_s^{i^*} - \mu^*)/\sigma_* \sim Z$ and $S^2_{i^*}(s) \sim \sigma_*^2 U_{s-1}/s$ where Z has a standard normal distribution and $U_{s-1} \sim \chi^2_{s-1}$, Z and U_{s-1} independent,

$$\begin{aligned}
\mathbb{P}\left(A^*_{s,t,\tilde{\varepsilon}}\right) &= \mathbb{P}\left(\bar{X}_s^{i^*} + S_{i^*}(s)\sqrt{t^{\frac{2}{s-2}}-1} < \mu^* - \tilde{\varepsilon}\right) \\
&= \mathbb{P}\left(\mu^* + Z\frac{\sigma_*}{\sqrt{s}} + \sigma_*\frac{\sqrt{U_{s-1}}}{\sqrt{s}}\sqrt{t^{\frac{2}{s-2}}-1} < \mu^* - \tilde{\varepsilon}\right) \\
&= \mathbb{P}\left(Z + \sqrt{U_{s-1}}\sqrt{t^{\frac{2}{s-2}}-1} < -\frac{\tilde{\varepsilon}}{\sigma_*}\sqrt{s}\right).
\end{aligned} \tag{34}$$

Observing the symmetry of the standard normal distribution, the above may be rewritten as

$$\begin{aligned}
\mathbb{P}\left(A^*_{s,t,\tilde{\varepsilon}}\right) &= \mathbb{P}\left(\frac{\tilde{\varepsilon}}{\sigma_*}\sqrt{s} + \sqrt{U_{s-1}}\sqrt{t^{\frac{2}{s-2}}-1} < Z\right) \\
&\leqslant \frac{e^{-(\tilde{\varepsilon}/\sigma_*)^2 s/2}(s-2)}{2(\tilde{\varepsilon}/\sigma_*)^2 s\sqrt{e(s-1)}}\left(\frac{t^{-1}}{\ln t}\right) \\
&\leqslant \frac{e^{-(\tilde{\varepsilon}/\sigma_*)^2 s/2}}{2(\tilde{\varepsilon}/\sigma_*)^2}\frac{1}{\sqrt{es}}\left(\frac{t^{-1}}{\ln t}\right) \\
&= \left(\frac{1}{2(\tilde{\varepsilon}/\sigma_*)^2\sqrt{e}}\right)\frac{e^{-(\tilde{\varepsilon}/\sigma_*)^2 s/2}}{\sqrt{s}}\left(\frac{t^{-1}}{\ln t}\right),
\end{aligned} \tag{35}$$

where the first inequality follows as an application of Proposition 3, and the second since $s \geqslant 3$.

Applying a union bound to Eq. (33),

$$\begin{aligned}
\mathbb{E}\left[n_4^i(n,\varepsilon)\right] &\leqslant \sum_{t=3N}^{n}\sum_{s=3}^{t}\mathbb{P}\left(A^*_{s,t,\tilde{\varepsilon}}\right) \\
&\leqslant \sum_{t=3N}^{n}\sum_{s=3}^{t}\left(\frac{1}{2(\tilde{\varepsilon}/\sigma_*)^2\sqrt{e}}\right)\frac{e^{-(\tilde{\varepsilon}/\sigma_*)^2 s/2}}{\sqrt{s}}\left(\frac{t^{-1}}{\ln t}\right) \\
&\leqslant \left(\frac{1}{2(\tilde{\varepsilon}/\sigma_*)^2\sqrt{e}}\right)\int_{s=0}^{\infty}\frac{e^{-(\tilde{\varepsilon}/\sigma_*)^2 s/2}}{\sqrt{s}}ds\int_{t=e}^{n}\left(\frac{t^{-1}}{\ln t}\right)dt \qquad (36)\\
&= \left(\frac{1}{2(\tilde{\varepsilon}/\sigma_*)^2\sqrt{e}}\right)\frac{\sqrt{2\pi}}{(\tilde{\varepsilon}/\sigma_*)}\ln\ln n \\
&= \sqrt{\frac{\pi}{2e}}\frac{\sigma_*^3}{\tilde{\varepsilon}^3}\ln\ln n.
\end{aligned}$$

The bounds follow, removing the dependence of the s-sum on t by extending it to ∞, and bounding the sums by integrals of the (decreasing) summands by slightly extending the range of each.

From the above results, and observing that $T_\pi^i(n) \leqslant T_\pi^i(n+1)$, it follows from Eq. (26) that for any ε such that $0 < \varepsilon < 1$,

$$\begin{aligned}
\mathbb{E}\left[T_\pi^i(n)\right] &\leqslant 3 + \frac{2\ln n}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + \frac{8}{\varepsilon^2} + \frac{2\sigma_i^2}{\tilde{\varepsilon}^2} + \sqrt{\frac{\pi}{2e}}\frac{\sigma_*^3}{\tilde{\varepsilon}^3}\ln\ln n \\
&= 3 + \frac{2\ln n}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\frac{(1-\varepsilon)^2}{(1+\varepsilon)}\right)} + \frac{8}{\varepsilon^2} + \frac{8\sigma_i^2}{\Delta_i^2\varepsilon^2} + \sqrt{\frac{\pi}{2e}}\frac{8\sigma_*^3}{\Delta_i^3\varepsilon^3}\ln\ln n. \qquad (37)
\end{aligned}$$

The result then follows from the definition of regret in Eq. (2). ■

Remark 2. It is interesting to note in the above proof the effect of the -2 in the exponent on t in Eq. (35) and Eq. (36), as this is effectively what differentiates the asymptotically optimal π_{CHK} from the sub-optimal π_{BK}. With the -2, the application of Proposition 3 yields a $t^{-1}/\ln t$ bound, while without the -2, the resulting t-term is $t^{-1+2/s}/\ln t$.

Remark 3. Numerical Regret Comparison: Figure 1 shows the results of a small simulation study done on a set of six populations with means and variances given in Table 1. It provides plots of the regrets when implementing policies π_{CHK} (the index policy of Eq. (13)), π_{ACF} (the index policy of Eq. (3)) , and π_G a 'greedy' policy that always activates the bandit with the current highest average. Each policy was implemented over a horizon of 100,000 activations, each replicated 10,000 times to produce a good estimate of the average regret $R_\pi(n)$ over the times indicated. The left plot is on the time scale of the first $10,000$ activations, and the right is on the full time scale of $100,000$ activations.

μ_i	8	8	7.9	7	-1	0
σ_i^2	1	1.4	0.5	3	1	4

Table 1

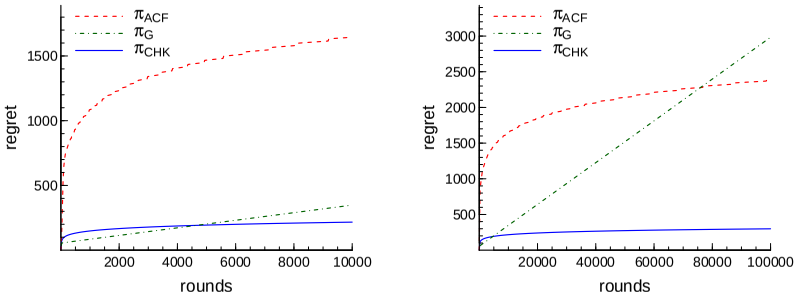

Figure 1: Numerical Regret Comparison of π_{ACF}, π_{CHK}, and π_{G}; Left: $[0,10,000]$ range, Right: $[0,100,000]$ range.

Remark 4. *Bounds and Limits:* Figure 2 shows first (left) a comparison of the theoretical bounds on the regret, $B_{\pi_{\text{ACF}}}(n)$ and $B_{\pi_{\text{CHK}}}(n)$ representing the theoretical regret bounds of the RHS of Eq. (4) and Eq. (17) respectively, taking $\varepsilon = (\ln n)^{1/4}$ in the latter case, for the means and variances indicated in Table 1. Additionally, Figure 2 (right) shows the convergence of $R_{\pi_{\text{CHK}}}(n)/\ln n$ to the theoretical lower bound $\mathbb{M}_{\text{BK}}(\underline{\mu},\underline{\sigma^2})$. It is worth noting that the convergence to the asymptotic limit from below is an artifact of the specific bandit parameters chosen in this case. Alternative parameters can be found that result in convergence from above, for instance parameter choices that force the initial activation period to accumulate regret above this limit.

3. A Comparison of π_{CHK} and Thompson Sampling

Honda and Takemura (2013) considered the following policy:

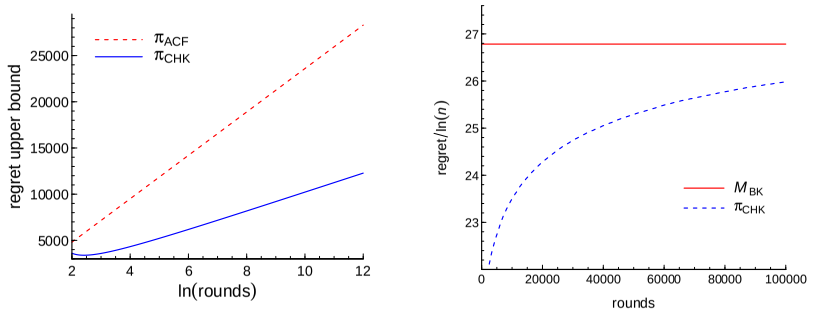

Figure 2: Left: Plots of $B_{\pi_{\text{ACF}}}(n)$ and $B_{\pi_{\text{CHK}}}(n)$. Right: Convergence of $R_{\pi_{\text{CHK}}}(n)/\ln(n)$ to $\mathbb{M}_{\text{BK}}(\underline{\mu},\underline{\sigma}^2)$.

Policy π_{TS} (TS-NORMAL$^{\alpha}$)

i) Initially, sample each bandit $\tilde{n} \geqslant \max(2, 3-\lfloor 2\alpha \rfloor)$ times.

ii) For $n \geqslant \tilde{n}$: For each i generate a random sample

$$U_n^i \sim \bar{X}^i_{T^i_\pi(n)} + S_i(T^i_\pi(n)) \frac{T_{i,n}(T^i_\pi(n)+2\alpha-1)}{\sqrt{T^i_\pi(n)+2\alpha-1}},$$

with $T_{i,n}(d)$ a t-distribution with degree d, i.e., the posterior distribution for μ_i, given $\left(\bar{X}^i_{T^i_\pi(n)}, S_i^2(T^i_\pi(n))\right)$, and a prior for $(\mu_i,\sigma_i^2) \propto (\sigma_i^2)^{-1-\alpha}$.

iii) Then, take

$$\pi_{\text{TS}}(n+1) = \arg\max_i U_n^i. \tag{38}$$

It was proven in Honda and Takemura (2013) that for $\alpha < 0$, the above Thompson sampling algorithm is asymptotically optimal, i.e., $\lim_{n\to\infty} R_{\pi_{\text{TS}}}(n)/\ln n = \mathbb{M}_{\text{BK}}(\underline{\mu},\underline{\sigma}^2)$, and further that $R_{\pi_{\text{TS}}}(n) = \mathbb{M}_{\text{BK}}(\underline{\mu},\underline{\sigma}^2)\ln n + O((\ln n)^{4/5})$.

Policies π_{TS} and π_{CHK} differ decidedly in structure. One key difference, π_{TS} is an inherently randomized policy, while decisions under π_{CHK} are completely determined given the bandit results at a given time. Given that both π_{TS} and π_{CHK} are asymptotically optimal, it is interesting to compare the performances of these two algorithms over finite time horizons,

and observe any practical differences between them. To that end, two small simulation studies were done for different sets of bandit parameters $(\underline{\mu},\underline{\sigma}^2)$. In each case, the uniform prior $\alpha = -1$ was used. The simulations were carried out on a 10,000 round time horizon, and replicated sufficiently many times to get good estimates for the expected regret over the times indicated.

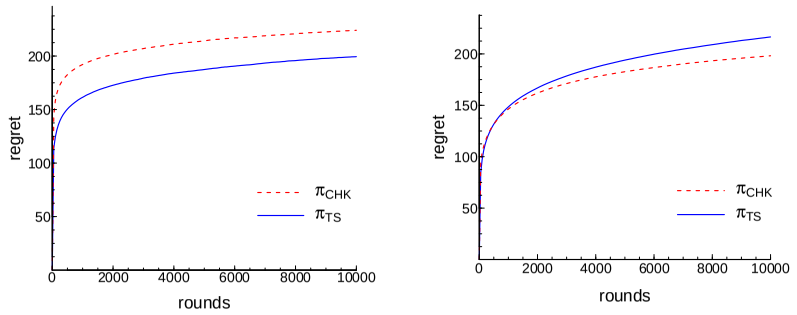

Figure 3: Numerical Regret Comparison of $\pi_{\text{CHK}}$and π_{TS} for the parameters, of Table 1, left and Table 2, right.

μ_i	10	9	8	7	-1	0
σ_i^2	8	1	1	0.5	1	4

Table 2

We observe from the above, and from general sampling of bandit parameters, that π_{TS} and π_{CHK} generally produce comparable expected regret. A general exploration of random parameters suggests that, on average, π_{TS} is slightly superior to π_{CHK} in cases where all bandits have roughly equal variances, while π_{CHK} has an edge when the optimal bandits have large variance relative to the other bandits, and the size of the bandit discrepancies. We additionally plot the variance in sample regret associated with the previous simulations (Fig. 4). Additional numerical experiments, not pictured here, indicate that the superior policy in each case may exhibit a slightly heavier tail distribution towards larger regret. In general, the question of which policy is superior seems largely context specific.

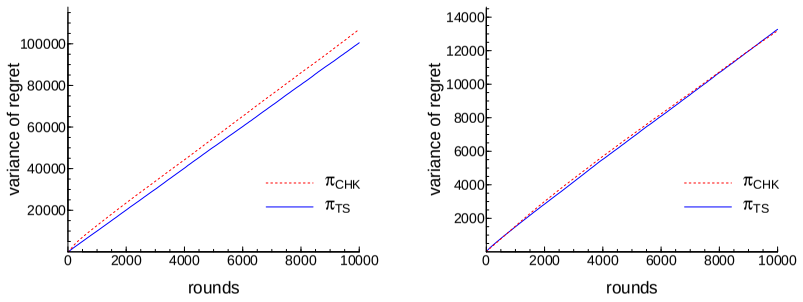

Figure 4: Numerical comparison of variance of sample regret for $\pi_{\text{CHK}}$and π_{TS} for different parameters, of Table 1, left and Table 2, right.

Appendix A. Additional Proofs

Proof [of Proposition 3] Let $P = \mathbb{P}\left(\delta + \sqrt{U}\sqrt{k^{2/p}-1} < Z\right)$. Note immediately, $P \geqslant \mathbb{P}\left(\delta + \sqrt{U}k^{1/p} < Z\right)$. Further,

$$\begin{aligned} P &\geqslant \mathbb{P}\left(\delta + \sqrt{U}k^{1/p} < Z \text{ and } \sqrt{U}k^{1/p} \geqslant \delta\right) \\ &\geqslant \mathbb{P}\left(2\sqrt{U}k^{1/p} < Z \text{ and } \sqrt{U}k^{1/p} \geqslant \delta\right) \\ &= \int_{\frac{\delta^2}{k^{2/p}}}^{\infty} \int_{2\sqrt{u}k^{1/p}}^{\infty} \frac{e^{-z^2/2}}{\sqrt{2\pi}} f_d(u) dz du. \end{aligned} \tag{39}$$

Where $f_d(u)$ is taken to be the density of a χ^2_d-random variable. Letting $\tilde{u} = k^{2/p}u$,

$$\begin{aligned} P &\geqslant \frac{1}{k^{2/p}} \int_{\delta^2}^{\infty} \int_{2\sqrt{\tilde{u}}}^{\infty} \frac{e^{-z^2/2}}{\sqrt{2\pi}} f_d\left(\frac{\tilde{u}}{k^{2/p}}\right) dz d\tilde{u} \\ &= \frac{1}{k^{2/p}} \int_{\delta^2}^{\infty} \int_{2\sqrt{\tilde{u}}}^{\infty} \frac{e^{-z^2/2}}{\sqrt{2\pi}} \frac{1}{2^{d/2}\Gamma(d/2)} \left(\frac{\tilde{u}}{k^{2/p}}\right)^{d/2-1} e^{-\frac{\tilde{u}}{2k^{2/p}}} dz d\tilde{u} \\ &= \left(\frac{1}{k^{2/p}}\right)^{d/2} \int_{\delta^2}^{\infty} \int_{2\sqrt{\tilde{u}}}^{\infty} \frac{e^{-z^2/2}}{\sqrt{2\pi}} \frac{1}{2^{d/2}\Gamma(d/2)} \tilde{u}^{d/2-1} e^{-\frac{\tilde{u}}{2k^{2/p}}} dz d\tilde{u}. \end{aligned} \tag{40}$$

Observing that $k^{2/p} \geqslant 1$,

$$\begin{aligned} P &\geqslant \left(\frac{1}{k^{2/p}}\right)^{d/2} \int_{\delta^2}^{\infty} \int_{2\sqrt{\tilde{u}}}^{\infty} \frac{e^{-z^2/2}}{\sqrt{2\pi}} \frac{1}{2^{d/2}\Gamma(d/2)} \tilde{u}^{d/2-1} e^{-\frac{\tilde{u}}{2}} dz d\tilde{u} \\ &= k^{-d/p} \mathbb{P}\left(2\sqrt{U} \leqslant Z \text{ and } U \geqslant \delta^2\right) \\ &= \frac{1}{2} k^{-d/p} \mathbb{P}\left(4U \leqslant Z^2 \text{ and } U \geqslant \delta^2\right) = \frac{1}{2} k^{-d/p} \mathbb{P}\left(\frac{1}{4}Z^2 \geqslant U \geqslant \delta^2\right). \end{aligned} \tag{41}$$

The exchange from integral to probability is simply the interpretation of the integrand as the joint pdf of U and Z.

For the upper bound, we utilize the classic normal tail bound, $\mathbb{P}(x < Z) \leqslant e^{-x^2/2}/(x\sqrt{2\pi})$.

$$P \leqslant \mathbb{E}\left[\frac{e^{-\left(\delta+\sqrt{U}\sqrt{k^{2/p}-1}\right)^2/2}}{(\delta+\sqrt{U}\sqrt{k^{2/p}-1})\sqrt{2\pi}}\right] \leqslant \frac{e^{-\delta^2/2}}{\delta\sqrt{2\pi}} \mathbb{E}\left[e^{-\delta\sqrt{U}\sqrt{k^{2/p}-1}-\frac{1}{2}U\left(k^{2/p}-1\right)}\right]. \tag{42}$$

Observing the bound that for positive x, $e^{-x} \leqslant 1/x$, and recalling that $d \geqslant 2$,

$$\begin{aligned} P &\leqslant \frac{e^{-\delta^2/2}}{\delta\sqrt{2\pi}} \mathbb{E}\left[\frac{e^{-\frac{1}{2}U\left(k^{2/p}-1\right)}}{\delta\sqrt{U}\sqrt{k^{2/p}-1}}\right] \\ &= \frac{e^{-\delta^2/2}}{\delta^2\sqrt{2\pi}\sqrt{k^{2/p}-1}} \mathbb{E}\left[U^{-\frac{1}{2}} e^{-\frac{1}{2}U\left(k^{2/p}-1\right)}\right] \\ &= \frac{e^{-\delta^2/2}}{\delta^2\sqrt{2\pi}\sqrt{k^{2/p}-1}} \left(\frac{k^{(1-d)/p}\Gamma\left(\frac{d}{2}-\frac{1}{2}\right)}{\sqrt{2}\Gamma\left(\frac{d}{2}\right)}\right). \end{aligned} \tag{43}$$

Here we utilize the following bounds: $e^x - 1 \geqslant (e/2)x^2$, which is easy to prove, and $\Gamma(d/2-1/2)/\Gamma(d/2) \leqslant \sqrt{2\pi/d}$, which may be proved on integer $d \geqslant 2$ by induction. This yields:

$$P \leqslant \frac{e^{-(1+\delta^2)/2} p}{2\delta^2 \ln k} \frac{k^{(1-d)/p}}{\sqrt{d}}. \tag{44}$$

This completes the proof.

Remark 5. Room for Improvement: The choice of the $e^x - 1 \geqslant (e/2)x^2$ bound above was in fact arbitrary - other bounds, such as involving alternative powers of x, could be used. This would influence how the resulting bound on P is utilized, for instance in the proof of Theorem 4. The use of $e^{-x} \leqslant 1/x$ in Eq. (43) should be considered similarly. ■

Proposition 7 *In the case of normal distributions with unknown means and variances,*

$$\mathbb{M}_{BK}(\underline{\mu}, \underline{\sigma}^2) = \sum_{i:\mu_i \neq \mu^*} \frac{2\Delta_i}{\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\right)}. \tag{45}$$

Proof From Eq. (9) and Eq. (10), it suffices to show that in the case of normal distributions with unknown means and variances, for any sub-optimal bandit i,

$$\mathbb{K}((\mu_i, \sigma_i^2), \mu^*) = \inf_{(\tilde{\mu}, \tilde{\sigma}^2)} \{\mathbb{I}(f_{(\mu_i,\sigma_i^2)}; f_{(\tilde{\mu},\tilde{\sigma}^2)}) : \tilde{\mu} > \mu^*\} = \frac{1}{2}\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\right), \tag{46}$$

where again $\mathbb{I}(f;g)$ is the Kullback-Leibler divergence between densities f and g. Taking the densities here as normal, we have

$$\begin{aligned} \mathbb{I}(f_{(\mu_i,\sigma_i^2)}; f_{(\tilde{\mu},\tilde{\sigma}^2)}) &= \int_{-\infty}^{\infty} \ln\left(\frac{f_{(\mu_i,\sigma_i^2)}(x)}{f_{(\tilde{\mu},\tilde{\sigma}^2)}(x)}\right) f_{(\mu_i,\sigma_i^2)}(x) dx \\ &= \int_{-\infty}^{\infty} \left(-\frac{(x-\mu_i)^2}{2\sigma_i^2} + \frac{(x-\tilde{\mu})^2}{2\tilde{\sigma}^2} + \ln\left(\frac{\tilde{\sigma}}{\sigma_i}\right)\right) \frac{1}{\sigma_i\sqrt{2\pi}} e^{-\frac{(x-\mu_i)^2}{2\sigma_i^2}} dx \\ &= \frac{(\tilde{\mu}-\mu_i)^2 + (\sigma_i^2 - \tilde{\sigma}^2)}{2\tilde{\sigma}^2} + \ln\left(\frac{\tilde{\sigma}}{\sigma_i}\right). \end{aligned} \tag{47}$$

Restricting to $\tilde{\mu} > \mu^*$ and $\tilde{\sigma}^2 > 0$, the infimum is realized (since $\mu^* > \mu_i$) taking $\tilde{\mu} = \mu^*$ and $\tilde{\sigma}^2 = (\mu^* - \mu_i)^2 + \sigma_i^2$, yielding

$$\mathbb{K}((\mu_i, \sigma_i^2), \mu^*) = \frac{1}{2}\ln\left(1+\frac{(\mu^*-\mu_i)^2}{\sigma_i^2}\right) = \frac{1}{2}\ln\left(1+\frac{\Delta_i^2}{\sigma_i^2}\right). \tag{48}$$

■

Proposition 8 *For a χ^2_k random variable U_k, and $\varepsilon > 0$,*

$$\mathbb{P}(U_k > k(1+\varepsilon)) \leqslant (e^{-\varepsilon}(1+\varepsilon))^{k/2}. \tag{49}$$

Proof Let $r > 0$, and let Z be a standard normal random variable. We have that

$$\mathbb{P}(U_k > k(1+\varepsilon)) = \mathbb{P}(e^{rU_k} > e^{rk(1+\varepsilon)}) \leqslant \frac{\mathbb{E}\left[e^{rU_k}\right]}{e^{rk(1+\varepsilon)}} = \frac{\mathbb{E}\left[e^{rZ^2}\right]^k}{e^{rk(1+\varepsilon)}}, \tag{50}$$

the last step following from viewing the U_k as the sum of k independent squared standard normals. Hence,

$$\mathbb{P}(U_k > k(1+\varepsilon)) \leqslant \left(\frac{\mathbb{E}\left[e^{rZ^2}\right]}{e^{r(1+\varepsilon)}}\right)^k = \left(\frac{1}{e^{r(1+\varepsilon)}\sqrt{1-2r}}\right)^k, \tag{51}$$

if $0 < r < 1/2$. Taking $r = (1/2)(\varepsilon/(1+\varepsilon))$ completes the result. ■

Proposition 9 *Conjecture 1 is* **false** *and for each i, for* $\varepsilon > 0$*,*

$$\frac{\mathbb{P}\left(\bar{X}_j^i + S_i(j)\sqrt{k^{2/j}-1} < \mu_i - \varepsilon \text{ for some } 2 \leqslant j \leqslant k\right)}{1/k} \to \infty \text{ as } k \to \infty. \tag{52}$$

.

Proof Define the events $A^i_{j,k,\varepsilon} = \{\bar{X}_j^i + S_i(j)\sqrt{k^{2/j}-1} < \mu_i - \varepsilon\}$. As the samples are taken to be normally distributed with mean μ_i and variance σ_i^2, we have that $\bar{X}_j^i - \mu_i \sim Z\sigma_i/\sqrt{j}$ and $S_i^2(j) \sim \sigma_i^2 U/j$, where Z is a standard normal, $U \sim \chi^2_{j-1}$, and Z, U independent. Hence,

$$\mathbb{P}(A^i_{j,k,\varepsilon}) = \mathbb{P}\left(Z\frac{\sigma_i}{\sqrt{j}} + \sqrt{U\frac{\sigma_i^2}{j}}\sqrt{k^{2/j}-1} < -\varepsilon\right) = \mathbb{P}\left(\frac{\varepsilon}{\sigma_i}\sqrt{j} + \sqrt{U}\sqrt{k^{2/j}-1} < Z\right). \tag{53}$$

The last step is simply a re-arrangement, and an observation on the symmetry of the distribution of Z. For $j \geqslant 3$, we may apply Proposition 3 here for $d = j-1$, $p = j$, to yield

$$\mathbb{P}(A^i_{j,k,\varepsilon}) \geqslant \frac{1}{2}\frac{k^{1/j}}{k}\mathbb{P}\left(\frac{1}{4}Z^2 \geqslant U \geqslant \frac{\varepsilon^2}{\sigma_i^2}j\right). \tag{54}$$

For a fixed $j_0 \geqslant 3$, for $k \geqslant j_0$ we have

$$\mathbb{P}\left(A^i_{j,k,\varepsilon} \text{ for some } 2 \leqslant j \leqslant k\right) \geqslant \mathbb{P}(A^i_{j_0,k,\varepsilon}) \geqslant O(1/k)\,k^{1/j_0}. \tag{55}$$

The proposition follows immediately. ■

Proposition 10 *For* $G > 0$*,* $0 \leqslant \varepsilon < 1/2$*, the following holds:*

$$\frac{1}{\ln\left(1+G\frac{(1-\varepsilon)^2}{1+\varepsilon}\right)} \leqslant \frac{1}{\ln(1+G)} + \frac{10G}{(1+G)\left(\ln(1+G)\right)^2}\varepsilon. \tag{56}$$

Proof For any $G > 0$, the function $1/\ln\left(1+G\frac{(1-\varepsilon)^2}{1+\varepsilon}\right)$ is positive, increasing, and convex on $\varepsilon \in [0,1)$ (Proposition 11). For a given $G > 0$, noting that the above inequality holds (as equality) at $\varepsilon = 0$, due to the convexity it suffices to show that the inequality is satisfied at $\varepsilon = 1/2$, or

$$\frac{1}{\ln\left(1+\frac{G}{6}\right)} \leqslant \frac{5G}{(1+G)\left(\ln(1+G)\right)^2} + \frac{1}{\ln(1+G)}. \tag{57}$$

Equivalently, we consider the inequality

$$0 \leqslant \frac{5G}{(1+G)} + \ln(1+G) - \frac{\left(\ln(1+G)\right)^2}{\ln\left(1+\frac{G}{6}\right)}. \tag{58}$$

Define the function $F(G)$ to be the RHS of Ineq. (58). Note that as $G \to 0$, $F(G) \to 0$, and in simplified form we have (for $G > 0$ and the limit as $G \to 0$),

$$F'(G) = \frac{\left((1+G)\ln(1+G) - (6+G)\ln\left(1+\frac{G}{6}\right)\right)^2}{(1+G)^2(6+G)\ln\left(1+\frac{G}{6}\right)^2} \geqslant 0. \tag{59}$$

It follows that $F(G) \geqslant 0$, and hence the desired inequality holds at $\varepsilon = 1/2$. This completes the proof. ■

Proposition 11 *The function* $H_G(\varepsilon) = 1/\ln\left(1+G\frac{(1-\varepsilon)^2}{1+\varepsilon}\right)$ *is positive, increasing, and convex in* $\varepsilon \in [0,1)$*, for any constant* $G > 0$*.*

Proof That $H_G(\varepsilon)$ is positive and increasing in ε, follows immediately from inspection of H_G and H'_G, given the hypotheses on G, and ε.

To demonstrate convexity, by inspection of the terms of $H''_G(\varepsilon)$, it suffices to show that for all relevant G, and ε, the following inequality holds.

$$2G(1-\varepsilon)^2(3+\varepsilon)^2 + \left(-8(1+\varepsilon) + G(1-\varepsilon)^2(1+\varepsilon(6+\varepsilon))\right)\ln\left(1+G\frac{(1-\varepsilon)^2}{1+\varepsilon}\right) \geqslant 0. \tag{60}$$

Defining $C = G(1-\varepsilon)^2/(1+\varepsilon)$, it is sufficient to show that for all $C > 0$ and $\varepsilon \in [0,1)$ (eliminating a factor of $(1+\varepsilon)$ from the above),

$$2C(3+\varepsilon)^2 + (-8 + C(1+\varepsilon(6+\varepsilon)))\ln(1+C) \geqslant 0. \tag{61}$$

Defining $J_C(\varepsilon)$ as the LHS of the above, note that $J_C'(\varepsilon) = 2C(3+\varepsilon)(2+\ln(1+C)) > 0$. It suffices then to show $J_C(0) \geqslant 0$, or $18C + (C-8)\ln(1+C) \geqslant 0$. Note this holds at $C = 0$, and $d/dC[J_C(0)] = (10+19C)/(1+C) + \ln(1+C) > 0$ for $C \geqslant 0$. Hence, $J_C(\varepsilon) \geqslant 0$, and $H_G''(\varepsilon) \geqslant 0$. ■

Proof [of Theorem 2] In the interests of comparing π_{BK} and π_{CHK}, consider a general policy π depending on $a > b$ that initially samples each bandit a times, then for times greater than aN, samples according to the maximal index

$$u_i(n,k) = \bar{X}_k^i + S_i(k)\sqrt{n^{\frac{2}{k-b}} - 1}.$$

Note, π_{BK} corresponds to the choices $a = 2, b = 0$, and π_{CHK} corresponds to the choices $a = 3, b = 2$.

Let i^* be the optimal bandit, and let j be such that $\mu^* = \mu_{i^*} > \mu_j = \max_{k:\mu_k \neq \mu^*}$. Let $\tilde{\varepsilon} = 2\sigma_j$.

First, for $n > aN$, we have the following bound:

$$\sum_{t=aN}^{n} \mathbb{1}\{\pi(t+1) \neq i^*\} \geqslant \mathbb{1}\left\{\bigcap_{k=1}^{\infty}\{\bar{X}_k^j \geqslant \mu_j - \tilde{\varepsilon}\}\right\} \sum_{m=1}^{n-aN+1} \mathbb{1}\left\{\bigcap_{t=aN}^{aN+m-1}\left\{u_{i^*}(t,a) < \mu_j - \tilde{\varepsilon}\right\}\right\}. \tag{62}$$

The above inequality can be seen in the following way: In attempting to bound the sub optimal activations of π beyond time $t = aN$ from below, we may restrict ourselves to the event that the sample mean for $j \neq i^*$ is *never* below $\mu_j - \tilde{\varepsilon}$ (and hence, the index for j is never below $\mu_j - \tilde{\varepsilon}$) and count only the initial consecutive non-activations of i^* beyond time $t = aN$. The number of these initial consecutive non-activations, restricted in this way, is bound from below by the number of times the index for i^* is consecutively below $\mu_j - \tilde{\varepsilon}$, counted by the righthand sum.

Noting that $u_{i^*}(t,a)$ is an increasing function of t, we have that

$$\begin{aligned}
&\sum_{m=1}^{n-aN+1} \mathbb{1}\left\{\bigcap_{t=aN}^{aN+m-1}\left\{u_{i^*}(t,a) < \mu_j - \tilde{\varepsilon}\right\}\right\} \\
&= \sum_{m=1}^{n-aN+1} \mathbb{1}\left\{u_{i^*}(aN+m-1,a) < \mu_j - \tilde{\varepsilon}\right\} \\
&= \sum_{m=1}^{n-aN+1} \mathbb{1}\left\{\bar{X}_a^{i^*} + S_{i^*}(a)\sqrt{(aN+m-1)^{\frac{2}{a-b}} - 1} < \mu_j - \tilde{\varepsilon}\right\} \\
&= \mathbb{1}\left\{\bar{X}_a^{i^*} < \mu_j - \tilde{\varepsilon}\right\} \sum_{m=1}^{n-aN+1} \mathbb{1}\left\{m < \left(\left(\frac{(\mu_j - \tilde{\varepsilon}) - \bar{X}_a^{i^*}}{S_{i^*}(a)}\right)^2 + 1\right)^{\frac{a-b}{2}} + 1 - aN\right\} \qquad (63) \\
&\geqslant \mathbb{1}\left\{\bar{X}_a^{i^*} < \mu_j - \tilde{\varepsilon}\right\} \min\left\{n - aN + 1, \left(\left(\frac{(\mu_j - \tilde{\varepsilon}) - \bar{X}_a^{i^*}}{S_{i^*}(a)}\right)^2 + 1\right)^{\frac{a-b}{2}} - aN\right\} \\
&\geqslant \mathbb{1}\left\{\bar{X}_a^{i^*} < \mu_j - \tilde{\varepsilon}\right\} \min\left\{n, \left(\left(\frac{(\mu_j - \tilde{\varepsilon}) - \bar{X}_a^{i^*}}{S_{i^*}(a)}\right)^2 + 1\right)^{\frac{a-b}{2}}\right\} - aN.
\end{aligned}$$

From the above, we have that

$$\begin{aligned}
&\sum_{t=aN}^{n} \mathbb{1}\{\pi(t+1) \neq i^*\} \\
&\geqslant \mathbb{1}\left\{\bigcap_{k=1}^{\infty}\{\bar{X}_k^j \geqslant \mu_j - \tilde{\varepsilon}\}\right\} \mathbb{1}\left\{\bar{X}_a^{i^*} < \mu_j - \tilde{\varepsilon}\right\} \min\left\{n, \left(\left(\frac{(\mu_j - \tilde{\varepsilon}) - \bar{X}_a^{i^*}}{S_{i^*}(a)}\right)^2 + 1\right)^{\frac{a-b}{2}}\right\} - aN.
\end{aligned} \tag{64}$$

To compute the relevant expectations, note that (recycling the bound from Eq. (31)),

$$\mathbb{P}\left(\bigcap_{k=1}^{\infty}\{\bar{X}_k^j \geqslant \mu_j - \tilde{\varepsilon}\}\right) = 1 - \mathbb{P}\left(\bigcup_{k=1}^{\infty}\{\bar{X}_k^j < \mu_j - \tilde{\varepsilon}\}\right) \geqslant 1 - \sum_{k=1}^{\infty}\mathbb{P}\left(\bar{X}_k^j < \mu_j - \tilde{\varepsilon}\right) \geqslant \frac{1}{2}. \tag{65}$$

Hence,

$$\begin{aligned}
&\mathbb{E}\left[\sum_{t=aN}^{n}\mathbb{1}\{\pi(t+1)\neq i^*\}\right]+aN\\
&\geqslant\frac{1}{2}\mathbb{E}\left[\mathbb{1}\left\{\bar{X}_a^{i^*}<\mu_j-\tilde{\varepsilon}\right\}\min\left\{n,\left(\left(\frac{(\mu_j-\tilde{\varepsilon})-\bar{X}_a^{i^*}}{S_{i^*}(a)}\right)^2+1\right)^{\frac{a-b}{2}}\right\}\right]\\
&=\frac{1}{2}\mathbb{E}\left[\mathbb{1}\left\{\Delta_j+\tilde{\varepsilon}+\sigma_{i^*}Z/\sqrt{a}<0\right\}\min\left\{n,\left(\left(\frac{\Delta_j+\tilde{\varepsilon}+\sigma_{i^*}Z/\sqrt{a}}{\sigma_{i^*}\sqrt{U}/\sqrt{a}}\right)^2+1\right)^{\frac{a-b}{2}}\right\}\right]\\
&=\frac{1}{2}\mathbb{E}\left[\mathbb{1}\left\{\tilde{\Delta}+Z<0\right\}\min\left\{n,\left(\left(\frac{\tilde{\Delta}+Z}{\sqrt{U}}\right)^2+1\right)^{\frac{a-b}{2}}\right\}\right],
\end{aligned}\tag{66}$$

recalling that $\bar{X}_a^{i^*}\sim\mu^*+\sigma_{i^*}Z/\sqrt{a}$ and $S_{i^*}(a)\sim\sigma_{i^*}^2U/a$ where Z,U are independent, Z a standard normal and U a χ^2_{a-1} random variable, and taking $\tilde{\Delta}=\sqrt{a}(\Delta_j+\tilde{\varepsilon})/\sigma_{i^*}>0$. Taking $d=a-1$,

$$\begin{aligned}
&\mathbb{E}\left[\sum_{t=aN}^{n}\mathbb{1}\{\pi(t+1)\neq i^*\}\right]+aN\\
&\geqslant O(1)\int_0^\infty\int_{-\infty}^{-\tilde{\Delta}}\min\left\{n,\left(\left(\frac{\tilde{\Delta}+z}{\sqrt{u}}\right)^2+1\right)^{\frac{a-b}{2}}\right\}e^{-z^2/2}u^{\frac{d}{2}-1}e^{-u/2}dzdu.
\end{aligned}\tag{67}$$

Taking the transformation $(z,u)=(-\tilde{\Delta}-\cos(\theta)\sqrt{r},r\sin(\theta)^2)$, for $r\in[0,\infty)$, $\theta\in[0,\pi/2]$, we have $dzdu=2\sin(\theta)\sqrt{r}drd\theta$, and

$$\begin{aligned}
&\int_0^\infty\int_{-\infty}^{-\tilde{\Delta}}\min\left\{n,\left(\left(\frac{\tilde{\Delta}+z}{\sqrt{u}}\right)^2+1\right)^{\frac{a-b}{2}}\right\}e^{-z^2/2-u/2}u^{\frac{d}{2}-1}dzdu\\
&=2\int_0^{\pi/2}\int_0^\infty\min\left\{n,\csc(\theta)^{a-b}\right\}e^{-\frac{r}{2}-\tilde{\Delta}\cos(\theta)\sqrt{r}-\frac{\tilde{\Delta}^2}{2}}r^{\frac{d-1}{2}}\sin(\theta)^{d-1}drd\theta\\
&\geqslant 2\int_0^{\pi/2}\int_0^\infty\min\left\{n,\csc(\theta)^{a-b}\right\}e^{-\frac{r}{2}-\tilde{\Delta}\sqrt{r}-\frac{\tilde{\Delta}^2}{2}}r^{\frac{d-1}{2}}\sin(\theta)^{d-1}drd\theta\\
&=2\left(\int_0^\infty e^{-\frac{1}{2}(\tilde{\Delta}+\sqrt{r})^2}r^{\frac{d-1}{2}}dr\right)\left(\int_0^{\pi/2}\min\left\{n,\csc(\theta)^{a-b}\right\}\sin(\theta)^{a-2}d\theta\right)\\
&\geqslant 2\left(\int_0^\infty e^{-\frac{1}{2}(\tilde{\Delta}+\sqrt{r})^2}r^{\frac{d-1}{2}}dr\right)\left(\int_{\arcsin\left(n^{-\frac{1}{a-b}}\right)}^{\pi/2}\sin(\theta)^{b-2}d\theta\right).
\end{aligned}\tag{68}$$

From the above, for $b\geqslant 2$, the above integral converges to a constant as $n\to\infty$, and in that sense the bound is uninformative, giving an $O(1)$ lower bound. For $b<2$, taking the bounds that $\theta\geqslant\sin(\theta)$ on the indicated range, and $\arcsin(x)\leqslant\pi/2x$ for $x\in[0,1]$, we have

$$\mathbb{E}\left[\sum_{t=aN}^{n}\mathbb{1}\{\pi(t+1)\neq i^*\}\right]+aN\geqslant O(1)\int_{\frac{\pi}{2}n^{-\frac{1}{a-b}}}^{\pi/2}\theta^{b-2}d\theta=O(1)\int_{n^{-\frac{1}{a-b}}}^1\tau^{b-2}d\tau.\tag{69}$$

Noting that $R_\pi(n)\geqslant\Delta_j\mathbb{E}[\sum_{t=aN}^n\mathbb{1}\{\pi(t+1)\neq i^*\}]$, we may therefore summarize as

$$R_\pi(n)\geqslant\begin{cases}O(1) & \text{if } b>1,\\ O(\ln n) & \text{if } b=1,\\ O\left(\frac{n^{\frac{1-b}{a-b}}-1}{1-b}\right) & \text{if } b<1.\end{cases}\tag{70}$$

While the above bound is uninformative in the case of $\pi=\pi_{\mathrm{CHK}}$ (with $a=3,b=2$), it follows that $\pi=\pi_{\mathrm{BK}}$ (with $a=2,b=0$) suffers from at least $O(\sqrt{n})$ regret. ■

Abstract

We study binary classification in the presence of *class-conditional* random noise, where the learner gets to see labels that are flipped independently with some probability, and where the flip probability depends on the class. Our goal is to devise learning algorithms that are efficient and statistically consistent with respect to commonly used utility measures. In particular, we look at a family of measures motivated by their application in domains where cost-sensitive learning is necessary (for example, when there is class imbalance). In contrast to most of the existing literature on consistent classification that are limited to the classical 0-1 loss, our analysis includes more general utility measures such as the AM measure (arithmetic mean of True Positive Rate and True Negative Rate). For this problem of cost-sensitive learning under class-conditional random noise, we develop two approaches that are based on suitably modifying surrogate losses. First, we provide a simple unbiased estimator of any loss, and obtain performance bounds for empirical utility maximization in the presence of i.i.d. data with noisy labels. If the loss function satisfies a simple symmetry condition, we show that using unbiased estimator leads to an efficient algorithm for empirical maximization. Second, by leveraging a reduction of risk minimization under noisy labels to classification with weighted 0-1 loss, we suggest the use of a simple weighted surrogate loss, for which we are able to obtain strong utility bounds. This approach implies that methods already used in practice, such as biased SVM and weighted logistic regression, are provably noise-tolerant. For two practically important measures in our family, we show that the proposed methods are competitive with respect to recently proposed methods for dealing with label noise in several benchmark data sets.

Keywords: class-conditional label noise, statistical consistency, cost-sensitive learning

1. Introduction

Learning from noisy training data is a problem of theoretical as well as practical interest in machine learning. In many applications such as learning to classify images, it is often the case that the labels are noisy. Even human labelers are susceptible to errors in labeling; for instance, certain image categories may be hard to discern. Designing learning algorithms that help maximize a desired performance measure in such noisy settings, and understanding their statistical consistency properties are the objectives of our current work.

One of the earliest known attempts at learning in the presence of label noise was by Bylander (1994) that concerned learnability of linear threshold functions (LTFs) in the Probably Approximately Correct (PAC) model. In particular, he showed that if the noise rate is uniform and if there is a sufficient margin under the clean distribution, then it is possible to PAC-learn LTFs. He also extended the result to a more realistic noise model called monotonic noise (Bylander, 1998), where the noise rate is allowed to vary per example, but is assumed to be a monotonic function of the distance of the example from the true hyperplane. Blum and Mitchell (1998), and later Cohen (1997) improved the PAC-learnability results of Bylander (1994) showing that linear threshold functions are efficiently learnable without the margin requirement in the uniform label noise model. A Bayesian approach to the problem of noisy labels is taken by Graepel and Herbrich (2000) and Lawrence and Schölkopf (2001). Cesa-Bianchi et al. (2011) focus on online learning algorithms where only unbiased estimates of the gradient of the loss are needed to provide guarantees for learning with noisy data. However, they consider a much harder noise model where instances *as well as* labels are noisy. Because of the harder noise model, they necessarily require multiple noisy copies per clean example and the unbiased estimation schemes also become fairly complicated, particularly for non-smooth classification losses such as the hinge loss.

In order to more clearly understand the impact of label noise, it is useful to consider a more natural and simpler formalism for label noise, where a random noise process corrupts the labels (Biggio et al., 2011), which otherwise arise from some "clean" distribution. There has been a long line of work in the theoretical machine learning community on such formalisms. Soon after the introduction of the noise-free PAC model, Angluin and Laird (1988) proposed the *random classification noise* (RCN) model where each label is flipped independently with some probability $\rho \in [0, 1/2)$. It is known (Aslam and Decatur, 1996; Cesa-Bianchi et al., 1999) that finiteness of the VC dimension characterizes learnability in the RCN model. Similarly, in the online mistake bound model, the parameter that characterizes learnability without noise — the Littlestone dimension — continues to characterize learnability even in the presence of random label noise (Ben-David et al., 2009). These results are for the so-called 0-1 loss: if the true label is $y \in \{-1, +1\}$ and the prediction is t, the 0-1 loss defined as $\ell_{0\text{-}1}(y, t) = 1_{\{yt \leq 0\}}$ (where $1_{\{P\}}$ denotes the indicator function that takes value 1 if the predicate P is true or 0 otherwise), is a non-convex function of the prediction t. On the other hand, learning with convex losses has been addressed only under limiting assumptions like separability or uniform noise rates (Manwani and Sastry,

∗. The work in this manuscript was done when the author was a graduate student at the University of Texas at Austin.

2013). A great deal of practical work has also been done on the problem; see, for instance, the survey article by Nettleton et al. (2010).

In this paper, we consider the *class-conditional* random label noise (abbreviated CCN) setting. Here, the data consists of iid samples drawn from a noisy version D_ρ of an underlying "clean" distribution D, and where the noise rates depend on the class label. To the best of our knowledge, general results in this setting have not been obtained before. We note that developing guarantees in the presence of CCN label noise also has implications in varied partially-supervised settings such as learning from only positive and unlabeled data (Elkan and Noto, 2008), which can be cast under this setting. For the theoretical results presented in this work, we assume that the true noise rates (that characterize D_ρ) are known. In practice, one may use the domain knowledge to provide an estimate for noise rates (see Section 6.3), or use a plug-in estimator for noise rates such as the one prescribed by Scott (2015).

A key facet of the classification problem is the evaluation metric which captures discrepancy between the predicted label and the true label, and which we would want to minimize (or correspondingly, an evaluation utility measure which we would want to maximize). While classification accuracy is a popular utility measure, many other performance measures have also been considered in practice. One important family of measures constitutes cost-sensitive learning, and is motivated by applications and domains where misclassification cost could depend on the category of the example. For example, in disease diagnosis, false positives and false negatives often have very different associated impacts. Most, if not all, of the existing theoretical work on classification focuses on obtaining consistent learning algorithms for the 0-1 loss or its surrogates. In this paper, we consider a general class of utility measures that can be expressed as a linear combination of the entries of the "confusion matrix," namely, true positives, true negatives, false positives and false negatives.

Towards this problem of learning classifiers with respect to general utility measures and class conditional label noise, we develop two methods for suitably modifying *any given surrogate loss function* ℓ, and show that minimizing the sample average of the modified proxy loss function $\tilde{\ell}$ leads to provable utility bounds where the utility is calculated on the clean distribution.

In our first approach, the modified or proxy loss is an unbiased estimate of the loss function associated with the utility measure of interest. The idea of using unbiased estimators is well-known in stochastic optimization (Nemirovski et al., 2009). Nonetheless, we bring out some important aspects of using unbiased estimators of loss functions for empirical utility maximization under CCN. In particular, we give a simple symmetry condition on the loss (enjoyed, for instance, by the Huber, logistic, and squared losses) to ensure that the proxy loss is also convex. Hinge loss does not satisfy the symmetry condition, and thus leads to a non-convex problem. We nonetheless provide a convex surrogate, leveraging the fact that the non-convex hinge problem is "close" to a convex problem (Theorem 12). This is strikingly different from the online learning setting (examined in Section 4) that requires only the expected loss to be convex.

Our second approach is based on the fundamental observation that the minimizer of the risk (i.e. probability of misclassification) under the noisy distribution differs from that of the clean distribution *only* in where it thresholds $\eta(x) = P(Y = 1|x)$ to decide the label. In order to correct for the threshold, we then propose a simple weighted loss function, where

the weights are label-dependent, as the proxy loss function. Our analysis builds on the notion of consistency of weighted loss functions studied by Scott (2012). This approach leads to a remarkable result that appropriately weighted losses like biased SVMs studied by Liu et al. (2003) are robust to CCN.

The key contributions of the paper are summarized below:

1. We develop methods for learning, that are provably consistent, (a) in the presence of asymmetric label noise, and (b) with respect to general cost-sensitive utility measures beyond the classical 0-1 loss.

2. To the best of our knowledge, we are the first to provide guarantees for cost-sensitive learning under random label noise in the general setting of convex surrogates, without any assumptions on the true distribution.

3. As one consequence of our results, we resolve an elusive theoretical gap in the understanding of practical methods like biased SVM and weighted logistic regression: as we show, they are provably noise-tolerant (Theorem 18). We obtain the result as a consequence of being able to linearly relate the risk w.r.t. a weighted 0-1 loss under the noisy distribution to that w.r.t. the 0-1 loss under the clean distribution (Theorem 16).

4. Our proxy losses are easy to compute: the proposed approaches yield efficient algorithms.

5. Experiments on benchmark data sets show that the methods are robust even at high noise rates, for maximizing different performance measures from our family.

In a preliminary version of the paper (Natarajan et al., 2013), we provided guarantees for risk minimization (using the 0-1 loss) in the presence of class-conditional label noise. In this paper, we provide a more general and detailed treatment of the theory, by characterizing the optimal classifiers under more general performance measures used in practice (in Sections 4 and 5). We extend our earlier approach (Natarajan et al., 2013) to cost-sensitive learning (Section 3.2). Our results in this paper also serve to generalize some of the known consistency results for performance measures such as the AM measure, even in the noise-free setting.

We now expand on the organization of the paper. We begin by discussing some closely related work in Section 2. We introduce and set the problem up formally in Section 3. The class-conditional noise model is specified by two parameters ρ_{+1} and ρ_{-1} which correspond to the rates at which positive and negative labels are flipped (independently) respectively. To build the theory, we assume that the rates are known to the learner. We do not make any assumptions on the underlying distribution. We introduce the family of measures $\mathcal{U}$ that constitute cost-sensitive learning in Section 3. It is well-known that the classical 0-1 loss is optimized by thresholding $P(Y = 1|x)$ at $1/2$. Cost-sensitive measures are of particular interest to our work in this paper because their optimal decision function exhibits a simple form — thresholding the conditional probability $P(Y = 1|x)$ at a certain value (stated in Lemma 2). Study of consistent learning algorithms, for many performance measures other than classification accuracy, is limited even in the noise-free case. Menon et al. (2013)

showed consistency of certain empirical estimation algorithms for the AM measure (defined in Proposition 1). An important result that connects the excess risk of a decision function (in terms of the 0-1 loss), $R(f) - \min_f R(f)$, and its "utility deficit", $\max_f \mathcal{U}(f) - \mathcal{U}(f)$, is established in Lemma 3. As a consequence of this result, we are able to use the surrogates for 0-1 loss for empirical estimation, in order to maximize cost-sensitive measures.

We describe our first approach of using unbiased surrogate loss functions in Section 4. Here, the idea is to construct an unbiased estimator of a given loss function (a surrogate of the 0-1 loss). The unbiased estimator involves the noise rates ρ_{+1} and ρ_{-1}. For optimizing a given utility measure $\mathcal{U}$, we propose an empirical risk minimization procedure based on the unbiased surrogate thus obtained. We establish utility deficit bounds for the resulting empirical estimator in Theorem 9. Here, we also look at the online learning setting, where examples arrive sequentially (with noisy labels), and obtain similar consistency guarantees. Our second approach is detailed in Section 5. The key observation is that the optimal decision function for utility $\mathcal{U}$ in our family with respect to the noisy distribution is simply given by thresholding $P(Y = 1|x)$ with respect to the *clean* distribution, at a certain value that depends only on the distribution and the measure $\mathcal{U}$ itself. This enables us to use a weighted surrogate of the 0-1 loss, where the weights depend on the measure $\mathcal{U}$ and noise rates ρ_{+1} and ρ_{-1}. We provide rigorous guarantees for consistency of the resulting empirical estimator in Theorem 18.

We present detailed experimental results that support our theory in Section 6. We perform experiments on synthetic and benchmark data sets, on both the proposed approaches. We compare to state-of-the-art algorithms for learning with noisy data on different data sets and different noise settings. We use two performance measures in experiments: classification accuracy and the AM measure, as representatives of the family of measures considered in the paper.

2. Related Work

Stempfel and Ralaivola (2009) propose minimizing an unbiased proxy for the case of the hinge loss. However the hinge loss leads to a non-convex problem. Therefore, they propose heuristic minimization approaches for which no theoretical guarantees are provided. We address the issue in Section 4.1. As Adaboost is very sensitive to label noise, random label noise has also been considered in the context of boosting. Freund (2009) proposes a boosting algorithm based on a non-convex potential that is empirically seen to be robust against random label noise. Long and Servedio (2010) prove that any method based on a convex potential is inherently ill-suited to random label noise. Biggio et al. (2011) consider robust SVM formulation in the presence of random and adversarial label noise. However, they do not provide any theoretical justification. Practitioners have developed several noise tolerant versions of the perceptron algorithm, although many are heuristic and are not known to be provably robust. This includes the passive-aggressive family of algorithms (Crammer et al., 2006), confidence weighted learning (Dredze et al., 2008), AROW (Crammer et al., 2009) and the NHERD algorithm (Crammer and Lee, 2010). The survey article by Khardon and Wachman (2007) provides an overview of some of this literature. To the best of our knowledge, there are no known mistake-bounded perceptron algorithms under asymmetric label noise.

Manwani and Sastry (2013) consider whether empirical risk minimization of the loss itself on the noisy data is a good idea when the goal is to obtain small risk under the clean distribution. But the answer is affirmative only for 0-1 and squared losses. Therefore, if empirical risk minimization over noisy samples has to work, we necessarily have to change the loss used to calculate the empirical risk. More recently, Ghosh et al. (2014) prove that a loss function ℓ satisfying the symmetry condition $\ell(f(\mathbf{x}), 1) + \ell(f(\mathbf{x}), -1) = C, \forall \mathbf{x}, \forall f$ for some constant C are noise-tolerant, under the assumption that the classes are separable under the clean distribution (here, ℓ is said to be *noise-tolerant* if $E_{(X,Y)\sim D}\big[\ell_{0\text{-}1}(f^*_\ell(X), Y)\big] = E_{(X,Y)\sim D}\big[\ell_{0\text{-}1}(\tilde{f}^*_\ell(X), Y)\big]$, where f^*_ℓ and $\tilde{f}^*_\ell$ denote the minimizers of ℓ-risk under clean and noisy distribution respectively). Furthermore, they show that by choosing a sufficiently large value of a parameter in the loss functions such as sigmoid loss, ramp loss and probit loss, the losses can be made tolerant to non-uniform label noise (i.e. noise rate is allowed to depend on the example) as well. Unfortunately, the aforementioned loss functions are all non-convex, and convex losses used in practice do not satisfy the sufficiency conditions. It remains an open question if the symmetry condition is indeed necessary for noise tolerance, at least under the separability assumption.

van Rooyen and Williamson (2015) extend the idea behind the method of unbiased estimators to more general learning settings beyond binary classification. For example, they consider semi-supervised learning, classification with more than two classes, and learning with partial labels (a partial label is a *set* of labels containing the true label).

Scott et al. (2013) also study the problem of learning classifiers under the class-conditional noise model. However, they approach the problem from a different set of assumptions — the noise rates are *not* known, and the true distribution satisfies a certain "mutual irreducibility" property. They model the observed noisy instances as arising from "contaminated" mixtures of positive and negative classes and show that the mixture proportions can be consistently estimated by *maximal denoising* of the noisy distributions. Blanchard and Scott (2014) establish similar results for the multi-class classification problem. Scott (2015) provides a consistent estimator with convergence rates for the cost parameter α in our weighted surrogate loss (Equation 2). In this paper, however, we select α by cross-validation and also examine the sensitivity of selecting α (in Section 6.3).

3. Preliminaries

Let D be the underlying true distribution generating $(X, Y) \in \mathcal{X} \times \{\pm 1\}$ pairs from which n iid samples $(X_1, Y_1), \ldots, (X_n, Y_n)$ are drawn. Let $\eta(X) = P(Y = 1|X)$ under D.

3.1 Class-conditional Noise

After injecting random classification noise (independently for each i) into these samples, corrupted samples $(X_1, \tilde{Y}_1), \ldots, (X_n, \tilde{Y}_n)$ are obtained. The class-conditional random noise model (CCN, for short) is given by:

$$P(\tilde{Y} = -1|Y = +1) = \rho_{+1},$$
$$P(\tilde{Y} = +1|Y = -1) = \rho_{-1}, \text{ and}$$
$$\rho_{+1} + \rho_{-1} < 1.$$

The corrupted samples are what the learning algorithm sees. We will assume that the noise rates ρ_{+1} and ρ_{-1} are known to the learner. Let the distribution of $(X, \tilde{Y})$ be D_ρ. Noisy labels are denoted by $\tilde{y}$. Let $\tilde{\eta}(X) = P(\tilde{Y} = 1|X)$ under D_ρ.

3.2 Cost-sensitive Classification

Let $f : \mathcal{X} \to \mathbb{R}$ denote a real-valued decision function. The goal in classification is to learn f from a training sample, such that some cost or loss measure is minimized. The most common measure is the probability of misclassification, also called the **risk**, which is simply the expected 0-1 loss defined as

$$R(f) := R_D(f) := \mathbb{E}_{(X,Y)\sim D}\left[1_{\{\text{sign}(f(X))\neq Y\}}\right].$$

Minimizing the 0-1 loss on a training sample, over some class of decision functions, is often intractable. In practice, it is common to minimize a *surrogate* loss function that is chosen for its computational advantages such as convexity. Minimizing risk (or equivalently, maximizing the accuracy) of a classifier is however not always appropriate, and in fact practitioners have devised many alternative performance metrics to address specific needs of a target domain. Class imbalance is an important scenario where accuracy of classifier is not a good metric to optimize: a trivial classifier that assigns all the examples to the majority class will have a high accuracy. However, little is known about optimal classification or consistent algorithms for binary classification w.r.t. general performance measures, even when the observations are noise-free. An important family of performance measures that is preferred in many scenarios including heavy class imbalance and asymmetry in real-world costs associated with specific classes constitutes *cost-sensitive* learning. Cost-sensitive performance measures are given by a weighted combination of the four fundamental population quantities associated with the "confusion matrix" - true positives, false positives (also known as type-I error), false negatives (also known as type-II error) and true negatives as defined below:

$$TP(f;D) = E_{(X,Y)\sim D}[1_{\{f(X)=1,Y=1\}}], \quad TN(f;D) = E_{(X,Y)\sim D}[1_{\{f(X)=-1,Y=-1\}}]$$

$$FP(f;D) = E_{(X,Y)\sim D}[1_{\{f(X)=1,Y=-1\}}], \quad FN(f;D) = E_{(X,Y)\sim D}[1_{\{f(X)=-1,Y=1\}}].$$

We consider the family of measures $\mathcal{U}$ defined by:

$$\mathcal{U}(f;D) = a_{11}TP(f;D) + a_{10}FP(f;D) + a_{01}FN(f;D) + a_{00}TN(f;D), \tag{1}$$

given constants $a_0, a_{11}, a_{10}, a_{01}, a_{00}$ (that could depend on D). In the remainder of the paper, $\mathcal{U}$ refers to a measure in this family, unless specified otherwise. We will use the terms *performance* measure and *utility* measure interchangeably in this paper.

Next, we state two important, commonly-used measures in this family.

Proposition 1 *1. The Accuracy measure $\mathcal{U}_{Acc}(f;D)$ belongs in the family (1) with $a_{11} = a_{00} = 1$ and $a_{10} = a_{01} = 0$.*

2. The AM (Arithmetic Mean of TPR and TNR) measure defined as

$$\mathcal{U}_{AM}(f;D) := \frac{1}{2}\big(TPR(f;D) + TNR(f;D)\big),$$

where $TPR(f;D) = P(f(X) = 1|Y = 1)$ is the true positive rate and $TNR(f;D) = P(f(X) = -1|Y = -1)$ is the true negative rate, belongs in the family (1) with constants $a_{10} = a_{01} = 0$, $a_{11} = \frac{1}{2(1-\pi)}$ and $a_{00} = \frac{1}{2\pi}$, where $\pi = P(Y = 1)$ under D.

3.2.1 Cost-sensitive Classification without Label Noise

Before we present our approaches for cost-sensitive classification under class-conditional label noise, it will be useful to consider the setting without such label noise, and setup appropriate notation. Given a utility measure $\mathcal{U}$ and training data, our goal is to learn a decision function f that maximizes $\mathcal{U}$ with respect to the clean distribution. The optimal decision function (called Bayes optimal) that maximizes $\mathcal{U}$ over all real-valued decision functions is denoted as $f^\star(x) := \arg\max_f \mathcal{U}(f;D)$. We denote by $\mathcal{U}^*$ the optimal utility value, i.e. $\mathcal{U}^* = \mathcal{U}(f^\star)$. It is not always possible to characterize the Bayes optimal of arbitrary performance measures. Cost-sensitive measures are particularly interesting because their Bayes optimal exhibits a simple form, and as a consequence, consistent algorithms are readily obtained in practice in the noise-free case. Bayes optimal classifier for the family (1) is characterized in the following Lemma. Recall that $\eta(x) = P(Y = 1|x)$ under D.

Lemma 2 *The Bayes optimal of any measure $\mathcal{U}$ in family (1) is given by*

$$\arg\max_f \mathcal{U}(f;D) = \text{sign}(\eta(x) - \delta_D^*),$$

where the threshold is defined as

$$\delta_D^* = \frac{a_{00} - a_{10}}{a_{00} - a_{10} - a_{01} + a_{11}}.$$

The proof is simple and can be found elsewhere (Elkan, 2001). It is well-known that accuracy $\mathcal{U}_{Acc}(f;D)$ is maximized by $\text{sign}(\eta(x) - 1/2)$ which is also readily obtained by applying the above lemma. For the AM measure $\mathcal{U}_{AM}(f;D)$, one easily verifies that the threshold is $\pi = P(Y = 1)$.

For any general measure $\mathcal{U}$, we are interested in controlling the *deficit utility* which is $\mathcal{U}^* - \mathcal{U}(f;D)$. The following simple lemma relates the deficit utility for the family (1) to that of a certain weighted 0-1 risk.

Lemma 3 *Define α-weighted risk under distribution D as:*

$$R_\alpha(f) := R_{\alpha,D}(f) := E_{(X,Y)\sim D}\Big[(1-\alpha)1_{\{Y=1\}}1_{\{f(X)\leq 0\}} + \alpha 1_{\{Y=-1\}}1_{\{f(X)>0\}}\Big].$$

For any measure $\mathcal{U}$ in the family (1):

$$R_{\delta_D^*}(f) - R^*_{\delta_D^*} = \frac{1}{(a_{11} + a_{00}) - (a_{10} + a_{01})}(\mathcal{U}^* - \mathcal{U}(f;D)),$$

where $R^*_{\delta_D^*} = \min_f R_{\delta_D^*}(f)$.

Proof Let $c_1 = (a_{11}+a_{00})-(a_{10}-a_{01})$ and $c_2 = a_{00}-a_{10}$. From Lemma 2, we know $\delta_D^* = \frac{c_2}{c_1}$. Note that $1 > c_1 > 0$ for otherwise maximizing $\mathcal{U}$ would not make sense (See Remark 4), and therefore $0 \leq \delta_D^* \leq 1$. For any f, let θ denote the classifier $\theta(x) = \text{sign}(f(x))$. We can rewrite $\mathcal{U}(\theta)$ as $\mathcal{U}(\theta) = c_1[(1-\delta_D^*)TP + \delta_D^* TN] + \tilde{A}$, where $\tilde{A}$ is a constant. We have:

$$\begin{aligned}
R_{\delta_D^*}(\theta) &= E_{(X,Y)\sim D}\left[\left((1-\delta_D^*)1_{\{Y=1\}} + \delta_D^* 1_{\{Y=0\}}\right).1_{\{\theta(X)\neq Y\}}\right] \\
&= (1-\delta_D^*)P(Y=1,\theta(X)=-1) + \delta_D^* P(Y=-1,\theta(X)=1) \\
&= (1-\delta_D^*)FN + \delta_D^* FP \\
&= (1-\delta_D^*)(\pi - TP) + \delta_D^*(1-\pi-TN) \\
&= (1-\delta_D^*)\pi + \delta_D^*(1-\pi) - \left((1-\delta_D^*)TP + \delta_D^* TN\right) \\
&= (1-\delta_D^*)\pi + \delta_D^*(1-\pi) + \frac{\tilde{A}}{c_1} - \frac{1}{c_1}\mathcal{U}(\theta).
\end{aligned}$$

Observing that $(1-\delta_D^*)\pi + \delta_D^*(1-\pi) + \frac{\tilde{A}}{c_1}$ is a constant independent of θ, the proof is complete. ∎

Remark 4 *Note that we can assume $(a_{11}+a_{00}) - (a_{10}+a_{01}) > 0$, otherwise maximizing $\mathcal{U}$ would not make sense. If indeed, $(a_{11}+a_{00}) - (a_{10}+a_{01}) < 0$, then Lemma 3 still holds but with $\mathcal{U}^*$ interpreted as $\mathcal{U}^* = \min_f \mathcal{U}(f;D)$.*

Of course, minimizing the α-weighted risk on a training sample is not tractable. Scott (2012) extends the notion of the classification calibration defined by Bartlett et al. (2006) for the (unweighted) 0-1 loss. The following result of Scott (2012) tells us that by using a similarly weighted surrogate loss function ℓ_α, one can control the excess α-weighted risk. Define ℓ_α-risk, $R_{\ell_\alpha,D}(f) = E_{(X,Y)\sim D}[\ell_\alpha(f(X),Y)]$, and $R^*_{\ell_\alpha} = \min_f R_{\ell_\alpha,D}(f)$.

Lemma 5 (α-classification calibration (Scott, 2012)) *Given a loss function $\ell(t,y)$, and $\alpha \in (0,1)$, define the α-weighted loss:*

$$\ell_\alpha(t,y) = \left((1-\alpha)1_{\{y=1\}} + \alpha 1_{\{y=-1\}}\right)\ell(t,y)\ . \tag{2}$$

ℓ_α is α-classification calibrated (or α-CC) iff there exists a convex, non-decreasing and invertible *transformation $\psi_{\ell,\alpha}$, with $\psi_{\ell,\alpha}(0) = 0$, such that*

$$\psi_{\ell,\alpha}(R_\alpha(f) - R^*_\alpha) \leq R_{\ell_\alpha,D}(f) - R^*_{\ell_\alpha}\ .$$

In other words, consistency with respect to ℓ_α-risk implies consistency with respect to α-weighted (0-1) risk for α-CC losses. Also, for any ℓ that is classification-calibrated (Bartlett et al., 2006) (such as logistic, hinge and squared losses), the corresponding ℓ_α is α-CC.

If we choose $\alpha = \delta_D^*$, Lemmas 3 and 5 together guarantee the consistency of using a weighted surrogate loss function in practice, when we obtain samples from the clean distribution D. However, if the labels are noisy, the outlined procedure is no longer consistent. One necessarily has to change the loss function ℓ or rather ℓ_α to be able to tolerate the noise, as described in the next two sections.

Remark 6 *Most commonly used loss functions such as hinge and logistic losses are (even) margin losses, i.e. $\ell(t,y) = \phi(ty)$, for some $\phi : \mathbb{R} \to [0,\infty)$. We could also consider an* uneven margin *loss function of the form:*

$$\ell(t,y) = 1_{\{y=1\}}\phi(t) + 1_{\{y=-1\}}\beta\phi(-\gamma t),$$

for $\beta,\gamma > 0$. Scott (2012) showed that for convex ϕ, the above defined uneven margin loss ℓ is classification-calibrated, and in turn, the corresponding ℓ_α is α-CC, when $\beta = \frac{1}{\gamma}$. Such uneven margin losses have been used in practice mostly as heuristics as pointed out in (Scott, 2012). Thus, in principle, we could use uneven margin losses, and all the results in this manuscript will hold just the same.

Notation. We use letters with the 'tilde' accent to denote noisy versions of quantities or variables, e.g. $\tilde{\ell}$ is the loss function to be used on the noisy data, and $\tilde{y}$ denotes a noisy label. We use $\mathcal{F} : \mathcal{X} \to \mathbb{R}$ to denote a fixed class of real-valued decision functions. If f is not quantified in a minimization, then it is implicit that the minimization is over all measurable functions. Instances are denoted by $\mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^d$. Though most of our results apply to a general function class $\mathcal{F}$, we instantiate $\mathcal{F}$ to be the set of hyperplanes of bounded L_2 norm, $\mathcal{W} = \{\mathbf{w} \in \mathbb{R}^d : \|\mathbf{w}\|_2 \leq W_2\}$ for certain specific results.

4. Approach of Unbiased Surrogates

The method of unbiased surrogates uses the noise rates to construct an unbiased estimator $\tilde{\ell}(t,\tilde{y})$ for the loss $\ell(t,y)$. The following key lemma tells us how to construct unbiased estimator of the loss from noisy labels.

Lemma 7 *Let $\ell(t,y)$ be any bounded loss function. Then, if we define,*

$$\tilde{\ell}(t,y) := \frac{(1-\rho_{-y})\,\ell(t,y) - \rho_y\,\ell(t,-y)}{1-\rho_{+1}-\rho_{-1}}$$

we have, for any t,y, $\mathbb{E}_{\tilde{y}}\left[\tilde{\ell}(t,\tilde{y})\right] = \ell(t,y)$. In particular, for any given $\alpha \in (0,1)$, $\mathbb{E}_{\tilde{y}}\left[\tilde{\ell}_\alpha(t,\tilde{y})\right] = \ell_\alpha(t,y)$, where $\ell_\alpha(t,y)$ is defined as in (2).

Proof One could directly compute and see that $\tilde{\ell}$ is unbiased. But to give a little more insight into what motivates the definition of $\tilde{\ell}$, consider the conditions that unbiasedness imposes on it. We should have, for every t,

$$\mathbb{E}_{\tilde{y}\underset{y}{\sim}\rho}\left[\tilde{\ell}(t,\tilde{y})\right] = \ell(t,y)\ .$$

Considering the cases $y=+1$ and $y=-1$ separately, gives the equations

$$\begin{aligned}
(1-\rho_{+1})\tilde{\ell}(t,+1) + \rho_{+1}\tilde{\ell}(t,-1) &= \ell(t,+1)\ , \\
(1-\rho_{-1})\tilde{\ell}(t,-1) + \rho_{-1}\tilde{\ell}(t,+1) &= \ell(t,-1)\ .
\end{aligned}$$

Solving these two equations for $\tilde{\ell}(t,+1)$ and $\tilde{\ell}(t,-1)$ gives

$$\tilde{\ell}(t,+1) = \frac{(1-\rho_{-1})\ell(t,+1) - \rho_{+1}\ell(t,-1)}{1-\rho_{+1}-\rho_{-1}} ,$$
$$\tilde{\ell}(t,-1) = \frac{(1-\rho_{+1})\ell(t,-1) - \rho_{-1}\ell(t,+1)}{1-\rho_{+1}-\rho_{-1}} .$$

The second part of the lemma follows by observing that ℓ_α is bounded too. ■

In Section 3, we saw that in the noise-free case one can bound the deficit utility $\mathcal{U}^* - \mathcal{U}(f;D)$ by using a weighted surrogate loss approach with $\alpha = \delta_D^*$. In the presence of noisy labels, we can try to learn a good predictor that optimizes the measure $\mathcal{U}$ of the form (1) by minimizing the sample average

$$\hat{f} \leftarrow \operatorname*{argmin}_{f\in\mathcal{F}} \widehat{R}_{\tilde{\ell}_\alpha}(f) := \sum_{i=1}^{n} \tilde{\ell}_\alpha(f(X_i),\tilde{Y}_i) . \tag{3}$$

where $\alpha = \delta_D^*$ as before. By unbiasedness of $\tilde{\ell}_\alpha$ (Lemma 7), we know that, for any fixed $f \in \mathcal{F}$, the above sample average converges to $R_{\ell_\alpha,D}(f)$ even though the former is computed using noisy labels whereas the latter depends on the true labels. The following result gives a performance guarantee for this procedure in terms of the Rademacher complexity of the function class $\mathcal{F}$. The main idea in the proof is to use the contraction principle for Rademacher complexity to get rid of the dependence on the proxy loss $\tilde{\ell}_\alpha$. The price to pay for this is L_ρ, the Lipschitz constant of $\tilde{\ell}_\alpha$.

Lemma 8 *Let $\ell(t,y)$ be L-Lipschitz in t (for every y). Then, for any $\alpha \in (0,1)$, with probability at least $1-\delta$,*

$$\max_{f\in\mathcal{F}} |\widehat{R}_{\tilde{\ell}_\alpha}(f) - R_{\tilde{\ell}_\alpha,D_\rho}(f)| \le 2L_\rho\mathfrak{R}(\mathcal{F}) + \sqrt{\frac{\log(1/\delta)}{2n}}$$

where $\mathfrak{R}(\mathcal{F}) := \mathbb{E}_{X_i,\epsilon_i}\left[\sup_{f\in\mathcal{F}} \frac{1}{n}\epsilon_i f(X_i)\right]$ is the Rademacher complexity of the function class $\mathcal{F}$ and $L_\rho \le 2L/(1-\rho_{+1}-\rho_{-1})$ is the Lipschitz constant of $\tilde{\ell}_\alpha$. Note that ϵ_i's are iid Rademacher (symmetric Bernoulli) random variables.

Proof By the basic Rademacher bound on the maximal deviation between risks and empirical risks over $f \in \mathcal{F}$, we get

$$\max_{f\in\mathcal{F}} |\widehat{R}_{\tilde{\ell}_\alpha}(f) - R_{\tilde{\ell}_\alpha,D_\rho}(f)| \le 2\cdot\mathfrak{R}(\tilde{\ell}_\alpha\circ\mathcal{F}) + \sqrt{\frac{\log(1/\delta)}{2n}}$$

where

$$\mathfrak{R}(\tilde{\ell}_\alpha\circ\mathcal{F}) := \mathbb{E}_{X_i,\tilde{Y}_i,\epsilon_i}\left[\sup_{f\in\mathcal{F}} \frac{1}{n}\sum_{i=1}^{n}\epsilon_i\tilde{\ell}_\alpha(f(X_i),\tilde{Y}_i)\right]$$

If ℓ is L-Lipschitz then for any $\alpha \in (0,1)$, $\tilde{\ell}_\alpha$ is L_ρ Lipschitz for $L_\rho = (1+|\rho_{+1}-\rho_{-1}|)L/(1-\rho_{+1}-\rho_{-1}) \le 2L/(1-\rho_{+1}-\rho_{-1})$ and hence by the Lipschitz composition property of Rademacher averages, we have

$$\mathfrak{R}(\tilde{\ell}_\alpha\circ\mathcal{F}) \le L_\rho\cdot\mathfrak{R}(\mathcal{F}) .$$

■

The above lemma immediately leads to a performance bound for $\hat{f}$ with respect to the clean distribution D. Our first main result is stated in the theorem below. The proof relies on using the α-CC property of the modified surrogate loss function.

Theorem 9 *For any $\alpha \in (0,1)$, with probability at least $1-\delta$,*

$$R_{\ell_\alpha,D}(\hat{f}) \le \min_{f\in\mathcal{F}} R_{\ell_\alpha,D}(f) + 4L_\rho\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}} .$$

Furthermore, if ℓ_α is α-CC, then for the choice $\alpha = \delta_D^*$, there exists a nondecreasing function $\zeta_{\ell,\alpha}$ with $\zeta_{\ell,\alpha}(0) = 0$ such that,

$$\mathcal{U}^* - \mathcal{U}(\hat{f};D) \le \zeta_{\ell,\alpha}\left(\min_{f\in\mathcal{F}} R_{\ell_\alpha,D}(f) - \min_f R_{\ell_\alpha,D}(f) + 4L_\rho\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}}\right) .$$

Proof Let $f^\star$ be the minimizer of $R_{\ell_\alpha,D}(\cdot)$ over $\mathcal{F}$. We have

$$\begin{aligned}
&R_{\ell_\alpha,D}(\hat{f}) - R_{\ell_\alpha,D}(f^\star) \\
&= R_{\tilde{\ell}_\alpha,D_\rho}(\hat{f}) - R_{\tilde{\ell}_\alpha,D_\rho}(f^\star) \\
&= \widehat{R}_{\tilde{\ell}_\alpha}(\hat{f}) - \widehat{R}_{\tilde{\ell}_\alpha}(f^\star) + (R_{\tilde{\ell}_\alpha,D_\rho}(\hat{f}) - \widehat{R}_{\tilde{\ell}_\alpha}(\hat{f})) \\
&\quad + (\widehat{R}_{\tilde{\ell}_\alpha}(f^\star) - R_{\tilde{\ell}_\alpha,D_\rho}(f^\star)) \\
&\le 0 + 2\max_{f\in\mathcal{F}} |\widehat{R}_{\tilde{\ell}_\alpha}(f) - R_{\tilde{\ell}_\alpha,D_\rho}(f)| .
\end{aligned}$$

We can now apply Lemma 8 to control the last quantity above, and thus obtain the first statement of the theorem. Now, if ℓ_α is α-CC, then for $\alpha = \delta_D^*$, we know from Lemma 5 there exists a convex, invertible, nondecreasing transformation ψ_ℓ with $\psi_{\ell,\alpha}(0) = 0$ such that,

$$\psi_{\ell,\alpha}(R_\alpha(f) - R_\alpha^*) \le R_{\ell_\alpha,D}(f) - \min_f R_{\ell_\alpha,D}(f)$$

Subtracting $\min_f R_{\ell_\alpha,D}(f)$ off either sides of the first inequality in the theorem statement, and realizing that $\psi_{\ell,\alpha}^{-1}$ is nondecreasing as well, with $\psi_{\ell,\alpha}^{-1}(0) = 0$, we get:

$$R_\alpha(\hat{f}) - R_\alpha^* \le \psi_\ell^{-1}\left(\min_{f\in\mathcal{F}} R_{\ell,D}(f) - \min_f R_{\ell,D}(f) + 4L_\rho\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}}\right) .$$

Finally we can use Lemma 3 to bound $\mathcal{U}^* - \mathcal{U}(\hat{f};D)$, by setting $\zeta_{\ell,\alpha} = (a_{11}+a_{00}-a_{01}-a_{10})\psi_{\ell,\alpha}^{-1}$. ■

The term on the right hand side involves both approximation error (that is small if $\mathcal{F}$ is large) and estimation error (that is small if $\mathcal{F}$ is small). However, by appropriately increasing the richness of the class $\mathcal{F}$ with sample size, we can ensure that the utility of $\hat{f}$ approaches the optimal utility under the true distribution. This is despite the fact that the method of unbiased estimators computes the empirical minimizer $\hat{f}$ on a sample from the noisy distribution. Getting the optimal empirical minimizer $\hat{f}$ is efficient if $\tilde{\ell}_\alpha$, or rather $\tilde{\ell}$, is convex. Next, we address the issue of convexity of $\tilde{\ell}$.

4.1 Convex losses and their estimators

Note that the loss $\tilde{\ell}$ may not be convex even if we start with a convex ℓ. An example is provided by the familiar hinge loss $\ell_{\text{hin}}(t,y) = [1-yt]_+$. Stempfel and Ralaivola (2009) showed that $\tilde{\ell}_{\text{hin}}$ is not convex in general (of course, when $\rho_{+1} = \rho_{-1} = 0$, it is convex). Below we provide a simple condition to ensure convexity of $\tilde{\ell}$.

Lemma 10 *Suppose $\ell(t,y)$ is convex and twice differentiable almost everywhere in t (for every y) and also satisfies the symmetry property*

$$\forall t \in \mathbb{R},\ \ell''(t,y) = \ell''(t,-y)\ .$$

Then $\tilde{\ell}(t,y)$ is also convex in t.

Proof Let us compute $\tilde{\ell}''(t,y)$ (recall that differentiation is w.r.t. t) and show that it is non-negative under the symmetry condition $\ell''(t,y) = \ell''(t,-y)$. We have

$$\begin{aligned}
\tilde{\ell}''(t,y) &= \frac{(1-\rho_{-y})\ell''(t,y) - \rho_y \ell''(t,-y)}{1-\rho_{+1}-\rho_{-1}} \\
&= \frac{(1-\rho_{-y})\ell''(t,y) - \rho_y \ell''(t,y)}{1-\rho_{+1}-\rho_{-1}} \\
&= \frac{(1-\rho_{-y}-\rho_y)\ell''(t,y)}{1-\rho_{+1}-\rho_{-1}} \\
&= \ell''(t,y) \geq 0\ ,
\end{aligned}$$

since ℓ is convex in t. ■

Examples satisfying the conditions of the lemma above are the squared loss $\ell_{\text{sq}}(t,y) = (t-y)^2$, the logistic loss $\ell_{\log}(t,y) = \log(1+\exp(-ty))$ and the Huber loss:

$$\ell_{\text{Hub}}(t,y) = \begin{cases} -4yt & \text{if } yt < -1 \\ (t-y)^2 & \text{if } -1 \leq yt \leq 1 \\ 0 & \text{if } yt > 1 \end{cases}$$

Consider the case where $\tilde{\ell}$ turns out to be non-convex when ℓ is convex, as in $\tilde{\ell}_{\text{hin}}$. In the online learning setting (where the adversary chooses a sequence of examples, and the prediction of a learner at round i is based on the history of $i-1$ examples with independently

flipped labels) which we will discuss shortly, we would use a stochastic mirror descent type algorithm (Nemirovski et al., 2009) to arrive at risk bounds similar to Theorem 9. Then, we only need the expected loss to be convex and therefore ℓ_{hin} does not present a problem. At first blush, it may appear that we do not have much hope of obtaining $\hat{f}$ in the iid setting efficiently. However, Lemma 8 provides a clue.

We will now focus on the function class $\mathcal{W}$ of hyperplanes. Even though $\widehat{R}_{\tilde{\ell}}(\mathbf{w})$ is non-convex, it is uniformly close to $R_{\tilde{\ell},D_\rho}(\mathbf{w})$. Since $R_{\tilde{\ell},D_\rho}(\mathbf{w}) = R_{\ell,D}(\mathbf{w})$, this shows that $\widehat{R}_{\tilde{\ell}}(\mathbf{w})$ is uniformly close to a convex function over $\mathbf{w} \in \mathcal{W}$. The following result shows that we can therefore approximately minimize $F(\mathbf{w}) = \widehat{R}_{\tilde{\ell}}(\mathbf{w})$ by minimizing the biconjugate $F^{\star\star}$. Recall that the (Fenchel) biconjugate $F^{\star\star}$ is the largest convex function that minorizes F.

Lemma 11 *Let $F : \mathcal{W} \to \mathbb{R}$ be a non-convex function defined on function class $\mathcal{W}$ such it is ε-close to a convex function $G : \mathcal{W} \to \mathbb{R}$:*

$$\forall \mathbf{w} \in \mathcal{W},\ |F(\mathbf{w}) - G(\mathbf{w})| \leq \varepsilon$$

Then any minimizer of $F^{\star\star}$ is a 2ε-approximate (global) minimizer of F.

Proof Since $F \geq G - \varepsilon$ and $F^{\star\star}$ is the largest convex function that minorizes F, we must have $F^{\star\star} \geq G - \varepsilon$. This means that $F^{\star\star} + 2\varepsilon \geq G + \varepsilon \geq F$. Thus, F is sandwiched between $F^{\star\star} + 2\varepsilon$ and $F^{\star\star}$. The lemma follows directly from this. ■

Now, the following theorem establishes bounds for the case when $\tilde{\ell}$ is non-convex, via the solution obtained by minimizing the convex function $F^{\star\star}$.

Theorem 12 *Let ℓ be a loss, such as the hinge loss, for which $\tilde{\ell}$ is non-convex. Let $\mathcal{W} = \{\mathbf{w} : \|\mathbf{w}_2\| \leq W_2\}$, let $\|X_i\|_2 \leq X_2$ almost surely, and let $\hat{\mathbf{w}}_{\text{approx}}$ be any (exact) minimizer of the convex problem*

$$\min_{\mathbf{w}\in\mathcal{W}}\ F^{\star\star}(\mathbf{w})\ ,$$

where $F^{\star\star}(\mathbf{w})$ is the (Fenchel) biconjugate of the function $F(\mathbf{w}) = \widehat{R}_{\tilde{\ell}_\alpha}(\mathbf{w})$, where $\alpha = \delta_D^*$. Then, with probability at least $1-\delta$, $\hat{\mathbf{w}}_{\text{approx}}$ is a 2ε-minimizer of $\widehat{R}_{\tilde{\ell}_\alpha}(\cdot)$ where

$$\varepsilon = \frac{2L_\rho X_2 W_2}{\sqrt{n}} + \sqrt{\frac{\log(1/\delta)}{2n}}\ .$$

Therefore, with probability at least $1-\delta$,

$$R_{\ell_\alpha,D}(\hat{\mathbf{w}}_{\text{approx}}) \leq \min_{\mathbf{w}\in\mathcal{W}} R_{\ell_\alpha,D}(\mathbf{w}) + 4\varepsilon\ .$$

Proof The first part of the theorem follows by combining Lemma 8 and Lemma 11, using the fact that if $\|\mathbf{w}\|_2 \leq W_2$ for any $\mathbf{w}$ and $\|X_i\|_2 \leq X_2$ then, $\mathfrak{R}(\mathcal{W}) \leq W_2 X_2/\sqrt{n}$. Note that Theorem 9 is true also for 2ε-minimizers of the empirical risk $\widehat{R}_{\tilde{\ell}_\alpha}$ provided we add 2ε to the right hand side. ■

Numerical or symbolic computation of the biconjugate of a multidimensional function is difficult, in general, but can be done in special cases. It will be interesting to see if techniques from Computational Convex Analysis (Lucet, 2010) can be used to efficiently compute the biconjugate above.

4.2 Online learning setting

Consider the setting where an adversary chooses a sequence $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)$ of examples. At time i, the learner has to make a prediction based on $(\mathbf{x}_1, \tilde{y}_1), \ldots, (\mathbf{x}_{i-1}, \tilde{y}_{i-1})$ and $\mathbf{x}_i$. But the learner's cumulative loss as well as that of the best fixed predictor in hindsight are both computed using the true labels y_i. Note that if $\ell(t, y)$ is convex in t (for every y), and for a given $\alpha \in (0, 1)$ we choose $\lambda_1 \in \partial \ell_\alpha(t, y)$ and $\lambda_2 \in \partial \ell_\alpha(t, -y)$, (where $\partial \ell_\alpha$ is the subdifferential w.r.t. t) we have

$$\mathbb{E}_{\tilde{y}} \left[g(t, \tilde{y}) \right] \in \partial \ell_\alpha(t, y) \tag{4}$$

where

$$g(t, y) = \frac{(1 - \rho_{-y})\lambda_1 - \rho_y \lambda_2}{1 - \rho_{+1} - \rho_{-1}} \tag{5}$$

We show that Algorithm 1 indeed satisfies low regret (in expectation) on the original sequence chosen by the adversary even though it only receives noisy versions of the labels. We fix the function class to be the set $\mathcal{W}$ of bounded-norm hyperplanes.

Algorithm 1: Online learning using unbiased gradients

Choose learning rate $\gamma > 0$
$\mathcal{W} = \{\mathbf{w} : \|\mathbf{w}\|_2 \leq W_2\}$
$\Pi_{\mathcal{W}}(\cdot)$ = Euclidean projection onto $\mathcal{W}$
Initialize $\mathbf{w}_0 \leftarrow \mathbf{0}$
for $i = 1$ to n **do**
  Receive $\mathbf{x}_i \in \mathbb{R}^d$
  Predict $\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle$
  Receive noisy label $\tilde{y}_i$
  Update $\mathbf{w}_i \leftarrow \Pi_{\mathcal{W}} \left(\mathbf{w}_{i-1} - \gamma g(\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle, \tilde{y}_i) \mathbf{x}_i \right)$ where $g(\cdot, \cdot)$ is defined in (5)
end for

Theorem 13 *Let $\ell(t, y)$ be convex and L-Lipschitz in t (for every y). Fix an arbitrary sequence $(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)$, and $\alpha \in (0, 1)$. If Algorithm 1 is run on noisy data set $(\mathbf{x}_1, \tilde{y}_1), \ldots, (\mathbf{x}_n, \tilde{y}_n)$ with learning rate $\gamma = W_2/(X_2 L_\rho \sqrt{n})$ where $\tilde{y}_i$ is noisy version of y_i with noise rates ρ_{+1}, ρ_{-1}, then we have*

$$\mathbb{E}_{\tilde{y}_{1:n}} \left[\sum_{i=1}^{n} \ell_\alpha(\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle, y_i) \right] - \min_{\|\mathbf{w}\|_2 \leq W_2} \sum_{i=1}^{n} \ell_\alpha(\langle \mathbf{w}, \mathbf{x}_i \rangle, y_i) \leq L_\rho X_2 W_2 \sqrt{n} \ ,$$

where $L_\rho := (1 + |\rho_{+1} - \rho_{-1}|)L/(1 - \rho_{+1} - \rho_{-1})$ and it is assumed that $\|\mathbf{x}_i\| \leq X_2$ for all $i \in [n]$.

Proof Let us use the abbreviation g_i for $g(\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle, \tilde{y}_i)\mathbf{x}_i$ so that the update in Algorithm 1 becomes $\mathbf{w}_i \leftarrow \Pi_{\mathcal{W}} \left(\mathbf{w}_{i-1} - \gamma g_i \right)$. It is well known (Zinkevich, 2003) that, for any $\mathbf{w}$,

$$\sum_{i=1}^{n} \langle g_i, \mathbf{w}_{i-1} - \mathbf{w} \rangle \leq \frac{\gamma}{2} \sum_{i=1}^{n} \|g_i\|^2 + \frac{\|\mathbf{w}\|^2}{2\gamma} \ . \tag{6}$$

Since ℓ is L-Lipschitz, the λ_1, λ_2 appearing in the definition (5) of $g(\cdot, \cdot)$ satisfy $|\lambda_1|, |\lambda_2| \leq L$. This implies $|g(t, y)| \leq (1 + |\rho_{+1} - \rho_{-1}|)L/(1 - \rho_{+1} - \rho_{-1}) = L_\rho$ and hence $\|g_i\| \leq L_\rho X_2$. Thus, we have, for any $\mathbf{w}$ with $\|\mathbf{w}\| \leq W_2$, $\sum_{i=1}^{n} \langle g_i, \mathbf{w}_{i-1} - \mathbf{w} \rangle \leq \frac{\gamma L_\rho^2 X_2^2 n}{2} + \frac{W_2^2}{2\gamma}$. Choosing $\gamma = (W_2/L_\rho X_2)\frac{1}{\sqrt{n}}$, we get $\sum_{i=1}^{n} \langle g_i, \mathbf{w}_{i-1} - \mathbf{w} \rangle \leq L_\rho X_2 W_2 \sqrt{n}$. Note that $\mathbf{w}_{i-1}$ only depends on $\tilde{y}_{1:i-1}$. Hence

$$\mathbb{E}_{\tilde{y}_i} \left[\langle g_i, \mathbf{w}_{i-1} - \mathbf{w} \rangle \mid \tilde{y}_{1:i-1} \right] = \left\langle \mathbb{E}_{\tilde{y}_i} \left[g_i \mid \tilde{y}_{1:i-1} \right], \mathbf{w}_{i-1} - \mathbf{w} \right\rangle \geq \ell_\alpha(\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle, y_i) - \ell_\alpha(\langle \mathbf{w}, \mathbf{x}_i \rangle, y_i)$$

because $\mathbb{E}_{\tilde{y}_i} \left[g_i \mid \tilde{y}_{1:i-1} \right] \in \partial_{\mathbf{w}=\mathbf{w}_{i-1}} \ell_\alpha(\langle \mathbf{w}, \mathbf{x}_i \rangle, y_i)$ by (4) and the chain rule for differentiation, and $\ell_\alpha(\langle \mathbf{w}, \mathbf{x}_i \rangle, y_i)$ is convex in $\mathbf{w}$. Thus, for any $\mathbf{w}$ with $\|\mathbf{w}\|_2 \leq W_2$,

$$\mathbb{E}_{\tilde{y}_{1:n}} \left[\sum_{i=1}^{n} \ell_\alpha(\langle \mathbf{w}_{i-1}, \mathbf{x}_i \rangle, y_i) \right] - \sum_{i=1}^{n} \ell_\alpha(\langle \mathbf{w}, \mathbf{x}_i \rangle, y_i) \leq L_\rho X_2 W_2 \sqrt{n}.$$

Since the above inequality is true for any $\mathbf{w}$ with $\|\mathbf{w}\|_2 \leq 1$, the statement of the theorem follows. ■

5. Approach of Surrogates for Weighted 0-1 Loss

The second approach is based on directly obtaining weighted surrogates for $\mathcal{U}$. We develop the method of "label-dependent" costs from two key observations. First, the Bayes classifier under noisy distribution, denoted by $\tilde{f}^*$, simply uses a threshold that, in general, is different from that under clean distribution. Second, $\tilde{f}^*$ is the minimizer of a certain weighted 0-1 loss under the noisy distribution. The framework we develop here generalizes known results for the uniform noise rate setting $\rho_{+1} = \rho_{-1}$ and offers a more fundamental insight into the problem.

From Lemma 2, we know that the optimal Bayes classifier $\tilde{f}^*$ under D_ρ thresholds $\tilde{\eta}(X) = P(\tilde{Y} = 1|X)$ at a certain $\tilde{\delta}^*$. Now, noting that:

$$\tilde{\eta}(x) = (1 - \rho_{+1})\eta(x) + \rho_{-1}(1 - \eta(x)) = (1 - \rho_{+1} - \rho_{-1})\eta(x) + \rho_{-1},$$

we see that $\tilde{f}^*$ can be written as:

$$\tilde{f}^*(x) = \text{sign}\left(\eta(x) - \frac{\tilde{\delta}^* - \rho_{-1}}{1 - \rho_{+1} - \rho_{-1}} \right). \tag{7}$$

Not surprisingly, this optimal threshold simplifies for cost-sensitive performance measures. In particular, as shown in the following corollary, the optimal threshold for the AM measure does *not* change under the noisy distribution.

Corollary 14 *1. For the Accuracy measure:*

$$\arg\max_f \mathcal{U}_{Acc}(f; D_\rho) = \arg\min_f R_{D_\rho}(f) = \text{sign}\left(\eta(x) - \frac{1/2 - \rho_{-1}}{1 - \rho_{+1} - \rho_{-1}} \right).$$

2. For the AM Measure:

$$\arg\max_f \mathcal{U}_{AM}(f;D) = \arg\max_f \mathcal{U}_{AM}(f;D_\rho) = \text{sign}(\eta(x) - \pi).$$

Proof

1. For the 0-1 loss, $\delta^*_D = \tilde{\delta}^* = 1/2$ and the result is immediate.
2. We know $\delta^*_D = \pi$ from Lemma 2. Also, $\tilde{\delta}^* = P(\tilde{Y} = 1) = (1 - \rho_{-1} - \rho_{+1})\pi + \rho_{-1}$. Substituting in (7), we observe that the threshold remains π.

■

Interestingly, this *noisy* Bayes classifier can also be obtained as the minimizer of a weighted 0-1 loss; which as we will show, allows us to "correct" for the threshold under the noisy distribution. Let us first introduce the notion of label-dependent costs for binary classification. We can write the 0-1 loss as a label-dependent loss as follows:

$$1_{\{\text{sign}(f(X))\neq Y\}} = 1_{\{Y=1\}}1_{\{f(X)\leq 0\}} + 1_{\{Y=-1\}}1_{\{f(X)>0\}}$$

Clearly, the classical 0-1 loss is *unweighted*. Consider the α-weighted 0-1 loss (which is a special case of the weighted loss (2)):

$$U_\alpha(t,y) = (1-\alpha)1_{\{y=1\}}1_{\{t\leq 0\}} + \alpha 1_{\{y=-1\}}1_{\{t>0\}},$$

where $\alpha \in (0,1)$. In fact we see that minimization w.r.t. the 0-1 loss is equivalent to that w.r.t. $U_{1/2}(f(X), Y)$. It is not a coincidence that Bayes optimal f^* has a threshold $1/2$. The following lemma (Scott, 2012) shows that in fact for any α-weighted 0-1 loss, the minimizer thresholds $\eta(x)$ at α.

Lemma 15 (α-weighted Bayes optimal (Scott, 2012)) *For $\alpha \in (0,1)$,*

$$f^*_\alpha := \arg\min_f R_\alpha(f) = \text{sign}(\eta(x) - \alpha)\ .$$

At this juncture, we are interested in the following question: For a given δ, does there exist an $\alpha \in (0,1)$ such that the minimizer of U_α-risk under noisy distribution D_ρ has the same sign as that of the Bayes optimal f^*_δ? We now present our second main result in the following theorem that makes a stronger statement — the U_α-risk under noisy distribution D_ρ is linearly related to U_δ-risk under the clean distribution D. The corollary of the theorem answers the question in the affirmative.

Theorem 16 *For any given $\delta \in (0,1)$, for the choices,*

$$\alpha^* = \rho_{-1} + (1 - \rho_{+1} - \rho_{-1})\delta \text{ and } A_\rho = 1 - \rho_{+1} - \rho_{-1},$$

there exists a constant B_X that is independent of f such that, for all functions f,

$$R_{\alpha^*,D_\rho}(f) = A_\rho R_{\delta,D}(f) + B_X.$$

Proof For simplicity, let us think of f as $\{\pm 1\}$-valued. We have,

$$C_{\delta,D}(f) = \mathbb{E}_Y\left[(1-\delta)1_{\{Y=1\}}1_{\{f(X)\neq 1\}} + \delta 1_{\{Y=-1\}}1_{\{f(X)\neq -1\}}\right]$$

and

$$C_{\alpha,D_\rho}(f) = \mathbb{E}_{\tilde{Y}}\left[(1-\alpha)1_{\{\tilde{Y}=1\}}1_{\{f(X)\neq 1\}} + \alpha 1_{\{\tilde{Y}=-1\}}1_{\{f(X)\neq -1\}}\right].$$

Note that $R_{\delta,D}(f) = \mathbb{E}_X\left[C_{\delta,D}(f)\right]$, and $R_{\alpha,D_\rho}(f) = \mathbb{E}_X\left[C_{\alpha,D_\rho}(f)\right]$. Also note that $C_{\delta,D}(f) = (1-\delta)\eta(X)$ if $f(X) = -1$, and $C_{\delta,D}(f) = \delta(1-\eta(X))$ otherwise.
Similarly, $C_{\alpha,D_\rho}(f) = (1-\alpha)\tilde{\eta}(X)$ if $f(X) = -1$ and $C_{\alpha,D_\rho}(f) = \alpha(1-\tilde{\eta}(X))$ otherwise.
We want to find A and B such that the following equations hold simultaneously:

$$(1-\alpha)\tilde{\eta}(X) = A(1-\delta)\eta(X) + B$$
$$\alpha(1-\tilde{\eta}(X)) = A\delta(1-\eta(X)) + B$$

Using the relation between $\eta(X)$ and $\tilde{\eta}(X)$ and solving for A we get,

$$A = \frac{(1-\rho_{+1}-\rho_{-1})\eta(X) + \rho_{-1} - \alpha}{\eta(X) - \delta}.$$

Choosing $\alpha = \alpha^* = \rho_{-1} + (1-\rho_{+1}-\rho_{-1})\delta$, and simplifying, we get a constant A that depends only on the noise rates:

$$A = A_\rho = 1 - \rho_{+1} - \rho_{-1}.$$

Consequently,

$$B = \rho_{-1}(1-\alpha^*) + (\delta - \alpha^*)(1-\rho_{+1}-\rho_{-1})\eta(X).$$

Taking expectation with respect to X, we conclude:

$$R_{\alpha^*,D_\rho}(f) = A_\rho R_{\delta,D}(f) + B_X,$$

where $B_X = \mathbb{E}_X[B]$. ■

Corollary 17 *Let $\alpha^* = \rho_{-1} + (1-\rho_{+1}-\rho_{-1})\delta^*_D$. The $\alpha^\star$-weighted Bayes optimal classifier under noisy distribution coincides with that of $\mathcal{U}$ measure under clean distribution:*

$$\operatorname*{argmin}_f R_{\alpha^*,D_\rho}(f) = \operatorname*{argmin}_f R_{\delta^*_D,D}(f) = \operatorname*{argmin}_f \mathcal{U}(f;D).$$

We are now ready to state our next main result — a certain weighted ERM is consistent: i.e. the "true" performance of the empirical minimizer w.r.t. the noisy distribution converges to the optimal performance $\mathcal{U}^*$ at a steady rate. The resulting bound has a striking resemblance to that of our first result in Theorem 9. The proof technique is similar to that of Theorem 9, and crucially relies on using the relationship established in Theorem 16.

Theorem 18 *Given a convex loss function $\ell : \mathbb{R} \to [0, \infty)$ with Lipschitz constant L such that it is classification-calibrated (i.e. $\ell'(0) < 0$), consider the empirical risk minimization problem with noisy labels:*

$$\hat{f}_\alpha = \operatorname*{argmin}_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \ell_\alpha(f(X_i), \tilde{Y}_i). \tag{8}$$

where ℓ_α is defined as in (2). Then, for the choice of α^* in Corollary 17, there exists a nondecreasing function $\zeta_{\ell_{\alpha^\star}}$ with $\zeta_{\ell_{\alpha^\star}}(0) = 0$, such that the following bound holds with probability at least $1 - \delta$:

$$\mathcal{U}^* - \mathcal{U}(\hat{f}_{\alpha^*}; D) \leq \frac{1}{A_\rho} \zeta_{\ell_{\alpha^\star}} \left(\min_{f \in \mathcal{F}} R_{\alpha^*, D_\rho}(f) - \min_f R_{\alpha^*, D_\rho}(f) + 4L\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}} \right),$$

where $A_\rho = 1 - \rho_{+1} - \rho_{-1}$.

Proof From Corollary 4.1 of Scott (2012), we can infer that ℓ_α is α-CC for given $\alpha \in (0, 1)$, as ℓ is convex, classification-calibrated and $\ell'(0) < 0$. Then, from Theorem 3.1 of Scott (2012), there exists an *invertible*, *non-decreasing* convex transformation ψ_{ℓ_α} with $\psi_{\ell_\alpha}(0) = 0$ such that, for any f and any distribution D,

$$\psi_{\ell_\alpha}(R_{\alpha,D}(f) - \min_f R_{\alpha,D}(f)) \leq R_{\ell_\alpha,D}(f) - \min_f R_{\ell_\alpha,D}(f).$$

Fix distribution to be D_ρ, and let $f = \hat{f}_\alpha$. The RHS of the above inequality can then be controlled similarly as in the proof of Theorem 9. It is easy to see that the Lipschitz constant of ℓ_α is same as that of ℓ, denoted L. With probability at least $1 - \delta$:

$$R_{\ell_\alpha,D_\rho}(\hat{f}_\alpha) - \min_{f \in \mathcal{F}} R_{\ell_\alpha,D_\rho}(f) \leq 4L\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}}.$$

Now consider $R_{\alpha,D_\rho}(f) - \min_f R_{\alpha,D_\rho}(f)$. Using the linear relationship between R_{α,D_ρ} and $R_{\delta^*_D,D}$ at α^* (Theorem 16), we get $R_{\alpha^*,D_\rho}(f) - \min_f R_{\alpha^*,D_\rho}(f) = A_\rho(R_{\delta^*_D,D}(f) - R^*_{\delta^*_D})$. B_X vanishes because it is constant for the distribution D_ρ. Note that $\psi^{-1}_{\ell_{\alpha^*}}$ is nondecreasing as well and $\psi^{-1}_{\ell_{\alpha^*}}(0) = 0$. Subtracting $\min_f R_{\alpha^*,D_\rho}(f)$ from both sides of the second inequality above, we get: With probability at least $1 - \delta$,

$$R_{\delta^*_D,D}(\hat{f}_{\alpha^*}) - R^*_{\delta^*_D} \leq A_\rho^{-1} \psi^{-1}_{\ell_{\alpha^\star}} \left(\min_{f \in \mathcal{F}} R_{\alpha^*,D_\rho}(f) - \min_f R_{\alpha^*,D_\rho}(f) + 4L\mathfrak{R}(\mathcal{F}) + 2\sqrt{\frac{\log(1/\delta)}{2n}} \right).$$

Invoking Lemma 3 and setting $\zeta_{\ell_{\alpha^\star}} = (a_{11} + a_{00} - a_{10} - a_{01})\psi^{-1}_{\ell_{\alpha^\star}}$, the proof is complete. ■

6. Experiments

In our first set of experiments, we demonstrate the robustness of the proposed algorithms to increasing rates of label noise on synthetic and real-world data sets. In our second set of experiments, we also conduct a comparison of the performance of our two proposed methods with state-of-the-art methods for dealing with random label noise. In our experiments, we use the two utility measures listed in Proposition 1, i.e. $\mathcal{U}_{Acc}$ and $\mathcal{U}_{AM}$; note that the utility measures are computed with respect to the clean distribution. For given noise rates ρ_{+1} and ρ_{-1}, labels are flipped accordingly. To account for randomness in the flips to simulate a given noise rate, we repeat each experiment 3 times, with independent corruptions of the data set for same setting of ρ_{+1} and ρ_{-1}, and present the mean accuracy over the trials. Specifically, we divide each data set randomly into three training and test sets, and compute average utility over 3 train-test splits. We use cross-validation to tune parameters specific to the algorithms. Note that we perform cross-validation on a separate validation set with *noisy* labels. In our final set of experiments, we address a practical question of specifying true noise rates to the algorithms, and study how misspecification of noise rates affects the performance of the algorithms.

Proposed methods. For evaluation, we choose the following representative algorithms based on each of the two proposed methods: For the method in Section 4, we use unbiased estimator of the logistic loss. Here, the resulting ERM, i.e. (3) with $\ell_{\log}$, is solved using a gradient descent procedure. We refer to this as $\tilde{\ell}_{\log}$ for ease in the remainder of the section. For the method in Section 5 we use the widely-used C-SVM (Liu et al., 2003; Mordelet and Vert, 2014) method as well as weighted logistic regression, wherein we apply different costs on positive and negative examples in the respective loss functions. We use the `libsvm` library to solve the resulting ERM problems, i.e. (8) with ℓ_{hin} or $\ell_{\log}$ respectively. In all the cases, we tune the parameters α, ρ_{+1} and ρ_{-1} by cross-validation (on noisy validation set).

6.1 Synthetic data

First, we use the synthetic 2D linearly separable data set shown in Figure 1(a). We observe from experiments that our methods achieve over 90% accuracy even when $\rho_{+1} = \rho_{-1} = 0.4$. Figure 1 shows the performance of $\tilde{\ell}_{\log}$ on the data set for different noise rates. Next, we use a 2D UCI benchmark non-separable data set ('banana'). The data set and classification results using C-SVM (which corresponds to vanilla SVM for uniform noise rates, $\alpha^* = 1/2$) are shown in Figure 2. The results for higher noise rates are impressive as observed from Figures 2(d) and 2(e). The 'banana' data set has been used in previous research on classification with noisy labels. In particular, the Random Projection classifier (Stempfel and Ralaivola, 2007) that learns a kernel perceptron in the presence of noisy labels achieves about 84% accuracy at $\rho_{+1} = \rho_{-1} = 0.3$ as observed from our experiments (as well as shown by Stempfel and Ralaivola, 2007), and the random hyperplane sampling method (Stempfel et al., 2007) gets about the same accuracy at $(\rho_{+1}, \rho_{-1}) = (0.2, 0.4)$ (as reported by Stempfel et al., 2007). Contrast these with C-SVM that achieves about 90% accuracy at $\rho_{+1} = \rho_{-1} = 0.2$ and over 88% accuracy at $\rho_{+1} = \rho_{-1} = 0.4$.

6.2 Comparison with state-of-the-art methods on UCI benchmark data

We next compare our methods with three state-of-the-art methods for dealing with random classification noise: Random Projection (RP) classifier (Stempfel and Ralaivola, 2007), NHERD (Crammer and Lee, 2010) (*project* and *exact* variants, which were shown to be the

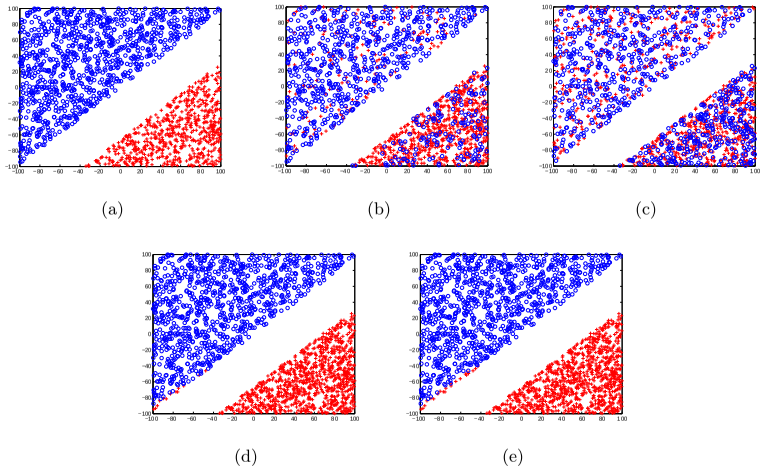

Figure 1: Classification of linearly separable synthetic data set using $\tilde{\ell}_{\log}$. The noise-free data is shown in the leftmost panel. Plots (b) and (c) show training data corrupted with noise rates ($\rho_{+1} = \rho_{-1} = \rho$) 0.2 and 0.4 respectively. Plots (d) and (e) show the corresponding classification results. The algorithm achieves 98.5% accuracy even at 0.4 noise rate per class. (Best viewed in color).

best performing variants from among the NHERD family of methods proposed by Crammer et al. 2006, 2009; Dredze et al. 2008), and perceptron algorithm with margin (PAM) which was shown to be robust to label noise by Khardon and Wachman (2007). We use seven standard UCI classification data sets listed in Table 1; here, data sets 1 through 6 are preprocessed and made available by Gunnar Rätsch.[1]

Using linear kernel. Results for the accuracy measure, for different settings of noise rates, using linear kernel in the compared methods, are shown in Table 2. C-SVM is competitive in 5 out of 7 data sets (Breast cancer, Thyroid, German, Image and Spambase), while relatively poorer in the other two. Note that in many cases, especially when $\rho_{+1} = \rho_{-1}$, the standard SVM (i.e. where positive and negative examples are weighted equally) as well as C-SVM (where α parameter that controls the relative weighting is tuned) yield the same accuracy, indicating that the cross-validation effectively selects equal weights; recall that the theory indeed suggests when the noise rates are equal, the optimal choice of weights are equal, i.e. $\alpha = 1/2$ (see Section 5). The corresponding results for the AM measure, for different settings of noise rates, are shown in Table 5. We find that C-SVM is competitive in three data sets, and NHERD is competitive in most of the data sets. Also observe that

1. `http://theoval.cmp.uea.ac.uk/matlab`

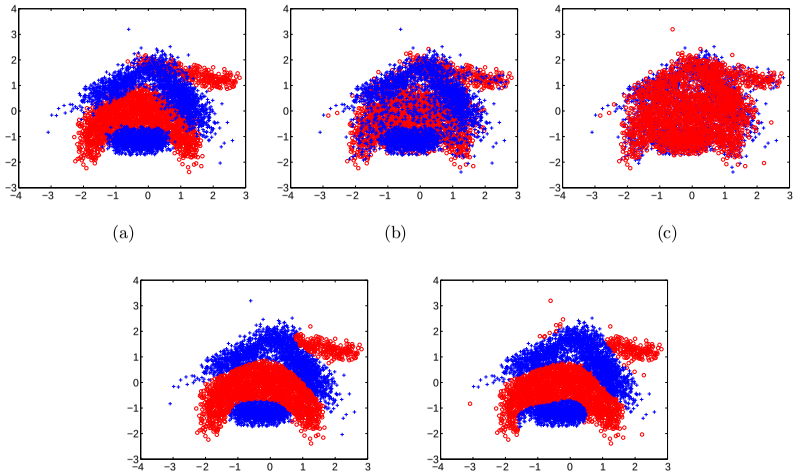

Figure 2: Classification of 'banana' data set using C-SVM. The noise-free data is shown in (a). Plots (b) and (c) show training data corrupted with noise rates ($\rho_{+1} = \rho_{-1} = \rho$) 0.2 and 0.4 respectively. Note that for $\rho_{+1} = \rho_{-1}$, $\alpha^* = 1/2$ (i.e. C-SVM reduces to regular SVM). Plots (d) and (e) show the corresponding classification results (Accuracies are 90.6% and 88.5% respectively). Even when 40% of the labels are corrupted ($\rho_{+1} = \rho_{-1} = 0.4$), the algorithm recovers the class structures as observed from plot (e). Note that the accuracy of the method at $\rho = 0$ is 90.8%.

at high noise rates AM is a more reliable measure of performance — in case of the four data sets Breast cancer, Diabetes, Thyroid and German which have class imbalance, the classifier optimized for the accuracy measure (Table 2) tends to bias its predictions towards the majority class (suggested by accuracy values matching the class imbalance ratio) but the achieved AM values are low.

We present the results for logistic loss based methods, using linear kernel, in Tables 3 and 6. As in the case of SVM based methods, we find, when $\rho_{+1} = \rho_{-1}$, the standard logistic regression (i.e. where positive and negative examples are weighted equally) as well as weighted logistic regression in the third column (where α parameter that controls the relative weighting is tuned) yield the same accuracy, indicating that the cross-validation effectively selects equal weights. In terms of accuracy, we find that $\tilde{\ell}_{\log}$ (in the second column) is competitive in all the data sets, wherease in terms of AM measure (see Table 6), (weighted) logistic regression performs the best more often.

Data set	Dim	Num. Positives	Num. Negatives

Table 2: $\mathcal{U}_{Acc}$ measure of classification (linear) algorithms on UCI benchmark data sets. Entries within 1% from the best in each row are in bold. All the methods use *linear* kernel. *All method-specific parameters are estimated through cross-validation.* We show the best performing NHERD variant ('project' and 'exact') in each case.

Using Gaussian kernel. For kernelized algorithms, we set the Gaussian kernel width parameter γ to $1/d$ where d is the dimensionality of data (the default parameter setting in `libsvm`). The results comparing SVM based methods are presented in Tables 4 and 7 for accuracy and AM measure respectively. We see a similar trend in performances as in the case of linear kernel. Note that the NHERD method is not kernelizable, so the results are omitted.

Overall, the experimental results support the theoretical guarantees; we observe that the proposed methods are competitive and are able to tolerate moderate to high amounts of label noise in the data.

6.3 Knowledge of noise rates

The proposed algorithms require the knowledge of noise rates ρ_{+1} and ρ_{-1}. However, in practice, we do not know the true value of noise rates, and therefore we resort to cross-validating the values in our experiments. In some cases (and domains), we may be able to approximately specify noise rates. This motivates our study presented in Figure 3. True noise rates $\rho_{+1} = \rho_{-1} = \rho$ are misspecified as $(\rho_{+1} \pm \epsilon, \rho_{-1} \pm \epsilon)$ for $\epsilon \in \{0.1, 0.2, 0.3, 0.4\}$. The ratio between the average accuracy for a given ϵ and the accuracy at $\epsilon = 0$, i.e. when true noise rates are specified, is a measure of sensitivity of the algorithms to ϵ-misspecification of noise rates. We would want the ratio to be close to 1 for a given ϵ, which would suggest that the method is fairly robust with respect to the ϵ-misspecification. The results in Figure 3 show that the proposed methods are robust to ϵ-misspecification of noise rates, which in turn suggests that our methods can find better use in applications where labels can be noisy *and* noise rates are approximately known, without resorting to ad-hoc cross-validation procedures on the noisy data. We emphasize here that in case the true noise rates are known, our methods can benefit from that knowledge as observed from our experiments, whereas the competitive methods *cannot* as they do not involve noise rates.

7. Conclusions and Future Work

We addressed learning in the presence of asymmetric random label noise with respect to general cost-sensitive utilities. We have obtained general theoretical results as well as efficient algorithms for this setting using the methods of unbiased estimators and weighted loss functions. The proposed algorithms are easy to implement and the classification performance is encouraging even at high noise rates and in particular is competitive with state-of-the-art methods on benchmark data. Our developments provide a new family of methods that can be applied to the positive-unlabeled learning problem (Elkan and Noto, 2008), but the implications of our methods for this setting should be carefully analyzed. We could consider harder noise models such as label noise depending on the example, and nastier variants of label noise where labels to flip are chosen adversarially.

Our analysis in this paper covers cost-sensitive classification losses, but there are other measures used in practice such as F_β, that are not covered by our family. Consistent learning for such general performance measures is beginning to be understood in the noise-free setting (Koyejo et al., 2014; Narasimhan et al., 2014). It would be interesting to see if we can extend some of the ideas in this paper to more general utility measures. It will also be of interest to extend our methods to deal with label noise in more general learning problems such as classification with a reject option, multiclass classification, learning with partial labels, learning to rank, and multilabel classification. Some of these extensions have begun to occur (van Rooyen and Williamson, 2015) but others are yet to be explored.

(a) $\tilde{\ell}_{\log}$ (b) Hinge online

(c) Huber online (d) Logistic online

Figure 3: Study of sensitivity of batch ($\tilde{\ell}_{\log}$) and online (Hinge, Huber and Logistic) methods (Algorithm 1) to specification of noise rates ρ_{+1} and ρ_{-1}. True noise rates $\rho_{+1} = \rho_{-1} = \rho$ are misspecified as $(\rho_{+1} \pm \epsilon, \rho_{-1} \pm \epsilon)$ for $\epsilon \in \{0.1, 0.2, 0.3, 0.4\}$. The ratio between the average accuracy for a given ϵ and the accuracy at $\epsilon = 0$, i.e. when true noise rates are specified, is plotted for different values of noise rates ρ. The ratio is computed for each of the 6 UCI data sets in Table 1 and the mean and the standard deviation of the ratios are shown. Ratio being equal to 1 for a given ϵ means that the performance of the algorithm, on average, is unaltered by misspecification of noise rates up to ϵ. As expected, the ratio decreases, i.e. the algorithms perform worse as ϵ increases. Most of the ratios being close to 1 suggests that the proposed methods are fairly robust with respect to ϵ-misspecification of noise rates.

Abstract

We consider the problem of matrix column subset selection, which selects a subset of columns from an input matrix such that the input can be well approximated by the span of the selected columns. Column subset selection has been applied to numerous real-world data applications such as population genetics summarization, electronic circuits testing and recommendation systems. In many applications the complete data matrix is unavailable and one needs to select representative columns by inspecting only a small portion of the input matrix. In this paper we propose the first provably correct column subset selection algorithms for partially observed data matrices. Our proposed algorithms exhibit different merits and limitations in terms of statistical accuracy, computational efficiency, sample complexity and sampling schemes, which provides a nice exploration of the tradeoff between these desired properties for column subset selection. The proposed methods employ the idea of feedback driven sampling and are inspired by several sampling schemes previously introduced for low-rank matrix approximation tasks (Drineas et al., 2008; Frieze et al., 2004; Deshpande and Vempala, 2006; Krishnamurthy and Singh, 2014). Our analysis shows that, under the assumption that the input data matrix has incoherent rows but possibly coherent columns, all algorithms provably converge to the best low-rank approximation of the original data as number of selected columns increases. Furthermore, two of the proposed algorithms enjoy a relative error bound, which is preferred for column subset selection and matrix approximation purposes. We also demonstrate through both theoretical and empirical analysis the power of feedback driven sampling compared to uniform random sampling on input matrices with highly correlated columns.

Keywords: Column subset selection, active learning, leverage scores

1. Introduction

Given a matrix $\mathbf{M} \in \mathbb{R}^{n_1 \times n_2}$, the *column subset selection* problem aims to find s exact columns in $\mathbf{M}$ that capture as much of $\mathbf{M}$ as possible. More specifically, we want to select s columns of $\mathbf{M}$ to form a column sub-matrix $\mathbf{C} \in \mathbb{R}^{n_1 \times s}$ to minimize the norm of the following residue

$$\min_{\mathbf{X} \in \mathbb{R}^{s \times n_2}} \|\mathbf{M} - \mathbf{C}\mathbf{X}\|_\xi = \|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_\xi, \tag{1}$$

where $\mathbf{C}^\dagger$ is the Moore-Penrose pseudoinverse of $\mathbf{C}$ and $\xi = 2$ or F denotes the spectral or Frobenius norm. In this paper we mainly focus on the Frobenius norm, as was the case in previous theoretical analysis for sampling based column subset selection algorithms (Drineas et al., 2008; Frieze et al., 2004; Deshpande and Vempala, 2006; Deshpande et al., 2006). To evaluate the performance of column subset selection, one compares the residue norm defined in Eq. (1) with $\|\mathbf{M} - \mathbf{M}_k\|_\xi$, where $\mathbf{M}_k$ is the best rank-k approximation of $\mathbf{M}$. Usually the number of selected columns s is larger than or equal to the target rank k. Two forms of error guarantee are common: additive error guarantee in Eq. (2) and relative error guarantee in Eq. (3), with $0 < \epsilon < 1$ and $c > 1$ (ideally $c = 1 + \epsilon$).

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_\xi \leq \|\mathbf{M} - \mathbf{M}_k\|_\xi + \epsilon\|\mathbf{M}\|_F; \tag{2}$$

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_\xi \leq c\|\mathbf{M} - \mathbf{M}_k\|_\xi. \tag{3}$$

In general, relative error bound is much more appreciated because $\|\mathbf{M}\|_\xi$ is usually large in practice, while $\|\mathbf{M} - \mathbf{M}_k\|_2$ is expected to be small when the goal is low-rank approximation. In addition, when $\mathbf{M}$ is an exact low-rank matrix Eq. (3) implies perfect reconstruction, while the error in Eq. (2) remains non-zero. The column subset selection problem can be considered as a form of *unsupervised feature selection* or *prototype selection*, which arises frequently in the analysis of large data sets. For example, column subset selection has been applied to various tasks such as summarizing population genetics, testing electronic circuits, recommendation systems, etc. Interested readers should refer to (Boutsidis et al., 2009; Balzano et al., 2010a) for further motivations.

Many methods have been proposed for the column subset selection problem (Chan, 1987; Gu and Eisenstat, 1996; Frieze et al., 2004; Deshpande et al., 2006; Drineas et al., 2008; Boutsidis et al., 2014). An excellent summarization of these methods and their theoretical guarantee is available in Table 1 in (Boutsidis et al., 2009). Most of these methods can be roughly categorized into two classes. One class of algorithms are based on *rank-revealing QR* (RRQR) decomposition (Chan, 1987; Gu and Eisenstat, 1996) and it has been shown in (Boutsidis et al., 2009) that RRQR is nearly optimal in terms of residue norm under the $s = k$ setting, that is, exact k columns are selected to reconstruct an input matrix. On the other hand, sampling based methods (Frieze et al., 2004; Deshpande et al., 2006; Drineas et al., 2008) try to select columns by sampling from certain distributions over all columns of an input matrix. Extension of sampling based methods to general low-rank matrix approximation problems is also investigated (Cohen et al., 2015; Bhojanapalli et al., 2015). These algorithms are much faster than RRQR and achieves comparable performance if the sampling distribution is carefully selected and slight over-sampling (i.e., $s > k$) is allowed (Deshpande et al., 2006; Drineas et al., 2008). In (Boutsidis et al., 2009) sampling based and RRQR based algorithms are unified to arrive at an efficient column subset selection method that uses exactly $s = k$ columns and is nearly optimal.

Although the column subset selection problem with access to the full input matrix has been extensively studied, often in practice it is hard or even impossible to obtain the complete data. For example, for the genetic variation detection problem it could be expensive and time-consuming to obtain full DNA sequences of an entire population. Several heuristic algorithms have been proposed recently for column subset selection with missing data, including the Block OMP algorithm (Balzano et al., 2010a) and the group Lasso formulation explored in (Bien et al., 2010). Nevertheless, no theoretical guarantee or error bounds have been derived for these methods. The presence of missing data poses new challenges for column subset selection, as many well-established algorithms seem incapable

of handling missing data in an elegant way. Below we identify a few key challenges that prevent application of previous theoretical results on column subset selection under the missing data setting:

- **Coherent matrix design**: most previous results on the completion or recovery of low rank matrices with incomplete data assume the underlying data matrix is *incoherent* (Recht, 2011; Candes and Plan, 2010; Keshavan et al., 2010), which intuitively assumes all rows and columns in the data matrix are weakly correlated. [1] On the other hand, previous algorithms on column subset selection and matrix CUR decomposition spent most efforts on dealing with coherent matrices (Deshpande et al., 2006; Drineas et al., 2008; Boutsidis et al., 2009; Boutsidis and Woodruff, 2014). In fact, one can show that under standard incoherence assumptions of matrix completion algorithms a high-quality column subset can be obtained by sampling each column uniformly at random, which trivializes the problem (Xu et al., 2015). Such gap in problem assumptions renders column subset selection on incomplete coherent matrices particularly difficult. In this paper, we explore the possibility of a weaker incoherence assumption that bridges the gap. We present and discuss detailed assumptions considered in this paper in Sec. 1.1.

- **Limitation of existing sampling schemes**: previous matrix completion methods usually assume the observed data are sampled uniformly at random. However, in (Krishnamurthy and Singh, 2014) it is proved that uniform sampling (in fact any sampling scheme with apriori fixed sampling distribution) is not sufficient to complete a coherent matrix. Though in (Chen et al., 2013) a provably correct sampling scheme was proposed for any matrix based on statistical leverage scores, which is also the key ingredient of many previous column subset selection and matrix CUR decomposition algorithms (Drineas et al., 2008; Boutsidis et al., 2009; Boutsidis and Woodruff, 2014), it is very difficult to approximate the leverage scores of an incomplete coherent matrix. Common perturbation results on singular vector space (e.g., Wedin's theorem) fail because closeness between two subspaces does not imply closeness in their leverage scores since the latter are defined in an infinity norm manner (see Section 2.1 for details).

- **Limitation of zero filling**: A straightforward algorithm for missing data column subset selection is to first fill all unobserved entries with zero and then properly scale the observed ones so that the completed matrix is consistent with the underlying data matrix in expectation (Achlioptas and McSherry, 2007; Achlioptas et al., 2013). Column subset selection algorithms designed for fully observed data could be applied afterwards on the zero-filled matrix. However, the zero filling procedure can change the underlying subspace of a matrix drastically (Balzano et al., 2010b) and usually leads to additive error bounds as in Eq. (2). To achieve stronger relative error bounds we need an algorithm that goes beyond the zero filling idea.

In this paper, we propose three column subset selection algorithms based on the idea of *active sampling* of the input matrix. In our algorithms, observed matrix entries are

1. The precise definition of incoherence is given in Section 1.3.

chosen sequentially and in a feedback-driven manner. We motivate this sampling setting from both practical and theoretical perspectives. In applications where each entry of a data matrix $\mathbf{M}$ represents results from an expensive or time-consuming experiment, it makes sense to carefully select which entry to query (experiment), possibly in a feedback-driven manner, so as to reduce experimental cost. For example, if $\mathbf{M}$ has drugs as its columns and targets (proteins) as its rows, it makes sense to cautiously select drug-target pairs for sequential experimental study in order to find important drugs/targets with typical drug-target interactions. From a theoretical perspective, we show in Section 7.1 that no passive sampling scheme is capable of achieving relative-error column subset selection with high probability, even if the column space of $\mathbf{M}$ is incoherent. Such results suggest that active/adaptive sampling is to some extent unavoidable, unless both row and column spaces of $\mathbf{M}$ are incoherent.

We also remark that the algorithms we consider make very few measurements of the input matrix, which differs from previous feedback-driven re-sampling methods in the theoretical computer science literature (e.g., (Wang and Zhang, 2013)) that requires access to the entire input matrix. Active sampling has been shown to outperform all passive schemes in several settings (cf. (Haupt et al., 2011; Kolar et al., 2011)), and furthermore it works for completion of matrices with incoherent rows/columns under which passive learning provably fails (Krishnamurthy and Singh, 2013, 2014). To the best of our knowledge, the algorithms proposed in this paper are the first column subset selection algorithms for coherent matrices that enjoy theoretical error guarantee with missing data, whether passive or active. Furthermore, two of our proposed methods achieve relative error bounds.

1.1 Assumptions

Completing/approximating partially observed low-rank matrices using a subset of columns requires certain assumptions on the input data matrix $\mathbf{M}$ (Candes and Plan, 2010; Chen et al., 2013; Recht, 2011; Xu et al., 2015). To see this, consider the extreme-case example where the input data matrix $\mathbf{M}$ consists of *exactly* one non-zero element (i.e., $\mathbf{M}_{ij} = 1\{i = i^*, j = j^*\}$ for some $i^* \in [n_1]$ and $j^* \in [n_2]$). In this case, the relative approximation quality $c = \|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_\xi / \|\mathbf{M} - \mathbf{M}_1\|_\xi$ in Eq. (3) would be infinity if column j^* is not selected in $\mathbf{C}$. In addition, it is clearly impossible to correctly identify j^* using $o(n_1 n_2)$ observations even with active sampling strategies. Therefore, additional assumptions on $\mathbf{M}$ are required to provably approximate a partially observed matrix using column subsets.

In this work we consider the assumption that the top-k *column space* of the input matrix $\mathbf{M}$ is incoherent (detailed mathematical definition given in Sec. 2.1), while placing no incoherence or spikiness assumptions on the actual *columns*, rows or the row space of $\mathbf{M}$. In addition to the necessity of incoherence assumptions for incomplete matrix approximation problems discussed above, we further motivate the "one-sided" incoherence assumption from two perspectives:

- Column subset selection with incomplete observation remains a non-trivial problem even if the column space is assumed to be incoherent. Due to the possible heterogeneity of the columns, naive methods such as column subsets sampled uniformly at random are in general bad approximations of the original data matrix $\mathbf{M}$. Existing column

subset selection algorithms for fully-observed matrices also need to be majorly revised to accommodate missing matrix components.

- Compared to existing work on approximating low-rank incomplete matrices, our assumptions (one-sided incoherence) are arguably weaker. Xu et al. (2015) analyzed matrix CUR approximation of partially observed matrices, but assumed that both column and row spaces are incoherent; Krishnamurthy and Singh (2014) derived an adaptive sampling procedure to complete a low-rank matrix with only one-sided incoherence assumptions, but only achieved additive error bounds for noisy low-rank matrices.

- Finally, the one-sided incoherence assumption is reasonable in a number of practical scenarios. For example, in the application of drug-target interaction prediction, the one-sided incoherence assumption allows for highly specialized or diverse drugs while assuming some predictability between target protein responses.

1.2 Our contributions

The main contribution of this paper is three provably correct algorithms for column subset selection, which are inspired by existing work on column subset selection for fully-observed matrices, but only inspect a small portion of the input matrix. The sampling schemes for the proposed algorithms and their main merits and drawbacks are summarized below:

1. **Norm sampling**: The algorithm is simple and works for any input matrix with incoherent column subspace. However, it only achieves an additive error bound as in Eq. (2). It is also inferior than the other two proposed methods in terms of residue error on both synthetic and real-world data sets.

2. **Iterative norm sampling**: The iterative norm sampling algorithm enjoys relative error guarantees as in Eq. (3) at the expense of being much more complicated and computationally expensive. In addition, its correctness is only proved for low-rank matrices with incoherent column space corrupted with i.i.d. Gaussian noise.

3. **Approximate leverage score sampling**: The algorithm enjoys relative error guarantee for general (high-rank) input matrices with incoherent column space. However, it requires more over-sampling and its error bound is worse than the one for iterative norm sampling on noisy low-rank matrices. Moreover, to actually reconstruct the data matrix [2] the approximate leverage score sampling scheme requires sampling a subset of both entire rows and columns, while both norm based algorithms only require sampling of some entire columns.

In summary, our proposed algorithms offer a rich, provably correct toolset for column subset selection with missing data. Furthermore, a comprehensive understanding of the design tradeoffs among statistical accuracy, computational efficiency, sample complexity, and sampling scheme, etc. is achieved by analyzing different aspects of the proposed methods. Our analysis could provide further insights into other matrix completion/approximation tasks on partially observed data.

2. See Section 1.3 for the distinction between selection and reconstruction.

We also perform comprehensive experimental study of column subset selection with missing data using the proposed algorithms as well as modifications of heuristic algorithms proposed recently (Balzano et al., 2010a; Bien et al., 2010) on synthetic matrices and two real-world applications: tagging Single Nucleotide Polymorphisms (tSNP) selection and column based image compression. Our empirical study verifies most of our theoretical results and reveals a few interesting observations that are previously unknown. For instance, though leverage score sampling is widely considered as the state-of-the-art for matrix CUR approximation and column subset selection, our experimental results show that under certain low-noise regimes (meaning that the input matrix is very close to low rank) iterative norm sampling is more preferred and achieves smaller error. These observations open new questions and suggest the need for new analysis in related fields, even for the fully observed case.

1.3 Notations

For any matrix $\mathbf{M}$ we use $\mathbf{M}^{(i)}$ to denote the i-th column of $\mathbf{M}$. Similarly, $\mathbf{M}_{(i)}$ denotes the i-th row of $\mathbf{M}$. All norms $\|\cdot\|$ are ℓ_2 norms or the matrix spectral norm unless otherwise specified.

We assume the input matrix is of size $n_1 \times n_2$, $n = \max(n_1, n_2)$. We further assume that $n_1 \leq n_2$. We use $\boldsymbol{x}_i = \mathbf{M}^{(i)} \in \mathbb{R}^{n_1}$ to denote the i-th column of $\mathbf{M}$. Furthermore, for any column vector $\boldsymbol{x}_i \in \mathbb{R}^{n_1}$ and index subset $\Omega \subseteq [n_1]$, define the subsampled vector $\boldsymbol{x}_{i,\Omega}$ and the scaled subsampled vector $\mathcal{R}_\Omega(\boldsymbol{x}_i)$ as

$$\boldsymbol{x}_{i,\Omega} = \mathbf{1}_\Omega \circ \boldsymbol{x}_i, \quad \mathcal{R}_\Omega(\boldsymbol{x}_i) = \frac{n_1}{|\Omega|}\mathbf{1}_\Omega \circ \boldsymbol{x}_i, \tag{4}$$

where $\mathbf{1}_\Omega \in \{0,1\}^{n_1}$ is the indicator vector of Ω and $\circ$ is the Hadamard product (entrywise product). We also generalize the definition in Eq. (4) to matrices by applying the same operator on each column.

We use $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_\xi$ to denote the *selection error* and $\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_\xi$ to denote the *reconstruction error*. The difference between the two types of error is that for selection error an algorithm is only required to output indices of the selected columns while for reconstruction error an algorithm needs to output both the selected columns $\mathbf{C}$ and the coefficient matrix $\mathbf{X}$ so that $\mathbf{C}\mathbf{X}$ is close to $\mathbf{M}$. We remark that the reconstruction error always upper bounds the selection error due to Eq. (1). On the other hand, there is no simple procedure to compute $\mathbf{C}^\dagger\mathbf{M}$ when $\mathbf{M}$ is not fully observed.

1.4 Outline of the paper

The paper is organized as follows: in Section 2 we provide background knowledge and review several concepts that are important to our analysis. We then present main results of the paper, the three proposed algorithms and their theoretical guarantees in Section 3. Proofs for main results given in Section 3 are sketched in Section 4 and some technical lemmas and complete proof details are deferred to the appendix. In Section 5 we briefly describe previously proposed heuristic based algorithm for column subset selection with missing data and their implementation details. Experimental results are presented in Section 6 and we discuss several aspects including the limitation of passive sampling and time complexity of proposed algorithms in Section 7.

2. Preliminaries

This section provides necessary background knowledge for the analysis in this paper. We first review the concept of *coherence*, which plays an important row in sampling based matrix algorithms. We then summarize three matrix sampling schemes proposed in previous literature.

2.1 Subspace and vector incoherence

Incoherence plays a crucial role in various matrix completion and approximation tasks (Recht, 2011; Krishnamurthy and Singh, 2014; Candes and Plan, 2010; Keshavan et al., 2010). For any matrix $\mathbf{M} \in \mathbb{R}^{n_1 \times n_2}$ of rank k, singular value decomposition yields $\mathbf{M} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, where $\mathbf{U} \in \mathbb{R}^{n_1 \times k}$ and $\mathbf{V} \in \mathbb{R}^{n_2 \times k}$ have orthonormal columns. Let $\mathcal{U} = \text{span}(\mathbf{U})$ and $\mathcal{V} = \text{span}(\mathbf{V})$ be the column and row space of $\mathbf{M}$. The *column space coherence* is defined as

$$\mu(\mathcal{U}) := \frac{n_1}{k} \max_{i=1}^{n_1} \|\mathbf{U}^\top \boldsymbol{e}_i\|_2^2 = \frac{n_1}{k} \max_{i=1}^{n_1} \|\mathbf{U}_{(i)}\|_2^2. \tag{5}$$

Note that $\mu(\mathcal{U})$ is always between 1 and n_1/k. Similarly, the *row space coherence* is defined as

$$\mu(\mathcal{V}) := \frac{n_2}{k} \max_{i=1}^{n_2} \|\mathbf{V}^\top \boldsymbol{e}_i\|_2^2 = \frac{n_2}{k} \max_{i=1}^{n_2} \|\mathbf{V}_{(i)}\|_2^2. \tag{6}$$

In this paper we also make use of incoherence level of vectors, which previously appeared in (Balzano et al., 2010b; Krishnamurthy and Singh, 2013, 2014). For a column vector $\boldsymbol{x} \in \mathbb{R}^{n_1}$, its incoherence is defined as

$$\mu(\boldsymbol{x}) := \frac{n_1 \|\boldsymbol{x}\|_\infty^2}{\|\boldsymbol{x}\|_2^2}. \tag{7}$$

It is an easy observation that if $\boldsymbol{x}$ lies in the subspace $\mathcal{U}$ then $\mu(\boldsymbol{x}) \leq k\mu(\mathcal{U})$. In this paper we adopt incoherence assumptions on the column space $\mathcal{U}$, which subsequently yields incoherent row vectors $\boldsymbol{x}_i$. No incoherence assumption on the row space $\mathcal{V}$ or row vectors $\mathbf{M}_{(i)}$ is made.

2.2 Matrix sampling schemes

Norm sampling: Norm sampling for column subset selection was proposed in (Frieze et al., 2004) and has found applications in a number of matrix computation tasks, e.g., approximate matrix multiplication (Drineas et al., 2006a) and low-rank or compressed matrix approximation (Drineas et al., 2006c,b). The idea is to sample each column with probability proportional to its squared ℓ_2 norm, i.e., $\Pr[i \in C] \propto \|\mathbf{M}^{(i)}\|_2^2$ for $i \in \{1, 2, \cdots, n_2\}$. These types of algorithms usually come with an additive error bound on their approximation performance.

Volume sampling: For volume sampling (Deshpande et al., 2006), a subset of columns C is picked with probability proportional to the volume of the simplex spanned by columns in C. That is, $\Pr[C] \propto \text{vol}(\Delta(C))$ where $\Delta(C)$ is the simplex spanned by $\{\mathbf{M}^{(C(1))}, \cdots, \mathbf{M}^{(C(k))}\}$. Computationally efficient volume sampling algorithms exist (Deshpande and Rademacher, 2010; Anari et al., 2016). These methods are based on the computation of characteristic polynomials of the projected data matrix (Deshpande and Rademacher, 2010) or an

Table 1: Summary of theoretical guarantees of proposed algorithms. s denotes the number of selected columns and m denotes the expected number of observed matrix entries. Dependency on failure probability δ and other poly-logarithmic dependency is omitted. $\mathcal{U}$ represents the column space of $\mathbf{A}$.

	Error type	Error bound	s	m	Assumptions
Norm	$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$	$\|\mathbf{M} - \mathbf{M}_k\|_F + \epsilon\|\mathbf{M}\|_F$	$\Omega(k/\epsilon^2)$	$\widetilde{\Omega}(\mu_1 n)$	$\max_{i=1}^{n_2} \mu(\mathbf{M}_{(i)}) \leq \mu_1$
	$\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F$	$\|\mathbf{M} - \mathbf{M}_k\|_F + 2\epsilon\|\mathbf{M}\|_F$	$\Omega(k/\epsilon^2)$	$\widetilde{\Omega}(k\mu_1 n/\epsilon^4)$	same as above
Iter. norm	$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$	$\sqrt{2.5^k(k+1)!}\|\mathbf{M} - \mathbf{M}_k\|_F$	k	$\widetilde{\Omega}(k^2\mu_0 n)$	$\mathbf{M} = \mathbf{A} + \mathbf{R}$; $\mu(\mathcal{U}) \leq \mu_0$
	$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$	$\sqrt{1+3\epsilon}\|\mathbf{M} - \mathbf{M}_k\|_F$	$\Theta(k^2 \log k + k/\epsilon)$	$\widetilde{\Omega}\left(\frac{k\mu_0 n}{\epsilon}\left(k + \frac{1}{\epsilon}\right)\right)$	same as above
	$\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F$	$\sqrt{1+3\epsilon}\|\mathbf{M} - \mathbf{M}_k\|_F$	$\Theta(k^2 \log k + k/\epsilon)$	$\widetilde{\Omega}\left(\frac{k\mu_0 n}{\epsilon}\left(k + \frac{1}{\epsilon}\right)\right)$	same as above
Lev. score	$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$	$3(1+\epsilon)\|\mathbf{M} - \mathbf{M}_k\|_F$	$\Omega(k^2/\epsilon^2)$	$\Omega(k^2\mu_0 n/\epsilon^2)$	$\mu(\mathcal{U}) \leq \mu_0$

MCMC sampling procedure (Anari et al., 2016). Under the partially observed setting, both approaches are difficult to apply. For the characteristic polynomials approach, one has to estimate the characteristic polynomial and essentially the least singular value of the target matrix $\mathbf{M}$ up to relative error bounds. This is not possible unless the matrix is very well-conditioned, which violates the setting that $\mathbf{M}$ is approximately low-rank. For the MCMC sampling procedure, it was shown in (Anari et al., 2016) that $O(kn_2)$ iterations are needed for the sampling Markov chain to mix. As each sampling iteration requires observing one entire column, performing $O(kn_2)$ iterations essentially requires observing $O(kn_2)$ columns, i.e., the entire matrix $\mathbf{M}$. On the other hand, an iterative norm sampling procedure is known to perform *approximate volume sampling* and therefore enjoys multiplicative approximation bounds for column subset selection (Deshpande and Vempala, 2006). In this paper we generalize the iterative norm sampling scheme to the partially observed setting and demonstrate similar multiplicative approximation error guarantees.

Leverage score sampling: The leverage score sampling scheme was introduced in (Drineas et al., 2008) to get relative error bounds for CUR matrix approximation and has later been applied to coherent matrix completion (Chen et al., 2013). For each row $i \in \{1, \cdots, n_1\}$ and column $j \in \{1, \cdots, n_2\}$ define $\mu_i := \frac{n_1}{k}\|\mathbf{U}^\top \boldsymbol{e}_i\|_2^2$ and $\nu_j := \frac{n_2}{k}\|\mathbf{V}^\top \boldsymbol{e}_j\|_2^2$ to be their *unnormalized leverage scores*, where $\mathbf{U} \in \mathbb{R}^{n_1 \times k}$ and $\mathbf{V} \in \mathbb{R}^{n_2 \times k}$ are the top-k left and right singular vectors of an input matrix $\mathbf{M}$. It was shown in (Drineas et al., 2008) that if rows and columns are sampled with probability proportional to their leverage scores then a relative error guarantee is possible for matrix CUR approximation and column subset selection.

3. Column subset selection via active sampling

In this section we propose three column subset selection algorithms that only observe a small portion of an input matrix. All algorithms employ the idea of active sampling to handle matrices with coherent rows. While Algorithm 1 achieves an additive reconstruction error guarantee for any matrix, Algorithm 2 achieves a relative-error reconstruction guarantee when the input matrix has certain structure. Finally, Algorithm 3 achieves a relative-error selection error bound for any general input matrix at the expense of slower error rate

Algorithm 1 Active norm sampling for column subset selection with missing data

1: **Input**: size of column subset s, expected number of samples per column m_1 and m_2.
2: **Norm estimation**: For each column i, sample each index in $\Omega_{1,i} \subseteq [n_1]$ i.i.d. from Bernoulli(m_1/n_1). observe $\boldsymbol{x}_{i,\Omega_{1,i}}$ and compute $\hat{c}_i = \frac{n_1}{m_1}\|\boldsymbol{x}_{i,\Omega_{1,i}}\|_2^2$. Define $\hat{f} = \sum_i \hat{c}_i$.
3: **Column subset selection**: Set $\mathbf{C} = \mathbf{0} \in \mathbb{R}^{n_1 \times s}$.
- For $t \in [s]$: sample $i_t \in [n_2]$ such that $\Pr[i_t = j] = \hat{c}_j/\hat{f}$. Observe $\mathbf{M}^{(i_t)}$ in full and set $\mathbf{C}^{(t)} = \mathbf{M}^{(i_t)}$.

4: **Matrix approximation**: Set $\widehat{\mathbf{M}} = \mathbf{0} \in \mathbb{R}^{n_1 \times n_2}$.
- For each column $\boldsymbol{x}_i$, sample each index in $\Omega_{2,i} \subseteq [n_1]$ i.i.d. from Bernoulli($m_{2,i}/n_1$), where $m_{2,i} = m_2 n_2 \hat{c}_i/\hat{f}$; observe $\boldsymbol{x}_{i,\Omega_{2,i}}$.
- Update: $\widehat{\mathbf{M}} = \widehat{\mathbf{M}} + (\mathcal{R}_{\Omega_{2,i}}(\boldsymbol{x}_i))\boldsymbol{e}_i^\top$.

5: **Output**: selected columns $\mathbf{C}$ and coefficient matrix $\mathbf{X} = \mathbf{C}^\dagger\widehat{\mathbf{M}}$.

and more sampled columns. Table 1 summarizes the main theoretical guarantees for the proposed algorithms.

3.1 ℓ_2 norm sampling

We first present an active norm sampling algorithm (Algorithm 1) for column subset selection under the missing data setting. The algorithm is inspired by the norm sampling work for column subset selection by Frieze et al. (Frieze et al., 2004) and the low-rank matrix approximation work by Krishnamurthy and Singh (Krishnamurthy and Singh, 2014).

The first step of Algorithm 1 is to estimate the ℓ_2 norm for each column by uniform subsampling. Afterwards, s columns of $\mathbf{M}$ are selected independently with probability proportional to their ℓ_2 norms. Finally, the algorithm constructs a sparse approximation of the input matrix by sampling each matrix entry with probability proportional to the square of the corresponding column's norm and then a $\mathbf{CX}$ approximation is obtained.

When the input matrix $\mathbf{M}$ has incoherent columns, the selection error as well as $\mathbf{CX}$ reconstruction error can be bounded as in Theorem 1.

Theorem 1 *Suppose* $\max_{i=1}^{n_2}\mu(\boldsymbol{x}_i) \le \mu_1$ *for some positive constant* μ_1. *Let* $\mathbf{C}$ *and* $\mathbf{X}$ *be the output of Algorithm 1. Denote* $\mathbf{M}_k$ *as the best rank-k approximation of* $\mathbf{M}$. *Fix* $\delta = \delta_1 + \delta_2 + \delta_3 > 0$. *With probability at least* $1 - \delta$, *we have*

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F \le \|\mathbf{M} - \mathbf{M}_k\|_F + \epsilon\|\mathbf{M}\|_F \tag{8}$$

provided that $s = \Omega(k\epsilon^{-2}/\delta_2)$, $m_1 = \Omega(\mu_1 \log(n/\delta_1))$. *Furthermore, if* $m_2 = \Omega(\mu_1 s \log^2(n/\delta_3)/(\delta_2\epsilon^2))$ *then with probability* $\ge 1 - \delta$ *we have the following bound on reconstruction error:*

$$\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F \le \|\mathbf{M} - \mathbf{M}_k\|_F + 2\epsilon\|\mathbf{M}\|_F. \tag{9}$$

Algorithm 2 Active iterative norm sampling for column subset selection for data corrupted by Gaussian noise

1: **Input**: target rank $k < \min(n_1, n_2)$, error tolerance parameter ϵ, δ and expected number of samples per column m.
2: **Entrywise sampling**: For each column i, sample each index in an index set $\Omega_i \subseteq [n_1]$ i.i.d. from Bernoulli(m/n_1). Observe $\boldsymbol{x}_{i,\Omega_i}$.
3: **Approximate volume sampling**: Set $C = \mathcal{U} = \emptyset$. Let $\mathbf{U}$ be an orthonormal basis of $\mathcal{U}$.
4: **for** $t = 1, 2, \cdots, k$ **do**
5: For $i \in \{1, \cdots, n_2\}$, compute $\hat{c}_i^{(t)} = \frac{n_1}{m}\|\boldsymbol{x}_{i,\Omega_i} - \mathbf{U}_{\Omega_i}(\mathbf{U}_{\Omega_i}^\top\mathbf{U}_{\Omega_i})^{-1}\mathbf{U}_{\Omega_i}^\top\boldsymbol{x}_{i,\Omega_i}\|_2^2$.
6: Set $\hat{f}^{(t)} = \sum_{i=1}^{n_2}\hat{c}_i^{(t)}$.
7: Select a column i_t at random, with probability $\Pr[i_t = j] = \hat{p}_j^{(t)} = \hat{c}_j^{(t)}/\hat{f}^{(t)}$.
8: Observe $\mathbf{M}^{(i_t)}$ in full and update: $C \leftarrow C \cup \{i_t\}$, $\mathcal{U} \leftarrow \text{span}(\mathcal{U}, \{\mathbf{M}^{(i_t)}\})$.
9: **end for**
10: **Active norm sampling**: set $T = (k+1)\log(k+1)$ and $s_1 = s_2 = \cdots = s_{T-1} = 5k$, $s_T = 10k/\epsilon\delta$; $S = \emptyset$, $\mathcal{S} = \emptyset$. Suppose $\mathbf{U}$ is an orthonormal basis of $\text{span}(\mathcal{U}, \mathcal{S})$.
11: **for** $t = 1, 2, \cdots, T$ **do**
12: For $i \in \{1, \cdots, n_2\}$, compute $\hat{c}_i^{(t)} = \frac{n_1}{m}\|\boldsymbol{x}_{i,\Omega_i} - \mathbf{U}_{\Omega_i}(\mathbf{U}_{\Omega_i}^\top\mathbf{U}_{\Omega_i})^{-1}\mathbf{U}_{\Omega_i}^\top\boldsymbol{x}_{i,\Omega_i}\|_2^2$.
13: Set $\hat{f}^{(t)} = \sum_{i=1}^{n_2}\hat{c}_i^{(t)}$.
14: Select s_t columns $S_t = (i_1, \cdots, i_{s_t})$ independently at random, with probability $\Pr[j \in S_t] = \hat{q}_j^{(t)} = \hat{c}_j^{(t)}/\hat{f}^{(t)}$.
15: Observe $\mathbf{M}^{(S_t)}$ in full and update: $S \leftarrow S \cup S_t$, $\mathcal{S} \leftarrow \text{span}(\mathcal{S}, \{\mathbf{M}^{(S_t)}\})$.
16: **end for**
17: **Matrix approximation**: $\widehat{\mathbf{M}} = \sum_{i=1}^{n_2}\mathbf{U}(\mathbf{U}_{\Omega_i}^\top\mathbf{U}_{\Omega_i})^{-1}\mathbf{U}_{\Omega_i}\boldsymbol{x}_{i,\Omega_i}\boldsymbol{e}_i^\top$, where $\mathbf{U} \in \mathbb{R}^{n_1 \times (s+k)}$ is an orthonormal basis of $\text{span}(\mathcal{U}_0, \mathcal{U}_1)$.
18: **Output**: selected column subsets $\mathbf{C} = (\mathbf{M}^{(C(1))}, \cdots, \mathbf{M}^{(C(k))}) \in \mathbb{R}^{n_1 \times k}$, $\mathbf{S} = (\mathbf{M}^{(C)}, \mathbf{M}^{(S_1)}, \cdots, \mathbf{M}^{(S_T)}) \in \mathbb{R}^{n_1 \times s}$ where $s = k + s_1 + \cdots + s_T$ and $\mathbf{X} = \mathbf{S}\mathbf{S}^\dagger\widehat{\mathbf{M}}$.

As a remark, Theorem 1 shows that one can achieve ϵ additive reconstruction error using Algorithm 1 with expected sample complexity (omitting dependency on δ)

$$\Omega\left(\mu_1 n_2 \log(n) + \frac{kn_1}{\epsilon^2} + \frac{k\mu_1 n_2 \log^2(n)}{\epsilon^4}\right) = \Omega(k\mu_1\epsilon^{-4} n \log^2 n).$$

3.2 Iterative norm sampling

In this section we present Algorithm 2, another active sampling algorithm based on the idea of iterative norm sampling and approximate volume sampling introduced in (Deshpande and Vempala, 2006). Though Algorithm 2 is more complicated than Algorithm 1, it achieves a relative error bound on inputs that are noisy perturbation of some underlying low-rank matrix.

Algorithm 2 employs the idea of *iterative norm sampling*. That is, after selecting l columns from $\mathbf{M}$, the next column (or next several columns depending on the error type) is sampled according to column norms of a *projected* matrix $\mathcal{P}_{\mathcal{C}^\perp}(\mathbf{M})$, where $\mathcal{C}$ is the subspace

spanned by currently selected columns. It can be shown that iterative norm sampling serves as an approximation of *volume sampling*, a sampling scheme that is known to have relative error guarantees (Deshpande et al., 2006; Deshpande and Vempala, 2006).

Theorem 2 shows that when the input matrix $\mathbf{M}$ is the sum of an exact low rank matrix $\mathbf{A}$ and a stochastic noise matrix $\mathbf{R}$, then by selecting exact k columns from $\mathbf{M}$ using iterative norm sampling one can upper bound the selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F$ by the best rank-k approximation error $\|\mathbf{M} - \mathbf{M}_k\|_F$ within a multiplicative factor that does not depend on the matrix size n. Such relative error guarantee is much stronger than the additive error bound provided in Theorem 1 as when $\mathbf{M}$ is exactly low rank the error is eliminated with high probability. In fact, when the input matrix $\mathbf{M}$ is exactly low rank the first phase of the proposed algorithm (Line 1 to Line 9 in Algorithm 2) resembles the adaptive sampling algorithm proposed in (Krishnamurthy and Singh, 2013, 2014) for matrix and tensor completion in the sense that at each iteration all columns falling exactly onto the span of already selected columns will have zero norm after projection and hence will never be sampled again. However, we are unable to generalize our algorithm to general full-rank inputs because it is difficult to bound the incoherence level of projected columns (and hence the projection accuracy itself later on) without a stochastic noise model. We present a new algorithm with slightly worse error bounds in Section 3.3 which can handle general high-rank inputs.

Though Eq. (10) is a relative error bound, the multiplicative factor scales exponentially with the intrinsic rank k, which is not completely satisfactory. As a remedy, we show that by slightly over-sampling the columns ($\Theta(k^2 \log k + k/\epsilon\delta)$ instead of k columns) the selection error as well as the $\mathbf{CX}$ reconstruction error could be upper bounded by $\|\mathbf{M} - \mathbf{M}_k\|_F$ within only a $(1 + 3\epsilon)$ factor, which implies that the error bounds are nearly optimal when the number of selected columns s is sufficiently large, for example, $s = \Omega(k^2 \log k + k/\epsilon\delta)$.

Theorem 2 *Fix $\delta > 0$. Suppose $\mathbf{M} = \mathbf{A} + \mathbf{R}$, where $\mathbf{A}$ is a rank-k deterministic matrix with incoherent column space (i.e., $\mu(\mathcal{U}(\mathbf{A})) \le \mu_0$) and $\mathbf{R}$ is a random matrix with i.i.d. zero-mean Gaussian distributed entries. Suppose $k = O(n_1/\log(n_2/\delta))$. Let $\mathbf{C}, \mathbf{S}$ and $\mathbf{X}$ be the output of Algorithm 2. Then the following holds:*

1. *If $m = \Omega(k^2 \mu_0 \log^2(n/\delta))$ then with probability $\ge 1 - \delta$*

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F^2 \le \frac{2.5^k (k+1)!}{\delta} \|\mathbf{R}\|_F^2. \tag{10}$$

   The column subset size is k and the corresponding sample complexity is $\Omega(k^2 \mu_0 n \log^2(n/\delta))$.

2. *If $m = \Omega(\epsilon^{-1} s \mu_0 \log^2(n/\delta))$ with $s = \Theta(k^2 \log k + k/\epsilon\delta)$, then with probability $\ge 1 - \delta$*

$$\|\mathbf{M} - \mathbf{S}\mathbf{S}^{\dagger}\mathbf{M}\|_F^2 \le \|\mathbf{M} - \mathbf{S}\mathbf{X}\|_F^2 \le (1 + 3\epsilon)\|\mathbf{R}\|_F^2. \tag{11}$$

   The column subset size is $\Theta(k^2 \log k + k/\epsilon\delta)$ and the sample complexity is (omitting dependence on δ)

$$\Omega\left(\frac{k^2 \mu_0 n \log k \log^2(n)}{\epsilon} + \frac{k \mu_0 n \log^2(n)}{\epsilon^2}\right).$$

Algorithm 3 Approximate leverage score sampling for column subset selection on general input matrices

1: **Input**: target rank k, size of column subset s, expected number of row samples m.
2: **Leverage score estimation**: Set $\mathcal{S} = \emptyset$.
- For each row i, with probability m/n_1 observe the row $\mathbf{M}_{(i)}$ in full and update $\mathcal{S} \leftarrow \text{span}(\mathcal{S}, \{\mathbf{M}_{(i)}\})$.
- Compute the first k right singular vectors of $\mathcal{S}$ (denoted by $\mathbf{S}_k \in \mathcal{R}^{n_2 \times k}$) and estimate the unnormalized row space leverage scores as $\tilde{l}_j = \|\mathbf{S}_k{}^{\top} \boldsymbol{e}_j\|_2^2$, $j \in \{1, 2, \cdots, n_1\}$.

3: **Column subset selection**: Set $C = \emptyset$.
- For $t \in \{1, 2, \cdots, s\}$ select a column $i_t \in [n_2]$ with probability $Pr[i_t = j] = \hat{p}_j = \tilde{l}_j/k$; update $C \leftarrow C \cup \{i_t\}$.

4: **Output**: the selected column indices $C \subseteq \{1, 2, \cdots, n_2\}$ and actual columns $\mathbf{C} = (\mathbf{M}^{(C(1))}, \cdots, \mathbf{M}^{(C(s))})$.

3.3 Approximate leverage score sampling

The third sampling-based column subset selection algorithm for partially observed matrices is presented in Algorithm 3. The proposed algorithm was based on the leverage score sampling scheme for matrix CUR approximation introduced in (Drineas et al., 2008). To compute the sampling distribution (i.e., leverage scores) from partially observed data, the algorithm subsamples a small number of rows from the input matrix and uses leverage scores of the row space of the subsampled matrix to form the sampling distribution. Note that we do not attempt to approximate leverage scores of the original input matrix directly; instead, we compute leverage scores of another matrix that is a good approximation of the original data. Such technique was also explored in (Drineas et al., 2012) to approximate statistical leverages in a fully observed setting. Afterwards, column sampling distribution is constructed using the estimated leverage scores and a subset of columns are selected according to the constructed sampling distribution.

We bound the selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F$ of the approximate leverage score sampling algorithm in Theorem 3. Note that unlike Theorem 1 and 2, only selection error bound is provided since for deterministic full-rank input matrices it is challenging to approximately compute the projection of $\mathbf{M}$ onto span($\mathbf{C}$) because the projected vector may no longer be incoherent (this is in fact the reason why Theorem 2 holds only for low-rank matrices perturbed by Gaussian noise, and we believe similar conclusion should also hold for Algorithm 3 is the stronger assumption of Gaussian noise perturbation is made). It remains an open problem to approximately compute $\mathbf{C}^{\dagger}\mathbf{M}$ given $\mathbf{C}$ with provable guarantee for general matrix $\mathbf{M}$ without observing it in full. Eq. (3) shows that Algorithm 3 enjoys a relative error bound on the selection error. In fact, when the input matrix $\mathbf{M}$ is exactly low rank then Algorithm 3 is akin to the two-step matrix completion method proposed in (Chen et al., 2013) for column incoherent inputs.

Although Theorem 3 shows that Algorithm 3 generalizes the relative selection error bound in Theorem 2 to general input matrices, it also reveals several drawbacks of the

approximate leverage score sampling algorithm compared to the iterative norm sampling method. First, Algorithm 3 always needs to over-sample columns (at the level of $\Theta(k^2/\epsilon^2)$, which is even more than Algorithm 2 for a $(1+\epsilon)$ reconstruction error bound); in contrast, the iterative norm sampling algorithm only requires exact k selected columns to guarantee a relative error bound. In addition, Eq. (12) shows that the selection error bound is suboptimal even if s is sufficiently large because of the $(3+3\epsilon)$ multiplicative term.

Theorem 3 *Suppose* $\mathbf{M}$ *is an input matrix with incoherent top-k column space (i.e.,* $\mu(\mathcal{U}_k(\mathbf{M})) \leq \mu_0$*) and* C *is the column indices output by Algorithm 3. If* $m = \Omega(\epsilon^{-2}\mu_0 k^2 \log(1/\delta))$ *and* $s = \Omega(\epsilon^{-2}k^2\log(1/\delta))$ *then with probability* $\geq 1-\delta$ *the following holds:*

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F \leq 3(1+\epsilon)\|\mathbf{M}-\mathbf{M}_k\|_F, \tag{12}$$

where $\mathbf{C} = [\mathbf{M}^{(C(1))}, \cdots, \mathbf{M}^{(C(s))}] \in \mathbb{R}^{n_1 \times s}$ *are the selected columns and* $\mathbf{M}_k$ *is the best rank-k approximation of* $\mathbf{M}$*.*

4. Proofs

In this section we provide proof sketches of the main results (Theorem 1, 2 and 3). Some technical lemmas and complete proof details are deferred to Appendix A and B.

4.1 Proof sketch of Theorem 1

The proof of Theorem 1 can be divided into two steps. First, in Lemma 1 we show that (approximate) column sampling yields an additive error bound for column subset selection. Its proof is very similar to the one presented in (Frieze et al., 2004) and we defer it to Appendix A. Second, we cite a lemma from (Krishnamurthy and Singh, 2014) to show that with high probability the first pass in Algorithm 1 gives accurate estimates of column norms of the input matrix $\mathbf{M}$.

Lemma 1 *Provided that* $(1-\alpha)\|\boldsymbol{x}_i\|_2^2 \leq \hat{c}_i \leq (1+\alpha)\|\boldsymbol{x}_i\|_2^2$ *for* $i = 1, 2, \cdots, n_2$*, with probability* $\geq 1-\delta$ *we have*

$$\|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F \leq \|\mathbf{M}-\mathbf{M}_k\|_F + \sqrt{\frac{(1+\alpha)k}{(1-\alpha)\delta s}}\|\mathbf{M}\|_F, \tag{13}$$

where $\mathbf{M}_k$ *is the best rank-k approximation of* $\mathbf{M}$*.*

Lemma 2 ((Krishnamurthy and Singh, 2014), Lemma 10) *Fix* $\alpha, \delta \in (0,1)$*. Assume* $\mu(\boldsymbol{x}_i) \leq \mu_0$ *holds for* $i = 1, 2, \cdots, n_2$*. For some fixed* $i \in \{1, \cdots, n_2\}$ *with probability* $\geq 1-2\delta$ *we have*

$$(1-\alpha)\|\boldsymbol{x}_i\|_2^2 \leq \hat{c}_i \leq (1+\alpha)\|\boldsymbol{x}_i\|_2^2 \tag{14}$$

with $\alpha = \sqrt{\frac{2\mu_0}{m_1}\log(1/\delta)} + \frac{2\mu_0}{3m_1}\log(1/\delta)$*. Furthermore, if* $m_1 = \Omega(\mu_0 \log(n_2/\delta))$ *with carefully chosen constants then Eq. (14) holds uniformly for all columns with* $\alpha = 0.5$*.*

Combining Lemma 1 and Lemma 2 and setting $s = \Omega(k\epsilon^{-2}/\delta)$ for some target accuracy threshold ϵ we have that with probability $1-3\delta$ the selection error bound Eq. (8) holds.

In order to bound the reconstruction error $\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F^2$, we cite another lemma from (Krishnamurthy and Singh, 2014) that analyzes the performance of the second pass of Algorithm 1. At a higher level, Lemma 3 is a consequence of matrix Bernstein inequality (Tropp, 2012) which asserts that the *spectral norm* of a matrix can be preserved by a sum of properly scaled randomly sampled sub-matrices.

Lemma 3 ((Krishnamurthy and Singh, 2014), Lemma 9) *Provided that* $(1-\alpha)\|\boldsymbol{x}_i\|_2^2 \leq \hat{c}_i \leq (1+\alpha)\|\boldsymbol{x}_i\|_2^2$ *for* $i = 1, 2, \cdots, n_2$*, with probability* $\geq 1-\delta$ *we have*

$$\|\mathbf{M} - \widehat{\mathbf{M}}\|_2 \leq \|\mathbf{M}\|_F \sqrt{\frac{1+\alpha}{1-\alpha}} \left(\frac{4}{3}\sqrt{\frac{n_1\mu_0}{m_2 n_2}} \log\left(\frac{n_1+n_2}{\delta}\right) + \sqrt{\frac{4}{m_2}\max\left(\frac{n_1}{n_2}, \mu_0\right)\log\left(\frac{n_1+n_2}{\delta}\right)} \right). \tag{15}$$

The complete proof of Theorem 1 is deferred to Appendix A.

4.2 Proof sketch of Theorem 2

In this section we give proof sketch of Eq. (10) and Eq. (11) separately.

4.2.1 Proof sketch of $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$ error bound

We take three steps to prove the $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$ error bound in Theorem 2. At the first step, we show that when the input matrix has a low rank plus noise structure then with high probability *for all small subsets of columns* the spanned subspace has incoherent column space (assuming the low-rank matrix has incoherent column space) and furthermore, the projection of the other columns onto the orthogonal complement of the spanned subspace are incoherent, too. Given the incoherence condition we can easily prove a norm estimation result similar to Lemma 2, which is the second step. Finally, we note that the approximate iterative norm sampling procedure is an approximation of *volume sampling*, a column sampling scheme that is known to yield a relative error bound.

STEP 1: We first prove that when the input matrix $\mathbf{M}$ is a noisy low-rank matrix with incoherent column space, with high probability *a fixed* column subset also has incoherent column space. This is intuitive because the Gaussian perturbation matrix is highly incoherent with overwhelming probability. A more rigorous statement is shown in Lemma 4.

Lemma 4 *Suppose* $\mathbf{A}$ *has incoherent column space, i.e.,* $\mu(\mathcal{U}(\mathbf{A})) \leq \mu_0$*. Fix* $C \subseteq [n_2]$ *to be any subset of column indices that has* s *elements and* $\delta > 0$*. Let* $\mathbf{C} = [\mathbf{M}^{(C(1))}, \cdots, \mathbf{M}^{(C(s))}] \in \mathbb{R}^{n_1 \times s}$ *be the compressed matrix and* $\mathcal{U}(C) = \mathrm{span}(\mathbf{C})$ *denote the subspace spanned by the selected columns. Suppose* $\max(s,k) \leq n_1/4 - k$ *and* $\log(4n_2/\delta) \leq n_1/64$*. Then with probability* $\geq 1-\delta$ *over the random drawn of* $\mathbf{R}$ *we have*

$$\mu(\mathcal{U}(C)) = \frac{n_1}{s}\max_{1\leq i\leq n_1}\|\mathcal{P}_{\mathcal{U}(C)}\boldsymbol{e}_i\|_2^2 = O\left(\frac{k\mu_0 + s + \sqrt{s\log(n_1/\delta)} + \log(n_1/\delta)}{s}\right); \tag{16}$$

furthermore, with probability $\geq 1-\delta$ *the following holds:*

$$\mu(\mathcal{P}_{\mathcal{U}(C)^\perp}(\mathbf{M}^{(i)})) = O(k\mu_0 + \log(n_1 n_2/\delta)), \quad \forall i \notin C. \tag{17}$$

At a higher level, Lemma 4 is a consequence of the Gaussian white noise being highly incoherent, and the fact that the randomness imposed on each column of the input matrix is independent. The complete proof can be found in Appendix B.

Given Lemma 4, Corollary 1 holds by taking a uniform bound over all $\sum_{j=1}^{s}\binom{n_2}{j} = O(s(n_2)^s)$ column subsets that contain no more than s elements. The $2s\log(4n_2/\delta) \leq n_1/64$ condition is only used to ensure that the desired failure probability δ is not exponentially small. Typically, in practice the intrinsic dimension k and/or the target column subset size s is much smaller than the ambient dimension n_1.

Corollary 1 *Fix* $\delta > 0$ *and* $s \geq k$. *Suppose* $s \leq n_1/8$ *and* $2s\log(4n_2/\delta) \leq n_1/64$. *With probability* $\geq 1-\delta$ *the following holds: for any subset* $C \subseteq [n_2]$ *with at most* s *elements, the spanned subspace* $\mathcal{U}(C)$ *satisfies*

$$\mu(\mathcal{U}(C)) \leq O((k+s)|C|^{-1}\mu_0 \log(n/\delta)); \tag{18}$$

furthermore,

$$\mu(\mathcal{P}_{\mathcal{U}(C)^\perp}(\mathbf{M}^{(i)})) = O((k+s)\mu_0 \log(n/\delta)), \quad \forall i \notin C. \tag{19}$$

STEP 2: In this step, we prove that the norm estimation scheme in Algorithm 2 works when the incoherence conditions in Eq. (18) and (19) are satisfied. More specifically, we have the following lemma bounding the norm estimation error:

Lemma 5 *Fix* $i \in \{1, \cdots, n_2\}$, $t \in \{1, \cdots, k\}$ *and* $\delta, \delta' > 0$. *Suppose Eq. (18) and (19) hold with probability* $\geq 1-\delta$. *Let* $\mathcal{S}_t$ *be the subspace spanned by selected columns at the* t*-th round and let* $\hat{c}_i^{(t)}$ *denote the estimated squared norm of the* i*th column. If* m *satisfies*

$$m = \Omega(k\mu_0 \log(n/\delta)\log(k/\delta')), \tag{20}$$

then with probability $\geq 1-\delta-4\delta'$ *we have*

$$\frac{1}{2}\|[\mathbf{E}_t]_{(i)}\|_2^2 \leq \hat{c}_i^{(t)} \leq \frac{5}{4}\|[\mathbf{E}_t]_{(i)}\|_2^2. \tag{21}$$

Here $\mathbf{E}_t = \mathcal{P}_{\mathcal{S}_t^\perp}(\mathbf{M})$ *denotes the projected matrix at the* t*-th round.*

Lemma 5 is similar with previous results on subspace detection (Balzano et al., 2010b) and matrix approximation (Krishnamurthy and Singh, 2014). The intuition behind Lemma 5 is that one can accurately estimate the ℓ_2 norm of a vector by uniform subsampling entries of the vector, provided that the vector itself is incoherent. The proof of Lemma 5 is deferred to Appendix B.

Similar to the first step, by taking a union bound over all possible subsets of picked columns and $n_2 - k$ unpicked columns we can prove a stronger version of Lemma 5, as shown in Corollary 2.

Corollary 2 *Fix* $\delta, \delta' > 0$. *Suppose Eq. (18) and (19) hold with probability* $\geq 1-\delta$. *If*

$$m \geq \Omega(k^2\mu_0 \log(n/\delta)\log(n/\delta')) \tag{22}$$

then with probability $\geq 1-\delta-4\delta'$ *the following property holds for any selected column subset by Algorithm 2:*

$$\frac{2}{5}\frac{\|[\mathbf{E}_t]_{(i)}\|_2^2}{\|\mathbf{E}_t\|_F^2} \leq \hat{p}_i^{(t)} \leq \frac{5}{2}\frac{\|[\mathbf{E}_t]_{(i)}\|_2^2}{\|\mathbf{E}_t\|_F^2}, \forall i \in [n_2], t \in [k], \tag{23}$$

where $\hat{p}_i^{(t)} = \hat{c}_i^{(t)}/\hat{f}^{(t)}$ *is the sampling probability of the* i*th column at round* t.

STEP 3: To begin with, we define *volume sampling* distributions:

Definition 1 (volume sampling, (Deshpande et al., 2006)) *A distribution* p *over column subsets of size* k *is a volume sampling distribution if*

$$p(C) = \frac{\mathrm{vol}(\Delta(C))^2}{\sum_{T:|T|=k}\mathrm{vol}(\Delta(T))^2}, \quad \forall |C| = k. \tag{24}$$

Volume sampling has been shown to achieve a relative error bound for column subset selection, which is made precise by Theorem 4 cited from (Deshpande and Vempala, 2006; Deshpande et al., 2006).

Theorem 4 ((Deshpande and Vempala, 2006), Theorem 4) *Fix a matrix* $\mathbf{M}$ *and let* $\mathbf{M}_k$ *denote the best rank-k approximation of* $\mathbf{M}$. *If the sampling distribution* p *is a volume sampling distribution defined in Eq. (24) then*

$$\mathbb{E}_C\left[\|\mathbf{M} - \mathcal{P}_{\mathcal{V}(C)}(\mathbf{M})\|_F^2\right] \leq (k+1)\|\mathbf{M} - \mathbf{M}_k\|_F^2; \tag{25}$$

furthermore, applying Markov's inequality one can show that with probability $\geq 1-\delta$

$$\|\mathbf{M} - \mathcal{P}_{\mathcal{V}(C)}(\mathbf{M})\|_F^2 \leq \frac{k+1}{\delta}\|\mathbf{M} - \mathbf{M}_k\|_F^2. \tag{26}$$

In general, exact volume sampling is difficult to employ under partial observation settings, as we explained in Sec. 2.2. However, in (Deshpande and Vempala, 2006) it was shown that iterative norm sampling serves as an approximate of volume sampling and achieves a relative error bound as well. In Lemma 6 we present an extension of this result. Namely, *approximate* iterative column norm sampling is an approximate of volume sampling, too. Its proof is very similar to the one presented in (Deshpande and Vempala, 2006) and we defer it to Appendix B.

Lemma 6 *Let* p *be the volume sampling distribution defined in Eq. (24). Suppose the sampling distribution of a* k*-round sampling strategy* $\hat{p}$ *satisfies Eq. (23). Then we have*

$$\hat{p}_C \leq 2.5^k k! p_C, \quad \forall |C| = k. \tag{27}$$

We can now prove the error bound for selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F$ of Algorithm 2 by combining Corollary 1, 2, Lemma 6 and Theorem 4, with failure probability δ, δ' set at $O(1/k)$ to facilitate a union bound argument across all iterations. In particular, Corollary 1 and 2 guarantees that Algorithm 2 estimates column norms accurately with high probability; then one can apply Lemma 6 to show that the sampling distribution employed in the algorithm is actually an approximate volume sampling distribution, which is known to achieve relative error bounds (by Theorem 4).

4.2.2 Proof sketch of $\|\mathbf{M} - \mathbf{S}\mathbf{X}\|_F$ error bound

We first present a theorem, which is a generalization of Theorem 2.1 in (Deshpande et al., 2006).

Theorem 5 ((Deshpande et al., 2006), Theorem 2.1) *Suppose $\mathbf{M} \in \mathbb{R}^{n_1 \times n_2}$ is the input matrix and $\mathcal{U} \subseteq \mathbb{R}^{n_1}$ is an arbitrary vector space. Let $\mathbf{S} \in \mathbb{R}^{n_1 \times s}$ be a random sample of s columns in $\mathbf{M}$ from a distribution q such that*

$$\frac{(1-\alpha)\|\mathbf{E}^{(i)}\|_2^2}{(1+\alpha)\|\mathbf{E}\|_F^2} \leq q_i \leq \frac{(1+\alpha)\|\mathbf{E}^{(i)}\|_2^2}{(1-\alpha)\|\mathbf{E}\|_F^2}, \quad \forall i \in \{1, 2, \cdots, n_2\}, \tag{28}$$

where $\mathbf{E} = \mathcal{P}_{\mathcal{U}^\perp}(\mathbf{M})$ is the projection of $\mathbf{M}$ onto the orthogonal complement of $\mathcal{U}$. Then

$$\mathbb{E}_S\left[\|\mathbf{M} - \mathcal{P}_{\mathrm{span}(\mathcal{U},\mathbf{S}),k}(\mathbf{M})\|_F^2\right] \leq \|\mathbf{M} - \mathbf{M}_k\|_F^2 + \frac{(1+\alpha)k}{(1-\alpha)s}\|\mathbf{E}\|_F^2, \tag{29}$$

where $\mathbf{M}_k$ denotes the best rank-k approximation of $\mathbf{M}$.

Intuitively speaking, Theorem 5 states that relative estimation of residues $\mathcal{P}_{\mathcal{U}^\perp}(\mathbf{M})$ would yield relative estimation of the data matrix $\mathbf{M}$ itself.

In the remainder of the proof we assume $s = \Omega(k^2\log(k) + k/\epsilon\delta)$ is the number of columns selected in $\mathbf{S}$ in Algorithm 2. Corollary 1 asserts that with high probability $\mu(\mathcal{U}(\mathbf{S})) = O(s|C|^{-1}\mu_0\log(n/\delta))$ and $\mu(\mathcal{P}_{\mathcal{U}(\mathbf{S})^\perp}(\mathbf{M}^{(i)})) = O(s\mu_0\log(n/\delta))$ for any subset S with $|S| \leq s$. Subsequently, we can apply Lemma 5 and a union bound over n_2 columns and T rounds to obtain the following proposition:

Proposition 1 *Fix $\delta, \delta' > 0$. If $m = \Omega(s\mu_0\log(n/\delta)\log(nT/\delta'))$ then with probability $\geq 1 - \delta - \delta'$*

$$\frac{2\|\mathbf{E}_t^{(i)}\|_2^2}{5\|\mathbf{E}_t\|_F^2} \leq \hat{q}_i^{(t)} \leq \frac{5\|\mathbf{E}_t^{(i)}\|_2^2}{2\|\mathbf{E}_t\|_F^2}, \quad \forall i \in \{1, 2, \cdots, n_2\}, t \in \{1, 2, \cdots, T\}. \tag{30}$$

Here $\mathbf{E}_t = \mathbf{M} - \mathcal{P}_{\mathrm{span}(\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_{t-1})}(\mathbf{M})$ is the residue at round t of the active norm sampling procedure.

Note that we do not need to take a union bound over all $\binom{n_2}{s}$ column subsets because this time we do not require the sampling distribution of Algorithm 2 to be close uniformly to the true active norm sampling procedure.

Consequently, combining Theorem 5 and Proposition 1 we obtain Lemma 7. Its proof is deferred to Appendix B.

Lemma 7 *Fix $\delta, \delta' > 0$. If $m = \Omega(s\mu_0\log^2(n/\delta))$ and $s_1 = \cdots = s_{T-1} = 5k$, $s_T = 10k/\epsilon\delta'$ then with probability $\geq 1 - 2\delta - \delta''$*

$$\|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_T}(\mathbf{M})\|_F^2 \leq (1+\epsilon/2)\|\mathbf{M} - \mathbf{M}_k\|_F^2 + \frac{\epsilon/2}{2^T}\|\mathbf{M} - \mathcal{P}_{\mathcal{U}}(\mathbf{M})\|_F^2. \tag{31}$$

Applying Theorem 4, Lemma 6 and note that $2^{(k+1)\log(k+1)} = (k+1)^{(k+1)} \geq (k+1)!$, we immediately have Corollary 3.

Corollary 3 *Fix $\delta > 0$. Suppose $T = (k+1)\log(k+1)$ and $m, s_1, \cdots, s_T$ be set as in Lemma 7. Then with probability $\geq 1 - 4\delta$ one has*

$$\|\mathbf{M} - \mathbf{S}\mathbf{S}^\dagger\mathbf{M}\|_F^2 = \|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_T}(\mathbf{M})\|_F^2 \leq (1+\epsilon)\|\mathbf{M} - \mathbf{M}_k\|_F^2 \leq (1+\epsilon)\|\mathbf{R}\|_F^2. \tag{32}$$

To reconstruct the coefficient matrix $\mathbf{X}$ and to further bound the reconstruction error $\|\mathbf{M} - \mathbf{S}\mathbf{X}\|_F$, we apply the $\mathbf{U}(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega$ operator on every column to build a low-rank approximation $\widehat{\mathbf{M}}$. It was shown in (Krishnamurthy and Singh, 2013; Balzano et al., 2010b) that this operator recovers all components in the underlying subspace $\mathcal{U}$ with high probability, and hence achieves a relative error bound for low-rank matrix approximation. More specifically, we have Lemma 8, which is proved in Appendix B.

Lemma 8 *Fix $\delta, \delta'' > 0$ and $\epsilon > 0$. Let $\mathbf{S} \in \mathbb{R}^{n_1 \times s}$ and $\mathbf{X} \in \mathbb{R}^{s \times n_2}$ be the output of Algorithm 2. Suppose Corollary 3 holds with probability $\geq 1 - \delta$. If m satisfies*

$$m = \Omega(\epsilon^{-1}s\mu_0\log(n/\delta)\log(n/\delta'')), \tag{33}$$

then with probability $\geq 1 - \delta - \delta''$ we have

$$\|\mathbf{M} - \widehat{\mathbf{M}}\|_F^2 \leq (1+\epsilon)\|\mathbf{M} - \mathbf{S}\mathbf{S}^\dagger\mathbf{M}\|_F^2. \tag{34}$$

Note that all columns of $\widehat{\mathbf{M}}$ are in the subspace $\mathcal{U}(S)$. Therefore, $\mathbf{S}\mathbf{X} = \mathbf{S}\mathbf{S}^\dagger\widehat{\mathbf{M}} = \widehat{\mathbf{M}}$. The proof of Eq. (11) is then completed by noting that $(1+\epsilon)^2 \leq 1 + 3\epsilon$ whenever $\epsilon \leq 1$.

4.3 Proof of Theorem 3

Before presenting the proof, we first present a theorem cited from (Drineas et al., 2008). In general, Theorem 6 claims that if columns are selected with probability proportional to their row-space leverage scores then the resulting column subset is a relative-error approximation of the original input matrix.

Theorem 6 ((Drineas et al., 2008), Theorem 3) *Let $\mathbf{M} \in \mathbb{R}^{n_1 \times n_2}$ be the input matrix and k be a rank parameter. Suppose a subset of columns $C = \{i_1, i_2, \cdots, i_s\} \subseteq [n_2]$ is selected such that*

$$\Pr[i_t = j] = p_j \geq \frac{\beta\|\mathbf{V}_k^\top\boldsymbol{e}_j\|_2^2}{k}, \quad \forall t \in \{1, \cdots, s\}, j \in \{1, \cdots, n_2\}. \tag{35}$$

Here $\mathbf{V}_k \in \mathbb{R}^{n_2 \times k}$ *is the top-*k *right singular vectors of* $\mathbf{M}$. *If* $s = \Omega(\beta^{-1}\epsilon^{-2}k^2\log(1/\delta))$ *then with probability* $\geq 1-\delta$ *one has*

$$\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F \leq (1+\epsilon)\|\mathbf{M} - \mathbf{M}_k\|_F. \tag{36}$$

In the sequel we use $\mathcal{Q}_S(\mathbf{M})$ to denote the matrix formed by projecting each row of $\mathbf{M}$ to a row subspace $\mathcal{S}$ and $\mathcal{P}_C(\mathbf{M})$ to denote the matrix formed by projecting each column of $\mathbf{M}$ to a column subspace $\mathcal{C}$. Since $\mathbf{M}$ has incoherent column space, the uniform sampling distribution $p_j = 1/n_1$ satisfies Eq. (35) with $\beta = 1/\mu_0$. Consequently, by Theorem 6 the computed row space $\mathcal{S}$ satisfies

$$\|\mathbf{M} - \mathcal{Q}_S(\mathbf{M})\|_F \leq (1+\epsilon)\|\mathbf{M} - \mathbf{M}_k\|_F \tag{37}$$

with high probability when $m = \Omega(k^2/\beta\epsilon^2) = \Omega(\mu_0 k^2/\epsilon^2)$.

Next, note that though we do not know $\mathcal{Q}_S(\mathbf{M})$, we know its row space $\mathcal{S}$. Subsequently, we can compute the exact leverage scores of $\mathcal{Q}_S(\mathbf{M})$, i.e., $\|\mathbf{S}_k^{\top}\boldsymbol{e}_j\|_2^2$ for $j = 1, 2, \cdots, n_2$. With the computed leverage scores, performing leverage score sampling on $\mathcal{Q}_S(\mathbf{M})$ as in Algorithm 3 and applying Theorem 6 we obtain

$$\|\mathcal{Q}_S(\mathbf{M}) - \mathcal{P}_C(\mathcal{Q}_S(\mathbf{M}))\|_F \leq (1+\epsilon)\|\mathcal{Q}_S(\mathbf{M}) - [\mathcal{Q}_S(\mathbf{M})]_k\|_F, \tag{38}$$

where $[\mathcal{Q}_S(\mathbf{M})]_k$ denotes the best rank-k approximation of $\mathcal{Q}_S(\mathbf{M})$. Note that

$$\|\mathcal{Q}_S(\mathbf{M}) - [\mathcal{Q}_S(\mathbf{M})]_k\|_F \leq \|\mathcal{Q}_S(\mathbf{M}) - \mathcal{Q}_S(\mathbf{M}_k)\|_F = \|\mathcal{Q}_S(\mathbf{M} - \mathbf{M}_k)\|_F \leq \|\mathbf{M} - \mathbf{M}_k\|_F \tag{39}$$

because $\mathcal{Q}_S(\mathbf{M}_k)$ has rank at most k. Consequently, the selection error $\|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F$ can be bounded as follows:

$$\begin{aligned}
\|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F &\leq \|\mathbf{M} - \mathcal{Q}_S(\mathbf{M})\|_F + \|\mathcal{Q}_S(\mathbf{M}) - \mathcal{P}_C(\mathcal{Q}_S(\mathbf{M}))\|_F + \|\mathcal{P}_C(\mathcal{Q}_S(\mathbf{M})) - \mathcal{P}_C(\mathbf{M})\|_F \\
&\leq \|\mathbf{M} - \mathcal{Q}_S(\mathbf{M})\|_F + \|\mathcal{Q}_S(\mathbf{M}) - \mathcal{P}_C(\mathcal{Q}_S(\mathbf{M}))\|_F + \|\mathcal{Q}_S(\mathbf{M}) - \mathbf{M}\|_F \\
&\leq 3(1+\epsilon)\|\mathbf{M} - \mathbf{M}_k\|_F.
\end{aligned}$$

5. Related work on column subset selection with missing data

In this section we review two previously proposed algorithms for column subset selection with missing data. Both algorithms are heuristic based and no theoretical analysis is available. We also remark that both methods employ the passive sampling scheme as observation models. In fact, they work for any subset of observed matrix entries.

5.1 Block orthogonal matching pursuit (Block OMP)

A block OMP algorithm was proposed in (Balzano et al., 2010a) for column subset selection with missing data. Let $\mathbf{W} \in \{0,1\}^{n_1 \times n_2}$ denote the "mask" of observed entries; that is,

$$\mathbf{W}_{ij} = \begin{cases} 1, & \text{if } \mathbf{M}_{ij} \text{ is observed;} \\ 0, & \text{if } \mathbf{M}_{ij} \text{ is not observed.} \end{cases}$$

Algorithm 4 A block OMP algorithm for column subset selection with missing data

Input: size of column subset s, observation mask $\mathbf{W} \in \{0,1\}^{n_1 \times n_2}$.
Initialization: Set $C = \emptyset$, $\mathcal{C} = \emptyset$, $\mathbf{Y} = \mathbf{W} \circ \mathbf{M}$, $\mathbf{Y}^{(1)} = \mathbf{Y}$.
for $t = 1, 2, \cdots, s$ **do**
  Compute $\mathbf{D} = \mathbf{Y}^{\top}(\mathbf{W} \circ \mathbf{Y}^{(t)})$. Let $\{\boldsymbol{d}_i\}_{i=1}^{n_2}$ be rows of $\mathbf{D}$.
  Column selection: $i_t = \text{argmax}_{1 \leq i \leq n_2}\|\boldsymbol{d}_i\|_2$; update: $C \leftarrow C \cup \{i_t\}$, $\mathcal{C} \leftarrow \text{span}(\mathcal{C}, \mathbf{Y}_{(i_t)})$.
  Back projection: $\mathbf{Y}^{(t+1)} = \mathbf{Y}^{(t)} - \mathcal{P}_{\mathcal{C}}(\mathbf{Y}^{(t)})$.
end for
Output: the selected column indices $C \subseteq \{1, 2, \cdots, n_2\}$.

We also use $\circ$ to denote the Hadamard product (entrywise product) between two matrices of the same dimension.

The pseudocode is presented in Algorithm 4. Note that Algorithm 4 has very similar framework compared with the iterative norm sampling algorithm: both methods select columns in an iterative manner and after each column is selected, the contribution of selected columns is removed from the input matrix by projecting onto the complement of the subspace spanned by selected columns. Nevertheless, there are some major differences. First, in iterative norm sampling we select a column according to their residue norms while in block OMP we base such selection on inner products between the original input matrix and the residue one. In addition, due to the passive sampling nature Algorithm 4 uses the zero-filled data matrix to approximate subspace spanned by selected columns. In contrast, iterative norm sampling computes this subspace exactly by active sampling.

5.2 Group Lasso

The group Lasso formulation was originally proposed in (Bien et al., 2010) as a convex optimization alternative for matrix column subset selection and CUR decomposition for fully-observed matrices. It was briefly remarked in (Balzano et al., 2010a) that group Lasso could be extended to the case when only partial observations are available. In this paper we make such extension precise by proposing the following convex optimization problem:

$$\min_{\mathbf{X} \in \mathbb{R}^{n_1 \times n_2}} \|\mathbf{W} \circ \mathbf{M} - (\mathbf{W} \circ \mathbf{M})\mathbf{X}\|_F^2 + \lambda\|\mathbf{X}\|_{1,2}, \quad s.t.\ \text{diag}(\mathbf{X}) = \mathbf{0}. \tag{40}$$

Here in Eq. (40) $\mathbf{W} \in \{0,1\}^{n_1 \times n_2}$ denotes the mask for observed matrix entries and $\circ$ denotes the Hadamard (entrywise) matrix product. $\|\mathbf{X}\|_{1,2} = \sum_{i=1}^{n_2}\|\mathbf{X}_{(i)}\|_2$ denotes the 1,2-norm of matrix $\mathbf{X}$, which is the sum of ℓ_2 norm of all rows in $\mathbf{X}$. The nonzero rows in the optimal solution $\mathbf{X}$ correspond to the selected columns.

Eq. (40) could be solved using standard convex optimization methods, e.g., proximal gradient descent (Mosci et al., 2010). However, to make Eq. (40) a working column subset selection algorithm one needs to carefully choose the regularization parameter λ so that the resulting optimal solution $\mathbf{X}$ has no more than s nonzero columns. Such selection could be time-consuming and inexact. As a workaround, we implement the solution path algorithm for group Lasso problems in (Yang and Zou, 2014).

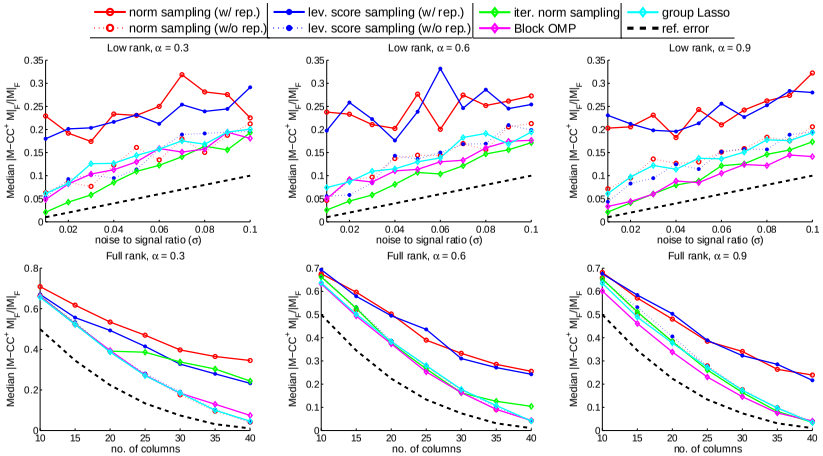

Figure 1: Selection error on Gaussian random matrices. Top row: low-rank plus noise inputs, $s = k = 15$; bottom row: full-rank inputs. The black dashed lines denote noise-to-signal ratio σ in the first row and $\|\mathbf{M} - \mathbf{M}_k\|_F$ in the second row. α indicates the observation rate (i.e., the number of observed entries divided by $n_1 n_2$, the total number of matrix entries). All algorithms are run for 8 times on each data set and the median error is reported. We report the median instead of the mean because the performance of norm and leverage score sampling is quite variable.

5.3 Discussion on theoretical assumptions of block OMP and group Lasso

We discuss theoretical assumptions required for block OMP and group Lasso approaches. It should be noted that for the particular matrix column subset selection problem, neither Balzano et al. (2010a) or Bien et al. (2010) provides rigorous theoretical guarantee of approximation error of the selected column subsets. However, it is informative to compare to typical assumptions that are used to analyze block OMP and group Lasso for regression problems in the existing literature (Yuan and Lin, 2006; Lounici et al., 2011). In most cases, certain "restricted eigenvalue" conditions on the design matrix $\mathbf{X}$, which roughly corresponds to a "weak correlation" condition among columns of a data matrix. This explains the worse performance of both methods on data sets that have highly correlated columns (e.g., many repeated columns), as we shown in later sections on experimental results.

6. Experiments

In this section we report experimental results on both synthetic and real-world data sets for our proposed column subset selection algorithms as well as other competitive methods. All algorithms are implemented in Matlab. To make fair comparisons, all input matrices $\mathbf{M}$ are normalized so that $\|\mathbf{M}\|_F^2 = 1$.

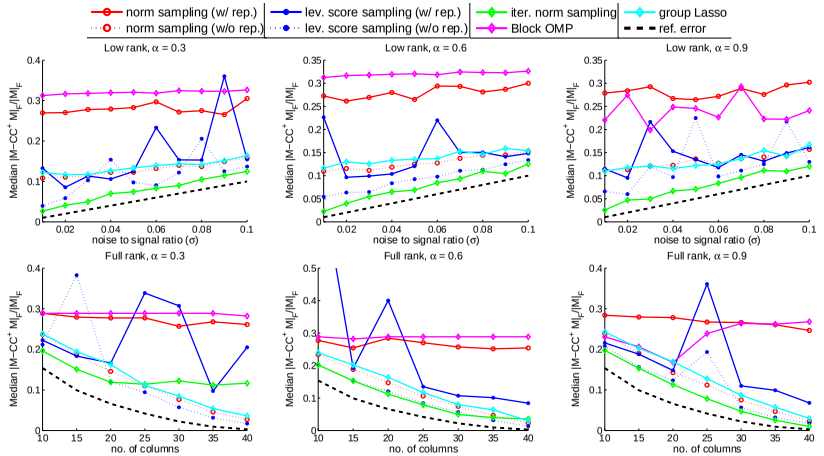

Figure 2: Selection error on matrices with coherent columns. Top row: low-rank plus noise inputs, $s = k = 15$; bottom row: full-rank inputs. α indicates the observation rate. The black dashed lines denote noise-to-signal ratio σ in the first row and $\|\mathbf{M} - \mathbf{M}_k\|_F$ in the second row. All algorithms are run for 8 times on each data set and the median error is reported.

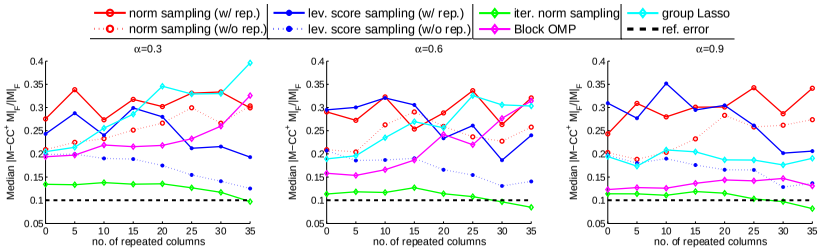

Figure 3: Selection error on matrices with varying number of repeated columns. Both s and k are set to 15 and the noise-to-signal ratio σ is set to 0.1. α indicates the observation rate. All algorithms are run for 8 times on each data set and the median error is reported.

6.1 Synthetic data sets

We first test the proposed algorithms on synthetic data sets. The input matrix has dimension $n_1 = n_2 = n = 50$. To generate the synthetic data, we consider two different settings listed below:

1. **Random Gaussian matrices**: for random Gaussian matrices each entry $\mathbf{M}_{ij}$ are i.i.d. sampled from a normal distribution $\mathcal{N}(0, 1)$. For low rank matrices, we first

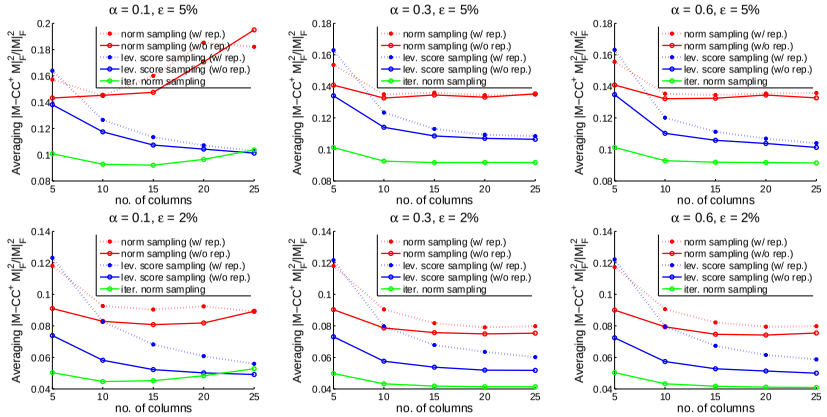

Figure 4: Selection error or sampling based algorithm on Hapmap phase2 data set. α indicates the observation rate. Top row: top-k PCA captures 95% variance within each SNP window; bottom row: top-k PCA captures 98% variance within each SNP window.

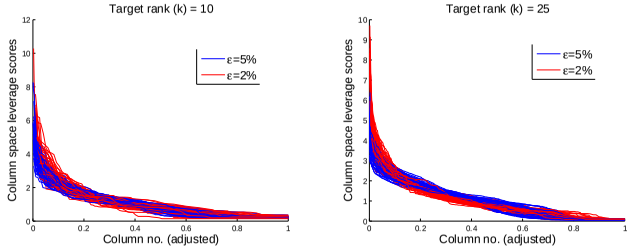

Figure 5: Sorted column space leverage scores for different ε and k settings. For each setting 50 windows are picked at random and their leverage scores are plotted. Each plotted line is properly scaled along the X axis so that they have the same length even though actual window sizes vary.

generate a random Gaussian matrix $\mathbf{B} \in \mathbb{R}^{n\times k}$ where k is the intrinsic rank and then form the data matrix $\mathbf{M}$ as $\mathbf{M} = \mathbf{B}\mathbf{B}^\top$. I.i.d. Gaussian noise $\mathbf{R}$ with $\mathbf{R}_{ij} \sim \mathcal{N}(0, \sigma^2)$ is then appended to the synthesized low-rank matrix. We remark that data matrices generated in this manner have both incoherent column and row space with high probability.

