Interested readers can find discussions regarding why such changes are natural in Allen-Zhu and Orecchia (2017). We call the resulting algorithms `Katyusha2` and `Katyusha2`$^{\mathsf{ns}}$, and include them in Appendix E for completeness' sake. We state our final theorems below (recall $\overline{L} = \frac{1}{n}\sum_{i=1}^n L_i$).

Theorem 6.1 (ext. of Theorem 2.1) *If each $f_i(x)$ is convex and L_i-smooth with respect to some norm $\|\cdot\|$, $V_x(y)$ is a Bregman divergence function for $\|\cdot\|$, and $\psi(x)$ is σ-strongly convex with respect to $V_x(y)$, then* `Katyusha2`$(x_0, S, \sigma, (L_1, \dots, L_n))$ *satisfies*

$$\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \begin{cases} O\Big(\Big(1 + \sqrt{\sigma/(9\overline{L}m)}\Big)^{-Sm}\Big) \cdot \big(F(x_0) - F(x^*)\big), & \text{if } m\sigma/\overline{L} \le \frac{9}{4}; \\ O\big(1.5^{-S}\big) \cdot \big(F(x_0) - F(x^*)\big), & \text{if } m\sigma/\overline{L} > \frac{9}{4}. \end{cases}$$

In other words, choosing $m = \Theta(n)$, `Katyusha2` *achieves an ε-additive error (i.e., $\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \varepsilon$) using at most $O\big(\big(n + \sqrt{n\overline{L}/\sigma}\big) \cdot \log \frac{F(x_0)-F(x^*)}{\varepsilon}\big)$ iterations.*

Theorem 6.2 (ext. of Theorem 4.1) *If each $f_i(x)$ is convex and L_i-smooth with respect to some norm $\|\cdot\|$, $V_x(y)$ is a Bregman divergence function for $\|\cdot\|$, and $\psi(\cdot)$ is not necessarily strongly convex, then* `Katyusha2`$^{\mathsf{ns}}(x_0, S, (L_1, \dots, L_n))$ *satisfies*

$$\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le O\Big(\frac{F(x_0) - F(x^*)}{S^2} + \frac{\overline{L}V_{x_0}(x^*)}{nS^2}\Big) \ .$$

In other words, `Katyusha2`$^{\mathsf{ns}}$ *achieves an ε-additive error (i.e., $\mathbb{E}\big[F(\widetilde{x}^S)\big] - F(x^*) \le \varepsilon$) using at most $O\Big(\frac{n\sqrt{F(x_0)-F(x^*)}}{\sqrt{\varepsilon}} + \frac{\sqrt{nLV_{x_0}(x^*)}}{\sqrt{\varepsilon}}\Big)$ iterations.*

The proofs of Theorem 6.1 and Theorem 6.2 follow exactly the same proof structures of Theorem 2.1 and Theorem 4.1, so we include them only in Appendix E.

6.2 Remarks

We highlight one main difference between the proof of `Katyusha2` and that of `Katyusha`: if ξ is a random vector and $\|\cdot\|$ is an arbitrary norm, we do not necessarily have $\mathbb{E}[\|\xi-\mathbb{E}[\xi]\|_*^2] \le \mathbb{E}[\|\xi\|_*^2]$. Therefore, we only used $\mathbb{E}[\|\xi-\mathbb{E}[\xi]\|_*^2] \le 2\mathbb{E}[\|\xi\|_*^2]+2\|\mathbb{E}[\xi]\|_*^2$ (see Lemma E.2) and this loses a constant factor in some parameters. (For instance, α now becomes $\frac{1}{9\tau_1\overline{L}}$ as opposed to $\frac{1}{3\tau_1 L}$).

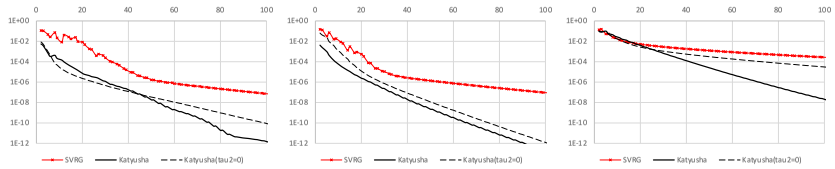
More interestingly, one may ask how our revised algorithms `Katyusha2` or `Katyusha2`$^{\mathsf{ns}}$ perform in the mini-batch setting (just like we have studied in Section 5 for the Euclidean case). We are optimistic here, but unfortunately do not have a clean worst-case statement for how much speed-up we can get. The underlying reason is that, if $\mathcal{D}$ is a distribution for vectors, $\mu = \mathbb{E}_{\xi\sim\mathcal{D}}[\xi]$ is its expectation, and $\xi_1,\dots,\xi_b$ are b i.i.d. samples from $\mathcal{D}$, then letting $\overline{\xi} = \frac{1}{b}(\xi_1+\cdots+\xi_b)$, we do not necessarily have $\mathbb{E}[\|\overline{\xi}-\mu\|_*^2] \le \frac{1}{b}\mathbb{E}_{\xi\sim\mathcal{D}}[\|\xi-\mu\|_*^2]$. In other words, using a mini-batch version of the gradient estimator, the "variance" with respect to an arbitrary norm may not necessarily go down by a factor of b. For such reason, in the mini-batch setting, the best total work we can cleanly state, say for `Katyusha2` in the SC setting, is only $O\Big(\big(n+\sqrt{bn\overline{L}/\sigma}\big)\cdot\log\frac{F(x_0)-F(x^*)}{\varepsilon}\Big)$.

7. Empirical Evaluations

We conclude this paper with empirical evaluations to our theoretical speed-ups. We work on Lasso and ridge regressions (with regularizer $\frac{\lambda}{2}\|x\|^2$ for ridge and regularizer $\lambda\|x\|_1$ for Lasso) on the following six datasets: adult, web, mnist, rcv1, covtype, sensit. We defer dataset and implementation details to Appendix B.

Algorithms and Parameter Tuning. We have implemented the following algorithms, all with mini-batch size 1 for this version of the paper:

- SVRG (Johnson and Zhang, 2013) with default epoch length $m = 2n$. We tune only *one parameter*: the learning rate.
- `Katyusha` for ridge and `Katyusha`$^{\mathsf{ns}}$ for Lasso. We tune only *one parameter*: the learning rate.
- SAGA (Defazio et al., 2014). We tune only *one parameter*: the learning rate.
- Catalyst (Lin et al., 2015) on top of SVRG. We tune *three parameters*: SVRG's learning rate, Catalyst's learning rate, as well as the regularizer weight in the Catalyst reduction.
- APCG (Lin et al., 2014). We tune the learning rate. For Lasso, we also tune the ℓ_2 regularizer weight.
- APCG+AdaptReg (Lasso only). Since APCG intrinsically require an ℓ_2 regularizer to be added on Lasso, we apply AdaptReg from Allen-Zhu and Hazan (2016b) to adaptively learn this regularizer and improve APCG's performance. Two parameters to be tuned: APCG's learning rate and σ_0 in AdaptReg.



(a) web, ridge $\lambda = 10^{-6}$ (b) mnist, ridge $\lambda = 10^{-6}$ (c) rcv1, ridge $\lambda = 10^{-6}$

Figure 1: Comparing SVRG vs. `Katyusha` vs. `Katyusha` with $\tau_2 = 0$.

All of the parameters were equally, fairly, and automatically tuned by our code base. For interested readers, we discuss more details in Appendix B.

We emphasize that `Katyusha` is *as simple as SAGA or SVRG in terms of parameter tuning*. In contrast, APCG for Lasso requires two parameters to be tuned, and Catalyst requires three. (Lin, 2016)

Performance Plots. Following the tradition of ERM experiments, we use the number of "passes" of the dataset as the x-axis. Letting n be the number of feature vectors, each new stochastic gradient computation $\nabla f_i(\cdot)$ counts as $1/n$ pass, and a full gradient computation $\nabla f(\cdot)$ counts as 1 pass.

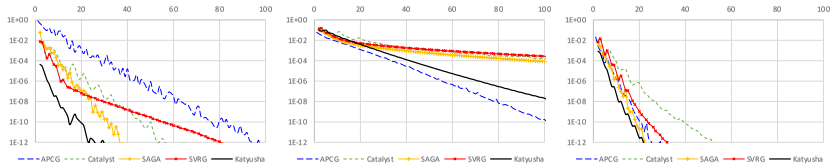
The y-axis in our plots represents the training objective distance to the minimum. Since we aim to evaluate our theoretical finding, we did not include the test error. We emphasize that it is practically also crucial to study high-accuracy regimes (such as objective distance $\le 10^{-7}$). This is because nowadays there is an increasing number of methods that reduce large-scale machine learning tasks to multiple black-box calls to ERM solvers (Allen-Zhu and Li, 2017b,a; Frostig et al., 2016). In all such applications, due to error blowups between oracle calls, the ERM solver is required to be *very accurate in training error*.

7.1 Effectiveness of Katyusha Momentum

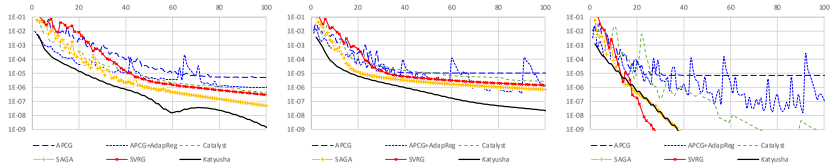
In our `Katyusha` method, τ_1 controls to the classical Nesterov's momentum and τ_2 controls our newly introduced Katyusha momentum. We find in our theory that setting $\tau_2 = 1/2$ is a good choice so we universally set it to be $1/2$ without tuning in all our experiments. (Of course, if time permits, tuning τ_2 could only help in performance.)

Before this paper, researchers have tried heuristics that is to add Nesterov's momentums directly to stochastic gradient methods (Nitanda, 2014), and this corresponds to setting $\tau_2 = 0$ in `Katyusha`. In Figure 1, we compare `Katyusha` with $\tau_2 = 1/2$ and $\tau_2 = 0$ in order to illustrate the importance and effectiveness of our Katyusha momentum.

We conclude that the old heuristics (i.e., $\tau_2 = 0$) sometimes indeed make the method faster after careful parameter tuning. However, for certain tasks such as Figure 1(c), without Katyusha momentum the algorithm does not even enjoy an accelerated convergence rate.



(a) covtype, ridge $\lambda = 10^{-6}$ (small) (b) rcv1, ridge $\lambda = 10^{-7}$ (small) (c) adult, ridge $\lambda = 10^{-4}$ (large)



(d) web, ridge $\lambda = 10^{-6}$ (small) (e) mnist, ridge $\lambda = 10^{-6}$ (small) (f) sensit, ridge $\lambda = 10^{-4}$ (large)

Figure 2: Some representative performance charts where λ is the regularizer weight. See Figure 3 and Figure 4 in the appendix for the full plots.

7.2 Performance Comparison Across Algorithms

For each of the six datasets and each objective (ridge or lasso), we experiment on three different magnitudes of regularizer weights.[18] This totals 36 performance charts, and we include them in full at the end of this paper. For the sake of cleanness, in Figure 2 we select 6 representative charts for ridge regression and make the following observations.

- Accelerated methods are more powerful when the regularizer weights are small (cf. Shalev-Shwartz and Zhang (2014); Allen-Zhu et al. (2016c); Lin et al. (2014)). For instance, Figure 2(c) and 2(f) are for large values of λ and `Katyusha` performs relatively the same as compared with SVRG / SAGA; however, `Katyusha` significantly outperforms SVRG / SAGA for small values of λ, see for instance Figure 2(b) and 2(e).
- `Katyusha` almost always either outperform or equal-perform its competitors. The only notable place it gets outperformed is by SVRG (see Figure 2(f)); however, this performance gap cannot be large because `Katyusha` is capable of recovering SVRG if $\tau_1 = \tau_2 = 0$.[19]
- Catalyst does not work as beautiful as its theory in high-accuracy regimes, even though we have carefully tuned parameters α_0 and κ in Catalyst in addition to its learning rate. Indeed, in Figure 2(a), 2(c) and 2(f) Catalyst (which is a reduction on SVRG) is outperformed by SVRG.
- APCG performs poorly on all Lasso tasks (cf. Figure 2(d), 2(e), 2(f)) because it is not designed for non-SC objectives. The reduction in Allen-Zhu and Hazan (2016b) helps to fix this issue, but not by a lot.
- APCG can sometimes be largely dominated by SVRG or SAGA (cf. Figure 2(f)): this is because for datasets such as sensit, dual-based methods (such as APCG) cannot make use of the implicity local strong convexity in the objective. In such cases, `Katyusha` is not lost to SVRG or SAGA.

18. We choose three values λ that are powers of 10 and around $10/n, 1/n, 1/10n$. This range can be verified to contain the best regularization weights using cross validation.
19. The only reason `Katyusha` does not match the performance of SVRG in Figure 2(f) is because we have not tuned parameter τ_2. If we also tune τ_2 for the best performance, `Katyusha` shall no longer be outperformed by SVRG. In any case, it is not really necessary to tune τ_2 because the performance of `Katyusha` is already superb.

8. Conclusion

The Katyusha momentum technique introduced in this paper gives rise to accelerated convergence rates even in the stochastic setting. For many classes of the problems, such convergence rates are the first to match the theoretical lower bounds (Woodworth and Srebro, 2016). The algorithms generated by Katyusha momentum are simple yet highly practical and parallelizable.

More importantly, this new technique has the potential to enrich our understanding of accelerated methods in a broader sense. Currently, although acceleration methods are becoming more and more important to the field of computer science, they are still often regarded as "analytical tricks" (Juditsky, 2013; Bubeck et al., 2015) and lacking complete theoretical understanding. The Katyusha momentum presented in this paper, however, adds a new level of decoration on top of the classical Nesterov momentum. This decoration is shown valuable for stochastic problems in this paper, but may also lead to future applications as well. In general, the author hopes that the technique and analysis in this paper could facilitate more studies in this field and thus become a stepping stone towards the ultimate goal of unveiling the mystery of acceleration.

Acknowledgements

We would like to specially thank Shai Shalev-Shwartz for useful feedbacks and suggestions on this paper, thank Blake Woodworth and Nati Srebro for pointer to their paper (Woodworth and Srebro, 2016), thank Guanghui Lan for correcting our citation of (Dang and Lan, 2014), thank Weston Jackson, Xu Chen and Zhe Li for verifying the proofs and correcting typos, thank Hongzhou Lin for discussing the experiments, thank Robert Hannah for discussing lower bounds, and thank anonymous reviewers for a number of writing suggestions. This paper is partially supported by an NSF Grant, no. CCF-1412958, and a Microsoft Research Grant, no. 0518584. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of NSF or Microsoft.

Appendix

Appendix A. Other Related Works

For smooth convex minimization problems, (full) gradient descent converges at a rate $\frac{L}{\varepsilon}$ —or $\frac{L}{\sigma}\log\frac{1}{\varepsilon}$ if the objective is σ-strongly convex. This is not optimal among the class of first-order methods. Nesterov showed that the optimal rate should be $\frac{\sqrt{L}}{\sqrt{\varepsilon}}$ —or $\frac{\sqrt{L}}{\sqrt{\sigma}}\log\frac{1}{\varepsilon}$ if the objective is σ-strongly convex— and this was achieved by his celebrated accelerated (full) gradient descent method (Nesterov, 1983).

Sum-of-Nonconvex Optimization. One important generalization of Problem (1.1) is the case when the functions $f_i(x)$ are non-convex but their average $f(x)=\frac{1}{n}\sum_{i=1}^n f_i(x)$ is convex. Solvers for this "sum-of-nonconvex" setting can be applied to PCA/SVD, online eigenvector, general non-convex optimization, and more. See (Allen-Zhu, 2018a) and the references therein.

Variance reduction was first introduced to solve this problem by Shalev-Shwartz (2016), and APPA/Catalyst also accelerates SVRG for this problem (Garber et al., 2016). One can similarly ask whether one can design a *directly accelerated* method for this more general problem, and this was achieved by the `KatyushaX` method in (Allen-Zhu, 2018a). It is a sister paper to us but uses very different sets of techniques.

Online Stochastic Optimization. Some literatures also focus on the (more general) online variant of Problem (1.1), that is for n being sufficiently large so that the algorithm cannot access $f(x)$ or compute its full gradient $\nabla f(x)$. In this regime, without additional assumption, the optimal convergence rate is $1/\varepsilon^2$ (or $1/\varepsilon$ if the function is strongly convex). This is obtained by SGD and its hybrid variants (Lan, 2011; Hu et al., 2009).

Coordinate Descent. Another way to define gradient estimator is to set $\widetilde{\nabla}_k = d\nabla_j f(x_k)$ where j is a random coordinate. This is *(randomized) coordinate descent* as opposed to stochastic gradient descent. Designing accelerated methods for coordinate descent is significantly easier than designing that for stochastic gradient descent, and has indeed been done in many previous results including (Nesterov, 2012; Lin et al., 2014; Lu and Xiao, 2013; Allen-Zhu et al., 2016c).[20] The fastest rate is $O\big(\sum_i \sqrt{L_i/\varepsilon}\big)$ where parameters L_i correspond to the coordinate smoothness of $f(x)$ (Allen-Zhu et al., 2016c). Coordinate descent *cannot* be applied to solve Problem (1.1) because in our *stochastic* setting, only one copy $\nabla f_i(\cdot)$ is computed in every iteration.

Hybrid Stochastic Methods. Several recent results study hybrid methods with convergence rates that are generally *non-accelerated* and only accelerated in *extreme cases*.

- Lan (2011); Hu et al. (2009) obtained iteration complexity of the form $O(L/\sqrt{\varepsilon}+\sigma/\varepsilon^2)$ in the presence of stochastic gradient with variance σ. These results can be interpreted as follows, if σ is very small, then one can directly apply Nesterov's accelerated gradient method and achieve $O(L/\sqrt{\varepsilon})$; or if σ is large then they match the SGD iteration complexity $O(\sigma/\varepsilon^2)$. For Problem (1.1), these algorithms do not give faster running time than `Katyusha` unless σ is very small.[21]
- Nitanda (2014) adds momentum to the non-accelerated variance-reduction method in a naive manner. It corresponds to this paper but *without* Katyusha momentum (i.e., $\tau_2=0$). The theoretical running time of Nitanda (2014) is always slower than this paper and cannot even outperform SVRG (Johnson and Zhang, 2013; Zhang et al., 2013) unless $\kappa > n^2$ —which is usually false in practice (see page 7 of Nitanda (2014)).[22] We have included an experiment in Section 7.1 to illustrate why Katyusha momentum is necessary.

Linear Coupling. Allen-Zhu and Orecchia (2017) proposed a framework called *linear coupling* that facilitates the design of accelerated gradient methods. The simplest use of linear coupling can reconstruct Nesterov's accelerated full-gradient method (Allen-Zhu and Orecchia, 2017), or to provide faster coordinate descent (Allen-Zhu et al., 2016c). More careful use of linear coupling can also give accelerated methods for non-smooth problems (such as positive LP (Allen-Zhu and Orecchia, 2015b,a), positive SDP (Allen-Zhu et al., 2016a), matrix scaling (Allen-Zhu et al., 2017)) or for general non-convex problems (Allen-Zhu and Hazan, 2016a). This present paper falls into this linear-coupling framework, but our Katyusha momentum technique was not present in any of these cited results.

Acceleration in Nonconvex Optimization. One can also ask how does acceleration help in non-convex optimization? This is a new area with active research going on.

In the deterministic setting, under standard Lipschitz smoothness, gradient descent finds a point x with $\|\nabla f(x)\|\le\varepsilon$ in $O(\varepsilon^{-2})$ iterations (Nesterov, 2004), and acceleration is not known to help. If second-order Lipschitz smoothness is added, then one can use momentum to non-trivially improve the rate to $O(\varepsilon^{-1.75})$ (Carmon et al., 2016; Agarwal et al., 2017).

In the finite-sum stochastic setting, gradient descent finds a point x with $\|\nabla f(x)\|\le\varepsilon$ in $T=O(n\varepsilon^{-2})$ stochastic gradient computations under standard Lipschitz smoothness. If second-order Lipschitz smoothness is added, then one can use momentum to non-trivially improve the complexity $T=O(n\varepsilon^{-1.5}+n^{0.75}\varepsilon^{-1.75})$ (Agarwal et al., 2017).

In the online stochastic setting, SGD finds a point x with $\|\nabla f(x)\|\le\varepsilon$ in $T=O(\varepsilon^{-4})$ stochastic gradient iterations under the standard Lipschitz smoothness assumption. Perhaps surprisingly, without using momentum, one can already improve this rate to $T=O(\varepsilon^{-3.5})$ (using SGD) (Allen-Zhu, 2018b), $T=O(\varepsilon^{-3.333})$ (Lei et al., 2017), or even to $T=O(\varepsilon^{-3.25})$ (Allen-Zhu, 2017) if second-order Lipschitz smoothness is added. It is unclear whether such rates can be improved using momentum. We stress that, even if "improved rates" can be obtained using momentum, one also needs to prove from the lower-bound side that such "improved rates" cannot be obtained by any momentum-free method.

20. The reason behind it can be understood as follows. If a function $f(\cdot)$ is L smooth with respect to coordinate j, then a coordinate descent step $x'\leftarrow x-\frac{1}{L}\nabla_j f(x)\mathbf{e}_j$ always decreases the objective, i.e., $f(x+\frac{1}{L}\nabla_j f(x)\mathbf{e}_j)<f(x)$. In contrast, this is *false* for stochastic gradient descent, because $f(x_k-\eta\widetilde{\nabla}_k)$ may be even larger than $f(x_k)$.

21. When σ is large, even if n is large, the iteration complexity of (Lan, 2011; Hu et al., 2009) becomes $O(\sigma/\varepsilon^2)$. In this regime, almost all variance-reduction methods, including SVRG and `Katyusha`, can be shown to satisfy $\varepsilon\le O(\frac{\sqrt{\sigma}}{\sqrt{T}})$ within the first epoch, if the learning rates are appropriately chosen. Therefore, `Katyusha` and SVRG are no slower than Lan (2011); Hu et al. (2009).

22. Nitanda's method is usually not considered as an accelerated method, since it requires mini-batch size to be very large in order to be accelerated. If mini-batch is large then one can use full-gradient method directly and acceleration is trivial. This is confirmed by (Konečnỳ et al., 2016, Section IV.F). In contrast, our acceleration holds even if mini-batch size is 1.

Appendix B. Experiment Details

The datasets we used in this paper are downloaded from the LibSVM website (Fan and Lin):

- the adult (a9a) dataset (32,561 samples and 123 features).
- the web (w8a) dataset (49,749 samples and 300 features).
- the covtype (binary.scale) dataset (581,012 samples and 54 features).
- the mnist (class 1) dataset (60,000 samples and 780 features).
- the rcv1 (train.binary) dataset (20,242 samples and 47,236 features).
- the sensit (combined) dataset (78,823 samples and 100 features).

To make easier comparison across datasets, we scale every vector by the average Euclidean norm of all the vectors in the dataset. In other words, we ensure that the data vectors have an average Euclidean norm 1. This step is for comparison only and not necessary in practice.

Parameter-tuning details. We select learning rates from the set $\{10^{-k}, 2\times 10^{-k}, 5\times 10^{-k} : k\in\mathbb{Z}\}$, and select regularizer weights (for APCG) from the set $\{10^{-k} : k\in\mathbb{Z}\}$. We have fully automated the parameter tuning procedure to ensure a fair and strong comparison.

While the learning rates were explicitly defined for SVRG and SAGA, there were implicit for all accelerated methods. For Catalyst, the learning rate is in fact their α_0 in the paper (Lin, 2016). Instead of choosing it to be the theory-predicted value, we multiply it with an extra factor to be tuned and call this factor the "learning rate". Similarly, for `Katyusha` and `Katyusha`$^{\mathsf{ns}}$, we multiply the theory-predicted τ_1 with an extra factor and this serves as a learning rate. For APCG, we use their Algorithm 1 in the paper and multiply their theory-predicted μ with an extra factor.

For Catalyst, in principle one also has to tune the stopping criterion. After communicating with an author of Catalyst, we learned that one can terminate the inner loop whenever the duality gap becomes no more than, say one fourth, of the last duality gap from the previous epoch (Lin, 2016). This stopping criterion was also found by the authors of (Allen-Zhu and Hazan, 2016b) to be a good choice for reduction-based methods.

Appendix C. Appendix for Section 4

C.1 Proof of Theorem 4.1

Proof [Proof of Theorem 4.1] First of all, the parameter choices satisfy the presumptions in Lemma 2.6, so again by defining $D_k \stackrel{\text{def}}{=} F(y_k) - F(x^*)$ and $\widetilde{D}^s \stackrel{\text{def}}{=} F(\widetilde{x}^s) - F(x^*)$, we can rewrite Lemma 2.7 as follows:

$$0 \le \frac{\alpha_s(1-\tau_{1,s}-\tau_2)}{\tau_{1,s}} D_k - \frac{\alpha_s}{\tau_{1,s}} \mathbb{E}\big[D_{k+1}\big] + \frac{\alpha_s \tau_2}{\tau_{1,s}} \widetilde{D}^s + \frac{1}{2}\|z_k - x^*\|^2 - \frac{1}{2}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .$$

Summing up the above inequality for all the iterations $k = sm, sm+1, \ldots, sm+m-1$, we have

$$\begin{aligned} &\mathbb{E}\Big[\alpha_s \frac{1-\tau_{1,s}-\tau_2}{\tau_{1,s}} D_{(s+1)m} + \alpha_s \frac{\tau_{1,s}+\tau_2}{\tau_{1,s}} \sum_{j=1}^{m} D_{sm+j}\Big] \\ &\le \alpha_s \frac{1-\tau_{1,s}-\tau_2}{\tau_{1,s}} D_{sm} + \alpha_s \frac{\tau_2}{\tau_{1,s}} m\widetilde{D}^s + \frac{1}{2}\|z_{sm} - x^*\|^2 - \frac{1}{2}\mathbb{E}\big[\|z_{(s+1)m} - x^*\|^2\big] \ . \end{aligned} \tag{C.1}$$

Note that in the above inequality we have assumed all the randomness in the first $s-1$ epochs are fixed and the only source of randomness comes from epoch s.

If we define $\widetilde{x}^s = \frac{1}{m}\sum_{j=1}^{m} y_{(s-1)m+j}$, then by the convexity of function $F(\cdot)$ we have $m\widetilde{D}^s \le \sum_{j=1}^{n} D_{(s-1)m+j}$. Therefore, using the parameter choice $\alpha_s = \frac{1}{3\tau_{1,s}L}$, for every $s \ge 1$ we can derive from (C.1) that

$$\begin{aligned} &\mathbb{E}\Big[\frac{1}{\tau_{1,s}^2} D_{(s+1)m} + \frac{\tau_{1,s}+\tau_2}{\tau_{1,s}^2} \sum_{j=1}^{m-1} D_{sm+j}\Big] \\ &\le \frac{1-\tau_{1,s}}{\tau_{1,s}^2} D_{sm} + \frac{\tau_2}{\tau_{1,s}^2} \sum_{j=1}^{m-1} D_{(s-1)m+j} + \frac{3L}{2}\|z_{sm} - x^*\|^2 - \frac{3L}{2}\mathbb{E}\big[\|z_{(s+1)m} - x^*\|^2\big] \ . \end{aligned} \tag{C.2}$$

For the base case $s = 0$, we can also rewrite (C.1) as

$$\begin{aligned} &\mathbb{E}\Big[\frac{1}{\tau_{1,0}^2} D_m + \frac{\tau_{1,0}+\tau_2}{\tau_{1,0}^2} \sum_{j=1}^{m-1} D_j\Big] \\ &\le \frac{1-\tau_{1,0}-\tau_2}{\tau_{1,0}^2} D_0 + \frac{\tau_2 m}{\tau_{1,0}^2} \widetilde{D}^0 + \frac{3L}{2}\|z_0 - x^*\|^2 - \frac{3L}{2}\mathbb{E}\big[\|z_m - x^*\|^2\big] \ . \end{aligned} \tag{C.3}$$

At this point, if we choose $\tau_{1,s} = \frac{2}{s+4} \le \frac{1}{2}$, it satisfies

$$\frac{1}{\tau_{1,s}^2} \ge \frac{1-\tau_{1,s+1}}{\tau_{1,s+1}^2} \quad \text{and} \quad \frac{\tau_{1,s}+\tau_2}{\tau_{1,s}^2} \ge \frac{\tau_2}{\tau_{1,s+1}^2} \ .$$

Using these two inequalities, we can telescope (C.3) and (C.2) for all $s = 0, 1, \ldots, S-1$. We obtain in the end that

$$\begin{aligned} &\mathbb{E}\Big[\frac{1}{\tau_{1,S-1}^2} D_{Sm} + \frac{\tau_{1,S-1}+\tau_2}{\tau_{1,S-1}^2} \sum_{j=1}^{m-1} D_{(S-1)m+j} + \frac{3L}{2}\|z_{Sm} - z^*\|^2\Big] \\ &\qquad \le \frac{1-\tau_{1,0}-\tau_2}{\tau_{1,0}^2} D_0 + \frac{\tau_2 m}{\tau_{1,0}^2} \widetilde{D}^0 + \frac{3L}{2}\|z_0 - x^*\|^2 \end{aligned} \tag{C.4}$$

Since we have $\widetilde{D}^S \le \frac{1}{m}\sum_{j=1}^m D_{(S-1)m+j}$ which is no greater than $\frac{2\tau_{1,S-1}^2}{m}$ times the left hand side of (C.4), we conclude that

$$\mathbb{E}\big[F(\widetilde{x}^S)-F(x^*)\big] = \mathbb{E}\big[\widetilde{D}^S\big] \le O\big(\tfrac{\tau_{1,S}^2}{m}\big)\cdot\Big(\frac{1-\tau_{1,0}-\tau_2}{\tau_{1,0}^2}D_0 + \frac{\tau_2 m}{\tau_{1,0}^2}\widetilde{D}^0 + \frac{3L}{2}\|z_0-x^*\|^2\Big)$$
$$= O\big(\tfrac{1}{mS^2}\big)\cdot\Big(m\big(F(x_0)-F(x^*)\big)+L\|x_0-x^*\|^2\Big)\ .$$

■

Appendix D. Appendix for Section 5

D.1 One-Iteration Analysis

Similar as Section 2.1, we first analyze the behavior of `Katyusha1` in a single iteration (i.e., for a fixed k). We view y_k, z_k and x_{k+1} as fixed in this section so the only randomness comes from the choice of i in iteration k. We abbreviate in this subsection by $\widetilde{x}=\widetilde{x}^s$ where s is the epoch that iteration k belongs to, and denote by $\sigma_{k+1}^2 \stackrel{\text{def}}{=} \|\nabla f(x_{k+1})-\widetilde{\nabla}_{k+1}\|^2$.

Our first lemma is analogous to Lemma 2.3, where note that we have replaced the use of L in Lemma 2.3 with $L_\diamond \ge L$:

Lemma D.1 (proximal gradient descent) *If $L_\diamond \ge L$ and*

$$y_{k+1} = \arg\min_y \Big\{\frac{3L_\diamond}{2}\|y-x_{k+1}\|^2 + \langle\widetilde{\nabla}_{k+1}, y-x_{k+1}\rangle + \psi(y)-\psi(x_{k+1})\Big\}\ , \qquad \textit{and}$$
$$\mathsf{Prog}(x_{k+1}) \stackrel{\text{def}}{=} -\min_y \Big\{\frac{3L_\diamond}{2}\|y-x_{k+1}\|^2 + \langle\widetilde{\nabla}_{k+1}, y-x_{k+1}\rangle + \psi(y)-\psi(x_{k+1})\Big\} \ge 0\ ,$$

we have (where the expectation is only over the randomness of $\widetilde{\nabla}_{k+1}$)

$$F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] \ge \mathbb{E}\big[\mathsf{Prog}(x_{k+1})\big] - \frac{1}{4L_\diamond}\mathbb{E}\big[\sigma_{k+1}^2\big]\ .$$

Proof

$$\begin{aligned}\mathsf{Prog}(x_{k+1}) &= -\min_y\Big\{\frac{3L_\diamond}{2}\|y-x_{k+1}\|^2 + \langle\widetilde{\nabla}_{k+1}, y-x_{k+1}\rangle + \psi(y)-\psi(x_{k+1})\Big\}\\ &\stackrel{①}{=} -\Big(\frac{3L_\diamond}{2}\|y_{k+1}-x_{k+1}\|^2 + \langle\widetilde{\nabla}_{k+1}, y_{k+1}-x_{k+1}\rangle + \psi(y_{k+1})-\psi(x_{k+1})\Big)\\ &= -\Big(\frac{L_\diamond}{2}\|y_{k+1}-x_{k+1}\|^2 + \langle\nabla f(x_{k+1}), y_{k+1}-x_{k+1}\rangle + \psi(y_{k+1})-\psi(x_{k+1})\Big)\\ &\quad + \Big(\langle\nabla f(x_{k+1})-\widetilde{\nabla}_{k+1}, y_{k+1}-x_{k+1}\rangle - L_\diamond\|y_{k+1}-x_{k+1}\|^2\Big)\\ &\stackrel{②}{\le} -\Big(f(y_{k+1})-f(x_{k+1})+\psi(y_{k+1})-\psi(x_{k+1})\Big) + \frac{1}{4L_\diamond}\|\nabla f(x_{k+1})-\widetilde{\nabla}_{k+1}\|^2\ .\end{aligned}$$

Above, ① is by the definition of y_{k+1}, and ② uses the smoothness of function $f(\cdot)$, as well as Young's inequality $\langle a,b\rangle - \frac{1}{2}\|b\|^2 \le \frac{1}{2}\|a\|^2$. Taking expectation on both sides we arrive at the desired result. ■

The following lemma is analogous to Lemma 2.4. The main difference is that since we have not chosen a mini-batch of size b, one should expect the variance to decrease by a factor of b. Also, since we are in the non-uniform case one should expect the use of L in Lemma 2.4 to be replaced with $\overline{L}$:

Lemma D.2 (variance upper bound)

$$\mathbb{E}\big[\|\widetilde{\nabla}_{k+1}-\nabla f(x_{k+1})\|^2\big] \le \frac{2\overline{L}}{b}\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}), \widetilde{x}-x_{k+1}\rangle\big)\ .$$

Proof Each $f_i(x)$, being convex and L_i-smooth, implies the following inequality which is classical in convex optimization and can be found for instance in Theorem 2.1.5 of the textbook of Nesterov (2004).

$$\|\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\|^2 \le 2L_i\cdot\big(f_i(\widetilde{x})-f_i(x_{k+1})-\langle\nabla f_i(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)$$

Therefore, taking expectation over the random choice of i, we have

$$\begin{aligned}&\mathbb{E}\big[\|\widetilde{\nabla}_{k+1}-\nabla f(x_{k+1})\|^2\big]\\ &= \mathbb{E}_{S_k}\Big[\Big\|\Big(\frac{1}{b}\sum_{i\in S_k}\Big(\nabla f(\widetilde{x})+\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)\Big)\Big)-\nabla f(x_{k+1})\Big\|^2\Big]\\ &= \frac{1}{b}\mathbb{E}_{i\sim\mathcal{D}}\Big[\Big\|\Big(\nabla f(\widetilde{x})+\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)\Big)-\nabla f(x_{k+1})\Big\|^2\Big]\\ &= \frac{1}{b}\mathbb{E}_{i\sim\mathcal{D}}\Big[\Big\|\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)-\big(\nabla f(x_{k+1})-f(\widetilde{x})\big)\Big\|^2\Big]\\ &\stackrel{①}{\le} \frac{1}{b}\mathbb{E}_{i\sim\mathcal{D}}\Big[\Big\|\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)\Big\|^2\Big]\\ &\stackrel{②}{\le} \frac{1}{b}\cdot\sum_{i\in[n]}\frac{2L_i}{n^2p_i}\Big(f_i(\widetilde{x})-f_i(x_{k+1})-\langle\nabla f_i(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\Big)\\ &= \frac{2\overline{L}}{b}\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\ .\end{aligned}$$

Above, ① is because for any random vector $\zeta\in\mathbb{R}^d$, it holds that $\mathbb{E}\|\zeta-\mathbb{E}\zeta\|^2 = \mathbb{E}\|\zeta\|^2-\|\mathbb{E}\zeta\|^2$; ② follows from the first inequality in this proof. ■

The next lemma is completely identical to Lemma 2.5 so we skip the proof.