2. **Matrices with coherent columns**: we took a simple procedure to generate matrices with coherent columns in order to highlight the power of proposed algorithms and baseline methods. After generating a random Gaussian matrix $\mathbf{M} = \mathbf{B}\mathbf{B}^\top$, we pick

(a) The 512×512 8-bit gray scale Lena test image before compression.

(b) Norm sampling (without replacement). Selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F/\|\mathbf{M}\|_F = 0.106$.

(c) Iterative norm sampling. Selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F/\|\mathbf{M}\|_F = 0.088$.

(d) Approx. leverage score sampling (without replacement). $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F/\|\mathbf{M}\|_F = 0.103$.

Figure 6: Column-based image compression results on the Lena standard test image. Left: actively sampled image pixels; middle: the selected columns; right: the reconstructed images. Number of selected columns is set to 50 and the pixel subsampling rate α is set to 0.3.

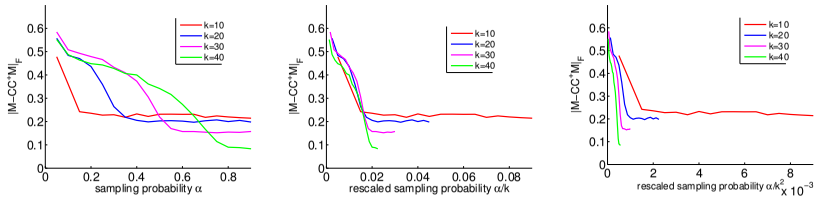

Figure 7: Selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F$ for the iterative norm sampling algorithm as a function of α (left), α/k (middle) and α/k^2 (right). Error curves plotted under 4 different rank (k) settings.

a column $\boldsymbol{x}$ from $\mathbf{M}$ uniformly at random. We then take $\tilde{\boldsymbol{x}} = 10\boldsymbol{x}$ and repeat the column for 5 times. As a result, the newly formed data matrix will have 5 identical columns with significantly higher norms compared to the other columns.

In Figure 1 we report the selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F$ of proposed and baseline algorithms on random Gaussian matrices and in Figure 2 we report the same results on matrices with coherent columns. Results on both low-rank plus noise and high-rank inputs are reported. For low-rank matrices, both the intrinsic rank k and the number of selected columns s are set to 15. Each algorithm is run for 8 times on the same input and the median selection error is reported. For norm sampling and approximate leverage score sampling, we implement two variants: in the *sampling with replacement* scheme the algorithm samples each column from a sampling distribution (based on either norm or leverage score estimation) with replacement; while in the *sampling without replacement* scheme a column is never sampled twice. Note that all theoretical results in Section 3 are proved for sampling with replacement algorithms.

From Figure 1 we observe that all algorithms perform similarly, with the exception of two sampling with replacement algorithms and iterative norm sampling when both rank and missing rate are high. [3] For the latter case, we conjecture that the degradation of performance is due to inaccurate norm estimation of column residues; in fact, the iterative norm sampling only provably works when the input matrix has a low-rank plus noise structure (see Theorem 2). On the other hand, when either the target rank or the missing rate is not too high iterative norm sampling works just as good; it is particularly competitive when the true rank of the input matrix is low (see the top row of Figure 1).

When the input matrix has coherent columns, as shown in Figure 2, it becomes easier to observe performance gaps among different algorithms. The block OMP algorithm completely fails in such cases and the selection error for group Lasso also increases considerably. This is due to the fact that both algorithms observe matrix entries by sampling uniformly at random and hence could be poorly informed when the underlying matrix is highly coherent. On the other hand, both leverage score sampling and iterative norm sampling are more robust to column coherence. The coherence among columns also makes the separation between norm sampling and volume sampling clearer in Figure 2. In particular, there is a

3. We discuss on the poor performance of with replacement algorithms in Section 7.5.

Table 2: Averaging SNP window sizes for different ε values and number of selected columns per window.

	5 columns	10 columns	15 columns	20 columns	25 columns
$\varepsilon = 95\%$	63.4	248.9	516.3	891.0	1405.7
$\varepsilon = 98\%$	18.8	62.1	123.4	203.8	309.7

significant gap between the two sampling with replacement curves and the norm sampling algorithm degrades to its worst-case additive error bound (see Theorem 1). The gap between the sampling without replacement curves is smaller since the coherent column is only repeated for 5 times in the design and so an algorithm can not be "too wrong" if it samples columns without replacement.

To further investigate how the proposed and baseline algorithms adapt to different levels of coherence, we report in Figure 3 the selection error on noisy low-rank matrices with varying number of repeated columns. Matrices with more repeated columns have higher coherence level. We can see that there is a clear separation of two groups of algorithms: the first group includes norm sampling, block OMP and group Lasso, whose error increases as the matrix becomes more coherent. Also, design matrix assumptions (e.g., restricted isometry) are violated for group Lasso. This suggests that these algorithms only have additive error bounds, or adapt poorly to column coherence of the underlying data matrix. On the other hand, the selection error of volume sampling and iterative norm sampling remains stable or slightly decreases. This is consistent with our theoretical results that both volume sampling and iterative norm sampling enjoy relative error bounds.

6.2 Application to tagging Single Nucleotide Polymorphisms (tSNPs) selection

We apply our proposed methods on real-world genetic data sets. We consider the tagging Single Nucleotide Polymorphisms (tSNP) selection task as described in (Ke and Cardon, 2003; Paschou et al., 2007). The task aims at selecting a small set of SNPs in human genes such that the selected SNPs (called tagging SNPs) capture the genetic information within a specific genome region. More specifically, given an $n_1 \times n_2$ matrix with each row corresponding to the genome expression for an individual, we want to select k columns (typically $k \ll n_2$) corresponding to k tagging SNPs that best capture the entire SNP matrix across different individuals. Matrix column subset selection methods have been successfully applied to the tSNP selection problem (Paschou et al., 2007).

In this section we demonstrate that our proposed algorithms could achieve the same objective while allowing many missing entries in the raw data matrix. We also compare the selection error of the proposed methods under different missing rate and number of tSNP settings. We did not apply Block OMP and group Lasso because the former cannot handle coherent data matrices and the latter does not scale well. The data set we used is the HapMap Phase 2 data set (international HapMap consortium, 2003). For demonstration purposes, we use gene data for the first chromosome of a joint east Asian population consisting of Han Chinese in Beijing (CHB) and Japanese in Tokyo (JPT). The data matrix

consists of 89 rows (individuals) and 311,854 columns (SNPs). Each matrix entry has two letters $b_1 b_2$ describing a specific gene expression for an individual.

We follow the same step as described in (Javed et al., 2011) to preprocess the data. We first convert the raw data matrix into a numerical matrix $\mathbf{M}$ with +1/0/-1 entries as follows: let B_1 and B_2 be the bases that appear for the jth SNP. Fix an individual i with its gene expression $b_1 b_2$. If $b_1 b_2 = B_1 B_1$ then $\mathbf{M}_{ij}$ is set to -1; else if $b_1 b_2 = B_2 B_2$ then $\mathbf{M}_{ij}$ is set 1; otherwise $\mathbf{M}_{ij}$ is set to 0. We further split the SNPs into multiple consecutive "windows" so that within each window w the SVD reconstruction error $\|\mathbf{M}^{(w)} - \mathbf{M}_k^{(w)}\|_F^2 / \|\mathbf{M}^{(w)}\|_F^2$ is no larger than ε with ε set to 5% and 2%. We refer the readers to Figure 1 in (Javed et al., 2011) for details of the preprocessing steps. Averaging window length (i.e., number of SNPs within each window) are shown in Table 2 for different k and ε settings. After preprocessing, column subset selection algorithms are performed for each SNP window and the selection error is averaged across all windows, as reported in Figure 4. The number of selected columns per window (k) ranges from 5 to 25 and the sampling budget α ranges from 10% to 60%.

In Figure 4 we observe that iterative norm sampling and approximate leverage score sampling outperform norm sampling by a large margin. This is because the truncated data matrix within each window is very close to an exact low-rank matrix and hence relative error algorithms achieve much better performance than additive error ones. In addition, approximate leverage score sampling significantly outperforms norm sampling under both the with replacement and without replacement schemes. This shows that the heterogeneity of human SNPs cannot be captured merely by their norms because the norm is simply the proportion of heterozygous within a population and provides little information about its importance across the entire chromosome. The spikiness of leverage score distribution is empirically verified in Figure 5. Finally, we remark that sampling without replacement is much better than sampling with replacement and should always be preferred in practice. We discuss this aspect in Section 7.5.

6.3 Application to column-based image compression

In this section we show how active sampling can be applied to column-based image compression without observing entire images. Given an image, we first actively subsample a small number of pixels from the original image. We then select a subset of columns based on the observed pixels and reconstruct the entire image by projecting each column to the space spanned by the selected column subsets.

In Figure 6 we depicted the final compressed image as well as intermediate steps (e.g., subsampled pixels and selected columns) on the 512×512 8-bit gray scale Lena standard test image. We also report the mean and standard deviation of selection error across 10 runs under different settings of target column subset sizes in Table 3.

Table 3 shows that the iterative norm sampling algorithm consistently outperforms norm sampling and so is the leverage score sampling method when the target column subset size is large, which implies small oracle error $\|\mathbf{M} - \mathbf{M}_k\|_F^2$. To get an intuitive sense of why this is the case, we refer the readers to the selected columns for each of the sampling algorithm as shown in Figure 6 (the middle column). It can be seen that the norm sampling algorithm (Figure 6b) oversamples columns in relatively easy regions (e.g., the white bar on the left

Table 3: Relative selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger\mathbf{M}\|_F / \|\mathbf{M}\|_F$ on the standard Lena test image (512×512) for norm sampling (Norm), iterative norm sampling (Iter. norm) and approximate leverage score sampling (Lev. score). Results also compared to a uniform sampling baseline (Uniform) and the truncated SVD lower bound (SVD). The percentage of observed entries α is set to $\alpha = 30\%$. Number of columns used for reconstruction varies from 25 to 100.

	Uniform	Norm	Iter. norm	Lev. score	SVD
25 columns	$.151 \pm .009$	$.147 \pm .004$	$\mathbf{.136 \pm .004}$	$.148 \pm .007$	.092
50 columns	$.104 \pm .004$	$.103 \pm .003$	$\mathbf{.092 \pm .001}$	$.105 \pm .003$	.059
100 columns	$.064 \pm .002$	$.065 \pm .001$	$\mathbf{.053 \pm .001}$	$.061 \pm .002$	.032

side and the smooth part of the face) because these regions have large pixel values (i.e., they are whiter than the other pixels) and hence have larger column norms. In contrast, the iterative norm sampling algorithm (Figure 6c) focuses most sampled columns on the tassel and hair parts which are complicated and cannot be well approximated by other columns. This shows that the iterative norm sampling method has the power to adapt to highly heterogeneous columns and produce better approximations. Finally, we remark that though both leverage score sampling and iterative norm sampling have relative error guarantees, in practice the iterative norm sampling performs much better than leverage score sampling for matrices whose rank is not very high.

7. Discussion

We discuss on several aspects of the proposed algorithms and their analysis.

7.1 Limitation of passive sampling

In most cases the observed entries of a partially observable matrix are sampled according to some sampling schemes. We say a sampling scheme is *passive* when the sampling distribution (i.e., probability of observing a particular matrix entry) is fixed a priori and does not depend on the data matrix. On the other hand, an *active* sampling scheme adapts its sampling distribution according to previous observations and requests unknown data points in a feedback driven way. We mainly focus on active sampling methods in this paper (both Algorithm 1 and 2 perform active sampling). However, Algorithm 3 only requires passive sampling because the sampling distribution of rows is the uniform distribution and is fixed a priori.

Passive sampling is known to work poorly for coherent matrices (Krishnamurthy and Singh, 2014; Chen et al., 2013). In this section, we make the following three remarks on the power of passive sampling for column subset selection:

Remark 1 The $\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_\xi$ reconstruction error bound for column subset selection is hard for passive sampling. In particular, it can be shown that no passive sampling algorithm achieves relative reconstruction error bound with high probability unless it observes $\Omega(n_1 n_2)$

entries of an $n_1 \times n_2$ matrix $\mathbf{M}$. This holds true even if $\mathbf{M}$ is assumed to be exact low rank and has incoherent column space.

This remark can be formalized by noting that when $\mathbf{M}$ is exact low rank then relative reconstruction error implies exact recovery of $\mathbf{M}$, or in other words, matrix completion. Here we cite the hardness result in (Krishnamurthy and Singh, 2014) for completing coherent matrix by passive sampling. Similar results could also be obtained by applying Theorem 6 in (Chen et al., 2013).

Theorem 7 (Theorem 2, (Krishnamurthy and Singh, 2014)) *Let $\mathcal{X}$ denote all $n_1 \times n_2$ matrices whose rank is no more than k and column space has incoherence μ_0 as defined in Eq. (5). Fix $m < n_1 n_2$ and let $\mathcal{Q}$ denote all passive sampling distributions over m samples of $n_1 n_2$ matrix entries. Let $\mathcal{F} = \{f : \mathbb{R}^m \to \mathcal{X}\}$ be the collection of (possibly random) matrix completion algorithms. We then have*

$$R^*_{\text{mc}} := \inf_{f \in \mathcal{F}} \inf_{q \in \mathcal{Q}} \sup_{\mathbf{X} \in \mathcal{X}} \Pr_{\Omega \sim q; f} [f(\Omega, \mathbf{X}_\Omega) \neq \mathbf{X}] \geq \frac{1}{2} - \left\lceil \frac{m}{(1 - \frac{k-1}{k\mu_0})n_1} \right\rceil \frac{1}{2(n-k)}, \tag{41}$$

where $n = \max(n_1, n_2)$. As a remark, when μ_0 is a constant then $R^*_{\text{mc}} = \Omega(1)$ whenever $m = o(n_1(n_2 - k))$.

Remark 2 For the $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger \mathbf{M}\|_\xi$ selection error (with only column indices C output by an CSS algorithm), it is possible for a passive sampling algorithm to achieve a relative error bound with high probability. In fact, Algorithm 3 and Theorem 3 precisely accomplish this. In addition, when the input matrix is exact low rank, Theorem 3 implies that there exists a passive sampling algorithm that outputs a small subset of columns which span the entire column subspace of a row-coherent matrix with high probability. This result shows column subset selection is easier than matrix completion when only indices of the selected column subset are required. It does not violate Theorem 7, however, because knowing which columns span the column space of an input matrix does not imply we can complete the matrix without further samples.

Remark 3 Although Remark 2 and Theorem 3 shows that it is possible to achieve relative $\|\mathbf{M} - \mathbf{C}\mathbf{C}^\dagger \mathbf{M}\|_F$ error bound for row coherent matrices via passive sampling, we show in this section that passive sampling is insufficient under a slightly weaker notion of column incoherence. In particular, instead of assuming $\mu(\mathcal{U}) \leq \mu_0$ on the column space as in Eq. (5), we assume $\mu(\boldsymbol{x}_i) \leq \mu_1$ where μ_1 is independent of k for every column $\boldsymbol{x}_i$ as in Eq. (7). Note that if $\text{rank}(\mathcal{U}) = k$ and $\boldsymbol{x}_i \in \mathcal{U}$ then $\mu(\boldsymbol{x}_i) \leq k\mu(\mathcal{U})$. So for exact low rank matrices the vector-based incoherence assumption in Eq. (7) is weaker than the subspace-based incoherence assumption in Eq. (5). We then have the following theorem, which is proved in Appendix C.

Theorem 8 *Let $\mathcal{X}'$ denote all $n_1 \times n_2$ matrices whose rank is no more than k and incoherence $\mu_1 \geq 1 + \frac{1}{n_1 - 1}$ as defined in Eq. (7) for each column. Fix $m < n_1 n_2$ and let $\mathcal{Q}$ denote all passive sampling distributions over m samples of $n_1 n_2$ matrix entries. Let $\mathcal{F}' = \{f : \mathbb{R}^m \to [n_2]^k\}$ be the collection of (possibly random) column subset selection algorithms. We then have*

$$R^*_{\text{css}} := \inf_{f \in \mathcal{F}'} \inf_{q \in \mathcal{Q}} \sup_{\mathbf{X} \in \mathcal{X}'} \Pr_{\Omega \sim q; f} [\mathbf{X} \neq \mathbf{X}_C \mathbf{X}_C^\dagger \mathbf{X}] \geq \frac{1}{2} - \frac{m}{2n_1(n_2 - k)}, \tag{42}$$

where $C = f(\mathbf{X}, \mathbf{X}_\Omega)$ is the output column subset of f. As a remark, the failure probability R^*_{css} satisfies $R^*_{\text{css}} = \Omega(1)$ whenever $m = o(n_1(n_2 - k))$.

Theorem 8 combined with Theorem 7 shows a separation of hardness between column subset selection and matrix completion. It also formalizes the intuitive limited power of passive sampling over coherent matrices.

7.2 Time complexity

In this section we report the theoretical time complexity of our proposed algorithms as well as the optimization based methods for comparison in Table 4. We assume the input matrix $\mathbf{M}$ is square $n \times n$ and we are using s columns to approximate the top-k component of $\mathbf{M}$. Let $\alpha = m/n^2$ be the percentage of observed data. $\texttt{svd}(a, b, c)$ denotes the time for computing the top-c truncated SVD of an $a \times b$ matrix.

Suppose the observation ratio α is a constant and the `svd` operation takes quadratic time. Then the time complexity for all algorithms can be sorted as

$$\begin{aligned}\textsc{Norm}; O(n^2) < \textsc{Lev. score}; O(kn^2) < \textsc{Iter. norm}, \textsc{Block OMP}; O(sn^3) \\ < \textsc{gLasso}, O(T(n^3 + s^2 n^2)).\end{aligned} \tag{43}$$

Perhaps not surprisingly, in Section 6.2 and 6.3 on real-world data sets we show the reverse holds for selection error for the first three algorithms in Eq. (43).

7.3 Sample complexity, column subset size and selection error

We remark on the connection of sample complexity (i.e., number of observed matrix entries), size of column subsets and reconstruction error for column subset selection. For column subset selection when the target column subset size is fixed the sample complexity acts more like a threshold: if not enough number of matrix entries are observed then the algorithm fails since the column norms are not accurately estimated, but when a sufficient number of observations are available the reconstruction error does not differ much. Such phase transition was also observed in other matrix completion/approximation tasks as well, for example, in (Krishnamurthy and Singh, 2014). In fact, the guarantee in Eq. (8), for example, is exactly the same as in (Frieze et al., 2004) under the fully observed setting, i.e., $m_1 = n_1$.

The bottom three plots in Figure 2 are an excellent illustration of this phenomenon. When $\alpha = 0.3$ the selection error of Algorithm 2 is very high, which means the algorithm

Table 4: Time complexity of proposed and baseline algorithms. k denotes the intrinsic rank and s denotes the number of selected columns. Dependency on failure probability δ and other poly-logarithmic dependency is omitted.

Algorithm	Norm	Iter. norm*	Lev. score	Block OMP*	gLasso†
Time Complexity	$O(\alpha n^2)$	$O(\alpha^2 s n^3)$	$O(\text{svd}(\alpha n, n, k))$	$O(\alpha^2 s n^3)$	$O(T(n^3 + s^2 n^2))$

*Assume $\alpha n > s$ and $\alpha^2 n > 1$.

†Using solution path implementation; T is the desired number of λ values.

does not have enough samples. However, for $\alpha = 0.6$ and $\alpha = 0.9$ the performance of Algorithm 2 is very similar.

7.4 Sample complexity of the iterative norm sampling algorithm

We try to verify the sample complexity dependence on the intrinsic matrix rank k for the iterative norm sampling algorithm (Algorithm 2). To do this, we run Algorithm 2 under various settings of intrinsic dimension k and the sampling probability α (which is basically proportional to the expected number of per-column samples m). We then plot the selection error $\|\mathbf{M} - \mathbf{C}\mathbf{C}^{\dagger}\mathbf{M}\|_F$ against α, α/k and α/k^2 in Figure 7.

Theorem 2 states that the dependence of m on k should be $m = \widetilde{O}(k^2)$ ignoring logarithmic factors. However, in Figure 7 one can observe that when the selection error is plotted against α/k the different curves coincide. This suggests that the actual dependence of m on k should be close to linear instead of quadratic. It is an interesting question whether we can get rid of the use of union bounds over all n_2-choose-k column subsets in the proof of Theorem 2 in order to get a near linear dependence over k. Note that the curves converge to different values for different k settings because selection error decreases when more columns are used to reconstruct the input matrix.

7.5 Sampling with and without replacement

In the experiments we observe that for norm sampling (Algorithm 1) and approximate leverage score sampling (Algorithm 3) the two column sampling schemes, i.e., sampling with and without replacement, makes a big difference in practice (e.g., see Figure 1, 2, and 4). In fact, sampling without replacement always outperforms sampling with replacement because under the latter scheme there is a positive probability of sampling the same column more than once. Though we analyzed both algorithm under the sampling with replacement scheme, in practice sampling without replacement should always be used since it makes no sense to select a column more than once. Finally, we remark that for iterative norm sampling (Algorithm 2) a column will never be picked more than once since the (estimated) projected norm of an already selected column is zero with probability 1.

Acknowledgments

We would like to thank Akshay Krishnamurthy for helpful discussion on the proof of Theorem 2 and James Duyck for a solution path implementation of group Lasso for column subset selection. This work is supported in part by grants NSF-1252412 and AFOSR-FA9550-14-1-0285.

A. Analysis of the active norm sampling algorithm

Proof [Proof of Lemma 1] This lemma is a direct corollary of Theorem 2 from (Frieze et al., 2004). First, let $P_i = \hat{c}_i/\hat{f}$ be the probability of selecting the i-th column of $\mathbf{M}$.

By assumption, we have $P_i \geq \frac{1-\alpha}{1+\alpha}\|\boldsymbol{x}_i\|_2^2/\|\mathbf{M}\|_F^2$. Applying Theorem 2 [4] from (Frieze et al., 2004) we have that with probability at least $1-\delta$, there exists an orthonormal set of vectors $\boldsymbol{y}^{(1)}, \cdots, \boldsymbol{y}^{(k)} \in \mathbb{R}^{n_1}$ in span($\mathbf{C}$) such that

$$\left\| \mathbf{M} - \left(\sum_{j=1}^{k} \boldsymbol{y}^{(j)} \boldsymbol{y}^{(j)^\top} \right) \mathbf{M} \right\|_F^2 \leq \|\mathbf{M} - \mathbf{M}_k\|_F^2 + \frac{(1+\alpha)k}{(1-\alpha)\delta s}\|\mathbf{M}\|_F^2. \tag{44}$$

Finally, to complete the proof, note that every column of $\left(\sum_{j=1}^{k} \boldsymbol{y}^{(j)} \boldsymbol{y}^{(j)^\top}\right) \mathbf{M}$ can be represented as a linear combination of columns in $\mathbf{C}$; furthermore,

$$\|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F = \min_{\mathbf{X} \in \mathbb{R}^{k \times n_2}} \|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F \leq \left\| \mathbf{M} - \left(\sum_{j=1}^{k} \boldsymbol{y}^{(j)} \boldsymbol{y}^{(j)^\top} \right) \mathbf{M} \right\|_F. \tag{45}$$

■

Proof [Proof of Theorem 1] First, set $m_1 = \Omega(\mu_0 \log(n_2/\delta_1))$ we have that with probability $\geq 1 - \delta_1$ the inequality

$$(1-\alpha)\|\boldsymbol{x}_i\|_2^2 \leq \hat{c}_i \leq (1+\alpha)\|\boldsymbol{x}_i\|_2^2$$

holds with $\alpha = 0.5$ for every column i, using Lemma 2. Next, putting $s \geq 6k/\delta_2\epsilon^2$ and applying Lemma 1 we get

$$\|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F \leq \|\mathbf{M} - \mathbf{M}_k\|_F + \epsilon\|\mathbf{M}\|_F \tag{46}$$

with probability at least $1 - \delta_2$. Finally, note that when $\alpha \leq 1/2$ and $n_1 \leq n_2$ the bound in Lemma 3 is dominated by

$$\|\mathbf{M} - \widehat{\mathbf{M}}\|_2 \leq \|\mathbf{M}\|_F \cdot O\left(\sqrt{\frac{\mu_0}{m_2}} \log\left(\frac{n_1 + n_2}{\delta} \right) \right). \tag{47}$$

Consequently, for any $\epsilon' > 0$ if $m_2 = \Omega((\epsilon')^{-2}\mu_0 \log^2((n_1+n_2)/\delta_3)$ we have with probability $\geq 1 - \delta_3$

$$\|\mathbf{M} - \widehat{\mathbf{M}}\|_2 \leq \epsilon'\|\mathbf{M}\|_F. \tag{48}$$

The proof is then completed by taking $\epsilon' = \epsilon/\sqrt{s}$:

$$\begin{aligned}
\|\mathbf{M} - \mathbf{C}\mathbf{X}\|_F &= \|\mathbf{M} - \mathcal{P}_C(\widehat{\mathbf{M}})\|_F \\
&\leq \|\mathbf{M} - \mathcal{P}_C(\mathbf{M})\|_F + \|\mathcal{P}_C(\mathbf{M} - \widehat{\mathbf{M}})\|_F \\
&\leq \|\mathbf{M} - \mathbf{M}_k\|_F + \epsilon\|\mathbf{M}\|_F + \sqrt{s}\|\mathcal{P}_C(\mathbf{M} - \widehat{\mathbf{M}})\|_2 \\
&\leq \|\mathbf{M} - \mathbf{M}_k\|_F + \epsilon\|\mathbf{M}\|_F + \sqrt{s} \cdot \epsilon'\|\mathbf{M}\|_F \\
&\leq \|\mathbf{M} - \mathbf{M}_k\|_F + 2\epsilon\|\mathbf{M}\|_F.
\end{aligned}$$

■

4. The original theorem concerns random samples of rows; it is essentially the same for random samples of columns.

B. Analysis of the iterative norm sampling algorithm

Proof [Proof of Lemma 4]

We first prove Eq. (16). Observe that $\dim(\mathcal{U}(C)) \leq s$. Let $\mathbf{R}_C = (\mathbf{R}^{(C(1))}, \cdots, \mathbf{R}^{(C(s))}) \in \mathbb{R}^{n_1 \times s}$ denote the selected s columns in the noise matrix $\mathbf{R}$ and let $\mathcal{R}(C) = \text{span}(\mathbf{R}_C)$ denote the span of selected columns in $\mathbf{R}$. By definition, $\mathcal{U}(C) \subseteq \mathcal{U} \cup \mathcal{R}(C)$, where $\mathcal{U} = \text{span}(\mathbf{A})$ denotes the subspace spanned by columns in the deterministic matrix $\mathbf{A}$. Consequently, we have the following bound on $\|\mathcal{P}_{\mathcal{U}(C)}\boldsymbol{e}_i\|$ (assuming each entry in $\mathbf{R}$ follows a zero-mean Gaussian distribution with σ^2 variance):

$$\begin{aligned}
\|\mathcal{P}_{\mathcal{U}(C)}\boldsymbol{e}_i\|_2^2 &\leq \|\mathcal{P}_{\mathcal{U}}\boldsymbol{e}_i\|_2^2 + \|\mathcal{P}_{\mathcal{U}^\perp \cap \mathcal{R}(C)}\boldsymbol{e}_i\|_2^2 \\
&\leq \|\mathcal{P}_{\mathcal{U}}\boldsymbol{e}_i\|_2^2 + \|\mathcal{P}_{\mathcal{R}(C)}\boldsymbol{e}_i\|_2^2 \\
&\leq \frac{k\mu_0}{n_1} + \|\mathbf{R}_C\|_2^2 \|(\mathbf{R}_C^\top \mathbf{R}_C)^{-1}\|_2^2 \|\mathbf{R}_C^\top \boldsymbol{e}_i\|_2^2 \\
&\leq \frac{k\mu_0}{n_1} + \frac{(\sqrt{n_1}+\sqrt{s}+\epsilon)^2\sigma^2}{(\sqrt{n_1}-\sqrt{s}-\epsilon)^4\sigma^4} \cdot \sigma^2(s + 2\sqrt{s\log(2/\delta)} + 2\log(2/\delta)).
\end{aligned}$$

For the last inequality we apply Lemma 14 to bound the largest and smallest singular values of $\mathbf{R}_C$ and Lemma 12 to bound $\|\mathbf{R}_C^\top \boldsymbol{e}_i\|_2^2$, because $\mathbf{R}_C^\top \boldsymbol{e}_i$ follow i.i.d. Gaussian distributions with covariance $\sigma^2 \mathbf{I}_{s\times s}$. If ϵ is set as $\epsilon = \sqrt{2\log(4/\delta)}$ then the last inequality holds with probability at least $1-\delta$. Furthermore, when $s \leq n_1/2$ and δ is not exponentially small (e.g., $\sqrt{2\log(4/\delta)} \leq \frac{\sqrt{n_1}}{4}$), the fraction $\frac{(\sqrt{n_1}+\sqrt{s}+\epsilon)^2}{(\sqrt{n_1}-\sqrt{s}-\epsilon)^4}$ is approximately $O(1/n_1)$. As a result, with probability $1 - n_1\delta$ the following holds:

$$\begin{aligned}
&\mu(\mathcal{U}(C)) = \frac{n_1}{s} \max_{1\leq i\leq n_1} \|\mathcal{P}_{\mathcal{U}(C)}\boldsymbol{e}_i\|_2^2 \\
&\leq \frac{n_1}{s}\left(\frac{k\mu_0}{n_1} + O\left(\frac{s + \sqrt{s\log(1/\delta)} + \log(1/\delta)}{n_1}\right)\right) = O\left(\frac{k\mu_0 + s + \sqrt{s\log(1/\delta)} + \log(1/\delta)}{s}\right).
\end{aligned} \tag{49}$$

Finally, putting $\delta' = n_1/\delta$ we prove Eq. (16).

Next we try to prove Eq. (17). Let $\boldsymbol{x}$ be the i-th column of $\mathbf{M}$ and write $\boldsymbol{x} = \boldsymbol{a} + \boldsymbol{r}$, where $\boldsymbol{a} = \mathcal{P}_{\mathcal{U}}(\boldsymbol{x})$ and $\boldsymbol{r} = \mathcal{P}_{\mathcal{U}^\perp}(\boldsymbol{x})$. Since the deterministic component of $\boldsymbol{x}$ lives in $\mathcal{U}$ and the random component of $\boldsymbol{x}$ is a vector with each entry sampled from i.i.d. zero-mean Gaussian distributions, we know that $\boldsymbol{r}$ is also a zero-mean random Gaussian vector with i.i.d. sampled entries. Note that $\mathcal{U}(C)$ does not depend on the randomness over $\{\mathbf{M}^{(i)} : i \notin C\}$. Therefore, in the following analysis we will assume $\mathcal{U}(C)$ to be a fixed subspace $\widetilde{\mathcal{U}}$ with dimension at most s.

The projected vector $\boldsymbol{x}' = \mathcal{P}_{\widetilde{\mathcal{U}}^\perp}\boldsymbol{x}$ can be written as $\tilde{\boldsymbol{x}} = \tilde{\boldsymbol{a}} + \tilde{\boldsymbol{r}}$, where $\tilde{\boldsymbol{a}} = \mathcal{P}_{\widetilde{\mathcal{U}}^\perp}\boldsymbol{a}$ and $\tilde{\boldsymbol{r}} = \mathcal{P}_{\widetilde{\mathcal{U}}^\perp}\boldsymbol{r}$. By definition, $\tilde{\boldsymbol{a}}$ lives in the subspace $\mathcal{U} \cap \widetilde{\mathcal{U}}^\perp$. So it satisfies the incoherence assumption

$$\mu(\tilde{\boldsymbol{a}}) = \frac{n_1\|\tilde{\boldsymbol{a}}\|_\infty^2}{\|\tilde{\boldsymbol{a}}\|_2^2} \leq k\mu(\mathcal{U}) \leq k\mu_0. \tag{50}$$

On the other hand, because $\tilde{\boldsymbol{r}}$ is an orthogonal projection of some random Gaussian variable, $\tilde{\boldsymbol{r}}$ is still a Gaussian random vector, which lives in $\mathcal{U}^\perp \cap \widetilde{\mathcal{U}}^\perp$ with rank at least $n_1 - k - s$.

Subsequently, we have

$$\begin{aligned}
\mu(\tilde{\boldsymbol{x}}) &= n_1\frac{\|\tilde{\boldsymbol{x}}\|_\infty^2}{\|\tilde{\boldsymbol{x}}\|_2^2} \leq 3n_1\frac{\|\tilde{\boldsymbol{a}}\|_\infty^2 + \|\tilde{\boldsymbol{r}}\|_\infty^2}{\|\tilde{\boldsymbol{a}}\|_2^2 + \|\tilde{\boldsymbol{r}}\|_2^2} \\
&\leq 3n_1\frac{\|\tilde{\boldsymbol{a}}\|_\infty^2}{\|\tilde{\boldsymbol{a}}\|_2^2} + 3n_1\frac{\|\tilde{\boldsymbol{r}}\|_\infty^2}{\|\tilde{\boldsymbol{r}}\|_2^2} \\
&\leq 3k\mu_0 + \frac{6\sigma^2 n_1\log(2n_1n_2/\delta)}{\sigma^2(n_1-k-s) - 2\sigma^2\sqrt{(n_1-k-s)\log(n_2/\delta)}}.
\end{aligned}$$

For the second inequality we use the fact that $\frac{\sum_i a_i}{\sum_i b_i} \leq \sum_i \frac{a_i}{b_i}$ whenever $a_i, b_i \geq 0$. For the last inequality we use Lemma 13 on the enumerator and Lemma 12 on the denominator. Finally, note that when $\max(s,k) \leq n_1/4$ and $\log(n_2/\delta) \leq n_1/64$ the denominator can be lower bounded by $\sigma^2 n_1/4$; subsequently, we can bound $\mu(\tilde{\boldsymbol{x}})$ as

$$\mu(\tilde{\boldsymbol{x}}) \leq 3k\mu_0 + \frac{24\sigma^2 n_1\log(2n_1n_2/\delta)}{\sigma^2 n_1} \leq 3k\mu_0 + 24\log(2n_1n_2/\delta). \tag{51}$$

Taking a union bound over all $n_2 - s$ columns yields the result. ■

To prove the norm estimation consistency result in Lemma 5 we first cite a seminal theorem from (Krishnamurthy and Singh, 2014) which provides a tight error bound on a subsampled projected vector in terms of the norm of the true projected vector.

Theorem 9 *Let $\mathcal{U}$ be a k-dimensional subspace of $\mathbb{R}^n$ and $\boldsymbol{y} = \boldsymbol{x} + \boldsymbol{v}$, where $\boldsymbol{x} \in \mathcal{U}$ and $\boldsymbol{v} \in \mathcal{U}^\perp$. Fix $\delta' > 0$, $m \geq \max\{\frac{8}{3}k\mu(\mathcal{U})\log\left(\frac{2k}{\delta'}\right), 4\mu(\boldsymbol{v})\log(1/\delta')\}$ and let Ω be an index set with entries sampled uniformly with replacement with probability m/n. Then with probability at least $1 - 4\delta'$:*

$$\frac{m(1-\alpha) - k\mu(\mathcal{U})\frac{\beta}{1-\gamma}}{n}\|\boldsymbol{v}\|_2^2 \leq \|\boldsymbol{y}_\Omega - \mathcal{P}_{U_\Omega}\boldsymbol{y}_\Omega\|_2^2 \leq (1+\alpha)\frac{m}{n}\|\boldsymbol{v}\|_2^2, \tag{52}$$

where $\alpha = \sqrt{2\frac{\mu(\boldsymbol{v})}{m}\log(1/\delta')} + 2\frac{\mu(\boldsymbol{v})}{3m}\log(1/\delta')$, $\beta = (1+2\sqrt{\log(1/\delta')})^2$ and $\gamma = \sqrt{\frac{8k\mu(\mathcal{U})}{3m}\log(2k/\delta')}$.

We are now ready to prove Lemma 5.

Proof [Proof of Lemma 5] By Algorithm 2, we know that $\dim(\mathcal{S}_t) = t$ with probability 1. Let $\boldsymbol{y} = \mathbf{M}^{(i)}$ denote the i-th column of $\mathbf{M}$ and let $\boldsymbol{v} = \mathcal{P}_{\mathcal{S}_t}\boldsymbol{y}$ be the projected vector. We can apply Theorem 9 to bound the estimation error between $\|\boldsymbol{v}\|$ and $\|\boldsymbol{y}_\Omega - \mathcal{P}_{\mathcal{S}_t(\Omega)}\boldsymbol{y}_\Omega\|$.

First, when m is set as in Eq. (20) it is clear that the conditions $m \geq \frac{8}{3}t\mu(\mathcal{U})\log\left(\frac{2t}{\delta'}\right) = \Omega(k\mu_0\log(n/\delta)\log(k/\delta'))$ and $m \geq 4\mu(\boldsymbol{v})\log(1/\delta') = \Omega(k\mu_0\log(n/\delta)\log(1/\delta'))$ are satisfied. We next turn to the analysis of α, β and γ. More specifically, we want $\alpha = O(1)$, $\gamma = O(1)$ and $\frac{t\mu(\mathcal{U})}{m}\beta = O(1)$.

For α, $\alpha = O(1)$ implies $m = \Omega(\mu(\boldsymbol{v})\log(1/\delta')) = \Omega(k\mu_0\log(n/\delta)\log(1/\delta'))$. Therefore, by carefully selecting constants in $\Omega(\cdot)$ we can make $\alpha \leq 1/4$.

For γ, $\gamma = O(1)$ implies $m = \Omega(t\mu(\mathcal{U})\log(t/\delta')) = \Omega(k\mu_0\log(n/\delta)\log(k/\delta'))$. By carefully selecting constants in $\Omega(\cdot)$ we can make $\gamma \leq 0.2$.

For β, $\frac{t\mu(\mathcal{U})}{m}\beta = O(1)$ implies $m = O(t\mu(\mathcal{U})\beta) = O(k\mu_0\log(n/\delta)\log(1/\delta'))$. By carefully selecting constants we can have $\beta \leq 0.2$. Finally, combining bounds on α, β and γ we prove the desired result. ■

Before proving Lemma 6, we first cite a lemma from (Deshpande et al., 2006) that connects the volume of a simplex to the permutation sum of singular values.

Lemma 9 ((Deshpande et al., 2006)) *Fix $\mathbf{A} \in \mathbb{R}^{m\times n}$ with $m \leq n$. Suppose $\sigma_1, \cdots, \sigma_m$ are singular values of $\mathbf{A}$. Then*

$$\sum_{S\subseteq[n],|S|=k} \mathrm{vol}(\Delta(S))^2 = \frac{1}{(k!)^2} \sum_{1\leq i_1<i_2<\cdots<i_k\leq m} \sigma_{i_1}^2\sigma_{i_2}^2\cdots\sigma_{i_k}^2. \tag{53}$$

Now we are ready to prove Lemma 6.

Proof [Proof of Lemma 6] Let $\mathbf{M}_k$ denote the best rank-k approximation of $\mathbf{M}$ and assume the singular values of $\mathbf{M}$ are $\{\sigma_i\}_{i=1}^{n_1}$. Let $C = \{i_1, \cdots, i_k\}$ be the selected columns. Let $\tau \in \Pi_k$, where Π_k denotes all permutations with k elements. By $\mathcal{H}_{\tau,t}$ we denote the linear subspace spanned by $\{\mathbf{M}^{(\tau(i_1))}, \cdots, \mathbf{M}^{(\tau(i_t))}\}$ and let $d(\mathbf{M}^{(i)}, \mathcal{H}_{\tau,t})$ denote the distance between column $\mathbf{M}^{(i)}$ and subspace $\mathcal{H}_{\tau,t}$. We then have

$$\begin{aligned}
\hat{p}_C &\leq \sum_{\tau\in\Pi_k} \left(\frac{5}{2}\right)^k \frac{\|\mathbf{M}^{(\tau(i_1))}\|_2^2}{\|\mathbf{M}\|_F^2} \frac{d(\mathbf{M}^{(\tau(i_2))}, \mathcal{H}_{\tau,1})^2}{\sum_{i=1}^{n_2} d(\mathbf{M}^{(i)}, \mathcal{H}_{\tau,1})^2} \cdots \frac{d(\mathbf{M}^{(\tau(i_k))}, \mathcal{H}_{\tau,k-1})^2}{\sum_{i=1}^{n_2} d(\mathbf{M}^{(i)}, \mathcal{H}_{\tau,k-1})^2} \\
&\leq 2.5^k \cdot \frac{\sum_{\tau\in\Pi_k} \|\mathbf{M}^{(\tau(i_1))}\|^2 d(\mathbf{M}^{(\tau(i_2))}, \mathcal{H}_{\tau,1})^2 \cdots d(\mathbf{M}^{(\tau(i_k))}, \mathcal{H}_{\tau,k-1})^2}{\|\mathbf{M}\|_F^2 \|\mathbf{M}-\mathbf{M}_1\|_F^2 \cdots \|\mathbf{M}-\mathbf{M}_{k-1}\|_F^2} \\
&= 2.5^k \cdot \frac{\sum_{\tau\in\Pi_k} (k!)^2 \mathrm{vol}(\Delta(C))^2}{\|\mathbf{M}\|_F^2 \|\mathbf{M}-\mathbf{M}_1\|_F^2 \cdots \|\mathbf{M}-\mathbf{M}_{k-1}\|_F^2} \\
&= 2.5^k \cdot \frac{(k!)^3 \mathrm{vol}(\Delta(C))^2}{\sum_{i=1}^{n_1}\sigma_i^2 \sum_{i=2}^{n_1}\sigma_i^2 \cdots \sum_{i=k}^{n_1}\sigma_i^2} \\
&\leq 2.5^k \cdot \frac{(k!)^3 \mathrm{vol}(\Delta(C))^2}{\sum_{1\leq i_1<i_2<\cdots<i_k\leq n_1} \sigma_{i_1}^2\sigma_{i_2}^2\cdots\sigma_{i_k}^2} \\
&= 2.5^k \cdot \frac{k! \mathrm{vol}(\Delta(C))^2}{\sum_{T:|T|=k} \mathrm{vol}(\Delta(T))^2} = 2.5^k k! p_C.
\end{aligned}$$

For the first inequality we apply Eq. (23) and for the second to last inequality we apply Lemma 9. ■

Lemma 7 can be proved by applying Theorem 5 for T rounds, given the norm estimation accuracy bound in Proposition 1.

Proof [Proof of Lemma 7] First note that

$$\|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_T}(\mathbf{M})\|_F^2 \leq \|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_T,k}(\mathbf{M})\|_F^2.$$

Applying Theorem 5 with $\frac{1+\alpha}{1-\alpha} = \frac{5}{2}$, we have

$$\begin{aligned}
&\mathbb{E}\left[\|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\cup\mathcal{S}_T}(\mathbf{M})\|_F^2\right] \\
\leq\ & \|\mathbf{M}-\mathbf{M}_k\|_F^2 + \frac{5k}{2s_T}\mathbb{E}\left[\|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\mathcal{S}_{T-1}}(\mathbf{M})\|_F\right]^2 \\
\leq\ & \|\mathbf{M}-\mathbf{M}_k\|_F^2 + \frac{5k}{2s_T}\left(\|\mathbf{M}-\mathbf{M}_k\|_F^2 + \frac{5k}{2s_{T-1}}\mathbb{E}\left[\|\mathbf{M} - \mathcal{P}_{\mathcal{U}\cup\mathcal{S}_1\cup\cdots\mathcal{S}_{T-2}}(\mathbf{M})\|_F^2\right]\right) \\
\leq\ & \cdots \\
\leq\ & \left(1 + \frac{5}{2}\frac{k}{s_T} + \left(\frac{5}{2}\right)^2 \frac{k^2}{s_T s_{T-1}} + \cdots + \left(\frac{5}{2}\right)^{T-1} \frac{k^{T-1}}{s_{T-1}\cdots s_1}\right)\|\mathbf{M}-\mathbf{M}_k\|_F^2 \\
&+ \left(\frac{5}{2}\right)^T \frac{k^T}{s_T s_{T-1}\cdots s_1}\|\mathbf{M} - \mathcal{P}_{\mathcal{U}}(\mathbf{M})\|_F^2 \\
\leq\ & \left(1 + \frac{\epsilon}{4\delta} + \frac{\epsilon}{20\delta} + \cdots\right)\|\mathbf{M}-\mathbf{M}_k\|_F^2 + \frac{\epsilon/2}{2^T\delta}\|\mathbf{E}\|_F^2 \\
\leq\ & \left(1 + \frac{\epsilon}{2\delta}\right)\|\mathbf{M}-\mathbf{M}_k\|_F^2 + \frac{\epsilon/2}{2^T\delta}\|\mathbf{E}\|_F^2.
\end{aligned}$$

Finally applying Markov's inequality we complete the proof. ■

To prove the reconstruction error bound in Lemma 8 we need the following two technical lemmas, cited from (Krishnamurthy and Singh, 2013; Balzano et al., 2010b).

Lemma 10 ((Krishnamurthy and Singh, 2013)) *Suppose $\mathcal{U} \subseteq \mathbb{R}^n$ has dimension k and $\mathbf{U} \in \mathbb{R}^{n\times k}$ is the orthogonal matrix associated with $\mathcal{U}$. Let $\Omega \subseteq [n]$ be a subset of indices each sampled from i.i.d. Bernoulli distributions with probability m/n_1. Then for some vector $\boldsymbol{y} \in \mathbb{R}^n$, with probability at least $1-\delta$:*

$$\|\mathbf{U}_\Omega^\top \boldsymbol{y}_\Omega\|_2^2 \leq \beta\frac{m}{n_1}\frac{k\mu(\mathcal{U})}{n_1}\|\boldsymbol{y}\|_2^2, \tag{54}$$

where β is defined in Theorem 9.

Lemma 11 ((Balzano et al., 2010b)) *With the same notation in Lemma 10 and Theorem 9. With probability $\geq 1-\delta$ one has*

$$\|(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\| \leq \frac{n_1}{(1-\gamma)m}, \tag{55}$$

provided that $\gamma < 1$.

Now we can prove Lemma 8.

Proof [Proof of Lemma 8] Let $\mathcal{U} = \mathcal{U}(S)$ and $\mathbf{U} \in \mathbb{R}^{n_1\times s}$ be the orthogonal matrix associated with $\mathcal{U}$. Fix a column i and let $\boldsymbol{x} = \mathbf{M}^{(i)} = \boldsymbol{a} + \boldsymbol{r}$, where $\boldsymbol{a} \in \mathcal{U}$ and $\boldsymbol{r} \in \mathcal{U}^\perp$. What we want is to bound $\|\boldsymbol{x} - \mathbf{U}(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top\boldsymbol{x}_\Omega\|_2^2$ in terms of $\|\boldsymbol{r}\|_2^2$.

Write $\boldsymbol{a} = \mathbf{U}\tilde{\boldsymbol{a}}$. By Lemma 11, if m satisfies the condition given in the Lemma then with probability over $1-\delta-\delta''$ we know $(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)$ is invertible and furthermore, $\|(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\|_2 \leq 2n_1/m$. Consequently,

$$\mathbf{U}(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top\boldsymbol{a}_\Omega = \mathbf{U}(\mathbf{U}_\Omega^\top\mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top\mathbf{U}_\Omega\tilde{\boldsymbol{a}} = \mathbf{U}\tilde{\boldsymbol{a}} = \boldsymbol{a}. \tag{56}$$

That is, the subsampled projector preserves components of $\boldsymbol{x}$ in subspace $\mathcal{U}$.

Now let's consider the noise term $\boldsymbol{r}$. By Corollary 1 with probability $\geq 1-\delta$ we can bound the incoherence level of $\boldsymbol{y}$ as $\mu(\boldsymbol{y}) = O(s\mu_0 \log(n/\delta))$. The incoherence of subspace $\mathcal{U}$ can also be bounded as $\mu(\mathcal{U}) = O(\mu_0 \log(n/\delta))$. Subsequently, given $m = \Omega(\epsilon^{-1} s\mu_0 \log(n/\delta)\log(n/\delta''))$ we have (with probability $\geq 1-\delta-2\delta''$)

$$\begin{aligned} & \|\boldsymbol{x} - \mathbf{U}(\mathbf{U}_\Omega^\top \mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top(\boldsymbol{a}+\boldsymbol{r})|_2^2 \\ = \; & \|\boldsymbol{a}+\boldsymbol{r} - \mathbf{U}(\mathbf{U}_\Omega^\top \mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top(\boldsymbol{a}+\boldsymbol{r})\|_2^2 \\ = \; & \|\boldsymbol{r} - \mathbf{U}(\mathbf{U}_\Omega^\top \mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top\boldsymbol{r}\|_2^2 \\ \leq \; & \|\boldsymbol{r}\|_2^2 + \|(\mathbf{U}_\Omega^\top \mathbf{U}_\Omega)^{-1}\|_2^2 \|\mathbf{U}_\Omega^\top \boldsymbol{r}\|_2^2 \\ \leq \; & (1+O(\epsilon))\|\boldsymbol{r}\|_2^2. \end{aligned}$$

For the second to last inequality we use the fact that $\boldsymbol{r} \in \mathcal{U}^\perp$. By carefully selecting constants in Eq. (22) we can make

$$\|\boldsymbol{x} - \mathbf{U}(\mathbf{U}_\Omega^\top \mathbf{U}_\Omega)^{-1}\mathbf{U}_\Omega^\top \boldsymbol{x}\|_2^2 \leq (1+\epsilon)\|\mathcal{P}_{\mathcal{U}^\perp}\boldsymbol{x}\|_2^2. \tag{57}$$

Summing over all n_2 columns yields the desired result. ■

C. Proof of lower bound for passive sampling

Proof [Proof of Theorem 8] Let $\widetilde{\mathcal{X}} = \{\mathbf{X}_1, \cdots, \mathbf{X}_T\} \subseteq \mathcal{X}'$ be a finite subset of $\mathcal{X}'$ which we specify later. Let π be any prior distribution over $\widetilde{\mathcal{X}}$. We then have the following chain of inequalities:

$$\begin{aligned} R^*_{\text{css}} &= \inf_{f\in\mathcal{F}'} \inf_{q\in\mathcal{Q}} \sup_{\mathbf{X}\in\mathcal{X}'} \Pr_{\Omega\sim q;f}[\mathbf{X} \neq \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}] \\ &\geq \inf_{f\in\mathcal{F}'} \inf_{q\in\mathcal{Q}} \Pr_{\Omega\sim q;\mathbf{X}\sim\pi;f}[\mathbf{X} \neq \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}] \qquad (58) \\ &\geq \inf_{f\in\mathcal{F}'} \min_{|\Omega|=m} \Pr_{\mathbf{X}\sim\pi;f}[\mathbf{X} \neq \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}]. \qquad (59) \end{aligned}$$

Here Eq. (58) uses the fact that the maximum dominates any expectation over the same set and for Eq. (59) we apply Yao's principle, which asserts that the worst-case performance of a randomized algorithm is better (i.e., lower bounded) by the averaging performance of a deterministic algorithm. Hence, when the input matrix $\mathbf{X}$ is randomized by a prior π it suffices to consider only deterministic sampling schemes, which corresponds to a subset of matrix entries Ω fixed a priori, with size $|\Omega| = m$.

We next construct the subset $\widetilde{\mathcal{X}}$ and let π be the uniform distribution over $\widetilde{\mathcal{X}}$. Let $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_{k-2} \in \mathbb{R}^{n_1}$ be an arbitrary set of linear independent column vectors with $[\boldsymbol{x}_i]_1 = 0$ for all $i = 1, 2, \cdots, k-2$ and $\mu(\boldsymbol{x}_1), \cdots, \mu(\boldsymbol{x}_{k-2}) = 1 + \frac{1}{n_1-1}$. This can be done by setting all nonzero entries in $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_{k-2}$ to ± 1. In addition, we define $\boldsymbol{y} := (1, 1, \cdots, 1)$ and $\boldsymbol{e}_j = (0, \cdots, 0, 1, 0, \cdots, 0)$ with the only nonzero entry at the jth position. Next, define $\widetilde{\mathbf{X}} = \{\mathbf{X}^{i,j}\}_{i=k-1,j=1}^{n_2,n_1}$ with

$$\mathbf{X}^{i,j}_{(\ell)} = \begin{cases} \boldsymbol{x}_\ell & \text{if } \ell \leq k-2, \\ \boldsymbol{y} - 2\boldsymbol{e}_j & \text{if } \ell = i, \\ \boldsymbol{y} & \text{otherwise.} \end{cases} \tag{60}$$

It follows by definition that $\text{rank}(\mathbf{X}^{i,j}) = k$ and $\mu(\mathbf{X}^{i,j}_{(\ell)}) \leq \mu_1 = 1 + \frac{1}{n_1-1}$ for all i, j and ℓ. Furthermore, for fixed i and j one necessary condition for $\mathbf{X} = \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}$ is $\{1, 2, \cdots, k-2, i\} \subseteq C$. Therefore, if for distinct i_1, i_2, i_3, i_4 and some j_1, j_2, j_3, j_4 one has $\mathbf{X}^{i_1,j_1}_\Omega = \cdots = \mathbf{X}^{i_4,j_4}_\Omega$ then the best a column subset selection algorithm f could do is random guessing and hence $\Pr[\mathbf{X} \neq \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}] \geq 1/2$. Consequently, for fixed Ω one has

$$\inf_{f\in\mathcal{F}'} \Pr_{\mathbf{X}\sim\pi;f}[\mathbf{X} \neq \mathbf{X}_C\mathbf{X}_C^\dagger\mathbf{X}] \geq \frac{1}{2} - \frac{1}{2}\left|\left\{\mathbf{X}^{i,j} : \mathbf{X}^{i',j'}_\Omega \neq \mathbf{X}^{i,j}_\Omega, \forall i' \neq i, j' \in [n_1]\right\}\right|. \tag{61}$$

The final step is to bound the size of the set $E = \{\mathbf{X}^{i,j} : \mathbf{X}^{i',j'}_\Omega \neq \mathbf{X}^{i,j}_\Omega, \forall i' \neq i, j' \in [n_1]\}$. Note that if $\mathbf{X}_\Omega$ is $+1$ on all entries (i,j) with $i > k-2$ then $\mathbf{X} \notin E$ because for every $\mathbf{X}' \in \widetilde{\mathcal{X}}$, $\mathbf{X}'_\Omega = \mathbf{X}_\Omega$. Consequently,

$$|E| \leq \frac{|\Omega|}{n_1(n_2-k+2)} \leq \frac{m}{n_1(n_2-k)}. \tag{62}$$

Plugging Eq. (62) into Eq. (61) we complete the proof of Theorem 8. ■

D. Some concentration inequalities

Lemma 12 ((Laurent and Massart, 2000)) *Let $X \sim \chi^2_d$. Then with probability $\geq 1-2\delta$ the following holds:*

$$-2\sqrt{d\log(1/\delta)} \leq X - d \leq 2\sqrt{d\log(1/\delta)} + 2\log(1/\delta). \tag{63}$$

Lemma 13 *Let $X_1, \cdots, X_n \sim \mathcal{N}(0, \sigma^2)$. Then with probability $\geq 1-\delta$ the following holds:*

$$\max_i |X_i| \leq \sigma\sqrt{2\log(2n/\delta)}. \tag{64}$$

Lemma 14 ((Vershynin, 2010)) *Let $\mathbf{X}$ be an $n \times t$ random matrix with i.i.d. standard Gaussian random entries. If $t < n$ then for every $\epsilon \geq 0$ with probability $\geq 1 - 2\exp(-\epsilon^2/2)$ the following holds:*

$$\sqrt{n} - \sqrt{t} - \epsilon \leq \sigma_{\min}(\mathbf{X}) \leq \sigma_{\max}(\mathbf{X}) \leq \sqrt{n} + \sqrt{t} + \epsilon. \tag{65}$$

Lemma 15 (Noncommutative Bernstein Inequality, (Gross et al., 2010; Recht, 2011)) *Let $\mathbf{X}_1, \cdots, \mathbf{X}_m$ be independent zero-mean square $n \times n$ random matrices. Suppose $\rho_k^2 = \max(\|\mathbb{E}[\mathbf{X}_k\mathbf{X}_k^\top]\|_2, \|\mathbb{E}[\mathbf{X}_k^\top\mathbf{X}_k]\|_2)$ and $\|\mathbf{X}_k\|_2 \leq M$ with probability 1 for all k. Then for any $t > 0$,*

$$\Pr\left[\left\|\sum_{k=1}^m \mathbf{X}_k\right\|_2 > t\right] \leq 2n\exp\left(-\frac{t^2/2}{\sum_{k=1}^m \rho_k^2 + Mt/3}\right). \tag{66}$$

Abstract

Supervised manifold learning methods learn data representations by preserving the geometric structure of data while enhancing the separation between data samples from different classes. In this work, we propose a theoretical study of supervised manifold learning for classification. We consider nonlinear dimensionality reduction algorithms that yield linearly separable embeddings of training data and present generalization bounds for this type of algorithms. A necessary condition for satisfactory generalization performance is that the embedding allow the construction of a sufficiently regular interpolation function in relation with the separation margin of the embedding. We show that for supervised embeddings satisfying this condition, the classification error decays at an exponential rate with the number of training samples. Finally, we examine the separability of supervised nonlinear embeddings that aim to preserve the low-dimensional geometric structure of data based on graph representations. The proposed analysis is supported by experiments on several real data sets.

Keywords: Manifold learning, dimensionality reduction, classification, out-of-sample extensions, RBF interpolation

1. Introduction

In many data analysis problems, data samples have an intrinsically low-dimensional structure although they reside in a high-dimensional ambient space. The learning of low-dimensional structures in collections of data has been a well studied topic of the last two decades (Tenenbaum et al., 2000), (Roweis and Saul, 2000), (Belkin and Niyogi, 2003), (He and Niyogi, 2004), (Donoho and Grimes, 2003), (Zhang and Zha, 2005). Following these works, many classification methods have been proposed in the recent years to apply such manifold learning techniques to learn classifiers that are adapted to the geometric structure of low-dimensional data (Hua et al., 2012), (Yang et al., 2011), (Zhang et al., 2012), (Sugiyama, 2007), (Raducanu and Dornaika, 2012). The common approach in such works is to learn a data representation that enhances the between-class separation while preserving the intrinsic low-dimensional structure of data. While many efforts have focused on the practical aspects of learning such supervised embeddings for training data, the generalization performance of these methods as supervised classification algorithms has not been investigated much yet. In this work, we aim to study nonlinear supervised dimensionality reduction methods and present performance bounds based on the properties of the embedding and the interpolation function used for generalizing the embedding.

Several supervised manifold learning methods extend the Laplacian eigenmaps algorithm (Belkin and Niyogi, 2003), or its linear variant LPP (He and Niyogi, 2004) to the classification problem. The algorithms proposed by Hua et al. (2012), Yang et al. (2011), Zhang et al. (2012) provide a supervised extension of the LPP algorithm and learn a linear projection that preserves the proximity of neighboring samples from the same class, while increasing the distance between nearby samples from different classes. The method by Sugiyama (2007) proposes an adaptation of the Fisher metric for linear manifold learning, which is in fact shown to be equivalent to the above methods by Yang et al. (2011), Zhang et al. (2012). In (Li et al., 2013), (Cui and Fan, 2012), (Wang and Chen, 2009), some other similar Fisher-based linear manifold learning methods are proposed. In (Raducanu and Dornaika, 2012) a method relying on a similar formulation as in (Hua et al., 2012), (Yang et al., 2011), (Zhang et al., 2012) is presented, which, however, learns a nonlinear embedding. The main advantage of linear dimensionality reduction methods over nonlinear ones is that the generalization of the learnt embedding to novel (initially unavailable) samples is straightforward. However, nonlinear manifold learning algorithms are more flexible as the possible data representations they can learn belong to a wider family of functions, e.g., one can always find a nonlinear embedding to make training samples from different classes linearly separable. On the other hand, when a nonlinear embedding is used, one must also determine a suitable interpolation function to generalize the embedding to new samples, and the choice of the interpolator is critical for the classification performance.

The common effort in all of these supervised dimensionality reduction methods is to learn an embedding that increases the separation between different classes, while preserving the geometric structure of data. It is interesting to note that supervised manifold learning methods achieve separability by reducing the dimension of data, while kernel methods in traditional classifiers achieve this by increasing the dimension of data. Meanwhile, making training data linearly separable in supervised manifold learning does not mean much only by itself. Assuming that the data are sampled from a continuous distribution (hence two samples coincide with 0 probability), it is almost always possible to separate a discrete set of samples from different classes with a nonlinear embedding, e.g., even with a simple embedding such as the one mapping each sample to a vector encoding its class label. What actually matters is how the embedding generalizes to test data, i.e., where the test samples will be mapped to in the low-dimensional domain of embedding and how well the performance will be. The generalization for test data is straightforward for kernel methods, it is determined by the underlying main algorithm. However, in nonlinear supervised manifold learning, this question has rather been overlooked so far. In this work we aim to fill this gap and look into the generalization capabilities of supervised manifold learning algorithms. We study the conditions that must be satisfied by the embedding of the training samples and the interpolation function for satisfactory generalization of the classifier. We then ex-

∗. Most part of the work was performed while the first author was at INRIA.

amine the rates of convergence of supervised manifold learning algorithms that satisfy these conditions.

In Section 2, we consider arbitrary supervised manifold learning algorithms that compute a linearly separable embedding of training samples. We study the generalization capability of such algorithms for two types of out-of-sample interpolation functions. We first consider arbitrary interpolation functions that are Lipschitz-continuous on the support of each class, and then focus on out-of-sample extensions with radial basis function (RBF) kernels, which is a popular family of interpolation functions. For both types of interpolators, we derive conditions that must be satisfied by the embedding of the training samples and the regularity of the interpolation function that generalizes the embedding to test samples, when a nearest neighbor or linear classifier is used in the low-dimensional domain of embedding. These conditions enforce the Lipschitz constant of the interpolator to be sufficiently small, in comparison with the separation margin between training samples from different classes in the low-dimensional domain of embedding. The practical value of these results resides in their implications about what must really be taken into account when designing a supervised dimensionality reduction algorithm: Achieving a good separation margin does not suffice by itself; the geometric structure must also be preserved so as to ensure that a sufficiently regular interpolator can be found to generalize the embedding to the whole ambient space. We then particularly consider Gaussian RBF kernels and show the existence of an optimal value for the kernel scale by studying the condition in our main result that links the separation with the Lipschitz constant of the kernel.

Our results in Section 2 also provide bounds on the rate of convergence of the classification error of supervised embeddings. We show that the misclassification error probability decays at an exponential rate with the number of samples, provided that the interpolation function is sufficiently regular with respect to the separation margin of the embedding. These convergence rates are higher than those reported in previous results on RBF networks (Niyogi and Girosi, 1996), (Lin et al., 2014), (Hernández-Aguirre et al., 2002), and regularized least-squares regression algorithms (Caponnetto and De Vito, 2007), (Steinwart et al., 2009). The essential difference between our results and such previous works is that those assume a general setting and do not focus on a particular data model, whereas our results are rather relevant to settings where the support of each class admits some certain structure, so as to allow the existence of an interpolator that is sufficiently regular on the support of each class. Moreover, in contrast with these previous works, our bounds are independent of the ambient space dimension and vary only with the intrinsic dimensions of the class supports as they characterize the error in terms of the covering numbers of the supports.

The results in Section 2 assume an embedding that makes training samples from different classes linearly separable. Even if most nonlinear dimensionality reduction methods are observed to yield separable embeddings in practice, we aim to verify this theoretically in Section 3. In particular, we focus on the nonlinear version of the supervised Laplacian eigenmaps embeddings (Raducanu and Dornaika, 2012), (Hua et al., 2012), (Yang et al., 2011), (Zhang et al., 2012). Supervised Laplacian eigenmaps methods embed the data with the eigenvectors of the linear combination of two graph Laplacian matrices that encode the links between neighboring samples from the same class and different classes. In such a data representation, the coordinates of neighboring data samples change slowly within the same

class and rapidly across different classes. We study the conditions for the linear separability of these embeddings and characterize their separation margin in terms of some graph and algorithm parameters.

In Section 4, we evaluate our results with experiments on several real data sets. We study the implications of the condition derived in Section 2 on the separability margin - interpolator regularity tradeoff. The experimental comparison of several supervised dimensionality reduction algorithms shows that this compromise between the separation and interpolator regularity can indeed be related to the practical classification performance of a supervised manifold learning algorithm. This suggests that, one can possibly improve the accuracy of supervised dimensionality reduction algorithms by considering more carefully the generalization capability of the embedding during the learning. We then study the variation of the classification performance with parameters such as the sample size, the RBF kernel scale, and the dimension of the embedding, in view of the generalization bounds presented in Section 2. Finally, we conclude in Section 5.

2. Performance Bounds for Supervised Manifold Learning Methods

2.1 Notation and Problem Formulation

Consider a setting with M data classes where the samples of each class $m \in \{1, \dots, M\}$ are drawn from a probability measure ν_m in a Hilbert space H such that ν_m has a bounded support $\mathcal{M}_m \subset H$. Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of N training samples such that each x_i is drawn from one of the probability measures ν_m, and the samples drawn from each ν_m are independent and identically distributed. We denote the class label of x_i by $C_i \in \{1, 2, \dots, M\}$.

Let $Y = \{y_i\}_{i=1}^N \subset \mathbb{R}^d$ be a d-dimensional embedding of $\mathcal{X}$, where each y_i corresponds to x_i. We consider supervised embeddings such that Y is linearly separable. Linear separability is defined as follows:

Definition 1 *The data representation Y is linearly separable with a margin of $\gamma > 0$, if for any two classes $k, l \in \{1, 2, \dots, M\}$, there exists a separating hyperplane defined by $\omega_{kl} \in \mathbb{R}^d$, $\|\omega_{kl}\| = 1$ and $b_{kl} \in \mathbb{R}$ such that*

$$\begin{aligned} \omega_{kl}^T y_i + b_{kl} &\geq \gamma/2 \qquad \text{if } C_i = k \\ \omega_{kl}^T y_i + b_{kl} &\leq -\gamma/2 \qquad \text{if } C_i = l. \end{aligned} \tag{1}$$

The above definition of separability implies the following. For any given class m, there exists a set of hyperplanes $\{\omega_{mk}\}_{k \neq m} \subset \mathbb{R}^d$, $\|\omega_{mk}\| = 1$, and a set of real numbers $\{b_{mk}\}_{k \neq m} \subset \mathbb{R}$ that separate class m from other classes, such that for all y_i of class $C_i = m$

$$\omega_{mk}^T y_i + b_{mk} > \gamma/2, \quad \forall k \neq m \tag{2}$$

and for all y_i of class $C_i \neq m$, there exists a k such that

$$\omega_{mk}^T y_i + b_{mk} < -\gamma/2. \tag{3}$$

These hyperplanes are obtained by setting $\omega_{km} = -\omega_{mk}$, $b_{km} = -b_{mk}$.

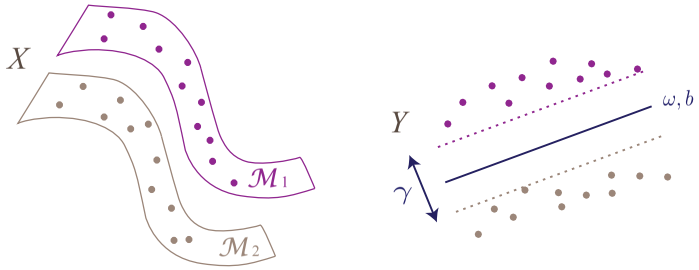

Figure 1: Illustration of a linearly separable embedding. Data in X are sampled from two different classes with supports $\mathcal{M}_1$, $\mathcal{M}_2$. The samples X are mapped to the coordinates Y with a low-dimensional embedding, where the two classes become linearly separable with margin γ with the hyperplane given by ω, b.

Figure 1 shows an illustration of a linearly separable embedding of data samples from two classes. Manifold learning methods typically compute a low-dimensional embedding Y of training data $\mathcal{X}$ in a pointwise manner, i.e., the coordinates y_i are computed only for the initially available training samples x_i. However, in a classification problem, in order to estimate the class label of a new data sample x of unknown class, x needs to be mapped to the low-dimensional domain of embedding as well. The construction of a function $f : H \to \mathbb{R}^d$ that generalizes the learnt embedding to the whole space is known as the out-of-sample generalization problem. Smooth functions are commonly used for out-of-sample interpolation, e.g. as in (Qiao et al., 2013), (Peherstorfer et al., 2011).

Now let x be a test sample drawn from the probability measure ν_m, hence, the true class label of x is m. In our study, we consider two basic classification schemes in the domain of embedding:

Linear classifier. The embeddings of the training samples are used to compute the separating hyperplanes, i.e., the classifier parameters $\{\omega_{mk}\}$ and $\{b_{mk}\}$. Then, mapping x to the low-dimensional domain as $f(x) \in \mathbb{R}^d$, the class label of x is estimated as $\hat{C}(x) = l$ if there exists $l \in \{1, \ldots, M\}$ such that

$$\omega_{lk}^T f(x) + b_{lk} > 0, \quad \forall k \in \{1, \ldots, M\} \setminus \{l\}. \tag{4}$$

Note that the existence of such an l is not guaranteed in general for any x, but for a given x there cannot be more than one l satisfying the above condition. Then x is classified correctly if the estimated class label agrees with the true class label, i.e., $\hat{C}(x) = l = m$.

Nearest neighbor classification. The test sample x is assigned the class label of the closest training point in the domain of embedding, i.e., $\hat{C}(x) = C_{i'}$, where

$$i' = \arg \min_{i=1,\ldots,N} \|y_i - f(x)\|.$$

In the rest of this section, we study the generalization performance of supervised dimensionality reduction methods. We first consider in Section 2.2 interpolation functions that

vary regularly on each class support and we search for a lower bound on the probability of correctly classifying a new data sample in terms of the regularity of f, the separation of the embedding, and the sampling density. Then in Section 2.3, we study the classification performance for a particular type of interpolation functions, namely RBF interpolators, which is one of the most popular ones (Peherstorfer et al., 2011), (Chin and Suter, 2008). We focus particularly on Gaussian RBF interpolators in Section 2.4 and derive some results regarding the existence of an optimal kernel scale parameter. Lastly, we discuss our results in comparison with previous literature in Section 2.5.

In the results in Sections 2.2-2.4, we keep a generic formulation and simply treat the supports $\{\mathcal{M}_m\}$ as arbitrary bounded subsets of H, each of which represents a different data class. Nevertheless, from the perspective of manifold learning, our results are of interest especially when the data is assumed to have an underlying low-dimensional structure. In Section 2.5, we study the implications of our results for the setting where $\mathcal{M}_m$ are low-dimensional manifolds. We then examine how the proposed bounds vary in relation to the intrinsic dimensions of $\{\mathcal{M}_m\}$.

2.2 Out-of-Sample Interpolation with Regular Functions

Let $f : H \to \mathbb{R}^d$ be an out-of-sample interpolation function such that $f(x_i) = y_i$ for each training sample x_i, $i = 1, \ldots, N$. Assume that f is Lipschitz continuous with constant $L > 0$ when restricted to any one of the supports $\mathcal{M}_m$; i.e., for any $m \in \{1, \ldots, M\}$ and any $u, v \in \mathcal{M}_m$

$$\|f(u) - f(v)\| \leq L \|u - v\|,$$

where $\|\cdot\|$ denotes above the ℓ_2-norm if the argument is in $\mathbb{R}^d$, and the norm induced from the inner product in H if the argument is in H.

We will find a relation between the classification accuracy and the number of training samples via the covering number of the supports $\mathcal{M}_m$. Let $B_\epsilon(x) \subset H$ denote an open ball of radius ϵ around x

$$B_\epsilon(x) = \{u \in H : \|x - u\| < \epsilon\}.$$

The covering number $\mathcal{N}(\epsilon, A)$ of a set $A \subset H$ is defined as the smallest number of open balls B_ϵ of radius ϵ whose union contains A (Kulkarni and Posner, 1995)

$$\mathcal{N}(\epsilon, A) = \inf\{k : \exists\, u_1, \ldots, u_k \in H \text{ s.t. } A \subset \bigcup_{i=1}^{k} B_\epsilon(u_i)\}.$$

We assume that the supports $\mathcal{M}_m$ are totally bounded, i.e., $\mathcal{M}_m$ has a finite covering number $\mathcal{N}(\epsilon, \mathcal{M}_m)$ for any $\epsilon > 0$.

We state below a lower bound for the probability of correctly classifying a sample x drawn from ν_m, in terms of the number of training samples drawn from ν_m, the separation of the embedding and the regularity of f.

Theorem 2 *For some ϵ with $0 < \epsilon \leq \gamma/(2L)$, let the training set $\mathcal{X}$ contain at least N_m samples drawn i.i.d. according to a probability measure ν_m such that*

$$N_m \geq \mathcal{N}(\epsilon/2, \mathcal{M}_m).$$

Let Y be an embedding of the training samples $\mathcal{X}$ that is linearly separable with margin larger than γ, and let f be an interpolation function that is Lipschitz continuous with constant L on the support $\mathcal{M}_m$. Then the probability of correctly classifying a test sample x drawn from ν_m independently from the training samples with the linear classifier (4) *is lower bounded as*

$$P\left(\hat{C}(x) = m\right) \geq 1 - \frac{\mathcal{N}(\epsilon/2, \mathcal{M}_m)}{2N_m}.$$

The proof of the theorem is given in Appendix A.1. Theorem 2 establishes a link between the classification performance and the separation of the embedding of the training samples. In particular, due to the condition $\epsilon \leq \gamma/(2L)$, the increase in the separation γ allows a larger value for ϵ, provided that the interpolator regularity is not affected much. This reduces the covering number $\mathcal{N}(\epsilon/2, \mathcal{M}_m)$ in return and increases the probability of correct classification. Similarly, from the condition $\epsilon \leq \gamma/(2L)$, one can also observe that at a given separation γ, a smaller Lipschitz constant L for the interpolation function allows the parameter ϵ to take a larger value. This reduces the covering number $\mathcal{N}(\epsilon/2, \mathcal{M}_m)$ and therefore increases the correct classification probability. Thus, choosing a more regular interpolator at a given separation helps improve the classification performance. If the ϵ parameter is fixed, the Lipschitz constant of the interpolator is allowed to increase only proportionally to the separation margin. The condition that the interpolator must be sufficiently regular in comparison with the separation suggests that increasing the separation too much at the cost of impairing the interpolator regularity may degrade the classifier performance. In the case that the supports $\mathcal{M}_m$ are low-dimensional manifolds, the covering number $\mathcal{N}(\epsilon/2, \mathcal{M}_m)$ increases at a geometric rate with the intrinsic dimension D of the manifold, since a D-dimensional manifold is locally homeomorphic to $\mathbb{R}^D$. Therefore, from the condition on the number of samples, N_m should increase at a geometric rate with D.

In Theorem 2 the probability of misclassification decreases with the number N_m of training samples at a rate of $O(N_m^{-1})$. In the rest of this section, we show that it is in fact possible to obtain an exponential convergence rate with linear and NN-classifiers under certain assumptions. We first present the following lemma.

Lemma 3 *Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let x be a test sample randomly drawn according to the probability measure ν_m of class m. Let*

$$A = \{x_i \in \mathcal{X} : x_i \in B_\delta(x), x_i \sim \nu_m\} \tag{5}$$

be the set of samples in $\mathcal{X}$ that are in a δ-neighborhood of x and also drawn from the measure ν_m. Assume that A contains $|A| = Q$ samples. Then

$$P\left(\|f(x) - \frac{1}{Q}\sum_{x_j \in A} f(x_j)\| \leq L\delta + \sqrt{d}\epsilon\right) \geq 1 - 2d\exp\left(-\frac{Q\,\epsilon^2}{2L^2\delta^2}\right). \tag{6}$$

Lemma 3 is proved in Appendix A.2. The inequality in (6) shows that as the number Q of training samples falling in a neighborhood of a test point x increases, the probability of the deviation of $f(x)$ from its average within the neighborhood decreases. The parameter ϵ captures the relation between the amount and the probability of deviation.

When studying the classification accuracy in the main result below, we will use the following generalized definition of the linear separation.

Definition 4 *Let Y be a linearly separable embedding with margin γ such that each pair (k, l) of classes are separated with the hyperplanes given by ω_{kl}, b_{kl} as defined in Definition 1. We say that the linear classifier given by $\{\omega_{kl}\}$, $\{b_{kl}\}$ has a Q-mean separability margin of $\gamma_Q > 0$ if any choice of Q samples $\{y_{k,i}\}_{i=1}^Q \subset Y$ from class k and Q samples $\{y_{l,i}\}_{i=1}^Q \subset Y$ from class l, $l \neq k$, satisfies*

$$\begin{aligned} \omega_{kl}^T\left(\frac{1}{Q}\sum_{i=1}^Q y_{k,i}\right) + b_{kl} &\geq \gamma_Q/2 \\ \omega_{kl}^T\left(\frac{1}{Q}\sum_{i=1}^Q y_{l,i}\right) + b_{kl} &\leq -\gamma_Q/2. \end{aligned} \tag{7}$$

The above definition of separability is more flexible than the one in Definition 1. Clearly, an embedding that is linearly separable with margin γ has a Q-mean separability margin of $\gamma_Q \geq \gamma$ for any Q. As in the previous section, we consider that the test sample x is classified with the linear classifier (4) in the low-dimensional domain, defined with respect to the set of hyperplanes given by $\{\omega_{mk}\}$ and $\{b_{mk}\}$ as in (2) and (3).

In the following result, we show that an exponential convergence rate can be obtained with linear classifiers in supervised manifold learning. We define beforehand a parameter depending on δ, which gives the smallest possible measure of the δ-neighborhood $B_\delta(x)$ of a point x in support $\mathcal{M}_m$.

$$\eta_{m,\delta} := \inf_{x \in \mathcal{M}_m} \nu_m(B_\delta(x)).$$

Theorem 5 *Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let Y be an embedding of $\mathcal{X}$ in $\mathbb{R}^d$ that is linearly separable with a Q-mean separability margin larger than γ_Q. For a given $\epsilon > 0$ and $\delta > 0$, let f be a Lipschitz-continuous interpolator such that*

$$L\delta + \sqrt{d}\epsilon \leq \frac{\gamma_Q}{2}. \tag{8}$$

Consider a test sample x randomly drawn according to the probability measure ν_m of class m. If $\mathcal{X}$ contains at least N_m training samples drawn i.i.d. from ν_m such that

$$N_m > \frac{Q}{\eta_{m,\delta}},$$

then the probability of correctly classifying x with the linear classifier given in (4) *is lower bounded as*

$$P\left(\hat{C}(x) = m\right) \geq 1 - \exp\left(-\frac{2\,(N_m\,\eta_{m,\delta} - Q)^2}{N_m}\right) - 2d\exp\left(-\frac{Q\,\epsilon^2}{2L^2\delta^2}\right). \tag{9}$$

Theorem 5 is proved in Appendix A.3. The theorem shows how the classification accuracy is influenced by the separation of the classes in the embedding, the smoothness of the out-of-sample interpolant, and the number of training samples drawn from the density of each class. The condition in (8) points to the tradeoff between the separation and the regularity of the interpolation function. As the Lipschitz constant L of the interpolation function f increases, f becomes less "regular", and a higher separation γ_Q is needed to meet the condition. This is coherent with the expectation that, when f becomes irregular, the classifier becomes more sensitive to the perturbations of the data, e.g., due to noise. The requirement of a higher separation is then for ensuring a larger margin in the linear classifier, which compensates for the irregularity of f. From (8), it is also observed that the separation should increase with the dimension d as well, and also with ϵ, whose increase improves the confidence of the bound (9). Note that the condition in (8) implies also the following: When computing an embedding, it is not advisable to increase the separation of training data unconditionally. In particular, increasing the separation too much may violate the preservation of the geometry and yield an irregular interpolator. Hence, when designing a supervised dimensionality reduction algorithm, one must pay attention to the regularity of the resulting interpolator as much as the enhancement of the separation margin.

Next, we discuss the roles of the parameters Q and δ. The term $\exp(-Q\,\epsilon^2/(2L^2\delta^2))$ in the correct classification probability bound (9) shows that, for fixed δ, the confidence increases with the value of Q. Meanwhile, due to the numerator of the term $\exp(-2\,(N_m\,\eta_{m,\delta}-Q)^2/N_m)$, for a high confidence, the number of samples N_m should also be relatively big with respect to Q to have a high overall confidence. Similarly, at fixed Q, δ should be made smaller to increase the confidence due to the term $\exp(-(Q\,\epsilon^2)/(2L^2\delta^2))$, which then reduces the parameter $\eta_{m,\delta}$ and eventually requires the number of samples N_m to take a sufficiently large value in order to make the term $\exp(-2\,(N_m\,\eta_{m,\delta}-Q)^2/N_m)$ small and have a high confidence. Therefore, these two parameters Q and δ behave in a similar way, and determine the relation between the number of samples and the correct classification probability, i.e., they indicate how large N_m should be in order to have a certain confidence of correct classification.

Theorem 5 studies the setting where the class labels are estimated with a linear classifier in the domain of embedding. We also provide another result below that analyses the performance when a nearest-neighbor classifier is used in the domain of embedding.

Theorem 6 *Let $\mathcal{X}=\{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let Y be an embedding of $\mathcal{X}$ in $\mathbb{R}^d$ such that*

$$\begin{aligned}&\|y_i-y_j\|<D_\delta,\ \text{if } \|x_i-x_j\|\le\delta \text{ and } C_i=C_j\\&\|y_i-y_j\|>\gamma,\quad \text{if } C_i\neq C_j,\end{aligned}$$

hence, nearby samples from the same class are mapped to nearby points, and samples from different classes are separated by a distance of at least γ in the embedding.

For given $\epsilon>0$ and $\delta>0$, let f be a Lipschitz-continuous interpolation function such that

$$L\delta+\sqrt{d}\epsilon+D_{2\delta}\le\frac{\gamma}{2}. \tag{10}$$

Consider a test sample x randomly drawn according to the probability measure ν_m of class m. If $\mathcal{X}$ contains at least N_m training samples drawn i.i.d. from ν_m such that

$$N_m>\frac{Q}{\eta_{m,\delta}},$$

then the probability of correctly classifying x with nearest-neighbor classification in $\mathbb{R}^d$ is lower bounded as

$$P\left(\hat{C}(x)=m\right)\ge 1-\exp\left(-\frac{2\,(N_m\,\eta_{m,\delta}-Q)^2}{N_m}\right)-2d\exp\left(-\frac{Q\,\epsilon^2}{2L^2\delta^2}\right). \tag{11}$$

Theorem 6 is proved in Appendix A.4. Theorem 6 is quite similar to Theorem 5 and can be interpreted similarly. Unlike in the previous result, the separability condition of the embedding is based on the pairwise distances of samples from different classes here. The condition (10) suggests that the result is useful when the parameter $D_{2\delta}$ is sufficiently small, which requires the embedding to map nearby samples from the same class in the ambient space to nearby points.

In this section, we have characterized the regularity of the interpolation functions via their rates of variation when restricted to the supports $\mathcal{M}_m$. While the results of this section are generic in the sense that they are valid for any interpolation function with the described regularity properties, we have not examined the construction of such functions. In a practical classification problem where one uses a particular type of interpolation functions, one would also be interested in the adaptation of these results to obtain performance guarantees for the particular type of function used. Hence, in the following section we focus on a popular family of smooth functions; radial basis function (RBF) interpolators, and study the classification performance of this particular type of interpolators.

2.3 Out-of-Sample Interpolation with RBF Interpolators

Here we consider an RBF interpolation function $f: H\to\mathbb{R}^d$ of the form

$$f(x)=[f^1(x)\,f^2(x)\,\ldots\,f^d(x)],$$

such that each component f^k of f is given by

$$f^k(x)=\sum_{i=1}^N c_i^k\,\phi(\|x-x_i\|),$$

where $\phi:\mathbb{R}\to\mathbb{R}^+$ is a kernel function, $c_i^k\in\mathbb{R}$ are coefficients, and x_i are kernel centers. In interpolation with RBF functions, it is common to choose the set of kernel centers as the set of available data samples. Hence, we assume that the set of kernel centers $\{x_i\}_{i=1}^N$ is selected to be the same as the set of training samples $\mathcal{X}$. We consider a setting where the coefficients c_i^k are set such that $f(x_i)=y_i$, i.e., f maps each training point in $\mathcal{X}$ to its embedding previously computed with supervised manifold learning.

We consider the RBF kernel ϕ to be a Lipschitz continuous function with constant $L_\phi>0$, hence, for any $u,v\in\mathbb{R}$

$$|\phi(u)-\phi(v)|\le L_\phi\,|u-v|.$$

Also, let $\mathcal{C}$ be an upper bound on the coefficient magnitudes such that for all $k = 1, \ldots, d$

$$\sum_{i=1}^{N} |c_i^k| \leq \mathcal{C}.$$

In the following, we analyze the classification accuracy and extend the results in Section 2.2 to the case of RBF interpolators. We first give the following result, which probabilistically bounds how much the value of the interpolator f at a point x randomly drawn from ν_m may deviate from the average interpolator value of the training points of the same class within a neighborhood of x.

Lemma 7 *Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let x be a test sample randomly drawn according to the probability measure ν_m of class m. Let*

$$A = \{x_i \in \mathcal{X} : x_i \in B_\delta(x), x_i \sim \nu_m\} \tag{12}$$

be the set of samples in $\mathcal{X}$ that are in a δ-neighborhood of x and also drawn from the measure ν_m. Assume that A contains $|A| = Q$ samples. Then

$$P\left(\|f(x) - \frac{1}{Q}\sum_{x_j \in A} f(x_j)\| \leq \sqrt{d}\mathcal{C}(L_\phi \delta + \epsilon)\right) \geq 1 - 2N \exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2 \delta^2}\right). \tag{13}$$

The proof of Lemma 7 is given in Appendix A.5. The lemma states a result similar to the one in Lemma 3; however, is specialized to the case where f is an RBF interpolator.

We are now ready to present the following main result.

Theorem 8 *Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let Y be an embedding of $\mathcal{X}$ in $\mathbb{R}^d$ that is linearly separable with a Q-mean separability margin larger than γ_Q. For a given $\epsilon > 0$ and $\delta > 0$, let f be an RBF interpolator such that*

$$\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon) \leq \frac{\gamma_Q}{2}. \tag{14}$$

Consider a test sample x randomly drawn according to the probability measure ν_m of class m. If $\mathcal{X}$ contains at least N_m training samples drawn i.i.d. from ν_m such that

$$N_m > \frac{Q}{\eta_{m,\delta}},$$

then the probability of correctly classifying x with the linear classifier given in (4) is lower bounded as

$$P\left(\hat{C}(x) = m\right) \geq 1 - \exp\left(-\frac{2\,(N_m\,\eta_{m,\delta} - Q)^2}{N_m}\right) - 2N \exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2 \delta^2}\right). \tag{15}$$

The theorem is proved in Appendix A.6. The theorem bounds the classification accuracy in terms of the smoothness of the RBF interpolation function and the number of samples. The condition in (14) characterizes the compromise between the separation and the regularity of the interpolator, which depends on the Lipschitz constant of the RBF kernels and the coefficient magnitude. As the Lipschitz constant L_ϕ and the coefficient magnitude parameter $\mathcal{C}$ increase (i.e., f becomes less "regular"), a higher separation γ_Q is required to provide a performance guarantee. When the separation margin of the embedding and the interpolator satisfy the condition in (14), the misclassification probability decays exponentially as the number of training samples increases, similarly to the results in Section 2.2.

Theorem 8 studies the misclassification probability when the class labels in the low-dimensional domain are estimated with a linear classifier. We also present below a bound on the misclassification probability when the nearest-neighbor classifier is used in the low-dimensional domain.

Theorem 9 *Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples such that each x_i is drawn i.i.d. from one of the probability measures $\{\nu_m\}_{m=1}^M$. Let Y be an embedding of $\mathcal{X}$ in $\mathbb{R}^d$ such that*

$$\begin{aligned} &\|y_i - y_j\| < D_\delta, \ \text{if } \|x_i - x_j\| \leq \delta \text{ and } C_i = C_j \\ &\|y_i - y_j\| > \gamma, \quad \text{if } C_i \neq C_j. \end{aligned}$$

For given $\epsilon > 0$ and $\delta > 0$, let f be an RBF interpolator such that

$$\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon) + D_{2\delta} \leq \frac{\gamma}{2}. \tag{16}$$

Consider a test sample x randomly drawn according to the probability measure ν_m of class m. If $\mathcal{X}$ contains at least N_m training samples drawn i.i.d. from ν_m such that

$$N_m > \frac{Q}{\eta_{m,\delta}},$$

then the probability of correctly classifying x with nearest-neighbor classification in $\mathbb{R}^d$ is lower bounded as

$$P\left(\hat{C}(x) = m\right) \geq 1 - \exp\left(-\frac{2\,(N_m\,\eta_{m,\delta} - Q)^2}{N_m}\right) - 2N \exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2 \delta^2}\right). \tag{17}$$

Theorem 9 is proved in Appendix A.7. While it provides the exact convergence rate as in Theorem 8, the necessary condition in (16) includes also the parameter $D_{2\delta}$. Hence, if the embedding maps nearby samples from the same class to nearby points, and a compromise is achieved between the separation and the interpolator regularity, the misclassification probability can be upper bounded.

2.4 Optimizing the Scale of Gaussian RBF Kernels

In data interpolation with RBFs, it is known that the accuracy of interpolation is quite sensitive to the choice of the shape parameter for several kernels including the Gaussian kernel (Baxter, 1992). The relation between the shape parameter and the performance of interpolation has been an important problem of interest (Piret, 2007). In this section, we focus on the Gaussian RBF kernel, which is a popular choice for RBF interpolation due to its smoothness and good spatial localization properties. We study the choice of the scale parameter of the kernel within the context of classification.

We consider the RBF kernel given by

$$\phi(r) = e^{-\frac{r^2}{\sigma^2}},$$

where σ is the scale parameter of the Gaussian function. We focus on the condition (14) in Theorem 8

$$\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon) \leq \gamma_Q/2,$$

(or equivalently the condition (16) if the nearest neighbor classifier is used), which relates the interpolation function properties with the separation. In particular, for a given separation margin, this condition is satisfied more easily when the term on the left hand side of the inequality is smaller. Thus, in the following, we derive an expression for the left hand side of the above inequality by deriving the Lipschitz constant L_ϕ and the coefficient bound $\mathcal{C}$ in terms of the scale parameter σ of the Gaussian kernel. We then study the scale parameter that minimizes $\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon)$.

Writing the condition $f(x_i) = y_i$ in a matrix form for each dimension $k = 1, \ldots, d$, we have

$$\Phi c^k = y^k, \tag{18}$$

where $\Phi \in \mathbb{R}^{N\times N}$ is a matrix whose (i,j)-th entry is given by $\Phi_{ij} = \phi(\|x_i - x_j\|)$, $c^k \in \mathbb{R}^{N\times 1}$ is the coefficient vector whose i-th entry is c_i^k, and $y^k \in \mathbb{R}^{N\times 1}$ is the data coordinate vector giving the k-th dimensions of the embeddings of all samples, i.e., $y_i^k = Y_{ik}$. Assuming that the embedding is computed with the usual scale constraint $Y^TY = I$, we have $\|y^k\| = 1$. The norm of the coefficient vector can then be bounded as

$$\|c^k\| \leq \|\Phi^{-1}\|\|y^k\| = \|\Phi^{-1}\|. \tag{19}$$

In the rest of this section, we assume that the data $\mathcal{X}$ are sampled from the Euclidean space, i.e., $H = \mathbb{R}^n$. We first use a result by Narcowich et al. (1994) in order to bound the norm $\|\Phi^{-1}\|$ of the inverse matrix. From (Narcowich et al., 1994, Theorem 4.1) we get[1]

$$\|\Phi^{-1}\| \leq \beta\, \sigma^{-n} e^{\alpha\sigma^2}, \tag{20}$$

where $\alpha > 0$ and $\beta > 0$ are constants depending on the dimension n and the minimum distance between the training points $\mathcal{X}$ (separation radius) (Narcowich et al., 1994). As the

1. The result stated in (Narcowich et al., 1994, Theorem 4.1) is adapted to our study by taking the measure as $\beta(\rho) = \delta(\rho - \rho_0)$ so that the RBF kernel defined in (Narcowich et al., 1994, (1.1)) corresponds to a Gaussian function as $F(r) = \exp(-\rho_0\, r^2)$. The scale of the Gaussian kernel is then given by $\sigma = {\rho_0}^{-1/2}$.

ℓ_1-norm of the coefficient vector can be bounded as $\|c^k\|_1 \leq \sqrt{N}\|c^k\|$, from (19) one can set the parameter $\mathcal{C}$ that upper bounds the coefficients magnitudes as

$$\mathcal{C} = a\sigma^{-n} e^{\alpha\sigma^2},$$

where $a = \beta\sqrt{N}$.

Next, we derive a Lipschitz constant for the Gaussian kernel $\phi(r)$ in terms of σ. Setting the second derivative of ϕ to zero

$$\frac{d^2\phi}{dr^2} = e^{-\frac{r^2}{\sigma^2}} \left(\frac{4r^2}{\sigma^4} - \frac{2}{\sigma^2}\right) = 0,$$

we get that the maximum value of $|d\phi/dr|$ is attained at $r = \sigma/\sqrt{2}$. Evaluating $|d\phi/dr|$ at this value, we obtain

$$L_\phi = \sqrt{2} e^{-\frac{1}{2}} \sigma^{-1}.$$

Now rewriting the condition (14) of the theorem, we have

$$\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon) = a_1 \sigma^{-n-1} e^{\alpha\sigma^2} + a_2 \sigma^{-n} e^{\alpha\sigma^2} \leq \gamma_Q/2,$$

where $a_1 = \sqrt{2d}\, a\, e^{-1/2}\delta$ and $a_2 = \sqrt{d}\, a\, \epsilon$. We thus determine the Gaussian scale parameter σ that minimizes

$$F(\sigma) = a_1 \sigma^{-n-1} e^{\alpha\sigma^2} + a_2 \sigma^{-n} e^{\alpha\sigma^2}.$$

First, notice that as $\sigma \to 0$ and $\sigma \to \infty$, the function $F(\sigma) \to \infty$. Therefore, it has at least one minimum. Setting

$$\frac{dF}{d\sigma} = e^{\alpha\sigma^2} \sigma^{-n-2} \big(2\alpha a_2 \sigma^3 + 2\alpha a_1 \sigma^2 - a_2 n\sigma - a_1(n+1)\big) = 0,$$

we need to solve

$$2\alpha a_2 \sigma^3 + 2\alpha a_1 \sigma^2 - a_2 n\sigma - a_1(n+1) = 0. \tag{21}$$

The leading and the second-degree coefficients are positive, while the first-degree and the constant coefficients are negative in the above cubic polynomial. Then, the sum of the roots is negative and the product of the roots is positive. Therefore, there is one and only one positive root σ_{opt}, which is the unique minimizer of $F(\sigma)$.

The existence of an optimal scale parameter $0 < \sigma_{opt} < \infty$ for the RBF kernel can be intuitively explained as follows. When σ takes too small values, the support of the RBF function concentrated around the training points does not sufficiently cover the whole class supports $\mathcal{M}_m$. This manifests itself in (14) with the increase in the term L_ϕ, which indicates that the interpolation function is not sufficiently regular. This weakens the guarantee that a test sample will be interpolated sufficiently close to its neighboring training samples from the same class and mapped to the correct side of the hyperplane in the linear classifier. On the other hand, when σ increases too much, the stability of the linear system (18) is impaired and the coefficients c increase too much. This results in an overfitting of the interpolator and, therefore, decreases the classification performance. Hence, the analysis in this section provides a theoretical justification of the common knowledge that σ should be set to a sufficiently large value while avoiding overfitting.

Remark: It is also interesting to observe how the optimal scale parameter changes with the number of samples N. In the study (Narcowich et al., 1994), the constants α and β in (20) are shown to vary with the separation radius q at rates $\alpha = O(q^{-2})$ and $\beta = O(q^n)$, where the separation radius q is proportional to the smallest distance between two distinct training samples. Then a reasonable assumption is that the separation radius q should typically decrease at rate $O(N^{-1/n})$ as N increases. Using this relation, we get that α and β should vary at rates $\alpha = O(N^{2/n})$ and $\beta = O(N^{-1})$ with N. It follows that $a = \beta\sqrt{N} = O(N^{-1/2})$, and the parameters a_1, a_2 of the cubic polynomial in (21) also vary with N at rates $a_1 = O(N^{-1/2})$, $a_2 = O(N^{-1/2})$. The equation (21) in σ can then be rearranged as

$$b_3\sigma^3 + b_2\sigma^2 - b_1\sigma - b_0 = 0,$$

such that the constants vary with N at rates $b_3 = O(N^{2/n})$, $b_2 = O(N^{2/n})$, $b_1 = O(1)$, $b_0 = O(1)$. We can then inspect how the roots of this equation change with N as N increases. Since b_3 and b_2 dominate the other coefficients for large N, three real roots will exist if N is sufficiently large, two of which are negative and one is positive. The sum of the pairwise products of the roots is negative and it decays with N at rate $O(N^{-2/n})$, and the product of the roots also decays with N. Then at least two of the roots must decay with N. Meanwhile, the sum of the three roots is $O(1)$ and negative. This shows that one of the negative roots is $O(1)$, i.e., does not decay with N. From the product of three roots, we then observe that the product of the two decaying roots is $O(N^{-2/n})$. However, their sum also decays at the same rate (from the sum of the pairwise products), which is possible if their dominant terms have the same rate and cancel each other. We conclude that both of the decaying roots vary at rate $O(N^{-1/n})$, one of which is the positive root and the optimal value σ_{opt} of the scale parameter.

This analysis shows that the scale parameter of the Gaussian kernel should be adapted to the number of training samples, and a smaller kernel scale must be preferred for a larger number of training samples. In fact, the relation $\sigma_{opt} = O(N^{-1/n})$ is quite intuitive, as the average or typical distance between two samples will also decrease at rate $O(N^{-1/n})$ as the number of samples N increases in an n-dimensional space. Then the above result simply suggests that the kernel scale should be chosen as proportional to the average distance between the training samples.

2.5 Discussion of the Results in Relation with Previous Results

In Theorems 8 and 9, we have presented a result that characterizes the performance of classification with RBF interpolation functions. In particular, we have considered a setting where an RBF interpolator is fitted to each dimension of a low-dimensional embedding where different classes are separable. Our study has several links with RBF networks or least-squares regression algorithms. In this section, we interpret our findings in relation with previously established results.

Several previous works study the performance of learning by considering a probability measure ρ defined on $X \times Y$, where X and Y are two sets. The "label" set Y is often taken as an interval $[-L, L]$. Given a set of data pairs $\{(x_j, y_j)\}_{j=1}^N$ sampled from the distribution

ρ, the RBF network estimates a function $\hat{f}$ of the form

$$\hat{f}(x) = \sum_{i=1}^{R} c_i \, \phi\left(\frac{\|x - t_i\|}{\sigma_i}\right). \tag{22}$$

The number of RBF terms R may be different from the number of samples N in general. The function $\hat{f}$ minimizes the empirical error

$$\hat{f} = \arg\min_f \sum_{j=1}^{N} \left(f(x_j) - y_j\right)^2.$$

The function $\hat{f}$ estimated from a finite collection of data samples is often compared to the regression function (Cucker and Smale, 2002)

$$f_o(x) = \int_Y y \, d\rho(y|x),$$

where $d\rho(y|x)$ is the conditional probability measure on Y. The regression function f_o minimizes the expected risk as

$$f_o = \arg\min_f \int_{X\times Y} \left(f(x) - y\right)^2 d\rho.$$

As the probability measure ρ is not known in practice, the estimate $\hat{f}$ of f_o is obtained from data samples. Several previous works have characterized the performance of learning by studying the approximation error (Niyogi and Girosi, 1996), (Lin et al., 2014)

$$\mathbb{E}[(f_o - \hat{f})^2] = \int_X (f_o(x) - \hat{f}(x))^2 d\rho_X(x), \tag{23}$$

where ρ_X is the marginal probability measure on X. This definition of the approximation error can be adapted to our setting as follows. In our problem the distribution of each class is assumed to have a bounded support, which is a special case of modeling the data with an overall probability distribution ρ. If the supports $\mathcal{M}_m$ are assumed to be nonintersecting, the regression function f_o is given by

$$f_o(x) = \sum_{m=1}^{M} m \, I_m(x),$$

which corresponds to the class labels $m = 1, \ldots, M$, where I_m is the indicator function of the support $\mathcal{M}_m$. It is then easy to show that the approximation error $\mathbb{E}[(f_o - \hat{f})^2]$ can be bounded as a constant times the probability of misclassification $P(\hat{C}(x) \neq m)$. Hence, we can compare our misclassification probability bounds in Section 2.3 with the approximation error in other works.

The study in (Niyogi and Girosi, 1996) assumes that the regression function is an element of the Bessel potential space of a sufficiently high order and that the sum of the coefficients

$|c_i|$ is bounded. It is then shown that for data sampled from $\mathbb{R}^n$, with probability greater than $1-\delta$ the approximation error in (23) can be bounded as

$$\mathbb{E}[(f_o - \hat{f})^2] \leq O\left(\frac{1}{R}\right) + O\left(\sqrt{\frac{Rn\log(RN) - \log(\delta)}{N}}\right), \tag{24}$$

where R is the number of RBF terms.

The analysis by Lin et al. (2014) considers families of RBF kernels that include the Gaussian function. Supposing that the regression function f_o is of Sobolev class W_2^r, and that the number of RBF terms is given by $R = N^{\frac{n}{n+2r}}$ in terms of the number of samples N, the approximation error is bounded as

$$\mathbb{E}[(f_o - \hat{f})^2] \leq O(N^{-\frac{2r}{n+2r}}\log^2(N)). \tag{25}$$

Next, we overview the study by Hernández-Aguirre et al. (2002), which studies the performance of RBFs in a Probably Approximately Correct (PAC)-learning framework. For $X \subset \mathbb{R}^n$, a family $\mathcal{F}$ of measurable functions from X to $[0,1]$ is considered and the problem of approximating a target function f_0 known only through examples with a function in $\hat{f} \in \mathcal{F}$ is studied. The authors use a previous result from (Vidyasagar, 1997) that relates the accuracy of empirical risk minimization to the covering number of $\mathcal{F}$ and the number of samples. Combining this result with the bounds on covering number estimates of Lipschitz continuous functions (Kolmogorov and Tihomirov, 1961), the following result is obtained for PAC function learning with RBF neural networks with Gaussian kernel. Let the coefficients be bounded as $|c_i| \leq A$, a common scale parameter be chosen as $\sigma_i = \sigma$, and $\mathbb{E}[|f_0 - \hat{f}|]$ be computed under a uniform probability measure ρ. Then if the number of samples satisfies

$$N \geq \frac{8}{\varepsilon^2}\log\left(\frac{\sqrt{2}RnA}{e^{-1/2}\sigma\zeta}\right), \tag{26}$$

an approximation of the target function is obtained with accuracy parameter ε and confidence parameter ζ:

$$P(\mathbb{E}[|f_0 - \hat{f}|] > \varepsilon) \leq \zeta. \tag{27}$$

In the above expression, the expectation is over the test samples, whereas the probability is over the training samples; i.e., over all possible distributions of training samples, the probability of having the average approximation error larger than ε is bounded. Note that, our results in Theorems 8 and 9, when translated into the above PAC-learning framework, correspond to a confidence parameter of $\zeta = 0$. This is because the misclassification probability bound of a test sample is valid for any choice of the training samples, provided that the condition (14) (or the condition (16)) holds. Thus, in our result the probability running over the training samples in (27) has no counterpart. When we take $\zeta = 0$, the above result does not provide a useful bound since $N \to \infty$ as $\zeta \to 0$. By contrast, our result is valid only if the conditions (14), (16) on the interpolation function holds. It is easy to show that, assuming nonintersecting class supports $\mathcal{M}_m$, the expression $\mathbb{E}[|f_0 - \hat{f}|]$ is given by a constant times the probability of misclassification. The accuracy parameter ε can then be seen as the counterpart of the misclassification probability upper bound given on the right hand sides of (15) and (17) (the expression subtracted from 1). At fixed N, the dependence

of the accuracy on the kernel scale parameter is monotonic in the bound (26); ε decreases as σ increases. Therefore, this bound does not guide the selection of the scale parameter of the RBF kernel, while the discussion in Section 2.4 (confirmed by the experimental results in Section 4.2) suggests the existence of an optimal scale.

Finally, we mention some results on the learning performance of regularized least squares regression algorithms. In (Caponnetto and De Vito, 2007) optimal rates are derived for the regularized least squares method in a Reproducing Kernel Hilbert Space (RKHS) in the minimax sense. It is shown that, under some hypotheses concerning the data probability measure and the complexity of the family of learnt functions, the maximum error (yielded by the worst distribution) obtained with the regularized least squares method converges at a rate of $O(1/N)$. Next, the work in (Steinwart et al., 2009) shows that, in regularized least squares regression over a RKHS, if the eigenvalues of the kernel integral operator decay sufficiently fast, and if the ℓ_∞-norms of regression functions can be bounded, the error of the classifier converges at a rate of up to $O(1/N)$ with high probability. Steinwart et al. also examine the learning performance in relation with the exponent of the function norm in the regularization term and show that the learning rate is not affected by the choice of the exponent of the function norm.

We now overview the three bounds given in (24), (25), and (26) in terms of the dependence of the error on the number of samples. The results in (24) and (25) provide a useful bound only in the case where the number of samples N is larger than the number of RBF terms R, contrary to our study where we treat the case $R = N$. If it is assumed that N is sufficiently larger than R, the result in (24) predicts a rate of decay of only $O(\sqrt{\log(N)/N})$ in the misclassification probability. The bound in (25) improves with the Sobolev regularity of the regression function; however, the dependence of the error on the number of samples is of a similar nature to the one in (24). Considering ε as a misclassification error parameter in the bound in (26), the error decreases at a rate of $O(N^{-1/2})$ as the number of samples increases. The analysis in (Caponnetto and De Vito, 2007) and (Steinwart et al., 2009) also provide the similar rates of convergence of $O(N^{-1})$. Meanwhile, our results in Theorems 8 and 9 predict an exponential decay in the misclassification probability as the number of samples N increases (under the reasonable assumption that $N_m = O(N)$ for each class m). The reason why we arrive at a more optimistic bound is the specialization of the analysis to the considered particular setting, where the support of each class is assumed to be restricted to a totally bounded region in the ambient space, as well as the assumed relations between the separation margin of the embedding and the regularity of the interpolation function.

Another difference between these previous results and ours is the dependence on the dimension. The results in (24), (25), and (26) predict an increase in the error at the respective rates of $O(\sqrt{n})$, $O(e^{-1/n})$, and $O(\sqrt{\log n})$ with the ambient space dimension n. While these results assume that the data $\mathcal{X} \subset \mathbb{R}^n$ is in an Euclidean space of dimension n, our study assumes the data $\mathcal{X}$ to be in a generic Hilbert space H. The results in Theorems 5-8 involve the dimension d of the low-dimensional space of embedding and does not explicitly depend on the dimension of the ambient Hilbert space H (which could be infinite-dimensional). However, especially in the context of manifold learning, it is interesting to analyze the dependence of our bound on the intrinsic dimension of the class supports $\mathcal{M}_m$.

In order to put the expressions (15), (17) in a more convenient form, let us reduce one parameter by setting $Q = N_m \eta_{m,\delta}/2$. Then the misclassification probability is of

$$O\left(\exp(-N_m \eta_{m,\delta}^2) + N \exp\left(-\frac{N_m\, \eta_{m,\delta}\, \epsilon^2}{L_\phi^2\, \delta^2}\right)\right).$$

We can relate the dependence of this expression on the intrinsic dimension as follows. Since the supports $\mathcal{M}_m$ are assumed to be totally bounded, one can define a parameter Θ that represents the "diameter" of $\mathcal{M}_m$, i.e., the largest distance between any two points on $\mathcal{M}_m$. Then the measure $\eta_{m,\delta}$ of the minimum ball of radius δ in $\mathcal{M}_m$ is of $O((\delta/\Theta)^D)$, where D is the intrinsic dimension of $\mathcal{M}_m$. Replacing this in the above expression gives the probability of misclassification as

$$O\left(\exp\left(-\frac{N_m\, \delta^{2D}}{\Theta^{2D}}\right) + N \exp\left(-\frac{N_m\, \delta^{D-2}\, \epsilon^2}{L_\phi^2\, \Theta^D}\right)\right).$$

This shows that in order to retain the correct classification guarantee, as the intrinsic dimension D grows, the number of samples N_m should increase at a geometric rate with D. In supervised manifold learning problems, data sets usually have a low intrinsic dimension, therefore, this geometric rate of increase can often be tolerated. Meanwhile the dimension of the ambient space is typically high, so that performance bounds independent of the ambient space dimension are of particular interest. Note that generalization bounds in terms of the intrinsic dimension have been proposed in some previous works as well (Bickel and Li, 2007), (Kpotufe, 2011), for the local linear regression and the K-NN regression problems.

3. Separability of Supervised Nonlinear Embeddings

In the results in Section 2, we have presented generalization bounds for classifiers based on linearly separable embeddings. One may wonder if the separability assumption is easy to satisfy when computing structure-preserving nonlinear embeddings of data. In this section, we try to answer this question by focusing on a particular family of supervised dimensionality reduction algorithms, i.e., supervised Laplacian eigenmaps embeddings, and analyze the conditions of separability. We first discuss the supervised Laplacian eigenmaps embeddings in Section 3.1 and then present results in Section 3.2 about the linearly separability of these embeddings.

3.1 Supervised Laplacian Eigenmaps Embeddings

Let $\mathcal{X} = \{x_i\}_{i=1}^N \subset H$ be a set of training samples, where each x_i belongs to one of M classes. Most manifold learning algorithms rely on a graph representation of data. This graph can be a complete graph in some works, in which case an edge exists between each pair of samples. Meanwhile, in some manifold learning algorithms, in order to better capture the intrinsic geometric structure of data, each data sample is connected only to its nearest neighbors in the graph. In this case, an edge exists only between neighboring data samples.

In our analysis, we consider a weighted data graph G each vertex of which represents a point x_i. We write $x_i \sim x_j$, or simply $i \sim j$ if the graph contains an edge between the

data samples x_i, x_j. We denote the edge weight as $w_{ij} > 0$. The weights w_{ij} are usually determined as a positive and monotonically decreasing function of the distance between x_i and x_j in H, where the Gaussian function is a common choice. Nevertheless, we maintain a generic formulation here without making any assumption on the neighborhood or weight selection strategies.

Now let G_w and G_b represent two subgraphs of G, which contain the edges of G that are respectively within the same class and between different classes. Hence, G_w contains an edge $i \sim_w j$ between samples x_i and x_j, if $i \sim j$ and $C_i = C_j$. Similarly, G_b contains an edge $i \sim_b j$ if $i \sim j$ and $C_i \neq C_j$. We assume that all vertices of G are contained in both G_w and G_b; and that G_w has exactly M connected components such that the training samples in each class form a connected component[2]. We also assume that G_w and G_b do not contain any isolated vertices; i.e., each data sample x_i has at least one neighbor in both graphs.

The $N \times N$ weight matrices W_w and W_b of G_w and G_b have entries as follows.

$$W_w(i,j) = \begin{cases} w_{ij} & \text{if } i \sim j \text{ and } C_i = C_j \\ 0 & \text{otherwise} \end{cases}$$

$$W_b(i,j) = \begin{cases} w_{ij} & \text{if } i \sim j \text{ and } C_i \neq C_j \\ 0 & \text{otherwise} \end{cases}$$

Let $d_w(i)$ and $d_b(i)$ denote the degrees of x_i in G_w and G_b

$$d_w(i) = \sum_{j \sim_w i} w_{ij}, \qquad d_b(i) = \sum_{j \sim_b i} w_{ij},$$

and D_w, D_b denote the $N \times N$ diagonal degree matrices given by $D_w(i,i) = d_w(i)$, $D_b(i,i) = d_b(i)$. The normalized graph Laplacian matrices L_w and L_b of G_w and G_b are then defined as

$$L_w := D_w^{-1/2}(D_w - W_w)D_w^{-1/2}, \qquad L_b := D_b^{-1/2}(D_b - W_b)D_b^{-1/2}.$$

Supervised extensions of the Laplacian eigenmaps and LPP algorithms seek a d-dimensional embedding of the data set $\mathcal{X}$, such that each x_i is represented by a vector $y_i \in \mathbb{R}^{d\times 1}$. Denoting the new data matrix as $Y = [y_1\, y_2\, \ldots\, y_N]^T \in \mathbb{R}^{N\times d}$, the coordinates of data samples are computed by solving the problem

$$\text{"Minimize } \mathrm{tr}(Y^T L_w Y) \text{ while maximizing } \mathrm{tr}(Y^T L_b Y)." \tag{28}$$

The reason behind this formulation can be explained as follows. For a graph Laplacian matrix $L = D^{-1/2}(D - W)D^{-1/2}$, where D and W are respectively the degree and the weight matrices, defining the coordinates $Z = D^{-1/2}Y$ normalized with the vertex degrees, we have

$$\mathrm{tr}(Y^T L\, Y) = \mathrm{tr}(Z^T(D - W)Z) = \sum_{i\sim j} \|z_i - z_j\|^2 w_{ij}, \tag{29}$$

2. The straightforward application of common graph construction strategies, like connecting each training sample to its K-nearest neighbors or to its neighbors within a given distance, may result in several disconnected components in a single class in the graph if there is much diversity in that class. However, this difficulty can be easily overcome by introducing extra edges to bridge between graph components that are originally disconnected.

where z_i is the i-th row of Z giving the normalized coordinates of the embedding of the data sample x_i. Hence, the problem in (28) seeks a representation Y that maps nearby samples in the same class to nearby points, while mapping nearby samples from different classes to distant points. In fact, when the samples x_i are assumed to come from a manifold $\mathcal{M}$, the term $y^T L y$ is the discrete equivalent of

$$\int_{\mathcal{M}} \|\nabla f(x)\|^2 dx,$$

where $f : \mathcal{M} \to \mathbb{R}$ is a continuous function on the manifold that extends the one-dimensional coordinates y to the whole manifold. Hence, the term $\mathrm{tr}(Y^T L Y)$ captures the rate of change of the learnt coordinate vectors Y over the underlying manifold. Then, in a setting where the samples of different classes come from M different manifolds $\{\mathcal{M}_m\}_{m=1}^M$, the formulation in (28) looks for a function that has a slow variation on each manifold $\mathcal{M}_m$, while having a fast variation "between" different manifolds.

The supervised learning problem in (28) has so far been studied by several authors with slight variations in their problem formulations. Raducanu and Dornaika (2012) minimize a weighted difference of the within-class and between-class similarity terms in (28) in order to learn a nonlinear embedding. Meanwhile, linear dimensionality reduction methods pose the manifold learning problem as the learning of a linear projection matrix $P \in \mathbb{R}^{d \times n}$; therefore, solve the problem in (28) under the constraint $y_i = P\, x_i$, where $x_i \in \mathbb{R}^{n \times 1}$ and $d < n$. Hua et al. (2012) formulate the problem as the minimization of the difference of the within-class and the between-class similarity terms in (28) as well. Thus, their algorithm can be seen as the linear version of the method by Raducanu and Dornaika (2012). Sugiyama (2007) proposes an adaptation of the Fisher discriminant analysis algorithm to preserve the local structures of data. Data sample pairs are weighted with respect to their affinities in the construction of the within-class and the between-class scatter matrices in Fisher discriminant analysis. Then the trace of the ratio of the between-class and the within-class scatter matrices is maximized to learn a linear embedding. Meanwhile, the within-class and the between-class local scatter matrices are closely related to the two terms in (28) as shown by Yang et al. (2011). The terms $Y^T L_w Y$ and $Y^T L_b Y$, when evaluated under the constraint $y_i = P\, x_i$, become equal to the locally weighted within-class and between-class scatter matrices of the projected data. Cui and Fan (2012) and Wang and Chen (2009) propose to maximize the ratio of the between-class and the within-class local scatters in the learning. Yang et al. (2011) optimize the same objective function, while they construct the between-class graph only on the centers of mass of the classes. Zhang et al. (2012) similarly optimize a Fisher metric to maximize the ratio of the between- and within-class scatters; however, the total scatter is also taken into account in the objective function in order to preserve the overall manifold structure.

All of the above methods use similar formulations of the supervised manifold learning problem and give comparable results. In our study, we base our analysis on the following formal problem definition

$$\min_Y \mathrm{tr}(Y^T L_w Y) - \mu\, \mathrm{tr}(Y^T L_b Y) \text{ subject to } Y^T Y = I, \tag{30}$$

which minimizes the difference of the within-class and the between-class similarity terms as in works such as (Raducanu and Dornaika, 2012) and (Hua et al., 2012). Here I is the

$d \times d$ identity matrix and $\mu > 0$ is a parameter adjusting the weights of the two terms. The condition $Y^T Y = I$ is a commonly used constraint to remove the scale ambiguity of the coordinates. The solution of the problem (30) is given by the first d eigenvectors of the matrix

$$L_w - \mu L_b$$

corresponding to its smallest eigenvalues.

Our purpose in this section is then to theoretically study the linear separability of the learnt coordinates of training data, with respect to the definition of linear separability given in (1). In the following, we determine some conditions on the graph properties and the weight parameter μ that ensure the linear separability. We derive lower bounds on the margin γ and study its dependence on the model parameters. Let us give beforehand the following definitions about the graphs G_w and G_b.

Definition 10 *The volume of the subgraph of G_w that corresponds to the connected component containing samples from class k is*

$$V_k := \sum_{i:\, C_i = k} d_w(i).$$

We define the maximal within-class volume as

$$V_{max} := \max_{k=1,..,M} V_k.$$

The volume of the component of G_b containing the edges between the samples of classes k and l is [3]

$$V_{kl}^b := \sum_{\substack{i \sim_b j \\ C_i = k, C_j = l}} 2\, w_{ij}.$$

We then define the maximal pairwise between-class volume as

$$V_{max}^b := \max_{k \neq l} V_{kl}^b.$$

In a connected graph, the distance between two vertices x_i and x_j is the number of edges in a shortest path joining x_i and x_j. The diameter of the graph is then given by the maximum distance between any two vertices in the graph (Chung, 1996). We define the diameter of the connected component of G_w corresponding to class k as follows.

Definition 11 *For any two vertices x_i and x_j such that $C_i = C_j = k$, consider a within-class shortest path joining x_i and x_j, which contains samples only from class k. Then the diameter D_k of the connected component of G_w corresponding to class k is the maximum number of edges in the within-class shortest path joining any two vertices x_i and x_j from class k.*

Definition 12 *The minimum edge weight within class k is defined as*

$$w_{min,k} := \min_{\substack{i \sim_w j \\ C_i = C_j = k}} w_{ij}.$$

3. In order to keep the analogy with the definition of V_k, a 2 factor is introduced in this expression as each edge is counted only once in the sum.

3.2 Separability Bounds for Two Classes

We now present a lower bound for the linear separability of the embedding obtained by solving (30) in a setting with two classes $C_i \in \{1,2\}$. We first show that an embedding of dimension $d = 1$ is sufficient to achieve linear separability for the case of two classes. We then derive a lower bound on the separation in terms of the graph parameters and the algorithm parameter μ.

Consider a one-dimensional embedding $Y = y = [y_1\, y_2\, \ldots\, y_N]^T \in \mathbb{R}^{N\times 1}$, where $y_i \in \mathbb{R}$ is the coordinate of the data sample x_i in the one-dimensional space. The coordinate vector y is given by the eigenvector of $L_w - \mu L_b$ corresponding to its smallest eigenvalue. We begin with presenting the following result, which states that the samples from the two classes are always mapped to different halves (nonnegative or nonpositive) of the real line.

Lemma 13 *The learnt embedding y of dimension $d = 1$ satisfies*

$$\begin{aligned} y_i &\le 0 \qquad \text{if } C_i = 1 \text{ (or respectively } C_i\text{=2)} \\ y_i &\ge 0 \qquad \text{if } C_i = 2 \text{ (or respectively } C_i\text{=1)} \end{aligned}$$

for any $\mu > 0$ and for any choice of the graph parameters.

Lemma 13 is proved in Appendix B.1. The lemma states that in one-dimensional embeddings of two classes, samples from different classes always have coordinates with different signs. Therefore, the hyperplane given by $\omega = 1$, $b = 0$ separates the data as $\omega^T y_i \le 0$ for $C_i = 1$ and $\omega^T y_i \ge 0$ for $C_i = 2$ (since the embedding is one dimensional, the vector ω is a scalar in this case). However, this does not guarantee that the data is separable with a positive margin $\gamma > 0$. In the following result, we show that a positive margin exists and give a lower bound on it. In the rest of this section, we assume without loss of generality that classes 1 and 2 are respectively mapped to the negative and positive halves of the real axis.

Theorem 14 *Defining the normalized data coordinates $z = D_w^{-1/2} y$, let*

$$z_{1,max} := \max_{i:\, C_i=1} z_i \qquad z_{2,min} := \min_{i:\, C_i=2} z_i$$

denote the maximum and minimum coordinates that classes 1 and 2 are respectively mapped to with a one-dimensional embedding learnt with supervised Laplacian eigenmaps. We also define the parameters

$$\overline{w}_{min} = \min_{k\in\{1,2\}} \frac{w_{min,k}}{D_k}\,, \qquad \beta_i = \frac{d_w(i)}{d_b(i)}\,, \qquad \beta_{max} = \max_i \beta_i\,,$$

where D_k is the diameter of the graph corresponding to class k as defined in Definition 11. Then, if the weight parameter is chosen such that $0 < \mu < \overline{w}_{min}/(\beta_{max} V^b_{max})$, any supervised Laplacian embedding of dimension $d \ge 1$ is linearly separable with a positive margin lower bounded as below:

$$z_{2,min} - z_{1,max} \ge \frac{1}{\sqrt{V_{max}}} \left(1 - \sqrt{\frac{\mu \beta_{max} V^b_{max}}{\overline{w}_{min}}}\right). \tag{31}$$

The proof of Theorem 14 is given in Appendix B.2. The proof is based on a variational characterization of the eigenvector of $L_w - \mu L_b$ corresponding to its smallest eigenvalue, whose elements are then bounded in terms of the parameters of the graph such as the diameters and volumes of its connected components.

Theorem 14 states that an embedding learnt with the supervised Laplacian eigenmaps method makes two classes linearly separable if the weight parameter μ is chosen sufficiently small. In particular, the theorem shows that, for any $0 < \delta < {V_{max}}^{-1/2}$, a choice of the weight parameter μ satisfying

$$0 < \mu \le \frac{\overline{w}_{min}}{\beta_{max}\, V^b_{max}} \left(1 - \sqrt{V_{max}}\, \delta\right)^2$$

guarantees a separation of $z_{2,min} - z_{1,max} \ge \delta$ between classes 1 and 2 at $d = 1$. Here, we use the symbol δ to denote the separation in the normalized coordinates z. In practice, either one of the normalized eigenvectors z or the original eigenvectors y can be used for embedding the data. If the original eigenvectors y are used, due to the relation $y = D_w^{1/2} z$, we can lower bound the separation as $y_{2,min} - y_{1,max} \ge \sqrt{d_{w,min}}(z_{2,min} - z_{1,max})$ where $d_{w,min} = \min_i d_w(i)$. Thus, for any embedding of dimension $d \ge 1$, there exists a hyperplane that results in a linear separation with a margin γ of at least

$$\gamma \ge \sqrt{\frac{d_{w,min}}{V_{max}}} \left(1 - \sqrt{\frac{\mu \beta_{max} V^b_{max}}{\overline{w}_{min}}}\right).$$

Next, we comment on the dependence of the separation on μ. The inequality in (31) shows that the lower bound on the separation $z_{2,min} - z_{1,max}$ has a variation of $O(1 - \sqrt{\mu})$ with the weight parameter μ. The fact that the separation decreases with the increase in μ seems counterintuitive at first; this parameter weights the between-class dissimilarity in the objective function. This can be explained as follows. When μ is high, the algorithm tries to increase the distance between neighboring samples from different classes as much as possible by moving them away from the origin (remember that different classes are mapped to the positive and the negative sides of the real line). However, since the normalized coordinate vector z has to respect the equality $z^T D_w z = 1$, the total squared norm of the coordinates cannot be arbitrarily large. Due to this constraint, setting μ to a high value causes the algorithm to map non-neighboring samples from different classes to nearby coordinates close to the origin. This occurs since the increase in μ reduces the impact of the first term $y^T L_w y$ in the overall objective and results in an embedding with a weaker link between the samples of the same class. This causes a polarization of the data and eventually reduces the separation. Hence, the μ parameter should be carefully chosen and should not take too large values.

Theorem 14 characterizes the separation at $d = 1$ in terms of the distance between the supports of the two classes. Meanwhile, it is also interesting to determine the individual distances of the supports of the two classes to the origin. In the following corollary, we present a lower bound on the distance between the coordinates of any sample and the origin.

Corollary 15 *The distance between the supports of the first and the second classes and the origin in a one-dimensional embedding is lower bounded in terms of the separation between the two classes as*

$$\min\{|z_{1,max}|,\ |z_{2,min}|\} \geq \frac{1}{2}\frac{\beta_{min}}{\beta_{max}}(z_{2,min} - z_{1,max})$$

where

$$\beta_{min} = \min_i \beta_i, \qquad \beta_{max} = \max_i \beta_i.$$

Corollary 15 is proved in Appendix B.3. The proof is based on a Lagrangian formulation of the embedding as a constrained optimization problem, which then allows us to establish a link between the separation and the individual distances of class supports to the origin. The corollary states a lower bound on the portion of the overall separation lying in the negative or the positive sides of the real line. In particular, if the vertex degrees are equal for all samples in G_w and G_b (which is the case, for instance, if all vertices have the same number of neighbors and a constant weight of $w_{ij} = 1$ is assigned to the edges), since $\beta_{min} = \beta_{max}$, the portions of the overall separation in the positive and negative sides of the real line will be equal.

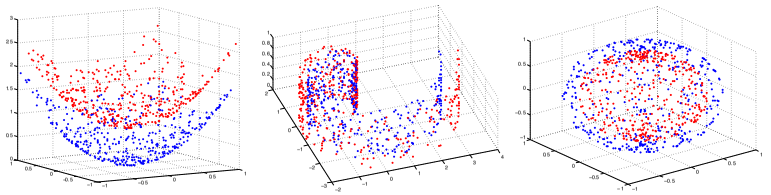
We have examined the linear separability of supervised Laplacian embeddings for the case of two classes in this section. An extension of these results to the case of multiple classes under some assumptions is available in the accompanying technical report (Vural and Guillemot, 2016b).

4. Experimental Results

In this section, we present results on synthetical and real data sets. We compare several supervised manifold learning methods and study their performances in relation with our theoretical results.

4.1 Separability of Embeddings with Supervised Manifold Learning

We first present results on synthetical data in order to study the embeddings obtained with supervised dimensionality reduction. We test the supervised Laplacian eigenmaps algorithm in a setting with two classes. We generate samples from two nonintersecting and linearly nonseparable surfaces in $\mathbb{R}^3$ that represent two different classes. We experiment on three different types of surfaces; namely, quadratic surfaces, Swiss rolls and spheres. The data sampled from these surfaces are shown in Figure 2. We choose $N = 200$ samples from each class. We construct the graph G_w by connecting each sample to its K-nearest neighbors from the same class, where K is chosen between 20 and 30. The graph G_b is constructed similarly, where each sample is connected to its $K/5$ nearest neighbors from the other class. The graph weights are determined as a Gaussian function of the distance between the samples. The embeddings are then computed by minimizing the objective function in (30). The one-dimensional, two-dimensional, and three-dimensional embeddings obtained for the quadratic surface are shown in Figure 3, where the weight parameter is taken as $\mu = 0.57$



(a) Quadratic surfaces (b) Swissrolls (c) Spheres

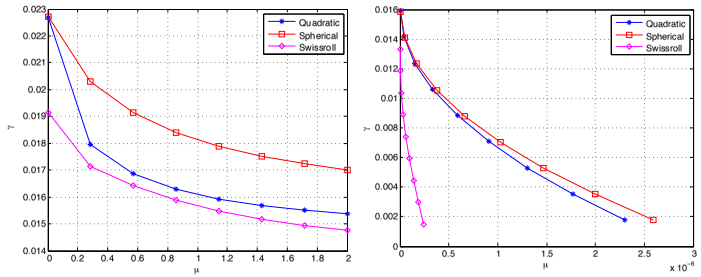
(a) 1-D embedding (b) 2-D embedding (c) 3-D embedding

Figure 3: Supervised Laplacian embeddings of data sampled from quadratic surfaces.

(to have a visually clear embedding for the purpose of illustration). Similar results are obtained on the Swiss roll and the spherical surface. One can observe that the data samples that were initially linearly nonseparable become linearly separable when embedded with the supervised Laplacian eigenmaps algorithm. The two classes are mapped to different (positive or negative) sides of the real line in Figure 3(a) as predicted by Lemma 13. The separation in the 2-D and 3-D embeddings in Figure 3 is close to the separation obtained with the 1-D embedding.

We then compute and plot the separation obtained at different values of μ. Figure 4(a) shows the experimental value of the separation $\gamma = z_{2,min} - z_{1,max}$ obtained with the 1-D embedding for the three types of surfaces. Figure 4(b) shows the theoretical upper bound for μ in Theorem 14 that guarantees a separation of at least γ. Both the experimental value and the theoretical bound for the separation γ decrease with the increase in the parameter μ. This is in agreement with (31), which predicts a decrease of $O(1-\sqrt{\mu})$ in the separation with respect to μ. The theoretical bound for the separation is seen to decrease at a relatively faster rate with μ for the Swiss roll data set. This is due to the particular structure of this data set with a nonuniform sampling density where the sampling is sparser away from the spiral center. The parameter $\overline{w}_{min}$ then takes a small value, which consequently leads to a



(a) Experimental value of the separation γ (b) Theoretical upper bound for μ that guarantees a separation of at least γ

Figure 4: Variation of the separation γ between the two classes with the parameter μ for the synthetic data sets

fast rate of decrease for the separation due to (31). Comparing Figures 4(a) and 4(b), one observes that the theoretical bounds for the separation are numerically more pessimistic than their experimental values, which is a result of the fact that our results are obtained with a worst-case analysis. Nevertheless, the theoretical bounds capture well the actual variation of the separation margin with μ.

4.2 Classification Performance of Supervised Manifold Learning Algorithms

We now study the overall performance of classification obtained in a setting with supervised manifold learning, where the out-of-sample generalization is achieved with smooth RBF interpolators. We evaluate the theoretical results of Section 2 on several real data sets: the COIL-20 object database (Nene et al., 1996), the Yale face database (Georghiades et al., 2001), the ETH-80 object database (Leibe and Schiele, 2003), and the MNIST handwritten digit database (LeCun et al., 1998). The COIL-20, Yale face, ETH-80, and MNIST databases contain a total of 1420, 2204, 3280, and 70046 images from 20, 38, 8, and 10 image classes respectively. The images in the COIL-20, Yale and ETH-80 data sets are converted to greyscale, normalized, and downsampled to a resolution of respectively 32×32, 20×17, and 20×20 pixels.

4.2.1 Comparison of Supervised Manifold Learning to Baseline Classifiers

We first compare the performance of supervised manifold learning with some reference classification methods. The performances of SVM, K-NN, kernel regression, and the supervised Laplacian eigenmaps methods are evaluated and compared. Figure 5 reports the results obtained on the COIL-20 data set, the ETH-80 data set, the Yale data set, a subset of the Yale data set consisting of its first 10 classes (reduced Yale data set), and the MNIST data set. The SVM, K-NN, and kernel regression algorithms are applied in the original

(e) MNIST data set

Figure 5: Comparison of the performance of several supervised classification methods

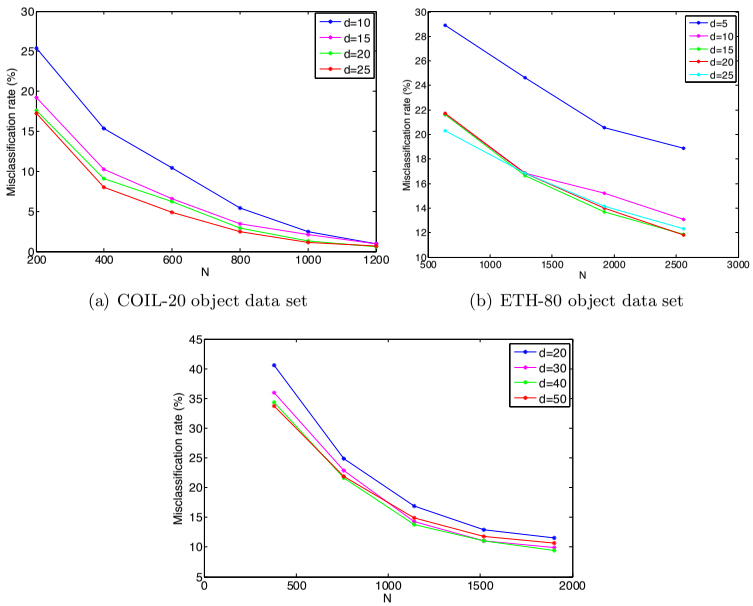
domain and their hyperparameters are optimized with cross-validation. In the supervised Laplacian eigenmaps method, the embedding of the training images into a low-dimensional space is computed. Then, an out-of-sample interpolator with Gaussian RBFs is constructed that maps the training samples to their embedded coordinates as described in Section 2.3.

Test samples are mapped to the low-dimensional domain via the RBF interpolator and the class labels of test samples are estimated via nearest-neighbor classification in the low-dimensional domain. The supervised Laplacian eigenmaps and the SVM methods are also tested over an alternative representation of the image data sets based on deep learning. The images are provided as input to the pretrained AlexNet convolutional neural network proposed in (Krizhevsky et al., 2012), and the activation values at the second fully connected layer are used as the feature representations of the images. The feature representations of training and test images are then provided to the supervised Laplacian eigenmaps and the SVM methods. The plots in Figure 5 show the variation of the misclassification rate of test samples in percentage with the ratio of the number of training samples in the whole data set. The results are the average of 5 repetitions of the experiment with different random choices for the training and test samples.

The results in Figure 5 show that the best results are obtained with the supervised Laplacian eigenmaps algorithm in general. The performances of the algorithms improve with the number of training images as expected. In the COIL-20 and ETH-80 object data sets, the supervised Laplacian eigenmaps and the SVM algorithms yield significantly smaller error when applied to the feature representations of the images obtained with deep learning. Meanwhile, in the Yale face data set these two methods perform better on raw image intensity maps. This can be explained with the fact that the AlexNet model may be more successful in extracting useful features for object images rather than face images as it is trained on many common object and animal classes. It is interesting to compare Figures 5(c) and 5(d). While the performances of the supervised Laplacian eigenmaps and the SVM methods are closer in the reduced version of the Yale database with 10 classes, the performance gap between the supervised Laplacian eigenmaps method and the other methods is larger for the full data set with 38 classes. This can be explained with the fact that the linear separability of different classes degrades as the number of classes increases, thus causing a degradation in the performance of the classifiers in comparison. Meanwhile, the performance of the supervised Laplacian eigenmaps method is not much affected by the increase in the number of classes. The K-NN and kernel regression classifiers are seen to give almost the same performance in the plots in Figure 5. The number of neighbors is set as $K = 1$ for the K-NN algorithm in these experiments, where it has been observed to attain its best performance; and the scale parameter of the kernel regression algorithm is optimized to get the best accuracy, which has turned out to take relatively small values. Hence the performances of these two classifiers practically correspond to that of the nearest-neighbor classifier in the original domain.

4.2.2 Variation of the Error with Algorithm Parameters and Sample Size

We first study the evolution of the classification error with the number of training samples. Figures 6(a)- 6(c) show the variation of the misclassification rate of test samples with respect to the total number of training samples N for the COIL-20, ETH-80 and Yale data sets. Each curve in the figure shows the errors obtained at a different value of the dimension d of the embedding. The decrease in the misclassification rate with the number of training samples is in agreement with the results in Section 2 as expected.



(a) COIL-20 object data set

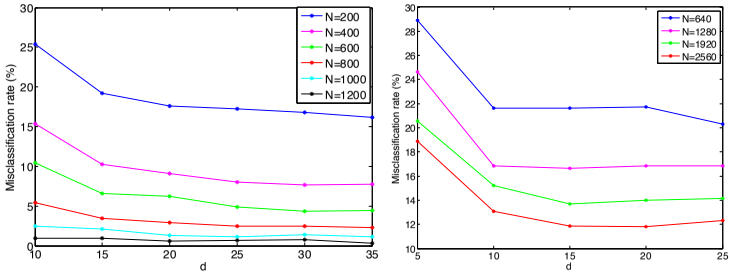
(b) ETH-80 object data set

(c) Yale face data set

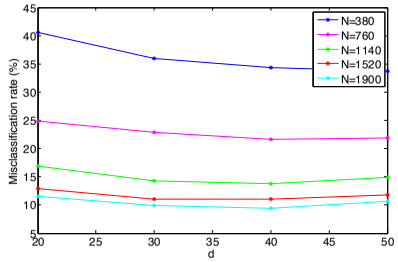
Figure 6: Variation of the misclassification rate with the number of training samples

The results of Figure 6 are replotted in Figure 7, where the variation of the misclassification rate is shown with respect to the dimension d of the embedding at different N values. It is observed that there may exist an optimal value of the dimension that minimizes the misclassification rate. This can be interpreted in light of the conditions (14) and (16) in Theorems 8 and 9, which impose a lower bound on the separability margin γ_Q in terms of the dimension d of the embedding. In the supervised Laplacian eigenmaps algorithm, the first few dimensions are critical and effective for separating different classes. The decrease in the error with the increase in the dimension for small values of d can be explained with the fact that the separation increases with d at small d, thereby satisfying the conditions (14), (16). Meanwhile, the error may stagnate or increase if the dimension d increases beyond a certain value, as the separation does not necessarily increase at the same rate.

We then examine the variation of the misclassification rate with the separation. We obtain embeddings at different separation values γ by changing the parameter μ of the supervised Laplacian eigenmaps algorithm. Figure 8 shows the variation of the misclassification rate with the separation γ. Each curve is obtained at a different value of the scale parameter σ of the RBF kernels. It is seen that the misclassification rate decreases

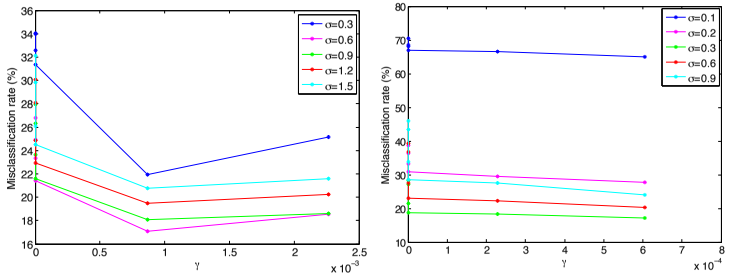


(a) COIL-20 object data set (b) ETH-80 object data set

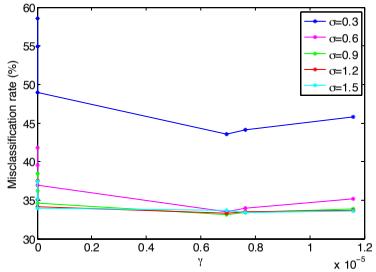


(c) Yale face data set

Figure 7: Variation of the misclassification rate with the dimension of the embedding



(a) COIL-20 object data set (b) ETH-80 object data set



(c) Yale face data set

Figure 8: Variation of the misclassification rate with the separation

in general with the separation for small γ values. This is in agreement with our results, as the conditions (14), (16) require the separation to be higher than a threshold. On the other hand, the possible increase in the error at relatively large values of the separation is due to the following. These parts of the plots are obtained at very small μ values, which typically result in a deformed embedding with a degenerate geometry. The deformation of structure at too small values of μ may cause the interpolation function to be irregular and hence result in an increase in the error. The tradeoff between the separation and the interpolation function regularity is further studied in Section 4.2.3.

Finally, Figure 9 shows the relation between the misclassification error and the scale parameter σ of the Gaussian RBF kernels. Each curve is obtained at a different value of the μ parameter. The optimum value of the scale parameter minimizing the misclassification error can be observed in most experiments. These results confirm the findings of Section 2.4, suggesting that there exists a unique value of σ that minimizes the left hand side of the conditions (14), (16), which probabilistically guarantee the correct classification of data.

4.2.3 Performance Analysis of Several Supervised Manifold Learning Algorithms

Next, we compare several supervised manifold learning methods. We aim to interpret the performance differences of different types of embeddings in light of our theoretical results in Section 2.3. First, remember from Theorem 8 that the condition

$$\sqrt{d}\,\mathcal{C}\,(L_\phi \delta + \epsilon) \leq \gamma/2 \tag{32}$$

needs to be satisfied (or, equivalently the condition (16) from Theorem 9) in order for the generalization bounds to hold. This preliminary condition basically states that a compromise must be achieved between the regularity of the interpolation function, captured via the terms $\mathcal{C}$ and L_ϕ, and the separation γ of the embedding of training samples, in order to bound the misclassification error. In other words, increasing the separation too much in the embedding of training samples does not necessarily lead to good classification performance if the interpolation function has poor regularity.

Hence, when comparing different embeddings in the experiments of this section, we define a condition parameter given by

$$\frac{\sqrt{d}\mathcal{C}L_\phi}{\gamma},$$

which represents the ratio of the left and right hand sides of (32) (by fixing the probability parameters δ and ϵ). Setting the Lipschitz constant of the Gaussian RBF kernel as $L_\phi = \sqrt{2}e^{-\frac{1}{2}}\sigma^{-1}$ (see Section 2.4 for details), we can equivalently define the condition parameter as

$$\kappa = \frac{\sqrt{d}\mathcal{C}}{\sigma\gamma} \tag{33}$$

and study this condition parameter for the supervised dimensionality methods in comparison. Note that a smaller condition parameter means that the necessary conditions of Theorems 8 and 9 are more likely to be satisfied, hence hinting at the expectation of a better classification accuracy.

We compare the following supervised embeddings:

- Supervised Laplacian eigenmaps embedding obtained by solving (30):

$$\min_Y \operatorname{tr}(Y^T L_w Y) - \mu \operatorname{tr}(Y^T L_b Y) \text{ subject to } Y^T Y = I.$$

- Fisher embedding[4], obtained by solving

$$\max_Y \frac{\operatorname{tr}(Y^T L_b Y)}{\operatorname{tr}(Y^T L_w Y)}. \tag{34}$$

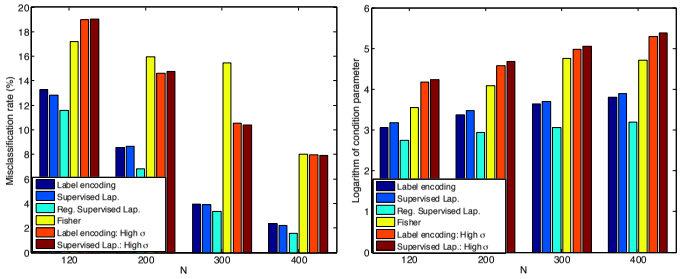
- Label encoding, which maps each data sample to its label vector of the form

$$[0\ 0 \ldots 1 \ldots 0],$$

where the only nonzero entry corresponds to its class.

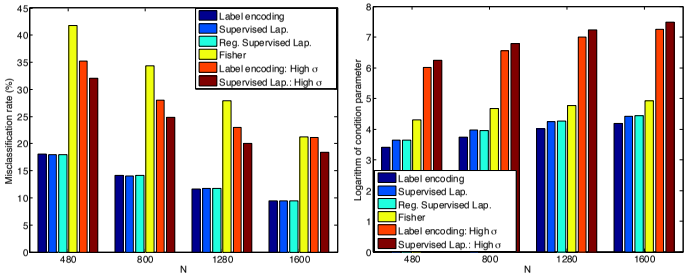
The label encoding method is included in the experiments to provide a reference, which can also be regarded as a degenerate supervised manifold learning algorithm that provides maximal separation between data samples from different classes. In all of the above methods the training samples are embedded into the low-dimensional domain, and test samples are mapped via Gaussian RBF interpolators and assigned labels via nearest neighbor classification in the low-dimensional domain. The scale parameter σ of the RBF kernel is set to a reference value in each data set within the typical range $[0.5, 1]$ where the best accuracy is attained. We have fixed the weight parameter as $\mu = 0.01$ in all setups, and set the dimension of the embedding as equal to the number of classes. In order to study the properties of the interpolation function in relation with the condition parameter in (33), we also test the supervised Laplacian eigenmaps and the label encoding methods under RBF

4. We use a nonlinear version of the formulation in (Wang and Chen, 2009) by removing the constraint that the embedding be given by a linear projection of the data.



(a) (b)

Figure 10: Misclassification rates and the condition parameters of the embeddings for the COIL-20 object data set

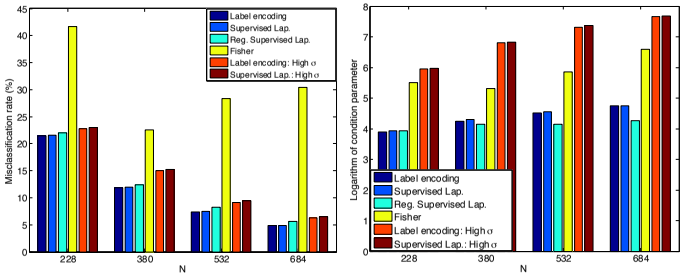


(a) (b)

Figure 11: Misclassification rates and the condition parameters of the embeddings for the ETH-80 object data set

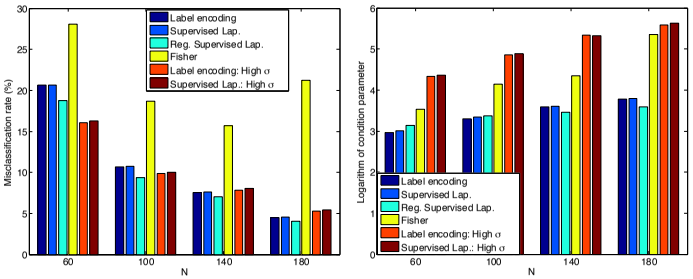
interpolators with high scale parameters, which are chosen as a few times the reference σ value giving the best results. Finally, we also include in the comparisons a regularized version of the supervised Laplacian eigenmaps embedding by controlling the magnitude of the interpolation function.

The results obtained on the COIL-20, ETH-80, Yale and reduced Yale data sets are reported respectively in Figures 10-13. In each figure, panel (a) shows the misclassification rates of the embeddings and panel (b) shows the condition parameters of the embeddings at different total number of training samples (N). The logarithm of the condition parameter is plotted for ease of visualization.



(a) (b)

Figure 12: Misclassification rates and the condition parameters of the embeddings for the Yale face data set



(a) (b)

Figure 13: Misclassification rates and the condition parameters of the embeddings for the reduced Yale face data set

The plots in Figures 10-13 show that the label encoding, supervised Laplacian eigenmaps, and the regularized supervised Laplacian eigenmaps embeddings yield better classification accuracy than the other three methods (supervised Fisher, and the embeddings with high scale parameters) in all experiments, with the only exception of the cases $N = 60$ and $N = 100$ for the reduced Yale data set. Meanwhile, examining the condition parameters of the embeddings, we observe that label encoding, supervised Laplacian eigenmaps, and the regularized supervised Laplacian eigenmaps embeddings always have a smaller condition parameter than the other three methods. This observation confirms the intuition provided by the necessary conditions of Theorems 8 and 9: A compromise between the separation and the interpolator regularity is required for good classification accuracy. The increase in the condition parameter as N increases is since the coefficient bound $\mathcal{C}$ involves a summation over all training samples. The reason why the embeddings with high σ parameters yield better classification accuracy than the other ones in the cases $N = 60$ and $N = 100$ for the reduced Yale data set is that a larger RBF scale helps better cover up the ambient space when the number of training samples is particularly low.

In the COIL-20 and the reduced Yale data sets, the best classification accuracy is obtained with the regularized supervised Laplacian eigenmaps method, while this is also the method having the smallest condition number, except for the smallest two values of N in the reduced Yale data set. In the ETH-80 and Full Yale data sets, the classification accuracy of label encoding attains that of the supervised Laplacian eigenmaps method. The condition parameter of the label encoding embedding is relatively small in these two data sets; in fact, in ETH-80 the label encoding embedding has the smallest condition number among all methods. This may be useful for explaining why this simple classification method has quite favorable performance in this data set. Likewise, if we leave aside the versions of the methods with high-scale interpolators, the Fisher embedding has the highest misclassification rate compared to label encoding, the supervised Laplacian, and the regularized supervised Laplacian embeddings, while it also has the highest condition parameter among these methods. [5]

To conclude, the results in this section suggest that the experimental findings are in agreement with the main results in Section 2.3, justifying the pertinence of the conditions (14) and (16) to classification accuracy, hence suggesting that a balance must be sought between the separability margin of the embedding and the regularity of the interpolation function in supervised manifold learning.

5. Conclusions

Most of the current supervised manifold learning algorithms focus on learning representations of training data, while the generalization properties of these representations have not been understood well yet. In this work, we have proposed a theoretical analysis of the performance of supervised manifold learning methods. We have presented generalization bounds for nonlinear supervised manifold learning algorithms and explored how the classification accuracy relates to several setup parameters such as the linear separation

5. The formulation in (34) has been observed to give highly polarized embeddings in (Vural and Guillemot, 2016a), where the samples of only few classes stretch out along each dimension and all the other classes are mapped close to zero.

margin of the embedding, the regularity of the interpolation function, the number of training samples, and the intrinsic dimensions of the class supports (manifolds). Our results suggest that embeddings of training data with good generalization capacities must allow the construction of sufficiently regular interpolation functions that extend the mapping to new data. We have then examined whether the assumption of linear separability is easy to satisfy for structure-preserving supervised embedding algorithms. We have taken the supervised Laplacian eigenmaps algorithms as reference, and showed that these methods can yield linearly separable embeddings. Providing insight about the generalization capabilities of supervised dimensionality reduction algorithms, our findings can be helpful in the classification of low-dimensional data sets.

Acknowledgments

We would like to thank Pascal Frossard and Alhussein Fawzi for the helpful discussions that contributed to this study.

Appendix A. Proof of the Results in Section 2

A.1 Proof of Theorem 2

Proof Given x, let $x_i \in \mathcal{X}$ be the nearest neighbor of x in $\mathcal{X}$ that is sampled from ν_m

$$i = \arg\min_j \|x - x_j\| \text{ s.t. } x_j \sim \nu_m.$$

Due to the separation hypothesis,

$$\omega_{mk}^T y_i + b_{mk} > \gamma/2, \quad \forall k = 1, \ldots, M-1.$$

We have

$$\begin{aligned} \omega_{mk}^T f(x) + b_{mk} &= \omega_{mk}^T f(x_i) + b_{mk} + \omega_{mk}^T (f(x) - f(x_i)) \\ &\geq \omega_{mk}^T y_i + b_{mk} - \left|\omega_{mk}^T (f(x) - f(x_i))\right| \\ &> \gamma/2 - \|f(x) - f(x_i)\| \ \geq \ \gamma/2 - L\|x - x_i\|. \end{aligned}$$

Then if the condition $L\|x - x_i\| \leq \gamma/2$ is satisfied, from the above inequality we have $\omega_{mk}^T f(x) + b_{mk} > 0$ for all $k = 1, \ldots, M-1$. This gives $\hat{C}(x) = m$ and thus ensures that x is classified correctly.

In the sequel, we lower bound the probability that the distance $\|x - x_i\|$ between x and its nearest neighbor from the same class is smaller than $\gamma/2$. We employ the following result by Kulkarni and Posner (1995). It is demonstrated in the proof of Theorem 1 in (Kulkarni and Posner, 1995) that, if $\mathcal{X}$ contains at least N_m samples drawn i.i.d. from ν_m such that $N_m \geq \mathcal{N}(\epsilon/2, \mathcal{M}_m)$ for some $\epsilon > 0$, then the probability of $\|x - x_i\|$ being larger than ϵ can be upper bounded in terms of the covering number of $\mathcal{M}_m$ as

$$P(\|x - x_i\| > \epsilon) \leq \frac{\mathcal{N}(\epsilon/2, \mathcal{M}_m)}{2N_m}.$$

Therefore, for any ϵ such that $\epsilon \leq \gamma/(2L)$ and $N_m \geq \mathcal{N}(\epsilon/2, \mathcal{M}_m)$, with probability at least $1 - \mathcal{N}(\epsilon/2, \mathcal{M}_m)/(2N_m)$, we have

$$\|x - x_i\| \leq \epsilon \leq \gamma/(2L),$$

thus, the class label of x is correctly estimated as $\hat{C}(x) = m$ due to the above discussion. ■

A.2 Proof of Lemma 3

Proof We first bound the deviation of $f(x)$ from the sample average of f in the neighborhood of x as

$$\left\| f(x) - \frac{1}{Q} \sum_{x_j \in A} f(x_j) \right\| \leq \|f(x) - m_f\| + \left\| \frac{1}{Q} \sum_{x_j \in A} f(x_j) - m_f \right\|, \tag{35}$$

where m_f is the conditional expectation of $f(u)$, given $u \in B_\delta(x)$

$$m_f = \mathbb{E}_u\big[f(u) \,|\, u \in B_\delta(x)\big] = \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} f(u)\; d\nu_m(u).$$

The first term in (35) can be bounded as

$$\begin{aligned} \|f(x) - m_f\| &= \left\| \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} \big(f(x) - f(u)\big)\, d\nu_m(u) \right\| \\ &\leq \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} \|f(x) - f(u)\|\, d\nu_m(u) \leq \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} L\|x - u\|\, d\nu_m(u) \\ &\leq \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} L\delta\, d\nu_m(u) = L\delta, \end{aligned} \tag{36}$$

where the second inequality follows from the fact that f is Lipschitz continuous on the support $\mathcal{M}_m$, where the measure ν_m is nonzero.

The second term in (35) is given by

$$\left\| \frac{1}{Q} \sum_{x_j \in A} f(x_j) - m_f \right\| = \left(\sum_{k=1}^{d} \left| \frac{1}{Q} \sum_{x_j \in A} f^k(x_j) - m_f^k \right|^2 \right)^{1/2}, \tag{37}$$

where m_f^k denotes the k-th component of m_f, for $k = 1, \ldots, d$. Consider the random variables $f^k(x_j)$. Defining

$$f^k_{\min} = \inf_{u \in B_\delta(x)} f^k(u), \qquad f^k_{\max} = \sup_{u \in B_\delta(x)} f^k(u),$$

it follows that $f^k_{\max} - f^k_{\min} \leq 2L\delta$ due to the Lipschitz continuity of f. Then from Hoeffding's inequality, we have

$$P\left(\left| \frac{1}{Q} \sum_{x_j \in A} f^k(x_j) - m_f^k \right| \geq \epsilon \right) \leq 2\exp\left(-\frac{2Q\epsilon^2}{(f^k_{\max} - f^k_{\min})^2} \right) \leq 2\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2} \right).$$

From the union bound, we get that with probability at least $1 - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$, for all k

$$\left| \frac{1}{Q} \sum_{x_j \in A} f^k(x_j) - m_f^k \right| \leq \epsilon,$$

which yields from (37)

$$\left\| \frac{1}{Q} \sum_{x_j \in A} f(x_j) - m_f \right\| \leq \sqrt{d}\epsilon.$$

Combining this result with the bound in (36), we conclude that with probability at least $1 - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$

$$\left\| f(x) - \frac{1}{Q} \sum_{x_j \in A} f(x_j) \right\| \leq L\delta + \sqrt{d}\epsilon.$$

■

A.3 Proof of Theorem 5

Proof Given the test sample x and a training sample x_i drawn i.i.d. with respect to ν_m, the probability that x_i lies within a δ-neighborhood of x is given by

$$P(x_i \in B_\delta(x)) = \nu_m(B_\delta(x)) \geq \eta_{m,\delta}.$$

Then, among the N_m samples drawn with respect to ν_m, the probability that $B_\delta(x)$ contains at least Q samples is given by

$$\begin{aligned} P(|A| \geq Q) &= \sum_{q=Q}^{N_m} \binom{N_m}{q} \Big(\nu_m(B_\delta(x))\Big)^q \Big(1 - \nu_m(B_\delta(x))\Big)^{N_m - q} \\ &\geq \sum_{q=Q}^{N_m} \binom{N_m}{q} (\eta_{m,\delta})^q \left(1 - \eta_{m,\delta}\right)^{N_m - q}, \end{aligned}$$

where the set A is defined as in (5). The last expression above is the probability of having at least Q successes out of N_m realizations of a Bernoulli random variable with probability parameter $\eta_{m,\delta}$. This probability can be lower bounded using a tail bound for binomial distributions. We thus have

$$P(|A| \geq Q) \geq 1 - \exp\left(\frac{-2\left(N_m\, \eta_{m,\delta} - Q\right)^2}{N_m} \right),$$

which simply follows from interpreting $|A|$ as the sum of of N_m i.i.d. observations of a Bernoulli distributed random variable and then applying Hoeffding's inequality as shown by Herbrich (1999), under the hypothesis that $N_m > Q/\eta_{m,\delta}$.

Assuming that $B_\delta(x)$ contains at least Q samples, Lemma 3 states that with probability at least

$$1 - 2d\exp\left(-\frac{|A|\epsilon^2}{2L^2\delta^2}\right) \geq 1 - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$$

the deviation between $f(x)$ and the sample average of its neighbors is bounded as

$$\left\| f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j) \right\| \leq L\delta + \sqrt{d}\epsilon.$$

Hence, with probability at least

$$\left(1 - \exp\left(\frac{-2\left(N_m\,\eta_{m,\delta} - Q\right)^2}{N_m}\right)\right)\left(1 - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)\right)$$
$$\geq 1 - \exp\left(\frac{-2\left(N_m\,\eta_{m,\delta} - Q\right)^2}{N_m}\right) - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$$

we have

$$\left\| f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j) \right\| \leq L\delta + \sqrt{d}\epsilon. \tag{38}$$

The class label of a test sample x drawn from ν_m is correctly estimated with respect to the classifier (4) if

$$\omega_{mk}^T f(x) + b_{mk} > 0, \quad \forall k = 1,\ldots,M-1,\ k \neq m.$$

If the condition in (38) is satisfied, for all $k \neq m$, we have

$$\begin{aligned}
\omega_{mk}^T f(x) + b_{mk} &= \omega_{mk}^T \frac{1}{|A|}\sum_{x_j\in A} f(x_j) + b_{mk} + \omega_{mk}^T\left(f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j)\right) \\
&\geq \omega_{mk}^T \frac{1}{|A|}\sum_{x_j\in A} f(x_j) + b_{mk} - \left\| f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j)\right\| \\
&> \gamma_Q/2 - \left\| f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j)\right\| \geq \gamma_Q/2 - L\delta - \sqrt{d}\epsilon \geq 0.
\end{aligned}$$

Here, we obtain the second inequality from the hypothesis that the embedding is Q-mean separable with margin larger than γ_Q, which implies that the embedding is also R-mean separable with margin larger than γ_Q, for $R > Q$. Then the last inequality is due to the condition (8) on the interpolation function in the theorem. We thus get that with probability at least

$$1 - \exp\left(\frac{-2\left(N_m\,\eta_{m,\delta} - Q\right)^2}{N_m}\right) - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right),$$

$\omega_{mk}^T f(x) + b_{mk} > 0$ for all $k \neq m$, hence, the sample x is correctly classified. This concludes the proof of the theorem. ■

A.4 Proof of Theorem 6

Proof Remember from the proof of Theorem 5 that with probability at least

$$1 - \exp\left(\frac{-2\left(N_m\,\eta_{m,\delta} - Q\right)^2}{N_m}\right) - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$$

the δ-neighborhood $B_\delta(x)$ of a test sample x from class m contains at least Q samples from class m, and

$$\left\| f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j) \right\| \leq L\delta + \sqrt{d}\epsilon, \tag{39}$$

where A is the set of training samples in $B_\delta(x)$ from class m.

Let $x_i, x_j \in A$ be two training samples from class m in $B_\delta(x)$. As $\|x_i - x_j\| \leq 2\delta$, by the hypothesis on the embedding, we have $\|y_i - y_j\| = \|f(x_i) - f(x_j)\| \leq D_{2\delta}$, which gives

$$\|f(x_i) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j)\| = \left\| \frac{1}{|A|}\sum_{x_j\in A}\left(f(x_i) - f(x_j)\right)\right\| \leq \frac{1}{|A|}\sum_{x_j\in A}\|f(x_i) - f(x_j)\| \leq D_{2\delta}.$$

Then, for any $x_i \in B_\delta(x)$,

$$\begin{aligned}
\|f(x) - f(x_i)\| &= \|f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j) + \frac{1}{|A|}\sum_{x_j\in A} f(x_j) - f(x_i)\| \\
&\leq \|f(x) - \frac{1}{|A|}\sum_{x_j\in A} f(x_j)\| + D_{2\delta}.
\end{aligned}$$

Combining this with (39), we get that with probability at least

$$1 - \exp\left(\frac{-2\left(N_m\,\eta_{m,\delta} - Q\right)^2}{N_m}\right) - 2d\exp\left(-\frac{Q\epsilon^2}{2L^2\delta^2}\right)$$

$B_\delta(x)$ will contain at least Q samples x_i from class m such that

$$\|f(x) - f(x_i)\| \leq L\delta + \sqrt{d}\epsilon + D_{2\delta}. \tag{40}$$

Now, assuming (40), let x_i' be a training sample from another class (other than m). We have

$$\|f(x) - f(x_i')\| \geq \|f(x_i) - f(x_i')\| - \|f(x) - f(x_i)\| > \gamma - (L\delta + \sqrt{d}\epsilon + D_{2\delta}),$$

which follows from (40) and the hypothesis on the embedding that $\|f(x_i) - f(x_i')\| > \gamma$.

It follows from the condition (10) that $\gamma \geq 2L\delta + 2\sqrt{d}\epsilon + 2D_{2\delta}$. Using this in the above equation, we get

$$\|f(x) - f(x_i')\| > L\delta + \sqrt{d}\epsilon + D_{2\delta}.$$

This means that the distance of $f(x)$ to the embedding of any other sample from another class is more than $L\delta + \sqrt{d}\epsilon + D_{2\delta}$, while there are samples from its own class within a distance of $L\delta + \sqrt{d}\epsilon + D_{2\delta}$ to $f(x)$. Therefore, x is classified correctly with nearest-neighbor classification in the low-dimensional domain of embedding. ■

A.5 Proof of Lemma 7

Proof The deviation of each component $f^k(x)$ of the interpolator from the sample average in the neighborhood of x is given by

$$\left| f^k(x) - \frac{1}{Q}\sum_{x_j\in A} f^k(x_j) \right| = \left| \sum_{i=1}^{N} c_i^k \left(\phi(\|x-x_i\|) - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|) \right) \right|. \tag{41}$$

We thus proceed by studying the term

$$\phi(\|x-x_i\|) - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|), \tag{42}$$

which will then be used in the above expression to arrive at the stated result.

Now let $x_i \in \mathcal{X}$ be any training sample. In order to study the term in (42), we first look at

$$\left| \phi(\|x-x_i\|) - \mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big] \right|,$$

where $\mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big]$ denotes the conditional expectation of $\phi(\|u-x_i\|)$ over u, given $u\in B_\delta(x)$. The conditional expectation is given by

$$\mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big] = \frac{1}{\nu_m\big(B_\delta(x)\big)}\int_{B_\delta(x)} \phi(\|u-x_i\|)\, d\nu_m(u).$$

We have

$$\begin{aligned}
&\left| \phi(\|x-x_i\|) - \mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big] \right| \\
&\qquad = \frac{1}{\nu_m\big(B_\delta(x)\big)} \left| \int_{B_\delta(x)} \big(\phi(\|x-x_i\|) - \phi(\|u-x_i\|)\big)\, d\nu_m(u) \right| \\
&\qquad \le \frac{1}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} \big|\phi(\|x-x_i\|) - \phi(\|u-x_i\|)\big|\, d\nu_m(u).
\end{aligned}$$

The term in the integral is bounded as

$$\big|\phi(\|x-x_i\|) - \phi(\|u-x_i\|)\big| \le L_\phi \big|\|x-x_i\| - \|u-x_i\|\big| \le L_\phi \|x-u\|.$$

Using this in the above term, we get

$$\begin{aligned}
&\left| \phi(\|x-x_i\|) - \mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big] \right| \\
&\qquad \le \frac{L_\phi}{\nu_m\big(B_\delta(x)\big)} \int_{B_\delta(x)} \|x-u\|\, d\nu_m(u) = L_\phi\, \mathbb{E}_u\big[\|u-x\|\,|\,u\in B_\delta(x)\big] \\
&\qquad \le L_\phi\, \delta.
\end{aligned} \tag{43}$$

We now analyze the term in (42) for a given x_i for two different cases, i.e., for $x_i \notin B_\delta(x)$ and $x_i \in B_\delta(x)$. We first look at the case $x_i \notin B_\delta(x)$. For $x_j \in B_\delta(x)$, let

$$\zeta_j := \phi(\|x_j - x_i\|).$$

The observations ζ_j are i.i.d. (since x_j are i.i.d.) with mean $m_\zeta = \mathbb{E}_u\big[\phi(\|u-x_i\|)\,|\,u\in B_\delta(x)\big]$ and take values in the interval $\zeta_{\min} \le \zeta_j \le \zeta_{\max}$, where

$$\zeta_{\min} := \inf_{u\in B_\delta(x)} \phi(\|u-x_i\|), \qquad \zeta_{\max} := \sup_{u\in B_\delta(x)} \phi(\|u-x_i\|).$$

Since for any $u_1, u_2 \in B_\delta(x)$, $\|u_1-u_2\| \le 2\delta$, it follows from the Lipschitz continuity of ϕ that $\zeta_{\max} - \zeta_{\min} \le 2L_\phi\delta$. Using this together with the Hoeffding's inequality, we get

$$P\left(\left| \frac{1}{Q}\sum_{x_j\in A} \zeta_j - m_\zeta \right| \ge \epsilon \right) \le 2\exp\left(-\frac{2\,Q\,\epsilon^2}{(\zeta_{\max}-\zeta_{\min})^2} \right) \le 2\exp\left(-\frac{Q\,\epsilon^2}{2L_\phi^2\delta^2} \right). \tag{44}$$

We have

$$\left| \phi(\|x-x_i\|) - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|) \right| \le \big|\phi(\|x-x_i\|) - m_\zeta\big| + \left| m_\zeta - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|) \right|.$$

Using (43) and (44) in the above equation, it holds with probability at least

$$1 - 2\exp\left(-\frac{Q\,\epsilon^2}{2L_\phi^2\delta^2} \right)$$

that

$$\left| \phi(\|x-x_i\|) - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|) \right| \le L_\phi\delta + \epsilon.$$

Next, we study the case $x_i \in B_\delta(x)$. For any fixed $x_i \in B_\delta(x)$, hence $x_i \in A$, we have

$$\begin{aligned}
&\left| \phi(\|x-x_i\|) - \frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|) \right| \\
&= \left| \frac{1}{Q}\phi(\|x-x_i\|) + \frac{Q-1}{Q}\phi(\|x-x_i\|) - \frac{1}{Q}\phi(\|x_i-x_i\|) - \frac{1}{Q}\sum_{x_j\in A\setminus\{x_i\}}\phi(\|x_j-x_i\|) \right| \\
&\le \frac{1}{Q}\left|\phi(\|x-x_i\|) - \phi(\|x_i-x_i\|)\right| + \frac{Q-1}{Q}\left| \phi(\|x-x_i\|) - \frac{1}{Q-1}\sum_{x_j\in A\setminus\{x_i\}}\phi(\|x_j-x_i\|) \right|.
\end{aligned}$$

The first term above is bounded as

$$\frac{1}{Q}\left|\phi(\|x-x_i\|) - \phi(\|x_i-x_i\|)\right| \le \frac{L_\phi\delta}{Q}.$$

Next, similarly to the analysis of the case $x_i \ne B_\delta(x)$, we get that for $x_i \in B_\delta(x)$ with probability at least

$$1 - 2\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2} \right)$$

it holds that

$$\left| \phi(\|x-x_i\|) - \frac{1}{Q-1}\sum_{x_j\in A\setminus\{x_i\}}\phi(\|x_j-x_i\|) \right| \le L_\phi\delta + \epsilon,$$

hence

$$\left|\phi(\|x-x_i\|)-\frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|)\right|\leq\frac{L_\phi\delta}{Q}+\frac{Q-1}{Q}(L_\phi\delta+\epsilon)\leq L_\phi\delta+\epsilon.$$

Combining the analyses of the cases $x_i\neq B_\delta(x)$ and $x_i\in B_\delta(x)$, we conclude that for any given $x_i\in\mathcal{X}$,

$$P\left(\left|\phi(\|x-x_i\|)-\frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|)\right|\leq L_\phi\delta+\epsilon\right)\geq 1-2\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right).$$

Therefore, applying the union bound on all N samples x_i in $\mathcal{X}$, we get that with probability at least

$$1-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right)$$

it holds that

$$\left|\phi(\|x-x_i\|)-\frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|)\right|\leq L_\phi\delta+\epsilon \tag{45}$$

for all $x_i\in\mathcal{X}$.

We can now use this in (41) to bound the deviation of $f^k(x)$ from the empirical mean of f^k in the neighbourhood of x. Assuming that the condition (45) holds for all $x_i\in\mathcal{X}$, we obtain

$$\begin{aligned}\left|f^k(x)-\frac{1}{Q}\sum_{x_j\in A}f^k(x_j)\right|&=\left|\sum_{i=1}^N c_i^k\left(\phi(\|x-x_i\|)-\frac{1}{Q}\sum_{x_j\in A}\phi(\|x_j-x_i\|)\right)\right|\\&\leq(L_\phi\delta+\epsilon)\sum_{i=1}^N|c_i^k|\leq\mathcal{C}(L_\phi\delta+\epsilon),\end{aligned}$$

which gives

$$\|f(x)-\frac{1}{Q}\sum_{x_j\in A}f(x_j)\|=\left(\sum_{k=1}^d\left(f^k(x)-\frac{1}{Q}\sum_{x_j\in A}f^k(x_j)\right)^2\right)^{1/2}\leq\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon).$$

We thus get

$$P\left(\|f(x)-\frac{1}{Q}\sum_{x_j\in A}f(x_j)\|\leq\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)\right)\geq 1-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right),$$

which completes the proof. ■

A.6 Proof of Theorem 8

Proof

Remember from the proof of Theorem 5 that

$$P(|A|\geq Q)\geq 1-\exp\left(\frac{-2\,(N_m\,\eta_{m,\delta}-Q)^2}{N_m}\right).$$

Lemma 7 states that, if $B_\delta(x)$ contains at least Q samples from class m, i.e., $|A|\geq Q$, then

$$\begin{aligned}P\left(\|f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\|\leq\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)\right)&\geq 1-2N\exp\left(-\frac{(|A|-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right)\\&\geq 1-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right).\end{aligned}$$

Hence, combining these two results (multiplying both probabilities), we get that with probability at least

$$\begin{aligned}&\left(1-\exp\left(\frac{-2\,(N_m\,\eta_{m,\delta}-Q)^2}{N_m}\right)\right)\left(1-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right)\right)\\&\geq 1-\exp\left(\frac{-2\,(N_m\,\eta_{m,\delta}-Q)^2}{N_m}\right)-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right)\end{aligned}$$

it holds that

$$\|f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\|\leq\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon). \tag{46}$$

A test sample x drawn from ν_m is classified correctly with the linear classifier if

$$\omega_{mk}^T\,f(x)+b_{mk}>0,\quad\forall k=1,\ldots,M-1,\,k\neq m.$$

If the condition in (46) is satisfied, for all $k\neq m$, we have

$$\begin{aligned}\omega_{mk}^T\,f(x)+b_{mk}&=\omega_{mk}^T\frac{1}{|A|}\sum_{x_j\in A}f(x_j)+b_{mk}+\omega_{mk}^T\left(f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\right)\\&\geq\omega_{mk}^T\frac{1}{|A|}\sum_{x_j\in A}f(x_j)+b_{mk}-\|f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\|\\&>\gamma_Q/2-\|f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\|\geq\gamma_Q/2-\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)\geq 0.\end{aligned}$$

We thus conclude that with probability at least

$$1-\exp\left(\frac{-2\,(N_m\,\eta_{m,\delta}-Q)^2}{N_m}\right)-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right),$$

$\omega_{mk}^T\,f(x)+b_{mk}>0$ for all $k\neq m$, hence, the class label of x is estimated correctly. ■

A.7 Proof of Theorem 9

Proof First, recall from the proof of Theorem 8 that, with probability at least

$$1-\exp\left(\frac{-2\left(N_m\,\eta_{m,\delta}-Q\right)^2}{N_m}\right)-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right)$$

the δ-neighborhood $B_\delta(x)$ of a test sample x from class m contains at least Q samples from class m, and

$$\|f(x)-\frac{1}{|A|}\sum_{x_j\in A}f(x_j)\|\le\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon), \tag{47}$$

where A is the set of training samples in $B_\delta(x)$ from class m.

Then it is easy to show that (as in the proof of Theorem 6), with probability at least

$$1-\exp\left(\frac{-2\left(N_m\,\eta_{m,\delta}-Q\right)^2}{N_m}\right)-2N\exp\left(-\frac{(Q-1)\,\epsilon^2}{2L_\phi^2\delta^2}\right),$$

$B_\delta(x)$ will contain at least Q samples x_i from class m such that

$$\|f(x)-f(x_i)\|\le\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)+D_{2\delta}. \tag{48}$$

Hence, for a training sample x_i' from another class (other than m), we have

$$\|f(x)-f(x_i')\|\ge\|f(x_i)-f(x_i')\|-\|f(x)-f(x_i)\|>\gamma-(\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)+D_{2\delta}),$$

which follows from (48) and the hypothesis on the embedding that $\|f(x_i)-f(x_i')\|>\gamma$.

Due to the condition (16), we have $\gamma\ge 2\sqrt{d}\,\mathcal{C}\,(L_\phi\delta+\epsilon)+2D_{2\delta}$. Using this above equation, we obtain

$$\|f(x)-f(x_i')\|>\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)+D_{2\delta}.$$

Therefore, the distance of $f(x)$ to the embedding of the samples from other classes is more than $\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)+D_{2\delta}$, while there are samples from its own class within a distance of $\sqrt{d}\mathcal{C}(L_\phi\delta+\epsilon)+D_{2\delta}$ to $f(x)$. We thus conclude that the class label of x is estimated correctly with nearest-neighbor classification in the low-dimensional domain of embedding. ■

Appendix B. Proof of the Results in Section 3

B.1 Proof of Lemma 13

Proof The coordinate vector y is the eigenvector of the matrix $L_w-\mu L_b$ corresponding to its minimum eigenvalue. Hence,

$$y=\arg\min_{\substack{\xi\\ \|\xi\|=1}}\xi^T(L_w-\mu L_b)\xi.$$

Equivalently, defining the degree-normalized coordinates $z=D_w^{-1/2}y$, and thus replacing the above ξ by $D_w^{1/2}\xi$, we have

$$\begin{aligned} z&=\arg\min_{\substack{\xi\\ \xi^TD_w\xi=1}}N(\xi)\\ N(\xi)&=\xi^TD_w^{1/2}(L_w-\mu L_b)D_w^{1/2}\xi\\ &=\xi^T(D_w-W_w)\xi-\mu\,\xi^T(D_wD_b^{-1})^{1/2}\,(D_b-W_b)\,(D_b^{-1}D_w)^{1/2}\xi. \end{aligned} \tag{49}$$

Then, denoting $\beta_i=d_w(i)/d_b(i)$, the term $N(\xi)$ can be rearranged as

$$\begin{aligned} N(\xi)&=\sum_i\xi_i\Big(d_w(i)\,\xi_i-\sum_{j\sim_w i}\xi_j\,w_{ij}\Big)-\mu\sum_i\xi_i\Big(d_w(i)\,\xi_i-\sum_{j\sim_b i}\xi_j\,w_{ij}\,\sqrt{\beta_i\beta_j}\Big)\\ &=\sum_i\xi_i\sum_{j\sim_w i}(\xi_i-\xi_j)w_{ij}-\mu\sum_i\xi_i\sum_{j\sim_b i}(\beta_i\xi_i-\sqrt{\beta_i\beta_j}\,\xi_j)w_{ij}\\ &=\sum_i\sum_{j\sim_w i}(\xi_i^2-\xi_i\xi_j)w_{ij}-\mu\sum_i\sum_{j\sim_b i}(\beta_i\xi_i^2-\sqrt{\beta_i\beta_j}\xi_i\xi_j)w_{ij}, \end{aligned}$$

which gives [6]

$$N(\xi)=\sum_{i\sim_w j}(\xi_i-\xi_j)^2\,w_{ij}-\mu\sum_{i\sim_b j}\left(\sqrt{\beta_i}\xi_i-\sqrt{\beta_j}\xi_j\right)^2\,w_{ij} \tag{50}$$

by grouping the neighboring (i,j) pairs in the inner sums. Now, for any $\xi\in\mathbb{R}^{N\times 1}$ such that $\xi^TD_w\xi=1$, we define ξ^* as follows

$$\xi_i^*=\begin{cases}-|\xi_i| & \text{if } C_i=1\\ \ \ |\xi_i| & \text{if } C_i=2.\end{cases} \tag{51}$$

Clearly, ξ^* also satisfies $(\xi^*)^TD_w\xi^*=1$. From (50), it can be easily checked that $N(\xi^*)\le N(\xi)$ for any ξ, Then, a minimizer z of the problem (49) has to be of the separable form defined in (51); otherwise z^* would yield a smaller value for the function N, which would contradict the fact that z is a minimizer. Note that the equality $N(z^*)=N(z)$ holds only if $z=z^*$ or $z=-z^*$, thus when z is separable. Therefore, the embedding z satisfies the condition

$$z_i\le 0\ \text{ if } C_i=1,\qquad\qquad z_i\ge 0\ \text{ if } C_i=2,$$

or the equivalent condition

$$z_i\le 0\ \text{ if } C_i=2,\qquad\qquad z_i\ge 0\ \text{ if } C_i=1.$$

Finally, since $y_i=\sqrt{d_w(i)}\,z_i$, the same property also holds for the embedding y. ■

6. In our notation, the terms $i\sim_w j$ and $i\sim_b j$ in the summation indices as in (50) refer to edges rather than neighboring (i,j)-pairs; i.e., each pair is counted only once in the summation.

B.2 Proof of Theorem 14

Proof From (49) and (50), we have

$$z = \arg \min_{\substack{\xi \\ \xi^T D_w \xi = 1}} \sum_{i \sim_w j} (\xi_i - \xi_j)^2 \, w_{ij} - \mu \sum_{i \sim_b j} \left(\sqrt{\beta_i} \xi_i - \sqrt{\beta_j} \xi_j \right)^2 \, w_{ij}. \tag{52}$$

Thus, at the optimal solution z the objective function takes the value

$$N(z) = \sum_{i \sim_w j} (z_i - z_j)^2 \, w_{ij} - \mu \sum_{i \sim_b j} \left(\sqrt{\beta_i} z_i - \sqrt{\beta_j} z_j \right)^2 \, w_{ij}. \tag{53}$$

In the following, we derive a lower bound for the first sum and an upper bound for the second sum in (53). We begin with the first sum. Let $i_{1,min}$, $i_{1,max}$, $i_{2,min}$ and $i_{2,max}$ denote the indices of the data samples in class 1 and class 2 that are respectively mapped to the extremal coordinates $z_{1,min}$, $z_{1,max}$, $z_{2,min}$, $z_{2,max}$, where

$$z_{k,min} = \min_{i:\, C_i = k} z_i \,, \qquad\qquad z_{k,max} = \max_{i:\, C_i = k} z_i \,.$$

Let $P_1 = \{(x_{k_{i-1}}, x_{k_i})\}_{i=1}^{L_1}$ be a shortest path of length L_1 joining $x_{i_{1,min}}$ and $x_{i_{1,max}}$ and $P_2 = \{(x_{n_{i-1}}, x_{n_i})\}_{i=1}^{L_2}$ be a shortest path of length L_2 joining $x_{i_{2,min}}$ and $x_{i_{2,max}}$. We have

$$\begin{aligned} \sum_{i \sim_w j} (z_i - z_j)^2 \, w_{ij} &\geq \sum_{i=1}^{L_1} (z_{k_i} - z_{k_{i-1}})^2 \, w_{k_{i-1} k_i} + \sum_{i=1}^{L_2} (z_{n_i} - z_{n_{i-1}})^2 \, w_{n_{i-1} n_i} \\ &\geq w_{min,1} \sum_{i=1}^{L_1} (z_{k_i} - z_{k_{i-1}})^2 + w_{min,2} \sum_{i=1}^{L_2} (z_{n_i} - z_{n_{i-1}})^2 \,, \end{aligned} \tag{54}$$

where the first inequality simply follows from the fact that the set of edges making up $P_1 \cup P_2$ are contained in the set of all edges in G_w. For a sequence $\{a_i\}_{i=0}^{L}$, the following inequality holds

$$\begin{aligned} (a_L - a_0)^2 &= \sum_{i=1}^{L} (a_i - a_{i-1})^2 + \sum_{\substack{i,j=1 \\ i \neq j}}^{L} (a_i - a_{i-1})(a_j - a_{j-1}) \\ &\leq \sum_{i=1}^{L} (a_i - a_{i-1})^2 + \frac{1}{2} \sum_{\substack{i,j=1 \\ i \neq j}}^{L} \left((a_i - a_{i-1})^2 + (a_j - a_{j-1})^2 \right) = L \sum_{i=1}^{L} (a_i - a_{i-1})^2. \end{aligned}$$

Hence,

$$\sum_{i=1}^{L} (a_i - a_{i-1})^2 \geq \frac{1}{L} (a_L - a_0)^2.$$

Using this inequality in (54), we get

$$\sum_{i \sim_w j} (z_i - z_j)^2 \, w_{ij} \geq \frac{w_{min,1}}{L_1} (z_{1,max} - z_{1,min})^2 + \frac{w_{min,2}}{L_2} (z_{2,max} - z_{2,min})^2.$$

Since the path lengths L_1 and L_2 are upper bounded by the diameters D_1 and D_2, we finally obtain the lower bound

$$\sum_{i \sim_w j} (z_i - z_j)^2 \, w_{ij} \geq \frac{w_{min,1}}{D_1} (z_{1,max} - z_{1,min})^2 + \frac{w_{min,2}}{D_2} (z_{2,max} - z_{2,min})^2. \tag{55}$$

Next, we find an upper bound for the second sum in (53). Using Lemma 13, we obtain the following inequality

$$\begin{aligned} \sum_{i \sim_b j} \left(\sqrt{\beta_i} z_i - \sqrt{\beta_j} z_j \right)^2 \, w_{ij} &\leq \sum_{i \sim_b j} (z_{2,max} - z_{1,min})^2 \, \beta_{max} \, w_{ij} \\ &= \frac{1}{2} (z_{2,max} - z_{1,min})^2 \, \beta_{max} V^b_{max}. \end{aligned} \tag{56}$$

Now, since the solution z in (52) minimizes the objective function $N(\xi)$, we have

$$N(z) = \lambda_{\min}(L_w - \mu L_b),$$

where $\lambda_{\min}(\cdot)$ and $\lambda_{\max}(\cdot)$ respectively denote the minimum and the maximum eigenvalues of a matrix. For two Hermitian matrices A and B, the inequality $\lambda_{\min}(A+B) \leq \lambda_{\min}(A) + \lambda_{\max}(B)$ holds. As L_w and L_b are graph Laplacian matrices, we have $\lambda_{\min}(L_w) = \lambda_{\min}(L_b) = 0$ and thus

$$N(z) = \lambda_{\min}(L_w - \mu L_b) \leq \lambda_{\min}(L_w) + \lambda_{\max}(-\mu L_b) = \lambda_{\min}(L_w) - \mu \lambda_{\min}(L_b) = 0.$$

Using in (53) the above inequality and the lower and upper bounds in (55) and (56), we obtain

$$\begin{aligned} 0 \geq N(z) &= \sum_{i \sim_w j} (z_i - z_j)^2 \, w_{ij} - \mu \sum_{i \sim_b j} \left(\sqrt{\beta_i} z_i - \sqrt{\beta_j} z_j \right)^2 \, w_{ij} \\ &\geq \frac{w_{min,1}}{D_1} (z_{1,max} - z_{1,min})^2 + \frac{w_{min,2}}{D_2} (z_{2,max} - z_{2,min})^2 \\ &\quad - \frac{1}{2} \mu (z_{2,max} - z_{1,min})^2 \, \beta_{max} V^b_{max}. \end{aligned}$$

Hence

$$\frac{w_{min,1}}{D_1} (z_{1,max} - z_{1,min})^2 + \frac{w_{min,2}}{D_2} (z_{2,max} - z_{2,min})^2 \leq \frac{1}{2} \mu (z_{2,max} - z_{1,min})^2 \, \beta_{max} V^b_{max}. \tag{57}$$

The RHS of the above inequality is related to the overall support $z_{2,max} - z_{1,min}$ of the data, whereas the terms on the LHS are related to the individual supports $z_{1,max} - z_{1,min}$ and $z_{2,max} - z_{2,min}$ of the two classes in the learnt embedding. Meanwhile, the separation $z_{2,min} - z_{1,max}$ between the two classes is given by the gap between the overall support and the sums of the individual supports. In order to use the above inequality in view of this observation, we first derive a lower bound on the RHS term. Since $z^T D_w z = 1$, we have

$$\begin{aligned} 1 = \sum_i z_i^2 \, d_w(i) &= \sum_{i:\, C_i = 1} z_i^2 \, d_w(i) + \sum_{i:\, C_i = 2} z_i^2 \, d_w(i) \\ &\leq z^2_{1,min} \sum_{i:\, C_i = 1} d_w(i) + z^2_{2,max} \sum_{i:\, C_i = 2} d_w(i) = z^2_{1,min} V_1 + z^2_{2,max} V_2. \end{aligned}$$

This gives

$$z_{1,min}^2 + z_{2,max}^2 \geq \frac{1}{V_{max}}.$$

Hence, we obtain the following lower bound on the overall support

$$(z_{2,max} - z_{1,min})^2 \geq z_{2,max}^2 + z_{1,min}^2 \geq \frac{1}{V_{max}}. \tag{58}$$

Denoting the supports of class 1 and class 2 and the overall support as

$$S_1 = z_{1,max} - z_{1,min}, \qquad S_2 = z_{2,max} - z_{2,min}, \qquad S = z_{2,max} - z_{1,min},$$

we have from (57)

$$\overline{w}_{min}(S_1^2 + S_2^2) \leq \frac{1}{2}\,\mu\, S^2\, \beta_{max} V_{max}^b,$$

which yields the following upper bound on the total support of the two classes

$$S_1 + S_2 \leq \sqrt{2(S_1^2 + S_2^2)} \leq S\sqrt{\frac{\mu \beta_{max} V_{max}^b}{\overline{w}_{min}}}.$$

We can thus lower bound the separation $z_{2,min} - z_{1,max}$ as

$$z_{2,min} - z_{1,max} = S - (S_1 + S_2) \geq S\left(1 - \sqrt{\frac{\mu \beta_{max} V_{max}^b}{\overline{w}_{min}}}\right),$$

provided that $\mu < \overline{w}_{min}/(\beta_{max} V_{max}^b)$. From the lower bound on the overall support in (58), we lower bound the separation as follows

$$z_{2,min} - z_{1,max} \geq \frac{1}{\sqrt{V_{max}}}\left(1 - \sqrt{\frac{\mu \beta_{max} V_{max}^b}{\overline{w}_{min}}}\right).$$

Finally, since the separation of any embedding with dimension $d \geq 1$ is at least as much as the separation $z_{2,min} - z_{1,max}$ of the embedding of dimension $d = 1$, the above lower bound holds for any $d \geq 1$ as well. ■

B.3 Proof of Corollary 15

Proof The one-dimensional embedding z is given as the solution of the constrained optimization problem

$$z = \arg\min N(\xi) \text{ s.t. } D(\xi) = 1,$$

where

$$N(\xi) = \xi^T D_w^{1/2}(L_w - \mu L_b) D_w^{1/2}\xi, \qquad D(\xi) = \xi^T D_w \xi.$$

Defining the Lagrangian function

$$\Lambda(\xi, \lambda) = N(\xi) + \lambda(D(\xi) - 1)$$

at the optimal solution z, we have

$$\nabla_\xi \Lambda = \nabla_\lambda \Lambda = 0,$$

where ∇_ξ and ∇_λ respectively denote the derivatives of Λ with respect to ξ and λ. Thus, at $\xi = z$,

$$\frac{\partial \Lambda}{\partial \xi_i} = \frac{\partial N(\xi)}{\partial \xi_i} + \lambda \frac{\partial D(\xi)}{\partial \xi_i} = 0$$

for all $i = 1, \ldots, N$. From (50), the derivatives of $N(\xi)$ and $D(\xi)$ at z are given by

$$\left.\frac{\partial N(\xi)}{\partial \xi_i}\right|_{\xi=z} = \sum_{j \sim_w i} 2(z_i - z_j) w_{ij} - \mu \sum_{j \sim_b i} 2\left(\sqrt{\beta_i} z_i - \sqrt{\beta_j} z_j\right)\sqrt{\beta_i}\, w_{ij}$$
$$\left.\frac{\partial D(\xi)}{\partial \xi_i}\right|_{\xi=z} = 2\, d_w(i)\, z_i,$$

which yields

$$\sum_{j \sim_w i} (z_i - z_j) w_{ij} - \mu \sum_{j \sim_b i} \left(\sqrt{\beta_i} z_i - \sqrt{\beta_j} z_j\right)\sqrt{\beta_i}\, w_{ij} + \lambda\, d_w(i)\, z_i = 0 \tag{59}$$

for all i. At $i = i_{1,max}$, as z attains its maximal value $z_{1,max}$ for class 1, we have

$$\begin{aligned}\lambda\, d_w(i_{1,max})\, z_{1,max} &= \sum_{j \sim_w i_{1,max}} (z_j - z_{1,max}) w_{i_{1,max} j} \\ &\quad + \mu \sum_{j \sim_b i_{1,max}} \left(\sqrt{\beta_{i_{1,max}}} z_{1,max} - \sqrt{\beta_j} z_j\right)\sqrt{\beta_{i_{1,max}}}\, w_{i_{1,max} j} \\ &\leq -\mu\, \beta_{min}\, (z_{2,min} - z_{1,max})\, d_b(i_{1,max}).\end{aligned}$$

Hence

$$|z_{1,max}| = -z_{1,max} \geq \frac{\mu\, \beta_{min}\, (z_{2,min} - z_{1,max}) d_b(i_{1,max})}{\lambda\, d_w(i_{1,max})} \geq \frac{\mu\, \beta_{min}\, (z_{2,min} - z_{1,max})}{\lambda\, \beta_{max}}. \tag{60}$$

We proceed by deriving an upper bound for λ. The gradients of $N(\xi)$ and $D(\xi)$ are given by

$$\nabla_\xi N = 2D_w^{1/2}(L_w - \mu L_b) D_w^{1/2}\xi, \qquad \nabla_\xi D = 2D_w \xi.$$

From the condition $\nabla_\xi \Lambda = 0$ at $\xi = z$, we have

$$\begin{aligned} D_w^{1/2}(L_w - \mu L_b) D_w^{1/2} z + \lambda D_w z &= 0 \\ (L_w - \mu L_b) y + \lambda y &= 0.\end{aligned}$$

Since $y = D_w^{1/2} z$ is the unit-norm eigenvector of $L_w - \mu L_b$ corresponding to its smallest eigenvalue, the Lagrangian multiplier λ is given by

$$\lambda = -\lambda_{\min}(L_w - \mu L_b).$$

We can lower bound the minimum eigenvalue as

$$\lambda_{\min}(L_w - \mu L_b) \geq \lambda_{\min}(L_w) + \lambda_{\min}(-\mu L_b) = 0 - \mu\lambda_{\max}(L_b) \geq -2\mu$$

since the eigenvalues of a graph Laplacian are upper bounded by 2. This gives $\lambda \leq 2\mu$. Using this upper bound on λ in (60), we obtain

$$|z_{1,max}| \geq \frac{1}{2}\frac{\beta_{min}}{\beta_{max}}(z_{2,min} - z_{1,max}).$$

Repeating the same steps for $i = i_{2,min}$ following (59), one can similarly show that

$$z_{2,min} \geq \frac{1}{2}\frac{\beta_{min}}{\beta_{max}}(z_{2,min} - z_{1,max}).$$

Abstract

Ranking and comparing items is crucial for collecting information about preferences in many areas, from marketing to politics. The Mallows rank model is among the most successful approaches to analyze rank data, but its computational complexity has limited its use to a particular form based on Kendall distance. We develop new computationally tractable methods for Bayesian inference in Mallows models that work with any right-invariant distance. Our method performs inference on the consensus ranking of the items, also when based on partial rankings, such as top-k items or pairwise comparisons. We prove that items that none of the assessors has ranked do not influence the maximum a posteriori consensus ranking, and can therefore be ignored. When assessors are many or heterogeneous, we propose a mixture model for clustering them in homogeneous subgroups, with cluster-specific consensus rankings. We develop approximate stochastic algorithms that allow a fully probabilistic analysis, leading to coherent quantifications of uncertainties. We make probabilistic predictions on the class membership of assessors based on their ranking of just some items, and predict missing individual preferences, as needed in recommendation systems. We test our approach using several experimental and benchmark data sets.

Keywords: Incomplete rankings, Pairwise comparisons, Preference learning with uncertainty, Recommendation systems, Markov Chain Monte Carlo

1. Introduction

Various types of data have ranks as their natural scale. Companies recruit panels to rank novel products, market studies are often based on interviews where competing services or items are compared or ranked. In recent years, analyzing preference data collected over the internet (for example, movies, books, restaurants, political candidates) has been receiving much attention, and often these data are in the form of partial rankings.

Some typical tasks for rank or preference data are: (i) aggregate, merge, summarize multiple individual rankings to estimate the consensus ranking; (ii) predict the ranks of unranked items at individual level; (iii) partition the assessors into classes, each sharing a consensus ranking of the items, and classify new assessors to a class. In this paper we phrase all these tasks (and their combinations) in a unified Bayesian inferential setting, which allows us to also quantify posterior uncertainty of the estimates. Uncertainty evaluations of the estimated preferences and class memberships are a fundamental aspect of information in marketing and decision making. When predictions are too unreliable, actions based on these might better be postponed until more data are available and safer predictions can be made, so as not to unnecessarily annoy users or clients.

There exist many probabilistic models for ranking data which differ both in the data generation mechanism and in the parametric space. Two of the most commonly used are the Plackett-Luce, PL, (Luce, 1959; Plackett, 1975) and the Mallows models (Mallows, 1957). The PL model is a stage-wise probabilistic model on permutations, while the Mallows model is based on a distance function between rankings. Inferring the parameters of the PL distribution is typically done by maximum likelihood estimation, using a minorize/maximize algorithm (Hunter, 2004). A Bayesian approach was first proposed by Guiver and Snelson (2009). Caron and Teh (2012) perform Bayesian inference in a Plackett-Luce model with time-dependent preference probabilities, and further develop the framework in Caron et al. (2014), where a Dirichlet process mixture is used to cluster assessors based on their preferences. The parameters in the PL model are continuous, which gives to this model much flexibility. Volkovs and Zemel (2014) develop a generalization of the PL model, called multinomial preference model, which deals with pairwise preferences, even inconsistent ones, and extends to supervised problems. One difficulty of this method is the use of gradient optimization in a non-convex problem (which can lead to local optima), and the somewhat arbitrary way of imputing missing ranks. Compared to the PL model, the Mallows model has the advantage of being flexible in the choice of the distance function between permutations. It is also versatile in its ability to adapt to different kinds of data (pairwise comparisons, partial rankings). However, for some distances exact inference is very demanding, because the partition function normalizing the model is very expensive to compute. Therefore most work on the Mallows has been limited to a few particular distances, like the Kendall distance, for which the partition function can be computed analytically. Maximum Likelihood inference about the consensus ranking in the Mallows model is generally very difficult, and in many cases NP-hard, which lead to the development of heuristic algorithms. The interesting proposal of Lu and Boutilier (2014) makes use of the Generalized Repeated Insertion Model (GRIM), based on the EM algorithm, and allows also for data in the form of pairwise preferences. Their model focuses on the Kendall distance only, and it provides no uncertainty quantification. Another interesting EM-based approach is Khan et al. (2014), which

is driven by expectation propagation approximate inference, and scales to very large data sets without requiring strong factorization assumptions. Among probabilistic approaches, Meilă and Chen (2010) use Dirichlet process mixtures to perform Bayesian clustering of assessors in the Mallows model, but they again focus on the Kendall distance only. Jacques and Biernacki (2014) also propose clustering based on partial rankings, but in the context of the Insertion Sorting Rank (ISR) model. Hence, the approach is probabilistic but it is far from the general form of the Mallows, even though it has connections with the Mallows with Kendall distance. See Section 5 for a more detailed presentation of related work. For the general background on statistical methods for rank data, we refer to the excellent monograph by Marden (1995), and to the book by Alvo and Yu (2014).

The contributions of this paper are summarized as follows. We develop a Bayesian framework for inference in Mallows models that works with any right-invariant metric. In particular, the method is able to handle some of the right-invariant distances poorly considered in the existing literature, because of their well-known intractability. In this way the main advantage of the Mallows models, namely its flexibility in the choice of the distance, is fully exploited. We propose a Metropolis-Hastings iterative algorithm, which converges to the Bayesian posterior distribution, if the exact partition function is available. In case the exact partition function is not available, we propose to approximate it using an off-line importance sampling scheme, and we document the quality and efficiency of this approximation. Using data augmentation techniques, our method handles incomplete rankings, like the important cases of top-k rankings, pairwise comparisons, and ranks missing at random. For the common situation when the pool of assessors is heterogeneous, and cannot be assumed to share a common consensus, we develop a Bayesian clustering scheme which embeds the Mallows model. Our approach unifies clustering, classification and preference prediction in a single inferential procedure, thus leading to coherent posterior credibility levels of learned rankings and predictions. The probabilistic Bayesian setting allows us to naturally compute complex probabilities of interest, like the probability that an item has consensus rank higher than a given level, or the probability that the consensus rank of an item is higher than that of another item of interest. For incomplete rankings this can be done also at the individual assessor level, allowing for individual recommendations.

In Section 2, we introduce the Bayesian Mallows model for rank data. In Section 2.1, we discuss how the choice of the distance function influences the calculation of the partition function, and Section 2.2 is devoted to the choice of the prior distributions. In Sections 2.3 and 2.4, we show how efficient Bayesian computation can be performed for this model, using a novel leap-and-shift proposal distribution. The tuning of the hyperparameters is discussed in the Supplementary Material, Section 1. In Section 3 we develop and test an importance sampling scheme for computing the partition function, based on a pseudo-likelihood approximation of the Mallows model. We carefully test and study this importance sampling estimation of the partition function (Section 3.1), and the effect of this estimation on inference, both theoretically (Section 3.2) and by simulations (Section 3.3). Section 4 is dedicated to partial rankings and clustering of assessors. In Section 4.1 we extend the Bayesian Mallows approach to partial rankings, and we prove some results on the effects of unranked items on the consensus ranking (Section 4.1.1). Section 4.2 considers data in the form of ordered subsets or pairwise comparisons of items. In Section 4.3 we describe a mixture model to deal with the possible heterogeneity of assessors, finding cluster-

specific consensus rankings. Section 4.4 is dedicated to prediction in a realistic setup, which requires both the cluster assignment and personalized preference learning. We show that our approach works well in a simulation context. In Section 5 we review related methods which have been proposed in the literature, and compare by simulation some algorithms with our procedure (Section 5.1). In Section 6, we then move to the illustration of the performance of our method on real data: the selected case studies illustrate the different incomplete data situations considered. This includes the Sushi (Section 6.3) and Movielens (Section 6.4) benchmark data. Section 7 presents some conclusions and extensions.

2. A Bayesian Mallows Model for Complete Rankings

Assume we have a set of n items, labelled $\mathcal{A} = \{A_1, A_2, \ldots, A_n\}$. We first assume that each of N assessors ranks all items individually with respect to a considered feature. The ordering provided by assessor j is represented by $\mathbf{X}_j$, whose n components are items in $\mathcal{A}$. The item with rank 1 appears as the first element, up to the item with rank n appearing as the n-th element. The observations $\mathbf{X}_1, \ldots, \mathbf{X}_N$ are hence N permutations of the labels in $\mathcal{A}$. Let $R_{ij} = \mathbf{X}_j^{-1}(A_i),\ i = 1, \ldots, n,\ j = 1, \ldots, N$, denote the rank given to item A_i by assessor j, and let $\mathbf{R}_j = (R_{1j}, R_{2j}, \ldots, R_{nj}),\ j = 1, \ldots, N$, denote the ranking (that is the full set of ranks given to the items), of assessor j. Letting $\mathcal{P}_n$ be the set of all permutations of $\{1, \ldots, n\}$, we have $\mathbf{R}_j \in \mathcal{P}_n,\ j = 1, \ldots, N$. Finally, let $d(\cdot, \cdot) : \mathcal{P}_n \times \mathcal{P}_n \to [0, \infty)$ be a distance function between two rankings.

The Mallows model (Mallows, 1957) is a class of non-uniform joint distributions for a ranking $\mathbf{r}$ on $\mathcal{P}_n$, of the form $P(\mathbf{r}|\alpha, \boldsymbol{\rho}) = Z_n(\alpha, \boldsymbol{\rho})^{-1} \exp\{-(\alpha/n) d(\mathbf{r}, \boldsymbol{\rho})\} 1_{\mathcal{P}_n}(\mathbf{r})$, where $\boldsymbol{\rho} \in \mathcal{P}_n$ is the latent consensus ranking, α is a scale parameter, assumed positive for identification purposes, $Z_n(\alpha, \boldsymbol{\rho}) = \sum_{\mathbf{r} \in \mathcal{P}_n} e^{-\frac{\alpha}{n} d(\mathbf{r}, \boldsymbol{\rho})}$ is the partition function, and $1_S(\cdot)$ is the indicator function of the set S. We assume that the N observed rankings $\mathbf{R}_1, \ldots, \mathbf{R}_N$ are conditionally independent given α and $\boldsymbol{\rho}$, and that each of them is distributed according to the Mallows model with these parameters. The likelihood takes then the form

$$P(\mathbf{R}_1, \ldots, \mathbf{R}_N | \alpha, \boldsymbol{\rho}) = \frac{1}{Z_n(\alpha, \boldsymbol{\rho})^N} \exp\left\{ -\frac{\alpha}{n} \sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho}) \right\} \prod_{j=1}^{N} \{1_{\mathcal{P}_n}(\mathbf{R}_j)\}. \tag{1}$$

For a given α, the maximum likelihood estimate of $\boldsymbol{\rho}$ is obtained by computing

$$\underset{\boldsymbol{\rho} \in \mathcal{P}_n}{\operatorname{argmax}} \frac{\exp\left\{ -\frac{\alpha}{n} \sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho}) \right\}}{Z_n(\alpha, \boldsymbol{\rho})^N}. \tag{2}$$

For large n this optimization problem is not feasible, because the space of permutations has $n!$ elements. This has impact both on the computation of $Z_n(\alpha, \boldsymbol{\rho})$, and on the minimization of the sum in the exponential of (2), which is typically NP-hard (Bartholdi et al., 1989).

2.1 Distance Measures and Partition Function

Right-invariant distances (Diaconis, 1988) play an important role in the Mallows models. A right-invariant distance is unaffected by a relabelling of the items, which is a reasonable assumption in many situations. For any right-invariant distance it holds $d(\boldsymbol{\rho_1}, \boldsymbol{\rho_2}) =$

$d(\boldsymbol{\rho_1}\boldsymbol{\rho_2}^{-1}, \mathbf{1}_n)$, where $\mathbf{1}_n = \{1, 2, ..., n\}$, and therefore the partition function $Z_n(\alpha, \boldsymbol{\rho})$ of (1) is independent on the latent consensus ranking $\boldsymbol{\rho}$. We write $Z_n(\alpha, \boldsymbol{\rho}) = Z_n(\alpha) = \sum_{\mathbf{r}\in\mathcal{P}_n} \exp\{-\frac{\alpha}{n} d(\mathbf{r}, \mathbf{1}_n)\}$. All distances considered in this paper are right-invariant. Importantly, since the partition function $Z_n(\alpha)$ does not depend on the latent consensus $\boldsymbol{\rho}$, it can be computed off-line over a grid for α, given n (details in Section 3). For some choices of right-invariant distances, the partition function can be analytically computed. For this reason, most of the literature considers the Mallows model with Kendall distance (Lu and Boutilier, 2014; Meilă and Chen, 2010), for which a closed form of $Z_n(\alpha)$ is given in Fligner and Verducci (1986), or with the Hamming (Irurozki et al., 2014) and Cayley (Irurozki et al., 2016b) distances. There are important and natural right-invariant distances for which the computation of the partition function is not feasible, in particular the footrule (l_1) and the Spearman's (l_2) distances. For precise definitions of all distances involved in the Mallows model we refer to Marden (1995). Following Irurozki et al. (2016a), $Z_n(\alpha)$ can be written in a more convenient way. Since $d(\mathbf{r}, \mathbf{1}_n)$ takes only the finite number of discrete values $\mathcal{D} = \{d_1, ..., d_a\}$, where a depends on n and on the distance $d(\cdot, \cdot)$, we define $L_i = \{\mathbf{r} \in \mathcal{P}_n : d(\mathbf{r}, \mathbf{1}_n) = d_i\} \subset \mathcal{P}_n$, $i = 1, ..., a$, to be the set of permutations at the same given distance from $\mathbf{1}_n$, and $|L_i|$ corresponds to its cardinality. Then

$$Z_n(\alpha) = \sum_{d_i\in\mathcal{D}} |L_i| \exp\{-(\alpha/n)d_i\}. \tag{3}$$

In order to compute $Z_n(\alpha)$ one thus needs $|L_i|$, for all values $d_i \in \mathcal{D}$. In the case of the footrule distance, the set $\mathcal{D}$ includes all even numbers, from 0 to $\lfloor n^2/2 \rfloor$, and $|L_i|$ corresponds to the sequence A062869 available for $n \leq 50$ on the On-Line Encyclopedia of Integer Sequences (OEIS) (Sloane, 2017). In the case of Spearman's distance, the set $\mathcal{D}$ includes all even numbers, from 0 to $2\binom{n}{3}$, and $|L_i|$ corresponds to the sequence A175929 available for $n \leq 14$ in the OEIS. When the partition function is needed for larger values of n, we suggest an importance sampling scheme which efficiently approximates $Z_n(\alpha)$ to an arbitrary precision (see Section 3). An interesting asymptotic approximation for $Z_n(\alpha)$, when $n \to \infty$, has been studied in Mukherjee (2016), and we apply it in an example where $n = 200$ (see Section 6.4, and Section 2 in the Supplementary Material).

2.2 Prior Distributions

To complete the specification of the Bayesian model for the rankings $\mathbf{R}_1, \ldots, \mathbf{R}_N$, a prior for its parameters is needed. We assume a priori that α and $\boldsymbol{\rho}$ are independent.

An obvious choice for the prior for $\boldsymbol{\rho}$ in the context of the Mallows likelihood is to utilize the Mallows model family also in setting up a prior for $\boldsymbol{\rho}$, and let $\pi(\boldsymbol{\rho}) = \pi(\boldsymbol{\rho}|\alpha_0, \boldsymbol{\rho}_0) \propto \exp\left\{-\frac{\alpha_0}{n} d(\boldsymbol{\rho}, \boldsymbol{\rho}_0)\right\}$. Here α_0 and $\boldsymbol{\rho}_0$ are fixed hyperparameters, with $\boldsymbol{\rho}_0$ specifying the ranking that is a priori thought most likely, and α_0 controlling the tightness of the prior around $\boldsymbol{\rho}_0$. Since α_0 is fixed, $Z_n(\alpha_0)$ is a constant. Note that combining the likelihood with the prior $\pi(\boldsymbol{\rho}|\alpha_0, \boldsymbol{\rho}_0)$ above has the same effect on inference as involving an additional hypothetical assessor $j = 0$, say, who then provides the ranking $\mathbf{R}_0 = \boldsymbol{\rho}_0$ as data, with α_0 fixed.

If we were to elicit a value for α_0, we could reason as follows. Consider, for $\boldsymbol{\rho}_0$ fixed, the prior expectation $g_n(\alpha_0) := E_{\pi(\boldsymbol{\rho})}(d(\boldsymbol{\rho}, \boldsymbol{\rho}_0)|\alpha_0, \boldsymbol{\rho}_0)$. Because of the assumed right invariance

of the distance $d(\cdot, \cdot)$, this expectation is independent of $\boldsymbol{\rho}_0$, which is why $g_n(\cdot)$ depends only on α_0. Moreover, $g_n(\alpha_0)$ is obviously decreasing in α_0. For the footrule and Spearman distances, which are defined as sums of item specific deviations $|\rho_{0i} - \rho_i|$ or $|\rho_{0i} - \rho_i|^2$, $g_n(\alpha_0)$ can be interpreted as the expected (average, per item) error in the prior ranking $\pi(\boldsymbol{\rho}|\alpha_0, \boldsymbol{\rho}_0)$ of the consensus. A value for α_0 is now elicited by first choosing a target level τ_0, say, which would realistically correspond to such an a priori expected error size, and then finding the value α_0 such that $g_n(\alpha_0) = \tau_0$. This procedure requires numerical evaluation of the function $g_n(\alpha_0)$ over a range of suitable α_0 values. In this paper, we employ only the uniform prior $\pi(\boldsymbol{\rho}) = (n!)^{-1} 1_{\mathcal{P}_n}(\boldsymbol{\rho})$ in the space $\mathcal{P}_n$ of $n-$dimensional permutations, corresponding to $\alpha_0 = 0$.

For the scale parameter α we have in this paper used a truncated exponential prior, with density $\pi(\alpha|\lambda) = \lambda e^{-\lambda\alpha} 1_{[0,\alpha_{\max}]}(\alpha)/(1 - e^{-\lambda\alpha_{\max}})$, where the cut-off point $\alpha_{\max} < \infty$ is large compared to the values supported by the data. In practice, in the computations involving sampling of values for α, truncation was never applied. We show in Figure 3 of Section 3.3 on simulated data, that the inferences on $\boldsymbol{\rho}$ are almost completely independent of the choice of the value of λ. Also a theoretical argument for this is provided in that same section, although it is tailored more specifically to the numerical approximations of $Z_n(\alpha)$. For these reasons, in all our data analyses, we assigned λ a fixed value. We chose values for λ close to 0, depending on the complexity of the data, thus implying a prior density for α which is quite flat in the region supported in practice by the likelihood. If a more elaborate elicitation of the prior for α for some reason were preferred, this could be achieved by computing, by numerical integration, values of the function $E_{\pi(\alpha)}(g_n(\alpha)|\lambda)$, selecting a realistic target τ, and solving $E_{\pi(\alpha)}(g_n(\alpha)|\lambda) = \tau$ for λ. In a similar fashion as earlier, also $E_{\pi(\alpha)}(g_n(\alpha)|\lambda)$ can be interpreted as an expected (average, per item) error in the ranking, but now by *errors* is meant those made by the assessors, relative to the consensus, and expectation is with respect to the prior $\pi(\alpha|\lambda)$.

2.3 Inference

Given the prior distributions $\pi(\boldsymbol{\rho})$ and $\pi(\alpha)$, and assuming prior independence of these variables, the posterior distribution for $\boldsymbol{\rho}$ and α is given by

$$P(\boldsymbol{\rho}, \alpha|\mathbf{R}_1, \ldots, \mathbf{R}_N) \propto \frac{\pi(\boldsymbol{\rho})\pi(\alpha)}{Z_n(\alpha)^N} \exp\left\{-\frac{\alpha}{n}\sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho})\right\}. \tag{4}$$

Often one is interested in computing posterior summaries of this distribution. One such summary is the marginal posterior mode of $\boldsymbol{\rho}$ (the maximum a posteriori, MAP) from (4), which does not depend on α, and in case of uniform prior for $\boldsymbol{\rho}$ coincides with the ML estimator of $\boldsymbol{\rho}$ in (2). The marginal posterior distribution of $\boldsymbol{\rho}$ is given by

$$P(\boldsymbol{\rho}|\mathbf{R}_1, \ldots, \mathbf{R}_N) \propto \pi(\boldsymbol{\rho}) \int_0^\infty \frac{\pi(\alpha)}{Z_n(\alpha)^N} \exp\left\{-\frac{\alpha}{n}\sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho})\right\} \mathrm{d}\alpha. \tag{5}$$

Given the data, $\mathbf{R} = \{\mathbf{R}_1, \ldots, \mathbf{R}_N\}$ and the consensus ranking $\boldsymbol{\rho}$, the sum of distances, $T(\boldsymbol{\rho}, \mathbf{R}) = \sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho})$, takes only a finite set of discrete values $\{t_1, t_2, ...t_m\}$, where m

depends on the distance $d(\cdot,\cdot)$, on the sample size N, and on n. Therefore, the set of all permutations $\mathcal{P}_n$ can be partitioned into the sets $H_i = \{\boldsymbol{r} \in \mathcal{P}_n : T(\boldsymbol{r},\ \mathbf{R}) = t_i\}$ for each distance t_i. These sets are level sets of the posterior marginal distribution in (5), as all $\boldsymbol{r} \in H_i$ have the same posterior marginal probability. The level sets do not depend on α but the posterior distribution shared by the permutations in each set does.

In applications, the interest often lies in computing posterior probabilities of more complex functions of the consensus $\boldsymbol{\rho}$, for example the posterior probability that a certain item has consensus rank lower than a given level ("among the top 5", say), or that the consensus rank of a certain item is higher than the consensus rank of another one. These probabilities cannot be readily obtained within the maximum likelihood approach, while the Bayesian setting very naturally allows to approximate any posterior summary of interest by means of a Markov Chain Monte Carlo algorithm, which at convergence samples from the posterior distribution (4).

2.4 Metropolis-Hastings Algorithm for Complete Rankings

In order to obtain samples from the posterior in equation (4), we iterate between two steps. In one step we update the consensus ranking. Starting with $\alpha \geq 0$ and $\boldsymbol{\rho} \in \mathcal{P}_n$, we first update $\boldsymbol{\rho}$ by proposing $\boldsymbol{\rho}'$ according to a distribution which is centered around the current rank $\boldsymbol{\rho}$.

Definition 1 *Leap-and-Shift Proposal (L&S). Fix an integer $L \in \{1,\dots,\lfloor (n-1)/2 \rfloor\}$ and draw a random number $u \sim \mathcal{U}\{1,\dots,n\}$. Define, for a given $\boldsymbol{\rho}$, the set of integers $\mathcal{S} = \{\max(1,\rho_u - L), \min(n,\rho_u + L)\} \setminus \{\rho_u\}$, $\mathcal{S} \subseteq \{1,\dots,n\}$, and draw a random number r uniformly in $\mathcal{S}$. Let $\boldsymbol{\rho}^* \in \{1,2,...n\}^n$ have elements $\rho^*_u = r$ and $\rho^*_i = \rho_i$ for $i \in \{1,\dots,n\} \setminus \{u\}$, constituting the leap step. Now, define $\Delta = \rho^*_u - \rho_u$ and the proposed $\boldsymbol{\rho}' \in \mathcal{P}_n$ with elements*

$$\rho'_i = \begin{cases} \rho^*_u & \text{if } \rho_i = \rho_u \\ \rho_i - 1 & \text{if } \rho_u < \rho_i \leq \rho^*_u \text{ and } \Delta > 0 \\ \rho_i + 1 & \text{if } \rho_u > \rho_i \geq \rho^*_u \text{ and } \Delta < 0 \\ \rho_i & \text{else}\ , \end{cases}$$

for $i = 1,\dots,n$, constituting the shift step.

The probability mass function associated to the transition is given by

$$\begin{aligned} P_L(\boldsymbol{\rho}'|\boldsymbol{\rho}) &= \sum_{u=1}^{n} P_L(\boldsymbol{\rho}'|U=u,\boldsymbol{\rho}) P(U=u) \\ &= \frac{1}{n}\sum_{u=1}^{n}\left\{ 1_{\{\boldsymbol{\rho}_{-u}\}}(\boldsymbol{\rho}^*_{-u}) \cdot 1_{\{0<|\rho_u - \rho^*_u|\leq L\}}(\boldsymbol{\rho}^*_u) \cdot \left[\frac{1_{\{L+1,\dots,n-L\}}(\boldsymbol{\rho}_u)}{2L} + \sum_{l=1}^{L} \frac{1_{\{l\}}(\boldsymbol{\rho}_u) + 1_{\{n-l+1\}}(\boldsymbol{\rho}_u)}{L+l-1} \right] \right\} \\ &+ \frac{1}{n}\sum_{u=1}^{n}\left\{ 1_{\{\boldsymbol{\rho}_{-u}\}}(\boldsymbol{\rho}^*_{-u}) \cdot 1_{\{|\rho_u - \rho^*_u|=1\}}(\boldsymbol{\rho}^*_u) \cdot \left[\frac{1_{\{L+1,\dots,n-L\}}(\boldsymbol{\rho}^*_u)}{2L} + \sum_{l=1}^{L} \frac{1_{\{l\}}(\boldsymbol{\rho}^*_u) + 1_{\{n-l+1\}}(\boldsymbol{\rho}^*_u)}{L+l-1} \right] \right\}, \end{aligned}$$

where $\boldsymbol{\rho}_{-u} = \{\rho_i;\ i \neq u\}$.

Proposition 1 *The leap-and-shift proposal $\boldsymbol{\rho}' \in \mathcal{P}_n$ is a local perturbation of $\boldsymbol{\rho}$, separated from $\boldsymbol{\rho}$ by a Ulam distance 1 .*

Proof From the definition and by construction, $\boldsymbol{\rho}^* \notin \mathcal{P}_n$, since there exist two indices $i \neq j$ such that $\rho^*_i = \rho^*_j$. The shift of the ranks by Δ brings $\boldsymbol{\rho}^*$ to $\boldsymbol{\rho}'$ back into $\mathcal{P}_n$. The Ulam distance $d(\boldsymbol{\rho},\boldsymbol{\rho}')$ is the number of edit operations needed to convert $\boldsymbol{\rho}$ to $\boldsymbol{\rho}'$, where each edit operation involves deleting a character and inserting it in a new place. This is equal to 1, following Gopalan et al. (2006). ■

The acceptance probability when updating $\boldsymbol{\rho}$ in the Metropolis-Hastings algorithm is

$$\min\left\{1, \frac{P_L(\boldsymbol{\rho}|\boldsymbol{\rho}')\pi(\boldsymbol{\rho}')}{P_L(\boldsymbol{\rho}'|\boldsymbol{\rho})\pi(\boldsymbol{\rho})} \exp\left[-\frac{\alpha}{n}\sum_{j=1}^{N}\left\{ d(\mathbf{R}_j,\boldsymbol{\rho}') - d(\mathbf{R}_j,\boldsymbol{\rho}) \right\} \right] \right\}. \tag{6}$$

The leap-and-shift proposal is not symmetric, thus the ratio $P_L(\boldsymbol{\rho}|\boldsymbol{\rho}')/P_L(\boldsymbol{\rho}'|\boldsymbol{\rho})$ does not cancel in (6). The parameter L is used for tuning this acceptance probability.

The term $\sum_{j=1}^{N}\{d(\mathbf{R}_j,\boldsymbol{\rho}') - d(\mathbf{R}_j,\boldsymbol{\rho})\}$ in (6) can be computed efficiently, since most elements of $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ are equal. Let $\rho_i = \rho'_i$ for $i \in E \subset \{1,\dots,n\}$, and $\rho_i \neq \rho'_i$ for $i \in E^c$. For the footrule and Spearman distances, we then have

$$\sum_{j=1}^{N}\left\{ d(\mathbf{R}_j,\boldsymbol{\rho}') - d(\mathbf{R}_j,\boldsymbol{\rho}) \right\} = \sum_{j=1}^{N}\left\{ \sum_{i\in E^c} |R_{ij} - \rho'_i|^p - \sum_{i\in E^c} |R_{ij} - \rho_i|^p \right\}, \tag{7}$$

for $p \in \{1,2\}$. For the Kendall distance, instead, we get

$$\begin{aligned} &\sum_{j=1}^{N}\left\{ d(\mathbf{R}_j,\boldsymbol{\rho}') - d(\mathbf{R}_j,\boldsymbol{\rho}) \right\} = \\ &= \sum_{j=1}^{N}\left\{ \sum_{1\leq k<l\leq n} 1\left[(R_{kj} - R_{lj})(\rho'_k - \rho'_l) > 0 \right] - 1\left[(R_{kj} - R_{lj})(\rho_k - \rho_l) > 0 \right] \right\} \\ &= \sum_{j=1}^{N}\left\{ \sum_{k\in E^c\setminus\{n\}} \sum_{l\in\{E^c\cap\{l>k\}\}} 1\left[(R_{kj} - R_{lj})(\rho'_k - \rho'_l) > 0 \right] - 1\left[(R_{kj} - R_{lj})(\rho_k - \rho_l) > 0 \right] \right\}. \end{aligned}$$

Hence, by storing the set E^c at each MCMC iteration, the computation of (6) involves a sum over fewer terms, speeding up the algorithm consistently.

The second step of the algorithm updates the value of α. We sample a proposal α' from a lognormal distribution $\log\mathcal{N}(\log(\alpha),\sigma^2_\alpha)$ and accept it with probability

$$\min\left\{1, \frac{Z_n(\alpha)^N \pi(\alpha')\alpha'}{Z_n(\alpha')^N \pi(\alpha)\alpha} \exp\left[-\frac{(\alpha'-\alpha)}{n}\sum_{j=1}^{N} d(\mathbf{R}_j,\boldsymbol{\rho}) \right] \right\}, \tag{8}$$

where σ^2_α can be tuned to obtain a desired acceptance probability. A further parameter, named α_{jump}, can be used to update α only every α_{jump} updates of $\boldsymbol{\rho}$: the possibility to

tune this parameter ensures a better mixing of the MCMC in the different sparse data applications. The above described MCMC algorithm is summarized as Algorithm 1 of Appendix B. Note that the MCMC Algorithm 1 using the exact partition function $Z_n(\alpha)$ samples from the Mallows posterior in equation (4), as the number of MCMC iterations tends to infinity.

Section 3 investigates approximations of $Z_n(\alpha)$, and how they affect the MCMC and the estimate of the consensus $\boldsymbol{\rho}$. In Section 1 of the Supplementary Material we instead focus on aspects related to the practical choices involved in the use of our MCMC algorithm, and in particular we aim at defining possible strategies for tuning the MCMC parameters L and σ_α.

3. Approximating the Partition Function $Z_n(\alpha)$ via Off-line Importance Sampling

For Kendall's, Hamming and Cayley distances, the partition function $Z_n(\alpha)$ is available in close form, but this is not the case for footrule and Spearman distances. To handle these cases, we propose an approximation of the partition function $Z_n(\alpha)$ based on importance sampling. Since we focus on right-invariant distances, the partition function does not depend on $\boldsymbol{\rho}$. Hence, we can obtain an off-line approximation of the partition function on a grid of α values, interpolate it to yield an estimate of $Z_n(\alpha)$ over a continuous range, and then read off needed values to compute the acceptance probabilities very rapidly.

We study the convergence of the importance sampler theoretically (Section 3.2) and numerically (Sections 3.1, 3.3), with a series of experiments aimed at demonstrating the quality of the approximation, and its impact in inference. We here show the results obtained with the footrule distance, but we obtained similar results with the Spearman distance. We also summarize in the Supplementary Material (Section 2) a further possible approximation of $Z_n(\alpha)$, namely the asymptotic proposal in Mukherjee (2016).

We briefly discuss the pseudo-marginal approaches for tackling intractable Metropolis-Hastings ratios, which could in principle be an interesting alternative. We refer to Beaumont (2003), Andrieu and Roberts (2009), and Murray et al. (2012) for a full description of the central methodologies. The idea is to replace $P(\boldsymbol{\rho}, \alpha|\mathbf{R})$ in (4) with a non-negative unbiased estimator $\hat{P}$, such that for some $C > 0$ we have $\mathbb{E}[\hat{P}] = CP$. The approximate acceptance ratio then uses $\hat{P}$, but this results in an algorithm still targeting the exact posterior. An unbiased estimate of the posterior P can be obtained via importance sampling if it is possible to simulate directly from the likelihood. This is not the case in our model, as there are no algorithms available to sample from the Mallows model with, say, the footrule distance. Neither is use of exact simulation possible for our model. The approach in Murray et al. (2012) extends the model by introducing an auxiliary variable, and uses a proposal distribution in the MCMC such that the partition functions cancel. A useful proposal for this purpose would in our case be based on the Mallows likelihood, so that again one would need to be able to sample from it, which is not feasible.

Our suggestion is instead to estimate the partition function directly, using an Importance Sampling (IS) approach. For K rank vectors $\mathbf{R}^1, \ldots, \mathbf{R}^K$ sampled from an IS auxiliary

distribution $q(\mathbf{R})$, the unbiased IS estimate of $Z_n(\alpha)$ is given by

$$\hat{Z}_n(\alpha) = K^{-1} \sum_{k=1}^{K} \exp\{-(\alpha/n) d(\mathbf{R}^k, \mathbf{1}_n)\} q(\mathbf{R}^k)^{-1}. \tag{9}$$

The more $q(\mathbf{R})$ resembles the Mallows likelihood (1), the smaller is the variance of $\hat{Z}_n(\alpha)$. On the other hand, it must be computationally feasible to sample from $q(\mathbf{R})$. We use the following pseudo-likelihood approximation of the target (1). Let $\{i_1, \ldots, i_n\}$ be a uniform sample from $\mathcal{P}_n$, which gives the order of the pseudo-likelihood factorization. Then

$$P(\mathbf{R}|\mathbf{1}_n) = P(R_{i_1}|R_{i_2}, \ldots, R_{i_n}, \mathbf{1}_n) P(R_{i_2}|R_{i_3}, \ldots, R_{i_n}, \mathbf{1}_n) \cdots P(R_{i_{n-1}}|R_{i_n}, \mathbf{1}_n) P(R_{i_n}|\mathbf{1}_n),$$

and the conditional distributions are given by

$$\begin{aligned}
P\left(R_{i_n}|\mathbf{1}_n\right) &= \frac{\exp\left\{-(\alpha/n) d\left(R_{i_n}, i_n\right)\right\} \cdot 1_{[1,\ldots,n]}(R_{i_n})}{\sum_{r_n \in \{1,\ldots,n\}} \exp\left\{-(\alpha/n) d\left(r_n, i_n\right)\right\}}, \\
P\left(R_{i_{n-1}}|R_{i_n}, \mathbf{1}_n\right) &= \frac{\exp\left\{-(\alpha/n) d\left(R_{i_{n-1}}, i_{n-1}\right)\right\} \cdot 1_{[\{1,\ldots,n\}\setminus\{R_{i_n}\}]}(R_{i_{n-1}})}{\sum_{r_{n-1} \in \{1,\ldots,n\}\setminus\{R_{i_n}\}} \exp\left\{-(\alpha/n) d\left(r_{n-1}, i_{n-1}\right)\right\}}, \\
&\vdots \\
P\left(R_{i_2}|R_{i_3}, \ldots, R_{i_n}, \mathbf{1}_n\right) &= \frac{\exp\left\{-(\alpha/n) d\left(R_{i_2}, i_2\right)\right\} \cdot 1_{[\{1,\ldots,n\}\setminus\{R_{i_3},\ldots,R_{i_n}\}]}(R_{i_2})}{\sum_{r_2 \in \{1,\ldots,n\}\setminus\{R_{i_3},\ldots,R_{i_n}\}} \exp\left\{-(\alpha/n) d\left(r_2, i_2\right)\right\}}, \\
P\left(R_{i_1}|R_{i_2}, \ldots, R_{i_n}, \mathbf{1}_n\right) &= 1_{[\{1,\ldots,n\}\setminus\{R_{i_2},\ldots,R_{i_n}\}]}(R_{i_1}).
\end{aligned}$$

Each factor is a simple univariate distribution. We sample R_{i_n} first, and then conditionally on that, $R_{i_{n-1}}$ and so on. The k-th full sample $\mathbf{R}^k$ has probability $q(\mathbf{R}^k) = P(R^k_{i_n}|\mathbf{1}_n)$ $P(R^k_{i_{n-1}}|R^k_{i_n}, \mathbf{1}_n) \cdots P(R^k_{i_2}|R^k_{i_3}, \ldots, R^k_{i_n}, \mathbf{1}_n)$. We observe that this pseudo-likelihood construction is similar to the sequential representation of the Plackett-Luce model with a Mallows parametrization of probabilities.

Note that, in principle, we could sample rankings $\mathbf{R}^k$ from the Mallows model with a different distance than the one of the target model (for example Kendall), or use the pseudo-likelihood approach with a different "proposal distance" other than the target distance. We experimented with these alternatives, but keeping the pseudo-likelihood with the same distance as the one in the target was most accurate and efficient (results not shown). In what follows the distance in (9) is the same as the distance in (4).

3.1 Testing the Importance Sampler

We experimented by increasing the number K of importance samples in powers of ten, over a discrete grid of 100 equally spaced α values between 0.01 and 10 (this is the range of α which turned out to be relevant in all our applications, typically $\alpha < 5$). We produced a smooth partition function simply using a polynomial of degree 10. The ratio $\hat{Z}^K_n(\alpha)/Z_n(\alpha)$ as a function of α is shown in Figure 1 for $n = 10, 20, 50$ and when using different values of K: the ratio quickly approaches 1 when increasing K; for larger n, a larger K is needed to ensure precision, but $K = 10^6$ seems enough to give very precise estimates.

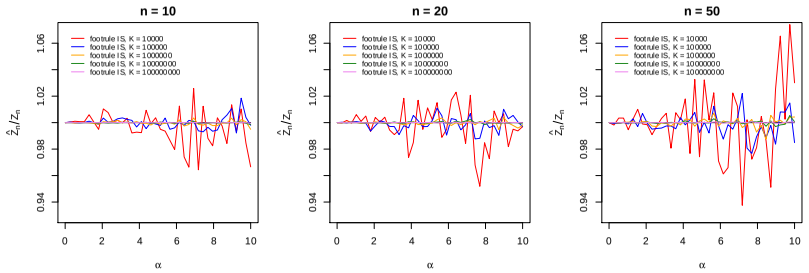

Figure 1: Ratio of the approximate partition function computed via IS to the exact, $\hat{Z}_n(\alpha)/Z_n(\alpha)$, as a function of α, when using the footrule distance. From left to right, $n = 10, 20, 50$; different colors refer to different values of K, as stated in the legend.

K	10^2	10^3	10^4	10^5	10^6	10^7	10^8
$n = 75$	152.036	0.921	0.373	0.084	0.056	0.005	0.004
$n = 100$	67.487	1.709	0.355	0.187	0.045	0.018	0.004

Table 1: Approximation of the partition function via the IS for the footrule model: maximum relative error ϵ_K from equation (10), between the current and the previous K, for $n = 75$ and 100.

When n is larger than 50, no exact expression for $Z_n(\alpha)$ is available. Then, we directly compare the estimated $\hat{Z}_n^K(\alpha)$ for increasing K, to check whether the estimates stabilize. We thus inspect the maximum relative error

$$\epsilon_K = \max_{\alpha} \left[\frac{\left| \hat{Z}_n^K(\alpha) - \hat{Z}_n^{K/10}(\alpha) \right|}{\left| \hat{Z}_n^{K/10}(\alpha) \right|} \right] \tag{10}$$

for $K = 10^2, \ldots, 10^8$. Results are shown in Table 1 for $n = 75$ and 100. For both values of n we see that the estimates quickly stabilize, and $K = 10^6$ appears to give good approximations. The computations shown here were performed on a desktop computer, and the off-line computation with $K = 10^6$ samples for $n = 10$ took less than 15 minutes, with no efforts for parallelizing the algorithm, which would be easy and beneficial. $K = 10^6$ samples for $n = 100$ were obtained on a 64-cores computing cluster in 12 minutes.

3.2 Effect of $\hat{Z}_n(\alpha)$ on the MCMC

In this Section we report theoretical results regarding the convergence of the MCMC, when using the IS approximation of the partition function.

Proposition 2 *Algorithm 1 of Appendix B using $\hat{Z}_n(\alpha)$ in (9) instead of $Z_n(\alpha)$ converges to the posterior distribution proportional to*

$$\frac{1}{\hat{C}(\mathbf{R})} \pi(\boldsymbol{\rho}) \pi(\alpha) \hat{Z}_n(\alpha)^{-N} \exp\left\{ -\frac{\alpha}{n} \sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho}) \right\}, \tag{11}$$

with the normalizing factor $\hat{C}(\mathbf{R}) = \int \frac{\pi(\alpha)}{\hat{Z}_n(\alpha)^N} \sum_{\boldsymbol{\rho} \in \mathcal{P}_n} \pi(\boldsymbol{\rho}) \exp\left\{ -\frac{\alpha}{n} \sum_{j=1}^{N} d(\mathbf{R}_j, \boldsymbol{\rho}) \right\} d\alpha$.

Proof The acceptance probability of the MCMC in Algorithm 1 with the approximate partition function is given by (8) using $\hat{Z}_n(\alpha)$ in (9) instead of $Z_n(\alpha)$, which is exactly the acceptance probability needed for (11). ■

That $\hat{C}(\mathbf{R}) < \infty$ is an obvious consequence of our assumption, in Section 2.2, that the prior $\pi(\alpha)$ is supported by a finite interval $[0, \alpha_{\max}]$. The IS approximation $\hat{Z}_n(\alpha)$ converges to $Z_n(\alpha)$ as the number K of IS samples converges to infinity. In order to study this limit, let us change the notation to explicitly show this dependence and write $\hat{Z}_n^K(\alpha)$. Clearly, the approximate posterior (11) converges to the correct posterior (4) if K increases with N, $K = K(N)$, and

$$\lim_{N \to \infty} \left(\frac{\hat{Z}_n^{K(N)}(\alpha)}{Z_n(\alpha)} \right)^N = 1, \quad \text{for all } \alpha. \tag{12}$$

Proposition 3 *There exists a factor $c(\alpha, n, d(\cdot,\cdot))$ not depending on N, such that, if $K = K(N)$ tends to infinity as $N \to \infty$ faster than $c(\alpha, n, d(\cdot,\cdot)) \cdot N^2$, then (12) holds.*

Proof We see that

$$\left(\frac{\hat{Z}_n^{K(N)}(\alpha)}{Z_n(\alpha)} \right)^N = \exp\left\{ N \log\left(1 + \frac{\hat{Z}_n^{K(N)}(\alpha) - Z_n(\alpha)}{Z_n(\alpha)} \right) \right\}$$

tends to 1 in probability as $K(N) \to \infty$ when $N \to \infty$ if

$$\frac{\hat{Z}_n^{K(N)}(\alpha) - Z_n(\alpha)}{Z_n(\alpha)} \tag{13}$$

tends to 0 in probability faster than $1/N$. Since (9) is a sum of i.i.d. variables, there exists a constant $c = c(\alpha, n, d(\cdot,\cdot))$ depending on α, n and the distance $d(\cdot,\cdot)$ (but not on N) such that

$$\sqrt{K(N)} (\hat{Z}_n^{K(N)}(\alpha) - Z_n(\alpha)) \xrightarrow{\mathcal{L}} \mathcal{N}(0, c^2),$$

in law as $K(N) \to \infty$. Therefore, for (13) tending to 0 faster than $1/N$, it is sufficient that $K(N)$ grows faster than N^2. The speed of convergence to 1 of (12) depends on $c = c(\alpha, n, d(\cdot,\cdot))$. ■

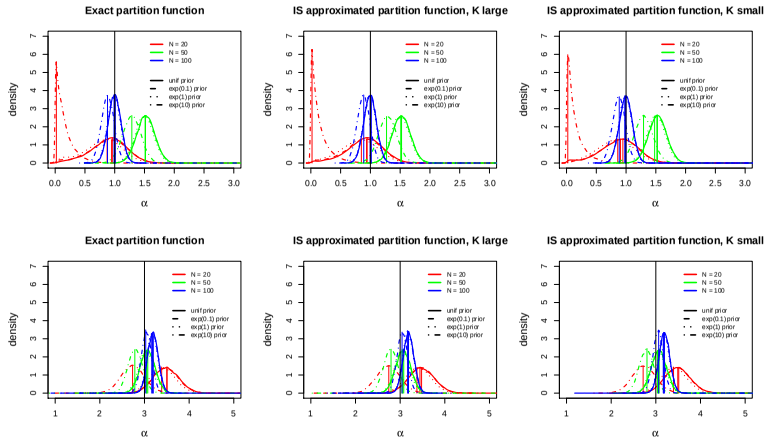

Figure 2: Results of the simulations described in Section 3.3, when $n = 20$. In each plot, posterior density of α (the black vertical line indicates α_{true}) obtained for various choices of N (different colors), and for different choices of the prior for α (different line types), as stated in the legend. From left to right, MCMC run with the exact $Z_n(\alpha)$, with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^8$, and with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^4$. First row: $\alpha_{\text{true}} = 1$; second row: $\alpha_{\text{true}} = 3$.

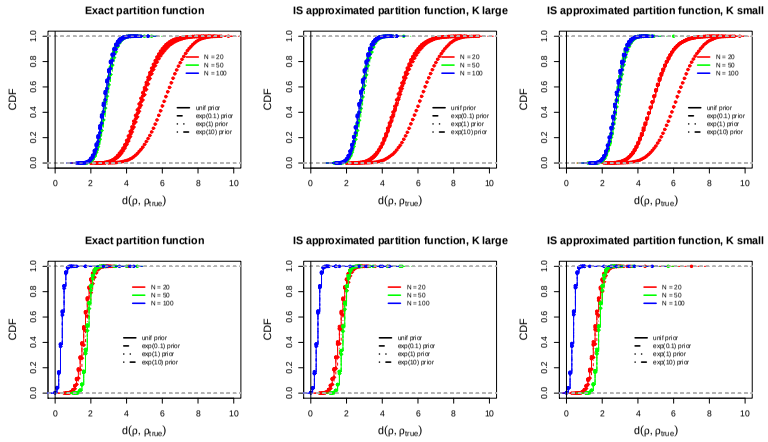

Figure 3: Results of the simulations described in Section 3.3, when $n = 20$. In each plot, posterior CDF of $d(\boldsymbol{\rho}, \boldsymbol{\rho}_{\text{true}})$ obtained for various choices of N (different colors), and for different choices of the prior for α (different line types), as stated in the legend. From left to right, MCMC run with the exact $Z_n(\alpha)$, with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^8$, and with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^4$. First row: $\alpha_{\text{true}} = 1$; second row: $\alpha_{\text{true}} = 3$.

3.3 Testing Approximations of the MCMC in Inference

We report results from extensive simulation experiments carried out in several different parameter settings, to investigate if our algorithm provides correct posterior inferences. In addition, we study the sensitivity of the posterior distributions to differences in the prior specifications, and demonstrate their increased precision when the sample size N grows. We explore the robustness of inference when using approximations of the partition function $Z_n(\alpha)$, both when obtained by applying our IS approach, and when using, for large n, the asymptotic approximation $Z_{\text{lim}}(\alpha)$ proposed in Mukherjee (2016). We focus here on the footrule distance since it allows us to explore all these different settings, being also the preferred distance in the experiments reported in Section 6. Some model parameters are kept fixed in the various cases: $\alpha_{\text{jump}} = 10$, $\sigma_\alpha = 0.15$, and $L = n/5$ (for the tuning of the two latter parameters, see the simulation study in the Supplementary Material, Section 1). Computing times for the simulations, performed on a laptop computer, varied depending on the value of n and N, from a minimum of $24''$ in the smallest case with $n = 20$ and $N = 20$, to a maximum of $3'22''$ for $n = 100$ and $N = 1000$.

First, we generated data from a Mallows model with $n = 20$ items, using samples from $N = 20, 50$, and 100 assessors, a setting of moderate complexity. The value of α_{true} was chosen to be either 1 or 3, and $\boldsymbol{\rho}_{\text{true}}$ was fixed at $(1, \ldots, n)$. To generate the data, we run the MCMC sampler (see Appendix C) for 10^5 burn-in iterations, and collected one sample every 100 iterations after that (these settings were kept in all data generations). In the analysis, we considered the performance of the method when using the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^4$ and 10^8, then comparing the results with those based on the exact $Z_n(\alpha)$. In each case, we run the MCMC for 10^6 iterations, with 10^5 iterations for burn-in. Finally, we varied the prior for α to be either the nonintegrable uniform or the exponential using hyperparameter values $\lambda = 0.1, 1$ and 10. The results are shown in Figures 2 for α and 3 for $\boldsymbol{\rho}$. As expected, we can see the precision and the accuracy of the marginal posterior distributions increasing, both for α and $\boldsymbol{\rho}$, with N becoming larger. For smaller values of α_{true}, the marginal posterior for α is more dispersed, and $\boldsymbol{\rho}$ is stochastically farther from $\boldsymbol{\rho}_{\text{true}}$. These results are remarkably stable against varying choices of the prior for α, even when the quite strong exponential prior with $\lambda = 10$ was used (with one exception: in the case of $N = 20$ the rather dispersed data generated by $\alpha_{\text{true}} = 1$ were not sufficient to overcome the control of the exponential prior with $\lambda = 10$, which favored even smaller values of α; see Figure 2, top panels). Finally and most importantly, we see that inference on both α and $\boldsymbol{\rho}$ is completely unaffected by the approximation of $Z_n(\alpha)$ already when $K = 10^4$.

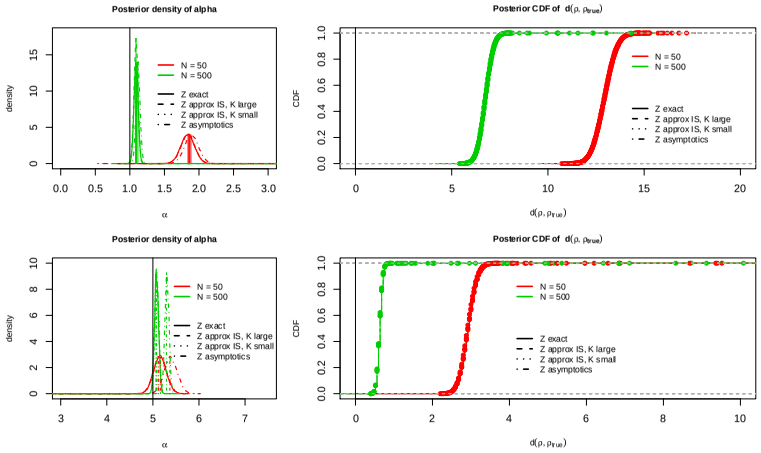

Figure 4: Results of the simulations described in Section 3.3, when $n = 50$. Left, posterior density of α (the black vertical line indicates α_{true}) obtained for various choices of N (different colors), and when using the exact, or different approximations to the partition function (different line types), as stated in the legend. Right, posterior CDF of $d(\boldsymbol{\rho}, \boldsymbol{\rho}_{\text{true}})$ in the same settings. First row: $\alpha_{\text{true}} = 1$; second row: $\alpha_{\text{true}} = 5$.

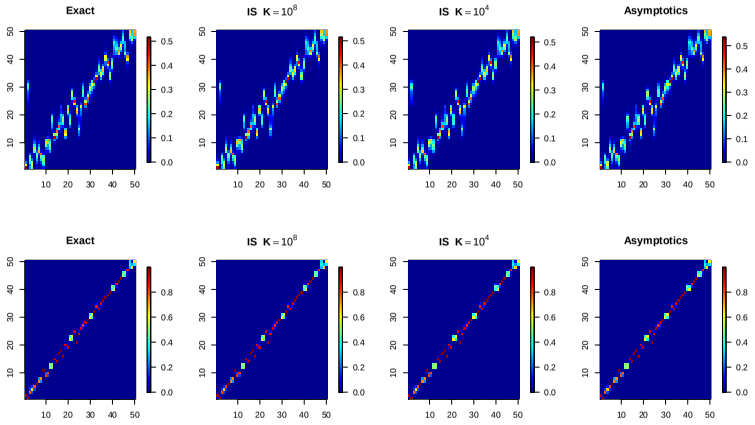

Figure 5: Results of the simulations described in Section 3.3, when $n = 50$ and $\alpha_{\text{true}} = 5$. In the x-axis items are ordered according to the true consensus $\boldsymbol{\rho}_{\text{true}}$. Each column j represents the posterior marginal density of item j in the consensus $\boldsymbol{\rho}$. Concentration along the diagonal is a sign of success of inference. From left to right, results obtained with the exact $Z_n(\alpha)$, with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^8$, with the IS approximation $\hat{Z}_n^K(\alpha)$ with $K = 10^4$, and with $Z_{\text{lim}}(\alpha)$. First row: $N = 50$; second row: $N = 500$.

In a second experiment, we generated data using $n = 50$ items, $N = 50$ or 500 assessors, and scale parameter $\alpha_{\text{true}} = 1$ or 5. This increase in the value of n gave us some basis for comparing the results obtained by using the IS approximation of $Z_n(\alpha)$ with those from the asymptotic approximation $Z_{\text{lim}}(\alpha)$ of Mukherjee (2016), while still retaining also the possibility of using the exact $Z_n(\alpha)$. For the analysis, all the previous MCMC settings were kept, except for the prior for α: since results from $n = 20$ turned out to be independent of the choice of the prior, here we used the same exponential prior with $\lambda = 0.1$ in all comparisons (see the discussion in Section 2.2). The results are shown in Figures 4 and 5. Again, we observe substantially more accurate results for larger values of N and α_{true}. Concerning the impact of approximations to $Z_n(\alpha)$, we notice that, even in this case of larger n, the marginal posterior of $\boldsymbol{\rho}$ appears completely unaffected by the partition function not being exact (see Figure 4, right panels, and Figure 5). In the marginal posterior for α (Figure 4, left panels), there are no differences between using the IS approximations and the exact, but there is a difference between Z_{lim} and the other approximations: Z_{lim} appears to be systematically slightly worse.

Finally, we generated data from the Mallows model with $n = 100$ items, $N = 100$ or 1000 assessors, and using $\alpha_{\text{true}} = 5$ or 10. Because of this large value of n we were no longer able to compute the exact $Z_n(\alpha)$, hence we only compared results from the different

approximations. We kept the same MCMC settings as for $n = 50$, both in data generation and analysis. The results are shown in Figures 3 and 4 of the Supplementary Material, Section 3. Also in this case, we observe substantially more accurate estimates with larger values of N and α_{true}, establishing an overall stable performance of the method. Here, using the small number $K = 10^4$ of samples in the IS approximation has virtually no effect on the accuracy of the marginal posterior for α, while a small effect can be detected from using the asymptotic approximation (Figure 3 of the Supplementary Material, left panels). However, again, the marginal posterior for $\boldsymbol{\rho}$ appears completely unaffected by the considered approximations in the partition function (Figure 3, right panels, and Figure 4 of the Supplementary Material).

In conclusion, the main positive result from the perspective of practical applications was the relative lack of sensitivity of the posterior inferences to the specification of the prior for the scale parameter α, and the apparent robustness of the marginal posterior inferences on $\boldsymbol{\rho}$ on the choice of the approximation of the partition function $Z_n(\alpha)$. The former property was not an actual surprise, as it can be understood to be a consequence of the well-known Bernstein-von Mises principle: with sufficient amounts of data, the likelihood dominates the influence of the prior.

The second observation deserves a somewhat closer inspection, however. The marginal posterior $P(\alpha|\mathbf{R})$, considered in Figures 2 and 4 (left), and in Figure 3 (left) of the Supplementary Material, is obtained from the joint posterior (4) by simple summation over $\boldsymbol{\rho}$, then getting the expression

$$P(\alpha|\mathbf{R}) \propto \pi(\alpha)C(\alpha;\mathbf{R})/(Z_n(\alpha))^N, \tag{14}$$

where $C(\alpha;\mathbf{R}) = \sum_{\boldsymbol{\rho}\in\mathcal{P}_n} \pi(\boldsymbol{\rho}) \exp\left\{-\frac{\alpha}{n}\sum_{j=1}^N d(\mathbf{R}_j,\boldsymbol{\rho})\right\}$. For a proper understanding of the structure of the joint posterior and its modification (11), it is helpful to first factorize (4) into the product

$$P(\alpha,\boldsymbol{\rho}|\mathbf{R}) = P(\alpha|\mathbf{R})P(\boldsymbol{\rho}|\alpha,\mathbf{R}), \tag{15}$$

where then

$$P(\boldsymbol{\rho}|\alpha,\mathbf{R}) = [C(\alpha;\mathbf{R})]^{-1}\pi(\boldsymbol{\rho}) \exp\left\{-\frac{\alpha}{n}\sum_{j=1}^N d(\mathbf{R}_j,\boldsymbol{\rho})\right\}. \tag{16}$$

The joint posterior (11), which arises from replacing the partition function $Z_n(\alpha)$ by its approximation $\hat{Z}_n(\alpha)$, can be similarly expressed as the product

$$\hat{P}(\alpha,\boldsymbol{\rho}|\mathbf{R}) = \hat{P}(\alpha|\mathbf{R})P(\boldsymbol{\rho}|\alpha,\mathbf{R}), \tag{17}$$

where

$$\hat{P}(\alpha|\mathbf{R}) = [\hat{C}(\mathbf{R})]^{-1}(Z_n(\alpha)/\hat{Z}_n(\alpha))^N P(\alpha|\mathbf{R}). \tag{18}$$

This requires that the normalizing factor $\hat{C}(\mathbf{R})$ already introduced in (11), and here expressed as

$$\hat{C}(\mathbf{R}) \equiv \int (Z_n(\alpha)/\hat{Z}_n(\alpha))^N P(\alpha|\mathbf{R})d\alpha, \tag{19}$$

is finite. By comparing (15) and (17) we see that, under this condition, the posterior $\hat{P}(\alpha,\boldsymbol{\rho}|\mathbf{R})$ arises from $P(\alpha,\boldsymbol{\rho}|\mathbf{R})$ by changing the expression (14) of the marginal posterior for α into (18), while the conditional posterior $P(\boldsymbol{\rho}|\alpha,\mathbf{R})$ for $\boldsymbol{\rho}$, given α, remains the same in both cases. Thus, the marginal posteriors $P(\boldsymbol{\rho}|\mathbf{R})$ and $\hat{P}(\boldsymbol{\rho}|\mathbf{R})$ for $\boldsymbol{\rho}$ arise as mixtures of the same conditional posterior $P(\boldsymbol{\rho}|\alpha,\mathbf{R})$ with respect to two different mixing distributions, $P(\alpha|\mathbf{R})$ and $\hat{P}(\alpha|\mathbf{R})$.

It is obvious from (18) and (19) that $\hat{P}(\alpha|\mathbf{R}) = P(\alpha|\mathbf{R})$ would hold if the ratio $Z_n(\alpha)/\hat{Z}_n(\alpha)$ would be exactly a constant in α, and this would also entail the exact equality $\hat{P}(\boldsymbol{\rho}|\mathbf{R}) = P(\boldsymbol{\rho}|\mathbf{R})$. It was established in (12) that, in the IS scheme, $Z_n(\alpha)/\hat{Z}_n(\alpha) \to 1$ as $K \to \infty$. Thus, for large enough K, $(Z_n(\alpha)/\hat{Z}_n(\alpha))^N \approx 1$ holds as an approximation (see Proposition 3). Importantly, however, (18) shows that the approximation is only required to hold well on the effective support of $P(\alpha|\mathbf{R})$, and this support is narrow when N is large. This is demonstrated clearly in Figures 2 and 4 (left), and in Figure 3 (left) of the Supplementary Material. On this support, because of uniform continuity in α, also the integrand $P(\boldsymbol{\rho}|\alpha,\mathbf{R})$ in (16) remains nearly a constant. In fact, experiments (results not shown) performed by varying α over a much wider range of fixed values, while keeping the same $\mathbf{R}$, gave remarkably stable results for the conditional posterior $P(\boldsymbol{\rho}|\alpha,\mathbf{R})$. This contributes to the high degree of robustness in the posterior inferences on $\boldsymbol{\rho}$, making requirements of using large values of K much less stringent.

In Figures 3 and 4 (right), and in Figure 3 (right) of the Supplementary Material, we considered and compared the marginal posterior CDF's of the distance $d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}})$ under the schemes $P(\cdot|\mathbf{R})$ and $\hat{P}(\cdot|\mathbf{R})$. Using the shorthand $d^* = d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}})$, let

$$\begin{aligned}
F_{d^*}(x|\alpha,\mathbf{R}) &\equiv P(d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}}) \le x|\alpha,\mathbf{R}) = \sum_{\{\boldsymbol{\rho}:d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}})\le x\}} P(\boldsymbol{\rho}|\alpha,\mathbf{R}), \qquad (20)\\
F_{d^*}(x|\mathbf{R}) &\equiv \sum_{\{\boldsymbol{\rho}:d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}})\le x\}} P(\boldsymbol{\rho}|\mathbf{R}) = \int F_{d^*}(x|\alpha,\mathbf{R})P(\alpha|\mathbf{R})d\alpha,\\
\hat{F}_{d^*}(x|\mathbf{R}) &\equiv \sum_{\{\boldsymbol{\rho}:d(\boldsymbol{\rho},\boldsymbol{\rho}_{\text{true}})\le x\}} \hat{P}(\boldsymbol{\rho}|\mathbf{R}) = \int F_{d^*}(x|\alpha,\mathbf{R})\hat{P}(\alpha|\mathbf{R})d\alpha.
\end{aligned}$$

For example, in Figure 3 we display, for different priors, the CDF's $F_{d^*}(x|\mathbf{R})$ on the left, and $\hat{F}_{d^*}(x|\mathbf{R})$ in the middle and on the right, corresponding to two different IS approximations of the partition function. Like the marginal posteriors $P(\boldsymbol{\rho}|\mathbf{R})$ and $\hat{P}(\boldsymbol{\rho}|\mathbf{R})$ above, $F_{d^*}(x|\mathbf{R})$ and $\hat{F}_{d^*}(x|\mathbf{R})$ can be thought of as mixtures of the same function, here $F_{d^*}(x|\alpha,\mathbf{R})$, but with respect to two different mixing distributions, $P(\alpha|\mathbf{R})$ and $\hat{P}(\alpha|\mathbf{R})$. The same arguments, which were used above in support of the robustness of the posterior inferences on $\boldsymbol{\rho}$, apply here as well. Extensive empirical evidence for their justification is provided in Figures 3 and 4 (right), and in Figure 3 (right) of the Supplementary Material. Finally note that these arguments also strengthen considerably our earlier conclusion of the lack of sensitivity of the posterior inferences on $\boldsymbol{\rho}$ to the specification of the prior for α. For this, we only need to consider alternative priors, say, $\pi(\alpha)$ and $\hat{\pi}(\alpha)$, in place of the mixing distributions $P(\alpha|\mathbf{R})$ and $\hat{P}(\alpha|\mathbf{R})$.

4. Extensions to Partial Rankings and Heterogeneous Assessor Pool

We now relax two assumptions of the previous Sections, namely that each assessor ranks all n items and that the assessors are homogeneous, all sharing a common consensus ranking. This allows us to treat the important situation of pairwise comparisons, and of multiple classes of assessors, as incomplete data cases, within the same Bayesian Mallows framework.

4.1 Ranking of the Top Ranked Items

Often only a subset of the items is ranked: ranks can be missing at random, the assessors may only have ranked the, in-their-opinion, top-k items, or can be presented with a subset of items that they have to rank. These situations can be handled conveniently in our Bayesian framework, by applying data augmentation techniques. We start by explaining the method in the case of the top-k ranks, and then show briefly how it can be generalized to the other cases mentioned.

Suppose that each assessor j has ranked the subset of items $\mathcal{A}_j \subseteq \{A_1, A_2, \ldots, A_n\}$, giving them top ranks from 1 to $n_j = |\mathcal{A}_j|$. Let $R_{ij} = \mathbf{X}_j^{-1}(A_i)$ if $A_i \in \mathcal{A}_j$, while for $A_i \in \mathcal{A}_j^c$, R_{ij} is unknown, except for the constraint $R_{ij} > n_j$, $j = 1,\ldots,N$, and follows a symmetric prior on the permutations of $(n_j+1,\ldots,n)$. We define augmented data vectors $\tilde{\mathbf{R}}_1,\ldots,\tilde{\mathbf{R}}_N$ by assigning ranks to these non-ranked items randomly, using an MCMC algorithm, and do this in a way which is compatible with the rest of the data. Let $\mathcal{S}_j = \{\tilde{\mathbf{R}}_j \in \mathcal{P}_n : \tilde{R}_{ij} =$

$\mathbf{X}_j^{-1}(A_i)$ if $A_i \in \mathcal{A}_j\}$, $j = 1, \ldots, N$, be the set of possible augmented random vectors, that is the original partially ranked items together with the allowable "fill-ins" of the missing ranks. Our goal is to sample from the posterior distribution

$$P(\alpha, \boldsymbol{\rho}|\mathbf{R}_1, \ldots, \mathbf{R}_N) = \sum_{\tilde{\mathbf{R}}_1 \in \mathcal{S}_1} \cdots \sum_{\tilde{\mathbf{R}}_N \in \mathcal{S}_N} P\left(\alpha, \boldsymbol{\rho}, \tilde{\mathbf{R}}_1, \ldots, \tilde{\mathbf{R}}_N|\mathbf{R}_1, \ldots, \mathbf{R}_N\right).$$

Our MCMC algorithm alternates between sampling the augmented ranks given the current values of α and $\boldsymbol{\rho}$, and sampling α and $\boldsymbol{\rho}$ given the current values of the augmented ranks. For the latter, we sample from the posterior $P(\alpha, \boldsymbol{\rho}|\tilde{\mathbf{R}}_1, \ldots, \tilde{\mathbf{R}}_N)$ as in Section 2.4. For the former, fixing α and $\boldsymbol{\rho}$ and the observed ranks $\mathbf{R}_1, \ldots, \mathbf{R}_N$, we see that $\tilde{\mathbf{R}}_1, \ldots, \tilde{\mathbf{R}}_N$ are conditionally independent, and moreover, that each $\tilde{\mathbf{R}}_j$ only depends on the corresponding $\mathbf{R}_j$. This enables us to consider the sampling of new augmented vectors $\tilde{\mathbf{R}}'_j$ separately for each $j, j = 1, \ldots, N$. Specifically, given the current $\tilde{\mathbf{R}}_j$ (which embeds information contained in $\mathbf{R}_j$) and the current values for α and $\boldsymbol{\rho}$, $\tilde{\mathbf{R}}'_j$ is sampled in $\mathcal{S}_j$ from a uniform proposal distribution, meaning that the highest ranks from 1 to n_j have been reserved for the items in $\mathcal{A}_j$, while compatible ranks are randomly drawn for items in $\mathcal{A}_j^c$. The proposed $\tilde{\mathbf{R}}'_j$ is then accepted with probability

$$\min\left\{1, \exp\left[-\frac{\alpha}{n}\left(d(\tilde{\mathbf{R}}'_j, \rho) - d(\tilde{\mathbf{R}}_j, \rho)\right)\right]\right\}. \tag{21}$$

The MCMC algorithm described above and used in the case of partial rankings is given in Algorithm 3 of Appendix B. Our algorithm can also handle situations of generic partial ranking, where each assessor is asked to provide the mutual ranking of some subset $\mathcal{A}_j \subset \{A_1, ..., A_n\}$ consisting of $n_j \leq n$ items, not necessarily the top-n_j. In this case, we can only say that in $\tilde{\mathbf{R}}_j = (\tilde{R}_{1j}, ..., \tilde{R}_{nj})$ the order between items $A_i \in \mathcal{A}_j$ must be preserved as in $\mathbf{R}_j$, whereas the ranks of the augmented "fill-ins" $A_i \in \mathcal{A}_j^c$ are left open. More exactly, the latent rank vector $\tilde{\mathbf{R}}_j$ takes values in the set $\mathcal{S}_j = \{\tilde{\mathbf{R}}_j \in \mathcal{P}_n : \text{if } R_{i_1 j} < R_{i_2 j}, \text{ with } A_{i_1}, A_{i_2} \in \mathcal{A}_j \Rightarrow \tilde{R}_{i_1 j} < \tilde{R}_{i_2 j}\}$. The MCMC is then easily adjusted so that the sampling of each $\tilde{\mathbf{R}}_j$ is restricted to the corresponding $\mathcal{S}_j$, thus respecting the mutual rank orderings in the data.

4.1.1 Effects of Unranked Items on the top-k Consensus Ranking

In applications in which the number of items is large there are often items which none of the assessors included in their top-list. What is the exact role of such "left-over" items in the top-k consensus ranking of all items? Can we ignore such "left-over" items and consider only the items explicitly ranked by at least one assessor? In the following we first show that only items explicitly ranked by the assessors appear in top positions of the consensus ranking. We then show that, when considering the MAP consensus ranking, excluding the left-over items from the ranking procedure already at the start has no effect on how the remaining ones will appear in such consensus ranking.

For a precise statement of these results, we need some new notation. Suppose that assessor j has ranked a subset $\mathcal{A}_j$ of n_j items. Let $\mathcal{A} = \bigcup_{j=1,\ldots,N} \mathcal{A}_j$, and denote $n = |\mathcal{A}|$. Let n^* be the total number of items, including left-over items which have not been explicitly ranked by any assessor. Denote by $\mathcal{A}^* = \{A_i; i = 1, \ldots, n^*\}$ the collection of all items, and by $\mathcal{A}^c = \mathcal{A}^* \setminus \mathcal{A}$ the left-over items. Each rank vector $\mathbf{R}_j$ for assessor j contains, in some

order, the ranks from 1 to n_j given to items in $\mathcal{A}_j$. In the original data the ranks of all remaining items are left unspecified, apart from the fact that implicitly, for assessor j, they would have values which are at least as large as $n_j + 1$.

The results below are formulated in terms of the two different modes of analysis, which we need to compare and which correspond to different numbers of items being included. The first alternative is to include in the analysis the complete set $\mathcal{A}^*$ of n^* items, and to complement each data vector $\mathbf{R}_j$ by assigning (originally missing) ranks to all items which are not included in $\mathcal{A}_j$; their ranks will then form some permutation of the sequence $(n_j + 1, \ldots, n^*)$. We call this mode of analysis *full analysis*, and denote the corresponding probability measure by P_{n^*}. The second alternative is to include in the analysis only the items which have been explicitly ranked by at least one assessor, that is, items belonging to the set $\mathcal{A}$. We call this second mode *restricted analysis*, and denote the corresponding probability measure by P_n. The probability measure P_n is specified as before, including the uniform prior on the consensus ranking $\boldsymbol{\rho}$ across all $n!$ permutations of $(1, 2, \ldots, n)$, and the uniform prior of the unspecified ranks R_{ij} of items $A_i \in \mathcal{A}_j^c$ across the permutations of $(n_j + 1, \ldots, n)$. The definition of P_{n^*} is similar, except that then the uniform prior distributions are assumed to hold in the complete set $\mathcal{A}^*$ of items, that is, over permutations of $(1, 2, \ldots, n^*)$ and $(n_j + 1, \ldots, n^*)$, respectively. In the posterior inference carried out in both modes of analysis, the augmented ranks, which were not recorded in the original data, are treated as random variables, with values being updated as part of the MCMC sampling.

Proposition 4 *Consider two latent consensus rank vectors $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ such that*

(i) in the ranking $\boldsymbol{\rho}$ all items in $\mathcal{A}$ have been included among the top-n-ranked, while those in $\mathcal{A}^c$ have been assigned ranks between $n + 1$ and n^*,

(ii) $\boldsymbol{\rho}'$ is obtained from $\boldsymbol{\rho}$ by a permutation, where the rank in $\boldsymbol{\rho}$ of at least one item belonging to $\mathcal{A}$ has been transposed with the rank of an item in $\mathcal{A}^c$.

Then, $P_{n^*}(\boldsymbol{\rho}|data) \geq P_{n^*}(\boldsymbol{\rho}'|data)$, for the footrule, Kendall and Spearman distances in the full analysis *mode.*

Remark. The above proposition says, in essence, that any consensus lists of top-n ranked items, which contains one or more items with their ranks completely missing in the data (that is, the item was not explicitly ranked by any of the assessors), can be improved *locally*, in the sense of increasing the associated posterior probability with respect to P_{n^*}. This happens by trading such an item in the top-n list against another, which had been ranked but which had not yet been selected to the list. In particular, the MAP estimate(s) for consensus ranking assign n highest ranks to explicitly ranked items in the data (which corresponds to the result in Meilă and Bao (2010) for Kendall distance). The following statement is an immediate implication of Proposition 4, following from a marginalization with respect to P_{n^*}.

Corollary 1 *Consider, for $k \leq n$, collections $\{A_{i_1}, A_{i_2}, \ldots, A_{i_k}\}$ of k items and the corresponding ranks $\{\rho_{i_1}, \rho_{i_2}, \ldots, \rho_{i_k}\}$. In* full analysis *mode, the maximal posterior probability $P_{n^*}(\{\rho_{i_1}, \rho_{i_2}, \ldots, \ \rho_{i_k}\} = \{1, 2, \ldots, k\}|data)$, is attained when $\{A_{i_1}, A_{i_2}, \ldots, A_{i_k}\} \subset \mathcal{A}$.*

Another consequence of Proposition 4 is the coincidence of the MAP estimates under the two probability measures P_n and P_{n^*}.

Corollary 2 *Denote by $\boldsymbol{\rho}^{MAP*}$ the MAP estimate for consensus ranking obtained in a* full analysis, $\boldsymbol{\rho}^{MAP*} := \text{argmax}_{\boldsymbol{\rho}\in\mathcal{P}_{n^*}} P_{n^*}(\boldsymbol{\rho}|data)$, *and by $\boldsymbol{\rho}^{MAP}$ the MAP estimate for consensus ranking obtained in a* restricted analysis, $\boldsymbol{\rho}^{MAP} := \text{argmax}_{\boldsymbol{\rho}\in\mathcal{P}_n} P_n(\boldsymbol{\rho}|data)$. *Then,* $\boldsymbol{\rho}^{MAP*}|_{i:A_i\in\mathcal{A}} \equiv \boldsymbol{\rho}^{MAP}$.

Remark. The above result is very useful in the context of applications, since it guarantees that the top-n items in the MAP consensus ranking do not depend on which version of the analysis is performed. Recall that a full analysis cannot always be carried out in practice, due to the fact that left-over items might be unknown, or their number might be too large for any realistic computation.

4.2 Pairwise Comparisons

In many situations, assessors compare pairs of items rather than ranking all or a subset of items. We extend our Bayesian data augmentation scheme to handle such data. Our approach is an alternative to Lu and Boutilier (2014), who treated preferences by applying their Repeated Insertions Model (RIM). Our approach is simpler, it is fully integrated into our Bayesian inferential framework, and it works for any right-invariant distance.

As an example of paired comparisons, assume assessor j stated the preferences $\mathcal{B}_j = \{A_1 \prec A_2, A_2 \prec A_5, A_4 \prec A_5\}$. Here $A_r \prec A_s$ means that A_s is preferred to A_r, so that A_s has a lower rank than A_r. Let $\mathcal{A}_j$ be the set of items constrained by assessor j, in this case $\mathcal{A}_j = \{A_1, A_2, A_4, A_5\}$. Differently from Section 4.1, the items which have been considered by each assessor are now not necessarily fixed to a given rank. Hence, in the MCMC algorithm, we need to propose augmented ranks which obey the partial ordering constraints given by each assessor, to avoid a large number of rejections, with the difficulty that none of the items is now fixed to a given rank. Note that we can also handle the case when assessors give ties as a result of some pairwise comparisons: in such a situation, each pair of items resulting in a tie is randomized to a preference at each data augmentation step inside the MCMC, thus correctly representing the uncertainty of the preference between the two items. None of the experiments included in the paper involves ties, thus this randomization is not needed.

We assume that the pairwise orderings in $\mathcal{B}_j$ are mutually compatible, and define by $\text{tc}(\mathcal{B}_j)$ the transitive closure of $\mathcal{B}_j$, containing all pairwise orderings of the elements in $\mathcal{A}_j$ induced by $\mathcal{B}_j$. In the example, $\text{tc}(\mathcal{B}_j) = \mathcal{B}_j \cup \{A_1 \prec A_5\}$. For the case of ordered subsets of items, the transitive closure is simply the single set of pairwise preferences compatible with the ordering, for example, $\{A_1 \prec A_2 \prec A_5\}$ yields $\text{tc}(\mathcal{B}_j) = \{A_1 \prec A_2, A_2 \prec A_5, A_1 \prec A_5\}$. The R packages `sets` (Meyer and Hornik, 2009) and `relations` (Meyer and Hornik, 2014) efficiently compute the transitive closure.

The main idea of our method for handling such data remains the same as in Section 4.1, and the algorithm is the same as Algorithm 3. However, here a "modified" leap-and-shift proposal distribution, rather than a uniform one, is used to sample augmented ranks which are compatible with the partial ordering constraint. Suppose that, from the latest step of the MCMC, we have a full augmented rank vector $\tilde{\mathbf{R}}_j$ for assessor j, which is

compatible with $\text{tc}(\mathcal{B}_j)$. Draw a random number u uniformly from $\{1,\dots,n\}$. If $A_u \in \mathcal{A}_j$, let $l_j = \max\{\tilde{R}_{kj} : A_k \in \mathcal{A}_j, k \neq u, (A_k \succ A_u) \in \text{tc}(\mathcal{B}_j)\}$, with the convention that $l_j = 0$ if the set is empty, and $r_j = \min\{\tilde{R}_{kj} : A_k \in \mathcal{A}_j, k \neq u, (A_k \prec A_u) \in \text{tc}(\mathcal{B}_j)\}$, with the convention that $r_j = n+1$ if the set is empty. Now complete the leap step by drawing a new proposal $\tilde{R}'_{uj}$ uniformly from the set $\{l_j+1,\dots,r_j-1\}$. Otherwise, if $A_u \in \mathcal{A}_j^c$, we complete the leap step by drawing $\tilde{R}'_{uj}$ uniformly from $\{1,\dots,n\}$. The shift step remains unchanged. Note that this modified leap-and-shift is symmetric.

4.3 Clustering Assessors Based on their Rankings of All Items

So far we have assumed that there exists a unique consensus ranking shared by all assessors. In many cases the assumption of homogeneity is unrealistic: the possibility of dividing assessors into more homogeneous subsets, each sharing a consensus ranking of the items, brings the model closer to reality. We then introduce a mixture of Mallows models, able to handle heterogeneity. We here assume that the data consist of complete rankings.

Let $z_1,\dots,z_N \in \{1,\dots,C\}$ assign each assessor to one of C clusters. The assessments within each cluster $c \in \{1,\dots,C\}$ are described by a Mallows model with parameters α_c and $\boldsymbol{\rho}_c$, the cluster consensus. Assuming conditional independence across the clusters, the augmented data formulation of the likelihood for the observed rankings $\mathbf{R}_1,\dots,\mathbf{R}_N$ is given by

$$P\left(\mathbf{R}_1,\dots,\mathbf{R}_N|\,\{\boldsymbol{\rho}_c,\alpha_c\}_{c=1,\dots,C}, z_1,\dots,z_N\right) = \prod_{j=1}^{N} \frac{1_{\mathcal{P}_n}(\mathbf{R}_j)}{Z_n(\alpha_{z_j})} \exp\left\{-\frac{\alpha_{z_j}}{n} d(\mathbf{R}_j,\boldsymbol{\rho}_{z_j})\right\}.$$

For the scale parameters, we assume the prior $\pi(\alpha_1,\dots,\alpha_C) \propto \prod_{c=1}^{C}\pi(\alpha_c)$, where $\pi(\alpha_c) = \lambda\exp(-\lambda\alpha_c)1_{[0,\alpha_{\max}]}(\alpha_c)/(1-e^{-\lambda\alpha_{\max}})$. We further assume that the cluster labels are a priori distributed according to $P(z_1,\dots,z_N|\tau_1,\dots,\tau_C) = \prod_{j=1}^{N}\tau_{z_j}$, where τ_c is the probability that an assessor belongs to the c-th subpopulation; $\tau_c \geq 0$, $c = 1,\dots,C$ and $\sum_{c=1}^{C}\tau_c = 1$. Finally $\tau_1,\dots,\tau_C$ are assigned the standard symmetric Dirichlet prior $\pi(\tau_1,\dots,\tau_C) = \Gamma(\psi C)\Gamma(\psi)^{-C}\prod_{c=1}^{C}\tau_c^{\psi-1}$, using the gamma function $\Gamma(\cdot)$.

The number of clusters C is often not known, and the selection of C can be based on different criteria. Here we inspect the posterior distribution of the within-cluster sum of distances of the observed ranks from the corresponding cluster consensus (see Section 6.3 for more details). This approach is a Bayesian version of the more classical within-cluster sum-of-squares criterion for model selection, and we expect to observe an elbow in the within-cluster distance posterior distribution as a function of C, identifying the optimal number of clusters.

Label switching is not explicitly handled inside our MCMC, to ensure full convergence of the chain (Jasra et al., 2005; Celeux et al., 2000). MCMC iterations are re-ordered after convergence is achieved, as in Papastamoulis (2015). The MCMC algorithm alternates between sampling $\boldsymbol{\rho}_1,\dots,\boldsymbol{\rho}_C$ and $\alpha_1,\dots,\alpha_C$ in a Metropolis-Hastings step, and $\tau_1,\dots,\tau_C$ and $z_1,\dots,z_N$ in a Gibbs sampler step. The former is straightforward, since $(\boldsymbol{\rho}_c,\alpha_c)_{c=1,\dots,C}$ are conditionally independent given $z_1,\dots,z_N$. In the latter, we exploit the fact that the Dirichlet prior for $\tau_1,\dots,\tau_C$ is conjugate to the multinomial conditional prior for $z_1,\dots,z_N$ given $\tau_1,\dots,\tau_C$. Therefore in the Gibbs step for $\tau_1,\dots,\tau_C$, we sample from $\mathcal{D}(\psi+n_1,\dots,\psi+$

$n_C)$, where $\mathcal{D}(\cdot)$ denotes the Dirichlet distribution and $n_c = \sum_{j=1}^{N} 1_c(z_j)$, $c = 1, \ldots, C$. Finally, in the Gibbs step for z_j, $j = 1, \ldots, N$, we sample from $P(z_j = c|\tau_c, \boldsymbol{\rho}_c, \alpha_c, R_j) \propto \tau_c P(\mathbf{R}_j|\boldsymbol{\rho}_c, \alpha_c) = \tau_c Z_n(\alpha_c)^{-1} \exp\{-(\alpha_c/n) d(\mathbf{R}_j, \boldsymbol{\rho}_c)\}$. The pseudo-code of the clustering algorithm is sketched in Algorithm 2 of Appendix B.

It is not difficult to treat situations where data are incomplete (in any way described before) and the assessors must be divided into separate clusters. Algorithms 2 and 3 are merged in an obvious way, by iterating between augmentation, clustering, and α and $\boldsymbol{\rho}$ updates. The MCMC algorithm for clustering based on partial rankings or pairwise preferences is sketched in Algorithm 4 of Appendix B.

4.4 Example: Preference Prediction

Consider a situation in which the assessors have expressed their preferences on a collection of items, by performing only partial rankings. Or, suppose that they have been asked to respond to some queries containing different sets of pairwise comparisons. One may then ask how the assessors would have ranked some subset of items of interest when such ranking could not be concluded directly from the data they provided. Sometimes the interest is to predict the assessors' top preferences, accounting for the possibility that such top lists could contain items which some assessors had not seen. Problems of this type are commonly referred to as *personalized ranking*, or *preference learning* (Fürnkranz and Hüllermeier, 2010), being a step towards *personalized recommendation*. There is a large and rapidly expanding literature describing a diversity of methods in this area.

Our framework, based on the Bayesian Mallows model, and its estimation algorithms as described in the previous Sections, form a principled approach for handling such problems. Assuming a certain degree of similarity in the individual preferences, and with different assessors providing partly complementary information, it is natural to try to borrow strength from such partial preference information from different assessors for forming a consensus. Expanding the model to include clusters allows handling heterogeneity that may be present in the assessment data (Francis et al., 2010). The Bayesian estimation procedure provides then the joint posterior distribution, expressed numerically in terms of the MCMC output consisting of sampled values of all cluster membership indicators, z_j, and of complete individual rankings, $\tilde{\mathbf{R}}_j$. For example, if assessor j did not compare A_1 to A_2, we might be interested in computing $P(A_1 \prec_j A_2|\text{data})$, the predictive probability that this assessor would have preferred item A_2 to item A_1. This probability is then readily obtained from the MCMC output, as a marginal of the posterior $P(\tilde{\mathbf{R}}_j|\text{data})$.

To illustrate how this is possible with our approach, we present a small simulated experiment, corresponding to a heterogeneous collection of assessors expressing some of their pairwise preferences, and then want to predict the full individual ranking $\tilde{\mathbf{R}}_j$ of all items, for all j. For this, we generated pairwise preference data from a mixture of Mallows models with footrule distance, using the procedure explained in Appendix C. We generated the data with $N = 200$, $n = 15$, $C = 3$, $\alpha_1, ..., \alpha_C = 4$, $\psi_1, ..., \psi_C = 50$, obtaining the true $\tilde{\mathbf{R}}_{j,\text{true}}$ for every assessor. Then, we assigned to each assessor j a different number, $T_j \sim \text{TruncPoiss}(\lambda_T, T_{\max})$, of pair comparisons, sampled from a truncated Poisson distribution with $\lambda_T = 20$, denoting by $T_{\max} = n(n-1)/2$ the total number of possible pairs

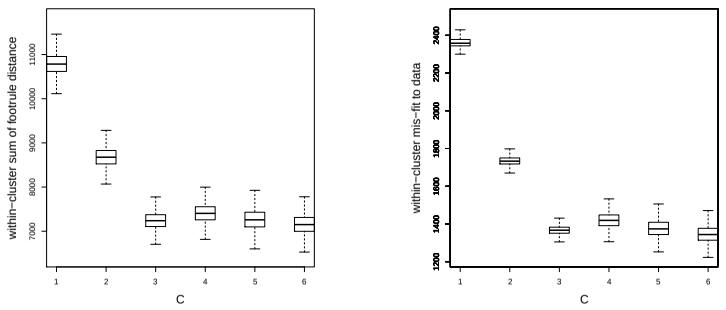

Figure 6: Results of the simulation in Section 4.4. Boxplots of the posterior distribution of the within-cluster sum of footrule distances (left), and of the within-cluster indicator of mis-fit to the data (right), for different choices of C.

from n items. Each pair comparison was then ordered according to the true $\tilde{\mathbf{R}}_{j,\text{true}}$. The average number of pairs per assessor was around 20, less than 20% of $T_{\max}$.

In the analysis, we run Algorithm 4 of Appendix B on these data, using the exact partition function, for 10^5 iterations (of which 10^4 were for burn-in). Separate analyses were performed for $C \in \{1, \ldots, 6\}$. Then, in order to inspect if our method correctly identified the true number of clusters we computed two quantities: the within-cluster sum of footrule distances, given by $\sum_{c=1}^{C} \sum_{j:z_j=c} d(\tilde{\mathbf{R}}_j, \boldsymbol{\rho}_c)$, and a within-cluster indicator of mis-fit to the data, $\sum_{c=1}^{C} \sum_{j:z_j=c} |\{B \in \text{tc}(\mathcal{B}_j) : B \text{ is not consistent with } \boldsymbol{\rho}_c\}|$, where a pair comparison $B \in \text{tc}(\mathcal{B}_j), B = (A_r \prec A_s)$ is not consistent with $\boldsymbol{\rho}_c$ if $\rho_{c,s} > \rho_{c,r}$. The number of such non-consistent pairs in $\mathcal{B}_j$ gives an indication of the mis-fit of the j-th assessor to its cluster. Notice that, while the latter measure takes into account the data directly, the former is based on the augmented ranks $\tilde{\mathbf{R}}_j$ only. Hence, the within-cluster sum of footrule distances could be more sensitive to possible misspecifications in $\tilde{\mathbf{R}}_j$ when the data are very sparse. Notice also that the second measure is a 'modified' version of the Kendall distance between the data and the cluster centers. The boxplots of the posterior distributions of these two quantities are shown in Figure 6: the two measures are very consistent in indicating a clear elbow at $C = 3$, thus correctly identifying the value we used to generate the data.

We then studied the success rates of correctly predicting missing individual pairwise preferences. A pairwise preference between items A_{i_1} and A_{i_2} was considered missing for assessor j if it was not among the sampled pairwise comparisons included in the data as either $A_{i_1} \prec_{j,\text{true}} A_{i_2}$ or $A_{i_2} \prec_{j,\text{true}} A_{i_1}$, nor could such ordering be concluded from the data indirectly by transitivity. Thus we computed, for all assessors j, the predictive probabilities $P(A_{i_1} \prec_j A_{i_2}|\text{data})$ for all pairs of items $\{A_{i_1}, A_{i_2}\}$ not ordered in $\text{tc}(\mathcal{B}_j)$. The rule for practical prediction was to always bet on the ordering with the larger predictive probability of these two probabilities, then at least 0.5. Each resulting predictive probability is a direct

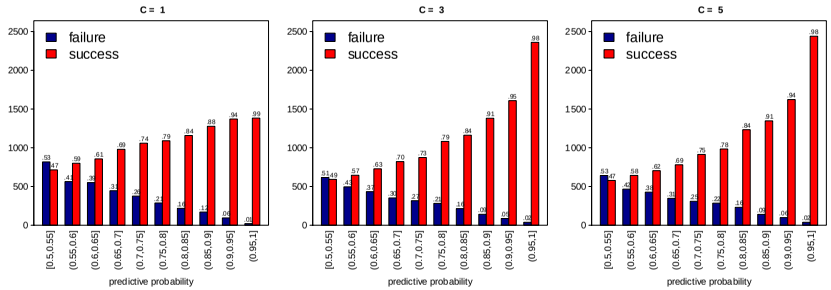

Figure 7: Results of the simulation in Section 4.4. Barplots of the frequency of successes (red columns) and failures (blue columns) obtained fixing $C = 1$ (left), 3 (middle), and 5 (right), for the data generated with $\lambda_T = 20$. For $C = 1$, 75% of all predictions were correct, for $C = 3$, 79.1%, and for $C = 5$, 79%.

quantification of the uncertainty in making the bet: a value close to 0.5 expresses a high degree of uncertainty, while a value close to 1 would signal greater confidence in that the bet would turn out right. In the experiment, these bets were finally compared to the orderings of the same pairs in the simulated true rankings $\tilde{\mathbf{R}}_{j,\text{true}}$. If they matched, this was registered as a success, and if not, then as a failure.

In Figure 7 are shown the barplots of the results from this experiment, expressed in terms of the frequency of successes (red columns) and failures (blue columns), obtained by combining the outcomes from all individual assessors. For this presentation, the predictive probabilities used for betting were grouped into the respective intervals $[0.50, 0.55], (0.55, 0.60], \ldots, (0.95, 1.00]$ on the horizontal axis, so that pair preferences become more difficult to predict the more one moves to the left, along the x-axis. On top of each column the percentage of successes, or failures, of the corresponding bets is shown. For the results considered on the left, the predictions were made without assuming a cluster structure ($C = 1$) in the analysis, in the middle graph the same number ($C = 3$) of clusters was assumed in the analysis as in the data generation, and on the right, we wanted to study whether assuming an even larger number ($C = 5$) of clusters in the analysis might influence the performance of our method for predicting missing preferences.

Two important conclusions can be made from the results of this experiment. First, from comparing the three graphs, we can see that not assuming a cluster structure ($C = 1$) in the data analysis led to an overall increased proportion of uncertain bets, in the sense of being based on predictive probabilities closer to the 0.5 end of the horizontal axis, than if either $C = 3$ or $C = 5$ was assumed. On the other hand, there is almost no difference between the graphs corresponding to $C = 3$ and $C = 5$. Thus, moderate overfitting of clusters neither improved nor deteriorated the quality of the predictions (this seems consistent with the very similar within-cluster distances in these two cases, shown in Figure 6). A second, and more interesting, observation is that, in all three cases considered, the predictive probabilities

used for betting turned out to be empirically very well calibrated (see, for example, Dawid (1982) and Little (2011)). For example, of the bets based on predictive probabilities in the interval $(0.70, 0.75]$, 74% were successful for $C = 1$, 73% when $C = 3$, and 75% when $C = 5$. By inspection, such correspondence can be seen to hold quite well on all intervals in all three graphs. That the same degree of empirical calibration holds also when an incorrect number of clusters was fitted to the data as with the correct one, signals a certain amount of robustness of this aspect towards variations in the modeling.

We repeated the same experiment with less data, namely using $\lambda_T = 10$. This gives an average number of pairs per assessor around 10% of $T_{\max}$. Results are displayed in Figure 5 of the Supplementary Material, Section 3. Predictive probabilities are still very well calibrated, but of course the quality of prediction is worse. Nonetheless, for $C = 3$, 76.8% of all predictions were correct.

5. Related Work

We briefly review the literature which uses the Mallows model, or is based on other probabilistic approaches, as these are most closely related to our method.

The Mallows model was studied almost exhaustively in the case of Kendall distance, of which the partition function is easy to compute. Among probabilistic approaches, one of the most interesting is Meilă and Chen (2010), who proposed a Dirichlet process mixture of the Generalized Mallows model of Fligner and Verducci (1986) over incomplete rankings. In this paper two Gibbs sampling techniques for estimating the posterior density were studied. This framework was further extended in Meilă and Bao (2010), who developed an algorithm for the ML estimation of their Generalized Mallows model for infinite rankings (IGM), based on Kendall distance. They also considered Bayesian inference with the conjugate prior, showing that such inference is much harder.

In terms of focus and aim, the proposal in Lu and Boutilier (2014) is very close to our approach: they develop a method to form clusters of assessors and perform preference learning and prediction from pairwise comparison data in the Mallows model framework. Their approach is connected to our extension to preference data (Section 4.2), but differs most notably in the general model and algorithm. Their generalized repeated insertion model (GRIM), based on Kendall distance only, generalizes the repeated insertion method for unconditional sampling of Mallows models of Doignon et al. (2004). Lu and Boutilier (2014) perform ML estimation of the consensus ranking using a method based on the EM algorithm, thus not providing uncertainty quantification for their estimates. Our target, on the other hand, is the full posterior distribution of the unknown consensus ranking. The fact that, for the uniform prior, the MAP estimates and the ML estimates coincide, establishes a natural link between these inferential targets. Two of our illustrations, in Sections 6.3 and 6.4, use the same data as in Lu and Boutilier (2014).

In the frequentist framework, the Mallows model with other distances than Kendall was studied by Irurozki et al. (2014) and Irurozki et al. (2016b), who also developed the `PerMallows` R package (Irurozki et al., 2016a). Moreover, mixtures of Mallows models have been used to analyze heterogeneous rank data by several authors. Murphy and Martin (2003) studied mixtures of Mallows with Kendall, footrule and Cayley distances, applying their method to the benchmark American Psychological Association (Diaconis, 1988)

election data set, where only $n = 5$ candidates (items) are ranked. The difficulties in the computation of the partition function for the footrule distance, which arise for larger values of n, were not discussed. Gormley and Murphy (2006) use mixtures of Plackett-Luce models in a maximum likelihood framework for clustering. Lee and Yu (2012) use mixtures of weighted distance-based models to cluster ranking data. Also Busse et al. (2007) proposed a mixture approach for clustering rank data, but focusing on the Kendall distance only.

Other probabilistic approaches, less related to the Mallows model, include the Insertion Sorting Rank (ISR) model of Jacques and Biernacki (2014). It is implemented in the R package `rankcluster` (Jacques et al., 2014), and allows clustering of partial rankings. Sun et al. (2012) developed a non-parametric probabilistic model on preferences, which can handle also heterogeneous assessors. This work extends the non-parametric kernel density estimation approach over rankings introduced by Lebanon and Mao (2008), enabling it then to handle ranking data of arbitrary incompleteness and tie structure. However, the approach is based on a random-censoring assumption, which could be easily violated in practice.

Among machine learning approaches, those pertaining to the area of learning to rank, or rank aggregation, are also related to ours. Their aim is to find the best consensus ranking by optimizing some objective function (for example Kemeny or Borda rankings), but they generally do not provide uncertainty quantifications of the derived point estimates. A simple comparison of our approach to two such methods is shown below, in Section 5.1.

5.1 Comparisons with Other Methods

The procedure we propose is Bayesian, and one of its strengths is its ability to quantify the uncertainty related to the parameter estimates and predictions. In order to compare our results with the ones obtained by other methods which provide only point estimates, we need to summarize the posterior density of the model parameters into a single point estimate, for example MAP, mode, mean, cumulative probability consensus. The cumulative probability (CP) consensus ranking is the ranking arising from the following sequential scheme: first select the item which has the maximum a posteriori marginal probability of being ranked 1st; then the item which has the maximum a posteriori marginal posterior probability of being ranked 1st or 2nd among the remaining ones, etc. The CP consensus can be seen as a sequential MAP. We generated the data from the Mallows model (for details refer to Appendix C) with Kendall distance, since this is the unique distance handled by existing competitors based on the Mallows model. We compare our procedure (here denoted by `BayesMallows`) with the following methods:

- `PerMallows` (Irurozki et al., 2016a): MLE of the Mallows and the Generalized Mallows models, with some right-invariant distance functions, but not footrule nor Spearman.
- `rankcluster` (Jacques et al., 2014): Inference for the Insertion Sorting Rank (ISR) model.
- `RankAggreg` (Pihur et al., 2009): Rank aggregation via several different algorithms. Here we use the Cross-Entropy Monte Carlo algorithm.
- Borda count (de Borda, 1781): Easy and classic way to aggregate ranks. Basically equivalent to the average rank method, thus not a probabilistic approach.

α_T	method	$\hat{\alpha}$ or $\hat{\pi}$	$\frac{1}{n}d(\hat{\boldsymbol{\rho}}, \boldsymbol{\rho}_T)$	$T(\hat{\boldsymbol{\rho}}, \mathbf{R})$
1	`BayesMallows` - CP	1.01 (0.22)	0.53 (0.26)	19.07 (0.54)

Table 2: Results of the simulations of Section 5.1. $\hat{\alpha}$ refers to the posterior mean (row: `BayesMallows`) or to MLE (row: `PerMallows`). $\hat{\pi}$ is the dispersion parameter of ISR. $\hat{\boldsymbol{\rho}}$ is the consensus ranking estimated by the different procedures: MAP (row: `BayesMallows` (MAP)), CP (row: `BayesMallows` (CP)), MLE (row: `PerMallows` and `rankcluster`), point estimate (row: `RankAggreg` and Borda). Standard deviations are reported in parenthesis. Parameters setting: $N = 100$, $n = 10$.

The results of the comparisons are shown in Table 2. The `BayesMallows` estimates are obtained through Algorithm 1 of Appendix B, with the available exact partition function corresponding to Kendall distance, and for 10^5 iterations (after a burn-in of 10^4 iterations). All quantities shown are averages over 50 independent repetitions of the whole simulation experiment. $\hat{\alpha}$ is the posterior mean (for `BayesMallows`) or the MLE (for `PerMallows`), while $\hat{\pi}$ is the MLE estimate of the dispersion parameter of ISR (for `rankcluster`). $\hat{\boldsymbol{\rho}}$ is the consensus ranking estimated by the different procedures: for `BayesMallows` it is either given by the CP consensus (`BayesMallows` - CP), or by the MAP (`BayesMallows` - MAP). We compare the goodness of fit of the methods by evaluating two quantities: first, the normalized Kendall distance between the estimated consensus ranking and the true one, used to generate the data, $d(\hat{\boldsymbol{\rho}}, \boldsymbol{\rho}_T)/n$. Second, the average of Kendall distances between the data points and the estimated consensus ranking, $T(\hat{\boldsymbol{\rho}},\ \mathbf{R}) = \frac{1}{N}\sum_{j=1}^{N} d(\hat{\boldsymbol{\rho}}, \mathbf{R}_j)$. This quantity makes sense here, being independent on the likelihood assumed by the different models.

The first remark about the results in Table 2 is the clear improvement of the performance in terms of $\frac{1}{n}d(\hat{\boldsymbol{\rho}}, \boldsymbol{\rho}_{\mathrm{T}})$, of all the methods, for increasing α. This obvious result is a consequence of the easier task of rank aggregation when the assessors are more concentrated around the consensus. Because the data were generated with the same model which `BayesMallows` and `PerMallows` used for inference, we expected that the Mallows-based methods would perform better than the rank aggregation methods we considered. The results of Table 2 confirm this claim: `BayesMallows` and `PerMallows` outperform the other rank aggregation methods, with the exception of Borda count, which gives the same results as `PerMallows`. This is not surprising, since the `PerMallows` MLE of the consensus is approximated though the Borda algorithm. Moreover, when the summary of the Bayesian posterior is the CP consensus, the performance of `BayesMallows`, both in terms of $\frac{1}{n}d(\hat{\boldsymbol{\rho}}, \boldsymbol{\rho}_{\mathrm{T}})$ and $T(\hat{\boldsymbol{\rho}}, \mathbf{R})$, was better than the others. This is another advantage of our approach on the competitors: being the output a full posterior distribution of the consensus, we can select any strategy to summarize it, possibly driven by the application at hand. To conclude, our approach gives slightly better results than the other existing methods, and in the worst cases the performance is still equivalent. In Section 6 we will compare inferential results on real data, not necessarily generated from the Mallows model.

6. Experiments

The experiments considered in this section illustrate the use of our approach in various situations corresponding to different data structures.

6.1 Meta-Analysis of Differential Gene Expression

Studies of differential gene expression between two conditions produce lists of genes, ranked according to their level of differential expression as measured by, for example, p-values. There is often little overlap between gene lists found by independent studies comparing the same condition. This situation raises the question of whether a consensus top list over all available studies can be found.

We handle this situation in our Bayesian Mallows model by considering each study $j \in \{1, \ldots, N\}$ to be an assessor, providing a top-n_j list of differentially expressed genes, which are the ranked items. This problem was studied by DeConde et al. (2006), Deng et al. (2014), and Lin and Ding (2009), who all used the same 5 studies comparing prostate cancer patients with healthy controls (Dhanasekaran et al., 2001; Luo et al., 2001; Singh et al., 2002; True et al., 2006; Welsh et al., 2001). We consider the same 5 studies, and we aim at estimating a consensus with uncertainty. Data consist of the top-25 lists of genes from each study, in total 89 genes. Here we perform a restricted analysis (see 4.1.1), and in this case $n_j = 25$ for all $j = 1, \ldots, 5$, and $n = 89$.

Table 3 shows the result of analyzing the five gene lists with the Mallows footrule model for partial data (Section 4.1). We run 20 different chains, for a total of 10^7 iterations (computing time was $16'4''$), and discarded the first $5 \cdot 10^4$ iterations of each as burn-in. For the partition function, we used the IS approximation $Z_n^K(\alpha)$ with $K = 10^7$, computed off-line on a grid of α's in $(0, 40]$. After some tuning, we set $L = 40$, $\sigma_\alpha = 0.95$, $\lambda = 0.05$ and $\alpha_{\mathrm{jump}} = 1$, and used the footrule distance. Like DeConde et al. (2006), Deng et al. (2014), and Lin and Ding (2009), our method ranked the genes HPN and AMACR first and

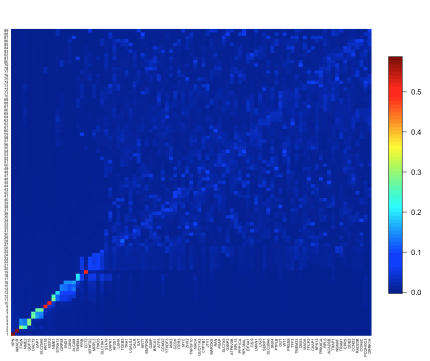

Figure 8: Heat plot of the posterior probabilities, for 89 genes, for being ranked as the $k-$th most preferred, for $k = 1, ..., 89$. On the x-axis the genes are ordered according to the estimated CP consensus.

25	TRAM1	0.14	0.04	0.14

Table 3: Top-25 genes in the MAP consensus ranking from a total of 89 genes. The cumulative probability of each gene in the top-25 positions in the MAP of being in that position, or higher, is shown in the third column of the Table, $P(\rho \leq i)$. The probabilities of being among the top-10 and top-25 are also shown for each gene.

second in the MAP consensus ranking. The low value of the posterior mean of α, being 0.56 (mode 0.43, high posterior density, HPD, interval $(0.04, 1.29)$), is an indicator of a generally low level of agreement between the studies. In addition, the fact that $n > N$, and having partial data, both contribute to keeping α small. However, the posterior probability for each gene to be among the top-10 or top-25 is not so low, thus demonstrating that our approach can provide a valid criterion for consensus. In the hypothetical situation in which we had included in our analysis all n^* genes following a *full analysis* mode, with n^* being at least 7567, the largest number of genes included in in any of the five original studies (DeConde et al., 2006), this would have had the effect of making the posterior probabilities in Table 3 smaller. On the other hand, because of Corollary 2, the ranking order obtained from such hypothetical analysis based on all n^* genes would remain the same as in Table 3.

Next we compared the result shown in Table 3 with other approaches: Table 4 (left) reports results obtained with `RankAggreg` (Pihur et al., 2009), which is specifically targeted to meta-analysis problems, while in Table 4 (right) different aggregation methods implemented in `TopKLists` (Schimek et al., 2015) are considered. The results obtained via `RankAggreg` turned out unstable, with the final output changing in every run, and the list shown in Table 4 differs from that in Pihur et al. (2009). Overall, apart from the genes ranked to the top-2 places, there is still considerable variation in the exact rankings of

Table 4: Results given by the `RankAggreg` R package (left) and by the `TopKLists` R package (right).

the genes. Rather than considering such exact rankings, however, it may in practice be of more interest to see to what extent the same genes are shared between different top$-k$ lists. Here the results are more positive. For example, of the 10 genes on top of the MAP consensus list of Table 3, always 9 genes turned out to be in common with each of the lists of Table 4, with the exception of the median (column 3 of Table 4, right), where only 7 genes are shared. Column 4 of Table 3 provides additional support to the MAP selection of the top-10: all genes included in that list have posterior probability at least 0.56 for being among the top-10, while for those outside the list it is maximally 0.15.

In order to have a quantification of the quality of the different estimates, we compute the footrule distance for partial data (Critchlow, 2012, p. 30) between $\boldsymbol{\rho}$ and $\mathbf{R}_j$, averaged over the assessors, defined as follows

$$T_{\text{partial}}(\boldsymbol{\rho},\ \mathbf{R}) = \frac{1}{N}\sum_{j=1}^{N}\sum_{i=1}^{n}|\nu_{R_{ij}} - \nu_{\rho_i}|,$$

where $\nu_{\boldsymbol{\rho}}$, $\nu_{\mathbf{R}_j} \in \mathcal{P}_n$ are equal to $\boldsymbol{\rho}$ and $\mathbf{R}_j$ in their top$-n_j$ ranks (top-25 in the case of gene lists), while the rank $\frac{n+n_j+1}{2}$ is assigned to the items whose rank in $\boldsymbol{\rho}$ and $\mathbf{R}_j$ is not in their top$-n_j$. Note that $\frac{n+n_j+1}{2}$ (equal to 57.5 in this case) is the average of the ranks of the excluded items. Table 5 reports the values of T_{partial} for the various methods. We notice that the minimum value is achieved by the Mallows MAP consensus list.

6.2 Beach Preference Data

Here we consider pair comparison data (Section 4.2) generated as follows: first we chose $n = 15$ images of tropical beaches, shown in Figure 9, such that they differ in terms of

	MAP	CE	GA	mean	median	geo.mean	l2norm
$T_{\text{partial}}(\boldsymbol{\rho},\ \mathbf{R})$	12.56	12.67	12.98	13.52	15.26	14.05	13.04

Table 5: Values of the average footrule distance for partial data T_{partial} between the partial gene lists and the different estimated consensus rankings.

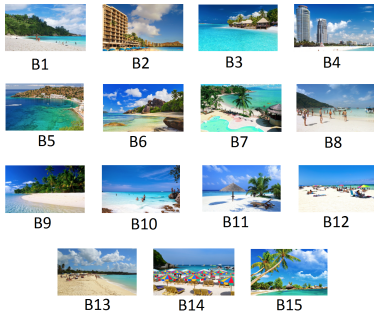

Figure 9: The 15 images used for producing the Beach data set.

$\boldsymbol{\rho}$	CP	$P(\rho_i \le i)$	95% HPDI

14	B12	0.94	(12,15)
15	B2	1	(14,15)

Table 6: Results of the pair comparisons. Beaches arranged according to the CP consensus ordering together with the corresponding 95% highest posterior density intervals.

presence of building and people. For example, beach B9 depicts a very isolated scenery, while beach B2 presents a large hotel seafront.

The pairwise preference data were collected as follows. Each assessor was shown a sequence of 25 pairs of images, and asked on every pair the question: *"Which of the two beaches would you prefer to go to in your next vacation?"*. Each assessor was presented with a random set of pairs, arranged in random order. As there are 105 possible pairs, 25 pairs is less than 25% of the total. We collected $N = 60$ answers. Seven assessors did not answer to all questions, but we kept these responses as our method is able to analyze also incomplete data. Nine assessors returned orderings which contained at least one non-transitive pattern of comparisons. In this analysis we dropped the non-transitive patterns from the data. Systematic methods for dealing with non-transitive rank data will be considered elsewhere.

We run the MCMC for 10^6 iterations, and discarded the first 10^5 iterations as burn-in. We set $L = 2$, $\sigma_\alpha = 0.1$, $\lambda = 0.1$ and $\alpha_{\text{jump}} = 100$. Computing time was less than $2'$.

$\boldsymbol{\rho}$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Table 7: Consensus ordering given by other methods: `BT` is the Bradley Terry given by the `BradleyTerry2` R package (Firth and Turner, 2012), `PR` is the popular Google PageRank output (Brin and Page, 1998) given by the `igraph` R package (Csardi and Nepusz, 2006). Most preferred to the left.

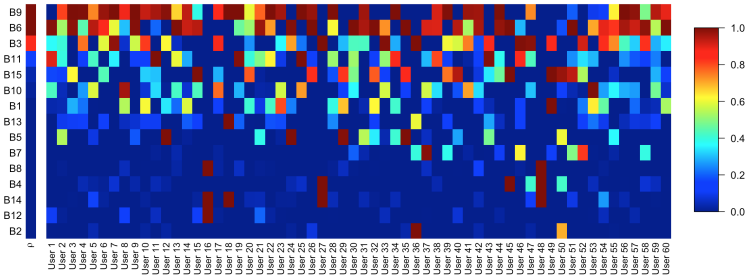

Figure 10: Posterior probability, for each beach, of being ranked among the top-3 in $\boldsymbol{\rho}$ (column 1), and in $\mathbf{R}_j$, $j = 1, ..., 60$ (next columns).

The posterior mean of α was $\mathbb{E}(\alpha|\text{data}) = 3.38\,(2.94, 3.82)$. In Table 6 we report the CP consensus ranking of the beaches (column 2), the cumulative probability of each item i to be in the top$-i$ positions, i.e., $P(\rho_i \leq i)$ (column 3), and the 95% HPDI for each item (column 4), which represents the posterior uncertainty. In Table 7 we give the consensus ranking obtained by two other methods, for comparison.

With our method we also estimate the latent full ranking of each assessor. Figure 10 was obtained as follows: in the separate column on the left, we display the posterior probability $P(\rho_{\text{B}i} \leq 3|\text{data})$ that a given beach Bi, $i = 1, ..., 15$, is among the top-3 in the consensus $\boldsymbol{\rho}$. In the other columns we show, for each beach Bi, the individual posterior probabilities $P(\tilde{R}_{j,\text{B}i} \leq 3|\text{data})$, of being among the top$-3$ for each assessor j, $j = 1, ..., 60$. We see for example that beach B5, which was ranked only 9th in the consensus, had, for 4 assessors, posterior probability very close to 1 of being included among their top-3 beaches.

6.3 Sushi Data

We illustrate clustering based on full rankings using the benchmark data set of sushi preferences collected across Japan (Kamishima, 2003), see also Lu and Boutilier (2014). $N = 5000$ people were interviewed, each giving a complete ranking of $n = 10$ sushi variants. Cultural differences among Japanese regions influence food preferences, so we expect the assessors to

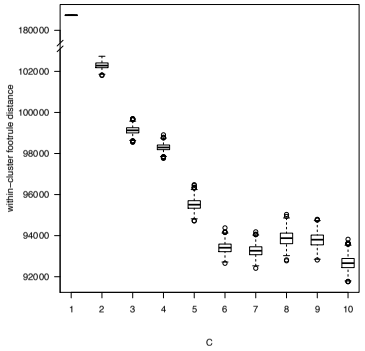

Figure 11: Results of the Sushi experiment. Boxplots of the posterior distributions of the within-cluster sum of footrule distances of assessors' ranks from the corresponding cluster consensus for different choices of C (note the y-axis break, for better visualization).

be clustered according to different shared consensus rankings. We analyzed the sushi data using mixtures of Mallows models (Section 4.3) with the footrule distance (with the exact partition function of the Mallows model, see Section 2.1). We run the MCMC for 10^6 iterations, and discarded the first 10^5 iterations as burn-in. After some tuning, we set $L = 1$, $\sigma_\alpha = 0.1$, $\lambda = 0.1$ and $\alpha_{\text{jump}} = 100$. In the Dirichlet prior for $\boldsymbol{\tau}$, we set the hyper-parameter $\psi = N/C$, thus favoring high-entropy distributions. Computing time varied depending on C, from order of minutes to an hour. For each possible number of clusters $C \in \{1, \ldots, 10\}$, we used a thinned subset of MCMC samples to compute the posterior footrule distance between $\boldsymbol{\rho}_c$ and the ranking of each assessor assigned to that cluster, $\sum_{c=1}^{C} \sum_{j:z_j=c} d(\mathbf{R}_j, \boldsymbol{\rho}_c)$. The posterior of this quantity, over all assessors and cluster centers, was then used for choosing the appropriate value for C, see Figure 11. We found an elbow at $C = 6$, which was then used to further inspect results.

Table 8 shows the results when the number of clusters is set to $C = 6$: for each cluster, the MAP estimates for $\boldsymbol{\tau}$ and $\boldsymbol{\alpha}$, together with their 95% HPDIs, are shown on the top of the table. Table 8 also shows the sushi items, arranged in cluster-specific lists according to the MAP consensus ordering (in this case equal to the CP consensus). Our results can be compared with the ones in Lu and Boutilier (2014) (Table 1 in Section 5.3.2): the correspondence of ours-Lu and Boutilier (2014) clusters could be 1-4, 2-1, 3-2, 4-5, 5-4, 6-0. Note that the dispersion parameter α in our Bayesian Mallows model is connected to the dispersion parameter ϕ in Lu and Boutilier (2014) by the link $\alpha = -n \log(\phi)$. Hence, we can also observe that the cluster-specific α values reported in Table 8 are quite comparable to the dispersion parameters of Lu and Boutilier (2014).

We investigate the stability of the clustering in Figure 12, which shows the heatplot of the posterior probabilities, for all 5000 assessors (on the x-axis), of being assigned to each of the

Table 8: Results of the Sushi experiment when setting $C = 6$. Sushi items arranged according to the MAP consensus ranking found from the posterior distribution of $\boldsymbol{\rho}_c$, $c = 1, \ldots, 6$. At the top of the Table, corresponding MAP estimates for $\boldsymbol{\tau}$ and $\boldsymbol{\alpha}$, with 95% HPDIs (in parenthesis). Results are based on 10^6 MCMC iterations.

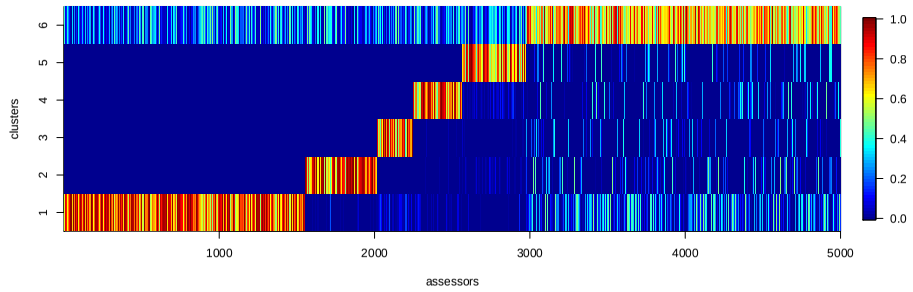

Figure 12: Heatplot of posterior probabilities for all 5000 assessors (on the x-axis) of being assigned to each cluster ($c = 1, \ldots, 6$ from bottom to top).

6 clusters in Table 8 (clusters $c = 1, \ldots, 6$ from bottom to top in Figure 12): most of these individual probabilities were concentrated on some particular preferred value of c among the six possibilities, indicating a reasonably stable behavior in the cluster assignments.

6.4 Movielens Data

The Movielens data set[1] contains movie ratings from 6040 users. In this example, we focused on the $n = 200$ most rated movies, and on the $N = 6004$ users who rated (not equally) at

1. www.grouplens.org/datasets/.

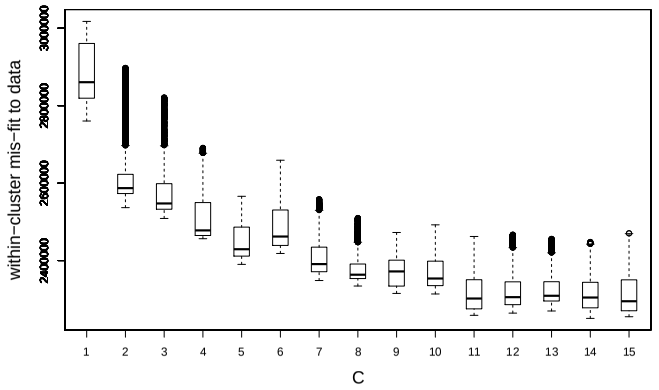

Figure 13: Results of the Movielens experiment. Boxplots of the posterior distributions of the within-cluster indicator of mis-fit to the data, as introduced in Section 4.4, for different choices of C.

least 3 movies. Each user had considered only a subset of the n movies (30.2 on average). We converted the ratings given by each user from a 1-5 scale to pairwise preferences as described in Lu and Boutilier (2014): each movie was preferred to all movies which the user had rated strictly lower. We selected users whose rating included at least 3 movies, because two of them were needed to create at least a pairwise comparison, and the third one was needed for prediction, as explained in the following.

Since we expected heterogeneity among users, due to age/gender/social factors/education, we applied the clustering scheme for pairwise preferences, with the footrule distance. Since $n = 200$, we used the asymptotic approximation for $Z_n(\alpha)$ described in Mukherjee (2016) and in Section 2 of the Supplementary Material. We run the MCMC for 10^5 iterations, after a burn-in of $5 \cdot 10^4$ iterations. We set: $L = 20$, $\sigma_\alpha = 0.05$, $\alpha_{\text{jump}} = 10$ and $\lambda = 0.1$, after some tuning. Note that the label switching problem only affects inference on cluster-specific parameters, but it does not affect predictive distributions (Celeux et al., 2006). We varied the number C of clusters in the set $\{1, \ldots, 15\}$, and inspected the within-cluster indicator of mis-fit to the data, $\sum_{c=1}^{C} \sum_{j:z_j=c} |\{B \in \text{tc}(\mathcal{B}_j) : B \text{ is not consistent with } \boldsymbol{\rho}_c\}|$, introduced in Section 4.4, see Figure 13: the posterior within-cluster indicator shows two possible elbows: $C = 5$, and $C = 11$. Hence, according to these criteria, both choices seemed initially conceivable. However, it is beyond the scope of this paper to discuss ways to decide the number of clusters.

In order to select one of these two models, we examined their predictive performance. Before converting ratings to preferences, we discarded for each user j one of the rated movies at random. Then, we randomly selected one of the other movies rated by the same user, and

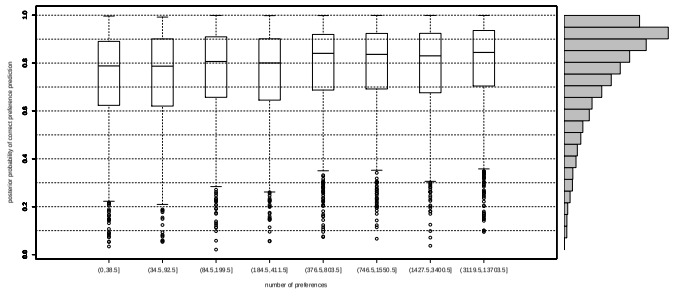

Figure 14: Results of the Movielens experiment. Boxplots of the posterior probability for correctly predicting the discarded preference conditionally on the number of preferences stated by the user, for the model with $C = 5$. The histogram on the right shows the marginal posterior probability for correct preference prediction.

used it to create a pairwise preference involving the discarded movie. This preference was then not used for inference. After running the Bayesian Mallows model, we computed for each user the predictive probabilities $P(\tilde{\mathbf{R}}_j|\text{data})$, and thereby the probabilities for correctly predicting the discarded preference. The median, across all users, of these probabilities was 0.8225 for the model with $C = 5$ clusters, and 0.796 for $C = 11$ clusters. Moreover, for $C = 5$, 88 % of these probabilities were higher than 0.5. These are very positive results, and they suggest that the predictive performance of the model with 5 clusters is slightly better than the one with 11 clusters. It appears that the larger number of clusters in the latter model leads to a slight overfitting, and this is likely to be the main cause of the loss in the predictive success. Figure 14 shows the boxplots of the posterior distribution of the probability for correct preference prediction of the left out comparison, stratified with respect to the number of preferences given by each user, for the model with $C = 5$. The histogram on the right shows the same posterior probability for correctly predicting the discarded preference for all users, for the same model, regardless of how many preferences each user had expressed. Interestingly, in this data, the predictive power is rather stable and high, irrespectively from how many movies the users rated. In other applications, we would expect the predictions to become better the more preferences are expressed by a user. In this case, a figure similar to Figure 14 could guide personal recommendation algorithms, which should not rely on estimated point preferences, if these are too uncertain, as happens for users who have given a few ratings only.

In Table 9 the MAP estimates for $\boldsymbol{\tau}$ and $\boldsymbol{\alpha}$, together with their 95% HPDIs, are shown at the top. The table also shows a subset of the movies, arranged in cluster-specific top-10 lists according to the CP consensus ranking, from the posterior distribution of $\boldsymbol{\rho}_c$, $c = 1, \ldots, 5$. We note that all α values correspond to a reasonable within-cluster variability. Moreover, the lists reported in Table 9 characterize the users in the same cluster as individuals sharing a reasonably well interpretable preference profile. Since in the Movielens data set additional

	$c = 1$	$c = 2$	$c = 3$	$c = 4$	$c = 5$

information on the users is available, we compared the estimated cluster assignments with the age, gender, and the occupation of the users. While occupation showed no interesting patterns, the second and fifth clusters had more males than expected, in contrast to the first and fourth clusters which included more females than average, the former above 45 and the latter below 35 of age.

7. Discussion

In this paper, we developed a fully Bayesian hierarchical framework for the analysis of rank data. An important advantage of the Bayesian approach is that it offers coherently propagated and directly interpretable ways to quantify posterior uncertainties of estimates of any quantity of interest. Earlier Bayesian treatments of the Mallows rank model are extended in many ways: we develop an importance sampling scheme for $Z_n(\alpha)$ allowing the use of other distances than Kendall's, and our MCMC algorithm efficiently samples from the posterior distribution of the unknown consensus ranking and of the latent assessor-specific full rankings. We also develop various extensions of the model, motivated by applications in which data take particular forms.

The Mallows model performs very well with a large number of assessors N, as we show in the Sushi experiment of Section 6.3, and in the Movielens experiment of Section 6.4. On the other hand, it may not be computationally feasible when the number of items is extremely large, for example $n \geq 10^4$, which is not uncommon in certain applications (Volkovs and Zemel, 2014). For the footrule and Spearman distances, there exist asymptotic approximations for $Z_n(\alpha)$ as $n \to \infty$ (Mukherjee, 2016), which we successfully used in Section 6.4, although the MCMC algorithm converges slowly in such large spaces. Maximum likelihood estimation of $\boldsymbol{\rho}$ runs into the same problem when n gets large (Aledo et al., 2013; Ali and Meilă, 2012). Volkovs and Zemel (2014) developed the multinomial preference model (MPM) for cases with very large n, which can be efficiently computed by maximizing a concave log-likelihood function. The MPM thus seems a useful choice when n is very large and real time performance is needed.

All methods presented have been implemented in C++, and run efficiently on a desktop computer, with the exception of the Movielens experiment, which needed to be run on a cluster. Obtaining a sufficiently large sample from the posterior distribution takes from

a few seconds, for small problems, to several minutes, in the examples involving massive data augmentation. We are also working on distributed versions of the MCMC on parallel synchronous and asynchronous machines.

Many of the extensions we propose for solving specific problems (for example, clustering, preference prediction, pairwise comparisons) are needed jointly in real applications, as we illustrate for example in the Movielens data. Our general framework is flexible enough to handle such extensions.

There are many situations in which rankings vary over time, as in political surveys (Regenwetter et al., 1999) or book bestsellers (Caron and Teh, 2012). We have extended our approach to this setting (Asfaw et al., 2017). We assume to observe ranks at discrete time-points indexed by $t = 0, 1, \ldots, T$ and let $\boldsymbol{\rho}^{(t)}$ and $\alpha^{(t)}$ denote the parameters of the Mallows model at time t. Interestingly, this model allows for prediction (with uncertainty quantification) of rankings in future time instances.

A natural generalization of our model is to allow for item-specific α's. This is known as generalized Mallows's model, first implemented in Fligner and Verducci (1986), for Kendall and Cayley distances, and further extended in Meilă and Bao (2010), for Kendall distance only, to the Bayesian framework. To our knowledge, the Mallows model with footrule and Spearman has not yet been generalized to handle item-specific α's, mostly because of the obvious computational difficulties. Within our framework this appears as feasible.

Acknowledgments

Valeria Vitelli and Øystein Sørensen contributed equally to this paper and are joint first authors. Marta Crispino contributed to the project as a visiting PhD student at OCBE, University of Oslo, and was partially funded by Cariplo. The authors thank Tyler Lu and Craig Boutilier for their help with the Movielens data, and Magne Thoresen for helpful discussions. The authors would also like to thank the Editor and three anonymous reviewers for their useful comments and suggestions on a previous version of the paper.

Appendix A. Proofs of Results from Section 4.1.1

Proof of Proposition 4.
Having assumed the uniform prior across all permutations of latent consensus ranks, the desired result will hold if and only if $\sum_{j=1,\ldots,N} d(\mathbf{R}_j, \boldsymbol{\rho}) \leq \sum_{j=1,\ldots,N} d(\mathbf{R}_j, \boldsymbol{\rho}')$. This is true if $d(\mathbf{R}_j, \boldsymbol{\rho}) \leq d(\mathbf{R}_j, \boldsymbol{\rho}')$ holds separately for each assessor j, for $j = 1, \ldots, N$. We consider first the footrule distance d, and then show that the result holds also for the Kendall and Spearman distances. This proof follows Proposition 4 in Meilă and Bao (2010).

Suppose first, for simplicity, that all assessors have ranked the same n items, that is, $\mathcal{A}_1 = \mathcal{A}_2 = \ldots = \mathcal{A}_N = \mathcal{A}$. Later we allow the sets $\mathcal{A}_j$ of ranked items to be different for different assessors. Thus there are $n^* - n$ items, which nobody ranked in the original data.

We now introduce synthetic rankings for all these items as well, that is, we augment each $\mathbf{R}_j$ as recorded in the data by replacing the missing ranks of the items $A_i \in \mathcal{A}^c$ by some permutation of their possible ranks from $n+1$ to n^*. We then show that the desired

inequality holds regardless of how these ranks $\{R_{ij}, A_i \in \mathcal{A}^c\}$ were assigned. The proof is by induction, and it is carried out in several steps.

For the first step, let $\boldsymbol{\rho}$ be a rank vector were the ranks from 1 to n, in any order, have been assigned to the items in $\mathcal{A}$, and the ranks R_{ij} between $n+1$ and n^* are given to items in $\mathcal{A}^c$. Let $\boldsymbol{\rho}'$ be a rank vector obtained from $\boldsymbol{\rho}$ by a transposition of the ranks of two items, say, of $A_{i_0} \in \mathcal{A}^c$ and $A_{i_1} \in \mathcal{A}$, with $\rho_{i_0} = \rho'_{i_1} \geq n+1$ and $\rho_{i_1} = \rho'_{i_0} \leq n$. Fixing these two items, we want to show that $d(\mathbf{R}_j, \boldsymbol{\rho}) \leq d(\mathbf{R}_j, \boldsymbol{\rho}')$. For the footrule distance we have to show that $\sum_{i=1}^{n} |R_{ij} - \rho_i| \leq \sum_{i=1}^{n} |R_{ij} - \rho'_i|$. Since $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ coincide for all their coordinates $i \neq i_0, i_1$, it is enough to compare here the terms $|R_{i_0 j} - \rho_{i_0}|$ and $|R_{i_1 j} - \rho_{i_1}|$ on the left to the corresponding terms $|R_{i_0 j} - \rho'_{i_0}|$ and $|R_{i_1 j} - \rho'_{i_1}|$ on the right. We need to distinguish between two situations:

(i) Suppose $R_{i_1 j} \leq \rho_{i_1}$. Then, $\rho'_{i_1} - R_{i_1 j} > \rho_{i_1} - R_{i_1 j}$. On the other hand, $\rho_{i_0} \geq n+1$ implies that $A_{i_0} \in \mathcal{A}^c$, and it is therefore ranked by assessor j with $R_{i_0 j} \geq n+1$. Therefore, $|R_{i_0 j} - \rho'_{i_0}| \geq |R_{i_0 j} - \rho_{i_0}|$. By combining these two results we get that $|R_{i_0 j} - \rho_{i_0}| + |R_{i_1 j} - \rho_{i_1}| \leq |R_{i_0 j} - \rho'_{i_0}| + |R_{i_1 j} - \rho'_{i_1}|$.

(ii) Now, suppose that $R_{i_1 j} > \rho_{i_1}$. Then, $R_{i_1 j} - \rho_{i_1} \leq n - \rho_{i_1} \leq R_{i_0 j} - \rho'_{i_0}$. Moreover, since $|R_{i_0 j} - \rho_{i_0}| \leq |R_{i_1 j} - \rho_{i_0}| = |R_{i_1 j} - \rho'_{i_1}|$, we have that again $|R_{i_0 j} - \rho_{i_0}| + |R_{i_1 j} - \rho_{i_1}| \leq |R_{i_0 j} - \rho'_{i_0}| + |R_{i_1 j} - \rho'_{i_1}|$ holds.

The same reasoning holds also for the Kendall distance, since the Kendall distance between the two rank vectors, which are obtained from each other by a transposition of a pair of items, is the same as the footrule distance. For the Spearman distance, we only need to form squares of the distance between pairs of items, and the inequality remains valid.

For the general step of the induction, suppose that $\boldsymbol{\rho}$ has been obtained from its original version with all items in $\mathcal{A}$ ranked to the first n positions, via a sequence of transpositions between items originally in $\mathcal{A}$ and items originally in $\mathcal{A}^c$. Let $\boldsymbol{\rho}'$ be a rank vector where one more transposition of this type from $\boldsymbol{\rho}$ to $\boldsymbol{\rho}'$ has been carried out. Then the argument of the proof can still be carried through, and the conclusion $d(\mathbf{R}_j, \boldsymbol{\rho}) \leq d(\mathbf{R}_j, \boldsymbol{\rho}')$ holds. This argument needs to be complemented by considering the uniform random permutations, corresponding to the assumed prior of the ranks originally missing in the data, across their possible values from $n+1$ to n^*. But this is automatic, because the conclusion holds separately for all permutations of such ranks.

Finally, the argument needs to be extended to the situation in which the sets $\mathcal{A}_j$ of ranked items can be different for different assessors. In this case we are led to consider, as a by-product of the data augmentation scheme, a joint distribution of the rank vectors $\{\tilde{\mathbf{R}}_j; j = 1, \ldots, N\}$. Here, for each j, the n_j items which were ranked first have been fixed by the data. The remaining $n - n_j$ items are assigned augmented random ranks with values between $n_j + 1$ and n, where the probabilities, corresponding to the model P_{n^*}, are determined by the inference from the assumed Mallows model and the data. The conclusion remains valid regardless of the particular way in which the augmentation was done, and so it holds also when taking an expectation with respect to P_{n^*}. ■

Proof of Corollary 2.
It follows from Proposition 4 that the n top ranks in $\boldsymbol{\rho}^{MAP*}$ are all assigned to items $A_i \in \mathcal{A}$.

Therefore, using shorthand $\boldsymbol{\rho}_{\mathcal{A}} = (\boldsymbol{\rho}_i; A_i \in \mathcal{A})$ and $\boldsymbol{\rho}_{\mathcal{A}^c} = (\boldsymbol{\rho}_i; A_i \in \mathcal{A}^c)$ we see that $\boldsymbol{\rho}^{MAP*}$ must be of the form $\boldsymbol{\rho}^{MAP*} = (\boldsymbol{\rho}^{MAP*}_{\mathcal{A}}, \boldsymbol{\rho}^{MAP*}_{\mathcal{A}^c}) = (\boldsymbol{\pi}, \boldsymbol{\pi}')$, where $\boldsymbol{\pi}$ is a permutation of the set $(1, 2, \ldots, n)$, and similarly $\boldsymbol{\pi}'$ is some permutation of $(n+1, \ldots, n^*)$.

To prove the statement, we show the following: (i) the posterior probabilities $P_{n^*}(\boldsymbol{\rho}_{\mathcal{A}} = \boldsymbol{\pi}, \boldsymbol{\rho}_{\mathcal{A}^c} = \boldsymbol{\pi}'|\text{data})$ and $P_{n^*}(\boldsymbol{\rho}_{\mathcal{A}} = \boldsymbol{\pi}|\boldsymbol{\rho}_{\mathcal{A}^c} = \boldsymbol{\pi}', \text{data})$ are invariant under permutations of $\boldsymbol{\pi}'$, and (ii) the latter conditional probabilities $P_{n^*}(\boldsymbol{\rho}_{\mathcal{A}} = \boldsymbol{\pi}|\boldsymbol{\rho}_{\mathcal{A}^c} = \boldsymbol{\pi}', \text{data})$ coincide with $P_n(\boldsymbol{\rho}_{\mathcal{A}} = \boldsymbol{\pi}|\text{data})$. As a consequence, a list of top-n items obtained from the *full analysis* estimate $\boldsymbol{\rho}^{MAP*}$ qualifies also as the *restricted analysis* estimate $\boldsymbol{\rho}^{MAP}$, and conversely, $\boldsymbol{\rho}^{MAP}$ can be augmented with any permutation $\boldsymbol{\pi}'$ of $(n+1, \ldots, n^*)$ to jointly form $\boldsymbol{\rho}^{MAP*}$.

The first part of (i) follows by noticing that the likelihood in the *full analysis*, when considering consensus rankings of the form $\boldsymbol{\rho} = (\boldsymbol{\rho}_{\mathcal{A}}, \boldsymbol{\rho}_{\mathcal{A}^c}) = (\boldsymbol{\pi}, \boldsymbol{\pi}')$, only depends on the observed data via $\boldsymbol{\pi}$. Since the assessors act independently, each imposing a uniform prior on their unranked items, also the posterior $P_{n^*}(\boldsymbol{\rho}_{\mathcal{A}} = \boldsymbol{\pi}, \boldsymbol{\rho}_{\mathcal{A}^c} = \boldsymbol{\pi}'|\text{data})$ will depend only on $\boldsymbol{\pi}$. The second part follows from the first, either by direct conditioning in the joint distribution, or by first computing the marginal $P_{n^*}(\boldsymbol{\rho}_{\mathcal{A}^c} = \boldsymbol{\pi}'|\text{data})$ by summation, and then dividing. (ii) follows then because, for both posterior probabilities, the sample space, the prior, and the likelihood are the same. ■

Appendix B. Pseudo-codes of the Algorithms

We here report the pseudo-codes of the algorithms. The available distance functions are: Kendall, footrule, Spearman. Cayley and Hamming are easy to implement. For Kendall, Cayley and Hamming, there is no need to run the IS to approximate $Z_n(\alpha)$, as the closed form is available (Fligner and Verducci, 1986). For footrule ($n \leq 50$) and Spearman ($n \leq 14$) the algorithm exploits the results presented in Section 2.1. For footrule ($n > 50$) and Spearman ($n > 14$) the IS procedure has to be run off-line, before the MCMC.

Algorithm 1: Basic MCMC Algorithm for Complete Rankings

input : $\mathbf{R}_1, \ldots, \mathbf{R}_N$; λ, σ_α, α_{jump}, L, $d(\cdot,\cdot)$, $Z_n(\alpha)$, M.
output: Posterior distributions of $\boldsymbol{\rho}$ and α.
Initialization of the MCMC: randomly generate $\boldsymbol{\rho}_0$ and α_0.

for $m \leftarrow 1$ **to** M **do**

  end
end

Appendix C. Sample from the Mallows Model

We here explain our proposed procedure to sample rankings from the Mallows model.

To sample full rankings $\mathbf{R}_1, ..., \mathbf{R}_N \sim \text{Mallows}(\boldsymbol{\rho}, \alpha)$, we use the following scheme (sketched in Algorithm 5). We run a basic Metropolis-Hastings algorithm with fixed consensus $\boldsymbol{\rho} \in \mathcal{P}_n$, $\alpha > 0$ and with a given distance measure, $d(\cdot,\cdot)$, until convergence. Once convergence is achieved, we continue sampling, and store the so obtained rankings at regular intervals (large enough to achieve independence) until we have reached the desired data dimension.

In case of heterogeneous rankings, we sample from Algorithm 6. As inputs, we give the number of clusters C, the fixed consensuses $\boldsymbol{\rho}_1, ..., \boldsymbol{\rho}_C$, the fixed $\alpha_1, ..., \alpha_C$, the hyper-

Algorithm 5: MCMC Sampler for full rankings

input : $\boldsymbol{\rho}$, α, d, N, L
output: $\mathbf{R}_1, ..., \mathbf{R}_N$
Initialization of the MCMC: randomly generate $\mathbf{R}_{1,0}, ..., \mathbf{R}_{N,0}$
for $m \leftarrow 1$ **to** M **do**
  for $j \leftarrow 1$ **to** N **do**
    sample $\mathbf{R}_j' \sim \text{L\&S}(\mathbf{R}_{j,m-1}, L)$
    compute: $ratio = \frac{P_L(\mathbf{R}_j|\mathbf{R}_j')}{P_L(\mathbf{R}_j'|\mathbf{R}_j)} \exp\left\{-\frac{\alpha}{n}\sum_{j=1}^N \left[d(\mathbf{R}_j', \boldsymbol{\rho}) - d(\mathbf{R}_j, \boldsymbol{\rho})\right]\right\}$ with $\mathbf{R}_j \leftarrow \mathbf{R}_{j,m-1}$
    sample: $u \sim \mathcal{U}(0,1)$
    if $u < ratio$ **then**
      $\mathbf{R}_{j,m} \leftarrow \mathbf{R}_j'$
    else
      $\mathbf{R}_{j,m} \leftarrow \mathbf{R}_{j,m-1}$
    end
  end
end

parameter $\boldsymbol{\psi} = (\psi_1, ..., \psi_C)$ of the Dirichlet density over the proportion of assessors in the clusters, and $d(\cdot,\cdot)$. The algorithm then returns the rankings $\mathbf{R}_1, ..., \mathbf{R}_N$, sampled from a Mixture of Mallows models, as well as the the cluster assignments $z_1, ..., z_N$.

Algorithm 6: MCMC Sampler for full rankings with clusters

input : C, $\boldsymbol{\rho}_{1:C}$, $\alpha_{1:C}$, $\boldsymbol{\psi}$, d, N, L
output: $\mathbf{R}_1, ..., \mathbf{R}_N$ and $z_1, ..., z_N$
Initialization of the MCMC: randomly generate $\mathbf{R}_{1,0}, ..., \mathbf{R}_{N,0}$
randomly generate $\tau_1, ..., \tau_C \sim \text{Dir}(\boldsymbol{\psi})$
randomly generate $z_1, ..., z_N \sim \text{Mn}(1, \tau_1, ..., \tau_C)$
for $m \leftarrow 1$ **to** M **do**
  for $c \leftarrow 1$ **to** C **do**
    compute: $N_c = \sum_{j=1}^N 1\!\!1_c(z_j)$,
    sample N_c ranks with Algortihm 5
  end
end

For generating top-k rankings, we simply generate $\mathbf{R}_1, ..., \mathbf{R}_N$ with Algorithm 5, and then keep only the top-k items. In case of clusters, we do the same as above, but starting with Algorithm 6.

Finally, to sample the sets of pairwise comparisons $\mathcal{B}_1, ..., \mathcal{B}_N$, we first generate $\mathbf{R}_1, ..., \mathbf{R}_N$ with Algorithm 5. We then select the number $T_1, ..., T_N$ of pairwise comparisons that each assessor will evaluate[2]. Finally, given $\mathbf{R}_1, ..., \mathbf{R}_N$ and $T_1, ..., T_N$, we randomly sample without replacement T_j pairs (for each assessor $j = 1, \ldots, N$) from the collection of all possible $n(n-1)/2$ pairs, and obtain pairwise preferences by ordering all pairs according to $\mathbf{R}_j$. For generating pairwise comparisons with clusters, we follow the previous procedure, but starting with Algorithm 6.

2. Here it is possible to choose the same number of comparisons $T_j = T \leq n(n-1)/2$, $\forall j = 1, ..., N$, but also to have a different number of pairs per assessor. In this paper, for a given mean parameter λ_T, we independently sample $T_1, ..., T_N \sim \text{TruncPoiss}(\lambda_T, n(n-1)/2)$.

Abstract

Let P be a distribution with support S. The salient features of S can be quantified with persistent homology, which summarizes topological features of the sublevel sets of the distance function (the distance of any point x to S). Given a sample from P we can infer the persistent homology using an empirical version of the distance function. However, the empirical distance function is highly non-robust to noise and outliers. Even one outlier is deadly. The distance-to-a-measure (DTM), introduced by Chazal et al. (2011), and the kernel distance, introduced by Phillips et al. (2014), are smooth functions that provide useful topological information but are robust to noise and outliers. Chazal et al. (2015) derived concentration bounds for DTM. Building on these results, we derive limiting distributions and confidence sets, and we propose a method for choosing tuning parameters.

Keywords: Topological data analysis, persistent homology, RKHS.

1. Introduction

Figure 1 shows three complex point clouds, based on a model used for simulating cosmology data. Visually, the three samples look very similar. Below the data plots are the persistence diagrams, which are summaries of topological features defined in Section 2. The persistence diagrams make it clearer that the third data set is from a different data generating process than the first two.

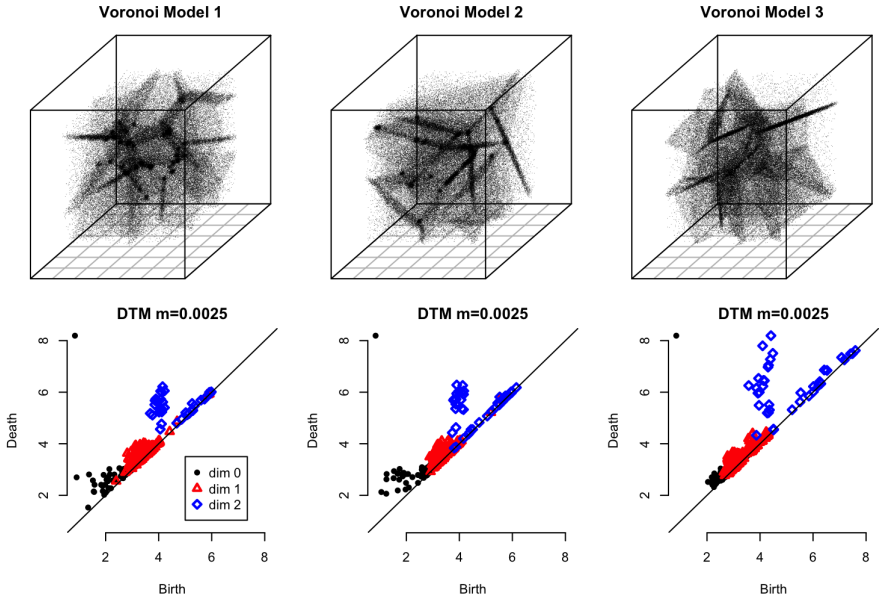

Figure 1: The first two datasets come from the same data generating mechanism. In the third one, the particles are more concentrated around the walls of the Voronoi cells. Although the difference is not clear from the scatterplots, it is evident from the persistence diagrams of the sublevel sets of the distance-to-measure functions. See Example 3 for more details on the Voronoi Models.

This is an example of how topological features can summarize structure in point clouds. The field of topological data analysis (TDA) is concerned with defining such topological features; see Carlsson (2009). When performing TDA, it is important to use topological measures that are robust to noise. This paper explores some of these robust topological measures.

Let P be a distribution with compact support $S \subset \mathbb{R}^d$. One way to describe the shape of S is by using homology. Roughly speaking, the homology of S measures the topological features of S, such as the connected components, the holes, and the voids. A more nuanced way to describe the shape of S is using persistent homology, which is a multiscale version of homology. To describe persistent homology, we begin with the distance function $\Delta_S \colon \mathbb{R}^d \to \mathbb{R}$ for S which is defined by

$$\Delta_S(x) = \inf_{y \in S} \|x - y\|. \tag{1}$$

The sublevel sets $L_t = \{x : \ \Delta_S(x) \leq t\}$ provide multiscale topological information about S. As t varies from zero to ∞, topological features — connected components, loops, voids — are born and die. Persistent homology quantifies the evolution of these topological features as a function of t. See Figure 2. Each point on the persistence diagram represents the birth and death time of a topological feature.

Given a sample $X_1, \ldots, X_n \sim P$, the empirical distance function is defined by

$$\widehat{\Delta}(x) = \min_{X_i} \|x - X_i\|. \tag{2}$$

If P is supported on S, and has a density bounded away from zero and infinity, then $\widehat{\Delta}$ is a consistent estimator of Δ_S, i.e., $\sup_x |\widehat{\Delta}(x) - \Delta_S(x)| \xrightarrow{P} 0$. However, if there are outliers, or noise, then $\widehat{\Delta}(x)$ is no longer consistent. Figure 3 (bottom) shows that a few outliers completely change the distance function. In the language of robust statistics, the empirical distance function has breakdown point zero.

A more robust approach is to estimate the persistent homology of the super-level sets of the density p of P. As long as P is concentrated near S, we expect the level sets of p to provide useful topological information about S. Specifically, some level sets of p are homotopic to S under weak conditions, and this implies that we can estimate the homology of S. Note that, in this case, we are using the persistent homology of the super-level sets of p, to estimate the homology of S. This is the approach suggested by Bubenik (2015), Fasy et al. (2014b) and Bobrowski et al. (2014). A related idea is to use persistent homology based on a kernel distance (Phillips et al., 2014). In fact, the sublevel sets of the kernel distance are a rescaling of the super-level sets of p, so these two ideas are essentially equivalent. We discuss this approach in Section 5.

A different approach, more closely related to the distance function, but robust to noise, is to use the *distance-to-a-measure (DTM)*, $\delta \equiv \delta_{P,m}$, from Chazal et al. (2011); see Section 2. An estimate $\widehat{\delta}$ of δ is obtained by replacing the true probability measure with the empirical probability measure P_n, or with a deconvolved version of the observed measure Caillerie et al. (2011). One then constructs a persistence diagram based on the sub-level sets of the DTM. See Figure 1. This approach is aimed at estimating the persistent homology of S. (The DTM also suggests new approaches to density estimation; see Biau et al. (2011).)

The density estimation approach and the DTM are both trying to probe the topology of S. But the former is using persistent homology to estimate the homology of S, while the DTM is directly trying to estimate the persistent homology of distance function of S. We discuss this point in detail in Section 9.1.

In this paper, we explore some statistical properties of these methods. In particular:

1. We show that $\sqrt{n}(\widehat{\delta}^2(x) - \delta^2(x))$ converges to a Gaussian process. (Theorem 5).
2. We show that the bootstrap provides asymptotically valid confidence bands for δ. This allows us to identify significant topological features. (Theorem 19).
3. We find the limiting distribution of a key topological quantity called the bottleneck distance. (Section 4.1).
4. We also show that, under additional assumptions, there is another version of the bootstrap—which we call the bottleneck bootstrap—that provides more precise inferences. (Section 6).
5. We show similar results for the kernel distance. (Section 5).
6. We propose a method for choosing the tuning parameter m for DTM and the bandwidth h for the kernel distance. (Section 7.1).
7. We show that the DTM and the kernel density estimator (KDE) both suffer from boundary bias and we suggest a method for reducing the bias. (Section 7.2).

Notation. $B(x, \epsilon)$ is a Euclidean ball of radius ϵ, centered at x. We define $A \oplus \epsilon = \bigcup_{x \in A} B(x, \epsilon)$, the union of ϵ-balls centered at points in A. If x is a vector then $||x||_\infty = \max_j |x_j|$. Similarly, if f is a real-valued function then $||f||_\infty = \sup_x |f(x)|$. We write $X_n \rightsquigarrow X$ to mean that X_n converges in distribution to X, and we use symbols like $c, C, \ldots,$ as generic positive constants.

Remark: The computing for the examples in this paper were done using the R package **TDA**. See Fasy et al. (2014a). The package can be downloaded from `http://cran.r-project.org/web/packages/TDA/index.html`.

Remark: In this paper, we discuss the DTM which uses a smoothing parameter m and the kernel density estimator which uses a smoothing bandwidth h. Unlike in traditional function estimation, we do not send these parameters to zero as n increases. In TDA, the topological features created with a fixed smoothing parameter are of interest. Thus, all the theory in this paper treats the smoothing parameters as being bounded away from 0. See also Section 4.4 in Fasy et al. (2014b). In Section 7.1, we discuss the choice of these smoothing parameters.

2. Background

In this section, we define several distance functions and distance-like functions, and we introduce the relevant concepts from computational topology. For more detail, we refer the reader to Edelsbrunner and Harer (2010).

2.1 Distance Functions and Persistent Homology

Let $S \subset \mathbb{R}^d$ be a compact set. The *homology* of S characterizes certain topological features of S, such as its connected components, holes, and voids. *Persistent homology* is a multiscale version of homology. Recall that the distance function Δ_S for S is

$$\Delta_S(x) = \inf_{y \in S} \|x - y\|. \tag{3}$$

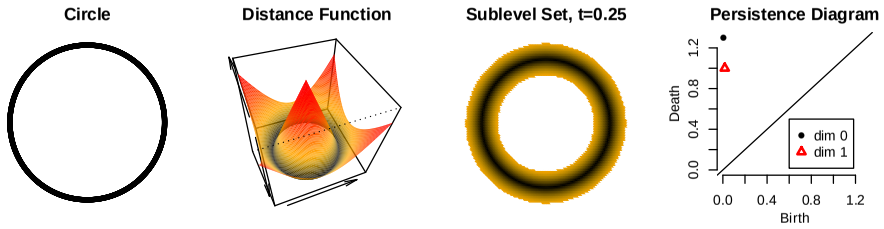

Figure 2: The left plot shows a one-dimensional curve. The second plot is the distance function. The third plot shows a typical sublevel set of the distance function. The fourth plot is the persistence diagram which shows the birth and death times of loops (triangles) and connected components (points) of the sublevel sets.

Let $L_t = \{x : \ \Delta_S(x) \leq t\}$. We will refer to the parameter t as "time."

Given the nested family of the sublevel sets of Δ_S, the topology of L_t changes as t increases: new connected components can appear, existing connected components can merge, cycles and cavities can appear or be filled, etc. Persistent homology tracks these changes, identifies *features* and associates an *interval* or *lifetime* (from t_{birth} to t_{death}) to them. For instance, a connected component is a feature that is born at the smallest t such that the component is present in L_t, and dies when it merges with an older connected component. Intuitively, the longer a feature persists, the more relevant it is.

A feature, or more precisely its lifetime, can be represented as a segment whose extremities have abscissae t_{birth} and t_{death}; the set of these segments is called the *barcode* of Δ_S. An interval can also be represented as a point in the plane with coordinates $(u, v) = (t_{\text{birth}}, t_{\text{death}})$. The set of points (with multiplicity) representing the intervals is called the *persistence diagram* of Δ_S. Note that the diagram is entirely contained in the half-plane above the diagonal defined by $u = v$, since death always occurs after birth. This diagram is well-defined for any compact set S (Chazal et al. (2012), Theorem 2.22). The most persistent features (supposedly the most important) are those represented by the points furthest from the diagonal in the diagram, whereas points close to the diagonal can be interpreted as (topological) noise.

Figure 2 shows a simple example. Here, the points on the circle are regarded as a subset of $\mathbb{R}^2$. At time zero, there is one connected component and one loop. As t increases, the loop dies.

Let S_1 and S_2 be compact sets with distance functions Δ_1 and Δ_2 and diagrams D_1 and D_2. The bottleneck distance between D_1 and D_2 is defined by

$$W_\infty(D_1, D_2) = \min_{g:\ D_1 \to D_2} \sup_{z \in D_1} \|z - g(z)\|_\infty, \tag{4}$$

where the minimum is over all bijections between D_1 and D_2. In words, the bottleneck distance is the maximum distance between the points of the two diagrams, after minimizing over all possible pairings of the points (including the points on the diagonals).

A fundamental property of persistence diagrams is their *stability*. According to the Persistence Stability Theorem (Cohen-Steiner et al. (2005); Chazal et al. (2012))

$$W_\infty(D_1, D_2) \leq ||\Delta_1 - \Delta_2||_\infty = H(S_1, S_2). \tag{5}$$

Here, H is the Hausdorff distance, namely,

$$H(A, B) = \inf\Big\{\epsilon : \ A \subset B \oplus \epsilon \text{ and } B \subset A \oplus \epsilon\Big\},$$

where we recall that $A \oplus \epsilon = \bigcup_{x \in A} B(x, \epsilon)$. More generally, the definition of persistence diagrams and the above stability theorem do not restrict to distance functions but also extend to families of sublevel sets (resp. upper-level sets) of functions defined on $\mathbb{R}^d$ under very weak assumption. We refer the reader to Edelsbrunner and Harer (2010); Chazal et al. (2009, 2012) for a detailed exposition of the theory.

Given a sample $X_1, \ldots, X_n \sim P$, the empirical distance function is defined by

$$\widehat{\Delta}(x) = \min_{X_i} \|x - X_i\|. \tag{6}$$

Lemma 1 (Lemma 4 in Fasy et al., 2014b) *Suppose that P is supported on S, and has a density bounded away from zero and infinity. Then*

$$\sup_x |\widehat{\Delta}(x) - \Delta_S(x)| \xrightarrow{P} 0.$$

See also Cuevas and Rodríguez-Casal (2004). The previous lemma justifies using $\widehat{\Delta}$ to estimate the persistent homology of sublevel sets of Δ_S. In fact, the sublevel sets of $\widehat{\Delta}$ are just unions of balls around the observed data. That is,

$$L_t = \big\{x : \ \widehat{\Delta}(x) \leq t\big\} = \bigcup_{i=1}^n B(X_i, t).$$

The persistent homology of the union of the balls as t increases may be computed by creating a combinatorial representation (called a Cech complex) of the union of balls, and then applying basic operations from linear algebra (Edelsbrunner and Harer, 2010, Sections VI.2 and VII.1).

However, as soon as there is noise or outliers, the empirical distance function becomes useless, as illustrated in Figure 3. More specifically, suppose that

$$P = \pi R + (1 - \pi)(Q \star \Phi_\sigma), \tag{7}$$

where $\pi \in [0, 1]$, R is an outlier distribution (such as a uniform on a large set), Q is supported on S, $\star$ denotes convolution, and Φ_σ is a compactly supported noise distribution with scale parameter σ.

Recovering the persistent homology of Δ_S exactly (or even the homology of S) is not possible in general since the problem is under-identified. But we would still like to find a function that is similar to the distance function for S. The empirical distance function fails miserably even when π and σ are small. Instead, we now turn to the DTM.

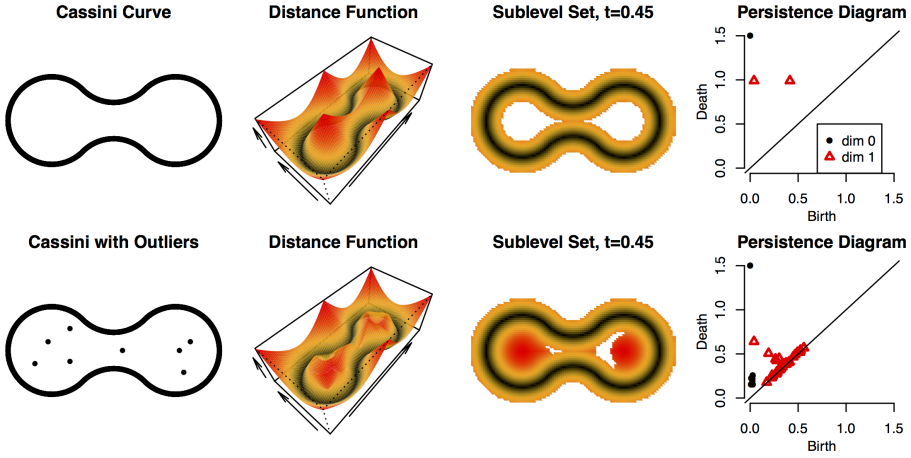

Figure 3: Top: data on the Cassini curve, the distance function $\widehat{\Delta}$, a typical sublevel set $\{x : \widehat{\Delta}(x) \leq t\}$ and the resulting persistence diagram. Bottom: the effect of adding a few outliers. Note that the distance function and persistence diagram are dramatically different.

2.2 Distance to a Measure

Given a probability measure P, for $0 < m < 1$, the *distance-to-measure (DTM)* at resolution m (Chazal et al., 2011) is defined by

$$\delta(x) \equiv \delta_{P,m}(x) = \sqrt{\frac{1}{m}\int_0^m (G_x^{-1}(u))^2 du}, \tag{8}$$

where $G_x(t) = P(\|X - x\| \leq t)$. Alternatively, the DTM can be defined using the cdf of the squared distances, as in the following lemma:

Lemma 2 (Chazal et al., 2015) *Let $F_x(t) = P(\|X - x\|^2 \leq t)$. Then*

$$\delta_{P,m}^2(x) = \frac{1}{m}\int_0^m F_x^{-1}(u) du.$$

Proof For any $0 < u < 1$,

$$\begin{aligned}\left[G_x^{-1}(u)\right]^2 &= \inf\left\{t^2 : G_x(t) \geq u\right\} = \inf\left\{t^2 : P(\|X - x\| \leq t) \geq u\right\} \\ &= \inf\left\{t : P(\|X - x\|^2 \leq t) \geq u\right\} = \inf\left\{t : F_x(t) \geq u\right\} = F_x^{-1}(u).\end{aligned}$$

Therefore

$$\delta_{P,m}^2(x) = \frac{1}{m}\int_0^m (G_x^{-1}(u))^2 du = \frac{1}{m}\int_0^m F_x^{-1}(u) du.$$

■

Given a sample $X_1, \ldots, X_n \sim P$, let P_n be the probability measure that puts mass $1/n$ on each X_i. It is easy to see that the distance to the measure P_n at resolution m is

$$\widehat{\delta}^2(x) \equiv \delta_{P_n,m}^2(x) = \frac{1}{k}\sum_{X_i \in N_k(x)} \|X_i - x\|^2, \tag{9}$$

where $k = \lceil mn \rceil$ and $N_k(x)$ is the set containing the k nearest neighbors of x among $X_1, \ldots, X_n$. We will use $\widehat{\delta}$ to estimate δ.

Now we summarize some important properties of the DTM, all of which are proved in Chazal et al. (2011) and Buchet et al. (2013). First, recall that the *Wasserstein distance of order p* between two probability measures P and Q is given by

$$W_p(P, Q) = \inf_J \left(\int \|x - y\|^p \, dJ(x, y)\right)^{1/p}, \tag{10}$$

where the infimum is over all joint distributions J for (X, Y) such that $X \sim P$ and $Y \sim Q$. We say that P satisfies the (a, b)-*condition* if there exist $a, b > 0$ such that, for every x in the support of P and every $\epsilon > 0$,

$$P\Big(B(x, \epsilon)\Big) \geq a\epsilon^b. \tag{11}$$

This means that the support does not have long, thin components.

Theorem 3 (Properties of DTM) *The following properties hold:*

1. *The distance to measure is 1-Lipschitz: for any probability measure P on $\mathbb{R}^d$ and any $(x, x') \in \mathbb{R}^d$,*
$$|\delta_{P,m}(x) - \delta_{P,m}(x')| \leq \|x - x'\|.$$
2. *If Q satisfies (11) and is supported on a compact set S, then*
$$\sup_x |\delta_{Q,m}(x) - \Delta_S(x)| \leq a^{-1/b} m^{1/b}. \tag{12}$$
In particular, $\sup_x |\delta_{Q,m}(x) - \Delta_S(x)| \to 0$ as $m \to 0$.
3. *If P and Q are two distributions, then*
$$\sup_x |\delta_{P,m}(x) - \delta_{Q,m}(x)| \leq \frac{1}{\sqrt{m}} W_2(P, Q). \tag{13}$$
4. *If Q satisfies (11) and is supported on a compact set S and P is another distribution (not necessarily supported on S), then*
$$\sup_x |\delta_{P,m}(x) - \Delta_S(x)| \leq a^{-1/b} m^{1/b} + \frac{1}{\sqrt{m}} W_2(P, Q) \tag{14}$$
Hence, if $m \asymp W_2(P, Q)^{2b/(2+b)}$, then $\sup_x |\delta_{P,m}(x) - \Delta_S(x)| = O(W_2(P, Q)^{2/(2+b)})$.

5. Let D_P be the diagram from $\delta_{P,m}$ and let D_Q be the diagram from $\delta_{Q,m}$, then

$$W_\infty(D_P, D_Q) \leq ||\delta_{P,m} - \delta_{Q,m}||_\infty. \tag{15}$$

For any compact set $A \subset \mathbb{R}^d$, let $r(A)$ denotes the radius of the smallest enclosing ball of A centered at zero:

$$r(A) = \inf\{r > 0 : A \subset B(0,r)\}.$$

We conclude this section by bounding the distance between the diagrams $D_{\delta_{P,m}}$ and D_{Δ_S}.

Lemma 4 (Comparison of Diagrams) *Let $P = \pi R + (1-\pi)(Q \star \Phi_\sigma)$ where Q is supported on S and satisfies (11), R is uniform on a compact set $A \subset \mathbb{R}^d$ and $\Phi_\sigma = N(0, \sigma^2 I)$. Then,*

$$W_\infty\left(D_{\delta_{P,m}}, D_{\Delta_S}\right) \leq a^{-1/b} m^{1/b} + \frac{\pi\sqrt{r(A)^2 + 2r(S)^2 + 2\sigma^2} + \sigma}{\sqrt{m}}.$$

Proof We first apply the stability theorem and parts 4 and 5 of the previous result:

$$W_\infty\left(D_{\delta_{P,m}}, D_{\Delta_S}\right) \leq a^{-1/b} m^{1/b} + \frac{1}{\sqrt{m}} W_2(P,Q).$$

The term $W_2(P,Q)$ can be upper bounded as follows:

$$W_2(P,Q) \leq W_2(P, Q \star \Phi_\sigma) + W_2(Q \star \Phi_\sigma, Q)$$

These two terms can be bounded with simple transport plans. Let Z be a Bernoulli random variable with parameter π. Let X and Y be random variables with distributions R and $Q \star \Phi_\sigma$. We take these three random variables to be independent. Then, the random variable V defined by $V = ZX + (1-Z)Y$ has for distribution the mixture distribution P. By definition of W_2, one has

$$\begin{aligned} W_2^2(P, Q \star \Phi_\sigma) &\leq \mathbb{E}\left(\|V - Y\|^2\right) \\ &\leq \mathbb{E}\left(|Z|^2\right)\mathbb{E}\left(\|X - Y\|^2\right), \end{aligned}$$

by definition of V and by independence of Z and $X - Y$. Next, we have $\mathbb{E}\left(\|X\|^2\right) \leq r(A)^2$ and $\mathbb{E}\left(\|Y\|^2\right) \leq 2[r(S)^2 + \sigma^2]$. Thus

$$W_2^2(P, Q \star \Phi_\sigma) \leq \pi^2\left(r(A)^2 + 2r(S)^2 + 2\sigma^2\right).$$

It can be checked in a similar way that $W_2(Q \star \Phi_\sigma, Q) \leq \sigma$ (see for instance the proof of Proposition 1 in Caillerie et al. (2011)) and the Lemma is proved. ■

Remark: Note that when π and σ are small (and m tends to 0) we see that the diagrams $D_{\delta_{P,m}}$ and D_{Δ_S} are close.

3. Limiting Distribution of the Empirical DTM

In this section, we find the limiting distribution of $\widehat{\delta}$ and we use this to find confidence bands for $\delta(x)$. We start with the pointwise limit.

Let $\delta(x) \equiv \delta_{P,m}(x)$ and $\widehat{\delta}(x) \equiv \delta_{P_n,m}(x)$, as defined in the previous section.

Theorem 5 (Convergence to Normal Distribution) *Let P be some distribution in $\mathbb{R}^d$. For some fixed x, assume that F_x is differentiable at $F_x^{-1}(m)$, for $m \in (0,1)$, with positive derivative $F_x'(F_x^{-1}(m))$. Then we have*

$$\sqrt{n}(\widehat{\delta}^2(x) - \delta^2(x)) \rightsquigarrow N(0, \sigma_x^2), \tag{16}$$

where

$$\sigma_x^2 = \frac{1}{m^2}\int_0^{F_x^{-1}(m)}\int_0^{F_x^{-1}(m)} [F_x(s \wedge t) - F_x(s)F_x(t)]\, ds\, dt.$$

Remark 6 *Note that assuming that F_x is differentiable is not a strong assumption. According to the Lebesgue differentiation theorem on $\mathbb{R}$, it will be satisfied as soon as the push forward measure of P by the function $\|x - \cdot\|^2$ is absolutely continuous with respect to the Lebesgue measure on $\mathbb{R}$.*

Proof From Lemma 2,

$$\delta^2(x) = \frac{1}{m}\int_0^m (G_x^{-1}(t))^2 dt = \frac{1}{m}\int_0^m F_x^{-1}(t)dt$$

where $G_x(t) = \mathbb{P}(\|X - x\| \leq t)$ and $F_x(t) = \mathbb{P}(\|X - x\|^2 \leq t)$. So

$$\sqrt{n}(\widehat{\delta}^2(x) - \delta^2(x)) = \frac{1}{m}\int_0^m \sqrt{n}[\widehat{F}_x^{-1}(t) - F_x^{-1}(t)]dt. \tag{17}$$

First suppose that $\widehat{F}_x^{-1}(m) > F_x^{-1}(m)$. Then, by integrating "horizontally" rather than

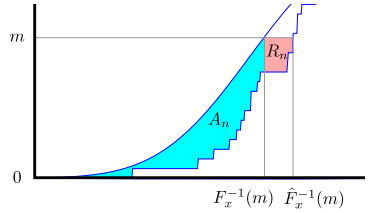

Figure 4: The integral of (17) can be decomposed into two parts, A_n and R_n.

"vertically", we can split the integral into two parts, as illustrated in Figure 4:

$$\begin{aligned} \frac{1}{m}\int_0^m \sqrt{n}[\widehat{F}_x^{-1}(t) - F_x^{-1}(t)]dt &= \frac{1}{m}\int_0^{F_x^{-1}(m)} \sqrt{n}[F_x(t) - \widehat{F}_x(t)]dt + \frac{1}{m}\int_{F_x^{-1}(m)}^{\widehat{F}_x^{-1}(m)} \sqrt{n}[m - \widehat{F}_x(t)]dt \\ &\equiv A_n(x) + R_n(x) \end{aligned} \tag{18}$$

Next, it can be easily checked that (18) is also true when $\widehat{F}_x^{-1}(m) < F_x^{-1}(m)$ if we take $\int_a^b f(u)du := -\int_b^a f(u)du$ when $a > b$. Now, since F_x is differentiable at m, we have that $\left|F_x^{-1}(m) - \widehat{F}_x^{-1}(m)\right| = O_P(1/\sqrt{n})$, see for instance Corollary 21.5 in van der Vaart (2000). According to the DKW (Dvoretsky-Kiefer-Wolfowitz) inequality we have that $\sup_t \left|F_x(t) - \widehat{F}_x(t)\right| = O_P(\sqrt{1/n})$ and thus

$$|R_n| \leq \frac{\sqrt{n}}{m} \left|F_x^{-1}(m) - \widehat{F}_x^{-1}(m)\right| \sup_t \left|F_x(t) - \widehat{F}_x(t)\right| = o_P(1).$$

Next, note that $\sqrt{n}[F_x(t) - \widehat{F}_x(t)] \rightsquigarrow \mathbb{B}(t)$, where $\mathbb{B}(t)$ is a Gaussian process with covariance function $[F_x(s \wedge t) - F_x(s)F_x(t)]$ (See, for example, van der Vaart and Wellner (1996)). By taking the integral, which is a bounded operator, we have that

$$A_n \rightsquigarrow \int_0^{F_x^{-1}(m)} \mathbb{B}(t)\, dt \stackrel{d}{=} N(0, \sigma_x^2),$$

where

$$\sigma_x^2 = \frac{1}{m^2} \int_0^{F_x^{-1}(m)} \int_0^{F_x^{-1}(m)} [F_x(s \wedge t) - F_x(s)F_x(t)]\, ds\, dt.$$

■

Now, we consider the functional limit of the distance to measure, on a compact domain $\mathcal{X} \subset \mathbb{R}^d$. The functional convergence of the DTM requires assumptions on the regularity of the quantile functions F_x^{-1}. We say that $\omega_x : (0,1) \to \mathbb{R}^+$ is a *modulus of (uniform) continuity* of F_x^{-1} if, for any $u \in (0,1)$,

$$\sup_{(m,m') \in (0,1)^2\,,\, |m'-m|<u} |F_x^{-1}(m') - F_x^{-1}(m)| \leq \omega_x(u),$$

with $\lim_{u \to 0} \omega_x(u) = \omega_x(0) = 0$. We say that $\omega_{\mathcal{X}} : (0,1) \to \mathbb{R}^+$ is an *uniform modulus of continuity* for the family of quantiles functions $(F_x^{-1})_{\mathcal{X}}$ if, for any $u \in (0,1)$ and any $x \in \mathcal{X}$,

$$\sup_{(m,m') \in (0,1)^2\,,\, |m'-m|<u} |F_x^{-1}(m') - F_x^{-1}(m)| \leq \omega_{\mathcal{X}}(u),$$

with $\lim_{u \to 0} \omega_{\mathcal{X}}(u) = \omega_{\mathcal{X}}(0) = 0$. When such modulus of continuity ω exists, note that it always can be chosen nondecreasing and this allows us to consider its generalized inverse ω^{-1}.

One may ask if the existence of the uniform modulus of continuity over a compact domain $\mathcal{X}$ is a strong assumption or not. To answer this issue, let us introduce the following assumption:

$(H_{\omega,\mathcal{X}})$: for any $x \in \mathcal{X}$, the push forward measure P_x of P by $\|x - \cdot\|^2$ is supported on a finite closed interval.

Note that Assumption $(H_{\omega,\mathcal{X}})$ is not very strong. For instance it is satisfied for a measure P supported on a compact and connected manifold, with P_x absolutely continuous for the Hausdorff measure on P. The following Lemma derives from general results on quantile functions given in Bobkov and Ledoux (2014) (see their Appendix A); the lemma shows that a uniform modulus of continuity for the quantiles exists under Assumption $(H_{\omega,\mathcal{X}})$.

Lemma 7 (Existence of Uniform Modulus of Continuity) *Let $\mathcal{X}$ be a compact domain and let P be a measure with compact support in $\mathbb{R}^d$. Assume that Assumption $(H_{\omega,\mathcal{X}})$ is satisfied. Then there exists a uniform modulus of continuity for the family of quantile functions F_x^{-1} over $\mathcal{X}$.*

Proof Let $x \in \mathcal{X}$. According to Propositions A.7 and A.12 in Bobkov and Ledoux (2014), Assumption $(H_{\omega,\mathcal{X}})$ is equivalent to assuming the existence of a uniform modulus of continuity of F_x^{-1} (it tends to zero at zero). We can then define ω_x on $(0,1)$ by

$$u \in (0,1) \mapsto \omega_x(u) := \sup_{(m,m') \in (0,1)^2\,,\, |m'-m|<u} \left|F_x^{-1}(m') - F_x^{-1}(m)\right|.$$

According to Lemma 8, we have that for any $(x, x') \in \mathcal{X}^2$:

$$\left|F_{x'}^{-1}(m) - F_x^{-1}(m)\right| \leq C\|x' - x\|, \tag{19}$$

where C only depends on P and $\mathcal{X}$. According to (19), for any $(m, m') \in (0,1)^2$, and for any $(x, x') \in \mathcal{X}^2$:

$$\left|F_x^{-1}(m') - F_x^{-1}(m)\right| \leq \left|F_{x'}^{-1}(m') - F_{x'}^{-1}(m)\right| + 2C\|x' - x\|.$$

By taking the supremum over the m and the m' such that $|m' - m| < u$, it yields:

$$\omega_x(u) \leq \omega_{x'}(u) + 2C\|x' - x\|,$$

and $x \mapsto \omega_x(u)$ is thus Lipschitz at any u. For any $u \in (0,1)$, let

$$\omega_{\mathcal{X}}(u) := \sup_{x \in \mathcal{X}} \omega_x(u),$$

which is finite because the function $x \mapsto \omega_x(u)$ is continuous on the compact $\mathcal{X}$ for any $u \in (0,1)$. We only need to prove that $\omega_{\mathcal{X}}$ is continuous at 0. Let $(u_n) \in (0,1)^{\mathbb{N}}$ be a decreasing sequence to zero. Since $\omega_{\mathcal{X}}$ is a non decreasing function, $\omega_{\mathcal{X}}(u_n)$ has a limit. For any $n \in \mathbb{N}$, there exists a point $x_n \in \mathcal{X}$ such that $\omega_{\mathcal{X}}(u_n) = \omega_{x_n}(u_n)$. Let $x_{\phi(n)}$ be a subsequence which converges to $\bar{x} \in \mathcal{X}$. According to (19),

$$\begin{aligned} \omega_{\mathcal{X}}(u_{\phi(n)}) &\leq \left|\omega_{x_{\phi(n)}}(u_{\phi(n)}) - \omega_{\bar{x}}(u_{\phi(n)})\right| + \left|\omega_{\bar{x}}(u_{\phi(n)})\right| \\ &\leq C\left\|x_{\phi(n)} - \bar{x}\right\| + \left|\omega_{\bar{x}}(u_{\phi(n)})\right| \end{aligned}$$

which gives that $\omega_{\mathcal{X}}(u_{\phi(n)})$ and $\omega_{\mathcal{X}}(u_n)$ both tend to zero because $\omega_{\bar{x}}$ is continuous at zero. Thus $\omega_{\mathcal{X}}$ is continuous at zero and the Lemma is proved. ■

We will also need the the following result, which shows that on any compact domain $\mathcal{X}$, the function $x \mapsto F_x^{-1}(m)$ is Lipschitz. For a domain $\mathcal{X} \in \mathbb{R}^d$, a probability P and a level m, we introduce the quantity $q_{P,\mathcal{X}}(m) \in \bar{\mathbb{R}}$, defined by

$$q_{P,\mathcal{X}}(m) := \sup_{x \in \mathcal{X}} F_x^{-1}(m).$$

Lemma 8 (Lipschitz Lemma) *Let P be a measure on $\mathbb{R}^d$ and let $m \in (0,1)$. Then, for any $(x, x') \in \mathbb{R}^d$,*

$$\left|\sqrt{F_{x'}^{-1}(m)} - \sqrt{F_x^{-1}(m)}\right| \leq \|x' - x\|.$$

Moreover, if $\mathcal{X}$ is a compact domain in $\mathbb{R}^d$, then $q_{P,\mathcal{X}}(m) < \infty$ and for any $(x, x') \in \mathcal{X}^2$:

$$\left|F_{x'}^{-1}(m) - F_x^{-1}(m)\right| \leq 2\sqrt{q_{P,\mathcal{X}}(m)}\ \|x' - x\|.$$

Proof Let $(x, a) \in \mathbb{R}^2$, note that

$$B\left(x, \sqrt{F_x^{-1}(m)}\right) \subseteq B\left(x + a, \sqrt{F_x^{-1}(m)} + \|a\|\right),$$

which implies

$$m = \mathbb{P}\left[B\left(x, \sqrt{F_x^{-1}(m)}\right)\right] \leq \mathbb{P}\left[B\left(x + a, \sqrt{F_x^{-1}(m)} + \|a\|\right)\right].$$

Therefore $\sqrt{F_{x+a}^{-1}(m)} \leq \sqrt{F_x^{-1}(m)} + \|a\|$. Similarly,

$$m = \mathbb{P}\left[B\left(x + a, \sqrt{F_{x+a}^{-1}(m)}\right)\right] \leq \mathbb{P}\left[B\left(x, \sqrt{F_{x+a}^{-1}(m)} + \|a\|\right)\right],$$

which implies $\sqrt{F_x^{-1}(m)} \leq \sqrt{F_{x+a}^{-1}(m)} + \|a\|$.

Let $\mathcal{X}$ be a compact domain of $\mathbb{R}^d$, then according to the previous result for some fixed $x \in \mathcal{X}$ and for any $x' \in \mathcal{X}$, $\sqrt{F_{x'}^{-1}(m)} \leq \|x' - x\| + \sqrt{F_x^{-1}(m)}$ which is bounded on $\mathcal{X}$. The last statement follows from the fact that $|x - y| = |\sqrt{x} - \sqrt{y}|\ |\sqrt{x} + \sqrt{y}|$. ■

We are now in position to state the functional limit of the distance to measure to the empirical measure.

Theorem 9 (Functional Limit) *Let P be a measure on $\mathbb{R}^d$ with compact support. Let $\mathcal{X}$ be a compact domain on $\mathbb{R}^d$ and $m \in (0,1)$. Assume that there exists a uniform modulus of continuity $\omega_{\mathcal{X}}$ for the family $(F_x^{-1})_{\mathcal{X}}$. Then $\sqrt{n}(\widehat{\delta}^2(x) - \delta^2(x)) \rightsquigarrow \mathbb{B}(x)$ for a centered Gaussian process $\mathbb{B}(x)$ with covariance kernel*

$$\kappa(x, y) = \frac{1}{m^2}\int_0^{F_x^{-1}(m)}\int_0^{F_y^{-1}(m)}\left(\mathbb{P}\left[B(x, \sqrt{t}) \cap B(y, \sqrt{s})\right] - F_x(t)F_y(s)\right) ds\, dt.$$

Remark 10 *Note that the functional limit is valid for any value of $m \in (0,1)$. A local version of this result could be also proposed by considering the (local) modulii of continuity of the quantile functions at m. For the sake of clarity, we prefer to give a global version.*

Remark 11 *By the delta method (as described in Section 4) a similar result holds for $\sqrt{n}(\widehat{\delta}(x) - \delta(x))$ as long as $\inf_x \delta(x) > 0$.*

Proof In the proof of Theorem 5 we showed that $\sqrt{n}(\widehat{\delta}^2(x) - \delta^2(x)) = A_n(x) + R_n(x)$ where

$$A_n(x) = \frac{1}{m}\int_0^{F_x^{-1}(m)} \sqrt{n}[F_x(t) - \widehat{F}_x(t)]dt$$
$$R_n(x) = \frac{1}{m}\int_{F_x^{-1}(m)}^{\widehat{F}_x^{-1}(m)} \sqrt{n}[m - \widehat{F}_x(t)]dt.$$

First, we show that $\sup_{x\in\mathcal{X}}|R_n(x)| = o_P(1)$. Then we prove that $A_n(x)$ converges to a Gaussian process.

Note that $|R_n(x)| \leq \frac{\sqrt{n}}{m}|S_n(x)||T_n(x)|$ where

$$S_n(x) = \left|F_x^{-1}(m) - \widehat{F}_x^{-1}(m)\right|, \quad T_n(x) = \sup_t\left|F_x(t) - \widehat{F}_x(t)\right|.$$

Let $\xi_i \sim$Uniform (0,1), for $i = 1, \ldots, n$ and let H_n be their empirical distribution function. Define $k = mn$. Then $\widehat{F}_x^{-1}(m) \stackrel{d}{=} F_x^{-1}(\xi_{(k)}) = F_x^{-1}\left(H_n^{-1}(m)\right)$, where $\xi_{(k)}$ is the kth order statistic. Thus, for any $m > 0$ and any $x \in \mathcal{X}$:

$$\begin{aligned}
\mathbb{P}\left(|S_n(x)| > \epsilon\right) &= \mathbb{P}\left(|F_x^{-1}(H_n^{-1}(m)) - F_x^{-1}(m)| > \epsilon\right) \\
&\leq \mathbb{P}\left(\omega_{\mathcal{X}}(|m - H_n^{-1}(m)|) > \epsilon\right) \\
&\leq \mathbb{P}\left(|m - H_n^{-1}(m)| > \omega_{\mathcal{X}}^{-1}(\epsilon)\right) \\
&\leq 2\exp\left\{-\frac{n\left[\omega_{\mathcal{X}}^{-1}(\epsilon)\right]^2}{m}\frac{1}{1 + \frac{2\omega_{\mathcal{X}}^{-1}(\epsilon)}{3m}}\right\} \qquad (20)
\end{aligned}$$

In the last line we used inequality 1 page 453 and Point (12) of Proposition 1 page 455 of Shorack and Wellner (2009). Note that $\omega_{\mathcal{X}}^{-1}(\epsilon) > 0$ for any $\varepsilon > 0$ because $\omega_{\mathcal{X}}$ is assumed to be continuous at zero by definition.

Fix $\varepsilon > 0$. There exists an absolute constant $C_{\mathcal{X}}$ such that there exists an integer $N \leq C_{\mathcal{X}}\varepsilon^{-d}$ and N points $(x_1, \ldots, x_N)$ laying in $\mathcal{X}$ such that $\bigcup_{j=1\ldots N} B_j \supseteq \mathcal{X}$, where $B_j = B(x_j, \varepsilon)$. Now, we apply Lemma 8 with P, and with P_n and we find that for any $x \in B_j$:

$$\left|F_x^{-1}(m) - F_{x_j}^{-1}(m)\right| \leq 2\sqrt{q_{P,\mathcal{X}}(m)}\ \varepsilon \quad \text{and} \quad \left|\widehat{F}_x^{-1}(m) - \widehat{F}_{x_j}^{-1}(m)\right| \leq 2\sqrt{q_{P_n,\mathcal{X}}(m)}\ \varepsilon.$$

Thus, for any $x \in B_j$,

$$\begin{aligned}
\left|F_x^{-1}(m) - \widehat{F}_x^{-1}(m)\right| &\leq \left|F_x^{-1}(m) - F_{x_j}^{-1}(m)\right| + \left|F_{x_j}^{-1}(m) - \widehat{F}_{x_j}^{-1}(m)\right| + \left|\widehat{F}_{x_j}^{-1}(m) - \widehat{F}_x^{-1}(m)\right| \\
&\leq 2\left[\sqrt{q_{P,\mathcal{X}}(m)} + \sqrt{q_{P_n,\mathcal{X}}(m)}\right]\varepsilon + |F_{x_j}^{-1}(m) - \widehat{F}_{x_j}^{-1}(m)| \\
&\leq C\varepsilon + |F_{x_j}^{-1}(m) - \widehat{F}_{x_j}^{-1}(m)| \qquad (21)
\end{aligned}$$

where C is a positive constant which only depends on $\mathcal{X}$ and P. Using a union bound together with (20) , we find that

$$P\left(\sup_{x\in\mathcal{X}}|S_n(x)|>2C\varepsilon\right)\leq P\left(\sup_{j=1\dots N}|S_n(x_j)|>C\varepsilon\right)$$
$$\leq 2C_{\mathcal{X}}\varepsilon^{-d}\exp\left\{-\frac{n\left[\omega_{\mathcal{X}}^{-1}(C\epsilon)\right]^2}{m}\frac{1}{1+\frac{2\omega_{\mathcal{X}}^{-1}(C\epsilon)}{3m}}\right\}.$$

Thus, $\sup_{x\in\mathcal{X}}|S_n(x)|=o_P(1)$. Then

$$\sup_{x\in\mathcal{X}}|T_n(x)|=\sup_{x\in\mathcal{X}}\sup_t|\widehat{F}_x(t)-F_x(t)|$$
$$=\sup_{x\in\mathcal{X}}\sup_t\left|\mathbb{P}_n\left(B(x,\sqrt{t}\right)-\mathbb{P}\left(B(x,\sqrt{t}\right)\right|$$
$$\leq\sup_{B\in\mathcal{B}_d}|\mathbb{P}_n(B)-\mathbb{P}(B)|=O_P\left(\sqrt{\frac{d}{n}}\right)\tag{22}$$

where $\mathcal{B}_d$ is the set of balls in $\mathbb{R}^d$ and we used the Vapnik-Chervonenkis theorem. Finally, we obtain that

$$\sup_{x\in\mathcal{X}}|R_n(x)|\leq\frac{\sqrt{n}}{m}\sup_{x\in\mathcal{X}}|S_n(x)|\sup_{x\in\mathcal{X}}|T_n(x)|=o_P(1).\tag{23}$$

Since $\sup_{x\in\mathcal{X}}|R_n(x)|=o_P(1)$, it only remains to prove that the process A_n converges to a Gaussian process.

Now, we consider the process A_n on $\mathcal{X}$. Let us denote $\nu_n:=\sqrt{n}(P_n-P)$ the empirical process. Note that

$$A_n(x)=\frac{1}{m}\nu_n\left(\int_0^{F_x^{-1}(m)}I_{\|x-X\|^2\leq t}dt\right)=\frac{1}{m}\nu_n\left(f_x\right)$$

where $f_x(y):=\left[F_x^{-1}(m)-\|x-y\|^2\right]\wedge 0$. For any $(x,x')\in\mathcal{X}$ and any $y\in\mathbb{R}^d$, we have

$$|f_x(y)-f_x(y)|\leq|F_x^{-1}(m)-F_{x'}^{-1}(m)|+\|x-x'\|\left[\|x\|+\|x'\|+2\|y\|\right]$$
$$\leq 2\left[r(\mathcal{X})+\|y\|+\sqrt{q_{P,\mathcal{X}}(m)}\right]\|x-x'\|$$

Since P is compactly supported, then the collection of functions $(f_x)_{x\in\mathcal{X}}$ is P-Donsker (see for instance 19.7 in van der Vaart (2000)) and $A_n(x)\rightsquigarrow\mathbb{B}(x)$ for a centered Gaussian process $\mathbb{B}(x)$ with covariance kernel

$$\kappa(x,y)=\mathrm{Cov}(A_n(x),A_n(y))=\mathbb{E}[A_n(x)A_n(y)]$$
$$=\frac{1}{m^2}\int_0^{F_x^{-1}(m)}\int_0^{F_y^{-1}(m)}\mathbb{E}\left[\left(\widehat{F}_x(t)-F_x(t)\right)\left(\widehat{F}_y(s)-F_y(s)\right)\right]\,ds\,dt$$
$$=\frac{1}{m^2}\int_0^{F_x^{-1}(m)}\int_0^{F_y^{-1}(m)}\left(\mathbb{P}\left[B(x,\sqrt{t})\cap B(y,\sqrt{s})\right]-F_x(t)F_y(s)\right)\,ds\,dt.$$

■

4. Hadamard Differentiability and The Bootstrap

In this section, we use the bootstrap to get a confidence band for δ. Define c_α by

$$\mathbb{P}(\sqrt{n}||\widehat{\delta}-\delta||_\infty>c_\alpha)=\alpha.$$

Let $X_1^*,\dots,X_n^*$ be a sample from the empirical measure P_n and let $\widehat{\delta}^*$ be the corresponding empirical DTM. The bootstrap estimate $\widehat{c}_\alpha$ is defined by

$$\mathbb{P}(\sqrt{n}||\widehat{\delta}^*-\widehat{\delta}||_\infty>\widehat{c}_\alpha\mid X_1,\dots,X_n)=\alpha.$$

As usual, $\widehat{c}_\alpha$ can be approximated by Monte Carlo. Below we show that this bootstrap is valid. It then follows that

$$\mathbb{P}\left(||\delta-\widehat{\delta}||_\infty<\frac{\widehat{c}_\alpha}{\sqrt{n}}\right)\to 1-\alpha.$$

A different approach to the bootstrap is considered in Section 6.

To prepare for our next result, let $\mathcal{B}$ denote the class of all closed Euclidean balls in $\mathbb{R}^d$ and let $\mathbb{B}$ denote the P-Brownian bridge on $\mathcal{B}$, i.e. the centered Gaussian process on $\mathcal{B}$ with covariance function $\kappa(B,C)=P(B\cap C)-P(B)P(C)$, with B,C in $\mathcal{B}$. We will denote with $\mathbb{B}_x(r)$ the value of $\mathbb{B}$ at $B(x,r)$, the closed ball centered at $x\in\mathbb{R}^d$ and with radius $r>0$.

Theorem 12 (Bootstrap Validity) *Let P be a measure on $\mathbb{R}^d$ with compact support S, $m\in(0,1)$ be fixed and $\mathcal{X}$ be a compact domain in $\mathbb{R}^d$. Assume that $F_{P,x}=F_x$ is differentiable at $F_x^{-1}(m)$ and that there exist a constant $C>0$ such that for all small $\eta\in\mathbb{R}$,*

$$\sup_{x\in\mathcal{X}}\left|F_x\left(F_x^{-1}(m)\right)-F_x(F_x^{-1}(m)+\eta)\right|<\epsilon\quad\textit{implies}\quad|\eta|<C\epsilon.\tag{24}$$

for all $x\in\mathcal{X}$. Then, $\sup_{x\in\mathcal{X}}\sqrt{n}\left|\left(\widehat{\delta}^*(x)\right)^2-\left(\widehat{\delta}(x)\right)^2\right|$ converges in distribution to

$$\sup_{x\in\mathcal{X}}\left|\frac{1}{m}\int_0^{F_x^{-1}(m)}\mathbb{B}_x(u)du\right|$$

conditionally given $X_1,X_2,\dots$, in probability.

We will establish the above result using the functional delta method, which entails showing that the distance to measure function is Hadamard differentiable at P. In fact, the proof further shows that the process

$$x\in\mathcal{X}\mapsto\sqrt{n}\left(\delta^2(x)-\widehat{\delta}^2(x)\right),$$

converges weakly to the Gaussian process

$$x\in\mathcal{X}\mapsto-\frac{1}{m}\int_0^{F_x^{-1}(m)}\mathbb{B}_x(u)du.$$

Remark 13 *This result is consistent with the result established in Theorem 9, but in order to establish Hadamard differentiability, we use a slightly different assumption. Theorem 9 is proved by assuming a uniform modulus of continuity on the quantile functions F_x^{-1} whereas in Theorem 12 a uniform lower bound on the derivatives is required. These two assumptions are consistent: they both say that F_x^{-1} is well-behaved in a neighborhood of m for all x. However, the condition used in Theorem 12 is stronger than the condition used in Theorem 9.*

Proof [Proof of Theorem 12] Let us first give the definition of Hadamard differentiability, for which we refer the reader to, e.g., Section 3.9 of van der Vaart and Wellner (1996). A map ϕ from a normed space $(\mathcal{D}, \|\cdot\|_{\mathcal{D}})$ to a normed space $(\mathcal{E}, \|\cdot\|_{\mathcal{E}})$ is Hadamard differentiable at the point $x \in \mathcal{D}$ if there exists a continuous linear map $\phi'_x : \mathcal{D} \to \mathcal{E}$ such that

$$\left\| \frac{\phi(x + th_t) - \phi(x)}{t} - \phi'_x(h) \right\|_{\mathcal{E}} \to 0, \tag{25}$$

whenever $\|h_t - h\|_{\mathcal{D}} \to 0$ as $t \to 0$.

We also recall the functional delta method (see, e.g. van der Vaart and Wellner, 1996, Theorem 3.9.4): suppose that T_n takes values in $\mathcal{D}$, $r_n \to \infty$, $r_n(T_n - \theta) \rightsquigarrow T$, and suppose that ϕ is Hadamard differentiable at θ. Then $r_n(\phi(T_n) - \phi(\theta)) \rightsquigarrow \phi'_\theta(T)$. Moreover, by Theorem 3.9.11 of van der Vaart and Wellner (1996) the bootstrap has the same limit. More precisely, given $X_1, X_2, \ldots$, we have that $r_n(\phi(T_n^*) - \phi(T_n))$ converges conditionally in distribution to $\phi'_\theta(T)$, in probability. This implies the validity of the bootstrap confidence sets.

We define $\mathcal{M}$ to be the space of finite, σ-finite signed measures on $(\mathbb{R}^d, \mathcal{B}^d)$ supported on the compact set S and the mapping $\|\cdot\|_{\mathcal{B}} \colon \mathcal{M} \mapsto \mathbb{R}$ given by

$$\|\mu\|_{\mathcal{B}} = \sup_{B \in \mathcal{B}} |\mu(B)|, \quad \mu \in \mathcal{M}.$$

In Lemma 14 we show that this is a normed space.

For our purposes, instead of using $\mathcal{M}$ it will be convenient to work with the equivalent space of the evaluations of all $\mu \in \mathcal{M}$ over the balls $\mathcal{B}$. Formally, let $\ell^\infty(\mathcal{B})$ denote the normed space of bounded functions on $\mathcal{B}$ equipped with the supremum norm. Then, by Lemma 14, the mapping from $\mathcal{M}$ into $\ell^\infty(\mathcal{B})$ given by

$$\mu \mapsto (\mu \colon \mathcal{B} \to [0, 1]) \tag{26}$$

is a bijection on its image, which we will denote by $\mathcal{D}$. By definition, the supremum norm on $\mathcal{D}$ is exactly the norm $\|\cdot\|_{\mathcal{B}}$, so that $\mathcal{D} \subset \ell^\infty(\mathcal{B})$ equipped with the supremum norm is a normed space. With a slight abuse of notation, we will identify measures in $\mathcal{M}$ with the corresponding points in $\mathcal{D}$ and write $\mu \in \mathcal{D}$ to denote the signed measure μ corresponding to the point $\{\mu(B), B \in \mathcal{B}\}$ in $\mathcal{D}$.

The advantage of using the space $\mathcal{D}$ instead of $\mathcal{M}$ is that the convergence of the empirical process $(\sqrt{n}(\mathbb{P}_n(B) - P(B)) : \ B \in \mathcal{B})$ to the Brownian bridge takes place in $\mathcal{D}$, as required by the delta-method for the bootstrap (see van der Vaart and Wellner, 1996, Theorem 3.9.).

For a signed measure μ in $\mathcal{M}$, $x \in \mathbb{R}^d$ and $r > 0$, we set $F_{\mu,x}(r) = \mu\left(B(x, \sqrt{r})\right)$. Notice if P is a probability measure, then $F_{P,x}$ is the c.d.f. of the univariate random variable $\|X - x\|^2$, with $X \sim P$. For a general $\mu \in \mathcal{M}$, $F_{\mu,x}$ is a cadlag function, though not monotone. For any $m \in \mathbb{R}$, μ in $\mathcal{M}$ and $x \in \mathbb{R}^d$, set

$$F^{-1}_{\mu,x}(m) = \inf\left\{ r > 0 \colon \mu(B(x, \sqrt{r})) \geq m \right\},$$

where the infimum over the empty set is define to be ∞. If P is a probability measure and $m \in (0, 1)$ then $F^{-1}_{P,x}(m)$ is just the m-th quantile of the random variable $\|X - x\|^2$, $X \sim P$.

Fix a $m \in (0, 1)$ and let $\mathcal{M}_m = \mathcal{M}_m(\mathcal{X})$ denote the subset of $\mathcal{M}$ consisting of all finite signed measure μ such that, there exists a value of $r > 0$ for which $\inf_{x \in \mathcal{X}} \mu\left(B(x, \sqrt{r})\right) \geq m$. Thus, for any $\mu \in \mathcal{M}_m$ and $x \in \mathcal{X}$, $F^{-1}_{\mu,x}(m) < \infty$. Let $\mathcal{D}_m$ be the image of $\mathcal{M}_m$ by the mapping (26).

Let $\mathcal{E}$ the set of bounded, real-valued function on $\mathcal{X}$, a normed space with respect to the sup norm. Finally, we define $\phi \colon \mathcal{D}_m \to \mathcal{E}$ to be the mapping

$$\mu \in \mathcal{D}_m \mapsto \phi(\mu)(x) = F^{-1}_{\mu,x}(m) - \frac{1}{m} \int_0^{F^{-1}_{\mu,x}(m)} F_{\mu,x}(u) du, \quad x \in \mathcal{X} \tag{27}$$

Notice that if P is a probability measure, simple algebra shows that $\phi(P)(x)$ is the square value of the distance to measure of P at the point x, i.e. $\delta_P^2(x)$; see Figure 5.

Below we will show that, for any probability measure P, the mapping (27) is Hadamard differentiable at P.

For an arbitrary $Q \in \mathcal{D}$, let $\{Q_t\}_{t>0} \subset \mathcal{D}$ be a sequence of signed measure such that $\lim_{t \to 0} \|Q_t - Q\|_{\mathcal{B}} = 0$ and such that $P + tQ_t \in \mathcal{D}_m$ for all t. Sequences of this form exist: since $\|tQ_t\|_{\mathcal{B}} \to 0$ as $t \to 0$, for any arbitrary $0 < \epsilon < 1 - m$ and all t small enough,

$$\inf_{x \in \mathcal{X}} (P + tQ_t)\left(B\left(x, F^{-1}_{P,x}(m + \epsilon)\right)\right) \geq m + \epsilon/2.$$

By the boundedness of $\mathcal{X}$ and compactness of S, this implies that there exists a number $r > 0$ such that

$$\inf_x (P + tQ_t)\left(B\left(x, r\right)\right) \geq m,$$

so the image of $P + tQ_t$ by (27) is an element of $\mathcal{E}$ (i.e. it is a bounded function).

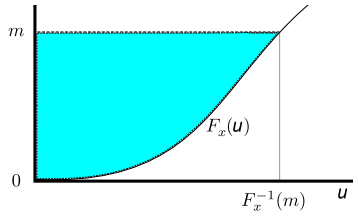

Figure 5: The integral $\int_0^m F^{-1}_{P,x}(u)du$ is equivalent to $mF^{-1}_{P,x}(m) - \int_0^{F^{-1}_{P,x}(m)} F_{P,x}(u)du$.

For sake of readability, below we will write $F_{x,t}$ and $F^{-1}_{x,t}(m)$ for $F_{P+tQ_t,x}$ and $F^{-1}_{P+tQ_t,x}(m)$, respectively, and F_x for $F_{P,x}$. Also, for each $x \in \mathcal{X}$ and $z \in \mathbb{R}_+$ we the set $\mathcal{A}_{x,z} = \{y : \|y - x\|^2 \leq z\}$ and $F_{x,t}(z) = (P + tQ_t)(\mathcal{A}_{x,z})$.

Thus,

$$\phi(P)(x) = \delta_P^2(x) = F_x^{-1}(m) - \frac{1}{m}\int_0^{F_x^{-1}(m)} F_x(u)du$$

and

$$\phi(P + tQ_t)(x) = F_{x,t}^{-1}(m) - \frac{1}{m}\int_0^{F_{x,t}^{-1}(m)} F_{x,t}(u)du.$$

Some algebra show that, for any x,

$$\frac{\phi(P)(x) - \phi(P + tQ_t)(x)}{t} = \frac{F_x^{-1}(m) - F_{x,t}^{-1}(m)}{t} - \frac{A(x,t)}{mt}, \tag{28}$$

where

$$A(x,t) = \begin{cases} \int_0^{F_x^{-1}(m)} [F_x(u) - F_{x,t}(u)]\, du - \int_{F_x^{-1}(m)}^{F_{x,t}^{-1}(m)} F_{x,t}(u)du & \text{if } F_x^{-1}(m) \le F_{x,t}^{-1}(m) \\ \int_0^{F_x^{-1}(m)} [F_x(u) - F_{x,t}(u)]\, du + \int_{F_{x,t}^{-1}(m)}^{F_x^{-1}(m)} F_{x,t}(u)du & \text{if } F_x^{-1}(m) > F_{x,t}^{-1}(m). \end{cases}$$

To demonstrate Hadamard differentiability (see 25), we will prove that, as $t \to 0$, the expression in (28), as a bounded function of $x \in \mathcal{X}$, will converge in $\mathcal{E}$ to the bounded function

$$x \in \mathcal{X} \mapsto -\frac{1}{m}\int_0^{F_x^{-1}(m)} Q(\mathcal{A}_{x,u})du.$$

Towards that end, we have, for all t and any $x \in \mathcal{X}$,

$$\begin{aligned} \frac{A(x,t)}{t} &= \frac{1}{t}\left[\int_0^{F_x^{-1}(m)} tQ_t(\mathcal{A}_{x,u})du - \int_{F_x^{-1}(m)}^{F_{x,t}^{-1}(m)} (P + tQ_t)(\mathcal{A}_{x,u})du\right] \\ &= \int_0^{F_x^{-1}(m)} Q_t(\mathcal{A}_{x,u})du - \frac{1}{t}\int_{F_x^{-1}(m)}^{F_{x,t}^{-1}(m)} P(\mathcal{A}_{x,u})du - \int_{F_x^{-1}(m)}^{F_{x,t}^{-1}(m)} (Q_t)(\mathcal{A}_{x,u})du \\ &\equiv A_1(x,t) - A_2(x,t) - A_3(x,t), \end{aligned}$$

where, for $a < b$, we write $\int_b^a = -\int_a^b$.

To handle the three terms appearing in the last display, we use Lemma 15 below which shows that $\sup_{x\in\mathcal{X}} \left|m - F_x\left(F_{x,t}^{-1}(m)\right)\right| = O(t)$ and that $\sup_{x\in\mathcal{X}} |F_x^{-1}(m) - F_{x,t}^{-1}(m)| = O(t)$ as $t \to 0$.

We now analyze the terms $A_1(x,t)$, $A_2(x,t)$ and $A_3(x,t)$ separately.

- **Term $A_1(x,t)$.** As $t \to 0$, $Q_t \to Q$ and, uniformly in $x \in \mathcal{X}$ and $z > 0$, $|Q_t(\mathcal{A}_{x,z})| \le |Q_t(S)| = |Q(S)| + o(1) < \infty$. Furthermore, $\sup_{x\in\mathcal{X}} F_x^{-1}(m) < \infty$ by compactness of $\mathcal{X}$ and S. Therefore, using the dominated convergence theorem,

$$\lim_{t\to 0}\sup_{x\in\mathcal{X}}\left|\frac{A_1(x,t)}{m} - \frac{1}{m}\int_0^{F_x^{-1}(m)} Q(\mathcal{A}_{x,u})du\right| = 0. \tag{29}$$

- **Term $A_2(x,t)$.** Since $P(\mathcal{A}_{x,u})$ is non-decreasing in u for all x, we have

$$\frac{F_{x,t}^{-1}(m) - F_x^{-1}(m)}{t} \times \min\left\{m, F_x(F_{x,t}^{-1}(m))\right\} \le A_2(x,t) \le \frac{F_{x,t}^{-1}(m) - F_x^{-1}(m)}{t} \times \max\left\{m, F_x(F_{x,t}^{-1}(m))\right\}.$$

  Using (32), we conclude that

$$\lim_{t\to 0}\sup_{x\in\mathcal{X}}\left|\frac{F_x^{-1}(m) - F_{x,t}^{-1}(m)}{t} - \frac{A_2(x,t)}{m}\right| = 0. \tag{30}$$

- **Term $A_3(x,t)$.** Finally, since $|Q_t(S)| \le |Q(S)| + o(1)$ as $t \to 0$ and using (35), we obtain

$$\sup_x |A_3(x,t)| = O\Big(\sup_x \left|F_{x,t}^{-1}(m) - F_x^{-1}(m)\right|\Big) = o(1) \tag{31}$$

  as $t \to 0$.

Therefore, from (28), (29), (30), and (31),

$$\lim_{t\to 0}\sup_x\left|\frac{\phi(P)(x) - \phi(P + tQ_t)(x)}{t} + \frac{1}{m}\int_0^{F_x^{-1}(m)} Q(\mathcal{A}_{x,u})du\right| = 0,$$

which shows that

$$x \in \mathcal{X} \mapsto -\frac{1}{m}\int_0^{F_x^{-1}(m)} Q(\mathcal{A}_{x,u})du$$

is the Hadamard derivative of δ^2 at P.

The statement of the theorem now follows from an application of Theorem 3.9.11 in van der Vaart and Wellner (1996) and the fact that, since $\mathcal{B}$ is a Donsker class, the empirical process $(\sqrt{n}(\mathbb{P}_n(B) - P(B)) : B \in \mathcal{B})$ converges to the Brownian bridge $\mathbb{B}$ on $\mathcal{B}$ with covariance kernel $\kappa(B,C) = P(B \cap C) - P(B)P(C)$. ■

Lemma 14 (Normed Space) *The pair $(\mathcal{M}, \|\cdot\|_{\mathcal{B}})$ is a normed space.*

Proof It is clear that $\mathcal{M}$ is closed under addition and scalar multiplication, and so it is a linear space. We then need to show that the mapping $\|\cdot\|_{\mathcal{B}}$ is a norm. It is immediate to see that it absolutely homogeneous and satisfies the triangle inequality: for any μ and ν in $\mathcal{M}$ and $c \in \mathbb{R}$, $\|c\mu\|_{\mathcal{B}} = |c|\|\mu\|_{\mathcal{B}}$ and $\|\mu + \nu\|_{\mathcal{B}} \le \|\mu\|_{\mathcal{B}} + \|\nu\|_{\mathcal{B}}$. It remains to prove that $\|\mu\|_{\mathcal{B}} = 0$ if and only if μ is identically zero, i.e. $\mu(A) = 0$ for all Borel sets A. One direction is immediate: if $\|\mu\|_{\mathcal{B}} > 0$, then there exists a ball B such that $\mu(B) \neq 0$, so that $\mu \neq 0$. For the other direction, assume that $\mu \in \mathcal{M}$ is such that $\|\mu\|_{\mathcal{B}} = 0$. By the Jordan decomposition, μ can be represented as the difference of two singular, non-negative finite measures: $\mu = \mu_+ - \mu_-$. The condition $\mu(B) = 0$ for all $B \in \mathcal{B}$ is equivalent to $\mu_+(B) = \mu_-(B)$ for all $B \in \mathcal{B}$. We will show that this further implies that the supports of μ_+ and μ_-, denoted with S_+ and S_- respectively, are both empty, and therefore that μ is identically zero. Indeed, recall that the support of a Borel measure λ over a topological space $\mathbb{X}$ is the set of points $x \in \mathbb{X}$ all of whose open neighborhoods have positive λ-measure.