Lemma D.3 (proximal mirror descent) *Suppose $\psi(\cdot)$ is σ-SC. Then, fixing $\widetilde{\nabla}_{k+1}$ and letting*

$$z_{k+1} = \arg\min_z\Big\{\frac{1}{2}\|z-z_k\|^2 + \alpha\langle\widetilde{\nabla}_{k+1}, z-z_k\rangle + \alpha\psi(z)-\alpha\psi(z_k)\Big\}\ ,$$

it satisfies for all $u\in\mathbb{R}^d$,

$$\alpha\langle\widetilde{\nabla}_{k+1}, z_{k+1}-u\rangle + \alpha\psi(z_{k+1})-\alpha\psi(u) \le -\frac{1}{2}\|z_k-z_{k+1}\|^2 + \frac{1}{2}\|z_k-u\|^2 - \frac{1+\alpha\sigma}{2}\|z_{k+1}-u\|^2\ .$$

The following lemma combines Lemma D.1, Lemma D.2 and Lemma D.3 all together, using the special choice of x_{k+1} which is a convex combination of y_k, z_k and $\widetilde{x}$:

Lemma D.4 (coupling step 1) *If $x_{k+1} = \tau_1 z_k + \tau_2 \widetilde{x} + (1-\tau_1-\tau_2) y_k$, where $\tau_1 \le \frac{1}{3\alpha L_\diamond}$ and $\tau_2 = \frac{\overline{L}}{2L_\diamond b}$,*

$$\begin{aligned}
&\alpha\langle \nabla f(x_{k+1}), z_k - u\rangle - \alpha\psi(u) \\
\le\ & \frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] + \tau_2 F(\widetilde{x}) - \tau_2 f(x_{k+1}) - \tau_2\langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle\Big) \\
&+ \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - u\|^2\big] + \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\psi(y_k) - \frac{\alpha}{\tau_1}\psi(x_{k+1}) \ .
\end{aligned}$$

Proof We first apply Lemma D.3 and get

$$\begin{aligned}
&\alpha\langle \widetilde{\nabla}_{k+1}, z_k - u\rangle + \alpha\psi(z_{k+1}) - \alpha\psi(u) \\
=\ & \alpha\langle \widetilde{\nabla}_{k+1}, z_k - z_{k+1}\rangle + \alpha\langle \widetilde{\nabla}_{k+1}, z_{k+1} - u\rangle + \alpha\psi(z_{k+1}) - \alpha\psi(u) \\
\le\ & \alpha\langle \widetilde{\nabla}_{k+1}, z_k - z_{k+1}\rangle - \frac{1}{2}\|z_k - z_{k+1}\|^2 + \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\|z_{k+1} - u\|^2 \ . \qquad \text{(D.1)}
\end{aligned}$$

By defining $v \stackrel{\text{def}}{=} \tau_1 z_{k+1} + \tau_2 \widetilde{x} + (1-\tau_1-\tau_2) y_k$, we have $x_{k+1} - v = \tau_1(z_k - z_{k+1})$ and therefore

$$\begin{aligned}
&\mathbb{E}\Big[\alpha\langle \widetilde{\nabla}_{k+1}, z_k - z_{k+1}\rangle - \frac{1}{2}\|z_k - z_{k+1}\|^2\Big] = \mathbb{E}\Big[\frac{\alpha}{\tau_1}\langle \widetilde{\nabla}_{k+1}, x_{k+1} - v\rangle - \frac{1}{2\tau_1^2}\|x_{k+1} - v\|^2\Big] \\
=\ & \mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle \widetilde{\nabla}_{k+1}, x_{k+1} - v\rangle - \frac{1}{2\alpha\tau_1}\|x_{k+1} - v\|^2 - \psi(v) + \psi(x_{k+1})\Big) + \frac{\alpha}{\tau_1}\Big(\psi(v) - \psi(x_{k+1})\Big)\Big] \\
\overset{①}{\le}\ & \mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle \widetilde{\nabla}_{k+1}, x_{k+1} - v\rangle - \frac{3L_\diamond}{2}\|x_{k+1} - v\|^2 - \psi(v) + \psi(x_{k+1})\Big) + \frac{\alpha}{\tau_1}\Big(\psi(v) - \psi(x_{k+1})\Big)\Big] \\
\overset{②}{\le}\ & \mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - F(y_{k+1}) + \frac{1}{4L_\diamond}\sigma_{k+1}^2\Big) + \frac{\alpha}{\tau_1}\Big(\psi(v) - \psi(x_{k+1})\Big)\Big] \\
\overset{③}{\le}\ & \mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - F(y_{k+1}) + \frac{\overline{L}}{2L_\diamond b}\big(f(\widetilde{x}) - f(x_{k+1}) - \langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle\big)\Big) \\
&+ \frac{\alpha}{\tau_1}\Big(\tau_1\psi(z_{k+1}) + \tau_2\psi(\widetilde{x}) + (1-\tau_1-\tau_2)\psi(y_k) - \psi(x_{k+1})\Big)\Big] \ . \qquad \text{(D.2)}
\end{aligned}$$

Above, ① uses our choice $\tau_1 \le \frac{1}{3\alpha L}$, ② uses Lemma D.1, ③ uses Lemma D.2 together with the convexity of $\psi(\cdot)$ and the definition of v. Finally, noticing that $\mathbb{E}[\langle \widetilde{\nabla}_{k+1}, z_k - u\rangle] = \langle \nabla f(x_{k+1}), z_k - u\rangle$ and $\tau_2 = \frac{1}{2}$, we obtain the desired inequality by combining (D.1) and (D.2). ■

The next lemma simplifies the left hand side of Lemma D.4 using the convexity of $f(\cdot)$, and gives an inequality that relates the objective-distance-to-minimizer quantities $F(y_k) - F(x^*)$, $F(y_{k+1}) - F(x^*)$, and $F(\widetilde{x}) - F(x^*)$ to the point-distance-to-minimizer quantities $\|z_k - x^*\|^2$ and $\|z_{k+1} - x^*\|^2$.

Lemma D.5 (coupling step 2) *Under the same choices of τ_1, τ_2 as in Lemma D.4, we have*

$$\begin{aligned}
0 \le\ & \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - F(x^*)) - \frac{\alpha}{\tau_1}\big(\mathbb{E}\big[F(y_{k+1})\big] - F(x^*)\big) + \frac{\alpha\tau_2}{\tau_1}\big(F(\widetilde{x}) - F(x^*)\big) \\
&+ \frac{1}{2}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .
\end{aligned}$$

Proof We first compute that

$$\begin{aligned}
&\alpha\big(f(x_{k+1}) - f(u)\big) \overset{①}{\le} \alpha\langle \nabla f(x_{k+1}), x_{k+1} - u\rangle \\
=\ & \alpha\langle \nabla f(x_{k+1}), x_{k+1} - z_k\rangle + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \\
\overset{②}{=}\ & \frac{\alpha\tau_2}{\tau_1}\langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle + \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\langle \nabla f(x_{k+1}), y_k - x_{k+1}\rangle + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \\
\overset{③}{\le}\ & \frac{\alpha\tau_2}{\tau_1}\langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle + \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(f(y_k) - f(x_{k+1})) + \alpha\langle \nabla f(x_{k+1}), z_k - u\rangle \ .
\end{aligned}$$

Above, ① uses the convexity of $f(\cdot)$, ② uses the choice that $x_{k+1} = \tau_1 z_k + \tau_2\widetilde{x} + (1-\tau_1-\tau_2)y_k$, and ③ uses the convexity of $f(\cdot)$ again. By applying Lemma D.4 to the above inequality, we have

$$\begin{aligned}
&\alpha\big(f(x_{k+1}) - F(u)\big) \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - f(x_{k+1})) \\
&+\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] + \tau_2 F(\widetilde{x}) - \tau_2 f(x_{k+1})\Big) + \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - u\|^2\big] - \frac{\alpha}{\tau_1}\psi(x_{k+1})
\end{aligned}$$

which implies

$$\begin{aligned}
&\alpha\big(F(x_{k+1}) - F(u)\big) \le \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - F(x_{k+1})) \\
&+\frac{\alpha}{\tau_1}\Big(F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] + \tau_2 F(\widetilde{x}) - \tau_2 F(x_{k+1})\Big) + \frac{1}{2}\|z_k - u\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - u\|^2\big] \ .
\end{aligned}$$

After rearranging and setting $u = x^*$, the above inequality yields

$$\begin{aligned}
0 \le\ & \frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k) - F(x^*)) - \frac{\alpha}{\tau_1}\big(\mathbb{E}\big[F(y_{k+1}) - F(x^*)\big]\big) + \frac{\alpha\tau_2}{\tau_1}\big(F(\widetilde{x}) - F(x^*)\big) \\
&+ \frac{1}{2}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .
\end{aligned}$$

■

D.2 Proof of Theorem 5.2

We are now ready to combine the analyses across iterations, and derive our final Theorem 5.2. Our proof next requires a careful telescoping of Lemma D.5 together with our specific parameter choices.

Proof [Proof of Theorem 5.2] Define $D_k \stackrel{\text{def}}{=} F(y_k) - F(x^*)$, $\widetilde{D}^s \stackrel{\text{def}}{=} F(\widetilde{x}^s) - F(x^*)$, and rewrite Lemma D.5:

$$0 \le \frac{(1-\tau_1-\tau_2)}{\tau_1}D_k - \frac{1}{\tau_1}D_{k+1} + \frac{\tau_2}{\tau_1}\mathbb{E}\big[\widetilde{D}^s\big] + \frac{1}{2\alpha}\|z_k - x^*\|^2 - \frac{1+\alpha\sigma}{2\alpha}\mathbb{E}\big[\|z_{k+1} - x^*\|^2\big] \ .$$

At this point, let us θ be an arbitrary value in $\big[1, 1+\alpha\sigma\big]$ and multiply the above inequality by θ^j for each $k = sm + j$. Then, we sum up the resulting m inequalities for all $j =$

$0, 1, \dots, m-1$:

$$0 \le \mathbb{E}\Big[\frac{(1-\tau_1-\tau_2)}{\tau_1}\sum_{j=0}^{m-1} D_{sm+j}\cdot\theta^j - \frac{1}{\tau_1}\sum_{j=0}^{m-1} D_{sm+j+1}\cdot\theta^j\Big] + \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1}{2\alpha}\|z_{sm}-x^*\|^2 - \frac{\theta^m}{2\alpha}\big[\|z_{(s+1)m}-x^*\|^2\big] \ .$$

Note that in the above inequality we have assumed all the randomness in the first $s-1$ epochs are fixed and the only source of randomness comes from epoch s. We can rearrange the terms in the above inequality and get

$$\mathbb{E}\Big[\frac{\tau_1+\tau_2-(1-1/\theta)}{\tau_1}\sum_{j=1}^{m} D_{sm+j}\cdot\theta^j\Big] \le \frac{(1-\tau_1-\tau_2)}{\tau_1}\Big(D_{sm}-\theta^m\mathbb{E}\big[D_{(s+1)m}\big]\Big) + \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1}{2\alpha}\|z_{sm}-x^*\|^2 - \frac{\theta^m}{2\alpha}\mathbb{E}\big[\|z_{(s+1)m}-x^*\|^2\big] \ .$$

Using the special choice that $\widetilde{x}^{s+1} = \big(\sum_{j=0}^{m-1}\theta^j\big)^{-1}\cdot\sum_{j=0}^{m-1} y_{sm+j+1}\cdot\theta^j$ and the convexity of $F(\cdot)$, we derive that $\widetilde{D}^{s+1} \le \big(\sum_{j=0}^{m-1}\theta^j\big)^{-1}\cdot\sum_{j=0}^{m-1} D_{sm+j+1}\cdot\theta^j$. Substituting this into the above inequality, we get

$$\frac{\tau_1+\tau_2-(1-1/\theta)}{\tau_1}\theta\mathbb{E}\big[\widetilde{D}^{s+1}\big]\cdot\sum_{j=0}^{m-1}\theta^j \le \frac{(1-\tau_1-\tau_2)}{\tau_1}\Big(D_{sm}-\theta^m\mathbb{E}\big[D_{(s+1)m}\big]\Big) + \frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1}{2\alpha}\|z_{sm}-x^*\|^2 - \frac{\theta^m}{2\alpha}\mathbb{E}\big[\|z_{(s+1)m}-x^*\|^2\big] \ . \quad \text{(D.3)}$$

We consider two cases (and four subcases) next.

Case 1. Suppose $L \le \frac{\overline{L}m}{b}$. In this case, we choose

$$\tau_2 = \min\Big\{\frac{\overline{L}}{2Lb}, \frac{1}{2}\Big\} \in \Big[\frac{1}{2m}, \frac{1}{2}\Big] \quad \text{and} \quad L_\diamond = \frac{\overline{L}}{2b\tau_2} \ge L$$

Case 1.1. Suppose $\frac{m\sigma b}{\overline{L}} \le \frac{3}{8}$. In this subcase, we choose

$$\alpha = \frac{\sqrt{b}}{\sqrt{6m\sigma\overline{L}}} \ , \qquad \tau_1 = \frac{1}{3\alpha L_\diamond} = 4m\alpha\sigma\tau_2 = \frac{\sqrt{8\tau_2^2 bm\sigma}}{\sqrt{3\overline{L}}} \in \big[0,\tau_2\big] \subseteq \big[0,\frac{1}{2}\big] \ , \quad \text{and} \quad \theta = 1+\alpha\sigma$$

We have

$$\alpha\sigma = \frac{1}{\sqrt{6m^2}}\frac{\sqrt{b\sigma m}}{\sqrt{\overline{L}}} \le \frac{1}{4m}$$

and therefore the following inequality holds:

$$\tau_2(\theta^{m-1}-1)+(1-1/\theta) = \tau_2((1+\alpha\sigma)^{m-1}-1)+(1-\frac{1}{1+\alpha\sigma}) \le 2\tau_2 m\alpha\sigma+\alpha\sigma \le 4\tau_2 m\alpha\sigma = \tau_1 \ .$$

In other words, we have $\tau_1+\tau_2-(1-1/\theta) \ge \tau_2\theta^{m-1}$ and thus (D.3) implies that

$$\mathbb{E}\Big[\frac{\tau_2}{\tau_1}\widetilde{D}^{s+1}\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{(s+1)m} + \frac{1}{2\alpha}\|z_{(s+1)m}-x^*\|^2\Big] \le \theta^{-m}\cdot\Big(\frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{sm} + \frac{1}{2\alpha}\|z_{sm}-x^*\|^2\Big) \ .$$

If we telescope the above inequality over all epochs $s = 0, 1, \dots, S-1$, we obtain

$$\begin{aligned}\mathbb{E}\big[F(x^{\mathsf{out}})-F(x^*)\big] &\overset{①}{\le} \frac{1}{\tau_2 m+(1-\tau_1-\tau_2)}\mathbb{E}\big[\tau_2\widetilde{D}^S\cdot\sum_{j=0}^{m-1}\theta^j + \big(1-\tau_1-\tau_2\big)D_{Sm}\big] \\ &\overset{②}{\le} \theta^{-Sm}\cdot O\Big(\widetilde{D}^0 + D_0 + \frac{\tau_1}{\alpha\tau_2 m}\|x_0-x^*\|^2\Big) \\ &\overset{③}{\le} \theta^{-Sm}\cdot O\Big(1+\frac{\tau_1}{\alpha\tau_2 m\sigma}\Big)\cdot\big(F(x_0)-F(x^*)\big) \\ &\overset{④}{=} O((1+\alpha\sigma)^{-Sm})\cdot\big(F(x_0)-F(x^*)\big) \ . \end{aligned} \quad \text{(D.4)}$$

Above, inequality ① uses the choice $x^{\mathsf{out}} = \frac{\tau_2 m\widetilde{x}^S+(1-\tau_1-\tau_2)y_{Sm}}{\tau_2 m+(1-\tau_1-\tau_2)}$, the convexity of $F(\cdot)$, and the fact $\sum_{j=0}^{m-1}\theta^j \ge m$; inequality ② uses the fact that $\sum_{j=0}^{m-1}\theta^j \le O(m)$ (because $\alpha\sigma \le \frac{1}{4m}$), and the fact that $\tau_2 \ge \frac{1}{2m}$; inequality ③ uses the strong convexity of $F(\cdot)$ which implies $F(x_0)-F(x^*) \ge \frac{\sigma}{2}\|x_0-x^*\|^2$; and inequality ④ uses our choice of τ_1.

Case 1.2. Suppose $\frac{m\sigma b}{\overline{L}} > \frac{3}{8}$. In this case, we choose

$$\tau_1 = \tau_2 \quad \text{and} \quad \alpha = \frac{1}{3\tau_1 L_\diamond} = \frac{2b}{3\overline{L}} \ge \frac{1}{4\sigma m} \ , \quad \theta = 1+\frac{1}{4m}$$

(Note that we can choose $\theta = 1+\frac{1}{4m}$ because $\frac{1}{4m} \le \alpha\sigma$.)

Under these parameter choices, we can calculate that

$$\frac{(\tau_1+\tau_2-(1-1/\theta))\theta}{\tau_2} = 2-\frac{1-2\tau_2}{4m\tau_2} \ge \frac{3}{2} > \frac{5}{4} \quad \text{and} \quad \theta^m \ge \frac{5}{4}$$

thus (D.3) implies that

$$\mathbb{E}\Big[\frac{\tau_2}{\tau_1}\widetilde{D}^{s+1}\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{(s+1)m} + \frac{1}{2\alpha}\|z_{(s+1)m}-x^*\|^2\Big] \le \frac{4}{5}\cdot\Big(\frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{sm} + \frac{1}{2\alpha}\|z_{sm}-x^*\|^2\Big) \ .$$

If we telescope the above inequality over all epochs $s = 0, 1, \ldots, S-1$, we obtain

$$\begin{aligned}\mathbb{E}\big[F(x^{\mathsf{out}}) - F(x^*)\big] &\overset{①}{\le} \frac{1}{\tau_2 m + (1-\tau_1-\tau_2)}\mathbb{E}\big[\tau_2 \widetilde{D}^S \cdot \sum_{j=0}^{m-1}\theta^j + \big(1-\tau_1-\tau_2\big)D_{Sm}\big] \\ &\overset{②}{\le} \big(\frac{5}{4}\big)^{-S}\cdot O\Big(\widetilde{D}^0 + D_0 + \frac{\tau_1}{\alpha\tau_2 m}\|x_0 - x^*\|^2\Big) \\ &\overset{③}{\le} \big(\frac{5}{4}\big)^{-S}\cdot O\Big(1 + \frac{\tau_1}{\alpha\tau_2 m\sigma}\Big)\cdot\big(F(x_0) - F(x^*)\big) \\ &\overset{④}{=} O((5/4)^{-S})\cdot\big(F(x_0) - F(x^*)\big)\ . \end{aligned} \tag{D.5}$$

Above, inequality ① uses the choice $x^{\mathsf{out}} = \frac{\tau_2 m\widetilde{x}^S + (1-\tau_1-\tau_2)y_{Sm}}{\tau_2 m + (1-\tau_1-\tau_2)}$, the convexity of $F(\cdot)$, and the fact $\sum_{j=0}^{m-1}\theta^j \ge m$; inequality ② uses the fact that $\sum_{j=0}^{m-1}\theta^j \le O(m)$, and the fact that $\tau_2 \ge \frac{1}{2m}$; inequality ③ uses the strong convexity of $F(\cdot)$ which implies $F(x_0) - F(x^*) \ge \frac{\sigma}{2}\|x_0 - x^*\|^2$; and inequality ④ uses our choice of τ_1 and α.