In our setting this is equivalent to the set of points in $\mathbb{R}^d$ such that all open balls centered at those points have positive measure, which in turn is equivalent to the set of points such that all closed balls centered at those points have positive measure. Therefore, using the fact that $\mu^+(B) = \mu^-(B)$, for all $B \in \mathcal{B}$,

$$S_+ = \left\{x \in \mathbb{R}^d \colon \mu_+(B(x,r)) > 0, \forall r > 0\right\} = \left\{x \in \mathbb{R}^d \colon \mu_-(B(x,r)) > 0, \forall r > 0\right\} = S_-.$$

where $B(X,r) = \{y \in \mathbb{R}^d \colon \|y - x\| \leq r\}$. It then follows that S_+ and S_- must be empty, for otherwise μ_+ and μ_- would be mutually singular, non-zero measures with the same support, a contradiction. ■

Lemma 15 *Under the assumptions of the theorem and as $t \to 0$,*

$$\sup_{x \in \mathcal{X}} \left| m - F_x\left(F_{x,t}^{-1}(m)\right)\right| = O(t), \tag{32}$$

and

$$\sup_{x \in \mathcal{X}} |F_x^{-1}(m) - F_{x,t}^{-1}(m)| = O(t). \tag{33}$$

Proof Set $\mathcal{A}_{x,t} = \{y \colon \|y - x\|^2 \leq F_{x,t}^{-1}(m)\}$ and let γ_t be any positive, decreasing function of t such that $\gamma_t = o(t)$ as $t \to 0$. Then, for all small enough t and all $x \in \mathcal{X}$, the set $\mathcal{A}_{x,t,\gamma_t} = \{y \colon \|y - x\|^2 \leq F_{x,t}^{-1}(m) - \gamma_t\}$ is non-empty and

$$F_x\left(F_{x,t}^{-1}(m) - \gamma_t\right) + tQ_t(\mathcal{A}_{x,t,\gamma_t}) \leq m \leq F_x\left(F_{x,t}^{-1}(m)\right) + tQ_t(\mathcal{A}_{x,t}), \tag{34}$$

because $P(\mathcal{A}_{x,t}) = F_x(F_{x,t}^{-1}(m))$ and $P(\mathcal{A}_{x,t,\gamma}) = F_x(F_{x,t}^{-1}(m) - \gamma_t)$. Rearranging and using the bound $\sup_{x\in\mathcal{X}} F_x(F_{x,t}^{-1}(m) - \gamma_t) = \sup_{x\in\mathcal{X}} F_x(F_{x,t}^{-1}(m)) + O(\gamma_t)$, which holds for all small enough t, we obtain that, for all such values of t,

$$\sup_{x \in \mathcal{X}} \left| m - F_x\left(F_{x,t}^{-1}(m)\right)\right| \leq t \sup_{x \in \mathcal{X}} \max\left\{|Q_t(\mathcal{A}_{x,t})|, |Q_t(\mathcal{A}_{x,t,\gamma_t})|\right\} + o(t) = tO\left(|Q(S)|\right),$$

since $|Q_t(S)| = |Q(S)| + o(1)$ as $t \to 0$. This establishes (32). Next, by the monotonicity of F_x for each $x \in \mathcal{X}$ and the facts – both implied by (24) – that $m = F_x(F_x^{-1}(m))$ and $\inf_{x\in\mathcal{X}} F_x'(F_x^{-1}(m))$ is bounded away from 0, (32) yields that

$$\lim_{t \to 0} \sup_{x \in \mathcal{X}} |F_x^{-1}(m) - F_{x,t}^{-1}(m)| = 0. \tag{35}$$

Combining the last display with the bound

$$\sup_{x \in \mathcal{X}} \left| F_x\left(F_x^{-1}(m)\right) - F_x\left(F_{x,t}^{-1}(m)\right)\right| = tO\left(|Q(S)|\right)$$

and assumption (24) again, we obtain that

$$\sup_{x \in \mathcal{X}} \left|F_x^{-1}(m) - F_{x,t}^{-1}(m)\right| \leq CtO(|Q(S)|) = O(t),$$

for all t small enough, where C is the constant in (24). This completes the proof of (33). ■

4.1 Significance of Topological Features

Fasy et al (2014) showed how to use the bootstrap to test the significance of a topological feature. They did this for distance functions and density estimators but the same idea works for DTM as we now explain. We assume in this section that the support of the distribution is contained in a compact set. The supremum norm refers to the supremum over this set.

Given a feature with birth and death time (u, v), we will say that the feature is significant if $|v - u| > 2c_\alpha/\sqrt{n}$ where c_α is defined by

$$\mathbb{P}(\sqrt{n}\|\widehat{\delta}(x) - \delta(x)\|_\infty > c_\alpha) = \alpha.$$

In particular, c_α can be estimated from the bootstrap as we showed in the previous section. Specifically, define $\widehat{c}_\alpha$ by

$$\mathbb{P}(\sqrt{n}\|\widehat{\delta}^*(x) - \widehat{\delta}(x)\|_\infty > \widehat{c}_\alpha | X_1, \ldots, X_n) = \alpha.$$

Then $\widehat{c}_\alpha$ is a consistent estimate of c_α.

To see why this makes sense, let $\mathcal{D}$ be the set of all persistence diagrams. Let $D \equiv D_\delta$ be the true diagram and let $\widehat{D} \equiv D_{\widehat{\delta}}$ be the estimated diagram. Let

$$\mathcal{C}_n = \left\{E \in \mathcal{D} \colon\ W_\infty(\widehat{D}, E) \leq \frac{\widehat{c}_\alpha}{\sqrt{n}}\right\}.$$

Then

$$\mathbb{P}(D \in \mathcal{C}_n) = \mathbb{P}\left(W_\infty(D, \widehat{D}) \leq \frac{\widehat{c}_\alpha}{\sqrt{n}}\right) \geq \mathbb{P}(\sqrt{n}\|\widehat{\delta}(x) - \delta(x)\|_\infty \leq \widehat{c}_\alpha) \to 1 - \alpha$$

as $n \to \infty$. Now $|v - u| > 2\widehat{c}_\alpha/\sqrt{n}$ if and only if the feature cannot be matched to the diagonal for any diagram in $\mathcal{C}$. (Recall that the diagonal corresponds to features with zero lifetime.)

We can visualize the significant features by putting a band of size $2c_\alpha/\sqrt{n}$ around the diagonal of $\widehat{D}$. See Figure 6.

5. Theory for Kernels

In this section, we consider an alternative to the DTM, namely, kernel based methods. This includes the kernel distance and the kernel density estimator.

Phillips et al. (2014) suggest using the kernel distance for topological inference. Given a kernel $K(x, y)$, the kernel distance between two probability measures P and Q is

$$D_K(P,Q) = \sqrt{\iint K(x,y)dP(x)dP(y) + \iint K(x,y)dQ(x)dQ(y) - 2\iint K(x,y)dP(x)dQ(y)}.$$

It can be shown that $D_K(P,Q) = \|\mu_P - \mu_Q\|$ for vectors μ_P and μ_Q in an appropriate reproducing kernel Hilbert space (RKHS). Such distances are popular in machine learning; see Sriperumbudur et al. (2009), for example.

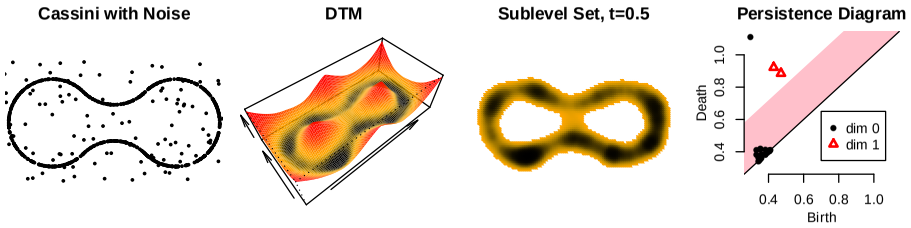

Figure 6: The left plot shows a sample from the Cassini curve together with a few outliers. The second plot is the empirical DTM. The third plot is one sub-level set of the DTM. The last plot is the persistence diagram. Points not in the shaded band are significant features. Thus, this method detects one significant connected component and two significant loops in the sublevel set filtration of the empirical DTM function.

Given a sample $X_1, \ldots, X_n \sim P$, let P_n be the probability measure that puts mass $1/n$ on each X_i. Let ϑ_x be the Dirac measure that puts mass one on x. Phillips et al. (2014) suggest using the discrete kernel distance

$$\widehat{D}_K(x) \equiv D_K(P_n, \vartheta_x) = \sqrt{\frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n} K(X_i, X_j) + K(x,x) - \frac{2}{n}\sum_{i=1}^{n} K(x, X_i)} \tag{36}$$

for topological inference. This is an estimate of the population quantity

$$D_K(x) \equiv D_K(P, \vartheta_x) = \sqrt{\iint K(z,y)dP(z)dP(y) + K(x,x) - 2\int K(x,y)dP(y)}.$$

The most common choice of kernel is the Gaussian kernel $K(x,y) \equiv K_h(x,y) = \exp\left(-\frac{\|x-y\|^2}{2h^2}\right)$, which has one tuning parameter h. We recall that, in topological inference, we generally do not let h tend to zero. The reason is that topological features can be detected with $h > 0$ and keeping h bounded way from 0 reduces the variance of the estimator. See the related discussion in Section 4.4 of Fasy et al. (2014b).

Recall that the kernel density estimator is defined by

$$\widehat{p}_h(x) = \frac{1}{n(\sqrt{2\pi}h)^d}\sum_i K(x, X_i).$$

Let $p_h(x) = \mathbb{E}[\widehat{p}_h(x)]$. We see that

$$\begin{aligned}
\widehat{D}_K^2(x) &= h^d\left(\frac{(\sqrt{2\pi})^d}{n}\sum_i \widehat{p}_h(X_i) + h^{-d}K(0,0) - 2(\sqrt{2\pi})^d\widehat{p}_h(x)\right) \\
&= h^d\left(\frac{(\sqrt{2\pi})^d}{n}\sum_i [\widehat{p}_h(X_i) - p_h(X_i)] + \frac{(\sqrt{2\pi})^d}{n}\sum_i p_h(X_i) + h^{-d}K(0,0) - 2(\sqrt{2\pi})^d\widehat{p}_h(x)\right) \\
&= (\sqrt{2\pi})^d h^d(c + o_P(1)) + O_P\left(\sqrt{\frac{\log n}{n}}\right) + K(0,0) - 2(\sqrt{2\pi}h)^d\widehat{p}_h(x).
\end{aligned}$$

Here, we used the fact that $n^{-1}\sum_{i=1}^n p_h(X_i) = c + o_P(1)$ and $||\widehat{p}_h - p_h||_\infty = O_P(\sqrt{\log n/n})$ where $c = \int p_h p$.

We see that up to small order terms, the sublevel sets of $D_K(x)$ are a rescaled version of the super-level sets of the kernel density estimator. Hence, the kernel distance approach and the density estimator approach are essentially the same, up to a rescaling. However, D_K^2 has some nice properties; see Phillips et al. (2014).

The limiting properties of $\widehat{D}_K^2(x)$ follow immediately from well-known properties of kernel density estimators. In fact, the conditions needed for $\widehat{D}_K^2$ are weaker than for the DTM.

Theorem 16 (Limiting Behavior of Kernel Distance) *We have that*

$$\sqrt{n}(\widehat{D}_K^2 - D_K^2) \rightsquigarrow \mathbb{B},$$

where $\mathbb{B}$ is a Brownian bridge. The bootstrap version converges to the same limit, conditionally almost surely.

The proof of the above theorem is based on the aforementioned equivalence of D_K to the rescaled density function and the well known fact that $\sqrt{n}(\widehat{p}_h(x) - p_h(x))$ converges to a Brownian bridge. This theorem justifies using the bootstrap to construct L_∞ bands for $p_h = \mathbb{E}(\widehat{p}_h)$ or D_K.

As we mentioned before, for topological inference, we keep the bandwidth h fixed. Thus, it is important to keep in mind that we view $\widehat{p}_h$ as an estimate of $p_h(x) = \mathbb{E}[\widehat{p}_h(x)] = \int K_h(x,u)dP(u)$.

6. The Bottleneck Bootstrap

More precise inferences can be obtained by directly bootstrapping the persistence diagram. Let $X_1^*, \ldots, X_n^*$ be as before a sample from the empirical measure P_n and let $\widehat{D}^*$ be the (random) persistence diagram defined on this point cloud. Define $\widehat{t}_\alpha$ by

$$\mathbb{P}(\sqrt{n}W_\infty(\widehat{D}^*, \widehat{D}) > \widehat{t}_\alpha \,|\, X_1, \ldots, X_n) = \alpha. \tag{37}$$

The quantile $\widehat{t}_\alpha$ can be estimated by Monte Carlo. We then use a band of size $2\widehat{t}_\alpha$ on the diagram D.

In the following, we show that $\widehat{t}_\alpha$ consistently estimates the population value t_α defined by

$$\mathbb{P}(\sqrt{n}W_\infty(\widehat{D}, D) > t_\alpha) = \alpha. \tag{38}$$

The reason why the bottleneck bootstrap can lead to more precise inferences than the functional bootstrap from the previous section is that the functional bootstrap uses the fact that $W_\infty(\widehat{D}, D) \leq ||\widehat{\delta} - \delta||_\infty$ and finds an upper bound for $||\widehat{\delta} - \delta||_\infty$. But in many cases the inequality is not sharp so the confidence set can be very conservative. Moreover, we can obtain different critical values for different dimensions (connected components, loops, voids, ...) and so the inferences are tuned to the specific features we are estimating. See Figure 7.

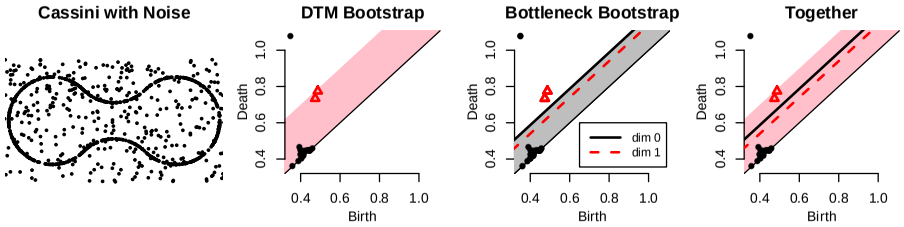

Figure 7: The left plot shows a sample from the Cassini curve together with a few outliers. The second plot shows the DTM persistence diagram with a 95% confidence band constructed using the method of Section 4. The third plot shows the same persistence diagram with two 95% confidence bands constructed using the bottleneck bootstrap with zero-dimensional features and one-dimensional features. The fourth plot shows the three confidence bands at the same time. In Section 8, we use this compact form to show multiple confidence bands.

Although the bottleneck bootstrap can be used with either the DTM or the KDE, we shall only prove its validity for the KDE. First, we need the following result. For any function p, let $g = \nabla p$ denote its gradient and let $H = \nabla^2 p$ denotes its Hessian. We say that x is a critical point if $g(x) = (0, \ldots, 0)^T$. We then call $p(x)$ a critical value. A function is Morse if the Hessian is non-degenerate at each critical point. The Morse index of a critical point x is the number of negative eigenvalues of $H(x)$.

Lemma 17 (Stability of Critical Points) *Let p be a density with compact support S. Assume that S is a d-dimensional compact submanifold of $\mathbb{R}^d$ with boundary. Assume p is a Morse function with finitely many, distinct, critical values with corresponding critical points $c_1, \ldots, c_k$. Also assume that p is of class $\mathcal{C}^2$ on the interior of S, continuous and differentiable with non vanishing gradient on the boundary of S. Then, there exist $\epsilon_0 > 0$ and $c > 0$ such that for all $0 < \epsilon < \epsilon_0$, there exists $\eta \geq c\epsilon$ such that, for any density q with*

support S satisfying

$$\sup_x |p(x) - q(x)| < \eta, \qquad \sup_x |\nabla p(x) - \nabla q(x)| < \eta, \qquad \sup_x |\nabla^2 p(x) - \nabla^2 q(x)| < \eta,$$

q is a Morse function with exactly k critical points $c'_1, \ldots, c'_k$ say, and, after a suitable re-labeling of indices,

$$\max_j ||c_j - c'_j|| \leq \epsilon.$$

Moreover, c_j and c'_j have the same Morse index.

Proof This lemma is a consequence of classical stability properties of Morse functions. First, from Theorem 5.31, p.140 in Banyaga and Hurtubise (2004) and Proposition II.2.2, p.79 in Golubitsky and Guillemin (1986), there exists $\epsilon_1 > 0$ such that if q is at distance less than ϵ_1 in the $\mathcal{C}^2$ topology (i.e. such that the sup-norm of $p - q$ and its first and second derivatives are bounded by ϵ_1) then q is a Morse function. Moreover, there exist two diffeomorphisms $h : \mathbb{R} \to \mathbb{R}$ and $\phi : S \to S$ such that $q = h \circ p \circ \phi$. As the notion of critical point and of index are invariant by diffeomorphism, p and q have the same number of critical points with same index. More precisely, the critical points of q are the points $c'_i = \phi^{-1}(c_i)$.

Now let $\epsilon > 0$ be small enough such that $2\epsilon < \min_{i \neq j} \|c_i - c_j\|$, and for any $i \neq j$, $p(B(c_i, \epsilon)) \cap p(B(c_j, \epsilon)) = \emptyset$. Then $\eta_1 = \eta_1(\epsilon) = \min_{i \neq j} d(p(B(c_i, \epsilon)), p(B(c_j, \epsilon)))$ where $d(A, B) = \min_{a \in A, b \in B} |a - b|$ and $\eta_2 = \eta_2(\epsilon) = \inf\{\|\nabla p(x)\| : x \in S \setminus \cup_{i=1}^k B(c_i, \epsilon)\}$ are both positive. If q satisfies the assumptions of the lemma for any $0 < \eta \leq \min(\eta_1, \eta_2)$, then the critical values of q have to be in $\cup_i p(B(c_i, \epsilon))$ and the critical points c'_i have to be in $\cup_i B(c_i, \epsilon)$.

More precisely, notice that since p is a Morse function, for ϵ small enough, $\eta_2 = O(\epsilon)$, and, for any $i \in \{1, \cdots, k\}$, the Taylor series of ∇p about c_j yields

$$\nabla p(x) = H_i(x - c_i) + \|x - c_i\| r(x - c_i),$$

where $r(z) \to 0$ as $\|z\| \to 0$ and H_i is the Hessian of p at c_i. Let $\lambda_{\min}$ be the smallest absolute eigenvalue of the Hessians at all the critical points. Since p is a Morse function, the matrix H_i is full rank and $\lambda_{\min}$ is positive. As a consequence, for all $x \in S \setminus \cup_{i=1}^k B(c_i, \epsilon)$ and ϵ small enough, $\|\nabla p(x)\| \geq \frac{\lambda_{\min}}{2}\epsilon$. Since η_1 is a non-increasing function of ϵ, we have that, for ϵ small enough, $\eta = \eta_2 \geq \frac{\lambda_{\min}}{2}\epsilon$.

To conclude the proof of the lemma, we need to prove that each ball $B(c_i, \epsilon)$ contains exactly one critical point of q. Indeed, for $t \in [0, 1]$, the functions $q_t(x) = p(x) + t(q(x) - p(x))$ are Morse functions satisfying the same properties as q. Now, since each c_i is a non-degenerate point of p, it follows from the continuity of the critical points (see, e.g. Prop. 4.6.1 in Demazure (2013)) that, restricting ϵ if necessary, there exist smooth functions $c_i : [0, 1] \to S$, $c_i(0) = c_i, c_i(1) = c'_i$ such that $c_i(t)$ is the unique critical point of q_t in $B(c_i, \epsilon)$. Moreover, since all the q_t are Morse functions and since the Hessian of q_t at $c_i(t)$ is a continuous function of t, then for any $t \in [0, 1]$, $c_i(t)$ is a non-degenerate critical point of q_t with same index as c_i. ■

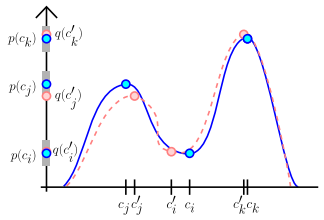

Figure 8: This figure illustrates the assumptions of Lemma 18. The functions p and q are shown in solid blue and dashed pink, respectively. The grey regions on the y-axis represent the sets $p(c) \pm b$ for critical points c of p.

Consider now two smooth functions such that the critical points are close, as illustrated in Figure 8. Next we show that, in this circumstance, the bottleneck distance takes a simple form.

Lemma 18 (Critical Distances) *Let p and q be two Morse functions as in Lemma 17, with finitely many critical points $C = \{c_1, \ldots, c_k\}$ and $C' = \{c'_1, \ldots, c'_k\}$ respectively. Let D_p and D_q be the persistence diagrams from the upper level set (i.e. super level sets) filtrations of p and q respectively and let $a = \min_{i \neq j} |p(c_i) - p(c_j)|$ and $b = \max_j |p(c_j) - q(c'_j)|$. If $b \leq a/2 - ||p - q||_\infty$ and $a/2 > 2||p - q||_\infty$, then $W_\infty(D_p, D_q) = b$.*

Proof The topology of the upper level sets of the Morse functions p and q only changes at critical values (Theorem 3.1 in Milnor (1963)). As a consequence the non-diagonal points of D_p (resp. D_q) have their coordinates among the set $\{p(c_1), \ldots, p(c_k)\}$ (resp. $\{q(c'_1), \ldots, p(c'_k)\}$) and each $p(c_i)$ is the coordinate of exactly one point in D_p. Moreover, the pairwise distances between the points of D_p are lower bounded by a and all non-diagonal points of D_p are at distance at least a from the diagonal. From the persistence stability theorem Cohen-Steiner et al. (2005); Chazal et al. (2012), $W_\infty(D_p, D_q) \leq ||p - q||_\infty$. Since $a > 4||p - q||_\infty$ and $a \geq 2b + 2||p - q||_\infty$, the (unique) optimal matching realizing the bottleneck distance $W_\infty(D_p, D_q)$ is such that if $(p(c_i), p(c_j)) \in D_p$ then it is matched to the point $(q(c'_i), q(c'_j))$ which thus have to be in D_q. It follows that $W_\infty(D_p, D_q) = b$. ■

Now we establish the limiting distribution of $\sqrt{n} W_\infty(\widehat{D}, D)$.

Theorem 19 (Limiting Distribution) *Let $p_h(x) = \mathbb{E}[\widehat{p}_h(x)]$, where $\widehat{p}_h(x)$ is the Kernel Density Estimator evaluated in x. Assume that p_h is a Morse function with two uniformly bounded continuous derivatives and finitely many critical points $c = \{c_1, \ldots, c_k\}$. Let D be the persistence diagram of the upper level sets of p_h and let $\widehat{D}$ be the diagram of upper level sets of $\widehat{p}_h$. Then*

$$\sqrt{n} W_\infty(\widehat{D}, D) \rightsquigarrow ||Z||_\infty$$

where $Z = (Z_1, \ldots, Z_k) \sim N(0, \Sigma)$ and

$$\Sigma_{jk} = \int K_h(c_j, u) K_h(c_k, u) dP(u) - \int K_h(c_j, u) dP(u) \int K_h(c_k, u) dP(u).$$

Proof Let $\widehat{c} = \{\widehat{c}_1, \widehat{c}_2, \ldots\}$ be the set of critical points of $\widehat{p}_h$. Let g and H be the gradient and Hessian of p_h. Let $\widehat{g}$ and $\widehat{H}$ be the gradient and Hessian of $\widehat{p}_h$. By a standard concentration of measure argument (and recalling that the support is compact), for any $\eta > 0$ there is an event $A_{n,\eta}$ such that, on $A_{n,\eta}$,

$$\sup_x ||\widehat{p}_h^{(i)}(x) - p_h^{(i)}(x)|| < \eta \tag{39}$$

for $i = 0, 1, 2$, and $\mathbb{P}(A_{n,\eta}^c) \leq e^{-nc\eta^2}$. This is proved for $i = 0$ in Rao (1983), Giné and Guillou (2002), Yukich (1985), and the same proof gives the results for $i = 1, 2$. It follows that $\sup_x ||g(x) - \widehat{g}(x)|| = O_P(1/\sqrt{n})$ and $\sup_x ||H(x) - \widehat{H}(x)||_{\max} = O_P(1/\sqrt{n})$.

For η smaller than a fixed value η_0, we can apply Lemma 17, we get that on $A_{n,\eta}$, $\widehat{c}$ and c have the same number of elements and can be indexed so that

$$\max_{j=1,\ldots,k} \|\widehat{c}_j - c_j\| \leq \frac{\eta}{C}$$

where C is the same constant is in Lemma 17. We then take $\eta_n := \sqrt{\frac{\log n}{n}}$ and we consider the events $A_n := A_{n,\eta_n}$. Then, for n large enough, on A_n we get

$$\max_{j=1,\ldots,k} \|\widehat{c}_j - c_j\| = O\left(\sqrt{\frac{\log n}{n}}\right)$$

whereas $P(A_n^c) = o(1)$. In the following, we thus can restrict to A_n.

The critical values of p_h are $v = (v_1 \equiv p_h(c_1), \ldots, v_k \equiv p_h(c_k))$ and the critical values of $\widehat{p}_h$ are $\widehat{v} = (\widehat{v}_1 \equiv \widehat{p}_h(\widehat{c}_1), \ldots, \widehat{v}_k \equiv \widehat{p}_h(\widehat{c}_k))$. Now we use Lemma 18 to conclude that $W_\infty(\widehat{D}, D) = \max_j \|\widehat{v}_j - v_j\|_\infty$ for n large enough. Hence,

$$W_\infty(\widehat{D}, D) = \max_{j=1,\ldots,k} |\widehat{p}_h(\widehat{c}_j) - p_h(c_j)|.$$

Then, using a Taylor expansion, for each j,

$$\widehat{p}_h(\widehat{c}_j) = \widehat{p}_h(c_j) + (\widehat{c}_j - c_j)^T \widehat{g}(c_j) + O(||\widehat{c}_j - c_j||^2).$$

Since $g(c_j) = (0, \ldots, 0)$ we can write the last equation as

$$\widehat{p}_h(\widehat{c}_j) = \widehat{p}_h(c_j) + (\widehat{c}_j - c_j)^T (\widehat{g}(c_j) - g(c_j)) + O(||\widehat{c}_j - c_j||^2).$$

So,

$$\begin{aligned}
\sqrt{n}(\widehat{v}_j - v_j) &= \sqrt{n}(\widehat{p}_h(\widehat{c}_j) - p_h(c_j)) \\
&= \sqrt{n}(\widehat{p}_h(c_j) - p_h(c_j)) + \sqrt{n}(\widehat{c}_j - c_j)^T (\widehat{g}(c_j) - g(c_j)) + O(||\widehat{c}_j - c_j||^2) \\
&= \sqrt{n}(\widehat{p}_h(c_j) - p_h(c_j)) + \sqrt{n}(\widehat{c}_j - c_j)^T (\widehat{g}(c_j) - g(c_j)) + o(1/\sqrt{n}).
\end{aligned}$$

For the second term, note that $\sqrt{n}(\widehat{c}_j - c_j) = O(\log n)$ and $(\widehat{g}(c_j) - g(c_j)) = O_P(1/\sqrt{n})$. So

$$\sqrt{n}(\widehat{v}_j - v_j) = \sqrt{n}(\widehat{p}_h(c_j) - p_h(c_j)) + o_P(1).$$

Therefore,

$$\sqrt{n}W_\infty(\widehat{D}, D) = \sqrt{n}\max_j |\widehat{v}_j - v_j| = \max_j |\sqrt{n}(\widehat{p}_h(c_j) - p_h(c_j))| + o_P(1).$$

By the multivariate Berry-Esseen theorem (Bentkus, 2003),

$$\sup_A |\mathbb{P}(\sqrt{n}(\widehat{p}_h(c) - p_h(c)) \in A) - \mathbb{P}(Z \in A)| \leq \frac{C_1}{\sqrt{n}}$$

where the supremum is over all convex sets $A \in \mathbb{R}^k$, $C_1 > 0$ depends on k and the third moment of $h^{-d}K(x - X/h)$ (which is finite since h is fixed and the support is compact), $Z = (Z_1, \ldots, Z_k) \sim N(0, \Sigma)$ and

$$\Sigma_{jk} = \int K_h(c_j, u)K_h(c_k, u)dP(u) - \int K_h(c_j, u)dP(u) \int K_h(c_k, u)dP(u).$$

Hence,

$$\sup_t \left| \mathbb{P}\Big(\max_j |\sqrt{n}(\widehat{p}_h(c_j) - p_h(c_j))| \leq t\Big) - \mathbb{P}(||Z||_\infty \leq t) \right| \leq \frac{C_1}{\sqrt{n}}.$$

By Lemma 18, $W_\infty(\widehat{D}, D) = \max_j |\widehat{v}_j - v_j|$. The result follows. ■

Let

$$\widehat{F}_n(t) = \mathbb{P}(\sqrt{n}W_\infty(\widehat{D}, D) \leq t).$$

Let $X_1^*, \ldots, X_n^* \sim P_n$ where P_n is the empirical distribution. Let $\widehat{D}^*$ be the diagram from $\widehat{p}_h^*$ and let

$$\widehat{F}_n(t) = \mathbb{P}\Big(\sqrt{n}W_\infty(\widehat{D}^*, \widehat{D}) \leq t \;\Big|\; X_1, \ldots, X_n\Big)$$

be the bootstrap approximation to F_n.

Next we show that the bootstrap quantity $F_n(t)$ converges to the same limit as $F_n(t)$.

Corollary 20 *Assume the same conditions as the last theorem. Then,*

$$\sup_t |\widehat{F}_n(t) - F_n(t)| \xrightarrow{P} 0.$$

Proof The proof is essentially the same as the proof of Theorem 19 except that $\widehat{p}_h$ replaces p_h and $\widehat{p}_h^*$ replaces $\widehat{p}_h$. Using the same notations as in the proof of Theorem 19, we note that on the set A_n, for n larger than a fixed value n_0, the function $\widehat{p}_h$ is a Morse function with two uniformly bounded continuous derivatives and finitely many critical points $\widehat{c} = \{\widehat{c}_1, \ldots, \widehat{c}_k\}$. We can restrict the analysis to the sequence of events A_n since $P(A_n)$ tends

to zero. Assuming that A_n is satisfied, using the same argument as in Theorem 19, we get that:

$$\sup_t \left| \mathbb{P}\Big(\max_j |\sqrt{n}(\widehat{p}_h^*(\widehat{c}_j) - \widehat{p}_h(\widehat{c}_j))| \leq t \;\Big|\; X_1, \ldots, X_n\Big) - \mathbb{P}(||\widetilde{Z}||_\infty \leq t) \right| \leq \frac{C_2^*}{\sqrt{n}}$$

where $\widetilde{Z} \sim N(0, \widehat{\Sigma})$ with

$$\widehat{\Sigma}_{jk} = \frac{1}{n}\sum_i K_h(\widehat{c}_j, X_i)K_h(\widehat{c}_k, X_i) - \frac{1}{n}\sum_i K_h(\widehat{c}_j, X_i)\frac{1}{n}\sum K_h(\widehat{c}_k, X_i)$$

and C_2^* depends on the empirical third moments of $h^{-d}K((x - X^*)/h)$. There exists an upper bound C_2 on C_2^* that only depends on K and P. Since $\max_{j,k} |\widehat{\Sigma}_{j,k} - \Sigma_{j,k}| = O_P(\log n/\sqrt{n})$ and $\max_j \|\widehat{c}_j - c_j\| = O_P(\log n/\sqrt{n})$, we conclude that

$$\sup_t |\mathbb{P}(||\widetilde{Z}||_\infty \leq t) - \mathbb{P}(||Z||_\infty \leq t)| = O_P\left(\frac{\log n}{\sqrt{n}}\right).$$

Then

$$\sup_t |\widehat{F}_n(t) - F_n(t)| \leq \sup_t |\widehat{F}_n(t) - \mathbb{P}(||\widetilde{Z}||_\infty \leq t)| + \sup_t |\mathbb{P}(||\widetilde{Z}||_\infty \leq t) - \mathbb{P}(||Z||_\infty \leq t)| + \sup_t |F_n(t) - \mathbb{P}(||Z||_\infty \leq t)| = O_P\left(\frac{\log n}{\sqrt{n}}\right).$$

The result follows. ■

7. Extensions

In this section, we discuss how to deal with three issues that can arise: choosing the parameters, correcting for boundary bias, and dealing with noisy data.

7.1 A Method for Choosing the Smoothing Parameter

An unsolved problem in topological inference is how to choose the smoothing parameter m (or h). Guibas et al. (2013) suggested tracking the evolution of the persistence of the homological features as the tuning parameter varies. Here we make this method more formal, by selecting the parameter that maximizes the total amount of significant persistence.

Let $\ell_1(m), \ell_2(m), \ldots,$ be the lifetimes of the features at scale m. Let $c_\alpha(m)/\sqrt{n}$ be the significance cutoff at scale m. We define two quantities that measure the amount of significant information using parameter m:

$$N(m) = \#\left\{i : \ \ell(i) > \frac{c_\alpha(m)}{\sqrt{n}}\right\}, \quad S(m) = \sum_i \left[\ell_i - \frac{c_\alpha(m)}{\sqrt{n}}\right]_+.$$

These measures are small when m is small since $c_\alpha(m)$ is large. On the other hand, they are small when m is large since then all the features are smoothed out. Thus we have a kind of topological bias-variance trade-off. We choose m to maximize $N(m)$ or $S(m)$. The same idea can be applied to the kernel distance and kernel density estimator. See the example in Figure 9.

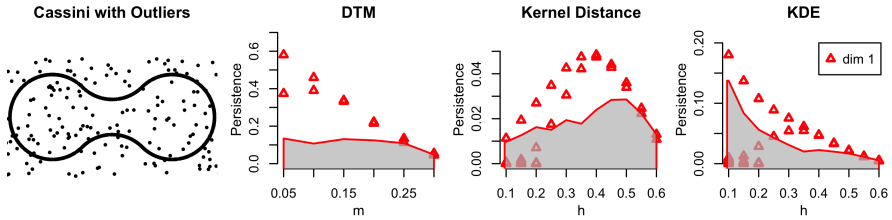

Figure 9: Max Persistence Method with Bottleneck Bootstrap Bands for 1-dimensional features. DTM: $\text{argmax}_m N(m) = \{0.05, 0.10, 0.15, 0.20\}$, $\text{argmax}_m S(m) = 0.05$; Kernel Distance: $\text{argmax}_h N(h) = \{0.25, 0.30, 0.35, 0.40, 0.45, 0.50\}$, $\text{argmax}_h S(h) = 0.35$; KDE: $\text{argmax}_h N(h) = \{0.25, 0.30, 0.35, 0.40, 0.45, 0.50\}$, $\text{argmax}_h S(h) = 0.3$ The plots show how to choose the smoothing parameters to maximize the number of significant features. The red triangles are the lifetimes of the features versus the tuning parameter.The red line is the significance cutoff.

7.2 Boundary Bias

It is well known that kernel density estimators suffer from boundary bias. For topological inference, this bias manifests itself in a particular form and the same problem affects the DTM. Consider Figure 10. Because of the bounding box, many of the loops are incomplete. The result is that, using either the DTM or the KDE we will miss many of the loops.

There is a large literature on reducing boundary bias in the kernel density estimation literature. Perhaps the simplest approach is to reflect the data around the boundaries (see for example Schuster (1958)). But there is a simpler fix for topological inference: we merely need to close the loops at the boundary. This can be done by adding points uniformly around the boundary.

7.3 Two Methods for Improving Performance

We can improve the performance of all the methods if we can mitigate the outliers and noise. Here we suggest two methods to do this. We focus on the kernel density estimator.

First, a simple method to reduce the number of outliers is to truncate the density, that is, we eliminate $\{X_i : \widehat{p}(X_i) < t\}$ for some threshold t. Then we re-estimate the density.

Secondly, we sharpen the data as described in Choi and Hall (1999) and Hall and Minnotte (2002). The idea of sharpening is to move each data point X_i slightly in the direction of the gradient $\nabla\widehat{p}(X_i)$ and then re-estimate the density. The authors show that this reduces the bias at peaks in the density which should make it easier to find topological features. It can be seen that the sharpening method amounts to running one or more steps if the mean-shift algorithm. This is a gradient ascent which is intended to find modes of the density estimator. Given a point x, we move x to

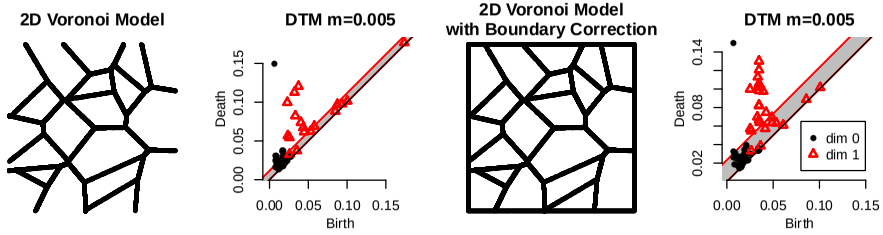

Figure 10: First: 10,000 points sampled from a 2D Voronoi model with 20 nuclei. Second: the corresponding persistence diagram of sublevel sets of the distance to measure function. Note that only 9 loops are detected as significant. Third: 2,000 points have been added on the boundary of the square delimiting the Voronoi model. Fourth: now the corresponding persistence diagram shows 16 significant loops.

$$\frac{\sum_i X_i K_h(x, X_i)}{\sum_i K_h(x, X_i)},$$

which is simply the local average centered at x. For data sharpening, we do one (or a few) iterations of this to each data point X_i. Then the density is re-estimated.
In fact, we could also use the subspace constrained mean shift algorithm (SCMS) which moves points towards ridges of the density; see Ozertem and Erdogmus (2011).
Figure 11 shows these methods applied to a simple example.

8. Examples

Example 1 (Noisy Grid) *The data in Figure 12 are 10,000 data points on a 2D grid. We add Gaussian noise plus 1,000 outliers and compute the persistence diagrams of Kernel Density Estimator, Kernel distance, and Distance to Measure. The pink bands show 95% confidence sets obtained by bootstrapping the corresponding functions. The black lines show 95% confidence bands obtained with the bottleneck bootstrap for dimension 0, while the red lines show 95% confidence bands obtained with the bottleneck bootstrap for dimension 1. The Distance to Measure, which is less sensitive to the density of the points, correctly captures the topology of the data. The Kernel Distance and KDE find some extra significant connected component, corresponding to high density regions at the intersection of the grid.*

Example 2 (Soccer) *Figure 13 shows the field position of two soccer players. The data come from body-sensor traces collected during a professional soccer game in late 2013 at the Alfheim Stadium in Tromso, Norway. The data are sampled at 20 Hz. See Pettersen et al. (2014). Although the data is a function observed over time, we treat it as a point cloud. Points on the boundary of the field have been added to avoid boundary bias. The DTM*

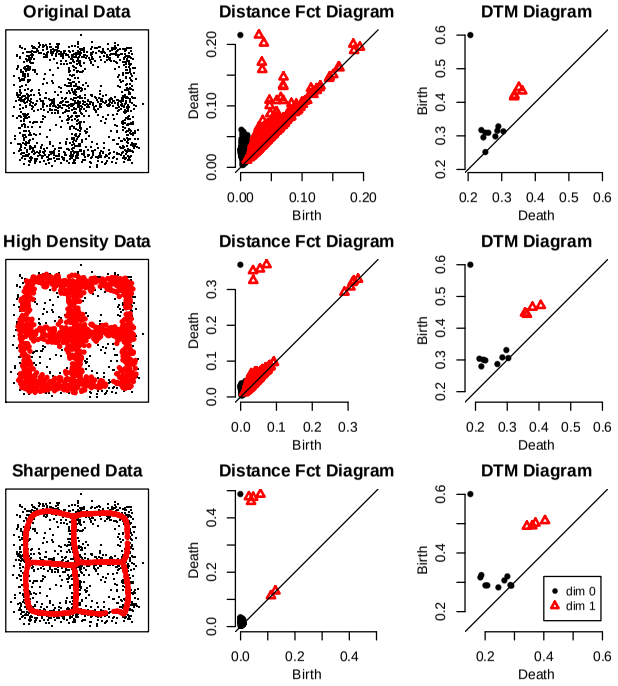

Figure 11: Top: 1,300 points sampled along a 2×2 grid with Gaussian noise; the diagram of the distance function shows many loops due to noise. Middle: the red points are the high density data (density > 0.15); the corresponding diagram of the distance function correctly captures the 4 loops, plus a few features with short lifetime. Bottom: the red points represent the sharpened high density data; now most of the noise in the corresponding diagram is eliminated. Note that the diagram of the distance to measure function does a good job with the original data. The bottom left plot shows a slight improvement, in the sense that the persistence of the 4 loops has increased.

captures the difference between the two players: the defender leaves one big portion of the filed uncovered (1 significant loop in the persistence diagram), while the midfielder does not cover the 4 corners (4 significant loops). Nonetheless, the Kernel distance, which is more sensible to the density of these points, fails to detect significant topological features.

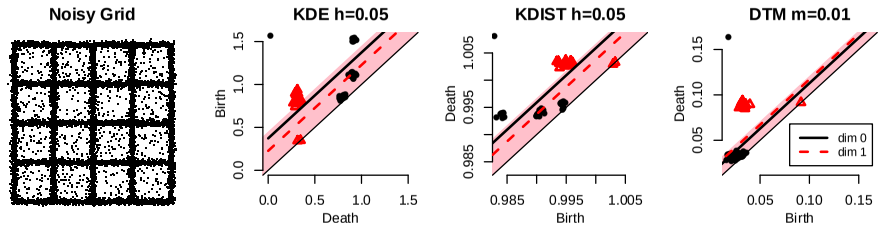

Figure 12: 10,000 data points on a 2D grid and the corresponding persistence diagrams of Kernel Density Estimator, Kernel distance, and Distance to Measure. For more details see Example 1.

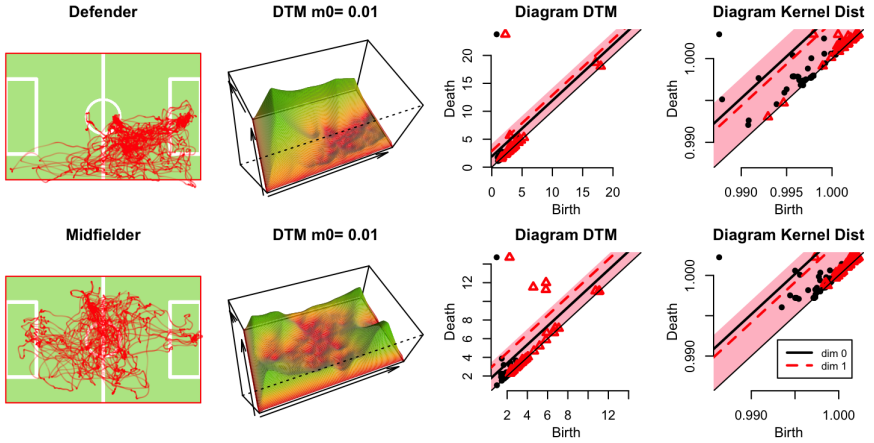

Figure 13: Top: data for a defender. We show the DTM, the digram for the DTM and the digram for the kernel distance. Bottom: same but for a midfielder. The midfielder data has more loops.

Example 3 (Voronoi Models) *Given k points (nuclei) $\{z_1, \ldots, z_k\} \subset \mathbb{R}^3$, let the Voronoi region R_k be $R_k = \left\{x \in \mathbb{R}^3 : \|x - z_k\| \leq \|x - x_j\| \text{ for all } j \neq k\right\}$. The Voronoi regions $R_1, \ldots, R_k$ partition the space, forming what is known as the Voronoi diagram. A face is formed by the intersection of 2 adjacent Voronoi regions; a line is formed at the intersection of two faces and a node is formed at the intersection of two or more lines.*

We will sample points around the the nodes, lines and faces that are formed at the intersection of the Voronoi regions. A Voronoi wall model is a sampling scheme that returns points within or around the Voronoi faces. Similarly, by sampling points exclusively around the lines or exclusively around the nodes, we can construct Voronoi filament models and Voronoi cluster models.

These models were introduced by Icke and van de Weygaert (1991) to mimic key features of cosmological data; see also van de Weygaert et al. (2011).

In this example we generate data from filament models and wall models using the basic definition of Voronoi diagram, computed on a fine grid in $[0, 50]^3$. *We also add random Gaussian noise. See Figure 14: the first two rows show 100K particles concentrated around the filaments of 8 and 64 Voronoi cells, respectively. The last two rows show 100K particles concentrated around the walls of 8 and 64 Voronoi cells. 60K points on the boundary of the boxes have been added to mitigate boundary bias. For each model we present the persistent diagrams of the distance function, distance to measure and kernel density estimator. We chose the smoothing parameters by maximizing the quantity* $S(\cdot)$, *defined in Section 7.1.*

The diagrams illustrate the evolution of the filtrations for the three different functions: at first, the connected components appear (black points in the diagrams); then they merge forming loops (red triangle), that eventually evolve into 3D voids (blue squares).

The persistence diagrams of the three functions allow us to distinguish the different models (see Figure 1 for a less trivial example) and the confidence bands, generated using the bootstrap method of Section 4.1, allow us to separate the topological signal from the topological noise. In general, the DTM performs better than the KDE, which is more affected by the high density of points around the nodes and filaments. For instance, this is very clear in the third row of Figure 14. The DTM diagram correctly captures the topology of the Voronoi wall model with 8 nuclei: one connected component and 8 voids are significant, while the remaining homological features fall into the band and are classified as noise.

9. Discussion

In this paper, we showed how the DTM and KDE can be used for robust topological inference. Further, we showed how to use the bootstrap to identify topological features that are distinguishable from noise. We conclude by discussing two issues: comparing DTM and KDE, and using persistent homology versus selecting a single level set.

9.1 Comparison of DTM and Kernel Distance

The DTM and the KDE have the same broad aim: to provide a means for extracting topological features from data. However, these two methods are really focused on different goals. Consider again the model $P = \pi R + (1 - \pi)(Q \star \Phi_\sigma)$ and let S be the support of Q. As before, we assume that S is a "small set" meaning that either it has dimension $k < d$ or that it is full dimensional but has small Lebesgue measure. When π and σ are small, the persistent homology of the upper level sets of the density p will be dominated by features corresponding to the homology of S. In other words, we are using the persistent homology of $\{p > t\}$ to learn about the homology of S. In contrast, the DTM is aimed at estimating the persistent homology of S. Both are useful, but they have slightly different goals.

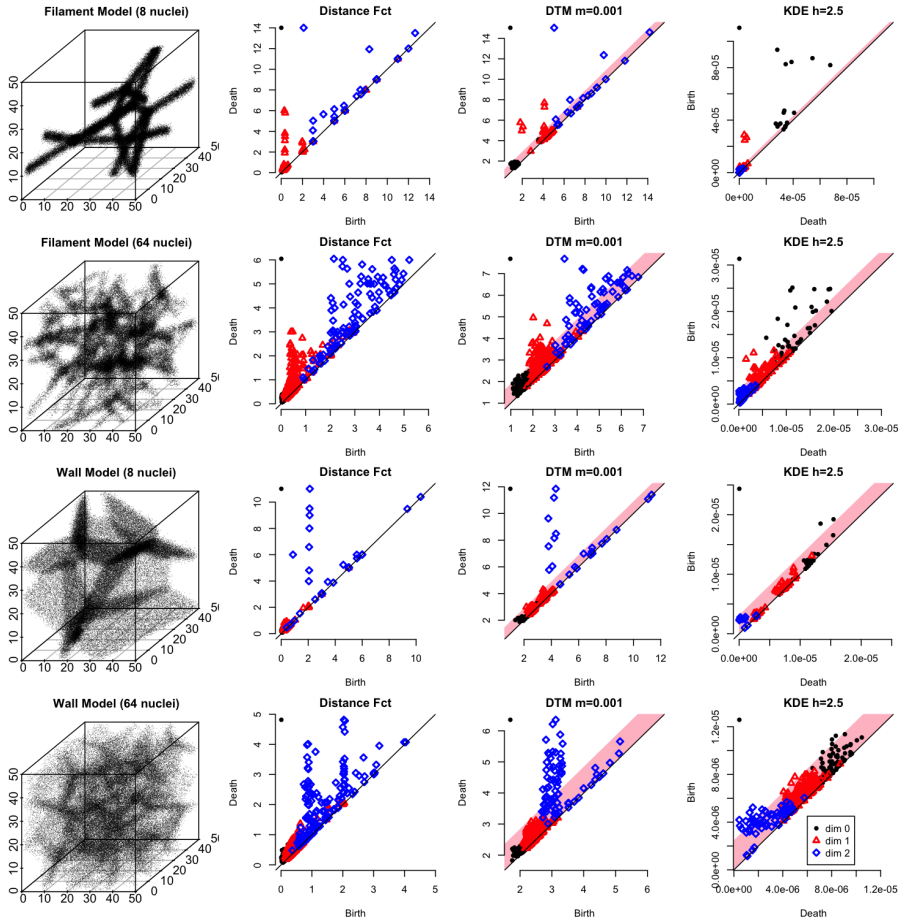

Figure 14: Data from four Voronoi foam models. In each case we show the diagrams of the distance function, the DTM and the KDE. A boundary correction was included.

This also raises the intriguing idea of extracting more information from both the KDE and DTM by varying more parameters. For example, if we look at the sets $\{p_h > t\}$ for fixed t but varying h, we get information very similar to that of the DTM. Conversely, for

the DTM, we can vary the tuning parameter m. There are many possibilities here which we will investigate in future work.

9.2 Persistent Homology Versus Choosing One Level Set

We have used the persistent homology of the upper level sets $\{\widehat{p}_h > t\}$ to probe the homology of S. This is the approach used in Bubenik (2015) and Phillips et al. (2014).

Bobrowski et al (2014) suggest a different approach. They select a particular level set $\{p > t\}$ and they form a robust estimate of the homology of this one level set. They have a data-driven method for selecting t. (This approach is only one part of the paper. They also consider persistent homology.)

They make two key assumptions. The first is that there exists $A < B$ such that $\{p > t\}$ is homotopic to S for all $A < t < B$. (If two sets are homotopic, then they have the same homology.) This is a very reasonable assumption. In the mixture model $P = \pi R + (1 - \pi)(Q \star \Phi_\sigma)$ this assumption will be satisfied when S is a small set and when π and σ are small. In this case, persistent homology will also work well: the dominant features in the persistence diagram will correspond to the homology of S.

Bobrowski et al (2014) make an additional assumption. They assume that the dimension k of S is known and that the rank of the k^{th} homology group is 0 for all $t > B$. This assumption is critical for their approach to choosing a single level set. Currently, it is not clear how strong this assumption is. In future work, we plan to compare the robustness of the single-level approach versus persistent homology.

9.3 Future Work

Lastly, we would like to mention that several issues deserve future attention. In particular, the methods we discussed for choosing the tuning parameters, for mitigating boundary bias and for sharpening the data, all deserve further investigation.

In a companion paper we will show how the ideas presented in this work can be used to develop hypothesis tests for comparing point clouds.

Acknowledgments

The authors are grateful to Jérome Dedecker for pointing out the key decomposition (18) of the DTM. The authors also would like to thank Jessi Cisewski and Jisu Kim for their comments and two referees for helpful suggestions. Abstract

How can we train a statistical mixture model on a massive data set? In this work we show how to construct *coresets* for mixtures of Gaussians. A coreset is a weighted subset of the data, which guarantees that models fitting the coreset also provide a good fit for the original data set. We show that, perhaps surprisingly, Gaussian mixtures admit coresets of size polynomial in dimension and the number of mixture components, while being *independent* of the data set size. Hence, one can harness computationally intensive algorithms to compute a good approximation on a significantly smaller data set. More importantly, such coresets can be efficiently constructed both in distributed and streaming settings and do not impose restrictions on the data generating process. Our results rely on a novel reduction of statistical estimation to problems in computational geometry and new combinatorial complexity results for mixtures of Gaussians. Empirical evaluation on several real-world data sets suggests that our coreset-based approach enables significant reduction in training-time with negligible approximation error.

Keywords: Gaussian mixture models, coresets, streaming and distributed computation

1. Introduction

We consider the problem of training statistical mixture models, in particular mixtures of Gaussians on massive data sets. In contrast to parameter estimation for models with compact sufficient statistics, mixture models generally require inference over latent variables, which in turn depends on the full data set. Such data sets are often distributed across a cluster of machines, or arrive in a data stream, and have to be processed with limited memory. In this paper, we show that Gaussian mixture models (GMMs) admit small *coresets*: A weighted subset of the data which guarantees that models fitting the coreset will also provide a good fit for the original data set. As a result, solving the estimation problem on the coreset $\mathcal{C}$ is almost as good as solving the estimation problem on the large data set $\mathcal{X}$. Critically, we show that the size of these coresets is *independent* of the size of the data set.

We focus on training mixtures of λ-semi-spherical Gaussians, where the covariance matrix Σ_i of each component $i \in [k]$ has eigenvalues bounded in $[\lambda, 1/\lambda]$. More formally, given a data set $\mathcal{X}$ of n points in $\mathbb{R}^d$, some $\varepsilon > 0$ and an integer $k \geq 1$, one can efficiently construct a weighted set $\mathcal{C} \subseteq \mathcal{X}$ of $\Theta\left(d^4 k^6 \varepsilon^{-2} \lambda^{-4}\right)$ points, such that for any mixture of k λ-semi-spherical Gaussians $\theta = [(w_i, \mu_i, \Sigma_i)]_{i=1}^k$ it holds that the log-likelihood $\ln P(\mathcal{X} \mid \theta)$ of $\mathcal{X}$ under θ is approximated by the (properly weighted) log-likelihood $\ln P(\mathcal{C} \mid \theta)$ of $\mathcal{C}$ under θ to arbitrary accuracy as $\varepsilon \to 0$. Moreover, these coresets can be efficiently constructed in parallel (using a merge-reduce style computation), as well as in the streaming setting using space and update time per point polynomial in d, k, λ^{-1}, ε^{-1}, $\log n$ and $\log(1/\delta)$.

2. Background and Problem Statement

We first discuss the problem of parameter estimation of Gaussian mixture models by maximum likelihood estimation. We then turn our attention to the problem of approximating the log-likelihood using a weighted subset of the data set and formally define the desired coreset property.

2.1 Fitting Gaussian Mixture Models by Maximum Likelihood Estimation

Given a data set $\mathcal{X} = \{x_1, \ldots, x_n\} \subset \mathbb{R}^d$ we consider fitting a mixture of Gaussians $\theta = [(w_1, \mu_1, \Sigma_1), \ldots, (w_k, \mu_k, \Sigma_k)]$, that is, the distribution

$$P(x \mid \theta) = \sum_{i=1}^{k} w_i \mathcal{N}(x; \mu_i, \Sigma_i)$$

where $w_1, \ldots, w_k \geq 0$ are the mixture weights and $\sum_i w_i = 1$. The i-th mixture component is modelled as a multivariate Normal distribution parametrized by mean $\mu_i \in \mathbb{R}^d$ and covariance $\Sigma_i \in \mathbb{R}^{d \times d}$,

$$\mathcal{N}(x; \mu_i, \Sigma_i) = \frac{1}{\sqrt{|2\pi\Sigma_i|}} \exp\left(-\frac{1}{2}(x - \mu_i)^T \Sigma_i^{-1} (x - \mu_i)\right).$$

Assuming the data was generated i.i.d., the negative log-likelihood of the data is

$$\mathcal{L}(\mathcal{X} \mid \theta) = -\sum_j \ln P(x_j \mid \theta),$$

and we wish to obtain the maximum likelihood estimate (MLE) of the parameters

$$\theta^* = \operatorname*{argmin}_{\theta \in \mathfrak{C}} \mathcal{L}(\mathcal{X} \mid \theta),$$

where $\mathfrak{C}$ is a set of constraints ensuring that degenerate solutions are avoided. Hereby, for a symmetric matrix $\mathbf{A}$, let $\mathrm{spec}(\mathbf{A})$ be the set of all eigenvalues of $\mathbf{A}$. We define $\mathfrak{C} = \mathfrak{C}_\lambda = \{\theta = [(w_i, \mu_i, \Sigma_i)]_{i=1}^k \mid \forall_i : \mathrm{spec}(\Sigma_i) \subseteq [\lambda, 1/\lambda]\}$ for some small $\lambda \in (0, 1)$.

2.2 Approximating the Log-likelihood

Ideally, we would like to obtain $(1+\varepsilon)$-multiplicative approximation for the likelihood

$$\prod_{x\in\mathcal{X}} P(x \mid \theta)$$

which implies an additive ε error for the sum of log-likelihoods. What kind of approximation accuracy may we hope to expect? Notice that there is a non-trivial issue of scale: Suppose we have a MLE θ^* for $\mathcal{X}$, and let $\alpha > 0$. Then straightforward linear algebra shows that we can obtain a MLE θ^*_α for a scaled data set $\alpha D = \{\alpha x : x \in \mathcal{X}\}$ by simply scaling all means by α, and covariance matrices by α^2. For the log-likelihood, however, it holds that $\frac{1}{n}\mathcal{L}(\alpha D \mid \theta^*_\alpha) = d\ln\alpha + \frac{1}{n}\mathcal{L}(\mathcal{X} \mid \theta^*)$. Therefore, optimal solutions on one scale can be efficiently transformed to optimal solutions on a different scale, while maintaining the same *additive error*. Thus, we cannot expect to obtain a $(1+\varepsilon)$-multiplicative approximation to the likelihood since any algorithm which achieves absolute error ε at any scale could be used to compute parameter estimates (for means, covariances) with arbitrarily small error, simply by applying the algorithm to a scaled data set and transforming back the obtained solution.

An alternative, scale-invariant approach, may be to strive towards a *multiplicative error* $(1+\varepsilon)$ for the sum of log-likelihoods. Unfortunately, this goal is also hard to achieve: Choosing a scaling parameter α such that $d\ln\alpha + \mathcal{L}(\mathcal{X} \mid \theta^*) = 0$ would require any algorithm that achieves any bounded multiplicative error to essentially incur *no error at all* when evaluating $\mathcal{L}(\alpha\mathcal{X} \mid \theta^*)$. The above observations hold even for the case $k = 1$ and $\Sigma = I$, where the mixture θ consists of a single Gaussian, and the log-likelihood is the sum of squared distances to a point μ and an additive term.

Motivated by the scaling issues discussed above, our goal is to approximate the data set $\mathcal{X}$ by a weighted set $C = \{(\gamma_1, \mathbf{x}'_1), \ldots, (\gamma_m, \mathbf{x}'_m)\} \subseteq \mathbb{R}_+ \times \mathbb{R}^d$ such that $\mathcal{L}(\mathcal{X} \mid \theta) \approx \mathcal{L}(\mathcal{C} \mid \theta)$ for all $\theta \in \mathfrak{C}_\lambda$, where we define

$$\mathcal{L}(\mathcal{C} \mid \theta) = -\sum_i \gamma_i \ln P(\mathbf{x}'_i \mid \theta).$$

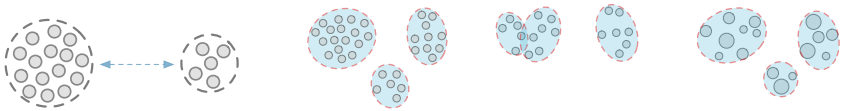
The key idea is to decompose the negative log-likelihood into a data-dependent term, and a data-independent term, with the goal of approximating the latter with a coreset. To this end, we apply the following decomposition suggested by Arora and Kannan (2005):

$$\begin{aligned}\mathcal{L}(\mathcal{X} \mid \theta) &= -\sum_{j=1}^{n} \ln \sum_{i=1}^{k} \frac{w_i}{\sqrt{|2\pi\Sigma_i|}} \exp\left(-\frac{1}{2}(x_j-\mu_i)^T\Sigma_i^{-1}(x_j-\mu_i)\right) \\ &= -n\ln Z(\theta) + \operatorname{cost}(\mathcal{X},\theta),\end{aligned}$$

where $Z(\theta) = \sum_i \frac{w_i}{\sqrt{|2\pi\Sigma_i|}}$ is a normalizer, and the function cost is defined as

$$\operatorname{cost}(\mathcal{X},\theta) = -\sum_{j=1}^{n} \ln \sum_{i=1}^{k} \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}} \exp\left(-\frac{1}{2}(x_j-\mu_i)^T\Sigma_i^{-1}(x_j-\mu_i)\right).$$

Hereby, $Z(\theta)$ is a normalizing term which can be computed *exactly* and independently of the set $\mathcal{X}$. Furthermore, function $\operatorname{cost}(\mathcal{X},\theta)$ captures all dependencies of $\mathcal{L}(\mathcal{X} \mid \theta)$ on $\mathcal{X}$.



(a) Simple failure case (b) Full data set (c) Uniform sample (d) Coreset

Figure 1: Figure (a) illustrates a simple example of well-separated Gaussians for which uniform subsampling fails arbitrarily badly. Consider two spherical Gaussian mixtures with weights $w_1 = 1/\sqrt{n}$ and $w_2 = 1 - 1/\sqrt{n}$. Unless the number of samples $m \in \Theta(\sqrt{n})$, the uniform sample will consist only of points from the first Gaussian, with high probability. Hence, moving the means of the Gaussians apart, the difference in MLEs on the full data set and the one on the uniform subsample can be made arbitrarily high. Figure (b) shows a GMM with 3 components fit on the full data set, (c) the model fit on the uniform subsample, and (d) the model fit on a coreset. The uniform subsample is likely to miss small clusters in presence of unbalanced data.

2.3 Coresets for Semi-spherical Gaussian Mixtures

We proceed by showing that it suffices to approximate $\operatorname{cost}(\mathcal{X},\theta)$ uniformly over $\theta \in \mathfrak{C}$.

Definition 1 *We call a weighted data set $\mathcal{C}$ a (k,ε)-*coreset *for another (possibly weighted) set $\mathcal{X} \subset \mathbb{R}^d$, if for all mixtures $\theta \in \mathfrak{C}$ of k Gaussians it holds that*

$$(1-\varepsilon)\operatorname{cost}(\mathcal{X},\theta) \leq \operatorname{cost}(\mathcal{C},\theta) \leq (1+\varepsilon)\operatorname{cost}(\mathcal{X},\theta).$$

Hereby, $\operatorname{cost}(\mathcal{C},\theta)$ is generalized to weighted data sets $\mathcal{C}$ in the natural way (weighing the contribution of each summand $\mathbf{x}'_j \in \mathcal{C}$ by its weight γ_j). Thus, as $\varepsilon \to 0$, for a sequence of (k,ε)-coresets $\mathcal{C}_\varepsilon$ we have that

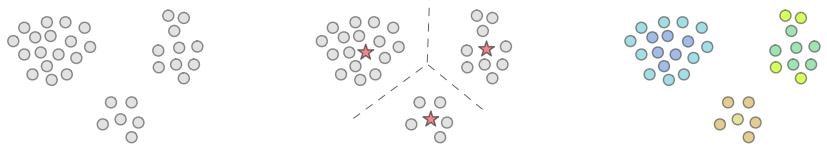
$$\sup_{\theta\in\mathfrak{C}} |\mathcal{L}(\mathcal{C}_\varepsilon \mid \theta) - \mathcal{L}(\mathcal{X} \mid \theta)| = \sup_{\theta\in\mathfrak{C}} |\operatorname{cost}(\mathcal{C}_\varepsilon,\theta) - \operatorname{cost}(\mathcal{X} \mid \theta)| \to 0$$

which implies that $\mathcal{L}(\mathcal{C}_\varepsilon \mid \theta)$ uniformly approximates $\mathcal{L}(\mathcal{X} \mid \theta)$ (over $\theta \in \mathfrak{C}$).

The main motivation for constructing a (k,ε)-coreset $\mathcal{C}$ is to reduce the problem of fitting a mixture model on $\mathcal{X}$ to one of fitting a model on $\mathcal{C}$, since the optimal solution $\theta_\mathcal{C}$ is a good approximation (in terms of log-likelihood) of θ^*. While finding the optimal $\theta_\mathcal{C}$ is a difficult problem, one can use a (weighted) variant of the EM algorithm to find a good solution. Moreover, if $|\mathcal{C}| \ll |\mathcal{X}|$, running EM on $\mathcal{C}$ is orders of magnitude faster than running EM on $\mathcal{X}$.

3. Efficient Coreset Construction

We start by contrasting the coreset approach with the "naive" approach of fitting the model on a uniform subsample. We show that the uniform subsampling approach can perform arbitrarily badly, while explicit worst-case guarantees can be given for the coreset based approach. We then present a simple coreset construction algorithm and conclude with a bound on the sufficient coreset size.



(a) Data set (b) k-means approximation (c) Distribution $q(x)$

Figure 2: Illustration of the coreset construction on a synthetic data set. Figure (a) shows the original data set and (b) the k-means bicriteria approximation. Figure (c) illustrates the computed sensitivity (blue-low, orange-high). The coreset sampling probabilities are inversely proportional to the size of the cluster which results in more representative samples.

3.1 Naive Approach via Uniform Sampling

A naive approach towards approximating the log-likelihood of $\mathcal{X}$ is to just pick a subset $\mathcal{C}$ uniformly at random. Unfortunately, such a simple strategy may result in arbitrary bad approximations of the log-likelihood as illustrated by the following example. Suppose the data set is generated from a mixture of two spherical Gaussians ($\Sigma_i = \mathbf{I}$) with weights $w_1 = \frac{1}{\sqrt{n}}$ and $w_2 = 1 - \frac{1}{\sqrt{n}}$. Unless $m = \Omega(\sqrt{n})$ points are sampled, with constant probability no data point generated from the second Gaussian is sampled. By moving the means of the Gaussians apart, $\mathcal{L}(\mathcal{X} \mid \theta_{\mathcal{C}})$ can be made arbitrarily worse than $\mathcal{L}(\mathcal{X} \mid \theta_{\mathcal{X}})$, where $\theta_{\mathcal{C}}$ and $\theta_{\mathcal{X}}$ are MLEs on $\mathcal{C}$ and $\mathcal{X}$ respectively. Thus, even for two well-separated Gaussians, uniform subsampling can perform arbitrarily poorly which is illustrated in Figure 2. The problem becomes even more pronounced as k and d grow.

This example already suggests that we must devise a sampling scheme that adaptively selects representative points from all "clusters" present in the data set. However, this implies that obtaining a coreset requires solving a chicken-and-egg problem, where we need to understand the density of the data to obtain the coreset, but simultaneously would like to use the coreset for density estimation.

3.2 Better Approximation via Importance Sampling

The key idea behind the coreset construction is that we can break the chicken-and-egg problem by first obtaining a rough approximation of the problem on $\mathcal{X}$ and use it to construct a non-uniform sampling scheme. This non-uniform sampling can be understood as an importance-weighted estimate of the log-likelihood $\mathcal{L}(\mathcal{X} \mid \theta)$, where the weights are optimized in order to reduce the variance. Feldman and Langberg (2011) successfully used the same idea to construct coresets for geometric clustering problems.

The critical insight is that, even though we seek to fit GMMs, it suffices to consider approximate solutions to the k-means clustering of $\mathcal{X}$ to construct a good sampling strategy. Intuitively, such a solution partitions $\mathcal{X}$ into Voronoi cells for which we can compute the density and the variance. Hence, one can bias the sampling towards less dense regions of $\mathcal{X}$. We prove that the resulting sampling strategy yields valid coresets in Appendix A.3. Our main result is the following Theorem which establishes the sufficient sample size which

Algorithm 1 Coreset

require: Data set $\mathcal{X}$, bicriteria approximation $\mathcal{B}$, approximation factor α, coreset size m.
for $j \leftarrow 1$ **to** $|\mathcal{B}|$
  $\mathcal{X}_j \leftarrow$ Set of points from $\mathcal{X}$ closest to point $\mathcal{B}_j$. Ties may be broken arbitrarily.
for $j \leftarrow 1$ **to** $|\mathcal{B}|$, **for each** $x \in \mathcal{X}_j$
  $s(x) \leftarrow \alpha \mathrm{d}(x, \mathcal{B})^2 + \frac{2\alpha}{|\mathcal{X}_j|} \sum_{x' \in \mathcal{X}_j} \mathrm{d}(x', \mathcal{B})^2 + \frac{2}{|\mathcal{X}_j|} \sum_{x' \in \mathcal{X}} \mathrm{d}(x', \mathcal{B})^2$
for each $x \in \mathcal{X}$
  $q(x) \leftarrow \frac{s(x)}{\sum_{x' \in \mathcal{X}} s(x')}$
$\mathcal{C} \leftarrow$ Sample m weighted points from $\mathcal{X}$, where each point x is sampled with probability $q(x)$ and assigned a weight $\frac{1}{m \cdot q(x)}$.
return $\mathcal{C}$

Algorithm 2 K-Means++

require: Data set $\mathcal{X}$, number of clusters k.
$\mathcal{B} \leftarrow \{$Sample $x \in \mathcal{X}$ uniformly at random$\}$
for $j \leftarrow 2$ **to** k
  for x **in** $\mathcal{X}$
    $p(x) \leftarrow \frac{\mathrm{d}^2(x, \mathcal{B})}{\sum_{x' \in \mathcal{X}} \mathrm{d}^2(x', \mathcal{B})}$
  Sample $x \in \mathcal{X}$ with probability $p(x)$ and add it to $\mathcal{B}$.
return $\mathcal{B}$

Algorithm 3 Adaptive sampling

require: $\mathcal{X}$, k, failure probability δ.
$R \leftarrow D, \mathcal{B} \leftarrow \emptyset, c \leftarrow \lceil 10dk \ln(1/\delta) \rceil$
while $|R| > c$
  $S \leftarrow$ Sample c points uniformly from R
  $P \leftarrow \lceil |R|/2 \rceil$ points from R closest to S
  $R \leftarrow R \setminus P$
  $\mathcal{B} \leftarrow \mathcal{B} \cup S$
$\mathcal{B} \leftarrow \mathcal{B} \cup R$
return $\mathcal{B}$

is independent of n, and only polynomial in k, d and ε. For clarity, we define $\mathrm{d}(x, \mathcal{B}) = \min_{b \in \mathcal{B}} ||x - b||$ and $\phi(\mathcal{X}, \mathcal{B}) = \sum_{x \in \mathcal{X}} \mathrm{d}(x, \mathcal{B})^2$.

Theorem 2 *Let $\mathcal{X} \subset \mathbb{R}^d$, $\delta \in (0,1)$, $\varepsilon \in (0, 1/2)$, $k \in \mathbb{N}$, and $\lambda \in (0,1)$. Let $\mathcal{B}_1, \ldots, \mathcal{B}_p$ be the outputs of $p = \lceil \log_2 1/\delta \rceil$ independent runs of Algorithm 2 with input $\mathcal{X}$ and k. Let $\mathcal{C}$ be the output of Algorithm 1 with $\alpha = 16(\log_2 k + 2)$, $\mathcal{B}^\star = \operatorname{argmin}_{i \in \{1,\ldots,p\}} \phi(\mathcal{X}, \mathcal{B}_i)$ and coreset size*

$$m \geq c \cdot \frac{d^4 k^6 + k^2 \log \frac{1}{\delta}}{\lambda^4 \varepsilon^2},$$

where $c > 0$ is an absolute constant. Then, with probability at least $1 - \delta$, the set $\mathcal{C}$ is a (k, ε)-coreset of $\mathcal{X}$.

To establish the result we first reduce the MLE problem to the Euclidean space where the log-likelihood contribution of a data point given a model $\theta \in \mathfrak{C}$ can be expressed in a purely geometric manner. We then apply a coreset construction framework introduced by Feldman and Langberg (2011), which formalizes the intuition that one should sample the points with a potentially large impact more often. We then show that to compute the sampling distribution $q(x)$ it suffices to consider a rough approximation so the k-means clustering of $\mathcal{X}$. To guarantee uniform convergence over $\mathfrak{C}$ we bound the combinatorial complexity of the family of functions induced by the MLE of GMMs and show that it has a polynomial dependency on k and d. The full proof is presented in the Appendix.

Several implementation choices are available. Firstly, we prove that one can use any (α, β)-*bicriteria solution* to k-means (α approximate with respect to the optimal k-means clustering, using βk centers). The suggested algorithm, `k-means++`, provides a solution $\mathcal{B}$ of size k with approximation $\mathcal{O}(\log_2 k)$ in expectation in time $\mathcal{O}(nkd)$ and results in coresets of size *independent* of the data set size (Theorem 2). For other bicriteria approximation algorithms offering different tradeoffs in terms of computational complexity and the approximation guarantee we refer the reader to Bachem et al. (2016a,b), Makarychev et al. (2016) and Feldman and Langberg (2011) presented in Algorithm 3. Furthermore, all steps of the algorithm are parallelizable. The bicriteria approximation can be computed via k-means|| (Bahmani et al., 2012) and other quantities (i.e. $s(x)$, $q(x)$) can be computed in parallel. Finally, the importance sampling step can be implemented to run in constant-time per point with linear-time preprocessing (Vose, 1991).

4. Fitting a GMM on the Coreset using Weighted EM

Once the coreset $\mathcal{C}$ is constructed, we need to fit a mixture model that takes into account the point weights. Since the coreset size is independent of the cardinality of $\mathcal{X}$ we can (at least from the perspective of developing a polynomial time algorithm) afford to use a more "expensive" method. In geometric clustering problems such as k-means or k-median, where data points are hard-assigned to the closest cluster (point, subspace, etc.), it is possible to find the *optimal* clustering via exhaustive search, by simply considering all possible partitions of the coreset, and picking the best one. This procedure – constructing a coreset of size independent of n, and then using exhaustive search on the coreset – yields a (randomized) polynomial time approximation scheme (PTAS): It is guaranteed to achieve multiplicative error $1+\varepsilon$, in time which is polynomial in n, but exponential in all other quantities (in particular $1/\varepsilon$). For mixture models, this exhaustive search algorithm is not feasible, since points are not hard-assigned to a cluster, but "soft-assigned" (according to the cluster membership probabilities). One approach, which we employ in our experiments, is to use a natural generalization of the EM algorithm, which takes the coreset weights into account. The details are presented in Algorithm 4 and the derivation of the EM update equations is presented in Appendix B.

Since the EM algorithm is applied on a significantly smaller data set, it can be initialized using multiple random restarts. In our experiments, we show that running weighted EM on the coreset typically leads to comparable performance (in terms of log-likelihood) as running EM on the full data set. A practical issue when using EM to fit a Gaussian mixture model is to ensure non-degeneracy which occurs when the MLE estimate for the (co)variance is zero implying infinite density and infinite log-likelihood (Bishop, 2006). The generally accepted remedy is to constrain the variances to be greater than some small apriori chosen value $\lambda > 0$ which is the strategy we employ in the experimental evaluation (Bishop, 2006). The alternative is to consider a fully Bayesian framework whereby one introduces a prior on the covariance matrices which induces large penalties for small values of the (co)variance in the resulting *maximum a posteriori* estimation problem (Murphy, 2012).

Algorithm 4 EM for GMMs

require: Data set $\mathcal{X}$, point weights γ, number of components k, prior threshold λ.
$\eta \leftarrow$ Weighted-K-Means$(\mathcal{X}, \gamma, k)$ ▷ $\eta_{ij} = 1$ iff x_i was assigned to cluster j.
$w, \mu, \Sigma \leftarrow$ Maximization$(\mathcal{X}, \eta, \lambda)$
while not converged
  $\eta \leftarrow$ Expectation$(\mathcal{X}, \gamma, w, \mu, \Sigma)$
  $w, \mu, \Sigma \leftarrow$ Maximization$(\mathcal{X}, \eta, \lambda)$
return w, μ, Σ

Algorithm 5 Expectation

require: Data set $\mathcal{X}$, point weights γ, component weights w, means μ, covariances Σ.
$z \leftarrow 0_n$
for $i \in [n]$, $j \in [k]$
  $\eta_{ij} \leftarrow w_j \mathcal{N}(x_i \mid \mu_j, \Sigma_j)$
  $z_i \leftarrow z_i + \eta_{ij}$
for $i \in [n]$, $j \in [k]$
  $\eta_{ij} \leftarrow \gamma_i \eta_{ij} \,/\, z_i$
return η

Algorithm 6 Maximization

require: $\mathcal{X}$, responsibilities η, threshold λ.
$z \leftarrow 0_k, \mu \leftarrow 0_{k \times d}, \Sigma \leftarrow 0_{k \times d \times d}$
for $j \in [k], i \in [n]$
  $z_j \leftarrow z_j + \eta_{ij}$
  $\mu_j \leftarrow \mu_j + \eta_{ij} x_j$
  $\Sigma_j \leftarrow \Sigma_j + \eta_{ij}(x_i - \mu_j)(x_i - \mu_j)^T$
for $j \in [k]$
  $w_j \leftarrow z_j / ||z||_1$
  $\mu_j \leftarrow \mu_j \,/\, z_j$
  $\Sigma_j \leftarrow \Sigma_j \,/\, z_j + I_\lambda$
return (w, μ, Σ)

5. Streaming and Parallel Computation

One advantage of coresets is that they can be constructed in parallel, as well as in a streaming setting where data points arrive one by one, and it is impossible to remember the entire data set due to memory constraints. The key insight is that coresets satisfy certain composition properties, which have previously been used by Har-Peled and Mazumdar (2004) for streaming and parallel construction of coresets for geometric clustering problems such as k-median and k-means.

1. Let $\mathcal{C}_1$ be a (k, ε)-coreset for $\mathcal{X}_1$, and $\mathcal{C}_2$ be a (k, ε)-coreset for $\mathcal{X}_2$. Then $\mathcal{C}_1 \cup \mathcal{C}_2$ is a (k, ε)-coreset for $\mathcal{X}_1 \cup \mathcal{X}_2$.
2. Let $\mathcal{C}$ be a (k, ε)-coreset for $\mathcal{X}$, and $\mathcal{C}'$ be a (k, δ)-coreset for $\mathcal{C}$. Then $\mathcal{C}'$ is a $(k, (1+\varepsilon)(1+\delta) - 1)$-coreset for $\mathcal{X}$.

5.1 Streaming Computation

In the streaming setting, we assume that points arrive one-by-one, but we do not have enough memory to remember the entire data set. Thus, we wish to maintain a coreset over time, while keeping only a small subset of $\mathcal{O}(\log n)$ coresets in memory, where n is the number of points seen. The idea is to construct and store in memory a coreset for every block of $\text{poly}(d, k, \lambda^{-1}, \varepsilon^{-1})$ consecutive points arriving in a stream (Bentley and Saxe, 1980; Har-Peled and Mazumdar, 2004). When we have two ε-coresets in memory we first merge them

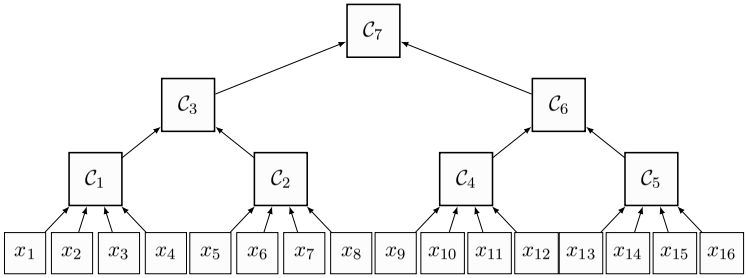


Figure 3: Coreset construction in the streaming setting. Black arrows indicate "merge-and-compress" operations. The (intermediate) coresets $\mathcal{C}_1, \ldots, \mathcal{C}_7$ are enumerated in the order in which they would be generated in the streaming case. In the parallel case, $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_4$ and $\mathcal{C}_5$ would be constructed in parallel, followed by parallel construction of $\mathcal{C}_3$ and $\mathcal{C}_6$, finally resulting in $\mathcal{C}_7$.

which results in a (k, ε)-coreset via property (1). To maintain a small size, we compress them by computing a single coreset from the merged coresets via property (1) which increases the error. A naive approach that merges and compresses immediately as soon as two coresets have been constructed can incur an exponential increase in approximation error. Fortunately, it is possible to organize the merge-and-compress operations in a binary tree of height $\mathcal{O}(\log n)$, where we need to store in memory a single coreset for each level of the tree (Feldman et al., 2013b, Theorem 10.1.).

Consider Figure 3 which illustrates the tree computation for an example data set. In the following, ε-coreset denotes a (ε, k)-coreset (k is fixed). In the first step, we construct a ε-coreset for $x_1, \ldots, x_4$. We then construct a ε-coreset for $x_5, \ldots, x_8$. At this point we have two ε-coresets and their union is, by property (1), a ε-coreset for $x_1, \ldots, x_8$. By property (2) a coreset $\mathcal{C}_3$ of the union of those two coresets is a 4ε-coreset for $x_1, \ldots, x_8$ since $(1+\varepsilon)^2 \leq 1 + 4\varepsilon$, for $0 \leq \varepsilon \leq 1$. Hence, we discard coresets $\mathcal{C}_1$ and $\mathcal{C}_2$ and keep only $\mathcal{C}_3$ in memory. We apply the same approach for $x_9, \ldots, x_{16}$ and obtain $\mathcal{C}_6$, a 4ε-coreset for $x_9, \ldots, x_{16}$. Once again, we obtained two coresets at the same level of the tree ($\mathcal{C}_3$ and $\mathcal{C}_6$) and merging them we obtain a 4ε-coreset for $x_1, \ldots, x_{16}$. By property (2), the coreset of the union of $\mathcal{C}_3$ and $\mathcal{C}_6$ is a 13ε-coreset for the whole data set since $(1+4\varepsilon)(1+\varepsilon) \leq 1+13\varepsilon$. Finally, only coreset C_7 is kept in memory.

In general, to ensure an error of ε, it suffices that the intermediate coreset error is bounded by $\varepsilon' = \frac{\varepsilon}{6 \log_2 n}$ as the height of the tree is at most $\lceil \log_2 n \rceil$ and $(1+\varepsilon')^{\lceil \log n \rceil} = (1 + \frac{\varepsilon}{6 \log n})^{\lceil \log n \rceil} \leq e^{\frac{\varepsilon}{6}} \leq 1 + \frac{\varepsilon}{3}.(1+\varepsilon')^{\lceil \log_2 n \rceil} \leq 1 + \frac{\varepsilon}{3}$. Thus, by property (2), a $(\varepsilon/3)$-coreset of the union of all coresets in memory has the approximation error bounded by $(1+\varepsilon/3)^2 \leq 1+\varepsilon$. As we do not know n *a priori*, we compute coresets for data batches of exponentially increasing size – the total time and space requirements are dominated by the last batch whose size is upper bounded by n (Feldman et al., 2013b).

Theorem 3 *A (k, ε)-coreset for a stream of n points in $\mathbb{R}^d$ can be computed for the λ-semi-spherical GMM using update time per point and memory* $\mathrm{poly}(d, k, \lambda^{-1}, \varepsilon^{-1}, \log n, \log(1/\delta))$ *with probability at least $1 - \delta$.*

In order to construct a coreset for the union of two (weighted) coresets, we use weighted versions of Algorithms 1 and 2, where we consider a weighted point as copies of a non-weighted point (possibly with fractional weight).

5.2 Distributed Computation

Using the same ideas from the streaming model, a (non-parallel) coreset construction can be transformed into a parallel one. We partition the data and compute a coreset for each partition independently. We then in parallel merge via property (1) two coresets, and compute a single coreset for every pair of such coresets exploiting the property (2). Continuing in this manner yields a process that takes $\mathcal{O}(\log n)$ iterations of parallel computation. This computation is naturally suited for map-reduce (Dean and Ghemawat, 2004) style computations, where the map tasks compute coresets for disjoint parts of $\mathcal{X}$, and the reduce tasks perform the merge-and-compress operations. Figure 3 illustrates this parallel construction.

Theorem 4 *A (k, ε)-coreset for a set of n points in $\mathbb{R}^d$ can be computed for the λ-semi-spherical GMM using m machines in time* $(n/m) \cdot \mathrm{poly}(d, k, \lambda^{-1}, \varepsilon^{-1}, \log(1/\delta), \log n)$ *with probability at least $1 - \delta$.*

Furthermore, if we have enough memory on one of the machines we can apply a simpler algorithm. First, partition the data to m machines and compute a $(\varepsilon/3)$-coreset on each, producing coresets $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_m$. Then the union $C = \cup_{i=1}^m \mathcal{C}_i$ is a $(\varepsilon/3)$-coreset for the whole data set and its size is bounded by $m \cdot \max_i |\mathcal{C}_i|$. To obtain a coreset of size independent of the number of machines m, it suffices to construct a $(\varepsilon/3)$-coreset of $\mathcal{C}$.

Finally, Feldman and Tassa (2015) unified the streaming and distributed approaches when the data set size is unknown apriori. They propose splitting the input stream into several smaller streams whereby each machine proceeds to construct the coreset tree for its own stream.

6. Experimental Evaluation

The goal of this section is to demonstrate the effectiveness of using coresets for training Gaussian mixture models. To this end, we compare our coreset based approach to the "naive" approach of uniformly subsampling the data using models trained on the full data set as a baseline.

We construct coresets and uniform subsamples of sizes ranging from 1'000 to 10'000. For uniform subsampling, we subsample the data set and fit the model using Algorithm 4 where we set the weight of each point to one. For the coreset based approach with k mixture components we first construct a bicriteria approximation using Algorithm 2 and construct the coreset using Algorithm 1. Finally, we fit a GMM on the weighed coreset using Algorithm 4. We stop iterating between EM steps if the number of iterations is greater than 100, or the relative log-likelihood changed is smaller than 10^{-3} and apply prior thresholding with $\lambda = 0.001$ (Section 4).

We compare the median results from 200 runs for the subsampling methods and *best* out of 100 runs on the full data set. For each run we store the sampling time, solving time and the log-likelihood C on the test set. Finally, we calculate the *relative error*

$\eta = |(C - C_{full})/C_{full}|$ for both uniform subsampling and coresets. For each data set we use 80% of the data for training and the remaining 20% for computing the error. We perform the evaluation on four real-world data sets and summarize our observations as follows:

1. Higgs. Contains 11'000'000 instances describing signal processes which produce Higgs bosons and background processes which do not (Baldi et al., 2014). We consider the first two principal components components and fit GMMs with 150 components. For $m = 10'000$ the coreset based approach leads to a speedup of 57.5× with a relative error of 4%. At the same time, uniform subsampling leads to a relative error of 12.2%.

2. csn. Contains 80'000 instances with 17 features extracted from acceleration data recorded from volunteers carrying and operating their phone in normal conditions (Faulkner et al., 2011). We fit GMM with 100 components. For $m = 10'000$ the coreset based approach leads to a speedup of 7× with a relative error of 6.6%. At the same time, uniform subsampling leads to a relative error of 58.7%.

3. Kdd. Contains 145'000 instances with 74 features measuring the match between a protein and a native sequence. We fit GMMs with 10 components. For $m = 10'000$ the coreset based approach leads to a speedup of 8.3× with a relative error of 2.7%. At the same time, uniform subsampling leads to a relative error of 16.8%. We observe that models trained on the uniform subsample may be more sensitive to initialization.

4. msyp. Contains 515'345 instances with 90 features which represent timbre average and timbre covariance for mostly western, commercial tracks ranging from 1922–2011. We consider the top 25 principal components and fit GMMs with 50 components. For $m = 5'000$ the coreset based approach leads to a speedup of 78× with a relative error of 2.3%. At the same time, uniform subsampling leads to a relative error of 3.9%.

We observe that, for a fixed subsample size, coresets enjoy smaller approximation errors and obtain significant speedups with respect to solving the problem on the full data set.

7. Related Work

This paper is an extended version of Feldman et al. (2011) and provides significant improvements over the prior work. The theoretical analysis is executed directly on the negative log-likelihood function. This in turn leads to a novel importance sampling sampling strategy as well as a more practical algorithm with linear running time in n. Furthermore, we prove that one can use *any* bicriteria approximation for the k-means clustering problem as a basis for the importance sampling scheme. Overall, we are able to construct larger coresets in less time (approximately two orders of magnitude) and significantly improve the experimental results. To ensure the uniform convergence over $\mathfrak{C}$, we present new proof for the complexity (pseudo-dimension) of a mixture of Gaussians by forging a link to VC analysis of neural networks. The empirical evaluation considers data sets two orders of magnitude larger than those in prior work.

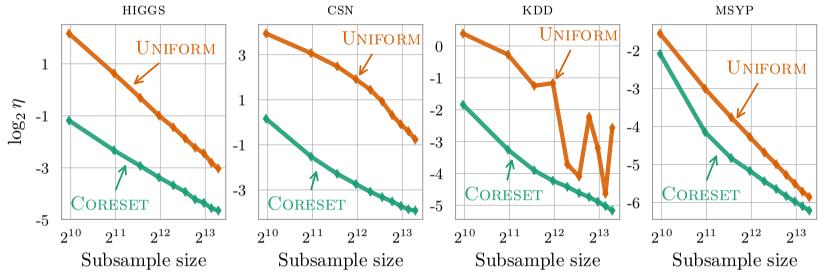

Figure 4: Median relative error η with respect to the best models trained on the full data set (100 runs) with respect to the coreset/subsample (200 runs) For a fixed subsample size, models trained on coresets outperform models trained on the uniform subsample. Furthermore, we observe that the uniform subsampling may be much more sensitive to initialization (KDD).

7.1 Learning Mixtures of Gaussians

The fundamental problem of learning Gaussian mixture models has received a great deal of interest. Dasgupta (1999) was the first to show that, given common covariance, bounded eccentricity, a bound on the smallest component weight, as well as a separation which scales with $\Omega(\sqrt{d})$, parameters of an unknown GMM θ can be estimated in polynomial time, with arbitrary accuracy ε, given i.i.d. samples from θ. Subsequent works relax the assumption on separation to $d^{1/4}$ (Dasgupta and Schulman, 2000) and $k^{1/4}$ (Vempala and Wang, 2004). Feldman et al. (2006b) provide the first result that does not require any separation, but assumes that the Gaussians are axis-aligned. Moitra and Valiant (2010) and Belkin and Sinha (2010) prove that arbitrary GMMs with fixed number of components can be learned in polynomial time and sample complexity (but exponential dependence on k). Anandkumar et al. (2012, 2014) demonstrate that a spectral decomposition technique yields consistent parameter estimates from low-order observable moments, without additional separation assumptions. The aforementioned results hinge on non-degeneracy, that is, that the component means indeed span a k-dimensional subspace and the vector w has strictly positive entries. The problem of fitting a mixture model with near-optimal log-likelihood for arbitrary data is studied by Arora and Kannan (2005). They provide a polynomial-time approximation scheme, provided that the Gaussians are identical spheres. In contrast, as detailed in Section 2, our results make only mild assumptions about the Gaussian components and allow one to explicitly trade-off the coreset size and the assumption strength. Critically, none of the algorithms described above applies to the streaming or parallel setting.

7.2 Approximation Algorithms via Coresets

Existence and construction of coresets have been investigated for a number of problems in computational geometry (Agarwal et al., 2005; Czumaj and Sohler, 2007) and have been used to great effect for a host of geometric and graph problems, including k-median (Har-

Peled and Mazumdar, 2004), k-means (Feldman et al., 2007), k-center (Har-Peled and Varadarajan, 2004), k-line median (Feldman et al., 2006a), subspace approximation (Feldman et al., 2006a; Mahoney and Drineas, 2009), (k, m)-segment mean (Feldman et al., 2012), PCA and projective clustering (Feldman et al., 2013b), distributed k-means and k-median (Balcan et al., 2013), dictionary learning (Feldman et al., 2013a), k-segmentation of streaming data (Rosman et al., 2014), non-parametric estimation (Bachem et al., 2015), and clustering with Bregman divergences (Lucic et al., 2016b). A framework that generalizes and improves several of these results has appeared in Feldman and Langberg (2011). Notably, coresets also imply streaming algorithms for many of these problems (Har-Peled and Mazumdar, 2004; Agarwal et al., 2005; Frahling and Sohler, 2005; Feldman et al., 2007). Recently, coresets were leveraged to establish a space-time-data-risk tradeoff in the context of unsupervised learning (Lucic et al., 2015). Promising results in the context of empirical risk minimization have been demonstrated by Reddi et al. (2015). This paper uses the sensitivity framework of Feldman and Langberg (2011) and the quadratic dependency on the total sensitivity can be reduced to near-linear via Braverman et al. (2016). For a survey of the recent results we refer the reader to Bachem et al. (2017b); Phillips (2016).

8. Conclusion

We have shown how to efficiently construct coresets for estimating parameters of Gaussian mixture models by exploiting a connection between statistical estimation and clustering problems in computational geometry. We prove existence of coresets of size *independent* of the original data set size. To our knowledge, our results provide the first rigorous guarantees for obtaining compressed ε-approximations of the log-likelihood of mixture models for large data sets. The coreset construction algorithm is based on a simple importance sampling scheme and and has linear running time in n. We demonstrate that, by exploiting certain closure properties of coresets, it is possible to construct them in parallel, or in a single pass through a stream of data, using only $\text{poly}(d, k, \lambda^{-1}, \varepsilon^{-1}, \log n, \log(1/\delta))$ space and update time. Critically, our coresets provide guarantees for any given (possibly unstructured) data, without assumptions on the distribution or model that generated it. In an empirical evaluation on several real-world data sets we observe a reduction in computational time of *up to two orders of magnitude*, while achieving a hold-out set likelihood competitive with the models trained on the full data set.

There are two interesting open problems: Is it possible to compute a coreset (i) for any set of k mixture of Gaussians, i.e., whose size is independent of λ, and (ii) of size independent of d, as in Barger and Feldman (2016).

Acknowledgments

Appendix A. Bounding the Coreset Size

Let $f : \mathcal{X} \times \mathfrak{C} \to \mathbb{R}_+$ be defined as

$$f_\theta(x) = -\ln\left(\sum_{i=1}^{k} \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}} \exp\left(-\frac{1}{2}\left\|{\Sigma_i}^{-1/2}(x-\mu_i)\right\|_2^2\right)\right),$$

where $Z(\theta) = \sum_i w_i/\sqrt{|2\pi\Sigma_i|}$. For a point $x \in \mathcal{X}$ and a *query* θ – a parametrization of the mixture model – $f_\theta(x)$ measures the contribution of the point x to the log-likelihood. Intuitively, to select the points for the coreset, we would like to perform importance sampling on points $x \in \mathcal{X}$, such that we sample points proportionally to the impact on the log-likelihood. Langberg and Schulman (2010) show that it suffices to perform importance sampling with respect to *sensitivity* – the worst-case contribution of a point.

Definition 5 (Sensitivity) *Sensitivity of $x \in \mathcal{X}$ w.r.t. $\mathcal{F} = \{f_\theta(\cdot) \mid \theta \in \mathfrak{C}\}$ is defined as*

$$\sigma_{\mathfrak{C}}(x) = \sup_{\theta \in \mathfrak{C}} \frac{f_\theta(x)}{\frac{1}{|\mathcal{X}|}\sum_{x' \in \mathcal{X}} f_\theta(x')}.$$

Total sensitivity is defined as $\mathfrak{S} = \frac{1}{|\mathcal{X}|}\sum_{x \in \mathcal{X}} \sigma_{\mathfrak{C}}(x)$.

For the Gaussian mixture model, the *query space* $\mathfrak{C}$ is the space of all possible GMMs with k components in d dimensions. While the exact sensitivity is hard to compute, Langberg and Schulman (2010) show that any uniform upper bound $s_{\mathfrak{C}}(x)$ to $\sigma_{\mathfrak{C}}(x)$ can be used. Looser bounds will lead to larger coresets, so one should aim to provide the tightest bound possible.

A.1 Total Sensitivity by Reduction to the Euclidean Space

The following lemma bounds the difference in log-likelihood contribution of two points for any fixed λ-semi-spherical GMM.

Lemma 6 *Let $\mathfrak{C}_\lambda$ be the family of λ-semi-spherical Gaussian mixtures of k components. For a fixed $\theta \in \mathfrak{C}_\lambda$ define $f_\theta : \mathcal{X} \to [0, +\infty)$ as*

$$f_\theta(x) = -\ln\sum_{i=1}^{k} \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}} \exp\left(-\frac{1}{2}(x-\mu_i)^T\Sigma_i^{-1}(x-\mu_i)\right),$$

where $Z(\theta) = \sum_{i=1}^{k} \frac{w_i}{\sqrt{|2\pi\Sigma_i|}}$. Then, for every $x, y \in \mathbb{R}^d$ it holds that

$$f_\theta(x) \leq \frac{1}{\lambda}\|x-y\|_2^2 + 2f_\theta(y).$$

Proof Let $a, x \in \mathbb{R}^d$. By the weak triangle inequality for a fixed $i \in [k]$,

$$\left\|\Sigma_i^{-1/2}(x-\mu_i)\right\|_2^2 \leq 2\left\|\Sigma_i^{-1/2}(x-a)\right\|_2^2 + 2\left\|\Sigma_i^{-1/2}(a-\mu_i)\right\|_2^2. \quad (1)$$

Let UDU^T denote the SVD of Σ_i and note that U is an orthogonal matrix. As such,

$$\left\|\Sigma_i^{-1/2}(x-a)\right\|_2 = \left\|UD^{-1/2}U^T(x-a)\right\|_2 = \left\|D^{-1/2}U^T(x-a)\right\|_2$$
$$\leq \frac{\left\|U^T(x-a)\right\|_2}{\sqrt{\lambda}} \leq \frac{\|x-a\|_2}{\sqrt{\lambda}},$$

which combined with (1) yields

$$\left\|\Sigma_i^{-1/2}(x-\mu_i)\right\|_2^2 \leq \frac{2}{\lambda}\|x-a\|_2^2 + 2\left\|\Sigma_i^{-1/2}(a-\mu_i)\right\|_2^2.$$

As such,

$$f_\theta(x) \leq -\ln\left(\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}}\exp\left(-\frac{1}{\lambda}\|x-a\|_2^2 - \left\|\Sigma_i^{-1/2}(a-\mu_i)\right\|_2^2\right)\right)$$
$$= \frac{1}{\lambda}\|x-a\|_2^2 - \ln\left(\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}}\exp\left(-\frac{1}{2}\left\|\Sigma_i^{-1/2}(a-\mu_i)\right\|_2^2\right)^2\right)$$
$$\leq \frac{1}{\lambda}\|x-a\|_2^2 - \ln\left(\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}}\exp\left(-\frac{1}{2}\left\|\Sigma_i^{-1/2}(a-\mu_i)\right\|_2^2\right)\right)^2$$
$$= \frac{1}{\lambda}\|x-a\|_2^2 + 2f_\theta(a),$$

by Jensen's inequality and the fact that

$$\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}} = \frac{1}{Z(\theta)}\sum_{i=1}^k \frac{w_i}{\sqrt{|2\pi\Sigma_i|}} = 1.$$

■

The critical insight necessary to compute an upper-bound on the sensitivity of each point is to note that the denominator in (5) can be lower-bounded by a rough approximation to the optimal k-means clustering of $\mathcal{X}$.

Lemma 7 *Let $\mathfrak{C}_\lambda$ be the family of λ-semi-spherical Gaussian mixtures with k components. Let $\mathcal{X} \subset \mathbb{R}^d$, and $C^\star = \min_{C\subset\mathbb{R}^{d\times k}} \phi(\mathcal{X}, C)$. Let $\mathcal{B} \subset \mathbb{R}^{d\times\beta}$ such that $\phi(\mathcal{X},\mathcal{B}) \leq \alpha\phi(\mathcal{X}, C^\star)$. The sensitivity of $x \in \mathcal{X}$ with respect to $\mathfrak{C}_\lambda$,*

$$\sigma(x) = \sup_{\theta\in\mathfrak{C}_\lambda} \frac{f_\theta(x)}{\frac{1}{|\mathcal{X}|}\sum_{x'\in\mathcal{X}} f_\theta(x')},$$

is bounded by

$$\sigma(x) \leq s(x) = |\mathcal{X}|\frac{2}{\lambda^2}\left(\frac{\alpha \mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2} + \frac{2\alpha}{|\mathcal{X}_j|}\frac{\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2} + \frac{2}{|\mathcal{X}_j|}\right).$$

Furthermore, it holds that

$$\mathfrak{S} \leq \frac{1}{|\mathcal{X}|}\sum_{x\in\mathcal{X}} s(x) = \frac{1}{\lambda^2}(6\alpha + 4\beta).$$

Proof Set $\mathcal{B}$ partitions $\mathcal{X}$ into β Voronoi cells, $\mathcal{X}_1, \ldots, \mathcal{X}_\beta$. Consider some $x \in \mathcal{X}_j$ and $\theta \in \mathfrak{C}_\lambda$. By Lemma 6 it holds that

$$\frac{f_\theta(x)}{\sum_{x'\in\mathcal{X}} f_\theta(x')} \leq \underbrace{\frac{1}{\lambda}\frac{\mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}} f_\theta(x')}}_{\mathtt{u}} + \underbrace{\frac{2f_\theta(y)}{\sum_{x'\in\mathcal{X}} f_\theta(x')}}_{\mathtt{v}}. \tag{2}$$

We now upper-bound the right hand side. To bound $\mathtt{u}$, let $\Sigma_i = UDU^T$ be the singular value decomposition of Σ_i and μ_i the corresponding mean. Since U is a rotation matrix

$$\left\|\Sigma_i^{-1/2}(x-\mu_i)\right\|_2 = \left\|UD^{-1/2}U^T(x-\mu_i)\right\|_2 = \left\|D^{-1/2}U^T(x-\mu_i)\right\|_2$$
$$\geq \sqrt{\lambda}\left\|U^T(x-\mu_i)\right\|_2 = \sqrt{\lambda}\|x-\mu_i\|_2 \geq \sqrt{\lambda}\mathrm{d}(x,\mu)$$

where $\mu = \{\mu_1, \ldots, \mu_k\}$. Noting that $Z(\theta)$ is a normalization constant it follows that

$$f_\theta(x) \geq -\ln\left(\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}}\exp\left(-\frac{\lambda}{2}\mathrm{d}(x,\mu)^2\right)\right) = \frac{\lambda}{2}\mathrm{d}(x,\mu)^2$$

Summing over $x' \in \mathcal{X}$ yields

$$\sum_{x'\in\mathcal{X}} f_\theta(x') \geq \frac{\lambda}{2}\sum_{x'\in\mathcal{X}}\mathrm{d}(x,\mu)^2 \geq \frac{\lambda}{2}\min_{C\subset\mathbb{R}^{d\times k}}\sum_{x'\in\mathcal{X}}\mathrm{d}(x',C)^2 \geq \frac{\lambda}{2\alpha}\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2,$$

where the last inequality follows by the definition of $\mathcal{B}$. Thus,

$$\mathtt{u} = \frac{1}{\lambda}\frac{\mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}} f_\theta(x')} \leq \frac{2\alpha}{\lambda^2}\frac{\mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2}. \tag{3}$$

To upper-bound $\mathtt{v}$ consider again the Voronoi partitioning of $\mathcal{X}$ induced by $\mathcal{B}$. Let $x \in \mathcal{X}$ with the corresponding cell $\mathcal{X}_j \subseteq \mathcal{X}$, and $y = \mathcal{B}_j$ such that $\mathrm{d}(x,\mathcal{B}) = \|x-y\|_2$ (y induced the cell $\mathcal{X}_j$). By swapping x and y in Lemma 6 we have

$$f_\theta(y) \leq \frac{1}{\lambda}\mathrm{d}(x,\mathcal{B})^2 + 2f_\theta(x)$$

and summing over $x' \in \mathcal{X}_j$ yields

$$|\mathcal{X}_j| f_\theta(y) \leq \frac{1}{\lambda}\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2 + 2\sum_{x'\in\mathcal{X}_j} f_\theta(x')$$
$$\leq \frac{1}{\lambda}\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2 + 2\sum_{x'\in\mathcal{X}} f_\theta(x').$$

where the last inequality follows from $f_\theta(x) \geq 0$. Hence,

$$\frac{f_\theta(y)}{\sum_{x'\in\mathcal{X}} f_\theta(x')} \leq \frac{1}{\lambda}\frac{\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2}{|\mathcal{X}_j|\sum_{x'\in\mathcal{X}} f_\theta(x')} + \frac{2}{|\mathcal{X}_j|}$$
$$\leq \frac{2\alpha}{\lambda^2}\frac{\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2}{|\mathcal{X}_j|\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2} + \frac{2}{|\mathcal{X}_j|}. \tag{4}$$

Since the choice of θ was arbitrary, by applying the obtained bounds (3) and (4) to (2) it follows that

$$\begin{aligned}\sigma(x) &\leq |\mathcal{X}|\frac{2}{\lambda^2}\left(\frac{\alpha \mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2}+\frac{2\alpha}{|\mathcal{X}_j|}\frac{\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2}+\frac{2\lambda^2}{|\mathcal{X}_j|}\right)\\ &\leq |\mathcal{X}|\frac{2}{\lambda^2}\left(\frac{\alpha \mathrm{d}(x,\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2}+\frac{2\alpha}{|\mathcal{X}_j|}\frac{\sum_{x'\in\mathcal{X}_j}\mathrm{d}(x',\mathcal{B})^2}{\sum_{x'\in\mathcal{X}}\mathrm{d}(x',\mathcal{B})^2}+\frac{2}{|\mathcal{X}_j|}\right)\\ &:= s(x)\end{aligned}$$

since $\lambda \in (0,1)$. Hence, the total sensitivity may be bounded by

$$\mathfrak{S} \leq \frac{1}{|\mathcal{X}|}\sum_{x\in\mathcal{X}} s(x) = \frac{1}{\lambda^2}(6\alpha+4\beta).$$

■

An attractive property of this result is that the total sensitivity is independent of $|\mathcal{X}|$. Furthermore, to compute the bound we only need a bicriteria approximation to the k-means objective which can be computed in linear time with the popular k-Means++ algorithm (Arthur and Vassilvitskii, 2007) for which $\alpha = \mathcal{O}(\log_2 k)$ and $\beta = k$ resulting in total sensitivity of $\mathcal{O}\big(k/\lambda^2\big)$. As shown in Lucic et al. (2016a), this bound on the total sensitivity is tight (up to a constant) as there exists a data set $\mathcal{X}$ for which $\mathfrak{S} \in \Theta(k)$.

A.2 Pseudo-dimension of Gaussian Mixtures

The other key factor in bounding the coreset size is the combinatorial complexity of the function family $\mathcal{F}$ induced by the maximum likelihood estimation of the Gaussian mixture. More complex models require more samples for uniform convergence. We first introduce the required definitions to ensure that the exposition is self-contained.

Definition 8 (VC dimension) *Let $\mathcal{X}$ be a ground set and $\mathcal{F}$ be a set of functions from $\mathcal{X}$ to $\{0,1\}$. Fix a set $S = \{x_1,\ldots,x_n\} \subset \mathcal{X}$ and a function $f \in \mathcal{F}$. We call $S_f = \{x_i \in S \mid f(x_i) = 1\}$ the induced subset of S by f. A subset $S = \{x_1,\ldots,x_n\}$ of $\mathcal{X}$ is shattered by $\mathcal{F}$ if $|\{S_f \mid f \in \mathcal{F}\}| = 2^n$. VC dimension of $\mathcal{F}$ is the size of the largest subset of $\mathcal{X}$ shattered by $\mathcal{F}$. If $\mathcal{F}$ can shatter sets of arbitrary size VC dimension of $\mathcal{F}$ is ∞.*

These notions naturally extend to functions mapping to $\mathbb{R}$ (or a subset thereof).

Definition 9 (Pseudo-dimension) *Let $\mathcal{X}$ be a ground set and $\mathcal{F}$ be a set of functions from $\mathcal{X}$ to the interval $[0,1]$. Fix a set $S = \{x_1,\ldots,x_n\} \subset \mathcal{X}$, a set of reals $R = \{r_1,\ldots,r_n\}, r_i \in [0,1]$ and a function $f \in \mathcal{F}$. We call $S_f = \{x_i \in S \mid f(x_i) \geq r_i\}$ the induced subset of S formed by f and R. Subset S with associated values R is shattered by $\mathcal{F}$ if $|\{S_f \mid f \in \mathcal{F}\}| = 2^n$. Pseudo-dimension of $\mathcal{F}$ is the cardinality of the largest shattered subset of $\mathcal{X}$. If $\mathcal{F}$ can shatter sets of arbitrary size pseudo-dimension of $\mathcal{F}$ is ∞.*

Clearly, for every space of a given pseudo-dimension we can construct a space with the same VC dimension as formalized by the following lemma.

Lemma 10 *For any $f \in \mathcal{F}$ let B_f be the indicator function of the region below or on the graph of f, i.e. $B_f(x,y) = \mathrm{sgn}(f(x)-y)$. The pseudo-dimension of $\mathcal{F}$ is precisely the VC-dimension of the subgraph class $B_{\mathcal{F}} = \{B_f \mid f \in \mathcal{F}\}$.*

For the Gaussian mixture model, each f_θ consists exclusively of applications of the exponential function and arithmetic operations on real numbers. The problem of bounding the combinatorial complexity of such function classes has received a great deal of interest which culminated in the following result (Anthony and Bartlett, 2009, Theorem 8.14):

Theorem 11 *Let h be a function from $\mathbb{R}^m \times \mathbb{R}^d$ to $\{0,1\}$, determining the class*

$$\mathcal{H} = \{x \mapsto h(\,x) : \theta \in \mathbb{R}^m\}.$$

Suppose that h can be computed by an algorithm that takes as input the pair $(\theta, x) \in \mathbb{R}^m \times \mathbb{R}^d$ and returns $h(\theta, x)$ after no more than t of the following operations:

(i) the exponential function $\alpha \mapsto e^\alpha$ on real numbers,

(ii) the arithmetic operations $+, -, \times,$ and $/$ on real numbers,

(iii) jumps conditioned on $>, \geq, <, \leq, =,$ and $\neq$ comparisons of real numbers, and

(iv) output $0, 1$.

If the t operations include no more than p in which the exponential function is evaluated, then the VC-dimension of $\mathcal{H}$ is $\mathcal{O}\big(m^2p^2 + mp(t + \log mp)\big)$.

Theorem 12 *Let $\mathfrak{C}_\lambda$ be the family of λ-semi-spherical Gaussian mixtures with k components. Let $\mathcal{X} \subset \mathbb{R}^d$ and $m = k(d+1)(d+2)/2 - 1$. Define $f_\theta : \mathcal{X} \to [0,\infty)$ as*

$$f_\theta(x) = -\ln\left(\sum_{i=1}^k \frac{w_i}{Z(\theta)\sqrt{|2\pi\Sigma_i|}}\exp\left(-\frac{1}{2}\left\|{\Sigma_i}^{-1/2}(x-\mu_i)\right\|_2^2\right)\right),$$

where $Z(\theta) = \sum_i \frac{w_i}{\sqrt{|2\pi\Sigma_i|}}$. Let $\mathcal{F} = \{f_\theta(x) \mid \theta \in \mathfrak{C}_\lambda \subset \mathbb{R}^m\}$. Then, $\dim \mathcal{F} \in \mathcal{O}\big(d^4k^4\big)$.

Proof Let $\theta \in \mathfrak{C}_\lambda$ and $r \in \mathbb{R}$. Define $h : \mathbb{R}^{m+1} \times \mathbb{R}^d \to \{0,1\}$ such that $h_{\theta,r}(x) = 1$ iff $f_\theta(x) \geq r$. Let the corresponding function class be defined as

$$\mathcal{H} = \{h_{\theta,r}(\cdot) \mid h_{\theta,r} : \mathcal{X} \to \{0,1\} \mid \theta \in \mathfrak{C}_\lambda \subset \mathbb{R}^m, r \in \mathbb{R}\}.$$

For a fixed query θ, all $\Sigma_i^{-1}, \forall i \in [k]$ are well defined as $\theta \in \mathfrak{C}_\lambda$. Furthermore, $\tilde{w}_i = w_i/(Z(\theta)\sqrt{|2\pi\Sigma_i|}) \in \mathbb{R}, \forall i \in [k]$ and $\sum_{i=1}^k \tilde{w}_i = 1$. As shown in Figure 5 the function $h_{\theta,r}(x)$ can be evaluated using $t = \mathcal{O}(m)$ arithmetic operations out of which exactly $k+1$ are evaluations of the exponential function. Furthermore, it can be evaluated without using the natural logarithm by computing e^{-r}. By Lemma 10 and Theorem 11 we have

$$\dim \mathcal{F} = \dim_{\mathrm{VC}} \mathcal{H} \in \mathcal{O}\big(m^2k^2 + mk(t + \log mk)\big) \in \mathcal{O}\big(k^4d^4\big).$$

■

The lower-bound of $\Omega(kd^2)$ was established by Akama and Irie (2011). It is an open problem whether this gap can be closed further in the general setting.

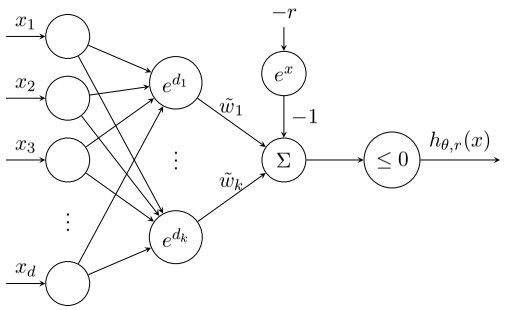

Figure 5: Feed-forward network which calculates $h_{\theta,r}(x)$ whereby the immediate nodes compute the exponents of quadratic forms, and the resulting sum is compared to zero.

A.3 Sufficient Coreset Size

Given the pseudo-dimension $\dim \mathcal{F}$ and some upper bound on the total sensitivity $\mathfrak{S}$ we may bound the coreset size by using the following theorem from Bachem et al. (2017b).

Theorem 13 (Coreset size) *Let $\varepsilon > 0$ and $\delta \in (0,1)$. Let $\mathcal{X}$ be a weighted data set, $\mathcal{Q}$ the set of all possible queries and $f_Q(x) : \mathcal{X} \times \mathcal{Q} \to \mathbb{R}_{\geq 0}$ a cost function. Let $s(x) : \mathcal{X} \to \mathbb{R}_{\geq 0}$ denote any upper bound on the sensitivity $\sigma(x)$ and define $S = \sum_{i=1}^{n} \mu_{\mathcal{X}}(x) s(x)$. Let $\mathfrak{C}$ be a sample of m points from $\mathcal{X}$ with replacement where each point $x \in \mathcal{X}$ is sampled with probability $q(x) = \frac{\mu_{\mathcal{X}}(x)s(x)}{S}$ and each point $x \in \mathfrak{C}$ is assigned the weight $\mu_{\mathfrak{C}}(x) = \frac{\mu_{\mathcal{X}}(x)}{mq(x)}$. Let $\mathcal{F} = \left\{ \frac{\mu_{\mathcal{X}}(\cdot) f_Q(\cdot)}{\mathrm{cost}(\mathcal{X},Q) S q(\cdot)} \mid Q \in \mathcal{Q} \right\}$ and $d' = \dim \mathcal{F}$. Then, the set $\mathfrak{C}$ is an ε-coreset of $\mathcal{X}$ with probability at least $1 - \delta$ for*

$$m \geq \frac{cS^2}{\varepsilon^2} \left(d' + \log \frac{1}{\delta} \right),$$

where $c > 0$ is an absolute constant.

A bound on the coreset size can also be obtained by applying the main theorem of Feldman and Langberg (2011), where one needs to bound the primal shattering dimension instead of the pseudo-dimension. For a detailed discussion of the effects introduced by this difference we refer the reader to Bachem et al. (2017a).

Now we are ready to present the proof of the Theorem 2 which states that, under natural assumptions, we can uniformly approximate the log-likelihood of the model trained on the coreset and the likelihood of the model trained on the full data set as $\varepsilon \to 0$.

Theorem 2 *Let $\mathcal{X} \subset \mathbb{R}^d$, $\delta \in (0,1)$, $\varepsilon \in (0, 1/2)$, $k \in \mathbb{N}$, and $\lambda \in (0,1)$. Let $\mathcal{B}_1, \ldots, \mathcal{B}_p$ be the outputs of $p = \lceil \log_2 1/\delta \rceil$ independent runs of Algorithm 2 with input $\mathcal{X}$ and k. Let $\mathcal{C}$ be the output of Algorithm 1 with $\alpha = 16(\log_2 k + 2)$, $\mathcal{B}^\star = \mathrm{argmin}_{i \in \{1,\ldots,p\}} \phi(\mathcal{X}, \mathcal{B}_i)$ and coreset size*

$$m \geq c \cdot \frac{d^4 k^6 + k^2 \log \frac{1}{\delta}}{\lambda^4 \varepsilon^2},$$

where $c > 0$ is an absolute constant. Then, with probability at least $1 - \delta$, the set $\mathcal{C}$ is a (k, ε)-coreset of $\mathcal{X}$.

Proof Since all p runs are independent, it holds that

$$\mathbb{P}\left[\phi(\mathcal{X}, \mathcal{B}^\star) > t\right] = \mathbb{P}\left[\min_{i \in \{1,\ldots,p\}} \phi(\mathcal{X}, \mathcal{B}_i) > t\right] = \Pi_{i=1}^{p} \mathbb{P}\left[\phi(\mathcal{X}, \mathcal{B}_i) > t\right] \leq \left(\frac{\mathbb{E}[\phi(\mathcal{X}, \mathcal{B}_1)]}{t} \right)^p$$

by Markov's inequality. By Theorem 5 of Arthur and Vassilvitskii (2007), it holds that

$$\mathbb{E}[\phi(\mathcal{X}, \mathcal{B}_1)] \leq 8(\log_2 k + 2)\phi(\mathcal{X}, OPT).$$

Hence, for $p = \lceil \log_2 1/\delta \rceil$, with probability at least $1 - \delta$,

$$\phi(\mathcal{X}, \mathcal{B}^\star) \leq 16(\log_2 k + 2)\phi(\mathcal{X}, OPT).$$

By Lemma 7 we have that

$$s(x) = |\mathcal{X}| \frac{2}{\lambda^2} \left(\frac{\alpha \mathrm{d}(x, \mathcal{B})^2}{\sum_{x' \in \mathcal{X}} \mathrm{d}(x', \mathcal{B})^2} + \frac{2\alpha}{|\mathcal{X}_j|} \frac{\sum_{x' \in \mathcal{X}_j} \mathrm{d}(x', \mathcal{B})^2}{\sum_{x' \in \mathcal{X}} \mathrm{d}(x', \mathcal{B})^2} + \frac{2}{|\mathcal{X}_j|} \right) \geq \sigma(x)$$

for each $x \in \mathcal{X}$ and

$$\mathfrak{S} \leq \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} s(x) = \frac{4\alpha + 2\beta}{\lambda^2} \in \mathcal{O}\left(\frac{k}{\lambda^2} \right) \tag{5}$$

since $\alpha = \mathcal{O}(\log_2 k)$ and $\beta = k$. We conclude the proof by instantiating Theorem 13 with $\mu_{\mathcal{X}}(x) = 1/|\mathcal{X}|$, Theorem 12 and the total sensitivity bound (5). ■

A.4 Directly Approximating the Log-Likelihood

Under additional assumptions on the eigenvalues we can derive a stronger result directly relating the approximated log-likelihood with the true likelihood.

Theorem 14 *Let the conditions of Theorem 2 hold. If $\prod_{\lambda_j \in \mathrm{spec}(\Sigma_i)} \lambda_j \geq \frac{1}{(2\pi)^d}$ we have*

$$|\mathcal{L}(\mathcal{X} \mid \theta) - \mathcal{L}(\mathcal{C} \mid \theta)| \leq \varepsilon \mathcal{L}(\mathcal{X} \mid \theta).$$

Proof By Theorem 2, for $\alpha = 16(\log_2 k + 2)$, $\beta = k$, $m \in \Theta\big(d^4 k^6 \lambda^{-4} \varepsilon^{-2}\big)$, with probability at least $1 - \delta$, it holds that

$$(1 - \varepsilon)\,\mathrm{cost}(\mathcal{X}, \theta) \leq \mathrm{cost}(\mathcal{C}, \theta) \leq (1 + \varepsilon)\,\mathrm{cost}(\mathcal{X}, \theta).$$

By assumption that all eigenvalues are sufficiently large, namely $\prod_{\lambda_j \in \mathrm{spec}(\Sigma_i)} \lambda_j \geq \frac{1}{(2\pi)^d}$, for all components i, the log-normalizer $\ln Z(\theta)$ is negative since

$$Z(\theta) = \sum_i \frac{w_i}{\sqrt{|2\pi\Sigma_i|}} \leq \max_i \frac{1}{\sqrt{|2\pi\Sigma_i|}} = \max_i \frac{1}{\sqrt{(2\pi)^d \prod_{\lambda_j \in \mathrm{spec}(\Sigma_i)} \lambda_j}} \leq 1.$$

Hence,

$$\begin{aligned}\mathcal{L}(\mathcal{C} \mid \theta) &= -n \ln Z(\theta) + \text{cost}(\mathcal{C}, \theta) \leq -n \ln Z(\theta) + (1+\varepsilon)\,\text{cost}(\mathcal{X}, \theta) \\ &\leq (1+\varepsilon)\big(-n \ln Z(\theta) + \text{cost}(\mathcal{X}, \theta)\big) = (1+\varepsilon)\mathcal{L}(\mathcal{X} \mid \theta),\end{aligned}$$

and similarly,

$$\begin{aligned}\mathcal{L}(\mathcal{C} \mid \theta) &= -n \ln Z(\theta) + \text{cost}(\mathcal{C}, \theta) \geq -n \ln Z(\theta) + (1-\varepsilon)\,\text{cost}(\mathcal{X}, \theta) \\ &\geq (1-\varepsilon)\big(-n \ln Z(\theta) + \text{cost}(\mathcal{X}, \theta)\big) = (1-\varepsilon)\mathcal{L}(\mathcal{X} \mid \theta).\end{aligned}$$

■

Appendix B. Convergence of Weighted EM for Gaussian Mixtures

We present the EM update equations for fitting a weighted set of points using Algorithm 4. Since we are interested in an MLE we begin by stating the necessary conditions for a stationary point of

$$\mathcal{L}(\mathcal{C} \mid \theta) = -n \ln Z(\theta) + \text{cost}(\mathcal{C}, \theta) = -\sum_i \gamma_i \ln P(\mathbf{x}'_i \mid \theta).$$

By assumption, all covariance matrices are non-singular. Taking the derivative of $\mathcal{L}(\mathcal{C} \mid \theta)$ with respect to μ_i and Σ_i and setting it equal to zero yields

$$\mu_i = \frac{1}{N_i}\sum_{j=1}^{n} \eta_{i,j} x_j \quad \text{and} \quad \Sigma_i = \frac{1}{N_i}\sum_{j=1}^{n} \eta_{i,j}(x_j - \mu_i)(x_j - \mu_i)^T$$

where

$$N_i = \sum_{j=1}^{n} \eta_{i,j}\gamma_j \quad \text{and} \quad \eta_{i,j} = \gamma_j \frac{w_i \mathcal{N}(\mathbf{x}'_j; \mu_i, \Sigma_i)}{\sum_\ell w_\ell \mathcal{N}(\mathbf{x}'_j; \mu_\ell, \Sigma_\ell)}.$$

To find the mixing weights we minimize the negative log-likelihood under the constraint

$$\sum_{i=1}^{k} w_i = 1, w_i \geq 0, i = 1, \ldots, k.$$

To this end we introduce a Lagrange multiplier λ and minimize $\mathcal{L}(\mathcal{C} \mid \theta) + \lambda(\sum_{i=1}^{k} w_i - 1)$. Setting the derivative with respect to w_i to zero yields

$$w_i = \frac{N_i}{\sum_{j=1}^{n} \eta_{i,j}}$$

As expected, the only difference to the non-weighted version of the EM algorithm is that the updates are now scaled proportionally to the weight of each point. As shown in Dempster et al. (1977) this algorithm will converge to a stationary point.

Abstract

We propose a scheme for finding a "good" estimator for the gradient of a function on a high-dimensional space with few function evaluations, for applications where function evaluations are expensive and the function under consideration is not sensitive in all coordinates locally, making its gradient almost sparse. Exploiting the latter aspect, our method combines ideas from Spall's Simultaneous Perturbation Stochastic Approximation with compressive sensing. We theoretically justify its computational advantages and illustrate them empirically by numerical experiments. In particular, applications to estimating gradient outer product matrix as well as standard optimization problems are illustrated via simulations.

Keywords: Gradient estimation; Compressive sensing; Sparsity; Gradient descent; Gradient outer product matrix.

1. Introduction

Estimating the gradient of a given function (with or without noise) is often an important part of problems in reinforcement learning, optimization and manifold learning. In reinforcement learning, policy-gradient methods are used to obtain an unbiased estimator for the gradient. The policy parameters are then updated with increments proportional to the estimated gradient (Sutton et. al, 2000). The objective is to learn a locally optimum policy. REINFORCE and PGPE methods (policy gradients with parameter-based exploration) are popular instances of this approach (Zhao et. al, 2012) for details and comparisons, (Grondman et. al, 2012) for a survey on policy gradient methods in the context of actor-critic algorithms). In manifold learning, various finite difference methods have been explored for gradient estimation (Mukherjee, Wu and Zhou, 2010; Wu et. al, 2010). The idea is to use the estimated gradient to find the lower dimensional manifold where the given function actually lives. Optimization, i.e., finding maximum or minimum of a function, is a ubiquitous problem that appears in many fields wherein one seeks zeroes of the gradient. But the gradient itself might be hard to compute. Gradient estimation techniques prove particularly useful in such scenarios.

A further theoretical justification is facilitated by the results of Austin (2016). In Austin (2016), it was shown that given a connected and locally connected metric probability space (X, d, μ) (i.e., X is a compact metric space with metric d and μ is a probability measure on the Borel σ-algebra of (X, d)), under suitable conditions, any function $f : X^n \mapsto \mathbb{R}$ is close (in $L^1(\mu^n)$) to a function on a lower dimensional factor space obtained by averaging out the remaining arguments w.r.t. the corresponding product of μ (see Austin, 2016, Theorem 1.1). As a special case, a similar fact can be proved for real-values 1-Lipschitz functions on $\mathbb{R} \setminus \mathbb{Z}$ with metric $|\cdot|_\infty^n$ (see Austin, 2016, Theorem 1.2). This suggests that sparse gradients can be expected for functions on high dimensional spaces with adequate regularity conditions.

Over the years gradient estimation has also become an interesting problem in its own right. One would expect that the efficiency of a given method for gradient estimation also depends on the properties of function f. We consider one such class of problems in this paper. Suppose we have a continuously differentiable function $f : \mathbb{R}^n \mapsto \mathbb{R}$ where n is large, such that the gradient ∇f lives mostly in a lower dimensional subspace. This means that one can throw out most of the coordinates of ∇f in a suitable local basis without incurring too much error. In this case, computing $\frac{\partial f}{\partial x_i}$ $\forall i$ is clearly a waste of means. If in addition the function evaluations are expensive, most gradient estimation methods become inefficient. Such is the case, e.g., if a single function evaluation is the output of a large time-consuming simulation. This situation is our specific focus. The problem of expensive function evaluations does not seem to have attracted much attention in machine learning literature, though there has been quite a lot of work on this theme in other communities such as engineering and operations research (Joseph and Murthy, 2017; Xu, Caramanis and Mannor, 2016). Most methods, however, focus on learning a good surrogate for the original function (see Jones, Schonlau and Welch, 1998; Pandita, Bilionis and Panchal, 2016; Shan and Wang, 2010).

To handle the first issue, ideas from compressive sensing can be applied. Compressive sensing theory tells us that an s-sparse vector can be reconstructed from $m \sim s \log(n/s)$ measurements. This means that one does not need the information about ∇f in all n directions, a much smaller number of measurements would suffice. These ideas are frequently used in signal as well as image processing (see Chan et. al, 2008; Duarte et. al, 2008). To remedy the latter difficulty, we use an idea from Simultaneous Perturbation Stochastic Approximation (SPSA) due to Spall (Spall, 1992), viz., the Simultaneous Perturbation (SP).

We begin by explaining the proposed method for gradient estimation. Important ideas and results from compressive sensing and SPSA that are relevant to this work are discussed in Section 2.1 and Section 2.2 respectively. We state the main result in Section 2.3. Section 3 presents applications to manifold learning and optimization with simulated examples.

Some notational preliminaries are as follows. By $\|\cdot\|_1$ and $\|\cdot\|$ we denote the l_1 and l_2 norms in $\mathbb{R}^n$ respectively. By abuse of notation, we also denote the Frobenius norm for matrices over $\mathbb{R}$ by $\|\cdot\|$. Throughout, 'a.s.' stands for 'almost surely', i.e., with probability one.

2. Gradient Estimation: Combining Compressive Sensing and SP

As mentioned above, if function evaluations are expensive, SP works well to avoid the problem of computing function multiple times. However, if the gradient is sparse it makes sense to use the ideas of compressive sensing to our advantage. Combining these two techniques helps us overcome the problem of too many function evaluations and also exploit the sparse structure of the gradient. The idea is to use SP to get sufficient number of observations to be able to recover the gradient via l_1-minimization. We describe the method in detail in the following sub-sections.

2.1 Compressive Sensing

Assume that $\nabla f \in \mathbb{R}^n$ is an approximately sparse vector. The idea of compressive sensing is based on the fact that typically a sparse vector contains much less information or complexity than its apparent dimension. Therefore one should be able to reconstruct ∇f with considerable accuracy with much less information than that of order n. We will make these ideas more precise in the forthcoming discussion on compressive sensing. We state all the results for vectors in $\mathbb{R}^n$. All of these results also hold for vectors over $\mathbb{C}$. We start by defining what we mean by sparse vectors.

Definition 1 (Sparsity) *The support of a vector $x \in \mathbb{R}^n$ is defined as:*

$$supp(x) := \{j \in [n] : x_j \neq 0\}.$$

where $[n] = \{1, 2, \ldots, n\}$. The vector $x \in \mathbb{R}^n$ is called s-sparse if at most s of its entries are nonzero, i.e., if

$$\|x\|_0 := card(supp(x)) \leq s.$$

We assume that the observed data $y \in \mathbb{R}^m$ is related to the original vector $x \in \mathbb{R}^n$ via $Ax = y$ for some matrix $A \in \mathbb{R}^{m \times n}$, where $m < n$. In other words, we have a linear measurement process for observing x. The theory of compressive sensing tells us that if x is sparse, then it can be recovered from y by solving a convex optimization problem. In particular, given a suitable matrix A and appropriate m, the following l_1-minimization problem recovers x exactly.

$$\min_{z \in \mathbb{R}^n} \|z\|_1 \text{ subject to } y = Az \tag{1}$$

where $y = Ax$ are the m observations. These ideas were introduced by E. Candés and T. Tao in their seminal paper on near-optimal signal reconstruction (Candés and Tao, 2006). In this paper, the authors proved that the matrices suitable for the recovery need to have what is called the restricted isometry property (RIP). A large class of random matrices satisfy the RIP with quantifiable 'high probability' and are therefore suitable for reconstruction via l_1-minimization. In particular, subgaussian matrices have been shown to have RIP with high probability and are suitable for the aforementioned reconstruction scheme for $m \sim s \log(n/s)$. This gives the explicit relationship between the sparsity level s, the dimension of the original vector n and the dimension of the observed data m. In recent times some work has been done to construct deterministic matrices with this restricted isometry property (Bandeira et. al, 2013). The current known lower bound on m for

deterministic matrices is of the order of s^2 where s is the sparsity. Thus random matrices are a better choice for linear measurement for reconstruction via compressive sensing if one is willing to settle for probabilistic guarantees.

For the scope of this paper, we consider robust recovery options using Gaussian random matrices, i.e., matrices whose entries are realizations of independent standard normal random variables.

Remark 2 *Matrices with more structure such as random partial Fourier matrix or more generally, bounded orthonormal systems $\{\phi_i\}_{i=1}^N$ can also be used as meaurement matrices for compressive sensing techniques. Given a random draw of such a matrix with associated constant $K_0 \geq 1$ (where K_0 is the bound on $\|\phi_i\|_\infty$), a fixed s-sparse vector x can be reconstructed via l_1-minimization with high probability provided $m \geq CK_0^2 s \log n$. For more details on random sampling matrices in compressive sensing (see Foucart and Rauhut, 2013, Chap. 12).*

The crucial point here is that it is enough that the given vector is sparse in some basis. A more detailed discussion on various aspects of compressive sensing can be found in Foucart and Rauhut (2013). In real-life situations the measurements are almost always noisy. A more general statement of problem in (1), that takes into account bounded noise in measurement, bounded in norm by η, is given by:

$$\min_{z \in \mathbb{R}^n} \|z\|_1 \text{ subject to } \|Az - y\| \leq \eta \tag{2}$$

It may also happen that the original vector x is not sparse but is close to a sparse vector. In other words, we would like the reconstruction scheme to be robust and stable. Foucart and Rauhut (2013, Theorem 9.13) gives explicit error bounds for stable and robust recovery where A is a subgaussian matrix. The bound is expressed in terms of $\sigma_s(x) := \inf\{\|x - z\| : z \in \mathbb{R}^n \text{ is } s\text{-sparse}\}$, the distance of x from the nearest s-sparse vector, and the measurement error. See Candés, Romberg and Tao (2006); Candés et. al (2005); Kabanava and Rauhut (2015) for more on robust and stable recovery via compressive sensing.

We assume that our observations $y = (y_1, \ldots, y_m)$ are noisy. The following theorem gives an error bound on the reconstruction from noisy measurements using a Gaussian matrix.

Theorem 3 (Theorem 9.20 in (Foucart and Rauhut, 2013)) *Let $x \in \mathbb{R}^n$ be a s-sparse vector. Let $M \in \mathbb{R}^{m \times n}$ be a randomly drawn Gaussian. Assume that noisy measurements $y = Mx + \xi$ are taken with $\|\xi\| \leq \eta$. If for $0 < \epsilon < 1$ and some $\tau > 0$,*

$$\frac{m^2}{m+1} \geq 2s \left(\sqrt{\log(en/s)} + \sqrt{\frac{\log(\epsilon^{-1})}{s}} + \frac{\tau}{\sqrt{s}} \right)^2, \tag{3}$$

then with probability at least $1 - \epsilon$ every minimizer $\hat{x}$ of $\|z\|_1$ subject to $\|Mz - Mx\| \leq \eta$ satisfies

$$\|x - x^*\| \leq \frac{2\eta}{\tau}.$$

See Theorem 9.29 in Foucart and Rauhut (2013) for a statement for stable and robust recovery via Gaussian matrices.

2.2 Simultaneous Perturbation Stochastic Approximation

As discussed above we have a fairly good reconstruction of a sparse gradient ∇f given a sufficient number of observations $\{y_i\}$. However, as mentioned before, the problem often is the unavailability of these observations. Even though observations for ∇f are not readily available, one may compute y_i's using the available information, that is, noisy measurements of the function f. Note that we have, however, assumed that the function evaluations are computationally expensive. We will now address this issue of estimating ∇f with low computational overheads.

Let e_i denote the i^{th} coordinate direction for $1 \leq i \leq n$. We consider the finite difference approximation

$$\frac{\partial f(x(k))}{\partial x_i} \approx \frac{f(x(k)+\delta e_i) - f(x(k)-\delta e_i)}{2\delta}$$

where $x(k) = (x_1(k), \ldots, x_n(k))$ and $\delta > 0$. By Taylor's theorem, the error of estimation is $O(\delta \|\nabla^2 f(x(k))\|)$ where $\nabla^2 f$ denotes the Hessian. This estimate requires $2n$ function evaluations. Replacing the 'two sided differences' $(f(x(k)+\delta e_i) - f(x(k)-\delta e_i))/2$ above by 'one sided differences' $(f(x(k)+\delta e_i) - f(x(k)))$ reduces this to $n+1$, which is still large for large n. Given that we have assumed f to be such that the function evaluations are computationally expensive, an alternative method is desirable. We use the method devised by Spall (Spall, 1992) in the context of stochastic gradient descent, known as Simultaneous Perturbation Stochastic Approximation (SPSA).

Recall the stochastic gradient descent scheme (Borkar, 2008)

$$x(k+1) = x(k) + a(k)\left[-\nabla f(x(k)) + M(k+1)\right], \tag{4}$$

where:

- $\{M(k)\}$ is a square-integrable martingale difference sequence, viz., a sequence of zero mean random variables with finite second moment satisfying

  $$E\left[M(k+1)|x(m), M(m), m \leq k\right] = 0 \;\forall\; k \geq 0,$$

  i.e., it is uncorrelated with the past. We assume that it also satisfies

  $$\sup_k E\left[\|M(k+1)\|^2 | x(m), M(m), m \leq k\right] < \infty, \tag{5}$$

- $\{a(k)\}$ are step-sizes satisfying

  $$a(k) > 0 \;\forall k,\; \sum_k a(k) = \infty,\; \sum_k a(k)^2 < \infty. \tag{6}$$

The term in square bracket in (4) stands for a noisy measurement of the gradient. Under mild technical conditions, $x(k)$ can be shown to converge a.s. to a local minimum of f (Borkar, 2008). The idea is that the incremental adaptation due to the slowly decreasing step-size $a(k)$ averages out the noise $\{M(k)\}$, rendering this a close approximation of

the classical gradient descent with vanishing error (Borkar, 2008). In practice the noisy gradient is often unavailable and one has to use an approximation $\widehat{\nabla f}$ thereof using noisy evaluations of f, e.g., the aforementioned finite difference approximations, which lead to the Kiefer-Wolfowitz scheme. That is where the SP scheme comes in. We describe this next.

Let $\{\Delta_i(k), 1 \leq i \leq n, k \geq 0\}$ be i.i.d. zero mean random variables such that

- $\Delta(k) = (\Delta_1(k), \ldots \Delta_n(k))$ is independent of $M(\ell), \ell \leq k+1$.
- $P(\Delta_i(k) = 1) = P(\Delta_i(k) = -1) = 1/2$.

Then by Taylor's theorem, we have that for $\delta > 0$:

$$\frac{f(x(k)+\delta\Delta(k)) - f(x(k))}{\delta\Delta_i(k)} \approx \frac{\partial f}{\partial x_i}(x(k)) + \sum_{j\neq i} \frac{\partial f}{\partial x_i}(x(k))\frac{\Delta_j}{\Delta_i}. \tag{7}$$

Note that since Δ_j's are i.i.d. zero mean random variables, we have for $j \neq i$,

$$\mathbb{E}\left[\frac{\partial f}{\partial x_i}(x(k))\frac{\Delta_j}{\Delta_i}\Big| x(m), M(m), m \leq k-1\right] = 0.$$

Hence for the purpose of stochastic gradient descent, the second term in (7) acts as a zero mean noise (i.e., martingale difference) term that can be clubbed with $M(k+1)$ as martingale difference noise and gets averaged out by the iteration. This serves our purpose, since the above scheme requires only two function evaluations per iterate given by

$$x_i(k+1) = x_i(k) + a(k)\left[-\frac{f(x(k)+\delta\Delta(k)) - f(x(k))}{\delta\Delta_i(k)}\right] + M_i(k+1).$$

Our idea is to generate $\widetilde{\nabla f}$ according to the scheme discussed above.

It should be mentioned that Spall also introduced another approximation based on a single function evaluation (see Borkar, 2008, chap. 10). But this suffers from numerical issues due to the 'small divisor' problem, so we do not pursue it here.

2.3 Main result

As mentioned in the introduction, the idea is to combine the SP and compressive sensing to obtain a sparse approximation of ∇f. Note that while SP gives an estimate with zero-mean error, the final estimate of gradient obtained after compressive sensing may not be unbiased. To avoid the error from piling up we need to average out the error at SP stage. We propose the following algorithm for estimating gradient of f. Let a_i denote the row vectors of A.

Algorithm 1 Gradient Estimation at some $x \in \mathbb{R}^n$ with SP and Compressive Sensing

Initialization:

$A = (a_{ij})_{m\times n} \leftarrow$ random Gaussian matrix.

$\delta \leftarrow$ small positive scalar.

- $y_i^\ell = \frac{f(x+\delta\sum_j^m \Delta_j^\ell a_j) - f(x)}{\delta\Delta_i^\ell}$ for $i = 1,\dots,m;\ \ell = 1,\dots,k,$
  where Δ_j^ℓ are i.i.d. zero mean Bernoulli random variables taking values in $\{-1, 1\}$.
- Set $\bar{y}_i := \frac{\sum_{\ell=1}^k y_i^\ell}{k},\ i = 1,\dots,m.$
- $y = (\bar{y}_1,\dots,\bar{y}_m) = A\nabla f(x) + \zeta$ where ζ denotes the bounded error with bound $\|\zeta\| \le \eta$.
- Solve the l_1-minimization problem stated below to obtain $\widetilde{\nabla f}$:

$$\text{minimize } \|z\|_1 \ \text{ subject to } \ \|Az - y\| \le \eta$$

Output: estimated gradient $\widetilde{\nabla f}(x)$.

There are several algorithms for the l_1-minimization problem that appears in the last step of the algorithm above. A detailed discussion of these algorithms, including the Homotopy method (used in Section 3 for the l_1-minimization step), can be found in Yang et. al (2010) and Foucart and Rauhut (2013, Chap. 15).
The following theorem states that with high probability such an approximation is "close" to the actual gradient.

Theorem 4 *Let $f : \mathbb{R}^n \mapsto \mathbb{R}$ be a continuously differentiable function with bounded sparse gradient. Then for $m \in \mathbb{N}$ such that it satisfies the bound in (3), $0 < \epsilon << \frac{1}{m}$, and given $\delta > 0$ (as in (7)) and $\tau > 0$ (as in Theorem 3), ∇f can be estimated by a sparse vector $\widetilde{\nabla f}$ such that with probability at least $1 - \epsilon m$,*

$$\|\widetilde{\nabla f} - \nabla f\| < \frac{2t}{\tau}$$

where $t > 2mO(\delta)$.

Proof Let $A \in \mathbb{R}^{m\times n}$ be a Gaussian matrix such that m satisfies (3). Then, following the same idea as in (7), we have:

$$\begin{aligned} y_i &= \frac{f(x+\delta\sum_{j=1}^m \Delta_j a_j) - f(x)}{\delta\Delta_i} \\ &= \langle\nabla f(x), a_i\rangle + \sum_{j\neq i}\frac{\Delta_j\langle\nabla f, a_i\rangle}{\Delta_i} + O(\delta). \end{aligned}$$

So we get

$$y = A\nabla f + \text{ 'error'}, \tag{8}$$

where we quantify the 'error' below.

The above computation is carried out k times independently, keeping the matrix A fixed and choosing the random vector Δ according to the distribution defined in Section 2.2. The reason for this additional averaging is as follows. The reconstruction in compressive sensing need not give an unbiased estimate, since it performs a nonlinear (minimization) operation. Thus it is better to do some pre-processing of the SP estimate (which is nearly, i.e., modulo the $O(\delta)$ term, unbiased) to reduce its variance. We do so by repeating it k times with independent perturbations and taking its arithmetic mean. This may seem to defeat our original objective of reducing function evaluations, but the k required to get reasonable error bounds is not large as our analysis shows later, and the computational saving is still significant (see 'Remark 5' below).

Denote by y^l the measurement obtained at l^{th} iteration of SP. The error for a single iteration is given by

$$\eta^l = \left(\sum_{j\neq 1}\frac{\Delta_j^l\langle\nabla f, a_1\rangle}{\Delta_1^l} + O(\delta),\dots,\sum_{j\neq m}\frac{\Delta_j^l\langle\nabla f, a_m\rangle}{\Delta_m^l} + O(\delta)\right).$$

Denote by $X_{ij}^l = \frac{\Delta_j^l\langle\nabla f, a_i\rangle}{\Delta_i^l},\ j \neq i.$ X_{ij}^l are zero-mean conditionally (given past iterates) independent random variables.

The error vector after k iterations is given by

$$\begin{aligned} \eta &= \frac{1}{k}\sum_{l=1}^k \eta^l \\ &= \frac{1}{k}\sum_{l=1}^k\left(\sum_{j\neq 1}X_{1j}^l + O(\delta),\dots,\sum_{j\neq m}X_{mj}^l + O(\delta)\right) \\ &= \left(\frac{1}{k}\sum_{l=1}^k\sum_{j\neq 1}X_{1j}^l + O(\delta),\dots,\frac{1}{k}\sum_{l=1}^k\sum_{j\neq m}X_{mj}^l + O(\delta)\right). \end{aligned} \tag{9}$$

In order to apply the ideas from compressive sensing as in Theorem 3, we need to have a bound on the error $\|\eta\|$. This is obtained as follows. Let $K > 0$ be a constant such that the $O(\delta)$ term above is bounded in absolute value by $K\delta$. K can, e.g., be a bound on $\|\nabla^2 f\|\|A\|$ by the mean value theorem, where we use the Frobenius norm. Choose $C \ge \sup|\langle\nabla f, a_i\rangle|$

and $t > 2mK\delta$. Then, by Hoeffding's inequality we have,

$$\begin{aligned} P(\|\eta\| \geq t) &\leq \sum_{i=1}^{m} P\left(\left|\frac{1}{k}\sum_{l=1}^{k}\sum_{j\neq i} X_{ij}^{l} + O(\delta)\right| > t/m\right) \\ &\leq \sum_{i=1}^{m} P\left(\left|\sum_{l=1}^{k}\sum_{j\neq i} X_{ij}^{l}\right| > kt/2m\right) \\ &\leq 2me^{-\frac{kt^2}{2m^2(m-1)C^2}}. \end{aligned}$$

Choose the number of iterations, $k > \frac{2m^3C^2}{t^2}\log\left(\frac{2}{\epsilon}\right)$. Then,

$$P(\|\eta\| \geq t) \leq \epsilon m. \tag{10}$$

We define $\widetilde{\nabla f}$ to be the reconstruction of the gradient using m measurements. That is, $\widetilde{\nabla f}$ solves the following optimization problem:

$$\min_{z\in\mathbb{R}^n} \|z\|_1 \text{ subject to } \quad \|Az - y\| \leq t,$$

where y is as in (8). Our claim then follows from the bound in (10) and Theorem 3. ■

Remark 5 *Note that the minimum number of iterations of SP required to obtain a "good" estimate of ∇f is given by*

$$\begin{aligned} k &> \frac{2m^3C^2}{t^2}\log\left(\frac{2}{\epsilon}\right) \\ &\geq \frac{mC^2}{2K^2\delta^2}\log\left(\frac{2}{\epsilon}\right) \\ &\geq \frac{s\tilde{C}}{\delta^2}\log\left(\frac{n}{s}\right)\log\left(\frac{2}{\epsilon}\right). \end{aligned}$$

for a suitable constant $\tilde{C}$.

The above $\widetilde{\nabla f}$ can now be used as an effective gradient in various problems involving gradients of high-dimensional functions. Three such applications are discussed in the next section.

3. Applications

We consider the application of our method to manifold learning and optimization problems. The gradient estimates obtained using our method can be used to estimate the gradient outer product matrix or can be plugged into an optimization scheme. In the former case, along with an example, we also provide error bounds on the estimated and actual gradient outer product matrix. For the latter case, we look at an example and provide suitable

modifications to existing algorithms to achieve faster convergence. Algorithm 1 described in Section 2.3 is used for gradient estimation.

As mentioned before, there are various algorithms available for carrying out the l_1-minimization. Here we use the homotopy method (see Donoho and Tsaig, 2008; Foucart and Rauhut, 2013; Yang et. al, 2010). Homotopy method solves the quadratically constrained l_1-minimization problem (2) by considering the following l_1-regularized least squares functional:

$$F_\lambda(x) = \frac{1}{2}\|Az - y\| + \lambda\|z\|_1 \quad \text{for } \lambda > 0 \tag{11}$$

The algorithm traces the piece-wise linear and continuous solution path $\lambda \mapsto x_\lambda$ and at each step, an element is added or removed from the support set of the current minimizer. If the minimizer x^* of (1) is unique then the minimizer x_λ of (11) converges to x^*. The idea is to start with a large λ such that the minimizer x_λ of (11) is zero and then trace the solution trajectory in the direction of decreasing λ.

We consider a Gaussian matrix A and get $y(n) \quad \leftarrow A\nabla f(x(n)) +$ error as obtained in equation (8). The last step is to obtain $\widetilde{\nabla f}(x)$ via l_1-recovery from observations y and Gaussian random matrix A using the homotopy method described above. All the simulations were performed on MATLAB using the available toolbox for l_1-minimization. (Berkeley database: http://www.eecs.berkeley.edu/ yang/software/ l1benchmark/).

Consider a function $f : \mathbb{R}^{25000} \mapsto \mathbb{R}$ given by $f(x) = x^T MM^T x$ where, M is 25000×3-dimensional matrix with 3 non-zero elements per column. Let A be a random Gaussian matrix that is used for measurement. We consider $m = 50$ measurements.

Figure 1 shows the performance of the proposed method with varying number of SP iterations. Figures 2 and 3 show the comparison between our method and naive SP for estimating gradient with gradually increasing number of iterations for averaging over SP (The quantity 'k' in (9)). As mentioned earlier, since the gradient is assumed to be sparse, using naive SP to compute derivative in each direction seems wasteful. Although the error diminishes as the number of iterations for SP increase, the proposed method combining compressive sensing with SP consistently performs better.

Figures 4 and 5 show that the proposed method works well with higher sparsity levels too. It also shows that with higher s, performance of naive SP improves. This is expected. The extremely high error in the naive SP method (especially for small s) is owing to the fact that the actual gradient is extremely sparse and in the beginning SP method ends up populating almost all the coordinates. That contributes to the high percentage of error as seen in the aforementioned figures.

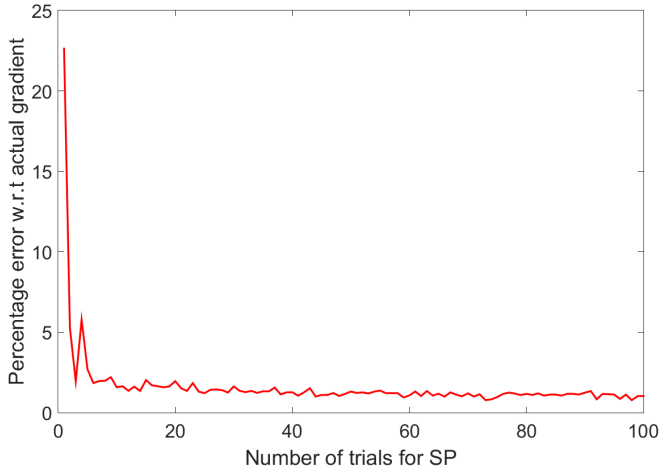

Figure 1: Percentage error of $\|\nabla f - \widetilde{\nabla f}\|$ in our method, with varying number of iterations k for SP. Here, $n = 25000, s = 3$ and $m = 50$.

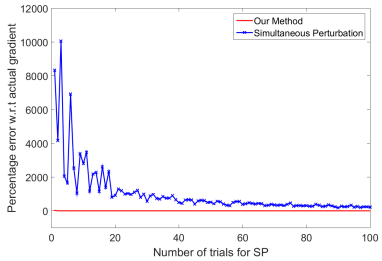

Figure 2: Performance of the proposed algorithm vs. the SP method with varying number iterations k at SP step. Here $n = 25000, s = 3$ and $m = 50$

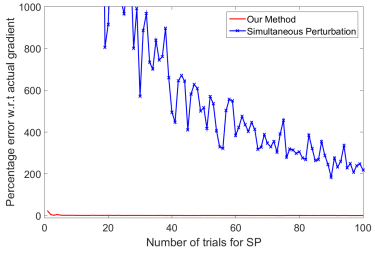

Figure 3: A closer look at Figure 2 : Performance of the proposed algorithm vs. the SP method with varying number iterations k at SP step. Here $n = 25000, s = 3$ and $m = 50$.

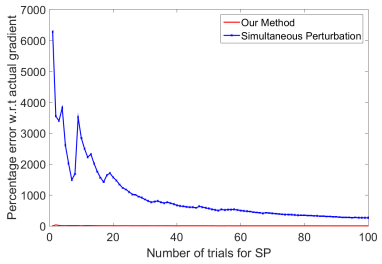

Figure 4: Performance of the proposed algorithm vs. the SP method with varying number iterations k at SP step. Here $s = 50$ and $m = 500$.

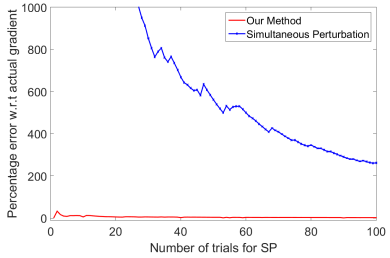

Figure 5: A closer look at Figure 4: Performance of the proposed algorithm vs. the SP method with varying number iterations k at SP step. Here $s = 50$ and $m = 500$.

Before we consider specific applications, we illustrate how the percentage error of estimated gradient with varying k for different sparsity levels s. For appropriately large m, for small k the error is high (this matches with the discussion in Remark 5). As k increases the error is much less. As long as m satisfies (3), the compressive sensing results apply. Figures 6 and 7 show the behaviour of the proposed method with variation in the sparsity, but with constant number of observations. We consider 10000-dimensional vector with $m = 50$ observations. As expected, for a fixed m, as the sparsity increases, increasing k no longer helps as the compressive sensing results do not apply and the error increases. $f(x) = x(1)^2 + \ldots + x(s)^2$ was used as a test function for both the simulations.

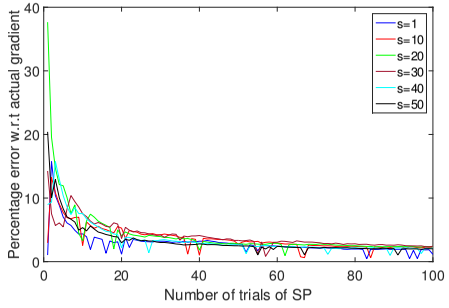

Figure 6: Performance of the proposed algorithm with variation k for different sparsity levels.

3.1 Manifold Learning: Estimating e.d.r. space

Consider the following semi-parametric model

$$Y = f(X) + \epsilon$$

where ϵ is noise and f is a smooth function $\mathbb{R}^n \mapsto \mathbb{R}^m$ of the form $f(X) = g(b_1^T X, \ldots, b_d^T X)$. Define by B the matrix $(b_1, b_2, \ldots, b_d)^T$. B maps the data to a d-dimensional relevant subspace. This means that the function f depends on a subspace of smaller dimension given by Range(B) (Note that this is essentially the local view in manifold learning : B can vary with location.). The vectors or the directions given by the vectors b_i are called the effective dimension reducing directions or e.d.r. The question is: how to find the matrix B? It turns out that if f doesn't vary in some direction v, then $v \in Null(E_X[G])$ where G is the gradient outer product matrix defined as

$$G = [[G_{ij}]] \text{ where } G_{ij} = \Big\langle \frac{\partial f}{\partial x_i}(X), \frac{\partial f}{\partial x_j}(X) \Big\rangle$$

and $E_X[\,\cdot\,]$ denotes the expectation over X. Lemma 1 from (Wu et. al, 2010) stated below implies that to find the e.d.r. directions it is enough to compute $E_X[G]$.

Lemma 6 *Consider the semi-parametric model*

$$Y = g(b_1^T X, \ldots, b_d^T X) + \epsilon, \tag{12}$$

where ϵ represents zero mean finite variance noise. Then the expected gradient outer product (EGOP) matrix G is of rank at most d. Furthermore, if $\{v_1, \ldots, v_d\}$ are the eigenvectors associated to the nonzero eigenvalues of G, the following holds:

$$Span(B) = Span(v_1, \ldots, v_d).$$

Clearly, calculating $E_X[G(X)]$ is computationally heavy. We therefore try to estimate this matrix. Several methods are known for estimating the EGOP and this has been a very popular problem in statistics for a while. The idea of using EGOP for obtaining e.d.r. originated in Li (1991). While there are other methods based on inverse regression etc., most of the efforts have been directed towards getting an efficient way to estimate gradients in order to finally estimate EGOP (see Xia et. al, 2002). In Mukherjee, Wu and Zhou (2010), the authors use their method of gradient estimation for this purpose. The idea is to use sample observations $\{f(x_i)\}$ for $\{x_i\}$ in a neighborhood of the given point x and minimize over z the error

$$\frac{1}{n^2} \sum_{i,j=1}^{n} w_{ij}[y_i - f(x_j) - \langle z, (x_i - x_j)\rangle]^2,$$

where $w_{ij} \geq 0$ are weights ('kernel') that favor locality $x_i \approx x$ and are typically Gaussian, with regularization in a reproducing kernel Hilbert space (RKHS). The minimizer then is the desired estimate. In Trivedi et. al (2014) a rather simple rough estimator using directional derivative along each coordinate direction is provided. The authors demonstrate that for the purpose of finding e.d.r., a rough estimate such as theirs suffices. We also propose a method via gradient estimation. Take $\widehat{G}$ to be the matrix defined by

$$\widehat{G}_{ij} = \Big\langle \widetilde{\frac{\partial f}{\partial x_i}}, \widetilde{\frac{\partial f}{\partial x_j}} \Big\rangle.$$

In other words, $\widehat{G} = \widetilde{\nabla f} \widetilde{\nabla f}^T$, where $\widetilde{\nabla f}$ denotes the estimate of ∇f obtained by algorithm 1. We impose our previous restrictions on f. That is, the function evaluations at any point are expensive and the gradient of f is sparse. In this case we propose an estimate for $E_X[G]$ by the mean of $\widehat{G}$ over a sample of r points given by the set $\chi = \{(x_i, f(x_i))\}_{1 \leq i \leq r}$. By $\langle\, \cdot\, \rangle$, we shall denote the empirical mean over the sample set χ. Thus,

$$\langle G(X) \rangle = \frac{1}{r} \sum_{x_i \in \chi} \nabla f(x_i) \nabla f(x_i)^T$$

and

$$\langle \widehat{G}(X) \rangle = \frac{1}{r} \sum_{x_i \in \chi} \widetilde{\nabla f}(x_i) \widetilde{\nabla f}(x_i)^T.$$

Theorem 7 *Let $f : \mathbb{R}^n \mapsto \mathbb{R}^k$ from the semi-parametric model in (12) be a continuously differentiable function with bounded sparse gradient. Then, for $0 < \epsilon << \frac{1}{m}$ and some $\tau > 0$, with probability at least $1 - \epsilon m$,*

$$\Big\| E_X[G] - \langle \widehat{G} \rangle \Big\| < \frac{6R^2}{\sqrt{r}} \left(\sqrt{\ln n} + \sqrt{\ln \frac{1}{\epsilon}} \right) + \frac{2t}{\tau} \left(\frac{2t}{\tau} + 2R \right)$$

where r is the sample size, R is such that $\|\nabla f\| \leq R$, t is as in Theorem 4 and $m \in \mathbb{N}$ is such that it satisfies the bound in (3).

The proof closely follows the line of argument in Trivedi et. al (2014).

Proof Note that,

$$\|E_X[G(X)] - \langle \widehat{G}(X)\rangle\| \leq \|E_X[G(X)] - \langle G(X)\rangle\| + \|\langle G(X)\rangle - \langle \widehat{G}(X)\rangle\|.$$

The idea is to bound each term. We use concentration inequality for sum of random matrices (see Trivedi et. al, 2014, Lemma 1) and (Tropp, 2012) for more general results, to claim that for $\epsilon > 0$,

$$\|E_X[G(X)] - \langle G(X)\rangle\| \leq \frac{6R^2}{\sqrt{r}}\left(\sqrt{\ln n} + \sqrt{\ln \frac{1}{\epsilon}}\right)$$

with probability $\geq 1 - \epsilon$. For the second term, it is enough to show that it is bounded for any single sample point x. Observe that for any two vectors v and w, $\|vv^T - ww^T\| \leq \|(v-w)(v+w)^T\|$ Using this we get, for a fixed x,

$$\begin{aligned}
\|G(x) - \widehat{G}(x)\| &= \|\nabla f(x)\nabla f(x)^T - \widetilde{\nabla} f(x)\widetilde{\nabla} f(x)^T\| \\
&\leq \|\nabla f(x) - \widetilde{\nabla} f(x)\|\|\nabla f(x) + \widetilde{\nabla} f(x)\| \\
&\leq \|\nabla f(x) - \widetilde{\nabla} f(x)\|\left(\|\nabla f(x) - \widetilde{\nabla} f(x)\| + 2\|\nabla f(x)\|\right) \\
&\leq \frac{2t}{\tau}\left(\frac{2t}{\tau} + 2R\right)
\end{aligned}$$

with probability $\geq 1 - \epsilon m$, where the last inequality is obtained by applying the bound from Theorem 4. ■

We now simulate an example to illustrate the decay of the error $\|\langle G(X)\rangle - \langle \widehat{G}(X)\rangle\|_F$ (See Figure 8). Consider a function $f : R^{25000} \mapsto R^3$ given by: $f_i(x) = x^T M_i M_i^T x$ where, M_i is a 25000-dimensional vector with 3 non-zero elements and $f_i(x)$ corresponds to the i^{th} dimension of $f(x)$. A 25000×100 Gaussian random matrix is used for the compressive sensing part of the algorithm. The plot of percentage in normed error between $\langle G(X)\rangle$ and $\langle \widehat{G}(X)\rangle$, i.e. $\|\langle G(X)\rangle - \langle \widehat{G}(X)\rangle\|_F^2$ is shown below by varying number of samples $r = 1$ to 25. Remember that due to the bias at compressive sensing step, we need to average out the gradient estimation error at SP step. This is done in $k = 100$ iterations.

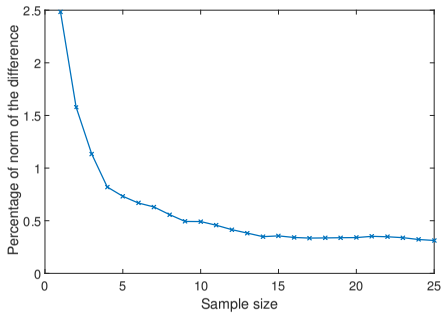

Figure 8: Percentage error in $\|\langle G(X)\rangle - \langle \widehat{G}(X)\rangle\|$ with number of samples r varying from 1 to 25. Here, $n = 25000, s = 3, m = 100$ and $k = 100$.

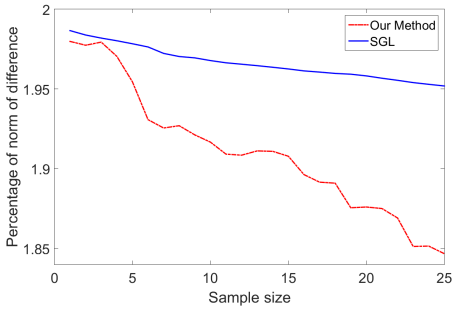

Figure 9: Comparison of percentage error of $\|\langle G(X)\rangle - \langle \widehat{G}(X)\rangle\|$ computed by plugging gradient estimates by proposed method vs SGL method. Here, $n = 10000, s = 30, m = 100$ and $k = 100$. Number of samples for SGL method are 100.

Learning e.d.r. by estimating the gradient using the method proposed in this paper was compared with the SGL (Sparse Gradient Learning) method proposed in (Mukherjee, Wu and Zhou, 2010) using the same function as above and an exponential kernel (See `http://www2.stat.duke.edu/~sayan/soft.html` for details). This is illustrated in Figure 9. Here, $n = 10000$ and the measurement matrix is a 10000×100 Gaussian matrix. The SP step is averaged over 100 iterations. 100 samples were considered for the SGL method with the neighborhood radius of of 0.05. Sparsity of the gradient vector is 30.

3.2 Optimization

We consider next a typical problem of function minimization, but only consider a function with sparse gradient. In other words, we want to minimize $f(x)$ where

$$f : \mathbb{R}^n \mapsto \mathbb{R}$$

is a continuously differentiable real-valued Lipschitz function such that function evaluation at a point in $\mathbb{R}^n$ is typically expensive. We also assume that n is large and that ∇f is sparse. In addition, we assume that the critical points of f (i.e., the zeros of ∇f) are isolated. (This is generically true unless there is overparametrization.) The idea is to use the stochastic gradient scheme (4) with the standard assumptions (5), (6). It follows from the theory of stochastic approximation (see Borkar, 2008, chap. 2) that under above conditions, the solution of the random difference equation (4) tracks with probability one the trajectory of the solution of a limiting o.d.e. as long as the iterates remain bounded, which they do under mild additional conditions on f. Following (Borkar, 2008, chap. 2), we use this so called 'o.d.e. approach' which states that the algorithm will a.s. converge to the equilibria of the limiting o.d.e., which is

$$\dot{x}(t) = -\nabla f(x(t)). \tag{13}$$

For this, f itself serves as the Lyapunov function, leading to the conclusion that the trajectories of (13) and therefore a.s., the iterates of (4) will converge to one of its equilibria, viz., the critical points of f. In fact under additional conditions on the noise, it will converge to a (possibly random) stable equilibrium thereof, viz., a local minimum (*ibid.*, Chapter 4).

The stochastic gradient scheme requires $\nabla f(x)$ at each iteration. The problem often is the unavailability of $\nabla f(x)$, as already noted. It is therefore important to have a good method for estimating the gradient. Typically one would obtain noisy measurements and hence the estimate will have a non-zero error η. It is known that if the error remains small, the iterates converge a.s. to a small neighbourhood of some point in the set of equilibria of (13). We analyze the resultant error below. Also, the error obtained in SP is zero-mean modulo higher order terms, so one can even take an empirical average over a few separate estimates in order to reduce variance. For high dimensional problems, the number of function evaluations remains still small as compared with, e.g., the classical Kiefer-Wolfowitz scheme. We use Theorem 4 to justify using SP (Simultaneous Perturbation Stochastic Approximation) combined with compressed sensing to obtain an approximation for the gradient and then use the above scheme to minimize f.

Consider the following stochastic approximation scheme:

$$x_{n+1} = x_n + a(n)[-\nabla f(x_n) + M_{n+1} + \eta(n)] \tag{14}$$

where $\{\eta(n)\}$ is the additional error arising due to the error in gradient estimation. That is, $\widetilde{\nabla} f(x_n) = \nabla f(x_n) - \eta(n)$. If $\sup_n \|\eta(n)\| < \epsilon_0$ for some small ϵ_0, then the iterates of (14) converge to a small neighbourhood A of some point x^* in $H = \{x : \nabla f(x) = 0\}$ (see Tadic and Doucet, 2017) and (Borkar, 2008, chap. 10)). This is ensured by a Lyapunov argument as follows. The limiting o.d.e. is of the form

$$\dot{x}(t) = -\nabla f(x(t)) + \breve{\eta}(t)$$

for some measurable $\breve{\eta}(\cdot)$ with $\|\breve{\eta}(t)\| \leq \epsilon_0 \ \forall t$. Then

$$\frac{d}{dt} f(x(t)) = -\|\nabla f(x(t))\|^2 + \langle \nabla f(x(t)), \breve{\eta}(t) \rangle,$$

which is < 0 as long as $\|\nabla f(x(t))\|^2 > |\langle \nabla f(x(t)), \breve{\eta}(t) \rangle|$. Therefore $x(t)$ will converge to the set

$$\{x : \|\nabla f(x)\| \leq \epsilon_0\}.$$

Assume that the Hessian $\nabla^2 f(x^*)$ is positive definite, which is generically so for isolated local minima. Then for A small enough, the lowest eigenvalue $\lambda_m(x)$ of $\nabla^2 f(x)$ for $x \in A$ is > 0. By mean value theorem, $\nabla f(x) = \nabla^2 f(x')(x - x^*)$ for some $x' \in A$, so $\|\nabla f(x)\| \geq \lambda_m(x')\|x - x^*\|$. Thus there is convergence to a ball of radius $\frac{\epsilon_0}{\lambda_m}$ around x^*. (A statement to this result without the estimate on the radius of the ball is contained in Theorem 1 of (Hirsch, 1989).) Thus we have:

Theorem 8 *The stochastic gradient scheme*

$$x_{n+1} = x_n + a(n)[-\widetilde{\nabla} f(x_n) + M_{n+1}]$$

a.s. converges to a ball of radius $O(\epsilon_0)$ centered at some local minimum of f, where $\widetilde{\nabla} f$ is the reconstructed gradient as in Theorem 4 and ϵ_0 is a bound on $\|\widetilde{\nabla} f - \nabla f\|$.

Proof The claim is immediate from the above observations about the perturbed differential equation and Theorem 6, pp. 58-59, (Borkar, 2008). □

See Tadic and Doucet (2017) for a finer analysis. Also, observe that we have only discussed asymptotic convergence above. For real-life optimization problems, however, we must ensure that the scheme in (14) converges to a neighbourhood of x^* in finite time. This is indeed true and recent concentration-type results (see Kamal, 2010; Thoppe and Borkar , 2015)) strengthen the theoretical basis for plugging $\widetilde{\nabla} f(x)$ in place of $\nabla f(x)$ in stochastic gradient descent schemes. The results in Kamal (2010) involve estimates on lock-in probability, i.e., the probability of convergence to a stable equilibrium given that the iterates visit its domain of attraction. An estimate on the number of steps needed to be within a prescribed neighborhood of the desired limit set with a prescribed probability is also obtained. Specifically, the result states that if the n_0th iterate is in the domain of attraction of a stable equilibrium x^*, then after a certain number of additional steps, the iterates remain in a small tube around the differential equation trajectory converging to x^* with probability exceeding

$$1 - \mathrm{O}\left(e^{-\frac{C}{(\sum_{m=n_0}^{\infty} a(m)^2)^{\frac{1}{4}}}} \right),$$

ipso facto implying an analogous claim for the probability of remaining in a small neighborhood of x^* after a certain number of iterates. We refer the reader to Kamal (2010) for details. In Thoppe and Borkar (2015), an improvement on this estimate is proved under additional regularity conditions on ∇f (twice continuous differentiability) using Alekseev's

formula. We have omitted the details of both the cases as it needs much additional notation to replicate them here. These would, however, apply to the exact stochastic gradient descent. Since we have an additional error due to approximate gradient as in the preceding theorem, we need to combine the results of *ibid.* with the above theorem to make a weaker claim regarding how small the neighborhood of x^* in question can be. Furthermore, these claims are about iterates which are in the domain of attraction of a stable equilibrium. This, however, is not a problem, as 'avoidance of traps' results as in Section 4.3 of Borkar (2008) (also see Benaim, 1996; Brandiére and Duflo, 1996; Pemantle, 1990) ensure that if the noise is rich enough in a certain precise sense, unstable equilibria are avoided with probability one.

Remark 9 *Note that the gradient descent is a stochastic approximation scheme which itself averages out the noise. So in principle the averaging over k steps at the SP stage in the original algorithm can be skipped. This means that for a stochastic gradient descent scheme, we cut down the cost of function evaluation even further. The simulations in the next section confirm that good results are obtained without averaging over SP iterations. There is, however, a standard trade-off involved between per step computation / speed of convergence, and fluctuations (equivalently, variance) of the estimates: any additional averaging improves the latter at the expense of the former.*

3.3 Numerical experiments

We compare following three algorithms.

1. *Actual Gradient Descent*

   This is the classical stochastic gradient descent with exact gradient.

Algorithm 2 Stochastic Gradient Decent with Compressive Sensing

---

Initialization:

$x(0) = x_{initial}, A \leftarrow random\ Gaussian\ matrix$
$a(n)$ be a sequence that satisfies the properties of stepsize listed above.

Iteration: *Repeat until convergence criteria is met at* $n = n^{\#}$. *At* n^{th} *iteration:*

$$\begin{aligned} y(n) &\leftarrow A\nabla f(x(n)) + error \\ \widetilde{\nabla f}(x(n)) &\leftarrow l_1 - \ minimization\ with\ Homotopy(y(n), A) \\ x(n+1) &\leftarrow x(n) - a(n)[\widetilde{\nabla f}(x(n))] \end{aligned}$$

Output: *Approximate minimizer of* f *i.e.* $x(n^{\#})$

Here $Homotopy(y(n), A)$ denotes the l_1-recovery from observations $y(n)$ and Gaussian random matrix A using the homotopy method.

2. *Accelerated Gradient Method*

   Accelerated gradient scheme was proposed by Nesterov (Nesterov, 1983). While Gradient Descent algorithm has a rate of convergence of order $1/s$ after s steps, Nesterov's method achieves a rate of order $1/s^2$. We implement the method here to achieve an improvement in the time complexity further. The idea is to replace the n^{th} iteration above by the following.

At n^{th} iteration:

$$\begin{aligned} y(n) &\leftarrow A\nabla f(x(n)) + \text{error} \\ \widetilde{\nabla f}(x(n)) &\leftarrow l_1 - \ \text{minimization with } Homotopy(y(n), A) \\ z(n+1) &\leftarrow x(n) - a(n)[\widetilde{\nabla f}(x(n))] \\ x(n+1) &\leftarrow (1-\gamma(n))z(n+1) + \gamma(n)z(n) \end{aligned}$$

where, λ and γ are as follows:

$$\lambda(0) = 0,\ \lambda(n) = \frac{1+\sqrt{1+4\lambda^2(n-1)}}{2},\ \text{and } \gamma(n) = \frac{1-\lambda(n)}{\lambda(n+1)}.$$

This gives us faster convergence towards the minimum.

3. *Adaptive Method*

   Another way to achieve a faster convergence rate is to perform the l_1-minimization adaptively with the gradient descent. The idea is to again use the homotopy method for l_1-minimization but this part of the algorithm is run for very few iterations. The intermediate approximation of ∇f is then used for performing the stochastic gradient descent. As expected, the errors are high in the beginning but the convergence is faster.

We consider the following function to test our algorithms:

$$f(x) = (x^T M_1^T M_1 x)^3 + (x^T M_2^T M_2 x)^2 + x^T M_1^T M_2 x \tag{15}$$

where, function $f : \mathbb{R}^n \mapsto \mathbb{R}$ and M_1, M_2 are $n \times s$ random matrices. This is to ensure sparsity of the gradient. Here, $n = 25000$ and number of non-zero entries in each column of M_1 and M_2 are $s = 3$. Number of measurements, $m = 500$. A is a $n \times m$ random Gaussian matrix.

Figure 10 show the comparisons between various algorithms described above for the same function.

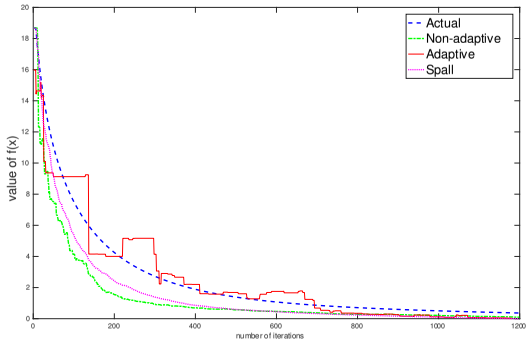

Figure 10: Comparison of Gradient descent with actual gradient ∇f and estimated gradient $\widetilde{\nabla f}$ using non-adaptive, adaptive schemes and Spall's SPSA. Here, $n = 25000, s = 3$ and $m = 500$

Algorithm Used	n = 1000 (sec)	n = 10000 (sec)	n = 25000 (sec)
Adaptive Method	4.3	62.3	85.4
Without Adaptive	50.572	612.3	1004.5
Spall's SPSA	25.0	459.8	864.5
Actual Gradient Method	64.1	4641.12	7526

As expected, adaptive method turns out to be faster compared to the non-adaptive method which in turn is much faster than the algorithm that computes actual gradients. Incidentally, the classical scheme all but converges in under 1000 iterations. Even so it takes more time than the other two which take more iterations. This is because of the heavy per iterate computation for the classical scheme. From the above table it is clear that as the dimensionality of the problem increases, adaptive method proves more and more useful compared to the other two algorithms.

We also compared our method with the method proposed in (Mukherjee, Wu and Zhou, 2010) (See Figure 11). The function in (15) is used for the comparison with $n = 10000$ and $s = 50$. Figure 12 is a scaled down version with $n = 10000, s = 100$ and $m = 500$. Number of samples for the SGL method were 10, chosen with neighbourhood radius 0.05.

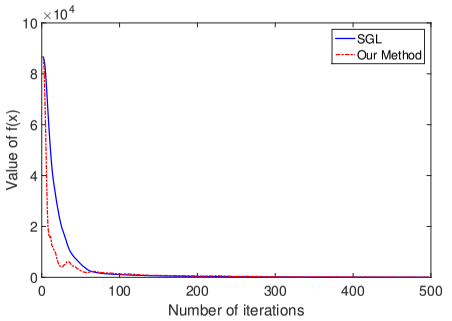

Figure 11: Comparison of Gradient descent using estimated gradient from proposed method vs the SGL method proposed in (Mukherjee, Wu and Zhou, 2010). Here, $n = 10000, s = 50$ and $m = 500$. Number of samples for the SGL method = 10.

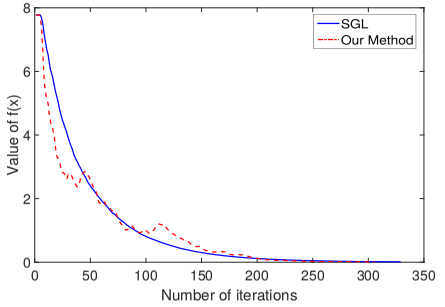

Figure 12: Comparison of Gradient descent using estimated gradient from proposed method vs the SGL method proposed in (Mukherjee, Wu and Zhou, 2010). Here, $n = 10000, s = 100$ and $m = 500$. Number of samples for the SGL method = 10.

The time taken by the SGL method and our method was 993 and 83 seconds respectively. As mentioned earlier, the aim of this paper is to provide a good estimation of gradient when the function evaluations are expensive. In such cases, our method would provide a significant gain in terms of function evaluations needed. While in this example we do see a significant improvement in time taken for the estimation, there is no a priori reason to always expect it. It will indeed be the case when the function evaluations are 'expensive' in terms of the time they take. One expects this to be so when the ambient dimension is high.

3.3.1 An Example: Longitude Estimation

In this section, we test our method on real data. Gradient estimation technique proposed in this paper is applied on UJIIndoorLoc Data Set (Torres-Sospedra et. al, 2014) to estimate the longitude information from signal strengths of 520 wireless access points. The Data-set has 19937 samples for training and 1111 samples for testing. We assume that longitude l is linearly dependent on signal strengths of access points x. Let $\theta \in \mathbb{R}^n$ be the vector assigning weights of signal strengths to each access points. Then, $l(\theta) = \theta^T x$. We recover θ by minimizing regularized l_1 norm of the error:

$$f(\theta) = \sum_{i=1}^{M} \frac{1}{M} \|l_{actual} - l(\theta)\|_1 + \lambda \|\theta\|$$

where, l_{actual} denotes the actual longitude. In this example, $M = 19937$, $n = 520$ and $m = 100$, where m is as in theorem 2.3.

Note that we do not have a closed form expression for the gradient of $f(\theta)$. We compare the proposed method with Spall's SPSA. Parameters like k (number of trials of SP) and iteration for l_1 minimization are chosen so that both methods converge empirically in least number of iterations. Taking into account the higher error in SPSA, we take number of trials of SP to be 20 for Spall's SPSA and 10 for our method. Maximum number of iterations in Homotopy method are limited to 50.

Algorithm:	Proposed Method	Spall's SPSA
Mean percentage error on training data	5.43	5.54
Mean percentage error on test data	5.55	5.48
Time taken to train (sec)	16.77	84.81

We can see that both methods obtain similar performance but the method proposed in this paper is much faster. Figure 13 shows the training performance of both methods. Figures 14, 15 show percentage error in reconstruction of training and test data respectively. Percentage error is sorted for better visualization.

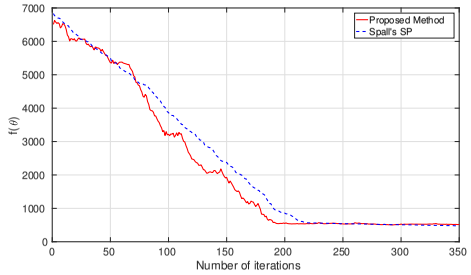

Figure 13: Optimizing $f(\theta)$ using Spall's SPSA and proposed method.

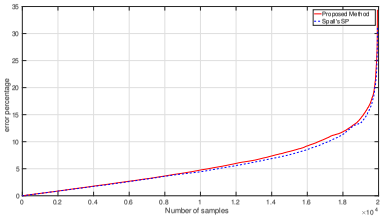

Figure 14: Sorted percentage error on train data.

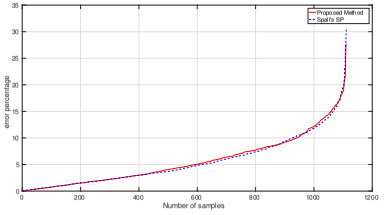

Figure 15: Sorted percentage error on test data.

4. Concluding remarks

We have proposed an estimation scheme for gradient in high dimensions that combines ideas from Spall's SPSA with compressive sensing and thereby tries to economize on the number of function evaluations. This has theoretical justification by the results of (Austin, 2016). Our method can be extremely useful when the function evaluation is very expensive, e.g., when a single evaluation is the output of a long simulation. This situation does not seem to have been addressed much in literature. In very high dimensional problems with sparse gradient, computing estimates for partial derivatives in every direction is inefficient because of the large number of function evaluations needed. SP simplifies the problem of repeated function evaluation by concentrating on a single *random* direction at each step. When the gradient vectors in such cases live in a lower dimensional subspace, it also makes sense to exploit ideas from compressive sensing. We have computed the error bound in this case and have also shown theoretically that this kind of estimation of gradient works well with high probability for the gradient descent problems and in other high dimensional problems such as estimating EGOP in manifold learning where gradients are actually low-dimensional and gradient estimation is relevant. Simulations show that our method works much better than pure SP.

Acknowledgments

We thank GPU Centre of Excellence, IIT Bombay for providing us with the facility to carry out simulations and Prof. Chandra Murthy of Indian Institute of Science for helpful discussions regarding compressive sensing.

Editor: David Blei

Abstract

Latent Dirichlet Allocation (LDA) is a well known topic model that is often used to make inference regarding the properties of collections of text documents. LDA is a hierarchical Bayesian model, and involves a prior distribution on a set of latent topic variables. The prior is indexed by certain hyperparameters, and even though these have a large impact on inference, they are usually chosen either in an ad-hoc manner, or by applying an algorithm whose theoretical basis has not been firmly established. We present a method, based on a combination of Markov chain Monte Carlo and importance sampling, for estimating the maximum likelihood estimate of the hyperparameters. The method may be viewed as a computational scheme for implementation of an empirical Bayes analysis. It comes with theoretical guarantees, and a key feature of our approach is that we provide theoretically-valid error margins for our estimates. Experiments on both synthetic and real data show good performance of our methodology.

Keywords: Empirical Bayes inference, latent Dirichlet allocation, Markov chain Monte Carlo, model selection, topic modelling.

1. Introduction

Latent Dirichlet Allocation (LDA, Blei et al. 2003) is a model that is used to describe high-dimensional sparse count data represented by feature counts. Although the model can be applied to many different kinds of data, for example collections of annotated images and social networks, for the sake of concreteness, here we focus on data consisting of a collection of documents. Suppose we have a corpus of documents, say a collection of news articles, and these span several different topics, such as sports, medicine, politics, etc. We imagine that for each word in each document, there is a latent (i.e. unobserved) variable indicating a topic from which that word is drawn. There are several goals, but two principal ones are to recover an interpretable set of topics, and to make inference on the latent topic variables for each document.

To describe the LDA model, we first set up some terminology and notation. There is a vocabulary $\mathcal{V}$ of V words; typically, this is taken to be the union of all the words in all the documents of the corpus, after removing stop (i.e. uninformative) words. (Throughout, we use "word" to refer to either an actual word, or to a phrase, such as "heart attack"; LDA has implementations that deal with each of these.) There are D documents in the corpus, and for $d = 1, \ldots, D$, document d has n_d words, $w_{d1}, \ldots, w_{dn_d}$. The order of the words is considered uninformative, and so is neglected. Each word is represented as an index vector of dimension V with a 1 at the s^{th} element, where s denotes the term selected from the vocabulary. Thus, document d is represented by the matrix $\boldsymbol{w}_d = (w_{d1}, \ldots, w_{dn_d})$ and the corpus is represented by the list $\boldsymbol{w} = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_D)$. The number of topics, K, is finite and known. By definition, a topic is a distribution over $\mathcal{V}$, i.e. a point in the simplex $\mathbb{S}_V = \{a \in \mathbb{R}^V : a_1, \ldots, a_V \geq 0, \sum_{j=1}^V a_j = 1\}$. For $d = 1, \ldots, D$, for each word w_{di}, z_{di} is an index vector of dimension K which represents the latent variable that denotes the topic from which w_{di} is drawn. The distribution of $z_{d1}, \ldots, z_{dn_d}$ will depend on a document-specific variable θ_d which indicates a distribution on the topics for document d.

We will use $\mathrm{Dir}_L(a_1, \ldots, a_L)$ to denote the finite-dimensional Dirichlet distribution on the simplex $\mathbb{S}_L$. Also, we will use $\mathrm{Mult}_L(b_1, \ldots, b_L)$ to denote the multinomial distribution with number of trials equal to 1 and probability vector $(b_1, \ldots, b_L)$. We will form a $K \times V$ matrix $\boldsymbol{\beta}$, whose t^{th} row is the t^{th} topic (how $\boldsymbol{\beta}$ is formed will be described shortly). Thus, $\boldsymbol{\beta}$ will consist of vectors $\beta_1, \ldots, \beta_K$, all lying in $\mathbb{S}_V$. The LDA model is indexed by hyperparameters $\eta \in (0, \infty)$ and $\boldsymbol{\alpha} \in (0, \infty)^K$. It is represented graphically in Figure 1, and described formally by the following hierarchical model:

1. $\beta_t \overset{\text{iid}}{\sim} \mathrm{Dir}_V(\eta, \ldots, \eta)$, $t = 1, \ldots, K$.
2. $\theta_d \overset{\text{iid}}{\sim} \mathrm{Dir}_K(\boldsymbol{\alpha})$, $d = 1, \ldots, D$, and the θ_d's are independent of the β_t's.
3. Given $\theta_1, \ldots, \theta_D$, $z_{di} \overset{\text{iid}}{\sim} \mathrm{Mult}_K(\theta_d)$, $i = 1, \ldots, n_d$, $d = 1, \ldots, D$, and the D matrices $(z_{11}, \ldots, z_{1n_1}), \ldots, (z_{D1}, \ldots, z_{Dn_D})$ are independent.
4. Given $\boldsymbol{\beta}$ and the z_{di}'s, the w_{di}'s are independently drawn from the row of $\boldsymbol{\beta}$ indicated by z_{di}, $i = 1, \ldots, n_d$, $d = 1, \ldots, D$.

From the description of the model, we see that there is a latent topic variable for every word that appears in the corpus. Thus it is possible that a document spans several topics. Also, because $\boldsymbol{\beta}$ is chosen once, at the top of the hierarchy, it is shared among the D documents. Thus the model encourages different documents to share the same topics, and moreover, all the documents in the corpus share a single set of topics defined by $\boldsymbol{\beta}$.

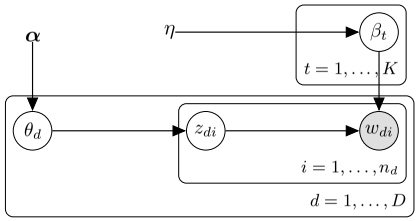

Figure 1: Graphical model representation for LDA. Nodes denote random variables, shaded nodes denote observed variables, edges denote conditional dependencies, and plates denote replicated processes.

Let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_D)$, $\boldsymbol{z}_d = (z_{d1}, \ldots, z_{dn_d})$ for $d = 1, \ldots, D$, $\boldsymbol{z} = (\boldsymbol{z}_1, \ldots, \boldsymbol{z}_D)$, and let $\boldsymbol{\psi} = (\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z})$. The model is indexed by the hyperparameter vector $h = (\eta, \boldsymbol{\alpha}) \in (0, \infty)^{K+1}$. For any given h, lines 1–3 induce a prior distribution on $\boldsymbol{\psi}$, which we will denote by ν_h. Line 4 gives the likelihood. The words $\boldsymbol{w}$ are observed, and we are interested in $\nu_{h,\boldsymbol{w}}$, the posterior distribution of $\boldsymbol{\psi}$ given $\boldsymbol{w}$ corresponding to ν_h. In step 2 it is common to take the distribution of the θ_d's to

be a symmetric Dirichlet, although arbitrary Dirichlets are sometimes used. Our model allows for arbitrary Dirichlets, for the sake of generality, but in all our examples we use symmetric Dirichlets because a high-dimensional hyperparameter can cause serious problems. We return to this point at the end of Section 2.1.

The hyperparameter vector h is not random, and must be selected in advance. It has a strong effect on the distribution of the parameters of the model. For example, when η is large, the topics tend to be probability vectors which spread their mass evenly among many words in the vocabulary, whereas when η is small, the topics tend to put most of their mass on only a few words. Also, in the special case where $\boldsymbol{\alpha} = (\alpha, \ldots, \alpha)$, so that $\mathrm{Dir}_K(\boldsymbol{\alpha})$ is a symmetric Dirichlet indexed by the single parameter α, when α is large, each document tends to involve many different topics; on the other hand, in the limiting case where $\alpha \to 0$, each document involves a single topic, and this topic is randomly chosen from the set of all topics.

The preceding paragraph is about the effect of h on the prior distribution of the parameters. We may think about the role of h on statistical inference by considering posterior distributions. Let g be a function of the parameter $\boldsymbol{\psi}$. For example, $g(\boldsymbol{\psi})$ might be the indicator of the event $\|\theta_i - \theta_j\| \leq \epsilon$, where i and j are the indices of two particular documents, ϵ is some user-specified small number, and $\|\cdot\|$ denotes ordinary Euclidean distance in $\mathbb{R}^K$. In this case, the value of $g(\boldsymbol{\psi})$ gives a way of determining whether the topics for documents i and j are nearly the same ($g(\boldsymbol{\psi}) = 1$), or not ($g(\boldsymbol{\psi}) = 0$). Of interest then is the posterior probability $\nu_{h,\boldsymbol{w}}(\|\theta_i - \theta_j\| \leq \epsilon)$, which is given by the integral $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$. In another example, the function g might be taken to measure the distance between two topics of interest. In Section 2.4 we demonstrate empirically that the posterior expectation given by the integral $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ can vary considerably with h.

To summarize: the hyperparameter h can have a strong effect not only on the prior distribution of the parameters in the model, but also on their posterior distribution; therefore it is important to choose it carefully. Yet in spite of the very widespread use of LDA, there is no method for choosing the hyperparameter that has a firm theoretical basis. In the literature, h is sometimes selected in some ad-hoc or arbitrary manner. A principled way of selecting it is via maximum likelihood: we let $m_{\boldsymbol{w}}(h)$ denote the marginal likelihood of the data as a function of h, and use $\hat{h} = \arg\max_h m_{\boldsymbol{w}}(h)$ which is, by definition, the empirical Bayes choice of h. We will write $m(h)$ instead of $m_{\boldsymbol{w}}(h)$ unless we need to emphasize the dependence on $\boldsymbol{w}$. Unfortunately, the function $m(h)$ is analytically intractable: $m(h)$ is the likelihood of the data with all latent variables integrated or summed out, and from the hierarchical nature of the model, we see that $m(h)$ is a very large sum, because we are summing over all possible values of $\boldsymbol{z}$. Blei et al. (2003) propose estimating $\arg\max_h m(h)$ via a combination of the EM algorithm and "variational inference" (VI-EM). Very briefly, $\boldsymbol{w}$ is viewed as "observed data," and $\boldsymbol{\psi}$ is viewed as "missing data." Because the "complete data likelihood" $p_h(\boldsymbol{\psi}, \boldsymbol{w})$ is available, the EM algorithm is a natural candidate for estimating $\arg\max_h m(h)$, since $m(h)$ is the "incomplete data likelihood." But the E-step in the algorithm is infeasible because it requires calculating an expectation with respect to the intractable distribution $\nu_{h,\boldsymbol{w}}$. Blei et al. (2003) substitute an approximation to this expectation. Unfortunately, because there are no useful bounds on the approximation, and because the approximation is used at every iteration of the algorithm, there are no results regarding the theoretical properties of this method. Wallach (2006) (see also Wallach (2008)) proposed a "Gibbs-EM" algorithm, in which the E-step is approximated by a Markov chain Monte Carlo estimate. This method can perform well empirically but, as for the VI-EM algorithm, its theoretical validity has not been established. The

advantages and disadvantages of these two approximations to the EM algorithm are discussed in Section 5.1.

Wallach et al. (2009) give an overview of a class of methods for estimating a combination of some parameter components and some hyperparameter components and, in principle, these procedures could be adapted to the problem of estimating h. The methods they present differ from EM-based approaches in two fundamental respects: (1) they work with an objective function which is not the marginal likelihood function $m(h)$, but rather a measure of the "predictive performance of the LDA model indexed by h," and (2) evaluation of their objective function at hyperparameter value h requires running a Markov chain, and this has to be done "for each value of h" before doing the maximization of the objective function, which can impose a heavy computational burden. This paper is discussed further in Section 5.

Another approach for dealing with the problem of having to make a choice of the hyperparameter vector is the fully Bayes approach, in which we simply put a prior on the hyperparameter vector, that is, add one layer to the hierarchical model. For example, we can either put a flat prior on each component of the hyperparameter, or put a gamma prior instead. While this approach can be useful, there are reasons why one may want to avoid it. On the one hand, if we put a flat prior then one problem is that we are effectively skewing the results towards large values of the hyperparameter components. A more serious problem is that the posterior may be improper. In this case, insidiously, if we use Gibbs sampling to estimate the posterior, it is possible that all conditionals needed to implement the sampler are proper; but Hobert and Casella (1996) have shown that the Gibbs sampler output may not give a clue that there is a problem. On the other hand, if we use a gamma prior, then at least in the case of a symmetric Dirichlet on the θ_d's, we have not made things any easier: we have to specify four gamma hyperparameters. Another reason to avoid the fully Bayes approach is that, in broad terms, the general interest in empirical Bayes methods arises in part from a desire to select a specific value of the hyperparameter vector because this gives a model that is more parsimonious and interpretable. This point is discussed more fully (in a general context) in George and Foster (2000) and Robert (2001, Chapter 7).

In the present paper we show that while it is not possible to compute $m(h)$ itself, it is nevertheless possible, with a single MCMC run, to estimate the entire function $m(h)$ up to a multiplicative constant. Before proceeding, we note that if c is a constant, then the information regarding h given by the two functions $m(h)$ and $cm(h)$ is the same: the same value of h maximizes both functions, and the second derivative matrices of the logarithm of these two functions are identical. In particular, the Hessians of the logarithm of these two functions at the maximum (i.e. the observed Fisher information) are the same and, therefore, the standard point estimates and confidence regions based on $m(h)$ and $cm(h)$ are identical. Let g be a function of $\boldsymbol{\psi}$ and let $I(h) = \int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ denote the posterior expectation of $g(\boldsymbol{\psi})$. We also show that it is possible to estimate the entire function $I(h)$ with a single MCMC run.

As we will see in Section 2, our approach for estimating $m(h)$ up to a single multiplicative constant and $I(h)$ has two requirements: (i) we need a formula for the ratio $\nu_{h_1}(\boldsymbol{\psi})/\nu_{h_2}(\boldsymbol{\psi})$ for any two hyperparameter values h_1 and h_2, and (ii) for any hyperparameter value h, we need an ergodic Markov chain whose invariant distribution is the posterior $\nu_{h,\boldsymbol{w}}$. This paper is organized as follows. In Section 2 we explain our method for estimating the function $m(h)$ up to a single multiplicative constant (and hence its argmax) and for estimating the family of posterior expectations $\{I(h),\, h \in \mathcal{H}\}$; and we also explain how to form error margins for our estimates, paying particular attention to theoretical underpinnings. Additionally, we provide the formula for the ratio $\nu_{h_1}(\boldsymbol{\psi})/\nu_{h_2}(\boldsymbol{\psi})$.

In Section 3 we consider synthetic data sets generated from a simple model in which h is low dimensional and known, and we show that our method correctly estimates the true value of h. In Section 4 we describe two Markov chains which satisfy requirement (ii) above. In Section 5 we compare, both theoretically and empirically, the various methods of estimating the maximizer of the marginal likelihood function, in terms of accuracy. Then we compare the various choices of the hyperparameter that are used in the literature—those that are ad-hoc and those that estimate the maximizer of the marginal likelihood function—through a standard criterion that is used to evaluate topic models, and we show that our method performs favorably. In Section 6 we make some concluding remarks, and the Appendix contains some of the technical material that is needed in the paper.

2. Estimation of the Marginal Likelihood up to a Multiplicative Constant and Estimation of Posterior Expectations

This section consists of four parts. In Section 2.1 we show how the marginal likelihood function can be estimated (up to a constant) with a single MCMC run. Section 2.2 concerns estimation of the posterior expectation of a function g of the parameter $\boldsymbol{\psi}$, given by the integral $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$, and which depends on h. We show how the entire family of posterior expectations $\{I(h),\, h \in \mathcal{H}\}$ can be estimated with a single MCMC run. In Section 2.3 we explain that the simple estimates given in Sections 2.1 and 2.2 can have large variances, and we present estimates which are far more reliable. In Section 2.4 we illustrate our methodology on a corpus created from Wikipedia.

Let $\mathcal{H} = (0, \infty)^{K+1}$ be the hyperparameter space. For any $h \in \mathcal{H}$, ν_h and $\nu_{h,\boldsymbol{w}}$ are prior and posterior distributions, respectively, of the vector $\boldsymbol{\psi} = (\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z})$, for which some components are continuous and some are discrete. We will use $\ell_{\boldsymbol{w}}(\boldsymbol{\psi})$ to denote the likelihood function (which is given by line 4 of the LDA model).

2.1 Estimation of the Marginal Likelihood up to a Multiplicative Constant

Note that $m(h)$ is the normalizing constant in the statement "the posterior is proportional to the likelihood times the prior," i.e.

$$\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}) = \frac{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})}{m(h)}.$$

Now suppose that we have a method for constructing a Markov chain on $\boldsymbol{\psi}$ whose invariant distribution is $\nu_{h,\boldsymbol{w}}$ and which is ergodic. Two Markov chains which satisfy these criteria are discussed in later in this section. Let $h_* \in \mathcal{H}$ be fixed but arbitrary, and let $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots$ be an ergodic Markov chain with invariant distribution $\nu_{h*,\boldsymbol{w}}$. For any $h \in \mathcal{H}$, as $n \to \infty$ we have

$$\begin{aligned}
\frac{1}{n}\sum_{i=1}^{n} \frac{\nu_h(\boldsymbol{\psi}_i)}{\nu_{h_*}(\boldsymbol{\psi}_i)} &\xrightarrow{\text{a.s.}} \int \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) \\
&= \frac{m(h)}{m(h_*)} \int \frac{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})/m(h)}{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_{h_*}(\boldsymbol{\psi})/m(h_*)}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) \\
&= \frac{m(h)}{m(h_*)} \int \frac{\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})}{\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) \\
&= \frac{m(h)}{m(h_*)}.
\end{aligned} \tag{2.1}$$

The almost sure convergence statement in (2.1) follows from ergodicity of the chain. (There is a slight abuse of notation in (2.1) in that we have used $\nu_{h_*,\boldsymbol{w}}$ to denote a probability measure when we write $d\nu_{h_*,\boldsymbol{w}}$, whereas in the integrand, ν_h, ν_{h_*}, and $\nu_{h_*,\boldsymbol{w}}$ refer to probability densities.) The significance of (2.1) is that this result shows that we can estimate the entire family $\{m(h)/m(h_*),\, h \in \mathcal{H}\}$ with a single Markov chain run. Since $m(h_*)$ is a constant, the remarks made in Section 1 apply, and we can estimate $\arg\max_h m(h)$. The usefulness of (2.1) stems from the fact that the average on the left side involves *only the priors*, so we effectively bypass having to deal with the posterior distributions.