Case 2. Suppose $L > \frac{\overline{L}m}{b}$. In this case, we choose

$$L_\diamond = L \quad \text{and} \quad \tau_2 = \frac{\overline{L}}{2L_\diamond b} = \frac{\overline{L}}{2Lb} \in \big[0, \frac{1}{2m}\big]$$

Case 2.1. Suppose $\frac{m^2\sigma}{L} \le \frac{3}{8}$. In this subcase, we choose

$$\alpha = \frac{1}{\sqrt{6\sigma L}}\ , \qquad \tau_1 = \frac{1}{3\alpha L} = 2\alpha\sigma = \frac{\sqrt{2\sigma}}{\sqrt{3L}} \in \big[0, \frac{1}{2m}\big]\ , \quad \theta = 1 + \alpha\sigma$$

We have $\alpha\sigma \le \frac{1}{4m}$ and therefore the following inequality holds:

$$\tau_2(\theta^{m-1} - 1) + (1 - 1/\theta) = \tau_2((1+\alpha\sigma)^{m-1} - 1) + (1 - \frac{1}{1+\alpha\sigma}) \le 2\tau_2 m\alpha\sigma + \alpha\sigma \le 2\alpha\sigma = \tau_1\ .$$

In other words, we have $\tau_1 + \tau_2 - (1 - 1/\theta) \ge \tau_2\theta^{m-1}$ and thus (D.3) implies that

$$\begin{aligned}&\mathbb{E}\Big[\frac{\tau_2}{\tau_1}\widetilde{D}^{s+1}\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{(s+1)m} + \frac{1}{2\alpha}\|z_{(s+1)m} - x^*\|^2\Big] \\ &\le \theta^{-m}\cdot\Big(\frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{sm} + \frac{1}{2\alpha}\|z_{sm} - x^*\|^2\Big)\ .\end{aligned}$$

If we telescope the above inequality over all epochs $s = 0, 1, \ldots, S-1$, we obtain

$$\begin{aligned}\mathbb{E}\big[F(x^{\mathsf{out}}) - F(x^*)\big] &\overset{①}{\le} \frac{1}{\tau_2 m + (1-\tau_1-\tau_2)}\mathbb{E}\big[\tau_2 \widetilde{D}^S \cdot \sum_{j=0}^{m-1}\theta^j + \big(1-\tau_1-\tau_2\big)D_{Sm}\big] \\ &\overset{②}{\le} \theta^{-Sm}\cdot O\Big(\widetilde{D}^0 + D_0 + \frac{\tau_1}{\alpha}\|x_0 - x^*\|^2\Big) \\ &\overset{③}{\le} \theta^{-Sm}\cdot O\Big(1 + \frac{\tau_1}{\alpha\sigma}\Big)\cdot\big(F(x_0) - F(x^*)\big) \\ &\overset{④}{=} O((1+\alpha\sigma)^{-Sm})\cdot\big(F(x_0) - F(x^*)\big)\ . \end{aligned} \tag{D.6}$$

Above, inequality ① uses the choice $x^{\mathsf{out}} = \frac{\tau_2 m\widetilde{x}^S + (1-\tau_1-\tau_2)y_{Sm}}{\tau_2 m + (1-\tau_1-\tau_2)}$, the convexity of $F(\cdot)$, and the fact $\sum_{j=0}^{m-1}\theta^j \ge m$; inequality ② uses the fact that $\sum_{j=0}^{m-1}\theta^j \le O(m)$ (because $\alpha\sigma \le \frac{1}{4m}$), and the fact that $\tau_2 m + (1-\tau_1-\tau_2) \ge 1 - \tau_1 + (m-1)\tau_2 \ge 1/2$; inequality ③ uses the strong convexity of $F(\cdot)$ which implies $F(x_0) - F(x^*) \ge \frac{\sigma}{2}\|x_0 - x^*\|^2$; and inequality ④ uses our choice of τ_1.

Case 2.2. Suppose $\frac{m^2\sigma}{L} > \frac{3}{8}$. In this case, we choose

$$\tau_1 = \frac{1}{2m} \quad \text{and} \quad \alpha = \frac{1}{3\tau_1 L} = \frac{2m}{3L} > \frac{1}{4\sigma m}\ , \quad \theta = 1 + \frac{1}{4m}$$

(Note that we can choose $\theta = 1 + \frac{1}{4m}$ because $\frac{1}{4m} \le \alpha\sigma$.)

Under these parameter choices, we can calculate that

$$\frac{(\tau_1+\tau_2-(1-1/\theta))\theta}{\tau_2} = \frac{\tau_1+\tau_2}{\tau_2} - \frac{1-2\tau_2}{4m\tau_2} \ge 1 + \frac{\tau_1 - 1/4m}{\tau_2} \ge \frac{3}{2} > \frac{5}{4} \quad \text{and} \quad \theta^m \ge \frac{5}{4}$$

thus (D.3) implies that

$$\begin{aligned}&\mathbb{E}\Big[\frac{\tau_2}{\tau_1}\widetilde{D}^{s+1}\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{(s+1)m} + \frac{1}{2\alpha}\|z_{(s+1)m} - x^*\|^2\Big] \\ &\le \frac{4}{5}\cdot\Big(\frac{\tau_2}{\tau_1}\widetilde{D}^s\cdot\sum_{j=0}^{m-1}\theta^j + \frac{1-\tau_1-\tau_2}{\tau_1}D_{sm} + \frac{1}{2\alpha}\|z_{sm} - x^*\|^2\Big)\ .\end{aligned}$$

If we telescope the above inequality over all epochs $s = 0, 1, \ldots, S-1$, we obtain

$$\begin{aligned}\mathbb{E}\big[F(x^{\mathsf{out}}) - F(x^*)\big] &\overset{①}{\le} \frac{1}{\tau_2 m + (1-\tau_1-\tau_2)}\mathbb{E}\big[\tau_2 \widetilde{D}^S \cdot \sum_{j=0}^{m-1}\theta^j + \big(1-\tau_1-\tau_2\big)D_{Sm}\big] \\ &\overset{②}{\le} \big(\frac{5}{4}\big)^{-S}\cdot O\Big(\widetilde{D}^0 + D_0 + \frac{\tau_1}{\alpha}\|x_0 - x^*\|^2\Big) \\ &\overset{③}{\le} \big(\frac{5}{4}\big)^{-S}\cdot O\Big(1 + \frac{\tau_1}{\alpha\sigma}\Big)\cdot\big(F(x_0) - F(x^*)\big) \\ &\overset{④}{=} O((5/4)^{-S})\cdot\big(F(x_0) - F(x^*)\big)\ . \end{aligned} \tag{D.7}$$

Above, inequality ① uses the choice $x^{\mathsf{out}} = \frac{\tau_2 m\widetilde{x}^S + (1-\tau_1-\tau_2)y_{Sm}}{\tau_2 m + (1-\tau_1-\tau_2)}$, the convexity of $F(\cdot)$, and the fact $\sum_{j=0}^{m-1}\theta^j \ge m$; inequality ② uses the fact that $\sum_{j=0}^{m-1}\theta^j \le O(m)$, and that $\tau_2 m + (1-\tau_1-\tau_2) \ge 1 - \tau_1 + (m-1)\tau_2 \ge 1/2$; inequality ③ uses the strong convexity of $F(\cdot)$ which implies $F(x_0) - F(x^*) \ge \frac{\sigma}{2}\|x_0 - x^*\|^2$; and inequality ④ uses our choice of τ_1 and α. ■

Appendix E. Appendix for Section 6

In this section, we first include the complete pseudo-codes for `Katyusha2` and `Katyusha2`$^{\mathsf{ns}}$. Then, we provide a one-iteration analysis for both algorithms, in the same spirit as Section 2.1.

The final proofs of Theorem 6.1 and Theorem 6.2 are direct corollaries of such one-iteration analysis, where the details we have already given in Section 2.2 and in Section C.1 respectively.

E.1 Pseudo-Codes

Algorithm 4 `Katyusha2`$(x_0, S, \sigma, (L_1, \dots, L_n))$

$m \leftarrow n$; $\overline{L} = (L_1 + \cdots + L_n)/n$;
$\tau_2 \leftarrow \frac{1}{2}$, $\tau_1 \leftarrow \min\{\sqrt{m\sigma/9\overline{L}}, \frac{1}{2}\}$, $\alpha \leftarrow \frac{1}{9\tau_1\overline{L}}$;
$y_0 = z_0 = \widetilde{x}^0 \leftarrow x_0$;
for $s \leftarrow 0$ **to** $S-1$ **do**
  $\mu^s \leftarrow \nabla f(\widetilde{x}^s)$;
  for $j \leftarrow 0$ **to** $m-1$ **do**
    $k \leftarrow (sm) + j$;
    $x_{k+1} \leftarrow \tau_1 z_k + \tau_2 \widetilde{x}^s + (1-\tau_1-\tau_2) y_k$;
    Pick i randomly from $\{1, 2, \dots, n\}$, each with probability $L_i/n\overline{L}$;
    $\widetilde{\nabla}_{k+1} \leftarrow \mu^s + \nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x}^s)$;
    $z_{k+1} = \arg\min_z \{\frac{1}{\alpha} V_{z_k}(z) + \langle \widetilde{\nabla}_{k+1}, z\rangle + \psi(z)\}$;
      ◇ *$V_x(y)$ is the Bregman divergence function, see Section 6*
    $y_{k+1} \leftarrow \arg\min_y \{\frac{9\overline{L}}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y\rangle + \psi(y)\}$;
  end for
  $\widetilde{x}^{s+1} \leftarrow \big(\sum_{j=0}^{m-1}(1+\alpha\sigma)^j\big)^{-1} \cdot \big(\sum_{j=0}^{m-1}(1+\alpha\sigma)^j \cdot y_{sm+j+1}\big)$;
end for
return $\widetilde{x}^S$.

Algorithm 5 `Katyusha2`$^{\mathsf{ns}}(x_0, S, \sigma, (L_1, \dots, L_n))$

$m \leftarrow n$; $\overline{L} = (L_1 + \cdots + L_n)/n$;
$\tau_2 \leftarrow \frac{1}{2}$;
$y_0 = z_0 = \widetilde{x}^0 \leftarrow x_0$;
for $s \leftarrow 0$ **to** $S-1$ **do**
  $\tau_{1,s} \leftarrow \frac{2}{s+4}$, $\alpha_s \leftarrow \frac{1}{9\tau_{1,s}\overline{L}}$
  $\mu^s \leftarrow \nabla f(\widetilde{x}^s)$;
  for $j \leftarrow 0$ **to** $m-1$ **do**
    $k \leftarrow (sm) + j$;
    $x_{k+1} \leftarrow \tau_{1,s} z_k + \tau_2 \widetilde{x}^s + (1-\tau_{1,s}-\tau_2) y_k$;
    Pick i randomly from $\{1, 2, \dots, n\}$, each with probability $L_i/n\overline{L}$;
    $\widetilde{\nabla}_{k+1} \leftarrow \mu^s + \nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x}^s)$;
    $z_{k+1} = \arg\min_z \{\frac{1}{\alpha_s} V_{z_k}(z) + \langle \widetilde{\nabla}_{k+1}, z\rangle + \psi(z)\}$;
      ◇ *$V_x(y)$ is the Bregman divergence function, see Section 6*
    $y_{k+1} \leftarrow \arg\min_y \{\frac{9\overline{L}}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y\rangle + \psi(y)\}$;
  end for
  $\widetilde{x}^{s+1} \leftarrow \frac{1}{m}\sum_{j=1}^{m} y_{sm+j}$;
end for
return $\widetilde{x}^S$.

E.2 One-Iteration Analysis

Similar as Section 2.1, we first analyze the behavior of `Katyusha2` in a single iteration (i.e., for a fixed k). We view y_k, z_k and x_{k+1} as fixed in this section so the only randomness comes from the choice of i in iteration k. We abbreviate in this subsection by $\widetilde{x} = \widetilde{x}^s$ where s is the epoch that iteration k belongs to, and denote by $\sigma_{k+1}^2 \stackrel{\text{def}}{=} \|\nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}\|_*^2$.

Our first lemma is analogous to Lemma E.1 except the change of the parameter and the norm.

Lemma E.1 (proximal gradient descent) *If*

$$y_{k+1} = \arg\min_y \Big\{\frac{9\overline{L}}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\}\ , \qquad \textit{and}$$

$$\mathsf{Prog}(x_{k+1}) \stackrel{\text{def}}{=} -\min_y \Big\{\frac{9\overline{L}}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\} \geq 0\ ,$$

we have (where the expectation is only over the randomness of $\widetilde{\nabla}_{k+1}$)

$$F(x_{k+1}) - \mathbb{E}\big[F(y_{k+1})\big] \geq \mathbb{E}\big[\mathsf{Prog}(x_{k+1})\big] - \frac{1}{16\overline{L}}\mathbb{E}\big[\sigma_{k+1}^2\big]\ .$$

Proof

$$\begin{aligned}
\mathsf{Prog}(x_{k+1}) &= -\min_y \Big\{\frac{9\overline{L}}{2}\|y - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y - x_{k+1}\rangle + \psi(y) - \psi(x_{k+1})\Big\} \\
&\stackrel{①}{=} -\Big(\frac{9\overline{L}}{2}\|y_{k+1} - x_{k+1}\|^2 + \langle \widetilde{\nabla}_{k+1}, y_{k+1} - x_{k+1}\rangle + \psi(y_{k+1}) - \psi(x_{k+1})\Big) \\
&= -\Big(\frac{\overline{L}}{2}\|y_{k+1} - x_{k+1}\|^2 + \langle \nabla f(x_{k+1}), y_{k+1} - x_{k+1}\rangle + \psi(y_{k+1}) - \psi(x_{k+1})\Big) \\
&\quad + \Big(\langle \nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}, y_{k+1} - x_{k+1}\rangle - 4\overline{L}\|y_{k+1} - x_{k+1}\|^2\Big) \\
&\stackrel{②}{\leq} -\Big(f(y_{k+1}) - f(x_{k+1}) + \psi(y_{k+1}) - \psi(x_{k+1})\Big) + \frac{1}{16\overline{L}}\|\nabla f(x_{k+1}) - \widetilde{\nabla}_{k+1}\|_*^2\ .
\end{aligned}$$

Above, ① is by the definition of y_{k+1}, and ② uses the smoothness of function $f(\cdot)$, as well as Young's inequality $\langle a, b\rangle - \frac{1}{2}\|b\|^2 \leq \frac{1}{2}\|a\|_*^2$. Taking expectation on both sides we arrive at the desired result. ■

The next lemma is analogous to Lemma 2.4 but with slightly different proof.

Lemma E.2 (variance upper bound)

$$\mathbb{E}\big[\|\widetilde{\nabla}_{k+1} - \nabla f(x_{k+1})\|_*^2\big] \leq 8\overline{L} \cdot \big(f(\widetilde{x}) - f(x_{k+1}) - \langle \nabla f(x_{k+1}), \widetilde{x} - x_{k+1}\rangle\big)\ .$$

Proof Each $f_i(x)$, being convex and L_i-smooth, implies the following inequality which is classical in convex optimization and can be found for instance in Theorem 2.1.5 of the textbook of Nesterov (2004).

$$\|\nabla f_i(x_{k+1}) - \nabla f_i(\widetilde{x})\|_*^2 \leq 2L_i \cdot \big(f_i(\widetilde{x}) - f_i(x_{k+1}) - \langle \nabla f_i(x_{k+1}), \widetilde{x} - x_{k+1}\rangle\big) \qquad \text{(E.1)}$$

Therefore, taking expectation over the random choice of i, we have

$$\begin{aligned}
&\mathbb{E}\big[\|\widetilde{\nabla}_{k+1}-\nabla f(x_{k+1})\|_*^2\big]\\
&=\mathbb{E}\big[\big\|\frac{1}{np_i}\big(\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big)-\big(\nabla f(x_{k+1})-\nabla f(\widetilde{x})\big)\big\|_*^2\big]\\
&\overset{①}{\le} 2\mathbb{E}\big[\frac{1}{n^2p_i^2}\big\|\nabla f_i(x_{k+1})-\nabla f_i(\widetilde{x})\big\|_*^2\big]+2\big\|\nabla f(x_{k+1})-\nabla f(\widetilde{x})\big\|_*^2\\
&\overset{②}{\le} 4\cdot\mathbb{E}\big[\frac{L_i}{n^2p_i^2}\big(f_i(\widetilde{x})-f_i(x_{k+1})-\langle\nabla f_i(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\big]+2\big\|\nabla f(x_{k+1})-\nabla f(\widetilde{x})\big\|_*^2\\
&\overset{③}{=} 4\overline{L}\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)+2\big\|\nabla f(x_{k+1})-\nabla f(\widetilde{x})\big\|_*^2\\
&\le 8\overline{L}\cdot\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\ .
\end{aligned}$$

Above, inequality ① is because $\|a+b\|_*^2\le(\|a\|_*+\|b\|_*)^2\le 2\|a\|_*^2+2\|b\|_*^2$; inequality ② follows from (E.1); equality ③ follows from the probability distribution that we select i with probability $p_i=L_i/(n\overline{L})$; inequality ④ uses (E.1) again but replacing $f_i(\cdot)$ with $f(\cdot)$. ■

The next lemma is classical for mirror descent with respect to a general Bregman divergence.