The development in (2.1) is not new (although we do not know who first noticed it), and the estimate on the left side of (2.1) is not the one we will ultimately use (cf. Section 2.3); we present (2.1) primarily for motivation. Note that (2.1) is generic, i.e. it is not specific to the LDA model: it is potentially valid for any Bayesian model for which we have a data vector $\boldsymbol{w}$, a corresponding likelihood function $\ell_{\boldsymbol{w}}(\boldsymbol{\psi})$, and parameter vector $\boldsymbol{\psi}$ having prior ν_h, with hyperparameter $h \in \mathcal{H}$. We now discuss carefully the scope of its applicability. In order to be able to use (2.1) to obtain valid estimators of the family $m(h)/m(h_*),\, h \in \mathcal{H}$, we need the following.

C1 A closed-form expression for the ratio of densities $\nu_h(\boldsymbol{\psi})/\nu_{h_*}(\boldsymbol{\psi})$ for some fixed $h_* \in \mathcal{H}$.

C2 A method for generating an ergodic Markov chain with invariant distribution $\nu_{h_*,\boldsymbol{w}}$.

We need C1 in order to write down the estimators, and we need C2 for the estimators to be valid.

For notational convenience, let $B_n(h) = (1/n)\sum_{i=1}^{n}[\nu_h(\boldsymbol{\psi}_i)/\nu_{h_*}(\boldsymbol{\psi}_i)]$, and define $B(h) = m(h)/m(h_*)$. In order to use (2.1) to obtain a valid estimator, together with a confidence interval (confidence set, if $\dim(h) > 1$) for $\arg\max_h m(h)$, we need in addition the following.

C3 A result that says that the convergence in the first line of (2.1) is uniform in h.

C4 A result that says that if $G_n(h)$ is the centered and scaled version of the estimate on the left side of (2.1) given by $G_n(h) = n^{1/2}(B_n(h) - B(h))$, then $G_n(\cdot)$ converges in distribution to a Gaussian process indexed by h.

We now explain these last two conditions. Generally speaking, for real-valued functions f_n and f defined on $\mathcal{H}$, the pointwise convergence condition $f_n(h) \to f(h)$ for each $h \in \mathcal{H}$ does not imply that $\arg\max_h f_n(h) \to \arg\max_h f(h)$. Indeed, counterexamples are easy to construct, and in Section A.2 of the Appendix we provide a simple one. In order to be able to conclude that $\arg\max_h f_n(h) \to \arg\max_h f(h)$, which is a global condition, we need the convergence of f_n to f to be uniform (this is discussed rigorously in Section A.2 of the Appendix). Hence we need C3. Regarding confidence intervals (or sets) for $\arg\max_h f(h)$, we note that $B_n(h)$ is simply an average, and so under suitable regularity conditions, it satisfies a central limit theorem (CLT). However, we are not interested in a central limit theorem for $B_n(h)$, but rather in a CLT for $\arg\max_h B_n(h)$. In this regard, C4 is a "uniform in h CLT" that is necessary to obtain a CLT of the form $n^{1/2}(\arg\max_h B_n(h) - \arg\max_h B(h)) \xrightarrow{d} \mathcal{N}(0, \Sigma)$ for some positive definite matrix Σ, which is what is needed to form confidence sets for $\arg\max_h B(h)$. Again, this is discussed rigorously in Section A.2 of the Appendix.

We now discuss Conditions C1–C4. Condition C1 is satisfied by the LDA model, and in Section A.1 of the Appendix we show that the ratio of densities ν_h/ν_{h_*} is given by

$$\frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})} = \left[\prod_{d=1}^{D}\left(\frac{\Gamma\left(\sum_{j=1}^K \alpha_j\right)}{\prod_{j=1}^K \Gamma(\alpha_j)}\frac{\prod_{j=1}^K \Gamma(\alpha_j^*)}{\Gamma\left(\sum_{j=1}^K \alpha_j^*\right)}\prod_{j=1}^K \theta_{dj}^{\alpha_j-\alpha_j^*}\right)\right]\left[\prod_{j=1}^K\left(\frac{\Gamma(V\eta)}{\Gamma(\eta)^V}\frac{\Gamma(\eta^*)^V}{\Gamma(V\eta^*)}\prod_{t=1}^V \beta_{jt}^{\eta-\eta^*}\right)\right], \tag{2.2}$$

where $h_* = (\eta^*, \boldsymbol{\alpha}^*)$.

There are many extensions and variants of the LDA model described in Section 1—too many to even list them all here—and versions of (2.2) can be obtained for these models. This has to be done separately for each case. The features of the LDA model that make it possible to obtain a ratio of densities formula are that it is a hierarchical model, and at every stage the distributions are explicitly finite dimensional. For other models, a ratio of densities formula is obtainable routinely as long as these features exist: when they do, we have a closed-form expression for the prior distribution $\nu_h(\boldsymbol{\psi})$, and hence a closed-form expression for the ratio $\nu_h(\boldsymbol{\psi})/\nu_{h_*}(\boldsymbol{\psi})$.

Unfortunately, a ratio of densities formula is not always available. A prominent example is the "Hierarchical Dirichlet Processes" model introduced in Teh et al. (2006), which effectively allows infinitely many topics but with finitely many realized in any given document. Very briefly, in this model, for word i in document d, there is an unobserved topic ψ_{di}. The latent topic vector $\boldsymbol{\psi}_d = (\psi_{d1}, \ldots, \psi_{dn_d})$ has a complicated joint distribution with strength of dependence governed by a hyperparameter h_1 (the precision parameter of the Dirichlet process in the middle of the hierarchy), and the D vectors $\boldsymbol{\psi}_1, \ldots, \boldsymbol{\psi}_D$ also have a complicated dependence structure, with strength of dependence governed by a hyperparameter h_2 (the precision parameter of the Dirichlet process at the top of the hierarchy). The parameter vector for the model is $\boldsymbol{\psi} = (\boldsymbol{\psi}_1, \ldots, \boldsymbol{\psi}_D)$ and the hyperparameter is $h = (h_1, h_2)$. Unfortunately, the joint (prior) distribution of $\boldsymbol{\psi}$ is not available in closed form, and our efforts to obtain a formula for $\nu_h(\boldsymbol{\psi})/\nu_{h_*}(\boldsymbol{\psi})$ have been fruitless.

Regarding Condition C2, we note that Griffiths and Steyvers have developed a "collapsed Gibbs sampler" (CGS) which runs over the vector $\boldsymbol{z}$. The invariant distribution of the CGS is the conditional distribution of $\boldsymbol{z}$ given $\boldsymbol{w}$. The CGS cannot be used directly, because to apply (2.1) we need a Markov chain on the triple $(\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z})$, whose invariant distribution is $\nu_{h_*,\boldsymbol{w}}$. In Section 4 we obtain the conditional distribution of $(\boldsymbol{\beta}, \boldsymbol{\theta})$ given $\boldsymbol{z}$ and $\boldsymbol{w}$, and we show how to sample from this distribution. Therefore, given a Markov chain $\boldsymbol{z}^{(1)}, \ldots, \boldsymbol{z}^{(n)}$ generated via the CGS, we can form triples $(\boldsymbol{z}^{(1)}, \boldsymbol{\beta}^{(1)}, \boldsymbol{\theta}^{(1)}), \ldots, (\boldsymbol{z}^{(n)}, \boldsymbol{\beta}^{(n)}, \boldsymbol{\theta}^{(n)})$, and it is easy to see that this sequence forms a Markov chain with invariant distribution $\nu_{h_*,\boldsymbol{w}}$. We will refer to this Markov chain as the Augmented Collapsed Gibbs Sampler, and use the acronym ACGS. In Section 4 we show that the ACGS is not only geometrically ergodic, but actually is uniformly ergodic. We also show how to sample from the conditional distribution of $\boldsymbol{z}$ given $(\boldsymbol{\beta}, \boldsymbol{\theta})$ and $\boldsymbol{w}$. This enables us to construct a two-cycle Gibbs sampler which runs on the pair $(\boldsymbol{z}, (\boldsymbol{\beta}, \boldsymbol{\theta}))$. We will refer to this chain as the Grouped Gibbs Sampler, and use the acronym GGS. Either the ACGS or the GGS may be used, and we see that Condition C2 is satisfied for the LDA model.

The theorem below pertains to the LDA model and states that for this model, $\arg\max_h B_n(h)$ converges to $\arg\max_h m(h)$ almost surely, and that $\arg\max_h B_n(h)$ satisfies a CLT. The theorem also gives a procedure for constructing confidence sets for $\arg\max_h m(h)$. The result is explicit. Therefore, given a desired level of precision, we can determine the Markov chain length needed to estimate $\arg\max_h m(h)$ with that level of precision. The proof of the theorem is in Section A.2 of the Appendix. The theorem is valid under some natural and mild regularity conditions which

are given in the Appendix. (We have relegated the regularity conditions and a discussion of their significance to the Appendix in order to avoid making the present section too technical.) Let p be the dimension of h. So $p = 2$ if we take the distribution of the θ_d's to be a symmetric Dirichlet, and $p = K + 1$ if we allow this distribution to be an arbitrary Dirichlet.

Theorem 1 *Let $\psi_1, \psi_2, \ldots$ be generated according to the Augmented Collapsed Gibbs Sampling algorithm described above, let $B_n(h)$ be the estimate on the left side of* (2.1)*, and assume that Conditions A1–A6 in Section A.2 of the Appendix hold. Then:*

1. $\arg\max_h B_n(h) \xrightarrow{a.s.} \arg\max_h m(h)$.
2. $n^{1/2}\big(\arg\max_h B_n(h) - \arg\max_h m(h)\big) \xrightarrow{d} \mathcal{N}_p(0, \Sigma)$ *for some positive definite matrix* Σ.
3. *Let $\widehat{\Sigma}_n$ be the estimate of Σ obtained by the method of batching described in Section A.2 of the Appendix. Then $\widehat{\Sigma}_n \xrightarrow{a.s.} \Sigma$, and in particular $\widehat{\Sigma}_n$ is invertible for large n. Consequently, the ellipse $\mathcal{E}$ given by*

$$\mathcal{E} = \big\{h : (\arg\max_u B_n(u) - h)^\top \widehat{\Sigma}_n^{-1} (\arg\max_u B_n(u) - h) \le \chi^2_{p,.95}/n\big\}$$

is an asymptotic 95% confidence set for $\arg\max_h m(h)$. Here, $\chi^2_{p,.95}$ denotes the .95 quantile of the chi-square distribution with p degrees of freedom.

Remark 2 *The mathematical development in the proof requires a stipulation (Condition A5) which says that the distinguished point h_* is not quite arbitrary: if we specify $\mathcal{H} = [\eta^{(L)}, \eta^{(U)}] \times [\alpha_1^{(L)}, \alpha_1^{(U)}] \times \cdots \times [\alpha_K^{(L)}, \alpha_K^{(U)}]$, then h_* must satisfy*

$$\eta^* < 2\eta^{(L)} \quad \text{and} \quad \alpha_j^* < 2\alpha_j^{(L)},\ j = 1, \ldots, K. \tag{2.3}$$

(Condition (2.3) *is replaced by the obvious simpler analogue in the case of symmetric Dirichlets.) Thus, Condition A5 provides guidelines regarding the user-selected value of h_*.*

Remark 3 *Part 3 suggests that one should not use arbitrary Dirichlets when K is large. The ellipse is centered at $\arg\max_u B_n(u)$ and the lengths of its principal axes are governed by the term $\chi^2_{p,.95}$. When $p = K + 1$ and K is large, $\chi^2_{K+1,.95}$ is on the order of $K + 1$, and the confidence set for the empirical Bayes estimate of h is then huge. In other words, when we use an arbitrary Dirichlet, our estimates are very inaccurate.*

Actually, the problem that arises when $\dim(h) = K$ is not limited to our Monte Carlo scheme for estimating $\arg\max_h m(h)$. There is a fundamental problem, which has to do with the fact that there is not enough information in the corpus to estimate a high-dimensional h. Suppose we view the D documents as being drawn from some idealized population generated according to the LDA model indexed by h_0. Leaving aside computational issues, suppose we are able to calculate $\hat{h} = \arg\max_h m(h)$, the maximum likelihood estimate of h_0, to infinite accuracy. Standard asymptotics give $D^{1/2}(\hat{h} - h_0) \xrightarrow{d} \mathcal{N}_p(0, \Omega^{-1})$ as $D \to \infty$, where Ω is the Fisher information matrix. Therefore, a 95% confidence set for h_0 is given by the ellipse $\big\{h : (\hat{h} - h)^\top \Omega (\hat{h} - h) \le \chi^2_{K+1,.95}/D\big\}$, and we see that for high-dimensional h, D must be very large for us to be able to accurately estimate h_0.

2.2 Estimation of the Family of Posterior Expectations

Let g be a function of $\boldsymbol{\psi}$, and let $I(h) = \int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ be the posterior expectation of $g(\boldsymbol{\psi})$ when the prior is ν_h. Suppose that we are interested in estimating $I(h)$ for all $h \in \mathcal{H}$. Proceeding as we did for estimation of the family of ratios $\{m(h)/m(h_*),\, h \in \mathcal{H}\}$, let $h_* \in \mathcal{H}$ be fixed but arbitrary, and let $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots$ be an ergodic Markov chain with invariant distribution $\nu_{h*,\boldsymbol{w}}$. To estimate $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$, the obvious approach is to write

$$\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}) = \int g(\boldsymbol{\psi}) \frac{\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})}{\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) \tag{2.4}$$

and then use the importance sampling estimate $(1/n)\sum_{i=1}^n g(\boldsymbol{\psi}_i)[\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}_i)/\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}_i)]$. This will not work because we do not know the normalizing constants for $\nu_{h,\boldsymbol{w}}$ and $\nu_{h_*,\boldsymbol{w}}$. This difficulty is handled by rewriting $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$, via (2.4), as

$$\begin{aligned}
\int g(\boldsymbol{\psi}) \frac{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})/m(h)}{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_{h_*}(\boldsymbol{\psi})/m(h_*)}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) &= \frac{m(h_*)}{m(h)} \int g(\boldsymbol{\psi}) \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi}) \\
&= \frac{\frac{m(h_*)}{m(h)} \int g(\boldsymbol{\psi}) \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})}{\frac{m(h_*)}{m(h)} \int \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})} \qquad (2.5a) \\
&= \frac{\int g(\boldsymbol{\psi}) \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})}{\int \frac{\nu_h(\boldsymbol{\psi})}{\nu_{h_*}(\boldsymbol{\psi})}\, d\nu_{h_*,\boldsymbol{w}}(\boldsymbol{\psi})}, \qquad (2.5b)
\end{aligned}$$

where in (2.5a) we have used the fact that the integral in the denominator is just 1, in order to cancel the unknown constant $m(h_*)/m(h)$ in (2.5b). The idea to express $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ in this way was proposed in a different context by Hastings (1970). Expression (2.5b) is the ratio of two integrals with respect to $\nu_{h_*,\boldsymbol{w}}$, each of which may be estimated from the sequence $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots, \boldsymbol{\psi}_n$. We may estimate the numerator and the denominator by

$$\frac{1}{n}\sum_{i=1}^n g(\boldsymbol{\psi}_i)[\nu_h(\boldsymbol{\psi}_i)/\nu_{h_*}(\boldsymbol{\psi}_i)] \quad \text{and} \quad \frac{1}{n}\sum_{i=1}^n [\nu_h(\boldsymbol{\psi}_i)/\nu_{h_*}(\boldsymbol{\psi}_i)]$$

respectively. Thus, if we let

$$w_i^{(h)} = \frac{\nu_h(\boldsymbol{\psi}_i)/\nu_{h_*}(\boldsymbol{\psi}_i)}{\sum_{e=1}^n [\nu_h(\boldsymbol{\psi}_e)/\nu_{h_*}(\boldsymbol{\psi}_e)]},$$

then these are weights, and we see that the desired integral may be estimated by the weighted average

$$\hat{I}(h) = \sum_{i=1}^n g(\boldsymbol{\psi}_i) w_i^{(h)}. \tag{2.6}$$

The significance of this development is that it shows that with a single Markov chain run, we can estimate the entire family of posterior expectations $\{I(h),\, h \in \mathcal{H}\}$. As was the case for the estimate on the left side of (2.1), the estimate (2.6) is remarkable in its simplicity. To compute it, we need to know only the ratio of the *priors*, and not the posteriors.

2.3 Serial Tempering

Unfortunately, (2.6) suffers a serious defect: unless h is close to h_*, ν_h can be nearly singular with respect to ν_{h_*} over the region where the $\boldsymbol{\psi}_i$'s are likely to be, resulting in a very unstable estimate. A similar remark applies to the estimate on the left side of (2.1). In other words, there is effectively a "radius" around h_* within which one can safely move. To state the problem more explicitly: there does not exist a single h_* for which the ratios $\nu_h(\boldsymbol{\psi})/\nu_{h_*}(\boldsymbol{\psi})$ have small variance simultaneously for all $h \in \mathcal{H}$. One way of dealing with this problem is to select J fixed points $h_1, \ldots, h_J \in \mathcal{H}$ that "cover" $\mathcal{H}$ in the sense that for every $h \in \mathcal{H}$, ν_h is "close to" at least one of $\nu_{h_1}, \ldots, \nu_{h_J}$. We then replace ν_{h_*} in the denominator by $(1/J)\sum_{j=1}^J b_j \nu_{h_j}$, for some suitable choice of positive constants $b_1, \ldots, b_J$. Operating intuitively, we say that for any $h \in \mathcal{H}$, because there exists at least one j for which ν_h is close to ν_{h_j}, the variance of $\nu_h(\boldsymbol{\psi})/[(1/J)\sum_{j=1}^J b_j \nu_{h_j}(\boldsymbol{\psi})]$ is small; hence the variance of $\nu_h(\boldsymbol{\psi})/[(1/J)\sum_{j=1}^J b_j \nu_{h_j}(\boldsymbol{\psi})]$ is small simultaneously for all $h \in \mathcal{H}$. Whereas for the estimates (2.1) and (2.6) we need a Markov chain with invariant distribution is $\nu_{h*,\boldsymbol{w}}$, in the present situation we need a Markov chain whose invariant distribution is the mixture $(1/J)\sum_{j=1}^J \nu_{h_j,\boldsymbol{w}}$. This approach may be implemented by a methodology called serial tempering (Marinari and Parisi (1992); Geyer and Thompson (1995)), originally developed for the purpose of improving mixing rates of certain Markov chains that are used to simulate physical systems in statistical mechanics. However, it can be used for a very different purpose, namely to increase the range of values over which importance sampling estimates have small variance. We now summarize this methodology, in the present context, and show how it can be used to produce estimates that are stable over a wide range of h values. Our explanations are detailed, because the material is not trivial and because we wish to deal with estimates of both marginal likelihood and posterior expectations. The reader who is not interested in the detailed explanations can skip the rest of this subsection with no loss regarding understanding the rest of the material in this paper, and simply regard serial tempering as a black box that produces estimates of the marginal likelihood (up to a constant) and of posterior expectations (cf. (2.1) and (2.6)) that are stable over a wide h-region.

To simplify the discussion, suppose that in line 2 of the LDA model we take $\boldsymbol{\alpha} = (\alpha, \ldots, \alpha)$, i.e. $\mathrm{Dir}_K(\boldsymbol{\alpha})$ is a symmetric Dirichlet, so that $\mathcal{H}$ is effectively two-dimensional, and suppose that we take $\mathcal{H}$ to be a bounded set of the form $\mathcal{H} = [\eta_L, \eta_U] \times [\alpha_L, \alpha_U]$. Our goal is to generate a Markov chain with invariant distribution $(1/J)\sum_{j=1}^J \nu_{h_j,\boldsymbol{w}}$. The updates will sample different components of this mixture, with jumps from one component to another. We now describe this carefully. Let Ψ denote the state space for $\boldsymbol{\psi}$. Recall that $\boldsymbol{\psi}$ has some continuous components and some discrete components. To proceed rigorously, we will take ν_h and $\nu_{h,\boldsymbol{w}}$ to all be densities with respect to a measure μ on Ψ. Define $\mathcal{L} = \{1, \ldots, J\}$, and for $j \in \mathcal{L}$, suppose that Φ_j is a Markov transition function on Ψ with invariant distribution equal to the posterior $\nu_{h_j,\boldsymbol{w}}$. On occasion we will write ν_j instead of ν_{h_j}. This notation is somewhat inconsistent, but we use it in order to avoid having double and triple subscripts. We have $\nu_{h,\boldsymbol{w}} = \ell_{\boldsymbol{w}}\, \nu_h/m(h)$ and $\nu_{h_j,\boldsymbol{w}} = \ell_{\boldsymbol{w}}\, \nu_j/m(h_j)$, $j = 1, \ldots, J$.

Serial tempering involves considering the state space $\mathcal{L} \times \Psi$, and forming the family of distributions $\{P_\zeta,\, \zeta \in \mathbb{R}^J\}$ on $\mathcal{L} \times \Psi$ with densities

$$p_\zeta(j, \boldsymbol{\psi}) \propto \ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_j(\boldsymbol{\psi})/\zeta_j. \tag{2.7}$$

(To be pedantic, these are densities with respect to $\mu \times \sigma$, where σ is counting measure on $\mathcal{L}$.) The vector ζ is a tuning parameter, which we discuss shortly. For any value of ζ, by standard methods involving the Metropolis-Hastings algorithm, we can generate a Markov chain having invariant dis-

tribution equal to (2.7). If we take $\zeta_j = am(h_j)$ for $j = 1, \ldots, J$, where a is an arbitrary constant, then the ψ-marginal of p_ζ is exactly $(1/J)\sum_{j=1}^J \nu_{h_j,\boldsymbol{w}}$, so we can generate a Markov chain with the desired invariant distribution. Unfortunately, the values $m(h_1), \ldots, m(h_J)$ are unknown (our objective is precisely to estimate them). It will turn out that for any value of ζ, a Markov chain with invariant distribution (2.7) enables us to estimate the vector $(m(h_1), \ldots, m(h_j))$ up to a constant, and the closer ζ is to a constant multiple of $(m(h_1), \ldots, m(h_j))$, the better is our estimate. This gives rise to a natural iterative procedure for estimating $(m(h_1), \ldots, m(h_j))$. We now give the details.

Let $\Gamma(j, \cdot)$ be a Markov transition function on $\mathcal{L}$. In our context, we would typically take $\Gamma(j, \cdot)$ to be the uniform distribution on $\mathcal{N}_j$, where $\mathcal{N}_j$ is a set consisting of the indices of the h_l's which are close to h_j. Serial tempering is a Markov chain on $\mathcal{L} \times \Psi$ which can be viewed as a two-block Metropolis-Hastings (i.e. Metropolis-within-Gibbs) algorithm, and is run as follows. Suppose that the current state of the chain is $(L_{i-1}, \boldsymbol{\psi}_{i-1})$.

- A new value $j \sim \Gamma(L_{i-1}, \cdot)$ is proposed. We set $L_i = j$ with the Metropolis probability

$$\rho = \min\left\{1, \frac{\Gamma(j, L_{i-1})}{\Gamma(L_{i-1}, j)} \frac{\nu_j(\boldsymbol{\psi}_{i-1})/\zeta_j}{\nu_{L_{i-1}}(\boldsymbol{\psi}_{i-1})/\zeta_{L_{i-1}}}\right\}, \tag{2.8}$$

  and with the remaining probability we set $L_i = L_{i-1}$.

- Generate $\boldsymbol{\psi}_i \sim \Phi_{L_i}(\boldsymbol{\psi}_{i-1}, \cdot)$.

By standard arguments, the density (2.7) is an invariant density for the serial tempering chain. A key observation is that the ψ-marginal density of p_ζ is

$$f_\zeta(\boldsymbol{\psi}) = (1/c_\zeta)\sum_{j=1}^J \ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_j(\boldsymbol{\psi})/\zeta_j, \qquad \text{where} \qquad c_\zeta = \sum_{j=1}^J m(h_j)/\zeta_j. \tag{2.9}$$

Suppose that $(L_1, \boldsymbol{\psi}_1), (L_2, \boldsymbol{\psi}_2), \ldots$ is a serial tempering chain. To estimate $m(h)$, consider

$$\widehat{M}_\zeta(h) = \frac{1}{n}\sum_{i=1}^n \frac{\nu_h(\boldsymbol{\psi}_i)}{(1/J)\sum_{j=1}^J \nu_j(\boldsymbol{\psi}_i)/\zeta_j}. \tag{2.10}$$

Note that this estimate depends only on the $\boldsymbol{\psi}$-part of the chain. Assuming that we have established that the chain is ergodic, we have

$$\begin{aligned}\widehat{M}_\zeta(h) &\xrightarrow{\text{a.s.}} \int \frac{\nu_h(\boldsymbol{\psi})}{(1/J)\sum_{j=1}^J \nu_j(\boldsymbol{\psi})/\zeta_j} \frac{\sum_{j=1}^J \ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_j(\boldsymbol{\psi})/\zeta_j}{c_\zeta}\, d\mu(\boldsymbol{\psi}) \\ &= \int \frac{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})}{c_\zeta/J}\, d\mu(\boldsymbol{\psi}) \\ &= \frac{m(h)}{c_\zeta/J}.\end{aligned} \tag{2.11}$$

This means that for any ζ, the family $\{\widehat{M}_\zeta(h),\, h \in \mathcal{H}\}$ can be used to estimate the family $\{m(h),\, h \in \mathcal{H}\}$, up to a single multiplicative constant.

To estimate the family of integrals $\{\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}),\, h \in \mathcal{H}\}$, we proceed as follows. Let

$$\widehat{U}_\zeta(h) = \frac{1}{n}\sum_{i=1}^n \frac{g(\boldsymbol{\psi}_i)\nu_h(\boldsymbol{\psi}_i)}{(1/J)\sum_{j=1}^J \nu_j(\boldsymbol{\psi}_i)/\zeta_j}. \tag{2.12}$$

By ergodicity we have

$$\begin{aligned}\widehat{U}_\zeta(h) &\xrightarrow{\text{a.s.}} \int \frac{g(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})}{(1/J)\sum_{j=1}^J \nu_j(\boldsymbol{\psi})/\zeta_j} \frac{\sum_{j=1}^J \ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_j(\boldsymbol{\psi})/\zeta_j}{c_\zeta}\, d\mu(\boldsymbol{\psi}) \\ &= \int \frac{\ell_{\boldsymbol{w}}(\boldsymbol{\psi})g(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi})}{c_\zeta/J}\, d\mu(\boldsymbol{\psi}) \\ &= \frac{m(h)}{c_\zeta/J}\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}).\end{aligned} \tag{2.13}$$

Combining the convergence statements (2.13) and (2.11), we see that

$$\hat{I}^{\text{st}}_\zeta(h) \coloneqq \frac{\widehat{U}_\zeta(h)}{\widehat{M}_\zeta(h)} \xrightarrow{\text{a.s.}} \int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}). \tag{2.14}$$

Suppose that for some constant a, we have

$$(\zeta_1, \ldots, \zeta_J) = a(m(h_1), \ldots, m(h_J)). \tag{2.15}$$

Then $c_\zeta = J/a$, and as noted earlier, $f_\zeta(\boldsymbol{\psi}) = (1/J)\sum_{j=1}^J \nu_{h_j,\boldsymbol{w}}(\boldsymbol{\psi})$, i.e. the ψ-marginal of p_ζ (see (2.9)) gives equal weight to each of the component distributions in the mixture. (Expressing this slightly differently, if (2.15) is true, then the invariant density (2.7) becomes $p_\zeta(j, \boldsymbol{\psi}) = (1/J)\nu_{h_j,\boldsymbol{w}}(\boldsymbol{\psi})$, so the L-marginal distribution of p_ζ gives mass $(1/J)$ to each point in $\mathcal{L}$.) Therefore, for large n, the proportions of time spent in the J components of the mixture are about the same, a feature which is essential if serial tempering is to work well. In practice, we cannot arrange for (2.15) to be true, because $m(h_1), \ldots, m(h_J)$ are unknown. However, the vector $(m(h_1), \ldots, m(h_J))$ may be estimated (up to a multiplicative constant) iteratively as follows. If the current value is $\zeta^{(t)}$, then set

$$\big(\zeta_1^{(t+1)}, \ldots, \zeta_J^{(t+1)}\big) = \big(\widehat{M}_{\zeta^{(t)}}(h_1), \ldots, \widehat{M}_{\zeta^{(t)}}(h_J)\big). \tag{2.16}$$

From the convergence result (2.11), we get $\widehat{M}_{\zeta^{(t)}}(h_j) \xrightarrow{\text{a.s.}} m(h_j)/a_{\zeta^{(t)}}$, where $a_{\zeta^{(t)}}$ is a constant, i.e. (2.15) is nearly satisfied by $\big(\zeta_1^{(t+1)}, \ldots, \zeta_J^{(t+1)}\big)$. To determine the number of iterations needed, at each iteration we record the proportions of time spent in the J different components of the mixture, i.e. the vector $\big((1/n)\sum_{i=1}^n I(L_i = 1), \ldots, (1/n)\sum_{i=1}^n I(L_i = J)\big)$, and we stop the iteration when this vector is nearly uniform. In all our examples, three or four iterations were sufficient. Pseudocode is given in Algorithm 1.

To sum up, we estimate the family of marginal likelihoods (up to a constant) and the family of posterior expectations as follows. First, we obtain the vector of tuning parameters ζ via the iterative scheme given by (2.16). To estimate the family of marginal likelihoods (up to a constant) we use

Algorithm 1: Serial tempering. See the discussion in Sec. 2.3 and Appendices A.1 and 4.

Data: Observed words $\boldsymbol{w}$
Result: A Markov chain on $\mathcal{L} \times \Psi$

specify $h_1, \ldots, h_J \in \mathcal{H}$;
initialize $\zeta_1^{(1)}, \ldots, \zeta_J^{(1)}$;
initialize $\boldsymbol{\psi}_0 = (\boldsymbol{\beta}^{(0)}, \boldsymbol{\theta}^{(0)}, \boldsymbol{z}^{(0)})$, L_0;
compute count statistics n_{dk} and m_{dkv}, for $d = 1, \ldots, D$, $k = 1, \ldots, K$, $v = 1, \ldots, V$;
for *tuning iteration* $t = 1, \ldots$ **do**
  for *MCMC iteration* $i = 1, \ldots$ **do**
    `// The Metropolis-Hastings update`
    `// Set` L_i `via the probability` ρ `given by` (2.8)
    propose index $j \sim \Gamma(L_{i-1}, \cdot)$;
    sample $U \sim \text{Uniform}(0, 1)$;
    if $U < \rho$ **then**
      set $L_i = j$;
    else
      set $L_i = L_{i-1}$;
    `// Generate` $\boldsymbol{\psi}_i = (\boldsymbol{\beta}^{(i)}, \boldsymbol{\theta}^{(i)}, \boldsymbol{z}^{(i)}) \sim \Phi_{L_i}(\boldsymbol{\psi}_{i-1}, \cdot)$

      for *word* w_{dr}, $r = 1, \ldots, n_d$ **do**
        sample topic index $z_{dr}^{(i)}$ via the CGS (Griffiths and Steyvers, 2004);
        update count statistics n_{dk} and m_{dkv} according to $z_{dr}^{(i)}$ and w_{dr};
    for *topic* $k = 1, \ldots, K$ **do**
      sample topic $\beta_k^{(i)}$ via (4.5);
    for *document* $d = 1, \ldots, D$ **do**
      sample the distribution on topics $\theta_d^{(i)}$ via (4.5);
  `// Update tuning parameters` $\zeta_1, \ldots, \zeta_J$
  compute the estimates $\widehat{M}_{\zeta^{(t)}}(h_1), \ldots, \widehat{M}_{\zeta^{(t)}}(h_J)$ via (2.10) using $\boldsymbol{\psi}_i$ and $\zeta_1^{(t)}, \ldots, \zeta_J^{(t)}$;
  set $\big(\zeta_1^{(t+1)}, \ldots, \zeta_J^{(t+1)}\big) = \big(\widehat{M}_{\zeta^{(t)}}(h_1), \ldots, \widehat{M}_{\zeta^{(t)}}(h_J)\big)$;

$\widehat{M}_\zeta(h)$ defined in (2.10), and to estimate the family of posterior expectations we use $\hat{I}_\zeta^{\text{st}}(h) = \widehat{U}_\zeta(h)/\widehat{M}_\zeta(h)$ (see (2.12) and (2.10)).

We point out that it is possible to estimate the family of marginal likelihoods (up to a constant) by

$$\widetilde{M}_\zeta(h) = \frac{1}{n}\sum_{i=1}^{n} \frac{\nu_h(\boldsymbol{\psi}_i)}{\nu_{L_i}(\boldsymbol{\psi}_i)/\zeta_{L_i}}. \tag{2.17}$$

Note that $\widetilde{M}_\zeta(h)$ uses the sequence of pairs $(L_1, \boldsymbol{\psi}_1), (L_2, \boldsymbol{\psi}_2), \ldots$, and not just the sequence $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots$. To see why (2.17) is a valid estimator, observe that by ergodicity we have

$$\begin{aligned}
\widetilde{M}_\zeta(h) &\xrightarrow{\text{a.s.}} \iint \frac{\nu_h(\boldsymbol{\psi})}{\nu_L(\boldsymbol{\psi})/\zeta_L} \cdot \left[\frac{1}{c_\zeta}\ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_L(\boldsymbol{\psi})/\zeta_L\right] d\mu(\boldsymbol{\psi})\, d\sigma(L) \\
&= \iint \frac{m(h)}{c_\zeta}\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})\, d\mu(\boldsymbol{\psi})\, d\sigma(L) \\
&= J\frac{m(h)}{c_\zeta}.
\end{aligned} \tag{2.18}$$

(Note that the limit in (2.18) is the same as the limit in (2.11).) Similarly, we may estimate the integral $\int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ by the ratio

$$\tilde{I}_\zeta^{\text{st}}(h) = \sum_{i=1}^{n} \frac{g(\boldsymbol{\psi}_i)\nu_h(\boldsymbol{\psi}_i)}{\nu_{L_i}(\boldsymbol{\psi}_i)/\zeta_{L_i}} \Big/ \sum_{i=1}^{n} \frac{\nu_h(\boldsymbol{\psi}_i)}{\nu_{L_i}(\boldsymbol{\psi}_i)/\zeta_{L_i}}.$$

The estimate $\tilde{I}_\zeta^{\text{st}}(h)$ is also based on the pairs $(L_1, \boldsymbol{\psi}_1), (L_2, \boldsymbol{\psi}_2), \ldots$, and it is easy to show that $\tilde{I}_\zeta^{\text{st}}(h) \xrightarrow{\text{a.s.}} \int g(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$.

The estimates $\widetilde{M}_\zeta(h)$ and $\tilde{I}_\zeta^{\text{st}}(h)$ are the ones that are used by Marinari and Parisi (1992) and Geyer and Thompson (1995), but $\widehat{M}_\zeta(h)$ and $\hat{I}_\zeta^{\text{st}}(h)$ appear to significantly outperform $\widetilde{M}_\zeta(h)$ and $\tilde{I}_\zeta^{\text{st}}(h)$ in terms of accuracy. We demonstrate this in Section 2.4.

Remark 4 *Theorem 1 continues to be true when we use the serial tempering chain, as opposed to the simple ACGS. The needed changes are that in the statement of the theorem B_n is replaced with $\widetilde{M}_\zeta$, and Condition A5 is replaced by the following. If $h^{(1)}, \ldots, h^{(J)}$ are the grid points used in running the serial tempering chain, then the stipulation on h_* given by* (2.3) *is satisfied by $h^{(j)}$ for at least one index j. See the proof of Theorem 1 in the Appendix.*

Globally-Valid Confidence Bands for $\{I(h),\, h \in \mathcal{H}\}$ Based on Serial Tempering Here we explain how to form confidence bands for the family $\{I(h),\, h \in \mathcal{H}\}$ based on $\{\hat{I}_\zeta^{\text{st}}(h),\, h \in \mathcal{H}\}$. Our arguments are informal, and we focus primarily on the algorithm for constructing the bands. The proof that the method works is given in Section A.3 of the Appendix. We will write $\hat{I}$ instead of $\hat{I}_\zeta^{\text{st}}$ to lighten the notation. Suppose that $\sup_{h\in\mathcal{H}} n^{1/2}|\hat{I}(h) - I(h)|$ has a limiting distribution as $n \to \infty$ (in the Appendix we explain why such a result is true), and suppose that we know the .95 quantile of this distribution, i.e. we know the value $c_{.95}$ such that

$$P\Big(\sup_{h\in\mathcal{H}} n^{1/2}|\hat{I}(h) - I(h)| \le c_{.95}\Big) = .95. \tag{2.19}$$

In this case we may rewrite (2.19) as

$$P\Big(\hat{I}(h) - c_{.95}/n^{1/2} \le I(h) \le \hat{I}(h) + c_{.95}/n^{1/2} \text{ for all } h \in \mathcal{H}\Big) = .95,$$

meaning that the band $\hat{I}(h) \pm c_{.95}/n^{1/2}$ is a globally-valid confidence band for $\{I(h),\, h \in \mathcal{H}\}$. (In contrast, for a pointwise band $(L(h), U(h))$, $h \in \mathcal{H}$, we can only make the statement $P\big(L(h) \le$

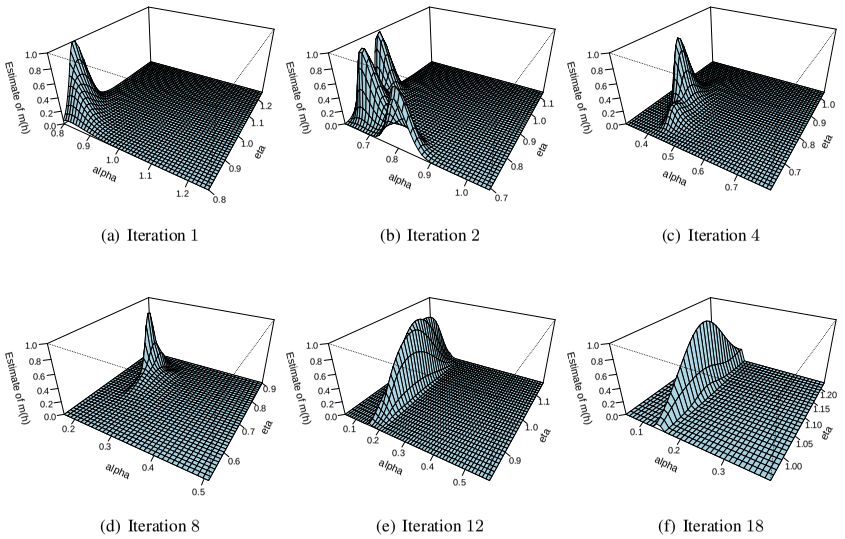
$I(h) \le U(h)\big) = .95$ for each $h \in \mathcal{H}$, and we cannot make any statement regarding simultaneous coverage.)

The difficulty is in obtaining $c_{.95}$, and we now show how this quantity can be estimated through the method of batching, which is described as follows. The sequence $\psi_1, \ldots, \psi_n$ is broken up into J consecutive pieces of equal lengths called batches. For $j = 1, \ldots, J$, let $\hat{I}_j(h)$ be the estimate of $I(h)$ produced by batch j. Now the $\hat{I}_j(h)$'s are each formed from a sample of size n/J. Informally, if n is large and n/J is also large, then for $j = 1, \ldots, J$, $\sup_{h\in\mathcal{H}}(n/J)^{1/2}|\hat{I}_j(h) - I(h)|$ and $\sup_{h\in\mathcal{H}} n^{1/2}|\hat{I}(h) - I(h)|$ have approximately the same distribution. Therefore, to estimate $c_{.95}$, we let $S_j = \sup_{h\in\mathcal{H}}(n/J)^{1/2}|\hat{I}_j(h) - I(h)|$, and as our estimate of $c_{.95}$ we use the 95^{th} percentile of the sequence $S_1, \ldots, S_J$. Unfortunately, the S_j's are not available, because they involve $I(h)$, which is unknown. So instead we use $\mathcal{S}_j = \sup_{h\in\mathcal{H}}(n/J)^{1/2}|\hat{I}_j(h) - \hat{I}(h)|$, in which we have substituted $\hat{I}(h)$ for $I(h)$. To conclude, let $\mathcal{S}_{[1]} \le \mathcal{S}_{[2]} \le \cdots \le \mathcal{S}_{[J]}$ denote the ordered values of the sequence $\mathcal{S}_1, \ldots, \mathcal{S}_J$. We estimate $c_{.95}$ via $\mathcal{S}_{[.95J]}$, and our 95% globally-valid confidence band for $\{I(h),\, h \in \mathcal{H}\}$ is $\big\{\hat{I}(h) \pm \mathcal{S}_{[.95J]}/n^{1/2},\, h \in \mathcal{H}\big\}$. In the Appendix we show that the probability that the entire function $\{I(h),\, h \in \mathcal{H}\}$ lies inside the band converges to .95 as $n \to \infty$. There are conditions on J: we need that $J \to \infty$ and $n/J \to \infty$; a good choice is $J = n^{1/2}$. The Markov chain length n should be chosen such that the band is acceptably narrow.

Iterative Scheme for Choosing the Grid The performance of serial tempering depends crucially on the choice of grid points $h_1, \ldots, h_J$, and it is essential that $\arg\max_h m(h)$ be close to at least one of the grid points, for the reason discussed at the beginning of this section. This creates a circular problem: the ideal grid is one that is centered or nearly centered at $\arg\max_h m(h)$, but $\arg\max_h m(h)$ is unknown. The problem is compounded by the fact that the grid has to be "tight," i.e. the points $h_1, \ldots, h_J$ need to be close together. This is because when the corpus is large, if h_j and $h_{j'}$ are not close, then for $j \ne j'$, ν_{h_j} and $\nu_{h_{j'}}$ are nearly singular (each is a product of a large number of terms—see (2.2)). In the serial tempering chain, this near singularity causes the proposal $j \sim \Gamma(L_{i-1}, \cdot)$ (see (2.8)) to have high probability of being rejected, and the chain does not mix well. To deal with this problem, we use an iterative scheme which proceeds as follows. We initialize the experiment with a fixed $h^{(0)}$ (for example $h^{(0)} = (1, 1)$) and a subgrid that "covers" $h^{(0)}$ (for example a subgrid with convex hull equal to $[1/2, 2] \times [1/2, 2]$). We then subsample a small set of documents from the corpus and run the serial tempering chain to find the estimate of the maximizer of the marginal likelihood for the subsampled corpus, using the current grid setting. We iterate: at iteration t, we set $h^{(t)}$ to be the estimate of the maximizer obtained from the previous iteration, and select a subgrid that covers $h^{(t)}$. As the iteration number t increases, the grid is made more narrow, and the number of subsampled documents is increased. This scheme works because in the early iterations the number of documents is small, so the near-singularity problem does not arise, and we can use a wide grid. In our experience, decreasing the dimensions of the α- and η-grids by 10% and increasing the number of subsampled documents by 10% at each iteration works well. It is very interesting to note that convergence may occur before the subsample size is equal to the number of documents in the corpus, in which case there is no need to ever deal with the entire corpus, and in fact this is typically what happens, unless the corpus is small. (By "convergence" we mean that $h^{(t)}$ is nearly the same as the values from the previous iterations.) Of course, for small corpora the near-singularity problem does not arise, and the iterative scheme can be skipped entirely.

To illustrate the scheme, we generated a corpus according to the LDA model with $D = 10^5$, $K = 50$, $V = 500$, $n_d = 80$ for all d, and $h_{\text{true}} = (\eta, \alpha) = (.8, .2)$, and ran the scheme using

Markov chains of length $n = 50{,}000$ and grids of size $J = 100$. As will be clear shortly, our results would have been identical if D had been *any* number bigger than 10^5. Figure 2 shows the marginal likelihood surfaces as the iterations progress. At iteration 1, the α-value of the maximizer is outside the convex hull of the grid, and at the second iteration, the grid is centered at that point. Figure 3 gives precise information on the number of subsampled documents (left panel), and the lower and upper endpoints of the α- and η-values used in the grids, as the iterations progress (right panel). The right panel also gives α- and η-values of the estimate of the argmax as the iterations progress. As can be seen from Figure 3, the scheme has effectively converged after about 18 iterations, and at convergence the number of subsampled documents is only 200.



(a) Iteration 1 (b) Iteration 2 (c) Iteration 4

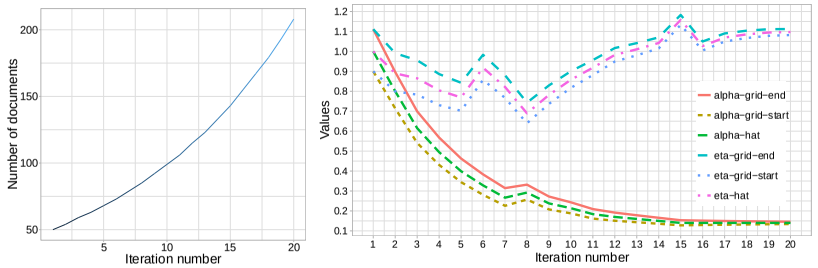
(d) Iteration 8 (e) Iteration 12 (f) Iteration 18

Figure 2: Values of $\widehat{M}(h)$ for iterations 1, 2, 4, 8, 12, 18 using a synthetic corpus generated according to the LDA model with $K = 20$, $n_d = 100$ for each d, $V = 100$, and $h_{\text{true}} = (.8, .2)$.

Serial tempering is a method for enhancing the simple estimator (2.1) which works well when $\dim(h)$ is low. The method does not scale well when $\dim(h)$ increases. In Section 6 we discuss this issue and present an idea on a different way to enhance (2.1) when h is high dimensional.

2.4 Illustration on a Wikipedia Corpus

In Section 1 we mentioned that the hyperparameter h has a strong effect on the prior distribution of the parameters in the model. Here we show empirically that it has a strong impact on the posterior distribution, and hence on inference based on this posterior distribution. To this end, we considered a corpus of articles from Wikipedia, constructed as follows. When a Wikipedia article is created, it



(a) Number of documents (b) Grid configurations and α- and η-values of estimate of the argmax

Figure 3: Iterations in the serial tempering scheme used on the synthetic corpus in Figure 2: left panel gives the number of documents subsampled at each iteration; right panel gives the specifications for the grid at each iteration.

is typically tagged to one or more categories, one of which is the "primary category." The corpus consists of 8 documents from the category *Leopardus*, 8 from the category *Lynx*, and 7 from *Prionailurus*. There are 303 words in the vocabulary, and the total number of words in the corpus is 7788. We took $K = 3$, so implicitly we envisage a topic being induced by each of the three categories. The corpus is quite small, but it is challenging to analyze because the topics are very close to each other, so in the posterior distribution there is a great deal of uncertainty regarding the latent topic indicator variables, and this is why we chose this data set. (In our analysis of this corpus, we treat the articles as unlabeled, i.e. we act as if for each article we don't know the category from which the article is taken.) As mentioned in Section 1, two quantities of interest are the posterior probability that the topic indicator variables for documents i and j are close, i.e. $\nu_{h,\boldsymbol{w}}(\|\theta_i - \theta_j\| \leq \epsilon)$, and the posterior expectation of the distance between topics i and j, which is given by the integral $\int \|\beta_i - \beta_j\| \, d\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$. Figure 4 gives plots of estimates of these posterior probabilities and expectations, as h varies, together with 95% globally-valid confidence sets. The plots clearly show that these posterior probabilities and expectations vary considerably with h.

Each plot was constructed from a serial tempering chain, using the methodology described in Section 2.3. Details regarding the chain and the plots are as follows. We took the sequence $h_1, \ldots, h_J$ to consist of an 11×20 grid of 220 evenly-spaced values over the region $(\eta, \alpha) \in [.6, 1.1] \times [.15, 1.1]$. For each hyperparameter value h_j ($j = 1, \ldots, 220$), we took Φ_j to be the Markov transition function of the Augmented Collapsed Gibbs Sampler alluded to earlier and described in detail in Section 4 (in all our experiments we used the Augmented Collapsed Gibbs Sampler, but the Grouped Gibbs Sampler gives results which are very similar). We took the Markov transition function $K(j, \cdot)$ on $\mathcal{L} = \{1, \ldots, 220\}$ to be the uniform distribution on $\mathcal{N}_j$ where $\mathcal{N}_j$ is the subset of $\mathcal{L}$ consisting of the indices of the h_l's that are neighbors of the point h_j. (An interior point has eight neighbors, an edge point has five, and a corner point has three.)[1]

1. Software for implementation of our algorithms as well as datasets we use are available as an R package at `https://github.com/clintpgeorge/ldamcmc`

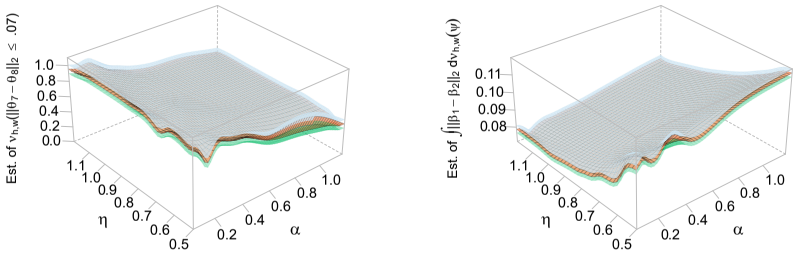


Figure 4: Variability of posterior probabilities and expectations for the Cats corpus from Wikipedia. Left panel: estimate of the posterior probability that documents 7 and 8 have essentially the same topics, in the sense that $\|\theta_7 - \theta_8\| \leq .07$, as h varies. Right panel: estimate of the posterior expectation of the (Euclidean, i.e. L_2) distance between topics 1 and 2 as h varies.

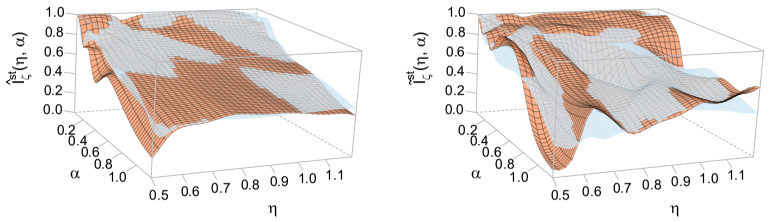
In Section 2.3, we stated that $\widehat{M}_\zeta(h)$ and $\hat{I}^{\text{st}}_\zeta(h)$ appear to significantly outperform $\widetilde{M}_\zeta(h)$ and $\tilde{I}^{\text{st}}_\zeta(h)$ in terms of accuracy. We now provide some evidence for this, and we will deal with the estimates of $I(h)$ (a comparison of $\widehat{M}_\zeta(h)$ and $\widetilde{M}_\zeta(h)$ is given in George (2015)). We considered the Wikipedia Cats corpus described above, and we took $I(h) = \nu_{h,\boldsymbol{w}}(\|\theta_7 - \theta_8\| \leq .07)$. We calculated $\hat{I}^{\text{st}}_\zeta(h)$ twice, using two different seeds, and also calculated $\tilde{I}^{\text{st}}_\zeta(h)$ twice, using two different seeds, in every case using the same h-range that was used in Figure 4. The four surfaces were constructed via four independent serial tempering experiments, each involving two iterations (each of length 50,000 after a short burn-in period) to form the tuning parameter ζ, which was given initial value $\zeta^{(0)} = (\zeta_1^{(0)}, \ldots, \zeta_{220}^{(0)}) = (1, \ldots, 1)$, and one final iteration (of length 100,000) to form the estimate of $I(h)$. Figure 5(a) shows the two estimates $\hat{I}^{\text{st}}_\zeta(h)$, and Figure 5(b) shows the two estimates $\tilde{I}^{\text{st}}_\zeta(h)$. The figures show that the two independent estimates $\hat{I}^{\text{st}}_\zeta(h)$ are close to each other, whereas the two independent estimates $\tilde{I}^{\text{st}}_\zeta(h)$ are not.

Although the variability of $\hat{I}^{\text{st}}_\zeta(h)$ is significantly smaller than that of $\tilde{I}^{\text{st}}_\zeta(h)$, the figures perhaps don't show this very clearly because a visual comparison of two surfaces is not easy. Therefore, we extracted two one-dimensional slices from each panel in Figure 5, which we used to create Figure 6. The figure shows the values of the two versions of $\hat{I}^{\text{st}}_\zeta(\eta, \alpha)$ and the two versions of $\tilde{I}^{\text{st}}_\zeta(\eta, \alpha)$ when η is fixed at .70 (two left panels); and it shows these plots when η is fixed at 1.00 (two right panels). The superiority of $\hat{I}^{\text{st}}_\zeta$ over $\tilde{I}^{\text{st}}_\zeta$ is striking. We mention that, ostensibly, $\widehat{M}_\zeta(h)$ and $\hat{I}^{\text{st}}_\zeta(h)$ require more computation, but the quantities $(1/J) \sum_{j=1}^{J} \nu_j(\boldsymbol{\psi}_i)/\zeta_j$, $i = 1, \ldots, n$ are calculated once, and stored. Doing this essentially eliminates the increased computing cost.



(a) $\hat{I}^{\text{st}}_\zeta(\eta, \alpha)$ (b) $\tilde{I}^{\text{st}}_\zeta(\eta, \alpha)$

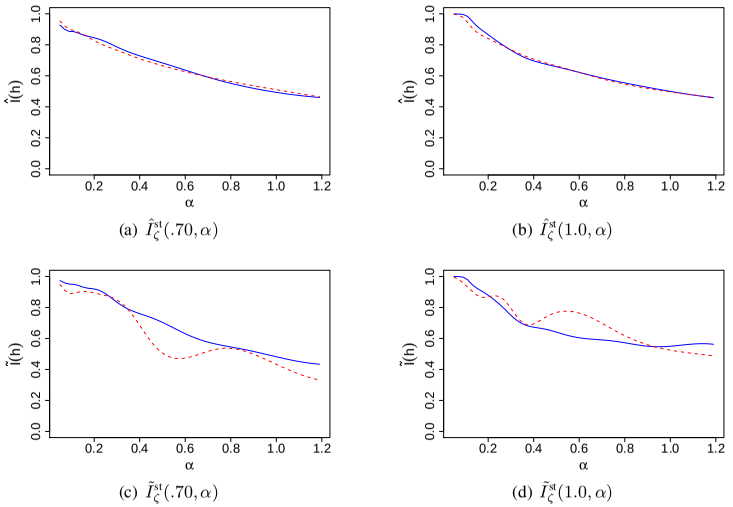
Figure 5: Comparison of the variability of $\hat{I}^{\text{st}}_\zeta$ and $\tilde{I}^{\text{st}}_\zeta$. Left panel shows two independent estimates of $I(\eta, \alpha) = \nu_{h,\boldsymbol{w}}(\|\theta_7 - \theta_8\| \leq .07)$ using $\hat{I}^{\text{st}}_\zeta(\eta, \alpha)$. Right panel uses $\tilde{I}^{\text{st}}_\zeta$ instead of $\hat{I}^{\text{st}}_\zeta$.

3. Empirical Assessment of the Estimator of the Argmax

Consider the LDA model with a given hyperparameter value, which we will denote by h_{true}, and suppose we carry out steps 1–4 of the model, where in the final step we generate the corpus $\boldsymbol{w}$. The maximum likelihood estimate of h is $\hat{h} = \arg\max_h m(h)$ and, as we mentioned earlier, for any constant a, known or unknown, $\arg\max_h m(h) = \arg\max_h am(h)$. As noted earlier, the family $\{\widehat{M}_\zeta(h),\, h \in \mathcal{H}\}$, where $\widehat{M}_\zeta(h)$ is given by (2.10), may be used to estimate the family $\{m(h),\, h \in \mathcal{H}\}$ up to a multiplicative constant. So we may use $\arg\max_h \widehat{M}_\zeta(h)$ to estimate $\hat{h}$.

Recall that $B_n(h)$ is the estimate of $m(h)/m(h_*)$ given by the left side of equation (2.1). In theory, $\arg\max_h B_n(h)$ can also be used. However, as we pointed out earlier, $B_n(h)$ is stable only for h close to h_*—a similar remark applies to $\hat{I}(h)$—and unless the region of hyperparameter values of interest is small, we would not use $B_n(h)$ and $\hat{I}(h)$, and we would use estimates based on serial tempering instead. We have included the derivations of $B_n(h)$ and $\hat{I}(h)$ primarily for motivation, as these makes it easier to understand the development of the serial tempering estimates. In Section 2.4 we presented an experiment which strongly suggested that $\hat{I}^{\text{st}}_\zeta(h)$ is significantly better than $\tilde{I}^{\text{st}}_\zeta(h)$ in terms of variance. George (2015) gives experimental evidence that, analogously, $\widehat{M}_\zeta(h)$ is significantly better than $\widetilde{M}_\zeta(h)$. Therefore, for the rest of this paper, we use only $\widehat{M}_\zeta(h)$ and $\hat{I}^{\text{st}}_\zeta(h)$.

Here we present the results of some experiments which demonstrate good performance of $\hat{\hat{h}} := \arg\max_h \widehat{M}_\zeta(h)$ as an estimate of h_{true}. We took $\boldsymbol{\alpha} = (\alpha, \ldots, \alpha)$, i.e. $\text{Dir}_K(\boldsymbol{\alpha})$ is a symmetric Dirichlet, so that the hyperparameter in the model reduces to $h = (\eta, \alpha) \in (0, \infty)^2$. Our experiment is set up as follows: the vocabulary size is $V = 40$, the number of documents is $D = 400$, the document lengths are $n_d = 80$, $d = 1, \ldots, D$, and the number of topics is $K = 8$. We used four settings for the hyperparameter under which we generate the model: h_{true} is taken to be $(.25, .25)$, $(.25, 4)$, $(4, .25)$, and $(4, 4)$. We estimated the marginal likelihood surfaces (up to a constant) on an



(a) $\hat{I}^{\text{st}}_\zeta(.70, \alpha)$ (b) $\hat{I}^{\text{st}}_\zeta(1.0, \alpha)$

(c) $\tilde{I}^{\text{st}}_\zeta(.70, \alpha)$ (d) $\tilde{I}^{\text{st}}_\zeta(1.0, \alpha)$

Figure 6: Two one-dimensional views of the plots in Figure 5. Each of the top two panels shows two independent estimates of $I(\eta, \alpha)$, using $\hat{I}^{\text{st}}_\zeta(\eta, \alpha)$. For the left panel, $\eta = 0.70$, and for the right panel, $\eta = 1.00$. The bottom two panels use $\tilde{I}^{\text{st}}_\zeta$ instead of $\hat{I}^{\text{st}}_\zeta$. The plots show that the variability of $\hat{I}^{\text{st}}_\zeta$ is much smaller than that of $\tilde{I}^{\text{st}}_\zeta$.

evenly-spaced 50×50 grid of 2500 values using $\widehat{M}_\zeta(h)$ calculated from a serial tempering chain implemented as follows. The size of the subgrid was taken to be $11 \times 11 = 121$, and we used ten iterations of the iterative scheme described in Section 2.3 to form the final subgrid. The subgrid for each of the four corpora is shown in the first section of the supplementary document George and Doss. For each hyperparameter value h_j ($j = 1, \ldots, 121$), we took Φ_j to be the Markov transition function of the Augmented Collapsed Gibbs sampler. We took the Markov transition function $K(j, \cdot)$ on $\mathcal{L} = \{1, \ldots, 121\}$ to be the uniform distribution on $\mathcal{N}_j$ where $\mathcal{N}_j$ is the subset of $\mathcal{L}$ consisting of the indices of the h_l's that are neighbors of the point h_j. We obtained the value ζ^{final} via three iterations of the scheme given by (2.16), in which we ran the serial tempering chain in each tuning iteration for 100,000 iterations after a short burn-in period, and we initialized $\zeta^{(0)} = (\zeta^{(0)}_1, \ldots, \zeta^{(0)}_{121}) = (1, \ldots, 1)$. Using ζ^{final}, we ran the final serial tempering chain for the same number of iterations as in the tuning stage.

Figure 7 gives plots of the estimates $\widehat{M}_\zeta(h)$ and also of their Monte Carlo standard errors (MCSE) for the four specifications of h_{true}. We computed these standard error estimates using the method of batch means, which is implemented in the R package `mcmcse` (Flegal et al., 2016); they are valid pointwise, as opposed to globally, over the h-region of interest. They indicate that the accuracy of $\widehat{M}_\zeta(\cdot)$ is adequate over the entire h-range for each of the four cases of h_{true}. (We

produced error margins that are valid locally, as opposed to globally, because it is of interest to see the regions where the variability is high.) In the supplementary document George and Doss we show plots of the occupancy times for the 121 components of the mixture distribution. For each of the four values of h_{true}, these occupancy times are close to uniform, indicating adequate mixing. We note that $\arg\max_h \widetilde{M}_\zeta(h)$ can be obtained through a grid search from the plots in Figure 7, which is what we did in this particular illustration, but in practice these plots don't need to be generated, and $\arg\max_h \widehat{M}_\zeta(h)$ can be found very quickly through standard optimization algorithms such as those that work through gradient-based approaches (which are very easy to implement here, since $\dim(h)$ is only 2). These algorithms take very little time because they require calculation of $\widehat{M}_\zeta(\cdot)$ for only a few values of h. For the case where $\dim(h)$ is large, we mention in particular Bergstra and Bengio (2012), who argue that random search is more efficient than grid search when only a few components of h matter. As can be seen from the figure, $\arg\max_h \widehat{M}_\zeta(h)$ provides fairly good estimates of h_{true}. This experiment involves modest sample sizes; when we increase the number of documents, the surfaces become more peaked, and $\hat{\hat{h}}$ is closer to h_{true} (experiments not shown).

George (2015) shows that estimates based on $\widetilde{M}_\zeta$ also provide good estimates of h_{true}, and he compares the $\widetilde{M}_\zeta$ and the $\widehat{M}_\zeta$ estimates. From his comparison, we can conclude that the extent of the superiority of the estimates based on $\widehat{M}_\zeta$ is about the same on the synthetic corpora of the present section as in the real data illustration of Section 2.4.

4. Construction of Two Markov Chains with Invariant Distribution $\nu_{h_*,\boldsymbol{w}}$

In order to develop Markov chains on $\boldsymbol{\psi} = (\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z})$ whose invariant distribution is the posterior $\nu_{h,\boldsymbol{w}}$, we first express the posterior in a convenient form. We start with the familiar formula

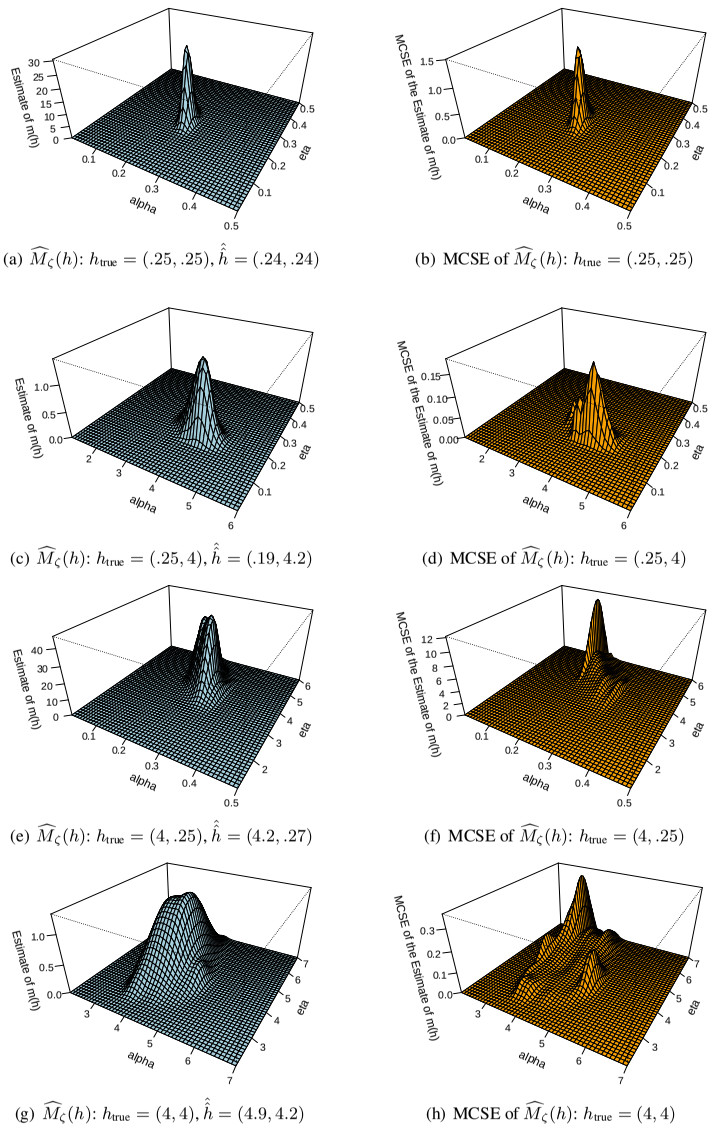
$$\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}) \propto \ell_{\boldsymbol{w}}(\boldsymbol{\psi})\nu_h(\boldsymbol{\psi}), \tag{4.1}$$

where the likelihood $\ell_{\boldsymbol{w}}(\boldsymbol{\psi}) = p^{(h)}_{\boldsymbol{w}\,|\,\boldsymbol{z},\boldsymbol{\theta},\boldsymbol{\beta}}(\boldsymbol{w}\,|\,\boldsymbol{z},\boldsymbol{\theta},\boldsymbol{\beta})$ is given by line 4 of the LDA model statement. For $d = 1,\ldots,D$ and $j = 1,\ldots,K$, let $S_{dj} = \{i : 1 \le i \le n_d \text{ and } z_{dij} = 1\}$, which is the set of indices of all words in document d whose latent topic variable is j. With this notation, from line 4 of the model statement we have

$$\begin{aligned} p^{(h)}_{\boldsymbol{w}\,|\,\boldsymbol{z},\boldsymbol{\theta},\boldsymbol{\beta}}(\boldsymbol{w}\,|\,\boldsymbol{z},\boldsymbol{\theta},\boldsymbol{\beta}) &= \prod_{d=1}^{D}\prod_{i=1}^{n_d}\prod_{j:z_{dij}=1}^{}\prod_{t=1}^{V}\beta_{jt}^{w_{dit}} = \prod_{d=1}^{D}\prod_{j=1}^{K}\prod_{t=1}^{V}\prod_{i\in S_{dj}}\beta_{jt}^{w_{dit}} \\ &= \prod_{d=1}^{D}\prod_{j=1}^{K}\prod_{t=1}^{V}\beta_{jt}^{\sum_{i\in S_{dj}} w_{dit}} = \prod_{d=1}^{D}\prod_{j=1}^{K}\prod_{t=1}^{V}\beta_{jt}^{m_{djt}}, \end{aligned} \tag{4.2}$$

where $m_{djt} = \sum_{i\in S_{dj}} w_{dit}$ counts the number of words in document d for which the latent topic is j and the index of the word in the vocabulary is t. Recalling the definition of n_{dj} given just before (A.1), and noting that $\sum_{i\in S_{dj}} w_{dit} = \sum_{i=1}^{n_d} z_{dij}w_{dit}$, we see that

$$m_{djt} = \sum_{i=1}^{n_d} z_{dij}w_{dit} \quad \text{and} \quad \sum_{t=1}^{V} m_{djt} = n_{dj}. \tag{4.3}$$



(a) $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (.25, .25)$, $\hat{\hat{h}} = (.24, .24)$ (b) MCSE of $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (.25, .25)$

(c) $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (.25, 4)$, $\hat{\hat{h}} = (.19, 4.2)$ (d) MCSE of $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (.25, 4)$

(e) $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (4, .25)$, $\hat{\hat{h}} = (4.2, .27)$ (f) MCSE of $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (4, .25)$

(g) $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (4, 4)$, $\hat{\hat{h}} = (4.9, 4.2)$ (h) MCSE of $\widehat{M}_\zeta(h)$: $h_{\text{true}} = (4, 4)$

Figure 7: $\widehat{M}_\zeta(h)$ and MCSE of $\widehat{M}_\zeta(h)$ for four values of h_{true}. In each case, $\hat{\hat{h}}$ is close to h_{true}.

Plugging the likelihood (4.2) and the prior (A.1) into (4.1), and absorbing Dirichlet normalizing constants into an overall constant of proportionality, we have

$$\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi}) \propto \left[\prod_{d=1}^{D}\prod_{j=1}^{K}\prod_{t=1}^{V}\beta_{jt}^{m_{djt}}\right]\left[\prod_{d=1}^{D}\prod_{j=1}^{K}\theta_{dj}^{n_{dj}}\right]\left[\prod_{d=1}^{D}\prod_{j=1}^{K}\theta_{dj}^{\alpha_j-1}\right]\left[\prod_{j=1}^{K}\prod_{t=1}^{V}\beta_{jt}^{\eta-1}\right]. \tag{4.4}$$

The expression for $\nu_{h,\boldsymbol{w}}(\boldsymbol{\psi})$ above also appears in the unpublished report Fuentes et al. (2011).

The Conditional Distributions of $(\boldsymbol{\beta},\boldsymbol{\theta})$ Given $\boldsymbol{z}$ and of $\boldsymbol{z}$ Given $(\boldsymbol{\beta},\boldsymbol{\theta})$

All distributions below are conditional distributions given $\boldsymbol{w}$, which is fixed, and henceforth this conditioning is suppressed in the notation. Note that in (4.4), the terms m_{djt} and n_{dj} depend on $\boldsymbol{z}$. By inspection of (4.4), we see that given $\boldsymbol{z}$,

$$\begin{aligned}&\theta_1,\ldots,\theta_D \text{ and } \beta_1,\ldots,\beta_K \text{ are all independent,}\\ &\theta_d \sim \mathrm{Dir}_K\big(n_{d1}+\alpha_1,\ldots,n_{dK}+\alpha_K\big),\\ &\beta_j \sim \mathrm{Dir}_V\big(\textstyle\sum_{d=1}^{D} m_{dj1}+\eta,\ldots,\sum_{d=1}^{D} m_{djV}+\eta\big).\end{aligned} \tag{4.5}$$

From (4.4) we also see that

$$\begin{aligned}p^{(h)}_{\boldsymbol{z}\,|\,\boldsymbol{\theta},\boldsymbol{\beta}}(\boldsymbol{z}\,|\,\boldsymbol{\theta},\boldsymbol{\beta}) &\propto \prod_{d=1}^{D}\prod_{j=1}^{K}\left(\left[\prod_{t=1}^{V}\beta_{jt}^{m_{djt}}\right]\theta_{dj}^{n_{dj}}\right)\\ &= \prod_{d=1}^{D}\prod_{i=1}^{n_d}\prod_{j=1}^{K}\left[\prod_{t=1}^{V}\beta_{jt}^{z_{dij}w_{dit}}\theta_{dj}^{z_{dij}w_{dit}}\right] &(4.6)\\ &= \prod_{d=1}^{D}\prod_{i=1}^{n_d}\prod_{j=1}^{K}\left[\prod_{t=1}^{V}\big(\beta_{jt}\theta_{dj}\big)^{w_{dit}}\right]^{z_{dij}}, &(4.7)\end{aligned}$$

where (4.6) follows from (4.3). Let $p_{dij} = \prod_{t=1}^{V}\big(\beta_{jt}\theta_{dj}\big)^{w_{dit}}$. By inspection of (4.7) we see immediately that given $(\boldsymbol{\theta},\boldsymbol{\beta})$,

$$\begin{aligned}&z_{11},\ldots,z_{1n_1},z_{21},\ldots,z_{2n_2},\ldots,z_{D1},\ldots,z_{Dn_D} \text{ are all independent,}\\ &z_{di} \sim \mathrm{Mult}_K(p_{di1},\ldots,p_{diK}).\end{aligned} \tag{4.8}$$

The conditional distribution of $(\boldsymbol{\beta},\boldsymbol{\theta})$ given by (4.5) can be used, in conjunction with the CGS of Griffiths and Steyvers (2004), to create a Markov chain on $\boldsymbol{\psi}$ whose invariant distribution is $\nu_{h,\boldsymbol{w}}$: if $\boldsymbol{z}^{(1)},\boldsymbol{z}^{(2)},\ldots$ is the CGS, then for $l=1,2,\ldots$, we generate $(\boldsymbol{\beta}^{(l)},\boldsymbol{\theta}^{(l)})$ from $p^{(h)}_{\boldsymbol{\theta},\boldsymbol{\beta}\,|\,\boldsymbol{z}}(\cdot\,|\,\boldsymbol{z}^{(l)})$ given by (4.5) and form $(\boldsymbol{z}^{(l)},\boldsymbol{\beta}^{(l)},\boldsymbol{\theta}^{(l)})$—this is what we have called the Augmented CGS. The CGS is uniformly ergodic (Theorem 1 of Chen and Doss (2017)) and an easy argument shows that the resulting ACGS is therefore also uniformly ergodic (and in fact, the rate of convergence of the ACGS is exactly the same as that of the CGS; see Diaconis et al. (2008, Lemma 2.4)).

The two conditionals (4.5) and (4.8) also enable a direct construction of a two-cycle Gibbs sampler that runs on the pair $(\boldsymbol{z},(\boldsymbol{\beta},\boldsymbol{\theta}))$—this is what we have called the Grouped Gibbs Sampler. This Gibbs sampler has the very attractive feature that it can be parallelized: From (4.5), we see that

given $\boldsymbol{z}$ and $\boldsymbol{w}$, the θ_d's and β_t's are all independent, so can be updated simultaneously by different processors; and from (4.8), we see that given $(\boldsymbol{\beta},\boldsymbol{\theta})$ and $\boldsymbol{w}$, all the components of $\boldsymbol{z}$ are independent, so can also be updated simultaneously by different processors. This scheme was noted earlier by Newman et al. (2009), who dismissed it on the grounds that the Collapsed Gibbs Sampler has superior mixing properties because, according to Liu et al. (1994), collapsing improves the mixing rate. However, the theorem from Liu et al. (1994) that Newman et al. (2009) are citing does not apply to the present situation. To be specific, Liu et al. (1994) consider a Gibbs sampling situation involving three variables X, Y, and Z. They show that a Gibbs sampler on the pair (X,Y) (with Z integrated out), which they call a collapsed Gibbs sampler, is superior to a Gibbs sampler on the triple (X,Y,Z). But for the LDA model, the CGS on $\boldsymbol{z}=(z_{11},\ldots,z_{1n_1},\ldots,z_{D1},\ldots,z_{Dn_D})$ is not a collapsed version of the Gibbs sampler that runs on the pair $\big(\boldsymbol{z},(\boldsymbol{\beta},\boldsymbol{\theta})\big)$ in any sense, so which of the two Gibbs samplers is superior in terms of mixing rate is an open question. George (2015) compared the mixing rates for various parameters empirically, and found that the mixing rate for the CGS is faster, but not much faster. A paper based on George (2015) that studies this Grouped Gibbs Sampler, including its mixing rate and computational complexity, is under preparation (Doss and George, 2017).

5. Evaluation: Choice of Estimator of $\arg\max_h m(h)$ and Resulting Model Fit

The maximizer of the marginal likelihood, $\hat{h}=\arg\max_h m(h)$, may be estimated via the MCMC scheme described in the present paper, or by some version of the EM algorithm (VI-EM or Gibbs-EM). Our main goal in this section is two-fold. (1) We show empirically that neither the VI-EM nor the Gibbs-EM method provides estimates of $\hat{h}$ that are as accurate as ours, and we briefly discuss why theoretically neither VI-EM nor Gibbs-EM, at least in its current implementation, can be expected to work correctly. We also compare VI-EM to Gibbs-EM in terms of accuracy, which to the best of our knowledge has not been done before, and compare VI-EM, Gibbs-EM, and our estimator in terms of speed. This is done in Section 5.1. (2) We consider some of the default choices of h used in the literature that use ad-hoc (i.e. non-principled) criteria. We look at model fit and show empirically that when we use any of the three estimates of $\hat{h}$ (VI-EM, Gibbs-EM, or our serial tempering method), model fit is better than if we use any of the ad-hoc choices. This is done in Section 5.2.

5.1 Comparison of Methods for Estimating $\arg\max_h m(h)$

For uniformity of notation, let $\hat{\hat{h}}_{\mathrm{ST}}$, $\hat{\hat{h}}_{\mathrm{VEM}}$, and $\hat{\hat{h}}_{\mathrm{GEM}}$ be the estimates of $\hat{h}$ formed from serial tempering MCMC, VI-EM, and Gibbs-EM, respectively, and recall that $\hat{\hat{h}}_{\mathrm{ST}}=\hat{\hat{h}}=\arg\max_h \widehat{M_\zeta}(h)$.

VI-EM The estimate $\hat{\hat{h}}_{\mathrm{VEM}}$ proposed by Blei et al. (2003) is obtained as follows. If $h^{(k)}$ is the current value of h, the E-step of the EM algorithm is to calculate $E_{h^{(k)}}\big(\log(p_h(\boldsymbol{\psi},\boldsymbol{w}))\big)$, where $p_h(\boldsymbol{\psi},\boldsymbol{w})$ is the joint distribution of $(\boldsymbol{\psi},\boldsymbol{w})$ under the LDA model indexed by h, and the subscript to the expectation indicates that the expectation is taken with respect to $\nu_{h^{(k)},\boldsymbol{w}}$. This step is infeasible because $\nu_{h^{(k)},\boldsymbol{w}}$ is analytically intractable. We consider $\{q_\phi,\ \phi\in\Phi\}$, a (finite-dimensional) parametric family of analytically tractable distributions on $\boldsymbol{\psi}$, and within this family, we find the distribution, say q_{ϕ_*}, which is "closest" to $\nu_{h^{(k)},\boldsymbol{w}}$. Let $Q(h)$ be the expected value of $\log(p_h(\boldsymbol{\psi},\boldsymbol{w}))$

with respect to q_{ϕ_*}. We view $Q(h)$ as a proxy for $E_{h^{(k)}}\big(\log(p_h(\boldsymbol{\psi}, \boldsymbol{w}))\big)$, and the M-step is then to maximize $Q(h)$ with respect to h, to produce $h^{(k+1)}$. The maximization is done analytically.

The implementation of the EM algorithm through variational inference methods outlined above describes what Blei et al. (2003) do *conceptually*, but not exactly. Actually, Blei et al. (2003) apply VI-EM to a model that is different from ours. In that model, $\boldsymbol{\beta}$ is viewed as a fixed but unknown parameter, to be estimated, and the latent variable is $\boldsymbol{\vartheta} = (\boldsymbol{\theta}, \boldsymbol{z})$. Thus, the observed and missing data are, respectively, $\boldsymbol{w}$ and $\boldsymbol{\vartheta}$, and the marginal likelihood is a function of two variables, h and $\boldsymbol{\beta}$. Abstractly speaking, the description of VI-EM given above is exactly the same. We implemented VI-EM to the version of the LDA model considered in this paper, by modifying the Blei et al. (2003) code. While VI-EM can handle very large corpora with many topics, there are no theoretical results regarding convergence of the sequence $h^{(k)}$ to $\arg\max_h m(h)$, and VI-EM has the following problems: it may have poor performance if the approximation of $\nu_{h^{(k)},\boldsymbol{w}}$ by q_{ϕ_*} is not good; and if the likelihood surface is multimodal, as in Figure 7(e), then it can fail to find the global maximum (as is the case for all EM-type algorithms and also gradient-based approaches).

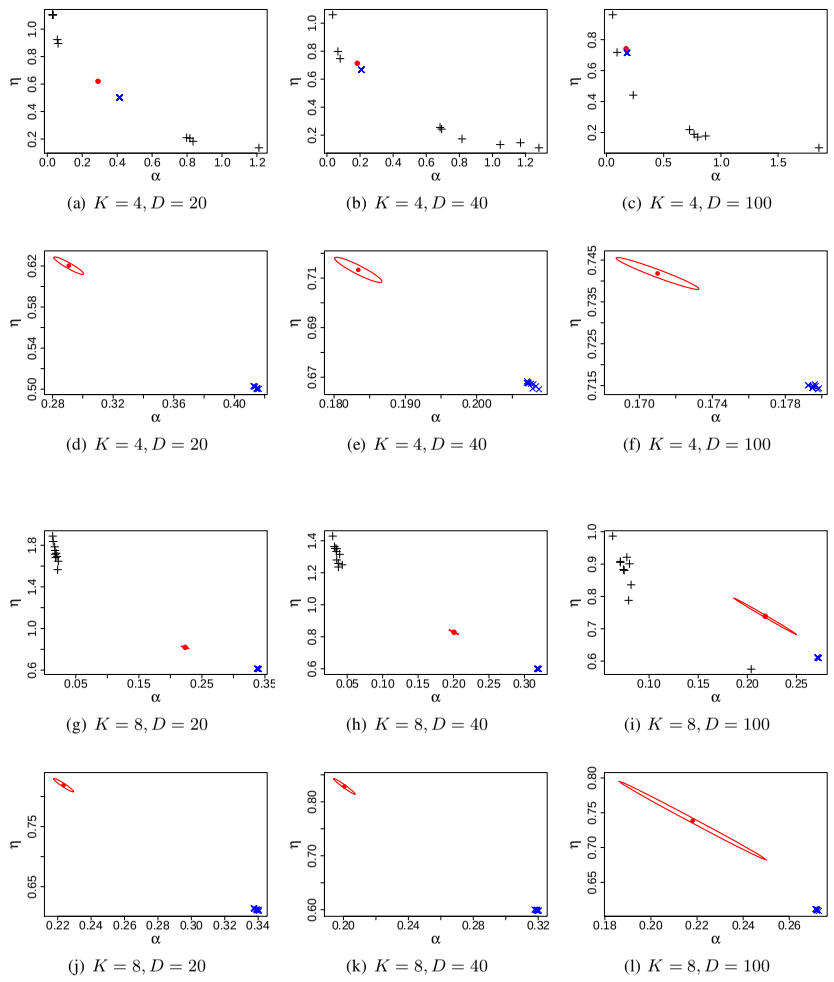
Gibbs-EM Monte Carlo EM (MC-EM), in which the E-step is replaced by a Monte Carlo estimate, dates back to Wei and Tanner (1990), and was introduced to the machine learning community in Andrieu et al. (2003). As mentioned earlier, since an error is introduced at every iteration, there is no reason to expect that the algorithm will converge at all, let alone to the true maximizer of the likelihood. In fact, Wei and Tanner (1990) recognized this problem and suggested that the Markov chain length be increased at every iteration of the EM algorithm. We will let m_k denote the MC length at the k^{th} iteration. Convergence of MC-EM (of which the Gibbs-EM algorithm of Wallach (2008) is a special case) is a nontrivial issue. It was studied by Fort and Moulines (2003), who showed that a minimal condition is that $m_k \to \infty$ at the rate of k^a, for some $a > 1$. However, they do not give guidelines for choosing a. Other conditions imposed in Fort and Moulines (2003) are fairly stringent, and it is not clear whether they are satisfied in the LDA model. In the current implementation of Gibbs-EM (Wallach, 2006), the latent variable is taken to be $\boldsymbol{z}$ (because the standard Markov chain used to estimate posterior distributions in this model is the CGS). At the k^{th} iteration, a Markov chain $\boldsymbol{z}_1, \ldots, \boldsymbol{z}_{m_k}$ with invariant distribution equal to the posterior distribution of $\boldsymbol{z}$ given $\boldsymbol{w}$ is generated, and the function $G(h) = (1/m_k)\sum_{i=1}^{m_k} \log(p_h(\boldsymbol{z}_i, \boldsymbol{w}))$ must be maximized. This is done by solving the equation $\nabla G(h) = 0$ using fixed-point iteration, and because $\nabla G(h)$ is computationally intractable, an approximation (Minka, 2003) is used (in effect, a lower bound to $G(h)$ is found, and the lower bound is what is maximized). This approximation introduces a second potential problem for Gibbs-EM. A third potential problem is that, as for VI-EM, the iterations may get stuck near a local maximum when the likelihood surface is multimodal.

To evaluate the performance of the VI-EM, Gibbs-EM, and serial tempering MCMC methods of estimating $\hat{h}$, we generated small synthetic corpora according to the LDA model with the following specifications: the true hyperparameter value is $h = (\eta, \alpha) = (.8, .2)$, the vocabulary size is $V = 20$, the number of words in each document is $n_d = 80$, the number of topics is $K = 4$ and 8, and the number of documents is $D = 20$, 40, and 100, for a total of 6 specifications. For each specification, we formed $\hat{\hat{h}}_{\text{ST}}$, $\hat{\hat{h}}_{\text{VEM}}$, and $\hat{\hat{h}}_{\text{GEM}}$. For $\hat{\hat{h}}_{\text{GEM}}$, we used the algorithm given in Wallach (2006), in which the Markov chain is the CGS. We took the number of cycles of the Gibbs sampler to be 10,000—this is considerably greater than the default value of 20 in the MALLET package (McCallum, 2002); and we formed 10 independent estimates, using 10 different initial values. Likewise, for VI-EM we formed 10 estimates using 10 different initial values. For the

serial tempering estimate, our principal goal was to form a confidence set for $\hat{h}$, and we did this as follows. We ran 10 independent serial tempering chains, for which the sequence $h_1, \ldots, h_J$ consisted of a 7×9 grid of 63 values over the region $(\eta, \alpha) \in [.6, .9] \times [.1, .3]$ (this region was obtained from a small number of iterations of the iterative scheme described in Section 2.3), and the rest of the specifications were the same as those described in the experiments of Section 2.4; each chain was run for 100,000 iterations. Let $\hat{\hat{h}}_{\text{ST}}^{[\ell]}$ be the estimate of $\hat{h}$ formed from serial tempering chain ℓ, for $\ell = 1, \ldots, 10$. According to Theorem 1 in Section 2.1 and Remark 4 in Section 2.3, the independent variables $\hat{\hat{h}}_{\text{ST}}^{[1]}, \ldots, \hat{\hat{h}}_{\text{ST}}^{[10]}$ are approximately bivariate normally distributed with mean vector $\hat{h}$. Therefore, they can be used to form a 95% confidence ellipse for $\hat{h}$, based on Hotelling's T^2 distribution (this ellipse is simply the two-dimensional analogue of the standard t-interval, which is based on the t-distribution). The confidence set could also have been formed from a single long chain, using the method described in Theorem 1; the two methods use about the same computational resources. Figure 8 shows the results, and we make two general observations.

1. From the plots in rows 1 and 3 (plots (a), (b), (c), (g), (h), and (i)), we see that the VI-EM method does not perform well: in each of the 6 cases, the estimates are far from the true value, $\arg\max_h m(h)$, and also strongly depend on the starting values. We created plots (d), (e), (f), (j), (k), and (l), which are zoomed-in versions of plots (a), (b), (c), (g) (h), (i), respectively; these magnify a region which contains the serial tempering estimate and associated confidence ellipse. We see that while the plots in rows 1 and 3 show that the Gibbs-EM estimates greatly outperform the VI-EM estimates (they are both closer to the true value and less dependent on the starting value), the zoomed-in plots in rows 2 and 4 show that the Gibbs-EM points are far from being inside the 95% confidence ellipse. We carried out some experiments in which we followed the recommendations in Fort and Moulines (2003) to increase the number of cycles in the Gibbs sampling inner loop. Specifically, we took $m_1 = 2^7$ and doubled the length of the Gibbs sampler run with every iteration, i.e. we took $m_n = 2^{(6+n)}$, $n = 1, \ldots, 20$. Unfortunately, this did not give significant improvement. The Gibbs-EM estimates were never close to being inside the ellipse, The problem could be with our rate of increase, or that Gibbs-EM simply does not produce consistent estimates, or with the implementation of the maximization step (which uses an approximation).
2. Both Gibbs-EM and VI-EM improve as the number of documents, D, increases. A possible explanation of this is that as D increases, generally speaking the EM algorithm converges faster because the likelihood surface becomes more peaked. Of course, the larger the value of D, the weaker is the effect of the choice of h—this is the Bernstein-von Mises Theorem (see Freedman (1999) and the references therein), which loosely speaking states that as $D \to \infty$, the data swamp the prior.

To assess the computational burden, we computed $\hat{\hat{h}}_{\text{VEM}}$, $\hat{\hat{h}}_{\text{GEM}}$, and $\hat{\hat{h}}_{\text{ST}}$ for the six corpora we considered. For $\hat{\hat{h}}_{\text{VEM}}$, each run consisted of 100 EM iterations and in each EM iteration there were 100 variational inference iterations. For $\hat{\hat{h}}_{\text{GEM}}$, each run consisted of 50 EM iterations and in each EM iteration the CGS was run for 11,000 cycles, of which the first 1000 were deleted as burn-in. For $\hat{\hat{h}}_{\text{ST}}$, each run consisted of 2 tuning iterations with a chain length of 51,000 cycles, and a final iteration with a chain length of 101,000 cycles; and in each case, the first 1000 cycles were deleted as burn-in. Our experiments were conducted through the R programming language, using Rcpp, on a 3.70GHz quad core Intel Xeon Processor E5-1630V3. Table 1 gives the results. From the table,



(a) $K = 4, D = 20$ (b) $K = 4, D = 40$ (c) $K = 4, D = 100$

(d) $K = 4, D = 20$ (e) $K = 4, D = 40$ (f) $K = 4, D = 100$

(g) $K = 8, D = 20$ (h) $K = 8, D = 40$ (i) $K = 8, D = 100$

(j) $K = 8, D = 20$ (k) $K = 8, D = 40$ (l) $K = 8, D = 100$

Figure 8: Plots of estimates of $\hat{h}$ for the 6 corpora described in text. Points marked $\times$ are estimates formed by Gibbs-EM, points marked $+$ are estimates formed by VI-EM. A point marked $\bullet$ is the average of 10 independent estimates of $\hat{h}$ formed via ST chains, and the ellipse is a 95% confidence set for $\hat{h}$ formed from the 10 estimates. The three plots in row 2 are zoomed-in versions of the three plots in row 1, magnifying a region which contains the ST estimate, so the ellipse becomes visible. Similarly, the plots in row 4 are zoomed-in versions of the plots in row 3.

we see that the time for $\hat{\hat{h}}_{\mathrm{ST}}$ is about seven times the time for $\hat{\hat{h}}_{\mathrm{GEM}}$, and the time for $\hat{\hat{h}}_{\mathrm{GEM}}$ is about 55 times the time for $\hat{\hat{h}}_{\mathrm{VEM}}$. These numbers are not as extreme as they look, because for both $\hat{\hat{h}}_{\mathrm{GEM}}$ and $\hat{\hat{h}}_{\mathrm{ST}}$ we could have gotten comparable results with much smaller chain lengths.

K	D	Time for $\hat{\hat{h}}_{\mathrm{VEM}}$	Time for $\hat{\hat{h}}_{\mathrm{GEM}}$	Time for $\hat{\hat{h}}_{\mathrm{ST}}$
8	100	.34	11.64	90.55
8	40	.12	6.08	45.87
8	20	.04	2.96	31.35
4	100	.19	10.73	49.75
4	40	.08	4.88	25.71
4	20	.04	2.23	16.72

Table 1: Length of time, in minutes, it takes to compute the VI-EM, Gibbs-EM, and serial tempering estimates of $\hat{h}$ for six corpora.

5.2 Comparison of Model Fit: Empirical Bayes Choice vs. Ad-Hoc Choices of the Hyperparameter

In the literature, the following choices for $h = (\eta, \alpha)$ have been presented: $h_{\mathrm{DG}} = (0.1, 50/K)$, used in Griffiths and Steyvers (2004); $h_{\mathrm{DA}} = (0.1, 0.1)$, used in Asuncion et al. (2009); and $h_{\mathrm{DR}} = (1/K, 1/K)$, used in the `Gensim` topic modelling package (Řehůřek and Sojka, 2010), a well-known package used in the topic modelling community. These choices are ad-hoc, and not based on any particular principle.

Criterion for Model Fit The criterion we use is a score that is inversely related to the so-called "perplexity" score which is sometimes used in the machine learning literature. When applied to the LDA context, the score is obtained as follows. For $d = 1, \ldots, D$, let $\boldsymbol{w}_{(-d)}$ denote the corpus consisting of all the documents except for document d. To evaluate a given model (in our case the LDA model indexed by a given h), in essence we see how well the model based on $\boldsymbol{w}_{(-d)}$ predicts document d, the held-out document. We do this for $d = 1, \ldots, D$, and take the geometric mean (Wallach et al., 2009). We formalize this as follows. The predictive likelihood of h for the held-out document is

$$L_d(h) = \int \ell_{\boldsymbol{w}_d}(\boldsymbol{\psi})\, d\nu_{h,\boldsymbol{w}_{(-d)}}(\boldsymbol{\psi}), \tag{5.1}$$

where $\ell_{\boldsymbol{w}_d}(\boldsymbol{\psi})$ is the likelihood of $\boldsymbol{\psi}$ for the held-out document d, and $\nu_{h,\boldsymbol{w}_{(-d)}}$ is the posterior distribution of $\boldsymbol{\psi}$ given $\boldsymbol{w}_{(-d)}$. We form the score $S(h) = \left[\prod_{d=1}^{D} L_d(h)\right]^{1/D}$. Two different values of hyperparameter h are compared via their scores. Conceptually, it is easy to estimate $L_d(h)$ by direct Monte Carlo: let $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots$ be an ergodic Markov chain with invariant distribution $\nu_{h,\boldsymbol{w}_{(-d)}}$. We then approximate the integral by $(1/n)\sum_{i=1}^{n} \ell_{\boldsymbol{w}_d}(\boldsymbol{\psi}_i)$. Care needs to be exercised, however, because in (5.1), the variable $\boldsymbol{\psi}$ in the term $\ell_{\boldsymbol{w}_d}(\boldsymbol{\psi})$ has a dimension that is different than that of the variable $\boldsymbol{\psi}$ in the rest of the integral. Chen (2015) gives a careful description of an MCMC scheme for estimating the integral in (5.1).

Real Datasets Here we compare the fit of LDA models based on various choices of the hyperparameter, on several corpora of real documents. We created two sets of document corpora, one from the 20Newsgroups dataset[2], and the other from the English Wikipedia. The 20Newsgroups dataset is commonly used in the machine learning literature for experiments on applications of text classification and clustering algorithms. It contains approximately 20,000 articles that are partitioned relatively evenly across 20 different newsgroups or categories. We created the second set of corpora from web articles downloaded from the English Wikipedia, with the help of the MediaWiki API[3].

We created the 20Newsgroups corpora as follows. We formed five subsets of the 20Newsgroups dataset, which we call C-1–C-5, with the feature that the articles within the subsets are increasingly difficult to distinguish: for corpus C-1 the topics for the different articles are very different, and for corpus C-5 the topics for the different articles are similar. For each article, we took its true topic label to be the newsgroup to which the article is assigned. Thus, for corpora C-1–C-5, it becomes increasingly difficult to place the articles into the correct newsgroup. We built corpus C-1 from a random subset of articles from the 20Newsgroups categories Medicine, Christianity, and Baseball; these three categories are highly unrelated and easily recognizable from article texts. We built corpus C-2 from a random subset of articles from the categories Automobiles, Motorcycles, Baseball, and Hockey (all four of these categories are classified under the super-category Recreation in the 20Newsgroups dataset), and we built corpus C-3 from a random subset of articles from the categories Cryptography, Electronics, Medicine, and Space (all four of these categories are classified under the super-category Science in the 20Newsgroups dataset). Compared to the categories in corpus C-1, the categories in corpora C-2 and C-3 are moderately related. Lastly, we created corpus C-4 using articles under the categories Autos and Motorcycles, and corpus C-5 using articles under the categories PC Hardware and Mac Hardware. In corpora C-4 and C-5, the corresponding categories are closely related to each other and hard to distinguish from article texts.

We created the Wikipedia corpora as follows. When a Wikipedia article is created, it is typically tagged to one or more categories, one of which is the "primary category." For each article, we took its true topic label to be the primary category label for the article. We created corpus C-6 from a subset of the Wikipedia articles under the categories *Leopardus*, *Lynx*, and *Prionailurus* and corpus C-7 from a subset of the Wikipedia articles under the categories *Acinonyx*, *Leopardus*, *Prionailurus*, and *Puma*. All the categories of corpora C-6 and C-7 are part of the Wikipedia supercategory *Felines*. We created corpus C-8 from a subset of the Wikipedia articles under the categories *Coyotes*, *Jackals*, and *Wolves*. All three categories of corpus C-8 are under the Wikipedia supercategory *Canis*. Finally, we created corpus C-9 from a subset of the Wikipedia articles under the categories *Eagles*, *Falco (genus)*, *Falconry*, *Falcons*, *Harriers*, *Hawks*, *Kites*, and *Owls*. All eight categories of corpus C-9 are subcategories of the Wikipedia category *Birds of Prey*. For each of the four Wikipedia corpora that we created, the categories of the articles are closely related to each other, and fairly hard to distinguish from article texts.

Table 2 gives some information on the nine corpora we created. In the table, the column labeled V gives the vocabulary size for each corpus, the column labeled N gives the total number of words for each corpus, and the column labeled Categories gives newsgroup categories for each 20Newsgroup corpus, and Wikipedia categories for each Wikipedia corpus. The numbers shown in parentheses next to the category names are the number of documents associated with the corresponding categories. For each corpus, we took the number of topics K to be equal to the number of categories for the corpus.

Table 2: Corpora created from the 20Newsgroups dataset and the Wikipedia pages.

Comparison of Model Fit We now compare the performance of the LDA models indexed by $\hat{\hat{h}}_{\text{ST}}$, $\hat{\hat{h}}_{\text{GEM}}$, $\hat{\hat{h}}_{\text{VEM}}$, h_{DR}, h_{DA}, and h_{DG} for corpora C-1–C-9, using the estimate of the score $S(h)$, which we denote by $\widehat{S}(h)$, described in the beginning of this subsection. Details regarding how $\hat{\hat{h}}_{\text{ST}}$ was computed and regarding its accuracy are given in the supplementary document George and Doss. The actual values of $\hat{\hat{h}}_{\text{ST}}$, $\hat{\hat{h}}_{\text{GEM}}$, and $\hat{\hat{h}}_{\text{VEM}}$, are also given in George and Doss.

To compute $\widehat{S}(h)$ for a corpus, for every held-out document, we used Chen's (2015) method with a full Gibbs sampling chain of length 2,000, after discarding a short burn-in period. Table 3 gives the ratios $\widehat{S}(h)/\widehat{S}(\hat{\hat{h}}_{\text{ST}})$, where h is $\hat{\hat{h}}_{\text{GEM}}$, $\hat{\hat{h}}_{\text{VEM}}$, h_{DR}, h_{DA}, and h_{DG}, for all nine corpora. From the table, we make three main observations: (1) Any of the estimates of $\hat{\hat{h}}$ are better than any of the ad-hoc choices, uniformly, and by wide margins. (2) Within the estimates of $\hat{\hat{h}}$, ST does better than either GEM or VEM on the whole, although not in every case, and when it is outperformed, it is not by much. (3) As a general pattern, the lack of fit of the models indexed by the ad-hoc choices of h is worse for the Wikipedia corpora than for the 20Newsgroups corpora. The Wikipedia corpora may be considered "difficult," in the sense that for these corpora the articles are very similar, and thus hard to distinguish from article texts. On the other hand, within the group of estimates of $\hat{\hat{h}}$, it is not clear what are the characteristics of a corpus which affect the fit—there may be factors, beyond similarity of the documents, that are relevant.

Implementation Details To compute $\widehat{M}_{\zeta}(h)$, we implemented the serial tempering scheme described in Section 2 as follows. The size of the subgrid was taken to be $7 \times 13 = 91$, and we used six iterations of the iterative scheme described in Section 2.3 to form the final subgrid, using Markov chains of length 10,000. For the run using the final subgrid, we used three iterations of the scheme given by (2.16) to obtain ζ^{final}, with a Markov chain length of 50,000 per iteration (after a short burn-in period). The final run, using ζ^{final}, also used a Markov chain length of 50,000. To estimate the standard error of $\widehat{M}_{\zeta}(h)$, we used the method of batch means, which is implemented by the R package `mcmcse` in Flegal et al. (2016). Diagnostics that establish that the serial tempering

Corpus	$\hat{\hat{h}}_{\text{GEM}}$	$\hat{\hat{h}}_{\text{VEM}}$	h_{DR}	h_{DA}	h_{DG}
C-1	6.78×10^{-01}	4.83×10^{-01}	3.54×10^{-01}	$1.11 \times 10^{+00}$	8.24×10^{-04}

C-9	$1.04 \times 10^{+00}$	1.75×10^{-02}	2.17×10^{-02}	7.04×10^{-03}	5.56×10^{-09}

Table 3: Ratios of the estimates of the fit criterion $S(h)$ to estimate of $S(\hat{\hat{h}}_{\text{ST}})$ for five choices of h, for all nine corpora. A small number indicates a lack of fit, thus a poor choice of h, and by this criterion, all ad-hoc choices perform poorly.

chain mixes adequately are given in the supplementary document George and Doss. Table 4 gives the time it took to compute $\hat{\hat{h}}_{\text{VEM}}$, $\hat{\hat{h}}_{\text{GEM}}$, and $\hat{\hat{h}}_{\text{ST}}$, for three of the real corpora used in this section.

Corpus	K	$\hat{\hat{h}}_{\text{VEM}}$	$\hat{\hat{h}}_{\text{GEM}}$	$\hat{\hat{h}}_{\text{ST}}$
C-2	4	0.18	7.72	409.75
C-4	2	0.10	3.78	195.90
C-9	8	1.20	59.12	287.97

Table 4: Execution times, in minutes, for three corpora, on a 3.70GHz quad core Intel Xeon Processor E5-1630V3.

It is natural to ask why it has not been noted before that VI-EM and Gibbs-EM sometimes perform poorly. Evaluations have been typically done through a model fit criterion such as the one we used in this subsection, and to the best of our knowledge the literature has not given an assessment of how close $\hat{\hat{h}}_{\text{VEM}}$ and $\hat{\hat{h}}_{\text{GEM}}$ are to h_{true} for corpora generated from an LDA model indexed by h_{true}, as is done in Section 5.1.

6. Discussion

Inference from LDA depends heavily on the choice of hyperparameters used to fit the model. To estimate the hyperparameters, we view the analytically intractable $\hat{h} = \arg\max_h m(h)$, which is a function of the document corpus itself, as the gold standard, and we have developed a methodology for estimating $\hat{h}$. The basis for our approach is a stable method, based on a single serial tempering Markov chain, for estimating the entire marginal likelihood function $m(h)$ (up to a constant). For a given function of the parameters of the model, essentially the same method enables us to estimate the entire family of posterior expectations of the parameters as the hyperparameter varies, and

this feature enables us to carry out an analysis of sensitivity of our inference with respect to the hyperparameters.

Hyperparameter selection is a simple form of model selection and we note that, generally speaking, in carrying out model selection there are two competing goals. One goal is to select the correct model, and the other goal is to select the model that "provides the best inference." These two goals are not the same. The second goal is particularly relevant when the document corpus is a real data set, i.e. the corpus is not necessarily generated from the LDA model, and we use LDA as a convenient model through which to make inference. Selection of the hyperparameter via maximization of the marginal likelihood is akin to maximum likelihood estimation and, as such, should have the standard properties of maximum likelihood estimates. We will avoid giving a technical explanation of this last fact, and instead state it informally as follows: for a corpus generated according to the LDA model indexed by h_{true}, if the corpus is large, then $\hat{h}$ is close to h_{true}. So the empirical Bayes method achieves the first goal by its very nature, and we have verified this empirically in Section 3. The evaluation in Section 5 shows (at least empirically) that the empirical Bayes method also accomplishes the second goal.

A Fully Bayes Approach to Empirical Bayes Inference For serial tempering to work, it is necessary for the grid points $h_1, \ldots, h_J$ to cover $\mathcal{H}$. Unfortunately, when $\dim(\mathcal{H})$ is large, the value of J that is needed is huge, and the approach breaks down. Here we discuss an entirely different method. Although there is no inherent limitation on $\dim(\mathcal{H})$ for the method to work, we view it as useful for the case where $\dim(\mathcal{H})$ is moderate: we re-iterate our caution stated in Remark 3 of Section 2.1 that it is not advisable to use a high-dimensional h.

Suppose $\mathcal{H}$ is a bounded hyper-rectangle. We put a uniform distribution on $\mathcal{H}$, denoted $u(h)$, and in this fully-Bayes situation the parameter is now $(\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z}, h)$. The marginal posterior distribution of h is then $\pi(h) \propto m_{\boldsymbol{w}}(h)u(h) \propto m_{\boldsymbol{w}}(h)$, and we see that $\arg\max_h m_{\boldsymbol{w}}(h) = \arg\max_h \pi(h)$. Suppose that $(\boldsymbol{\beta}^{(1)}, \boldsymbol{\theta}^{(1)}, \boldsymbol{z}^{(1)}, h^{(1)}), \ldots, (\boldsymbol{\beta}^{(n)}, \boldsymbol{\theta}^{(n)}, \boldsymbol{z}^{(n)}, h^{(n)})$ is a Markov chain whose invariant distribution is the posterior distribution of $(\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{z}, h)$ given $\boldsymbol{w}$ [see Wallach (2008)]. From the marginal sequence $h^{(1)}, \ldots, h^{(n)}$ we may estimate $\pi(h)$ via a multivariate density estimator, and hence $\arg\max_h \pi(h)$. Call this estimate $\bar{h}$. We then use (2.1), with $\bar{h}$ as the value of h_*, to estimate $m_{\boldsymbol{w}}(h)$ in a small neighborhood of $\bar{h}$, which is all that we need in order to estimate $\arg\max_h m_{\boldsymbol{w}}(h)$. In effect, $\bar{h}$ is an initial coarse estimate of $\arg\max_h m_{\boldsymbol{w}}(h)$, and (2.1) is then used to fine-tune it. We hope to develop this idea fully in future work.

Acknowledgments

We are grateful to three referees for their very helpful constructive criticism. This work is supported by the International Center for Automated Research at the UF Levin College of Law, NSF Grant DMS-11-06395, and NIH grant P30 AG028740.

Appendix

A.1 A Likelihood Ratio Formula for the Parameters in the LDA Model

To obtain the ratio of densities formula (2.2), we note that from the hierarchical nature of the LDA model we have

$$\nu_h(\boldsymbol{\psi}) = \nu_h(\boldsymbol{\beta},\boldsymbol{\theta},\boldsymbol{z}) = p^{(h)}_{\boldsymbol{z}\,|\,\boldsymbol{\theta},\boldsymbol{\beta}}(\boldsymbol{z}\,|\,\boldsymbol{\theta},\boldsymbol{\beta})\, p^{(h)}_{\boldsymbol{\theta}}(\boldsymbol{\theta})\, p^{(h)}_{\boldsymbol{\beta}}(\boldsymbol{\beta})$$

in self-explanatory notation, where $p^{(h)}_{\boldsymbol{z}\,|\,\boldsymbol{\theta},\boldsymbol{\beta}}$, $p^{(h)}_{\boldsymbol{\theta}}$, and $p^{(h)}_{\boldsymbol{\beta}}$ are given by lines 3, 2, and 1, respectively, of the LDA model. Let $n_{dj} = \sum_{i=1}^{n_d} z_{dij}$, i.e. n_{dj} is the number of words in document d that are assigned to topic j. Using the Dirichlet and multinomial distributions specified in lines 1–3 of the model, we obtain

$$\nu_h(\boldsymbol{\psi}) = \left[\prod_{d=1}^{D}\prod_{j=1}^{K}\theta_{dj}^{n_{dj}}\right]\left[\prod_{d=1}^{D}\left(\frac{\Gamma(\sum_{j=1}^{K}\alpha_j)}{\prod_{j=1}^{K}\Gamma(\alpha_j)}\prod_{j=1}^{K}\theta_{dj}^{\alpha_j-1}\right)\right]\left[\prod_{j=1}^{K}\left(\frac{\Gamma(V\eta)}{\Gamma(\eta)^V}\prod_{t=1}^{V}\beta_{jt}^{\eta-1}\right)\right]. \tag{A.1}$$

We now apply (A.1) to ν_h and ν_{h_*} and obtain (2.2).

A.2 Proof of Theorem 1

The convergence in (2.1) holds for each fixed h; however, $\arg\max_h B_n(h)$ depends on the function $B_n(\cdot)$. Before proving Theorem 1 we provide an example to show that if f_n and f are real-valued functions, then convergence of f_n to f pointwise does not imply convergence of $\arg\max_h f_n(h)$ to $\arg\max_h f(h)$. In our example, the domain of the functions is the interval $[0,1]$, and the functions are displayed in Figure 9. The functions f_n and f are identical on the interval $[2/n, 1]$. Clearly $f_n(h) \to f(h)$ for each $h \in [0,1]$, but $\arg\max_h f_n(h) = 1/n$ while $\arg\max_h f(h) = .9$.

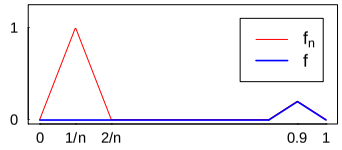

Figure 9: Non-convergence of the argmax.

Theorem 1 refers to the regularity conditions below.

A1 The hyperparameter space $\mathcal{H}$ is compact.

A2 The maximizer of $m(\cdot)$ is unique (thus it makes sense to talk about $\arg\max_h m(h)$).

A3 The maximizer of $m(\cdot)$ is in $\mathcal{H}$.

A4 For each n, the maximizer of $B_n(\cdot)$ is unique (thus we can talk about $\arg\max_h B_n(\cdot)$).

A5 The point $h_* = (\eta^*, \boldsymbol{\alpha}^*)$ satisfies $2\eta - \eta^* > 0$ and $2\alpha_j - \alpha_j^* > 0$, $j = 1,\ldots,K$ for all $h = (\eta, \boldsymbol{\alpha}) \in \mathcal{H}$.

A6 The marginal likelihood function $m(\cdot)$ is twice continuously differentiable in $\mathcal{H}$, and the $p \times p$ Hessian matrix $\nabla_h^2 m(\arg\max_h m(h))$ is nonsingular.

Proof of Part 1 Note the following:

- In Section 4 we showed that the ACGS is uniformly ergodic. So in particular, it is Harris ergodic.

- The LDA model is an exponential family with parameter (η, α) (Section 3.3 of Wainwright and Jordan (2008)).
- In their Remark 1, Doss and Park (2018) show that if $\{\nu_h,\ h \in \Omega\}$ is an exponential family, where Ω is the natural parameter space, and if $\mathcal{H}$ is a compact subset of the interior of Ω, then $\int \sup_{h\in\mathcal{H}}(\nu_h/\nu_{h_*})\, d\nu_{h_*,\boldsymbol{w}} < \infty$. (In empirical process theory, finiteness of this integral is the main condition that is needed to obtain uniformity in the Law of Large Numbers.)
- In the context of the present situation, Theorem 3 of Doss and Park (2018) states that under Harris ergodicity of the sequence $\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \ldots$ and finiteness of $\int \sup_{h\in\mathcal{H}}(\nu_h/\nu_{h_*})\, d\nu_{h_*,\boldsymbol{w}}$, the convergence in (2.1) is uniform on $\mathcal{H}$, i.e. Condition C3 of Section 2.1 holds.
- Suppose that f_n, $n = 1, 2, \ldots$ and f are real-valued functions defined on a compact subset X of Euclidean space. Suppose further that f is continuous and that each of f_n, $n = 1, 2, \ldots$ and f has a unique maximizer. Under these conditions, uniform convergence of f_n to f on X implies $\arg\max_{x\in\mathsf{X}} f_n(x) \to \arg\max_{x\in\mathsf{X}} f(x)$. Verification of this fact is routine. A detailed proof is given in Lemma 1 of Doss and Park (2018).

Combining these facts, we see that under A1–A4, $\arg\max_h B_n(h) \to \arg\max_h m(h)$ with probability one (Assumptions A5 and A6 are not needed for Part 1 of the theorem.) □

Proof of Part 2 Theorem 4 of Doss and Park (2018) asserts the asymptotic normality stated in Part 2 of Theorem 1 under A1–A4 and A6, the condition

$$\text{for every } h \in \mathcal{H} \text{ there exists } \epsilon > 0 \text{ such that } \int \|\nabla_h(\nu_h/\nu_{h_*})\|^{2+\epsilon}\, d\nu_{h_*,\boldsymbol{w}} < \infty, \tag{A.2}$$

where $\|\cdot\|$ is the Euclidean norm in $\mathbb{R}^p$, and the condition that the Markov chain used is geometrically ergodic. Using standard calculus, we can check that if $2\eta - \eta^* > 0$ and $2\alpha_j - \alpha_j^* > 0$, $j = 1,\ldots,K$, then for sufficiently small ϵ the integral in (A.2) is finite. Thus, Condition A5 implies (A.2). As mentioned in the proof of Part 1 of the theorem, the ACGS is uniformly ergodic; so in particular, it is geometrically ergodic. Thus, we have established the asymptotic normality stated in Part 2 of the theorem under A1–A6. □

Proof of Part 3 The variance matrix Σ in Part 2 is analytically intractable, but fortunately is easy to estimate via the method of batching, as follows. For $j = 1,\ldots,J$, let $h^{[j]}$ be the estimate of the argmax produced from batch j, and let $h^{[\cdot]}$ be the estimate of the argmax produced from the entire sequence. The batch-based estimate is $\widehat{\Sigma}_n = (n/J)\big\{[1/(J-1)]\sum_{j=1}^{J}\big(h^{[j]} - h^{[\cdot]}\big)\big(h^{[j]} - h^{[\cdot]}\big)^\top\big\}$. (The quantity inside the braces is essentially the sample covariance matrix of $h^{[1]},\ldots,h^{[J]}$, except that we use $h^{[\cdot]}$ instead of the average of $h^{[1]},\ldots,h^{[J]}$ as the centering value; and the term n/J is the number of samples per batch.) Estimates of the covariance matrix based on batching are consistent under very general conditions which include that $J \to \infty$ as $n \to \infty$. The literature recommends taking $J = n^{1/2}$; see Flegal et al. (2008) and also Jones et al. (2006). Invertibility of $\widehat{\Sigma}_n$ for large n follows from positive definiteness of Σ and the convergence $\widehat{\Sigma}_n \xrightarrow{\text{a.s.}} \Sigma$; in fact we have $\widehat{\Sigma}_n^{-1} \xrightarrow{\text{a.s.}} \Sigma^{-1}$. Therefore, applying Part 2, we get

$$n^{1/2}\big(\arg\max_h B_n(h) - \arg\max_h m(h)\big)\widehat{\Sigma}_n^{-1} n^{1/2}\big(\arg\max_h B_n(h) - \arg\max_h m(h)\big)^\top \xrightarrow{d} \chi^2_p,$$

which establishes the statement regarding the ellipse. □

Proof of Theorem 1 for the Serial Tempering Chain The main change in the proof is that the requirement (A.2) is replaced with

$$\text{for every } h \in \mathcal{H} \text{ there exists } \epsilon > 0 \text{ such that } \int \|\nabla_h(\nu_h/\nu_\zeta)\|^{2+\epsilon}\, df_\zeta < \infty, \tag{A.3}$$

where $\nu_\zeta = (1/J)\sum_{j=1}^{J} \nu_j(\boldsymbol{\psi}_i)/\zeta_j$, and f_ζ is given by (2.9). It is easy to see that (A.3) is satisfied if the stipulation on h_* given by (2.3) holds for $h^{(j)}$ for at least one index j. □

A.3 Proof of Validity of the Confidence Band for $\{I(h),\, h \in \mathcal{H}\}$

In addition to assuming that $J \to \infty$ and $n/J \to \infty$, we will need the following conditions:

A7 The stipulation on h_* given by (2.3) holds for $h^{(j)}$ for at least one index j.

A8 The function g satisfies the moment condition

$$\text{for every } h \in \mathcal{H} \text{ there exists } \epsilon > 0 \text{ such that } \int \left(g\frac{\nu_h}{\nu_\zeta}\right)^{2+\epsilon} df_\zeta < \infty.$$

Note that A8 is automatically satisfied if A7 holds and g is bounded (for example if g is an indicator function, as in Section 2.4). In the following, we will assume Conditions A1, A7, and A8.

The heart of the proof is the assertion that $\sup_{h\in\mathcal{H}} n^{1/2}\big|\hat{I}^{\text{st}}_\zeta(h) - I(h)\big|$ has a limiting distribution as $n \to \infty$, and we show this in three steps:

1. We observe that for each h, $n^{1/2}\big(\hat{I}^{\text{st}}_\zeta(h) - I(h)\big)$ has an asymptotic normal distribution.
2. We show that more can be said, and that the stochastic process $\big\{n^{1/2}\big(\hat{I}^{\text{st}}_\zeta(h) - I(h)\big),\, h \in \mathcal{H}\big\}$ converges in distribution to a mean-zero Gaussian process indexed by h.
3. We conclude from Step 2 that $\sup_{h\in\mathcal{H}} n^{1/2}\big|\hat{I}^{\text{st}}_\zeta(h) - I(h)\big|$ has a limiting distribution as $n \to \infty$.

We now provide the details.

1. Note that $\hat{I}^{\text{st}}_\zeta(h)$, defined in (2.14), is a ratio of $\widehat{M}_\zeta(h)$ and $\widehat{U}_\zeta(h)$, which are given by (2.10) and (2.12), respectively. Each of these is an average of a function of $\boldsymbol{\psi}_1, \ldots, \boldsymbol{\psi}_n$, so we have a bivariate central limit theorem, as follows. For economy of notation, let $U_i^{(h)}$ be the summands in (2.12) and let $M_i^{(h)}$ be the summands in (2.10). We have

$$n^{1/2}\begin{pmatrix} \frac{1}{n}\sum_{i=1}^{n} U_i^{(h)} - \frac{m(h)}{c_\zeta/J}\int g\, d\nu_{h,\boldsymbol{w}} \\ \frac{1}{n}\sum_{i=1}^{n} M_i^{(h)} - \frac{m(h)}{c_\zeta/J} \end{pmatrix} \xrightarrow{d} \mathcal{N}_2(0, \Sigma_h),$$

where Σ_h is a covariance matrix. (If the $\boldsymbol{\psi}$'s were an iid sequence, then Σ_h would be simply the covariance matrix of the pair $(U_1^{(h)}, M_1^{(h)})$; however, in the present situation, Σ_h is the more complicated covariance matrix that arises in the Markov chain central limit theorem.) Therefore, by the delta method applied to the function $\varphi\colon \mathbb{R}^2 \to \mathbb{R}$ defined by $\varphi(u, m) = u/m$, we have

$$n^{1/2}\left(\frac{\sum_{i=1}^{n} U_i^{(h)}}{\sum_{i=1}^{n} M_i^{(h)}} - \int g\, d\nu_{h,\boldsymbol{w}}\right) \xrightarrow{d} \mathcal{N}\big(0, (\nabla\varphi)^\top \Sigma_h \nabla\varphi\big), \tag{A.4}$$

where the gradient $\nabla\varphi$ is evaluated at $\big((1/n)\sum_{i=1}^{n} U_i^{(h)}, (1/n)\sum_{i=1}^{n} M_i^{(h)}\big)$. Now note that the quantity to the left of the "$\xrightarrow{d}$" sign in (A.4) is precisely $n^{1/2}\big(\hat{I}^{\text{st}}_\zeta(h) - I(h)\big)$.

2. To extend convergence in distribution for each fixed h to convergence as a stochastic process, we use Part 4 of Theorem 6 of Doss and Park (2018). Because we assume Conditions A1, A7, and A8 and because the distributions of the latent parameters in the LDA model form an exponential family, the regularity conditions for that theorem are satisfied, and we conclude that $n^{1/2}\big(\hat{I}^{\text{st}}_\zeta(\cdot) - I(\cdot)\big) \xrightarrow{d} G(\cdot)$, where $G(\cdot)$ is a mean-zero Gaussian process indexed by h. Here, convergence in distribution takes place in $C(\mathcal{H})$, the space of continuous real-valued functions defined on $\mathcal{H}$, endowed with the sup-norm topology.
3. The map $T\colon C(\mathcal{H}) \to [0, 1]$ defined by $T(f) = \sup_{h\in\mathcal{H}} |f(h)|$ is continuous, so from Step 2 we conclude that $\sup_{h\in\mathcal{H}} n^{1/2}\big|\hat{I}^{\text{st}}_\zeta(h) - I(h)\big| \xrightarrow{d} \sup_{h\in\mathcal{H}} |G(h)|$.

Substitution of the $\mathcal{S}_j$'s for the S_j's is valid under the assumption that $J \to \infty$, convergence in probability of $\mathcal{S}_{\lceil .95J\rceil}$ to $c_{.95}$ is a consequence of the condition $n/J \to \infty$, and the validity of the bands now follows. The literature's recommendation of $J = n^{1/2}$ is made in the different context of estimating the variance of an average, not for forming globally-valid confidence bands; nevertheless, in our experience this choice works well also in the present situation.

Abstract

It is well established that neural networks with deep architectures perform better than shallow networks for many tasks in machine learning. In statistical physics, while there has been recent interest in representing physical data with generative modelling, the focus has been on shallow neural networks. A natural question to ask is whether deep neural networks hold any advantage over shallow networks in representing such data. We investigate this question by using unsupervised, generative graphical models to learn the probability distribution of a two-dimensional Ising system. Deep Boltzmann machines, deep belief networks, and deep restricted Boltzmann networks are trained on thermal spin configurations from this system, and compared to the shallow architecture of the restricted Boltzmann machine. We benchmark the models, focussing on the accuracy of generating energetic observables near the phase transition, where these quantities are most difficult to approximate. Interestingly, after training the generative networks, we observe that the accuracy essentially depends only on the number of neurons in the first hidden layer of the network, and not on other model details such as network depth or model type. This is evidence that shallow networks are more efficient than deep networks at representing physical probability distributions associated with Ising systems near criticality.

Keywords: deep learning, restricted Boltzmann machine, deep belief network, deep Boltzmann machine

1. Introduction

It is empirically well supported that neural networks with deep architectures perform better than shallow networks for certain machine learning tasks involving data with complex, hierarchal structures (Hinton and Salakhutdinov, 2006). This has led to an intense focus on developing deep neural networks for use on data sets related to natural images, speech, video, social networks, etc. with demonstrable success. In regard to theoretical understanding, among the most profound questions facing the modern machine learning community is why, and under what conditions, are deep neural networks superior to shallow (single-hidden-layer) models. Further, does the success of deep architectures in extracting features from conventional big data translate into arenas with other highly complex data sets, such as those encountered in the physical sciences?

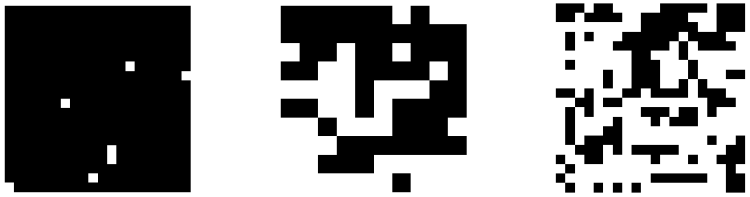
Very recently, the statistical physics community has become engaged in exploring the representational power of generative neural networks such as the restricted Boltzmann machine (RBM; Carleo and Troyer, 2017; Wetzel, 2017). There, the "curse of dimensionality" is manifest in the size of state space (Carrasquilla and Melko, 2017), which for example, grows as 2^N for a system of N binary (or *Ising*) variables. The central problem in much of statistical physics is related to determining and sampling the probability distribution of this state space. Therefore, the possibility of efficiently modelling a physical probability distribution with a generative neural network has broad implications for condensed matter, materials physics, quantum computing, and other areas of the physical sciences involving the statistical mechanics of N-body systems.

The universal approximation theorem, while establishing the capability of neural networks as generative models in theory, only requires the very weak assumption of exponentially large resources (Le Roux and Bengio, 2008; Montúfar and Morton, 2015). In both quantum and classical statistical physics applications, the goal is to calculate macroscopic *features* (for example, a heat capacity or a susceptibility) from the N-body equations. For this, an *efficient* representation is desired that demands computer resources which scale polynomially, typically in the number of particles or lattice sites, $\mathcal{O}(N^c)$ where c is a constant. In this case, "resources" could refer to memory or time; for example, the number of model parameters, the size of the data set for training, or the number of samples required of the model to accurately reproduce physical features.

Thus we can refine our question: are deep neural networks more efficient than shallow networks when modelling physical probability distributions, and if so, why? In this paper we address the dependence of generative modelling on network depth directly for the prototypical physical system of the two-dimensional (2D) lattice Ising model. The most important feature of this system is the existence of a phase transition (or *critical point*), with subtle physical features that are theoretically known to require a non-trivial multi-scale description. We define criteria for the accuracy of a generative model, based on the convergence of the energy and energy fluctuations of samples generated from it, to the exact physical values calculated near the phase transition. Using various types of generative neural networks with a multitude of widths and depths, we find the surprising result that accurate modelling depends only on the *architecture* of the network—defined as the set of integers specifying the number of neurons in each network layer. Furthermore, we show that the accuracy of the neural network only depends significantly on the number of hidden units in the first hidden layer. This illustrates that in this physical example, depth does not contribute to the representational efficiency of a generative neural network, even near a non-trivial scale-invariant phase transition.

2. The 2D Ising System Near Criticality

In order to benchmark the representational power of generative neural networks, we replace naturally occurring data common to machine learning applications with synthetic data for a system intimately familiar to statistical physicists, the 2D Ising model. This system is defined on an N-site square lattice, with binary variables (spins) $x_i \in \{0, 1\}$ at each lattice



(a) $T < T_c$ (b) $T \approx T_c$ (c) $T > T_c$

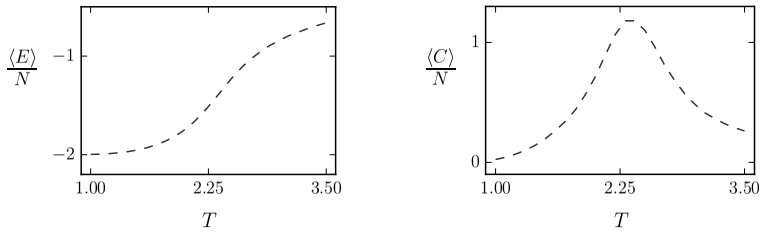
Figure 1: Representative Ising spin configurations on a $N = 20 \times 20$ site lattice. In (a) is the ferromagnetic phase below T_c; (b) is the critical point or phase transition; and (c) is above T_c in the paramagnetic phase. Such configurations play the role of 2D images for the training of generative neural networks in this paper.

site i. The physical probability distribution defining the Ising model is the Boltzmann distribution

$$q(x) = \frac{1}{Z} \exp(-\beta H(x)) \tag{1}$$

determined by the Hamiltonian (or physical energy) $H(x) = -\sum_{\langle i,j \rangle} \sigma_i \sigma_j$, where $\sigma_i = 2x_i - 1$. Here, Z is the normalization factor (or partition function), and $\langle i, j \rangle$ denotes nearest-neighbour sites. As a function of inverse temperature $\beta = 1/k_B T$ (with $k_B = 1$), the Ising system displays two distinct phases, with a phase transition at $T_c = 2/\log\left(1+\sqrt{2}\right) \approx 2.2693$ in the thermodynamic limit where $N \to \infty$ (Kramers and Wanniers, 1941; Onsager, 1944). In this limit, the length scale governing fluctuations—called the *correlation length* ξ—diverges to infinity resulting in emergent macroscopic behavior such as singularities in measured observables like heat capacity or magnetic susceptibility. Phase transitions with a diverging ξ are called *critical points*. Criticality makes understanding macroscopic phenomena (or features) from the microscopic interactions encoded in $H(x)$ highly non-trivial. The most successful theoretical approach is the renormalization group (RG), which is a muli-scale description where features are systematically examined at successively deeper coarse-grained levels of scale (Wilson and Fisher, 1972). Physicists have begun to explore in ernest the conceptual connection between deep learning and the RG (Mehta and Schwab, 2014; Koch-Janusz and Ringel, 2017).

We concentrate on two-dimensional lattices with finite N, where remnants of the true thermodynamic ($N \to \infty$) phase transition are manifest in physical quantities. We are interested in approximately modelling the physical distribution $q(x)$, both at and near this phase transition, using generative neural networks. Real-space spin configurations at fixed temperatures play the role of data sets for training and testing the generative models of the next section. Configurations—such as those illustrated in Figure 1—are sampled from Equation 1 using standard Markov Chain Monte Carlo techniques described elsewhere; see for example, Newman and Barkema (1999). For a given temperature T and lattice size N, training and testing sets of arbitrary size can be produced with relative ease, allowing us



(a) Energy per Ising spin. (b) Heat capacity per Ising spin.

Figure 2: Physical data for the energy and heat capacity of an $N = 64$ square-lattice Ising system, calculated using Markov Chain Monte Carlo.

to explore the representational power of different generative models without the concern of regularization due to limited data.

In order to quantify the representational power of a given neural network, we use the standard recently introduced by Torlai and Melko (2016), which is the faithful recreation of physical observables from samples of the visible layer of a fully-trained generative neural network. As a reference, observables such as average energy E and heat capacity $C = \partial E/\partial T$ are calculated from the physical distribution, that is, $\langle E \rangle = Z^{-1} \sum_x q(x) H(x)$ and $\langle C \rangle = (\langle E^2 \rangle - \langle E \rangle^2)/T^2$. Using shallow RBMs, Torlai and Melko examined the convergence of these and other physical observables for 2D Ising systems on different size lattices. For a lattice of N Ising spins, the number of hidden neurons in the RBM, N_{h_1} (see below), was increased until the observables modelled by the RBM approached the exact, physical values calculated by Monte Carlo. In the RBM, N also represents the number of visible units. Thus, the ratio $\alpha \equiv N_{h_1}/N$—describing the network resources per lattice site—serves as a convergence parameter measuring the overall efficiency of this machine learning approach. It was shown by Chen et al. (2017) that this ratio is bounded above by $\alpha = 2$ for the same 2D Ising model we consider in this paper, a bound consistent with the results of numerical simulations detailed in sections below.

In Figure 2 we illustrate the energy E and heat capacity C calculated via Monte Carlo for the $N = 64$ square-lattice Ising model. Near the critical point $T_c \approx 2.2693$, C retains a finite-size remnant of the divergence expected when $N \to \infty$. As observed by Torlai, it is here where the accuracy of the modelled neural network data suffers most from an insufficient number of hidden units. In this paper, we therefore concentrate on the convergence of E and C near T_c as a function of model parameters.

3. Generative Graphical Models

In this section, we briefly introduce the shallow and deep stochastic neural networks that serve as generative graphical models for reproducing Ising observables. These stochastic neural networks are made up of a set of binary neurons (nodes) which can be in the state 0

or 1, each with an associated bias, and weighted connections (edges) to other neurons. For this type of model, neurons are partitioned into two classes, visible and hidden neurons, such that the model defines a joint probability distribution $p(v, h)$ over the visible and hidden neurons, v and h respectively (or h_1, h_2, and so on for multiple hidden layers). The weights and biases of a model—collectively referred to as "model parameters", and indicated by θ—determine the state of each neuron given the state of other connected neurons. They therefore define the model and parametrize the probability distribution $p(v, h)$ given a fixed architecture, which we define to specify only the number of neurons in each layer that makes up the network. A model's parameters can be trained such that its distribution over the visible units matches a desired probability distribution $q(v)$, for example, the thermal distribution of Ising variables ($v = x$) in Equation 1. More explicitly, given data samples from $q(v)$, θ are adjusted so that

$$p(v) \equiv \sum_{\{h\}} p(v, h) \approx q(v).$$

Once training is complete, θ are fixed, and the states of both visible and hidden neurons can be importance sampled with block Gibbs sampling, as long as the graph is bipartite. Since the purpose of the model distribution is a faithful representation of the physical distribution, this allows us to calculate physical estimators from the neural network, for example, $\langle E \rangle = \|\mathcal{S}\|^{-1} \sum_{v \in \mathcal{S}} H(v)$, where $\mathcal{S}$ is a set of configurations importance sampled from the network's visible nodes. It is the convergence of these estimators—in particular, $\langle E \rangle$ and $\langle C \rangle$—to the true values obtained via Monte Carlo that we will focus on in later sections.

Training such generative models requires data, which in this paper is the binary spin configurations of an N-site 2D lattice Ising model. Training often presents practical limitations that dictate which types of stochastic neural network are effective. The major practical limitation is the problem of inferring the state of the hidden neurons given the state of the visible layer, which is often clamped to values from the data during training. Therefore, we only use models in which such inference can be done efficiently. Below we outline these models, which we compare and contrast for the task of modelling a physical distribution in Section 4.

3.1 Restricted Boltzmann Machines

When visible and hidden nodes are connected in an undirected graph by edges (representing a weight matrix), the model is called a *Boltzmann machine* (Ackley et al., 1985). The original Boltzmann machine with all-to-all connectivity suffers from intractable inference problems. When the architecture is restricted so that nodes are arranged in layers of visible and hidden units, with no connection between nodes in the same layer, this problem is alleviated. The resulting model, which is depicted in Figure 3, is known as an RBM (Smolensky, 1986). The joint probability distribution defining the RBM is

$$p(v, h) = \frac{\exp\left(b^T v + c^T h + v^T W h\right)}{Z},$$

where Z is a normalization constant or partition function, b and c are biases for the visible and hidden neurons respectively, and W is the matrix of weights associated to the connec-

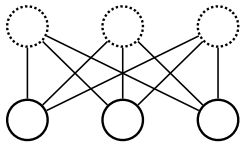


Figure 3: The restricted Boltzmann machine graph. The solid circles at bottom represent visible nodes, v. The dashed circles at top represent hidden nodes, h. Straight lines are the weights W.

tions between visible and hidden neurons. This is known as an energy-based model, because it follows the Boltzmann distribution for the "energy" function

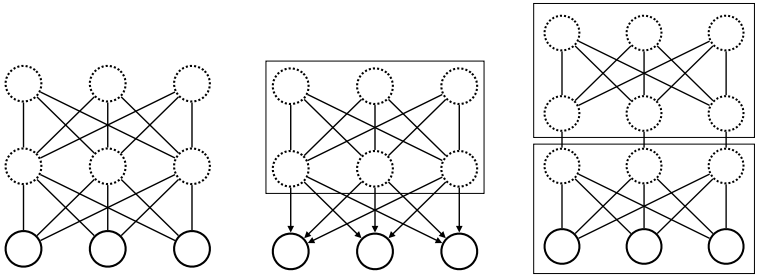
$$E_{\text{RBM}}(v, h) = -b^T v - c^T h - v^T W h.$$

In order to train the RBM (Hinton, 2012), the negative log-likelihood $\mathcal{L}$ of the training data set $\mathcal{D}$ is minimized over the space of model parameters θ, where $\mathcal{L}(\mathcal{D}) = -\frac{1}{\|\mathcal{D}\|} \sum_{v \in \mathcal{D}} \log p(v)$. In other words, the model parameters of the RBM are tuned such that the probability of generating a data set statistically similar to the training data set is maximized. This is done via stochastic gradient descent, where instead of summing over $v \in \mathcal{D}$, the negative log-likelihood of a mini-batch $\mathcal{B}$ (with $\|\mathcal{B}\| \ll \|\mathcal{D}\|$) is minimized. The mini-batch is changed every update step, and running through all $\mathcal{B} \in \mathcal{D}$ constitutes one epoch of training. The gradient of the negative log-likelihood must be calculated with respect to weights and biases, and consists of two terms as described in Appendix A; the data-dependent correlations, and the model-dependent correlations. The latter term is computed approximately by running a Markov chain through a finite number k steps starting from the mini-batch data. This approximation is called *contrastive divergence* (CD-k, Hinton, 2002) which we use to train the models in this paper. In order to use the CD-k learning algorithm, efficient block Gibbs sampling must be possible. Because of the restricted nature of the RBM, the hidden variables are conditionally independent given the visible variables, and the posterior factorizes. The state of the hidden units can then be exactly inferred from a known visible configuration in the RBM, using the conditional probability

$$p(h_i = 1|v) = \sigma\left(\left(c^T + v^T W\right)_i\right), \tag{2}$$

with a similar expression for $p(v_i = 1|h)$. For reference, we also provide the derivation of this conditional probability distribution in Appendix A.

Once trained, samples of the RBM's probability distribution can be generated by initializing v to random values, then running Gibbs sampling as a Markov Chain ($v_0 \mapsto h_0 \mapsto v_1 \mapsto h_1 \cdots$). Focussing on the visible configurations thus produced, like standard Monte Carlo after a sufficient warm-up (or equilibration) period, they will converge to importance samples of $p(v)$, allowing for the approximation of physical estimators, such as $\langle E \rangle$ or $\langle C \rangle$. Before showing results for these, we further discuss deep generalizations of the RBM in the next sections.



(a) DBM (b) DBN (c) DRBN

Figure 4: The deep generalizations of the restricted Boltzmann machine. Dashed circles represent hidden nodes, with h_1 in the layer above v, h_2 in the layer above h_1, and so on. Directed (undirected) edges depict a one-way (two-way) dependence of the neurons they connect. A closed rectangle indicates a constituent restricted Boltzmann machine.

3.2 Deep Boltzmann Machine

A *deep Boltzmann machine* (DBM; Salakhutdinov and Hinton, 2009) has one visible and two or more hidden layers of neurons, which we label $v, h_1, h_2, \cdots$ (Figure 4). It is a deep generalization of the restricted Boltzmann machine, and is similarly an energy-based model, with the energy for the two-hidden-layer case being

$$E_{\text{DBM}}(v, h_1, h_2) \quad = \quad -b^T v - c^T h_1 - d^T h_2 - v^T W_0 h_1 - h_1^T W_1 h_2.$$

Sampling $p(h_1, h_2|v)$ cannot be done exactly as in the case of the RBM. This is because the conditional probabilities of the neurons are

$$\begin{aligned} p(v_i = 1|h_1) &= \sigma\left(\left(b^T + W_0 h_1\right)_i\right) \\ p((h_1)_i = 1|v, h_2) &= \sigma\left(\left(c^T + v^T W_0 + W_1 h_2\right)_i\right) \\ p((h_2)_i = 1|h_1) &= \sigma\left(\left(d^T + h_1^T W_1\right)_i\right). \end{aligned}$$

However, notice that the even and odd layers are conditionally independent. That is, for a three layer DBM, h_1 may be sampled given knowledge of $\{v, h_2\}$, and $\{v, h_2\}$ may be sampled given the state of h_1. Therefore, in order to approximately sample $p(h_1, h_2|v_0)$ for some v_0, successive Gibbs sampling of even and odd layers with the visible neurons clamped to v_0 is performed. Under such conditions, the state of the hidden neurons will equilibrate to samples of $p(h_1, h_2|v_0)$. This is how the inference $v_0 \mapsto h_1, h_2$ is performed in our training procedure. In order to generate model-dependent correlations, the visible neurons are unclamped and Gibbs sampling proceeds for k steps. The parameter updates for the DBM are similar to the CD-k algorithm for the RBM described in Section 3.1 and explicitly given in Appendix A (Salakhutdinov and Hinton, 2009).

Pre-training the DBM provides a reasonable initialization of the weights and biases by training a stack of RBM's and feeding their weights and biases into the DBM. Our pre-training procedure was inspired by Hinton and Salakhutdinov (2012), however it varies slightly from their approach because the two-layer networks used in our numerical results below are small enough to be trained fully without ideal pre-training. Our procedure goes as follows for a two-layer DBM. First, an RBM is trained on the training data set $\mathcal{D}$, and is then used to infer a hidden data set $\mathcal{H}$ via sampling the distribution $p(h|v \in \mathcal{D})$. A second RBM is then trained on $\mathcal{H}$. Weights from the first and second RBMs initialize the weights in the first and second layers of the DBM respectively. DBM biases are similarly initialized from the RBM stack, however in the case where the biases in the first hidden layer of the DBM can be taken from either the hidden layer in the first RBM, or the visible layer in the second RBM, these two options are averaged. We emphasize that this procedure is not ideal for DBMs with more than three layers.

Once fully trained, the probability distribution associated to the DBM can be sampled, similarly to the RBM, by initializing all neurons randomly, then running the Markov chain even layers $\mapsto$ odd layers $\mapsto$ even layers $\cdots$ etc. until the samples generated on the visible neurons are uncorrelated with the initial conditions of the Markov chain.

3.3 Deep Belief Network

The *deep belief network* (DBN) of Figure 4 is another deep generalization of the RBM. It is not a true energy-based model, and only the deepest layer of connections are undirected. The deepest two hidden layers of the DBN form an RBM, with the layers connecting the hidden RBM to the visible units forming a feed forward neural network. The DBN is trained by first performing layer-wise training of a stack of RBMs as detailed by Hinton et al. (2006), and similarly to the aforementioned pre-training procedure in Section 3.2. The model parameters of the deepest hidden RBM are used to initialize the deepest two layers of the DBN. The remaining layers of the DBN take their weights and biases from the weights and visible biases of the corresponding RBMs in the pre-training stack. Note, there exists a fine tuning procedure called *the wake-sleep algorithm* (Hinton et al., 1995), which further adjusts the model parameters of the DBN in a non-layer-wise fashion. However, performing fine tuning of the DBN was found to have no influence on the results described below.

Once trained, a DBN can be used to generate samples by initializing the hidden RBM randomly, running Gibbs sampling in the hidden RBM until convergence to the model distribution is achieved, then propagating the configuration of the RBM neurons downwards to the visible neurons of the DBN using the same conditional probabilities used in an RBM, Equation 2.

3.4 Deep Restricted Boltzmann Network

The *deep restricted Boltzmann network* (DRBN) of Figure 4 is a simple, deep generalization of the RBM which, like the DBN, is also not a true energy-based model (Hu et al., 2016).

Inference in the DRBN is exactly the same as in the RBM, but with many layers,

$$\begin{aligned} p((x_l)_i|x_{l-1}) &= \sigma\left(\left(b_l^T + x_{l-1}^T W_{l-1}\right)_i\right) \\ p((x_{l-1})_i|x_l) &= \sigma\left(\left(b_{l-1}^T + W_{l-1}x_l\right)_i\right), \end{aligned}$$

where $x_0 \equiv v$, $x_1 \equiv h_1$ etc. However, Gibbs sampling in the DRBN is performed by doing a complete up (down) pass, where the state of neurons in all layers of the DRBN are inferred sequentially given the state of the bottom (top) neurons. The CD-k algorithm is applied to train the DRBN, as it was for the RBM, by first inferring data-dependent correlations from some initial data v_0, then performing k steps of Gibbs sampling in order to generate the model-dependent correlations.

Once trained, the DRBN is sampled by initializing the visible neurons randomly, then performing Gibbs sampling until the visible samples converge to samples of the model dependent distribution $p(v)$.

4. Training and Results

In this section, we investigate the ability of the generative graphical models, introduced in the previous section, to represent classical statistical mechanical probability distributions, with a particular interest in the comparison between deep and shallow models near the phase transition of the two-dimensional Ising system.

In order to produce training data, we use standard Markov chain Monte Carlo techniques with a combination of single-site Metropolis and Wolff cluster updates, where one Monte Carlo step consists of N single-site updates and one cluster update, and N is the number of sites on the lattice. Importance sampling thus obtained 10^5 independent spin configurations for each $T \in [1.0, 3.5]$ in steps of $\Delta T = 0.1$. An equilibration time of N^3 Monte Carlo steps and a decorrelation time of N steps were used, where in this paper we concentrate on $N = 64$ only.

Using these data sets, we trained shallow (RBM) and deep (DBM, DBN, DRBN) generative models to learn the underlying probability distribution of the Monte Carlo data for each value of T. Similar to the work done by Torlai and Melko (2016), restricted Boltzmann machines of architecture (N, N_{h_1}) for $N = 64$ and various N_{h_1} were trained. Further, we trained two-hidden-layer deep models of architecture (N, N_{h_1}, N_{h_2}) in order to investigate the efficiency with which deep architectures can represent the thermal distribution of Ising systems. Networks with two hidden layers were chosen to reduce the large parameter space to be explored, while still allowing us to quantify the difference between shallow and deep models. Training hyper-parameters for each model are given in Table 1, and values of N_{h_1} and N_{h_2} used in this work were $\{8, 16, 24, 32, 40, 48, 56, 64\}$.

In order to quantify how well the models captured the target physical probability distribution, each model was used to generate a set $\mathcal{S}$ of 10^4 spin configurations on which the observables $\langle E\rangle$ and $\langle C\rangle$ were computed and compared to the exact values from Monte Carlo simulations.

We begin by benchmarking our calculations on the case of the shallow RBM, studied previously by Torlai and Melko (2016). Similar to the results reported in that work, we find that for all temperatures an RBM with $N_{h_1} = N$ accurately captures the underlying Ising model distribution, a result consistent with the upper bound of $N_{h_1} \leq 2N$ found by Chen

hyperparameter	RBM	DBM	DBN	DRBN
k	10	10	10	5
equilibration steps	NA	10	NA	NA
training epochs	4×10^3	3×10^3	3×10^3	3×10^3
learning rate	5×10^{-3}	10^{-3}	10^{-4}	10^{-4}
mini-batch size	10^2	10^2	10^2	10^2

Table 1: Values of training hyper-parameters for each model, trained with contrastive divergence CD-k.

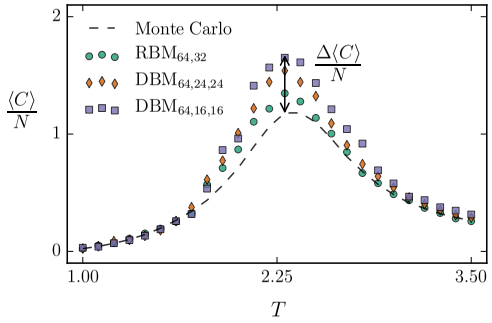


Figure 5: Measurements of heat capacity per Ising spin on samples generated by trained shallow and deep models of architecture $(64, 32)$, $(64, 16, 16)$, and $(64, 24, 24)$. Measurements are compared to Monte Carlo values of the data on which the models were trained.

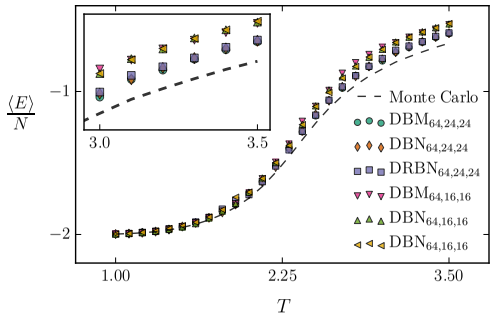

Figure 6: Measurements of energy E per Ising spin on samples generated by trained shallow and deep models of various architectures. Measurements are compared to Monte Carlo values of the data on which the models were trained.

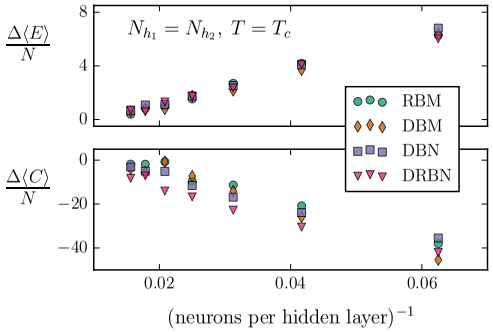

Figure 7: The error in reproducing the energy and heat capacity per Ising spin of the training data as a function of the number of hidden neurons per layer for all model types.

et al. (2017) for the 2D Ising model. RBMs with less hidden neurons fail to completely capture the observables of the data, particularly near the critical region defined by $T \approx T_c$. Furthermore, we find here that all deep models with architecture $N_{h_1} = N_{h_2} = N$ can also accurately represent the probability distribution generated by the $N = 64$ Ising Hamiltonian at any temperature. Below we concentrate on $N_{h_1}, N_{h_2} < N$ in order to systematically investigate and compare the representational power of each model type.

Figure 5 shows a heat capacity calculated from the spin configurations on the visible nodes. As an illustrative example, we present a shallow RBM with 32 hidden units, compared to two different DBMs each with two hidden layers. To reduce parameter space, we let $N_{h_1} = N_{h_2}$ for these deep models. From this figure it is clear that the DBM with the same number of total hidden neurons ($\mathrm{DBM}_{64,16,16}$) performs worse than the DBM with approximately the same total number of model parameters ($\mathrm{DBM}_{64,24,24}$) as the RBM. Remarkably, both deep networks are outperformed by the shallow RBM, suggesting it is more efficient to put additional network resources into the first hidden layer, than to add more layers in a deep architecture.

In Figure 6 we examine $\langle E\rangle$ for deep models with two different architectures, namely $N_{h_1} = N_{h_2} = 16$ and $N_{h_1} = N_{h_2} = 24$. In this plot, two families of curves become apparent, associated with these two different network architectures. From this, it appears that between all the different deep models, the differences in performance correspond only to the number and arrangement of hidden nodes (i.e. the "architecture" of the network), and not to the specific model type and training procedure, which varies considerably between DBM, DBN, and DRBN.

To further investigate this point, we next compare RBMs with deep models having the same number of hidden units in each hidden layer ($N_{h_1} = N_{h_2}$) as the RBMs do in h_1. Figure 7 compares the percent error at $T = T_c$ in reproducing the physical observables

energy and heat capacity. In this figure, we see the expected monotonic trends of both $\Delta\langle E\rangle$ and $\Delta\langle C\rangle$, which are defined as the difference between the generated quantity and its exact value at the critical point (see Figure 5). This demonstrates that, for all models, the accuracy of reconstructing physical observables increases with the number of neurons per hidden layer. More surprisingly however, since values of $\Delta\langle E\rangle$ and $\Delta\langle C\rangle$ are not significantly different across model types with equal architecture, it can also be said that adding a second hidden layer to an RBM does not improve its ability to generate accurate observables. This is the case even when the deep networks have greater total network resources (neurons or model parameters) than the shallow RBMs, as they do in Figure 7. This demonstrates again that the most efficient way to increase representational power in this case is not to add a second hidden layer, thereby increasing the depth of the neural network, but to increase the size of the only hidden layer in a shallow network.

We confirm this in a striking way in Figure 8, where we plot both $\langle E\rangle$ and $\langle C\rangle$ at the critical temperature for samples generated from deep models of architecture $(64, 24, N_{h_2})$, in comparison to an RBM with $N_{h_1} = 24$ and the exact Monte Carlo values. The fact that there is no clear systematic improvement in accuracy as N_{h_2} increases confirms that the accuracy of deep neural networks for the Ising system is essentially independent of the second hidden layer.

5. Conclusion

We have investigated the use of generative neural networks as an approximate representation of the many-body probability distribution of the two-dimensional Ising system, using the restricted Boltzmann machine and its deep generalizations; the deep Boltzmann machine, deep belief network, and deep restricted Boltzmann network. We find that it is

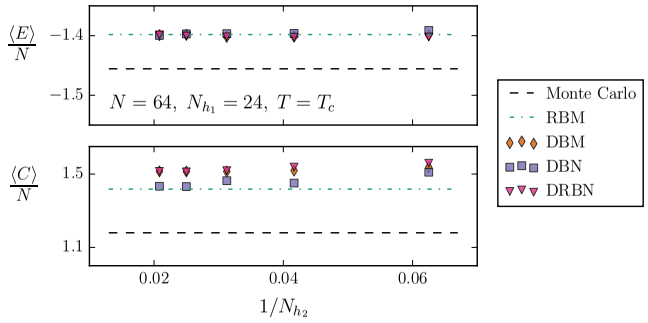

Figure 8: Energy E and heat capacity C per Ising spin at the critical temperature as measured on samples generated from deep models with various number of neurons in the second hidden layer. N_{h_1} is fixed, and model values are compared to Monte Carlo and an RBM, which serves as the $N_{h_2} = 0$ reference point.

possible to accurately represent the physical probability distribution, as determined by reproducing physical observables such as energy or heat capacity, with both shallow and deep generative neural networks. However we find that the most efficient representation of the Ising system—defined to be the most accurate model given some fixed amount of network resources—is given by a shallow RBM, with only one hidden layer.

In addition, we have also found that the performance of a deep generative network is independent of what specific model was used. Rather, the accuracy in reproducing observables is entirely dependent on the network architecture, and even more remarkably, on the number of units in the first hidden layer only. This result is consistent with that of Raghu et al. (2017), who find that trained networks are most sensitive to changes in the weights of the first hidden layer. Additionally, in the wake of recent developments in information based deep learning by Tishby and Zaslavsky (2015), we remark that such behavior may be a signature of the information bottleneck in neural networks.

It is interesting to view our results in the context of the empirically well-supported fact that deep architectures perform better for supervised learning of complex, hierarchal data (LeCun et al., 2015). In statistical mechanical systems there is often a very simple pattern of local, translation-invariant couplings between degrees of freedom. While there are multi-scale techniques in physics such as the renormalization group for analyzing physical systems, no obvious hierarchy of features exists to be leveraged by generative, deep learning algorithms. While it can be speculated that the power of deep networks also translates to the realm of unsupervised, generative models, for natural data sets commonly used by the machine learning community it is difficult to obtain quantitative measures of accuracy (Hinton et al., 2006; Le Roux and Bengio, 2008; Salakhutdinov and Hinton, 2009; Hu et al., 2016). Therefore, modelling physics data offers an opportunity to quantitatively measure

and compare the performance of deep and shallow models, due to the existence of physical observables such as energy and heat capacity.

However, considering our results, it is clear that there may be a fundamental difference between statistical physics data and real-world data common to machine learning practices, otherwise the established success of deep learning would more easily translate to applications of representing physics systems, such as thermal Ising distributions near criticality. It is interesting to ask what precisely this difference is.

The lines of inquiry addressed in this paper could also be continued by extending this analysis to consider the efficient representation of quantum many-body wave functions by deep neural networks (Torlai et al., 2017), and by investigating in more detail the nature of information flow in neural-network representations of physical probability distributions.

Research at Perimeter Institute is supported through Industry Canada and by the Province of Ontario through the Ministry of Research and Innovation.

Appendix A.

The gradient of the negative log-likelihood must be calculated with respect to weights and biases; for example, $\nabla_W(\mathcal{L}) = \langle vh^T \rangle_{p(h|v)} - \langle vh^T \rangle_{p(v,h)}$, where $\langle f \rangle_{P(x)}$ denotes the expectation value of f with respect to the probability density $P(x)$. The first term in the gradient is referred to as the data-dependent correlations, and is tractable as long as sampling $p(h|v)$ is efficient, which it is for RBMs. However, the second term, referred to as model-dependent correlations, is ideally computed by running the Markov chain $v_0 \mapsto h_0 \mapsto v_1 \mapsto h_1 \cdots$ an infinite number of steps in order to sample the model distribution without bias due to the initial conditions v_0. This cannot be done exactly, and the standard approximation to estimate the model-dependent term is to run the Markov chain for only $k < \infty$ steps from an initial value of v_0 given by the mini-batch data—in practice, k of order 1 may do. For concreteness, the full update rules for the weights and biases of an RBM are

then given by $\theta \mapsto \theta + \eta\Delta\theta$, where

$$\Delta W = \|\mathcal{B}\|^{-1} \sum_{v_0 \in \mathcal{B}} v_0 h_0^T - v_k h_k^T \quad \text{(A.1)}$$

$$\Delta b = \|\mathcal{B}\|^{-1} \sum_{v_0 \in \mathcal{B}} v_0 - v_k \quad \text{(A.2)}$$

$$\Delta c = \|\mathcal{B}\|^{-1} \sum_{v_0 \in \mathcal{B}} h_0 - h_k, \quad \text{(A.3)}$$

and η is a hyper-parameter of the learning algorithm called the *learning rate*.

In order to evaluate the parameter updates in Equations A.1 to A.3, conditional probabilities in an RBM such as $p(h_i = 1|v)$ must be known. Therefore, here we provide a derivation of the conditional probability distribution $p(h_i = 1|v) = \sigma\left(\left(c^T + v^T W\right)_i\right)$ of an RBM.

Firstly, the marginal distribution $p(v)$ is given by

$$\begin{aligned} p(v) &= \sum_h p(v,h) \\ &= \frac{1}{Z} \exp\left(b^T v + \sum_i \log\left(1 + \exp\left(\left(c^T + v^T W\right)_i\right)\right)\right) \\ &\equiv \frac{1}{Z} \exp(-\mathcal{F}(v)), \end{aligned}$$

where $\mathcal{F}(v)$ is known as the "free energy". One can interpret training an RBM as fitting $\mathcal{F}(v)$ to the Hamiltonian $H(v)$ of the training data set, sampled from Equation 1, a perspective taken by previous studies in physics (see Huang and Wang, 2017). Next, using Bayes' theorem, $p(h|v) = \frac{1}{Z'} \prod_i \exp\left((c^T + v^T W)_i h_i\right)$, meaning that the conditional probability factors, $p(h|v) = \prod_i p(h_i|v)$. Finally, by requiring normalization, the conditional activation probabilities are

$$p(h_i = 1|v) = \sigma\left(\left(c^T + v^T W\right)_i\right)$$

where $\sigma(x) = (1+\exp(-x))^{-1}$. The activation probabilities $p(v_i = 1|h)$ are derived similarly.

Editor: Balazs Kegl

Abstract

We present pomegranate, an open source machine learning package for probabilistic modeling in Python. Probabilistic modeling encompasses a wide range of methods that explicitly describe uncertainty using probability distributions. Three widely used probabilistic models implemented in pomegranate are general mixture models, hidden Markov models, and Bayesian networks. A primary focus of pomegranate is to abstract away the complexities of training models from their definition. This allows users to focus on specifying the correct model for their application instead of being limited by their understanding of the underlying algorithms. An aspect of this focus involves the collection of additive sufficient statistics from data sets as a strategy for training models. This approach trivially enables many useful learning strategies, such as out-of-core learning, minibatch learning, and semi-supervised learning, without requiring the user to consider how to partition data or modify the algorithms to handle these tasks themselves. pomegranate is written in Cython to speed up calculations and releases the global interpreter lock to allow for built-in multithreaded parallelism, making it competitive with—or outperform—other implementations of similar algorithms. This paper presents an overview of the design choices in pomegranate, and how they have enabled complex features to be supported by simple code. The code is available at `https://github.com/jmschrei/pomegranate`

Keywords: probabilistic modeling, Python, Cython, machine learning, big data.

1. Introduction

The Python ecosystem is becoming increasingly popular for the processing and analysis of data. This popularity is in part due to easy-to-use libraries such as numpy (van der Walt et al., 2011), scipy (Jones et al., 2001), and matplotlib (Hunter, 2007) that aim to provide fast general purpose functionality. However, equally important are the libraries that are built on top of these to provide higher level functionality, such as pandas (McKinney, 2010) for data analysis, scikit-image (van der Walt et al., 2014) for computer vision, Theano (Theano Development Team, 2016) for efficient evaluation of mathematical expressions, gensim (Řehůřek and Sojka, 2010) for topic modeling in natural language processing, and countless others. Naturally, many machine learning packages have also been developed for Python, including those that implement classic machine learning algorithms, such as scikit-learn (Pedregosa et al., 2011), mlpy (Albanese et al., 2012), shogun (Sonnenburg et al., 2017), and xgboost (Chen and Guestrin, 2016).

pomegranate fills a gap in the Python ecosystem that encompasses building probabilistic machine learning models that utilize maximum likelihood estimates for parameter updates. There are several packages that implement certain probabilistic models in this style individually, such as hmmlearn for hidden Markov models, libpgm for Bayesian networks, and scikit-learn for Gaussian mixture models and naive Bayes models. However, pomegranate implements a wider range of probabilistic models and does so in a more modular fashion than these other packages, having two main effects. The first is that the addition of a new probability distribution in pomegranate allows for all models to be built using that distribution immediately. The second is that improvements to one aspect of pomegranate immediately propagate to all models that would use that aspect. For example, when GPU support was added to multivariate Gaussian distributions, this immediately meant that all models with multivariate Gaussian emissions could be GPU accelerated without any additional code. pomegranate currently includes a library of basic probability distributions, naive Bayes classifiers, Bayes classifiers, general mixture models, hidden Markov models, Bayesian networks, Markov chains, as well as implementations of factor graphs and k-means++/|| that can be used individually but primarily serve as helpers to the primary models.

There are several already existing Python libraries that implement Bayesian methods for probabilistic modeling. These include, but are not limited to, PyMC3 (Salvatier et al., 2016), PyStan (Stan Development Team, 2016), Edward (Tran et al., 2016), pyro (Inc., 2017), and emcee (Foreman-Mackey et al., 2013). Bayesian approaches typically represent each model parameter as its own probability distribution, inherently capturing the uncertainty in that parameter, whereas maximum likelihood approaches typically represent each model parameter as a single value. An example of this distinction is that a mixture model can either be represented as a set of probability distributions and a vector of prior probabilities, or as a set of probability distributions that themselves have probability distributions over their respective parameters (such as the mean and standard deviation, should these distributions be normal distributions) and as a dirichlet distribution representing the prior probabilities. The first representation typically specifies models that are faster to both train and perform inference with, while the second is illustrative of the type of models one could build with packages that implement Bayesian methods, such as PyMC3. Both representations have strengths and weaknesses, but pomegranate implements models falling solely in the first representation.

pomegranate was designed to be easy to use while not sacrificing on computational efficiency. Models can either be specified by writing out each of the components individually if known beforehand, or learned directly from data if not. Key features, such as out-of-core learning and parallelization, can be toggled for each model independently of the definition or method calls, typically by simply passing in an optional parameter. The core computational bottlenecks are written in Cython and release the global interpreter lock (GIL), enabling multi-threaded parallelism that typically Python modules cannot take advantage of. Lastly, linear algebra operations such as matrix-matrix multiplications are implemented using BLAS with the ability to toggle a GPU if present.

All comparisons were run on a computational server with 24 Intel Xeon CPU E5-2650 cores with a clock speed of 2.2 GHz, a Tesla K40c GPU, and 256 GB of RAM running CentOS 6.9. The software used was pomegranate v0.8.1 and scikit-learn v0.19.0. pomegranate can be installed using `pip install pomegranate` or `conda install pomegranate` on all platforms. Pre-built wheels are available for Windows builds, removing the sometimes difficult requirement of a working compiler.

2. The API

pomegranate provides a simple and consistent API for all implemented models that mirrors the scikit-learn API as closely as possible. The most important methods are `fit`, `from_samples`, `predict` and `probability`. The `fit` method will use the given data and optional weights to update the parameters of an already initialized model, using either maximum-likelihood estimates (MLE) or expectation-maximization (EM) as appropriate. In contrast, the `from_samples` method will create a model directly from data in a manner similar to scikit-learn's `fit` method. For simple models like single distributions this corresponds only to MLE on the input data, but for most other models this corresponds to an initialization step plus a call to `fit`. This initialization can range from using k-means for mixture models to structure learning for Bayesian networks. The `predict` method returns the posterior estimate $argmax_M P(M|D)$, identifying the most likely component of

the model for each sample. The `probability` method returns the likelihood of the data given the model $P(D|M)$. The other methods include `predict_proba` which returns the probability of each component for each sample $P(M|D)$, `predict_log_proba` which returns the log of the previous value, and `summarize` and `from_summaries` that jointly implement the learning strategies detailed below.

3. Key Features

pomegranate supports many learning strategies that can be employed during training, including out-of-core learning for massive data sets, semi-supervised learning for data sets with a mixture of labeled and unlabeled data, and minibatch learning. In addition, one can employ multithreaded parallelism or a GPU for data-parallel speedups. These features are made possible by separating out the collection of sufficient statistics from a data set (using the `summarize` method) from the actual parameter update step (using the `from_summaries` method).

Sufficient statistics are the smallest set of numbers needed to calculate some statistic on a data set. As an example, fitting a normal distribution to data involves the calculation of the mean and the variance. The sufficient statistics for the mean and the variance are the sum of the weights of the points seen so far $\left(\sum_{i=1}^{n} w_i\right)$, the sum of the weighted samples $\left(\sum_{i=1}^{n} w_i X_i\right)$, and the sum of the weighted samples squared $\left(\sum_{i=1}^{n} w_i X_i^2\right)$. The mean and variance can then be directly calculated from these three numbers using the following two equations:

$$\mu = \frac{\sum_{i=1}^{n} w_i X_i}{\sum_{i=1}^{n} w_i} \qquad \sigma^2 = \frac{\sum_{i=1}^{n} w_i X_i^2}{\sum_{i=1}^{n} w_i} - \left(\frac{\sum_{i=1}^{n} w_i X_i}{\sum_{i=1}^{n} w_i}\right)^2 \tag{1}$$

Out-of-core Learning: The additive nature of the sufficient statistics means that if one were to summarize two batches of data successively and then add the sufficient statistics together, they would get the same sufficient statistics as if they were calculated from the full data set. This presents an intuitive way to handle data sets that are too large to fit in memory, by chunking the data set into batches that do fit in memory and summarizing them successively, adding the calculated sufficient statistics together afterwards. This can be done by passing in a `batch_size` parameter to your training method, for example `model.fit(X, batch_size=10000)` would train a pre-initialized model on more data than can fit in memory by successively summarizing batches of size 10,000 until the full data set has been seen. The `summarize` and `from_summaries` methods can also be used independently to implement custom out-of-core strategies.

Minibatch Learning: A natural extension of the out-of-core strategy is minibatch learning, where a parameter update is done after one or a few batches, instead of the full data set. This is in contrast to batch methods that calculate an update using the entire data set, and stochastic methods that typically update using only a single sample. Minibatching can be specified by passing values to both `batch_size` and `batches_per_epoch` parameters when using `fit` or `from_summaries`, where the `batches_per_epoch` is the number of batches to consider before making an update.

Semi-supervised Learning: Semi-supervised learning is the task of fitting a model to a mixture of both labeled and unlabeled data. Typically this arises in situations where labeled data is sparse, but unlabeled data is plentiful, and one would like to make use of both to learn an informed model.

pomegranate supports semi-supervised learning for `HiddenMarkovModel`, `BayesClassifier`, and `NaiveBayes` models as a combination of EM and MLE. Models are initialized using MLE on the labeled data. Next, a version of EM is used that combines the sufficient statistics calculated from the labeled data using MLE with the sufficient statistics calculated from the unlabeled data using EM at each iteration until convergence. This is automatically toggled whenever -1 is present in the label set, following scikit-learn conventions.

This EM-based approach compares favorably to scikit-learn. To demonstrate, we generate a data set of 100k samples in 10 dimensions from 2 overlapping Gaussian ellipses with means of 0 and 1 respectively and standard deviations of 2. It took pomegranate ∼0.04s to learn a Gaussian naive Bayes model with 10 iterations of EM, ∼0.2s to learn a multivariate Gaussian Bayes classifier with a full covariance matrix with 10 iterations of EM, whereas the scikit-learn label propagation model with a RBF kernel did not converge after ∼220s and 1000 iterations, and took ∼2s with a knn kernel with 7 neighbors. Both pomegranate models achieved validation accuracies over 0.75, whereas the scikit-learn models did no better than chance.

Parallelism: Another benefit of the use of additive sufficient statistics is that it presents a clear data-parallel way to parallelize model fitting. Simply, one would divide the data into several batches and calculate the sufficient statistics for each batch locally. These sufficient statistics can then be added together back on the main job and all parameters updated accordingly. This is implemented by dividing the data into batches and running `summarize` on each of them using separate threads and then running `from_summaries` after all threads finish. Typically, the global interpreter lock (GIL) in Python prevents multiple threads from running in parallel in the same python process. However, since the computationally intensive aspects are written in Cython the GIL can be released, allowing for multiple threads to run at once. On a synthetic data set with 3M samples with 1K dimensions it takes ∼65 seconds to train a Gaussian naive Bayes classifier using pomegranate with 1 thread, but only ∼17 seconds with 8 threads. For comparison, it takes ∼53 seconds to train a Gaussian naive Bayes classifier using scikit-learn. On another synthetic data set with 2M samples and 150 dimensions it takes pomegranate ∼470s to learn a Gaussian mixture model with a full covariance matrix with 1 thread, ∼135s with 4 threads, ∼57s with 16 threads, and ∼200s using a GPU. Lastly, we compared the speed at which pomegranate and hmmlearn could train a 10 state dense Gaussian hidden Markov model with diagonal covariance matrices. On a synthetic data set of 100 sequences, each containing 1,000 10 dimensional observations, it took hmmlearn ∼25s to run five iterations of Baum-Welch training, while it only took pomegranate ∼13s with 1 thread, ∼4s with 4 threads, and ∼2s with 16 threads.

4. Discussion

pomegranate aims to fill a niche in the Python ecosystem that exists between classic machine learning methods and Bayesian methods by serving as an implementation of flexible probabilistic models. The design choices that were made early on while building pomegranate allowed for a great number of useful features to be added later on without significant effort.

A clear area of improvement in the future is the handling of missing values, because many probabilistic models can intuitively modify the EM algorithm to infer these missing values. For example, when trying to learn a Bayesian network over a data set with missing values, one can identify the best structure over the incomplete data set, infer the missing values, and relearn the structure, iterating until convergence. Given the prevalence of missing data in the real world, extending pomegranate to handle missing data efficiently is a priority.

Acknowledgments

We would like to first acknowledge all of the contributors and users of pomegranate, whom without this project would not be possible. We would also like to acknowledge Adam Novak, who wrote the first iteration of the hidden Markov model code. Lastly, we would also like to acknowledge Dr. William Noble for suggestions and guidance during development. This work was partially supported by NSF IGERT grant DGE-1258485.

Abstract

The continuous dynamical system approach to deep learning is explored in order to devise alternative frameworks for training algorithms. Training is recast as a control problem and this allows us to formulate necessary optimality conditions in continuous time using the Pontryagin's maximum principle (PMP). A modification of the method of successive approximations is then used to solve the PMP, giving rise to an alternative training algorithm for deep learning. This approach has the advantage that rigorous error estimates and convergence results can be established. We also show that it may avoid some pitfalls of gradient-based methods, such as slow convergence on flat landscapes near saddle points. Furthermore, we demonstrate that it obtains favorable initial convergence rate per-iteration, provided Hamiltonian maximization can be efficiently carried out - a step which is still in need of improvement. Overall, the approach opens up new avenues to attack problems associated with deep learning, such as trapping in slow manifolds and inapplicability of gradient-based methods for discrete trainable variables.

Keywords: deep learning, optimal control, Pontryagin's maximum principle, method of successive approximations

1. Introduction

Supervised learning using deep neural networks has become an increasingly successful tool in modern machine learning applications (Bengio, 2009; Schmidhuber, 2015; LeCun et al., 2015; Goodfellow et al., 2016). Efficient training methods of very deep neural networks, however, remain an active area of research. The most commonly applied training method is stochastic gradient descent (Robbins and Monro, 1951; Bottou, 2010) and its variants (Duchi et al., 2011; Zeiler, 2012; Kingma and Ba, 2014; Johnson and Zhang, 2013), where incremental updates to the trainable parameters are performed using gradient information computed via back-propagation (Kelley, 1960; Bryson, 1975). While efficient to implement, the incremental updates to the parameter tend to be slow, especially in the initial stages of the training. Moreover, other than the computation of gradients through back-propagation, the specific structure of deep neural networks is not exploited. These observations point to the question of whether there exists alternative training methods tailored to deep neural networks.

In a series of papers, we introduce an alternative approach by exploring the optimal control viewpoint of deep learning (E, 2017). Our focus will be on ideas and algorithms derived from the powerful Pontryagin's maximum principle (Boltyanskii et al., 1960; Pontryagin, 1987), which has two major components: the Hamiltonian dynamics and the condition that at each time the optimal parameters maximize the Hamiltonian. The second component suggests that optimization can be performed independently at different layers. One can also derive an explicit error control estimate based on the maximum principle (see Lemma 2 below).

In this first paper, we will consider the simplest context in which the deep neural networks are replaced by continuous (or discretized) dynamical systems, and devise numerical algorithms that are based on the optimality conditions in the Pontryagin's maximum principle. This leads to a new approach for training deep learning models that have certain advantages, such as fast initial descent and resilience to stalling in flat landscapes. An additional advantage is that one has a good control of the error through explicit estimates.

The rest of the paper is organized as follows. In Section 2, we present a dynamical systems viewpoint of function approximation and deep learning. We then discuss the necessary optimality conditions, which is the well-known Pontryagin's maximum principle. In Section 3 and 4, we discuss numerical methods to solve the necessary conditions and obtain error estimates and convergence guarantees. Using benchmarking examples, we then compare our method with traditional gradient-descent based methods for optimizing deep neural networks in Section 5. In Section 6, we discuss and compare our work with existing literature. Conclusion and outlook are given in Section 7.

2. Function Approximation by Dynamical Systems

We start with a description of the (continuous) dynamical systems approach to machine learning (see E 2017). The essential task of supervised learning is to approximate some function

$$F : \mathcal{X} \to \mathcal{Y}$$

which maps inputs in $\mathcal{X} \subset \mathbb{R}^d$ (e.g. images, time-series) to labels in $\mathcal{Y}$ (categories, numerical predictions). Given a collection of K sample input-label pairs $\{x^i, y^i = F(x^i)\}_{i=1}^K$, one aims to approximate F using these data points. In the dynamical systems framework, we consider the inputs $x = (x^1, \ldots, x^K) \in \mathbb{R}^{d\times K}$ as the initial condition of a system of ordinary

differential equations

$$\dot{X}_t^i = f(t, X_t^i, \theta_t), \quad X_0^i = x^i, \quad 0 \le t \le T, \tag{1}$$

where $\theta : [0,T] \to \Theta \subset \mathbb{R}^p$, represents the control (training) parameters and $X_t = (X_t^1, \dots, X_t^K) \in \mathbb{R}^{d\times K}$ for all $t \in [0,T]$. The form of f is chosen as part of the machine learning model. For example, in deep learning, f is typically the composition (in either order) of a linear transformation and a component-wise nonlinear function (the activation function). For the solution to (1) to exist for any θ, we shall assume hereafter that f and $\nabla_x f$ are continuous in t, x, θ. Note that weaker but more complicated conditions can be considered (Clarke, 2005). For the i^{th} input sample, the prediction of the "network" is a deterministic transformation of the terminal state $g(X_T^i)$ for some $g : \mathbb{R}^d \to \mathcal{Y}$, which we can view collectively as a function of the initial state (input) x^i and the control parameters (weights) θ. The dynamics (1) are decoupled across samples except for the dependence on the control θ. We shall consider quite a general space of controls

$$\mathcal{U} := \{\theta : [0,T] \to \Theta : \theta \text{ is Lebesgue measurable}\}.$$

The aim is to select θ from $\mathcal{U}$ so that $g(X_T^i)$ most closely resembles y^i for $i = 1, \dots, K$. To this end, we define a loss function $\Phi : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ which is minimized when its arguments are equal, and we consider minimizing $\sum_i \Phi(g(x_T^i), y^i)$. Since g is fixed, we shall absorb it into the definition of the loss function by defining $\Phi_i(\cdot) := \Phi(\cdot, y_i)$. Then, the supervised learning problem in our framework is

$$\begin{aligned} &\min_{\theta\in\mathcal{U}} \sum_{i=1}^K \Phi_i(X_T^i) + \int_0^T L(\theta_t)dt, \\ &\dot{X}_t^i = f(t, X_t^i, \theta_t), \quad X_0^i = x^i, \quad 0 \le t \le T, \quad i = 1, \dots, K, \end{aligned} \tag{2}$$

where $L : \Theta \to \mathbb{R}$ is a running cost, or the regularizer[1]. We note here that alternatively, we can formulate the supervised learning problem more generally in terms of optimal control in function spaces, see Appendix A.

Problem (2) is a special case of a class of general optimal control problem for ordinary differential equations (Bertsekas, 1995; Athans and Falb, 2013). The advantage of this formulation is that we can write down and study the optimality conditions of (2) entirely in continuous time and derive numerical algorithms that can subsequently be discretized. In other words, we *optimize, then discretize*, as opposed to the traditional reverse approach in deep learning.

As was suggested in E (2017), deep residual networks (He et al., 2016) can be considered as the forward Euler discretization of the continuous approach described above. In this connection, the algorithms presented in this paper can also be formulated in the context of deep residual networks. For general deep neural networks, although one can also formulate similar algorithms, it is not clear at this moment that PMP holds and these algorithms are valid (e.g. converge to the right solution) in the general setting. This issue will be studied in future work.

1. We can also make L depend on X_t, but for simplicity of presentation and the fact that most current machine learning models do not regularize the states, we shall omit this general case.

The optimization problem (2) can be solved by first discretizing it into a discrete problem (a feed-forward neural network) and then applying back propagation and gradient descent approaches commonly used in deep learning. However, here we will present an alternative approach. Hereafter, for simplicity of notation we shall set $K = 1$ drop the scripts i on all functions, noting that analogous results can be obtained in the general case since the dynamics and loss functions are decoupled across samples. Equivalently, we can think of this as effectively concatenating all K sample inputs into a single input vector of dimension $d \times K$ and redefine our dynamics accordingly. Hence, all results remain valid if we perform full-batch training. The case of mini-batch training is discussed in Section 4.3.

2.1 Pontryagin's Maximum Principle

In this section, we introduce a set of necessary conditions for optimal solutions of (2), known as the Pontryagin's Maximum Principle (PMP) (Boltyanskii et al., 1960; Pontryagin, 1987). This shall pave way for an alternative numerical algorithm to train (2) and its discrete-time counter-part.

To begin with, we define the *Hamiltonian* $H : [0,T] \times \mathbb{R}^d \times \mathbb{R}^d \times \Theta \to \mathbb{R}$ given by

$$H(t, x, p, \theta) := p \cdot f(t, x, \theta) - L(\theta).$$

Theorem 1 (Pontryagin's Maximum Principle) *Let $\theta^* \in \mathcal{U}$ be an essentially bounded optimal control, i.e. a solution to (2) with $\operatorname{ess\,sup}_{t\in[0,T]} \|\theta_t^*\|_\infty < \infty$ (ess sup denotes the essential supremum). Denote by X^* the corresponding optimally controlled state process. Then, there exists an absolutely continuous co-state process $P^* : [0,T] \to \mathbb{R}^d$ such that the Hamilton's equations*

$$\dot{X}_t^* = \nabla_p H(t, X_t^*, P_t^*, \theta_t^*), \qquad X_0^* = x, \tag{3}$$

$$\dot{P}_t^* = -\nabla_x H(t, X_t^*, P_t^*, \theta_t^*), \qquad P_T^* = -\nabla\Phi(X_T^*), \tag{4}$$

are satisfied. Moreover, for each $t \in [0,T]$, we have the Hamiltonian maximization condition

$$H(t, X_t^*, P_t^*, \theta_t^*) \ge H(t, X_t^*, P_t^*, \theta) \text{ for all } \theta \in \Theta. \tag{5}$$

The proof of the PMP and its variants can be found in any optimal control theory reference, e.g. Athans and Falb (2013); Bertsekas (1995); Liberzon (2012). Some generalizations can be found in Clarke (2005) and references therein. For example, the requirement of the continuity of f with respect to t can be replaced by a much weaker measurability requirement if one assumes more conditions on $\nabla_x f$. In the statement of Theorem 1, we omitted a technicality involving an abnormal multiplier: the terminal condition for P^* should be $P_T^* = -\lambda\nabla\Phi(X_T^*)$ and the Hamiltonian should be defined as $H(t, x, p, \theta) = p \cdot f(t, x, \theta) - \lambda L(\theta)$ for some $\lambda \ge 0$ (abnormal multiplier) that we can choose. When we are forced to always take $\lambda = 0$, the problem is *singular* and in a sense ill-posed (Athans and Falb, 2013). On the contrary, if we can take a positive λ, we can then rescale the equation for P^* so that we can take $\lambda = 1$ without loss of generality. We shall hereafter assume that this is the case.

A few remarks are in order. First, Equation 3, 4 and 5 allow us to solve for the unknowns X^*, P^*, θ^* simultaneously as a function of t. In this sense, the resulting optimal control θ^* is *open-loop* and is not in a feed-back form $\theta_t^* = \theta^*(X_t^*)$. The latter is of closed-loop type and are typically obtained from dynamic programming and the Hamilton-Jacobi-Bellman formalism (Bellman, 2013). In this sense, the PMP gives a weaker control. However, open-loop solutions are sufficient for neural network applications, where the trained weights and biases are fixed and only depend on the layer number and not the inputs.

PMP can be regarded as a (highly non-trivial) generalization of the calculus of variations to non-smooth settings (since we only assume θ^* to be measurable). Perhaps more familiar to the optimization community, the PMP is related to the Karush-Kuhn-Tucker (KKT) conditions for non-linear constrained optimization. Indeed, we can view (2) as a non-linear program over the function space $\mathcal{U}$ where the constraint is the ODE (1). In this sense, the co-state process P^* plays the role of a continuous-time analogue of Lagrange multipliers. The key difference between the PMP and the KKT conditions (besides the lack of inequality constraints on the state) is the Hamiltonian maximization condition (5), which is stronger than a typical first-order condition that assumes smoothness with respect to θ (e.g. $\nabla_\theta H = 0$). In particular, the PMP says that H is not only stationary, but globally maximized at an optimal control - which is a much stronger statement if H is not concave. Moreover, the PMP makes minimal assumptions on the parameter space Θ; the PMP holds even when f is non-smooth with respect to θ, or worse, when Θ is a discrete subset of $\mathbb{R}^p$.

Last, we emphasize that the PMP is only a necessary condition, hence there can be cases where solutions to the PMP is not actually globally optimal for (2). Nevertheless, in practice the PMP is often strong enough to give good solution candidates, and when certain convexity assumptions are satisfied the PMP becomes sufficient (Bressan and Piccoli, 2007). In the next section, we will discuss numerical methods that can be used to solve the PMP.

3. Method of Successive Approximations

Now, our strategy is to devise numerical algorithms for training (2) via solving the PMP (Equation 3, 4 and 5). We derive and analyze algorithms entirely in continuous time, which allows us to characterize errors estimates and convergence in a more transparent fashion.

There are many methods for the numerical solution of the PMP, including two-point boundary value problem method (Bryson, 1975; Roberts and Shipman, 1972), and collocation methods (Betts, 1998) coupled with general non-linear programming techniques (Bertsekas, 1999; Bazaraa et al., 2013). See (Rao, 2009) for a more recent review. However, many of these methods concern small-scale problems typically encountered in control applications (e.g. trajectory optimization of spacecrafts) and do not scale well to modern machine learning problems with a large number of state and control variables. One exception is the method of successive approximations (MSA) (Chernousko and Lyubushin, 1982), which is an iterative method based on alternating propagation and optimization steps. We first introduce the simplest form of the MSA.

3.1 Basic MSA

Observe that (3) is simply the equation

$$\dot{X}_t^* = f(t, X_t^*, \theta_t^*),$$

and is independent of the co-state P^*. Therefore, we may proceed in the following manner. First, we make an initial guess of the optimal control $\theta^0 \in \mathcal{U}$. For each $k = 0, 1, 2, \ldots$, we first solve (3)

$$\dot{X}_t^{\theta^k} = f(t, X_t^{\theta^k}, \theta_t^k), \quad X_0^{\theta^k} = x. \tag{6}$$

for X^{θ^k}, which then allows us to solve (4)

$$\dot{P}_t^{\theta^k} = -\nabla_x H(t, X_t^{\theta^k}, P_t^{\theta^k}, \theta_t^k), \quad P_T^{\theta^k} = -\nabla\Phi(X_T^{\theta^k}), \tag{7}$$

to get P^{θ^k}. Finally, we use the maximization condition (5) to set

$$\theta_t^{k+1} = \arg\max_{\theta\in\Theta} H(t, X_t^{\theta^k}, P_t^{\theta^k}, \theta),$$

for $t \in [0, T]$. The algorithm is summarized in Algorithm 1.

Algorithm 1: Basic MSA

```
Initialize: θ^0 ∈ U ;
for k = 0 to #Iterations do
    Solve Ẋ_t^{θ^k} = f(t, X_t^{θ^k}, θ_t^k),   X_0^{θ^k} = x;
    Solve Ṗ_t^{θ^k} = −∇_x H(t, X_t^{θ^k}, P_t^{θ^k}, θ_t^k),   P_T^{θ^k} = −∇Φ(X_T^{θ^k});
    Set θ_t^{k+1} = arg max_{θ∈Θ} H(t, X_t^{θ^k}, P_t^{θ^k}, θ) for each t ∈ [0, T];
end
```

As is the case with the maximum principle, MSA consists of two major components: the forward-backward Hamiltonian dynamics and the maximization for the optimal parameters at each time. An important feature of MSA is that the Hamiltonian maximization step is decoupled for each $t \in [0, T]$. In the language of deep learning, the optimization step is decoupled for different network layers and only the Hamiltonian ODEs (Step 3,4 of Algorithm 1) involve propagation through the layers. This allows the parallelization of the maximization step, which is typically the most time-consuming step.

It has been shown that the basic MSA converges for a restricted class of linear quadratic regulators (Aleksandrov, 1968). However, in general it tends to diverge, especially if a bad initial θ^0 is chosen (Aleksandrov, 1968; Chernousko and Lyubushin, 1982). Our goal now is to modify the basic MSA to control its divergent behavior. Before we do so, it is important to understand why the MSA diverges, and in particular, the relationship between the maximization step in Algorithm 1 and the optimization problem (2).

3.2 Error Estimate for the Basic MSA

For each $\theta \in \mathcal{U}$, let us denote

$$J(\theta) := \Phi(X_T^\theta) + \int_0^T L(\theta_t)dt,$$

where X^θ satisfies (6). Our goal is to minimize $J(\theta)$. We show in the following Lemma the relationship between the values of J and the Hamiltonian maximization step. We start by making the following assumptions.

(A1) Φ is twice continuously differentiable, with Φ and $\nabla\Phi$ satisfying a Lipschitz condition, i.e. there exists $K > 0$ such that

$$|\Phi(x) - \Phi(x')| + \|\nabla\Phi(x) - \nabla\Phi(x')\| \le K\|x - x'\|,$$

for all $x, x' \in \mathbb{R}^d$.

(A2) $f(t, \cdot, \theta)$ is twice continuously differentiable in x, with $f, \nabla_x f$ satisfying a Lipschitz condition in x uniformly in θ and t, i.e. there exists $K > 0$ such that

$$\|f(t, x, \theta) - f(t, x', \theta)\| + \|\nabla_x f(t, x, \theta) - \nabla_x f(t, x', \theta)\|_2 \le K\|x - x'\|,$$

for all $x, x' \in \mathbb{R}^d$ and $t \in [0, T]$. Note that $\|\cdot\|_2$ denotes the induced 2-norm.

With these assumptions, we have the following estimate:

Lemma 2 *Suppose (A1)-(A2) holds. Then, there exists a constant $C > 0$ such that for any $\theta, \phi \in \mathcal{U}$,*

$$\begin{aligned} J(\phi) \le & J(\theta) - \int_0^T \Delta_{\phi,\theta} H(t)dt \\ & + C\int_0^T \|f(t, X_t^\theta, \phi_t) - f(t, X_t^\theta, \theta_t)\|^2 dt \\ & + C\int_0^T \|\nabla_x H(t, X_t^\theta, P_t^\theta, \phi_t) - \nabla_x H(t, X_t^\theta, P_t^\theta, \theta_t)\|^2 dt, \end{aligned}$$

where X^θ, P^θ satisfy Equations 6, 7 respectively and $\Delta H_{\phi,\theta}$ denotes the change in Hamiltonian

$$\Delta H_{\phi,\theta}(t) := H(t, X_t^\theta, P_t^\theta, \phi_t) - H(t, X_t^\theta, P_t^\theta, \theta_t).$$

Proof See Appendix B for the proof and discussion on relaxing the assumptions. ■

In essence, Lemma 2 says that the Hamiltonian maximization step in MSA (step 5 in Algorithm 1) is in some sense the optimal descent direction for J. However, the last two terms on the right hand side indicates that this descent can be nullified if substituting ϕ for θ incurs too much error in the Hamiltonian dynamics (step 3,4 in Algorithm 1). In other words, the last two integrals measure the degree of satisfaction of the Hamiltonian dynamics (3), (4), which can be viewed as a feasibility condition, when one replaces θ by ϕ. Hence, we shall hereafter refer to these errors as *feasibility errors*. The divergence of the basic MSA happens when the feasibility errors blow up. Armed with this understanding, we can then modify the basic MSA to ensure convergence.

3.3 Extended PMP and Extended MSA

As discussed previously in Lemma 2, the decrement of J is ensured if we can control the feasibility errors in the Hamiltonian dynamics in steps 3,4 of Algorithm 1. To this end, we employ a similar idea to augmented Lagrangians (Hestenes, 1969). Fix some $\rho > 0$ and introduce the augmented Hamiltonian

$$\begin{aligned} \tilde{H}(t, x, p, \theta, v, q) := & H(t, x, p, \theta) - \frac{1}{2}\rho\|v - f(t, x, \theta)\|^2 \\ & - \frac{1}{2}\rho\|q + \nabla_x H(t, x, p, \theta)\|^2. \end{aligned} \tag{8}$$

Then, we have the following set of alternative necessary conditions for optimality:

Proposition 3 (Extended PMP) *Suppose that θ^* is an essentially bounded solution to the optimal control problem (2). Then, there exists an absolutely continuous co-state process P^* such that the tuple $(X_t^*, P_t^*, \theta_t^*)$ satisfies the necessary conditions*

$$\dot{X}_t^* = \nabla_p \tilde{H}(t, X_t^*, P_t^*, \theta_t^*, \dot{X}_t^*, \dot{P}_t^*), \qquad X_0^* = x, \tag{9}$$

$$\dot{P}_t^* = -\nabla_x \tilde{H}(t, X_t^*, P_t^*, \theta_t^*, \dot{X}_t^*, \dot{P}_t^*), \qquad P_T^* = -\nabla_x \Phi(X_T^*), \tag{10}$$

$$\tilde{H}(t, X_t^*, P_t^*, \theta_t^*, \dot{X}_t^*, \dot{P}_t^*) \ge \tilde{H}(t, X_t^*, P_t^*, \theta, \dot{X}_t^*, \dot{P}_t^*), \qquad \theta \in \Theta, t \in [0, T]. \tag{11}$$

Proof If θ^* is optimal, then by the PMP there exists a co-state process P^* such that (3), (4) and (5) are satisfied. Then, for all $t \in [0, T]$ and $\theta \in \Theta$ we have

$$\begin{aligned} \nabla_x \tilde{H}(t, X_t^*, P_t^*, \theta, \dot{X}_t^*, \dot{P}_t^*) = & \nabla_x H(t, X_t^*, P_t^*, \theta), \\ \nabla_p \tilde{H}(t, X_t^*, P_t^*, \theta, \dot{X}_t^*, \dot{P}_t^*) = & \nabla_p H(t, X_t^*, P_t^*, \theta), \end{aligned}$$

which implies that (9) and (10) are satisfied. Lastly, we can write

$$\begin{aligned} & \tilde{H}(t, X_t^*, P_t^*, \theta, \dot{X}_t^*, \dot{P}_t^*) \\ = & H(t, X_t^*, P_t^*, \theta) - \frac{1}{2}\rho\|\dot{X}_t^* - f(t, X_t^*, \theta)\|^2 - \frac{1}{2}\rho\|\dot{P}_t^* + \nabla_x H(t, X_t^*, P_t^*, \theta)\|^2. \end{aligned}$$

For each t, θ^* maximizes all three terms on the RHS simultaneously, and hence (11) is also satisfied. ■

Compared with the usual PMP, the extended PMP is a weaker necessary condition. However, the advantage is that maximization of $\tilde{H}$ naturally penalizes errors in the Hamiltonian dynamical equations, and hence we should expect MSA applied to the extended PMP to converge for large enough ρ. Note that the Hamiltonian equation steps do not change (since the added terms have no effect on optimal solutions) and the only change is the maximization step. The extended MSA (E-MSA) algorithm is summarized in Algorithm 2.

To establish convergence, define

$$\mu_k := \int_0^T \Delta H_{\theta^{k+1},\theta^k}(t)dt \ge 0.$$

If $\mu_k = 0$, then from the Hamiltonian maximization step (11) we must have

$$0 = -\mu_k \le -\frac{1}{2}\rho\int_0^T \|f(t,X_t^{\theta^k},\theta_t^{k+1}) - f(t,X_t^{\theta^k},\theta_t^k)\|^2 dt$$
$$-\frac{1}{2}\rho\int_0^T \|\nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^{k+1}) - \nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^k)\|^2 dt. \le 0.$$

and so

$$\max_\theta \tilde{H}(X_t^{\theta^k},P_t^{\theta^k},\theta,\dot{X}_t^{\theta^k},\dot{P}_t^{\theta^k}) = \tilde{H}(X_t^{\theta^k},P_t^{\theta^k},\theta_k,\dot{X}_t^{\theta^k},\dot{P}_t^{\theta^k}),$$

i.e. $(X^{\theta^k},P^{\theta^k},\theta^k)$ satisfy the extended PMP. In other words, the quantity $\mu_k \ge 0$ measures the distance from a solution of the extended PMP, and if it equals 0, then we have a solution. We now prove the following result that guarantees the convergence of the extended MSA (Algorithm 2).

Theorem 4 *Let (A1)-(A2) be satisfied and $\theta^0 \in \mathcal{U}$ be any initial measurable control with $J(\theta^0) < +\infty$. Suppose also that $\inf_{\theta\in\mathcal{U}} J(\theta) > -\infty$. Then, for ρ large enough, we have under Algorithm 2,*

$$J(\theta^{k+1}) - J(\theta^k) \le -D\mu_k.$$

for some constant $D > 0$ and

$$\lim_{k\to 0}\mu_k = 0,$$

i.e. the extended MSA algorithm converges to the set of solutions of the extended PMP.

Proof Using Lemma 2 with $\theta \equiv \theta^k, \phi \equiv \theta^{k+1}$, we have

$$J(\theta^{k+1}) - J(\theta^k) \le -\mu_k + C\int_0^T \|f(t,X_t^{\theta^k},\theta_t^{k+1}) - f(t,X_t^{\theta^k},\theta_t^k)\|^2 dt$$
$$+ C\int_0^T \|\nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^{k+1}) - \nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^k)\|^2 dt.$$

From the Hamiltonian maximization step in Algorithm 2, we know that

$$H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^k) \le H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^{k+1})$$
$$-\frac{1}{2}\rho\|f(t,X_t^{\theta^k},\theta_t^{k+1}) - f(t,X_t^{\theta^k},\theta_t^k)\|^2$$
$$-\frac{1}{2}\rho\|\nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^{k+1}) - \nabla_x H(t,X_t^{\theta^k},P_t^{\theta^k},\theta_t^k)\|^2.$$

Hence, we have

$$J(\theta^{k+1}) - J(\theta^k) \le -(1-\frac{2C}{\rho})\mu_k.$$

Pick $\rho > 2C$, then we indeed have $J(\theta^{k+1}) - J(\theta^k) \le -D\mu_k$ with $D = (1-\frac{2C}{\rho}) > 0$. Moreover, we can rearrange and sum the above expression to get

$$\sum_{k=0}^M \mu_k \le D^{-1}(J(\theta^0) - J(\theta^{M+1})) \le D^{-1}(J(\theta^0) - \inf_{\theta\in\mathcal{U}} J(\theta)),$$

and hence $\sum_{k=0}^\infty \mu_k < +\infty$, which implies $\mu_k \to 0$ and the extended MSA converges to a solution of the extended PMP. ■

Algorithm 2: Extended MSA

4. Discrete-Time Formulation

In the previous section, we discussed the PMP and MSA in the continuous-time setting, where we showed that an appropriately extended version (E-MSA) converges to a solution of an extended PMP. Here, we shall discuss the discretized versions of PMP, MSA and E-MSA, as well as their connections to deep residual networks and back-propagation.

4.1 Discrete-Time PMP and Discrete-Time MSA

Applying Euler-discretization to Equation 1, we get

$$x_{n+1} = x_n + \delta f_n(x_n,\vartheta_n), \quad x_0 = x,$$

for $n = 0,\dots,N-1$, with $\delta = T/N$ (step-size), $x_n := X_{n\delta}$, $\vartheta_n := \theta_{n\delta}$ and $f_n(\cdot) := f(n\delta,\cdot)$. Then, the discrete-time analogue of the control problem (2) is

$$\min_{\{\vartheta_0,\dots,\vartheta_{N-1}\}\in\Theta^N} \Phi(x_N) + \delta\sum_{n=0}^{N-1} L(\vartheta_n),$$
$$x_{n+1} = x_n + \delta f_n(x_n,\vartheta_n), \quad x_0 = x, \quad 0 \le n \le N-1. \tag{12}$$

Observe that barring the constant δ, this is exactly the supervised learning problem for deep residual networks[2]. Therefore, when suitably discretized, one expects that the E-MSA provides a means to train residual neural networks via the solution of the extended PMP.

We now write down formally the discretized form of the PMP. Let us use the shorthand $g_n(x_n,\vartheta_n) := x_n + \delta f_n(x_n,\vartheta_n)$. Define the scaled discrete Hamiltonian

$$H_n(x,p,\vartheta) = p\cdot g_n(x,\vartheta) - \delta L(\vartheta).$$

Then, a discrete-time PMP is the following set of conditions:

$$x_{n+1}^* = g_n(x_n^*,\vartheta_n^*), \qquad x_0^* = x,$$
$$p_n^* = \nabla_x H_n(x_n^*,p_{n+1}^*,\vartheta_n), \qquad p_N^* = -\nabla_x\Phi(x_N^*),$$
$$H_n(x_n^*,p_{n+1}^*,\vartheta_n^*) \ge H_n(x_n^*,p_{n+1}^*,\vartheta), \qquad \vartheta\in\Theta, \quad n = 0,\dots,N-1.$$

2. If we pick ReLU activations (Hahnloser et al., 2000), then δ can be absorbed into ϑ

The issue of whether the PMP holds for discrete time dynamical systems is a delicate one and there are known counterexamples (Butkovsky, 1963; Jackson and Horn, 1965; Nahorski et al., 1984). Nevertheless, they must hold approximately for small time step size and this is the situation we will consider in the current paper. We expect Lemma 2, which implies monotonicity of the E-MSA algorithm, to hold in the discrete-time case under appropriate conditions. We leave a rigorous analysis of these statements to future work. For numerical experiments presented in the next section, we shall almost always work with residual networks that can be regarded as discretizations of continuous networks so that the PMP holds approximately at least (Halkin, 1966).

For completeness, we summarize the discrete-time version of E-MSA in Algorithm 3. Note that for residual networks ($g_n = x_n + \delta f_n$), this is equivalent to a forward Euler discretization on the state equation and a backward Euler discretization on the co-state equation in Algorithm 2. As before, the Hamiltonian maximization step is decoupled across layers and can be carried out in parallel.

Algorithm 3: Discrete-time E-MSA

1 Initialize: Initialize: $\vartheta_n^0 \in \Theta_n$, $n = 0, \ldots, N-1$. Hyper-parameter: ρ ;
2 **for** $k = 0$ **to** *#Iterations* **do**
3 Set $x_0^{\vartheta^k} = x$;
4 **for** $n = 0$ **to** $N-1$ **do**
5 $x_{n+1}^{\vartheta^k} = g_n(x_n^{\vartheta^k}, \vartheta_n^k)$;
6 **end**
7 Set $p_N^{\vartheta^k} = -\nabla\Phi(x_N^{\vartheta^k})$;
8 **for** $n = N-1$ **to** 0 **do**
9 $p_n^{\vartheta^k} = \nabla_x H_n(x_n^{\vartheta^k}, p_{n+1}^{\vartheta^k}, \vartheta_n^k)$;
10 **end**
11 **for** $n = 0$ **to** $N-1$ **do**
12 Set $\vartheta_n^{k+1} = \arg\max_{\vartheta\in\Theta_n} H_n(x_n^{\vartheta^k}, p_{n+1}^{\vartheta^k}, \vartheta) - \frac{1}{2}\rho\|x_{n+1}^{\vartheta^k} - g_n(x_n^{\vartheta^k}, \vartheta)\|_2^2 - \frac{1}{2}\rho\|p_n^{\vartheta^k} - \nabla_x H_n(x_n^{\vartheta^k}, p_{n+1}^{\vartheta^k}, \vartheta)\|_2^2$;
13 **end**
14 **end**

4.2 Relationship to Gradient Descent with Back-propagation

We note an interesting relationship of the MSA with classical gradient descent with back-propagation (Kelley, 1960; Bryson, 1975; LeCun et al., 1998). We have shown in Lemma 2 that the divergence of MSA can be attributed to the large errors in the Hamiltonian dynamics terms caused by the maximization step, which involve drastic changes in parameter values. Assuming each Θ_n is a continuum and g_n, L are differentiable in ϑ_n, a simple fix is to make the maximization step "soft": we replace step 12 in Algorithm 3 with a gradient ascent step:

$$\vartheta_n^{k+1} = \vartheta_n^k + \eta\nabla_\vartheta H_n(x_n^{\vartheta^k}, p_{n+1}^{\vartheta^k}, \vartheta_n^k), \tag{13}$$

for some small learning rate η. We now show that in the discrete-time setting, this is equivalent to the classical gradient descent with back-propagation.