Lemma E.3 (proximal mirror descent) *Suppose $\psi(\cdot)$ is σ-SC with respect to $V_x(y)$. Then, fixing $\widetilde{\nabla}_{k+1}$ and letting*

$$z_{k+1}=\arg\min_z\big\{V_{z_k}(z)+\alpha\langle\widetilde{\nabla}_{k+1},z-z_k\rangle+\alpha\psi(z)-\alpha\psi(z_k)\big\}\ ,$$

it satisfies for all $u\in\mathbb{R}^d$,

$$\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\le-\frac{1}{2}\|z_k-z_{k+1}\|^2+V_{z_k}(u)-(1+\alpha\sigma)V_{z_{k+1}}(u)\ .$$

Proof By the minimality definition of z_{k+1}, we have that

$$\nabla V_{z_k}(z_{k+1})+\alpha\widetilde{\nabla}_{k+1}+\alpha g=0$$

where g is *some* subgradient of $\psi(z)$ at point $z=z_{k+1}$. This implies that for every u it satisfies

$$0=\big\langle\nabla V_{z_k}(z_{k+1})+\alpha\widetilde{\nabla}_{k+1}+\alpha g,z_{k+1}-u\big\rangle\ .$$

At this point, using the equality $\langle\nabla V_{z_k}(z_{k+1}),z_{k+1}-u\rangle=V_{z_k}(z_{k+1})-V_{z_k}(u)+V_{z_{k+1}}(u)$ (known as the "three-point equality of Bregman divergence", see Rakhlin (2009)), as well as the inequality $\langle g,z_{k+1}-u\rangle\ge\psi(z_{k+1})-\psi(u)+\sigma V_{z_{k+1}}(u)$ which comes from the strong convexity of $\psi(\cdot)$, we can write

$$\begin{aligned}
&\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\
&=-\langle z_{k+1}-z_k,z_{k+1}-u\rangle-\langle\alpha g,z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\
&\le-V_{z_k}(z_{k+1})+V_{z_k}(u)-(1+\alpha\sigma)V_{z_{k+1}}(u)\ .
\end{aligned}$$

Finally, using $V_{z_k}(z_{k+1})\ge\frac{1}{2}\|z_k-z_{k+1}\|^2$ which comes from the strong convexity of $w(x)$ with respect to $\|\cdot\|$, we complete the proof. ■

The following lemma combines Lemma E.1, Lemma E.2 and Lemma E.3 all together, using the special choice of x_{k+1} which is a convex combination of y_k, z_k and $\widetilde{x}$:

Lemma E.4 (coupling step 1) *If $x_{k+1}=\tau_1z_k+\tau_2\widetilde{x}+(1-\tau_1-\tau_2)y_k$, where $\tau_1\le\frac{1}{9\alpha\overline{L}}$ and $\tau_2=\frac{1}{2}$,*

$$\begin{aligned}
&\alpha\langle\nabla f(x_{k+1}),z_k-u\rangle-\alpha\psi(u)\\
&\le\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-\mathbb{E}\big[F(y_{k+1})\big]+\tau_2F(\widetilde{x})-\tau_2\mathbb{E}\big[F(x_{k+1})\big]-\tau_2\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\Big)\\
&\quad+V_{z_k}(u)-(1+\alpha\sigma)\mathbb{E}\big[V_{z_{k+1}}(u)\big]+\frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}\psi(y_k)-\frac{\alpha}{\tau_1}\psi(x_{k+1})\ .
\end{aligned}$$

Proof We first apply Lemma E.3 and get

$$\begin{aligned}
&\alpha\langle\widetilde{\nabla}_{k+1},z_k-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\
&=\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle+\alpha\langle\widetilde{\nabla}_{k+1},z_{k+1}-u\rangle+\alpha\psi(z_{k+1})-\alpha\psi(u)\\
&\le\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle-\frac{1}{2}\|z_k-z_{k+1}\|^2+V_{z_k}(u)-(1+\alpha\sigma)V_{z_{k+1}}(u)\ . \qquad \text{(E.2)}
\end{aligned}$$

By defining $v\overset{\text{def}}{=}\tau_1z_{k+1}+\tau_2\widetilde{x}+(1-\tau_1-\tau_2)y_k$, we have $x_{k+1}-v=\tau_1(z_k-z_{k+1})$ and therefore

$$\begin{aligned}
&\mathbb{E}\Big[\alpha\langle\widetilde{\nabla}_{k+1},z_k-z_{k+1}\rangle-\frac{1}{2}\|z_k-z_{k+1}\|^2\Big]=\mathbb{E}\Big[\frac{\alpha}{\tau_1}\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{1}{2\tau_1^2}\|x_{k+1}-v\|^2\Big]\\
&=\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{1}{2\alpha\tau_1}\|x_{k+1}-v\|^2-\psi(v)+\psi(x_{k+1})\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\
&\overset{①}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(\langle\widetilde{\nabla}_{k+1},x_{k+1}-v\rangle-\frac{9\overline{L}}{2}\|x_{k+1}-v\|^2-\psi(v)+\psi(x_{k+1})\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\
&\overset{②}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-F(y_{k+1})+\frac{1}{16\overline{L}}\sigma_{k+1}^2\Big)+\frac{\alpha}{\tau_1}\Big(\psi(v)-\psi(x_{k+1})\Big)\Big]\\
&\overset{③}{\le}\mathbb{E}\Big[\frac{\alpha}{\tau_1}\Big(F(x_{k+1})-F(y_{k+1})+\frac{1}{2}\big(f(\widetilde{x})-f(x_{k+1})-\langle\nabla f(x_{k+1}),\widetilde{x}-x_{k+1}\rangle\big)\Big)\\
&\quad+\frac{\alpha}{\tau_1}\Big(\tau_1\psi(z_{k+1})+\tau_2\psi(\widetilde{x})+(1-\tau_1-\tau_2)\psi(y_k)-\psi(x_{k+1})\Big)\Big]\ . \qquad \text{(E.3)}
\end{aligned}$$

Above, ① uses our choice $\tau_1\le\frac{1}{9\alpha\overline{L}}$, ② uses Lemma E.1, ③ uses Lemma E.2 together with the convexity of $\psi(\cdot)$ and the definition of v. Finally, noticing that $\mathbb{E}[\langle\widetilde{\nabla}_{k+1},z_k-u\rangle]=\langle\nabla f(x_{k+1}),z_k-u\rangle$ and $\tau_2=\frac{1}{2}$, we obtain the desired inequality by combining (E.2) and (E.3). ■

The next lemma is completely analogous to Lemma 2.7 except that we use Lemma E.4 rather than Lemma 2.6. We ignore the proof since it is a simple copy-and-paste.

Lemma E.5 (coupling step 2) *Under the same choices of τ_1,τ_2 as in Lemma E.4, we have*

$$\begin{aligned}
0\le\frac{\alpha(1-\tau_1-\tau_2)}{\tau_1}(F(y_k)-F(x^*))-\frac{\alpha}{\tau_1}\big(\mathbb{E}\big[F(y_{k+1})\big]-F(x^*)\big)+\frac{\alpha\tau_2}{\tau_1}\big(F(\widetilde{x})-\tau_2F(x^*)\big)\\
+V_{z_k}(x^*)-(1+\alpha\sigma)\mathbb{E}\big[V_{z_{k+1}}(x^*)\big]\ .
\end{aligned}$$

Abstract

We show that the average stability notion introduced by Kearns and Ron (1999); Bousquet and Elisseeff (2002) is invariant to data preconditioning, for a wide class of generalized linear models that includes most of the known exp-concave losses. In other words, when analyzing the stability rate of a given algorithm, we may assume the optimal preconditioning of the data. This implies that, at least from a statistical perspective, explicit regularization is not required in order to compensate for ill-conditioned data, which stands in contrast to a widely common approach that includes a regularization for analyzing the sample complexity of generalized linear models. Several important implications of our findings include: a) We demonstrate that the excess risk of empirical risk minimization (ERM) is controlled by the preconditioned stability rate. This immediately yields a relatively short and elegant proof for the fast rates attained by ERM in our context. b) We complement the recent bounds of Hardt et al. (2015) on the stability rate of the Stochastic Gradient Descent algorithm.

1. Introduction

Central to statistical learning theory is the notion of (algorithmic) *stability*. Since being introduced by Bousquet and Elisseeff (2002), deep connections between the *generalization* ability and the algorithmic stability of a learning algorithm have been established. It was shown by Shalev-Shwartz et al. (2010); Mukherjee et al. (2006) that stability characterizes learnability. Furthermore, in expectation, some notion of stability exactly equals the generalization error of an algorithm (namely, to the gap between true loss and train loss).

For generalized linear learning problems, a prominent geometric property which upper bounds the stability rate is the condition number of the loss function. While uniform convergence bounds Shalev-Shwartz and Ben-David (2014)[Chapter 4] mostly yield bounds that scale with $1/\sqrt{n}$, where n is the size of the sample, *well-conditioned* problems admit faster (stability) rates that scale linearly with $1/n$. The caveat is that typical (large-scale) machine learning problems are ill-conditioned. While we defer the precise definition of the *condition number* to the next part, let us mention that the condition number is controlled by two related quantities corresponding to both the choice of the loss function and the choice of the coordinate system. In a nutshell, our paper establishes the following result:

The average stability of ERM is invariant to the choice of the coordinate system.

While this observation admits a one-line proof, it has far-reaching implications. In particular, in this paper we use this observation to establish fast rates for empirical risk minimization.

The rest of the paper is organized as follows. In Section 2 we define the setting and proceed to provide basic definitions and results in stability analysis. In Section 3 we state and prove our main result. Section 4 discusses the implications to linear regression as well as improved bounds on the stability of SGD. Related work is discussed in Section 5.

2. Preliminaries

2.1 Setup

We consider the problem of minimizing the *risk* associated with *generalized linear model*:

$$\min_{w\in\mathcal{W}} L(w) := \mathbb{E}_{(x,y)\sim\mathcal{D}}[\phi_y(w^\top x)] \ . \tag{1}$$

Here, both the *domain* $\mathcal{W}$ and the *instance space* $\mathcal{X}$ are assumed to be compact and convex subsets of $\mathbb{R}^d$. We denote by $\mathcal{D}$ an arbitrary probability distribution defined over $\mathcal{X}\times\mathcal{Y}$. Each element y in the *label set* $\mathcal{Y}$ induces a twice differentiable[1] *loss function* of the form $\phi_y : \{w^\top x : \ w\in\mathcal{W},\ x\in\mathcal{X}\} \to \mathbb{R}_+$. We make the following assumptions on the loss function:

(A1) For each $y\in\mathcal{Y}$, ϕ_y is ρ-Lipschitz, i.e., $|\phi_y'(z)|\leq\rho$ for all z.
(A2) For each $y\in\mathcal{Y}$, ϕ_y is α-strongly convex, i.e., $\phi_y''(z)\geq\alpha$ for all z.

Our main example is the following formulation of *linear regression* Orabona et al. (2012).

Example 1 ***(Linear Regression:)*** *Let $\mathcal{X}$ be any compact and convex subset of $\mathbb{R}^d$ and $\mathcal{Y}$ be an interval of the form $[-Y,Y]$. The domain $\mathcal{W}$ is given by*

$$\mathcal{W} = \{w\in\mathbb{R}^d : (\forall x\in\mathcal{X})\ |w^\top x|\leq Y\} \ .$$

For all $y\in\mathcal{Y}$, let ϕ_y be the square loss, $\phi_y(z)=\frac{1}{2}(z-y)^2$. Note that for any $y\in\mathcal{Y}$ and $z\in\{w^\top x : w\in\mathcal{W},\ x\in\mathcal{X}\}$,

$$|\phi_y'(z)| = \frac{1}{2}|2(z-y)| \leq |z|+|y| \leq 2Y, \quad \|\phi_y''(z)\| = 1 \ .$$

*Hence, the assumptions **(A1-2)** are satisfied with $\rho=2Y$ and $\alpha=1$.*

More generally, our setting captures most of the known *exp-concave* functions Kivinen and Warmuth (1999). A twice-continuously differentiable function $f:\mathcal{W}\to\mathbb{R}$ is said to be $\bar{\alpha}$-exp-concave if $\nabla^2 f(w)\succeq\bar{\alpha}\nabla f(w)\nabla f(w)^\top$ for all $w\in\mathcal{W}$.

1. As we do not require smoothness of the loss function, our results can easily be extended to continuous but non-differentiable functions.

Lemma 1 *Consider a risk of the form (1) that satisfies the assumptions **(A1-2)**. Then, for any $(x, y) \in \mathcal{X} \times \mathcal{Y}$, the function $w \in \mathcal{W} \mapsto \phi_y(w^\top x)$ is α/ρ^2-exp concave.*

Proof Fix a pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$. The gradient and the Hessian of the map $\ell(w) = \phi_y(w^\top x)$ are given by

$$\nabla \ell(w) = \phi'(w^\top x)x, \quad \nabla^2 \ell(w) = \phi''(w^\top x)xx^\top \ . \tag{2}$$

By assumption $|\phi'(w^\top x)| \le \rho$ and $\phi''(w^\top x) \ge \alpha$, hence ℓ is α/ρ^2-exp concave. ■

A learning algorithm $\mathcal{A}$ receives as an input a training sequence (a.k.a. sample) of n i.i.d. pairs, $S = ((x_i, y_i))_{i=1}^n \sim \mathcal{D}^n$, and outputs a predictor, $\mathcal{A}(S) \in \mathcal{W}$. The *empirical risk function*, $\hat{L} : \mathcal{W} \to \mathbb{R}$, is defined as

$$\hat{L}_S(w) = \hat{L}(w) = \frac{1}{n} \sum_{i=1}^n \underbrace{\phi_{y_i}(w^\top x_i)}_{:=\hat{\ell}_i(w)} \ . \tag{3}$$

In this paper we focus on the ERM algorithm, whose output is a minimizer of the empirical risk.[2] We denote the output of the ERM by $\hat{w}(S)$, or simply $\hat{w}$ when S is understood from the context. The generalization error and the excess risk of $\hat{w}$ are defined by $L(\hat{w}) - \hat{L}(w)$ and $L(\hat{w}) - L(w^\star)$, respectively. For ERM, it is immediate that any upper bound on the generalization error translates into the same bound on the excess risk.

Remark 2 *While we mostly focus on exact ERM, it should be emphasized that our results are easily extended to any algorithm that approximately minimizes the empirical risk. The formulation of Lemma 3 below highlights this idea.*

2.2 Stability

In this section we review basic definitions and results on stability. For completeness, we also provide proofs of the stated results.

Let $S = ((x_i, y_i))_{i=1}^n$ be a training sequence. For every $i \in [n]$, let $\hat{w}_i$ be a minimizer of the risk w.r.t. $S \setminus \{(x_i, y_i)\}$, namely,

$$\hat{w}_i \in \operatorname*{argmin}_{w \in \mathcal{W}} \frac{1}{n-1} \sum_{j \ne i} \hat{\ell}_j(w) \ .$$

The *average stability* of ERM is defined as

$$\Delta(S, \mathcal{W}) = \frac{1}{n} \sum_{i=1}^n (\hat{\ell}_i(\hat{w}_i) - \hat{\ell}_i(\hat{w})) \ . \tag{4}$$

We omit the dependency on $\mathcal{W}$ when it is clear from the context. The next lemma shows that the expected generalization error of the ERM is equal to the expected average stability.

2. The compactness of $\mathcal{W}$ implies that both the true and the empirical risks admit minimizers.

Lemma 3 *Let $\mathcal{A}$ be a possibly randomized algorithm and denote by $\hat{w}$ its output. The generalization error of $\mathcal{A}$ satisfies*

$$\mathbb{E}_{S \sim \mathcal{D}^{n-1}}[L(\hat{w}) - \hat{L}(\hat{w})] = \mathbb{E}_{S \sim \mathcal{D}^n}[\Delta(S)] \ . \tag{5}$$

Furthermore, if $\mathcal{A}$ satisfies, for every sample S, $\mathbb{E}[\hat{L}(\hat{w})] \le \min_{w \in \mathcal{W}} \hat{L}(w) + \epsilon$, where the expectation is with respect to $\mathcal{A}$'s own randomization, then the excess risk of $\mathcal{A}$ is bounded by

$$\mathbb{E}_{S \sim \mathcal{D}^{n-1}}[L(\hat{w}) - L(w^\star)] \le \mathbb{E}_{S \sim \mathcal{D}^n}[\Delta(S)] + \epsilon \ . \tag{6}$$

Proof Since $\hat{w}_i$ does not depend on the i.i.d. pair (x_i, y_i),

$$\mathbb{E}_{S \sim \mathcal{D}^n}[\hat{\ell}_i(\hat{w}_i)] = \mathbb{E}_{S \sim \mathcal{D}^{n-1}}[L(\hat{w}(S))] \ , i = 1, \ldots, n \ .$$

By linearity of expectation, we obtain

$$\mathbb{E}_{S \sim \mathcal{D}^n}\left[\frac{1}{n} \sum_{i=1}^n \hat{\ell}_i(\hat{w}_i)\right] = \mathbb{E}_{S \sim \mathcal{D}^{n-1}}[L(\hat{w}(S))] \ .$$

Therefore,

$$\mathbb{E}[\Delta(S)] = \mathbb{E}_{S \sim \mathcal{D}^n}\left[\frac{1}{n} \sum_{i=1}^n \hat{\ell}_i(\hat{w}_i)\right] - \mathbb{E}_{S \sim \mathcal{D}^n}\left[\frac{1}{n} \sum_{i=1}^n \hat{\ell}_i(\hat{w})\right] = \mathbb{E}_{S \sim \mathcal{D}^{n-1}}[L(\hat{w})] - \mathbb{E}[\hat{L}(\hat{w})] \ .$$

This establishes the first claim.

Next, by assumption, for every S, $\mathbb{E}[\hat{L}(\hat{w})] \le \hat{L}(w^\star) + \epsilon$. Hence,

$$\mathbb{E}_{S \sim \mathcal{D}^n}[\hat{L}(\hat{w})] \le \mathbb{E}_{S \sim \mathcal{D}^n}[\hat{L}(w^\star)] + \epsilon = L(w^\star) + \epsilon \ .$$

Combining this inequality with the first claim, concludes the proof. ■

2.2.1 Stability of Well-conditioned Objectives

Lemma 3 motivates us to derive an upper bound on the average stability. A key quantity that governs $\Delta(S)$ is the condition number of the objective. We next provide exact definitions and discuss this relation.

Fix a training sequence S. We denote the empirical covariance matrix by

$$\hat{C} := \hat{C}(S) = \frac{1}{n} \sum_{i=1}^n x_i x_i^\top \ .$$

The (average) empirical condition number of $\hat{C}$ is defined as

$$\kappa(\hat{C}) = \frac{\operatorname{tr}(\hat{C})}{\lambda_{\min}(\hat{C})} \ ,$$

where $\mathrm{tr}(\hat{C})$ is the trace of $\hat{C}$ and $\lambda_{\min}(\hat{C})$ is the smallest nonzero eigenvalue of $\hat{C}$. We define the functional condition number as the ratio between the squared Lipschitz parameter and the strong convexity parameter:

$$\kappa(\phi) = \frac{\rho^2}{\alpha} \ .$$

Finally, we define the condition number of the objective as the product between the empirical and the functional condition number:

$$\kappa = \kappa(\hat{C})\kappa(\phi) \ .$$

Lemma 4 *For every training sequence S,*

$$\Delta(S) \leq \frac{2\kappa}{n} = \frac{2\kappa(\hat{C})\kappa(\phi)}{n} = \frac{2\rho^2}{\alpha\, n}\kappa(\hat{C}) \ . \tag{7}$$

To the best of our knowledge, this result has only been proved in the context of regularized loss minimization (e.g., the bound on the uniform stability in Shalev-Shwartz and Ben-David (2014)[Corollary 13.6]). Inspecting the proofs, one can notice that the role of regularization is merely to ensure the strong convexity of the objective. This simple observation is crucial for our development.