Proposition 5 *The basic MSA in discrete-time (Algorithm 3 with $\rho = 0$) with step 12 replaced by* (13) *is equivalent to gradient descent with back-propagation.*

Proof Recall that the Hamiltonian is

$$H_n := p_{n+1} \cdot g_n(x_n, \vartheta_n) - \delta L(\vartheta_n),$$

and the total loss function is $J(\vartheta) = \Phi(x_N) + \delta\sum_{n=0}^{N-1} L(\vartheta_n)$. It is easy to see that $p_n = -\nabla_{x_n}\Phi(x_N)$ by working backwards from $n = N$ and the fact that $\nabla_{x_n} x_{n+1} = \nabla_x g_n(x_n, \vartheta_n)$. Then,

$$\begin{aligned}\nabla_{\vartheta_n} J(\vartheta) =& \nabla_{x_{n+1}}\Phi(x_N) \cdot \nabla_{\vartheta_n} x_{n+1} + \delta\nabla_{\vartheta_n} L(\vartheta_n)\\ =& -p_{n+1} \cdot \nabla_{\vartheta_n} g_n(x_n, \vartheta_n) + \delta\nabla_{\vartheta_n} L(\vartheta_n)\\ =& -\nabla_{\vartheta_n} H_n.\end{aligned}$$

Hence, (13) is simply the gradient descent step

$$\vartheta_n^{k+1} = \vartheta_n^k - \eta\nabla_{\vartheta_n} J(\vartheta^k).$$

■

As the proposition shows, gradient descent with back-propagation can be seen as a modification of the basic MSA by replacing the Hamiltonian maximization step with a gradient ascent step. However, we note that the PMP (and MSA convergence) holds, at least in continuous-time, even when differentiability with respect to ϑ is not satisfied, and hence is more general than the classical back-propagation. In fact, the PMP formalism shows that the back-propagation of information through a deep network is handled by the co-state equation and there is no requirement or relationship to the gradients with respect to the trainable parameters. In other words, optimization is performed at each layer separately (with or without gradient information), and propagation is independent of optimization.

4.3 A Remark on Mini-batch Algorithms

So far, our discussion has focused on full-batch algorithms, where the input x represents the full set of training inputs. As modern supervised learning tasks typically involve a large number of training samples, usually the optimization problem has to be solved in mini-batches, where at each iteration we sub-sample m input-label pairs and optimize the parameters θ (or ϑ in discrete time) based on losses evaluated on these pairs. In the context of continuous-time PMP, we can write the batch version of the three necessary conditions as

$$\begin{aligned}\dot{X}_t^{i,*} &= \nabla_p H(t, X_t^{i,*}, P_t^{i,*}, \theta_t^*), & X_0^{i,*} &= x^i,\\ \dot{P}_t^{i,*} &= -\nabla_x H(t, X_t^{i,*}, P_t^{i,*}, \theta_t^*), & P_T^{i,*} &= -\nabla\Phi^i(X_T^{i,*}),\\ \theta_t^* &= \arg\max_{\theta\in\Theta} \sum_{i=1}^M H(t, X_t^{i,*}, P_t^{i,*}, \theta), & t &\in [0,T],\end{aligned}$$

for samples $i = 1, \dots, M$. We omit for brevity the equivalent expressions for discrete-time. In particular, notice that the propagation steps are decoupled across samples, and hence can be carried out independently. The only difference is the maximization step, where in a mini-batch setting we would evaluate instead

$$\arg\max_{\theta \in \Theta} \sum_{i=1}^{m} H(t, X_t^{i,*}, P_t^{i,*}, \theta).$$

If m is large enough and the samples are independently and identically drawn, then uniform law of large numbers (Jennrich, 1969) holds under fairly general conditions and ensures that the mini-batch mean of Hamiltonians converges uniformly in θ to the full-batch sum. Hence, maximization performed on the mini-batch sum should be close to the actual maximization on the full Hamiltonian. Rigorous error estimates for the mini-batch version of our algorithm is out of the scope of the current work, and we use instead numerical results in Section 5 to demonstrate that the algorithm can also be carried out in a mini-batch fashion.

5. Numerical Experiments

In this section, we investigate the performance of E-MSA compared with the usual gradient-based approaches, namely stochastic gradient descent and its variants: Adagrad (Duchi et al., 2011) and Adam (Kingma and Ba, 2014). To illustrate key properties of E-MSA, we shall begin by investigating some synthetic examples. First, we consider a simple one-dimensional function approximation problem where we want to approximate $F(x) = \sin(x)$ for $x \in [-\pi, \pi]$ using a continuous time dynamical system. Let $T = 5$ and consider

$$\dot{X}_t = f(X_t, \theta_t) = \tanh(W_t X_t + b_t),$$

where $\theta_t = (W_t, b_t) \in \mathbb{R}^{5\times 5} \times \mathbb{R}^5$, i.e. a continuous analogue of a fully connected feed forward neural networks with 5 nodes per layer. To match dimensions, we shall concatenate the input x to form a five dimensional vector of identical components, which is now the initial condition to the dynamical system on $\mathbb{R}^d$. The output of the network is $\sum_{i=1}^5 X_T^i$. and we define the loss function due to one sample to be $\Phi(X_T) = (\sum_{i=1}^5 X_T^i - \sin(x))^2$. For multiple samples, we average the loss function over all samples in the usual way. We apply E-MSA with discretization size $\delta = 0.25$ (giving 20 layers) and compute the Hamiltonian maximization step using 10 iterations of limited memory BFGS method (L-BFGS) (Liu and Nocedal, 1989). In Figure 1(a), we compare the results with gradient descent based optimization approaches, where we observe that E-MSA has favorable convergence rate per-iteration. More interestingly, it is well-known that gradient descent may suffer slow convergence at flat regions or near saddle-points, where the gradients become very small and optimization may stall for a long time. This often occurs as a result of poor initialization of weights and biases (Sutskever et al., 2013). Here, we simulate this scenario by initializing all weights and biases (W_t, b_t) to be 0 and observe the optimization process. We see from Figure 1(b) that gradient descent based methods are more easily stalled at flat regions. We calculated numerically the eigenvalues of the Hessian at this region, which confirms that this is indeed very close to a saddle point. On the other hand, the Hamiltonian maximization in E-MSA can quickly escape the locally flat regions. One possible reason is that second-order information employed by L-BFGS can off-set the small gradients and provide larger updates.

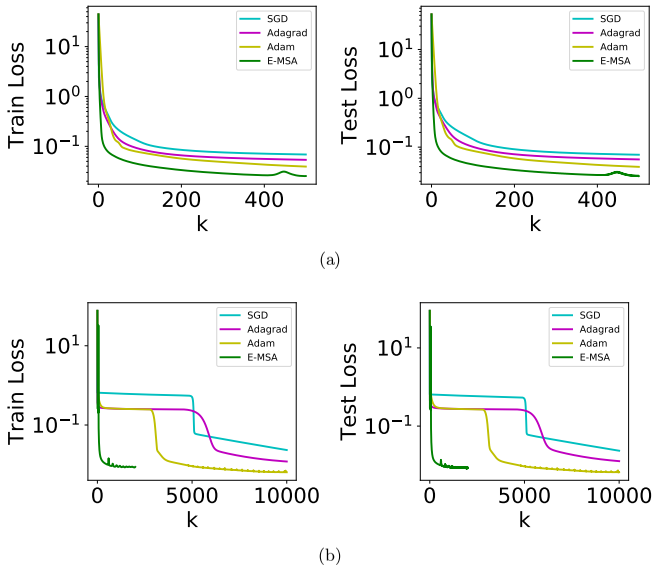

Figure 1: Comparison of E-MSA with gradient-based methods for approximating the sine function with a continuous, 5-dimensional dynamical system. A training and test set of 1000 samples each are used. (a) Loss function vs iterations for a good initialization, where weights are initialized with truncated random normal variables with standard deviation 0.1 and biases are initialized as constants equal to 0.1. We see that E-MSA has good convergence rate per iteration. (b) We use a poor initialization by setting all weights and biases to 0. We observe that gradient descent based methods tend to become stuck whereas E-MSA are better at escaping these slow manifolds, provided that ρ is well chosen (=1.0 in this case).

Next, we consider a familiar supervised learning test problem: the MNIST data set (LeCun, 1998) for handwritten digit recognition, with 55000 training samples and 10000 test samples. We employ a continuous dynamical system that resembles a (residual) convolution neural network (LeCun and Bengio, 1995) when discretized. More concretely, at each t we consider the map $f(t, x, \theta) = \tanh(W \star x + b)$ where W is a 3×3 convolution filter with 32 input and output channels. To match dimensions, we introduce two projection layers at the input (consisting of convolution, point-wise non-linearities followed by 2×2 max-pooling). We also use a fully-connected classification layer as the final layer, with softmax cross-entropy loss. Note that the input projection layers and fully-connected output layers

are not of residual form, but we can nevertheless apply Algorithm 3 with the appropriate g. We use a total of 10 layers (2 projections, 1 fully-connected and 7 residual layers with $\delta = 0.5$, i.e $T = 3.5$). The model is trained with mini-batch sizes of 100 using E-MSA and gradient-descent based methods, namely SGD, Adagrad, and Adam. For E-MSA, we approximately solve the Hamiltonian maximization step using either 10 iterations of L-BFGS. Note that since we have decoupled the layers through the PMP, the L-BFGS step used to maximize H is tractable since it involves much fewer parameters than directly minimizing J. Figure 2 compares the performance of E-MSA with the other gradient-descent based methods, where we observe that E-MSA has good performance per-iteration, especially at early stages of training. However, we also show in Figure 3 that the wall-clock performance of our methods are not currently competitive, because the Hamiltonian maximization step is time consuming and the performance gains per iteration is outweighed by the running time. Note that wall-clock times are compared on the CPU for fairness since we did not use a GPU implementation of L-BFGS. As a further test, we train the same model on a different data set, the fashion MNIST data set (Xiao et al., 2017), where we again observe similar phenomena (see Figure 4). Experiments on more complex data sets such as ImageNet (Deng et al., 2009) with larger residual networks is a direction of future work. In particular, this may require further improvements to the Hamiltonian maximization step current handled by direct minimization with L-BFGS, which can be significantly slower (on a wall-clock basis) for larger networks and data sets.

6. Discussion and Related Work

We commence this section by highlighting the distinguishing features of E-MSA from traditional gradient-descent based training methods. First, the formulations of PMP and E-MSA do not involve gradient information with respect to the trainable parameters. In fact, Theorem 1 and Algorithm 2 remain valid even when the trainable parameters can only take values in a discrete set. Second, due to a more drastic argmax step taken at each iteration, E-MSA tends to have better convergence rates at the early steps of training, as observed in our numerical experiments (Section 5). Third, in the PMP formalism, the Hamiltonian equations for the state and co-state are the "forward and backward propagations", whereas given the state and co-state values, the optimization step is decoupled across layers. This allows one to potentially parallelize the often time-consuming optimization step. Moreover, from Lemma 2, we show that as long as the Hamiltonian is sufficiently increased in a layer without causing too much loss in the Hamiltonian dynamics feasibility conditions, we can ensure decrement of the loss function. This is the reason why we can use a small number of iterations of L-BFGS at each step. Moreover, this suggests that the argmax updates need not happen synchronously, i.e. the optimization in each layer can be a separate thread or process that computes the argmax and updates that layer's parameters independent of other layers. The propagation may also potentially be allowed to happen asynchronously as long as updates are sufficiently frequent. We leave a rigorous analysis of an asynchronous version of the current approach to future work. In summary, the main strength of the PMP (over e.g. solving the KKT conditions using gradient methods) is that PMP says that at the optimum, the Hamiltonian is not only stationary (KKT), but globally maximized. This hints that heuristic global optimization methods can be applied to H to obtain algorithms that

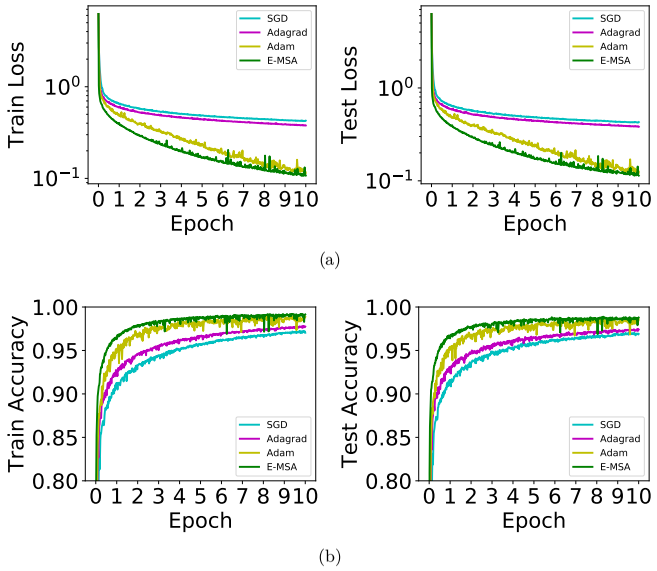

Figure 2: Comparison of E-MSA with gradient-based methods for the residual CNN on the MNIST data set. Mini-batch size of 100 is used so that each epoch of training consists of 550 iterations. (a) Train and test Loss vs epoch. (b) Train and test accuracy vs epoch. For each case, we tuned the associated hyper-parameters on a coarse grid for optimal performance. We observe that per-iteration, E-MSA performs favorably, at least at early times. This shows that if the augmented Hamiltonian can be efficiently maximized, we may obtain good performance.

are very different in behavior compared with gradient-descent based approaches. Again, Lemma 2 ensures that such heuristic global maximization need only be approximate.

As it currently stands, our experiments in Section 5 demonstrate that the Hamiltonian maximization step in E-MSA gives very different behavior compared with gradient-descent based methods. When the Hamiltonian is sufficiently maximized, we indeed obtain favorable performance compared with gradient descent based methods. Furthermore, we saw in Figure 1 that Hamiltonian maximization may avoid pitfalls such as a very flat landscape. Overall, the key to whether E-MSA (and other methods based on solving the PMP) will eventually constitute a replacement for gradient-descent based algorithm lies in the question of whether efficient Hamiltonian maximization can be performed at reasonable computational costs. Although this is still a non-convex optimization problem, it is much simpler than the original training problem because: (1) Optimization in the layers are decoupled and hence parameter space is greatly reduced; (2) The Hamiltonian is formally similar across

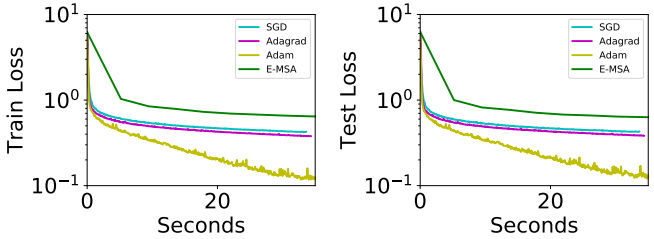

Figure 3: Comparison of E-MSA with gradient-based methods for the residual CNN on the MNIST data set on a wall-clock basis. We observe that currently, the gains per iteration is outweighed by the additional computational costs. Note that we did not use a GPU implementation for the L-BFGS algorithm used to maximize the augmented Hamiltonian, hence the wall-clock time for E-MSA is expected to be improved. Nevertheless, we expect that more efficient Hamiltonian maximization algorithms must be developed for E-MSA to out-perform gradient-based methods in terms of wall-clock efficiency.

different layers, loss functions and models, so specialized algorithms may be designed; (3) The Hamiltonian does not need to be maximized exactly, thus fast heuristic methods (Lee and El-Sharkawi, 2008) or learning (Andrychowicz et al., 2016; Jaderberg et al., 2016; Czarnecki et al., 2017) can potentially be used to perform this. All these are worthy of future exploration in order to make E-MSA truly competitive.

Next, we put our work in perspective by discussing related work in the optimal control, optimization and deep learning literature. First, the work on numerical algorithms for the solution of optimal control problem is abundant (see e.g. Rao 2009 for a survey). Many of the state-of-the-art techniques in the control theory literature assume a moderately small problem size, so that conventional non-linear programming techniques (Bertsekas, 1999; Bazaraa et al., 2013) as well as shooting (Roberts and Shipman, 1972) and collocation methods (Betts, 1998) produce efficient algorithms. This is usually not the case for large-scale machine learning problems, where often, the only scalable approach is to rely on iterative updates to the parameters. This is the reason for our focus on the MSA algorithms (Chernousko and Lyubushin, 1982), as they are straight-forward to implement and typically have linear scaling in computational complexity with respect to the input and parameter sizes. The basic MSA is discussed in Krylov and Chernousko (1962), and a number of improved variants are discussed in Chernousko and Lyubushin (1982) and references therein. For example, a popular improvement is based on needle-perturbations, where controls are varied on small intervals at each iteration. While convergent, the main issue with the needle-perturbation approach is the requirement of a sufficiently fine mesh (i.e. many layers in the discretized network), which impacts computational speed. A possible solution is the use of adaptive meshes, which is a future direction we plan to investigate. Our variant of the MSA presented in this work differs from classical approaches (Chernousko and Lyubushin, 1982) mainly in the sense that we solve a weaker sufficient condition (extended

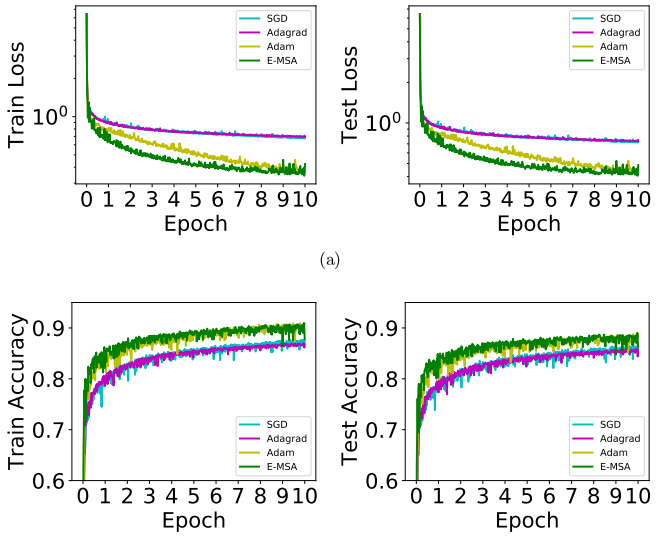

Figure 4: Comparison of E-MSA with gradient-based methods for the residual CNN on the fashion MNIST data set. We use the same network structure and mini-batch sizes as in Figure 2. The hyper-parameters have to be slightly re-tuned. (a) Train and test Loss vs epoch. (b) Train and test accuracy vs epoch. Again, we observe E-MSA performs favorably per-iteration.

PMP, Proposition 3), which then allows us to control errors in the Hamiltonian dynamical equations at every iteration without going into finer mesh-sizes. The regularization terms proportional to ρ is similar to the heuristic modifications suggested in Lyubushin (1982) by regularizing the distance between θ^k and θ^{k+1}, but we do not have to assume convexity of Θ or that f is Lipschitz in θ.

In the optimization literature, our work shares some similarity with the recently proposed ADMM methods (Taylor et al., 2016) for training deep neural networks, where the authors also considered necessary conditions with Lagrange multipliers that can decouple optimization across layers. The main difference in our work is that the PMP gives a stronger necessary condition (Hamiltonian maximization) that also applies to general parameter spaces (e.g., discrete, or bounded with non-linear constraints). Our modification of the basic MSA in terms of the augmented Hamiltonian is inspired by the method of augmented Lagrangians often applied in constrained optimization (Hestenes, 1969). The idea of viewing an initially discrete system as the discretization of a continuous-time system

has been explored in Li et al. (2017) in the form of stochastic optimization. Our current work is also in this flavor, but for neural network models.

In deep learning, there are a few works that share our perspective of deep neural networks as a discretization of a dynamical system. We note that the connection between the PMP and back-propagation has been pointed out qualitatively in LeCun (1988) and in the development of back-propagation (Bryson, 1975; Baydin et al., 2015), although to the best of our knowledge, this work is the first attempt to translate numerical algorithms for the PMP into training algorithms for deep learning that goes beyond gradient descent. The treatment of machine learning as function approximation via a dynamical system has been presented in E (2017). The recent work of Haber and Ruthotto (2017); Chang et al. (2017) also propose the dynamical systems viewpoint, and the authors used continuous-time tools to address stability issues. In contrast, our work focuses on the optimization aspects centered around the PMP. We also mention other recent approaches to decouple optimization in deep neural networks, such as synthetic gradients (Jaderberg et al., 2016; Czarnecki et al., 2017) and proximal back-propagation (Frerix et al., 2017).

7. Conclusion and Outlook

In this paper, we discuss the viewpoint that deep residual neural networks can be viewed as discretization of a continuous-time dynamical system, and hence supervised deep learning can be regarded as solving an optimal control problem in continuous time. We explore a concrete consequence of this connection, by modifying the classical method of successive approximations for solving optimal control problems (in particular the PMP) into a method for solving a weaker sufficient condition (extended PMP). We prove the convergence of the resulting algorithm (E-MSA) and test it on various benchmark problems, where we observe that the E-MSA algorithm performs favorably on a per-iteration basis, especially at early stages of training, compared with gradient-based approaches such as SGD, Adagrad and Adam.

There are many avenues of future research. On the algorithmic side, it is necessary to further improve the computational efficiency of the E-MSA, in particular the Hamiltonian maximization step. Moreover, adaptive selection of ρ depending on iteration number and/or layer can be explored, e.g. by designing adaptive tuning schemes using control theoretic tools (Li et al., 2017). Also, it is desirable to formulate and analyze the PMP and E-MSA from a discrete-time perspective in order to broaden the method's application. From a modeling perspective, viewing deep neural networks as continuous-time dynamical systems is useful in the sense that it allows one to think of neural network architectures as dynamical objects. Indeed, at each training iteration of the E-MSA, we do not have to use the same discretization scheme to compute the Hamiltonian dynamical equations. Also, as the PMP and E-MSA assume little structure on the parameter space Θ, it will also be interesting to apply the E-MSA to train neural networks that have discrete weights (e.g. those that can only take on binary values). Such networks have the advantage of fast inference speed and small memory requirement. However, training such networks is a challenge and most existing techniques rely on approximating or thresholding the derivatives (Courbariaux et al., 2015, 2016). With the PMP and MSA, we may be able to directly train discrete networks in a principled way.

Appendix A. Function Space Formulation

In this section, we give an alternative, non-rigorous formulation of the supervised learning problem as an optimal control problem on function spaces. This provides an alternative formulation of (continuous-time) deep learning that does not make reference to a specific set of input-outputs, but rather their conditional distributions. The idea is to consider the control of a continuity equation that describes the evolution of probability densities. Hereafter, we proceed formally by assuming all differentiability and integrability conditions are satisfied.

We would like to approximate, using a dynamical systems approach, some target joint probability density $\rho(x, y)$, where $x \in \mathcal{X} \subset \mathbb{R}^d$ is a sample input and $y \in \mathcal{Y}$ is the corresponding label. In the case where the labels are deterministically determined by the samples, i.e. there exists $F : \mathcal{X} \to \mathcal{Y}$ such that $y = F(x)$, we would have $\rho(x, y) = \overline{\rho}(x)\delta(F(x) - y)$. Here, $\overline{\rho}(x)$ is the marginal density of $\rho(x, y)$. In general, we can write $\rho(x, y) = \rho(y|x)\overline{\rho}(x)$.

As before, the idea is to consider passing the inputs through a dynamical system

$$\dot{X}_t = f(t, X_t, \theta_t), \qquad X_0 = x. \tag{14}$$

We begin with a guess of a conditional density $\rho_0(y|x)$ of y given x. In the deterministic case, we may set $\rho_0(y|x) = \delta(y - F_0(x))$ for some $F_0 : \mathcal{X} \to \mathcal{Y}$ (this is like the last layer of the neural network, be it a regressor or a classifier). Note that F_0 is potentially very different from F, so that $\rho_0(\cdot|x)$ is far from our target $\rho(\cdot|x)$.

To improve this approximation, we drive the initial condition by the controllable dynamical system (14). That is, we define the approximation at time t of $\rho(y|x)$ to be $\rho_t(y|x) := \langle \rho_0(y|\cdot), u_t \rangle$, with u_t denoting the probability density of X_t at time t (push-forward distribution of X_t according to (14)). It is well-known that u_t follows the continuity equation, or Liouville equation (Gibbs, 2014); or forward Kolmogorov equation in stochastic processes, but with zero noise (Risken, 1996),

$$\frac{d}{dt}u_t = -\mathrm{div}(f(t, \cdot, \theta_t)u_t), \qquad u_0 = \delta_x, \tag{15}$$

where $\mathrm{div} u = \sum_i \partial u / \partial x_i$ is the divergence operator and $\delta_x(x') = \delta(x - x')$ is a point-mass at x. We shall assume that $u_t \in \mathcal{H} \subset L^2(\mathbb{R}^d)$ for some function space $\mathcal{H}$, for all $t \in (0, T]$.

The goal now is to adjust $\theta \in \mathcal{U}$ so that $\rho_t(\cdot|x)$ is close to $\rho(\cdot|x)$. To this end, we define a differentiable loss function $\Phi(\rho_1, \rho_2)$ that measures distances between two conditional densities ρ_1, ρ_2 (e.g., L^2 loss, K-L divergence). Then, the learning problem can be formulated

as the following optimal control problem:

$$\min_{\theta\in\mathcal{U}} \mathbb{E}_{x\sim\overline{\rho}}\left[\Phi(\rho_t(\cdot|x),\rho(\cdot|x)) + \int_0^T L(\theta_t)dt\right],$$
$$\frac{d}{dt}u_t = -\mathrm{div}(f(t,\cdot,\theta_t)u_t), \qquad u_0 = \delta_x. \tag{16}$$

As before, L is a regularizer on the trainable parameters. Now, (16) is an optimal control problem on the function space $\mathcal{H}$.

We now write down formally a set of necessary conditions for optimality, in the form of the Pontryagin's maximum principle, for the present function-space control problem (16). Define the Hamiltonian functional $H : [0,T]\times\mathcal{H}\times\mathcal{H}\times\Theta\to\mathbb{R}$

$$\begin{aligned} H(t,u,v,\theta) &:= -\langle v, \mathrm{div}(f(t,\cdot,\theta)u)\rangle - L(\theta) \\ &= -\int_{\mathbb{R}^d} v(x)\sum_{i=1}^d \frac{\partial}{\partial x_i}(f(t,x,\theta)u(x))dx - L(\theta). \end{aligned}$$

Then, the Pontryagin's maximum principle for this system is expected to take the form: let $\theta^*\in\mathcal{U}$ be an optimal control, then there exists a co-state process $v_t\in\mathcal{H}$ such that

$$\begin{aligned} &\frac{d}{dt}u_t^* = D_v H(t,u_t^*,v_t^*,\theta_t^*), && u_0^* = \delta_x, \\ &\frac{d}{dt}v_t^* = -D_u H(t,u_t^*,v_t^*,\theta_t^*), && v_T^* = -D_u\Phi(\langle\rho_0,u_T^*\rangle,\rho(\cdot|x)) \\ &\mathbb{E}_{x\sim\overline{\rho}}H(t,u_t^*,v_t^*,\theta_t^*) \ge \mathbb{E}_{x\sim\overline{\rho}}H(t,u_t^*,v_t^*,\theta), && \theta\in\Theta, t\in[0,T], \end{aligned}$$

where D denotes the usual Fréchet derivative. Note that by definition, we have $D_v H = -\mathrm{div}(fu)$ and $D_u H = f\cdot\nabla_x v$. Observe that the co-state v^* satisfies the (time-reversed) adjoint Liouville's equation with a specified terminal condition. The PMP for similar functional optimal control problems has been studied in, among others, Pogodaev (2016); Roy and Borz (2017), albeit without the expectation over initial density.

In summary, the advantage of this formulation is that we make no explicit reference to the training data or target functions and formulate the entire problem as a control problem on probability densities. Of course, in practice, to implement an MSA-like algorithm, the terminal condition of the co-state will depend on the target joint density, which we can only access through the sampled data. A rigorous analysis of this function space control formulation and its consequences will be explored in future work.

Appendix B. Proof of Lemma 2

First, observe that assumptions (A1)-(A2) in the main text implies that the second derivatives of f and Φ are bounded by K. Provided that P_t^θ is bounded, they also imply that the second derivatives of H with respect to x and p are bounded when evaluated on $X_t^\theta, P_t^\theta, \theta_t$. We first establish the boundedness of P_t^θ.

Lemma 6 *Assume that (A1)-(A2) hold. Then, there exists a constant $K'>0$ such that for any θ,*

$$\|P_t^\theta\| \le K',$$

for all $t\in[0,T]$.

Proof Using (7) and setting $\tau := T-t$, $\tilde{P}_\tau^\theta := P_{T-\tau}^\theta$ we get

$$\dot{\tilde{P}}_\tau^\theta = \tilde{P}_\tau^\theta\cdot\nabla_x f(t, X_{T-\tau}^\theta, T-\tau), \qquad \tilde{P}_0^\theta = -\nabla\Phi(X_T^\theta).$$

Using (A1)-(A2), we have $\|P_T^\theta\| = \|\nabla_x\Phi(X_T^\theta)\| \le K$ and $\|\nabla_x f(t,X_t^\theta,\theta_t)\|_2 \le K$. Hence,

$$\|\dot{\tilde{P}}_\tau^\theta\| \le K\|\tilde{P}_\tau^\theta\|,$$

and by Gronwall's inequality,

$$\|\tilde{P}_\tau^\theta\| \le Ke^{KT} =: K'.$$

This proves the claim since it holds for any τ. ∎

We now prove Lemma 2. The approach here is similar to that employed in Rozonoer (1959).

Proof [Proof of Lemma 2] From (6) and the definition of the Hamiltonian, we have for any $\theta\in\mathcal{U}$,

$$I(X^\theta,P^\theta,\theta) := \int_0^T P_t^\theta\cdot\dot{X}_t^\theta - H(t,X_t^\theta,P_t^\theta,\theta_t) - L(\theta_t)dt \equiv 0.$$

Denote $\delta X_t = X_t^\phi - X_t^\theta$ and $\delta P_t = P_t^\phi - P_t^\theta$, then we have

$$\begin{aligned} 0 \equiv& I(X^\phi,P^\phi,\phi) - I(X^\theta,P^\theta,\theta) \\ =& \int_0^T P_t^\theta\cdot\delta\dot{X}_t + \delta P_t\cdot\dot{X}_t^\theta + \delta P_t\cdot\delta\dot{X}_t dt \\ &- \int_0^T H(t,X_t^\phi,P_t^\phi,\phi_t) - H(t,X_t^\theta,P_t^\theta,\theta_t)dt \\ &- \int_0^T L(\phi_t) - L(\theta_t)dt. \end{aligned} \tag{17}$$

Now, by integration by parts

$$\int_0^T P_t^\theta\cdot\delta\dot{X}_t dt = P_t^\theta\cdot\delta X_t\Big|_0^T - \int_0^T \dot{P}_t^\theta\cdot\delta X_t dt, \tag{18}$$

$$\int_0^T \delta P_t\cdot\delta\dot{X}_t dt = \delta P_t\cdot\delta X_t\Big|_0^T - \int_0^T \delta\dot{P}_t\cdot\delta X_t dt. \tag{19}$$

Using (6), (7) and (18), we have

$$\begin{aligned} &\int_0^T P_t^\theta\cdot\delta\dot{X}_t + \delta P_t\cdot\dot{X}_t^\theta dt \\ =& P_t^\theta\cdot\delta X_t\Big|_0^T + \int_0^T \Big(f(t,X_t^\theta;\theta_t)\cdot\delta P + \nabla_x H(t,X_t^\theta,P_t^\theta,\theta_t)\cdot\delta X\Big)dt \\ =& P_t^\theta\cdot\delta X_t\Big|_0^T + \int_0^T \Big(\nabla_z H(t,Z_t^\theta,\theta_t)\cdot\delta Z\Big)dt. \end{aligned} \tag{20}$$

where in the last line we defined $Z^\theta := (X^\theta, P^\theta)$. Similarly, from (19) we get

$$\begin{aligned}\int_0^T \delta P_t \cdot \delta \dot{X}_t dt =& \frac{1}{2}\int_0^T \delta P_t \cdot \delta \dot{X}_t dt + \frac{1}{2}\int_0^T \delta P_t \cdot \delta \dot{X}_t dt \\ =& \frac{1}{2}\delta P_t \cdot \delta X_t\Big|_0^T \\ &+ \frac{1}{2}\int_0^T \left([\nabla_z H(t, Z_t^\phi, \phi_t) - \nabla_z H(t, Z_t^\theta, \theta_t)] \cdot \delta Z_t \right) dt \\ =& \frac{1}{2}\delta P_t \cdot \delta X_t\Big|_0^T \\ &+ \frac{1}{2}\int_0^T [\nabla_z H(t, Z_t^\theta, \phi_t) - \nabla_z H(t, Z_t^\theta, \theta_t)] \cdot \delta Z_t dt \\ &+ \frac{1}{2}\int_0^T \delta Z_t \cdot \nabla_z^2 H(t, Z_t^\theta + r_1(t)\delta Z_t, \phi_t) \cdot \delta Z_t dt. \end{aligned} \tag{21}$$

where we have used Taylor's theorem in the last step with $r_1(t) \in [0,1]$. We now rewrite the boundary terms. Since $\delta X_0 = 0$, we have

$$\begin{aligned}&(P_t^\theta + \frac{1}{2}\delta P_t) \cdot \delta X_t\Big|_0^T = (P_T^\theta + \frac{1}{2}\delta P_T) \cdot \delta X_T \\ =& -\nabla\Phi(X_T^\theta) \cdot \delta X_T - \frac{1}{2}(\nabla\Phi(X_T^\phi) - \nabla\Phi(X_T^\theta)) \cdot \delta X_T \\ =& -\nabla\Phi(X_T^\theta) \cdot \delta X_T - \frac{1}{2}\delta X_T \cdot \nabla^2\Phi(X_T^\theta + r_2\delta X_T) \cdot \delta X_T \\ =& -(\Phi(X_T^\phi) - \Phi(X_T^\theta)) - \frac{1}{2}\delta X_T \cdot (\nabla^2\Phi(X_T^\theta + r_2\delta X_T) + \nabla^2\Phi(X_T^\theta + r_3\delta X_T)) \cdot \delta X_T, \end{aligned} \tag{22}$$

for some $r_2, r_3 \in [0,1]$. Lastly, for each $t \in [0,T]$ we have

$$\begin{aligned}H(t, Z_t^\phi, \phi_t) - H(t, Z_t^\theta, \theta_t) =& H(t, Z_t^\theta, \phi_t) - H(t, Z_t^\theta, \theta_t) \\ &+ \nabla_z H(t, Z_t^\theta, \phi_t) \cdot \delta Z_t \\ &+ \frac{1}{2}\delta Z_t \cdot \nabla_z^2 H(t, Z_t^\theta + r_4(t)\delta Z_t, \phi_t) \cdot \delta Z_t, \end{aligned} \tag{23}$$

where $r_4(t) \in [0,1]$.

Substituting (20), (21), (22), (23) into (17), we obtain

$$\begin{aligned}&\left[\Phi(X_T^\phi) + \int_0^T L(\phi_t)\right] - \left[\Phi(X_T^\theta) + \int_0^T L(\theta_t)\right] \\ =& \frac{1}{2}\delta X_T \cdot (\nabla^2\Phi(X_T^\theta + r_2\delta X_T) + \nabla^2\Phi(X_T^\theta + r_3\delta X_T)) \cdot \delta X_T \\ &- \int_0^T \Delta H_{\phi,\theta}(t) dt \\ &+ \frac{1}{2}\int_0^T (\nabla_z H(t, Z_t^\theta, \phi_t) - \nabla_z H(t, Z_t^\theta, \theta_t)) \cdot \delta Z_t dt \\ &+ \frac{1}{2}\int_0^T \left(\delta Z_t \cdot [\nabla_z^2 H(t, Z_t^\theta + r_1(t)\delta Z_t, \phi_t) - \nabla_z^2 H(t, Z_t^\theta + r_4(t)\delta Z_t, \phi_t)] \cdot \delta Z_t \right) dt. \end{aligned} \tag{24}$$

The left hand side is simply $J(\phi) - J(\theta)$, and so it remains to estimate the right hand side terms. First, let us estimate δX and δP. By definition,

$$\delta \dot{X}_t = f(t, X_t^\phi, \phi_t) - f(t, X_t^\theta, \theta_t).$$

Integrating, we get

$$\delta X_t = \int_0^t f(t, X_s^\phi, \phi_s) - f(t, X_s^\theta, \theta_s) ds,$$

and so

$$\begin{aligned}\|\delta X_t\| \le& \int_0^t \|f(t, X_s^\phi, \phi_s) - f(t, X_s^\theta, \theta_s)\| ds \\ \le& \int_0^t \|f(t, X_s^\phi, \phi_s) - f(t, X_s^\theta, \phi_s)\| ds \\ &+ \int_0^t \|f(t, X_s^\theta, \phi_s) - f(t, X_s^\theta, \theta_s)\| ds \\ \le& \int_0^T \|f(t, X_s^\theta, \phi_s) - f(t, X_s^\theta, \theta_s)\| ds \\ &+ K\int_0^t \|\delta X_s\| dt. \end{aligned} \tag{25}$$

By Gronwall's inequality, we have

$$\|\delta X_t\| \le e^{KT}\int_0^T \|f(t, X_s^\theta, \phi_s) - f(t, X_s^\theta, \theta_s)\| ds. \tag{26}$$

To estimate δP, we use the same substitution as in Lemma 6 with $\tau = T - t$ and $\tilde{\cdot}_\tau = \cdot_{T-t}$. We get

$$\delta \tilde{P}_\tau = \delta \tilde{P}_0 + \int_0^\tau \nabla_x H(t, \tilde{X}_s^\phi, \tilde{P}_s^\phi, \tilde{\phi}_s) - \nabla_x H(t, \tilde{X}_s^\theta, \tilde{P}_s^\theta, \tilde{\theta}_s) ds,$$

and hence using Lemma 6 and assumptions (A1)-(A2),

$$\begin{aligned}\|\delta \tilde{P}_\tau\| \le& \|\delta \tilde{P}_0\| + \int_0^\tau \|\nabla_x H(t, \tilde{X}_s^\phi, \tilde{P}_s^\phi, \tilde{\phi}_s) - \nabla_x H(t, \tilde{X}_s^\theta, \tilde{P}_s^\theta, \tilde{\theta}_s)\| ds \\ \le& K\|\delta X_T\| + KK'\int_0^T \|\delta X_s\| ds + K\int_0^\tau \|\delta \tilde{P}_s\| ds \\ &+ \int_0^T \|\nabla_x H(t, X_s^\theta, P_s^\theta, \phi_s) - \nabla_x H(t, X_s^\theta, P_s^\theta, \theta_s)\| ds \\ \le& e^{KT}K(\|\delta X_T\| + K'\int_0^T \|\delta X_s\| ds) \\ &+ e^{KT}\int_0^T \|\nabla_x H(t, X_s^\theta, P_s^\theta, \phi_s) - \nabla_x H(t, X_s^\theta, P_s^\theta, \theta_s)\| ds. \end{aligned} \tag{27}$$

Using estimate (26), we obtain

$$\begin{aligned}\|\delta P_t\| \leq & e^{2KT}K(1+K'T)\int_0^T \|f(t,X_s^\theta,\phi_s)-f(t,X_s^\theta,\theta_s)\|ds \\ & + e^{KT}\int_0^T \|\nabla_x H(t,X_s^\theta,P_s^\theta,\phi_s)-\nabla_x H(t,X_s^\theta,P_s^\theta,\theta_s)\|ds. \end{aligned} \tag{28}$$

Now, we substitute estimates (26) and (28) into (24) and rename constants for simplicity. Note that by assumptions (A1)-(A2) and Lemma 6, all the second derivative terms are bounded element-wise by some constant K''. Hence, we have $|\delta Z_t \cdot A \cdot \delta Z_t| \leq K''\|\delta Z\|^2$ for each A being a second derivative matrix. Thus we obtain

$$\begin{aligned} J(\phi)-J(\theta) \leq & -\int_0^T \Delta H_{\phi,\theta}(t)dt \\ & + \frac{1}{2}K''\|\delta X_T\|^2 \\ & + K''\int_0^T (\|\delta X_t\|^2+\|\delta P_t\|^2)dt \\ & + \frac{1}{2}\int_0^T \|\delta X_t\|\|f(t,X_t^\theta,\phi_t)-f(t,X_t^\theta,\theta_t)\|dt \\ & + \frac{1}{2}\int_0^T \|\delta P_t\|\|\nabla_x H(t,X_t^\theta,P_t^\theta,\phi_t)-\nabla_x H(t,X_t^\theta,P_t^\theta,\theta_t)\|dt \\ \leq & -\int_0^T \Delta H_{\phi,\theta}(t)dt \\ & + C\left(\int_0^T \|f(t,X_t^\theta,\phi_t)-f(t,X_t^\theta,\theta_t)\|dt\right)^2 \\ & + C\left(\int_0^T \|\nabla_x H(t,X_t^\theta,P_t^\theta,\phi_t)-\nabla_x H(t,X_t^\theta,P_t^\theta,\theta_t)\|^2 dt\right)^2 \\ \leq & -\int_0^T \Delta H_{\phi,\theta}(t)dt \\ & + C\int_0^T \|f(t,X_t^\theta,\phi_t)-f(t,X_t^\theta,\theta_t)\|^2 dt \\ & + C\int_0^T \|\nabla_x H(t,X_t^\theta,P_t^\theta,\phi_t)-\nabla_x H(t,X_t^\theta,P_t^\theta,\theta_t)\|^2 dt. \end{aligned} \tag{29}$$

■

Remark 7 *For applications, the global Lipschitz condition (A2) w.r.t. x on f may be restrictive. Note that this can be replaced by a local Lipschitz condition if we can show that X_t, $t \in [0,T]$ is bounded for all $\theta \in \mathcal{U}$. This is true if the parameter space Θ is bounded, which we can safely assume in practice, as long as a suitable regularization is used that prevents the parameters from getting arbitrarily large. Alternatively, a projection step can be used to restrict the parameters to a bounded set. In either cases, this should not negatively affect the performance of the model.*

Abstract

Hard Thresholding Pursuit (HTP) is an iterative greedy selection procedure for finding sparse solutions of underdetermined linear systems. This method has been shown to have strong theoretical guarantee and impressive numerical performance. In this article, we generalize HTP from compressed sensing to a generic problem setup of sparsity-constrained convex optimization. The proposed algorithm iterates between a standard gradient descent step and a hard-thresholding step with or without debiasing. We analyze the parameter estimation and sparsity recovery performance of the proposed method. Extensive numerical results confirm our theoretical predictions and demonstrate the superiority of our method to the state-of-the-art greedy selection methods in sparse linear regression, sparse logistic regression and sparse precision matrix estimation problems.[1]

Keywords: Hard Thresholding Pursuit, Sparsity Recovery, Greedy Selection

1. Introduction

In the past decade, high-dimensional data analysis has received broad research interest in data mining and scientific discovery, with many significant results obtained in theory, algorithm and application. The major driving force is the rapid development of data collection technologies in many application domains such as social networks, natural language processing, bioinformatics and computer vision. In these applications it is not unusual that data samples are represented with millions or even billions of features using which an underlying statistical learning model must be fit. In many circumstances, however, the number of collected samples is substantially smaller than the dimensionality of features, implying that consistent estimators cannot be hoped for unless additional assumptions are imposed on the model. One of the most popular prior assumptions is that the data exhibit low-dimensional structure, which can often be captured by imposing sparsity constraint on model parameter space. It is thus crucial to develop robust and efficient computational procedures for high-dimensional estimation with sparsity constraint.

1. A conference version of this work appeared in ICML 2014 (Yuan et al., 2014).

In this article, we consider the following generic sparsity-constrained loss minimization problem:

$$\min_{x\in\mathbb{R}^p} f(x), \quad \text{s.t. } \|x\|_0 \leq k, \tag{1}$$

where $f : \mathbb{R}^p \mapsto \mathbb{R}$ is a smooth convex loss function and $\|x\|_0$ denotes the number of nonzero entries in parameter vector x. Among others, several popular examples falling into this framework include: (i) Sparsity-constrained linear regression model (Tropp & Gilbert, 2007) where the residual error is used to measure data reconstruction error; (ii) Sparsity-constrained logistic regression model (Bahmani et al., 2013) where the sigmoid loss is used to measure prediction error; (iii) Sparsity-constrained graphical model learning (Jalali et al., 2011) where the likelihood of samples drawn from an underlying probabilistic model is used to measure data fidelity.

Due to the presence of cardinality constraint $\|x\|_0 \leq k$, problem (1) is generally NP-hard even for the quadratic loss function (Natarajan, 1995). Thus, one must instead seek approximate solutions. For the special case of (1) with least squares error loss in compressed sensing (Donoho, 2006), a number of low-complexity greedy pursuit methods have been studied including matching pursuit (MP) (Mallat & Zhang, 1993), orthogonal matching pursuit (OMP) (Pati et al., 1993), iterative hard thresholding (IHT) (Blumensath & Davies, 2009), compressed sampling matching pursuit (CoSaMP) (Needell & Tropp, 2009) and hard thresholding pursuit (HTP) (Foucart, 2011) to name a few. These algorithms successively select the position of nonzero entries and estimate their values via exploring the residual error from the previous iteration. Comparing to those first-order convex optimization methods developed for ℓ_1-regularized sparse learning (Beck & Teboulle, 2009; Langford et al., 2009; Agarwal et al., 2012), these greedy pursuit algorithms often exhibit more attractive computational efficiency and scalability in practice.

The least squares error used in compressed sensing, however, is not an appropriate measure of discrepancy in a variety of applications beyond signal processing. For example, in statistical machine learning the log-likelihood function is commonly used in logistic regression (Bishop, 2006) and graphical model learning (Jalali et al., 2011; Ravikumar et al., 2011). Thus, it is desirable to investigate theory and algorithms applicable to a broader class of sparse learning problems as formulated by (1). To this end, several forward selection algorithms have been proposed to select the nonzero entries in a sequential fashion (Kim & Kim, 2004; Shalev-Shwartz et al., 2010; Yuan & Yan, 2013; Jaggi, 2011). This category of methods dates back to the Frank-Wolfe method (Frank & Wolfe, 1956). In the meanwhile, the forward greedy selection method has been generalized to convex loss minimization over the linear hull of a collection of atoms (Tewari et al., 2011; Yuan & Yan, 2013). To make the greedy selection procedure more adaptive, Zhang (2008) proposed a forward-backward algorithm which takes backward steps adaptively whenever beneficial. Jalali et al. (2011) have applied this forward-backward selection method to learn the sparse structure of graphical model. Bahmani et al. (2013) proposed a gradient support pursuit method that generalizes CoSaMP from compressed sensing to the generic sparse minimization problem (1). Jain et al. (2014) presented and analyzed several HTP/IHT-style algorithms for high-dimensional sparse estimation. In the paper of Blumensath (2013), a nonlinear-IHT algorithm was investigated in the generic setting of sparsity-constrained loss minimization. Recently, the extensions of HTP/IHT-style methods to structured and stochastic sparse estimation have

been extensively studied in machine learning community (Jain et al., 2016; Li et al., 2016; Shen & Li, 2016; Liu et al., 2017; Nguyen et al., 2017).

1.1 Overview of Our Contribution

In this article, inspired by the success of Hard Thresholding Pursuit (HTP) (Foucart, 2011, 2012) in compressed sensing, we propose and analyze the Gradient Hard Thresholding Pursuit (GraHTP) method to encompass the sparse estimation problems arising from applications with general nonlinear models. At each iteration, GraHTP performs standard gradient descent followed by a hard thresholding operation which first selects the top k (in magnitude) entries of the resultant vector and then (optionally) conducts debiasing on the selected entries. We show that in various settings with or without assuming RIP-type conditions, GraHTP has strong theoretical guarantees analogous to HTP in terms of parameter estimation accuracy.

Apart from the accuracy of objective value and parameter estimation, in many applications such as compressed sensing and graphical models learning, one property of central importance for sparse estimation is the recovery of sparsity pattern, which corresponds to the set of indices of nonzero components of the model parameters. Once the sparsity pattern is recovered, computing the actual nonzero coefficients just boils down to solving a convex minimization problem over the supporting indices. For perfect measurements, the results obtained by Foucart (2011) show that under proper conditions HTP can exactly recover the underlying true model parameters. For noisy models, however, the sparsity recovery analysis is a crucial challenge remains unsolved for HTP-style methods. As a core contribution of this work, we provide a systematic sparsity recovery analysis for GraHTP. Since the output of GraHTP is always k-sparse, the parameter estimation error bounds established in this article roughly imply a sufficient condition for sparsity recovery: as long as the smallest (in magnitude) nonzero entry of a k-sparse target model is larger than the estimation error bound, exact recovery of such a target model can be guaranteed. With more insightful analysis, we further derive some refined sparsity recovery results for GraHTP and for the k-sparse minimizer of problem (1) as well. Some preliminary results on sparsity recovery of GraHTP have been presented in a prior work of ours (Yuan et al., 2016), which we have improved largely in this article.

Comparing to the prior analysis for HTP-style methods, the merits of our main results can be distilled to the following two aspects:

- **Parameter estimation accuracy analysis with/without RIP-type conditions.** Our parameter estimation accuracy analysis for GraHTP simultaneously covers the setting where the target solution is an arbitrary k-sparse solution for which the RIP-type conditions are required, and the setting where the target solution is certain $\bar{k}$-sparse solutions with $\bar{k} \ll k$ for which the RIP-type conditions can be waived;

- **Systematic sparsity recovery analysis.** We extensively investigate the sparsity recovery performance of GraHTP which is of great importance and practical vale in many sparse learning applications including compressed sensing and graphical models learning.

This Work	$\bar{x}$ with $\|\bar{x}\|_0 \le k$	$\times$ (for $\|\bar{x}\|_0 = k$), $\surd$ (for $\|\bar{x}\|_0 \ll k$)	$\surd$

Table 1: Comparison between the results obtained in this work and several representative prior results for HTP-style algorithms.

Table 1 summarizes a high level comparison between our results and several representative state-of-the-art results for HTP-style algorithms, in terms of target solution, dependence on RIP-type conditions, and sparsity recovery analysis.

We have applied GraHTP to sparse linear regression, sparse logistic regression and sparse precision matrix estimation problems, with its algorithm and/or theory substantialized for these models. Empirically we demonstrate that GraHTP is competitive to the state-of-the-art greedy selection methods in these sparse learning problems.

1.2 Notation

In the following, x is a vector, A is a matrix, and F is an index set. The following notations will be used in this article.

- $[x]_i$: the ith entry of vector x.
- x_F: the restriction of x on F, i.e., $[x_F]_i = [x]_i$ if $i \in F$, and $[x_F]_i = 0$ otherwise.
- x_k: the restriction of x on its top k (in modulus) entries.
- $\|x\| = \sqrt{x^\top x}$: the Euclidean norm of x.
- $\|x\|_1 = \sum_i |[x]_i|$: the ℓ_1-norm of x.
- $\|x\|_\infty = \max_i |[x]_i|$: the ℓ_∞-norm of x.
- $\|x\|_0$: the number of nonzero entries of x.
- $\mathrm{supp}(x)$: the index set of nonzero entries of x.
- $\mathrm{supp}(x, k)$: the index set of the top k (in modulus) entries of x.
- $x_{\min} = \min_{i \in \mathrm{supp}(x)} |[x]_i|$: the smallest absolute value of nonzero element of x.
- $[A]_{ij}$: the element on the ith row and jth column of matrix A.

- $\|A\| = \sup_{\|x\|\leq 1} \|Ax\|$: the spectral norm of matrix A.
- $|A|_\infty = \max_{i,j} |[A]_{ij}|$: the element-wise ℓ_∞-norm of A.
- $\mathrm{Tr}(A)$: the trace (sum of diagonal elements) of a square matrix A.
- A_F: the restriction of A on index set F.
- A^-: the restriction of a square matrix A on its off-diagonal entries.
- $\mathrm{vect}(A)$: (column wise) vectorization of a matrix A.
- $\lambda_{\max}(A,k) = \max_{\|x\|=1,\|x\|_0\leq k} x^\top Ax$: the largest k-sparse eigenvalue of a positive semi-definite matrix A.
- $\lambda_{\min}(A,k) = \min_{\|x\|=1,\|x\|_0\leq k} x^\top Ax$: the smallest k-sparse eigenvalue of a positive semi-definite matrix A.

1.3 Organization

This article proceeds as follows: We present in Section 2 the GraHTP algorithm. The parameter estimation error and exact sparsity recovery guarantees of GraHTP are respectively analyzed in Section 3 and Section 4. The implications of GraHTP in linear regression, logistic regression and Gaussian graphical model learning are discussed in Section 5. Monte-Carlo simulations and real data experimental results are presented in Section 6. We conclude this article in Section 7.

2. Algorithm

GraHTP is an iterative greedy selection procedure for approximately optimizing the nonconvex problem (1). A high level summary of GraHTP is described in the top panel of Algorithm 1. The procedure generates a sequence of intermediate k-sparse vectors $x^{(0)}, x^{(1)}, \ldots$ from an initial sparse approximation $x^{(0)}$ (typically $x^{(0)} = 0$). At the t-th iteration, the first step (**S1**), $\tilde{x}^{(t)} = x^{(t-1)} - \eta\nabla f(x^{(t-1)})$, computes the gradient descent at the point $x^{(t-1)}$ with step-size η. Then in the second step (**S2**), the k coordinates of the vector $\tilde{x}^{(t)}$ that have the largest magnitude are chosen as the support in which pursuing the minimization will be most effective. In the third step (**S3**), we find a vector with this support which minimizes the objective function, which becomes $x^{(t)}$. This last step, which is often referred to as *debiasing*, has been shown to improve the performance in other algorithms too (Yuan & Zhang, 2013; Bahmani et al., 2013). The iterations continue until the algorithm reaches certain terminating condition, e.g., the difference of objective value or model parameters between adjacent iterations converges. A more intuitive criterion is $F^{(t)} = F^{(t-1)}$ (see (**S2**) for the definition of $F^{(t)}$), since then $x^{(\tau)} = x^{(t)}$ for all $\tau \geq t$, although there is no guarantee that this should occur in general cases. It will be assumed throughout the article that the sparsity level k is known. In practice this integer parameter may be tuned via, for example, cross-validation in supervised learning tasks.

In the standard form of GraHTP, the debiasing step (**S3**) requires to minimize $f(x)$ over the supporting set $F^{(t)}$. If this step is judged too costly, we may consider instead a

fast variant of GraHTP, where the debiasing is replaced by a simple truncation operation $x^{(t)} = \tilde{x}^{(t)}_k$. This leads to the Fast GraHTP (FGraHTP) as described in the bottom panel of Algorithm 1, which can be understood as a projected gradient descent procedure for optimizing the nonconvex minimization problem (1). Up to the cost of truncation operation, its per-iteration computational overload is almost identical to that of the standard gradient descent procedure. The iteration procedure of FGraHTP is also known as the nonlinear-IHT algorithm (Blumensath, 2013). Comparing to that prior work, our analysis for FGraHTP is more comprehensive and the results are tighter especially in sparsity recovery analysis. While in this article we only study the FGraHTP outlined in Algorithm 1, we should mention that other fast variants of GraHTP can also be considered. For instance, to reduce the computational cost of the debiasing step (**S3**), we can take a restricted Newton step or a restricted gradient descent step to calculate $x^{(t)}$.

We close this section by pointing out that, in the special case where the squares error $f(x) = \frac{1}{2}\|y - Ax\|^2$ is the cost function, GraHTP reduces to HTP (Foucart, 2011). Specifically, the gradient descent step (**S1**) reduces to $\tilde{x}^{(t)} = x^{(t-1)} + \eta A^\top(y - Ax^{(t-1)})$ and the debiasing step (**S3**) reduces to the orthogonal projection $x^{(t)} = \arg\min\{\frac{1}{2}\|y-Ax\|^2, \mathrm{supp}(x) \subseteq F^{(t)}\}$. In the meanwhile, FGraHTP reduces to IHT (Blumensath & Davies, 2009), which is also known as Gradient Descent with Sparsification (Garg & Khandekar, 2009), of which the iteration is defined as $x^{(t)} = (x^{(t-1)} + \eta A^\top(y - Ax^{(t-1)}))_k$.

Algorithm 1: Gradient Hard Thresholding Pursuit (GraHTP).

repeat
  Compute $\tilde{x}^{(t)} = x^{(t-1)} - \eta\nabla f(x^{(t-1)})$;
  Compute $x^{(t)} = \tilde{x}^{(t)}_k$ as the truncation of $\tilde{x}^{(t)}$ with top k (in magnitude) entries preserved;
  $t = t + 1$;
until *halting condition holds*;

3. Parameter Estimation Analysis

In this section, we analyze the parameter estimation accuracy of GraHTP/FGraHTP. To simplify notation, we abbreviate $\nabla_F f = (\nabla f)_F$ and $\nabla_s f = (\nabla f)_s$. Our analysis relies on the conditions of Restricted Strong Convexity/Smoothness (RSC/RSS) which are conven-

tionally used in the analysis of greedy sparse optimization methods (Shalev-Shwartz et al., 2010; Bahmani et al., 2013; Jain et al., 2014).

Definition 1 (Restricted Strong Convexity/Smoothness) *For any integer $s > 0$, we say $f(x)$ is restricted m_s-strongly convex and M_s-smooth if there exist $m_s, M_s > 0$ such that*

$$\frac{m_s}{2}\|x-y\|^2 \leq f(x) - f(y) - \langle \nabla f(y), x-y\rangle \leq \frac{M_s}{2}\|x-y\|^2, \quad \forall \|x-y\|_0 \leq s. \tag{2}$$

The ratio number M_s/m_s, which measures the curvature of the loss function over sparse subspaces, will be referred to as *restricted strong condition number* in this article.

3.1 Main Results

The following theorem is our main result on the parameter estimation accuracy of GraHTP and FGraHTP with respect to arbitrary k-sparse target solutions. A proof of this theorem is provided in Appendix B.1.

Theorem 2 *Assume that f is M_{3k}-smooth and m_{3k}-strongly convex. Let $\bar{x}$ be an arbitrary k-sparse vector and $\rho = \sqrt{1 - 2\eta m_{3k} + \eta^2 M_{3k}^2}$.*

(a) Assume that $M_{3k}/m_{3k} < 2\sqrt{3}/3$ and the step-size η is chosen such that $\rho < 0.5$. Then GraHTP outputs $x^{(t)}$ satisfying

$$\|x^{(t)} - \bar{x}\| \leq \mu_1^t \|x^{(0)} - \bar{x}\| + \frac{2.83\eta\sqrt{k}}{1-2\rho}\|\nabla f(\bar{x})\|_\infty,$$

where $\mu_1 = \rho/(1-\rho) \in (0,1)$.

(b) Assume that $M_{3k}/m_{3k} < 1.26$ and the step-size η is chosen such that $\rho < 0.62$. Then FGraHTP outputs $x^{(t)}$ satisfying

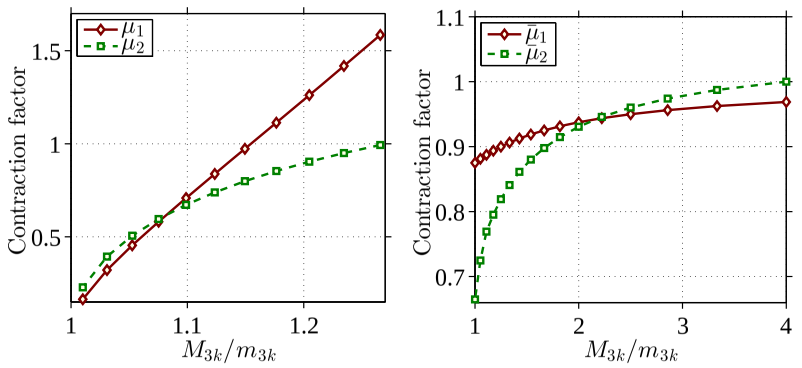
$$\|x^{(t)} - \bar{x}\| \leq \mu_2^t \|x^{(0)} - \bar{x}\| + \frac{2.81\eta\sqrt{k}}{1-1.62\rho}\|\nabla f(\bar{x})\|_\infty,$$

where $\mu_2 = 1.62\rho \in (0,1)$.

In the part (a) of Theorem 2, the contraction factor $\mu_1 < 1$ controls the convergence rate of GraHTP. The condition $\rho < 0.5$ requires the step-size to be selected according to

$$\frac{2m_{3k} - \sqrt{4m_{3k}^2 - 3M_{3k}^2}}{2M_{3k}^2} < \eta < \frac{2m_{3k} + \sqrt{4m_{3k}^2 - 3M_{3k}^2}}{2M_{3k}^2}, \tag{3}$$

from which we can see that $M_{3k}/m_{3k} < 2\sqrt{3}/3$ is a necessary condition to guarantee the existence of η such that $\rho < 0.5$ and $\mu_1 < 1$. The condition of $\rho < 0.5$ is analogous to the RIP condition for estimation from noisy measurements in compressed sensing (Candès et al., 2006; Needell & Tropp, 2009; Foucart, 2011). Indeed, in compressed sensing, GraHTP reduces to HTP which requires weaker RIP condition than prior compressed sensing algorithms. The condition in (3) also suggests that the value of η should be bounded from



(a) Theorem 2 (b) Theorem 5

Figure 1: Evolving curves of the contraction factors in Theorem 2 and Theorem 5.

above to guarantee convergence, and be bounded away from zero to avoid early stopping as well. Similarly, $M_{3k}/m_{3k} < 1.26$ in the part(b) is a necessary condition to guarantee the existence of η such that $\rho < 0.62$ and $\mu_2 < 1$. Figure 1(a) shows the evolving curves of contraction factors μ_1 and μ_2 as functions of M_{3k}/m_{3k} in the interval $[1, 1.26)$. It can be seen from this figure that $\mu_1 < \mu_2$ when $M_{3k}/m_{3k} \to 1$ and $\mu_1 > \mu_2$ for relatively larger M_{3k}/m_{3k}.

The non-vanishing terms in the error bounds of Theorem 2 indicate that the estimation errors of GraHTP and FGraHTP are controlled by the multiplier of $\sqrt{k}\|\nabla f(\bar{x})\|_\infty$. Particularly if the sparse vector $\bar{x}$ is sufficiently close to an unconstrained minimum of f, then the estimation error floor is negligible because $\|\nabla f(\bar{x})\|_\infty$ has small magnitude. The following corollary is a direct consequence of Theorem 2 which shows that exact support recovery is possible when $\bar{x}_{\min}$ is significantly larger than $\sqrt{k}\|\nabla f(\bar{x})\|_\infty$.

Corollary 3 *Assume the conditions in Theorem 2 hold.*

(a) Let $\bar{x}$ be an arbitrary k-sparse vector satisfying $\bar{x}_{\min} > \frac{5.66\eta\sqrt{k}}{1-2\rho}\|\nabla f(\bar{x})\|_\infty$. Then GraHTP will output $x^{(t)}$ satisfying $supp(x^{(t)}) = supp(\bar{x})$ after $t = \left\lceil \frac{1}{\mu_1} \ln\left(\frac{2\|x^{(0)} - \bar{x}\|}{\bar{x}_{\min}}\right)\right\rceil$ steps of iteration.

(b) Let $\bar{x}$ be an arbitrary k-sparse vector satisfying $\bar{x}_{\min} > \frac{5.62\eta\sqrt{k}}{1-1.62\rho}\|\nabla f(\bar{x})\|_\infty$. Then FGraHTP will output $x^{(t)}$ satisfying $supp(x^{(t)}) = supp(\bar{x})$ after $t = \left\lceil \frac{1}{\mu_2} \ln\left(\frac{2\|x^{(0)} - \bar{x}\|}{\bar{x}_{\min}}\right)\right\rceil$ steps of iteration.

Indeed, given the conditions in Corollary 3, for both GraHTP and FGraHTP we can show that $\|x^{(t)} - \bar{x}\| < \bar{x}_{\min}$ and thus $\text{supp}(x^{(t)}) = \text{supp}(\bar{x})$ must hold as $x^{(t)}$ and $\bar{x}$ are both k-sparse vectors.

Remark 4 *Corollary 3 shows that GraHTP/FGraHTP requires RIP-type conditions as in Theorem 2 to guarantee exact support recovery. As a comparison, the existing sparsity recovery results for ℓ_1-estimators (Wainwright, 2009; Li et al., 2015) are free of RIP-type conditions but instead relying on the irrepresentablility condition which is known to be stronger. For example, a case where the RIP-type condition holds while the irrepresentability condition does not was given by Van De Geer & Bühlmann (2009, Example 10.4).*

The RIP-type conditions assumed in Theorem 2 could still be restrictive in real-life high-dimensional statistical settings wherein pairs of variables can be arbitrarily correlated. In the following theorem, we further show that by properly relaxing sparsity levels, GraHTP and FGraHTP are able to accurately estimate parameters without assuming bounded restricted strong condition numbers. A proof of this theorem is deferred to Appendix B.2.

Theorem 5 *Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector with $\bar{k} \leq k$. Assume that $s = 2k + \bar{k} < p$.*

(a) Assume that f is M_{2k}-smooth and m_{2k}-strongly convex. Assume the step-size $\eta < 1/M_{2k}$. If $k \geq \left(2 + \frac{4}{\eta^2 m_{2k}^2}\right)\bar{k}$, then GraHTP outputs $x^{(t)}$ satisfying

$$\|x^{(t)} - \bar{x}\| \leq \sqrt{\frac{2\bar{\mu}_1^t \bar{\triangle}^{(0)}}{m_{2k}}} + \frac{2.83\sqrt{k}\|\nabla f(\bar{x})\|_\infty}{m_{2k}},$$

where $\bar{\mu}_1 = 1 - \eta m_{2k}(1 - \eta M_{2k})/2$ and $\bar{\triangle}^{(0)} = \max\{f(x^{(0)}) - f(\bar{x}), 0\}$.

(b) Assume that f is M_s-smooth and m_s-strongly convex. Assume the step-size $\eta < 2m_s/M_s^2$ such that $\rho = \sqrt{1 - 2\eta m_s + \eta^2 M_s^2} < 1$. If $k > \rho\bar{k}/(1-\rho)^2$, then FGraHTP outputs $x^{(t)}$ satisfying

$$\|x^{(t)} - \bar{x}\| \leq \bar{\mu}_2^t \|x^{(0)} - \bar{x}\| + \frac{\gamma\eta\sqrt{s}}{1 - \bar{\mu}_2}\|\nabla f(\bar{x})\|_\infty,$$

where $\bar{\mu}_2 = \rho\gamma \in (0, 1)$ and $\gamma = \sqrt{1 + \left(\bar{k}/k + \sqrt{(4 + \bar{k}/k)\bar{k}/k}\right)/2}$.

Remark 6 *When using step-size $\eta = \frac{1}{2M_{2k}}$, the part(a) of Theorem 5 tells that GraHTP converges linearly towards an arbitrary $\bar{k}$-sparse vector $\bar{x}$ if the sparsity level is chosen as $k \geq \left(2 + \frac{16M_{2k}^2}{m_{2k}^2}\right)\bar{k}$. The estimation error is controlled by the multiplier of $\sqrt{k}\|\nabla f(\bar{x})\|_\infty$. Similarly, the part(b) of Theorem 5 establishes the convergence result of FGraHTP with proper relaxed $k \gg \bar{k}$. Note that the condition $k > \rho\bar{k}/(1-\rho)^2$ in part(b) actually enforces the contraction factor $\bar{\mu}_2 < 1$. Figure 1(b) shows the evolving curves of contraction factors $\bar{\mu}_1$ and $\bar{\mu}_2$ as functions of M_{3k}/m_{3k}, with the same target sparsity $\bar{k}$. We can see from this figure that $\bar{\mu}_2$ is superior to $\bar{\mu}_1$ when M_{3k}/m_{3k} is relatively small.*

The following corollary of Theorem 5 shows that GrHTP/FGraHTP with certain relaxed sparsity levels can guarantee $\text{supp}(\bar{x}) \subseteq \text{supp}(x^{(t)})$ without assuming RIP-type conditions.

Corollary 7 *Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector with $\bar{k} \leq k$.*

(a) Under the conditions in Theorem 5(a), if $\bar{x}_{\min} > \frac{5.66\sqrt{k}}{m_{2k}}\|\nabla f(\bar{x})\|_\infty$, then GraHTP will output $x^{(t)}$ satisfying $\text{supp}(\bar{x}) \subseteq \text{supp}(x^{(t)})$ after $t = \left\lceil \frac{1}{\bar{\mu}_1} \ln\left(\frac{8\bar{\triangle}^{(0)}}{m_{2k}\bar{x}_{\min}^2}\right)\right\rceil$ steps of iteration.

(b) Under the conditions in Theorem 5(b), if $\bar{x}_{\min} > \frac{2\gamma\eta\sqrt{s}}{1-\bar{\mu}_2}\|\nabla f(\bar{x})\|_\infty$, then FGraHTP will output $x^{(t)}$ satisfying $\text{supp}(\bar{x}) \subseteq \text{supp}(x^{(t)})$ after $t = \left\lceil \frac{1}{\bar{\mu}_2} \ln\left(\frac{2\|x^{(0)} - \bar{x}\|}{\bar{x}_{\min}}\right)\right\rceil$ steps of iteration.

Indeed, the conditions in Corollary 7 imply $\|x^{(t)} - \bar{x}\| < \bar{x}_{\min}$ which leads to $\text{supp}(\bar{x}) \subseteq \text{supp}(x^{(t)})$. We note that the parameter estimation error bound derived by Jain et al. (2014, Theorem 3) implies a similar support recovery guarantee as in Corollary 7(a).

3.2 Comparison to Prior Results

Now we compare our method and parameter estimation error bounds to some prior relevant methods and results.

Our method versus nonlinear-IHT (Blumensath, 2013). As we remarked in Section 2 that FGraHTP is identical to the nonlinear-IHT method proposed by Blumensath (2013). The estimation error results of the two, however, are different: the error bound of nonlinear-IHT is relying on the objective value at the target solution; whereas ours in Theorem 2(b) is controlled by the infinity norm of gradient at the target solution.

Our method versus ℓ_1-norm ball constrained estimation (Agarwal et al., 2012). It is worthwhile to compare our ℓ_0-estimation results to those established by Agarwal et al. (2012, Theorem 1) for ℓ_1-norm ball constrained M-estimator (maximum likelihood type estimator). Let us consider $\bar{x}$ as the underlying $\bar{k}$-sparse nominal parameter in a statistical model. When using sparsity level $k = \bar{k}$, the $O(\sqrt{\bar{k}}\|\nabla f(\bar{x})\|_\infty)$ estimation error bound in Theorem 2, which is at the same order of statistical error, is essentially identical to the error bound derived by Agarwal et al. (2012, Theorem 1). Our analysis, however, requires a bounding assumption on the restricted strong condition number which is not required in their result. This can be interpreted as the price of using nonconvex sparsity constraint rather than its convex relaxation. By using properly relaxed sparsity level $k = O(\bar{k})$, we obtain similar estimation error bounds in Theorem 5 but without assuming bounded restricted strong condition number. In this case, at a slight sacrifice in sparsity level, our methods gain better dependence on restricted strong condition number than those for convex models. Concerning the efficiency of projection steps, the ℓ_0-projection used in FGraHTP is more efficient than the ℓ_1-projection required by those first-order convex minimization methods. The projection operation of GraHTP is more expensive as it requires an additional debiasing step right after ℓ_0-projection.

Our method versus GraSP (Bahmani et al., 2013). A similar estimation error bound as in Theorem 2(a) has been established for the GraSP method (Bahmani et al., 2013). At time instance t, GraSP first conducts debiasing over the union of the top k entries of $x^{(t-1)}$ and the top $2k$ entries of $\nabla f(x^{(t-1)})$, and then preserves the top k entries of the resultant vector, which becomes $x^{(t)}$. Our GraHTP is connected to GraSP in the sense that the k largest absolute elements after the gradient descent step will come from some combination of the largest elements in $x^{(t-1)}$ and the largest elements in the gradient $\nabla f(x^{(t-1)})$.

Although having similar convergence behavior, the per-iteration cost of GraHTP is cheaper than GraSP: at each iteration, GraSP needs to minimize the objective over a support of size at least $2k$ while that size for GraHTP is k. FGraHTP is even cheaper for iteration as it does not need any debiasing operation. We will compare the actual numerical performance of these methods in the experiment section.

Our results versus the results obtained by Jain et al. (2014). The RIP-condition-free estimation error bound in Theorem 5(a) has also been proved by Jain et al. (2014, Theorem 3) with relaxed sparsity levels. As pointed out in Remark 6, the contraction factor $\bar{\mu}_1$ derived in Theorem 5(a) is inferior to the rate $\bar{\mu}_2$ in Theorem 5(b) when the restricted strong condition number is relatively small. Moreover, from Figure 1(b) we can see that $\bar{\mu}_1$ is valued in a quite restrictive interval $(0.87, 1)$ while $\bar{\mu}_2$ can be varied in a much wider range of $(0.65, 1)$. Figure 1(a) shows that the contraction factors μ_1 and μ_2 derived in Theorem 2 can be widely valued in $(0, 1)$. The more favorable contraction factors in Theorem 5(b) and Theorem 2 are resulted from a more careful analysis of GraHTP/FGraHTP and using a tight hard-thresholding bound derived by Shen & Li (2016).

4. Sparsity Recovery Analysis

In this section, we further analyze the sparsity recovery performance of GraHTP. In Corollary 3 and Corollary 7, we have already established some general sparsity recovery results for GraHTP. Here we will provide a refined analysis without assuming bounded restricted strong condition number. Moreover, we will analyze the sparsity recovery behavior of the sparse estimator $x^\star = \arg\min_{\|x\|_0 \le k} f(x)$ which to our knowledge has not been addressed elsewhere in literature. The main results obtained in this section are highlighted in below:

- For GraHTP algorithm, we derive in Theorem 8 an improved RIP-condition-free result for exactly recovering the support of a target $\bar{k}$-sparse vector with $\bar{k} < k$.
- For the global k-sparse minimizer $x^\star$, we provide in Theorem 10 a set of sufficient conditions under which $x^\star$ is able to recover the support of a target sparse vector.

4.1 Sparsity Recovery of GraHTP

In the following theorem, we show that for proper $k > \bar{k}$, GraHTP is able to recover the support of certain target $\bar{k}$-sparse vector without assuming bounded restricted strong condition numbers. A proof of this theorem is given in Appendix C.1.

Theorem 8 *Assume that f is M_{2k}-smooth and m_{2k}-strongly convex. Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector satisfying $k \ge \left(1 + \frac{16M_{2k}^2}{m_{2k}^2}\right)\bar{k}$. Set the step-size to be $\eta = \frac{1}{2M_{2k}}$. If $\bar{x}_{\min} > 2.3\sqrt{\frac{f(\bar{x}) - f(x^\star)}{m_{2k}}}$, then GraHTP will terminate and output $x^{(t)}$ satisfying $supp(x^{(t)}, \bar{k}) = supp(\bar{x})$ after at most*

$$t = \left\lceil \frac{2kM_{2k}}{m_{2k}} \ln \frac{\triangle^{(0)}}{\triangle^{-\star}} \right\rceil$$

steps of iteration, where $\triangle^{(0)} = f(x^{(0)}) - f(x^\star)$ and

$$\triangle^{-\star} = \min_{\|x\|_0 \le k, supp(x) \ne supp(x^\star), f(x) > f(x^\star)} f(x) - f(x^\star).$$

Results	Target Solution	RIP Condition	x-min Condition
Corollary 3(a)	Arbitrary k-sparse $\bar{x}$	Required	$\bar{x}_{\min} > \mathcal{O}\left(\frac{\sqrt{k}\|\nabla f(\bar{x})\|_\infty}{m_{2k}}\right)$
Corollary 7(a)	$\|\bar{x}\|_0 = \mathcal{O}\left((\frac{m_{2k}}{M_{2k}})^2 k\right)$	Free	$\bar{x}_{\min} > \mathcal{O}\left(\frac{\sqrt{k}\|\nabla f(\bar{x})\|_\infty}{m_{2k}}\right)$
Theorem 8	$\|\bar{x}\|_0 = \mathcal{O}\left((\frac{m_{2k}}{M_{2k}})^2 k\right)$	Free	$\bar{x}_{\min} > \mathcal{O}\left(\sqrt{\frac{f(\bar{x}) - f(x^\star)}{m_{2k}}}\right)$

Table 2: Comparison of Theorem 8 against Corollary 3 and Corollary 7.

Remark 9 *The main message conveyed by Theorem 8 is: If $\bar{k} = \mathcal{O}\left(\frac{m_{2k}^2}{M_{2k}^2} k\right)$ and the nonzero elements in $\bar{x}$ are significantly larger than the value $\sqrt{(f(\bar{x}) - f(x^\star))/m_{2k}}$, then GraHTP will output $x^{(t)}$ whose top $\bar{k}$ entries are exactly the supporting set of $\bar{x}$. The implication of this result is that in order to recover certain $\bar{k}$-sparse signals, one may run GraHTP with a properly relaxed sparsity level k until convergence and then preserve the top $\bar{k}$ entries of the k-sparse output as the final estimation.*

In Table 2, we summarize the sparsity recovery results established in Theorem 8, Corollary 3 and Corollary 7. We claim that the x-min condition in Theorem 8 is no stronger than those in Corollary 3 and Corollary 7. Indeed, when $\bar{x} \ne x^\star$, from the restricted strong-convexity of f and the fact $x^\top y \le \|x\|_\infty \|y\|_1$ we can derive the following inequality:

$$f(\bar{x}) - f(x^\star) \le \frac{\|\nabla f(\bar{x})\|_\infty^2 \|\bar{x} - x^\star\|_1^2}{2m_{2k}\|\bar{x} - x^\star\|^2}.$$

It can be verified that the factor $\bar{l} = \|\bar{x} - x^\star\|_1^2 / \|\bar{x} - x^\star\|^2$ is valued in the interval $[1, k + \bar{k}]$ if $\bar{x} \ne x^\star$. Since $k > \bar{k}$, we then always have $\sqrt{(f(\bar{x}) - f(x^\star))/m_{2k}} \le \sqrt{k}\|\nabla f(\bar{x})\|_\infty / m_{2k}$. The closer $\bar{l}$ is to 1, the weaker lower bound condition can be imposed on $\bar{x}_{\min}$ in Theorem 8. In the extreme case when $\bar{l} = 1$, the $\bar{x}_{\min}$ condition becomes $\bar{x}_{\min} > \mathcal{O}(\|\nabla f(\bar{x})\|_\infty / m_{2k})$ which is not dependent on factor $\sqrt{k}$ and thus is weaker than those in Corollary 3 and Corollary 7.

4.2 Sparsity Recovery of $x^\star$

Given a target solution $\bar{x}$, the following result gives some sufficient conditions under which the sparse estimator $x^\star$ is able to exactly recover the supporting set of $\bar{x}$. A proof of this result is provided in Appendix C.2.

Theorem 10 *Assume that f is M_{2k}-smooth and m_{2k}-strongly convex. Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector with $\bar{k} \le k$. Then $supp(\bar{x}) = supp(x^\star, \bar{k})$ if either of the following two conditions holds:*

(1) $\bar{x}_{\min} > \frac{4.59\sqrt{k}}{m_{2k}} \|\nabla f(\bar{x})\|_\infty$;

(2) $k \ge \left(1 + \frac{4M_{2k}^2}{m_{2k}^2}\right)\bar{k}$ *and* $\bar{x}_{\min} > 2.3\sqrt{\frac{f(\bar{x}) - f(x^\star)}{m_{2k}}}$.

Remark 11 *Theorem 10 shows that when using sparsity level $k \geq \bar{k}$, the top $\bar{k}$ entries of the k-sparse global minimizer $x^\star$ is exactly the support of $\bar{x}$ if $\bar{x}_{\min}$ is significantly larger than $\sqrt{k}\|\nabla f(\bar{x})\|_\infty/m_{2k}$. By using a more relaxed sparsity level as in condition (2), the top $\bar{k}$ entries of $x^\star$ is exactly the support of $\bar{x}$ when $\bar{x}_{\min}$ is significantly larger than $\sqrt{(f(\bar{x}) - f(x^\star))/m_{2k}}$. Note that Theorem 10 is valid without imposing bounding assumptions on restricted strong condition number.*

We now compare the support recovery result in Theorem 10 for the ℓ_0-estimator (1) to those known for the following ℓ_1-regularized estimator:

$$\min_{x\in\mathbb{R}^p} f(x) + \lambda\|x\|_1, \tag{4}$$

where $f(x)$ is a convex loss function and λ is the regularization strength parameter. When the loss function is quadratic, a set of sufficient conditions were derived by Wainwright (2009) to guarantee exact sparsity recovery of Lasso-type estimators. For more general loss functions, a unified sparsity recovery analysis was presented in the paper of Li et al. (2015). We summarize in below a comparison between Theorem 10 and those sparsity recovery results for ℓ_1-regularized estimators (Li et al., 2015) with respect to several key conditions:

- **Local structured smoothness/convexity condition:** Theorem 10 only requires first-order local structured smoothness/convexity conditions (i.e., RSC/RSS) while the results obtained by Li et al. (2015, Theorem 5.1, Condition 1) rely on certain second-order and third-order local structured smoothness conditions.
- **Irrepresentablility condition:** Theorem 10 is free of the so called irrepresentablility condition which is typically required to guarantee the sparsistency of ℓ_1-regularized estimators (Li et al., 2015, Theorem 5.1, Condition 3).
- **x-min condition:** Comparing to the x-min condition derived by Li et al. (2015, Theorem 5.1, Condition 4) which is of order $\mathcal{O}(\sqrt{k}\|\nabla f(\bar{x})\|_\infty)$, the x-min condition (1) in Theorem 10 is comparable at the same order while the x-min condition (2) is sharper since $\sqrt{f(\bar{x}) - f(x^\star)/m_{2k}} \leq \sqrt{k}\|\nabla f(\bar{x})\|_\infty/m_{2k}$.

We comment that the above key differences also apply to the comparison between Theorem 8 for GraHTP and the sparsity recovery results for ℓ_1-regularized estimators. In Section 5.1, we will further specify our results to the setting of sparse linear regression and make a comparison against those sparsity recovery results for Lasso-type estimators (Wainwright, 2009).

5. Applications to Sparsity-Constrained M-estimation

We now specify GraHTP and its analysis to the M-estimation problem which is a popular formulation in statistical machine learning. Given a set of n independently drawn data samples $\{x^{(i)}\}_{i=1}^n$, the M-estimation problem is defined as to minimize the following empirical risk function averaged over the samples:

$$f(w) = \frac{1}{n}\sum_{i=1}^n \phi(x^{(i)} \mid w),$$

where ϕ is a loss function and w is a set of adjustable parameters. The sparsity-constrained M-estimation problem is then given by

$$\min_w f(w), \quad \text{subject to } \|w\|_0 \leq k. \tag{5}$$

In the subsections to follow, we will consider three instances of this model: linear regression, logistic regression and Gaussian precision matrix estimation.

5.1 Sparsity-constrained Linear Regression

Given a $\bar{k}$-sparse parameter vector $\bar{w}$, we assume the samples are generated according to the linear model $v^{(i)} = \bar{w}^\top u^{(i)} + \varepsilon^{(i)}$ where $\varepsilon^{(i)}$ are n i.i.d. sub-Gaussian random variables with parameter σ. The sparsity-constrained least squares regression model is then given by

$$\min_w f(w) = \frac{1}{2n}\sum_{i=1}^n \|v^{(i)} - w^\top u^{(i)}\|^2, \quad \text{subject to } \|w\|_0 \leq k. \tag{6}$$

In this case, GraHTP (and FGraHTP) reduces to the conventional HTP (and IHT) of which the parameter estimation performance has been extensively studied in compressed sensing (Foucart, 2011; Blumensath & Davies, 2009). Here we illustrate the sparsity recovery results we established in Section 4 and compare them against those for ℓ_1-estimators. Suppose $u^{(i)}$ are drawn from Gaussian distribution with covariance matrix $\Sigma \succ 0$. Then it holds with high probability that $f(w)$ has RSC constant $m_{2k} \geq \lambda_{\min}(\Sigma) - \mathcal{O}(\bar{k}\log p/n)$ and RSS constant $M_{2k} \leq \lambda_{\max}(\Sigma) + \mathcal{O}(\bar{k}\log p/n)$, and $\|\nabla f(\bar{w})\|_\infty = \mathcal{O}\left(\sigma\sqrt{\log p/n}\right)$. Assume that $k \geq \bar{k}$. We summarize in below the implications of our sparsity recovery results in sparse linear regression:

- Sparsity recovery of GraHTP. Corollary 3 shows that if $\bar{w}_{\min} > \mathcal{O}\left(\frac{\sigma\sqrt{k\log p/n}}{\lambda_{\min}(\Sigma)}\right)$ and $\frac{\lambda_{\max}(\Sigma)}{\lambda_{\min}(\Sigma)}$ is well upper bounded, then after sufficient iteration GraHTP and FGraHTP with $k = \bar{k}$ will guarantee support recovery $\mathrm{supp}(x^{(t)}) = \mathrm{supp}(\bar{x})$ with high probability. Corollary 7 indicates that when using certain relaxed sparsity level $k = \mathcal{O}\left(\frac{\lambda^2_{\max}(\Sigma)}{\lambda^2_{\min}(\Sigma)}\bar{k}\right)$, GraHTP and FGraHTP are able to guarantee $\mathrm{supp}(x^{(t)}) \supseteq \mathrm{supp}(\bar{x})$ without assuming bounded condition number. Since $f(\bar{x}) - f(x^\star) \leq \frac{\bar{l}\|\nabla f(\bar{x})\|^2_\infty}{2m_{2k}}$ where $\bar{l} = \|\bar{x} - x^\star\|_1^2/\|\bar{x} - x^\star\|^2 \in [1, k+\bar{k}]$, Theorem 8 implies that if $\bar{w}_{\min} > \mathcal{O}\left(\frac{\sigma\sqrt{\bar{l}\log p/n}}{\lambda_{\min}(\Sigma)}\right)$ and $k = \mathcal{O}\left(\frac{\lambda^2_{\max}(\Sigma)}{\lambda^2_{\min}(\Sigma)}\bar{k}\right)$, then after finite iteration GraHTP will guarantee $\mathrm{supp}(x^{(t)}, \bar{k}) = \mathrm{supp}(\bar{x})$ with high probability.
- Sparsity recovery of the least squares estimator (6). Let $w^\star$ be the global k-sparse minimizer of (6). Theorem 10 shows that $\mathrm{supp}(w^\star, \bar{k}) = \mathrm{supp}(\bar{w})$ holds with high probability if $\bar{w}_{\min} > \mathcal{O}\left(\frac{\sigma\sqrt{k\log p/n}}{\lambda_{\min}(\Sigma)}\right)$. To compare our sparsity recovery results for ℓ_0-estimators against those established by Wainwright (2009, Theorem 1) for Lasso-type estimators, the signal-noise-ratio condition of $\bar{w}_{\min} > \mathcal{O}\left(\frac{\sigma\sqrt{k\log p/n}}{\lambda_{\min}(\Sigma)}\right)$ is shared

in that paper. The key difference is that our analysis is valid without imposing the irrepresentablility condition on design matrix which is required in the sparsity recovery analysis of Lasso-type estimators.

5.2 Sparsity-constrained Logistic Regression

Logistic regression is one of the most popular models in statistical machine learning (Bishop, 2006). In this model the relation between the random feature vector $u \in \mathbb{R}^p$ and its associated random binary label $v \in \{-1, +1\}$ is determined by the conditional probability

$$\mathbb{P}(v|u; \bar{w}) = \frac{\exp(2v\bar{w}^\top u)}{1 + \exp(2v\bar{w}^\top u)}, \tag{7}$$

where $\bar{w} \in \mathbb{R}^p$ denotes parameter vector. Given a set of n independently drawn data samples $\{(u^{(i)}, v^{(i)})\}_{i=1}^n$, logistic regression learns the parameters so as to minimize the following logistic loss function:

$$l(w) := -\frac{1}{n} \log \prod_i \mathbb{P}(u^{(i)} \mid v^{(i)}; w) = \frac{1}{n} \sum_{i=1}^n \log(1 + \exp(-2v^{(i)} w^\top u^{(i)})),$$

which is known to be convex. Unfortunately, in high-dimensional setting, i.e., $n < p$, the problem can be underdetermined and thus its minimum is not unique. A conventional way to handle this issue is to impose ℓ_2-regularization to the logistic loss to avoid singularity. The ℓ_2-penalty, however, does not promote sparse solutions which are often desirable in high-dimensional learning tasks. The sparsity-constrained ℓ_2-regularized logistic regression is then given by

$$\min_w f(w) = l(w) + \frac{\lambda}{2}\|w\|^2, \quad \text{subject to } \|w\|_0 \le k, \tag{8}$$

where $\lambda > 0$ is the regularization strength parameter. Obviously $f(w)$ is λ-strongly convex. The cardinality constraint enforces the solution to be sparse.

Verifying restricted smoothness and strong convexity. Let $U = [u^{(1)}, ..., u^{(n)}] \in \mathbb{R}^{p\times n}$ be the design matrix and $\sigma(z) = 1/(1+\exp(-z))$ be the sigmoid function. In the case of ℓ_2-regularized logistic loss considered in this section we have $\nabla f(w) = Ua(w)/n + \lambda w$ in which the vector $a(w) \in \mathbb{R}^n$ is given by $[a(w)]_i = -2v^{(i)}(1-\sigma(2v^{(i)}w^\top u^{(i)}))$, and the Hessian $\nabla^2 f(w) = U\Lambda(w)U^\top/n + \lambda I$ where $\Lambda(w)$ is an $n \times n$ diagonal matrix whose diagonal entries $[\Lambda(w)]_{ii} = 4\sigma(2v_i w^\top u_i)(1 - \sigma(2v_i w^\top u_i))$. Given an integer s, recall that $\lambda_{\max}(A, s)$ denotes the largest s-sparse eigenvalue of a positive semi-definite matrix A and $\lambda_{\min}(A, s)$ denotes the smallest s-sparse eigenvalue of A. Assume that the algorithm is initialized with all-zero vector. Then it can be verified that $f(w)$ is $(\lambda_{\max}(UU^\top, s)+\lambda)$-smooth and $(\gamma_s+\lambda)$-strongly convex where $\gamma_s := \min_{f(w)\le f(0)} \lambda_{\min}(U\Lambda(w)U^\top, s)$.

Bounding the value of $\|\nabla f(\bar{w})\|_\infty$. We now bound the infinity norm $\|\nabla f(\bar{w})\|_\infty$ which controls the estimation error and sparisty recovery bounds of GraHTP/FGraHTP. In the following derivation, we assume that the joint density of the random vector $(u, v) \in \mathbb{R}^{p+1}$ is given by the following exponential family distribution:

$$\mathbb{P}(u, v; \bar{w}) = \exp\left(v\bar{w}^\top u + B(u) - A(\bar{w})\right), \tag{9}$$

where

$$A(\bar{w}) := \log \sum_{v=\{-1,1\}} \int_{\mathbb{R}^p} \exp\left(v\bar{w}^\top u + B(u)\right) du$$

is the log-partition function. The term $B(u)$ characterizes the marginal behavior of u. Obviously, the conditional distribution of v given u, $\mathbb{P}(v \mid u; \bar{w})$, is given by the Bernoulli distribution in (7). By doing some elementary manipulations (see, e.g., Wainwright & Jordan, 2008) we can obtain the following standard result which shows that the first derivative of the logistic log-likelihood $l(w)$ yields the cumulants of the random variables $v[u]_j$:

$$\frac{\partial l}{\partial [w]_j} = \frac{1}{n} \sum_{i=1}^n \left\{-v^{(i)}[u^{(i)}]_j + \mathbb{E}_v[v[u^{(i)}]_j \mid u^{(i)}]\right\}. \tag{10}$$

Here the expectation $\mathbb{E}_v[\cdot \mid u]$ is taken over the conditional distribution (7). We introduce the following sub-Gaussian condition on the random variate $v[u]_j$.

Assumption 1 *For all j, we assume that there exists constant $\sigma > 0$ such that for all ζ,*

$$\mathbb{E}[\exp(\zeta v[u]_j)] \le \exp\left(\sigma^2\zeta^2/2\right).$$

This assumption holds when $[u]_j$ are sub-Gaussian (e.g., Gaussian or bounded) random variables. The following result establishes the bound of $\|\nabla f(\bar{w})\|_\infty$.

Proposition 12 *If Assumption 1 holds, then with probability at least $1 - 4p^{-1}$,*

$$\|\nabla f(\bar{w})\|_\infty \le 4\sigma\sqrt{\ln p/n} + \lambda\|\bar{w}\|_\infty.$$

A proof of this result is provided in Appendix D.1. If we choose $\lambda = O(\sqrt{\ln p/n})$, then with overwhelming probability $\|\nabla f(\bar{w})\|_\infty$ vanishes at the rate of $O(\sqrt{\ln p/n})$. This bound is superior to the bound obtained by Bahmani et al. (2013, Section 4.2) which is not vanishing as sample size increases. Based on the above discussion, we can similarly specify our parameter estimation and sparsity recovery results to sparse logistic regression. Here we omit the detailed specification of results for the sake of redundance reducing.

5.3 Sparsity-constrained Gaussian Precision Matrix Estimation

As an important class of sparse learning problems for exploring the interrelationship among a large number of random variables, the sparse Gaussian precision (inverse covariance) matrix estimation problem has received significant interest in a variety of scientific and engineering domains, including computational biology, natural language processing and document analysis.

Let x be a p-variate random vector with zero-mean Gaussian distribution $\mathcal{N}(0, \bar{\Sigma})$. Its density is parameterized by the precision matrix $\bar{\Omega} = \bar{\Sigma}^{-1} \succ 0$ as

$$\phi(x; \bar{\Omega}) = \frac{1}{\sqrt{(2\pi)^p (\det \bar{\Omega})^{-1}}} \exp\left(-\frac{1}{2} x^\top \bar{\Omega} x\right).$$

It is well known that the conditional independence between the variables $[x]_i$ and $[x]_j$ given $\{[x]_k, k \ne i, j\}$ is equivalent to $[\bar{\Omega}]_{ij} = 0$. The conditional independence relations between

components of x, on the other hand, can be represented by a graph $\mathcal{G} = (V, E)$ in which the vertex set V has p elements corresponding to $[x]_1, ..., [x]_p$, and the edge set E consists of edges between node pairs $\{[x]_i, [x]_j\}$. The edge between $[x]_i$ and $[x]_j$ is excluded from E if and only if $[x]_i$ and $[x]_j$ are conditionally independent given other variables. This graphical model is known as Gaussian Markov random field (GMRF) (Edwards, 2000). Thus for multivariate Gaussian distribution, estimating the support of the precision matrix $\bar{\Omega}$ is equivalent to learning the structure of GMRF $\mathcal{G}$.

Given i.i.d. samples $\mathbb{X}_n = \{x^{(i)}\}_{i=1}^n$ drawn from $\mathcal{N}(0, \bar{\Sigma})$, the negative log-likelihood, up to a constant, can be written in terms of the precision matrix as

$$\mathcal{L}(\mathbb{X}_n; \bar{\Omega}) := -\log\det\bar{\Omega} + \langle\Sigma_n, \bar{\Omega}\rangle,$$

where Σ_n is the sample covariance matrix. We are interested in the problem of estimating a sparse precision $\bar{\Omega}$ with no more than a pre-specified number of off-diagonal nonzero entries. For this purpose, we consider the following cardinality constrained log-determinant program:

$$\min_{\Omega\succ 0} L(\Omega) := -\log\det\Omega + \langle\Sigma_n, \Omega\rangle, \quad \text{s.t. } \|\Omega^-\|_0 \le 2k, \tag{11}$$

where Ω^- is the restriction of Ω on the off-diagonal entries, $\|\Omega^-\|_0 = |\text{supp}(\Omega^-)|$ is the cardinality of the supporting set of Ω^- and the integer $k > 0$ controls the number of edges, i.e., $|E|$, in the graph.

Verifying restricted smoothness and strong convexity. It can be verified that the Hessian matrix of $L(\Omega)$ is given by $\nabla^2 L(\Omega) = \Omega^{-1} \otimes \Omega^{-1}$, where $\otimes$ denotes the Kronecker product operator. Suppose that $\|\Omega^-\|_0 \le s$ and $\alpha_s I \preceq \Omega \preceq \beta_s I$ for some $0 < \alpha_s \le \beta_s$. Due to the fact that the eigenvalues of Kronecker products of symmetric matrices are the products of the eigenvalues of their factors, it holds that $\beta_s^{-2} I \preceq \Omega^{-1} \otimes \Omega^{-1} \preceq \alpha_s^{-2} I$. Therefore we have $\beta_s^{-2} \le \|\nabla^2 L(\Omega)\| \le \alpha_s^{-2}$ which implies that $L(\Omega)$ is β_s^{-2}-strongly convex and α_s^{-2}-smooth. Inspired by this property, we consider applying GraHTP to the following variant of problem (11):

$$\min_{\alpha I\preceq\Omega\preceq\beta I} L(\Omega), \quad \text{s.t. } \|\Omega^-\|_0 \le 2k, \tag{12}$$

where $0 < \alpha \le \beta$ are two constants which respectively lower and upper bound the eigenvalues of the desired solution. To roughly estimate α and β, we employ a rule proposed by Lu (2009, Proposition 3.1) for the ℓ_1-regularized log-determinant program. Specifically, we set

$$\alpha = (\|\Sigma_n\|_2 + n\xi)^{-1}, \quad \beta = \xi^{-1}(n - \alpha\text{Tr}(\Sigma_n)),$$

where ξ is a small enough positive number (e.g., $\xi = 10^{-2}$ as used in our implementation).

Bounding the value of $|\nabla L(\bar{\Omega})|_\infty$. It is standard to know that $|\nabla L(\bar{\Omega})|_\infty = |\Sigma_n - \bar{\Sigma}|_\infty = \mathcal{O}(\sqrt{\log p/n})$ with probability at least $1 - c_0 p^{-c_1}$ for some positive constants c_0 and c_1 and sufficiently large n (see, e.g., Ravikumar et al., 2011, Lemma 1). Therefore, with overwhelming probability we have $|\nabla L(\bar{\Omega})|_\infty = \mathcal{O}(\sqrt{\log p/n})$ when n is sufficiently large.

A Modified GraHTP. Note that GraHTP is not directly applicable to the problem (12) due to the presence of the constraint $\alpha I \preceq \Omega \preceq \beta I$ in addition to the sparsity constraint. To address this issue, we need to accordingly modify the debiasing step (**S3**) of GraHTP to minimize $L(\Omega)$ over the constraints $\alpha I \preceq \Omega \preceq \beta I$ and $\text{supp}(\Omega) \subseteq F^{(t)}$:

$$\min_{\alpha I\preceq\Omega\preceq\beta I} L(\Omega), \quad \text{s.t. } \text{supp}(\Omega) \subseteq F^{(t)}. \tag{13}$$

Since this problem is convex, any off-the-shelf convex solver can be applied for optimization. In our implementation, we resort to the alternating direction method of multipliers (ADMM) (Boyd et al., 2010; Yuan, 2012) which has been observed to be efficient in our numerical practice. The implementation details of ADMM for solving the subproblem (13) are deferred to Appendix D.2. The modified GraHTP for sparse Gaussian precision matrix estimation is outlined in Algorithm 2.

Algorithm 2: A Modified GraHTP for Sparse Gaussian Precision Matrix Estimation.

Initialization: $\Omega^{(0)}$ *with* $\|(\Omega^{(0)})^-\|_0 \le 2k$ *and* $\alpha I \preceq \Omega^{(0)} \preceq \beta I$ *(typically* $\Omega^{(0)} = \alpha I$*)*, $t = 1$.

6. Experimental Results

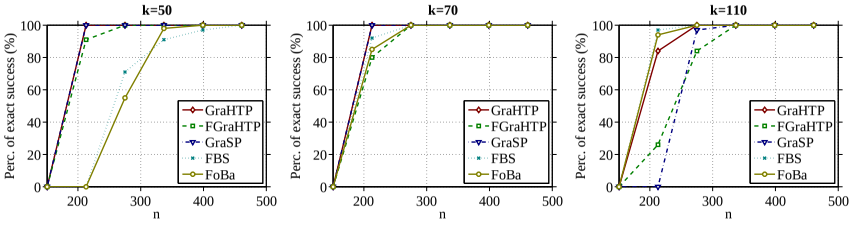
This section is devoted to illustrating the empirical performance of GraHTP/FGraHTP when applied to sparse learning tasks. Our algorithms are implemented in Matlab 7.12 running on a desktop with Intel Core i7 3.2G CPU and 16G RAM.

6.1 Sparsity-constrained Linear Regression

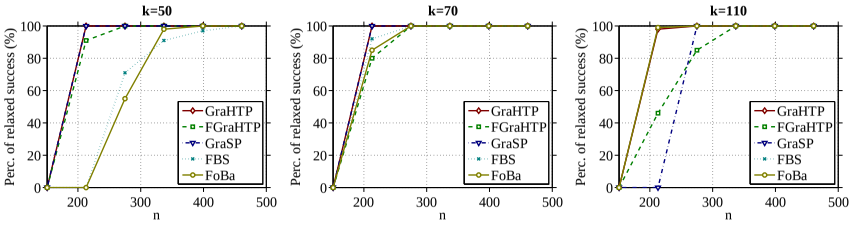
We conduct a group of Monte-Carlo simulation experiments on sparse linear regression model to verify the sparsity recovery results presented in Section 4.

Data generation. We consider a synthetic data model in which the sparse parameter $\bar{w}$ is a $p = 500$ dimensional vector that has $\bar{k} = 50$ nonzero entries drawn independently from a Gaussian distribution with significant mean. Each data sample u is a normally distributed dense vector. The responses are generated by $v = \bar{w}^\top u + \varepsilon$ where ε is a standard Gaussian noise. We allow the sample size n to be varying and for each n, we generate 100 random copies of data independently.

Baselines and evaluation metric. We test GraHTP and FGraHTP with varying sparsity level $k \ge \bar{k}$ and compare their performance with three state-of-the-art greedy selection methods: GraSP (Bahmani et al., 2013), FBS (Yuan & Yan, 2013) and FoBa (Zhang, 2008). As we have mentioned, GraSP is also a hard-thresholding-type method. This method



(a) Exact support recovery



(b) Relaxed support recovery

Figure 2: Sparse linear regression on simulated data: chance of success curves for support recovery under varying sample size and sparsity level.

simultaneously selects at each iteration k nonzero entries and update their values via exploring the top k entries in the previous iterate as well as the top $2k$ entries in the previous gradient. FBS is a forward-selection-type method which iteratively selects an atom from the dictionary and minimizes the objective function over the linear combinations of all the selected atoms. FoBa is an adaptive forward-backward greedy selection algorithm which allows elimination of selected variables when the objective value does not increase significantly. We use two metrics to measure the support recovery performance. We say a *relaxed support recovery* is successful if $\mathrm{supp}(\bar{w}) \subseteq \mathrm{supp}(w^{(t)})$ and an *exact support recovery* is successful if $\mathrm{supp}(\bar{w}) = \mathrm{supp}(w^{(t)}, \bar{k})$. We replicate the experiment over the 100 trials and record the percentage of relaxed success and percentage of exact success for each configuration of the pair (n, k).

Results. Figure 2 shows the percentage of exact (relaxed) success curves as functions of sample size n, under different sparsity levels $k \in \{50, 70, 110\}$. From these curves we can make the following observations:

- For each curve, the chance of success increases as sample size n increases. This is as expected because the larger sample size is, the easier the x-min conditions can be fulfilled so as to guarantee exact support recovery;
- GraHTP is superior to FGraHTP for sparsity recovery, especially when using sparsity level $k > \bar{k}$ and relatively small sample size. This indicates that the debiasing step conducted in GraHPT can significantly improve the accuracy of sparsity recovery, especially in noisy settings.
- The left panel of Figure 2 shows that when $k = \bar{k}$, GraHTP/FGraHTP and GraSP are comparable and they all significantly outperform FBS and FoBa, especially when the sample size is relatively small. This observation suggests that hard-thresholding-type methods are more accurate than forward and/or backward selection methods for sparsity recovery with exact sparsity level. The middle panel shows that for slightly increased sparsity level $k = 70$, GraHTP and GraSP still exhibit superior performance, while the performance gap among all the considered algorithms decreases. From the right panel we can see that for relatively large $k > \bar{k}$, FBS, Foba and GraHTP have much better performance than FGraHTP and GraSP.

From the above observations we conclude that GraHTP is able to achieve better trade-off between accuracy and stability of sparsity recovery than the other considered methods.

6.2 Sparsity-constrained Logistic Regression

We present in this subsection the experimental results on several synthetic and real-data sparse logistic regression tasks.

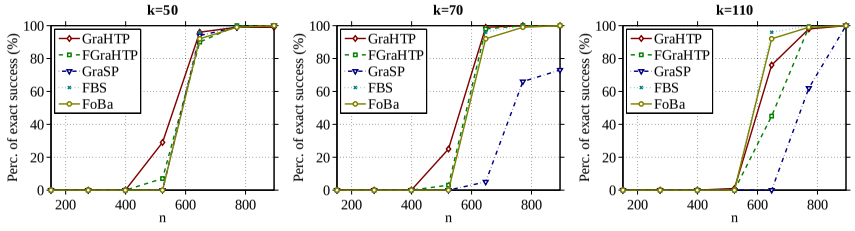
6.2.1 Monte-Carlo simulation

In this group of Monte-Carlo experiments, we use a simulated data to verify the sparsity recovery performance of GraHTP and FGraHTP on logistic regression model. The sparse parameter and design matrix are generated in an identical way to that of the linear regression model. The data labels, $v \in \{-1, 1\}$, are generated randomly according to the Bernoulli distribution $\mathbb{P}(v = 1|u; \bar{w}) = \exp(2\bar{w}^\top u)/(1 + \exp(2\bar{w}^\top u))$. The same experiment protocol as used in the previous linear regression setting applies here. Inspired by Theorem 8 and the discussion in Section 5.2, we set the step-size $\eta = \frac{1}{2M_{2k}}$ where $M_{2k} = \lambda_{\max}(UU^\top, 2k) + \lambda$. The sparse eigenvalue $\lambda_{\max}(UU^\top, 2k)$ can be computed using the truncated power method (Yuan & Zhang, 2013).

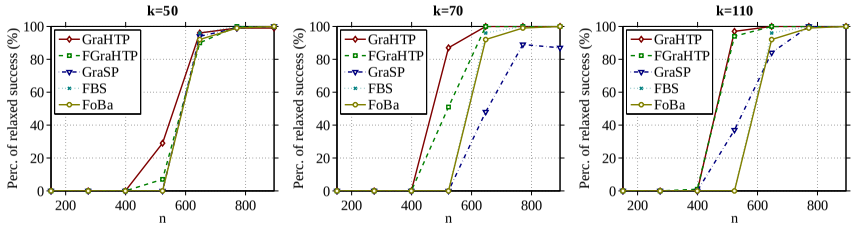
Results. For different sparsity levels $k \geq \bar{k}$, Figure 3 shows the chance of exact (relaxed) success curves as functions of sample size n. Again, from these curves we can observe that: 1) in a wide range of sparsity level, GraHP achieves better trade-off between accuracy and stability than the other considered sparsity recovery methods; and 2) GraHTP consistently outperforms FGraHTP in noisy settings when using $k > \bar{k}$.

6.2.2 Real data experiments

We further illustrate the performance of GraHTP/FGraHTP on real data for binary logistic regression. The data used for evaluation include two *dense* data sets gisette (Guyon et al., 2005) and breast cancer (Hess et al., 2006), and two *sparse* data sets rcv1.binary (Lewis et al., 2005) and news20.binary (Keerthi & DeCoste, 2005). Table 3 summaries the statistics of these data sets. For each data set, we test with sparsity parameters $k \in \{100, 200, ..., 1000\}$ and fix the regularization parameter $\lambda = 10^{-5}$. We initialize $w^{(0)} = 0$ and set the stopping criterion as $\|w^{(t)} - w^{(t-1)}\|/\|w^{(t-1)}\| \leq 10^{-4}$.



(a) Exact support recovery



(b) Relaxed support recovery

Figure 3: Sparse logistic regression on simulated data: chance of success curves for support recovery under varying sample size and sparsity level.

Datasets	Training Size	Testing Size	Dimensionality
gisette	6,000	1,000	5,000
breast cancer	54	79	22,283
rcv1.binary	20,242	20,000	47,236
news20.binary	10,000	9,996	1,355,191

Table 3: Statistics of data sets used in binary logistic regression experiment.

Results. The objective value, test classification error and CPU running time curves under varying sparsity level k are plot in Figure 4. From these curves we have the following observations:

- On optimality: GraHTP is superior to the other considered algorithms in most cases. FGraHTP is less optimal on gisette data, while it is comparable to the other algorithms on the other three data sets.

- On classification accuracy: GraHTP and GraSP are comparable to each other and they are slightly superior to the other algorithms in most cases; FGraHTP is average in classification accuracy in most cases.

(c) rcv1.binary (d) news20.binary

Figure 5: Sparse logistic regression on real data: comparison between GraHTP/FGraHTP and Lasso-type estimator in classification error and CPU running time.

- On execution time: FGraHTP is the most efficient one and GraHTP is the runner-up except on breast cancer. Particularly, as shown in Figure 4(d) that the computational advantage of FGraHTP/GraHTP over the other considered methods becomes significant on news20.binary which is relatively large in scale.

To summarize, GraHTP and FGraHTP are able to achieve desirable trade-off between accuracy and efficiency on the considered data sets.

Comparison against Lasso-type estimator. We have also conducted a set of experiments to compare GraHTP/FGraHTP against the Lasso-type estimator (4) for ℓ_1-regularized sparse learning. To make a fair comparison, we first solve the Lasso-type estimator (4) using an accelerated proximal gradient method (Beck & Teboulle, 2009), which we call Lasso-APG, and then run GraHTP with the sparsity level of the Lasso-APG solution. Figure 5 shows the test classification error and CPU running time curves under varying regularization parameter λ. We can observe from this group of results that: (1) GraHTP and FGraHTP outperform Lasso-APG in classification accuracy on three out of the four data sets in use; and (2) FGraHTP is the most efficient one on all the data sets and GraHTP is faster than Lasso-APG on three of the data sets. Based on these observations, we can conclude that GraHTP and FGraHTP tend to be more accurate and efficient than Lasso-type estimator when their output solutions are at the same sparsity level.

6.3 Sparsity-constrained Gaussian Precision Matrix Estimation

We further assess the performance of GraHTP/FGraHTP when applied to sparse precision matrix estimation.

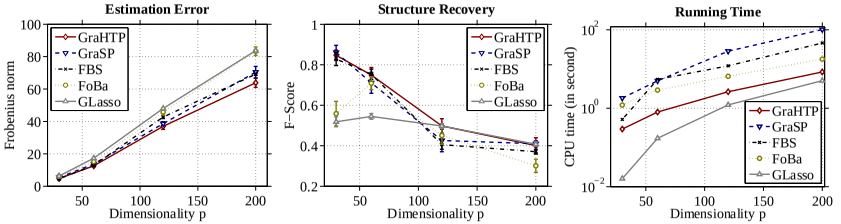

Figure 6: Sparse precision matrix estimation on simulated data: Matrix Frobenius norm loss, support recovery F-score and CPU running time curves under varying data dimensionality. The larger the F-score, the better the support recovery performance.

6.3.1 Monte-Carlo Simulation

Our simulation study employs the sparse precision matrix model $\bar{\Omega} = \Theta + \sigma I$ where each off-diagonal entry in Θ is generated independently and equals 1 with probability $P = 0.1$ or 0 with probability $1 - P = 0.9$. Θ has zeros on the diagonal, and σ is chosen so that the condition number of $\bar{\Omega}$ is p. Let $\bar{\Sigma} = \bar{\Omega}^{-1}$ be the covariance matrix. We generate a training sample of size $n = 100$ from $\mathcal{N}(0, \bar{\Sigma})$, and an independent sample of size 100 from the same distribution for tuning the parameter k. The numerical performance is evaluated with different values of $p \in \{30, 60, 120, 200\}$, replicated 100 times each.

We compare the modified GraHTP (as outlined in Algorithm 2) with GraSP, FBS and FoBa. To adopt GraSP to sparse precision matrix estimation, we modify the algorithm with a similar two-stage strategy as used in the modified GraHTP such that it can handle the eigenvalue bounding constraint in addition to the sparsity constraint. FBS and FoBa have already been applied to sparse precision matrix estimation problems in literature (Yuan & Yan, 2013; Jalali et al., 2011). Also, we compare GraHTP with Graphical Lasso (GLasso) which is one of the representative Lasso-type convex estimators for ℓ_1-penalized log-determinant program (Friedman et al., 2008). The quality of precision matrix estimation is measured by its distance to the truth in Frobenius norm and the support recovery F-score. The larger the F-score, the better the support recovery performance.

Figure 6 compares the matrix error in Frobenius norm, support recovery F-score and CPU running time achieved by each of the considered algorithms for different p. The results show that GraHTP performs favorably in terms of estimation error and support recovery accuracy. We note from the error bars in the curves that the standard error (in 100 replication) of GraHTP is relatively larger than Glasso. This is because GraHTP approximately solves a nonconvex problem via greedy selection at each iteration; the procedure is less stable than those convex solvers such as GLasso. Similar phenomenon of instability has also been observed for the other considered ℓ_0-estimators. The right panel of Figure 6 shows the computational time of the considered algorithms. We can see that GLasso is more efficient than the four greedy selection methods. Although inferior to GLasso, GraHTP is still computationally more attractive than the other considered greedy selection solvers.

Methods	Specificity	Sensitivity	MCC	CPU Time (sec.)
GraHTP	0.77 (0.11)	0.77 (0.19)	**0.49** (0.19)	1.92
GraSP	0.73 (0.10)	**0.78** (0.18)	0.45 (0.17)	4.06
FBS	0.78 (0.11)	0.74 (0.18)	0.48 (0.19)	8.73
FoBa	0.72 (0.11)	**0.78** (0.18)	0.44 (0.18)	6.73
GLasso	**0.81** (0.11)	0.64 (0.21)	0.45 (0.19)	**1.19**

Table 4: Sparse precision matrix estimation on breast cancer data: comparison of average (std) classification accuracy and average CPU running time over 100 replications.

6.3.2 Real Data

We consider the task of LDA (linear discriminant analysis) classification of tumors using the breast cancer data set. This data consists of 133 subjects, each of which is associated with 22,283 gene expression levels. Among these subjects, 34 are with pathological complete response (pCR) and 99 are with residual disease (RD). The pCR subjects are considered to have a high chance of cancer free survival in the long term. Based on the estimated precision matrix of the gene expression levels, we apply LDA to predict whether a subject can achieve the pCR state or the RD state.

Experiment protocol. In this experiment, we follow the same protocol as what was used in the paper of Cai et al. (2011). The data are randomly divided into the training and test sets. In each random division, 5 pCR subjects and 16 RD subjects are randomly selected to constitute the test data, and the remaining subjects form the training set with size $n = 112$. By using two-sample t test, $p = 113$ most significant genes are selected as covariates. Following the LDA framework, we assume that the normalized gene expression data are normally distributed as $\mathcal{N}(\mu_l, \bar{\Sigma})$, where the two classes are assumed to have the same covariance matrix, $\bar{\Sigma}$, but different means, μ_l, $l = 1$ for pCR state and $l = 2$ for RD state. Given a test data sample x, we calculate its LDA scores, $\delta_l(x) = x^\top \hat{\Omega}\hat{\mu}_l - \frac{1}{2}\hat{\mu}_l^\top \hat{\Omega}\hat{\mu}_l + \log \hat{\pi}_l$, $l = 1, 2$, using the precision matrix $\hat{\Omega}$ estimated by the considered methods. Here $\hat{\mu}_l = (1/n_l)\sum_{i\in \text{class}_l} x_i$ is the within-class mean in the training set and $\hat{\pi}_l = n_l/n$ is the proportion of class l subjects in the training set. The classification rule is $\hat{l}(x) = \arg\max_{l=1,2} \delta_l(x)$. Clearly, the classification performance is directly affected by the estimation quality of $\hat{\Omega}$. Hence, we assess the precision matrix estimation performance on the test data and compare GraHTP with GraSP, FBS, FoBa and GLasso. We use a 6-fold cross-validation on the training data for tuning the sparsity level parameter in ℓ_0-estimators and the regularization strength parameter in GLasso. We replicate the experiment 100 times.

Evaluation metric and results. To evaluate classification performance, we use the following defined specificity, sensitivity (or recall), and Mathews correlation coefficient (MCC) criteria as used by Cai et al. (2011):

$$\text{Specificity} = \frac{\text{TN}}{\text{TN}+\text{FP}}, \qquad \text{Sensitivity} = \frac{\text{TP}}{\text{TP}+\text{FN}},$$
$$\text{MCC} = \frac{\text{TP}\times\text{TN} - \text{FP}\times\text{FN}}{\sqrt{(\text{TP}+\text{FP})(\text{TP}+\text{FN})(\text{TN}+\text{FP})(\text{TN}+\text{FN})}},$$

where TP and TN stand for true positives (pCR) and true negatives (RD), respectively, and FP and FN stand for false positives/negatives, respectively. The larger the criterion value, the better the classification performance. Since one can adjust decision threshold in any specific algorithm to trade-off specificity and sensitivity (increase one while reduce the other), the MCC is more meaningful as a single performance metric. Table 4 lists the averages and standard deviations, in the parentheses, of the three classification criteria over 100 replications. It can be observed that GraHTP is quite competitive to the leading methods in all the three metrics. The average CPU running time of each considered method is listed in the rightmost column of Table 4.

7. Conclusion

In this article, we proposed GraHTP as a generalization of HTP from compressed sensing to the generic problem of sparsity-constrained loss minimization. The main idea is to force the gradient descent iteration to be sparse via hard thresholding. Theoretically, we proved that under mild conditions, GraHTP converges geometrically and its estimation error is controlled by the restricted norm of gradient at the target sparse solution. Under properly strengthened conditions, we further established the sparsity recovery performance of GraHTP which to our knowledge has not been systematically analyzed elsewhere in literature. Also, we have proposed and analyzed the FGraHTP algorithm as a fast variant of GraHTP without applying the debiasing operation after truncation. Empirically, we showed that GraHTP and FGraHTP are superior or competitive to the state-of-the-art greedy pursuit methods when applied to sparse learning problems including linear regression, logistic regression and precision matrix estimation. To conclude, simply combining gradient descent with hard thresholding leads to an accurate and computationally tractable procedure for solving sparsity-constrained loss minimization problems.

Appendix A. Technical Lemmas

We present in this appendix section a few technical lemmas to be used in the proofs of main results.

Lemma 13 *Let x be a k-sparse vector and $y = x - \eta\nabla f(x)$. If f is M_{2k}-smooth, then the following inequality holds:*

$$f(y_k) \le f(x) - \frac{1-\eta M_{2k}}{2\eta}\|y_k - x\|^2.$$

Proof Since f is M_{2k}-smooth, it follows that

$$\begin{aligned} f(y_k) - f(x) \le& \langle \nabla f(x), y_k - x\rangle + \frac{M_{2k}}{2}\|y_k - x\|^2 \\ \overset{\xi_1}{\le}& -\frac{1}{2\eta}\|y_k - x\|^2 + \frac{M_{2k}}{2}\|y_k - x\|^2 \\ =& -\frac{1-\eta M_{2k}}{2\eta}\|y_k - x\|^2, \end{aligned}$$

where "ξ_1" follows from the fact that y_k is the best k-support approximation to y such that

$$\|y_k - y\|^2 = \|y_k - x + \eta\nabla f(x)\|^2 \le \|x - x + \eta\nabla f(x)\|^2 = \|\eta\nabla f(x)\|^2,$$

which implies $2\eta\langle\nabla f(x), y_k - x\rangle \le -\|y_k - x\|^2$. ■

Lemma 14 *Assume that f is m_s-strongly convex. Then for any $\|x - x'\|_0 \le s$ it holds that*

$$\|x - x'\| \le \sqrt{\frac{2\max\{f(x) - f(x'), 0\}}{m_s}} + \frac{2\|\nabla_{F\cup F'} f(x')\|}{m_s},$$

where $F = supp(x)$ and $F' = supp(x')$.

Proof Since f is m_s-strongly convex, we have

$$\begin{aligned} f(x) \ge& f(x') + \langle\nabla f(x'), x - x'\rangle + \frac{m_s}{2}\|x - x'\|^2 \\ \ge& f(x') - \|\nabla_{F\cup F'} f(x')\|\|x - x'\| + \frac{m_s}{2}\|x - x'\|^2, \end{aligned}$$

where the second inequality follows from Cauchy-Schwarz inequality. From this above inequality we can see that if $f(x) \le f(x')$, then

$$\|x - x'\| \le \frac{2\|\nabla_{F\cup F'} f(x')\|}{m_s}.$$

If otherwise $f(x) > f(x')$, then we have

$$\begin{aligned} \|x - x'\| \le& \frac{\|\nabla_{F\cup F'} f(x')\| + \sqrt{\|\nabla_{F\cup F'} f(x')\|^2 + 2m_s(f(x) - f(x'))}}{m_s} \\ \le& \frac{2\|\nabla_{F\cup F'} f(x')\| + \sqrt{2m_s(f(x) - f(x'))}}{m_s}. \end{aligned}$$

By combining the above two cases we get the desired bound. ■

Lemma 15 *Assume that f is m_s-strongly convex and M_s-smooth. For any index set F with cardinality $|F| \le s$ and any x, y with $supp(x) \cup supp(y) \subseteq F$, if $\eta \in (0, 2m_s/M_s^2)$, then*

$$\|x - y - \eta\nabla_F f(x) + \eta\nabla_F f(y)\| \le \sqrt{1 - 2\eta m_s + \eta^2 M_s^2}\|x - y\|,$$

and $\sqrt{1 - 2\eta m_s + \eta^2 M_s^2} < 1$.

Proof By adding two copies of the inequality (2) with x and y interchanged and applying Theorem 2.1.5 in the textbook (Nesterov, 2004) on the supporting set F, we can show that

$$(x - y)^\top(\nabla f(x) - \nabla f(y)) \ge m_s\|x - y\|^2, \quad \|\nabla_F f(x) - \nabla_F f(y)\| \le M_s\|x - y\|.$$

Then for any $\eta > 0$ we have

$$\|x - y - \eta\nabla_F f(x) + \eta\nabla_F f(y)\|^2 \le (1 - 2\eta m_s + \eta^2 M_s^2)\|x - y\|^2.$$

It is clear that $1 - 2\eta m_s + \eta^2 M_s^2 \ge 1 - m_s^2/M_s^2 \ge 0$. The condition $\eta < 2m_s/M_s^2$ implies $\sqrt{1 - 2\eta m_s + \eta^2 M_s^2} < 1$. This proves the lemma. ■

Lemma 16 *Assume that f is M_s-smooth and m_s-strongly convex. Let F and F' be two index sets with cardinality $|F \cup F'| = s$. Let $x = \arg\min_{supp(y)\subseteq F} f(y)$ and $supp(x') \subseteq F'$. Then for any $\eta \in (0, 2m_s/M_s^2)$, the following two inequalities hold:*

$$\|(x - x')_F\| \le \frac{\rho\|x'_{F'\setminus F}\|}{1-\rho} + \frac{\eta\|\nabla_{F\cup F'} f(x')\|}{1-\rho}, \tag{14}$$

$$\|x - x'\| \le \frac{\|x'_{F'\setminus F}\|}{1-\rho} + \frac{\eta\|\nabla_{F\cup F'} f(x')\|}{1-\rho}, \tag{15}$$

where $\rho = \sqrt{1 - 2\eta m_s + \eta^2 M_s^2} < 1$.

Proof Since x is the minimum of $f(y)$ restricted over the supporting set F, we have $\langle\nabla f(x), z\rangle = 0$ whenever $\mathrm{supp}(z) \subseteq F$. Then

$$\begin{aligned} &\|(x - x')_F\|^2 \\ =& \langle x - x', (x - x')_F\rangle \\ =& \langle x - x' - \eta\nabla_{F\cup F'} f(x) + \eta\nabla_{F\cup F'} f(x'), (x - x')_F\rangle - \eta\langle\nabla_{F\cup F'} f(x'), (x - x')_F\rangle \\ \overset{\xi_1}{\le}& \sqrt{1 - 2\eta m_s + \eta^2 M_s^2}\|x - x'\|\|(x - x')_F\| + \eta\|\nabla_{F\cup F'} f(x')\|\|(x - x')_F\|, \end{aligned}$$

where "ξ_1" follows from Lemma 15. Let us abbreviate $\rho = \sqrt{1 - 2\eta m_s + \eta^2 M_s^2}$. After simplification, we have

$$\|(x - x')_F\| \le \rho\|x - x'\| + \eta\|\nabla_{F\cup F'} f(x')\|. \tag{16}$$

It follows that

$$\begin{aligned} \|x - x'\| \le& \|(x - x')_F\| + \|(x - x')_{F'\setminus F}\| \\ \le& \rho\|x - x'\| + \eta\|\nabla_{F\cup F'} f(x')\| + \|(x - x')_{F'\setminus F}\|. \end{aligned}$$

After rearrangement we obtain

$$\begin{aligned}\|x-x'\| \leq & \frac{\|(x-x')_{F'\setminus F}\|}{1-\rho}+\frac{\eta\|\nabla_{F\cup F'}f(x')\|}{1-\rho}\\ = & \frac{\|x'_{F'\setminus F}\|}{1-\rho}+\frac{\eta\|\nabla_{F\cup F'}f(x')\|}{1-\rho}.\end{aligned} \tag{17}$$

By combining (16) and (17) we get

$$\|(x-x')_F\| \leq \frac{\rho\|x'_{F'\setminus F}\|}{1-\rho}+\frac{\eta\|\nabla_{F\cup F'}f(x')\|}{1-\rho}.$$

This proves the desired bounds in this lemma. ■

The following lemma is established by Shen & Li (2016, Theorem 1) for bounding the estimation error of hard-thresholding operation. This result will be extensively used in our analysis.

Lemma 17 *Let $b\in\mathbb{R}^p$ be an arbitrary p-dimensional vector and $a\in\mathbb{R}^p$ be any k-sparse vector. Denote $\bar{k}=\|a\|_0\leq k$. Then, we have the following universal bound:*

$$\|b_k-a\|^2\leq\nu\|b-a\|^2,\quad \nu=1+\frac{\beta+\sqrt{(4+\beta)\beta}}{2},\quad \beta=\frac{\min\{\bar{k},p-k\}}{k-\bar{k}+\min\{\bar{k},p-k\}}.$$

Appendix B. Proofs of Main Theorems in Section 3

The technical proofs of main results in Section 3 are collected in this appendix section.

B.1 Proof of Theorem 2

Before proving Theorem 2, we first present two lemmas which are respectively key to the proof of part(a) and part(b) of Theorem 2.

Lemma 18 *Assume that f is M_{3k}-smooth and m_{3k}-strongly convex. Let $\bar{x}$ be an arbitrary k-sparse vector. Then at time instance t, for any $\eta\in(0,2m_{3k}/M_{3k}^2)$, GraHTP will output $x^{(t)}$ satisfying*

$$\|x^{(t)}-\bar{x}\|\leq\frac{\rho}{1-\rho}\|x^{(t-1)}-\bar{x}\|+\frac{2\eta\|\nabla_{2k}f(\bar{x})\|}{1-\rho},$$

where $\rho=\sqrt{1-2\eta m_{3k}+\eta^2M_{3k}^2}<1$.

Proof Denote $\bar{F}=\mathrm{supp}(\bar{x})$. Since $x^{(t)}$ is the minimum of $f(x)$ restricted over the supporting set $F^{(t)}$, it is directly known from the inequality (15) in Lemma 16 that

$$\|x^{(t)}-\bar{x}\|\leq\frac{\|(x^{(t)}-\bar{x})_{\bar{F}\setminus F^{(t)}}\|}{1-\rho}+\frac{\eta\|\nabla_{F^{(t)}}f(\bar{x})\|}{1-\rho}. \tag{18}$$

According to the definition of $F^{(t)}$,

$$\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{\bar{F}}\|\leq\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{F^{(t)}}\|.$$

By eliminating the contribution on $\bar{F}\cap F^{(t)}$ we get

$$\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{\bar{F}\setminus F^{(t)}}\|\leq\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{F^{(t)}\setminus\bar{F}}\|. \tag{19}$$

For the right-hand side, we can derive

$$\begin{aligned}&\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{F^{(t)}\setminus\bar{F}}\|\\ \leq&\|(x^{(t-1)}-\bar{x}-\eta\nabla f(x^{(t-1)})+\eta\nabla f(\bar{x}))_{F^{(t)}\setminus\bar{F}}\|+\eta\|\nabla_{F^{(t)}\setminus\bar{F}}f(\bar{x})\|.\end{aligned} \tag{20}$$

As for the left-hand side, we can see that

$$\begin{aligned}&\|(x^{(t-1)}-\eta\nabla f(x^{(t-1)}))_{\bar{F}\setminus F^{(t)}}\|\\ \geq&\|(x^{(t-1)}-\bar{x}-\eta\nabla f(x^{(t-1)})+\eta\nabla f(\bar{x}))_{\bar{F}\setminus F^{(t)}}-(x^{(t)}-\bar{x})_{\bar{F}\setminus F^{(t)}}-\eta\nabla_{\bar{F}\setminus F^{(t)}}f(\bar{x})\|\\ \geq&\|(x^{(t)}-\bar{x})_{\bar{F}\setminus F^{(t)}}\|-\|(x^{(t-1)}-\bar{x}-\eta\nabla f(x^{(t-1)})+\eta\nabla f(\bar{x}))_{\bar{F}\setminus F^{(t)}}\|\\ &-\eta\|\nabla_{\bar{F}\setminus F^{(t)}}f(\bar{x})\|.\end{aligned} \tag{21}$$

Denote $\bar{F}\Delta F^{(t)}$ the symmetric difference of $\bar{F}$ and $F^{(t)}$ and let $F=\bar{F}\cup F^{(t)}\cup F^{(t-1)}$. It can be shown from (19), (20) and (21) that

$$\begin{aligned}&\|(x^{(t)}-\bar{x})_{\bar{F}\setminus F^{(t)}}\|\\ \leq&\|(x^{(t-1)}-\bar{x}-\eta\nabla f(x^{(t-1)})+\eta\nabla f(\bar{x}))_{\bar{F}\Delta F^{(t)}}\|+\eta\|\nabla_{\bar{F}\Delta F^{(t)}}f(\bar{x})\|\\ \leq&\|x^{(t-1)}-\bar{x}-\eta\nabla_F f(x^{(t-1)})+\eta\nabla_F f(\bar{x})\|+\eta\|\nabla_{F^{(t)}\Delta\bar{F}}f(\bar{x})\|\\ \overset{\xi_1}{\leq}&\rho\|x^{(t-1)}-\bar{x}\|+\eta\|\nabla_{F^{(t)}\Delta\bar{F}}f(\bar{x})\|,\end{aligned} \tag{22}$$

where "ξ_1" follows from Lemma 15. As a final step, combining (18) and (22) gives us

$$\begin{aligned}\|x^{(t)}-\bar{x}\|\leq&\frac{\rho}{1-\rho}\|x^{(t-1)}-\bar{x}\|+\frac{2\eta\|\nabla_{F^{(t)}\cup\bar{F}}f(\bar{x})\|}{1-\rho}\\ \leq&\frac{\rho}{1-\rho}\|x^{(t-1)}-\bar{x}\|+\frac{2\eta\|\nabla_{2k}f(\bar{x})\|}{1-\rho}.\end{aligned}$$

This completes the proof. ■

Lemma 19 *Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector. Assume that $s=2k+\bar{k}\leq p$ and f is M_s-smooth and m_s-strongly convex. Then at time instance t, for any $\eta\in(0,2m_s/M_s^2)$, FGraHTP will output $x^{(t)}$ satisfying*

$$\|x^{(t)}-\bar{x}\|\leq\gamma\rho\|x^{(t-1)}-\bar{x}\|+\gamma\eta\|\nabla_s f(\bar{x})\|,$$

where $\rho=\sqrt{1-2\eta m_s+\eta^2M_s^2}<1$ and $\gamma=\sqrt{1+\left(\bar{k}/k+\sqrt{(4+\bar{k}/k)\bar{k}/k}\right)/2}$.

Proof Recall that $F^{(t)} = \text{supp}(x^{(t)})$ and $F = F^{(t-1)} \cup F^{(t)} \cup \text{supp}(\bar{x})$. Consider the following vector

$$y = x^{(t-1)} - \eta \nabla_F f(x^{(t-1)}).$$

By using triangular inequality,

$$\begin{aligned} \|y - \bar{x}\| &= \|x^{(t-1)} - \eta \nabla_F f(x^{(t-1)}) - \bar{x}\| \\ &\leq \|x^{(t-1)} - \bar{x} - \eta \nabla_F f(x^{(t-1)}) + \eta \nabla_F f(\bar{x})\| + \eta \|\nabla_F f(\bar{x})\| \\ &\leq \rho \|x^{(t-1)} - \bar{x}\| + \eta \|\nabla_s f(\bar{x})\|, \end{aligned}$$

where the last inequality follows from Lemma 15 and $\|\nabla_F f(\bar{x})\| \leq \|\nabla_s f(\bar{x})\|$. We note that $x^{(t)} = y_k$ in FGraHTP. Then, by invoking Lemma 17 we get

$$\|x^{(t)} - \bar{x}\| \leq \gamma \|y - \bar{x}\|,$$

where $\gamma = \sqrt{1 + \left(\bar{k}/k + \sqrt{(4 + \bar{k}/k)\bar{k}/k}\right)/2}$. It follows that

$$\|x^{(t)} - \bar{x}\| \leq \gamma\rho \|x^{(t-1)} - \bar{x}\| + \gamma\eta \|\nabla_s f(\bar{x})\|.$$

This proves the desired bound. ■

Equipped with Lemma 18 and Lemma 19, we can now prove Theorem 2 in a straightforward way.

Proof [of Theorem 2]

Part(a): Since $M_{3k}/m_{3k} < 2\sqrt{3}/3$, there exists $\eta \in (0, 2m_{3k}/M_{3k}^2)$ such that $\rho = \sqrt{1 - 2\eta m_{3k} + \eta^2 M_{3k}^2} < 0.5$ and thus $\rho/(1-\rho) < 1$. By recursively applying Lemma 18 and noting the fact $\|\nabla_s f(x)\| \leq \sqrt{s}\|\nabla f(x)\|_\infty$ we obtain the desired bound in this part.

Part(b): Note that $\gamma = 1.62$ when $\bar{k} = k$ in Lemma 19. Since $M_{3k}/m_{3k} < 1.26$, there exists $\eta \in (0, 2m_{3k}/M_{3k}^2)$ such that $\rho < 0.62$ and thus $1.62\rho < 1$. Then by recursively applying Lemma 19 with $\bar{k} = k$ we obtain the desired bound in this part. ■

B.2 Proof of Theorem 5

We need the following lemma to prove Theorem 5.

Lemma 20 *Assume that f is M_{2k}-smooth and m_{2k}-strongly convex. Assume the step-size $\eta < 1/M_{2k}$. Let $\bar{x}$ be an arbitrary $\bar{k}$-sparse vector with $k \geq \left(2 + \frac{4}{\eta^2 m_{2k}^2}\right)\bar{k}$. Then GraHTP outputs $x^{(t)}$ satisfying*

$$f(x^{(t)}) \leq f(\bar{x}) + (1 - \bar{\nu})^t \bar{\triangle}^{(0)},$$

where $\bar{\nu} = \eta m_{2k}(1 - \eta M_{2k})/2 \in (0, 0.125 m_{2k}/M_{2k})$ and $\bar{\triangle}^{(0)} = f(x^{(0)}) - f(\bar{x})$.

Proof From the definition of $\tilde{x}^{(t)}$ we know that the following inequality holds:

$$\|\tilde{x}^{(t)}_{F^{(t)}} - x^{(t-1)}\| \geq \eta \|\nabla_{F^{(t)} \setminus F^{(t-1)}} f(x^{(t-1)})\|. \tag{23}$$

From Lemma 13 we get

$$f(x^{(t)}) - f(x^{(t-1)}) \leq f(\tilde{x}^{(t)}_{F^{(t)}}) - f(x^{(t-1)}) \leq -\frac{1 - \eta M_{2k}}{2\eta} \|\tilde{x}^{(t)}_{F^{(t)}} - x^{(t-1)}\|^2. \tag{24}$$

Combining the above two inequalities (23) and (24) gives us

$$f(x^{(t)}) - f(x^{(t-1)}) \leq -\frac{(1 - \eta M_{2k})\eta}{2} \|\nabla_{F^{(t)} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2. \tag{25}$$

Let $\bar{F} = \text{supp}(\bar{x})$. Under the conditions in the theorem, we claim

$$\|\nabla_{F^{(t)} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2 \geq m_{2k} \left[f(x^{(t-1)}) - f(\bar{x}) \right]. \tag{26}$$

To prove this , let us distinguish the following two mutually complementary cases:

- Case I: $|F^{(t)} \setminus F^{(t-1)}| \geq \bar{k}$. In this case, we have $|F^{(t)} \setminus F^{(t-1)}| \geq |\bar{F} \setminus F^{(t-1)}|$. From the m_{2k}-strong convexity of f we have

$$\begin{aligned} &\frac{m_{2k}}{2} \|\bar{x} - x^{(t-1)}\|^2 \\ \leq & f(\bar{x}) - f(x^{(t-1)}) - (\bar{x} - x^{(t-1)})^\top \nabla f(x^{(t-1)}) \\ \overset{\xi_1}{\leq} & f(\bar{x}) - f(x^{(t-1)}) + \frac{m_{2k}}{2} \|\bar{x} - x^{(t-1)}\|^2 + \frac{1}{2m_{2k}} \|\nabla_{\bar{F} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2, \end{aligned}$$

  where "ξ_1" follows from Cauchy-Schwartz inequality, a basic inequality $ma^2/2 + b^2/(2m) \geq ab$ for any $m > 0$, and $\nabla_{F^{(t-1)}} f(x^{(t-1)}) = 0$. This implies

$$\|\nabla_{\bar{F} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2 \geq 2m_{2k} \left[f(x^{(t-1)}) - f(\bar{x}) \right]. \tag{27}$$

  Since $F^{(t)} \setminus F^{(t-1)}$ contains the top $|F^{(t)} \setminus F^{(t-1)}|$ (in magnitude) entries in $\nabla f(x^{(t-1)})$ and $|F^{(t)} \setminus F^{(t-1)}| \geq |\bar{F} \setminus F^{(t-1)}|$, it follows that

$$\|\nabla_{F^{(t)} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2 \geq \|\nabla_{\bar{F} \setminus F^{(t-1)}} f(x^{(t-1)})\|^2 \geq 2m_{2k} \left[f(x^{(t-1)}) - f(\bar{x}) \right].$$

- Case II: $|F^{(t)} \setminus F^{(t-1)}| < \bar{k}$. In this case, from the step (**S2**) we know that each element of $\tilde{x}^{(t)}$ over $\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})$ has smaller magnitude than that over $F^{(t)} \cap F^{(t-1)}$. This implies

$$\frac{\|\tilde{x}^{(t)}_{\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})}\|^2}{|\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})|} \leq \frac{\|\tilde{x}^{(t)}_{(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}}\|^2}{|(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}|}.$$

  Since $\tilde{x}^{(t)}_{\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})} = -\eta \nabla_{\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})} f(x^{(t-1)})$, $\tilde{x}^{(t)}_{(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}} = x^{(t-1)}_{(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}}$, $|\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})| \leq \bar{k}$ and $|(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}| \geq k - 2\bar{k}$, we have

$$\eta^2 \|\nabla_{\bar{F} \setminus (F^{(t)} \cup F^{(t-1)})} f(x^{(t-1)})\|^2 \leq \frac{\bar{k}}{k - 2\bar{k}} \|x^{(t-1)}_{(F^{(t)} \cap F^{(t-1)}) \setminus \bar{F}}\|^2.$$

From the m_{2k}-strong convexity of f we have

$$\begin{aligned}
&\frac{m_{2k}}{2}\|\bar{x}-x^{(t-1)}\|^2\\
\leq& f(\bar{x})-f(x^{(t-1)})-(\bar{x}-x^{(t-1)})^\top\nabla f(x^{(t-1)})\\
\overset{\xi_1}{\leq}& f(\bar{x})-f(x^{(t-1)})+\frac{m_{2k}}{4}\|\bar{x}-x^{(t-1)}\|^2+\frac{1}{m_{2k}}\|\nabla_{\bar{F}\setminus F^{(t-1)}}f(x^{(t-1)})\|^2\\
\leq& f(\bar{x})-f(x^{(t-1)})+\frac{m_{2k}}{4}\|\bar{x}-x^{(t-1)}\|^2+\frac{1}{m_{2k}}\|\nabla_{\bar{F}\setminus(F^{(t)}\cup F^{(t-1)})}f(x^{(t-1)})\|^2\\
&+\frac{1}{m_{2k}}\|\nabla_{(F^{(t)}\setminus F^{(t-1)})\cap\bar{F}}f(x^{(t-1)})\|^2\\
\overset{\xi_2}{\leq}& f(\bar{x})-f(x^{(t-1)})+\frac{m_{2k}}{4}\|\bar{x}-x^{(t-1)}\|^2+\frac{\bar{k}}{\eta^2(k-2\bar{k})m_{2k}}\|x^{(t-1)}_{(F^{(t)}\cap F^{(t-1)})\setminus\bar{F}}\|^2\\
&+\frac{1}{m_{2k}}\|\nabla_{F^{(t)}\setminus F^{(t-1)}}f(x^{(t-1)})\|^2\\
\overset{\xi_3}{\leq}& f(\bar{x})-f(x^{(t-1)})+\frac{m_{2k}}{4}\|\bar{x}-x^{(t-1)}\|^2+\frac{\bar{k}}{\eta^2(k-2\bar{k})m_{2k}}\|\bar{x}-x^{(t-1)}\|^2\\
&+\frac{1}{m_{2k}}\|\nabla_{F^{(t)}\setminus F^{(t-1)}}f(x^{(t-1)})\|^2,
\end{aligned}$$

where "ξ_1" follows from Cauchy-Schwartz inequality, $ma^2/4+b^2/(m)\geq ab$ for any $m>0$, and $\nabla_{F^{(t-1)}}f(x^{(t-1)})=0$, "$\xi_2$" follows from the preceding inequality, and "ξ_3" is due to $\|x^{(t-1)}_{(F^{(t)}\cap F^{(t-1)})\setminus\bar{F}}\|\leq\|\bar{x}-x^{(t-1)}\|$. Since $k\geq\left(2+\frac{4}{\eta^2 m_{2k}^2}\right)\bar{k}$, the above inequality leads to

$$\|\nabla_{\bar{F}\setminus F^{(t-1)}}f(x^{(t-1)})\|^2\geq m_{2k}\left[f(x^{(t-1)})-f(\bar{x})\right].$$

Since $\eta<1/M_{2k}$, from (25) and (26) we get that

$$\begin{aligned}
f(x^{(t)})&\leq f(x^{(t-1)})-\frac{\eta m_{2k}(1-\eta M_{2k})}{2}\left[f(x^{(t-1)})-f(\bar{x})\right]\\
&=f(x^{(t-1)})-\bar{\nu}\left[f(x^{(t-1)})-f(\bar{x})\right].
\end{aligned}$$

Therefore, we get

$$f(x^{(t)})-f(\bar{x})\leq(1-\bar{\nu})(f(x^{(t-1)})-f(\bar{x})).$$

Since $m_{2k}\leq M_{2k}$ and $\eta\in(0,1/M_{2k})$, it can be verified that $\bar{\nu}\in(0,0.125m_{2k}/M_{2k})$. By recursively applying the above inequality we obtain the desired result. ■

We are now in the position to prove Theorem 5.

Proof [of Theorem 5] **Part(a):** Since $\eta<1/M_{2k}$, it is directly known from Lemma 13 that $\{f(x^{(t)})\}$ is monotonically decreasing. From Lemma 14 we know that the result holds when

$f(x^{(t)})\leq f(\bar{x})$. Therefore, we only need to consider the case when $f(x^{(t)})>f(\bar{x})$. In this case, from Lemma 14 and Lemma 20 we get

$$\begin{aligned}
\|x^{(t)}-\bar{x}\|\leq&\sqrt{\frac{2(f(x^{(t)})-f(\bar{x}))}{m_{2k}}}+\frac{2\|\nabla_{2k}f(\bar{x})\|}{m_{2k}}\\
\leq&\sqrt{\frac{2(1-\bar{\nu})^t\bar{\triangle}^{(0)}}{m_{2k}}}+\frac{2\sqrt{2\bar{k}}\|\nabla f(\bar{x})\|_\infty}{m_{2k}}.
\end{aligned}$$

This proves the result in part(a).

Part(b): From the condition $k\geq\rho\bar{k}/(1-\rho)^2$ we can verify that $\bar{\mu}_2=\rho\gamma<1$. Thus, the result can be directly proved by recursively applying Lemma 19. ■

Appendix C. Proofs of Main Theorems in Section 4

The technical proofs of main results in Section 4 are collected in this appendix section.

C.1 Proof of Theorem 8

Before commencing with the actual proof, we first present an overview of the proof procedure which consists of the following three key ingredients:

(a) We first prove that under the given conditions, GraHTP will not terminate (i.e., $F^{(t)}\neq F^{(t-1)}$) whenever $\mathrm{supp}(\bar{x})\nsubseteq\mathrm{supp}(x^{(t-1)})$.

(b) We then show that $\mathrm{supp}(\bar{x})=\mathrm{supp}(x^{(t)},\bar{k})$ when GraHTP terminates at $x^{(t)}$.

(c) Finally we show that the conditions in the theorem guarantee finite termination of GraHTP and analyze its iteration complexity before termination.

Proof [of Theorem 8]

We first show that $F^{(t)}\neq F^{(t-1)}$ whenever $\mathrm{supp}(\bar{x})\nsubseteq\mathrm{supp}(x^{(t-1)})$. To this end, let us assume $\mathrm{supp}(\bar{x})\nsubseteq\mathrm{supp}(x^{(t-1)})$. Recall $x^\star=\arg\min_{\|x\|_0\leq k}f(x)$. Then

$$\begin{aligned}
\bar{x}_{\min}+\|x^{(t-1)}_{F^{(t-1)}\setminus\bar{F}}\|\leq&\|\bar{x}-x^{(t-1)}\|\\
\overset{\xi_1}{\leq}&\sqrt{\frac{2\max\left\{f(\bar{x})-f(x^{(t-1)}),0\right\}}{m_{2k}}}+\frac{2\|\nabla_{\bar{F}\setminus F^{(t-1)}}f(x^{(t-1)})\|}{m_{2k}}\\
\overset{\xi_2}{\leq}&\sqrt{\frac{2(f(\bar{x})-f(x^\star))}{m_{2k}}}+\frac{2\|\nabla_{\bar{F}\setminus F^{(t-1)}}f(x^{(t-1)})\|}{m_{2k}},
\end{aligned}$$

where "ξ_1" follows from Lemma 14 and "ξ_2" is due to the fact of $f(x^{(t-1)})\geq f(x^\star)$. Since it is assumed $\bar{x}_{\min}>1.62\sqrt{\frac{2(f(\bar{x})-f(x^\star))}{m_{2k}}}$, the above inequality implies

$$\|x^{(t-1)}_{F^{(t-1)}\setminus\bar{F}}\|<\frac{2\|\nabla_{\bar{F}\setminus F^{(t-1)}}f(x^{(t-1)})\|}{m_{2k}},$$

which then gives us

$$\sqrt{k-\bar{k}}x_{\min}^{(t-1)} < \frac{2\sqrt{\bar{k}}}{m_{2k}}\|\nabla f(x^{(t-1)})\|_\infty.$$

Since $\eta = \frac{1}{2M_{2k}}$ and $k \geq \left(1+\frac{16M_{2k}^2}{m_{2k}^2}\right)\bar{k}$, we then have

$$\eta\|\nabla f(x^{(t-1)})\|_\infty > x_{\min}^{(t-1)}.$$

This means that at least the smallest nonzero entry of $x^{(t-1)}$ and the largest entry of $\nabla f(x^{(t-1)})$ can be swapped in step (**S2**) of Algorithm 1, and thus $F^{(t)} \neq F^{(t-1)}$. Therefore, when the algorithm terminates at time instance t, i.e., $F^{(t)} = F^{(t-1)}$, we must have $\mathrm{supp}(\bar{x}) \subseteq \mathrm{supp}(x^{(t)})$.

Next we show that $\mathrm{supp}(\bar{x}) = \mathrm{supp}(x^{(t)}, \bar{k})$ when GraHTP terminates at time instance t with $\mathrm{supp}(\bar{x}) \subseteq \mathrm{supp}(x^{(t)})$. Assume otherwise $\mathrm{supp}(\bar{x}) \neq \mathrm{supp}(x^{(t)}, \bar{k})$. Then

$$\begin{aligned}
\bar{x}_{\min} &\leq \|\bar{x} - x_{\bar{k}}^{(t)}\| \\
&\overset{\xi_1}{\leq} 1.62\|\bar{x} - x^{(t)}\| \\
&\overset{\xi_2}{\leq} 1.62\left(\sqrt{\frac{2(f(\bar{x}) - f(x^\star))}{m_{2k}}} + \frac{2\|\nabla_{\bar{F}\setminus F^{(t)}} f(x^{(t)})\|}{m_{2k}}\right) \\
&\overset{\xi_3}{\leq} 1.62\sqrt{\frac{2(f(\bar{x}) - f(x^\star))}{m_{2k}}},
\end{aligned}$$

where "ξ_1" is based on the truncation error bound given by Shen & Li (2016, Theorem 1), "ξ_2" follows from Lemma 14 and the fact of $f(x^{(t)}) \geq f(x^\star)$, and "$\xi_3$" is the consequence of $\bar{F} \subseteq F^{(t)}$. This above inequality contradicts the assumption on $\bar{x}_{\min}$. Therefore, it must hold that $\mathrm{supp}(\bar{x}) = \mathrm{supp}(x^{(t)}, \bar{k})$.

Now we claim that GraHTP is finite under the assumed conditions. Indeed, based on Lemma 13 it is easy to verify that when $\eta = \frac{1}{2M_{2k}}$, the sequence $\{f(x^{(t)})\}$ generated by Algorithm 1 is monotonically decreasing. Since the number of k-support index sets is finite, the sequence $\{f(x^{(t)})\}$ will be eventually periodic, and thus must be eventually a constant. Therefore we deduce that $\tilde{x}_k^{(t)} = x^{(t-1)}$, i.e., $F^{(t)} = F^{(t-1)}$, when t is sufficiently enough.

Finally, we estimate the iteration complexity bound before algorithm termination. Suppose that $F^{(t)} \neq F^{(t-1)}$ (otherwise GraHTP terminates at time instance t). From the step (**S3**) we know that $\nabla_{F^{(t-1)}} f(x^{(t-1)}) = 0$. By definition of $F^{(t)}$ we may decompose $F^{(t)} = G_1 \cup (F^{(t-1)} \setminus G_2)$ with $G_1 \subseteq \mathrm{supp}(\nabla f(x^{(t-1)}))$, $G_2 \subseteq F^{(t-1)}$ and $|G_1| = |G_2| = k' \leq k$. Here, G_1 contains the top k' (in magnitude) entries in $\nabla f(x^{(t-1)})$ while G_2 contains the bottom k' nonzero entries in $x^{(t-1)}$. Since $F^{(t)} \neq F^{(t-1)}$, we have $k' \geq 1$. From the step (**S2**) we know that

$$\|x_{G_2}^{(t-1)}\| < \eta\|\nabla_{G_1} f(x^{(t-1)})\|. \tag{28}$$

Let $F = F^{(t-1)} \cup \mathrm{supp}(x^\star)$. From the conditions in the theorem we have

$$\begin{aligned}
\frac{m_{2k}}{2}\|x^\star - x^{(t-1)}\|^2 &\leq f(x^\star) - f(x^{(t-1)}) - (x^\star - x^{(t-1)})^\top \nabla f(x^{(t-1)}) \\
&\leq f(x^\star) - f(x^{(t-1)}) + \frac{m_{2k}}{2}\|x^\star - x^{(t-1)}\|^2 + \frac{1}{2m_{2k}}\|\nabla_F f(x^{(t-1)})\|^2,
\end{aligned}$$

where the second inequality follows from Cauchy-Schwartz inequality and a basic inequality $ma^2/2 + b^2/(2m) \geq ab$ for any $m > 0$. This implies

$$\|\nabla_F f(x^{(t-1)})\|^2 \geq 2m_{2k}\left[f(x^{(t-1)}) - f(x^\star)\right].$$

Let $F^\star = \mathrm{supp}(x^\star)$ and $k'' = |F^\star \setminus F^{(t-1)}|$. Obviously, we have $k'' \leq k$. Based on the above arguments, it can be verified that

$$\begin{aligned}
k\|\nabla_{G_1} f(x^{(t-1)})\|^2 &\geq (k''/k')\|\nabla_{G_1} f(x^{(t-1)})\|^2 \\
&\geq \|\nabla_F f(x^{(t-1)})\|^2 \\
&\geq 2m_{2k}\left[f(x^{(t-1)}) - f(x^\star)\right].
\end{aligned} \tag{29}$$

Now let $y^{(t)} := x^{(t-1)} + \delta^{(t-1)}$ in which

$$\delta^{(t-1)} = -\eta\nabla_{G_1} f(x^{(t-1)}) - x_{G_2}^{(t-1)}.$$

From the steps (**S1**) and (**S3**) in Algorithm 1 we get

$$\begin{aligned}
f(x^{(t)}) &\leq f(y^{(t)}) \\
&\leq f(x^{(t-1)}) + \langle \nabla f(x^{(t-1)}), \Delta^{(t-1)}\rangle + \frac{M_{2k}}{2}\|\Delta^{(t-1)}\|^2 \\
&\leq f(x^{(t-1)}) + \frac{M_{2k}}{2}\|x_{G_2}^{(t-1)}\|^2 - \frac{2\eta - \eta^2 M_{2k}}{2}\|\nabla_{G_1} f(x^{(t-1)})\|^2 \\
&\overset{\xi_1}{\leq} f(x^{(t-1)}) - (\eta - \eta^2 M_{2k})\|\nabla_{G_1} f(x^{(t-1)})\|^2 \\
&\overset{\xi_2}{\leq} f(x^{(t-1)}) - \frac{m_{2k}}{2kM_{2k}}(f(x^{(t-1)}) - f(x^\star)),
\end{aligned}$$

where "ξ_1" follows from (28) and "ξ_2" uses (29) and $\eta = \frac{1}{M_{2k}}$ as well. Therefore, we get

$$f(x^{(t)}) - f(x^\star) \leq \left(1 - \frac{m_{2k}}{2kM_{2k}}\right)(f(x^{(t-1)}) - f(x^\star)).$$

Note that $f(x^{(t)}) \geq f(x^\star)$ for all $t \geq 0$. By recursively using the above inequality we get

$$f(x^{(t)}) - f(x^\star) \leq \left(1 - \frac{m_{2k}}{2kM_{2k}}\right)^t (f(x^{(0)}) - f(x^\star)).$$

Let us define the following quantity

$$\triangle^{-\star} = \min_{\|x\|_0 \leq k, \mathrm{supp}(x) \neq \mathrm{supp}(x^\star), f(x) > f(x^\star)} f(x) - f(x^\star).$$

Then $f(x^{(t)}) - f(x^\star) \leq \triangle^{-\star}$ when $t \geq \frac{2kM_{2k}}{m_{2k}} \ln \frac{\triangle^{(0)}}{\triangle^{-\star}}$ (note that $\triangle^{-\star} > 0$ by definition). After that, we have $f(x^{(t)}) = f(x^\star)$, i.e., $x^{(t)}$ is also a k-sparse minimizer. Then according to Lemma 21 we have $x_{\min}^{(t)} \geq \frac{\|\nabla f(x^{(t)})\|_\infty}{M_{2k}} > \eta\|\nabla f(x^{(t)})\|_\infty$, and thus the algorithm terminates at $x^{(t)}$. Based on the above arguments, we can conclude that GraHTP terminates after at most $t = \left\lceil \frac{2kM_{2k}}{m_{2k}} \ln \frac{\triangle^{(0)}}{\triangle^{-\star}} \right\rceil$ steps of iteration. This completes the proof. ■

C.2 Proof of Theorem 10

The following lemma gives a necessary condition on the k-sparse minimizer $x^\star$. A similar result was proved by Beck & Eldar (2013).

Lemma 21 *If f is M_{2k}-smooth, then the following inequality holds for the global k-sparse minimizer $x^\star = \arg\min_{\|x\|_0\leq k} f(x)$:*

$$x^\star_{\min} \geq \frac{\|\nabla f(x^\star)\|_\infty}{M_{2k}}.$$

Proof Assume otherwise that $\vartheta^\star := \frac{M_{2k}x^\star_{\min}}{\|\nabla f(x^\star)\|_\infty} < 1$. Let us consider $\tilde{x}^\star = x^\star - \eta\nabla f(x^\star)$ with any $\eta \in (\vartheta^\star/M_{2k}, 1/M_{2k})$. From Lemma 13 we get that

$$f(\tilde{x}^\star_k)) \leq f(x^\star) - \frac{1-\eta M_{2k}}{2\eta}\|\tilde{x}^\star_k - x^\star\|^2.$$

Since $\eta < \frac{1}{M_{2k}}$ and $x^\star_{\min} = \frac{\vartheta^\star\|\nabla f(x^\star)\|_\infty}{M_{2k}} < \eta\|\nabla f(x^\star)\|_\infty$, we have $\tilde{x}^\star_k \neq x^\star$ and thus it follows from the above inequality that $f(\tilde{x}^\star_k) < f(x^\star)$ which contradicts the optimality of $x^\star$. ■

Now we can prove the main result in Theorem 10.

Proof [of Theorem 10] We first show that $\mathrm{supp}(\bar{x}) = \mathrm{supp}(x^\star, \bar{k})$ if the condition (1) is satisfied. Assume otherwise $\mathrm{supp}(\bar{x}) \neq \mathrm{supp}(x^\star, \bar{k})$. From the optimality of $x^\star$ and $k \geq \bar{k}$ we have $f(x^\star) \leq f(\bar{x})$. By invoking Lemma 14 and the truncation error bound by Shen & Li (2016, Theorem 1) we get

$$\bar{x}_{\min} \leq \|x^\star_{\bar{k}} - \bar{x}\| \leq 1.62\|x^\star - \bar{x}\| \leq \frac{3.24\sqrt{2k}\|\nabla f(\bar{x})\|_\infty}{m_{2k}} < \frac{4.59\sqrt{k}\|\nabla f(\bar{x})\|_\infty}{m_{2k}},$$

which contradicts the condition.

Next we prove that $\mathrm{supp}(\bar{x}) = \mathrm{supp}(x^\star, \bar{k})$ if the condition (2) is satisfied. Let $\bar{F} = \mathrm{supp}(\bar{x})$ and $F^\star = \mathrm{supp}(x^\star)$. We first claim that $\bar{F} \subseteq F^\star$. Indeed, if otherwise $\bar{F} \nsubseteq F^\star$, then

$$\begin{aligned}\bar{x}_{\min} + \|x^\star_{F^\star\setminus\bar{F}}\| &\leq \|\bar{x} - x^\star\| \\ &\overset{\xi_1}{\leq} \sqrt{\frac{2\max\{f(\bar{x}) - f(x^\star), 0\}}{m_{2k}}} + \frac{2\|\nabla_{\bar{F}\setminus F^\star} f(x^\star)\|}{m_{2k}} \\ &= \sqrt{\frac{2(f(\bar{x}) - f(x^\star))}{m_{2k}}} + \frac{2\|\nabla_{\bar{F}\setminus F^\star} f(x^\star)\|}{m_{2k}},\end{aligned}$$

where "ξ_1" follows from Lemma 14. Since $\bar{x}_{\min} > 1.62\sqrt{\frac{2(f(\bar{x})-f(x^\star))}{m_{2k}}}$, the above inequality leads to

$$\sqrt{k-\bar{k}}x^\star_{\min} \leq \|x^\star_{F^\star\setminus\bar{F}}\| < \frac{2\|\nabla_{\bar{F}\setminus F^\star} f(x^\star)\|}{m_{2k}} \leq \frac{2\sqrt{k}\|\nabla f(x^\star)\|_\infty}{m_{2k}}.$$

Since $k \geq \left(1 + \frac{4M^2_{2k}}{m^2_{2k}}\right)\bar{k}$, we thus have $x^\star_{\min} < \frac{\|\nabla f(x^\star)\|_\infty}{M_{2k}}$. This contradicts Lemma 21. Therefore we must have $\bar{F} \subseteq F^\star$. Now let us assume $\mathrm{supp}(\bar{x}) \neq \mathrm{supp}(x^\star, \bar{k})$. Then

$$\begin{aligned}\bar{x}_{\min} &\leq \|\bar{x} - x^\star_{\bar{k}}\| \\ &\overset{\xi_1}{\leq} 1.62\|\bar{x} - x^\star\| \\ &\overset{\xi_2}{\leq} 1.62\left(\sqrt{\frac{2(f(\bar{x}) - f(x^\star))}{m_{2k}}} + \frac{2\|\nabla_{\bar{F}\setminus F^\star} f(x^\star)\|}{m_{2k}}\right) \\ &\overset{\xi_3}{=} 1.62\sqrt{\frac{2(f(\bar{x}) - f(x^\star))}{m_{2k}}} < 2.3\sqrt{\frac{f(\bar{x}) - f(x^\star)}{m_{2k}}},\end{aligned}$$

where "ξ_1" is based on the truncation error bound by Shen & Li (2016, Theorem 1), "ξ_2" follows from Lemma 14 and the fact of $f(\bar{x}) \geq f(x^\star)$, and "$\xi_3$" is the consequence of $\bar{F} \subseteq F^\star$. This above inequality contradicts the assumption on $\bar{x}_{\min}$. Therefore, it must hold that $\mathrm{supp}(\bar{x}) = \mathrm{supp}(x^\star, \bar{k})$. ■

Appendix D. Some Technical Details in Section 5

In this appendix section, we give the proof of Proposition 12 and present some implementation details of the proposed ADMM method for solving the subproblem (13).

D.1 Proof of Proposition 12

Proof It is straightforward to show that

$$\|\nabla f(\bar{w})\|_\infty \leq \|\nabla l(\bar{w})\|_\infty + \lambda\|\bar{w}\|_\infty. \tag{30}$$

We next bound the term $\|\nabla l(\bar{w})\|_\infty$. From (10) we have

$$\begin{aligned}\left|\frac{\partial l}{\partial[\bar{w}]_j}\right| &= \left|\frac{1}{n}\sum_{i=1}^n -v^{(i)}[u^{(i)}]_j + \mathbb{E}_v[v[u^{(i)}]_j \mid u^{(i)}]\right| \\ &\leq \left|\frac{1}{n}\sum_{i=1}^n v^{(i)}[u^{(i)}]_j - \mathbb{E}[v[u]_j]\right| + \left|\frac{1}{n}\sum_{i=1}^n \mathbb{E}_v[v[u^{(i)}]_j \mid u^{(i)}] - \mathbb{E}[v[u]_j]\right|,\end{aligned}$$

where $\mathbb{E}[\cdot]$ is taken over the distribution (9). Therefore, for any $\varepsilon > 0$,

$$\begin{aligned}\mathbb{P}\left(\left|\frac{\partial l}{\partial[\bar{w}]_j}\right| > \varepsilon\right) \leq& \mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^n v^{(i)}[u^{(i)}]_j - \mathbb{E}[v[u]_j]\right| > \frac{\varepsilon}{2}\right) \\ &+ \mathbb{P}\left(\left|\frac{1}{n}\sum_{i=1}^n \mathbb{E}_v[v[u^{(i)}]_j \mid u^{(i)}] - \mathbb{E}[v[u]_j]\right| > \frac{\varepsilon}{2}\right) \\ \overset{\xi_1}{\leq}& 4\exp\left\{-\frac{n\varepsilon^2}{8\sigma^2}\right\},\end{aligned}$$

where "ξ_1" follows from the large deviation inequality of sub-Gaussian random variables which is standard (see, e.g., Vershynin, 2011). By the union bound we have

$$\mathbb{P}(\|\nabla l(\bar{w})\|_\infty > \varepsilon) \quad \leq \quad 4p\exp\left\{-\frac{n\varepsilon^2}{8\sigma^2}\right\}.$$

By choosing $\varepsilon = 4\sigma\sqrt{\ln p/n}$ in the above inequality we obtain that with probability at least $1 - 4p^{-1}$,

$$\|\nabla l(\bar{w})\|_\infty \leq 4\sigma\sqrt{\ln p/n}.$$

Combining the above bound with (30) yields the desired result. ■

D.2 The ADMM Method for Solving the Subproblem (13)

Now we present the algorithmic procedure of ADMM for solving the subproblem (13). By introducing an auxiliary variable $\Theta \in \mathbb{R}^{p\times p}$, this subproblem can be equivalently formulated as

$$\min_{\alpha I \preceq \Omega \preceq \beta I} L(\Omega), \quad \text{s.t. } \Omega = \Theta, \ \text{supp}(\Theta) \subseteq F. \tag{31}$$

Then, the augmented Lagrangian function of (31) is

$$J(\Omega, \Theta, \Gamma) := L(\Omega) - \langle \Gamma, \Omega - \Theta\rangle + \frac{\rho}{2}\|\Omega - \Theta\|_{Frob}^2,$$

where $\Gamma \in \mathbb{R}^{p\times p}$ is the multiplier of the linear constraint $\Omega = \Theta$ and $\rho > 0$ is the penalty strength parameter for the violation of the linear constraint. The ADMM method alternately solves the following problems to generate the new iterate:

$$\Omega^{(\tau)} = \underset{\alpha I \preceq \Omega \preceq \beta I}{\arg\min}\ J(\Omega, \Theta^{(\tau-1)}, \Gamma^{(\tau-1)}), \tag{32}$$

$$\Theta^{(\tau)} = \underset{\text{supp}(\Theta)\subseteq F}{\arg\min}\ J(\Omega^{(\tau)}, \Theta, \Gamma^{(\tau-1)}), \tag{33}$$

$$\Gamma^{(\tau)} = \Gamma^{(\tau-1)} - \rho(\Omega^{(\tau)} - \Theta^{(\tau)}).$$

Let us first consider the minimization problem (32) for updating $\Omega^{(\tau)}$. It is equivalent to the following minimization problem:

$$\Omega^{(\tau)} = \underset{\alpha I \preceq \Omega \preceq \beta I}{\arg\min}\ \frac{1}{2}\|\Omega - M\|_{Frob}^2 - \frac{1}{\rho}\log\det\Omega,$$

where

$$M = \Theta^{(\tau-1)} - \frac{1}{\rho}(\Sigma_n - \Gamma^{(\tau-1)}).$$

Let the eigenvalue decomposition of M be

$$M = V\Lambda V^\top, \quad \text{with } \Lambda = \text{diag}(\lambda_1, ..., \lambda_n).$$

It is easy to verify that the solution of problem (32) is given by

$$\Omega^{(\tau)} = V\tilde{\Lambda}V^\top, \quad \text{with } \tilde{\Lambda} = \text{diag}(\tilde{\lambda}_1, ..., \tilde{\lambda}_n),$$

where

$$\tilde{\lambda}_j = \min\left\{\beta, \max\left\{\alpha, \frac{\lambda_j + \sqrt{\lambda_j^2 + 4/\rho}}{2}\right\}\right\}.$$

Next, we consider the minimization problem (33) for updating $\Theta^{(\tau)}$. It is straightforward to see that the solution of problem (33) is given by

$$\Theta^{(\tau)} = \left[\Omega^{(\tau)} - \frac{1}{\rho}\Gamma^{(\tau-1)}\right]_F.$$

Abstract

In many sequential decision-making problems one is interested in minimizing an expected cumulative cost while taking into account *risk*, i.e., increased awareness of events of small probability and high consequences. Accordingly, the objective of this paper is to present efficient reinforcement learning algorithms for risk-constrained Markov decision processes (MDPs), where risk is represented via a chance constraint or a constraint on the conditional value-at-risk (CVaR) of the cumulative cost. We collectively refer to such problems as percentile risk-constrained MDPs. Specifically, we first derive a formula for computing the gradient of the Lagrangian function for percentile risk-constrained MDPs. Then, we devise policy gradient and actor-critic algorithms that (1) estimate such gradient, (2) update the policy in the descent direction, and (3) update the Lagrange multiplier in the ascent direction. For these algorithms we prove convergence to locally optimal policies. Finally, we demonstrate the effectiveness of our algorithms in an optimal stopping problem and an online marketing application.

Keywords: Markov Decision Process, Reinforcement Learning, Conditional Value-at-Risk, Chance-Constrained Optimization, Policy Gradient Algorithms, Actor-Critic Algorithms

1. Introduction

The most widely-adopted optimization criterion for Markov decision processes (MDPs) is represented by the *risk-neutral* expectation of a cumulative cost. However, in many applications one is interested in taking into account risk, i.e., increased awareness of events of small probability and high consequences. Accordingly, in *risk-sensitive* MDPs the objective is to minimize a risk-sensitive criterion such as the expected exponential utility, a variance-related measure, or percentile performance. There are several risk metrics available in the literature, and constructing a "good" risk criterion in a manner that is both conceptually meaningful and computationally tractable remains a topic of current research.

Risk-Sensitive MDPs: One of the earliest risk metrics used for risk-sensitive MDPs is the exponential risk metric $(1/\gamma)\mathbb{E}\big[\exp(\gamma Z)\big]$, where Z represents the cumulative cost for a sequence of decisions (Howard and Matheson, 1972). In this setting, the degree of risk-aversion is controlled by the parameter γ, whose selection, however, is often challenging. This motivated the study of several different approaches. In Collins (1997), the authors considered the maximization of a strictly concave functional of the distribution of the terminal state. In Wu and Lin (1999); Boda et al. (2004); Filar et al. (1995), risk-sensitive MDPs are cast as the problem of maximizing percentile performance. Variance-related risk metrics are considered, e.g., in Sobel (1982); Filar et al. (1989). Other mean, variance, and probabilistic criteria for risk-sensitive MDPs are discussed in the survey (White, 1988).

Numerous alternative risk metrics have recently been proposed in the literature, usually with the goal of providing an "intuitive" notion of risk and/or to ensure computational tractability. *Value-at-risk* (VaR) and *conditional value-at-risk* (CVaR) represent two promising such alternatives. They both aim at quantifying costs that might be encountered in the tail of a cost distribution, but in different ways. Specifically, for continuous cost distributions, VaR_α measures risk as the maximum cost that might be incurred with respect to a given confidence level α. This risk metric is particularly useful when there is a well-defined failure state, e.g., a state that leads a robot to collide with an obstacle. A VaR_α constraint is often referred to as a chance (probability) constraint, especially in the engineering literature, and we will use this terminology in the remainder of the paper. In contrast, CVaR_α measures risk as the expected cost given that such cost is greater than or equal to VaR_α, and provides a number of theoretical and computational advantages. CVaR optimization was first developed by Rockafellar and Uryasev (Rockafellar and Uryasev, 2002, 2000) and its numerical effectiveness has been demonstrated in several portfolio optimization and option hedging problems. Risk-sensitive MDPs with a conditional value at risk metric were considered in Boda and Filar (2006); Ott (2010); Bäuerle and Ott (2011), and a mean-average-value-at-risk problem has been solved in Bäuerle and Mundt (2009) for minimizing risk in financial markets.

The aforementioned works focus on the derivation of exact solutions, and the ensuing algorithms are only applicable to relatively small problems. This has recently motivated the application of reinforcement learning (RL) methods to risk-sensitive MDPs. We will refer to such problems as risk-sensitive RL.

Risk-Sensitive RL: To address large-scale problems, it is natural to apply reinforcement learning (RL) techniques to risk-sensitive MDPs. Reinforcement learning (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998) can be viewed as a class of sampling-based methods for solving MDPs. Popular reinforcement learning techniques include policy gradient (Williams, 1992; Marbach, 1998; Baxter and Bartlett, 2001) and actor-critic methods (Sutton et al., 2000; Konda and Tsitsiklis, 2000; Peters et al., 2005; Borkar, 2005; Bhatnagar et al., 2009; Bhatnagar and Lakshmanan, 2012), whereby policies are parameterized in terms of a parameter vector and policy search is performed via gradient flow approaches. One effective way to estimate gradients in RL problems is by simultaneous perturbation stochastic approximation (SPSA) (Spall, 1992). Risk-sensitive RL with expected exponential utility has been considered in Borkar (2001, 2002). More recently, the works in Tamar et al. (2012); Prashanth and Ghavamzadeh (2013) present RL algorithms for several variance-related risk measures, the works in Morimura et al. (2010); Tamar et al. (2015); Petrik and Subramanian (2012) consider CVaR-based formulations, and the works in Tallec (2007); Shapiro et al. (2013) consider nested CVaR-based formulations.

Risk-Constrained RL and Paper Contributions: Despite the rather large literature on risk-sensitive MDPs and RL, *risk-constrained* formulations have largely gone unaddressed, with only a few exceptions, e.g., Chow and Pavone (2013); Borkar and Jain (2014). Yet constrained formulations naturally arise in several domains, including engineering, finance, and logistics, and provide a principled approach to address multi-objective problems. The objective of this paper is to fill this gap by devising policy gradient and actor-critic algorithms for risk-constrained MDPs, where risk is represented via a constraint on the conditional value-at-risk (CVaR) of the cumulative cost or as a chance constraint. Specifically, the contribution of this paper is fourfold.

1. We formulate two risk-constrained MDP problems. The first one involves a CVaR constraint and the second one involves a chance constraint. For the CVaR-constrained optimization problem, we consider both discrete and continuous cost distributions. By re-writing the problems using a Lagrangian formulation, we derive for both problems a Bellman optimality condition with respect to an augmented MDP whose state consists of two parts, with the first part capturing the state of the original MDP and the second part keeping track of the cumulative constraint cost.

2. We devise a trajectory-based policy gradient algorithm for both CVaR-constrained and chance-constrained MDPs. The key novelty of this algorithm lies in an unbiased gradient estimation procedure under Monte Carlo sampling. Using an ordinary differential equation (ODE) approach, we establish convergence of the algorithm to locally optimal policies.

3. Using the aforementioned Bellman optimality condition, we derive several actor-critic algorithms to optimize policy and value function approximation parameters in an online fashion. As for the trajectory-based policy gradient algorithm, we show that the proposed actor-critic algorithms converge to locally optimal solutions.

4. We demonstrate the effectiveness of our algorithms in an optimal stopping problem as well as in a realistic personalized advertisement recommendation (ad recommendation) problem (see Derfer et al. (2007) for more details). For the latter problem, we empirically show that our CVaR-constrained RL algorithms successfully guarantee that the worst-case revenue is lower-bounded by the pre-specified company yearly target.

The rest of the paper is structured as follows. In Section 2 we introduce our notation and rigorously state the problem we wish to address, namely risk-constrained RL. The next two sections provide various RL methods to approximately compute (locally) optimal policies for CVaR constrained MDPs. A trajectory-based policy gradient algorithm is presented in Section 3 and its convergence analysis is provided in Appendix A (Appendix A.1 provides the gradient estimates of the CVaR parameter, the policy parameter, and the Lagrange multiplier, and Appendix A.2 gives their convergence proofs). Actor-critic algorithms are presented in Section 4 and their convergence analysis is provided in Appendix B (Appendix B.1 derives the gradient of the Lagrange multiplier as a function of the state-action value function, Appendix B.2.1 analyzes the convergence of the critic, and Appendix B.2.2 provides the multi-timescale convergence results of the CVaR parameter, the policy parameter, and the Lagrange multiplier). Section 5 extends the above policy gradient and actor-critic methods to the chance-constrained case. Empirical evaluation of our algorithms is the subject of Section 6. Finally, we conclude the paper in Section 7, where we also provide directions for future work.

This paper generalizes earlier results by the authors presented in Chow and Ghavamzadeh (2014).

2. Preliminaries

We begin by defining some notation that is used throughout the paper, as well as defining the problem addressed herein and stating some basic assumptions.

2.1 Notation

We consider decision-making problems modeled as a finite MDP (an MDP with finite state and action spaces). A finite MDP is a tuple $(\mathcal{X}, \mathcal{A}, C, D, P, P_0)$ where $\mathcal{X} = \{1, \ldots, n, x_{\text{Tar}}\}$ and $\mathcal{A} = \{1, \ldots, m\}$ are the state and action spaces, x_{Tar} is a recurrent target state, and for a state x and an action a, $C(x, a)$ is a cost function with $|C(x, a)| \leq C_{\max}$, $D(x, a)$ is a constraint cost function with $|D(x, a)| \leq D_{\max}$ [1], $P(\cdot|x, a)$ is the transition probability distribution, and $P_0(\cdot)$ is the initial state distribution. For simplicity, in this paper we assume $P_0 = \mathbf{1}\{x = x^0\}$ for some given initial state $x^0 \in \{1, \ldots, n\}$. Generalizations to non-atomic initial state distributions are straightforward, for which the details are omitted for the sake of brevity. A *stationary policy* $\mu(\cdot|x)$ for an MDP is a probability distribution over actions, conditioned on the current state. In policy gradient methods, such policies are parameterized by a κ-dimensional vector θ, so the space of policies can be written as $\{\mu(\cdot|x; \theta), x \in \mathcal{X}, \theta \in \Theta \subseteq R^\kappa\}$. Since in this setting a policy μ is uniquely defined by its parameter vector θ, policy-dependent functions can be written as a function of μ or θ, and we use $\mu(\cdot|x; \theta)$ to denote the policy and θ to denote the dependency on the policy (parameter).

Given a fixed $\gamma \in (0, 1)$, we denote by $d^\mu_\gamma(x|x^0) = (1-\gamma)\sum_{k=0}^\infty \gamma^k \mathbb{P}(x_k = x|x_0 = x^0; \mu)$ and $\pi^\mu_\gamma(x, a|x^0) = d^\mu_\gamma(x|x^0)\mu(a|x)$, the γ-discounted occupation measure of state x and state-action pair (x, a) under policy μ, respectively. This occupation measure is a γ-discounted probability distribution for visiting each state and action pair, and it plays an important role in sampling states and actions from the real system in policy gradient and actor-critic algorithms, and in guaranteeing their convergence. Because the state and action spaces are finite, Theorem 3.1 in Altman (1999) shows that the occupation measure $d^\mu_\gamma(x|x^0)$ is a well-defined probability distribution. On the other hand, when $\gamma = 1$ the occupation measure of state x and state-action pair (x, a) under policy μ are respectively defined by $d^\mu(x|x^0) = \sum_{t=0}^\infty \mathbb{P}(x_t = x|x^0; \mu)$ and $\pi^\mu(x, a|x^0) = d^\mu(x|x^0)\mu(a|x)$. In this case the occupation measures characterize the total sums of visiting probabilities (although they are not in general probability distributions themselves) of state x and state-action pair (x, a). To study the well-posedness of the occupation measure, we define the following notion of a transient MDP.

Definition 1 *Define $\mathcal{X}' = \mathcal{X} \setminus \{x_{Tar}\} = \{1, \ldots, n\}$ as a state space of transient states. An MDP is said to be transient if,*

1. *$\sum_{k=0}^\infty \mathbb{P}(x_k = x|x^0, \mu) < \infty$ for every $x \in \mathcal{X}'$ and every stationary policy μ,*

2. *$P(x_{Tar}|x_{Tar}, a) = 1$ for every admissible control action $a \in \mathcal{A}$.*

Furthermore let $T_{\mu,x}$ be the first-hitting time of the target state x_{Tar} from an arbitrary initial state $x \in \mathcal{X}$ in the Markov chain induced by transition probability $P(\cdot|x, a)$ and policy μ. Although transience implies the first-hitting time is square integrable and finite almost surely, we will make the stronger assumption (which implies transience) on the uniform boundedness of the first-hitting time.

1. Without loss of generality, we set the cost function $C(x, a)$ and constraint cost function $D(x, a)$ to zero when $x = x_{\text{Tar}}$.

Assumption 2 *The first-hitting time $T_{\mu,x}$ is bounded almost surely over all stationary policies μ and all initial states $x \in \mathcal{X}$. We will refer to this upper bound as T, i.e., $T_{\mu,x} \leq T$ almost surely.*

The above assumption can be justified by the fact that sample trajectories collected in most reinforcement learning algorithms (including policy gradient and actor-critic methods) consist of bounded finite stopping time (also known as a time-out). Note that although a bounded stopping time would seem to conflict with the time-stationarity of the transition probabilities, this can be resolved by augmenting the state space with a time-counter state, analogous to the arguments given in Section 4.7 in Bertsekas (1995).

Finally, we define the constraint and cost functions. Let Z be a finite-mean ($\mathbb{E}[|Z|] < \infty$) random variable representing cost, with the cumulative distribution function $F_Z(z) = \mathbb{P}(Z \leq z)$ (e.g., one may think of Z as the total cost of an investment strategy μ). We define the *value-at-risk* at confidence level $\alpha \in (0,1)$ as

$$\text{VaR}_\alpha(Z) = \min\big\{z \mid F_Z(z) \geq \alpha\big\}.$$

Here the minimum is attained because F_Z is non-decreasing and right-continuous in z. When F_Z is continuous and strictly increasing, $\text{VaR}_\alpha(Z)$ is the unique z satisfying $F_Z(z) = \alpha$. As mentioned, we refer to a constraint on the VaR as a chance constraint.

Although VaR is a popular risk measure, it is not a *coherent* risk measure (Artzner et al., 1999) and does not quantify the costs that might be suffered beyond its value in the α-tail of the distribution (Rockafellar and Uryasev, 2000), Rockafellar and Uryasev (2002). In many *financial applications* such as portfolio optimization where the probability of undesirable events could be small but the cost incurred could still be significant, besides describing risk as the probability of incurring costs, it will be more interesting to study the cost in the tail of the risk distribution. In this case, an alternative measure that addresses most of the VaR's shortcomings is the *conditional value-at-risk*, defined as (Rockafellar and Uryasev, 2000)

$$\text{CVaR}_\alpha(Z) := \min_{\nu \in \mathbb{R}} \Big\{\nu + \frac{1}{1-\alpha}\mathbb{E}\big[(Z-\nu)^+\big]\Big\}, \tag{1}$$

where $(x)^+ = \max(x, 0)$ represents the positive part of x. While it might not be an immediate observation, it has been shown in Theorem 1 of Rockafellar and Uryasev (2000) that the CVaR of the loss random variable Z is equal to the average of the worst-case α-fraction of losses.

We define the parameter $\gamma \in (0,1]$ as the *discounting factor* for the cost and constraint cost functions. When $\gamma < 1$, we are aiming to solve the MDP problem with more focus on optimizing current costs over future costs. For a policy μ, we define the cost of a state x (state-action pair (x,a)) as the sum of (discounted) costs encountered by the decision-maker when it starts at state x (state-action pair (x,a)) and then follows policy μ, i.e.,

$$\mathcal{G}^\theta(x) = \sum_{k=0}^{T-1} \gamma^k C(x_k, a_k) \mid x_0 = x,\ \mu(\cdot|\cdot,\theta), \qquad \mathcal{J}^\theta(x) = \sum_{k=0}^{T-1} \gamma^k D(x_k, a_k) \mid x_0 = x,\ \mu(\cdot|\cdot,\theta),$$

and

$$\mathcal{G}^\theta(x,a) = \sum_{k=0}^{T-1} \gamma^k C(x_k, a_k) \mid x_0 = x,\ a_0 = a,\ \mu(\cdot|\cdot,\theta),$$
$$\mathcal{J}^\theta(x,a) = \sum_{k=0}^{T-1} \gamma^k D(x_k, a_k) \mid x_0 = x,\ a_0 = a,\ \mu(\cdot|\cdot,\theta).$$

The expected values of the random variables $\mathcal{G}^\theta(x)$ and $\mathcal{G}^\theta(x,a)$ are known as the value and action-value functions of policy μ, and are denoted by

$$V^\theta(x) = \mathbb{E}\big[\mathcal{G}^\theta(x)\big], \qquad Q^\theta(x,a) = \mathbb{E}\big[\mathcal{G}^\theta(x,a)\big].$$

2.2 Problem Statement

The goal for standard discounted MDPs is to find an optimal policy that solves

$$\theta^* = \operatorname*{argmin}_\theta V^\theta(x^0).$$

For *CVaR-constrained* optimization in MDPs, we consider the discounted cost optimization problem with $\gamma \in (0,1)$, i.e., for a given confidence level $\alpha \in (0,1)$ and cost tolerance $\beta \in \mathbb{R}$,

$$\min_\theta V^\theta(x^0) \qquad \text{subject to} \qquad \text{CVaR}_\alpha\big(\mathcal{J}^\theta(x^0)\big) \leq \beta. \tag{2}$$

Using the definition of $H_\alpha(Z,\nu)$, one can reformulate (2) as:

$$\min_{\theta,\nu} V^\theta(x^0) \qquad \text{subject to} \qquad H_\alpha\big(\mathcal{J}^\theta(x^0),\nu\big) \leq \beta, \tag{3}$$

where

$$H_\alpha(Z,\nu) := \nu + \frac{1}{1-\alpha}\mathbb{E}\big[(Z-\nu)^+\big].$$

The equivalence between problem (2) and problem (3) can be shown as follows. Let $\theta_2 \in \Theta$ be any arbitrary feasible policy parameter of problem (2). With θ_2, one can always construct $\nu_2 = \text{VaR}_\alpha(\mathcal{J}^{\theta_2}(x^0))$, such that (θ_2, ν_2) is feasible to problem (3). This in turn implies that the solution of (3) is less than the solution of (2). On the other hand, the following chain of inequalities holds for any $\nu \in \mathbb{R}$: $\text{CVaR}_\alpha\big(\mathcal{J}^\theta(x^0)\big) \leq H_\alpha\big(\mathcal{J}^\theta(x^0),\nu\big) \leq \beta$. This implies that the feasible set of θ in problem (3) is a subset of the feasible set of θ in problem (2), which further indicates that the solution of problem (2) is less than the solution of problem (3). By combining both arguments, one concludes the equivalence relation of these two problems.

It is shown in Rockafellar and Uryasev (2000) and Rockafellar and Uryasev (2002) that the optimal ν actually equals VaR_α, so we refer to this parameter as the VaR parameter. Here we choose to analyze the discounted-cost CVaR-constrained optimization problem, i.e., with $\gamma \in (0,1)$, as in many financial and marketing applications where CVaR constraints are used, it is more intuitive to put more emphasis on current costs rather than on future costs. The analysis can be easily generalized for the case where $\gamma = 1$.

For *chance-constrained* optimization in MDPs, we consider the stopping cost optimization problem with $\gamma = 1$, i.e., for a given confidence level $\beta \in (0,1)$ and cost tolerance $\alpha \in \mathbb{R}$,

$$\min_\theta V^\theta(x^0) \qquad \text{subject to} \qquad \mathbb{P}\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) \leq \beta. \tag{4}$$

Here we choose $\gamma = 1$ because in many engineering applications, where chance constraints are used to ensure overall safety, there is no notion of discounting since future threats are often as important as the current one. Similarly, the analysis can be easily extended to the case where $\gamma \in (0,1)$.

There are a number of mild technical and notational assumptions which we will make throughout the paper, so we state them here:

Assumption 3 (Differentiability) *For any state-action pair (x,a), $\mu(a|x;\theta)$ is continuously differentiable in θ and $\nabla_\theta \mu(a|x;\theta)$ is a Lipschitz function in θ for every $a \in \mathcal{A}$ and $x \in \mathcal{X}$.*[2]

2. In actor-critic algorithms, the assumption on continuous differentiability holds for the augmented state Markovian policies $\mu(a|x,s;\theta)$.

Assumption 4 (Strict Feasibility) *There exists a transient policy $\mu(\cdot|x;\theta)$ such that*

$$H_\alpha\big(\mathcal{J}^\theta(x^0),\nu\big) < \beta$$

in the CVaR-constrained optimization problem, and $P\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) < \beta$ in the chance-constrained problem.

In the remainder of the paper we first focus on studying stochastic approximation algorithms for the CVaR-constrained optimization problem (Sections 3 and 4) and then adapt the results to the chance-constrained optimization problem in Section 5. Our solution approach relies on a Lagrangian relaxation procedure, which is discussed next.

2.3 Lagrangian Approach and Reformulation

To solve (3), we employ a Lagrangian relaxation procedure (Chapter 3 of Bertsekas (1999)), which leads to the unconstrained problem:

$$\max_{\lambda\geq 0}\min_{\theta,\nu}\Big(L(\nu,\theta,\lambda) := V^\theta(x^0) + \lambda\Big(H_\alpha\big(\mathcal{J}^\theta(x^0),\nu\big) - \beta\Big)\Big), \tag{5}$$

where λ is the Lagrange multiplier. Notice that $L(\nu,\theta,\lambda)$ is a linear function in λ and $H_\alpha\big(\mathcal{J}^\theta(x^0),\nu\big)$ is a continuous function in ν. The saddle point theorem from Chapter 3 of Bertsekas (1999) states that a local saddle point $(\nu^*,\theta^*,\lambda^*)$ for the maximin optimization problem $\max_{\lambda\geq 0}\min_{\theta,\nu} L(\nu,\theta,\lambda)$ is indeed a locally optimal policy θ^* for the CVaR-constrained optimization problem. To further explore this connection, we first have the following definition of a saddle point:

Definition 5 *A local saddle point of $L(\nu,\theta,\lambda)$ is a point $(\nu^*,\theta^*,\lambda^*)$ such that for some $r>0$, $\forall(\theta,\nu)\in\Theta\times\Big[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}\Big]\cap\mathcal{B}_{(\theta^*,\nu^*)}(r)$ and $\forall\lambda\geq 0$, we have*

$$L(\nu,\theta,\lambda^*) \geq L(\nu^*,\theta^*,\lambda^*) \geq L(\nu^*,\theta^*,\lambda), \tag{6}$$

where $\mathcal{B}_{(\theta^*,\nu^*)}(r)$ is a hyper-dimensional ball centered at (θ^*,ν^*) with radius $r>0$.

In Chapter 7 of Ott (2010) and in Bäuerle and Ott (2011) it is shown that there exists a *deterministic history-dependent* optimal policy for CVaR-constrained optimization. The important point is that this policy does not depend on the complete history, but only on the current time step k, current state of the system x_k, and accumulated discounted constraint cost $\sum_{i=0}^k \gamma^i D(x_k,a_k)$.

In the following two sections, we present a policy gradient (PG) algorithm (Section 3) and several actor-critic (AC) algorithms (Section 4) to optimize (5) (and hence find a locally optimal solution to problem (3)). While the PG algorithm updates its parameters after observing several trajectories, the AC algorithms are incremental and update their parameters at each time-step.

3. A Trajectory-based Policy Gradient Algorithm

In this section, we present a policy gradient algorithm to solve the optimization problem (5). The idea of the algorithm is to descend in (θ,ν) and ascend in λ using the gradients of $L(\nu,\theta,\lambda)$ w.r.t. θ, ν, and λ, i.e.,[3]

$$\nabla_\theta L(\nu,\theta,\lambda) = \nabla_\theta V^\theta(x^0) + \frac{\lambda}{(1-\alpha)}\nabla_\theta\mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0)-\nu\big)^+\Big], \tag{7}$$

$$\partial_\nu L(\nu,\theta,\lambda) = \lambda\Bigg(1+\frac{1}{(1-\alpha)}\partial_\nu\mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0)-\nu\big)^+\Big]\Bigg) \ni \lambda\Bigg(1-\frac{1}{(1-\alpha)}\mathbb{P}\big(\mathcal{J}^\theta(x^0)\geq\nu\big)\Bigg), \tag{8}$$

$$\nabla_\lambda L(\nu,\theta,\lambda) = \nu + \frac{1}{(1-\alpha)}\mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0)-\nu\big)^+\Big] - \beta. \tag{9}$$

The unit of observation in this algorithm is a trajectory generated by following the current policy. At each iteration, the algorithm generates N trajectories by following the current policy, uses them to estimate the gradients in (7)–(9), and then uses these estimates to update the parameters ν,θ,λ.

Let $\xi=\{x_0,a_0,c_0,x_1,a_1,c_1,\ldots,x_{T-1},a_{T-1},c_{T-1},x_T\}$ be a trajectory generated by following the policy θ, where $x_T = x_{\text{Tar}}$ is the target state of the system. The cost, constraint cost, and probability of ξ are defined as $\mathcal{G}(\xi)=\sum_{k=0}^{T-1}\gamma^k C(x_k,a_k)$, $\mathcal{J}(\xi)=\sum_{k=0}^{T-1}\gamma^k D(x_k,a_k)$, and $\mathbb{P}_\theta(\xi)=P_0(x_0)\prod_{k=0}^{T-1}\mu(a_k|x_k;\theta)P(x_{k+1}|x_k,a_k)$, respectively. Based on the definition of $\mathbb{P}_\theta(\xi)$, one obtains $\nabla_\theta\log\mathbb{P}_\theta(\xi)=\sum_{k=0}^{T-1}\nabla_\theta\log\mu(a_k|x_k;\theta)$.

Algorithm 1 contains the pseudo-code of our proposed policy gradient algorithm. What appears inside the parentheses on the right-hand-side of the update equations are the estimates of the gradients of $L(\nu,\theta,\lambda)$ w.r.t. θ,ν,λ (estimates of (7)–(9)). Gradient estimates of the Lagrangian function can be found in Appendix A.1. In the algorithm, Γ_Θ is an operator that projects a vector $\theta\in\mathbb{R}^\kappa$ to the closest point in a compact and convex set $\Theta\subset\mathbb{R}^\kappa$, i.e., $\Gamma_\Theta(\theta)=\arg\min_{\hat{\theta}\in\Theta}\|\theta-\hat{\theta}\|_2^2$, $\Gamma_\mathcal{N}$ is a projection operator to $[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]$, i.e., $\Gamma_\mathcal{N}(\nu)=\arg\min_{\hat{\nu}\in[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]}\|\nu-\hat{\nu}\|_2^2$, and Γ_Λ is a projection operator to $[0,\lambda_{\max}]$, i.e., $\Gamma_\Lambda(\lambda)=\arg\min_{\hat{\lambda}\in[0,\lambda_{\max}]}\|\lambda-\hat{\lambda}\|_2^2$. These projection operators are necessary to ensure the convergence of the algorithm; see the end of Appendix A.2 for details. Next we introduce the following assumptions for the step-sizes of the policy gradient method in Algorithm 1.

Assumption 6 (Step Sizes for Policy Gradient) *The step size schedules $\{\zeta_1(k)\}$, $\{\zeta_2(k)\}$, and $\{\zeta_3(k)\}$ satisfy*

$$\sum_k\zeta_1(k)=\sum_k\zeta_2(k)=\sum_k\zeta_3(k)=\infty, \tag{10}$$

$$\sum_k\zeta_1(k)^2,\quad\sum_k\zeta_2(k)^2,\quad\sum_k\zeta_3(k)^2<\infty, \tag{11}$$

$$\zeta_1(k)=o\big(\zeta_2(k)\big),\quad\zeta_2(k)=o\big(\zeta_3(k)\big). \tag{12}$$

These step-size schedules satisfy the standard conditions for stochastic approximation algorithms, and ensure that the ν update is on the fastest time-scale $\{\zeta_3(k)\}$, the policy θ update is on the intermediate time-scale $\{\zeta_2(k)\}$, and the Lagrange multiplier λ update is on the slowest time-scale $\{\zeta_1(k)\}$. This results in a three time-scale stochastic approximation algorithm.

In the following theorem, we prove that our policy gradient algorithm converges to a locally optimal policy for the CVaR-constrained optimization problem.

3. The notation $\ni$ in (8) means that the right-most term is a member of the sub-gradient set $\partial_\nu L(\nu,\theta,\lambda)$.

Theorem 7 *Under Assumptions 2–6, the sequence of policy updates in Algorithm 1 converges almost surely to a locally optimal policy θ^* for the CVaR-constrained optimization problem as k goes to infinity.*

While we refer the reader to Appendix A.2 for the technical details of this proof, a high level overview of the proof technique is given as follows.

1. First we show that each update of the multi-time scale discrete stochastic approximation algorithm $(\nu_k, \theta_k, \lambda_k)$ converges almost surely, but at different speeds, to the stationary point $(\nu^*, \theta^*, \lambda^*)$ of the corresponding continuous time system.

2. Then by using Lyapunov analysis, we show that the continuous time system is locally asymptotically stable at the stationary point $(\nu^*, \theta^*, \lambda^*)$.

3. Since the Lyapunov function used in the above analysis is the Lagrangian function $L(\nu, \theta, \lambda)$, we finally conclude that the stationary point $(\nu^*, \theta^*, \lambda^*)$ is also a local saddle point, which by the saddle point theorem (see e.g., Chapter 3 of Bertsekas (1999)), implies that θ^* is a locally optimal solution of the CVaR-constrained MDP problem (the primal problem).

This convergence proof procedure is standard for stochastic approximation algorithms, see (Bhatnagar et al., 2009; Bhatnagar and Lakshmanan, 2012; Prashanth and Ghavamzadeh, 2013) for more details, and represents the structural backbone for the convergence analysis of the other policy gradient and actor-critic methods provided in this paper.

Notice that the difference in convergence speeds between θ_k, ν_k, and λ_k is due to the step-size schedules. Here ν converges faster than θ and θ converges faster than λ. This multi-time scale convergence property allows us to simplify the convergence analysis by assuming that θ and λ are fixed in ν's convergence analysis, assuming that ν converges to $\nu^*(\theta)$ and λ is fixed in θ's convergence analysis, and finally assuming that ν and θ have already converged to $\nu^*(\lambda)$ and $\theta^*(\lambda)$ in λ's convergence analysis. To illustrate this idea, consider the following two-time scale stochastic approximation algorithm for updating $(x_k, y_k) \in \mathbf{X} \times \mathbf{Y}$:

$$x_{k+1} = x_k + \zeta_1(k)\big(f(x_k, y_k) + M_{k+1}\big), \tag{13}$$

$$y_{k+1} = y_k + \zeta_2(k)\big(g(x_k, y_k) + N_{k+1}\big), \tag{14}$$

where $f(x_k, y_k)$ and $g(x_k, y_k)$ are Lipschitz continuous functions, M_{k+1}, N_{k+1} are square integrable Martingale differences w.r.t. the σ-fields $\sigma(x_i, y_i, M_i, i \leq k)$ and $\sigma(x_i, y_i, N_i, i \leq k)$, and $\zeta_1(k)$ and $\zeta_2(k)$ are non-summable, square summable step sizes. If $\zeta_2(k)$ converges to zero faster than $\zeta_1(k)$, then (13) is a faster recursion than (14) after some iteration k_0 (i.e., for $k \geq k_0$), which means (13) has uniformly larger increments than (14). Since (14) can be written as

$$y_{k+1} = y_k + \zeta_1(k)\Big(\frac{\zeta_2(k)}{\zeta_1(k)}\big(g(x_k, y_k) + N_{k+1}\big)\Big),$$

and by the fact that $\zeta_2(k)$ converges to zero faster than $\zeta_1(k)$, (13) and (14) can be viewed as noisy Euler discretizations of the ODEs $\dot{x} = f(x, y)$ and $\dot{y} = 0$. Note that one can consider the ODE $\dot{x} = f(x, y_0)$ in place of $\dot{x} = f(x, y)$, where y_0 is constant, because $\dot{y} = 0$. One can then show (see e.g., Theorem 2 in Chapter 6 of Borkar (2008)) the main two-timescale convergence result, i.e., under the above assumptions associated with (14), the sequence (x_k, y_k) converges to $\big(\mu(y^\star), y^\star\big)$ as $i \to \infty$, with probability one, where $\mu(y_0)$ is a locally asymptotically stable equilibrium of the ODE $\dot{x} = f(x, y_0)$, μ is a Lipschitz continuous function, and $y^\star$ is a locally asymptotically stable equilibrium of the ODE $\dot{y} = g\big(\mu(y), y\big)$.