Proof (of Lemma 4) We first assume that $\hat{C}$ is of full rank. Note that for all w, the Hessian of $\hat{L}$ at w is given by

$$\nabla^2 \hat{L}(w) = \frac{1}{n}\sum_{i=1}^{n} \phi''(w^\top x_i) x_i x_i^\top \succeq \frac{1}{n}\sum_{i=1}^{n} \alpha\, x_i x_i^\top = \alpha\, \hat{C} \ . \tag{8}$$

In particular, $\hat{L}$ is strongly convex and $\hat{w}$ is uniquely defined. Denote the strong convexity parameter of $\hat{L}$ by $\hat{\mu}$. We also denote the Lipschitz parameter of each $\hat{\ell}_i$ by $\hat{\rho}_i$ and define $\hat{\rho}^2 = \frac{1}{n}\sum_{i=1}^{n} \hat{\rho}_i^2$. We will shortly derive upper and lower bounds on these parameters, but first let us relate them to the average stability.

Fix some $i \in [n]$ and let $\hat{\Delta}_i = \hat{\ell}_i(\hat{w}_i) - \hat{\ell}_i(\hat{w})$ (we do not assume that $\hat{w}_i$ is uniquely defined). The $\hat{\rho}_i$-Lipschitzness of $\hat{\ell}_i$ yields the bound

$$\hat{\Delta}_i \leq \hat{\rho}_i \|\hat{w}_i - \hat{w}\| \ .$$

The $\hat{\mu}$-strong convexity of $\hat{L}$ implies (e.g. using Shalev-Shwartz (2011)[Lemma 2.8]) that

$$\frac{\hat{\mu}}{2}\|\hat{w}_i - \hat{w}\|^2 \leq \hat{L}(\hat{w}_i) - \hat{L}(\hat{w}) \ .$$

On the other hand, since $\hat{w}_i$ minimizes the risk over $S \setminus \{(x_i, y_i)\}$, we have that

$$\hat{L}(\hat{w}_i) - \hat{L}(\hat{w}) = \frac{\sum_{j\neq i}(\hat{\ell}_j(\hat{w}_i) - \hat{\ell}_j(\hat{w}))}{n} + \frac{\hat{\ell}_i(\hat{w}_i) - \hat{\ell}_i(\hat{w})}{n} \leq 0 + \frac{\hat{\Delta}_i}{n} \ .$$

Combining the bounds, we conclude the following bound for every $i \in [n]$:

$$\hat{\Delta}_i^2 \leq \hat{\rho}_i^2 \|\hat{w}_i - \hat{w}\|^2 \leq \frac{2\hat{\rho}_i^2}{\hat{\mu}}(\hat{L}(\hat{w}_i) - \hat{L}(\hat{w})) \leq \frac{2\hat{\rho}_i^2}{n\hat{\mu}}\hat{\Delta}_i \ .$$

Dividing by $\hat{\Delta}_i$ (we may assume w.l.o.g. that $\hat{\Delta}_i > 0$), we obtain

$$\hat{\Delta}_i \leq \frac{2\hat{\rho}_i^2}{n\hat{\mu}} \ . \tag{9}$$

Let us remark that at this point, we can deduce a bound of $\max_{i\in[n]} \frac{2\hat{\rho}_i^2}{n\hat{\mu}}$ on the uniform stability. This matches the bound in Shalev-Shwartz and Ben-David (2014)[Corollary 13.6]. We next proceed to establish the claimed bound on the average stability.

By averaging (9) over $i = 1, \ldots, n$, we obtain

$$\hat{\Delta} = \frac{1}{n}\sum_{i=1}^{n} \hat{\Delta}_i \leq \left(\frac{1}{n}\sum_{i=1}^{n} \hat{\rho}_i^2\right)\frac{2}{n\hat{\mu}} = \frac{2\hat{\rho}^2}{n\hat{\mu}} \ . \tag{10}$$

It remains to derive bounds on $\hat{\rho}$ and $\hat{\mu}$. Note that

$$\|\nabla \hat{\ell}_i(w)\|^2 = \|\phi'(w^\top x_i)x_i\|^2 \leq \rho^2\|x_i\|^2 = \rho^2 \mathrm{tr}(x_i x_i^\top) \ .$$

Hence, $\hat{\rho}_i^2 \leq \rho^2 \mathrm{tr}(x_i x_i^\top)$. By averaging, we obtain that $\hat{\rho}^2 \leq \rho^2 \mathrm{tr}(\hat{C})$. Next, using (8) we obtain that $\hat{\mu} \geq \alpha\lambda_d(\hat{C})$. By substituting the bounds on $\hat{\rho}^2$ and $\hat{\mu}$ in (10), we conclude the desired bound.

Note that if $\hat{C}$ is not of full rank, we can replace each vector $x \in \mathbb{R}^d$ with $U^\top x$, where the columns of U form an orthonormal basis for $\mathrm{span}(\{x_1, \ldots, x_n\})$, without affecting $\hat{\Delta}, \hat{\Delta}_1, \ldots, \hat{\Delta}_n$ (this modification is only for the sake of the analysis). As a result, the new covariance matrix is of full rank and its eigenvalues are $\lambda_1(\hat{C}), \ldots, \lambda_{\min}(\hat{C})$. Repeating the above arguments, we conclude the proof. ■

Let us specify the bound to linear regression as formulated in Example (1). As $\alpha = 1$ and $\rho = 2Y$, the functional condition number is $4Y^2$. Hence, the average stability is bounded by

$$\Delta(S) \leq \frac{4Y^2}{n}\hat{\kappa}(\hat{C}) \ . \tag{11}$$

Using Lemma 3 we deduce the same bound on the excess risk. The weakness of this bound stems from the fact that empirically, the empirical condition number tends to be huge (e.g., see the empirical study in Gonen et al. (2016)).

In the next section we show that the (dependence on the) empirical condition number associated with our arbitrary choice of coordinate system can be replaced by the empirical condition number obtained by an optimal preconditioning.

3. Preconditioned Stability

We are now in position to describe our main result. Let P be a (symmetric) positive definite matrix, S_P be the training set obtained by replacing every x_j with $\tilde{x}_j = P^{-1/2}x_j$, and $\mathcal{W}_P = P^{1/2}\mathcal{W}$. We call $P^{-1/2}$ a *preconditioner*. Recall the definition of average stability from Equation (4). Our main theorem is:

Theorem 5 *For any training sequence S and positive definite matrix P,*

$$\Delta(S_P, \mathcal{W}_P) = \Delta(S, \mathcal{W}) \ .$$

In words, the average stability is invariant to the choice of the coordinate system.

Proof The crucial observation is that the empirical risk minimization with respect to S_P over the domain $\mathcal{W}_P$ is equivalent to the ERM w.r.t. S over the domain $\mathcal{W}$ in the following sense. For any pair $(w, \tilde{w} = P^{1/2}w) \in \mathcal{W} \times \mathcal{W}_P$ and any $j \in [n]$, the prediction $(\tilde{w})^\top \tilde{x}_j$ is equal to the prediction $w^\top x_j$. Therefore, the empirical risks $\hat{L}_{S_p}(\tilde{w})$ and $\hat{L}_S(w)$ are equal. By associating the corresponding minimizers of the empirical risk (i.e., $\hat{w}$ is associated with $P^{1/2}\hat{w}$ and for any $i \in [n]$, $\hat{w}_i$ is associated with $P^{1/2}\hat{w}_i$), we conclude our proof. ■

Theorem 5 tells us that we can analyze the stability of S_P instead of the stability of S. Crucially, this is true for every P, even one that is chosen based on S. Therefore, the expected suboptimality is upper bounded by the expected value of the quantity, $\inf_{P \succ 0} \Delta(S_P, \mathcal{W}_P)$, which we refer to as the *preconditioned average stability*. Equipped with this observation, we next choose P that leads to a minimal condition number, and consequently obtain a tighter bound on the excess risk.

Note that for every $P \succ 0$, the empirical covariance matrix that corresponds to the preconditioned training sequence, S_P, is

$$\frac{1}{n}\sum_{i=1}^{n}(P^{-1/2}x_i)(P^{-1/2}x_i)^\top = P^{-1/2}\left(\frac{1}{n}\sum_{i=1}^{n}x_i x_i^\top\right)P^{-1/2} = P^{-1/2}\hat{C}P^{-1/2} \ .$$

When $\hat{C}$ is of full rank, by choosing $P = \hat{C}$, we obtain that

$$\kappa(\underbrace{P^{-1/2}\hat{C}P^{-1/2}}_{I}) = \frac{\mathrm{tr}(I)}{\lambda_{\min}(I)} = d \ .$$

If $\hat{C}$ is not of full rank, we can add arbitrary "noise" in directions that do not lie in the column space of $\hat{C}$. For example, by choosing $P = \hat{C} + \delta(I - \hat{C}\hat{C}^\dagger)$, (where δ can be any positive scalar), we obtain that $\kappa(P^{-1/2}\hat{C}P^{-1/2}) = \mathrm{rank}(\hat{C}) \leq d$. It is easy to see that in both cases, we obtain the minimal value of $\kappa(P^{-1/2}\hat{C}P^{-1/2})$ over all matrices $P \succ 0$. Combining this bound with Lemma 3 and Lemma 4, we arrive at the following conclusion.

Corollary 6 *Consider the optimization problem (1), where for all $y \in \mathcal{Y}$, ϕ_y is ρ-Lipschitz and α-strongly convex. The expected excess risk of empirical risk minimization is bounded by*

$$\mathbb{E}_{S\sim\mathcal{D}^{n-1}}[L(\hat{w}) - L(w^\star)] \leq \mathbb{E}_{S\sim\mathcal{D}^n}[\Delta(S)] = \mathbb{E}_{S\sim\mathcal{D}^n}[\inf_{P\succ 0}\Delta(S_P)] \leq \frac{2\rho^2 d}{\alpha n} \ .$$

4. Some Implications

4.1 Linear Regression

We start by specifying our bounds to linear regression (Example (1)).

Corollary 7 ***(Linear Regression)*** *Consider linear regression as formulated in Example (1). The expected excess risk of ERM is bounded by*

$$\mathbb{E}_{S\sim\mathcal{D}^{n-1}}[L(\hat{w}) - L(w^\star)] \leq \Delta(S) \leq \frac{4Y^2 d}{n} \ .$$

Comparing the bounds in (11) and Corollary 7, we see that the dependence on $\hat{\kappa}(\hat{C})$ is replaced by the optimal empirical condition number, $\hat{\kappa}(I) = d$. As we mentioned above, this gap tends to be huge in practice.

As we discuss in Section 5, standard bounds for this setting depend on the geometry of $\mathcal{X}$ and $\mathcal{W}$. On the contrary, it follows from the generalized Cauchy-Schwarz inequality that for any choice of a norm $\|\cdot\|$ on $\mathbb{R}^d$, our bound applies to the sets[3]

$$\mathcal{X} = \mathcal{B}_{\|\cdot\|} = \{x \in \mathbb{R}^d : \|x\| \leq 1\}, \quad \mathcal{W} = Y\mathcal{B}_{\|\cdot\|^\star} := \{w \in \mathbb{R}^d : \|w\|^\star \leq Y\} \tag{12}$$

4.2 The Average Stability of Stochastic Gradient Descent

One of the most widely used algorithms in machine learning is Stochastic Gradient Descent (SGD). Besides its computational simplicity, its popularity stems also from its generalization abilities Shalev-Shwartz and Ben-David (2014)[Section 14.5]. Recently, Hardt et al. (2015) studied the (uniform) stability of SGD in various settings. Following our notation, theorem 3.9 of their paper implies a bound of $\max_i \frac{2\hat{\rho}_i^2}{\gamma n}$ on the uniform stability, where γ is the strong convexity of the entire objective, and for any $i \in [n]$, $\hat{\rho}_i$ is the Lipschitz parameter of $\hat{\ell}_i$. As the proof of Lemma 4 reveals, γ can be bounded by $\alpha\hat{\kappa}(\hat{C})$ and $\hat{\rho}_i$ is at most $\hat{\rho}^2\|x_i\|^2$. In particular, the bound depends on the choice of the coordinate system.

As implied by Bubeck (2015)[Theorem 3.2], SGD can be viewed in our context as an (approximate) ERM. Hence, the average stability of SGD is invariant to the choice of the coordinate system and the stability rate of SGD is bounded as in Corollary 6. It should be noted that our bound holds in the regime where SGD converges to a minimizer of the empirical risk, whereas the result of Hardt et al. holds for the entire trajectory of SGD.

5. Related Work

5.1 Slower rates

One of the most direct techniques for establishing bounds on the excess risk is via analyzing the Rademacher complexity Bartlett and Mendelson (2003) of the associated class of predictors. In our setting, these techniques have been employed by Kakade et al. (2009) to

3. In fact, under mild additional assumptions on $\mathcal{X}$, any two sets $\mathcal{X}$ and $\mathcal{W}$ that satisfy our assumptions can be presented in this way. Assume that $\mathcal{X}$ is symmetric (i.e., $x \in \mathcal{X}$ iff $-x \in \mathcal{X}$) and $0 \in \mathrm{int}(\mathcal{X})$. Then it is known Conway (2013) that $\mathcal{X}$ induces a norm on $\mathbb{R}^d$ through the Minkowsky functional

$$\|x\| := p(x) = \inf\{t \in \mathbb{R} : x \in tB\} \ .$$

It is immediate that the closed unit ball $\{x : \|x\| \leq 1\}$ is $\mathcal{X}$ itself. Therefore, the dual norm is simply the support function of $\mathcal{X}$

$$\|w\|^\star = \max_{x\in\mathcal{X}} w^\top x \ .$$

It follows that $\mathcal{X}$ and $\mathcal{W}$ can be described as in (12).

establish bounds of order $1/\sqrt{n}$ on the generalization error of ERM. We refer to these rates as slower due to the inferior dependence on the sample size n.

5.2 Dependence on Norm

Note that since both the uniform and the average stability of ERM are bounded above by its generalization error Shalev-Shwartz et al. (2010), the bounds of Kakade et al. (2009) translate into bounds on the average stability.

Unlike our fast rates, the exact bounds depend on the geometry of the set $\mathcal{X}$ and $\mathcal{W}$. For example: a) If both $\mathcal{X}$ and $\mathcal{W}$ are the Euclidean unit ball in $\mathbb{R}^d$, then the obtained bound scales with $1/\sqrt{n}$. b) If $\mathcal{X}$ is the unit ℓ_∞-ball and $\mathcal{W}$ is the ℓ_1-ball, then the obtained bound scales with $\sqrt{\log(d)/n}$.

5.3 Lower bounds on the excess risk

Lower bounds for stochastic minimization of exp-concave functions have been studied in Mahdavi et al. (2015). For our setting, theorem 2 in this paper implies a bound of $\Omega(d/n)$ on the excess risk of any algorithm.

For the special case of linear regression with

$$\mathcal{X} = \{x \in \mathbb{R}^d : \|x\|_2 \leq 1\},\ \mathcal{W} = \{w \in \mathbb{R}^d : \|w\|_2 \leq B\},\ \mathcal{Y} = [-Y, Y] \tag{13}$$

Shamir (2014) proved the lower bound $\Omega\left(\min\{Y^2, \frac{B^2+dY^2}{n}, \frac{BY}{\sqrt{n}}\}\right)$ on the generalization error of ERM. The left-most term is trivially attained by the predictor $w = 0$. The middle term is attained by combining the Vovk-Azoury-Warmuth forecaster Azoury and Warmuth (2001); Vovk (2001) with standard online-to-batch conversions (Cesa-Bianchi et al. (2004)). Last, the right term is attained by ERM, as implied by the aforementioned upper bound of Kakade et al. (2009).

It is left open whether the middle term in the lower bound is attained by ERM. Note that if $B = \omega(\sqrt{d}Y)$, then the middle term in the above lower bound is asymptotically larger than our upper bound. However, since in the setting of Shamir (2014), Equation (13)) the magnitude of the predictions is not uniformly upper bounded by Y, no contradiction arises.

5.4 Stability and Regularization

Previous work Bousquet and Elisseeff (2002); Shalev-Shwartz et al. (2010) studied the rate of uniform stability in various settings. For our setting, their bounds on the expected risk are identical to the bound in Lemma 4. As we explained above, these fast rates are often worse than the so-called slower rates due to the dependence on the empirical condition number. The standard approach for tackling this problem is add a regularization term. By adding the regularization term $\lambda\|w\|^2$ to the objective, one effectively increases the eigenvalues of $\hat{C}$ by λ, and consequently, the overall condition number is decreased. However, as explained in Shalev-Shwartz and Ben-David (2014)[Section 13.4], this modification usually does not preserve the fast rates.[4]

4. Namely, when tuning λ, we need to ensure that any $\epsilon/2$-approximate minimizer with respect to the regularized objective is also an ϵ-approximate minimizer with respect to the unregularized objective. As explained in Shalev-Shwartz and Ben-David (2014)[Section 13.3], by optimally controlling this tradeoff, we no longer obtain fast rates (i.e., the stability rate scales with $1/\sqrt{n}$ rather than $1/n$).

5.5 Stability and Exp-concavity

Informally, exp-concavity can be seen as a local and weaker form of strong convexity. Indeed, the Online Newton Step (ONS) of Hazan et al. (2007), which has been designed for online minimization of exp-concave functions, achieves improved (logarithmic) regret bounds that resemble the regret bounds for strongly convex functions Hazan et al. (2007). The online-to-batch analysis of Mahdavi et al. (2015) yields a bound on the excess risk that coincides with our bounds up to logarithmic factors. The main shortcoming of the ONS algorithm is that it employs expensive iterations (the runtime per iteration scales at least quadratically with d). Hence, it is natural to ask whether there exist simpler algorithms that achieve fast rates.

This question was answered affirmatively by Koren and Levy (2015). This work, which is most closely related to our work, considers the minimization of a risk of the form $F(w) = \mathbb{E}[f(w, Z)]$, where for any z, $f(\cdot, z)$ is $\bar{\beta}$-smooth[5] and $\bar{\alpha}$-exp-concave function. They established fast rates for any algorithm that minimizes the *regularized* risk $\hat{L}(w) + \frac{1}{n}R(w)$, where $R(w)$ is assumed to be a 1-strongly convex function (e.g., one can set $R(w) = \frac{1}{2}\|w\|^2$). While exp-concavity is weaker than strong convexity, Koren and Levy (2015)[section 4.2] interprets exp-concavity as strong convexity in the (local) norm induced by the outer products of the gradients and the regularization term. In other words, the problem is well-conditioned with respect to this local norm. Note that their formulation is more general in the sense that they do not assume a GLM structure. However, it should be emphasized that all the known exp-concave functions in machine learning are of the form (1)).

The above interpretation of Koren and Levy (2015) inspired us to make one step forward and directly show that regularization is not required as long as a related (preconditioned) problem is well conditioned. Besides the obvious importance of showing the insignificance of regularization in this context, we believe that the notion of preconditioned stability and its relation to the excess risk make these ideas more transparent and simplify the proofs.