Algorithm 1 Trajectory-based Policy Gradient Algorithm for CVaR MDP

Input: parameterized policy $\mu(\cdot|\cdot;\theta)$, confidence level α, and cost tolerance β
Initialization: policy $\theta = \theta_0$, VaR parameter $\nu = \nu_0$, and the Lagrangian parameter $\lambda = \lambda_0$
while TRUE **do**
  for $k = 0, 1, 2, \ldots$ **do**
    Generate N trajectories $\{\xi_{j,k}\}_{j=1}^N$ by starting at $x_0 = x^0$ and following the current policy θ_k.

$$\nu \textbf{ Update:} \quad \nu_{k+1} = \Gamma_{\mathcal{N}}\Big[\nu_k - \zeta_3(k)\Big(\lambda_k - \frac{\lambda_k}{(1-\alpha)N}\sum_{j=1}^N \mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\}\Big)\Big]$$

$$\theta \textbf{ Update:} \quad \theta_{k+1} = \Gamma_\Theta\Big[\theta_k - \zeta_2(k)\Big(\frac{1}{N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\mathcal{G}(\xi_{j,k}) + \frac{\lambda_k}{(1-\alpha)N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\big(\mathcal{J}(\xi_{j,k}) - \nu_k\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\}\Big)\Big]$$

$$\lambda \textbf{ Update:} \quad \lambda_{k+1} = \Gamma_\Lambda\Big[\lambda_k + \zeta_1(k)\Big(\nu_k - \beta + \frac{1}{(1-\alpha)N}\sum_{j=1}^N \big(\mathcal{J}(\xi_{j,k}) - \nu_k\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\}\Big)\Big]$$

  end for
  if $\{\lambda_k\}$ converges to $\lambda_{\max}$, i.e., $|\lambda_{i^*} - \lambda_{\max}| \leq \epsilon$ for some tolerance parameter $\epsilon > 0$ **then**
    Set $\lambda_{\max} \leftarrow 2\lambda_{\max}$.
  else
    return parameters ν, θ, λ and **break**
  end if
end while

4. Actor-Critic Algorithms

As mentioned in Section 3, the unit of observation in our policy gradient algorithm (Algorithm 1) is a system trajectory. This may result in high variance for the gradient estimates, especially when the length of the trajectories is long. To address this issue, in this section we propose two actor-critic algorithms that approximate some quantities in the gradient estimates by linear combinations of basis functions and update the parameters (linear coefficients) incrementally (after each state-action transition). We present two actor-critic algorithms for optimizing (5). These algorithms are based on the gradient estimates of Sections 4.1-4.3. While the first algorithm (SPSA-based) is fully incremental and updates all the parameters θ, ν, λ at each time-step, the second one updates θ at each time-step and updates ν and λ only at the end of each trajectory, thus is regarded as a semi-trajectory-based method. Algorithm 2 contains the pseudo-code of these algorithms. The projection operators Γ_Θ, $\Gamma_\mathcal{N}$, and Γ_Λ are defined as in Section 3 and are necessary to ensure the convergence of the algorithms. At each step of our actor critic algorithms (steps indexed by k in Algorithm 1 and in Algorithm 2) there are two parts:

- **Inner loop (critic update)**: For a fixed policy (given as $\theta \in \Theta$), take action $a_k \sim \mu(\cdot|x_k, s_k; \theta_k)$, observe the cost $c(x_k, a_k)$, the constraint cost $d(x_k, a_k)$, and the next state (x_{k+1}, s_{k+1}). Us-

ing the method of temporal differences (TD) from Chapter 6 of Sutton and Barto (1998), estimate the value function $V^\theta(x,s)$.

- **Outer loop (actor update)**: Estimate the gradient of $V^\theta(x,s)$ for policy parameter θ, and hence the gradient of the Lagrangian $L(\nu,\theta,\lambda)$, using the unbiased sampling based point estimator for gradients with respect to θ and λ and either: (1) using the SPSA method (20) to obtain an incremental estimator for gradient with respect to ν or (2) only calculating the gradient estimator with respect to ν at the end of the trajectory (see (23) for more details). Update the policy parameter $\theta \in \Theta$ in the descent direction, the VaR approximation $\nu \in \mathcal{N}$ in the descent direction, and the Lagrange multiplier $\lambda \in \Lambda$ in the ascent direction on specific timescales that ensure convergence to locally optimal solutions.

Next, we introduce the following assumptions for the step-sizes of the actor-critic method in Algorithm 2.

Assumption 8 (Step Sizes) *The step size schedules $\{\zeta_1(k)\}$, $\{\zeta_2(k)\}$, $\{\zeta_3(k)\}$, and $\{\zeta_4(k)\}$ satisfy*

$$\sum_k \zeta_1(k) = \sum_k \zeta_2(k) = \sum_k \zeta_3(k) = \sum_k \zeta_4(k) = \infty, \tag{15}$$

$$\sum_k \zeta_1(k)^2, \quad \sum_k \zeta_2(k)^2, \quad \sum_k \zeta_3(k)^2, \quad \sum_k \zeta_4(k)^2 < \infty, \tag{16}$$

$$\zeta_1(k) = o\big(\zeta_2(k)\big), \quad \zeta_2(k) = o\big(\zeta_3(k)\big), \quad \zeta_3(k) = o\big(\zeta_4(k)\big). \tag{17}$$

Furthermore, the SPSA step size $\{\Delta_k\}$ in the actor-critic algorithm satisfies $\Delta_k \to 0$ as $k \to \infty$ and $\sum_k (\zeta_2(k)/\Delta_k)^2 < \infty$.

These step-size schedules satisfy the standard conditions for stochastic approximation algorithms, and ensure that the critic update is on the fastest time-scale $\big\{\zeta_4(k)\big\}$, the policy and VaR parameter updates are on the intermediate time-scale, with the ν-update $\big\{\zeta_3(k)\big\}$ being faster than the θ-update $\big\{\zeta_2(k)\big\}$, and finally the Lagrange multiplier update is on the slowest time-scale $\big\{\zeta_1(k)\big\}$. This results in four time-scale stochastic approximation algorithms.

4.1 Gradient w.r.t. the Policy Parameters θ

The gradient of the objective function w.r.t. the policy θ in (7) may be rewritten as

$$\nabla_\theta L(\nu,\theta,\lambda) = \nabla_\theta \left(\mathbb{E}\big[\mathcal{G}^\theta(x^0)\big] + \frac{\lambda}{(1-\alpha)} \mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0) - \nu\big)^+\Big] \right). \tag{24}$$

Given the original MDP $\mathcal{M} = (\mathcal{X}, \mathcal{A}, C, D, P, P_0)$ and the parameter λ, we define the augmented MDP $\bar{\mathcal{M}} = (\bar{\mathcal{X}}, \bar{\mathcal{A}}, \bar{C}_\lambda, \bar{P}, \bar{P}_0)$ as $\bar{\mathcal{X}} = \mathcal{X} \times \mathcal{S}$, $\bar{\mathcal{A}} = \mathcal{A}$, $\bar{P}_0(x,s) = P_0(x)\mathbf{1}\{s_0 = s\}$, and

$$\bar{C}_\lambda(x,s,a) = \begin{cases} \lambda(-s)^+/(1-\alpha) & \text{if } x = x_{\text{Tar}}, \\ C(x,a) & \text{otherwise}, \end{cases}$$

$$\bar{P}(x',s'|x,s,a) = \begin{cases} P(x'|x,a)\mathbf{1}\{s' = \big(s - D(x,a)\big)/\gamma\} & \text{if } x \in \mathcal{X}', \\ \mathbf{1}\{x' = x_{\text{Tar}}, s' = 0\} & \text{if } x = x_{\text{Tar}}, \end{cases}$$

where x_{Tar} is the target state of the original MDP $\mathcal{M}$, $\mathcal{S}$ and s_0 are respectively the finite state space and the initial state of the s part of the state in the augmented MDP $\bar{\mathcal{M}}$. Furthermore, we denote by

Algorithm 2 Actor-Critic Algorithms for CVaR MDP

Input: Parameterized policy $\mu(\cdot|\cdot;\theta)$ and value function feature vector $\phi(\cdot)$ (both over the augmented MDP $\bar{\mathcal{M}}$), confidence level α, and cost tolerance β
Initialization: policy $\theta = \theta_0$; VaR parameter $\nu = \nu_0$; Lagrangian parameter $\lambda = \lambda_0$; value function weight vector $v = v_0$; initial condition $(x_0, s_0) = (x^0, \nu)$
while TRUE **do**
  // (1) SPSA-based Algorithm:
  for $k = 0, 1, 2, \ldots$ **do**
    Draw action $a_k \sim \mu(\cdot|x_k, s_k; \theta_k)$; Observe cost $\bar{C}_{\lambda_k}(x_k, s_k, a_k)$;
    Observe next state $(x_{k+1}, s_{k+1}) \sim \bar{P}(\cdot|x_k, s_k, a_k)$; *// note that* $s_{k+1} = (s_k - D(x_k, a_k))/\gamma$
    // AC Algorithm:

$$\textbf{TD Error:} \quad \delta_k(v_k) = \bar{C}_{\lambda_k}(x_k, s_k, a_k) + \gamma v_k^\top \phi(x_{k+1}, s_{k+1}) - v_k^\top \phi(x_k, s_k) \tag{18}$$

$$\textbf{Critic Update:} \quad v_{k+1} = v_k + \zeta_4(k)\delta_k(v_k)\phi(x_k, s_k) \tag{19}$$

$$\nu \textbf{ Update:} \quad \nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\Big(\lambda_k + \frac{v_k^\top\big[\phi\big(x^0, \nu_k + \Delta_k\big) - \phi\big(x^0, \nu_k - \Delta_k\big)\big]}{2\Delta_k}\Big)\right) \tag{20}$$

$$\theta \textbf{ Update:} \quad \theta_{k+1} = \Gamma_\Theta\Big(\theta_k - \frac{\zeta_2(k)}{1-\gamma}\nabla_\theta \log \mu(a_k|x_k, s_k; \theta) \cdot \delta_k(v_k)\Big) \tag{21}$$

$$\lambda \textbf{ Update:} \quad \lambda_{k+1} = \Gamma_\Lambda\Big(\lambda_k + \zeta_1(k)\big(\nu_k - \beta + \frac{1}{(1-\alpha)(1-\gamma)}\mathbf{1}\{x_k = x_{\text{Tar}}\}(-s_k)^+\big)\Big) \tag{22}$$

    if $x_k = x_{\text{Tar}}$ (reach a target state), **then** set $(x_{k+1}, s_{k+1}) = (x^0, \nu_{k+1})$
  end for
  // (2) Semi Trajectory-based Algorithm:
  Initialize $t = 0$
  for $k = 0, 1, 2, \ldots$ **do**
    Draw action $a_k \sim \mu(\cdot|x_k, s_k; \theta_k)$, observe cost $\bar{C}_{\lambda_k}(x_k, s_k, a_k)$, and next state $(x_{k+1}, s_{k+1}) \sim \bar{P}(\cdot|x_k, s_k, a_k)$; Update $(\delta_k, v_k, \theta_k, \lambda_k)$ using Eqs. (18), (19), (21), and (22)
    if $x_k = x_{\text{Tar}}$ **then**
      Update ν as

$$\nu \textbf{ Update:} \quad \nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\Big(\lambda_k - \frac{\lambda_k}{1-\alpha}\mathbf{1}\big\{x_k = x_{\text{Tar}}, s_k \le 0\big\}\Big)\right) \tag{23}$$

      Set $(x_{k+1}, s_{k+1}) = (x^0, \nu_{k+1})$ and $t = 0$
    else
      $t \leftarrow t + 1$
    end if
  end for
  if $\{\lambda_k\}$ converges to $\lambda_{\max}$, i.e., $|\lambda_{i^*} - \lambda_{\max}| \le \epsilon$ for some tolerance parameter $\epsilon > 0$ **then**
    Set $\lambda_{\max} \leftarrow 2\lambda_{\max}$.
  else
    return parameters $v, w, \nu, \theta, \lambda$, and **break**
  end if
end while

s_{Tar} the s part of the state in $\bar{\mathcal{M}}$ when a policy θ reaches a target state x_{Tar} (which we assume occurs before an upper-bound T number of steps), i.e.,

$$s_{\text{Tar}} = \frac{1}{\gamma^T}\left(\nu - \sum_{k=0}^{T-1}\gamma^k D(x_k, a_k)\right),$$

such that the initial state is given by $s_0 = \nu$. We will now use $n = |\bar{\mathcal{X}}|$ to indicate the size of the *augmented* state space $\bar{\mathcal{X}}$ instead of the size of the original state space $\mathcal{X}$. It can be later seen that the augmented state s in the MDP $\bar{\mathcal{M}}$ keeps track of the cumulative CVaR constraint cost. Similar to the analysis in Bäuerle and Ott (2011), the major motivation of introducing the aforementioned augmented MDP $\bar{\mathcal{M}}$ is that, by utilizing the augmented state $s \in \mathcal{S}$ that monitors the running constraint cost and thus the feasibility region of the original CVaR constrained MDP, one is able to define a Bellman operator on $\bar{\mathcal{M}}$ (whose exact definition can be found in Theorem 10), whose fixed point solution is equal to the solution of the original CVaR Lagrangian problem. Therefore by combining these properties, this reformulation allows one to transform the CVaR Lagrangian problem to a standard MDP problem.

We define a class of parameterized stochastic policies $\{\mu(\cdot|x, s; \theta), (x, s) \in \bar{\mathcal{X}}, \theta \in \Theta \subseteq R^{\kappa_1}\}$ for this augmented MDP. Recall that $\mathcal{G}^\theta(x)$ is the discounted cumulative cost and $\mathcal{J}^\theta(x)$ is the discounted cumulative constraint cost. Therefore, the total (discounted) cost of a trajectory can be written as

$$\sum_{k=0}^{T}\gamma^k \bar{C}_\lambda(x_k, s_k, a_k) \mid x_0 = x, s_0 = s, \mu \;=\; \mathcal{G}^\theta(x) + \frac{\lambda}{(1-\alpha)}\big(\mathcal{J}^\theta(x) - s\big)^+. \tag{25}$$

From (25), it is clear that the quantity in the parenthesis of (24) is the value function of the policy θ at state (x^0, ν) in the augmented MDP $\bar{\mathcal{M}}$, i.e., $V^\theta(x^0, \nu)$. Thus, it is easy to show that[4]

$$\nabla_\theta L(\nu, \theta, \lambda) = \nabla_\theta V^\theta(x^0, \nu) = \frac{1}{1-\gamma}\sum_{x,s,a}\pi_\gamma^\theta(x, s, a|x^0, \nu)\,\nabla \log \mu(a|x, s; \theta)\,Q^\theta(x, s, a),^5 \tag{26}$$

where π_γ^θ is the discounted occupation measure (defined in Section 2) and Q^θ is the action-value function of policy θ in the augmented MDP $\bar{\mathcal{M}}$. We can show that $\frac{1}{1-\gamma}\nabla \log \mu(a_k|x_k, s_k; \theta)\cdot\delta_k$ is an unbiased estimate of $\nabla_\theta L(\nu, \theta, \lambda)$, where

$$\delta_k = \bar{C}_\lambda(x_k, s_k, a_k) + \gamma\widehat{V}(x_{k+1}, s_{k+1}) - \widehat{V}(x_k, s_k)$$

is the temporal-difference (TD) error in the MDP $\bar{\mathcal{M}}$ from (18), and $\widehat{V}$ is an unbiased estimator of V^θ (see e.g., Bhatnagar et al. (2009)). In our actor-critic algorithms, the critic uses linear approximation for the value function $V^\theta(x, s) \approx v^\top\phi(x, s) = \tilde{V}^{\theta,v}(x, s)$, where the feature vector $\phi(\cdot)$ belongs to a low-dimensional space $\mathbb{R}^{\kappa_1}$ with dimension κ_1. The linear approximation $\tilde{V}^{\theta,v}$ belongs to a low-dimensional subspace $S_V = \{\Phi v | v \in \mathbb{R}^{\kappa_1}\}$, where Φ is the $n \times \kappa_1$ matrix whose

4. Note that the second equality in Equation (26) is the result of the policy gradient theorem (Sutton et al., 2000; Peters et al., 2005).
5. Notice that the state and action spaces of the original MDP are finite, and there is only a finite number of outcomes in the transition of s (due to the assumption of a bounded first hitting time). Therefore the augmented state s belongs to a finite state space as well.

rows are the transposed feature vectors $\phi^\top(\cdot)$. To ensure that the set of feature vectors forms a well-posed linear approximation to the value function, we impose the following assumption on the basis functions.

Assumption 9 (Independent Basis Functions) *The basis functions $\{\phi^{(i)}\}_{i=1}^{\kappa_1}$ are linearly independent. In particular, $\kappa_1 \leq n$ and Φ is full column rank. Moreover, for every $v \in \mathbb{R}^{\kappa_1}$, $\Phi v \neq e$, where e is the n-dimensional vector with all entries equal to one.*

The following theorem shows that the critic update v_k converges almost surely to v^*, the minimizer of the Bellman residual. Details of the proof can be found in Appendix B.2.

Theorem 10 *Define $v^* \in \arg\min_v \|B_\theta[\Phi v] - \Phi v\|^2_{d_\gamma^\theta}$ as the minimizer to the Bellman residual, where the Bellman operator is given by*

$$B_\theta[V](x, s) = \sum_a \mu(a|x, s; \theta)\left\{\bar{C}_\lambda(x, s, a) + \sum_{x', s'}\gamma\bar{P}(x', s'|x, s, a)V(x', s')\right\}$$

and $\tilde{V}^*(x, s) = (v^*)^\top\phi(x, s)$ is the projected Bellman fixed point of $V^\theta(x, s)$, i.e., $\tilde{V}^*(x, s) = \Pi B_\theta[\tilde{V}^*](x, s)$. Suppose the γ-occupation measure π_γ^θ is used to generate samples of (x_k, s_k, a_k) for any $k \in \{0, 1, \ldots, \}$. Then under Assumptions 8–9, the v-update in the actor-critic algorithm converges to v^* almost surely.

4.2 Gradient w.r.t. the Lagrangian Parameter λ

We may rewrite the gradient of the objective function w.r.t. the Lagrangian parameters λ in (9) as

$$\nabla_\lambda L(\nu, \theta, \lambda) = \nu - \beta + \nabla_\lambda\left(\mathbb{E}\big[\mathcal{G}^\theta(x^0)\big] + \frac{\lambda}{(1-\alpha)}\mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0) - \nu\big)^+\Big]\right) \overset{\text{(a)}}{=} \nu - \beta + \nabla_\lambda V^\theta(x^0, \nu). \tag{27}$$

Similar to Section 4.1, equality (a) comes from the fact that the quantity in parenthesis in (27) is $V^\theta(x^0, \nu)$, the value function of the policy θ at state (x^0, ν) in the augmented MDP $\bar{\mathcal{M}}$. Note that the dependence of $V^\theta(x^0, \nu)$ on λ comes from the definition of the cost function $\bar{C}_\lambda$ in $\bar{\mathcal{M}}$. We now derive an expression for $\nabla_\lambda V^\theta(x^0, \nu)$, which in turn will give us an expression for $\nabla_\lambda L(\nu, \theta, \lambda)$.

Lemma 11 *The gradient of $V^\theta(x^0, \nu)$ w.r.t. the Lagrangian parameter λ may be written as*

$$\nabla_\lambda V^\theta(x^0, \nu) = \frac{1}{1-\gamma}\sum_{x,s,a}\pi_\gamma^\theta(x, s, a|x^0, \nu)\frac{1}{(1-\alpha)}\mathbf{1}\{x = x_{Tar}\}(-s)^+. \tag{28}$$

Proof. See Appendix B.1. ■

From Lemma 11 and (27), it is easy to see that $\nu - \beta + \frac{1}{(1-\gamma)(1-\alpha)}\mathbf{1}\{x = x_{\text{Tar}}\}(-s)^+$ is an unbiased estimate of $\nabla_\lambda L(\nu, \theta, \lambda)$. An issue with this estimator is that its value is fixed to $\nu_k - \beta$ all along a trajectory, and only changes at the end to $\nu_k - \beta + \frac{1}{(1-\gamma)(1-\alpha)}(-s_{\text{Tar}})^+$. This may affect the incremental nature of our actor-critic algorithm. To address this issue, Chow and Ghavamzadeh (2014) previously proposed a different approach to estimate the gradients w.r.t. θ and λ which involves another value function approximation to the constraint. However this approach is less desirable in many practical applications as it increases the approximation error and impedes the speed of convergence.

Another important issue is that the above estimator is unbiased only if the samples are generated from the distribution $\pi_\gamma^\theta(\cdot|x^0,\nu)$. If we just follow the policy θ, then we may use $\nu_k - \beta + \frac{\gamma^k}{(1-\alpha)}\mathbf{1}\{x_k = x_{\text{Tar}}\}(-s_k)^+$ as an estimate for $\nabla_\lambda L(\nu,\theta,\lambda)$. Note that this is an issue for all discounted actor-critic algorithms: their (likelihood ratio based) estimate for the gradient is unbiased only if the samples are generated from π_γ^θ, and not when we simply follow the policy. This might also be the reason why, to the best of our knowledge, no rigorous convergence analysis can be found in the literature for (likelihood ratio based) discounted actor-critic algorithms under the sampling distribution.[6]

4.3 Sub-Gradient w.r.t. the VaR Parameter ν

We may rewrite the sub-gradient of our objective function w.r.t. the VaR parameter ν in (8) as

$$\partial_\nu L(\nu,\theta,\lambda) \ni \lambda\Big(1 - \frac{1}{(1-\alpha)}\mathbb{P}\Big(\sum_{k=0}^{\infty}\gamma^k D(x_k,a_k) \geq \nu \mid x_0 = x^0;\theta\Big)\Big). \tag{29}$$

From the definition of the augmented MDP $\bar{\mathcal{M}}$, the probability in (29) may be written as $\mathbb{P}(s_{\text{Tar}} \leq 0 \mid x_0 = x^0, s_0 = \nu;\theta)$, where s_{Tar} is the s part of the state in $\bar{\mathcal{M}}$ when we reach a target state, i.e., $x = x_{\text{Tar}}$ (see Section 4.1). Thus, we may rewrite (29) as

$$\partial_\nu L(\nu,\theta,\lambda) \ni \lambda\Big(1 - \frac{1}{(1-\alpha)}\mathbb{P}\big(s_{\text{Tar}} \leq 0 \mid x_0 = x^0, s_0 = \nu;\theta\big)\Big). \tag{30}$$

From (30), it is easy to see that $\lambda - \lambda\mathbf{1}\{s_{\text{Tar}} \leq 0\}/(1-\alpha)$ is an unbiased estimate of the sub-gradient of $L(\nu,\theta,\lambda)$ w.r.t. ν. An issue with this (unbiased) estimator is that it can only be applied at the end of a trajectory (i.e., when we reach the target state x_{Tar}), and thus, using it prevents us from having a fully incremental algorithm. In fact, this is the estimator that we use in our *semi-trajectory-based* actor-critic algorithm.

One approach to estimate this sub-gradient incrementally is to use the *simultaneous perturbation stochastic approximation* (SPSA) method (Chapter 5 of Bhatnagar et al. (2013)). The idea of SPSA is to estimate the sub-gradient $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)$ using two values of g at $\nu^- = \nu - \Delta$ and $\nu^+ = \nu + \Delta$, where $\Delta > 0$ is a positive perturbation (see Chapter 5 of Bhatnagar et al. (2013) or Prashanth and Ghavamzadeh (2013) for the detailed description of Δ).[7] In order to see how SPSA can help us to estimate our sub-gradient incrementally, note that

$$\partial_\nu L(\nu,\theta,\lambda) = \lambda + \partial_\nu\left(\mathbb{E}\big[\mathcal{J}^\theta(x^0)\big] + \frac{\lambda}{(1-\alpha)}\mathbb{E}\Big[\big(\mathcal{J}^\theta(x^0) - \nu\big)^+\Big]\right) \overset{\text{(a)}}{=} \lambda + \partial_\nu V^\theta(x^0,\nu). \tag{31}$$

Similar to Sections 4.1–4.3, equality (a) comes from the fact that the quantity in parenthesis in (31) is $V^\theta(x^0,\nu)$, the value function of the policy θ at state (x^0,ν) in the augmented MDP $\bar{\mathcal{M}}$. Since the critic uses a linear approximation for the value function, i.e., $V^\theta(x,s) \approx v^\top\phi(x,s)$, in our actor-critic algorithms (see Section 4.1 and Algorithm 2), the SPSA estimate of the sub-gradient would be of the form $g(\nu) \approx \lambda + v^\top\big[\phi(x^0,\nu^+) - \phi(x^0,\nu^-)\big]/2\Delta$.

6. Note that the discounted actor-critic algorithm with convergence proof in (Bhatnagar, 2010) is based on SPSA.
7. SPSA-based gradient estimate was first proposed in Spall (1992) and has been widely used in various settings, especially those involving a high-dimensional parameter. The SPSA estimate described above is two-sided. It can also be implemented single-sided, where we use the values of the function at ν and ν^+. We refer the readers to Chapter 5 of Bhatnagar et al. (2013) for more details on SPSA and to Prashanth and Ghavamzadeh (2013) for its application to learning in mean-variance risk-sensitive MDPs.

4.4 Convergence of Actor-Critic Methods

In this section, we will prove that the actor-critic algorithms converge to a locally optimal policy for the CVaR-constrained optimization problem. Define

$$\epsilon_\theta(v_k) = \|B_\theta[\Phi v_k] - \Phi v_k\|_\infty$$

as the residual of the value function approximation at step k, induced by policy $\mu(\cdot|\cdot,\cdot;\theta)$. By the triangle inequality and fixed point theorem $B_\theta[V^*] = V^*$, it can be easily seen that $\|V^* - \Phi v_k\|_\infty \leq \epsilon_\theta(v_k) + \|B_\theta[\Phi v_k] - B_\theta[V^*]\|_\infty \leq \epsilon_\theta(v_k) + \gamma\|\Phi v_k - V^*\|_\infty$. The last inequality follows from the contraction property of the Bellman operator. Thus, one concludes that $\|V^* - \Phi v_k\|_\infty \leq \epsilon_\theta(v_k)/(1-\gamma)$. Now, we state the main theorem for the convergence of actor-critic methods.

Theorem 12 *Suppose $\epsilon_{\theta_k}(v_k) \to 0$ and the γ-occupation measure π_γ^θ is used to generate samples of (x_k, s_k, a_k) for any $k \in \{0,1,\ldots\}$. For the SPSA-based algorithms, suppose the feature vector satisfies the technical Assumption 21 (provided in Appendix B.2.2) and suppose the SPSA step-size satisfies the condition $\epsilon_{\theta_k}(v_k) = o(\Delta_k)$, i.e., $\epsilon_{\theta_k}(v_k)/\Delta_k \to 0$. Then under Assumptions 2–4 and 8–9, the sequence of policy updates in Algorithm 2 converges almost surely to a locally optimal policy for the CVaR-constrained optimization problem.*

Details of the proof can be found in Appendix B.2.

5. Extension to Chance-Constrained Optimization of MDPs

In many applications, in particular in engineering (see, for example, Ono et al. (2015)), *chance constraints* are imposed to ensure mission success with high probability. Accordingly, in this section we extend the analysis of CVaR-constrained MDPs to chance-constrained MDPs (i.e., (4)). As for CVaR-constrained MDPs, we employ a Lagrangian relaxation procedure (Chapter 3 of Bertsekas (1999)) to convert a chance-constrained optimization problem into the following unconstrained problem:

$$\max_\lambda \min_{\theta,\alpha}\Big(L(\theta,\lambda) := \mathcal{G}^\theta(x^0) + \lambda\Big(\mathbb{P}\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) - \beta\Big)\Big), \tag{32}$$

where λ is the Lagrange multiplier. Recall Assumption 4 which assumed strict feasibility, i.e., there exists a transient policy $\mu(\cdot|x;\theta)$ such that $\mathbb{P}\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) < \beta$. This is needed to guarantee the existence of a local saddle point.

5.1 Policy Gradient Method

In this section we propose a policy gradient method for chance-constrained MDPs (similar to Algorithm 1). Since we do not need to estimate the ν-parameter in chance-constrained optimization, the corresponding policy gradient algorithm can be simplified and at each inner loop of Algorithm 1 we only perform the following updates at the end of each trajectory:

θ **Update:** $\theta_{k+1} = \Gamma_\Theta\Big[\theta_k - \frac{\zeta_2(k)}{N}\Big(\sum_{j=1}^{N}\nabla_\theta \log\mathbb{P}(\xi_{j,k})\mathcal{G}(\xi_{j,k}) + \lambda_k\nabla_\theta\log\mathbb{P}(\xi_{j,k})\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \alpha\big\}\Big)\Big]$

λ **Update:** $\lambda_{k+1} = \Gamma_\Lambda\Big[\lambda_k + \zeta_1(k)\Big(-\beta + \frac{1}{N}\sum_{j=1}^{N}\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \alpha\big\}\Big)\Big]$

Considering the multi-time-scale step-size rules in Assumption 6, the θ update is on the fast time-scale $\{\zeta_2(k)\}$ and the Lagrange multiplier λ update is on the slow time-scale $\{\zeta_1(k)\}$. This results in a two time-scale stochastic approximation algorithm. In the following theorem, we prove that our policy gradient algorithm converges to a locally optimal policy for the chance-constrained problem.

Theorem 13 *Under Assumptions 2–6, the sequence of policy updates in Algorithm 1 converges to a locally optimal policy θ^* for the chance-constrained optimization problem almost surely.*

Proof. [Sketch] By taking the gradient of $L(\theta,\lambda)$ w.r.t. θ, we have

$$\nabla_\theta L(\theta,\lambda) = \nabla_\theta \mathcal{G}^\theta(x^0) + \lambda \nabla_\theta \mathbb{P}\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) = \sum_\xi \nabla_\theta \mathbb{P}_\theta(\xi)\mathcal{G}(\xi) + \lambda \sum_\xi \nabla_\theta \mathbb{P}_\theta(\xi)\mathbf{1}\{\mathcal{J}(\xi) \geq \alpha\}.$$

On the other hand, the gradient of $L(\theta,\lambda)$ w.r.t. λ is given by

$$\nabla_\lambda L(\theta,\lambda) = \mathbb{P}\big(\mathcal{J}^\theta(x^0) \geq \alpha\big) - \beta.$$

One can easily verify that the θ and λ updates are therefore unbiased estimates of $\nabla_\theta L(\theta,\lambda)$ and $\nabla_\lambda L(\theta,\lambda)$, respectively. Then the rest of the proof follows analogously from the convergence proof of Algorithm 1 in steps 2 and 3 of Theorem 7. ■

5.2 Actor-Critic Method

In this section, we present an actor-critic algorithm for the chance-constrained optimization. Given the original MDP $\mathcal{M} = (\mathcal{X}, \mathcal{A}, C, D, P, P_0)$ and parameter λ, we define the augmented MDP $\bar{\mathcal{M}} = (\bar{\mathcal{X}}, \bar{\mathcal{A}}, \bar{C}_\lambda, \bar{P}, \bar{P}_0)$ as in the CVaR counterpart, except that $\bar{P}_0(x,s) = P_0(x)\mathbf{1}\{s = \alpha\}$ and

$$\bar{C}_\lambda(x,s,a) = \begin{cases} \lambda \mathbf{1}\{s \leq 0\} & \text{if } x = x_{\text{Tar}}, \\ C(x,a) & \text{otherwise.} \end{cases}$$

Thus, the total cost of a trajectory can be written as

$$\sum_{k=0}^{T} \bar{C}_\lambda(x_k, s_k, a_k) \mid x_0 = x, s_0 = \beta,\ \mu = \mathcal{G}^\theta(x) + \lambda \mathbb{P}(\mathcal{J}^\theta(x) \geq \beta). \tag{33}$$

Unlike the actor-critic algorithms for CVaR-constrained optimization, here the value function approximation parameter v, policy θ, and Lagrange multiplier estimate λ are updated episodically, i.e., after each episode ends by time T when $(x_k, s_k) = (x_{\text{Tar}}, s_{\text{Tar}})$[8], as follows:

$$\textbf{Critic Update:} \quad v_{k+1} = v_k + \zeta_3(k) \sum_{h=0}^{T} \phi(x_h, s_h)\delta_h(v_k) \tag{34}$$

$$\textbf{Actor Updates:} \quad \theta_{k+1} = \Gamma_\Theta\Big(\theta_k - \zeta_2(k) \sum_{h=0}^{T} \nabla_\theta \log \mu(a_h|x_h, s_h; \theta)|_{\theta=\theta_k} \cdot \delta_h(v_k)\Big) \tag{35}$$

$$\lambda_{k+1} = \Gamma_\Lambda\Big(\lambda_k + \zeta_1(k)\big(-\beta + \mathbf{1}\{s_{\text{Tar}} \leq 0\}\big)\Big) \tag{36}$$

From analogous analysis as for the CVaR actor-critic method, the following theorem shows that the critic update v_k converges almost surely to v^*.

8. Note that s_{Tar} is the state of s_t when x_t hits the (recurrent) target state x_{Tar}.

Theorem 14 *Let $v^* \in \arg\min_v \|B_\theta[\Phi v] - \Phi v\|^2_{d^\theta}$ be a minimizer of the Bellman residual, where the undiscounted Bellman operator at every $(x,s) \in \bar{\mathcal{X}}'$ is given by*

$$B_\theta[V](x,s) = \sum_{a\in\mathcal{A}} \mu(a|x,s;\theta)\Big\{\bar{C}_\lambda(x,s,a) + \sum_{(x',s')\in\bar{\mathcal{X}}'} \bar{P}(x',s'|x,s,a)V(x',s')\Big\}$$

and $\tilde{V}^*(x,s) = \phi^\top(x,s)v^*$ is the projected Bellman fixed point of $V^\theta(x,s)$, i.e., $\tilde{V}^*(x,s) = \Pi B_\theta[\tilde{V}^*](x,s)$ for $(x,s) \in \bar{\mathcal{X}}'$. Then under Assumptions 8–9, the v-update in the actor-critic algorithm converges to v^* almost surely.

Proof. [Sketch] The proof of this theorem follows the same steps as those in the proof of Theorem 10, except replacing the γ-occupation measure d^θ_γ with the occupation measure d^θ (the total visiting probability). Similar analysis can also be found in the proof of Theorem 10 in Tamar and Mannor (2013). Under Assumption 2, the occupation measure of any transient states $x \in \mathcal{X}'$ (starting at an arbitrary initial transient state $x_0 \in \mathcal{X}'$) can be written as $d^\mu(x|x^0) = \sum_{t=0}^{T_{\mu,x}} \mathbb{P}(x_t = x|x^0;\mu)$ when $\gamma = 1$. This further implies the total visiting probabilities are bounded as follows: $d^\mu(x|x^0) \leq T_{\mu,x}$ and $\pi^\mu(x,a|x^0) \leq T_{\mu,x}$ for any $x, x_0 \in \mathcal{X}'$. Therefore, when the sequence of states $\{(x_h, s_h)\}_{h=0}^T$ is sampled by the h-step transition distribution $\mathbb{P}(x_h, s_h \mid x^0, s^0, \theta)$, $\forall h \leq T$, the unbiased estimators of

$$A := \sum_{(y,s')\in\bar{\mathcal{X}}', a'\in\mathcal{A}} \pi^\theta(y,s',a'|x,s)\phi(y,s')\Big(\phi^\top(y,s') - \sum_{(z,s'')\in\bar{\mathcal{X}}'} \bar{P}(z,s''|y,s',a)\phi^\top(z,s'')\Big)$$

and

$$b := \sum_{(y,s')\in\bar{\mathcal{X}}', a'\in\mathcal{A}} \pi^\theta(y,s',a'|x,s)\phi(y,s')\bar{C}_\lambda(y,s',a')$$

are given by $\sum_{h=0}^T \phi(x_h,s_h)(\phi^\top(x_h,s_h) - \phi^\top(x_{h+1},s_{h+1}))$ and $\sum_{h=0}^T \phi(x_h,s_h)\bar{C}_\lambda(x_h,s_h,a_h)$, respectively. Note that in this theorem, we directly use the results from Theorem 7.1 in Bertsekas (1995) to show that every eigenvalue of matrix A has positive real part, instead of using the technical result in Lemma 20. ■

Recall that $\epsilon_\theta(v_k) = \|B_\theta[\Phi v_k] - \Phi v_k\|_\infty$ is the residual of the value function approximation at step k induced by policy $\mu(\cdot|\cdot,\cdot;\theta)$. By the triangle inequality and fixed-point theorem of stochastic stopping problems, i.e., $B_\theta[V^*] = V^*$ from Theorem 3.1 in Bertsekas (1995), it can be easily seen that $\|V^* - \Phi v_k\|_\infty \leq \epsilon_\theta(v_k) + \|B_\theta[\Phi v_k] - B_\theta[V^*]\|_\infty \leq \epsilon_\theta(v_k) + \kappa\|\Phi v_k - V^*\|_\infty$ for some $\kappa \in (0,1)$. Similar to the actor-critic algorithm for CVaR-constrained optimization, the last inequality also follows from the contraction mapping property of B_θ from Theorem 3.2 in Bertsekas (1995). Now, we state the main theorem for the convergence of the actor-critic method.

Theorem 15 *Under Assumptions 2–9, if $\epsilon_{\theta_k}(v_k) \to 0$, then the sequence of policy updates converges almost surely to a locally optimal policy θ^* for the chance-constrained optimization problem.*

Proof. [Sketch] From Theorem 14, the critic update converges to the minimizer of the Bellman residual. Since the critic update converges on the fastest scale, as in the proof of Theorem 12, one can replace v_k by $v^*(\theta_k)$ in the convergence proof of the actor update. Furthermore, by sampling the sequence of states $\{(x_h, s_h)\}_{h=0}^T$ with the h-step transition distribution $\mathbb{P}(x_h, s_h \mid x^0, s^0, \theta)$, $\forall h \leq T$, the unbiased estimator of the gradient of the linear approximation to the Lagrangian function is given by

$$\nabla_\theta \tilde{L}^v(\theta,\lambda) := \sum_{(x,s)\in\bar{\mathcal{X}}', a\in\mathcal{A}} \pi^\theta(x,s,a|x_0 = x^0, s_0 = \nu)\nabla_\theta \log \mu(a|x,s;\theta)\tilde{A}^{\theta,v}(x,s,a),$$

where $\tilde{Q}^{\theta,v}(x,s,a) - v^\top \phi(x,s)$ is given by $\sum_{h=0}^{T} \nabla_\theta \log \mu(a_h|x_h,s_h;\theta)|_{\theta=\theta_k} \cdot \delta_h(v^*)$ and the unbiased estimator of $\nabla_\lambda L(\theta,\lambda) = -\beta + \mathbb{P}(s_{\text{Tar}} \leq 0)$ is given by $-\beta + \mathbf{1}\{s_{\text{Tar}} \leq 0\}$. Analogous to equation (77) in the proof of Theorem 24, by convexity of quadratic functions, we have for any value function approximation v,

$$\sum_{(y,s')\in\bar{\mathcal{X}}',a'\in\mathcal{A}} \pi^\theta(y,s',a'|x,s)(A_\theta(y,s',a') - \tilde{A}^v_\theta(y,s',a')) \leq 2T\frac{\epsilon_\theta(v)}{1-\kappa},$$

which further implies that $\nabla_\theta L(\theta,\lambda) - \nabla_\theta \tilde{L}^v(\theta,\lambda) \to 0$ when $\epsilon_\theta(v) \to 0$ at $v = v^*(\theta_k)$. The rest of the proof follows identical arguments as in steps 3 to 5 of the proof of Theorem 12. ■

6. Examples

In this section we illustrate the effectiveness of our risk-constrained policy gradient and actor-critic algorithms by testing them on an American option stopping problem and on a long-term personalized advertisement-recommendation (ad-recommendation) problem.

6.1 The Optimal Stopping Problem

We consider an optimal stopping problem of purchasing certain types of goods, in which the state at each time step $k \leq T$ consists of a purchase cost c_k and time k, i.e., $x = (c_k, k)$, where T is the deterministic upper bound of the random stopping time. The purchase cost sequence $\{c_k\}_{k=0}^T$ is randomly generated by a Markov chain with two modes. Specifically, due to future market uncertainties, at time k the random purchase cost at the next time step c_{k+1} either grows by a factor $f_u > 1$, i.e., $c_{k+1} = f_u c_k$, with probability p, or drops by a factor $f_d < 1$, i.e., $c_{k+1} = f_d c_k$, with probability $1-p$. Here f_u and f_d are constants that represent the rates of appreciation (due to anticipated shortage of supplies from vendors) and depreciation (due to reduction of demands in the market) respectively. The agent (buyer) should decide either to accept the present cost ($u_k = 1$) or wait ($u_k = 0$). If he/she accepts the cost or when the system terminates at time $k = T$, the purchase cost is set at $\max(K, c_k)$, where K is the maximum cost threshold. Otherwise, to account for a steady rate of inflation, at each time step the buyer receives an extra cost of p_h that is independent to the purchase cost. Moreover, there is a discount factor $\gamma \in (0,1)$ to account for the increase in the buyer's affordability. Note that if we change cost to reward and minimization to maximization, this is exactly the American option pricing problem, a standard testbed to evaluate risk-sensitive algorithms (e.g., see Tamar et al. (2012)). Since the state space size n is exponential in T, finding an exact solution via dynamic programming (DP) quickly becomes infeasible, and thus the problem requires approximation and sampling techniques.

The optimal stopping problem can be reformulated as follows

$$\min_\theta \mathbb{E}\left[\mathcal{G}^\theta(x^0)\right] \qquad \text{subject to} \qquad \text{CVaR}_\alpha\left(\mathcal{G}^\theta(x^0)\right) \leq \beta \quad \text{or} \quad \mathbb{P}\left(\mathcal{G}^\theta(x^0) \geq \beta\right) \leq 1-\alpha^9, \tag{37}$$

where the discounted cost function is given by

$$\mathcal{G}^\theta(x) = \sum_{k=0}^{T} \gamma^k \left(\mathbf{1}\{u_k = 1\}\max(K, c_k) + \mathbf{1}\{u_k = 0\}p_h\right) \mid x_0 = x,\ \mu.$$

9. To ensure that the notation is consistent between the CVaR and chance constraints, in the chance constraint definition the confidence level is denoted by α and the tolerance threshold of $\mathcal{G}^\theta(x^0)$ is denoted by β.

We set the parameters of the MDP as follows: $x_0 = [1;0]$, $p_h = 0.1$, $T = 20$, $K = 5$, $\gamma = 0.95$, $f_u = 2$, $f_d = 0.5$, and $p = 0.65$. The confidence level and constraint threshold are given by $\alpha = 0.95$ and $\beta = 3$. The number of sample trajectories N is set to $500,000$ and the parameter bounds are $\lambda_{\max} = 5,000$ and $\Theta = [-20,20]^{\kappa_1}$, where the dimension of the basis functions is $\kappa_1 = 1024$. We implement the standard Gaussian radial basis functions (RBFs) as feature functions and search over the class of Boltzmann policies $\left\{\theta : \theta = \{\theta_{x,a}\}_{x\in\mathcal{X},a\in\mathcal{A}},\ \mu_\theta(a|x) = \frac{\exp(\theta_{x,a}^\top x)}{\sum_{a\in\mathcal{A}}\exp(\theta_{x,a}^\top x)}\right\}$.

We consider the following trajectory-based algorithms:

1. **PG:** This is a policy gradient algorithm that minimizes the expected discounted cost function without considering any risk criteria.

2. **PG-CVaR/PG-CC:** These are the CVaR/chance-constrained simulated trajectory-based policy gradient algorithms given in Section 3.

The experiments for each algorithm comprise the following two phases:

1. **Tuning phase:** We run the algorithm and update the policy until (ν,θ,λ) converges.

2. **Converged run:** Having obtained a converged policy θ^* in the tuning phase, in the converged run phase, we perform a Monte Carlo simulation of $10,000$ trajectories and report the results as averages over these trials.

We also consider the following incremental algorithms:

1. **AC:** This is an actor-critic algorithm that minimizes the expected discounted cost function without considering any risk criteria. This is similar to Algorithm 1 in Bhatnagar (2010).

2. **AC-CVaR/AC-CC:** These are the CVaR/chance-constrained semi-trajectory actor-critic algorithms given in Section 4.

3. **AC-CVaR-SPSA:** This is the CVaR-constrained SPSA actor-critic algorithm given in Section 4.

Similar to the trajectory-based algorithms, we use RBF features for $[x;s]$ and consider the family of augmented state Boltzmann policies. Similarly, the experiments comprise two phases: 1) the tuning phase, where the set of parameters (v,ν,θ,λ) is obtained after the algorithm converges, and 2) the converged run, where the policy is simulated with $10,000$ trajectories.

We compare the performance of PG-CVaR and PG-CC (given in Algorithm 1), and AC-CVaR-SPSA, AC-CVaR, and AC-CC (given in Algorithm 2), with PG and AC, their risk-neutral counterparts. Figures 1 and 2 show the distribution of the discounted cumulative cost $\mathcal{G}^\theta(x^0)$ for the policy θ learned by each of these algorithms. The results indicate that the risk-constrained algorithms yield a higher expected cost, but less worst-case variability, compared to the risk-neutral methods. More precisely, the cost distributions of the risk-constrained algorithms have lower right-tail (worst-case) distribution than their risk-neutral counterparts. Table 1 summarizes the performance of these algorithms. The numbers reiterate what we concluded from Figures 1 and 2.

Notice that while the risk averse policy satisfies the CVaR constraint, it is not tight (i.e., the constraint is not matched). In fact this is a problem of local optimality, and other experiments in the literature (for example see the numerical results in Prashanth and Ghavamzadeh (2013) and in

Bhatnagar and Lakshmanan (2012)) have the same problem of producing solutions which obey the constraints but not tightly. However, since both the expectation and the CVaR risk metric are sub-additive and convex, one can always construct a policy that is a linear combination of the risk neutral optimal policy and the risk averse policy such that it matches the constraint threshold and has a lower cost compared to the risk averse policy.

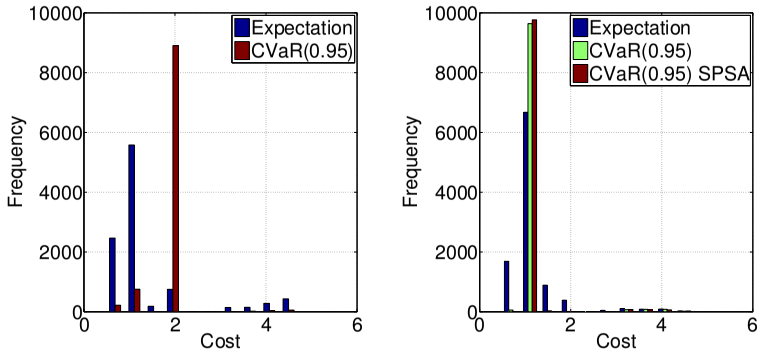

Figure 1: Cost distributions for the policies learned by the CVaR-constrained and risk-neutral policy gradient and actor-critic algorithms. The left figure corresponds to the PG methods and the right figure corresponds to the AC algorithms.

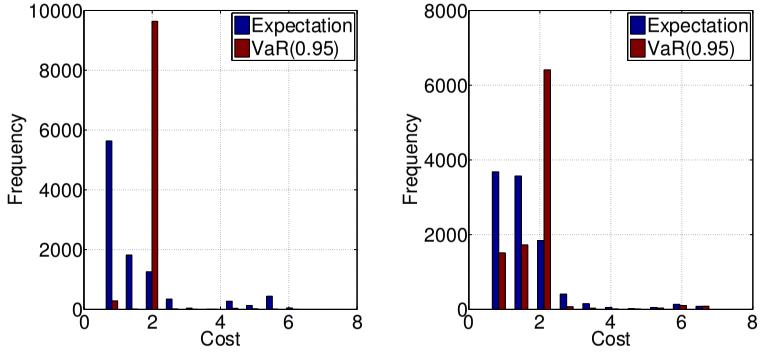

Figure 2: Cost distributions for the policies learned by the chance-constrained and risk-neutral policy gradient and actor-critic algorithms. The left figure corresponds to the PG methods and the right figure corresponds to the AC algorithms.

	$\mathbb{E}(\mathcal{G}^\theta(x^0))$	$\sigma(\mathcal{G}^\theta(x^0))$	$\text{CVaR}(\mathcal{G}^\theta(x^0))$	$\text{VaR}(\mathcal{G}^\theta(x^0))$
PG	1.177	1.065	4.464	4.005
PG-CVaR	1.997	0.060	2.000	2.000
PG-CC	1.994	0.121	2.058	2.000
AC	1.113	0.607	3.331	3.220
AC-CVaR-SPSA	1.326	0.322	2.145	1.283

AC-CC	1.817	0.753	4.006	2.300

Table 1: Performance comparison of the policies learned by the risk-constrained and risk-neutral algorithms. In this table $\sigma(\mathcal{G}^\theta(x^0))$ stands for the standard deviation of the total cost.

6.2 A Personalized Ad-Recommendation System

Many companies such as banks and retailers use user-specific targeting of advertisements to attract more customers and increase their revenue. When a user requests a webpage that contains a box for an advertisement, the system should decide which advertisement (among those in the current campaign) to show to this particular user based on a vector containing all her features, often collected by a cookie. Our goal here is to generate a strategy that for each user of the website selects an ad that when it is presented to her has the highest probability to be clicked on. These days, almost all the industrial personalized ad recommendation systems use supervised learning or contextual bandits algorithms. These methods are based on the i.i.d. assumption of the visits (to the website) and do not discriminate between a visit and a visitor, i.e., each visit is considered as a new visitor that has been sampled i.i.d. from the population of the visitors. As a result, these algorithms are myopic and do not try to optimize for the long-term performance. Despite their success, these methods seem to be insufficient as users establish longer-term relationship with the websites they visit, i.e., the ad recommendation systems should deal with more and more returning visitors. The increase in returning visitors violates (more) the main assumption underlying the supervised learning and bandit algorithms, i.e., there is no difference between a visit and a visitor, and thus, shows the need for a new class of solutions.

The reinforcement learning (RL) algorithms that have been designed to optimize the long-term performance of the system (expected sum of rewards/costs) seem to be suitable candidates for ad recommendation systems (Shani et al., 2002). The nature of these algorithms allows them to take into account all the available knowledge about the user at the current visit, and then selects an offer to maximize the total number of times she will click over multiple visits, also known as the user's life-time value (LTV). Unlike myopic approaches, RL algorithms differentiate between a visit and a visitor, and consider all the visits of a user (in chronological order) as a trajectory generated by her. In this approach, while the visitors are i.i.d. samples from the population of the users, their visits are not. This long-term approach to the ad recommendation problem allows us to make decisions that are not usually possible with myopic techniques, such as to propose an offer to a user that might be a loss to the company in the short term, but has the effect that makes the user engaged with the website/company and brings her back to spend more money in the future.

For our second case study, we use an Adobe personalized ad-recommendation (Theocharous and Hallak, 2013) simulator that has been trained based on real data captured with permission from the website of a Fortune 50 company that receives hundreds of visitors per day. The simulator produces a vector of 31 real-valued features that provide a compressed representation of all of the

available information about a user. The advertisements are clustered into four high-level classes that the agent must select between. After the agent selects an advertisement, the user either clicks (reward of $+1$) or does not click (reward of 0) and the feature vector describing the user is updated. In this case, we test our algorithm by maximizing the customers' life-time value in 15 time steps subject to a bounded tail risk.

Instead of using the cost-minimization framework from the problem statement in Section 2.2, by defining the return random variable (under a fixed policy θ) $\mathcal{R}^\theta(x^0)$ as the (discounted) total number of clicks along a user's trajectory, here we formulate the personalized ad-recommendation problem as a return maximization problem where the tail risk corresponds to the worst case return distribution:

$$\max_\theta \mathbb{E}\left[\mathcal{R}^\theta(x^0)\right] \qquad \text{subject to} \qquad \text{CVaR}_{1-\alpha}\big(-\mathcal{R}^\theta(x^0)\big) \leq \beta. \tag{38}$$

We set the parameters of the MDP as $T = 15$ and $\gamma = 0.98$, the confidence level and constraint threshold as $\alpha = 0.05$ and $\beta = -0.12$, the number of sample trajectories N to $1,000,000$, and the parameter bounds as $\lambda_{\max} = 5,000$ and $\Theta = [-60, 60]^{\kappa_1}$, where the dimension of the basis functions is $\kappa_1 = 4096$. Similar to the optimal stopping problem, we implement both the trajectory based algorithm (PG, PG-CVaR) and the actor-critic algorithms (AC, AC-CVaR) for risk-neutral and risk sensitive optimal control. Here we used the 3rd order Fourier basis with cross-products in Konidaris et al. (2011) as features and search over the family of Boltzmann policies. We compared the performance of PG-CVaR and AC-CVaR, our risk-constrained policy gradient (Algorithm 1) and actor-critic (Algorithms 2) algorithms, with their risk-neutral counterparts (PG and AC). Figure 3 shows the distribution of the discounted cumulative return $\mathcal{R}^\theta(x^0)$ for the policy θ learned by each of these algorithms. The results indicate that the risk-constrained algorithms yield a lower expected reward, but have higher left tail (worst-case) reward distributions. Table 2 summarizes the findings of this experiment.

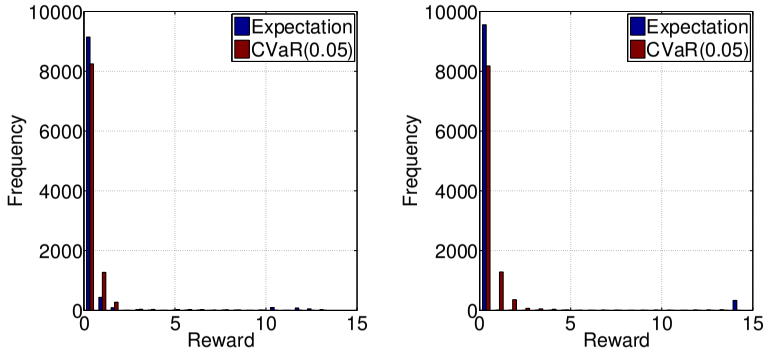

Figure 3: Reward distributions for the policies learned by the CVaR-constrained and risk-neutral policy gradient and actor-critic algorithms. The left figure corresponds to the PG methods and the right figure corresponds to the AC algorithms.

	$\mathbb{E}\big(\mathcal{R}^\theta(x^0)\big)$	$\sigma\big(\mathcal{R}^\theta(x^0)\big)$	$\text{CVaR}\big(\mathcal{R}^\theta(x^0)\big)$	$\text{VaR}\big(\mathcal{R}^\theta(x^0)\big)$
PG	0.396	1.898	0.037	1.000
PG-CVaR	0.287	0.914	0.126	1.795
AC	0.581	2.778	0	0
AC-CVaR	0.253	0.634	0.137	1.890

Table 2: Performance comparison of the policies learned by the CVaR-constrained and risk-neutral algorithms. In this table $\sigma\big(\mathcal{R}^\theta(x^0)\big)$ stands for the standard deviation of the total reward.

7. Conclusions and Future Work

We proposed novel policy gradient and actor-critic algorithms for CVaR-constrained and chance-constrained optimization in MDPs, and proved their convergence. Using an optimal stopping problem and a personalized ad-recommendation problem, we showed that our algorithms resulted in policies whose cost distributions have lower right-tail compared to their risk-neutral counterparts. This is important for a risk-averse decision-maker, especially if the right-tail contains catastrophic costs. Future work includes: 1) Providing convergence proofs for our AC algorithms when the samples are generated by following the policy and not from its discounted occupation measure , 2) Using importance sampling methods (Bardou et al., 2009; Tamar et al., 2015) to improve gradient estimates in the right-tail of the cost distribution (worst-case events that are observed with low probability), and 3) Applying the algorithms presented in this paper to a variety of applications ranging from operations research to robotics and finance.

Acknowledgments

We would like to thank Csaba Szepesvari for his comments that helped us with the derivation of the algorithms, Georgios Theocharous for sharing his ad-recommendation simulator with us, and Philip Thomas for helping us with the experiments with the simulator. We would also like to thank the reviewers for their very helpful comments and suggestions, which helped us to significantly improve the paper. Y-L. Chow is partially supported by The Croucher Foundation doctoral scholarship. L. Janson was partially supported by NIH training grant T32GM096982. M. Pavone was partially supported by the Office of Naval Research, Science of Autonomy Program, under Contract N00014-15-1-2673.

Appendix A. Convergence of Policy Gradient Methods

A.1 Computing the Gradients

i) $\nabla_\theta L(\nu, \theta, \lambda)$: Gradient of $L(\nu, \theta, \lambda)$ w.r.t. θ By expanding the expectations in the definition of the objective function $L(\nu, \theta, \lambda)$ in (5), we obtain

$$L(\nu, \theta, \lambda) = \sum_\xi \mathbb{P}_\theta(\xi)\mathcal{G}(\xi) + \lambda\nu + \frac{\lambda}{1-\alpha}\sum_\xi \mathbb{P}_\theta(\xi)\big(\mathcal{J}(\xi) - \nu\big)^+ - \lambda\beta.$$

By taking the gradient with respect to θ, we have

$$\nabla_\theta L(\nu, \theta, \lambda) = \sum_\xi \nabla_\theta \mathbb{P}_\theta(\xi)\mathcal{G}(\xi) + \frac{\lambda}{1-\alpha}\sum_\xi \nabla_\theta \mathbb{P}_\theta(\xi)\big(\mathcal{J}(\xi) - \nu\big)^+.$$

This gradient can be rewritten as

$$\nabla_\theta L(\nu,\theta,\lambda) = \sum_{\xi:\mathbb{P}_\theta(\xi)\neq 0} \mathbb{P}_\theta(\xi)\cdot\nabla_\theta \log \mathbb{P}_\theta(\xi)\left(\mathcal{G}(\xi)+\frac{\lambda}{1-\alpha}\big(\mathcal{J}(\xi)-\nu\big)\mathbf{1}\big\{\mathcal{J}(\xi)\geq\nu\big\}\right), \quad (39)$$

where in the case of $\mathbb{P}_\theta(\xi)\neq 0$, the term $\nabla_\theta \log \mathbb{P}_\theta(\xi)$ is given by:

$$\begin{aligned}\nabla_\theta \log \mathbb{P}_\theta(\xi) =& \nabla_\theta\left\{\sum_{k=0}^{T-1}\log P(x_{k+1}|x_k,a_k)+\log\mu(a_k|x_k;\theta)+\log\mathbf{1}\{x_0=x^0\}\right\}\\ =&\sum_{k=0}^{T-1}\nabla_\theta\log\mu(a_k|x_k;\theta)\\ =&\sum_{k=0}^{T-1}\frac{1}{\mu(a_k|x_k;\theta)}\nabla_\theta\mu(a_k|x_k;\theta).\end{aligned}$$

ii) $\partial_\nu L(\nu,\theta,\lambda)$: Sub-differential of $L(\nu,\theta,\lambda)$ w.r.t. ν From the definition of $L(\nu,\theta,\lambda)$, we can easily see that $L(\nu,\theta,\lambda)$ is a convex function in ν for any fixed $\theta\in\Theta$. Note that for every fixed ν and any ν', we have

$$\big(\mathcal{J}(\xi)-\nu'\big)^+-\big(\mathcal{J}(\xi)-\nu\big)^+\geq g\cdot(\nu'-\nu),$$

where g is any element in the set of sub-derivatives:

$$g\in\partial_\nu\big(\mathcal{J}(\xi)-\nu\big)^+ := \begin{cases}-1 & \text{if } \nu<\mathcal{J}(\xi),\\ -q:q\in[0,1] & \text{if } \nu=\mathcal{J}(\xi),\\ 0 & \text{otherwise.}\end{cases}$$

Since $L(\nu,\theta,\lambda)$ is finite-valued for any $\nu\in\mathbb{R}$, by the additive rule of sub-derivatives, we have

$$\partial_\nu L(\nu,\theta,\lambda)=\left\{-\frac{\lambda}{1-\alpha}\sum_\xi\mathbb{P}_\theta(\xi)\mathbf{1}\big\{\mathcal{J}(\xi)>\nu\big\}-\frac{\lambda q}{1-\alpha}\sum_\xi\mathbb{P}_\theta(\xi)\mathbf{1}\big\{\mathcal{J}(\xi)=\nu\big\}+\lambda\mid q\in[0,1]\right\}. \quad (40)$$

In particular for $q=1$, we may write the sub-gradient of $L(\nu,\theta,\lambda)$ w.r.t. ν as

$$\partial_\nu L(\nu,\theta,\lambda)|_{q=0}=\lambda-\frac{\lambda}{1-\alpha}\sum_\xi\mathbb{P}_\theta(\xi)\cdot\mathbf{1}\big\{\mathcal{J}(\xi)\geq\nu\big\}$$

or

$$\lambda-\frac{\lambda}{1-\alpha}\sum_\xi\mathbb{P}_\theta(\xi)\cdot\mathbf{1}\big\{\mathcal{J}(\xi)\geq\nu\big\}\in\partial_\nu L(\nu,\theta,\lambda).$$

iii) $\nabla_\lambda L(\nu,\theta,\lambda)$: Gradient of $L(\nu,\theta,\lambda)$ w.r.t. λ Since $L(\nu,\theta,\lambda)$ is a linear function in λ, one can express the gradient of $L(\nu,\theta,\lambda)$ w.r.t. λ as follows:

$$\nabla_\lambda L(\nu,\theta,\lambda)=\nu-\beta+\frac{1}{1-\alpha}\sum_\xi\mathbb{P}_\theta(\xi)\cdot\big(\mathcal{J}(\xi)-\nu\big)\mathbf{1}\big\{\mathcal{J}(\xi)\geq\nu\big\}. \quad (41)$$

A.2 Proof of Convergence of the Policy Gradient Algorithm

In this section, we prove the convergence of the policy gradient algorithm (Algorithm 1). Before going through the details of the convergence proof, a high level overview of the proof technique is given as follows.

1. First, by convergence properties of multi-time scale discrete stochastic approximation algorithms, we show that each update $(\nu_k,\theta_k,\lambda_k)$ converges almost surely to a stationary point $(\nu^*,\theta^*,\lambda^*)$ of the corresponding continuous time system. In particular, by adopting the step-size rules defined in Assumption 6, we show that the convergence rate of ν is fastest, followed by the convergence rate of θ, while the convergence rate of λ is the slowest among the set of parameters.

2. By using Lyapunov analysis, we show that the continuous time system is locally asymptotically stable at the stationary point $(\nu^*,\theta^*,\lambda^*)$.

3. Since the Lyapunov function used in the above analysis is the Lagrangian function $L(\nu,\theta,\lambda)$, we conclude that the stationary point $(\nu^*,\theta^*,\lambda^*)$ is a local saddle point. Finally by the local saddle point theorem, we deduce that θ^* is a locally optimal solution for the CVaR-constrained MDP problem.

This convergence proof procedure is standard for stochastic approximation algorithms, see (Bhatnagar et al., 2009; Bhatnagar and Lakshmanan, 2012) for further references.

Since ν converges on the faster timescale than θ and λ, the ν-update can be rewritten by assuming (θ,λ) as invariant quantities, i.e.,

$$\nu_{k+1}=\Gamma_{\mathcal{N}}\left[\nu_k-\zeta_3(k)\left(\lambda-\frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N\mathbf{1}\big\{\mathcal{J}(\xi_{j,k})\geq\nu_k\big\}\right)\right]. \quad (42)$$

Consider the continuous time dynamics of ν defined using differential inclusion

$$\dot\nu\in\Upsilon_\nu\left[-g(\nu)\right],\qquad \forall g(\nu)\in\partial_\nu L(\nu,\theta,\lambda), \quad (43)$$

where

$$\Upsilon_\nu[K(\nu)]:=\lim_{0<\eta\to 0}\frac{\Gamma_{\mathcal{N}}(\nu+\eta K(\nu))-\Gamma_{\mathcal{N}}(\nu)}{\eta}.$$

Here $\Upsilon_\nu[K(\nu)]$ is the left directional derivative of the function $\Gamma_{\mathcal{N}}(\nu)$ in the direction of $K(\nu)$. By using the left directional derivative $\Upsilon_\nu\left[-g(\nu)\right]$ in the sub-gradient descent algorithm for ν, the gradient will point in the descent direction along the boundary of ν whenever the ν-update hits its boundary.

Furthermore, since ν converges on a faster timescale than θ, and λ is on the slowest time-scale, the θ-update can be rewritten using the converged $\nu^*(\theta)$, assuming λ as an invariant quantity, i.e.,

$$\begin{aligned}\theta_{k+1}=&\Gamma_\Theta\Bigg[\theta_k-\zeta_2(k)\Bigg(\frac{1}{N}\sum_{j=1}^N\nabla_\theta\log\mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\mathcal{G}(\xi_{j,k})\\ &+\frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N\nabla_\theta\log\mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\big(\mathcal{J}(\xi_{j,k})-\nu\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k})\geq\nu^*(\theta_k)\big\}\Bigg)\Bigg].\end{aligned}$$

Consider the continuous time dynamics of $\theta \in \Theta$:

$$\dot{\theta} = \Upsilon_\theta \left[-\nabla_\theta L(\nu, \theta, \lambda)\right]|_{\nu=\nu^*(\theta)}, \tag{44}$$

where

$$\Upsilon_\theta[K(\theta)] := \lim_{0<\eta\to 0} \frac{\Gamma_\Theta(\theta + \eta K(\theta)) - \Gamma_\Theta(\theta)}{\eta}.$$

Similar to the analysis of ν, $\Upsilon_\theta[K(\theta)]$ is the left directional derivative of the function $\Gamma_\Theta(\theta)$ in the direction of $K(\theta)$. By using the left directional derivative $\Upsilon_\theta\left[-\nabla_\theta L(\nu, \theta, \lambda)\right]$ in the gradient descent algorithm for θ, the gradient will point in the descent direction along the boundary of Θ whenever the θ-update hits its boundary.

Finally, since the λ-update converges in the slowest time-scale, the λ-update can be rewritten using the converged $\theta^*(\lambda)$ and $\nu^*(\lambda)$, i.e.,

$$\lambda_{k+1} = \Gamma_\Lambda\left(\lambda_k + \zeta_1(k)\left(\nu^*(\lambda_k) + \frac{1}{1-\alpha}\frac{1}{N}\sum_{j=1}^{N}\left(\mathcal{J}(\xi_{j,k}) - \nu^*(\lambda_k)\right)^+ - \beta\right)\right). \tag{45}$$

Consider the continuous time system

$$\dot{\lambda}(t) = \Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}\right], \qquad \lambda(t) \geq 0, \tag{46}$$

where

$$\Upsilon_\lambda[K(\lambda)] := \lim_{0<\eta\to 0} \frac{\Gamma_\Lambda\big(\lambda + \eta K(\lambda)\big) - \Gamma_\Lambda(\lambda)}{\eta}.$$

Again, similar to the analysis of (ν, θ), $\Upsilon_\lambda[K(\lambda)]$ is the left directional derivative of the function $\Gamma_\Lambda(\lambda)$ in the direction of $K(\lambda)$. By using the left directional derivative $\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)\right]$ in the gradient ascent algorithm for λ, the gradient will point in the ascent direction along the boundary of $[0, \lambda_{\max}]$ whenever the λ-update hits its boundary.

Define

$$L^*(\lambda) = L(\nu^*(\lambda), \theta^*(\lambda), \lambda),$$

for $\lambda \geq 0$ where $(\theta^*(\lambda), \nu^*(\lambda)) \in \Theta \times [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ is a local minimum of $L(\nu, \theta, \lambda)$ for fixed $\lambda \geq 0$, i.e., $L(\nu, \theta, \lambda) \geq L(\nu^*(\lambda), \theta^*(\lambda), \lambda)$ for any $(\theta, \nu) \in \Theta \times [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}] \cap \mathcal{B}_{(\theta^*(\lambda),\nu^*(\lambda))}(r)$ for some $r > 0$.

Next, we want to show that the ODE (46) is actually a gradient ascent of the Lagrangian function using the envelope theorem from mathematical economics (Milgrom and Segal, 2002). The envelope theorem describes sufficient conditions for the derivative of L^* with respect to λ to equal the partial derivative of the objective function L with respect to λ, holding (θ, ν) at its local optimum $(\theta, \nu) = (\theta^*(\lambda), \nu^*(\lambda))$. We will show that $\nabla_\lambda L^*(\lambda)$ coincides with $\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}$ as follows.

Theorem 16 *The value function L^* is absolutely continuous. Furthermore,*

$$L^*(\lambda) = L^*(0) + \int_0^\lambda \nabla_{\lambda'} L(\nu, \theta, \lambda')\Big|_{\theta=\theta^*(s),\nu=\nu^*(s),\lambda'=s} ds, \;\; \lambda \geq 0. \tag{47}$$

Proof. The proof follows from analogous arguments to Lemma 4.3 in Borkar (2005). From the definition of L^*, observe that for any $\lambda', \lambda'' \geq 0$ with $\lambda' < \lambda''$,

$$\begin{aligned}
|L^*(\lambda'') - L^*(\lambda')| &\leq \sup_{\theta\in\Theta,\nu\in[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]} |L(\nu, \theta, \lambda'') - L(\nu, \theta, \lambda')| \\
&= \sup_{\theta\in\Theta,\nu\in[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]} \left|\int_{\lambda'}^{\lambda''} \nabla_\lambda L(\nu, \theta, s) ds\right| \\
&\leq \int_{\lambda'}^{\lambda''} \sup_{\theta\in\Theta,\nu\in[\frac{-D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]} |\nabla_\lambda L(\nu, \theta, s)|\, ds \leq \frac{3D_{\max}}{(1-\alpha)(1-\gamma)}(\lambda'' - \lambda').
\end{aligned}$$

This implies that L^* is absolutely continuous. Therefore, L^* is continuous everywhere and differentiable almost everywhere.

By the Milgrom–Segal envelope theorem in mathematical economics (Theorem 1 of Milgrom and Segal (2002)), one concludes that the derivative of $L^*(\lambda)$ coincides with the derivative of $L(\nu, \theta, \lambda)$ at the point of differentiability λ and $\theta = \theta^*(\lambda)$, $\nu = \nu^*(\lambda)$. Also since L^* is absolutely continuous, the limit of $(L^*(\lambda) - L^*(\lambda'))/(\lambda - \lambda')$ at $\lambda \uparrow \lambda'$ (or $\lambda \downarrow \lambda'$) coincides with the lower/upper directional derivatives if λ' is a point of non-differentiability. Thus, there is only a countable number of non-differentiable points in L^* and the set of non-differentiable points of L^* has measure zero. Therefore, expression (47) holds and one concludes that $\nabla_\lambda L^*(\lambda)$ coincides with $\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}$. ■

Before getting into the main result, we have the following technical proposition whose proof directly follows from the definition of $\log \mathbb{P}_\theta(\xi)$ and Assumption 3 that $\nabla_\theta \mu(a_k|x_k; \theta)$ is Lipschitz in θ.

Proposition 17 *$\nabla_\theta L(\nu, \theta, \lambda)$ is Lipschitz in θ.*

Proof. Recall that

$$\nabla_\theta L(\nu, \theta, \lambda) = \sum_\xi \mathbb{P}_\theta(\xi) \cdot \nabla_\theta \log \mathbb{P}_\theta(\xi) \left(\mathcal{G}(\xi) + \frac{\lambda}{1-\alpha}\big(\mathcal{J}(\xi) - \nu\big)\mathbf{1}\big\{\mathcal{J}(\xi) \geq \nu\big\}\right)$$

and $\nabla_\theta \log \mathbb{P}_\theta(\xi) = \sum_{k=0}^{T-1} \nabla_\theta \mu(a_k|x_k; \theta)/\mu(a_k|x_k; \theta)$ whenever $\mu(a_k|x_k; \theta) \in (0, 1]$. Now Assumption (A1) implies that $\nabla_\theta \mu(a_k|x_k; \theta)$ is a Lipschitz function in θ for any $a \in \mathcal{A}$ and $k \in \{0, \ldots, T-1\}$ and $\mu(a_k|x_k; \theta)$ is differentiable in θ. Therefore, by recalling that

$$\mathbb{P}_\theta(\xi) = \prod_{k=0}^{T-1} P(x_{k+1}|x_k, a_k)\mu(a_k|x_k; \theta)\mathbf{1}\{x_0 = x^0\}$$

and by combining these arguments and noting that the sum of products of Lipschitz functions is Lipschitz, one concludes that $\nabla_\theta L(\nu, \theta, \lambda)$ is Lipschitz in θ. ■

Remark 18 *The fact that $\nabla_\theta L(\nu, \theta, \lambda)$ is Lipschitz in θ implies that*

$$\|\nabla_\theta L(\nu, \theta, \lambda)\|^2 \leq 2(\|\nabla_\theta L(\nu, \theta_0, \lambda)\| + \|\theta_0\|)^2 + 2\|\theta\|^2$$

which further implies that

$$\|\nabla_\theta L(\nu, \theta, \lambda)\|^2 \leq K_1(1 + \|\theta\|^2).$$

for $K_1 = 2\max(1, (\|\nabla_\theta L(\nu, \theta_0, \lambda)\| + \|\theta_0\|)^2) > 0$. *Similarly, the fact that* $\nabla_\theta \log \mathbb{P}_\theta(\xi)$ *is Lipschitz implies that*

$$\|\nabla_\theta \log \mathbb{P}_\theta(\xi)\|^2 \leq K_2(\xi)(1 + \|\theta\|^2)$$

for a positive random variable $K_2(\xi)$. *Furthermore, since* $T < \infty$ *w.p.* 1, $\mu(a_k|x_k;\theta) \in (0, 1]$ *and* $\nabla_\theta \mu(a_k|x_k;\theta)$ *is Lipschitz for any* $k < T$, $K_2(\xi) < \infty$ *w.p.* 1.

Remark 19 *For any given* $\theta \in \Theta$, $\lambda \geq 0$, *and* $g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)$, *we have*

$$|g(\nu)| \leq 3\lambda(1 + |\nu|)/(1 - \alpha). \tag{48}$$

To see this, recall that the set of $g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)$ *can be parameterized by* $q \in [0, 1]$ *as*

$$g(\nu; q) = -\frac{\lambda}{(1-\alpha)} \sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\left\{\mathcal{J}(\xi) > \nu\right\} - \frac{\lambda q}{1-\alpha} \sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\left\{\mathcal{J}(\xi) = \nu\right\} + \lambda.$$

It is obvious that $|\mathbf{1}\left\{\mathcal{J}(\xi) = \nu\right\}|, |\mathbf{1}\left\{\mathcal{J}(\xi) > \nu\right\}| \leq 1 + |\nu|$. *Thus,* $\left|\sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\left\{\mathcal{J}(\xi) > \nu\right\}\right| \leq \sup_\xi |\mathbf{1}\left\{\mathcal{J}(\xi) > \nu\right\}| \leq 1 + |\nu|$, *and* $\left|\sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\left\{\mathcal{J}(\xi) = \nu\right\}\right| \leq 1 + |\nu|$. *Recalling that* $0 < (1 - q), (1 - \alpha) < 1$, *these arguments imply the claim of* (48).

We are now in a position to prove the convergence analysis of Theorem 7.

Proof. [Proof of Theorem 7] We split the proof into the following four steps:

Step 1 (Convergence of ν-update) Since ν converges on a faster time scale than θ and λ, according to Lemma 1 in Chapter 6 of Borkar (2008), one can analyze the convergence properties of ν in the following update rule for arbitrary quantities of θ and λ (i.e., here we have $\theta = \theta_k$ and $\lambda = \lambda_k$):

$$\nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k + \zeta_3(k)\left(\frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N \mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\} - \lambda + \delta\nu_{k+1}\right)\right), \tag{49}$$

and the Martingale difference term with respect to ν is given by

$$\delta\nu_{k+1} = \frac{\lambda}{1-\alpha}\left(-\frac{1}{N}\sum_{j=1}^N \mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\} + \sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\{\mathcal{J}(\xi) \geq \nu_k\}\right). \tag{50}$$

First, one can show that $\delta\nu_{k+1}$ is square integrable, i.e.,

$$\mathbb{E}[\|\delta\nu_{k+1}\|^2 \mid F_{\nu,k}] \leq 4\left(\frac{\lambda_{\max}}{1-\alpha}\right)^2$$

where $\mathcal{F}_{\nu,k} = \sigma\big(\nu_m,\, \delta\nu_m,\, m \leq k\big)$ is the filtration of ν_k generated by different independent trajectories.

Second, since the history trajectories are generated based on the sampling probability mass function $\mathbb{P}_\theta(\xi)$, expression (40) implies that $\mathbb{E}\left[\delta\nu_{k+1} \mid \mathcal{F}_{\nu,k}\right] = 0$. Therefore, the ν-update is a stochastic approximation of the ODE (43) with a Martingale difference error term, i.e.,

$$\frac{\lambda}{1-\alpha}\sum_\xi \mathbb{P}_\theta(\xi)\mathbf{1}\{\mathcal{J}(\xi) \geq \nu_k\} - \lambda \in -\partial_\nu L(\nu, \theta, \lambda)|_{\nu=\nu_k}.$$

Then one can invoke Corollary 4 in Chapter 5 of Borkar (2008) (stochastic approximation theory for non-differentiable systems) to show that the sequence $\{\nu_k\}$, $\nu_k \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ converges almost surely to a fixed point $\nu^* \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ of the differential inclusion (43), where

$$\nu^* \in N_c := \left\{\nu \in \left[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\right] : \Upsilon_\nu[-g(\nu)] = 0,\, g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\right\}.$$

To justify the assumptions of this corollary, 1) from Remark 19, the Lipschitz property is satisfied, i.e., $\sup_{g(\nu)\in\partial_\nu L(\nu,\theta,\lambda)} |g(\nu)| \leq 3\lambda(1+|\nu|)/(1-\alpha)$, 2) $[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ and $\partial_\nu L(\nu, \theta, \lambda)$ are convex compact sets by definition, which implies $\{(\nu, g(\nu)) \mid g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\}$ is a closed set, and further implies $\partial_\nu L(\nu, \theta, \lambda)$ is an upper semi-continuous set valued mapping, 3) the step-size rule follows from Assumption 6, 4) the Martingale difference assumption follows from (50), and 5) $\nu_k \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}], \forall i$ implies that $\sup_k \|\nu_k\| < \infty$ almost surely.

Consider the ODE for $\nu \in \mathbb{R}$ in (43), we define the set-valued derivative of L as follows:

$$D_t L(\nu, \theta, \lambda) = \big\{g(\nu)\Upsilon_\nu\big[-g(\nu)\big] \mid \forall g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\big\}.$$

One can conclude that

$$\max_{g(\nu)} D_t L(\nu, \theta, \lambda) = \max\big\{g(\nu)\Upsilon_\nu\big[-g(\nu)\big] \mid g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\big\}.$$

We now show that $\max_{g(\nu)} D_t L(\nu, \theta, \lambda) \leq 0$ and this quantity is non-zero if $\Upsilon_\nu\big[-g(\nu)\big] \neq 0$ for every $g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)$ by considering three cases. To distinguish the latter two cases, we need to define,

$$\mathcal{J}(\nu) := \left\{g(\nu) \in \partial L_\nu(\nu, \theta, \lambda) \,\middle|\, \forall \eta_0 > 0,\, \exists \eta \in (0, \eta_0] \text{ such that } \theta - \eta g(\nu) \notin \left[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\right]\right\}.$$

Case 1: $\nu \in (-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma})$.
For every $g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)$, there exists a sufficiently small $\eta_0 > 0$ such that $\nu - \eta_0 g(\nu) \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ and

$$\Gamma_{\mathcal{N}}\big(\theta - \eta_0 g(\nu)\big) - \theta = -\eta_0 g(\nu).$$

Therefore, the definition of $\Upsilon_\theta[-g(\nu)]$ implies

$$\max_{g(\nu)} D_t L(\nu, \theta, \lambda) = \max\big\{-g^2(\nu) \mid g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\big\} \leq 0. \tag{51}$$

The maximum is attained because $\partial_\nu L(\nu, \theta, \lambda)$ is a convex compact set and $g(\nu)\Upsilon_\nu\big[-g(\nu)\big]$ is a continuous function. At the same time, we have $\max_{g(\nu)} D_t L(\nu, \theta, \lambda) < 0$ whenever $0 \notin \partial_\nu L(\nu, \theta, \lambda)$.
Case 2: $\nu \in \{-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\}$ *and* $\mathcal{J}(\nu)$ *is empty.*
The condition $\nu - \eta g(\nu) \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ implies that

$$\Upsilon_\nu\big[-g(\nu)\big] = -g(\nu).$$

Then we obtain

$$\max_{g(\nu)} D_t L(\nu, \theta, \lambda) = \max\big\{-g^2(\nu) \mid g(\nu) \in \partial_\nu L(\nu, \theta, \lambda)\big\} \leq 0. \tag{52}$$

Furthermore, we have $\max_{g(\nu)} D_t L(\nu,\theta,\lambda) < 0$ whenever $0 \notin \partial_\nu L(\nu,\theta,\lambda)$.

Case 3: $\nu \in \{-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\}$ *and* $\mathcal{J}(\nu)$ *is nonempty*.

First, consider any $g(\nu) \in \mathcal{J}(\nu)$. For any $\eta > 0$, define $\nu_\eta := \nu - \eta g(\nu)$. The above condition implies that when $0 < \eta \to 0$, $\Gamma_{\mathcal{N}}[\nu_\eta]$ is the projection of ν_η to the tangent space of $[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$. For any element $\hat{\nu} \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$, since the set $\{\nu \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}] : \|\nu - \nu_\eta\|_2 \leq \|\hat{\nu} - \nu_\eta\|_2\}$ is compact, the projection of ν_η on $[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ exists. Furthermore, since $f(\nu) := \frac{1}{2}(\nu - \nu_\eta)^2$ is a strongly convex function and $\nabla f(\nu) = \nu - \nu_\eta$, by the first order optimality condition, one obtains

$$\nabla f(\nu_\eta^*)(\nu - \nu_\eta^*) = (\nu_\eta^* - \nu_\eta)(\nu - \nu_\eta^*) \geq 0, \quad \forall \nu \in \left[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\right]$$

where ν_η^* is the unique projection of ν_η (the projection is unique because $f(\nu)$ is strongly convex and $[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ is a convex compact set). Since the projection (minimizer) is unique, the above equality holds if and only if $\nu = \nu_\eta^*$.

Therefore, for any $\nu \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ and $\eta > 0$,

$$g(\nu)\Upsilon_\nu\big[-g(\nu)\big] = g(\nu)\left(\lim_{0<\eta\to 0}\frac{\nu_\eta^* - \nu}{\eta}\right)$$

$$= \left(\lim_{0<\eta\to 0}\frac{\nu - \nu_\eta}{\eta}\right)\left(\lim_{0<\eta\to 0}\frac{\nu_\eta^* - \nu}{\eta}\right) = \lim_{0<\eta\to 0}\frac{-\|\nu_\eta^* - \nu\|^2}{\eta^2} + \lim_{0<\eta\to 0}\big(\nu_\eta^* - \nu_\eta\big)\left(\frac{\nu_\eta^* - \nu}{\eta^2}\right) \leq 0.$$

Second, for any $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda) \cap \mathcal{J}(\nu)^c$, one obtains $\nu - \eta g(\nu) \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$, for any $\eta \in (0, \eta_0]$ and some $\eta_0 > 0$. In this case, the arguments follow from case 2 and the following expression holds: $\Upsilon_\nu\big[-g(\nu)\big] = -g(\nu)$.

Combining these arguments, one concludes that

$$\max_{g(\nu)} D_t L(\nu,\theta,\lambda)$$
$$\leq \max\big\{\max\big\{g(\nu)\,\Upsilon_\nu\big[-g(\nu)\big] \mid g(\nu) \in \mathcal{J}(\nu)\big\}, \max\big\{-g^2(\nu) \mid g(\nu) \in \partial_\nu L(\nu,\theta,\lambda) \cap \mathcal{J}(\nu)^c\big\}\big\} \leq 0. \tag{53}$$

This quantity is non-zero whenever $0 \notin \{g(\nu)\,\Upsilon_\nu\big[-g(\nu)\big] \mid \forall g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)\}$ (this is because, for any $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda) \cap \mathcal{J}(\nu)^c$, one obtains $g(\nu)\,\Upsilon_\nu\big[-g(\nu)\big] = -g(\nu)^2$). Thus, by similar arguments one may conclude that $\max_{g(\nu)} D_t L(\nu,\theta,\lambda) \leq 0$ and it is non-zero if $\Upsilon_\nu\big[-g(\nu)\big] \neq 0$ for every $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)$.

Now for any given θ and λ, define the following Lyapunov function

$$\mathcal{L}_{\theta,\lambda}(\nu) = L(\nu,\theta,\lambda) - L(\nu^*,\theta,\lambda)$$

where ν^* is a minimum point (for any given (θ,λ), L is a convex function in ν). Then $\mathcal{L}_{\theta,\lambda}(\nu)$ is a positive definite function, i.e., $\mathcal{L}_{\theta,\lambda}(\nu) \geq 0$. On the other hand, by the definition of a minimum point, one easily obtains $0 \in \{g(\nu^*)\,\Upsilon_\nu\big[-g(\nu^*)\big]|_{\nu=\nu^*} \mid \forall g(\nu^*) \in \partial_\nu L(\nu,\theta,\lambda)|_{\nu=\nu^*}\}$ which means that ν^* is also a stationary point, i.e., $\nu^* \in N_c$.

Note that $\max_{g(\nu)} D_t \mathcal{L}_{\theta,\lambda}(\nu) = \max_{g(\nu)} D_t L(\nu,\theta,\lambda) \leq 0$ and this quantity is non-zero if $\Upsilon_\nu\big[-g(\nu)\big] \neq 0$ for every $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)$. Therefore, by the Lyapunov theory for asymptotically stable differential inclusions (see Theorem 3.10 and Corollary 3.11 in Benaim et al. (2006), where the Lyapunov function $\mathcal{L}_{\theta,\lambda}(\nu)$ satisfies Hypothesis 3.1 and the property in (53) is equivalent

to Hypothesis 3.9 in the reference), the above arguments imply that with any initial condition $\nu(0)$, the state trajectory $\nu(t)$ of (43) converges to ν^*, i.e., $L(\nu^*,\theta,\lambda) \leq L(\nu(t),\theta,\lambda) \leq L(\nu(0),\theta,\lambda)$ for any $t \geq 0$.

As stated earlier, the sequence $\{\nu_k\}$, $\nu_k \in [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$ constitutes a stochastic approximation to the differential inclusion (43), and thus converges almost surely its solution (Borkar, 2008), which further converges almost surely to $\nu^* \in N_c$. Also, it can be easily seen that N_c is a closed subset of the compact set $[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$, and therefore a compact set itself.

Step 2 (Convergence of θ-update) Since θ converges on a faster time scale than λ and ν converges faster than θ, according to Lemma 1 in Chapter 6 of Borkar (2008) one can prove convergence of the θ update for any arbitrary λ (i.e., $\lambda = \lambda_k$). Furthermore, in the θ-update, we have that $\|\nu_k - \nu^*(\theta_k)\| \to 0$ almost surely. By the continuity condition of $\nabla_\theta L(\nu,\theta,\lambda)$, this also implies $\|\nabla_\theta L(\nu,\theta,\lambda)|_{\theta=\theta_k,\nu=\nu_k} - \nabla_\theta L(\nu,\theta,\lambda)|_{\theta=\theta_k,\nu=\nu^*(\theta_k)}\| \to 0$. Therefore, the θ-update can be rewritten as a stochastic approximation, i.e.,

$$\theta_{k+1} = \Gamma_\Theta\left(\theta_k + \zeta_2(k)\Big(-\nabla_\theta L(\nu,\theta,\lambda)|_{\theta=\theta_k,\nu=\nu^*(\theta_k)} + \delta\theta_{k+1}\Big)\right), \tag{54}$$

where

$$\begin{aligned}\delta\theta_{k+1} =& \nabla_\theta L(\nu,\theta,\lambda)|_{\theta=\theta_k,\nu=\nu^*(\theta_k)} - \frac{1}{N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})\,|_{\theta=\theta_k}\,\mathcal{G}(\xi_{j,k})\\ &- \frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\big(\mathcal{J}(\xi_{j,k}) - \nu^*(\theta_k)\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu^*(\theta_k)\big\}\\ &+ \frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\big(\nu^*(\theta_k) - \nu_k\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu^*(\theta_k)\big\}\\ &+ \frac{\lambda}{(1-\alpha)N}\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})|_{\theta=\theta_k}\big(\mathcal{J}(\xi_{j,k}) - \nu_k\big)\big(\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\} - \mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu^*(\theta_k)\big\}\big).\end{aligned} \tag{55}$$

First, we consider the last two components in (61). Recall that $\|\nu_k - \nu^*(\theta_k)\| \to 0$ almost surely. Furthermore by noticing that $\nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})$ is Lipschitz in θ, θ lies in a compact set Θ, both $\mathcal{J}(\xi_{j,k})$ and ν_k are bounded, and $\nu, \nu^*(\theta_k)$ lie in a compact set $\mathcal{N}$, one immediately concludes that as $i \to \infty$,

$$\begin{aligned}&\big(\nu^*(\theta_k) - \nu_k\big)\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu^*(\theta_k)\big\} \to 0, \quad \text{almost surely}\\ &\big(\mathcal{J}(\xi_{j,k}) - \nu_k\big)\big(\mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu_k\big\} - \mathbf{1}\big\{\mathcal{J}(\xi_{j,k}) \geq \nu^*(\theta_k)\big\}\big) \to 0, \quad \text{almost surely}\end{aligned} \tag{56}$$

Second, one can show that $\delta\theta_{k+1}$ is square integrable, i.e., $\mathbb{E}[\|\delta\theta_{k+1}\|^2 \mid F_{\theta,k}] \leq K_k(1 + \|\theta_k\|^2)$ for some $K_k > 0$, where $\mathcal{F}_{\theta,k} = \sigma\big(\theta_m, \delta\theta_m, m \leq k\big)$ is the filtration of θ_k generated by different

independent trajectories. To see this, notice that

$$
\begin{aligned}
&\|\delta\theta_{k+1}\|^2 \\
\leq& 2\left(\nabla_\theta L(\nu,\theta,\lambda)|_{\theta=\theta_k,\nu=\nu^*(\theta_k)}\right)^2 + \frac{2}{N^2}\left(\frac{C_{\max}}{1-\gamma}+\frac{2\lambda D_{\max}}{(1-\alpha)(1-\gamma)}\right)^2\left(\sum_{j=1}^N \nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})\ |_{\theta=\theta_k}\right)^2 \\
\leq& 2K_{1,k}(1+\|\theta_k\|^2) + \frac{2^N}{N^2}\left(\frac{C_{\max}}{1-\gamma}+\frac{2\lambda_{\max} D_{\max}}{(1-\alpha)(1-\gamma)}\right)^2\left(\sum_{j=1}^N \|\nabla_\theta \log \mathbb{P}_\theta(\xi_{j,k})\ |_{\theta=\theta_k}\|^2\right) \\
\leq& 2K_{1,k}(1+\|\theta_k\|^2) + \frac{2^N}{N^2}\left(\frac{C_{\max}}{1-\gamma}+\frac{2\lambda_{\max} D_{\max}}{(1-\alpha)(1-\gamma)}\right)^2\left(\sum_{j=1}^N K_2(\xi_{j,k})(1+\|\theta_k\|^2)\right) \\
\leq& 2\left(K_{1,k}+\frac{2^{N-1}}{N}\left(\frac{C_{\max}}{1-\gamma}+\frac{2\lambda_{\max} D_{\max}}{(1-\alpha)(1-\gamma)}\right)^2 \max_{1\leq j\leq N} K_2(\xi_{j,k})\right)(1+\|\theta_k\|^2).
\end{aligned}
$$

The Lipschitz upper bounds are due to the results in Remark 18. Since $K_2(\xi_{j,k}) < \infty$ w.p. 1, there exists $K_{2,k} < \infty$ such that $\max_{1\leq j\leq N} K_2(\xi_{j,k}) \leq K_{2,k}$. By combining these results, one concludes that $\mathbb{E}[\|\delta\theta_{k+1}\|^2 \mid F_{\theta,k}] \leq K_k(1+\|\theta_k\|^2)$ where

$$
K_k = 2\left(K_{1,k}+\frac{2^{N-1}K_{2,k}}{N}\left(\frac{C_{\max}}{1-\gamma}+\frac{2\lambda_{\max} D_{\max}}{(1-\alpha)(1-\gamma)}\right)^2\right) < \infty.
$$

Third, since the history trajectories are generated based on the sampling probability mass function $\mathbb{P}_{\theta_k}(\xi)$, expression (39) implies that $\mathbb{E}\left[\delta\theta_{k+1} \mid \mathcal{F}_{\theta,k}\right] = 0$. Therefore, the θ-update is a stochastic approximation of the ODE (44) with a Martingale difference error term. In addition, from the convergence analysis of the ν-update, $\nu^*(\theta)$ is an asymptotically stable equilibrium point for the sequence $\{\nu_k\}$. From (40), $\partial_\nu L(\nu,\theta,\lambda)$ is a Lipschitz set-valued mapping in θ (since $\mathbb{P}_\theta(\xi)$ is Lipschitz in θ), and thus it can be easily seen that $\nu^*(\theta)$ is a Lipschitz continuous mapping of θ.

Now consider the continuous time dynamics for $\theta \in \Theta$, given in (44). We may write

$$
\left.\frac{dL(\nu,\theta,\lambda)}{dt}\right|_{\nu=\nu^*(\theta)} = \left(\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right)^\top \Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right]. \tag{57}
$$

By considering the following cases, we now show that $dL(\nu,\theta,\lambda)/dt|_{\nu=\nu^*(\theta)} \leq 0$ and this quantity is non-zero whenever $\left\|\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right]\right\| \neq 0$.

Case 1: When $\theta \in \Theta^\circ = \Theta \setminus \partial\Theta$.
Since Θ° is the interior of the set Θ and Θ is a convex compact set, there exists a sufficiently small $\eta_0 > 0$ such that $\theta - \eta_0\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)} \in \Theta$ and

$$
\Gamma_\Theta\left(\theta - \eta_0\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right) - \theta = -\eta_0\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}.
$$

Therefore, the definition of $\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right]$ implies

$$
\left.\frac{dL(\nu,\theta,\lambda)}{dt}\right|_{\nu=\nu^*(\theta)} = -\left\|\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right\|^2 \leq 0. \tag{58}
$$

At the same time, we have $dL(\nu,\theta,\lambda)/dt|_{\nu=\nu^*(\theta)} < 0$ whenever $\|\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\| \neq 0$.

Case 2: When $\theta \in \partial\Theta$ and $\theta - \eta\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)} \in \Theta$ for any $\eta \in (0,\eta_0]$ and some $\eta_0 > 0$.
The condition $\theta - \eta\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)} \in \Theta$ implies that

$$
\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right] = -\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}.
$$

Then we obtain

$$
\left.\frac{dL(\nu,\theta,\lambda)}{dt}\right|_{\nu=\nu^*(\theta)} = -\left\|\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right\|^2 \leq 0. \tag{59}
$$

Furthermore, $dL(\nu,\theta,\lambda)/dt|_{\nu=\nu^*(\theta)} < 0$ when $\|\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\| \neq 0$.

Case 3: When $\theta \in \partial\Theta$ and $\theta - \eta\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)} \notin \Theta$ for some $\eta \in (0,\eta_0]$ and any $\eta_0 > 0$.
For any $\eta > 0$, define $\theta_\eta := \theta - \eta\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}$. The above condition implies that when $0 < \eta \to 0$, $\Gamma_\Theta[\theta_\eta]$ is the projection of θ_η to the tangent space of Θ. For any element $\hat{\theta} \in \Theta$, since the set $\{\theta \in \Theta : \|\theta - \theta_\eta\|_2 \leq \|\hat{\theta} - \theta_\eta\|_2\}$ is compact, the projection of θ_η on Θ exists. Furthermore, since $f(\theta) := \frac{1}{2}\|\theta - \theta_\eta\|_2^2$ is a strongly convex function and $\nabla f(\theta) = \theta - \theta_\eta$, by the first order optimality condition, one obtains

$$
\nabla f(\theta_\eta^*)^\top(\theta - \theta_\eta^*) = (\theta_\eta^* - \theta_\eta)^\top(\theta - \theta_\eta^*) \geq 0, \quad \forall\theta \in \Theta,
$$

where θ_η^* is the unique projection of θ_η (the projection is unique because $f(\theta)$ is strongly convex and Θ is a convex compact set). Since the projection (minimizer) is unique, the above equality holds if and only if $\theta = \theta_\eta^*$.

Therefore, for any $\theta \in \Theta$ and $\eta > 0$,

$$
\begin{aligned}
&\left(\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right)^\top \Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right] = \left(\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right)^\top \left(\lim_{0<\eta\to 0}\frac{\theta_\eta^* - \theta}{\eta}\right) \\
=& \left(\lim_{0<\eta\to 0}\frac{\theta - \theta_\eta}{\eta}\right)^\top \left(\lim_{0<\eta\to 0}\frac{\theta_\eta^* - \theta}{\eta}\right) = \lim_{0<\eta\to 0}\frac{-\|\theta_\eta^* - \theta\|^2}{\eta^2} + \lim_{0<\eta\to 0}\left(\theta_\eta^* - \theta_\eta\right)^\top\left(\frac{\theta_\eta^* - \theta}{\eta^2}\right) \leq 0.
\end{aligned}
$$

By combining these arguments, one concludes that $dL(\nu,\theta,\lambda)/dt|_{\nu=\nu^*(\theta)} \leq 0$ and this quantity is non-zero whenever $\left\|\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right]\right\| \neq 0$.

Now, for any given λ, define the Lyapunov function

$$
\mathcal{L}_\lambda(\theta) = L(\nu^*(\theta),\theta,\lambda) - L(\nu^*(\theta^*),\theta^*,\lambda),
$$

where θ^* is a local minimum point. Then there exists a ball centered at θ^* with radius r such that for any $\theta \in \mathcal{B}_{\theta^*}(r)$, $\mathcal{L}_\lambda(\theta)$ is a locally positive definite function, i.e., $\mathcal{L}_\lambda(\theta) \geq 0$. On the other hand, by the definition of a local minimum point, one obtains $\Upsilon_\theta[-\nabla_\theta L(\theta^*,\nu,\lambda)|_{\nu=\nu^*(\theta^*)}]|_{\theta=\theta^*} = 0$ which means that θ^* is a stationary point, i.e., $\theta^* \in \Theta_c$.

Note that $d\mathcal{L}_\lambda(\theta(t))/dt = dL(\theta(t),\nu^*(\theta(t)),\lambda)/dt \leq 0$ and the time-derivative is non-zero whenever $\left\|\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right]\right\| \neq 0$. Therefore, by the Lyapunov theory for asymptotically stable systems from Chapter 4 of Khalil and Grizzle (2002), the above arguments imply that with any initial condition $\theta(0) \in \mathcal{B}_{\theta^*}(r)$, the state trajectory $\theta(t)$ of (44) converges to θ^*, i.e., $L(\theta^*,\nu^*(\theta^*),\lambda) \leq L(\theta(t),\nu^*(\theta(t)),\lambda) \leq L(\theta(0),\nu^*(\theta(0)),\lambda)$ for any $t \geq 0$.

Based on the above properties and noting that 1) from Proposition 17, $\nabla_\theta L(\nu,\theta,\lambda)$ is a Lipschitz function in θ, 2) the step-size rule follows from Assumption 6, 3) expression (61) implies that $\delta\theta_{k+1}$ is a square integrable Martingale difference, and 4) $\theta_k \in \Theta$, $\forall i$ implies that $\sup_k \|\theta_k\| < \infty$ almost surely, one can invoke Theorem 2 in Chapter 6 of Borkar (2008) (multi-time scale stochastic approximation theory) to show that the sequence $\{\theta_k\},\ \theta_k \in \Theta$ converges almost surely to the solution of the ODE (44), which further converges almost surely to $\theta^* \in \Theta$.

Step 3 (Local Minimum) Now, we want to show that the sequence $\{\theta_k, \nu_k\}$ converges to a local minimum of $L(\nu,\theta,\lambda)$ for any fixed λ. Recall that $\{\theta_k,\nu_k\}$ converges to $(\theta^*,\nu^*) := (\theta^*,\nu^*(\theta^*))$. Previous arguments on the (ν,θ)-convergence imply that with any initial condition $(\theta(0),\nu(0))$, the state trajectories $\theta(t)$ and $\nu(t)$ of (43) and (44) converge to the set of stationary points (θ^*,ν^*) in the positive invariant set $\Theta_c \times N_c$ and $L(\theta^*,\nu^*,\lambda) \leq L(\theta(t),\nu^*(\theta(t)),\lambda) \leq L(\theta(0),\nu^*(\theta(0)),\lambda) \leq L(\theta(0),\nu(t),\lambda) \leq L(\theta(0),\nu(0),\lambda)$ for any $t \geq 0$.

By contradiction, suppose (θ^*,ν^*) is not a local minimum. Then there exists $(\bar\theta,\bar\nu) \in \Theta \times [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}] \cap \mathcal{B}_{(\theta^*,\nu^*)}(r)$ such that

$$L(\bar\theta,\bar\nu,\lambda) = \min_{(\theta,\nu)\in\Theta\times[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]\cap\mathcal{B}_{(\theta^*,\nu^*)}(r)} L(\nu,\theta,\lambda).$$

The minimum is attained by the Weierstrass extreme value theorem. By putting $\theta(0) = \bar\theta$, the above arguments imply that

$$L(\bar\theta,\bar\nu,\lambda) = \min_{(\theta,\nu)\in\Theta\times[-\frac{D_{\max}}{1-\gamma},\frac{D_{\max}}{1-\gamma}]\cap\mathcal{B}_{(\theta^*,\nu^*)}(r)} L(\nu,\theta,\lambda) < L(\theta^*,\nu^*,\lambda) \leq L(\bar\theta,\bar\nu,\lambda)$$

which is a contradiction. Therefore, the stationary point (θ^*,ν^*) is a local minimum of $L(\nu,\theta,\lambda)$ as well.

Step 4 (Convergence of λ-update) Since the λ-update converges in the slowest time scale, according to previous analysis, we have that $\|\theta_k - \theta^*(\nu^*(\lambda_k),\lambda_k)\| \to 0$, $\|\nu_k - \nu^*(\lambda_k)\| \to 0$ almost surely. By continuity of $\nabla_\lambda L(\nu,\theta,\lambda)$, we also have the following:

$$\left\| \nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda_k),\nu=\nu^*(\lambda_k),\lambda=\lambda_k} - \nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta_k,\nu=\nu_k,\lambda=\lambda_k} \right\| \to 0, \quad \text{almost surely.}$$

Therefore, the λ-update rule can be re-written as follows:

$$\lambda_{k+1} = \Gamma_\Lambda\left(\lambda_k + \zeta_1(k)\left(\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda_k),\nu=\nu^*(\lambda_k),\lambda=\lambda_k} + \delta\lambda_{k+1}\right)\right) \tag{60}$$

where

$$\begin{aligned}\delta\lambda_{k+1} = &-\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda),\lambda=\lambda_k} + \left(\nu^*(\lambda_k) + \frac{1}{1-\alpha}\frac{1}{N}\sum_{j=1}^N \left(\mathcal{J}(\xi_{j,k}) - \nu^*(\lambda_k)\right)^+ - \beta\right)\\ &+(\nu_k - \nu^*(\lambda_k)) + \frac{1}{1-\alpha}\frac{1}{N}\sum_{j=1}^N\left(\left(\mathcal{J}(\xi_{j,k}) - \nu_k\right)^+ - \left(\mathcal{J}(\xi_{j,k}) - \nu^*(\lambda_k)\right)^+\right).\end{aligned} \tag{61}$$

From the fact that $\|\theta_k - \theta^*(\nu^*(\lambda_k),\lambda_k)\| \to 0$ almost surely as $i \to \infty$, one can conclude that the last component of the above expression vanishes, i.e., both $\|\nu_k - \nu^*(\lambda_k)\| \to 0$ and $\|\left(\mathcal{J}(\xi_{j,k}) - \nu_k\right)^+ - \left(\mathcal{J}(\xi_{j,k}) - \nu^*(\lambda_k)\right)^+\| \to 0$ almost surely. Moreover, from (41), we see that $\nabla_\lambda L(\nu,\theta,\lambda)$ is a constant function of λ. Similar to the θ-update, one can easily show that $\delta\lambda_{k+1}$ is square integrable, i.e.,

$$\mathbb{E}[\|\delta\lambda_{k+1}\|^2 \mid \mathcal{F}_{\lambda,k}] \leq 2\left(\beta + \frac{3D_{\max}}{(1-\gamma)(1-\alpha)}\right)^2,$$

where $\mathcal{F}_{\lambda,k} = \sigma\left(\lambda_m,\ \delta\lambda_m,\ m \leq k\right)$ is the filtration of λ generated by different independent trajectories. Furthermore, expression (41) implies that $\mathbb{E}\left[\delta\lambda_{k+1} \mid \mathcal{F}_{\lambda,k}\right] = 0$. Therefore, the λ-update is a stochastic approximation of the ODE (46) with a Martingale difference error term. In addition, from the convergence analysis of the (θ,ν)-update, $(\theta^*(\lambda),\nu^*(\lambda))$ is an asymptotically stable equilibrium point for the sequence $\{\theta_k,\nu_k\}$. From (39), $\nabla_\theta L(\nu,\theta,\lambda)$ is a linear mapping in λ, and $(\theta^*(\lambda),\nu^*(\lambda))$ is a Lipschitz continuous mapping of λ.

Consider the ODE for $\lambda \in [0,\lambda_{\max}]$ in (46). Analogous to the arguments for the θ-update, we can write

$$\frac{d(-L(\nu,\theta,\lambda))}{dt}\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)} = -\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)} \Upsilon_\lambda\left[\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}\right],$$

and show that $-dL(\nu,\theta,\lambda)/dt|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)} \leq 0$. This quantity is non-zero whenever

$$\left\|\Upsilon_\lambda\left[dL(\nu,\theta,\lambda)/d\lambda|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}\right]\right\| \neq 0.$$

Consider the Lyapunov function

$$\mathcal{L}(\lambda) = -L(\theta^*(\lambda),\nu^*(\lambda),\lambda) + L(\theta^*(\lambda^*),\nu^*(\lambda^*),\lambda^*)$$

where λ^* is a local maximum point. Then there exists a ball centered at λ^* with radius r such that for any $\lambda \in \mathcal{B}_{\lambda^*}(r)$, $\mathcal{L}(\lambda)$ is a locally positive definite function, i.e., $\mathcal{L}(\lambda) \geq 0$. On the other hand, by the definition of a local maximum point, one obtains

$$\Upsilon_\lambda\left[dL(\nu,\theta,\lambda)/d\lambda|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda),\lambda=\lambda^*}\right]|_{\lambda=\lambda^*} = 0$$

which means that λ^* is also a stationary point, i.e., $\lambda^* \in \Lambda_c$. Since

$$\frac{d\mathcal{L}(\lambda(t))}{dt} = -\frac{dL(\theta^*(\lambda(t)),\nu^*(\lambda(t)),\lambda(t))}{dt} \leq 0$$

and the time-derivative is non-zero whenever $\left\|\Upsilon_\lambda[\nabla_\lambda L(\nu,\theta,\lambda)\ |_{\nu=\nu^*(\lambda),\theta=\theta^*(\lambda)}]\right\| \neq 0$, the Lyapunov theory for asymptotically stable systems implies that $\lambda(t)$ converges to λ^*.

Given the above results and noting that the step size rule is selected according to Assumption 6, one can apply the multi-time scale stochastic approximation theory (Theorem 2 in Chapter 6 of Borkar (2008)) to show that the sequence $\{\lambda_k\}$ converges almost surely to the solution of the ODE (46), which further converges almost surely to $\lambda^* \in [0,\lambda_{\max}]$. Since $[0,\lambda_{\max}]$ is a compact set, following the same lines of arguments and recalling the envelope theorem (Theorem 16) for local optima, one further concludes that λ^* is a local maximum of $L(\theta^*(\lambda),\nu^*(\lambda),\lambda) = L^*(\lambda)$.

Step 5 (Local Saddle Point) By letting $\theta^* = \theta^*\big(\nu^*(\lambda^*), \lambda^*\big)$ and $\nu^* = \nu^*(\lambda^*)$, we will show that $(\theta^*, \nu^*, \lambda^*)$ is a local saddle point of the Lagrangian function $L(\nu, \theta, \lambda)$ if $\lambda^* \in [0, \lambda_{\max})$, and thus by the local saddle point theorem, θ^* is a locally optimal solution for the CVaR-constrained optimization.

Suppose the sequence $\{\lambda_k\}$ generated from (60) converges to a stationary point $\lambda^* \in [0, \lambda_{\max})$. Since step 3 implies that (θ^*, ν^*) is a local minimum of $L(\nu, \theta, \lambda^*)$ over the feasible set $(\theta, \nu) \in \Theta \times [-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}]$, there exists a $r > 0$ such that

$$L(\theta^*, \nu^*, \lambda^*) \leq L(\nu, \theta, \lambda^*), \quad \forall (\theta, \nu) \in \Theta \times \left[-\frac{D_{\max}}{1-\gamma}, \frac{D_{\max}}{1-\gamma}\right] \cap \mathcal{B}_{(\theta^*, \nu^*)}(r).$$

In order to complete the proof, we must show

$$\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] \leq \beta, \tag{62}$$

and

$$\lambda^*\left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] - \beta\right) = 0. \tag{63}$$

These two equations imply

$$\begin{aligned} L(\theta^*, \nu^*, \lambda^*) =& V^{\theta^*}(x^0) + \lambda^*\left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] - \beta\right) \\ =& V^{\theta^*}(x^0) \\ \geq& V^{\theta^*}(x^0) + \lambda\left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] - \beta\right) = L(\theta^*, \nu^*, \lambda), \end{aligned}$$

which further implies that $(\theta^*, \nu^*, \lambda^*)$ is a saddle point of $L(\nu, \theta, \lambda)$. We now show that (62) and (63) hold.

Recall that

$$\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda), \nu=\nu^*(\lambda), \lambda=\lambda^*}\right]|_{\lambda=\lambda^*} = 0.$$

We show (62) by contradiction. Suppose

$$\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] > \beta.$$

This implies that for $\lambda^* \in [0, \lambda_{\max})$, we have

$$\Gamma_\Lambda\left(\lambda^* - \eta\left(\beta - \left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right]\right)\right)\right) = \lambda^* - \eta\left(\beta - \left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right]\right)\right)$$

for any $\eta \in (0, \eta_{\max}]$, for some sufficiently small $\eta_{\max} > 0$. Therefore,

$$\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)\Big|_{\theta=\theta^*(\lambda), \nu=\nu^*(\lambda), \lambda=\lambda^*}\right]\Big|_{\lambda=\lambda^*} = \nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] - \beta > 0.$$

This is in contradiction with the fact that $\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda), \nu=\nu^*(\lambda), \lambda=\lambda^*}\right]|_{\lambda=\lambda^*} = 0$. Therefore, (62) holds.

To show that (63) holds, we only need to show that $\lambda^* = 0$ if

$$\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] < \beta.$$

Suppose $\lambda^* \in (0, \lambda_{\max})$, then there exists a sufficiently small $\eta_0 > 0$ such that

$$\begin{aligned} &\frac{1}{\eta_0}\left(\Gamma_\Lambda\left(\lambda^* - \eta_0\left(\beta - \left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right]\right)\right)\right) - \Gamma_\Lambda(\lambda^*)\right) \\ =& \nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] - \beta < 0. \end{aligned}$$

This again contradicts the assumption $\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda), \nu=\nu^*(\lambda), \lambda=\lambda^*}\right]|_{\lambda=\lambda^*} = 0$. Therefore (63) holds.

When $\lambda^* = \lambda_{\max}$ and $\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right] > \beta$,

$$\Gamma_\Lambda\left(\lambda^* - \eta\left(\beta - \left(\nu^* + \frac{1}{1-\alpha}\mathbb{E}\left[\left(\mathcal{J}^{\theta^*}(x^0) - \nu^*\right)^+\right]\right)\right)\right) = \lambda_{\max}$$

for any $\eta > 0$ and

$$\Upsilon_\lambda\left[\nabla_\lambda L(\nu, \theta, \lambda)|_{\theta=\theta^*(\lambda), \nu=\nu^*(\lambda), \lambda=\lambda^*}\right]|_{\lambda=\lambda^*} = 0.$$

In this case one cannot guarantee feasibility using the above analysis, and $(\theta^*, \nu^*, \lambda^*)$ is not a local saddle point. Such a λ^* is referred to as a spurious fixed point (see e.g., Chapter 8 of Kushner and Yin (1997)). Notice that λ^* is bounded (otherwise we can conclude that the problem is infeasible), so that by incrementally increasing $\lambda_{\max}$ in Algorithm 1, we can always prevent ourselves from obtaining a spurious fixed point solution.

Combining the above arguments, we finally conclude that $(\theta^*, \nu^*, \lambda^*)$ is a local saddle point of $L(\nu, \theta, \lambda)$. Then by the saddle point theorem, θ^* is a locally optimal policy for the CVaR-constrained optimization problem. ■

Appendix B. Convergence of Actor-Critic Algorithms

Recall from Assumption 6 that the SPSA step size $\{\Delta_k\}$ satisfies $\Delta_k \to 0$ as $k \to \infty$ and $\sum_k (\zeta_2(k)/\Delta_k)^2 < \infty$.

B.1 Gradient with Respect to λ (Proof of Lemma 11)

By taking the gradient of $V^\theta(x^0,\nu)$ w.r.t. λ (recall that both V and Q depend on λ through the cost function $\bar{C}$ of the augmented MDP $\bar{\mathcal{M}}$), we obtain

$$\begin{aligned}
\nabla_\lambda V^\theta(x^0,\nu) &= \sum_{a\in\bar{\mathcal{A}}} \mu(a|x^0,\nu;\theta)\nabla_\lambda Q^\theta(x^0,\nu,a)\\
&= \sum_{a\in\bar{\mathcal{A}}} \mu(a|x^0,\nu;\theta)\nabla_\lambda\Big[\bar{C}(x^0,\nu,a)+\sum_{(x',s')\in\bar{\mathcal{X}}}\gamma\bar{P}(x',s'|x^0,\nu,a)V^\theta(x',s')\Big]\\
&= \underbrace{\sum_{a}\mu(a|x^0,\nu;\theta)\nabla_\lambda\bar{C}(x^0,\nu,a)}_{h(x^0,\nu)}+\gamma\sum_{a,x',s'}\mu(a|x^0,\nu;\theta)\bar{P}(x',s'|x^0,\nu,a)\nabla_\lambda V^\theta(x',s')\\
&= h(x^0,\nu)+\gamma\sum_{a,x',s'}\mu(a|x^0,\nu;\theta)\bar{P}(x',s'|x^0,\nu,a)\nabla_\lambda V^\theta(x',s') \qquad (64)\\
&= h(x^0,\nu)+\gamma\sum_{a,x',s'}\mu(a|x^0,\nu;\theta)\bar{P}(x',s'|x^0,\nu,a)\Big[h(x',s')\\
&\qquad +\gamma\sum_{a',x'',s''}\mu(a'|x',s';\theta)\bar{P}(x'',s''|x',s',a')\nabla_\lambda V^\theta(x'',s'')\Big].
\end{aligned}$$

By unrolling the last equation using the definition of $\nabla_\lambda V^\theta(x,s)$ from (64), we obtain

$$\begin{aligned}
\nabla_\lambda V^\theta(x^0,\nu) &= \sum_{k=0}^{\infty}\gamma^k\sum_{x,s}\mathbb{P}(x_k=x,s_k=s\mid x_0=x^0,s_0=\nu;\theta)h(x,s)\\
&= \frac{1}{1-\gamma}\sum_{x,s}d_\gamma^\theta(x,s|x^0,\nu)h(x,s)=\frac{1}{1-\gamma}\sum_{x,s,a}d_\gamma^\theta(x,s|x^0,\nu)\mu(a|x,s)\nabla_\lambda\bar{C}(x,s,a)\\
&= \frac{1}{1-\gamma}\sum_{x,s,a}\pi_\gamma^\theta(x,s,a|x^0,\nu)\nabla_\lambda\bar{C}(x,s,a)\\
&= \frac{1}{1-\gamma}\sum_{x,s,a}\pi_\gamma^\theta(x,s,a|x^0,\nu)\frac{1}{1-\alpha}\mathbf{1}\{x=x_{\text{Tar}}\}(-s)^+.
\end{aligned}$$

This completes the proof.

B.2 Proof of Convergence of the Actor-Critic Algorithms

Before going through the details of the convergence proof, a high level overview of the proof technique is given as follows.

1. By utilizing temporal difference techniques, we show the critic update converges (in the fastest time scale) almost surely to a fixed point solution v^* of the projected form of Bellman's equation, which is defined on the augmented MDP $\bar{\mathcal{M}}$.

2. Similar to the analysis of the policy gradient algorithm, by convergence properties of multi-time scale discrete stochastic approximation algorithms, we show that each update $(\nu_k,\theta_k,\lambda_k)$ converges almost surely to a stationary point $(\nu^*,\theta^*,\lambda^*)$ of the corresponding continuous time system. In particular, by adopting the step-size rules defined in Assumption 8, we show that the convergence rate of v is fastest, followed by the convergence rate of ν and the convergence rate of θ, while the convergence rate of λ is the slowest among the set of parameters. Different from the policy gradient algorithm, the parameters of the actor-critic algorithm are updated incrementally. To adjust for this difference in the convergence analysis, modifications to the gradient estimate of ν are introduced, either via the SPSA method or the semi-trajectory method, to ensure the gradient estimates are unbiased. Following from the arguments of Lyapunov analysis, we prove that the continuous time system is locally asymptotically stable at the stationary point $(\nu^*,\theta^*,\lambda^*)$.

3. Following the same line of arguments from the proof of the policy gradient algorithm, we conclude that the stationary point $(v^*,\nu^*,\theta^*,\lambda^*)$ is a local saddle point. Finally, by the the local saddle point theorem, we deduce that θ^* is a locally optimal solution for the CVaR-constrained MDP problem.

This convergence proof procedure is rather standard for stochastic approximation algorithms, see (Bhatnagar et al., 2009; Bhatnagar and Lakshmanan, 2012) for further references.

B.2.1 PROOF OF THEOREM 10: CRITIC UPDATE (v-UPDATE)

By the step size conditions, one notices that $\{v_k\}$ converges on a faster time scale than $\{\nu_k\}$, $\{\theta_k\}$, and $\{\lambda_k\}$. According to Lemma 1 in Chapter 6 of Borkar (2008), one can take (ν,θ,λ) in the v-update as arbitrarily fixed quantities (in this case we have $(\nu,\theta,\lambda)=(\nu_k,\theta_k,\lambda_k)$). Thus the critic update can be re-written as follows:

$$v_{k+1}=v_k+\zeta_4(k)\phi(x_k,s_k)\delta_k(v_k), \qquad (65)$$

where the scalar

$$\delta_k(v_k)=-v_k^\top\phi(x_k,s_k)+\gamma v_k^\top\phi(x_{k+1},s_{k+1})+\bar{C}_\lambda(x_k,s_k,a_k)$$

is the temporal difference (TD) from (18). Define

$$A:=\sum_{y,a',s'}\pi_\gamma^\theta(y,s',a'|x,s)\phi(y,s')\left(\phi^\top(y,s')-\gamma\sum_{z,s''}\bar{P}(z,s''|y,s',a)\phi^\top(z,s'')\right), \qquad (66)$$

and

$$b:=\sum_{y,a',s'}\pi_\gamma^\theta(y,s',a'|x,s)\phi(y,s')\bar{C}_\lambda(y,s',a'). \qquad (67)$$

It is easy to see that the critic update v_k in (65) can be re-written as the following stochastic approximation scheme:

$$v_{k+1}=v_k+\zeta_4(k)(b-Av_k+\delta A_{k+1}), \qquad (68)$$

where the noise term δA_{k+1} is a square integrable Martingale difference, i.e., $\mathbb{E}[\delta A_{k+1}\mid\mathcal{F}_k]=0$ if the γ-occupation measure π_γ^θ is used to generate samples of $(x_k,s_k,a_k)$with $\mathcal{F}_k$ being the filtration generated by different independent trajectories. By writing

$$\delta A_{k+1}=-(b-Av_k)+\phi(x_k,s_k)\delta_k(v_k)$$

and noting $\mathbb{E}_{\pi_\gamma^\theta}[\phi(x_k,s_k)\delta_k(v_k) \mid \mathcal{F}_k] = -Av_k + b$, one can easily verify that the stochastic approximation scheme in (68) is equivalent to the critic iterates in (65) and δA_{k+1} is a Martingale difference, i.e., $\mathbb{E}_{\pi_\gamma^\theta}[\delta A_{k+1} \mid \mathcal{F}_k] = 0$. Let

$$h(v) := -Av + b.$$

Before getting into the convergence analysis, we present a technical lemma whose proof can be found in Lemma 6.10 of Bertsekas and Tsitsiklis (1996).

Lemma 20 *Every eigenvalue of the matrix A has positive real part.*

We now turn to the analysis of the critic iteration. Note that the following properties hold for the critic update scheme in (65): 1) $h(v)$ is Lipschitz, 2) the step size satisfies the properties in Assumption 8, 3) the noise term δA_{k+1} is a square integrable Martingale difference, 4) the function $h_c(v) := h(cv)/c$, $c \geq 1$ converges uniformly to a continuous function $h_\infty(v)$ for any v in a compact set, i.e., $h_c(v) \to h_\infty(v)$ as $c \to \infty$, and 5) the ordinary differential equation (ODE) $\dot{v} = h_\infty(v)$ has the origin as its unique locally asymptotically stable equilibrium. The fourth property can be easily verified from the fact that the magnitude of b is finite and $h_\infty(v) = -Av$. The fifth property follows directly from the facts that $h_\infty(v) = -Av$ and all eigenvalues of A have positive real parts.

By Theorem 3.1 in Borkar (2008), these five properties imply:

The critic iterates $\{v_k\}$ are bounded almost surely, i.e., $\sup_k \|v_k\| < \infty$ almost surely.

The convergence of the critic iterates in (65) can be related to the asymptotic behavior of the ODE

$$\dot{v} = h(v) = b - Av. \tag{69}$$

Specifically, Theorem 2 in Chapter 2 of Borkar (2008) and the above conditions imply $v_k \to v^*$ with probability 1, where the limit v^* depends on (ν,θ,λ) and is the unique solution satisfying $h(v^*) = 0$, i.e., $Av^* = b$. Therefore, the critic iterates converge to the unique fixed point v^* almost surely, as $k \to \infty$.

B.2.2 PROOF OF THEOREM 12

Step 1 (Convergence of v-update) The proof of convergence for the critic parameter follows directly from Theorem 10.

Step 2 (Convergence of SPSA Based ν-update) In this section, we analyze the ν-update for the incremental actor-critic method. This update is based on the SPSA perturbation method. The idea of this method is to estimate the sub-gradient $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)$ using two simulated value functions corresponding to $\nu^- = \nu - \Delta$ and $\nu^+ = \nu + \Delta$. Here $\Delta \geq 0$ is a positive random perturbation that vanishes asymptotically. The SPSA-based estimate for a sub-gradient $g(\nu) \in \partial_\nu L(\nu,\theta,\lambda)$ is given by

$$g(\nu) \approx \lambda + \frac{1}{2\Delta}\left(\phi^\top\left(x^0,\nu+\Delta\right) - \phi^\top\left(x^0,\nu-\Delta\right)\right)v.$$

First, we consider the following assumption on the feature functions in order to prove that the SPSA approximation is asymptotically unbiased.

Assumption 21 *For any $v \in \mathbb{R}^{\kappa_1}$, the feature functions satisfy the following conditions*

$$|\phi^\top\left(x^0,\nu+\Delta\right)v - \phi^\top\left(x^0,\nu-\Delta\right)v| \leq K_1(v)(1+\Delta).$$

Furthermore, the Lipschitz constants are uniformly bounded, i.e., $\sup_{v\in\mathbb{R}^{\kappa_1}} K_1^2(v) < \infty$.

This assumption is mild as the expected utility objective function implies that $L(\nu,\theta,\lambda)$ is Lipschitz in ν, and $\phi_V^\top\left(x^0,\nu\right)v$ is just a linear function approximation of $V^\theta(x^0,\nu)$.

Next, we turn to the convergence analysis of the sub-gradient estimation and ν-update. Since ν converges faster than θ and λ. Consider the ν-update in (20):

$$\nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\left(\lambda + \frac{1}{2\Delta_k}\left(\phi^\top\left(x^0,\nu_k+\Delta_k\right) - \phi^\top\left(x^0,\nu_k-\Delta_k\right)\right)v_k\right)\right), \tag{70}$$

where according to Lemma 1 in Chapter 6 of Borkar (2008), (θ_k,λ_k) in this expression are viewed as constant quantities. Since v converges faster than ν, Lemma 1 in Chapter 6 of Borkar (2008) also implies $\|v_k - v^*(\nu_k)\| \to 0$ almost surely, where $v^*(\nu)$ is the converged critic parameter. Together with the above assumption that the feature function is bounded, one can rewrite the ν-update in (20) as follows:

$$\nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\left(\lambda + \frac{1}{2\Delta_k}\left(\phi^\top\left(x^0,\nu_k+\Delta_k\right) - \phi^\top\left(x^0,\nu_k-\Delta_k\right)\right)v^*(\nu_k) + \epsilon_k\right)\right), \tag{71}$$

where

$$\epsilon_k = \frac{1}{2\Delta_k}\left(\phi^\top\left(x^0,\nu_k+\Delta_k\right) - \phi^\top\left(x^0,\nu_k-\Delta_k\right)\right)(v_k - v^*(\nu_k)) \to 0, \quad \text{almost surely.}$$

Equipped with this intermediate result, we establish the bias and convergence of the stochastic sub-gradient estimate. Let

$$\overline{g}(\nu_k) \in \arg\max\left\{g : g \in \partial_\nu L(\nu,\theta,\lambda)|_{\nu=\nu_k}\right\},$$

and

$$\begin{aligned}
\Lambda_{1,k+1} =& \left(\frac{\left(\phi^\top\left(x^0,\nu_k+\Delta_k\right) - \phi^\top\left(x^0,\nu_k-\Delta_k\right)\right)v^*(\nu_k)}{2\Delta_k} - E_M(k)\right),\\
\Lambda_{2,k} =& \lambda_k + E_M^L(k) - \overline{g}(\nu_k),\\
\Lambda_{3,k} =& E_M(k) - E_M^L(k),
\end{aligned}$$

where

$$\begin{aligned}
E_M(k) :=& \mathbb{E}\left[\frac{1}{2\Delta_k}\left(\phi^\top\left(x^0,\nu_k+\Delta_k\right) - \phi^\top\left(x^0,\nu_k-\Delta_k\right)\right)v^*(\nu_k) \mid \Delta_k\right],\\
E_M^L(k) :=& \mathbb{E}\left[\frac{1}{2\Delta_k}\left(V^\theta\left(x^0,\nu_k+\Delta_k\right) - V^\theta\left(x^0,\nu_k-\Delta_k\right)\right) \mid \Delta_k\right].
\end{aligned}$$

Note that (71) is equivalent to

$$\nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\left(\overline{g}(\nu_k) + \Lambda_{1,k+1} + \Lambda_{2,k} + \Lambda_{3,k}\right)\right). \tag{72}$$

First, it is clear that $\Lambda_{1,k+1}$ is a Martingale difference as $\mathbb{E}[\Lambda_{1,k+1} \mid \mathcal{F}_k] = 0$, which implies that

$$M_{k+1} = \sum_{j=0}^{k} \zeta_3(j)\Lambda_{1,j+1}$$

is a Martingale w.r.t. the filtration $\mathcal{F}_k$. By the Martingale convergence theorem, we can show that if $\sup_{k\geq 0}\mathbb{E}[M_k^2] < \infty$, when $k \to \infty$, M_k converges almost surely and $\zeta_3(k)\Lambda_{1,k+1} \to 0$ almost surely. To show that $\sup_{k\geq 0}\mathbb{E}[M_k^2] < \infty$, for any $t \geq 0$ one observes that

$$\begin{aligned}\mathbb{E}[M_{k+1}^2] &= \sum_{j=0}^{k} (\zeta_3(j))^2\, \mathbb{E}[\mathbb{E}[\Lambda_{1,j+1}^2 \mid \Delta_j]] \\ &\leq 2\sum_{j=0}^{k} \mathbb{E}\Bigg[\left(\frac{\zeta_3(j)}{2\Delta_j}\right)^2 \Bigg\{\mathbb{E}\left[\left(\left(\phi^\top\left(x^0, \nu_j + \Delta_j\right) - \phi^\top\left(x^0, \nu_j - \Delta_j\right)\right)v^*(\nu_j)\right)^2 \mid \Delta_j\right] \\ &\qquad + \mathbb{E}\left[\left(\phi^\top\left(x^0, \nu_j + \Delta_j\right) - \phi^\top\left(x^0, \nu_j - \Delta_j\right)\right)v^*(\nu_j) \mid \Delta_j\right]^2\Bigg\}\Bigg].\end{aligned}$$

Now based on Assumption 21, the above expression implies

$$\mathbb{E}[M_{k+1}^2] \leq 2\sum_{j=0}^{k} \mathbb{E}\left[\left(\frac{\zeta_3(j)}{2\Delta_j}\right)^2 2K_1^2(1+\Delta_j)^2\right].$$

Combining the above results with the step size conditions, there exists $K = 4K_1^2 > 0$ such that

$$\sup_{k\geq 0}\mathbb{E}[M_{k+1}^2] \leq K\sum_{j=0}^{\infty} \mathbb{E}\left[\left(\frac{\zeta_3(j)}{2\Delta_j}\right)^2\right] + (\zeta_3(j))^2 < \infty.$$

Second, by the Min Common/Max Crossing theorem in Chapter 5 of Bertsekas (2009), one can show that $\partial_\nu L(\nu,\theta,\lambda)|_{\nu=\nu_k}$ is a non-empty, convex, and compact set. Therefore, by duality of directional directives and sub-differentials, i.e.,

$$\max\{g : g \in \partial_\nu L(\nu,\theta,\lambda)|_{\nu=\nu_k}\} = \lim_{\xi\downarrow 0}\frac{L(\nu_k+\xi,\theta,\lambda) - L(\nu_k-\xi,\theta,\lambda)}{2\xi},$$

one concludes that for $\lambda_k = \lambda$ (we can treat λ_k as a constant because it converges on a slower time scale than ν_k),

$$\lambda + E_M^L(k) = \overline{g}(\nu_k) + O(\Delta_k),$$

almost surely. This further implies that

$$\Lambda_{2,k} = O(\Delta_k), \quad \text{i.e.,} \quad \Lambda_{2,k} \to 0 \quad \text{as} \quad k \to \infty,$$

almost surely.

Third, since $d_\gamma^\theta(x^0, \nu | x^0, \nu) = 1$, from the definition of $\epsilon_\theta(v^*(\nu_k))$,

$$|\Lambda_{3,k}| \leq 2\epsilon_\theta(v^*(\nu_k))/\Delta_k.$$

As t goes to infinity, $\epsilon_\theta(v^*(\nu_k))/\Delta_k \to 0$ by assumption and $\Lambda_{3,k} \to 0$.

Finally, since $\zeta_3(k)\Lambda_{1,k+1} \to 0$, $\Lambda_{2,k} \to 0$, and $\Lambda_{3,k} \to 0$ almost surely, the ν-update in (72) is a noisy sub-gradient descent update with vanishing disturbance bias. Thus, the ν-update in (20) can be viewed as an Euler discretization of an element of the following differential inclusion,

$$\dot{\nu} \in \Upsilon_\nu\left[-g(\nu)\right], \qquad \forall g(\nu) \in \partial_\nu L(\nu,\theta,\lambda), \tag{73}$$

and the ν-convergence analysis is analogous to Step 1 of the proof of Theorem 7.

Step 2′ (Convergence of Semi-trajectory ν-update) Since ν converges on a faster timescale than θ and λ, according to Lemma 1 in Chapter 6 of Borkar (2008), the convergence property of ν in (23) can be shown for any arbitrarily fixed pair of (θ,λ) (in this case we have $(\theta,\lambda) = (\theta_k,\lambda_k)$), i.e.,

$$\nu_{k+1} = \Gamma_{\mathcal{N}}\left(\nu_k - \zeta_3(k)\left(\lambda - \frac{\lambda}{1-\alpha}\left(\mathbb{P}\left(s_{\text{Tar}} \leq 0 \mid x_0 = x^0, s_0 = \nu_k, \theta\right) + \delta\nu_{M,k+1}\right)\right)\right), \tag{74}$$

where

$$\delta\nu_{M,k+1} = -\mathbb{P}\left(s_{\text{Tar}} \leq 0 \mid x_0 = x^0, s_0 = \nu_k, \mu\right) + \mathbf{1}\left\{x_k = x_{\text{Tar}}, s_k \leq 0\right\} \tag{75}$$

is a square integrable stochastic term, specifically,

$$\mathbb{E}[(\delta\nu_{M,k+1})^2 \mid \mathcal{F}_{\nu,k}] \leq 2,$$

where $\mathcal{F}_{\nu,k} = \sigma(\nu_m,\, \delta\nu_m,\, m \leq k)$ is the filtration generated by ν. Since $\mathbb{E}\left[\delta\nu_{M,k+1} \mid \mathcal{F}_{\nu,k}\right] = 0$, $\delta\nu_{M,k+1}$ is a Martingale difference and the ν-update in (74) is a stochastic approximation of an element of the differential inclusion

$$\frac{\lambda}{1-\alpha}\mathbb{P}\left(s_{\text{Tar}} \leq 0 \mid x_0 = x^0, s_0 = \nu_k, \theta\right) - \lambda \in -\partial_\nu L(\nu,\theta,\lambda)|_{\nu=\nu_k}.$$

Thus, the ν-update in (23) can be viewed as an Euler discretization of the differential inclusion in (73), and the ν-convergence analysis is analogous to Step 1 of the proof of Theorem 7.

Step 3 (Convergence of θ-update) We first analyze the actor update (θ-update). Since θ converges on a faster time scale than λ, according to Lemma 1 in Chapter 6 of Borkar (2008), one can take λ in the θ-update as a fixed quantity (i.e., here we have that $\lambda = \lambda_k$). Furthermore, since v and ν converge on a faster scale than θ, one also have $\|v_k - v^*(\theta_k)\| \to 0$, $\|\nu_k - \nu^*(\theta_k)\| \to 0$ almost surely, and since convergence almost surely of the ν sequence implies convergence in distribution, we have $\|\pi_\gamma^{\theta_k}(x', s', a' | x_0 = x^0, s_0 = \nu_k) - \pi_\gamma^{\theta_k}(x', s', a' | x_0 = x^0, s_0 = \nu^*(\theta_k))\| \to 0$. In the following analysis, we assume that the initial state $x^0 \in \mathcal{X}$ is given. Consider the θ-update in (21)

$$\theta_{k+1} = \Gamma_\Theta\left(\theta_k - \zeta_2(k)\left(\nabla_\theta \log\mu(a_k|x_k,s_k;\theta)|_{\theta=\theta_k}\frac{\delta_k(v_k)}{1-\gamma}\right)\right). \tag{76}$$

Utilizing the above convergence properties, (76) can be rewritten as follows:

$$\theta_{k+1} = \Gamma_\Theta\left(\theta_k - \zeta_2(k)\left(\nabla_\theta \log\mu(a_k|x_k,s_k;\theta)|_{\theta=\theta_k}\left(\frac{\delta_k(v^*(\theta_k))}{1-\gamma} + \epsilon_k\right)\right)\right),$$

where we showed in the convergence analysis of the ν sequence that

$$\epsilon_k = \frac{\delta_k(v_k)}{1-\gamma} - \frac{\delta_k(v^*(\theta_k))}{1-\gamma} \to 0, \quad \text{almost surely.}$$

Consider the case in which the value function for a fixed policy θ (i.e., $\theta = \theta_k$) is approximated by a learned function approximation, $\phi^\top(x,s)v^*(\theta_k)$. If the approximation is sufficiently good, we might hope to use it in place of $V^\theta(x,s)$ and still point roughly in the direction of the true gradient. Recall the temporal difference error (random variable) for a given pair $(x_k, s_k) \in \mathcal{X} \times \mathbb{R}$:

$$\delta_k(v) = -v^\top \phi(x_k, s_k) + \gamma v^\top \phi(x_{k+1}, s_{k+1}) + \bar{C}_\lambda(x_k, s_k, a_k).$$

Define the v-dependent approximated advantage function

$$\tilde{A}^{\theta,v}(x,s,a) := \tilde{Q}^{\theta,v}(x,s,a) - v^\top \phi(x,s),$$

where

$$\tilde{Q}^{\theta,v}(x,s,a) = \gamma \sum_{x',s'} \bar{P}(x',s'|x,s,a) v^\top \phi(x',s') + \bar{C}_\lambda(x,s,a).$$

The following lemma, whose proof follows from the proof of Lemma 3 in Bhatnagar et al. (2009), shows that $\delta_k(v)$ is an unbiased estimator of $\tilde{A}^{\theta,v}$.

Lemma 22 *For any given policy μ and $v \in \mathbb{R}^{\kappa_1}$, we have*

$$\tilde{A}^{\theta,v}(x,s,a) = \mathbb{E}[\delta_k(v) \mid x_k = x, s_k = s, a_k = a].$$

Define

$$\nabla_\theta \tilde{L}_v(\nu,\theta,\lambda) := \frac{1}{1-\gamma} \sum_{x,a,s} \pi_\gamma^\theta(x,s,a|x_0 = x^0, s_0 = \nu) \nabla_\theta \log \mu(a|x,s;\theta) \tilde{A}^{\theta,v}(x,s,a)$$

as the linear function approximation of $\nabla_\theta \tilde{L}(\nu,\theta,\lambda)$. Similar to Proposition 17, we present the following technical lemma on the Lipschitz property of $\nabla_\theta \tilde{L}_v(\nu,\theta,\lambda)$.

Proposition 23 *$\nabla_\theta \tilde{L}_v(\nu,\theta,\lambda)$ is a Lipschitz function in θ.*

Proof. Consider the feature vector v. Recall that the feature vector satisfies the linear equation $Av = b$, where A and b are given by (66) and (67), respectively. From Lemma 1 in Bhatnagar and Lakshmanan (2012), by exploiting the inverse of A using Cramer's rule, one may show that v is continuously differentiable in θ. Now consider the γ-occupation measure π_γ^θ. By applying Theorem 2 in Altman et al. (2004) (or Theorem 3.1 in Shardlow and Stuart (2000)), it can be seen that the occupation measure π_γ^θ of the process (x_k, s_k) is continuously differentiable in θ. Recall from Assumption 3 in Section 2.2 that $\nabla_\theta \mu(a_k|x_k,s_k;\theta)$ is a Lipschitz function in θ for any $a \in \mathcal{A}$ and $k \in \{0,\ldots,T-1\}$, and $\mu(a_k|x_k,s_k;\theta)$ is differentiable in θ. By combining these arguments and noting that the sum of products of Lipschitz functions is Lipschitz, one concludes that $\nabla_\theta \tilde{L}_v(\nu,\theta,\lambda)$ is Lipschitz in θ. ■

We turn to the convergence proof of θ.

Theorem 24 *The sequence of θ-updates in* (21) *converges almost surely to an equilibrium point $\widehat{\theta}^*$ that satisfies $\Upsilon_\theta\left[-\nabla_\theta \tilde{L}_{v^*(\theta)}(\nu^*(\theta),\theta,\lambda)\right] = 0$, for a given $\lambda \in [0,\lambda_{\max}]$. Furthermore, if the function approximation error $\epsilon_\theta(v_k)$ vanishes as the feature vector v_k converges to v^*, then the sequence of θ-updates converges to θ^* almost surely, where θ^* is a local minimum point of $L(\nu^*(\theta),\theta,\lambda)$ for a given $\lambda \in [0,\lambda_{\max}]$.*

Proof. We will mainly focus on proving the convergence of $\theta_k \to \theta^*$ (second part of the theorem). Since we just showed in Proposition 23 that $\nabla_\theta \tilde{L}_{v^*(\theta)}(\nu^*(\theta),\theta,\lambda)$ is Lipschitz in θ, the convergence proof of $\theta_k \to \widehat{\theta}^*$ (first part of the theorem) follows from identical arguments.

Note that the θ-update in (76) can be rewritten as:

$$\theta_{k+1} = \Gamma_\Theta\left(\theta_k + \zeta_2(k)\left(-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta),\theta=\theta_k} + \delta\theta_{k+1} + \delta\theta_\epsilon\right)\right),$$

where

$$\delta\theta_{k+1} = \sum_{x',a',s'} \pi_\gamma^{\theta_k}(x',s',a'|x_0 = x^0, s_0 = \nu^*(\theta_k)) \nabla_\theta \log \mu(a'|x',s';\theta)|_{\theta=\theta_k} \frac{\tilde{A}^{\theta_k,v^*(\theta_k)}(x',s',a')}{1-\gamma}$$
$$- \nabla_\theta \log \mu(a_k|x_k,s_k;\theta)|_{\theta=\theta_k} \frac{\delta_k(v^*(\theta_k))}{1-\gamma}.$$

and

$$\delta\theta_\epsilon = \sum_{x',a',s'} \pi_\gamma^{\theta_k}(x',s',a'|x_0 = x^0, s_0 = \nu^*(\theta_k)) \cdot$$
$$\frac{\nabla_\theta \log \mu(a'|x',s';\theta)|_{\theta=\theta_k}}{1-\gamma} (A^{\theta_k}(x',s',a') - \tilde{A}^{\theta_k,v^*(\theta_k)}(x',s',a'))$$

First, one can show that $\delta\theta_{k+1}$ is square integrable, specifically,

$$\begin{aligned}
&\mathbb{E}[\|\delta\theta_{k+1}\|^2 \mid \mathcal{F}_{\theta,k}] \\
&\leq \frac{2}{1-\gamma} \|\nabla_\theta \log \mu(u|x,s;\theta)|_{\theta=\theta_k}\, \mathbf{1}\{\mu(u|x,s;\theta_k) > 0\}\, \|_\infty^2 \left(\|\tilde{A}^{\theta_k,v^*(\theta_k)}(x,s,a)\|_\infty^2 + |\delta_k(v^*(\theta_k))|^2\right) \\
&\leq \frac{2}{1-\gamma} \cdot \frac{\|\nabla_\theta \mu(u|x,s;\theta)|_{\theta=\theta_k}\|_\infty^2}{\min\{\mu(u|x,s;\theta_k) \mid \mu(u|x,s;\theta_k) > 0\}^2} \left(\|\tilde{A}^{\theta_k,v^*(\theta_k)}(x,s,a)\|_\infty^2 + |\delta_k(v^*(\theta_k))|^2\right) \\
&\leq 64 \frac{K^2\|\theta_k\|^2}{1-\gamma} \left(\max_{x,s,a} |\bar{C}_\lambda(x,s,a)|^2 + 2 \max_{x,s} \|\phi(x,s)\|^2 \sup_k \|v_k\|^2\right) \\
&\leq 64 \frac{K^2\|\theta_k\|^2}{1-\gamma} \left(\left|\max\left\{C_{\max}, \frac{2\lambda D_{\max}}{\gamma^T(1-\alpha)(1-\gamma)}\right\}\right|^2 + 2 \max_{x,s} \|\phi(x,s)\|^2 \sup_k \|v_k\|^2\right),
\end{aligned}$$

for some Lipschitz constant K, where the indicator function in the second line can be explained by the fact that $\pi_\gamma^{\theta_k}(x,s,u) = 0$ whenever $\mu(u \mid x,s;\theta_k) = 0$ and because the expectation is taken with respect to $\pi_\gamma^{\theta_k}$. The third inequality uses Assumption 3 and the fact that μ takes on finitely-many values (and thus its nonzero values are bounded away from zero). Finally, $\sup_k \|v_k\| < \infty$ follows from the Lyapunov analysis in the critic update.

Second, note that

$$\delta\theta_\epsilon \leq \frac{(1+\gamma)\|\psi_{\theta_k}\|_\infty}{(1-\gamma)^2} \epsilon_{\theta_k}(v^*(\theta_k)), \tag{77}$$

where $\psi_\theta(x,s,a) = \nabla_\theta \log \mu(a|x,s;\theta)$ is the "compatible feature." The last inequality is due to the fact that since π_γ^θ is a probability measure, convexity of quadratic functions implies

$$
\begin{aligned}
&\sum_{x',a',s'} \pi_\gamma^\theta(x',s',a'|x_0=x^0,s_0=\nu^*(\theta))(A^\theta(x',s',a') - \tilde{A}^{\theta,v}(x',s',a')) \\
\leq &\sum_{x',a',s'} \pi_\gamma^\theta(x',s',a'|x_0=x^0,s_0=\nu^*(\theta))(Q^\theta(x',s',a') - \tilde{Q}^{\theta,v}(x',s',a')) \\
&+ \sum_{x',s'} d_\gamma^\theta(x',s'|x_0=x^0,s_0=\nu^*(\theta))(V^\theta(x',s') - \widetilde{V}^{\theta,v}(x',s')) \\
= &\gamma \sum_{x',a',s'} \pi_\gamma^\theta(x',s',a'|x_0=x^0,s_0=\nu^*(\theta)) \sum_{x'',s''} \bar{P}(x'',s''|x',s',a')(V^\theta(x'',s'') - \phi^\top(x'',s'')v) \\
&+ \sqrt{\sum_{x',s'} d_\gamma^\theta(x',s'|x_0=x^0,s_0=\nu^*(\theta))(V^\theta(x',s') - \widetilde{V}^{\theta,v}(x',s'))^2} \\
\leq &\gamma \sqrt{\sum_{x',a',s'} \pi_\gamma^\theta(x',s',a'|x_0=x^0,s_0=\nu^*(\theta)) \sum_{x'',s''} \bar{P}(x'',s''|x',s',a')(V^\theta(x'',s'') - \phi^\top(x'',s'')v)^2} \\
&+ \frac{\epsilon_\theta(v)}{1-\gamma} \\
\leq &\sqrt{\sum_{x'',s''} \left(d_\gamma^\theta(x'',s''|x^0,\nu^*(\theta)) - (1-\gamma)1\{x^0=x'',\nu=s''\}\right)(V^\theta(x'',s'') - \phi^\top(x'',s'')v)^2} + \frac{\epsilon_\theta(v)}{1-\gamma} \\
\leq &\left(\frac{1+\gamma}{1-\gamma}\right)\epsilon_\theta(v).
\end{aligned}
$$

Then by Lemma 22, if the γ-occupation measure π_γ^θ is used to generate samples (x_k, s_k, a_k), one obtains $\mathbb{E}\left[\delta\theta_{k+1} \mid \mathcal{F}_{\theta,k}\right] = 0$, where $\mathcal{F}_{\theta,k} = \sigma(\theta_m,\, \delta\theta_m,\, m \leq k)$ is the filtration generated by different independent trajectories. On the other hand, $|\delta\theta_\epsilon| \to 0$ as $\epsilon_{\theta_k}(v^*(\theta_k)) \to 0$. Therefore, the θ-update in (76) is a stochastic approximation of the continuous system $\theta(t)$, described by the ODE

$$\dot{\theta} = \Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right],$$

with an error term that is a sum of a vanishing bias and a Martingale difference. Thus, the convergence analysis of θ follows analogously from Step 2 in the proof of Theorem 7, i.e., the sequence of θ-updates in (21) converges to θ^* almost surely, where θ^* is the equilibrium point of the continuous system θ satisfying

$$\Upsilon_\theta\left[-\nabla_\theta L(\nu,\theta,\lambda)|_{\nu=\nu^*(\theta)}\right] = 0. \tag{78}$$

■

Step 4 (Local Minimum) The proof that (θ^*,ν^*) is a local minimum follows directly from the arguments in Step 3 in the proof of Theorem 7.

Step 5 (λ-update and Convergence to Local Saddle Point) Note that the λ-update converges on the slowest time scale, according to previous analysis, we have that $\|\theta_k - \theta^*(\lambda_k)\| \to 0$, $\|\nu_k - \nu^*(\lambda_k)\| \to 0$ almost surely. By continuity of $\nabla_\lambda L(\nu,\theta,\lambda)$, we also have the following:

$$\left\| \nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda_k),\nu=\nu^*(\lambda_k),\lambda=\lambda_k} - \nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta_k,\nu=\nu_k,\lambda=\lambda_k} \right\| \to 0.$$

Thus, (20) may be rewritten as

$$\lambda_{k+1} = \Gamma_\Lambda\left(\lambda_k + \zeta_1(k)\left(\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda),\lambda=\lambda_k} + \delta\lambda_{k+1}\right)\right), \tag{79}$$

where

$$
\begin{aligned}
\delta\lambda_{k+1} = &-\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda),\lambda=\lambda_k} + \\
&\left(\underbrace{(\nu_k - \nu^*(\lambda_k))}_{\|\nu_k-\nu^*(\lambda_k)\|\to 0} + \nu^*(\lambda_k) + \frac{(-s_k)^+}{(1-\alpha)(1-\gamma)}\mathbf{1}\{x_k = x_{\text{Tar}}\} - \beta\right).
\end{aligned} \tag{80}
$$

From (41), $\nabla_\lambda L(\nu,\theta,\lambda)$ does not depend on λ. Similar to the θ-update, one can easily show that $\delta\lambda_{k+1}$ is square integrable, specifically,

$$\mathbb{E}[\|\delta\lambda_{k+1}\|^2 \mid \mathcal{F}_{\lambda,k}] \leq 8\left(\beta^2 + \left(\frac{D_{\max}}{1-\gamma}\right)^2 + \left(\frac{2D_{\max}}{(1-\gamma)^2(1-\alpha)}\right)^2\right),$$

where $\mathcal{F}_{\lambda,k} = \sigma\big(\lambda_m,\, \delta\lambda_m,\, m \leq k\big)$ is the filtration of λ generated by different independent trajectories. Similar to the θ-update, using the γ-occupation measure π_γ^θ, one obtains $\mathbb{E}\left[\delta\lambda_{k+1} \mid \mathcal{F}_{\lambda,k}\right] = 0$. As above, the λ-update is a stochastic approximation for the continuous system $\lambda(t)$ described by the ODE

$$\dot{\lambda} = \Upsilon_\lambda\left[\nabla_\lambda L(\nu,\theta,\lambda)\Big|_{\theta=\theta^*(\lambda),\nu=\nu^*(\lambda)}\right],$$

with an error term that is a Martingale difference. Then the λ-convergence and the analysis of local optima follow from analogous arguments in Steps 4 and 5 in the proof of Theorem 7.

Local Identifiability of ℓ_1-minimization Dictionary Learning: a Sufficient and Almost Necessary Condition

Abstract

We study the theoretical properties of learning a dictionary from N signals $\mathbf{x}_i \in \mathbb{R}^K$ for $i = 1, \ldots, N$ via ℓ_1-minimization. We assume that $\mathbf{x}_i$'s are *i.i.d.* random linear combinations of the K columns from a complete (i.e., square and invertible) reference dictionary $\mathbf{D}_0 \in \mathbb{R}^{K\times K}$. Here, the random linear coefficients are generated from either the s-sparse Gaussian model or the Bernoulli-Gaussian model. First, for the population case, we establish a sufficient and almost necessary condition for the reference dictionary $\mathbf{D}_0$ to be locally identifiable, i.e., a strict local minimum of the expected ℓ_1-norm objective function. Our condition covers both sparse and dense cases of the random linear coefficients and significantly improves the sufficient condition by Gribonval and Schnass (2010). In addition, we show that for a complete μ-coherent reference dictionary, i.e., a dictionary with absolute pairwise column inner-product at most $\mu \in [0, 1)$, local identifiability holds even when the random linear coefficient vector has up to $O(\mu^{-2})$ nonzero entries. Moreover, our local identifiability results also translate to the finite sample case with high probability provided that the number of signals N scales as $O(K \log K)$.

Keywords: dictionary learning, ℓ_1-minimization, local minimum, non-convex optimization, sparse decomposition

1. Introduction

Expressing signals as sparse linear combinations of a dictionary basis has enjoyed great success in applications ranging from image denoising to audio compression. Given a known dictionary matrix $\mathbf{D} \in \mathbb{R}^{d\times K}$ with K columns or atoms, one popular method to recover the sparse coefficients $\boldsymbol{\alpha} \in \mathbb{R}^K$ of a signal $\mathbf{x} \in \mathbb{R}^d$ is through solving the convex ℓ_1-minimization problem

$$\text{minimize } \|\boldsymbol{\alpha}\|_1 \text{ subject to } \mathbf{x} = \mathbf{D}\boldsymbol{\alpha}.$$

This approach, known as *basis pursuit* (Chen et al., 1998), along with many of its variants, has been studied extensively in statistics and signal processing communities. See e.g., Donoho and Elad (2003); Fuchs (2004); Candes and Tao (2005).

For certain data types such as natural image patches, predefined dictionaries like the wavelets (Mallat, 2008) are usually available. However, for a less-known data type, a new dictionary has to be designed to effectively represent the data. Dictionary learning, or sparse coding, learns adaptively a dictionary from a set of training signals such that they have sparse representations under this dictionary (Olshausen and Field, 1997). One formulation of dictionary learning involves solving a non-convex ℓ_1-minimization problem (Zibulevsky et al., 2001; Plumbley, 2007; Gribonval and Schnass, 2010; Geng et al., 2011). Concretely, define

$$l(\mathbf{x}, \mathbf{D}) = \min_{\boldsymbol{\alpha}\in\mathbb{R}^K} \{\|\boldsymbol{\alpha}\|_1, \text{ subject to } \mathbf{x} = \mathbf{D}\boldsymbol{\alpha}\}. \tag{1}$$

We learn a dictionary from the N signals $\mathbf{x}_i \in \mathbb{R}^d$ for $i = 1, \ldots, N$ by solving

$$\min_{\mathbf{D}\in\mathcal{D}} \; L_N(\mathbf{D}) = \min_{\mathbf{D}\in\mathcal{D}} \frac{1}{N}\sum_{i=1}^{N} l(\mathbf{x}_i, \mathbf{D}). \tag{2}$$

Here, $\mathcal{D} \subset \mathbb{R}^{d\times K}$ is a constraint set for candidate dictionaries. In many signal processing tasks, learning an adaptive dictionary via the optimization problem (2) and its variants is empirically demonstrated to have superior performance over fixed standard dictionaries (Elad and Aharon, 2006; Peyré, 2009; Grosse et al., 2012). For a review of dictionary learning algorithms and applications, see Elad (2010); Rubinstein et al. (2010); Mairal et al. (2014).

Apart from the empirical success of many dictionary learning formulations, recently there is a growing body of work on the theory of dictionary learning. One line of research treats the problem of *dictionary identifiability*: if the signals are generated using a dictionary $\mathbf{D}_0$ referred to as the *reference dictionary*, under what conditions can we recover $\mathbf{D}_0$ by solving the dictionary learning problem? Being able to identify the reference dictionary is important when there is a need to interpret the learned dictionary, see for example Wu et al. (2016). Let $\boldsymbol{\alpha}_i \in \mathbb{R}^K$ for $i = 1, \ldots, N$ be some random vectors. A popular signal generation model assumes that a signal vector can be expressed as a linear combination of the columns of the reference dictionary: $\mathbf{x}_i \approx \mathbf{D}_0\boldsymbol{\alpha}_i$ (Gribonval and Schnass, 2010; Geng et al., 2011; Gribonval et al., 2015). In this paper, we will study the problem of *local identifiability* of ℓ_1-minimization dictionary learning (2) under this generating model.

Local identifiability. A reference dictionary $\mathbf{D}_0$ is said to be *locally identifiable* with respect to an objective function $L(\mathbf{D})$ if $\mathbf{D}_0$ is one of the strict local minima of L. The pioneer work of Gribonval and Schnass (2010) (referred to as GS henceforth) analyzed the ℓ_1-minimization problem (2) for noiseless signals ($\mathbf{x}_i = \mathbf{D}_0\boldsymbol{\alpha}_i$) and complete ($K = d$ and full rank) dictionaries. Under the sparse Bernoulli-Gaussian model for the linear coefficients $\boldsymbol{\alpha}_i$'s, they showed that for a sufficiently incoherent reference dictionary $\mathbf{D}_0$, $N = O(K \log K)$ samples can guarantee local identifiability with respect to $L_N(\mathbf{D})$ in (2) with high probability. Still in the noiseless setting, Geng et al. (2011) extended the analysis to over-complete ($K > d$) dictionaries. More recently under the noisy linear generative model with possible outliers, Gribonval et al. (2015) established local identifiability results for (2) with $l(\mathbf{x}, \mathbf{D})$ replaced by the LASSO objective function of Tibshirani (1996). Other related works on local identifiability include Schnass (2014) and Schnass (2015), who gave respectively sufficient conditions for the local correctness of the K-SVD (Aharon et al., 2006b) algorithm and a maximum response formulation of dictionary learning.

Contributions. There has not been much work on necessary conditions for local dictionary identifiability. Numerical experiments demonstrate that local identifiability undergoes a phase transition (Figure 1; see also Figure 3 of GS). The bound implied by the sufficient condition in GS falls well below the empirical phase boundary. Thus, even though theoretical results for the more general scenarios are available, we adopt the noiseless signals and complete dictionary setting of GS in order to find better local identifiability conditions. We summarize our main contributions below:

- For the population case where $N = \infty$, we establish a sufficient and almost necessary condition for local identifiability under both the s-sparse Gaussian and the Bernoulli-Gaussian models. For the Bernoulli-Gaussian model, the phase boundary implied by our condition significantly improves the GS bound and agrees well with the empirical phase boundary (Figure 1).

- We provide lower and upper bounds to approximate the quantities in our local identifiability condition, as it generally requires to solve a series of second-order cone programs to compute those quantities.

- As a consequence, we show that a μ-coherent reference dictionary—a dictionary with absolute pairwise column inner-product at most $\mu \in [0, 1)$—is locally identifiable for sparsity level, measured by the average number of nonzeros in the random linear coefficient vectors, up to the order $O(\mu^{-2})$. Moreover, if the sparsity level is greater than $O(\mu^{-2})$, the reference dictionary is generally not locally identifiable. In comparison, the sufficient condition by GS demands the number of dictionary atoms $K = O(\mu^{-2})$, which is a much more stringent requirement. For over-complete dictionaries, Geng et al. (2011) requires the sparsity level to be of the order $O(\mu^{-1})$. It should also be noted that Schnass (2015) establishes the bound $O(\mu^{-2})$ for *approximate* local identifiability under a new response maximization formulation of dictionary learning. To the best of our knowledge, our result is the first in showing that $O(\mu^{-2})$ is achievable and optimal for *exact* local recovery under the ℓ_1-minimization criterion.

- We also extend our identifiability results to the finite sample case. We show that for a fixed sparsity level, we need $N = O(K \log K)$ *i.i.d.* signals to determine whether or not the reference dictionary can be identified locally. This sample requirement is the same as GS's and is the best known sample requirement among all previous studies on local identifiability.

Other related works. Apart from analyzing the local minima of dictionary learning, another line of research aims at designing provable algorithms for recovering the reference dictionary. Georgiev et al. (2005) and Aharon et al. (2006a) proposed combinatorial algorithms and gave deterministic conditions for dictionary recovery which require sample size N to be exponentially large in the number of dictionary atoms K. Spielman et al. (2012) established exact global recovery results for complete dictionaries through efficient convex programs. Agarwal et al. (2014c) and Arora et al. (2014) proposed clustering-based methods to estimate the reference dictionary in the over-complete setting. Agarwal et al. (2014a) and Arora et al. (2015) provided theoretical guarantees for their alternating minimization algorithms. Sun et al. (2017) proposed a non-convex optimization algorithm that provably

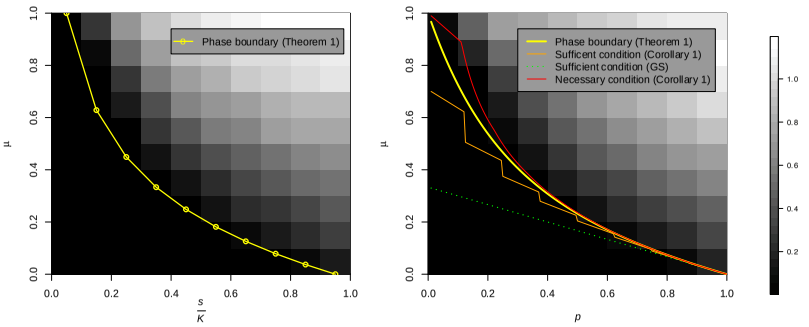

Figure 1: Local recovery errors for the s-sparse Gaussian model (Left) and the Bernoulli(p)-Gaussian model (Right). Under the s-sparse Gaussian model, the parameter $s \in \{1, \ldots, K\}$ is the number of nonzeros in each linear coefficient vector. Under the Bernoulli(p)-Gaussian model, $p \in (0, 1]$ is the probability of an entry of the linear coefficient vector being nonzero. The data are generated with the reference dictionary $\mathbf{D}_0 \in \mathbb{R}^{10\times 10}$ (i.e., $K = 10$) satisfying $\mathbf{D}_0^T\mathbf{D}_0 = \mu\mathbf{1}\mathbf{1}^T + (1-\mu)\mathbf{I}$ for $\mu \in [0, 1)$, see Example 5 for details. For each $(\mu, \frac{s}{K})$ or (μ, p) tuple, ten batches of $N = 2000$ signals $\{\mathbf{x}_i\}_{i=1}^{2000}$ are generated according to the noiseless linear model $\mathbf{x}_i = \mathbf{D}_0\boldsymbol{\alpha}_i$, with $\{\boldsymbol{\alpha}_i\}_{i=1}^{2000}$ drawn *i.i.d.* from the s-sparse Gaussian model or *i.i.d.* from the Bernoulli(p)-Gaussian model. For each batch, the dictionary is estimated through an alternating minimization algorithm in the `SPAMS` package (Mairal et al., 2010), with initial dictionary set to be $\mathbf{D}_0$. The grayscale intensity in the figure corresponds to the Frobenius error of the difference between the estimated dictionary and the reference dictionary $\mathbf{D}_0$, averaged for the ten batches. The "phase boundary" curve corresponds to the theoretical boundary that separates the region of local identifiability (below the curve) and the region of local non-identifiability (above the curve) according to Theorem 1 of this paper. The "Sufficient condition (Corollary 1)" and "Necessary condition (Corollary 1)" curves are the lower and upper bounds given by Corollary 1 to approximate the exact phase boundary. Finally, the "Sufficient condition (GS)" curve corresponds to the lower bound by GS. Note that for the s-sparse Gaussian model, the "Sufficient condition (Corollary 1)" and "Necessary condition (Corollary 1)" curves coincide with the phase boundary. See also Appendix Figures B.1 and B.2 for additional simulation results with $K = 20$ and $K = 50$.

recovers a complete reference dictionary for sparsity level up to $O(K)$. While in this paper we do not provide an algorithm, our identifiability conditions suggest theoretical limits of dictionary recovery for all algorithms attempting to solve the optimization problem (2). In particular, in the regime where the reference dictionary is not identifiable, no algorithm can simultaneously solve (2) and recover the ground truth reference dictionary.

Other related works include generalization bounds for signal reconstruction errors under the learned dictionary (Maurer and Pontil, 2010; Vainsencher et al., 2011; Mehta and Gray, 2013; Gribonval et al., 2013), dictionary identifiability through combinatorial matrix theory (Hillar and Sommer, 2015), as well as algorithms and theories for the closely related independent component analysis (Comon, 1994; Arora et al., 2012b) and nonnegative matrix factorization (Arora et al., 2012a; Recht et al., 2012).

The rest of the paper is organized as follows: In Section 2, we give basic assumptions and describe the two probabilistic models for signal generation. Section 3 develops sufficient and almost necessary local identifiability conditions under both models for the population problem, and establishes lower and upper approximating bounds. In Section 4, we will present local identifiability results for the finite sample problem. Detailed proofs for the theoretical results can be found in the Appendix.

2. Preliminaries

In this section, we will introduce notations and basic assumptions for our analysis.

2.1 Notations

For a positive integer m, define $[\![m]\!]$ to be the set of the first m positive integers, $\{1, \ldots, m\}$. The notation $\mathbf{x}[i]$ denotes the i-th entry of the vector $\mathbf{x} \in \mathbb{R}^m$. For a non-empty index set $S \subset [\![m]\!]$, we denote by $|S|$ the set cardinality and $\mathbf{x}[S] \in \mathbb{R}^{|S|}$ the sub-vector indexed by S. We define $\mathbf{x}[-j] := (\mathbf{x}[1], \ldots, \mathbf{x}[j-1], \mathbf{x}[j+1], \ldots, \mathbf{x}[m]) \in \mathbb{R}^{m-1}$ to be the vector $\mathbf{x}$ without its j-th entry.

For a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$, we denote by $\mathbf{A}[i, j]$ its (i, j)-th entry. For non-empty sets $S \subset [\![m]\!]$ and $T \subset [\![n]\!]$, denote by $\mathbf{A}[S, T]$ the sub-matrix of $\mathbf{A}$ with the rows indexed by S and columns indexed by T. Denote by $\mathbf{A}[i,]$ and $\mathbf{A}[, j]$ the i-th row and the j-th column of $\mathbf{A}$ respectively. Similar to the vector case, the notation $\mathbf{A}[-i, j] \in \mathbb{R}^{m-1}$ denotes the j-th column of $\mathbf{A}$ without its i-th entry.

For $p \geq 1$, the ℓ_p-norm of a vector $\mathbf{x} \in \mathbb{R}^m$ is defined as $\|\mathbf{x}\|_p = (\sum_{i=1}^m |\mathbf{x}[i]|^p)^{1/p}$, with the convention that $\|\mathbf{x}\|_0 = |\{i : \mathbf{x}[i] \neq 0\}|$ and $\|\mathbf{x}\|_\infty = \max_i |\mathbf{x}[i]|$. For any norm $\|.\|$ on $\mathbb{R}^m$, the dual norm of $\|.\|$ is defined as $\|\mathbf{x}\|^* = \sup_{\mathbf{y} \neq 0} \frac{\mathbf{x}^T \mathbf{y}}{\|\mathbf{y}\|}$.

For two sequences of real numbers $\{a_n\}_{n=1}^\infty$ and $\{b_n\}_{n=1}^\infty$, we denote by $a_n = O(b_n)$ if there is a constant $C > 0$ such that $a_n \leq C b_n$ for all $n \geq 1$. For $a \in \mathbb{R}$, denote by $\lfloor a \rfloor$ the integer part of a and $\lceil a \rceil$ the smallest integer greater than or equal to a. Throughout this paper, we shall agree that $\frac{0}{0} = 0$.

2.2 Basic Assumptions

We denote by $\mathcal{D} \subset \mathbb{R}^{d \times K}$ the constraint set of dictionaries for the optimization problem (2). In this paper, we consider square dictionaries, i.e., $d = K \geq 2$. As in GS, we choose $\mathcal{D}$ to

be the *oblique manifold* (Absil et al., 2008):

$$\mathcal{D} = \left\{ \mathbf{D} \in \mathbb{R}^{K \times K} : \ \|\mathbf{D}[, k]\|_2 = 1 \text{ for all } k = 1, \ldots, K \right\}.$$

We also call a dictionary column $\mathbf{D}[, k]$ an *atom* of the dictionary. Denote by $\mathbf{D}_0 \in \mathcal{D}$ the *reference dictionary*, i.e., the ground truth dictionary that generates the signals. With these notations, we now give a formal definition for local identifiability:

Definition 1 *(Local identifiability) Let $L(\mathbf{D}) : \mathcal{D} \to \mathbb{R}$ be an objective function. We say that the reference dictionary $\mathbf{D}_0$ is locally identifiable with respect to $L(\mathbf{D})$ if $\mathbf{D}_0$ is a strict local minimum of $L(\mathbf{D})$.*

Sign-permutation ambiguity. As noted by previous works GS and Geng et al. (2011), the ℓ_1-norm objective function $L(\mathbf{D}) = L_N(\mathbf{D})$ of (2) has an intrinsic sign-permutation ambiguity. Let $\mathbf{D}' = \mathbf{D}\mathbf{P}\mathbf{\Lambda}$ for some permutation matrix $\mathbf{P}$ and diagonal matrix $\mathbf{\Lambda}$ with ± 1 diagonal entries. It is easy to see that $\mathbf{D}'$ and $\mathbf{D}$ have the same objective value. Thus, the objective function $L_N(\mathbf{D})$ has at least $2^K K!$ local minima. We can only recover $\mathbf{D}_0$ up to column permutation and sign changes.

Note that if the dictionary atoms are linearly dependent, the effective dimension is strictly less than K and the problem essentially becomes over-complete. Since dealing with over-complete dictionaries is beyond the scope of this paper, we make the following assumption:

Assumption I *(Complete dictionaries). The reference dictionary $\mathbf{D}_0 \in \mathcal{D} \subset \mathbb{R}^{K \times K}$ is full rank.*

Let $\mathbf{M}_0 = \mathbf{D}_0^T \mathbf{D}_0$ be the *dictionary atom collinearity matrix* containing the inner-products between dictionary atoms. Since each dictionary atom has unit ℓ_2-norm, $\mathbf{M}_0[i, i] = 1$ for all $i \in [\![K]\!]$. In addition, as $\mathbf{D}_0$ is full rank, $\mathbf{M}_0$ is positive definite and $|\mathbf{M}_0[i, j]| < 1$ for all $i \neq j$.

We assume that a signal is generated as a random linear combination of the dictionary atoms. In this paper, we consider the following two probabilistic models for the random linear coefficients:

Probabilistic models for sparse coefficients. Denote by $\mathbf{z} \in \mathbb{R}^K$ a random vector from the K-dimensional standard normal distribution.

Model 1—$SG(s)$**.** Let $\mathbf{S}$ be a size-s subset uniformly drawn from all size-s subsets of $[\![K]\!]$. Define $\boldsymbol{\xi} \in \{0, 1\}^K$ by setting $\boldsymbol{\xi}[j] = I\{j \in \mathbf{S}\}$ for $j \in [\![K]\!]$, where $I\{.\}$ is the indicator function. Let $\boldsymbol{\alpha} \in \mathbb{R}^K$ be such that $\boldsymbol{\alpha}[j] = \boldsymbol{\xi}[j]\mathbf{z}[j]$. Then we say $\boldsymbol{\alpha}$ is drawn from the *s-sparse Gaussian model*, or $SG(s)$.

Model 2—$BG(p)$**.** For $j \in [\![K]\!]$, let $\boldsymbol{\xi}[j]$'s be *i.i.d.* Bernoulli random variable with success probability $p \in (0, 1]$. Let $\boldsymbol{\alpha} \in \mathbb{R}^K$ be such that $\boldsymbol{\alpha}[j] = \boldsymbol{\xi}[j]\mathbf{z}[j]$. Then we say $\boldsymbol{\alpha}$ is drawn from the *Bernoulli(p)-Gaussian model*, or $BG(p)$.

With the above two models, we state the following assumption for random signal generation:

Assumption II *(Signal generation). For $i \in [\![N]\!]$, let $\boldsymbol{\alpha}_i \in \mathbb{R}^K$ be either i.i.d. s-sparse Gaussian vectors or i.i.d. Bernoulli(p)-Gaussian vectors. The signals $\mathbf{x}_i \in \mathbb{R}^K$ are generated according to the noiseless linear model:*

$$\mathbf{x}_i = \mathbf{D}_0 \boldsymbol{\alpha}_i.$$

Remarks:
(1) The above two models and their variants were studied in a number of prior theoretical works, including Gribonval and Schnass (2010); Geng et al. (2011); Agarwal et al. (2014b); Sun et al. (2017).
(2) By construction, a random vector generated from the s-sparse model has exactly s nonzero entries. The data points $\mathbf{x}_i$'s therefore lie within the union of the linear spans of s dictionary atoms (Figure 2 Left). The Bernoulli(p)-Gaussian model, on the other hand, allows the random coefficient vector to have any number of nonzero entries ranging from 0 to K with a mean of pK. As a result, some data points, called "non-sparse outliers" in GS, can be outside of any sparse linear span of the dictionary atoms (Figure 2 Right and Figure 1 of GS). We refer readers to the remarks following Example 5 in Section 3 for a discussion of the effect of non-sparse outliers on local identifiability.
(3) Gribonval et al. (2015) assumed a more general distribution for the sparse coefficients. While our local identifiability results can potentially be extended to their model, such an extension would require significantly more complicated notations and make the corresponding results less interpretable. For the sake of accessibility and interpretability, we focus only on the two probabilistic models above.

In this paper, we study the problem of dictionary identifiability with respect to the population objective function $\mathbb{E}\, L_N(\mathbf{D})$ (Section 3) and the finite sample objective function $L_N(\mathbf{D})$ (Section 4). In order to analyze these objective functions, it is convenient to define the following "group LASSO"-type norms:

Definition 2 *Let $m \geq 1$ be an integer and $\mathbf{w} \in \mathbb{R}^m$.*

1. *For $k \in [\![m]\!]$, define*

$$|||\mathbf{w}|||_k = \frac{\sum_{|S|=k} \|\mathbf{w}[S]\|_2}{\binom{m-1}{k-1}}.$$

2. *For $p \in (0,1)$, define*

$$|||\mathbf{w}|||_p = \sum_{k=0}^{m-1} \texttt{pbinom}(k; m-1, p) |||\mathbf{w}|||_{k+1},$$

where `pbinom` *is the probability mass function of the binomial distribution:*

$$\texttt{pbinom}(k; n, p) = \binom{n}{k} p^k (1-p)^{n-k}.$$

Remarks:
(1) Note that the above norms $|||\mathbf{w}|||_k$ and $|||\mathbf{w}|||_p$ are in fact the expected values of $|\mathbf{w}^T \boldsymbol{\alpha}|$

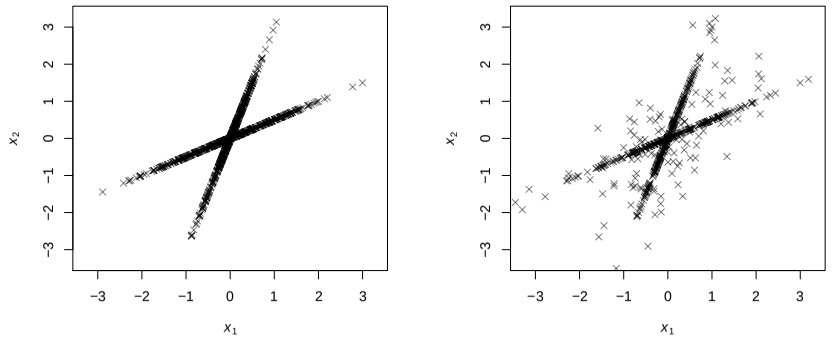

Figure 2: Data generation for $K = 2$. Left: the s-sparse Gaussian model with $s = 1$; Right: the Bernoulli(p)-Gaussian model with $p = 0.2$. The inner product between the two dictionary atoms is 0.7. A sample of $N = 1000$ data points are generated for both models. For the s-sparse model, all data points are perfectly aligned with the two lines corresponding to the two dictionary atoms. For the Bernoulli(p)-Gaussian model, a number of data points fall outside the two lines. According to our Theorem 1 and 3, despite those outliers and the high collinearity between the two atoms, the reference dictionary is still locally identifiable for $N = \infty$ and with high probability for finite samples.

with the random vector $\boldsymbol{\alpha}$ drawn from $SG(s)$ and $BG(p)$ models respectively. For invertible $\mathbf{D} \in \mathcal{D}$, it can be shown that the objective function for one signal $\mathbf{x} = \mathbf{D}_0 \boldsymbol{\alpha}$ is

$$l(\mathbf{x}, \mathbf{D}) = \|\mathbf{H}\boldsymbol{\alpha}\|_1 = \sum_{j=1}^{K} |\mathbf{H}[j,]\boldsymbol{\alpha}|,$$

where $\mathbf{H} = \mathbf{D}^{-1}\mathbf{D}_0$. Thus, taking the expectation of the objective function with respect to $\mathbf{x}$, we end up with a quantity involving either $\sum_{j=1}^K |||\mathbf{H}[j,]|||_s$ or $\sum_{j=1}^K |||\mathbf{H}[j,]|||_p$. This is the motivation of defining these norms.
(2) In particular, $|||\mathbf{w}|||_1 = \|\mathbf{w}\|_1$ and $|||\mathbf{w}|||_m = \|\mathbf{w}\|_2$.
(3) The norms defined above are special cases of the group LASSO penalty by Yuan and Lin (2006). For $|||\mathbf{w}|||_k$, the summation covers all size-k subsets of $[\![m]\!]$. The normalization factor is the number of times $\mathbf{w}[i]$ appears in the numerator. Thus, $|||\mathbf{w}|||_k$ is essentially the average of the ℓ_2-norms of all size-k sub-vectors of $\mathbf{w}$. On the other hand, $|||\mathbf{w}|||_p$ is a weighted average of $|||\mathbf{w}|||_k$'s with binomial probabilities.

3. Population Analysis

In this section, we establish local identifiability results for the case where infinitely many signals are observed. Denote by $\mathbb{E}\, l(\mathbf{x}_1, \mathbf{D})$ the expectation of the objective function $l(\mathbf{x}_1, \mathbf{D})$ of (1) with respect to the random signal $\mathbf{x}_1$. By the strong law of large numbers, as the number of signals N tends to infinity, the empirical objective function $L_N(\mathbf{D}) = \frac{1}{N}\sum_{i=1}^{N} l(\mathbf{x}_i, \mathbf{D})$ converges almost surely to its population mean $\mathbb{E}\, l(\mathbf{x}_1, \mathbf{D})$ for each fixed $\mathbf{D} \in \mathcal{D}$. Therefore the population version of the optimization problem (2) is

$$\min_{\mathbf{D}\in\mathcal{D}} \mathbb{E}\, l(\mathbf{x}_1, \mathbf{D}) \tag{3}$$

Since by assumption the reference dictionary $\mathbf{D}_0$ is full rank, we only need to work with $\mathbf{D} \in \mathcal{D}$ that is also full rank. Indeed, if the linear span of columns $\mathrm{span}(\mathbf{D}) \neq \mathbb{R}^K$, then $\mathbf{D}_0\boldsymbol{\alpha}_1 \notin \mathrm{span}(\mathbf{D})$ with nonzero probability. Thus $\mathbf{D}$ is infeasible with nonzero probability and so $\mathbb{E}\, l(\mathbf{x}_1, \mathbf{D}) = +\infty$. For a full rank dictionary $\mathbf{D}$, the following lemma gives the closed-form expression for the expected objective function $\mathbb{E}\, l(\mathbf{x}_1, \mathbf{D})$.

Lemma 1 *(Closed-form objective functions) Let $\mathbf{D}$ be a full rank dictionary in $\mathcal{D}$ and $\mathbf{x}_1 = \mathbf{D}_0\boldsymbol{\alpha}_1$, where $\boldsymbol{\alpha}_1 \in \mathbb{R}^K$ is a random vector. For notational convenience, let $\mathbf{H} = \mathbf{D}^{-1}\mathbf{D}_0$.*

1. *If $\boldsymbol{\alpha}_1$ is generated according to the $SG(s)$ model with $s \in [\![K-1]\!]$,*

$$L_{SG(s)}(\mathbf{D}) \coloneqq \mathbb{E}\, l(\mathbf{x}_1, \mathbf{D}) = \sqrt{\frac{2}{\pi}}\frac{s}{K}\sum_{j=1}^{K} |\!|\!| \mathbf{H}[j,] |\!|\!|_s. \tag{4}$$

2. *If $\boldsymbol{\alpha}_1$ is generated according to the $BG(p)$ model with $p \in (0,1)$,*

$$L_{BG(p)}(\mathbf{D}) \coloneqq \mathbb{E}\, l(\mathbf{x}_1, \mathbf{D}) = \sqrt{\frac{2}{\pi}}p\sum_{j=1}^{K} |\!|\!| \mathbf{H}[j,] |\!|\!|_p. \tag{5}$$

For the non-sparse cases where $s = K$ and $p = 1$, we have

$$L_{SG(s)}(\mathbf{D}) = L_{BG(p)}(\mathbf{D}) = \sqrt{\frac{2}{\pi}}\sum_{j=1}^{K} \|\mathbf{H}[j,]\|_2.$$

Remarks: It can be seen from the above closed-form expressions that the two models are closely related. First of all, it is natural to identify p with $\frac{s}{K}$, the fraction of expected number of nonzero entries in $\boldsymbol{\alpha}_1$. Next, by definition, $|\!|\!|.|\!|\!|_p$ is a binomial average of $|\!|\!|.|\!|\!|_k$. Therefore, the Bernoulli-Gaussian objective function $L_{BG(p)}(\mathbf{D})$ can be treated as a binomial average of the s-sparse objective function $L_{SG(s)}(\mathbf{D})$.

By analyzing the above closed-form expressions of the ℓ_1-norm objective function, we establish the following sufficient and almost necessary conditions for population local identifiability:

Theorem 1 *(Population local identifiability) Recall that $\mathbf{M}_0 = \mathbf{D}_0^T\mathbf{D}_0$ and $\mathbf{M}_0[-j,j]$ denotes the j-th column of the off-diagonal part of $\mathbf{M}_0$. Let $|\!|\!|.|\!|\!|_s^*$ and $|\!|\!|.|\!|\!|_p^*$ be the dual norm of $|\!|\!|.|\!|\!|_s$ and $|\!|\!|.|\!|\!|_p$ respectively.*

1. *($SG(s)$ models) For $K \geq 2$ and $s \in [\![K-1]\!]$, if*

$$\max_{j\in[\![K]\!]} |\!|\!| \mathbf{M}_0[-j,j] |\!|\!|_s^* < 1 - \frac{s-1}{K-1}.$$

   then $\mathbf{D}_0$ is locally identifiable with respect to $L_{SG(s)}$.

2. *($BG(p)$ models) For $K \geq 2$ and $p \in (0,1)$, if*

$$\max_{j\in[\![K]\!]} |\!|\!| \mathbf{M}_0[-j,j] |\!|\!|_p^* < 1 - p.$$

   then $\mathbf{D}_0$ is locally identifiable with respect to $L_{BG(p)}$.

Moreover, the above conditions are almost necessary in the sense that if the reversed strict inequalities hold, then $\mathbf{D}_0$ is not locally identifiable.

On the other hand, if $s = K$ or $p = 1$, then $\mathbf{D}_0$ is not locally identifiable with respect to $L_{SG(s)}$ or $L_{BG(p)}$.

Proof sketch. Let $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ be a collection of dictionaries $\mathbf{D}_t \in \mathcal{D}$ indexed by $t \in \mathbb{R}$ and $L(\mathbf{D}) = \mathbb{E}\, l(\mathbf{x}_1, \mathbf{D})$ be the population objective function. The reference dictionary $\mathbf{D}_0$ is a strict local minimum of $L(\mathbf{D})$ on the manifold $\mathcal{D}$ if and only if the following statement holds: for any $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ that is a smooth function of t with non-vanishing derivative at $t = 0$, $L(\mathbf{D}_t)$ has a strict local minimum at $t = 0$. For a fixed $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$, to ensure that $L(\mathbf{D}_t)$ achieves a strict local minimum at $t = 0$, it suffices to have the following one-sided derivative inequalities:

$$\lim_{t\downarrow 0^+} \frac{L(\mathbf{D}_t) - L(\mathbf{D}_0)}{t} > 0 \text{ and } \lim_{t\uparrow 0^-} \frac{L(\mathbf{D}_t) - L(\mathbf{D}_0)}{t} < 0.$$

It can be shown that the above inequalities are equivalent to:

$$\max_{j\in[\![K]\!]} \left|\mathbf{M}_0[-j,j]^T\mathbf{w}\right| < \begin{cases} 1 - \frac{s-1}{K-1} & \text{for } SG(s) \\ 1-p & \text{for } BG(p) \end{cases}$$

where $\mathbf{w} \in \mathbb{R}^{K-1}$ is a unit vector under norm $|\!|\!|.|\!|\!|_s$ or $|\!|\!|.|\!|\!|_p$ and corresponds to the direction in which $\mathbf{D}_t$ approaches $\mathbf{D}_0$ as t tends to zero. Since $t = 0$ has to be a strict local minimum for all smooth $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ or approaching directions, by taking the supremum over all such unit vectors the LHS of the above inequality becomes the dual norm of $|\!|\!|.|\!|\!|_s$ or $|\!|\!|.|\!|\!|_p$. On the other hand, $\mathbf{D}_0$ is not a local minimum if $\lim_{t\downarrow 0^+}(L(\mathbf{D}_t) - L(\mathbf{D}_0))/t < 0$ or $\lim_{t\uparrow 0^-}(L(\mathbf{D}_t) - L(\mathbf{D}_0))/t > 0$ for some $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$. Thus the sufficient condition is also almost necessary. We refer readers to Section A.1.2 for the detailed proof.

Local identifiability phase boundary. Theorem 1 indicates that population local identifiability undergoes a phase transition. The following equations

$$\max_{j\in[\![K]\!]} |\!|\!| \mathbf{M}_0[-j,j] |\!|\!|_s^* = 1 - \frac{s-1}{K-1} \text{ and } \max_{j\in[\![K]\!]} |\!|\!| \mathbf{M}_0[-j,j] |\!|\!|_p^* = 1 - p \tag{6}$$

define the phase boundaries which separate the regions of local identifiability and non-identifiability under respective models. It is unclear whether $\mathbf{D}_0$ is locally identifiable on the phase boundary. If either equality in (6) holds, the directional derivative of the objective function at $\mathbf{D}_0$ become zero in certain directions. Hence analyzing local identifiability in this case requires higher order derivative computations that quickly become complicated.

Collinearity and sparsity. These are the two factors that determine local identifiability. Intuitively, for $\mathbf{D}_0$ to be locally identifiable, neither can the atoms of $\mathbf{D}_0$ be too linearly dependent, nor can the random linear coefficients be too dense. For the s-sparse Gaussian model, the quantity $\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_s^*$ measures the size of the off-diagonal entries of $\mathbf{M}_0$ and hence the collinearity of the dictionary atoms. In addition, that quantity depends on the sparsity parameter s. By Lemma 7 in the Appendix, $\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_s^*$ is increasing with respect to s. Similar conclusion holds for the Bernoulli-Gaussian model. Therefore, sparser linear coefficients will lead to less restrictive requirement on dictionary atom collinearity. See, for example, the phase boundaries in Figure 1.

Next, we will present a few examples to gain more intuition for the local identifiability conditions.

Example 1 *(1-sparse Gaussian model) A full rank $\mathbf{D}_0$ is always locally identifiable at the population level under a 1-sparse Gaussian model. Indeed, by Corollary 7 in the Appendix, $|||\mathbf{M}_0[-j,j]|||_1^* = \max_{i\neq j} |\mathbf{M}_0[i,j]| < 1$ for all $j \in [\![K]\!]$. Thus, a full rank dictionary $\mathbf{D}_0$ always satisfies the sufficient condition.*

Example 2 *($(K-1)$-sparse Gaussian model) For $j \in [\![K]\!]$, by Corollary 7,*

$$|||\mathbf{M}_0[-j,j]|||_{K-1}^* = \|\mathbf{M}_0[-j,j]\|_2.$$

Therefore the phase boundary under the $(K-1)$-sparse model is

$$\max_{j\in[\![K]\!]} \|\mathbf{M}_0[-j,j]\|_2 = \frac{1}{K-1}.$$

Example 3 *(Orthogonal dictionaries) If $\mathbf{M}_0 = \mathbf{I}$, then*

$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_s^* = \max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_p^* = 0.$$

Therefore orthogonal dictionaries are always locally identifiable if $s < K$ or $p < 1$.

Example 4 *(Minimally dependent dictionary atoms) Let $\mu \in (-1,1)$. Consider a dictionary atom collinearity matrix $\mathbf{M}_0$ such that $\mathbf{M}_0[1,2] = \mathbf{M}_0[2,1] = \mu$ and $\mathbf{M}_0[i,j] = 0$ for all other $i \neq j$. By Corollary 8,*

$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_s^* = \max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j,j]|||_p^* = |\mu|.$$

Thus the phase boundaries under respective models are

$$|\mu| = 1 - \frac{s-1}{K-1} \text{ and } |\mu| = 1 - p.$$

Notice that for the Bernoulli-Gaussian model with $K = 2$, the phase boundary agrees with the empirical phase boundary in Figure 3 of GS.

Example 5 *(Constant inner-product dictionaries) Let $\mathbf{M}_0 = \mu \mathbf{1}\mathbf{1}^T + (1-\mu)\mathbf{I}$, i.e., $\mathbf{D}_0[,i]^T\mathbf{D}_0[,j] = \mu$ for $1 \leq i < j \leq K$. Note that $\mathbf{M}_0$ is positive definite if and only if $\mu \in (-\frac{1}{K-1}, 1)$. By Corollary 9, we have*

$$|||\mathbf{M}_0[-j,j]|||_s^* = \sqrt{s}|\mu|.$$

Thus for the s-sparse model, the phase boundary is

$$\sqrt{s}|\mu| = 1 - \frac{s-1}{K-1}.$$

Similarly for the Bernoulli(p)-Gaussian model, we have

$$|||\mathbf{M}_0[-j,j]|||_p^* = |\mu|p(K-1)\Big(\sum_{k=0}^{K-1} \texttt{pbinom}(k, K-1, p)\sqrt{k}\Big)^{-1}.$$

Thus the phase boundary is

$$|\mu| = \frac{1-p}{p(K-1)} \sum_{k=0}^{K-1} \texttt{pbinom}(k, K-1, p)\sqrt{k}.$$

Figures 3 shows the phase boundaries for different dictionary sizes under the two models. As K increases, the phase boundary moves toward the lower left of the region. This observation indicates that recovering the reference dictionary locally becomes increasingly difficult for larger dictionary size. See also Appendix Figures B.1 and B.2 for simulation results with larger K's.

The effect of non-sparse outliers. Example 5 demonstrates how the presence of non-sparse outliers in the Bernoulli-Gaussian model (Figure 2 Right) affects the requirements for local identifiability. Set $p = \frac{s}{K}$ in order to have the same level of sparsity with the $SG(s)$ model. Applying Jensen's inequality, one can show that

$$\frac{1-p}{p(K-1)} \sum_{k=0}^{K-1} \texttt{pbinom}(k, K-1, p)\sqrt{k} < \frac{1}{\sqrt{s}}(1 - \frac{s-1}{K-1}),$$

which indicates that the phase boundary of the s-sparse models is always above that of the Bernoulli-Gaussian model with the same level of sparsity. The gap between the two phase boundaries is the extra cost in terms of the collinearity parameter μ for locally recovering the dictionary in the presence of non-sparse outliers. One extreme example is the case where $s = 1$ and correspondingly $p = \frac{1}{K}$. By Example 1, under a 1-sparse model the reference dictionary $\mathbf{D}_0$ is always locally identifiable if $|\mu| < 1$. But for the $BG(\frac{1}{K})$ model, by the remarks under Corollary 1, $\mathbf{D}_0$ is not locally identifiable if $|\mu| > 1 - \frac{1}{K}$. Hence, the requirement for μ in the presence of outliers is at least $\frac{1}{K}$ more stringent than that in the case of no outliers.

However, such a difference diminishes as the number of dictionary atoms K increases. Indeed, by Lemma 2, one can establish the following lower bound for the phase boundary under the $BG(p)$ model

$$\frac{1-p}{p(K-1)} \sum_{k=0}^{K-1} \texttt{pbinom}(k, K-1, p)\sqrt{k} \geq \frac{1-p}{\sqrt{p(K-1)+1}} \approx \frac{1}{\sqrt{s}}(1 - \frac{s-1}{K-1}),$$

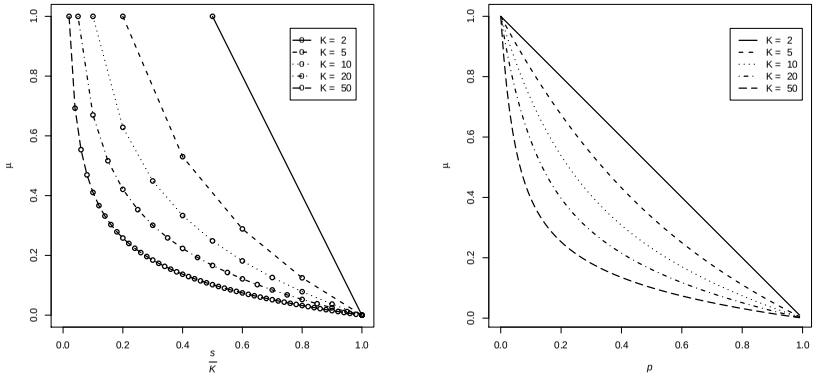

Figure 3: Local identifiability phase boundaries for constant inner-product dictionaries, under Left: the s-sparse Gaussian model; Right: the Bernoulli(p)-Gaussian model. For each model, phase boundaries for different dictionary sizes K are shown. Note that $\frac{s}{K} \in \{\frac{1}{K}, \frac{2}{K}, \ldots, 1\}$ and $p \in (0, 1]$. The area under the curves is the region where the reference dictionaries are locally identifiable at the population level. Due to symmetry, we only plot the portion of the phase boundaries for $\mu > 0$.

for fixed sparsity level $p = \frac{s}{K}$ and large K.

In general, the dual norms $|||.|||_s^*$ and $|||.|||_p^*$ have no closed-form expressions. According to Corollary 6 in the Appendix, computing those quantities involves solving a second order cone problem (SOCP) with exponentially many constraints. The following Lemma 2, on the other hand, gives computationally inexpensive approximation bounds.

Definition 3 *(Hyper-geometric distribution related quantities) Let m be a positive integer and $d, k \in \{0\} \cup [\![m]\!]$. Denote by $L_m(d, k)$ the hypergeometric random variable with parameter m, d and k, i.e., the number of 1's after drawing without replacement k elements from d 1's and $m - d$ 0's. Now for each $d \in \{0\} \cup [\![m]\!]$, define the function $\tau_m(d, .)$ with domain on $[0, m]$ as follows: set $\tau_m(d, 0) = 0$. For $a \in (k - 1, k]$ where $k \in [\![m]\!]$, define*

$$\tau_m(d, a) = \mathbb{E}\sqrt{L_m(d, k-1)} + (\mathbb{E}\sqrt{L_m(d, k)} - \mathbb{E}\sqrt{L_m(d, k-1)})(a - (k-1)).$$

Lemma 2 *(Lower and upper bounds for $|||.|||_s^*$ and $|||.|||_p^*$) Let m be a positive integer and $\mathbf{z} \in \mathbb{R}^m$.*

1. *For $s \in [\![m]\!]$,*

$$\max\left(\|\mathbf{z}\|_\infty, \sqrt{\frac{s}{m}} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}}\right) \le \frac{s}{m} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(|T|, s)} \le |||\mathbf{z}|||_s^* \le \max_{S \subset [\![m]\!], |S| = s} \|\mathbf{z}[S]\|_2.$$

2. *For $p \in (0, 1)$,*

$$\max\left(\|\mathbf{z}\|_\infty, \sqrt{p} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}}\right) \le p \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(|T|, pm)} \le |||\mathbf{z}|||_p^* \le \max_{S \subset [\![m]\!], |S| = k} \|\mathbf{z}[S]\|_2.$$

where $k = \lceil p(m-1) + 1 \rceil$.

Remarks:
(1) We refer readers to Lemma 10 and 11 for the detailed version of the above results.
(2) Since we agree that $\frac{0}{0} = 0$, the case where $T = \emptyset$ does not affect taking the maximum of all subsets.
(3) Consider a sparse vector $\mathbf{z} = (z, 0, \ldots, 0)^T \in \mathbb{R}^m$. By Corollary 8,

$$|||\mathbf{z}|||_s^* = |||\mathbf{z}|||_p^* = |z| = \|\mathbf{z}\|_\infty = \max_{S \subset [\![m]\!], |S| = 1} \|\mathbf{z}[S]\|_2.$$

So the all the bounds are achievable by a sparse vector.
(4) Now consider a dense vector $\mathbf{z} = (z, \ldots, z)^T \in \mathbb{R}^m$. By Corollary 9,

$$|||\mathbf{z}|||_s^* = \sqrt{s}|z| = \sqrt{\frac{s}{m}} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}} = \max_{S \subset [\![m]\!], |S| = s} \|\mathbf{z}[S]\|_2.$$

Thus the bounds for $|||\mathbf{z}|||_s^*$ can also be achieved by a dense vector. Similarly, by the upper-bound for $|||\mathbf{z}|||_p^*$,

$$|||\mathbf{z}|||_p^* \le \sqrt{pm + 1}|z|.$$

On the other hand,

$$|||\mathbf{z}|||_p^* \ge \sqrt{p} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}\|_1}{\sqrt{|T|}} = \sqrt{p}|z| \max_{T \subset [\![m]\!]} \sqrt{|T|} = \sqrt{pm}|z|.$$

Thus both bounds for $|||\mathbf{z}|||_p^*$ are basically the same for large pm.
(5) **Computation.** To compute the lower and upper bounds efficiently, we first sort the elements in $|\mathbf{z}|$ in descending order. Without loss of generality, we can assume that $|\mathbf{z}[1]| \ge |\mathbf{z}[2]| \ge \ldots \ge |\mathbf{z}[m]|$. Thus the upper-bound quantity becomes

$$\max_{S \subset [\![m]\!], |S| = k} \|\mathbf{z}[S]\|_2 = (\sum_{i=1}^k \mathbf{z}[i]^2)^{1/2}.$$

For the lower-bound quantities, note that

$$\max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(|T|, k)} = \max_{d \in [\![m]\!]} \max_{T \subset [\![m]\!], |T| = d} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(d, k)} = \max_{d \in [\![m]\!]} \frac{\sum_{i=1}^d |\mathbf{z}[i]|}{\tau_m(d, k)}.$$

Thus, the major computation burden now is $\tau_m(d, k) = \mathbb{E}\sqrt{L_m(d, k)}$, for all $d \in [\![m]\!]$. We do not know a closed-form formula for $\mathbb{E}\sqrt{L_m(d, k)}$ except for $d = 1$ or $d = m$. In practice, we compute $\mathbb{E}\sqrt{L_m(d, k)}$ using its definition formula. On an OS X laptop with 1.8 GHz Intel Core i7 processor and 4GB of memory, the function `dhyper` in the statistics software

R can compute $\mathbb{E}\sqrt{L_{2000}(d,1000)}$ for all $d \in [\![2000]\!]$ within 0.635 second. Note that the number of dictionary atoms in most applications is typically smaller than 2000.

When m is too large, the LHS lower bounds can be used. Note that

$$\max_{T\subset[\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}} = \max_{d\in[\![m]\!]} \frac{\sum_{i=1}^d |\mathbf{z}[i]|}{\sqrt{d}},$$

which can be computed easily.

For notational simplicity, we will define the following quantities:

Definition 4 *For $a \in (0,K)$, define*

$$\nu_a(\mathbf{M}_0) = \max_{1\le j\le K} \max_{S\subset[\![K]\!], j\notin S} \frac{\|\mathbf{M}_0[S,j]\|_1}{\tau_{K-1}(|S|,a)}.$$

Definition 5 *(Cumulative coherence) For $k \in [\![K-1]\!]$, define the k-th cumulative coherence of a reference dictionary $\mathbf{D}_0$ as*

$$\mu_k(\mathbf{M}_0) = \max_{1\le j\le K} \max_{S\subset[\![K]\!], |S|=k, j\notin S} \|\mathbf{M}_0[S,j]\|_2.$$

Remarks: The above quantity is actually the ℓ_2 analog of the ℓ_1 k-th cumulative coherence defined in Gribonval et al. (2015). Also, notice that $\mu_1(\mathbf{M}_0) = \max_{l\neq j} |\mathbf{M}_0[l,j]|$ which is the plain mutual coherence of the reference dictionary.

With the above definitions and as a direct consequence of Lemma 2, we obtain a sufficient condition and a necessary condition for population local identifiability:

Corollary 1 *Under the notations of Theorem 1, we have*

1. *Let $K \ge 2$ and $s \in [\![K-1]\!]$.*
   - *If $\mu_s(\mathbf{M}_0) < 1 - \frac{s-1}{K-1}$, then $\mathbf{D}_0$ is locally identifiable with respect to $L_{SG(s)}$;*
   - *If $\frac{s}{K-1}\nu_s(\mathbf{M}_0) > 1 - \frac{s-1}{K-1}$, then $\mathbf{D}_0$ is not locally identifiable with respect to $L_{SG(s)}$.*
2. *Let $K \ge 2$ and $p \in (0,1)$.*
   - *If $\mu_k(\mathbf{M}_0) < 1-p$, where $k = \lceil p(K-2)+1\rceil$, then $\mathbf{D}_0$ is locally identifiable with respect to $L_{BG(p)}$;*
   - *If $p\nu_k(\mathbf{M}_0) > 1-p$, where $k = p(K-1)$, then $\mathbf{D}_0$ is not locally identifiable with respect to $L_{BG(p)}$.*

Remarks:
(1) In particular, by Lemma 2, if $\mu_1(\mathbf{M}_0) > 1 - \frac{s-1}{K-1}$ or $\mu_1(\mathbf{M}_0) > 1-p$, then $\mathbf{D}_0$ is not locally identifiable.
(2) We can also replace $\frac{s}{K-1}\nu_s(\mathbf{M}_0)$ or $p\nu_k(\mathbf{M}_0)$ by the corresponding lower bound quantities in Lemma 2 which are easier to compute but give weaker necessary conditions.

Comparison with GS. Corollary 1 enables us to compare our local identifiability condition directly with that of GS. For the Bernoulli(p)-Gaussian model, the population version of the sufficient condition for local identifiability by GS is:

$$\mu_{K-1}(\mathbf{M}_0) = \max_{1\le j\le K} \|\mathbf{M}_0[-j,j]\|_2 < 1-p. \tag{7}$$

Note that $\mu_{K-1}(\mathbf{M}_0) \ge \mu_k(\mathbf{M}_0)$ for $k \le K-1$.

Thus, our local identifiability result implies that of GS. Moreover, the quantity $\|\mathbf{M}_0[-j,j]\|_2$ in inequality (7) computes the ℓ_2-norm of the entire $\mathbf{M}_0[-j,j]$ vector and is independent of the sparsity parameter p. On the other hand, in our sufficient condition, $\max_{|S|=k, j\notin S} \|\mathbf{M}_0[S,j]\|_2$ computes the largest ℓ_2-norm of all size-k sub-vectors of $\mathbf{M}_0[-j,j]$. Since $k = \lceil p(K-2)+1\rceil$ is essentially pK, when the random linear coefficients are sparse, the sufficient bound by GS is much more conservative compared to ours.

More concretely, let us consider constant inner-product dictionaries with parameter $\mu > 0$ as in Example 5. The sufficient conditions by GS and by our Corollary 1 are respectively

$$\sqrt{K}\mu \le 1-p \text{ and } \sqrt{pK+1}\mu \le 1-p,$$

showing that the sufficient condition by GS is much more conservative for small value of p. See Figure 1, Appendix Figures B.1 and B.2 for a graphical comparison of the bounds for $K = 10, 20$ and 50.

Local identifiability for sparsity level $O(\mu^{-2})$. For notational convenience, let $\mu = \mu_1(\mathbf{M}_0)$ be the mutual coherence of the reference dictionary. For the s-sparse model, by Lemma 2, $\mu_s(\mathbf{M}_0) \le \sqrt{s}\mu$. Thus the first part of the corollary implies a simpler sufficient condition:

$$\sqrt{s}\mu < 1 - \frac{s-1}{K-1}.$$

From the above inequality, it can be seen that if $1 - \frac{s-1}{K-1} > \delta$ for some $\delta > 0$, the reference dictionary is locally identifiable for sparsity level s up to the order $O(\mu^{-2})$.

Similarly for the Bernoulli(p)-Gaussian model, since for $k = \lceil p(K-2)+1\rceil$,

$$\mu_k(\mathbf{M}_0) \le \sqrt{pK+1}\mu,$$

we have the following sufficient condition for local identifiability:

$$\sqrt{pK+1}\mu \le 1-p.$$

As before, if $1-p > \delta$ for some $\delta > 0$, the reference dictionary is locally identifiable for sparsity level pK up to the order $O(\mu^{-2})$. On the other hand, the same arguments for the condition by GS leads to $K = O(\mu^{-2})$, which, does not take advantage of sparsity.

In addition, by Example 5 and Remark (4) under Lemma 2, we also know that the sparsity requirement $O(\mu^{-2})$ cannot be improved in general.

Our result seems to be the first to demonstrate that $O(\mu^{-2})$ is the optimal order of sparsity level for exact local recovery of a reference dictionary. For a predefined over-complete dictionary, classical results such as Donoho and Elad (2003) and Fuchs (2004) show that basis pursuit recovers an s-sparse linear coefficient vector with sparsity level s

up to the order $O(\mu^{-1})$. For over-complete dictionary learning, Geng et al. (2011) showed that exact local recovery is also possible for s-sparse model with s up to $O(\mu^{-1})$. While our results are only for complete dictionaries, we conjecture that $O(\mu^{-2})$ is also the optimal order of sparsity level for over-complete dictionaries. In fact, Schnass (2015) proved that the response maximization criterion—an alternative formulation of dictionary learning—can approximately recover the over-complete reference dictionary locally with sparsity level s up to $O(\mu^{-2})$. It will be of interest to investigate whether the same sparsity requirement hold for the ℓ_1-minimization dictionary learning (2) in the case of exact local recovery and over-complete dictionaries.

A note on global identifiability. With the notations in Definition 1, we say that the reference dictionary $\mathbf{D}_0$ is *globally identifiable* with respect to $L(\mathbf{D})$ if (1) $\mathbf{D}_0$ is a global minimum of $L(\mathbf{D})$, and (2) for any other dictionary $\mathbf{D}'$ that cannot be transformed to $\mathbf{D}_0$ under any column permutation and sign changes, $L(\mathbf{D}_0) < L(\mathbf{D}')$. It is easy to see that global identifiability implies local identifiability, and so any necessary conditions for local identifiability are also necessary for global identifiability. Sufficient conditions for the global case are much harder to find. However, for dictionaries with orthogonal columns, we can show the following:

Corollary 2 *Suppose that the reference dictionary $\mathbf{D}_0$ is orthogonal, i.e., $\mathbf{M}_0 = \mathbf{I}$.*

1. *$\mathbf{D}_0$ is globally identifiable with respect to $L_{SG(s)}$ if and only if $\frac{s}{K} < 1$.*
2. *$\mathbf{D}_0$ is globally identifiable with respect to $L_{BG(p)}$ if and only if $p < 1$.*

The above result indicates that for orthogonal dictionaries, we have global identifiability as long as the linear coefficients $\boldsymbol{\alpha}_i$'s are not entirely dense. Note that these conditions are exactly the same as in the local identifiability case, see Example 3. Naturally, it is of greater interest to derive global identifiability condition for non-orthogonal dictionaries. Simulation results in Figure 3 of GS demonstrate that for $K = 2$, global identifiability seems to share the same phase transition boundary with local identifiability, i.e., $\mu + p = 1$. Furthermore, the surface plot of the objective function in Figure 2 of GS shows no other spurious local minima. To establish global identifiability for non-orthogonal dictionaries, it is unavoidable to characterize global optima of the non-convex objective function. An on-going work of Y. Wang and the authors (Wang et al.) might help shed light on this challenging problem.

4. Finite Sample Analysis

In this section, we will present finite sample results for local dictionary identifiability. For notational convenience, we first define the following quantities:

$$\mathcal{P}_1(\epsilon, N; \mu, K) = 2\exp\left(-\frac{N\epsilon^2}{108K\mu}\right),$$
$$\mathcal{P}_2(\epsilon, N; p, K) = 2\exp\left(-p\frac{N\epsilon^2}{18p^2K + 9\sqrt{2pK}}\right),$$
$$\mathcal{P}_3(\epsilon, N; p, K) = 3\left(\frac{24}{\epsilon p} + 1\right)^K \exp\left(-p\frac{N\epsilon^2}{360}\right).$$

Recall that $\mathbf{M}_0 = \mathbf{D}_0^T\mathbf{D}_0$ and $\mu_1(\mathbf{M}_0)$ is the mutual coherence of the reference dictionary $\mathbf{D}_0$. The following two theorems give local identifiability conditions under the s-sparse Gaussian model and the Bernoulli-Gaussian model:

Theorem 2 *(Finite sample local identifiability for $SG(s)$) Let $\boldsymbol{\alpha}_i \in \mathbb{R}^K$, $i \in [\![N]\!]$, be i.i.d. $SG(s)$ random vectors with $s \in [\![K-1]\!]$. The signals $\mathbf{x}_i$'s are generated as $\mathbf{x}_i = \mathbf{D}_0\boldsymbol{\alpha}_i$. Assume $0 < \epsilon \le \frac{1}{2}$.*

1. *If*
$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j, j]|||_s^* \le 1 - \frac{s-1}{K-1} - \sqrt{\frac{\pi}{2}}\epsilon,$$
then $\mathbf{D}_0$ is locally identifiable with respect to $L_N(\mathbf{D})$ with probability exceeding
$$1 - K^2\left(\mathcal{P}_1(\epsilon, N; \mu_1(\mathbf{M}_0), K) + \mathcal{P}_2(\epsilon, N; \frac{s}{K}, K) + \mathcal{P}_3(\epsilon, N; \frac{s}{K}, K)\right).$$
2. *If*
$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j, j]|||_s^* \ge 1 - \frac{s-1}{K-1} + \sqrt{\frac{\pi}{2}}\epsilon,$$
then $\mathbf{D}_0$ is not locally identifiable with respect to $L_N(\mathbf{D})$ with probability exceeding
$$1 - K\left(\mathcal{P}_1(\epsilon, N; \mu_1(\mathbf{M}_0), K) + \mathcal{P}_2(\epsilon, N; \frac{s}{K}, K) + \mathcal{P}_3(\epsilon, N; \frac{s}{K}, K)\right).$$

Theorem 3 *(Finite sample local identifiability for $BG(p)$) Let $\boldsymbol{\alpha}_i \in \mathbb{R}^K$, $i \in [\![N]\!]$, be i.i.d. $BG(p)$ random vectors with $p \in (0, 1)$. The signals $\mathbf{x}_i$'s are generated as $\mathbf{x}_i = \mathbf{D}_0\boldsymbol{\alpha}_i$. Let $K_p = K + 2p^{-1}$ and assume $0 < \epsilon \le \frac{1}{2}$.*

1. *If*
$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j, j]|||_p^* \le 1 - p - \sqrt{\frac{\pi}{2}}\epsilon,$$
then $\mathbf{D}_0$ is locally identifiable with respect to $L_N(\mathbf{D})$ with probability exceeding
$$1 - K^2\left(\mathcal{P}_1(\epsilon, N; \mu_1(\mathbf{M}_0), K_p) + \mathcal{P}_2(\epsilon, N; p, K_p) + \mathcal{P}_3(\epsilon, N; p, K)\right).$$
2. *If*
$$\max_{j\in[\![K]\!]} |||\mathbf{M}_0[-j, j]|||_p^* \ge 1 - p + \sqrt{\frac{\pi}{2}}\epsilon,$$
then $\mathbf{D}_0$ is not locally identifiable with respect to $L_N(\mathbf{D})$ with probability exceeding
$$1 - K\left(\mathcal{P}_1(\epsilon, N; \mu_1(\mathbf{M}_0), K_p) + \mathcal{P}_2(\epsilon, N; p, K_p) + \mathcal{P}_3(\epsilon, N; p, K)\right).$$

Remarks: The conditions for finite sample local identifiability are essentially identical to their population counterparts. The main difference is an margin of $\sqrt{\frac{\pi}{2}}\epsilon$ on the RHS of the inequalities. Such a margin appears as a result of our proof techniques: we show that the derivative of L_N is within $O(\epsilon)$ of its expectation and then apply local identifiability results for the population case.

Sample size requirement. The theorems indicate that if the number of signals is a multiple of the following quantity,

$$\text{For } SG(s)\text{: } \frac{1}{\epsilon^2}\max\left\{\mu_1(\mathbf{M}_0)K\log K,\ s\log K,\ \frac{K}{s}K\log\left(\frac{K}{\epsilon s}\right)\right\}$$

$$\text{For } BG(p)\text{: } \frac{1}{\epsilon^2}\max\left\{\mu_1(\mathbf{M}_0)K\log K,\ pK\log K,\ \frac{1}{p}K\log\left(\frac{1}{\epsilon p}\right)\right\}$$

then with high probability we can determine the conditions for local identifiability. Thus, in the worst case, the sample size requirements for the two models are respectively

$$O(\frac{K\log K}{\frac{s}{K}}) \text{ and } O(\frac{K\log K}{p}).$$

Our sample size requirement is similar to that of GS, who shows that $O(\frac{K\log K}{p(1-p)})$ signals is enough for locally recovering an incoherent reference dictionary. Our result indicates the $1-p$ factor in their denominator is not necessary.

The following two corollaries are the finite sample counterparts of Corollary 1.

Corollary 3 *Under the same assumptions of Theorem 2,*

1. *(Sufficient condition for $SG(s)$) If*

$$\mu_s(\mathbf{M}_0) \le 1 - \frac{s-1}{K-1} - \sqrt{\frac{\pi}{2}}\epsilon,$$

then $\mathbf{D}_0$ is locally identifiable with respect to $L_N(\mathbf{D})$, with the same probability bound in the first part of Theorem 2.

2. *(Necessary condition for $SG(s)$) If*

$$\frac{s}{K-1}\nu_s(\mathbf{M}_0) \ge 1 - \frac{s-1}{K-1} + \sqrt{\frac{\pi}{2}}\epsilon,$$

then $\mathbf{D}_0$ is not locally identifiable with respect to $L_N(\mathbf{D})$, with the same probability bound in the second part of Theorem 2.

Corollary 4 *Under the same assumptions of Theorem 3,*

1. *(Sufficient condition for $BG(p)$) Let $k = \lceil p(K-1)+1\rceil$. If*

$$\mu_k(\mathbf{M}_0) \le 1 - p - \sqrt{\frac{\pi}{2}}\epsilon,$$

then $\mathbf{D}_0$ is locally identifiable with respect to $L_N(\mathbf{D})$, with the same probability bound in the first part of Theorem 3.

2. *(Necessary condition for $BG(p)$) Let $k = p(K-1)$. If*

$$p\nu_k(\mathbf{M}_0) \ge 1 - p + \sqrt{\frac{\pi}{2}}\epsilon,$$

then $\mathbf{D}_0$ is not locally identifiable with respect to $L_N(\mathbf{D})$, with the same probability bound in the second part of Theorem 3.

Remarks: As before, denote by $\mu \in [0,1)$ the coherence of the reference dictionary. The above two corollaries indicate that the reference dictionary is locally identifiable with high probability for sparsity level s or pK up to the order $O(\mu^{-2})$.

Proof sketch for Theorem 2 and 3. Similar to the population case, by taking one-sided derivatives of $L_N(\mathbf{D}_t)$ with respect to t at $t=0$ for all smooth $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$, we can derive a sufficient and almost necessary algebraic condition for the reference dictionary $\mathbf{D}_0$ to be a strict local minimum of $L_N(\mathbf{D})$. Using the concentration inequalities in Lemma 3—5, we show that the stochastic terms in the algebraic condition are close to their expectations with high probability. The population results for local identifiability can then be applied. The proofs for the two signal generation models are conceptually the same after establishing Lemma 8 to relate the $|||.|||_p^*$ norm to the $|||.|||_s^*$ norm. The detailed proof can be found in Section A.2.

Comparison with the proof by GS. The key difference between our analysis and that of GS is that we use an alternative but equivalent formulation of dictionary learning. Instead of (2), GS studied the following problem:

$$\min_{\mathbf{D}\in\mathcal{D},\boldsymbol{\alpha}_i} \frac{1}{N}\sum_{i=1}^{N}\|\boldsymbol{\alpha}_i\|_1 \qquad (8)$$
$$\text{subject to } \mathbf{x}_i = \mathbf{D}\boldsymbol{\alpha}_i \text{ for all } i \in [\![N]\!].$$

Note that the above formulation optimizes jointly over $\mathbf{D}$ and $\boldsymbol{\alpha}_i$ for $i \in [\![N]\!]$, as opposed to optimizing with respect to the only parameter $\mathbf{D}$ in our case. For complete dictionaries, this formulation is equivalent to the formulation in (2) in the sense that $\hat{\mathbf{D}}$ is a local minimum of (2) if and only if $(\hat{\mathbf{D}}, \hat{\mathbf{D}}^{-1}[\mathbf{x}_1,\ldots,\mathbf{x}_N])$ is a local minimum of (8), see Remark 3.1 of GS. The number of parameters to be estimated in (8) is $O(K^2+KN)$, compared to $O(K^2)$ free parameters in (2). The growing number of parameters make the GS formulation less tractable to analyze under a signal generation model.

GS did not directly study the population case. They first obtained an algebraic condition for local identifiability that is sufficient and almost necessary. However, the condition is convoluted and hard to interpret due to its direct dependence on the signals $\mathbf{x}_i$'s. In order to determine the number of signals required for successful local recovery, they further investigated their condition under the Bernoulli-Gaussian model. During the probabilistic analysis, the sharp algebraic condition was weakened, resulting in a sufficient condition that is far from being necessary.

In contrast, we start with probabilistic generative models. The number of parameters remains constant as N increases. This allows us to study the population problem directly

and to apply concentration inequalities for the finite sample problem. Therefore, studying the optimization problem (2) instead of (8) is the key to establishing an interpretable sufficient and almost necessary local identifiability condition.

5. Conclusions and Future Work

We have established sufficient and almost necessary conditions for local dictionary identifiability under both the s-sparse Gaussian model and the Bernoulli-Gaussian model in the case of noiseless signals and complete dictionaries. For finite samples with a fixed sparsity level, we have shown that as long as the number of $i.i.d.$ signals scales as $O(K \log K)$, with high probability we can determine the local identifiability conditions of a reference dictionary.

There are several directions for future research. In this paper, we focused mainly on the local behaviors of the ℓ_1-norm objective function. As we previously discussed, investigating global identifiability conditions is a natural next step. Simulations in GS suggest a close connection between local and global identifiability. To understand this problem further, we need to characterize global optima of the non-convex objective function. In an on-going work of Y. Wang and the authors, we are developing promising techniques to analyze global properties of ℓ_1-minimization dictionary learning in the non-orthogonal case.

Moreover, one can extend our results to a wider class of sub-Gaussian distributions other than the standard Gaussian distribution considered in this paper. We foresee little technical difficulty for this extension. However, it should be noted that the quantities involved in our local identifiability conditions, i.e., the $|||.|||_s^*$ and $|||.|||_p^*$ norms, are consequences of the standard Gaussian assumption. Under a different distribution, it can be even more computationally challenging to verify the resulting local identifiability conditions.

Finally, it would be also desirable to improve the sufficient condition by Geng et al. (2011) and Gribonval et al. (2015) for over-complete dictionaries and noisy signals. One interesting implication of our results is that local recovery is possible for sparsity level up to the order $O(\mu^{-2})$ for a μ-coherent reference dictionary. We conjecture the same sparsity requirement for the over-complete and/or noisy signal cases. In either scenario, the closed-form expression for the objective function is no longer available. A full characterization of local dictionary identifiability demands novel techniques for analyzing the local behaviors of the objective function.

Appendix A. Proofs

Let $L(\mathbf{D})$ be the dictionary learning objective function and $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ be the collection of dictionaries $\mathbf{D}_t \in \mathcal{D}$ parameterized by $t \in \mathbb{R}$. By definition, $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ passes through the reference dictionary $\mathbf{D}_0$ at $t = 0$. Similar to Gribonval and Schnass (2010), to ensure that $\mathbf{D}_0$ is a strict local minimum of $L(\mathbf{D})$, it suffices to have

$$\lim_{t\downarrow 0^+} \frac{L(\mathbf{D}_t) - L(\mathbf{D}_0)}{t} > 0 \text{ and } \lim_{t\uparrow 0^-} \frac{L(\mathbf{D}_t) - L(\mathbf{D}_0)}{t} < 0,$$

for all $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$ that is a smooth function of t with rate of approaching $\mathbf{D}_0$ bounded away from zero. On the other hand, if either of the above strict inequalities holds in the reversed direction for some smooth $\{\mathbf{D}_t\}_{t\in\mathbb{R}}$, then $\mathbf{D}_0$ is not a local minimum of $L(\mathbf{D})$.

Since $\mathbf{D}_0$ is full rank by assumption, the minimum eigenvalue of $\mathbf{M}_0 = \mathbf{D}_0^T\mathbf{D}_0$ is strictly greater than zero. By continuity of the minimum eigenvalue of $\mathbf{D}_t^T\mathbf{D}_t$ (see e.g., the Bauer-Fike Theorem), $\mathbf{D}_t$ should also be full rank when t is sufficiently small. Thus without loss of generality we can only consider full rank dictionaries $\mathbf{D}_t$. For any full rank $\mathbf{D} \in \mathcal{D}$, there is an invertible matrix $\mathbf{A} \in \mathbb{R}^{K\times K}$ such that $\mathbf{D} = \mathbf{D}_0\mathbf{A}$. For any $k \in [\![K]\!]$, by the constraint $\|\mathbf{D}[,k]\|_2 = 1$, $\mathbf{A}[,k]^T\mathbf{M}_0\mathbf{A}[,k] = 1$. Define the set for all such $\mathbf{A}$'s as

$$\mathcal{A} = \{\mathbf{A} \in \mathbb{R}^{K\times K} : \mathbf{A} \text{ is invertible and } \mathbf{A}[,k]^T\mathbf{M}_0\mathbf{A}[,k] = 1 \text{ for all } k \in [\![K]\!]\}. \quad (9)$$

It follows immediately that the set $\{\mathbf{D}_0\mathbf{A} : \mathbf{A} \in \mathcal{A}\}$ is the collection of $\mathbf{D} \in \mathcal{D}$ such that $\mathbf{D}$ is full rank. Thus, to ensure that $\mathbf{D}_0$ is a strict local minimum of $L(\mathbf{D})$, it suffices to show

$$\Delta^+(L, \{\mathbf{A}_t\}_t) := \lim_{t\downarrow 0^+} \frac{L(\mathbf{D}_0\mathbf{A}_t) - L(\mathbf{D}_0)}{t} > 0, \quad (10)$$

$$\Delta^-(L, \{\mathbf{A}_t\}_t) := \lim_{t\uparrow 0^-} \frac{L(\mathbf{D}_0\mathbf{A}_t) - L(\mathbf{D}_0)}{t} < 0, \quad (11)$$

for all smooth functions $\{\mathbf{A}_t\}_{t\in\mathbb{R}}$ with $\mathbf{A}_t \in \mathcal{A}$, $\mathbf{A}_0 = \mathbf{I}$ and nonzero derivative at $t = 0$. In addition, to demonstrate that $\mathbf{D}_0$ is not a local minimum of $L(\mathbf{D})$, it suffices to have (10) or (11) to hold in the reversed direction for some $\{\mathbf{A}_t\}_t$ with the aforementioned properties. We will be using this characterization of local minimum to prove local identifiability results for both the population case and the finite sample case.

A.1 Proofs of the Population Results

A.1.1 Proof of Lemma 1

Proof Since $\mathbb{E}||\mathbf{H}\boldsymbol{\alpha}_1||_1 = \sum_{j=1}^K \mathbb{E}|\mathbf{H}[j,]\boldsymbol{\alpha}_1|$, it suffices to compute $\mathbb{E}|\mathbf{H}[j,]\boldsymbol{\alpha}_1|$. Let S be any nonempty subset of $[\![K]\!]$. Recall that the random variable $\mathbf{S}_1 \subset [\![K]\!]$ denotes the support of random coefficient $\boldsymbol{\alpha}_1$. Conditioning on the event $\{\mathbf{S}_1 = S\}$, the random variable $\mathbf{H}[j,]\boldsymbol{\alpha}_1$ follows a normal distribution with mean 0 and standard deviation $\|\mathbf{H}[j,S]\|_2$. Hence

$$\mathbb{E}\,|\mathbf{H}[j,]\boldsymbol{\alpha}_1| = \mathbb{E}[\mathbb{E}[|\mathbf{H}[j,]\boldsymbol{\alpha}_1|\,|\mathbf{S}_1]] = \sqrt{\frac{2}{\pi}}\mathbb{E}\|\mathbf{H}[j,\mathbf{S}_1]\|_2.$$

(1) Under the s-sparse Gaussian model, $\mathbb{P}(\mathbf{S}_1 = S) = \binom{K}{s}^{-1}$ for any $|S| = s$. Thus we have

$$\mathbb{E}\|\mathbf{H}[j,\mathbf{S}_1]\|_2 = \binom{K}{s}^{-1} \sum_{S:|S|=s} \|\mathbf{H}[j,S]\|_2 = \frac{s}{K}|||\mathbf{H}[j,]|||_s.$$

Hence the objective function for the s-sparse Gaussian model is

$$L_{SG(s)}(\mathbf{D}) = \sum_{j=1}^{K} \mathbb{E}\,|\mathbf{H}[j,]\boldsymbol{\alpha}_1| = \sqrt{\frac{2}{\pi}}\frac{s}{K}\sum_{j=1}^{K}|||\mathbf{H}[j,]|||_s.$$

In particular, for $s = K$, $|||\mathbf{H}[j,]|||_K = \|\mathbf{H}[j,]\|_2$ and so

$$L_{SG(s)}(\mathbf{D}) = \sqrt{\frac{2}{\pi}}\sum_{j=1}^{K}\|\mathbf{H}[j,]\|_2.$$

(2) Under the Bernoulli(p)-Gaussian model, $\mathbb{P}(\mathbf{S}_1 = S) = p^{|S|}(1-p)^{K-|S|}$. So we have

$$\begin{aligned}\mathbb{E}[\|\mathbf{H}[j,\mathbf{S}_1]\|_2] &= \sum_{k=1}^{K}\sum_{S:|S|=k} p^k(1-p)^{K-k}\|\mathbf{H}[j,S]\|_2 \\ &= p\sum_{k=0}^{K-1}\texttt{pbinom}(k;K-1,p)|||\mathbf{H}[j,]|||_{k+1}.\end{aligned}$$

Therefore for $p \in (0,1)$, the objective function under the Bernoulli-Gaussian model is

$$L_{BG(p)}(\mathbf{D}) = \sum_{j=1}^{K}\mathbb{E}\,|\mathbf{H}[j,]\boldsymbol{\alpha}_1| = \sqrt{\frac{2}{\pi}}p\sum_{j=1}^{K}|||\mathbf{H}[j,]|||_p.$$

Finally, if $p = 1$, we have

$$L_{BG(p)}(\mathbf{D}) = \sqrt{\frac{2}{\pi}}\sum_{j=1}^{K}\|\mathbf{H}[j,]\|_2.$$

■

A.1.2 Proof of Theorem 1

Proof (1) Let us first consider the s-sparse Gaussian model. By (10) and (11), to ensure that $\mathbf{D}_0$ is a local minimum of $L_{SG(s)}(\mathbf{D})$, it suffices to show

$$\Delta^+(L_{SG(s)},\{\mathbf{A}_t\}_t) > 0 \text{ and } \Delta^-(L_{SG(s)},\{\mathbf{A}_t\}_t) < 0, \tag{12}$$

for all smooth functions $\{\mathbf{A}_t\}_t$ with $\mathbf{A}_t \in \mathcal{A}$, $\mathbf{A}_0 = \mathbf{I}$ and nonzero derivative at $t = 0$. Note that by Lemma 1,

$$\Delta^+(L_{SG(s)},\{\mathbf{A}_t\}_t) = \sqrt{\frac{2}{\pi}}\frac{s}{K}\sum_{j=1}^{K}\lim_{t\downarrow 0^+}\frac{1}{t}\left(\left|\left|\left|\mathbf{A}_t^{-1}[j,]\right|\right|\right|_s - |||\mathbf{I}[j,]|||_s\right). \tag{13}$$

For each $j \in [\![K]\!]$, we have

$$\binom{K-1}{s-1}\left|\left|\left|\mathbf{A}_t^{-1}[j,]\right|\right|\right|_s = \sum_{S:|S|=s,j\in S}\|\mathbf{A}_t^{-1}[j,S]\|_2 + \sum_{S:|S|=s,j\notin S}\|\mathbf{A}_t^{-1}[j,S]\|_2 \tag{14}$$

Denote by $\dot{\mathbf{A}}_0 \in \mathbb{R}^{K\times K}$ the derivative of $\{\mathbf{A}_t\}_t$ at $t = 0$. Since $\mathbf{A}_t \in \mathcal{A}$ for all $t \in \mathbb{R}$, it can be shown that

$$\mathbf{M}_0[,k]^T\dot{\mathbf{A}}_0[,k] = 0 \quad \text{for all } k \in [\![K]\!]. \tag{15}$$

By (15), we have

$$\dot{\mathbf{A}}_0[j,j] = -\sum_{i\neq j}\mathbf{M}_0[i,j]\dot{\mathbf{A}}_0[i,j] \text{ for all } j \in [\![K]\!]. \tag{16}$$

Now notice that

$$\left.\frac{d\mathbf{A}_t^{-1}}{dt}\right|_{t=0} = -\mathbf{A}_0^{-1}\dot{\mathbf{A}}_0\mathbf{A}_0^{-1} = -\dot{\mathbf{A}}_0. \tag{17}$$

Combining the above equality with Lemma 14 and 15, we have

$$\lim_{t\downarrow 0^+}\frac{1}{t}\left(\|\mathbf{A}_t^{-1}[j,S]\|_2 - \|\mathbf{I}[j,S]\|_2\right) = \begin{cases} -\dot{\mathbf{A}}_0[j,j] & \text{if } j \in S \\ \|\dot{\mathbf{A}}_0[j,S]\|_2 & \text{if } j \notin S\end{cases}$$

Therefore

$$\lim_{t\downarrow 0^+}\frac{1}{t}\left(\left|\left|\left|\mathbf{A}_t^{-1}[j,]\right|\right|\right|_s - |||\mathbf{I}[j,]|||_s\right) = -\dot{\mathbf{A}}_0[j,j] + \binom{K-1}{s-1}^{-1}\sum_{S:|S|=s,j\notin S}\|\dot{\mathbf{A}}_0[j,S]\|_2. \tag{18}$$

Combining (13), (14), (16) and (18), we have

$$\begin{aligned}\sqrt{\frac{\pi}{2}}\frac{K}{s}\Delta^+(L_{SG(s)},\{\mathbf{A}_t\}_t) &= -\sum_{j=1}^{K}\dot{\mathbf{A}}_0[j,j] + \binom{K-1}{s-1}^{-1}\sum_j\sum_{S:|S|=s,j\notin S}||\dot{\mathbf{A}}_0[j,S]||_2 \\ &= \sum_{j=1}^{K}\Big(\sum_{i\neq j}\mathbf{M}_0[i,j]\dot{\mathbf{A}}_0[j,i] + \binom{K-1}{s-1}^{-1}\sum_{S:|S|=s,j\notin S}\|\dot{\mathbf{A}}_0[j,S]\|_2\Big).\end{aligned}$$

Similarly, one can show

$$\sqrt{\frac{\pi}{2}}\frac{K}{s}\Delta^-(L_{SG(s)},\{\mathbf{A}_t\}_t) = \sum_{j=1}^{K}\Big(\sum_{i\neq j}\mathbf{M}_0[i,j]\dot{\mathbf{A}}_0[j,i] - \binom{K-1}{s-1}^{-1}\sum_{S:|S|=s,j\notin S}\|\dot{\mathbf{A}}_0[j,S]\|_2\Big).$$

Thus for $s \in [\![K-1]\!]$, to establish (12) it suffices to require for each $j \in [\![K]\!]$,

$$\Big|\sum_{i\neq j}\mathbf{M}_0[i,j]\dot{\mathbf{A}}_0[j,i]\Big| < \frac{K-s}{K-1}\binom{K-2}{s-1}^{-1}\sum_{S:|S|=s,j\notin S}\|\dot{\mathbf{A}}_0[j,S]\|_2 = \frac{K-s}{K-1}\left|\left|\left|\dot{\mathbf{A}}_0[j,-j]\right|\right|\right|_s. \tag{19}$$

for any $\dot{\mathbf{A}}_0$ such that $\dot{\mathbf{A}}_0[j,-j] \neq 0$. Since $\dot{\mathbf{A}}_0[j,i]$ is a free variable for $i \neq j$, (19) is equivalent to

$$\left|\mathbf{M}_0[-j,j]^T\mathbf{w}\right| < \frac{K-s}{K-1},$$

for all $\mathbf{w} \in \mathbb{R}^{K-1}$ such that $\|\mathbf{w}\|_s = 1$. Thus by the definition of the dual norm, it suffices to have

$$\|\mathbf{M}_0[-j,j]\|_s^* = \sup_{\|\mathbf{w}\|_s=1} \left|\mathbf{M}_0[-j,j]^T\mathbf{w}\right| < \frac{K-s}{K-1}.$$

Therefore, the condition

$$\max_{1\leq j\leq K} \|\mathbf{M}_0[-j,j]\|_s^* < \frac{K-s}{K-1} = 1 - \frac{s-1}{K-1}. \tag{20}$$

is sufficient for $\mathbf{D}_0$ to be locally identifiable with respect to the objective function $L_{SG(s)}$.

Similarly, one can check that if the reversed strict inequality in (20) holds, $\mathbf{D}_0$ is not a local minimum of $L_{SG(s)}(\mathbf{D})$. Thus we complete the proof for the s-sparse model.

(2) Now consider the Bernoulli(p)-Gaussian model for $p \in (0,1)$. First of all, note that we have

$$\begin{aligned}
&\sqrt{\frac{\pi}{2}}\frac{1}{p}\Delta^{\pm}(L_{BG(p)}, \{\mathbf{A}_t\}_t) = \sum_{j=1}^{K} \lim_{t\to 0^{\pm}} \frac{1}{t}\left(\|\|\mathbf{A}_t^{-1}[j,]\|\|_p - \|\|\mathbf{I}[j,]\|\|_p\right)\\
=&\sum_{j=1}^{K}\left(\sum_{i\neq j}\mathbf{M}_0[i,j]\dot{\mathbf{A}}_0[j,i] \pm (1-p)\sum_{k=0}^{K-2} p^k(1-p)^{K-2-k}\sum_{S:|S|=k+1, j\notin S}\|\dot{\mathbf{A}}_0[j,S]\|_2\right)\\
=&\sum_{j=1}^{K}\left(\dot{\mathbf{A}}_0[j,-j]^T\mathbf{M}_0[-j,j] \pm (1-p)\sum_{k=0}^{K-2}\texttt{pbinom}(k;K-2,p)\left\|\left|\dot{\mathbf{A}}_0[j,-j]\right|\right\|_{k+1}\right)\\
=&\sum_{j=1}^{K}\left(\dot{\mathbf{A}}_0[j,-j]^T\mathbf{M}_0[-j,j] \pm (1-p)\left\|\left|\dot{\mathbf{A}}_0[j,-j]\right|\right\|_p\right).
\end{aligned}$$

Thus, similar to the s-sparse Gaussian case, it can be shown that a sufficient condition for local identifiability is

$$\left|\mathbf{M}_0[-j,j]^T\mathbf{w}\right| < 1-p,$$

for all $j \in [\![K]\!]$ and all $\mathbf{w} \in \mathbb{R}^{K-1}$ such that $\|\mathbf{w}\|_p = 1$. The above condition is equivalent to

$$\max_{1\leq j\leq K} \|\mathbf{M}_0[-j,j]\|_p^* < 1-p.$$

The rest of the proof can be proceeded as in the case of the s-sparse Gaussian model.

(3) Let us consider the non-sparse case where $s = K$ or $p = 1$. In this case, since the objective functions are the same under both models (see Theorem 1), we only need to consider the s-sparse Gaussian model. If $s = K$, the RHS quantity in Inequality (19) is zero. Thus, the reference dictionary is not locally identifiable if

$$\left|\mathbf{M}_0[-j,j]^T\mathbf{w}\right| > 0,$$

for some $j \in [\![K]\!]$ and $\mathbf{w} \in \mathbb{R}^{K-1}$. Thus, if $\mathbf{M}_0$ is not the identity matrix, or equivalently, if the reference dictionary $\mathbf{D}_0$ is not orthogonal, $\mathbf{D}_0$ is not locally identifiable.

Next, let us deal with the case where $\mathbf{D}_0$ is orthogonal. Let $\mathbf{D} \in \mathcal{D}$ be a full rank dictionary and $\mathbf{W} = \mathbf{D}^{-1}$. Since $\mathbf{D}_0$ is orthogonal, $\|\mathbf{W}[j,]\mathbf{D}_0\|_2 = \|\mathbf{W}[j,]\|_2$. By the fact that $\mathbf{WD} = \mathbf{I}$ and $\|\mathbf{D}[,j]\|_2 = 1$, we have $1 = \mathbf{W}[j,]\mathbf{D}[,j] \leq \|\mathbf{W}[j,]\|_2\|\mathbf{D}[,j]\|_2 = \|\mathbf{W}[j,]\|_2$, where the equality holds if and only if $\mathbf{W}[j,]^T = \pm\mathbf{D}[,j]$.

Under the K-sparse Gaussian model,

$$L_{SG(K)}(\mathbf{D}) = \sqrt{\frac{2}{\pi}}\sum_{j=1}^{K}\|\mathbf{W}[j,]\mathbf{D}_0\|_2 = \sqrt{\frac{2}{\pi}}\sum_{j=1}^{K}\|\mathbf{W}[j,]\|_2 \geq \sqrt{\frac{2}{\pi}}K = L_{SG(K)}(\mathbf{D}_0),$$

where the equality holds for any $\mathbf{D}$ such that $\mathbf{D}^T\mathbf{D} = \mathbf{I}$. Thus, $L_{SG(K)}(\mathbf{D}_0) = L_{SG(K)}(\mathbf{D}_0\mathbf{U})$ for any orthogonal matrix $\mathbf{U} \in \mathbb{R}^{K\times K}$, i.e., the objective function remains the same as we rotate $\mathbf{D}_0$. Therefore, $\mathbf{D}_0$ is not a strict local minimum of $L_{SG(K)}$.

In conclusion, $\mathbf{D}_0$ is not locally identifiable when $s = K$ or $p = 1$. ■

A.1.3 Proof of Corollary 2

Proof Let $\mathbf{D} \in \mathcal{D}$ be a full rank dictionary and $\mathbf{W} = \mathbf{D}^{-1}$. Under the K-sparse Gaussian model, $\mathbf{D}_0$ is not locally identifiable by Theorem 1. Hence it is not a strict local minimum of $L_{SG(K)}(\mathbf{D})$ and cannot be a strict global minimum.

Now suppose $s < K$, by Lemma 1 and 7,

$$L_{SG(s)}(\mathbf{D}) = \sqrt{\frac{2}{\pi}}\frac{s}{K}\sum_{j=1}^{K}\|\|\mathbf{W}[j,]\mathbf{D}_0\|\|_s \geq \sqrt{\frac{2}{\pi}}\frac{s}{K}\sum_{j=1}^{K}\|\mathbf{W}[j,]\mathbf{D}_0\|_2 \geq \sqrt{\frac{2}{\pi}}s = L_{SG(s)}(\mathbf{D}_0).$$

So $\mathbf{D}_0$ is a global minimum. Next we will show $\mathbf{D}_0$ is the only strict global minimum up to column permutation and sign changes. In the above formula, for the first equality to hold, we have $\|\|\mathbf{W}[j,]\mathbf{D}_0\|\|_s = \|\mathbf{W}[j,]\mathbf{D}_0\|_2$ for all j, implying that the vector $\mathbf{W}[j,]\mathbf{D}_0$ has at most one nonzero entry, see Lemma 7. For the second inequality to hold, $\mathbf{W}[j,]^T = \pm\mathbf{D}[,j]$, see arguments in Part (3) of the Theorem 1 proof. Combining these two conditions, $\|\mathbf{W}[j,]\mathbf{D}_0\|_2 = \|\mathbf{D}[j,]\|_2 = 1$ and so the nonzero entry can only be ± 1. Therefore, $\mathbf{WD}_0$ is an identity matrix after proper column permutation and sign changes.

The proof for the Bernoulli-Gaussian model is similar and hence omitted. ■

A.2 Proofs of the Finite Sample Results: Theorem 2 and Theorem 3

Proof We will first recall the signal generation procedure in Section 2. Let $\mathbf{z}$ be a K-dimensional standard Gaussian vector, and $\boldsymbol{\xi} \in \{0,1\}^K$ be either an s-sparse random vector or a Bernoulli random vector with probability p. Let $\mathbf{z}_1,\ldots,\mathbf{z}_N$ and $\boldsymbol{\xi}_1,\ldots,\boldsymbol{\xi}_N$ be identical and independent copies of $\mathbf{z}$ and $\boldsymbol{\xi}$ respectively. For each $i \in [\![N]\!]$ and $j \in [\![K]\!]$, define

$\boldsymbol{\alpha}_i[j] = \mathbf{z}_i[j]\boldsymbol{\xi}_i[j]$. For $S \subset [\![K]\!]$, define

$$\chi_i(S) = \begin{cases} 1 & \text{if } \boldsymbol{\xi}_i[k] = 1 \text{ for all } k \in S \text{ and } \boldsymbol{\xi}_i[k] = 0 \text{ for all } k \in S^c, \\ 0 & \text{otherwise.} \end{cases}$$

As in the population case, in the following analysis we will work with full rank dictionaries. First of all, notice that

$$l(\mathbf{D}, \mathbf{x}_i) = \|\mathbf{D}^{-1}\mathbf{x}_i\|_1 = \|\mathbf{D}^{-1}\mathbf{D}_0\boldsymbol{\alpha}_i\|_1 = \sum_{j=1}^{K} \left|\mathbf{A}^{-1}[j,]\boldsymbol{\alpha}_i\right| = \sum_{j=1}^{K}\sum_{k=1}^{K}\left(\sum_{S:|S|=k} |\mathbf{A}^{-1}[j,S]\mathbf{z}_i[S]|\chi_i(S)\right).$$

Next, we have

$$\begin{aligned}\Delta^+(l(.,\mathbf{x}_i),\{\mathbf{A}_t\}_t) &= \lim_{t\downarrow 0^+}\frac{1}{t}\left(l(\mathbf{D}_0\mathbf{A}_t,\mathbf{x}_i) - l(\mathbf{D}_0,\mathbf{x}_i)\right) \\ &= \sum_{j=1}^{K}\Bigg(-\sum_{k=1}^{K}\sum_{S:j\in S,|S|=k}\dot{\mathbf{A}}_0[j,j]|\mathbf{z}_i[j]|\chi_i(S) \\ &\quad - \mathbf{sgn}(\mathbf{z}_i[j])\sum_{k=2}^{K}\sum_{S:j\in S,|S|=k}\sum_{l\in S,l\neq j}\dot{\mathbf{A}}_0[j,l]\mathbf{z}_i[l]\chi_i(S) \\ &\quad + \sum_{k=1}^{K-1}\sum_{S:j\notin S,|S|=k}|\dot{\mathbf{A}}_0[j,S]\mathbf{z}_i[S]|\chi_i(S)\Bigg). \end{aligned} \tag{21}$$

Here $\mathbf{sgn}(x)$ is the sign function of $x \in \mathbb{R}$ such that $\mathbf{sgn}(x) = 1$ for $x > 0$, $\mathbf{sgn}(x) = -1$ for $x < 0$ and $\mathbf{sgn}(x) = 0$ for $x = 0$. By (16), the first term in (21) can be rearranged as follows

$$\begin{aligned}-\sum_{j=1}^{K}|\mathbf{z}_i[j]|\sum_{k=1}^{K}\sum_{S:j\in S,|S|=k}\dot{\mathbf{A}}_0[j,j]\chi_i(S) &= \sum_{j=1}^{K}|\mathbf{z}_i[j]|\sum_{k=1}^{K}\sum_{S:j\in S,|S|=k}\sum_{l\neq j}\mathbf{M}_0[l,j]\dot{\mathbf{A}}_0[l,j]\chi_i(S) \\ &= \sum_{j=1}^{K}\sum_{l\neq j}\mathbf{M}_0[j,l]\dot{\mathbf{A}}_0[j,l]\left(|\mathbf{z}_i[l]|\sum_{k=1}^{K}\sum_{S:l\in S,|S|=k}\chi_i(S)\right).\end{aligned}$$

The second term in (21) can be rewritten as

$$-\sum_{j=1}^{K}\mathbf{sgn}(\mathbf{z}_i[j])\times\sum_{l\neq j}(\dot{\mathbf{A}}_0[j,l]\mathbf{z}_i[l])\times\sum_{k=2}^{K}\sum_{S:\{j,l\}\in S,|S|=k}\chi_i(S).$$

For $j, l \in [\![K]\!]$ such that $j \neq l$, define the following quantities

$$\mathbf{F}_i[l,j] = \mathbf{M}_0[j,l]|\mathbf{z}_i[l]|\sum_{k=1}^{K}\sum_{S:l\in S,|S|=k}\chi_i(S), \tag{22}$$

$$\mathbf{G}_i[l,j] = \mathbf{sgn}(\mathbf{z}_i[j])\mathbf{z}_i[l]\sum_{k=2}^{K}\sum_{S:\{j,l\}\in S,|S|=s}\chi_i(S), \tag{23}$$

whereas $\mathbf{F}[j,j] = \mathbf{G}[j,j] = 0$. For each $j \in [\![K]\!]$, also define

$$\mathbf{t}_i[j](\mathbf{w}) = \sum_{k=1}^{K-1}\sum_{S:j\notin S,|S|=k}|\mathbf{w}[S]^T\mathbf{z}_i[S]|\chi_i(S). \tag{24}$$

Let $\bar{\mathbf{F}}$, $\bar{\mathbf{G}}$ and $\bar{\mathbf{t}}$ be the sample average of $\mathbf{F}_i$, $\mathbf{G}_i$ and $\mathbf{t}_i$ respectively. With the definitions (22)—(24), we have

$$\begin{aligned}\Delta^+(L_N,\{\mathbf{A}_t\}_t) &= \frac{1}{N}\sum_{i=1}^{N}\Delta^+(l(.,\mathbf{x}_i),\{\mathbf{A}_t\}_t) \\ &= \sum_{j=1}^{K}\frac{1}{N}\sum_{i=1}^{N}\left(\dot{\mathbf{A}}_0[j,]\mathbf{F}_i[,j] + \dot{\mathbf{A}}_0[j,]\mathbf{G}_i[,j] + \mathbf{t}_i[j](\dot{\mathbf{A}}_0[j,])\right) \\ &= \sum_{j=1}^{K}\left(\dot{\mathbf{A}}_0[j,]\bar{\mathbf{F}}[,j] - \dot{\mathbf{A}}_0[j,]\bar{\mathbf{G}}[,j] + \bar{\mathbf{t}}[j](\dot{\mathbf{A}}_0[j,])\right)\end{aligned}$$

On the other hand,

$$\Delta^-(L_N,\{\mathbf{A}_t\}_t) = \sum_{j=1}^{K}\left(\dot{\mathbf{A}}_0[j,]\bar{\mathbf{F}}[,j] - \dot{\mathbf{A}}_0[j,]\bar{\mathbf{G}}[,j] - \bar{\mathbf{t}}[j](\dot{\mathbf{A}}_0[j,])\right).$$

Now for $j \in [\![K]\!]$, $s \in [\![K-1]\!]$ and $p \in (0,1)$, define

$$\mathcal{E}_j(s) = \{\mathbf{w} \in \mathbb{R}^K, \|\mathbf{w}[-j]\|_s = 1, \mathbf{w}[j] = 0\},$$

$$\mathcal{F}_j(p) = \{\mathbf{w} \in \mathbb{R}^K, \|\mathbf{w}[-j]\|_p = 1, \mathbf{w}[j] = 0\}.$$

Thus to ensure that $\mathbf{D}_0$ is a local minimum, it suffices to have for each $j \in [\![K]\!]$,

$$H_j(\mathbf{w}) \coloneqq \left|\mathbf{w}^T\bar{\mathbf{F}}[,j] - \mathbf{w}^T\bar{\mathbf{G}}[,j]\right| - \bar{\mathbf{t}}[j](\mathbf{w}) < 0,$$

for all $\mathbf{w} \in \mathcal{E}_j(s)$ for the s-sparse Gaussian model or all $\mathbf{w} \in \mathcal{F}_j(p)$ for the Bernoulli(p)-Gaussian model.

(1) For the s-sparse Gaussian model, let $j \in [\![K]\!]$ and define

$$h_j(\mathbf{w}) = \sqrt{\frac{2}{\pi}}\frac{s}{K}\left(\left|\mathbf{w}^T\mathbf{M}_0[,j]\right| - \frac{K-s}{K-1}\right),$$

which can be thought of as the expected value of $H_j(\mathbf{w})$. Note that by triangle inequality,

$$\begin{aligned}&\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w}) - h_j(\mathbf{w})| \\ \leq &\sup_{\mathbf{w}\in\mathcal{E}_j(s)}\left|\mathbf{w}^T\left(\bar{\mathbf{F}}[,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[,j]\right)\right| + \sup_{\mathbf{w}\in\mathcal{E}_j(s)}\left|\mathbf{w}^T\bar{\mathbf{G}}[,j]\right| + \sup_{\mathbf{w}\in\mathcal{E}_j(s)}\left|\bar{\mathbf{t}}[j](\mathbf{w}) - \sqrt{\frac{2}{\pi}}\frac{s}{K}\frac{K-s}{K-1}\right| \\ = &\left\|\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[-j,j]\right\|\right\|_s^* + \left\|\left\|\bar{\mathbf{G}}[-j,j]\right\|\right\|_s^* + \sup_{\mathbf{w}\in\mathcal{E}_j(s)}\left|\bar{\mathbf{t}}[j](\mathbf{w}) - \sqrt{\frac{2}{\pi}}\frac{s}{K}\frac{K-s}{K-1}\right|.\end{aligned} \tag{25}$$

Thus, $\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w})-h_j(\mathbf{w})|>\frac{s}{K}\epsilon$ implies at least one of the three terms on the RHS is greater than $\frac{s}{K}\frac{\epsilon}{3}$. Using a union bound and by Lemma 3—5, we have

$$\begin{aligned}\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w})-h_j(\mathbf{w})|>\frac{s}{K}\epsilon\right\}&\le 2K\exp\left(-\frac{N\epsilon^2}{108K\|\mathbf{M}_0[-j,j]\|_\infty}\right)\\&\quad+2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{18(s/K)s+9\sqrt{2s}}\right)\\&\quad+3\left(\frac{24K}{\epsilon s}+1\right)^K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{360}\right).\end{aligned}\tag{26}$$

It is easy to see that the event $\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w})-h_j(\mathbf{w})|\le\frac{s}{K}\epsilon\right\}$ implies

$$\sup_{\mathbf{w}\in\mathcal{E}_j(s)}h_j(\mathbf{w})-\frac{s}{K}\epsilon\le\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})\le\sup_{\mathbf{w}\in\mathcal{E}_j(s)}h_j(\mathbf{w})+\frac{s}{K}\epsilon.\tag{27}$$

On the other hand,

$$\sup_{\mathbf{w}\in\mathcal{E}_j(s)}h_j(\mathbf{w})=\sqrt{\frac{2}{\pi}}\frac{s}{K}\left(|||\mathbf{M}_0[-j,j]|||_s^*-\frac{K-s}{K-1}\right).$$

Thus, if $|||\mathbf{M}_0[-j,j]|||_s^*<\frac{K-s}{K-1}-\sqrt{\frac{\pi}{2}}\epsilon$, $\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})<0$ except with probability at most the bound in (26). To ensure $\mathbf{D}_0$ to be a local minimum, it suffices to have $\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})<0$ for all $j\in[\![K]\!]$. Thus, if $|||\mathbf{M}_0[-j,j]|||_s^*<\frac{K-s}{K-1}-\sqrt{\frac{\pi}{2}}\epsilon$ for all $j\in[\![K]\!]$, we have

$$\begin{aligned}\mathbb{P}\{\mathbf{D}_0\text{ is locally identifiable}\}&\ge\mathbb{P}\left\{\max_j\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})<0\right\}\\&\ge1-\mathbb{P}\left\{\max_j\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})\ge0\right\}\\&\ge1-\sum_{j=1}^K\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})\ge0\right\}\\&\ge1-\sum_{j=1}^K\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w})-h_j(\mathbf{w})|>\frac{s}{K}\epsilon\right\}\\&\ge1-2K^2\exp\left(-\frac{N\epsilon^2}{108K\max_{l\neq j}|\mathbf{M}_0[l,j]|}\right)\\&\quad-2K^2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{18(s/K)s+9\sqrt{2s}}\right)\\&\quad-3K\left(\frac{24K}{\epsilon s}+1\right)^K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{360}\right).\end{aligned}$$

On the other hand, to ensure $\mathbf{D}_0$ is not locally identifiable with high probability, it suffices to have $|||\mathbf{M}_0[-j,j]|||_s^*>\frac{K-s}{K-1}+\sqrt{\frac{\pi}{2}}\epsilon$ for some $j\in[\![K]\!]$. Indeed, under that condition, the

LHS inequality in (27) implies $\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})>0$. Therefore

$$\begin{aligned}\mathbb{P}\{\mathbf{D}_0\text{ is not locally identifiable}\}&\ge\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})>0\right\}\\&\ge1-\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}H_j(\mathbf{w})\le0\right\}\\&\ge1-\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}|H_j(\mathbf{w})-h_j(\mathbf{w})|>\frac{s}{K}\epsilon\right\}\\&\ge1-2K\exp\left(-\frac{N\epsilon^2}{108K\|\mathbf{M}_0[-j,j]\|_\infty}\right)\\&\quad-2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{18(s/K)s+9\sqrt{2s}}\right)\\&\quad-3\left(\frac{24K}{\epsilon s}+1\right)^K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{360}\right).\end{aligned}$$

(2) For the Bernoulli(p)-Gaussian model, define

$$\nu_j(\mathbf{w})=\sqrt{\frac{2}{\pi}}p\left(\left|\mathbf{w}^T\mathbf{M}_0[,j]\right|-(1-p)\right).$$

Similar to (25), by triangle inequality,

$$\begin{aligned}&\sup_{\mathbf{w}\in\mathcal{F}_j(p)}|H_j(\mathbf{w})-\nu_j(\mathbf{w})|\\&\le\left|\left|\left|\bar{\mathbf{F}}[-j,j]-\sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right|\right|\right|_p^*+|||\bar{\mathbf{G}}[-j,j]|||_p^*+\sup_{\mathbf{w}\in\mathcal{F}_j(p)}\left|\bar{\mathbf{t}}[j](\mathbf{w})-\sqrt{\frac{2}{\pi}}p(1-p)\right|.\end{aligned}$$

Then the analysis can be carried out in a similar manner using the parallel version of the concentration inequalities, i.e., Part 2 of Lemma 3—5. ■

A.3 Concentration Inequalities

We will make frequent use of the following version of Bernstein's inequality. The proof of the inequality can be found in, e.g., Chapter 14 of Bühlmann and van de Geer (2011).

Theorem 4 *(Bernstein's inequality) Let $Y_1,\ldots,Y_N$ be independent random variables that satisfy the moment condition*

$$\mathbb{E}Y_i^m\le\frac{1}{2}\times V\times m!\times B^{m-2},$$

for integers $m\ge2$. Then

$$\mathbb{P}\left\{\frac{1}{N}\left|\sum_{i=1}^N Y_i-\mathbb{E}Y_i\right|>\epsilon\right\}\le2\exp\left(-\frac{N\epsilon^2}{2V+2B\epsilon}\right).$$

Lemma 3 *(Uniform concentration of $\bar{\mathbf{F}}[-j,j]$) For $i \in [\![N]\!]$, let $\mathbf{F}_i \in \mathbb{R}^{K\times K}$ be defined as in (22) and $\bar{\mathbf{F}} = (1/N)\sum_{i=1}^N \mathbf{F}_i$.*

1. *Under the s-sparse Gaussian model with $s \in [\![K-1]\!]$,*

$$\mathbb{P}\left\{\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[-j,j]\right\|_s^* > \frac{s}{K}\epsilon\right\} \le 2K\exp\left(-\frac{N\epsilon^2}{12K\|\mathbf{M}_0[-j,j]\|_\infty}\right),$$

for $0 < \epsilon \le 1$.

2. *Under the Bernoulli-Gaussian model with parameter $p \in (0,1)$,*

$$\mathbb{P}\left\{\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right\|_p^* > p\epsilon\right\} \le 2K\exp\left(-\frac{N\epsilon^2}{12(K+2p^{-1})\|\mathbf{M}_0[-j,j]\|_\infty}\right),$$

for $0 < \epsilon \le 1$.

In particular, if $\|\mathbf{M}_0[-j,j]\|_\infty = 0$, then the RHS bound is trivially zero.

Proof (1) First of all, we will prove the inequality for the s-sparse model. Notice that by Lemma 2, we have

$$\begin{aligned}\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[-j,j]\right\|_s^* &\le \max_{|S|=s, j\notin S}\|\bar{\mathbf{F}}[S,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[S,j]\|_2\\ &\le \sqrt{s}\max_{l\neq j}|\bar{\mathbf{F}}[l,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[l,j]|.\end{aligned}$$

For convenience, define

$$\mathbf{v}_i[l] = |\mathbf{z}_i[l]|\sum_{k=1}^K\sum_{|S|=k, l\in S}\chi_i(S) - \sqrt{\frac{2}{\pi}}\frac{s}{K}.$$

for $i \in [\![N]\!]$ and $l \in [\![K]\!]$. Note that $\sum_{k=1}^K\sum_{l\in S,|S|=k}\chi_i(S) = 1$ with probability $\binom{K}{s}^{-1}\binom{K-1}{s-1} = \frac{s}{K}$. Thus

$$\mathbb{E}\left(\sum_{k=1}^K\sum_{|S|=k,l\in S}\chi_i(S)\right)^m = \frac{s}{K}.$$

For $m \ge 1$, by Jensen's inequality $|\frac{a+b}{2}|^m \le \frac{1}{2}(|a|^m + |b|^m)$ and $\mathbb{E}|Z|^m \ge (\mathbb{E}|Z|)^m = \left(\frac{2}{\pi}\right)^{\frac{m}{2}}$, where Z is a standard Gaussian variable. In addition, $\mathbb{E}|Z|^m \le (m-1)!! \le 2^{-\frac{m}{2}}m!$. Hence

$$\begin{aligned}\mathbb{E}|\mathbf{v}_i[l]|^m &\le 2^{m-1}\left(\mathbb{E}|\mathbf{z}_i[l]|^m + \left(\frac{2}{\pi}\right)^{\frac{m}{2}}\left(\frac{s}{K}\right)^m\right)\\ &\le 2\times\mathbb{E}|Z|^m\times 2^{m-1}\\ &\le 2\times\left(\frac{1}{2}\right)^{\frac{m}{2}}m!\times 2^{m-1}\\ &= \frac{1}{2}\times\frac{4s}{K}\times m!\times(\sqrt{2})^{m-2}.\end{aligned}$$

Thus by Bernstein's inequality, we have

$$\mathbb{P}\left\{\left|\frac{1}{N}\sum_{i=1}^N\mathbf{v}_i[l]\right| > \epsilon\right\} \le 2\exp\left(-\frac{N\epsilon^2}{2(4\frac{s}{K}+\sqrt{2}\epsilon)}\right).$$

Therefore,

$$\begin{aligned}\mathbb{P}\left\{\left|\mathbf{M}_0[j,l]\frac{1}{N}\sum_{i=1}^N\mathbf{v}_i[l]\right| > \frac{s}{K}\epsilon\right\} &\le 2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2(4\mathbf{M}_0[j,l]^2 + \sqrt{2}\,|\mathbf{M}_0[j,l]|\,\epsilon)}\right)\\ &\le 2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2\,|\mathbf{M}_0[j,l]|\,(4+\sqrt{2}\epsilon)}\right)\\ &\le 2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{12\,|\mathbf{M}_0[j,l]|}\right).\end{aligned}$$

for $\epsilon \le 1$. Notice that if $\mathbf{M}_0[j,l] = 0$ the LHS probability is trivially zero. Using a union bound, we have

$$\begin{aligned}\mathbb{P}\left\{\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[-j,j]\|_\infty > \frac{s}{K}\epsilon\right\} &= \mathbb{P}\left\{\max_{l\neq j}|\mathbf{M}_0[j,l]\frac{1}{N}\sum_{i=1}^N\mathbf{v}_i[l]| > \epsilon\right\}\\ &\le 2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{12\|\mathbf{M}_0[-j,j]\|_\infty}\right).\end{aligned}$$

Therefore

$$\begin{aligned}\mathbb{P}\left\{\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[-j,j]\right\|_s^* > \frac{s}{K}\epsilon\right\} &\le \mathbb{P}\left\{\sqrt{s}\|\bar{\mathbf{F}}[,j] - \sqrt{\frac{2}{\pi}}\frac{s}{K}\mathbf{M}_0[,j]\|_\infty > \frac{s}{K}\epsilon\right\}\\ &\le 2K\exp\left(-\frac{N\epsilon^2}{12K\|\mathbf{M}_0[-j,j]\|_\infty}\right).\end{aligned}$$

(2) Now let us consider the Bernoulli-Gaussian model. Notice that by Lemma 8, for $\frac{s-1}{K-1} \ge p$, we have

$$\begin{aligned}\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right\|_p^* &\le \left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right\|_s^*\\ &\le \sqrt{s}\left\|\bar{\mathbf{F}}[-j,j] - \sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right\|_\infty.\end{aligned}$$

Now let $s = \lceil pK - p + 1\rceil \le pK + 2$. For $i \in [\![N]\!]$ and $l \in [\![K]\!]$, define

$$\mathbf{u}_i[l] = |\mathbf{z}_i[l]|\sum_{k=1}^K\sum_{|S|=s,l\in S}\chi_i(S) - \sqrt{\frac{2}{\pi}}p.$$

Note that the event $\left\{\sum_{k=1}^{K}\sum_{|S|=k,l\in S}\chi_i(S)=1\right\}$ is the same as the event that $\{\boldsymbol{\alpha}_i[l]=1\}$, which, happens with probability p. Thus

$$\mathbb{E}\left(\sum_{k=1}^{K}\sum_{|S|=k,l\in S}\chi_i(S)\right)^m = p.$$

Similar to the case of s-sparse model,

$$\mathbb{E}\,|\mathbf{u}_i[l]|^m \le \frac{1}{2}\times 4p\times m!\times\left(\sqrt{2}\right)^{m-2}.$$

By Bernstein's inequality, we have

$$\mathbb{P}\left\{\left|\frac{1}{N}\sum_{i=1}^{N}\mathbf{u}_i[l]\right|>\epsilon\right\}\le 2\exp\left(-\frac{N\epsilon^2}{2(4p+\sqrt{2}\epsilon)}\right).$$

Therefore

$$\begin{aligned}\mathbb{P}\left\{\left\|\left\|\bar{\mathbf{F}}[-j,j]-\sqrt{\frac{2}{\pi}}p\mathbf{M}_0[-j,j]\right\|\right\|_p^*>p\epsilon\right\}&\le\mathbb{P}\left\{\sqrt{s}\|\bar{\mathbf{F}}[,j]-\sqrt{\frac{2}{\pi}}p\mathbf{M}_0[,j]\|_\infty>p\epsilon\right\}\\&\le 2K\exp\left(-\frac{p}{s}\frac{N\epsilon^2}{2\|\mathbf{M}_0[-j,j]\|_\infty(4+\sqrt{2}\epsilon)}\right)\\&\le 2K\exp\left(-\frac{N\epsilon^2}{12(K+2p^{-1})\|\mathbf{M}_0[-j,j]\|_\infty}\right),\end{aligned}$$

for $\epsilon\le 1$. ■

Lemma 4 *(Uniform concentration of $\bar{\mathbf{G}}[-j,j]$) For $i\in[\![N]\!]$, let $\mathbf{G}_i\in\mathbb{R}^{K\times K}$ be defined as in (23) and $\bar{\mathbf{G}}=(1/N)\sum_{i=1}^{N}\mathbf{G}_i$.*

1. *Under the s-sparse Gaussian model with $s\in[\![K-1]\!]$,*

$$\mathbb{P}\left\{\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_s^*>\frac{s}{K}\epsilon\right\}\le 2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2(s/K)s+\sqrt{2s}}\right),$$

   for $0<\epsilon\le 1$.

2. *Under the Bernoulli-Gaussian model with parameter $p\in(0,1)$,*

$$\mathbb{P}\left\{\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_p^*>p\epsilon\right\}\le 2K\exp\left(-p\frac{N\epsilon^2}{p(pK+2)+\sqrt{2(pK+2)}}\right),$$

   for $0<\epsilon\le 1$.

Proof The proof is highly similar to that of Lemma 3 and so we will omit some common steps.
(1) We first prove the concentration inequality for the s-sparse model. Notice that

$$\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_s^*\le\sqrt{s}\max_{l\neq j}|\bar{\mathbf{G}}[l,j]|.$$

In addition,

$$\begin{aligned}\mathbb{E}\left(\sum_{k=2}^{K}\sum_{\{j,l\}\in S,|S|=k}\chi_i(S)\right)^m&=\mathbb{E}\left(\sum_{k=2}^{K}\sum_{|S|=k,\{j,l\}\in S}\chi_i(S)\right)\\&=\binom{K}{s}^{-1}\binom{K-2}{s-2}=\frac{s(s-1)}{K(K-1)}\le(\frac{s}{K})^2.\end{aligned}$$

Thus

$$\mathbb{E}|\mathbf{G}_i[l,j]|^m\le 2^{-m/2}m!\times(\frac{s}{K})^2=\frac{1}{2}\times(\frac{s}{K})^2\times m!\times(\frac{1}{\sqrt{2}})^{m-2}.$$

By Bernstein inequality:

$$\mathbb{P}\left\{\left|\frac{1}{N}\sum_{i=1}^{N}\mathbf{G}_i[l,j]\right|>\epsilon\right\}\le 2\exp\left(-\frac{N\epsilon^2}{2(s/K)^2+\sqrt{2}\epsilon)}\right).$$

Thus we have

$$\begin{aligned}\mathbb{P}\left\{\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_s^*>\frac{s}{K}\epsilon\right\}&\le\mathbb{P}\left\{\sqrt{s}\max_{l\neq j}|\bar{\mathbf{G}}[l,j]|>\frac{s}{K}\epsilon\right\}\\&\le 2K\exp\left(-\frac{(s/K)^2N(\epsilon^2/s)}{2(s/K)^2+\sqrt{2}(s/K)(\epsilon/\sqrt{s}))}\right)\\&\le 2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2(s/K)s+\sqrt{2s}\epsilon}\right)\\&\le 2K\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2(s/K)s+\sqrt{2s}}\right),\end{aligned}$$

for $\epsilon\le 1$.
(2) For Bernoulli-Gaussian model, notice that

$$\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_p^*\le\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_s^*\le\sqrt{s}\max_{l\neq j}|\bar{\mathbf{G}}[l,j]|,$$

for $s=\lceil pK-p+1\rceil\le pK+2$. Also,

$$\mathbb{E}|\mathbf{G}_i[l,j]|^m\le 2^{-m/2}m!\times p^2=\frac{1}{2}\times p^2\times m!\times(\frac{1}{\sqrt{2}})^{m-2}.$$

Thus

$$\begin{aligned}\mathbb{P}\left\{\left|\left|\left|\bar{\mathbf{G}}[-j,j]\right|\right|\right|_s^*>p\epsilon\right\}&\le\mathbb{P}\left\{\sqrt{s}\max_{l\neq j}|\bar{\mathbf{G}}[l,j]|>p\epsilon\right\}\\&\le 2K\exp(-p\frac{N(\epsilon^2)}{2ps+\sqrt{2s}})\\&\le 2K\exp\left(-p\frac{N\epsilon^2}{p(pK+2)+\sqrt{2(pK+2)}}\right),\end{aligned}$$

for $\epsilon \le 1$. ■

Lemma 5 *(Uniform concentration of $\bar{\mathbf{t}}[j](\mathbf{w})$) For $i \in [\![N]\!]$, let $\mathbf{t}_i$ be the function from $\mathbb{R}^K$ to $\mathbb{R}^K$ defined as in (24) and $\bar{\mathbf{t}} = (1/N)\sum_{i=1}^N \mathbf{t}_i$. Recall that for $j \in [\![K]\!]$, $s \in [\![K-1]\!]$ and $p \in (0,1)$,*

$$\mathcal{E}_j(s) = \{\mathbf{w} \in \mathbb{R}^K, |||\mathbf{w}[-j]|||_s = 1, \mathbf{w}[j] = 0\},$$

$$\mathcal{F}_j(p) = \{\mathbf{w} \in \mathbb{R}^K, |||\mathbf{w}[-j]|||_p = 1, \mathbf{w}[j] = 0\}.$$

1. *Under the s-sparse Gaussian model with $s \in [\![K-1]\!]$,*

$$\mathbb{P}\left\{\sup_{w\in\mathcal{E}_j(s)}\left|\bar{\mathbf{t}}[j](\mathbf{w}) - \sqrt{\frac{2}{\pi}}\frac{s}{K}\frac{K-s}{K-1}\right| > \frac{s}{K}\epsilon\right\} \le 3\left(\frac{8K}{\epsilon s}+1\right)^K \exp\left(-\frac{s}{K}\frac{N\epsilon^2}{40}\right),$$

   for $0 < \epsilon \le \frac{1}{2}$.

2. *Under the Bernoulli-Gaussian model with parameter $p \in (0,1)$,*

$$\mathbb{P}\left\{\sup_{w\in\mathcal{F}_j(p)}\left|\bar{\mathbf{t}}[j](\mathbf{w}) - \sqrt{\frac{2}{\pi}}p(1-p)\right| > p\epsilon\right\} \le 3\left(\frac{8}{\epsilon p}+1\right)^K \exp\left(-p\frac{N\epsilon^2}{40}\right),$$

   for $0 < \epsilon \le \frac{1}{2}$.

Proof (1) Under the s-sparse model, we have

$$\begin{aligned}\mathbb{E}|\mathbf{t}_i[j](\mathbf{w})|^m &= \mathbb{E}\left(\sum_{|S|=s, j\notin S}|\mathbf{w}[S]^T\mathbf{z}_i[S]|\chi_i(S)\right)^m \\ &= \sum_{|S|=s,j\notin S}\mathbb{E}|\mathbf{w}[S]^T\mathbf{z}_i[S]|^m\mathbb{E}\chi_i(S) \\ &= \binom{K}{s}^{-1}\sum_{|S|=s,j\notin S}\mathbb{E}|\mathbf{w}[S]^T\mathbf{z}_i[S]|^m.\end{aligned}$$

Notice that we have used the facts that the events $\chi_i(S)$'s are mutually exclusive and that $\mathbf{z}_i[S]$ and $\chi_i(S)$ are independent. Since the random variable $\mathbf{w}[S]^T\mathbf{z}_i[S]$ has distribution $N(0, \|\mathbf{w}[S]\|_2)$, $\mathbb{E}|\mathbf{w}[S]^T\mathbf{z}_i[S]|^m = \|\mathbf{w}[S]\|_2^m\mathbb{E}|Z|^m \le 2^{-\frac{m}{2}}m!$. Therefore

$$\mathbb{E}|\mathbf{t}_i[j](\mathbf{w})|^m \le 2^{-\frac{m}{2}}m!\binom{K}{s}^{-1}\sum_{j\notin S,|S|=s}\|\mathbf{w}[S]\|_2^m.$$

Note that by Lemma 7, $|||\mathbf{w}[-j]|||_s \ge \|\mathbf{w}[-j]\|_2 \ge \|\mathbf{w}[S]\|_2$ for all S such that $j \notin S$. For $\mathbf{w} \in \mathcal{E}_j(s)$, $|||\mathbf{w}|||_s = 1$ and so $\|\mathbf{w}_S\|_2 \le 1$, which, further implies that $\|\mathbf{w}[S]\|_2^m \le \|\mathbf{w}[S]\|_2$.

Thus we have

$$\begin{aligned}\mathbb{E}|\mathbf{t}_i[j](\mathbf{w})|^m &\le 2^{-\frac{m}{2}}m!\binom{K}{s}^{-1}\sum_{j\notin S,|S|=s}\|\mathbf{w}[S]\|_2 \\ &\le 2^{-\frac{m}{2}}m!\frac{s(K-s)}{K(K-1)}|||\mathbf{w}[-j]|||_s \\ &= 2^{-\frac{m}{2}}m!\frac{s(K-s)}{K(K-1)}\end{aligned}$$

For a fixed j, define

$$U_i(\mathbf{w}) = \mathbf{t}_i[j](\mathbf{w}) - \sqrt{\frac{2}{\pi}}\frac{s}{K}\frac{K-s}{K-1}.$$

Notice that $\mathbb{E}U_i(\mathbf{w}) = 0$. In addition,

$$\mathbb{E}|U_i(\mathbf{w})|^m \le 2^m\mathbb{E}|\mathbf{t}_i[j](\mathbf{w})|^m \le \frac{1}{2}\times 4\frac{s}{K}\frac{K-s}{K-1}\times m!\times(\sqrt{2})^{m-2}.$$

By Bernstein's inequality

$$\mathbb{P}\left\{\frac{1}{N}\left|\sum_{i=1}^N U_i(\mathbf{w})\right| > \frac{s}{K}\epsilon\right\} \le 2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{2(4\frac{K-s}{K-1}+\sqrt{2}\epsilon)}\right) \le 2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{10}\right),$$

for $0 < \epsilon \le 1/2$. Now let $\{\mathbf{w}_i\}$ be an δ-cover of $\mathcal{E}_j(s)$. Since $\mathcal{E}_j(s)$ is contained in the unit ball $\{\mathbf{w} \in \mathbb{R}^{K-1} : \|\mathbf{w}\|_2 \le 1\}$, there exists a cover such that $|\{\mathbf{w}_l\}| \le \left(\frac{2}{\delta}+1\right)^{K-1}$. For any $\mathbf{w}, \mathbf{w}' \in \mathcal{E}_j(s)$, we have

$$\left|U_i(\mathbf{w}) - U_i(\mathbf{w}')\right| \le \sum_{j\notin S,|S|=s}\left|(\mathbf{w}[S]-\mathbf{w}'[S])^T\mathbf{z}_i[S]\right|\chi_i(S).$$

Let Z be a standard Gaussian variable. We have

$$\begin{aligned}\mathbb{P}\left\{\sum_{|S|=s,j\notin S}\left|\mathbf{w}[S]^T\mathbf{z}_i[S]\right|\chi_i(S) > \epsilon\right\} &= \binom{K-1}{s}^{-1}\sum_{|S|=s,j\notin S}\mathbb{P}\left\{\left|\mathbf{w}[S]^T\mathbf{z}_i[S]\right| > \epsilon\right\} \\ &= \binom{K-1}{s}^{-1}\sum_{|S|=s,j\notin S}\mathbb{P}\left\{\|\mathbf{w}[S]\|_2|Z| > \epsilon\right\} \\ &\le \mathbb{P}\left\{\|\mathbf{w}\|_2|Z| > \epsilon\right\}.\end{aligned}$$

Let Z_i, $i = 1, \ldots, N$, be *i.i.d.* standard Gaussian variables. By the one-sided Bernstein's inequality,

$$\mathbb{P}\left\{\frac{1}{N}\sum_{i=1}^N|Z_i| \ge 2\right\} \le \exp\left(-\frac{N(2-\sqrt{2/\pi})^2}{2(4+\sqrt{2}(2-\sqrt{2/\pi}))}\right) \le \exp\left(-\frac{N}{8}\right).$$

Now let $\delta = \frac{s}{K}\frac{\epsilon}{4}$. Thus

$$\begin{aligned}\mathbb{P}\left\{\sup_{\|\mathbf{w}-\mathbf{w}'\|_2\le\delta}\left|\frac{1}{N}\sum_{i=1}^{N}(U_i(\mathbf{w})-U_i(\mathbf{w}'))\right|>\frac{s}{K}\frac{\epsilon}{2}\right\} &\le \mathbb{P}\left\{\sup_{\|\mathbf{w}'-\mathbf{w}\|_2\le\delta}\frac{1}{N}\sum_{i=1}^{N}\left|U_i(\mathbf{w})-U_i(\mathbf{w}')\right|>\frac{s}{K}\frac{\epsilon}{2}\right\}\\ &\le \mathbb{P}\left\{\sup_{\|\mathbf{w}'-\mathbf{w}\|_2\le\delta}\frac{1}{N}\sum_{i=1}^{N}\|\mathbf{w}-\mathbf{w}'\|_2|Z_i|>\frac{s}{K}\frac{\epsilon}{2}\right\}\\ &\le \mathbb{P}\left\{\delta\frac{1}{N}\sum_{i=1}^{N}|Z_i|>\frac{s}{K}\frac{\epsilon}{2}\right\}\le\mathbb{P}\left\{\frac{1}{N}\sum_{i=1}^{N}|Z_i|>2\right\}\\ &\le \exp\left(-\frac{N}{8}\right).\end{aligned}$$

By triangle inequality

$$\sup_{\|\mathbf{w}'-\mathbf{w}\|_2\le\delta}\left|\frac{1}{N}\sum_{i=1}^{N}U_i(\mathbf{w}')\right|\le\sup_{\|\mathbf{w}'-\mathbf{w}\|_2\le\delta}\left|\frac{1}{N}\sum_{i=1}^{N}(U_i(\mathbf{w})-U_i(\mathbf{w}'))\right|+\left|\frac{1}{N}\sum_{i=1}^{N}U_i(\mathbf{w})\right|.$$

Using a union bound, we have

$$\begin{aligned}\mathbb{P}\{\sup_{\|\mathbf{w}'-\mathbf{w}\|_2\le\delta}\left|\frac{1}{N}\sum_{i=1}^{N}U_i(\mathbf{w}')\right|>\frac{s}{K}\epsilon\} &\le \mathbb{P}\left\{\sup_{\|\mathbf{w}-\mathbf{w}'\|_2\le\delta}\left|\frac{1}{N}\sum_{i=1}^{N}(U_i(\mathbf{w})-U_i(\mathbf{w}'))\right|>\frac{s}{K}\frac{\epsilon}{2}\right\}\\ &\quad+\mathbb{P}\left\{\left|\frac{1}{N}\sum_{i=1}^{N}U_i(\mathbf{w})\right|>\frac{s}{K}\frac{\epsilon}{2}\right\}\\ &\le \exp\left(-\frac{N}{8}\right)+2\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{40}\right)\\ &\le 3\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{40}\right),\end{aligned}$$

for $0<\epsilon\le 1$. Now apply union bound again,

$$\begin{aligned}\mathbb{P}\left\{\sup_{\mathbf{w}\in\mathcal{E}_j(s)}\frac{1}{N}\left|\sum_{i=1}^{N}U_i(\mathbf{w})\right|>\frac{s}{K}\epsilon\right\} &\le \mathbb{P}\left\{\max_{l}\sup_{||\mathbf{w}-\mathbf{w}_l||_2\le\delta}\frac{1}{N}\left|\sum_{i=1}^{N}U_i(\mathbf{w})\right|>\frac{s}{K}\epsilon\right\}\\ &\le 3\left(\frac{8K}{\epsilon s}+1\right)^{K}\exp\left(-\frac{s}{K}\frac{N\epsilon^2}{40}\right).\end{aligned}$$

(2) For $\mathbf{w}\in\mathcal{F}_j(p)$, under the Bernoulli-Gaussian model,

$$\begin{aligned}\mathbb{E}\left|\mathbf{t}_i[j](\mathbf{w})\right|^m &= \mathbb{E}|Z|^m\sum_{k=1}^{K-1}\sum_{|S|=k,j\notin S}\|\mathbf{w}[S]\|_2^m\times p^k(1-p)^{K-k}\\ &\le \mathbb{E}|Z|^m p\sum_{k=1}^{K-1}\sum_{|S|=k,j\notin S}\|\mathbf{w}[S]\|_2\times p^{k-1}(1-p)^{K-k}\\ &= \mathbb{E}|Z|^m p(1-p)\sum_{k=0}^{K-2}\sum_{|S|=k+1,j\notin S}\|\mathbf{w}[S]\|_2\times p^k(1-p)^{K-2-k}\\ &= \mathbb{E}|Z|^m p(1-p)|||\mathbf{w}[-j]|||_p=\mathbb{E}|Z|^m p(1-p)\\ &\le 2^{-m/2}m!p(1-p).\end{aligned}$$

Notice that we have used the fact that $\|\mathbf{w}[S]\|_2\le\|\mathbf{w}[-j]\|_2\le|||\mathbf{w}[-j]|||_p=1$ for all S such that $j\notin S$. For each fixed $\mathbf{w}$, define

$$V_i(\mathbf{w})=\mathbf{t}_i[j](\mathbf{w})-\sqrt{\frac{2}{\pi}}(1-p)p.$$

Now we have

$$\mathbb{E}|V_i(\mathbf{w})|^m\le 2^m\mathbb{E}|\mathbf{t}_i[j](\mathbf{w})|^m\le\frac{1}{2}\times 4p(1-p)\times m!\times(\sqrt{2})^{m-2}.$$

The remaining parts of the proof can be proceeded exactly as in the case of the s-sparse model, noticing that we only need to replace $\frac{s}{K}$ by p, and $\frac{K-s}{K-1}$ by $1-p$.

■

A.4 Dual Analysis of $|||.|||_s$ and $|||.|||_p$

In this section, we will characterize the dual norms $|||.|||_s^*$ and $|||.|||_p^*$ by second order cone programs (SOCP). The characterization is helpful for deriving bounds for these special norms in the next section.

Lemma 6 *For $i\in[\![M]\!]$, let $\mathbf{A}_i$ be an $k_i\times K$ with rank k_i. For $\mathbf{z}\in\mathbb{R}^K$, define*

$$\|\mathbf{z}\|_{\mathbf{A}}=\sum_{i=1}^{M}\|\mathbf{A}_i\mathbf{z}\|_2.$$

Then the dual norm of $\|.\|_{\mathbf{A}}$ is

$$\|\mathbf{v}\|_{\mathbf{A}}^*=\inf\left\{\max_i\|\mathbf{y}_i\|_2,\mathbf{y}_i\in\mathbb{R}^{k_i},\sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{y}_i=\mathbf{v}\right\}.$$

Proof

$$\|\mathbf{v}\|_{\mathbf{A}}^* = \sup_{\mathbf{z}\neq 0} \frac{\mathbf{v}^T\mathbf{z}}{\|\mathbf{z}\|_{\mathbf{A}}} = \sup\left\{\mathbf{v}^T\mathbf{z} : \|\mathbf{z}\|_{\mathbf{A}} \leq 1\right\}.$$

Introducing Lagrange multiplier $\lambda \geq 0$ for the inequality constraint, the above problem is equivalent to the following

$$\begin{aligned}\|\mathbf{v}\|_{\mathbf{A}}^* &= \sup_{\mathbf{z}}\left\{\inf_{\lambda\geq 0}\left\{\mathbf{v}^T\mathbf{z} + \lambda(1 - \|\mathbf{z}\|_{\mathbf{A}})\right\}\right\} \\ &= \sup_{\mathbf{z}}\left\{\inf_{\lambda\geq 0}\left\{\mathbf{v}^T\mathbf{z} + \lambda(1 - \sum_{i=1}^{M}\|\mathbf{A}_i\mathbf{z}\|_2)\right\}\right\}.\end{aligned}$$

The dual problem is

$$d = \inf_{\lambda\geq 0}\left\{\sup_{\mathbf{z}}\left\{\mathbf{v}^T\mathbf{z} + \lambda(1 - \sum_{i=1}^{M}\|\mathbf{A}_i\mathbf{z}\|_2)\right\}\right\}.$$

Notice that $\|\mathbf{A}_i\mathbf{z}\|_2 = \sup\{\mathbf{z}^T\mathbf{A}_i^T\mathbf{u}_i : \|\mathbf{u}_i\|_2 \leq 1\}$. Hence

$$d = \inf_{\lambda\geq 0}\left\{\lambda + \sup_{\mathbf{z},\mathbf{u}}\left\{\mathbf{z}^T(\mathbf{v} - \lambda\sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{u}_i) : \|\mathbf{u}_i\|_2 \leq 1\right\}\right\}.$$

Since the vector $\mathbf{z}$ can be arbitrary, in order to have a finite value, we must have $\lambda\sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{u}_i = \mathbf{v}$. Now let $\mathbf{y}_i = \lambda\mathbf{u}_i$, the problem becomes

$$d = \inf_{\lambda\geq 0}\left\{\lambda : \sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{y}_i = \mathbf{v}, \|\mathbf{y}_i\|_2 \leq \lambda\right\}.$$

The above problem is exactly equivalent to

$$\inf\left\{\max_i \|\mathbf{y}_i\|_2, \mathbf{y}_i \in \mathbb{R}^{k_i}, \sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{y}_i = \mathbf{v}\right\}.$$

Finally, notice that the original problem is convex and strictly feasible. Thus Slater's condition holds and the duality gap is zero. Hence

$$||\mathbf{v}||_{\mathbf{A}}^* = \inf\left\{\max_i \|\mathbf{y}_i\|_2, \mathbf{y}_i \in \mathbb{R}^{k_i}, \sum_{i=1}^{M}\mathbf{A}_i^T\mathbf{y}_i = \mathbf{v}\right\}.$$

■

The following corollary gives an alternative characterization of $|||.|||_s$ and $|||.|||_p$:

Corollary 5 *Denote by $\mathbf{y}_S \in \mathbb{R}^{|S|}$ a variable vector indexed by the set S (as opposed to being a sub-vector of $\mathbf{y}$). For $\mathbf{z} \in \mathbb{R}^m$, we have*

$$|||\mathbf{z}|||_s^* = \inf\left\{\max_{|S|=s}\|\mathbf{y}_S\|_2 : \mathbf{y}_S \in \mathbb{R}^s, \sum_{|S|=s}\mathbf{E}_S^T\mathbf{y}_S = \mathbf{z}\right\},$$

and

$$|||\mathbf{z}|||_p^* = \inf\left\{\max_S \|\mathbf{y}_S\|_2 : \mathbf{y}_S \in \mathbb{R}^{|S|}, \sum_{k=0}^{m-1}\texttt{pbinom}(k; m-1, p)\sum_{|S|=k+1}\mathbf{E}_S^T\mathbf{y}_S = \mathbf{z}\right\},$$

where $\mathbf{E}_S = \mathbf{I}[S,]/\binom{m-1}{|S|-1}$ and $\mathbf{I} \in \mathbb{R}^{m\times m}$ is the identity matrix.

Proof This is simply a direct application of Lemma 6. ■

Corollary 6 *The dual norms $|||.|||_s^*$ and $|||.|||_p^*$ can be computed via a Second Order Cone Program (SOCP).*

Proof Introducing additional variable $t \geq 0$, the problem of computing $|||\mathbf{z}|||_s^*$ is equivalent to the following formulation

$$\begin{aligned}\inf_{t,\mathbf{y}_S} \quad & t \;\; s.t. \;\; \|\mathbf{y}_S\|_2 \leq t \text{ for all } S \text{ such that } |S| = s \\ & \text{and } \sum_{|S|=s}\mathbf{E}_S^T\mathbf{y}_S = \mathbf{z}.\end{aligned}$$

Notice that the above program is already in the standard form of SOCP. The case of $|||.|||_p^*$ can be handled in a similar manner. ■

A.5 Inequalities of $|||.|||_s$ and $|||.|||_p$ and Their Duals

As demonstrated in the last section, it is in general expensive to compute $|||.|||_s^*$ and $|||.|||_p^*$. In this section, we will derive sharp and easy-to-compute lower and upper bounds to approximate these quantities.

Lemma 7 *(Monotonicity of $|||\mathbf{z}|||_s$ and $|||\mathbf{z}|||_p$) Let $\mathbf{z} \in \mathbb{R}^m$. $|||\mathbf{z}|||_1 = \|\mathbf{z}\|_1$ and $|||\mathbf{z}|||_m = \|\mathbf{z}\|_2$. For $1 \leq l < k \leq m$, we have $|||\mathbf{z}|||_l \geq |||\mathbf{z}|||_k$; similarly for $0 < p < q < 1$, $|||\mathbf{z}|||_p \geq |||\mathbf{z}|||_q$. Furthermore, the equalities hold iff the vector $\mathbf{z}$ contains at most one non-zero entry.*

Proof By definition, we have

$$|||\mathbf{w}|||_1 = \frac{\sum_{|S|=1}\|\mathbf{w}[S]\|_2}{\binom{m-1}{1-1}} = \|\mathbf{w}\|_1.$$

Similarly,

$$\|\mathbf{w}\|_m = \frac{\sum_{|S|=m} \|\mathbf{w}[S]\|_2}{\binom{m-1}{m-1}} = \|\mathbf{w}\|_2.$$

For $1 \le k \le m-1$, let S' be a subset of $[\![m]\!]$ such that $|S'| = k+1$. By triangle inequality

$$\sum_{|S|=k, S\subset S'} \|\mathbf{z}[S]\|_2 \ge k\|\mathbf{z}[S']\|_2,$$

where the equality holds iff $\|\mathbf{z}[S']\|_0 \le 1$. Thus

$$\sum_{|S'|=k+1} \sum_{|S|=k, S\subset S'} \|\mathbf{z}[S]\|_2 \ge k \sum_{|S'|=k+1} \|\mathbf{z}[S']\|_2,$$

and the equality holds iff $\|\mathbf{z}\|_0 \le 1$. Notice that the LHS of the above inequality is simply $(m-k)\sum_{|S|=k} \|\mathbf{z}[S]\|_2$. Therefore

$$\|\mathbf{z}\|_k = \binom{m-1}{k-1}^{-1} \sum_{|S|=k} \|\mathbf{z}[S]\|_2 \ge \binom{m-1}{k}^{-1} \sum_{|S|=k+1} \|\mathbf{z}[S]\|_2 = \|\mathbf{z}\|_{k+1},$$

and so the inequality holds.

For $\|.\|_p$, let Y be a random variable that follows the binomial distribution with parameters $m-1$ and p. Observe that $\|\mathbf{z}\|_p = \mathbb{E}\|\mathbf{z}\|_{Y+1}$, where the expectation is taken with respect to Y. If $\|\mathbf{z}\|_0 > 1$, $\|\mathbf{z}\|_k$ is strictly decreasing in k by the first part. Hence, $\|\mathbf{z}\|_p$ as a function of p is also strictly decreasing on $(0,1)$. Indeed, it can be shown that

$$\frac{d}{dp}\|\mathbf{z}\|_p = \sum_{k=0}^{m-1} \texttt{pbinom}(k; K-1, p)\left(\|\mathbf{z}\|_{k+1} - \|\mathbf{z}\|_k\right) < 0.$$

If $\|\mathbf{z}\|_0 \le 1$, then $\|\mathbf{z}\|_1 = \|\mathbf{z}\|_m$ and so $\frac{d}{dp}\|\mathbf{z}\|_p = 0$. Therefore $\|\mathbf{z}\|_p = \|\mathbf{z}\|_1$ is a constant in p. On the other hand, if $\|\mathbf{z}\|_p = \|\mathbf{z}\|_q$ for $0 < p < q < 1$, by the fact that $\frac{d}{dp}\|\mathbf{z}\|_p \le 0$, we must have $\frac{d}{dp}\|\mathbf{z}\|_p = 0$ and so $\|\mathbf{z}\|_{k-1} = \|\mathbf{z}\|_k$ for all $k \in [\![m]\!]$. Thus $\|\mathbf{z}\|_0 \le 1$. ■

Corollary 7 *(Monotonicity of $\|\mathbf{z}\|_s^*$ and $\|\mathbf{z}\|_p^*$) Let $\mathbf{z} \in \mathbb{R}^m$. $\|\mathbf{z}\|_1^* = \|\mathbf{z}\|_\infty$ and $\|\mathbf{z}\|_m^* = \|\mathbf{z}\|_2$. For $1 \le i < j \le m$, we have $\|\mathbf{z}\|_i^* \le \|\mathbf{z}\|_j^*$; similarly for $0 < p < q < 1$, $\|\mathbf{z}\|_p^* \le \|\mathbf{z}\|_q^*$. Furthermore, the equalities hold iff the vector $\mathbf{z}$ contains at most one non-zero entry.*

Proof This is a direct consequence of Lemma 7 and the dual norm definition $\|\mathbf{z}\|^* = \sup_{\mathbf{y}\neq 0} \frac{\mathbf{z}^T\mathbf{y}}{\|\mathbf{y}\|}$. ■

Lemma 8 *Let $p \in (0,1)$ and $k = \lceil (m-1)p + 1 \rceil$. For any $\mathbf{z} \in \mathbb{R}^m$, we have*

1. $\|\mathbf{z}\|_p \ge \|\mathbf{z}\|_k$.

2. $\|\mathbf{z}\|_p^* \le \|\mathbf{z}\|_k^*$.

Proof Define the function f with domain on $[1, m]$ as follows: let $f(1) = \|\mathbf{z}\|_1 = \|\mathbf{z}\|_1$; for $i \in [\![m-1]\!]$ and $a \in (i, i+1]$, define

$$f(a) = \|\mathbf{z}\|_i + (\|\mathbf{z}\|_{i+1} - \|\mathbf{z}\|_i)(a - i).$$

It is clear that f is piecewise linear by construction. In addition, by Lemma 12, f is also convex. Notice that $\|\mathbf{z}\|_p = \mathbb{E}\|\mathbf{z}\|_{Y+1} = \mathbb{E}f(Y+1)$, where Y is a random variable from the binomial distribution with parameters $m-1$ and p. By Jensen's inequality,

$$\mathbb{E}f(Y+1) \ge f(\mathbb{E}Y + 1) = f((m-1)p + 1).$$

Thus by Lemma 7, $\|\mathbf{z}\|_p \ge \|\mathbf{z}\|_k$ for all $k \ge (m-1)p + 1$. So the first part follows.

To upperbound $\|\mathbf{z}\|_p^*$, notice that if $k \ge (m-1)p + 1$,

$$\|\mathbf{z}\|_p^* = \sup_{\mathbf{w}\neq 0} \frac{\mathbf{w}^T\mathbf{z}}{\|\mathbf{w}\|_p} \le \sup_{\mathbf{w}\neq 0} \frac{\mathbf{w}^T\mathbf{z}}{\|\mathbf{w}\|_k} = \|\mathbf{z}\|_k^*.$$

■

For the following lemmas, the quantities $\tau_m(d,a)$ and $L_m(d,k)$ are defined as in Definition 3.

Lemma 9 *(Approximating $\tau_m(d,a)$) For $d \in [\![m]\!]$ and $a \in (0, m]$,*

$$\tau_m(d,a) \le \sqrt{\frac{da}{m}}.$$

Proof For $k \in [\![m]\!]$, by Jensen's inequality,

$$\mathbb{E}\sqrt{L_m(d,k)} \le \sqrt{\mathbb{E}L_m(d,k)} = \sqrt{\frac{dk}{m}}.$$

Note that the last equality follows from the expectation of a hypergeometric random variable. Now suppose $a \in (k-1, k]$. By the above inequality and apply Jensen's inequality one more time, we have

$$\begin{aligned}\tau_m(d,a) &= (k-a)\mathbb{E}\sqrt{L_m(d,k-1)} + (1-(k-a))\mathbb{E}\sqrt{L_m(d,k)} \\ &\le (k-a)\sqrt{\frac{d(k-1)}{m}} + (1-(k-a))\sqrt{\frac{dk}{m}} = \sqrt{\frac{da}{m}}.\end{aligned}$$

■

Lemma 10 *(Lower bounds for $\|\mathbf{z}\|_s^*$ and $\|\mathbf{z}\|_p^*$) Let $\mathbf{z} \in \mathbb{R}^m$. We have*

1. For $s \in [\![m]\!]$,

$$|||\mathbf{z}|||_s^* \geq \frac{s}{m} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(|T|, s)} \geq \max\left(\|\mathbf{z}\|_\infty, \sqrt{\frac{s}{m}} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}} \right).$$

2. For $p \in (0, 1)$,

$$\begin{aligned} |||\mathbf{z}|||_p^* &\geq p \max_{T \subset [\![m]\!]} \left\{ \Big(\sum_{k=0}^{m} \mathtt{pbinom}(k, m, p) \tau_m(|T|, k) \Big)^{-1} \|\mathbf{z}[T]\|_1 \right\} \\ &\geq p \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(|T|, pm)} = \max\left(\|\mathbf{z}\|_\infty, \sqrt{p} \max_{T \subset [\![m]\!]} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{|T|}} \right). \end{aligned}$$

Proof (1) Note that by definition,

$$|||\mathbf{z}|||_s^* = \sup_{\mathbf{w}} \frac{\mathbf{z}^T \mathbf{w}}{|||\mathbf{w}|||_s}$$

Let $d \in [\![m]\!]$ and $T \subset [\![m]\!]$ such that $|T| = d$. Define $\mathbf{w} \in \mathbb{R}^m$ such that $\mathbf{w}[i] = 1$ for $i \in T$ and $\mathbf{w}[i] = 0$ for $i \in T^c$. We have:

$$\begin{aligned} |||\mathbf{w}|||_s &= \binom{m-1}{s-1}^{-1} \sum_{|S|=s} \|\mathbf{w}[S]\|_2 = \binom{m-1}{s-1}^{-1} \sum_{l=\max(0,s+d-m)}^{\min(s,d)} \sum_{|S|=s, |S\cap T|=l} \|\mathbf{w}[S]\|_2 \\ &= \binom{m-1}{s-1}^{-1} \sum_{l=\max(0,s+d-m)}^{\min(s,d)} \sum_{|S|=s, |S\cap T|=l} \sqrt{l} \\ &= \binom{m-1}{s-1}^{-1} \sum_{l=\max(0,s+d-m)}^{\min(s,d)} \binom{d}{l} \binom{m-d}{s-l} \sqrt{l} \\ &= \frac{m}{s} \mathbb{E} \sqrt{L_m(d, s)} = \frac{m}{s} \tau_m(d, s). \end{aligned}$$

Thus for all $d \in [\![m]\!]$ and any subset T such that $|T| = d$, we have shown

$$|||\mathbf{z}|||_s^* \geq \frac{s}{m} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(d, s)}.$$

Note that if $d = 1$, $\mathbb{E}\sqrt{L_m(d, s)} = \frac{s}{m}$. Therefore

$$\frac{s}{m} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(d, s)} \geq \|\mathbf{z}\|_\infty,$$

Moreover, by Lemma 9,

$$\tau_m(d, s) \leq \sqrt{\frac{ds}{m}}.$$

Hence we have

$$\frac{s}{m} \frac{\|\mathbf{z}[T]\|_1}{\tau_m(d, s)} \geq \sqrt{\frac{s}{m}} \frac{\|\mathbf{z}[T]\|_1}{\sqrt{d}},$$

and the first part of the claim follows.
(2) For the same $\mathbf{w} \in \mathbb{R}^m$ defined previously,

$$\begin{aligned} |||\mathbf{w}|||_p &= \sum_{k=0}^{m-1} \mathtt{pbinom}(k, m-1, p) |||\mathbf{w}|||_{k+1} \\ &= m \sum_{k=0}^{m-1} \mathtt{pbinom}(k, m-1, p) \frac{\tau_m(d, k+1)}{k+1} \\ &= m \sum_{k=0}^{m-1} \binom{m-1}{k} p^k (1-p)^{m-k-1} \frac{1}{k+1} \tau_m(d, k+1) \\ &= \frac{1}{p} \sum_{k=0}^{m-1} \binom{m}{k+1} p^{k+1} (1-p)^{m-(k+1)} \tau_m(d, k+1) \\ &= \frac{1}{p} \sum_{k=0}^{m} \binom{m}{k} p^k (1-p)^{m-k} \tau_m(d, k). \end{aligned}$$

Thus for all $d \in [\![m]\!]$ and any subset T such that $|T| = d$, we have shown

$$|||\mathbf{z}|||_p^* \geq p \Big(\sum_{k=0}^{m} \mathtt{pbinom}(k, m, p) \tau_m(d, k) \Big)^{-1} \|\mathbf{z}[T]\|_1.$$

Next, we will show

$$\sum_{k=0}^{m} \mathtt{pbinom}(k, m, p) \tau_m(d, k) \leq \tau_m(d, pm).$$

To this end, let us first notice that the LHS quantity is a binomial average of $\tau_m(d, k)$ with respect to k. By construction, $\tau_m(d, .)$ is piecewise linear. Furthermore, $\tau_m(d, .)$ is also concave by Lemma 13. Now let Y be a random variable having the binomial distribution with parameters m and p. By Jensen's inequality,

$$\sum_{k=0}^{m} \mathtt{pbinom}(k, m, p) \tau_m(d, k) = \mathbb{E} \tau_m(d, Y) \leq \tau_m(d, \mathbb{E}Y) = \tau_m(d, mp).$$

In particular, if $d = 1$, it is easy to see that $\tau_m(d, mp) = p$. So

$$p \left(\max_{T \subset [\![m]\!], |T|=1} \Big(\sum_{k=0}^{m} \mathtt{pbinom}(k, m, p) \tau_m(|T|, k) \Big)^{-1} \|\mathbf{z}[T]\|_1 \right) \geq \|\mathbf{z}\|_\infty.$$

On the other hand, by Lemma 9,

$$\tau_m(d, pm) \leq \sqrt{\frac{d}{m}} \sqrt{pm} = \sqrt{pd}.$$

Therefore

$$p\Big(\sum_{k=0}^{m}\texttt{pbinom}(k,m,p)\tau_m(d,k)\Big)^{-1}\|\mathbf{z}[T]\|_1 \geq \sqrt{p}\frac{\|\mathbf{z}[T]\|_1}{\sqrt{d}},$$

and the proof is complete. ■

Lemma 11 *(Upper bounds for $\|\mathbf{z}\|_s^*$ and $\|\mathbf{z}\|_p^*$) Let $\mathbf{z}\in\mathbb{R}^m$.*

1. *For $s\in[\![m]\!]$,*
$$\|\mathbf{z}\|_s^* \leq \max_{|S|=s}\|\mathbf{z}[S]\|_2.$$
2. *For $p\in(0,1)$,*
$$\|\mathbf{z}\|_p^* \leq \max_{|S|=k}\|\mathbf{z}[S]\|_2,$$
where $k=\lceil p(m-1)+1\rceil$.

Proof To establish the upper bound, we will use the equivalent formulation of $\|\|.\|\|_s^*$ in Corollary 5. For $S\subset[\![m]\!]$ of size s, as in Corollary 5, let $\mathbf{E}_S=\mathbf{I}[S,]/\binom{m-1}{s-1}$ where $\mathbf{I}\in\mathbb{R}^{m\times m}$ is the identity matrix. If we set $\mathbf{y}_S=\mathbf{z}[S]$, then $\sum_{|S|=s}\mathbf{E}_S^T\mathbf{y}_S=\mathbf{z}$ and so $\{\mathbf{y}_S\}$ is feasible. Therefore

$$\|\mathbf{z}\|_s^* \leq \max_{|S|=s}\|\mathbf{z}[S]\|_2.$$

The upperbound of $\|\mathbf{z}\|_p^*$ follows from the inequality $\|\mathbf{z}\|_p^*\leq\|\mathbf{z}\|_k^*$ for $k=\lceil p(m-1)+1\rceil$ by the second part of Lemma 8. ■

Corollary 8 *(1-sparse vectors) Let $\mathbf{z}=(z,0,\ldots,0)^T\in\mathbb{R}^m$. We have*

$$\|\mathbf{z}\|_s^*=\|\mathbf{z}\|_p^*=|z|.$$

Proof These are direct consequences of Lemma 10 and Lemma 11. ■

Corollary 9 *(All-constant vectors) Let $\mathbf{z}\in\mathbb{R}^m$ be such that $\mathbf{z}[i]=z$ for all $i\in[\![m]\!]$. We have*

1. $\|\mathbf{z}\|_s^*=\sqrt{s}|z|$.
2. $\|\mathbf{z}\|_p^*=mp\Big/\Big(\sum_{k=0}^m\texttt{pbinom}(k,m,p)\sqrt{k}\Big)|z|$.

Proof First of all, note that $L_m(m,k)=k$ and $\mathbb{E}\sqrt{L_m(m,k)}=\sqrt{k}$. Thus by Lemma 10 and 11, we have

$$\|\mathbf{z}\|_s^*=\sqrt{s}|z|.$$

So the first part of the claim is verified. Next, by Lemma 10,

$$\|\mathbf{z}\|_p^*\geq mp\Big(\sum_{k=0}^m\texttt{pbinom}(k,m,p)\sqrt{k}\Big)^{-1}|z|.$$

On the other hand, for S such that $|S|=s$, we can define

$$\mathbf{y}_S=\frac{mp}{\sqrt{s}}\Big(\sum_{k=0}^m\texttt{pbinom}(k,m,p)\sqrt{k}\Big)^{-1}(z,\ldots,z)^T\in\mathbb{R}^s,$$

For notation simplicity, let $c=\frac{1}{mp}\Big(\sum_{k=0}^m\texttt{pbinom}(k,m,p)\sqrt{k}\Big)$. As in Corollary 5, for $S\subset[\![m]\!]$, let $\mathbf{E}_S=\mathbf{I}[S,]/\binom{m-1}{|S|-1}$. For $i\in[\![m]\!]$, we have

$$\begin{aligned}\sum_{k=0}^{m-1}\texttt{pbinom}(k;m-1,p)\sum_{|S|=k+1}(\mathbf{E}_S^T\mathbf{y}_S)[i] &= c^{-1}\sum_{k=0}^{m-1}\texttt{pbinom}(k;m-1,p)\frac{1}{\sqrt{k+1}}\\ &= c^{-1}\frac{z}{mp}\sum_{k=0}^{m}\texttt{pbinom}(k;m,p)\sqrt{k}=z.\end{aligned}$$

Thus by Corollary 5,

$$\|\mathbf{z}\|_p^*\leq\max_S\|\mathbf{y}_S\|_2=mp\Big(\sum_{k=0}^m\texttt{pbinom}(k,m,p)\sqrt{k}\Big)^{-1}|z|,$$

and the proof is complete. ■

Lemma 12 *(Convexity of $\|\|\mathbf{z}\|\|_k$) Let $\mathbf{z}\in\mathbb{R}^m$, where $m\geq3$. For $k\in[\![m-2]\!]$, we have the following inequality*

$$\|\mathbf{z}\|_k+\|\mathbf{z}\|_{k+2}\geq2\|\mathbf{z}\|_{k+1}. \tag{28}$$

Proof We will first show that the claim is true for $k=m-2$. Notice that in this case $\|\mathbf{z}\|_{k+2}=\|\mathbf{z}\|_m=\|\mathbf{z}\|_2$. If $\|\mathbf{z}\|_2=0$, the inequality (28) is trivially true. Now suppose $\|\mathbf{z}\|_2>0$, dividing both sides of the inequality by $\|\mathbf{z}\|_2$, we have

$$\binom{m-1}{m-3}^{-1}\sum_{|S|=m-2}\frac{\|\mathbf{z}[S]\|_2}{\|\mathbf{z}\|_2}+1\geq2\binom{m-1}{m-2}^{-1}\sum_{|S|=m-1}\frac{\|\mathbf{z}[S]\|_2}{\|\mathbf{z}\|_2}.$$

Now let $\mathbf{x}=(x_1,\ldots,x_m)^T\in\mathbb{R}^m$ be such that $x_i=\mathbf{z}[i]^2/\|\mathbf{z}\|_2^2$. It suffices to show

$$\sum_{|S|=m-2}\Big(\sum_{i\in S}x_i\Big)^{1/2}+\frac{(m-1)(m-2)}{2}\geq(m-2)\sum_{i=1}^m\sqrt{1-x_i}, \tag{29}$$

for all $\mathbf{x} \geq 0$ entry-wise such that $\sum_i x_i = 1$. We will now prove the above inequality by induction on m. First of all, notice that for the base case where $m = 3$, we need to show:

$$\sqrt{x_1} + \sqrt{x_2} + \sqrt{x_3} + 1 \geq \sqrt{1 - x_1} + \sqrt{1 - x_2} + \sqrt{1 - x_3},$$

with the constraints $x_i \geq 0$ and $x_1 + x_2 + x_3 = 1$. For fixed x_3, let

$$f(x_1) = \sqrt{x_1} + \sqrt{1 - x_1 - x_3} + \sqrt{x_3} + 1 - \sqrt{x_1 + x_3} - \sqrt{1 - x_1} - \sqrt{1 - x_3}.$$

We will show that $f(x_1)$ is minimized at $x_1 = 0$ or $x_1 = 1 - x_3$. Suppose now $x_1 > 0$. Taking derivative with respect to x_1:

$$f'(x_1) = \frac{1}{2}\Big(\frac{1}{\sqrt{x_1}} - \frac{1}{\sqrt{1 - x_1 - x_3}} - \frac{1}{\sqrt{x_1 + x_3}} + \frac{1}{\sqrt{1 - x_1}}\Big).$$

Let $l(x_1) = \frac{1}{\sqrt{x_1}} - \frac{1}{\sqrt{x_1 + x_3}}$. Note that $f'(x_1) = \frac{1}{2}l(x_1) - \frac{1}{2}l(1 - x_3 - x_1)$. Now we have

$$l'(x_1) = \frac{1}{2}(x_1 + x_3)^{-3/2} - \frac{1}{2}{x_1}^{-3/2}.$$

So $l(x_1)$ is decreasing on $(0, 1 - x_3)$ and by symmetry the function $l(1 - x_3 - x_1)$ is increasing on $(0, 1 - x_3)$. On the other hand, since $\lim_{x_1 \downarrow 0^+} l(x_1) = +\infty$ and $\lim_{x_1 \downarrow 0^+} l(1 - x_3 - x_1) = -\infty$, we know that $f'(x_1) > 0$ on $(0, \frac{1-x_3}{2})$ and < 0 on $(\frac{1-x_3}{2}, 1 - x_3)$. Thus, the minimum of f can only be attained at the boundaries, i.e., $x_1 = 0$ or $x_1 = 1 - x_3$. In either case we have

$$\begin{aligned}&\sqrt{x_1} + \sqrt{x_2} + \sqrt{x_3} + 1 - \sqrt{1 - x_1} - \sqrt{1 - x_2} - \sqrt{1 - x_3}\\ \geq &\sqrt{x_2} + \sqrt{x_3} - \sqrt{1 - x_2} - \sqrt{1 - x_3} = 0,\end{aligned}$$

as $x_2 + x_3 = 1$. So we establish (29) for $m = 3$.

Suppose (29) is also true for $m = n - 1$. For $m = n$, similar to the $m = 3$ case, for fixed $x_3, \ldots, x_n$, define

$$f(x_1) = \sum_{|S|=n-2} \Big(\sum_{i \in S} x_i\Big)^{1/2} + \frac{(n-1)(n-2)}{2} - (n-2)\sum_{i=1}^{n}\sqrt{1 - x_i},$$

subject to $x_i \geq 0$ and $\sum_i x_i = 1$. Again, we will show f attains its minimum at either $x_1 = 0$ or $x_1 = 1 - \sum_{i=3}^n x_i$. Notice that

$$\begin{aligned}\sum_{|S|=n-2} \Big(\sum_{j \in S} x_j\Big)^{1/2} =& \sum_{|S|=n-3,1,2\notin S} \Big(x_1 + \sum_{j \in S} x_j\Big)^{1/2} + \sum_{|S|=n-4,1,2\notin S} \Big(x_1 + x_2 + \sum_{j \in S} x_j\Big)^{1/2}\\ &+ \sum_{|S|=n-3,1,2\notin S} \Big(x_2 + \sum_{j \in S} x_j\Big)^{1/2} + \Big(\sum_{j=3}^{n} x_j\Big)^{1/2}\\ =&\sum_{i=3}^{n}\Big(x_1 + \sum_{j=3}^{n} x_j - x_i\Big)^{1/2} + \sum_{3 \leq i < j \leq n} (1 - x_i - x_j)^{1/2}\\ &+ \sum_{i=3}^{n}(1 - x_1 - x_i)^{1/2} + \Big(\sum_{j=3}^{n} x_j\Big)^{1/2}.\end{aligned}$$

In addition,

$$\sum_{i=1}^{n}(1 - x_i)^{1/2} = (1 - x_1)^{1/2} + \Big(x_1 + \sum_{j=3}^{n} x_j\Big)^{1/2} + \sum_{i=3}^{n}(1 - x_i)^{1/2}.$$

Taking derivative with respect to x_1,

$$\begin{aligned}f'(x_1) =& \frac{1}{2}\Big(\sum_{i=3}^{n}\Big(x_1 + \sum_{j=3}^{n} x_j - x_i\Big)^{-1/2} - \sum_{i=3}^{n}(1 - x_1 - x_i)^{-1/2}\\ &+ (n-2)(1 - x_1)^{-1/2} - (n-2)\Big(x_1 + \sum_{i=3}^{n} x_i\Big)^{-1/2}\Big).\end{aligned}$$

Now let

$$l(x_1) = \sum_{i=3}^{n}\Big(x_1 + \sum_{j=3}^{n} x_j - x_i\Big)^{-1/2} - (n-2)\Big(x_1 + \sum_{j=3}^{n} x_j\Big)^{-1/2}.$$

So $2f'(x_1) = l(x_1) - l(1 - \sum_{i=3}^n x_i - x_1)$. Again

$$l'(x_1) = -\frac{1}{2}\sum_{i=3}^{n}\Big(x_1 + \sum_{j=3}^{n} x_j - x_i\Big)^{-3/2} + \frac{n-2}{2}\Big(x_1 + \sum_{j=3}^{n} x_j\Big)^{-3/2}.$$

It is easy to see that $l'(x_1) < 0$ and so $l(x_1)$ is decreasing on $(0, 1 - \sum_{i=3}^n x_i - x_1)$. On the other hand $\lim_{x_1 \downarrow 0^+} l(x_1) = +\infty$. By symmetry $f'(x_1) > 0$ on $\big(0, \frac{1}{2}(1 - \sum_{i=3}^n x_i - x_1)\big)$ and < 0 on $\big(0, \frac{1}{2}(1 - \sum_{i=3}^n x_i - x_1)\big)$. So f attains its minimum at $x_1 = 0$ or $x_1 = 1 - \sum_{i=3}^n x_i$. Hence we have

$$\begin{aligned}&\sum_{|S|=n-2} \Big(\sum_{i \in S} x_i\Big)^{1/2} + \frac{(n-1)(n-2)}{2} - (n-2)\sum_{i=1}^{n}(1 - x_i)^{1/2}\\ \geq&\Big(\sum_{|S|=n-3,1\notin S} + \sum_{|S|=n-2,1\notin S}\Big)\Big(\sum_{j \in S} x_j\Big)^{1/2} + \frac{(n-2)(n-3)}{2} - (n-2)\sum_{i=2}^{n}(1 - x_i)^{1/2}. \quad (30)\end{aligned}$$

By the induction assumption that (29) holds when $m = n - 1$, we have

$$\sum_{|S|=n-3,1\notin S} \Big(\sum_{j \in S} x_j\Big)^{1/2} + \frac{(n-2)(n-3)}{2} \geq (n-3)\sum_{i=2}^{n}(1 - x_i)^{1/2}.$$

Thus (30) is greater than or equal to

$$\begin{aligned}&-\frac{(n-2)(n-3)}{2} + \sum_{|S|=n-2,1\notin S} \Big(\sum_{j \in S} x_j\Big)^{1/2} + \frac{(n-1)(n-2)}{2} - (n-2) - \sum_{i=2}^{n}(1 - x_i)^{1/2}\\ =&\sum_{|S|=n-2,1\notin S} \Big(\sum_{j \in S} x_j\Big)^{1/2} - \sum_{i=2}^{n}(1 - x_i)^{1/2} = \sum_{i=2}^{n}(1 - x_i)^{1/2} - \sum_{i=2}^{n}(1 - x_i)^{1/2} = 0.\end{aligned}$$

Thus we have verified the claim that (29) and hence (28) holds for $k = m-2$ for all $m \geq 3$. To establish the case for general $1 \leq k \leq m-2$, we again perform induction on the (m,k)-tuple. Note that the base case $m = 3$ and $k = 1$ has been previously proved. Suppose (28) holds for $m = n-1$ and $1 \leq k \leq n-3$. Now consider $m = n$ and $1 \leq k < n-2$. Notice that

$$\begin{aligned}
|||\mathbf{z}|||_k =& \frac{1}{n-k}\binom{n-1}{k-1}^{-1} \sum_{|T|=n-1} \sum_{|S|=k, S\subset T} \|\mathbf{z}[S]\|_2 \\
=& (n-1)\binom{n-2}{k-1}^{-1} \sum_{|T|=n-1} \sum_{|S|=k, S\subset T} \|\mathbf{z}[S]\|_2 \\
=& (n-1) \sum_{|T|=n-1} |||\mathbf{z}[T]|||_k.
\end{aligned}$$

By the induction assumption, for all T such that $|T| = n-1$, we have:

$$|||\mathbf{z}[T]|||_k + |||\mathbf{z}[T]|||_{k+2} \geq 2|||\mathbf{z}[T]|||_{k+1}.$$

Therefore

$$|||\mathbf{z}|||_k + |||\mathbf{z}|||_{k+2} - 2|||\mathbf{z}|||_{k+1} = (n-1) \sum_{|T|=n-1} (|||\mathbf{z}[T]|||_k + |||\mathbf{z}[T]|||_{k+2} - 2|||\mathbf{z}[T]|||_{k+1}) \geq 0.$$

Thus the claim also holds for $m = n$ and $1 \leq k < n-2$, completing the proof. ■

A.6 Miscellaneous

Lemma 13 *(Concavity of $\mathbb{E}\sqrt{L_m(d,k)}$) Let $d \in [\![m]\!]$. For $k \in [\![m-2]\!]$, we have*

$$\mathbb{E}\sqrt{L_m(d,k)} + \mathbb{E}\sqrt{L_m(d,k+2)} \leq 2\mathbb{E}\sqrt{L_m(d,k+1)}. \tag{31}$$

where the geometric random variable $L_m(d,k)$ is defined as in Definition 3.

Proof Suppose we are now sampling without replacement from a pool of numbers with d 1's and $m-d$ 0's. For $i \in [\![m]\!]$, denote by $X_i \in \{0,1\}$ the i-th outcome. It is easy to see that $L_m(d,k)$ and $\sum_{i=1}^k X_i$ have the same distribution. To show (31), it suffices to prove the following conditional expectation inequality:

$$\sqrt{L_m(d,k)} + \mathbb{E}[\sqrt{L_m(d,k+2)} \mid L_m(d,k)] \leq 2\mathbb{E}[\sqrt{L_m(d,k+1)} \mid L_m(d,k)]$$

Note that the above inequality follows if for all $0 \leq a \leq \min(d,k)$:

$$\sqrt{a} + \mathbb{E}\sqrt{a + X_{k+1} + X_{k+2}} \leq 2\mathbb{E}\sqrt{a + X_{k+1}}$$

It is easy to see that

$$\begin{aligned}
\mathbb{E}\sqrt{a+X_{k+1}} =& \frac{d-a}{m-k}\sqrt{a+1} + (1 - \frac{d-a}{m-k})\sqrt{a}. \\
\mathbb{E}\sqrt{a+X_{k+1}+X_{k+2}} =& \frac{d-a}{m-k} \times \frac{d-a-1}{m-k-1}\sqrt{a+2} + 2 \times \frac{d-a}{m-k} \times \frac{m-k-(d-a)}{m-k-1}\sqrt{a+1} \\
&+ \frac{m-k-(d-a)}{m-k} \times \frac{m-k-(d-a)-1}{m-k-1}\sqrt{a}.
\end{aligned}$$

By elementary algebra, it can be shown that

$$\begin{aligned}
&2\mathbb{E}\sqrt{a+X_{k+1}} - \sqrt{a} - \mathbb{E}\sqrt{a+X_{k+1}+X_{k+2}} \\
=& \frac{d-a}{m-k} \times \frac{d-a-1}{m-k-1} \times (2\sqrt{a+1} - \sqrt{a+2} - \sqrt{a}) \geq 0,
\end{aligned}$$

The inequality follows since $f(x) = \sqrt{x}$ is a concave function. Thus the proof is complete. ■

Lemma 14 *Let $\mathbf{x}(t) = (x_1(t), \ldots, x_m(t))^T \in \mathbb{R}^m$ be an m-dimensional function on $[0,\epsilon)$ such that: (1) $x_1(0) = 1$ and for all $i \geq 2$, $x_i(0) = 0$; (2) The derivative $\dot{x}_i(t)$ exists and is bounded for all $t \in (0,\epsilon)$. We have*

$$\lim_{t\downarrow 0^+} \frac{\|\mathbf{x}(t)\|_2 - \|\mathbf{x}(0)\|_2}{t} = \lim_{t\downarrow 0^+} \dot{x}_1(t).$$

Proof

$$\begin{aligned}
\lim_{t\downarrow 0^+} \frac{\|\mathbf{x}(t)\|_2 - \|\mathbf{x}(0)\|_2}{t} &= \lim_{t\downarrow 0^+} \frac{(\sum_{i=1}^m x_i^2(t))^{1/2} - 1}{t} \\
&= \lim_{t\downarrow 0^+} \frac{\sum_{i=1}^m x_i^2(t) - 1}{t} \left((\sum_{i=1}^m x_i^2(t))^{1/2} + 1 \right)^{-1} \\
&= \frac{1}{2} \lim_{t\downarrow 0^+} \frac{\sum_{i=1}^m x_i^2(t) - 1}{t} \\
&= \frac{1}{2} \left(\lim_{t\downarrow 0^+} \frac{x_1^2(t) - 1}{t} + \sum_{i=2}^m \lim_{t\downarrow 0^+} \frac{x_i^2(t)}{t} \right) \\
&= \frac{1}{2} \left(\lim_{t\downarrow 0^+} \frac{x_1(t) - 1}{t}(x_1(t) + 1) + \sum_{i=2}^m \lim_{t\downarrow 0^+} \frac{x_i^2(t)}{t} \right) \\
&= \lim_{t\downarrow 0^+} \frac{x_1(t) - 1}{t} + \frac{1}{2} \sum_{i=2}^m \lim_{t\downarrow 0^+} \frac{x_i^2(t)}{t}.
\end{aligned}$$

By mean value theorem, for each $t \in (0,\epsilon)$, there exists $\delta_t \in (0,t)$ such that $x_1(t) - 1 = \dot{x}_1(\delta_t)t$. Thus the first term simply becomes $\lim_{t\downarrow 0^+} \dot{x}_1(t)$. By the same argument, for each $i \in \{2, \ldots, m\}$, $x_i(t) = \dot{x}_i(\delta_t)t$ for some $\delta_t \in (0,t)$. Since $\dot{x}_i(t)$ is bounded, we have

$$\lim_{t\downarrow 0^+} \frac{x_i^2(t)}{t} = \lim_{t\downarrow 0^+} \dot{x}_i(\delta_t)^2 t = 0.$$

Therefore the claim is verified. ■

Lemma 15 *Let $\mathbf{x}(t) = (x_1(t), \ldots, x_m(t))^T \in \mathbb{R}^m$ be an m-dimensional function on $[0,\epsilon)$ such that: (1) $x_i(0) = 0$ for all $i = 1, \ldots, m$; (2) The derivative $\dot{x}_i(t)$ exists for all $t \in (0,\epsilon)$. We have*

$$\lim_{t\downarrow 0^+} \frac{\|\mathbf{x}(t)\|_2}{t} = \| \lim_{t\downarrow 0^+} \dot{\mathbf{x}}(t)\|_2.$$

Proof

$$\lim_{t\downarrow 0^+}\frac{\|\mathbf{x}(t)\|_2}{t}=\lim_{t\downarrow 0^+}\left(\sum_{i=1}^m(\frac{x_i(t)}{t})^2\right)^{1/2}=\left(\sum_{i=1}^m(\lim_{t\downarrow 0^+}\frac{x_i(t)}{t})^2\right)^{1/2}=\|\lim_{t\downarrow 0^+}\dot{\mathbf{x}}(t)\|_2.$$

■

Lemma 16 *Let* $\mathbf{a}=(a_1,\ldots,a_m)^T\in\mathbb{R}^m$ *where* $a_1\neq 0$ *and* $\mathbf{x}(t)=(x_1(t),\ldots,x_m(t))^T\in\mathbb{R}^m$ *be an* m*-dimensional function on* $[0,\epsilon)$ *such that: (1)* $x_1(0)=1$ *and for all* $i\geq 2$, $x_i(0)=0$*; (2) The derivative* $\dot{x}_i(t)$ *exists and is bounded for all* $t\in(0,\epsilon)$*. We have*

$$\lim_{t\downarrow 0^+}\frac{|\mathbf{a}^T\mathbf{x}(t)|-|a_1|}{t}=|a_1|\lim_{t\downarrow 0^+}\dot{x}_1(t)+\boldsymbol{sgn}(a_1)\sum_{i=2}^m a_i\lim_{t\downarrow 0^+}\dot{x}_i(t).$$

Proof Without loss of generality, assume $a_1>0$. Since $x_1(0)=1$ and for all $i\geq 2$, $x_i(0)=0$, by continuity, for sufficiently small t, we have

$$\frac{|\mathbf{a}^T\mathbf{x}(t)|-|a_1|}{t}=\frac{|a_1x_1(t)+\sum_{i=2}^m a_ix_i(t)|-a_1}{t}=\frac{a_1x_1(t)-a_1+\sum_{i=2}^m a_ix_i(t)}{t}.$$

Therefore, by the same argument in the proof of Lemma 14,

$$\begin{aligned}\lim_{t\downarrow 0^+}\frac{|\mathbf{a}^T\mathbf{x}(t)|-|a_1|}{t}&=\lim_{t\downarrow 0^+}\frac{a_1x_1(t)-a_1}{t}+\lim_{t\downarrow 0^+}\sum_{i=2}^m\frac{a_ix_i(t)}{t}\\&=a_1\lim_{t\downarrow 0^+}\dot{x}_1(t)+\sum_{i=2}^m a_i\lim_{t\downarrow 0^+}\dot{x}_i(t).\end{aligned}$$

■

Lemma 17 *Let* $\mathbf{a}=(a_1,\ldots,a_m)^T\in\mathbb{R}^m$ *and* $\mathbf{x}(t)=(x_1(t),\ldots,x_m(t))^T\in\mathbb{R}^m$ *be an* m*-dimensional function on* $[0,\epsilon)$ *such that: (1)* $x_i(0)=0$ *for all* $i=1,\ldots,m$*; (2) The derivative* $\dot{x}_i(t)$ *exists for all* $t\in(0,\epsilon)$*. We have*

$$\lim_{t\downarrow 0^+}\frac{|\mathbf{a}^T\mathbf{x}(t)|}{t}=\left|\sum_{i=1}^m a_i\lim_{t\downarrow 0^+}\dot{x}_i(t)\right|.$$

Proof The proof is similar to that of Lemma 15. ■

Abstract

Topic modeling is an important tool in natural language processing. Topic models provide two forms of output. The first is a predictive model. This type of model has the ability to predict unseen documents (e.g., their categories). When topic models are used in this way, there are ample measures to assess their performance. The second output of these models is the topics themselves. Topics are lists of keywords that describe the top words pertaining to each topic. Often, these lists of keywords are presented to a human subject who then assesses the meaning of the topic, which is ultimately subjective. One of the fundamental problems of topic models lies in assessing the quality of the topics from the perspective of human interpretability. Naturally, human subjects need to be employed to evaluate interpretability of a topic. Lately, crowdsourcing approaches are widely used to serve the role of human subjects in evaluation. In this work we study measures of interpretability and propose to measure topic interpretability from two perspectives: *topic coherence* and *topic consensus*. We start with an existing measure for topic coherence—model precision. It evaluates coherence of a topic by introducing an intruded word and measuring how well a human subject or a crowdsourcing approach could identify the intruded word: if it is easy to identify, the topic is coherent. We then investigate how we can measure coherence comprehensively by examining dimensions of topic coherence. For the second perspective of topic interpretability, we suggest topic consensus that measures how well the results of a crowdsourcing approach matches those given categories of topics. Good topics should lead to good categories, thus, high topic consensus. Therefore, if there is low topic consensus in terms of categories, topics could be of low interpretability. We then further discuss how topic coherence and topic consensus assess different aspects of topic interpretability and hope that this work can pave way for comprehensive measures of topic interpretability.

1. Introduction

Understanding natural language is one of the cornerstones of artificial intelligence research. Researchers can usually rely on text to give them signal for their specific problem. Text has been used to greatly aid artificial intelligence tasks such as opinion mining (Pang and Lee, 2008; Tumasjan et al., 2010), and user home location detection (Mahmud et al., 2012), and to find users in crisis situations (Morstatter et al., 2014). Topic modeling is one of the prominent text analysis techniques. Formally, topics are probability distributions over the words, but usually researchers treat them as lists of the most probable keywords. This process is akin to organizing newspaper articles by the "section" in which they appear, and simultaneously ranking words for that section. Topic models have been widely used for many tasks in social media research, such as using text to discover topics of discussion in crisis scenarios (Kireyev et al., 2009), event detection and analysis (Hu et al., 2012), and finding a Twitter user's home location (Eisenstein et al., 2010).

Topic modeling describes a family of approaches which work toward the above task. Latent Dirichlet Allocation (Blei et al., 2003), commonly known as LDA, is one example of a very popular topic model. LDA, and models like it, are used from two perspectives. The first is as a predictive model. When LDA is used in this way, the application is clear: there are many existing measures to assess the predictive performance. The other main use of LDA is to describe the dataset. The topics it learns are read by humans for them to get a better picture of the underlying themes in the dataset. When used this way, the topic distributions are manually inspected in many studies to show that some underlying pattern exists in the corpus. The meaning behind these topics is often interpreted by the individual who builds the model, and topics are often given a title or name to reflect their understanding of the underlying meaning of the topics. One key concern with topic models lies with how well human beings can actually understand the topics, or the problem of *topic interpretability*. It may be true that when presented with a group of words a human subject will always be able to assign some meaning. In this work, we question if we can tap on a group of human subjects or crowdsourcing in search of measures for topic interpretability. We focus on assessing the interpretability of topics from two perspectives: **coherence**, and **consensus**. Coherence measures how semantically close the top words of a topic are. Consensus measures how well the results of a crowdsourcing approach or generated by a group of human subjects match those given categories of topics.

The main contributions of this work are:

- We elaborate the need for measuring *topic coherence*, a novel dimension for measuring the semantic quality of topics. Based on this dimension, we propose "Model Precision Choose Two", a measure to comprehensively estimate how well a topic's top words are related to each other;
- We propose a *topic consensus* measure that estimates how well a statistical topic represents an underlying category of text in the corpus; and
- We demonstrate how these measures complement the existing framework and show how the results of these measures can help to further discover interpretable topics by a topic model.

2. Related Work

Topic modeling has been widely accepted in many communities such as machine learning, NLP, and social sciences (Ramage et al., 2009b). More recently topic modeling has been

widely applied to social media data. In the context of disaster-related tweets, Kireyev et al. (2009) tries to find disaster-related tweets, modeling two types of topics: informational and emotional. Joseph et al. (2012) studies the relation between users' posts and their geolocation. Several works (Yin et al., 2011; Hong et al., 2012; Pozdnoukhov and Kaiser, 2011) focus on identifying topics in geographical Twitter datasets, looking for topics that pertain to things such as local concerts and periods of mass unrest. Topic modeling was also used to find indication of bias in Twitter streams (Morstatter et al., 2013). Topic models exist have been developed to meet the unique needs of web data (Lin et al., 2014).

With such a wide acceptance, it is important that the topics produced by topic models are evaluated. Approaches to evaluating topic models follow two main avenues: evaluating the predictive performance of the model, and evaluating its interpretability. While we only focus on the latter in this work, we will cover the related work in the area of assessing the predictability before moving on to discuss the evaluation of interpretability.

2.1 Evaluating the Predictive Power of Topic Models

In the most general case, topic models are run over large corpora of data that do not contain a "ground truth" definition of the topics in the text. Because of this, we cannot apply supervised machine learning measures such as accuracy, precision, and recall to the task. Instead, the most often used measure for the predictive performance of topic models is "perplexity" (Jelinek et al., 1977; Jurafsky and Martin, 2000), which measures how well the topics match a set of held-out documents (Blei et al., 2003; Griffiths and Steyvers, 2004; Kawamae, 2016; Asuncion et al., 2009). Perplexity is defined as:

$$perp(q, x) = 2^{-\frac{1}{|x|}\sum_{i=1}^{|x|} log_2 q(x_i)}, \tag{1}$$

where q is the model we are testing, and x is the set of held-out documents. The intuition is that we are measuring how perplexed, or surprised, the model is. If the documents in x have a high probability of occurring, then the summation in the exponent will have a greater value, and thus the overall perplexity score will have a lower value.

Some specialized topic models can leverage ground truth labels. One such case is "Labeled LDA" (Ramage et al., 2009a), which is a different approach that takes labels into account when building the model. When evaluating its performance, traditional measures for supervised machine learning are applied such as F_1 (Frakes and Baeza-Yates, 1992), which is calculated as:

$$F_1 = \frac{2\pi\rho}{\pi + \rho}, \tag{2}$$

where $\pi = \frac{TP}{TP+FP}$ is the precision and $\rho = \frac{TP}{TP+FN}$ is the recall. Obtaining "true positives", "false positives", "true negatives", and "false negatives" requires data with ground truth, which is why we could not apply it when no labels are available.

2.2 Evaluating the Interpretability of Topic Models

Interpretability is largely a human issue. People generally read topics in order to assign meaning to them. Because of this, it is natural that humans would read topics in order to evaluate their interpretability. This issue has been addressed largely by two schools of

thought. The first school of thought is ad-hoc, where researchers manually read topics in order to judge their quality. In the second, researchers take a more principled approach, employing measures that can judge the quality of topics in a more automated manner. In the subsequent subsections, we provide more details regarding each approach and the related work that employs it.

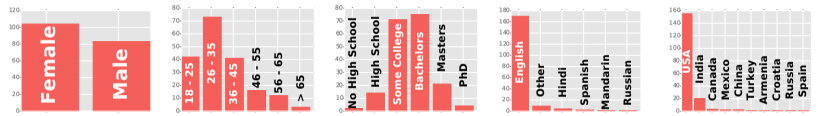
2.2.1 Eyeballing

The most common approach to assessing the quality of topics is the "eyeballing" approach, where topics are inspected carefully and manually assigned a label. After the topics are read, a "title" is assigned to each one based upon the top keywords in the text. In Grimmer and Stewart (2013), the authors manually label topics based upon the top words in the topic. These manual topic labels are supplemented with automatic labeling approaches such as Aletras and Stevenson (2014); Lau et al. (2011); Maiya et al. (2013); Mao et al. (2012), however the final call is made by a human. In other work, topic models were verified on scientific corpora to show that the topics that were produced by the model made sense (Blei et al., 2003; Griffiths and Steyvers, 2004). By displaying the top words from the topics to the reader, they make the case that the topics they find are of high quality. In the context of disaster-related tweets, Kireyev et al. (2009) try to find disaster-related tweets, labeling two types of topics: informational and emotional. This was done by interpreting a visualization of the topic clusters and manually assigning meaning to the topic groups. Other forms of visualization have been proposed to identify interpretable topics, such as that proposed in Le and Lauw (2016) where the authors show topics in a low-dimensional embedding. Another visualization approach is proposed in Sievert and Shirley (2014), where the authors show topics, their top words, and the size of the topic to the user to help them differentiate interpretable topics. Similarly, Hu et al. (2014) created an approach to iteratively add constraints to generate better topics.

The manual labeling of topics goes beyond mere text. For example, Schmidt (2012) uses LDA to cluster 1820's ship voyages. By treating trips as documents and nightly latitude/longitude checkins as words, the authors generate topics based upon these trips. Using manual inspection of topics, the authors are able to label topics as "trading" and "whaling" topics, amongst others. Other works focus on identifying topics in geographical Twitter datasets, looking for topics that pertain to things such as local concerts and periods of mass unrest (Yin et al., 2011; Hong et al., 2012).

While the manual inspection of topics is often used for topic labeling, it can also be used for topic filtering. In Kumar et al. (2013), the authors employ subject-matter experts to label the topics for them. In this case the authors had the labelers mark the topics as "relevant" to their study, or "not relevant". Ultimately those topics that were not deemed relevant were removed.

This method of evaluation, while common, has the issue that it is ad-hoc. This is a major problem in topic assessment as this evaluation can be subjective, sometimes coming down to just one researcher who assigns definitions to the topics learned from the model. To mitigate this issue, researchers have investigated imposing principled measures for topic interpretability. Additionally, this has implications for reproducibility, as a different researcher may have a different interpretation of the top words.



(a) Sex (b) Age (c) Education (d) First Language (e) Origin Country

Figure 1: Demographic breakdown of the Turkers who participated.

2.2.2 Principled Evaluation of Topic Interpretability

This method of assessing topic quality employs formal approaches and measures to assess the interpretability of statistical topics, generally through crowdsourcing. While aggregating the results of crowdsourced tasks is challenging, some work has focused on leveraging crowdsourcing to assess human interpretability (Zhou et al., 2014). Chang et al. (2009) proposed the first such framework for topic models in which a hybrid approach was employed. This approach focuses on crowdsourcing in order to assess topic interpretability. The results of the crowd are then aggregated through different measures to give a "score", which is a numerical value indicating the topic's interpretability. While not truly automated, it provides a reproducible framework that can be used by researchers to perform this assessment. In their paper, the authors focus on two main validation schemes for topic models: "Word Intrusion" which studies the top words within a topic by discovering how well participants can identify a word that does not belong. They also introduce "Topic Intrusion", which studies how well the topic probabilities for a document match a human's understanding of this document by showing three highly-probably *topics*, and one improbable topic, and asking the worker to select the "intruder".

Chang's influential paper provided the groundwork for a principled study of topic interpretability. Subsequent work aimed to provide automated approaches to replace the Turkers. Lau et al. (Lau et al., 2014) went about this by building heuristics to guess the actions of the workers. They provide an algorithm that will guess which answer a crowdsourced worker will choose when presented in an Human Intelligence Task (HIT). Other investigations into this measure include Roder et al. (Röder et al., 2015), who automatically explore the space of possible weights applied to existing interpretability measures and aggregation functions to find the measure that best approximates model precision.

2.3 Crowdsourcing Approaches to Evaluation

The crowdsourced experiments carried out in this work were performed using Amazon's Mechanical Turk[1] platform. Mechanical Turk is a crowdsourcing platform that allows requesters to coordinate Human Intelligence Tasks (HITs) to be solved by Turkers. The formulation of each HIT will be described in the corresponding section for each experiment. In all cases, each HIT was solved 8 times to overcome issues that arise from using non-expert annotators (Snow et al., 2008).

1. http://www.mturk.com

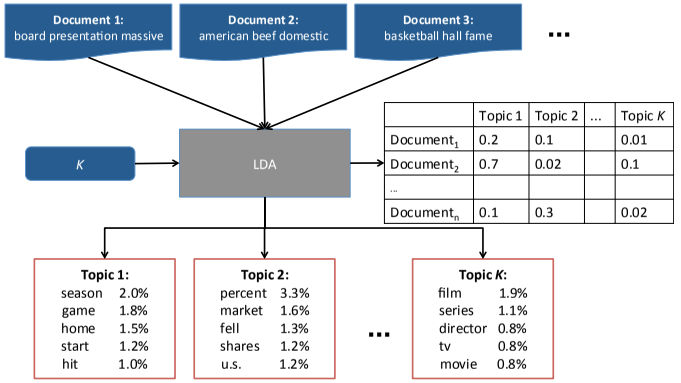


Figure 2: An overview of the LDA process. Each document is presented as a bag of words along with K, the number of topics the LDA operator wishes to discover. Two outputs are provided: the topics (on the bottom), and the document-topic associations (on the right).

In this paper we experiment with three measures that rely on crowdsourcing platforms like Amazon's Mechanical Turk. In order to ensure the reliability, as well as to account for noise in the results, it is important to have a basic understanding of the userbase solving the HITs we create. Prior to solving any HITs, we require the Turker to fill out a demographic survey. The demographic survey consists of five questions about the Turker's background: their sex, age, first language, country of origin, and highest level of education achieved. The demographic makeup of our Turkers can be seen in Figure 1. Figures 1(d) and 1(e) reveal a strong skew towards American Turkers who speak English as their first language. This could be partly attributed to a recent change in the Mechanical Turk terms of service that requires Turkers to provide their Social Security Number[2] in order to solve HITs on the site. Regardless, this allows us to go forward knowing that the participants are largely English speakers, and we cannot attribute poor performance in our analysis to a poor grasp of English.

This exercise in understanding the demographic makeup of our Turkers is done to give us a sense of the expected demographic makeup in future studies. We do not delete any Turkers who are non-native speakers. Instead, we investigate a Turkers' ability to solve our HITs based upon their performance at the "sanity" questions, the easiest HITs to solve in our set. These would be "control questions" to differentiate genuine workers (Liu et al., 2013). Initially, we planned to delete users who missed over 25% of these questions. Fortunately, no user fell below this threshold, and consequently no user was deleted from our study.

3. Topic Modeling

Topic modeling refers to a family of models that seek to discover abstract "topics" that occur within a corpus (Blei, 2012). Different approaches have been proposed for this task. For example, one of the first topic models was PLSA (Hofmann, 1999). LDA (Blei et al., 2003) built on this by adding a Dirichlet prior to the document-topic distribution. Many approaches have also been proposed for this task such as Hierarchical Dirichlet Processes (Teh et al., 2006), Correlated Topic Models (Blei and Lafferty, 2006), and Pachinko Allocation (Li and McCallum, 2006). While these are more recent than LDA, LDA is the most widely used topic modeling approach.

3.1 Latent Dirichlet Allocation

The goal of topic modeling is to learn "topics" from a large corpus of text. In LDA, each topic is a probability distribution over the entire vocabulary of the corpus. While each topic contains every word, the probabilities assigned to the word vary by topic. Furthermore, the model learns an association for each document over each of the topics. In other words, each document is described as a probability distribution over all of the topics in the corpus.

Formally, LDA takes two inputs:[3] A bag-of-words corpus containing d documents and a vocabulary of size v, and a scalar value K, which indicates the number of topics that the model will learn. LDA then outputs a model, m. The model, m, consists of two matrices:

1. A $Topic \times Vocabulary$ matrix, $\mathbf{T}^m \in \mathbb{R}^{K \times v}$. This is the matrix of topics that are learned by the model. $\mathbf{T}^m_{i,j}$ is the association of word j with topic i.

2. A $Document \times Topic$ matrix, $\mathbf{D}^m \in \mathbb{R}^{d \times K}$, with entry $\mathbf{D}^m_{i,j}$ representing the probability that document i is generated by topic j.

This is the fundamental input and output of the model, and can be seen in Figure 2. The model can be trained either through expectation maximization (Blei et al., 2003), or through Gibbs sampling (Griffiths and Steyvers, 2004). In this work we use the Mallet toolkit (McCallum, 2002), which uses the latter strategy to learn the parameters.

Beyond the notation, Figure 2 more clearly articulates the two schools of thought outlined in Section 2. When a researcher employs the "eyeballing" approach described in Section 2.2.1, what they are doing is having a human read the top words in the topic (depicted at the bottom of the figure) and divining a meaning for the topic. For example, a researcher may read the top words of "Topic 1" in Figure 2 and call it a "sports topic". While this ultimately may be an appropriate guess, there is no existing measure to determine the how well the definition fits the topic.

Principled evaluation, the second school of thought outlined in Section 2.2.2, consists of applying a standard framework to the practice of assessing topic quality. In (Chang et al., 2009), the authors propose a hybrid framework to assess topic quality, while (Mimno et al., 2011) propose a solution to do it automatically. The thrust of this work is to extend the existing principled framework in order to assess new dimensions of topic quality.

Going forward we will reproduce "Model Precision", one of the measures introduced in (Chang et al., 2009). Next, we will provide two new measures which can extend the existing framework and show how the insights they provide compare to the existing solution. The measures we propose are also hybrid, meaning that they depend on crowdsourcing to obtain their results. We note that while useful, this has major implications for reproducibility. These experiments require ample time and money in order to run, making it intractable for many researchers. Thus, we experiment with automated measures that can replace the effort performed by the crowdsourced workers.

3. For the sake of simplicity, we do not consider hyperparameters.

3.2 Data

We generate topics from LDA using two datasets. First, we use a dataset of scientific abstracts from the European Research Council. The text in these documents is of high quality, written by scientists who wish to argue their case in order to secure funding for their research. It is possible that topical misunderstanding can stem from a lack of understanding of the crowdsourced workers, who are not necessarily trained to understand scientific text. To complement this dataset, we use a large corpus of news articles curated by Yahoo News. We introduce both of these datasets in the subsequent sections.

3.2.1 Scientific Abstracts

The first text corpus focused upon in this study consists of 4,351 abstracts of accepted research proposals to the European Research Council.[4] In the first 7 years of its existence, the European Research Council (ERC) has funded approximately 4,500 projects, 4,351 of which are used in this study. Abstracts are limited to 2,000 characters, and when a researcher submits an abstract, they are required to select one of the three scientific domains their research fits into: Life Sciences (LS), Physical Sciences (PE), or Social Sciences and Humanities (SH). These labels will be used in the crowdsourced measure we propose later.

Mapping scientific research areas has become of growing interest to scientists, policymakers, funding agencies and industry. Traditional bibliometric data analyses such as cocitation analysis supply us with basic tools to map research fields. However, Social Sciences and Humanities (SH) are especially difficult to map and to survey, since the fields and disciplines are embedded in diverse and often diverging epistemic cultures. Some are specifically bound to local contexts, languages and terminologies, and the SH domain lacks coherent referencing bodies or citation indices, and dictionaries (Mayer and Pfeffer, 2014). Furthermore, SH terminology is often hard to identify as it resembles everyday speech. Innovative semantic technologies such as topic modeling promise alternative approaches to mapping SH, but the basic question here is: how interpretable are they and how can their results be evaluated in a systematic way? This raises further questions into the interpretability of the LDA topics we study in this paper.

The abstracts used in this research were accepted between 2007–2013, written in English, and classified by the authors[5] into one of the three main ERC domains. The first column of Table 1 shows some statistics of the corpus. The aim of each abstract is to provide a clear understanding of the objectives and methods to achieve them. Abstracts are also used to find reviewers or match authors to panels.

4. `http://erc.europa.eu/projects-and-results/erc-funded-projects`
5. The authors of the respective abstract, not the authors of this work.

Table 1: Properties of the European Research Council accepted abstracts and Yahoo News corpora. The values for each category represent the number of documents in the category.

Property	ERC Data	Yahoo News Data
Documents	4,351	258,919
Tokens	649,651	6,888,693
Types	10,016	214,957
Category 1	*LS:* 1,573	*S:* 88,934
Category 2	*PE:* 1,964	*B:* 90,159
Category 3	*SH:* 814	*E:* 79,826

3.2.2 News Data

The second text corpus used in this work consists of 258,919 news articles indexed by Yahoo News.[6] Yahoo News maintains a corpus of every news article published on its site between 2015-02-01 and 2015-06-03.[7] Similar to newspapers, these articles are tagged with a "section", which corresponds to a categorization. In this study, we select articles from three such categories: Sports (S), Business (B), and Entertainment (E).

The rationale for choosing this dataset is that discovering the topics of a corpus is very similar to automatically discovering the "sections" of a newspaper. When individuals read the top words of a topic, they often assign meanings to the topics, which could correspond to the types of categories seen in newspapers (Grimmer and Stewart, 2013). We employ this corpus because it can give us exactly this mapping, and, in the case of one of our measures, tells us exactly how well these topic understandings map onto the true distribution of the topic. Another important distinction of this dataset is that it consists of text that is meant to be read by everyone.

All of the articles in this corpus were written between February 1st, 2015 and June 3rd, 2015, in English, and classified by Yahoo into one of the three aforementioned categories. The summary statistics of our corpus can be seen in the second column of Table 1.

3.3 Extracting Topics from Text

We apply LDA to extract topics from the text. We run LDA on each dataset four times, with $K = 10, 25, 50, 100$, yielding a total of 185 ERC topics, and 185 Yahoo News topics. All LDA runs were carried out using the Mallet toolkit (McCallum, 2002). Before running LDA, we stripped the case of all words and removed stopwords according to the MySQL stopwords list.[8] Tokenization was performed using Mallet's preprocessing framework, using a special regular expression which preserves punctuation within words.[9] This allows for URLs, contractions, and possessives to be preserved. In all experiments, we fix the hyperparameter values to $\alpha = 5.0$ and $\beta = 0.01$.

6. `https://www.yahoo.com/news/`
7. `https://webscope.sandbox.yahoo.com/catalog.php?datatype=r&did=75`
8. `http://www.ranks.nl/stopwords`
9. We provided the regular expression '[\p{L}\p{P}]*\p{L}' to the "token-regex" argument in Mallet's import-file module.

Table 2: The LDA models generated for this study. These indicate the different values of "m" used throughout the experiments, *e.g.* in Equation 3.

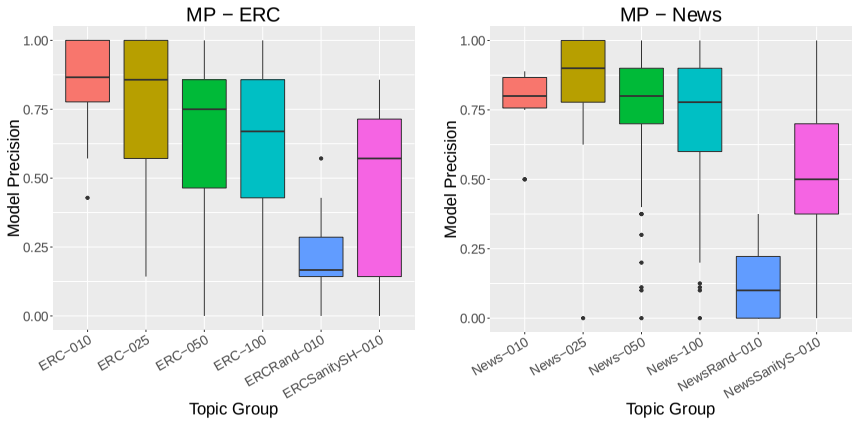
Name	Dataset	Strategy	Topics
ERC-010	ERC	LDA	10
ERC-025	ERC	LDA	25
ERC-050	ERC	LDA	50
ERC-100	ERC	LDA	100
ERCRand-010	ERC	Random	10
ERCSanitySH-010	ERC	Manual	10
News-010	News	LDA	10
News-025	News	LDA	25
News-050	News	LDA	50
News-100	News	LDA	100
NewsRand-010	News	Random	10
NewsSanityS-010	News	Manual	10

In addition to the LDA runs, we extract two additional topic groups from each corpus. This is done with the intent of giving some controls to understand the bounds of the topic measures. The first is a set of *random topics*. To generate these topics, we weight the words by their frequency in the corpus and randomly draw words from this distribution. These topics have a roughly equal mixture of the three categories in the corpus they represent.

To complement our random topics, we also create a set of "sanity" topics. These topics are handpicked to be a clear representation of one of the categories. In the ERC corpus, we calculate each word's probability of occurring in a SH, LS, or PE document. We then select words that occur most ($> 95\%$ of the time) in the SH category. Furthermore, we ensure that these words occur in fewer than $< 5\%$ of the documents from the other two categories. The intention behind these topics is that they provide a strictly pure representation of the SH category, and should provide as a useful sanity check of the Turker's labeling abilities. The same process is repeated with the Yahoo News data, by selecting topics similarly skewed towards the S category. These topics lie in contrast to the random topics in that they are strongly skewed to represent a single group.

In both cases of random and sanity topics, these topics are unlike traditional LDA topics, containing only a *set* of 5 words. We use both of these auxiliary topic sets for validation of the results obtained using the LDA topics. Table 2 shows an overview of all of the topic sets generated for this study.

These topic sets provide examples of how topic models can be applied to extract topics from real world data. We next investigate how to measure their interpretability from two perspectives: coherence, and consensus.



(a) ERC Data (b) Yahoo News Data

Figure 3: Results of "Model Precision" task on the topic sets from the two datasets. The horizontal bar represents the median, and the dots represent outliers.

4. Topic Coherence

One definition of coherence is "the quality or state of systematic or logical connection or consistency".[10] When a topic is a set of words, its coherence is about the relationships among the words. Since each individual can have their opinion of coherence, a crowdsourcing approach is used to obtain a group's feedback. This transforms an individual's opinion to a distribution of collective opinions. We first introduce Chang et al.'s ingenious measure of coherence.

4.1 Model Precision — A Measure of Coherence

Model Precision, introduced by (Chang et al., 2009), is a widely used measure of the "coherence" of an individual topic. It measures the distinctness of a randomly-inserted word into the top five words of a topic. The intuition is that if humans are consistently able to identify the randomly-inserted word, then the topic is more coherent because the intruded word is clearly distinct from the other 5 words. On the other hand, if the humans cannot consistently choose this randomly-inserted word, then the top 5 words of the topic are likely not coherent. This is because the humans are conflating the definition of the top words in the topic with a word that is far away.

For each topic, we show the Turker the top 5 most probable words from the topic's probability distribution along with one of the *least* probable words in the distribution. We call this word the "intruded" word. To prevent rare words from being selected as the

10. http://www.merriam-webster.com/dictionary/coherence

intruder, we ensure that it is also among the top 5 words from another topic. We then ask the Turker to select the word that they think is the intruded word. Model precision is the number of times a Turker was able to guess the intruded word divided by the number of times the HIT was solved, formally:

$$MP_k^m = \frac{1}{|\mathbf{s_k^m}|} \sum_{i=1}^{|\mathbf{s_k^m}|} \mathbb{1}(g_k^m = \mathbf{s}_{k,i}^m), \tag{3}$$

where MP_k^m is the model precision of the k-th topic from model m, g_k^m is the ground-truth intruded word for topic k, $\mathbf{s}_k^m$ is the vector of choices made by Turkers on topic k, and $\mathbb{1}(\cdot)$ is the indicator function which yields 1 if $g_k^m = \mathbf{s}_{k,i}^m$, and 0 otherwise.

The results of this measure on both of our datasets are shown in Figure 3. These figures show boxplots which depict the performance of the topics against this measure. Following traditional boxplot visualization techniques (Wickham and Stryjewski, 2011), the dark horizontal line in the middle of the box is the median, and the lower stem, lower box, upper box, and upper steam each account for 25% of the data. Dots represent topics determined to be outliers by a rule.[11]

We expect that the results would put the interpretability of the LDA topics somewhere in between the random and sanity topics. They should perform better than the random topics, as these are designed to be uninterpretable. Furthermore, our LDA topics should underperform when compared with the sanity topics, which are designed specifically to be highly interpretable. In fact, the results only partially back up this intuition. While the random topics do in fact perform very poorly, the LDA topics actually outperform the sanity topics. This is likely due to the homogeneity of the topics and the words from their vocabulary. When *all* of the choices are "SH" words in the ERC corpus, or "S" words in the News corpus, it is quite likely that the human workers will be confused.

While comparing the distributions of the results may shed light on the broad strokes, the outliers may also provide insight about the results of the experiments. For example, in both $K = 10$ cases, we see one outlier, indicating one underperforming topic. In the random topic set on the ERC data, we see one topic *over*performing, doing much better than the rest of the topics and even scoring near the median of the sanity topics. The four HITs are shown in Table 3. These results illuminate the issue of how these topics became outliers: the intruding word. In the bad topic modeling topics (rows 1, 2, and 3), the topics perform badly because they are not coherent. The words spread over many different concepts, and it is difficult to decipher the meaning. On the other hand the random topic which should have done badly (row 4) actually outperforms the rest of the topic set. Turkers coalesced around "can", and "seem" as the intruded words. Since these are randomly-generated topics, any word among the 6 could be considered "intruded", but only one answer is selected as correct from the setup of our HITs. It just so happened that "can" was the selected word, leading this topic to have an uncharacteristically high score.

These results may also give some inclination about how to use this measure. In fact, there are any number of ways to use these results. For example, if we set $K = 10$, we will get 10 topics from the dataset. On large corpora like those used here, we should expect these 10 topics to be very generic, encompassing major themes of the text. With $K = 100$ topics,

11. Outliers are determined using the "1.5 rule" (Frigge et al., 1989).

Table 3: Outlier topics from Model Precision.

Row	Model	Top 5 Words	Intruded Word
1	ERC-010	design, use, based, develop, can	accompany
2	News-010	news, state, network, april, day	bigeast.com
3	News-025	family, actress, life, -year-old, star	megan's
4	ERCRand-010	maps, resource, visual, manifestation, seem	can

we may also get generic topics, and additionally we are more likely to get fine-grained topics that discuss more specific issues. For example, if in the $K = 10$ case we get one "politics" topic, we may expect to get topics pertaining to specific candidates, issues, and localities in the $K = 100$ case. Interpretability measures can help to shed light on which topics are understandable by humans, and may give an indication of which topic model, or which topics within a model are the most interpretable.

In the following, we first examine what is not assessed by model precision in terms of coherence, and suggest the need for a new measure that can complement model precision for comprehensive measure of coherence.

4.2 A Missing Dimension of Model Precision

Model Precision works by asking the user to choose the word that does not fit within the rest of the set. We are measuring the top words in the topic by comparing them to an outlier. While this method is very useful for this task, it does not measure the coherence *within* the top words for the topic. This is because a good topic should have top words that are semantically close to each other, an aspect of topic quality which is not accounted for by Model Precision.

A diagram illustrating this phenomenon is shown in Figure 4. In Figure 4(a), we see a coherent topic. This topic is coherent because all 5 of the top words are close together, while the intruded word is far away. In Figure 4(b) we see a topic that is less coherent because the fifth word lies at a distance from the first four. In both cases, Model Precision gives us the intruder word in the topic, as seen in Figures 4(c), and 4(d). While this is the desired performance of Model Precision, it leaves us with no understanding of the coherence of the top words of the topic. Results are masked by the outlier, and do not give information about the intra-cluster distance, or coherence of the topic.

In light of this, we look for a way to separate topics not just by their distance from an outlier, but also by the distance within the top words in the topic. The next section of this paper investigates a method which can measure not just the intruder word, but also the coherence of the top words in the topic. In this way we separate topics such as those shown in Figure 4 based on the coherence of their top words.

4.3 Model Precision Choose Two — Another Dimension of Coherence

In this section we propose a new measure for the coherence of the top words of a topic. This experiment sets up the task as before: we select the top five words from a topic, and

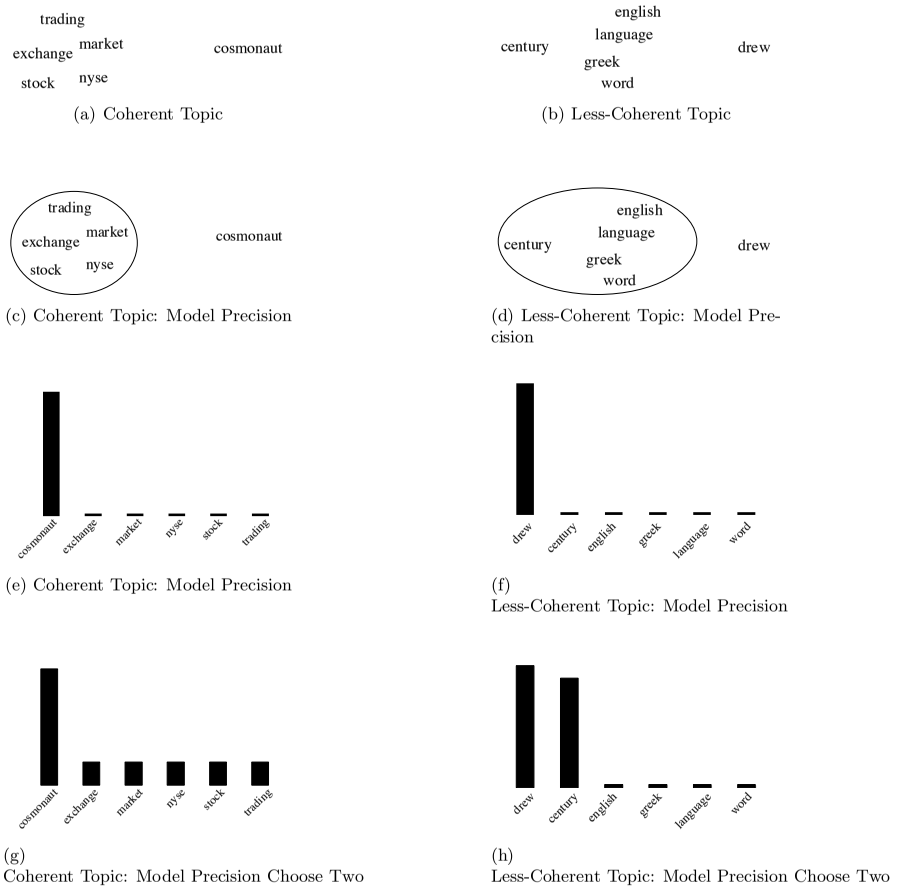


Figure 4: Comparison between Model Precision, and Model Precision Choose Two for two real topics from the Yahoo News corpus. In Figures 4(g) and 4(h), the height of the bars represents the number of times the word was selected in the crowdsourced experiments. Model Precision Choose Two can distinguish the less-coherent topic.

inject one low-probability word. The key difference is that we ask the Turker to select *two* intruded words among the six.

The intuition behind this experiment is that the Turkers' first choice will be the intruded word, just as in Model Precision. However, their second choice is what makes the topic's

quality clear. In a coherent topic the Turkers won't be able to distinguish a second word as all of the words will seem similar. A graphical representation of this phenomenon is shown in Figure 4(g). In the case of an incoherent, a strong "second-place" contender will emerge as the Turkers identify a 2nd intruder word, as in Figure 4(h).

4.3.1 Experimental Setup

To perform this experiment, we inject *one* low-probability word for each topic, and we ask the Turkers to select *two* words that do not fit within the group. We show the six words to the Turker in random order with the following prompt:

> You will be shown six words. Four words belong together, and two of them do not. Choose two words that do **not** belong in the group.

Coherent topics will cause the Turkers' responses regarding the second intruded word to be unpredictable. Thus, our measure of the goodness of the topic should be the predictability of the Turkers' second choice. We propose a new measure called "Model Precision Choose Two" to measure this. Model Precision Choose Two (MPCT) measures this spread as the peakedness of the probability distribution. We define $MPCT_k^m$ for topic k on model m as:

$$MPCT_k^m = H\big(p_{turk}(\mathbf{w}_{k,1}^m), ..., p_{turk}(\mathbf{w}_{k,5}^m)\big), \tag{4}$$

where $H(\cdot)$ is the Shannon entropy (Lin, 1991), $\mathbf{w}_k^m$ is the vector of the top words in topic k generated by model m, and $p_{turk}(\mathbf{w}_{k,i}^m)$ is the probability that a Turker selects $\mathbf{w}_{k,i}^m$. This measures the strength of the second-place candidate, with higher values indicating a smoother, more even distribution, and lower values indicating Turkers gravitation towards a second word.

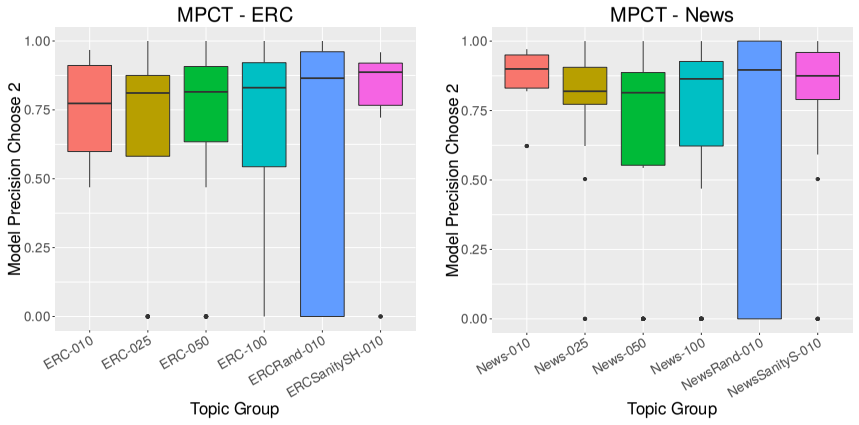
The intuition behind choosing entropy is that it will measure the unpredictability in the Turker selections. That is, if the Turkers are confused about which second word to choose, then their answers will be scattered amongst the remaining five words. As a result, the entropy will be *high*. Conversely, if the second word is obvious, the Turkers will begin to congregate around that second choice, meaning that their answers will be focused. As a result, the entropy will be *low*. Because entropy is able to measure the confusion of the Turkers responses about the second word, we use it directly in the design of our measure.

4.3.2 Results and Discussion of Model Precision Choose Two

The results of this experiment on both corpora are shown in Figure 5. The box plots show the distribution of the results across all of the topics in each topic group. These results illustrate the differences between the two datasets in terms of both performance as well as the appropriate value of K, the number of topics, to maximize the performance. In the ERC data a larger value of K consistently improved our results, while with the News dataset we achieved better results with a larger K.

The results of the MPCT experiments showed how to compute this measure on a topic set. While this new measure elicits another dimension of the topics, their coherence, they alone to not provide the whole picture of what makes a good topic.

Evidence of this is shown in both corpora in Figure 5. In both cases, the "sanity" topics do well, achieving among the best results. However, the median score from the "random"



(a) ERC Data (b) Yahoo News Data

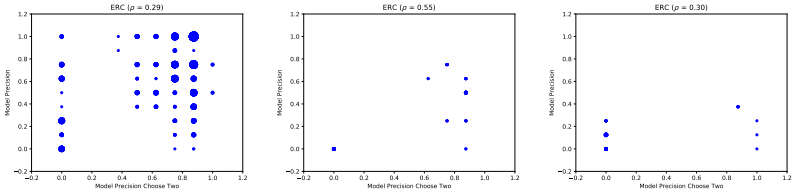
Figure 5: Results of "Model Precision Choose Two" on the topic sets from the two datasets. The figures are presented as before, with the horizontal bar indicating the median, and the dots representing outliers.

topics is also very high. It is easy to see why this occurs: in both very good *and* in very bad topic groups, the Turker has a difficult time choosing any second choice intruder, which drives the MPCT score up. Because of this, we need to combine these results with model precision in order to get a good understanding of the topic quality.

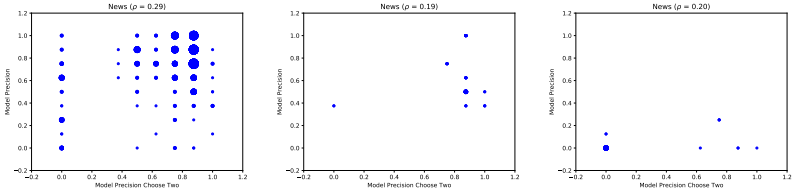
To better compare the results, we compare a case-by-case basis in Figure 6. Both yield similar results which show interesting properties about the dataset. First, Figures 6(c) and 6(f) confirm our hypothesis that random topics can have a high MPCT. However, these lousy topics all have a low MP score. Curiously, though, we see in Figures 6(a) and 6(d) show another interesting pattern: that it is possible for topics to have a high MP and a low MPCT.

To better demonstrate what these values mean for a topic, we show several topics alongside their MP and MPCT scores in Table 4. We show topics of varying quality from the perspective of both measures we introduce. By reading the topics, we can make several observations. First, row 1 and 2 have both high MP and high MPCT. Contrast these topics with rows 3 and 4 which have a high MP score, yet a low MPCT score. When we look at the intruded word in rows 1–4, they all seem equally "distant", however in rows 3–4, a second word also emerges to the Turkers.[12] In rows 5–8, all of the topics perform badly according to MP, but 5–6 are good according to MPCT, while 7–8 are bad according to both measures. After reading the topics in rows 5–8, it is difficult to understand the story. The results of this table tell us two things: 1) a high MP score is a necessary but not sufficient

12. In row 3, "large" was the word the turkers rallied around as the second choice. In row 4, it was "fans".



(a) ERC-* (b) ERCSanitySH-010 (c) ERCRand-010



(d) News-* (e) NewsSanityS-010 (f) NewsRand-010

Figure 6: Scatter plots of each topic's Model Precision Choose Two (x-axis), and Model Precision (y-axis) for each corpus. Above the plot is the correlation (ρ) of the values for all of the topics in the plot. The radius of the circle indicates the number of topics that received the score. "-*" means that all LDA-generated topic groups were considered for this scatter plot.

Table 4: Topics with varying MP and MPCT scores from models built on the two corpora in this work.

Row	Model	Top 5 Words	Intruded Word	MP Score	MPCT Score
1	ERC-100	production, plants, provide, food, plant	suppressor	1.00	0.99
2	News-100	number, system, transactions, card, money	flees	1.00	0.97
3	ERC-50	methods, data, information, analysis, large	diesel	1.00	0.00
4	News-25	series, fans, season, show, episode	leveon	1.00	0.00
5	ERC-100	nuclear, fundamental, water, understanding, surface	modularity	0.13	0.92
6	News-100	film, khan, ians, actor, bollywood	debonair	0.30	1.00
7	ERC-50	mechanisms, pathways, involved, molecular, role	specialized	0.00	0.00
8	News-100	injury, left, list, return, surgery	tests-results	0.00	0.25

condition to identify interpretable topics, and 2) by measuring coherence with MPCT we can identify quality topics better than with MP alone. A confusion matrix showing the differences between MP and MPCT are shown in Table 5.

Model Precision Choose Two is a new measure that rounds out the measurement of topic coherence. Coherence is one aspect of topic interpretability, however, we introduced two aspects of topic interpretability. We next investigate the interpretability from the second perspective: consensus.

Table 5: Qualitative assessment of the difference between low and high values. When MP is low, a topic is not interpretable regardless of the value of MPCT; when MP is high, a topic is interpretable when MPCT is high, otherwise it has limited interpretability. This is because high MP alone cannot reveal how interpretable a topic is as the topic is differentiable from an outlier term.

		MP	
		Low	**High**
MPCT	**High**	Uninterpretable	Interpretable
	Low	Uninterpretable	Uninterpretability Masked by Outliers

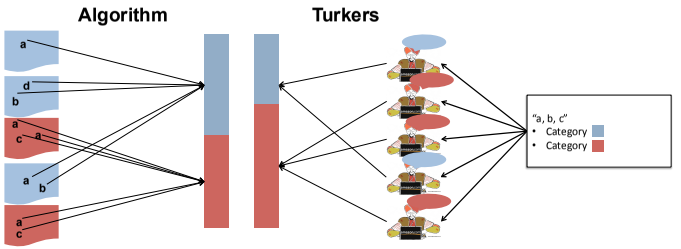


Figure 7: An overview of the setup of the topic consensus framework. The left stacked bar comes from the categories of the documents in which tokens appear. The right stacked bar comes from the aggregate of the Turker answers.

5. Topic Consensus

Understanding the underlying distribution of concepts in a topic is important. Since LDA is a mixture model, we can expect some of the topics identified by this model to contain a mixture of different topics. This phenomenon has been documented in the literature as "chimera" topics (Schmidt, 2012). Being able to identify these topics effectively is important, but we currently do not know how well crowdsourced workers will be able to identify them. In this section we propose a measure, "topic consensus," which measures how well the mixture of the documents in the LDA topic matches the mixture of labels from the workers.

Unlike topic coherence, topic consensus measures how well the results of a mixture of labels given by a group of human subjects match those given categories of topics, or human labels of topics. The "eyeballing" approach to topic interpretability, as discussed in Section 2.2.1 is the process of manually reading a topic and assigning it a title. These are explicit

titles such as "Environment", and "Judiciary" categories from congressional records (Grimmer and Stewart, 2013), or "disaster-related" categories from social media (Kireyev et al., 2009). Each title requires a human being to manually read these topics and to assign these category labels. Presumably, good topics should lead to good categories, thus, high topic consensus. Therefore, if there is low topic consensus in terms of categories, topics could be of low interpretability.

5.1 A New Measure for Topic Consensus

We discuss how well the topics from topic modeling conform to the natural categories underlying the text. Explicit topic categories are often present in many corpora, such as newspaper articles, due to their manual categorization by "sections" or categories. For example, our ERC abstracts which explicitly label each abstract with an ERC category, and we measure this conformity to the underlying topic distribution by leveraging the ground-truth topic category labels available as the ERC categories when the abstract is submitted.

The Turkers' answers reveal the labels that are assigned to topics. By showing the categories to the Turkers as multiple choice questions we can see the category label that a human would assign to the topic. Ideally, we would additionally ask the Turkers to assign confidence scores to their labels to better understand their labeling strategy and to get a better distribution of the category labels. However, since humans are bad at answering questions about themselves (i.e. their own internal confidence) (Bernard and Ryan, 2009), we instead ask many Turkers the same question about the same topic and aggregate the responses. By aggregating the category assignment of Turkers, we can obtain a distribution based on their understanding of the topic.

To understand how well the statistical topics mimic the underlying topics, we show the Turkers the top 20 words of a statistical topic and ask them to choose which of the three categories from that corpus the topic describes. For example, for a given ERC topic, we show the top 20 words along with options for "Life Sciences", "Physical Sciences", or "Social Sciences". We also provide a fourth option, "No Topic Matched", in case that any of the three categories do not make sense to the Turker. This is depicted in the right half of Figure 7, where Turkers are shown the HIT including top 3 words with 2 categories, and their answers are aggregated to make the distribution of Turker answers. In the figure, instead of 20 top words, top 3 words "a", "b", and "c" are chosen to be presented to Turkers.

To compute topic consensus, we compare the distribution of the Turkers' responses for that topic with the distribution of the topic over the ERC categories. To perform this analysis, we construct an LDA Topic × Category matrix $\mathbf{R}$, where $\mathbf{R}_{i,c}$ indicates topic i's probability of occurring in ERC category c. This can be seen in the lefthand side of Figure 7, where the tokens that are labeled with the topic are aggregated based upon the category label of the document they appear in to form the category distribution.

The structure of each row of $\mathbf{R}$ is dependent on the type of topic group it comes from. We construct the row of $\mathbf{R}$, which correspond to the automated distributions, as follows for each topic group:

- **ERC-* / News-*** — The $\mathbf{R}_i$ row vector for an ERC topic is created by taking the sum of the columns of the $\mathbf{D}$ matrix, as defined in Section 3.1. This sum is taken for each row (document) of $\mathbf{D}$ labeled with the corresponding ERC category. This is defined as:

$$\mathbf{R}_{i,c} = \frac{\sum_{j \in M_c} \mathbf{D}_{j,i}}{\sum \mathbf{D}_{*,i}}, \tag{5}$$

  where M_c is the set of documents containing the label corresponding to the column of $\mathbf{R}$, e.g., "SH", "LS", or "PE". This gives us an understanding of the category makeup for each LDA topic.

- **ERCSanitySH-010 / NewsSanityS-010** — The $\mathbf{R}_i$ row vector for an SH topic contains a 1 for the sanity category and a 0 for the others. This is due to the way the topics are generated, they contain purely words from that topic.

- **ERCRand-010 / NewsRand-010** — Turkers should not be able to read any definition from a random topic as it consists of random words from the vocabulary. Thus, the row vector for each topic in this set is a 1 for the "N/A" category, and a 0 for the other categories.

Using the responses from the Turkers, we build a separate $Topic \times Category$ matrix, $\mathbf{R^{AMT}}$ where $\mathbf{R^{AMT}}_{i,j}$ represents the Turkers' probability of choosing category j when presented with topic i. In this way, $\mathbf{R^{AMT}}$ is the representation of $\mathbf{R}$ obtained from the Turkers' responses. A row in $\mathbf{R^{AMT}}$ indicates the distribution over categories for a given LDA topic from the Turker's responses.

The consensus between the responses from the crowdsourced workers and the data is defined as:

$$\text{consensus}_t^m = 1 - \frac{JS(\mathbf{R^{AMT}}_t || \mathbf{R}_t)}{log_2(|c|+1)}, \tag{6}$$

where $|c|$ is the number of categories in the datasets (both the ERC and News datasets have $|c| = 3$ categories). We add 1 to account for the presence of the N/A answer. JS is the Jensen-Shannon divergence (Lin, 1991) between the two distributions $JS(\mathbf{R^{AMT}}_t || \mathbf{R}_t)$, defined as:

$$JS(\mathbf{R^{AMT}}_t || \mathbf{R}_t) = \frac{K(\mathbf{R^{AMT}}_t || M) + K(\mathbf{R}_t || M)}{2}, \tag{7}$$

where K is Kullback-Leibler divergence (Joyce, 2011), and $M = \frac{1}{2}(\mathbf{R^{AMT}}_t + \mathbf{R}_t)$. Jensen-Shannon is a natural choice as the rows of $\mathbf{R}$ and $\mathbf{R^{AMT}}$ are probability distributions over the 3 ERC or News categories and Jensen-Shannon is a measure of the similarity of two distributions. Jensen Shannon is bounded from $[0, log_2(|c|+1)]$; we divide by the upper bound to yield a number from $[0, 1]$. Finally, Jensen Shannon is a measure of *divergence*, meaning that a lower score means that the distributions are more aligned. Thus, we subtract the Jensen Shannon divergence from 1 in order to stay consistent with a consensus measure, where greater consensus means a better topic.

5.2 Topic Consensus Results

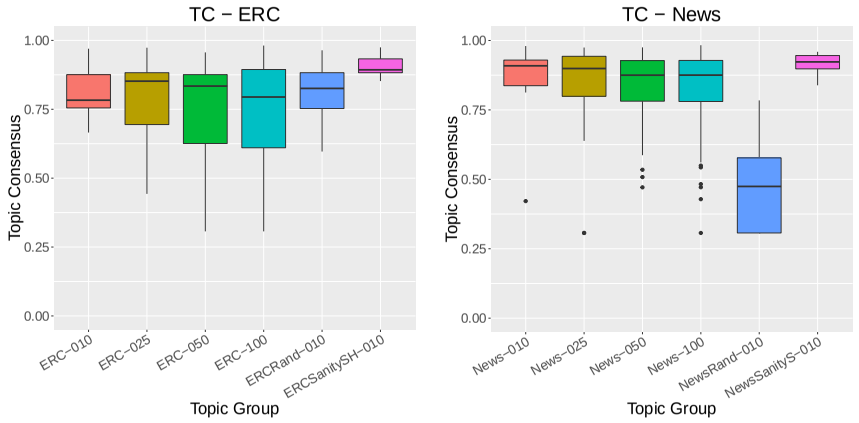
The results of the topic consensus experiment are shown in Figure 8. The results of both datasets indicate that the random topics perform worse than and the sanity topics perform better than the LDA topics. The results make sense: Sanity topics should have the highest

Table 6: Confusion matrix of ground truth ERC category assignments of topics against the category assignments made by the Turkers, taken from the outer product of the respective probability distributions. Rows are from the turkers, and columns are from LDA. In the ERC topics, we see that the Turkers are generally able to identify SH and LS topics, but overall fail to identify PE topics. The Turkers perform well when shown random topics, giving most of these topics a "not applicable" label.

	ERC-*				**ERCRand-010**				**ERCSanitySH-010**			
	Ground Truth											
	LS	SH	PE	NA	LS	SH	PE	NA	LS	SH	PE	NA
AMT Classification												
LS	29.69	5.21	13.39	0	0	0	0	0.59	0	0.09	0	0
SH	7.96	8.12	10.36	0	0	0	0	3.09	0	9.66	0	0
PE	16.62	8.14	36.21	0	0	0	0	0.61	0	0.11	0	0
NA	16.41	9.38	23.48	0	0	0	0	5.71	0	0.14	0	0
	News-*				**NewsRand-010**				**NewsSanityS-010**			
	Ground Truth											
	S	B	E	NA	S	B	E	NA	S	B	E	NA
AMT Classification												
S	35.31	7.74	8.36	0.00	0	0	0	4.26	9.84	0	0	0
B	9.88	50.00	8.61	0.00	0	0	0	1.96	0.04	0	0	0
E	10.00	7.12	21.67	0.00	0	0	0	2.60	0.08	0	0	0
NA	9.10	9.81	7.40	0.00	0	0	0	1.17	0.04	0	0	0

consensus and random topics the lowest consensus, and the performance of the other three topic models are in between.

To further investigate these answers we show a "confusion matrix" that compares the Turkers' responses with the ground truth in Table 6. Each cell in the matrix is the aggregation of the Turker's responses with the max of all the Turkers taken as the result. This is obtained from the sum of the outer product of the probability distributions from both the turkers (rows), and LDA (columns). The results for ERC-* and News-* topic sets show that most of the topics are understandable. In the case of the "PE" class in the ERC-* distribution, $\frac{52}{52+60+8+2} = 43\%$ of the topics are misclassified as NA. This could be because of the highly technical language in the physical sciences topics which causes users to select "NA". On the other hand the "SH" topics in the ERC corpus and the "B" topics in the News corpus are perfectly, and nearly-perfectly understood respectively. The sanity topics in both corpora achieve perfect scores. Finally, the random topics are vastly different between the two datasets. The random topics in the ERC corpus achieved 80% accuracy, however in the News domain the accuracy is 10%, with most of the misinterpretations leading the Turkers to categorize random topics as sports. We conjecture that the misclassification of sports may be a byproduct of the specific language of sports documents. For example, once a Turker sees a word like "football" in a random topic, they may be inclined to think that the topic is a sports topic.



(a) ERC (b) News

Figure 8: Topic consensus scores across all models across both corpora. Higher scores are better. On the left we see the form that is shown to the workers. On the right we see that the random topics perform worse than any of the ERC topics, and the SH topics perform the best.

5.3 Using Topic Interpretability Measures

We have employed three measures to identify interpretable topics from topic models thus far: Model Precision, Model Precision Choose Two, and Topic Consensus. At this point we will step back and discuss how to use these measures. There are two clear ways to use these measures. The first is for model selection, and the second is for topic selection.

Model selection is the process of choosing one model out of many (Kohavi et al., 1995). When selecting models for interpretability, we may choose the one that performs best. In the case of the News data, the model constructed with $K = 10$ performs best according to Topic Consensus, and the Model Precision Choose Two measures. Therefore, this model is the best one to choose from the perspective of interpretability.

The other strategy is topic selection. It may be that we are only using topic modeling to describe our dataset, and that we do not need the entire model in order to proceed. In this case, we can use the results of our topic interpretability measures to select a subset of topics that have high interpretability. This is favorable in cases where we need more topics. For example, in the case of Topic Consensus on the ERC data (Figure 8 (a)), we see that the median of $K = 25$ outperforms that of $K = 100$. However, the top quartile of $K = 25$ is worse than $K = 100$. This means that 25 of the 100 topics generated by the $K = 100$ model are, on average, better than the top 6 topics generated by the $K = 25$ model. Thus, if we are looking for topics which can help us to better understand our dataset, we may

decide to use topic selection with a larger K and use the interpretability measures proposed in this work to separate interpretable topics from less-interpretable ones.

6. Automating Measures of Topic Interpretability

In search of measures for topic interpretability, we resort to crowdsourcing approaches to measuring coherence and topic consensus. A natural question is whether we can replace crowdsourcing with automated measures. Crowdsourcing approaches could be costly, or not scalable without funds to recruit a sufficient numbers of Turkers. Furthermore, their results are hard to reproduce without good resources. In short, they present challenges in terms of scalability and reproducibility. The search for automated measures could replace Turkers and make empirical comparison available, saving researchers both time and cost of performing crowdsourced experiments. In this section, therefore, we investigate measures that can be used to automatically measure interpretable topics in terms of coherence and consensus. Mimno et al. (2011) are among researchers who first try to automate evaluation measures. They generated topics from medical literature and hired physicians, who are subject matter experts in their fields, to rate the quality of topics. They then proposed automated measures, Topic Size and Semantic Coherence, to replace these experts for reproducibility. Newman et al. (Newman et al., 2010) proposed a measure based on Pointwise Mutual Information. Aletras and Stevenson (2013) measured the quality of topics by inspecting the vector similarity between them. Morstatter et al. (2015) found that the peakedness of the distribution can be used to find interpretable topics. In the following, we introduce these measures, examine their correlations with the three measures of topic interpretability in this work, and then investigate if any of these automated measures can be used to accurately predict measures of topic coherence and topic consensus without the aid of the Turkers.

6.1 Automatic Topic Interpretability Measures

We introduce methods used for automatically assessing the quality of topics. Eight measures are given below:

i. **Topic Size (TS):** LDA soft assigns documents to topics by hard assigning the tokens within the document to a topic. At the end of training, each token in the corpus will have a topic assigned to it. "Topic Size" is the count of the number of tokens in the input corpus that are assigned to the topic after training. This was used in Mimno et al. (2011) as a possible measure for topic quality. The hypothesis behind this measure is that a larger topic (with more tokens) will represent more of the corpus, and thus will reveal a larger portion of the information within it.

ii. **Semantic Coherence (SC):** Also introduced by Mimno et al. (2011), this measures the probability of top words co-occuring within documents in the corpus:

$$SC(\mathbf{w}) = \sum_{j=2}^{|\mathbf{w}|} \sum_{k=1}^{j-1} log \frac{D(\mathbf{w}_j, \mathbf{w}_k) + 1}{D(\mathbf{w}_k)}, \tag{8}$$

where $\mathbf{w}$ is a vector of the top words in the topic sorted in descending order, and D is the number of documents containing all of the words provided as arguments. This measure is computed on the top 20 words of the topic.

iii. **Semantic Coherence Significance (SCS):** We adapt the **SC** measure above to understand the significance of the top words in the topic when compared to a random set of words. To calculate this measure we select 100 groups of words at random, following the topic's word distribution. We then recompute the Semantic Coherence measure for each of the random topics, obtaining a vector, $\mathbf{d}$, of topic coherence scores. We calculate the mean, $\bar{\mathbf{d}}$, and standard deviation, $std(\mathbf{d})$. Significance is defined as:

$$SCS(\mathbf{w}) = \frac{SC(\mathbf{w}) - \bar{\mathbf{d}}}{std(\mathbf{d})}. \tag{9}$$

iv. **Normalized Pointwise Mutual Information (NPMI):** Introduced by Bouma (2009), this metric measures the probability that two random variables coincide. This measure was used to estimate the performance of Model Precision in Lau et al. (2014), where the authors adapted it to measure the coincidence of the top $|\mathbf{w}|$ words. In this paper, two variables "coinciding" is the probability that they will co-occur in a document. The authors named this version OC-Auto-NPMI, formally:

$$\text{OC-Auto-NPMI}(\mathbf{w}) = \sum_{j=2}^{|\mathbf{w}|} \sum_{k=1}^{j-1} \frac{log \frac{P_D(\mathbf{w}_j, \mathbf{w}_k)}{P_D(\mathbf{w}_j) P_D(\mathbf{w}_k)}}{-log(P_D(\mathbf{w}_j, \mathbf{w}_k))}, \tag{10}$$

where $P_D(\cdot) = D(\cdot)/|N|$, where $|N|$ is the number of documents in the corpus. P_D measures the probability that a document in the corpus contains the words given to $D(\cdot)$. Going forward, we will refer to this measure as NPMI.

v. **Category-Distribution HHI (Cat-HHI):** The Herfindahl-Hirschman Index (Hirschman, 1945), or HHI, is a measure proposed to find the amount of competition in a market. This is calculated by measuring the market share of each firm in the market, formally:

$$HHI = \frac{(H - 1/N)}{(1 - 1/N)}, \tag{11}$$

Where $H = \sum_i s_i^2$, N is the number of firms in the market, and s_i is the market share of firm i, as a percentage. HHI ranges from 0 to 1, with 1 being a perfect monopoly (no competition), and 0 being an evenly split market. In this way we measure how focused the market is on a particular firm.

By treating the corpus categories as firms, and the market share distribution as $\mathbf{R}_i$, we can calculate how focused each topic is around a particular category.

vi. **Topic-Probability HHI (TP-HHI):** Using the same formulation as ERC-HHI, this time we treat every *word* in the vocabulary as a firm, and $\mathbf{T}_i^m$ as the probability distribution. In other words, the topic's probability distribution is the market, and TP-HHI measures the market's focus any word, or group of words. This measure varies from other significance measures, such as AlSumait et al. (2009), in that it focuses

purely on the peakedness of the distribution. This measures whether the focus of a topic is around a handful of words, or whether it is evenly spread across the entire vocabulary used to train the model.

vii. **No. of Word Senses:** The total number of word senses, according to WordNet, of the top five words in the topic. This varies slightly from the measure proposed in (Chang et al., 2009), where the authors also consider the intruded word. Because the intruded word is generally far away, we exclude it from our calculation.

viii. **Avg. Pairwise JCD:** The Jiang-Conrath (Jiang and Conrath, 1997) distance (JCD) is a measure of *semantic similarity*, or coherence, that considers the lowest common subsumer according to WordNet. Here we compute the average JCD of all $\binom{5}{2} = 10$ pairs of the top five words of the topic. This approach was introduced by (Chang et al., 2009), however we modify it slightly to only consider the topic's top five words.

ix. **Lesk Similarity:** The Lesk Algorithm (Banerjee and Pedersen, 2002) for word sense disambiguation uses WordNet to identify the most appropriate synset for an ambiguous word given a context. Following the use of this algorithm in (Newman et al., 2010), we adopt this technique in our automated measures. To turn the synset returned by this algorithm into a similarity measure, we evaluate the path similarity from the synset returned by this algorithm and all of the synsets in the context. The "context" is defined as the top 5 words in the topic, and the "ambiguous word" is the intruded word. When applying this to consensus, we use the same intruded word as in the MP and MPCT case.

6.2 Correlation with Crowdsourced Measures of Topic Interpretability

To see how well these automatic topic measures compare with the crowdsourced topic measures from the "Topic Interpretability" section, we calculate the Spearman's ρ (Spearman, 1904) rank correlation coefficient between the crowdsourced measure and the automatic measure. The correlations between each pair of crowdsourced and automatic measure are shown in Table 7. In this table, we present the Spearman's ρ, as well as an indication of the significance level for the following hypothesis test:

H_0 : The two sets of data are uncorrelated.

Instances where the hypothesis is rejected at the $\alpha = 0.05$ significance level are shown in Table 7. We see that the measure most correlated with Model Precision and Model Precision Choose Two (MPCT) is Avg. Pairwise JCD, meaning that documents whose words have a higher semantic similarity are more likely to achieve higher Model Precision (MP) values. We see that higher (better) values of Model Precision are accompanied by higher average JCD values. Table 7 shows the measure most correlated with Topic Consensus (TC) is TP-HHI. These correlations lead us to the next question: can we predict each of the three measures (MP, MPCT, and TC) of topic interpretability based on their correlations?

6.3 Predicting Crowdsourced Values of Topic Interpretability Measures

While correlation can be used to find the quality of a measure, we further ask if it is feasible to predict the *actual* value of the topics' crowdsourced measures. At first it may seem that

Table 7: Spearman's ρ between measures requiring Mechanical Turk and automated measures. Instances where we reject the null hypothesis at the significance level of $\alpha = 0.05$ are denoted with *, and instances where we reject the null hypothesis at the significance level of $\alpha = 10^{-4}$ are denoted with **.

	ERC-*			**News-***

Lesk	0.050	-0.034	0.189*	0.533**	0.503**	0.442**

Table 8: Errors of the predictive algorithm trained on all of the automated measures. Results are presented as RMSE $\pm$ the standard deviation. These results indicate that Topic Consensus is the most predictable.

	Model Precision	Model Precision Choose Two	Topic Consensus
ERC-*	0.280 ± 0.039	0.352 ± 0.064	0.131 ± 0.021
News-*	0.239 ± 0.049	0.307 ± 0.075	0.114 ± 0.034

the most correlated measure may be the most predictive, however, due to nonlinear patterns within the data this may not be the case. In this section, we investigate if we can predict the true scores of topic interpretability by using the above eight automated measures.

We train a linear regression model to predict the true value of the crowdsourced measures using the automated measures. We build three models: one where the dependent variable is "Model Precision" (MP), another where it is "Model Precision Choose Two" (MPCT), and the other where the dependent variable is "Topic Coherence" (TC). In all three cases, the independent variables are all of the automated measures introduced previously. We use 10-fold cross validation and report both the mean and standard deviation of the performance of the models across all 10 runs in Table 8. These results indicate that it is easiest to predict the raw scores of Topic Consensus, and that it is the hardest to predict those of Model Precision Choose Two. An advantage of this prediction approach is that it allows for inclusion of new automated measures in order to increase the predictive capability of the prediction model.

7. Conclusion and Future Work

Statistical topic models are a key component for machine learning, NLP, and the social sciences. In this work we investigate different measures for the interpretability of the topics generated by these approaches. We view topic interpretability from two perspectives: *topic coherence* and *topic consensus*. Coherence measures how semantically close the top words of a topic are. Consensus measures the agreement between the mixture of labels assigned by the humans and the mixture of labels from the documents assigned to the topic. We investigate what is needed for comprehensive measure of each perspective, understand how different these measures for topic coherence and consensus are, and show their experimental results using real-world datasets.

For topic coherence, we study Model Precision (MP) and propose Model Precision Choose Two (MPCT). The two measures complement each other to better measure the semantic closeness of topic words. MP works by making sure that the topic words should be far away from the intruded word. Additionally, MPCT complements MP by addressing the closeness of the 5 words within the topic. We compare MPCT with MP and show how these two measures can work in tandem to identify interpretable topics. One natural question that can arise from the MPCT setup is why only two words are requested, when in fact any number of words could be asked for. While this is theoretically attractive, the practical implications for the Turkers can present a challenge. By asking them to select one intruder and one additional word, we present a small, viable workload for the Turkers. Finding more strategies to effectively measure coherence is an area for future work.

For topic consensus, we assess how well the workers' aggregate understanding of the topic matches the aggregate of the categories provided by the corpus. In both corpora, each document is tagged with a category. When we train a topic model, each topic will ultimately be a mixture of these categories. This method reveals how well the topics generated can be understood in relation to the underlying categories in the corpus. One natural application of this measure is to identify chimera topics, *i.e.* those topics that are split between two concepts or categories. Furthermore, by inspecting the Turker's results on known topics, we can see the bounds of this measure on extremely good, and extremely bad topics.

All three measures of topic interpretability rely on crowdsourcing platforms, which motivates a need to automate them in order to improve reproducibility and scalability. Recreating these results with human workers requires significant investments of time to recruit the workers, as well as funds to pay them. We investigate how to estimate these crowdsourced topic measures without the need of crowdsourcing tools such as Mechanical Turk. We find some automated measures that are highly correlated with crowdsourced measures (MP, MPCT, and TC), allowing researchers to reproduce these topic quality measures at scale. In addition, we propose to construct a prediction model for predicting MP, MPCT, and TC based on the automated measures. This prediction model can take advantage of new automated measures to improve their predictive power.

Topic interpretability is a challenge to the problem of topic quality assessment. This work makes extensive efforts to solidify its measurement via topic coherence and topic consensus and demonstrates that both coherence and consensus can help understand topic interpretability. More research remains to be done. One direction for future work is to catalogue the performance of all crowdsourced measures across more and different datasets

to provide a benchmark for different types of data. This is because different types of data intuitively require corresponding crowdsourced measures. Model Precision Choose Two was designed to measure an additional dimension of topic interpretability, however increasing the number of words the turker should choose may lead to more dimensions of interpretability. Future work also includes investigating different models, e.g., those that take K out of the equation, as is the case with nonparametric topic models such as Hierarchical Dirichlet Processes (Teh et al., 2006). New NLP models offer new semantic properties, such as word embeddings which attempt to embed words with similar semantic meanings closer together. Designing measures for these properties is an important area for future work. Additionally, there is more work to be done in how the setup changes the output of these measures. For example, in the "topic consensus" results, we noted that words like "football" may draw a Turker to think that a topic is a sports topic more strongly than words like "field", or "goal". Challenges such as this provide exciting research directions in this area.

On the Behavior of Intrinsically High-Dimensional Spaces: Distances, Direct and Reverse Nearest Neighbors, and Hubness

Abstract

Over the years, different characterizations of the curse of dimensionality have been provided, usually stating the conditions under which, in the limit of the infinite dimensionality, distances become indistinguishable. However, these characterizations almost never address the form of associated distributions in the finite, although high-dimensional, case. This work aims to contribute in this respect by investigating the distribution of distances, and of direct and reverse nearest neighbors, in intrinsically high-dimensional spaces. Indeed, we derive a closed form for the distribution of distances from a given point, for the expected distance from a given point to its kth nearest neighbor, and for the expected size of the approximate set of neighbors of a given point in finite high-dimensional spaces. Additionally, the hubness problem is considered, which is related to the form of the function N_k representing the number of points that have a given point as one of their k nearest neighbors, which is also called the number of k-occurrences. Despite the extensive use of this function, the precise characterization of its form is a longstanding problem. We derive a closed form for the number of k-occurrences associated with a given point in finite high-dimensional spaces, together with the associated limiting probability distribution. By investigating the relationships with the hubness phenomenon emerging in network science, we find that the distribution of node (in-)degrees of some real-life, large-scale networks has connections with the distribution of k-occurrences described herein.

Keywords: high-dimensional data, distance concentration, distribution of distances, nearest neighbors, reverse nearest neighbors, hubness

1. Introduction

Although the size and the dimensionality of collected data are steadily growing, traditional techniques usually slow down exponentially with the number of attributes to be considered and are often overcome by linear scans of the whole data. In particular, the term *curse of dimensionality* (Bellmann, 1961), is used to refer to difficulties arising whenever high-dimensional data has to be taken into account.

One of the main aspects of this curse is known as *distance concentration* (Demartines, 1994), which is the tendency for distances to become almost indiscernible in high-dimensional spaces. This phenomenon may greatly affect the quality and performances of machine learning, data mining, and information-retrieval techniques. This effect results because almost all these techniques rely on the concept of distance, or dissimilarity, among data items in order to retrieve or analyze information. However, whereas low-dimensional spaces show good agreement between geometric proximity and the notion of similarity, as dimensionality increases, different counterintuitive phenomena arise that may be harmful to traditional techniques.

Over time, different characterizations of the curse of dimensionality and related phenomena have been provided (Demartines, 1994; Beyer et al., 1999; Aggarwal et al., 2001; Hinneburg et al., 2000; François et al., 2007). These characterizations usually state conditions under which, according to the limits of infinite dimensionality, distances become indistinguishable. However, almost never do these conditions address the form of associated distributions in finite, albeit high-dimensional, cases.

This work aims to contribute in this area by investigating the distribution of distances and of some related measures in intrinsically high-dimensional data. In particular, the analysis is conducted by applying the central limit theorem to the Euclidean distance random variable to approximate the distance probability distribution between pairs of random vectors, between a random vector and realizations of a random vector, and to obtain the expected distance from a given point to its kth nearest neighbor. It is then shown that an understanding of these distributions can be exploited to gain knowledge of the behavior of high-dimensional spaces, specifically the number of approximate nearest neighbors and the number of reverse nearest neighbors that are also investigated herein.

Nearest neighbors are transversal to many disciplines (Preparata and Shamos, 1985; Dasarathy, 1990; Beyer et al., 1999; Duda et al., 2000; Chávez et al., 2001; Shakhnarovich et al., 2006). In order to try to overcome the difficulty of answering nearest neighbor queries in high-dimensional spaces (Weber et al., 1998; Beyer et al., 1999; Pestov, 2000; Giannella, 2009; Kabán, 2012), the concept of the ϵ-approximate nearest neighbor (Indyk and Motwani, 1998; Arya et al., 1998) has been introduced. The ϵ-neighborhood of a query point is the set of points located at a distance not greater than $(1+\epsilon)$ times the distance separating the query from its true nearest neighbor.