The upper bound of Koren and Levy (2015) on the excess risk scales with $\frac{24\beta d}{\bar{\alpha}n} = \frac{24\beta d\rho^2}{\alpha n}$ (recall that the exp-concavity parameter $\bar{\alpha}$ is equal to α/ρ^2). Note that our analysis does not assume smoothness of the loss. This resolves the question raised by Koren and Levy (2015) regarding the necessity of the smoothness assumption. Note that for linear regression, the smoothness is 1, making our bounds identical to the bounds of Koren and Levy (2015) for this special case.

As discussed in Koren and Levy (2015), it is difficult to translate bounds on the average stability into high-probability bounds (while preserving the fast rate and introducing only logarithmic dependence on $1/\delta$).

5.6 Other Techniques and High-Probability Bounds

The bound on the expected excess risk in Corollary 6 can be obtained by using two additional techniques. Both of these techniques also yield high probability bounds. We next survey the corresponding results.

5. That is, the maximal eigenvalue of the Hessian of f at any point w is at most β.

A recent follow-up work by Mehta (2016) established a bound of $\tilde{O}(d\log(n)+\log(1/\delta)/n)$ on the excess risk of ERM, where δ is the confidence parameter.[6]. He also showed how to get rid of the $\log(n)$ factor by boosting the confidence of ERM. The proof is centered around a Bernstein condition which holds due to the exp-concavity assumption.

Another alternative, is to bound the excess risk by the local Rademacher complexity (LRC) of the associated class of predictors (e.g., using Corollary 5.3 in Bartlett et al. (2005)). In our setting, one can derive bounds on the LRC (e.g., using Koltchinskii (2008)) which coincide with our bounds.

All of these techniques employ arguably heavy machinery and lack the geometric interpretation, which is nicely captured by our notion of preconditioned stability.

Acknowledgments

We thank Iliya Tolstikhin for pointing out the alternative proof of Corollary 6 using local Rademacher complexities.

6. The dependence on the exp-concavity parameter as well as the diameter of the loss function is hidden.

Abstract

This work characterizes the benefits of averaging techniques widely used in conjunction with stochastic gradient descent (SGD). In particular, this work presents a sharp analysis of: (1) mini-batching, a method of averaging many samples of a stochastic gradient to both reduce the variance of a stochastic gradient estimate and for parallelizing SGD and (2) tail-averaging, a method involving averaging the final few iterates of SGD in order to decrease the variance in SGD's final iterate. This work presents sharp finite sample generalization error bounds for these schemes for the stochastic approximation problem of least squares regression.

Furthermore, this work establishes a precise problem-dependent extent to which mini-batching can be used to yield provable near-linear parallelization speedups over SGD with batch size one. This characterization is used to understand the relationship between learning rate versus batch size when considering the excess risk of the final iterate of an SGD procedure. Next, this mini-batching characterization is utilized in providing a highly parallelizable SGD method that achieves the minimax risk with nearly the same number of serial updates as batch gradient descent, improving significantly over existing SGD-style methods. Following this, a non-asymptotic excess risk bound for model averaging (which is a communication efficient parallelization scheme) is provided.

Finally, this work sheds light on fundamental differences in SGD's behavior when dealing with mis-specified models in the non-realizable least squares problem. This paper shows that maximal stepsizes ensuring minimax risk for the mis-specified case *must* depend on the noise properties.

The analysis tools used by this paper generalize the operator view of averaged SGD (Défossez and Bach, 2015) followed by developing a novel analysis in bounding these operators to characterize the generalization error. These techniques are of broader interest in analyzing various computational aspects of stochastic approximation.

1. Introduction and Problem Setup

With the ever increasing size of modern day datasets, practical algorithms for machine learning are increasingly constrained to spend less time and use less memory. This makes it particularly desirable to employ simple streaming algorithms that generalize well in a few passes over the dataset.

Stochastic gradient descent (SGD) is perhaps the simplest and most well studied algorithm that meets these constraints. The algorithm repeatedly samples an instance from the stream of data and updates the current parameter estimate using the gradient of the sampled instance. Despite its simplicity, SGD has been immensely successful and is the de-facto method for large scale learning problems. The merits of SGD for large scale learning and the associated computation versus statistics tradeoffs is discussed in detail by the seminal work of Bottou and Bousquet (2007).

While a powerful machine learning tool, unfortunately SGD in its simplest forms is inherently serial. Over the past years, as dataset sizes have grown there have been remarkable developments in processing capabilities with multi-core/distributed/GPU computing infrastructure available in abundance. The presence of this computing power has triggered the development of parallel/distributed machine learning algorithms (Mann et al. (2009); Zinkevich et al. (2011); Bradley et al. (2011); Niu et al. (2011); Li et al. (2014); Zhang and Xiao (2015)) that possess the capability to utilize multiple cores/machines. However, despite this exciting line of work, it is yet unclear how to best parallelize SGD and fully utilize these computing infrastructures.

This paper takes a step towards answering this question, by characterizing the behavior of constant stepsize SGD for the problem of strongly convex stochastic least square regression (LSR) under two averaging schemes widely believed to improve the performance of SGD. In particular, this work considers the natural parallelization technique of *mini-batching*, where multiple data-points are processed simultaneously and the current iterate is updated by the average gradient over these samples, and combine it with variance reducing technique of *tail-averaging*, where the average of many of the final iterates are returned as SGD's estimate of the solution.

In this work, parallelization arguments are structured through the lens of a *work-depth* tradeoff: *work* refers to the total computation required to reach a certain generalization error, and *depth* refers to the number of serial updates. Depth, defined in this manner, is a reasonable estimate of the runtime of the algorithm on a large multi-core architecture with shared memory, where there is no communication overhead, and has strong implications for parallelizability on other architectures.

1.1 Problem Setup and Notations

We use boldface small letters ($\mathbf{x}, \mathbf{w}$ etc.) for vectors, boldface capital letters ($\mathbf{A}, \mathbf{H}$ etc.) for matrices and normal script font letters ($\mathcal{M}, \mathcal{T}$ etc) for tensors. We use $\otimes$ to denote the outer product of two vectors or matrices. Loewner ordering between two PSD matrices is represented using $\succeq, \preceq$.
This paper considers the stochastic approximation problem of Least Squares Regression (LSR). Let $L : \mathbb{R}^d \to \mathbb{R}$ be the expected square loss over tuples $(\mathbf{x}, y)$ sampled from a distribution $\mathcal{D}$:

$$L(\mathbf{w}) = \frac{1}{2} \cdot \mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}[(y - \langle \mathbf{w}, \mathbf{x}\rangle)^2] \; \forall \, \mathbf{w} \in \mathbb{R}^d. \tag{1}$$

Let $\mathbf{w}^*$ be a minimizer of the problem (1). Now, let the Hessian of the problem (1) be denoted as:

$$\mathbf{H} \stackrel{\text{def}}{=} \nabla^2 L(\mathbf{w}) = \mathbb{E}\left[\mathbf{x}\mathbf{x}^\top\right].$$

Next, we define the fourth moment tensor $\mathcal{M}$ of the inputs $\mathbf{x}$ as:

$$\mathcal{M} \stackrel{\text{def}}{=} \mathbb{E}\left[\mathbf{x} \otimes \mathbf{x} \otimes \mathbf{x} \otimes \mathbf{x}\right].$$

Let the noise $\epsilon_{\mathbf{x},y}$ in a sample $(\mathbf{x}, y) \sim \mathcal{D}$ with respect to the minimizer $\mathbf{w}^*$ of (1) be denoted as:

$$\epsilon_{\mathbf{x},y} \stackrel{\text{def}}{=} y - \langle \mathbf{w}^*, \mathbf{x} \rangle.$$

Finally, let the noise covariance matrix $\mathbf{\Sigma}$ be denoted as:

$$\mathbf{\Sigma} \stackrel{\text{def}}{=} \mathbb{E}\left[\epsilon_{\mathbf{x},y}^2 \mathbf{x}\mathbf{x}^\top\right].$$

The *homoscedastic* (or, additive noise/well specified) case of LSR refers to the case when $\epsilon_{\mathbf{x},y}$ is mutually independent from $\mathbf{x}$. This is the case, say, when $\epsilon_{\mathbf{x},y}$ sampled from a Gaussian, $N(0, \sigma^2)$ independent of $\mathbf{x}$. In this case, $\mathbf{\Sigma} = \sigma^2 \mathbf{H}$, where, $\sigma^2 = \mathbb{E}\left[\epsilon^2\right]$, where the subscript on $\epsilon_{\mathbf{x},y}$ is suppressed owing to the independence of ϵ on any sample $(\mathbf{x}, y) \sim \mathcal{D}$. On the other hand, the *heteroscedastic* (or, mis-specified) case refers to the setting when $\epsilon_{\mathbf{x},y}$ is correlated with the input $\mathbf{x}$. In this paper, all our results apply to the general mis-specified case of the LSR problem.

1.1.1 ASSUMPTIONS

We make the following assumptions about the problem.

($\mathcal{A}1$) **Finite fourth moment:** The fourth moment tensor $\mathcal{M} = \mathbb{E}\left[\mathbf{x}^{\otimes 4}\right]$ exists and is finite.

($\mathcal{A}2$) **Strong convexity:** The Hessian of $L(\cdot)$, $\mathbf{H} = \mathbb{E}\left[\mathbf{x}\mathbf{x}^\top\right]$ is positive definite i.e., $\mathbf{H} \succ 0$.

($\mathcal{A}1$) is a standard regularity assumption for the analysis of SGD and related algorithms. ($\mathcal{A}2$) is also a standard assumption and guarantees that the minimizer of (1), i.e., $\mathbf{w}^*$ is unique.

1.1.2 IMPORTANT QUANTITIES

In this section, we will introduce some important quantities required to present our results. Let $\mathbf{I}$ denote the $d \times d$ identity matrix. For any matrix $\mathbf{A}$, $\mathcal{M}\mathbf{A} \stackrel{\text{def}}{=} \mathbb{E}\left[\left(\mathbf{x}^\top \mathbf{A} \mathbf{x}\right) \mathbf{x}\mathbf{x}^\top\right]$. Let $\mathcal{H}_{\mathcal{L}} = \mathbf{H} \otimes \mathbf{I}$ and $\mathcal{H}_{\mathcal{R}} = \mathbf{I} \otimes \mathbf{H}$ represent the left and right multiplication operators of the matrix $\mathbf{H}$ so that for any matrix $\mathbf{A}$, we have $\mathcal{H}_{\mathcal{L}}\mathbf{A} = \mathbf{H}\mathbf{A}$ and $\mathcal{H}_{\mathcal{R}}\mathbf{A} = \mathbf{A}\mathbf{H}$.

- **Fourth moment bound:** Let R^2 be the smallest number such that $\mathcal{M}\mathbf{I} \preceq R^2\mathbf{H}$.
- **Smallest eigenvalue:** Let μ be the smallest eigenvalue of $\mathbf{H}$ i.e., $\mathbf{H} \succeq \mu\mathbf{I}$.

The fourth moment bound implies that $\mathbb{E}\left[\|\mathbf{x}\|^2\right] \leq R^2$. Further more, ($\mathcal{A}2$) implies that the smallest eigenvalue μ of $\mathbf{H}$ is strictly greater than zero ($\mu > 0$).

1.1.3 STOCHASTIC GRADIENT DESCENT: MINI-BATCHING AND ITERATE AVERAGING

In this paper, we work with a stochastic first order oracle. This oracle, when queried at $\mathbf{w}$ samples an instance $(\mathbf{x}, y) \sim \mathcal{D}$ and uses this to return an unbiased estimate of the gradient of $L(\mathbf{w})$:

$$\widehat{\nabla L}(\mathbf{w}) = -(y - \langle \mathbf{w}, \mathbf{x} \rangle) \cdot \mathbf{x}; \;\; \mathbb{E}\left[\widehat{\nabla L}(\mathbf{w})\right] = \nabla L(\mathbf{w}).$$

We consider the stochastic gradient descent (SGD) method (Robbins and Monro, 1951), which minimizes $L(\mathbf{w})$ by following the direction opposite to this noisy stochastic gradient estimate, i.e.:

$$\mathbf{w}_t = \mathbf{w}_{t-1} - \gamma \cdot \widehat{\nabla L}_t(\mathbf{w}_{t-1}), \text{ with, } \widehat{\nabla L}_t(\mathbf{w}_{t-1}) = -(y_t - \langle \mathbf{w}_{t-1}, \mathbf{x}_t \rangle) \cdot \mathbf{x}_t$$

with $\gamma > 0$ being a constant step size/learning rate; $\widehat{\nabla L}_t(\mathbf{w}_{t-1})$ is the stochastic gradient evaluated using the sample $(\mathbf{x}_t, y_t) \sim \mathcal{D}$ at $\mathbf{w}_{t-1}$. We consider two algorithmic primitives used in conjunction with SGD namely, mini-batching and tail-averaging (also referred to as iterate/suffix averaging).

Mini-batching involves querying the gradient oracle several times and using the average of the returned stochastic gradients to take a single step. That is,

$$\mathbf{w}_t = \mathbf{w}_{t-1} - \gamma \cdot \left(\frac{1}{b}\sum_{i=1}^{b} \widehat{\nabla L}_{t,i}(\mathbf{w}_{t-1})\right),$$

where, b is the batch size. Note that at iteration t, mini-batching involves repeatedly querying the stochastic gradient oracle at $\mathbf{w}_{t-1}$ for a total of b times. For every query $i = 1, ..., b$ at iteration t, the oracle samples an instance $\{\mathbf{x}_{ti}, y_{ti}\}$ and returns a stochastic gradient estimate $\widehat{\nabla L}_{t,i}(\mathbf{w}_{t-1})$. These estimates $\{\widehat{\nabla L}_{t,i}(\mathbf{w}_{t-1})\}_{i=1}^b$ are averaged and then used to perform a single step from $\mathbf{w}_{t-1}$ to $\mathbf{w}_t$. Mini-batching enables the possibility of parallelization owing to the use of cheap matrix-vector multiplication for computing stochastic gradient estimates. Furthermore, mini-batching allows for the possible reduction of variance owing to the effect of averaging several stochastic gradient estimates.

Tail-averaging (or suffix averaging) refers to returning the average of the final few iterates of a stochastic gradient method as a means to improve its variance properties (Ruppert, 1988; Polyak and Juditsky, 1992). In particular, assuming the stochastic gradient method is run for $n-$steps, tail-averaging involves returning

$$\bar{\mathbf{w}} = \frac{1}{n-s}\sum_{t=s+1}^{n} \mathbf{w}_t$$

as an estimate of $\mathbf{w}^*$. Note that s can be interpreted as being cn, with $c < 1$ being some constant.

Typical excess risk bounds (or, generalization error bounds) for the stochastic approximation problem involve the contribution of two error terms namely, (i) the bias, which refers to the dependence on the starting conditions $\mathbf{w}_0$/initial excess risk $L(\mathbf{w}_0) - L(\mathbf{w}^*)$ and, (ii) the variance, which refers to the dependence on the noise introduced by the use of a stochastic first order oracle.

1.1.4 OPTIMAL ERROR RATES FOR THE STOCHASTIC APPROXIMATION PROBLEM

Under standard regularity conditions often employed in the statistics literature, the minimax optimal rate on the excess risk is achieved by the standard Empirical Risk Minimizer (or, Maximum Likelihood Estimator) (Lehmann and Casella, 1998; van der Vaart, 2000). Given n i.i.d. samples $\mathcal{S}_n = \{\mathbf{x}_i, y_i\}_{i=1}^n$ drawn from $\mathcal{D}$, define the empirical risk minimization problem as obtaining

$$\mathbf{w}_n^* = \arg\min_{\mathbf{w}} \frac{1}{2n}\sum_{i=1}^{n}(y_i - \langle \mathbf{w}, \mathbf{x}_i \rangle)^2.$$

Let us define the noise variance $\widehat{\sigma^2_{\text{MLE}}}$ to represent

$$\widehat{\sigma^2_{\text{MLE}}} = \mathbb{E}\left[\|\widehat{\nabla L}(\mathbf{w}^*)\|^2_{\mathbf{H}^{-1}}\right] = \text{Tr}[\mathbf{H}^{-1}\mathbf{\Sigma}].$$

The asymptotic minimax rate of the Empirical Risk Minimizer $\mathbf{w}_n^*$ on *every problem instance* is $\widehat{\sigma^2_{\text{MLE}}}/n$ (Lehmann and Casella, 1998; van der Vaart, 2000), i.e.,

$$\lim_{n\to\infty} \frac{\mathbb{E}_{\mathcal{S}_n}[L(\mathbf{w}_n^*)] - L(\mathbf{w}^*)}{\widehat{\sigma^2_{\text{MLE}}}/n} = 1.$$

For the well-specified case (i.e., the additive noise case, where, $\mathbf{\Sigma} = \sigma^2\mathbf{H}$), we have $\widehat{\sigma^2_{\text{MLE}}} = d\sigma^2$. Seminal works of Ruppert (1988); Polyak and Juditsky (1992) prove that tail-averaged SGD, with averaging from start, achieves the minimax rate for the *well-specified* case in the limit of $n \to \infty$.

Goal: In this paper, we seek to provide a non-asymptotic understanding of (a) mini-batching and issues of learning rate versus batch-size, (b) tail-averaging, (c) the effect of the model mis-specification, (d) a batch size doubling scheme for parallelizing statistical estimation, (e) a communication efficient parallelization scheme namely, parameter-mixing/model averaging and (f) the behavior of learning rate versus batch size on the final iterate of the mini-batch SGD procedure, on the behavior of excess risk of SGD (in terms of both the bias and the variance terms) for the streaming LSR problem, with the goal of achieving the minimax rate on every problem instance.

1.2 This Paper's Contributions

The main contributions of this paper are as follows:

- This work shows that mini-batching yields near-linear parallelization speedups over the standard serial SGD (i.e. with batch size 1), as long as the mini-batch size is smaller than a problem dependent quantity (which we denote by b_{thresh}). When batch-sizes increase beyond b_{thresh}, mini-batching is inefficient (owing to the lack of serial updates), thus obtaining only sub-linear speedups over mini-batching with a batch size b_{thresh}. A by-product of this analysis sheds light on how the step sizes naturally interpolate from ones used by standard serial SGD (with batch size 1) to ones used by batch gradient descent.

- While the final iterate of SGD decays the bias at a geometric rate but does not obtain minimax rates on the variance, the averaged iterate (Polyak and Juditsky, 1992; Défossez and Bach, 2015) decays the bias at a sublinear rate while achieving minimax rates on the variance. This work rigorously shows that tail-averaging obtains the best of both worlds: decaying the bias at a geometric rate and obtaining near-minimax rates (up to constants) on the variance. This result corroborates with empirical findings (Merity et al., 2017) that indicate the benefits of tail-averaging in general contexts such as training Long-Short term memory models (LSTMs).

- Next, this paper precisely characterizes the tradeoffs of learning rate versus batch size and its effect on the excess risk of the final iterate of an SGD procedure, which provides theoretical evidence to empirical observations (Goyal et al., 2017; Smith et al., 2017) described in the context of deep learning and non-convex optimization.

- Combining the above results, this paper provides a mini-batching and tail-averaging version of SGD that is highly parallelizable: the number of serial steps (which is a proxy for the un-parallelizable time) of this algorithm nearly matches that of *offline gradient descent* and is lower than the serial time of all existing streaming LSR algorithms. See Table 1 for comparison. We note that these results are obtained by providing a tight finite-sample analysis of the effects of mini-batching and tail-averaging with large constant learning rate schemes.

- We provide a non-asymptotic analysis of parameter mixing/model averaging schemes for the streaming LSR problem. Model averaging schemes are an attractive proposition for distributed learning owing to their communication efficient nature, and they are particularly effective in the regime when the estimation error (i.e. variance) is the dominating term in the excess risk. Here, we characterize the excess risk (in terms of both the bias and variance) of the model averaging procedure which sheds light on situations when it is an effective parallelization scheme (in that when this scheme yields linear parallelization speedups).

- All the results in this paper are established for the *general mis-specified* case of the streaming LSR problem. This establishes a fundamental difference in the behavior of SGD when dealing with mis-specified models in contrast to existing analyses that deal with the well-specified case. In particular, this analysis reveals a surprising insight that the maximal stepsizes (that ensure minimax optimal rates) are a function of the noise properties of the mis-specified problem instance. The main takeaway of this analysis is that the maximal step sizes (that permit achieving minimax rates) for the mis-specified case can be *much lower* than ones employed in the well-specified case: indeed, a problem instance that yields such a separation between the maximal learning rates for the well specified and the mis-specified case is presented.

The tool employed in obtaining these results generalizes the operator view of averaged SGD with batch size 1 (Défossez and Bach, 2015) and a clear exposition of the bias-variance decomposition from Jain et al. (2017a) to obtain a sharp bound on the excess risk for mini-batch, tail-averaged constant step-size SGD. Note that the work of Défossez and Bach (2015) does not establish minimax rates while working with large constant step sizes; this shortcoming is remedied by this paper through a novel sharp analysis that rigorously establishes minimax optimal rates while working with large constant step sizes. Furthermore, note that while straightforward operator norm bounds of the matrix operators suffice to show convergence of the SGD method, they turn out to be pretty loose bounds (particularly for bounding the variance). To tighten these bounds, this paper presents a fine grained analysis that bounds the trace of the SGD operators when applied to the relevant matrices. The bounds of this paper and its advantages compared to existing algorithms is indicated in table 1.

While this paper's results focus on strongly convex streaming least square regression, we believe that our techniques and results extend more broadly. This paper aims to serve as the basis for future work on analyzing SGD and parallelization of large scale algorithms for machine learning.

Paper organization: Section 2 presents the related work. Section 3 presents the main results of this work. Section 4 outlines the proof techniques. Section 5 presents experimental simulations to demonstrate the practical utility of the established mini-batching limits and tail-averaging. The proofs of all the claims and theorems are provided in the appendix.

2. Related Work

Stochastic approximation has been the focus of much efforts starting with the work of Robbins and Monro (1951), and has been analyzed in subsequent works including Nemirovsky and Yudin (1983); Kushner and Yin (1987, 2003). These questions and the related issues of computation versus statistics tradeoffs have received renewed attention owing to their relevance in the context of modern large scale machine learning, as highlighted by the work of Bottou and Bousquet (2007).

Geometric Rates on initial error: For *offline optimization* with strongly convex objectives, gradient descent (Cauchy, 1847) and fast gradient methods (Polyak, 1964; Nesterov, 1983) indicate linear

Algorithm	Final error	Runtime/Work	Depth	Streaming	Mis-specified
Gradient Descent (Cauchy, 1847)	$\mathcal{O}\left(\frac{\sigma^2 d}{n}\right)$	$\kappa n d \log \frac{n\cdot\Delta_0}{\sigma^2 d}$	$\kappa \log \frac{n\cdot\Delta_0}{\sigma^2 d}$	×	✓
SDCA (Shalev-Shwartz and Zhang, 2012)	$\mathcal{O}\left(\frac{\sigma^2 d}{n}\right)$	$(n+\frac{R^2}{\lambda_{\min}}d)d\cdot\log\frac{n\cdot\Delta_0}{\sigma^2 d}$	$(n+\frac{R^2}{\lambda_{\min}}d)\cdot\log\frac{n\cdot\Delta_0}{\sigma^2 d}$	×	✓
Averaged SGD (Défossez and Bach, 2015)[1]	$\mathcal{O}\left(\frac{1}{\lambda_{\min}^2 n^{2\gamma}}\cdot\Delta_0+\frac{\sigma^2 d}{n}\right)$	nd	n	✓	×
Streaming SVRG with initial error oracle [2] (Frostig et al., 2015b)	$\mathcal{O}\left(\exp\left(-\frac{n\lambda_{\min}(\mathbf{H})}{R^2}\right)\cdot\Delta_0\right)+\frac{\sigma^2 d}{n}$	nd	$(\frac{R^2}{\lambda_{\min}(\mathbf{H})})\cdot\log\frac{n\cdot\Delta_0}{\sigma^2 d}$	✓	✓
Algorithm 2 (this paper)	$\mathcal{O}\left(\left(\frac{R^2 t}{\|\mathbf{H}\|_2 n}\right)^{\frac{1}{\kappa\log(\kappa)}}\cdot\Delta_0+\frac{\sigma^2 d}{n}\right)$	nd	$\frac{t}{t-\kappa\log(\kappa)}\cdot\kappa\log(\kappa)\cdot\log\left(\frac{n\cdot\Delta_0}{\sigma^2 d}\cdot\frac{R^2 t}{\|\mathbf{H}\|_2}\right)$	✓	✓
Algorithm 2 with initial error oracle (this paper)	$\mathcal{O}\left(\exp\left(-\frac{n\lambda_{\min}(\mathbf{H})}{R^2\cdot\log(\kappa)}\right)\cdot\Delta_0+\frac{\sigma^2 d}{n}\right)$	nd	$\kappa\log(\kappa)\log\frac{n\cdot\Delta_0}{\sigma^2 d}$	✓	✓

Table 1: Comparison of Algorithm 2 with existing algorithms including offline methods such as Gradient Descent, SDCA and streaming methods such as averaged SGD, streaming SVRG given n samples for LSR, with $\Delta_0 = L(\mathbf{w}_0) - L(\mathbf{w}^*)$. The error of offline methods are obtained by running these algorithms so that their final error is $\mathcal{O}(\sigma^2 d/n)$ (which is the minimax rate for the well-specified case). The table is written assuming the additive noise/well specified case; for algorithms which support the mis-specified case, these bounds can be appropriately modified. Refer to Section 1.1 for the definitions of all quantities. We do not consider accelerated variants in this table. Note that the accelerated variants have served to improve running times of the offline algorithms, with the sole exception of Jain et al. (2017b). For Algorithm 2, we require $t \geq 24\kappa\log(\kappa)$. Finally, note that streaming SVRG does not conform to the first order oracle model (Agarwal et al. (2012)).

convergence. However, a multiplicative coupling of number of samples n and condition number in the computational effort is a major drawback in the large scale context. These limitations are addressed through developments in offline stochastic methods (Roux et al., 2012; Shalev-Shwartz and Zhang, 2012; Johnson and Zhang, 2013; Defazio et al., 2014) and their accelerated variants (Shalev-Shwartz and Zhang, 2013a; Frostig et al., 2015a; Lin et al., 2015; Defazio, 2016; Allen-Zhu, 2016) which offer near linear running time in the number of samples and condition number with $\log(n)$ passes over the dataset stored in memory.

For *stochastic approximation* with strongly convex objectives, SGD offers linear rates on the bias without achieving minimax rates on the variance (Bach and Moulines, 2011; Needell et al., 2016; Bottou et al., 2016). In contrast, iterate averaged SGD (Ruppert, 1988; Polyak and Juditsky, 1992) offers a sub-linear $\mathcal{O}(1/n^2)$ rate on the bias (Défossez and Bach, 2015; Dieuleveut and Bach, 2015) while achieving minimax rates on the variance. Note that all these results consider the well-specified (additive noise) case when stating the generalization error bounds. We are unaware of any results that provide sharp non-asymptotic analysis of SGD and the related step size issues in the general mis-specified case. Streaming SVRG (Frostig et al., 2015b) offers a geometric rate on the bias and optimal statistical error rates; we will return to a discussion of Streaming SVRG below. In terms of methods faster than SGD, our own effort (Jain et al., 2017b) provides the first accelerated stochastic approximation method that improves over SGD on every problem instance.

Parallelization of Machine Learning algorithms: In *offline optimization*, Bradley et al. (2011) study parallel co-ordinate descent for sparse optimization. Parallelization via mini-batching has been studied in Cotter et al. (2011); Takác et al. (2013); Shalev-Shwartz and Zhang (2013b); Takác et al. (2015). These results compare worst case upper bounds on the training error to argue parallelization speedups, thus providing weak upper bounds on mini-batching limits. Parameter mixing/Model averaging (Mann et al., 2009) guarantees linear parallelization speedups on the variance but do not improve the bias. Approaches that attempt to re-conciliate communication-computation tradeoffs (Li et al., 2014) indicate increased mini-batching hurts convergence, and this is likely an artifact of comparing weak upper bounds. Hogwild (Niu et al., 2011) indicates near-linear parallelization speedups in the harder asynchronous optimization setting, relying on specific input structures like hard sparsity; these bounds are obtained by comparing worst case upper bounds on training error. Refer to oracle models paragraph below for details on these worst case upper bounds.

In the *stochastic approximation* context, Dekel et al. (2012) study mini-batching in an oracle model that assumes bounded variance of stochastic gradients. These results compare worst case bounds on the generalization error to prescribe mini-batching limits, which renders these limits to be too loose (as mentioned in their paper). Our paper's mini-batching result offers guidelines on batch sizes for linear parallelization speedups by comparing generalization bounds that hold on a per problem basis as opposed to worst case bounds. Refer to the paragraph on oracle models for more details. Finally, parameter mixing in the stochastic approximation context (Rosenblatt and Nadler, 2014; Zhang et al., 2015) offers linear parallelization speedups on the variance error while not improving the bias (Rosenblatt and Nadler, 2014). Finally, Duchi et al. (2015) guarantees asymptotic optimality of asynchronous optimization with linear parallelization speedups on the variance.

Oracle models and optimality: In stochastic approximation, there are at least two lines of thought with regards to oracle models and notions of optimality. One line involves considering the case of bounded noise (Kushner and Yin, 2003; Kushner and Clark, 1978), or, bounded variance of the stochastic gradient, which in the least squares setting amounts to assuming bounds on

$$\widehat{\nabla L}(\mathbf{w}) - \nabla L(\mathbf{w}) = (\mathbf{x}\mathbf{x}^\top - \mathbf{H})(\mathbf{w} - \mathbf{w}^*) - \epsilon\mathbf{x}.$$

This implies additional assumptions are required on compactness of the parameter set (which are enforced via projection steps); such assumptions do not hold in practical implementation of stochastic gradient methods and in the setting considered by this paper. Thus, the mini-batching thresholds in Cotter et al. (2011); Niu et al. (2011); Dekel et al. (2012); Li et al. (2014) present bounds in the above worst-case oracle model by comparing weak upper bounds on the training/test error.

Another view of optimality (Anbar, 1971; Fabian, 1973) considers an objective where the goal is to match the rate of the statistically optimal estimator (referred to as the $M-$estimator) on every problem instance. Polyak and Juditsky (1992) consider this oracle model for the LSR problem and prove that the distribution of the averaged SGD estimator on every problem matches that of the $M-$estimator under certain regularity conditions (Lehmann and Casella, 1998). A recent line of work (Bach and Moulines, 2013; Frostig et al., 2015b) aims to provide non-asymptotic guarantees for SGD and its variants in this oracle model. This paper aims to understand mini-batching and other computational aspects of parallelizing stochastic approximation on every problem instance by working in this practically relevant oracle model. Refer to Jain et al. (2017b) for more details.

Comparing offline and streaming algorithms: Firstly, offline algorithms require performing multiple passes over a dataset stored in memory. Note that results and convergence rates established in the finite sum/offline optimization context do not translate to rates on the generalization error. Indeed, these results require going though concentration and a generalization error analysis for this translation to occur. Refer to Frostig et al. (2015b) for more details.

1. Défossez and Bach (2015)'s bound holds with learning rate $\gamma \to 0$. This work supports these bounds with $\gamma = 1/R^2$.
2. Initial error oracle provides initial excess risk $\Delta_0 = L(\mathbf{w}_0) - L(\mathbf{w}^*)$ and noise level σ^2.

Comparison to streaming SVRG: Streaming SVRG does not function in the stochastic first order oracle model (Agarwal et al., 2012) satisfied by SGD as run in practice since it requires gradients at two points from a single sample (Frostig et al., 2015b). Furthermore, in contrast to this work, its depth bounds depend on a stronger fourth moment property due to lack of mini-batching.

3. Main Results

We begin by writing out the behavior of the learning rate as a function of batch size.

Maximal Learning Rates: We write out a characterization of the largest learning rate $\gamma_{b,\max}^{div}$ that permits the convergence of the mini-batch Stochastic Gradient Descent update. The following generalized eigenvector problem allows for the computation of $\gamma_{b,\max}^{div}$:

$$\frac{2}{\gamma_{b,\max}^{div}} = \sup_{\mathbf{W}\in\mathcal{S}(d)} \frac{\langle \mathbf{W}, \mathcal{M}\mathbf{W}\rangle + (b-1)\cdot \operatorname{Tr}\mathbf{WHWH}}{b\cdot \operatorname{Tr}\mathbf{WHW}}. \tag{2}$$

This characterization generalizes the divergent stepsize characterization of Défossez and Bach (2015) for batch sizes > 1. The derivation of the above characterization can be found in appendix A.5.1. We note that this characterization sheds light on how the divergent learning rates interpolate from batch size 1 (which is $\leq 2/\operatorname{Tr}\mathbf{H}$) to the batch gradient descent learning rate (setting b to ∞), which turns out to be $2/\lambda_{\max}(\mathbf{H})$. A property of $\gamma_{b,\max}^{div}$ worth noting is that it does not depend on properties of the noise ($\mathbf{\Sigma}$), and depends only on the second and fourth moment properties of the covariate $\mathbf{x}$.

We note that in this paper, our interest does not lie in the non-divergent stepsizes $0 \leq \gamma \leq \gamma_{b,\max}^{div}$, but in the set of (maximal) stepsizes $0 \leq \gamma \leq \gamma_{b,\max}$ ($< \gamma_{b,\max}^{div}$) that are sufficient to guarantee minimax error rates of $\mathcal{O}(\widehat{\sigma^2_{\text{MLE}}}/n)$. For the LSR problem, these maximal learning rates $\gamma_{b,\max}$ are:

$$\gamma_{b,\max} \stackrel{\text{def}}{=} \frac{2b}{R^2\cdot\rho_{\text{m}} + (b-1)\|\mathbf{H}\|_2}, \text{ where, } \rho_{\text{m}} \stackrel{\text{def}}{=} \frac{d\|(\mathcal{H}_{\mathcal{L}}+\mathcal{H}_{\mathcal{R}})^{-1}\mathbf{\Sigma}\|_2}{\operatorname{Tr}\left((\mathcal{H}_{\mathcal{L}}+\mathcal{H}_{\mathcal{R}})^{-1}\mathbf{\Sigma}\right)}. \tag{3}$$

Note that $\rho_{\text{m}} \geq 1$ captures a notion of "degree" of model mismatch, and how it impacts the learning rate $\gamma_{b,\max}$; for the additive noise/well specified/homoscedastic case, $\rho_{\text{m}} = 1$. Thus, for problems where R^2 and $\|\mathbf{H}\|_2$ is held the same, the well-specified variant of the LSR problem admits a strictly larger learning rate (that achieves minimax rates on the variance) compared to the mis-specified case. Furthermore, in stark contrast to the well-specified case, $\gamma_{b,\max}$ in the mis-specified case depends not just on the second and fourth moment properties of the input, but also on the noise covariance $\mathbf{\Sigma}$. We show that our characterization of $\gamma_{b,\max}$ in the mis-specified case is tight in that there exist problem instances where $\gamma_{b,\max}$ (equation 3) is off the maximal learning rate in the well-specified case (obtained by setting $\rho_{\text{m}} = 1$ in equation 3) by a factor of the dimension d and $\gamma_{b,\max}$ is still the largest step size yielding minimax rates. We also note that there could exist mis-specified problem instances where a step size γ exceeding $\gamma_{b,\max}$ achieves minimax rates. Characterizing the maximal learning rate that achieves minimax rates on *every mis-specified* problem instance is an interesting open question. We return to the characterization of $\gamma_{b,\max}$ in section 3.1.

Note that this paper characterizes the performance of Algorithms 1 and 2 when run with a step size $\gamma \leq \frac{\gamma_{b,\max}}{2}$. The proofs turn out to be significantly complicated for $\gamma \in \left(\frac{\gamma_{b,\max}}{2}, \gamma_{b,\max}\right)$ and can be found in the initial version of this paper Jain et al. (2016b) and these were obtained through generalizing the operator view of analyzing SGD methods introduced by Défossez and Bach (2015). Note that for the well-specified case, this paper's results hold for the same learning rate regimes as

Algorithm 1 Minibatch-TailAveraging-SGD

Input: Initial point $\mathbf{w}_0$, stepsize γ, minibatch size b, initial iterations s, total samples n.

for $t = 1, 2, .., \lfloor \frac{n}{b} \rfloor$ **do**
  Sample "b" tuples $\{(x_{ti}, y_{ti})\}_{i=1}^{b} \sim \mathcal{D}^b$
  $\mathbf{w}_t \leftarrow \mathbf{w}_{t-1} - \frac{\gamma}{b}\sum_{i=1}^{b} \widehat{\nabla L_{ti}}(\mathbf{w}_{t-1})$

Output: $\bar{\mathbf{w}} = \frac{1}{\lfloor \frac{n}{b} \rfloor - s}\sum_{i>s} \mathbf{w}_i$

Bach and Moulines (2013); Frostig et al. (2015b), that are known to admit statistical optimality. We also note that in the additive noise case, we are unaware of a separation between $\gamma_{b,\max}$ and $\gamma_{b,\max}^{div}$; but as we will see, this is not of much consequence given that there exists a strict separation in the learning rate $\gamma_{b,\max}$ between the well-specified and mis-specified problem instances.

Finally, we note that the stochastic process viewpoint allows us to work with learning rates that are significantly larger compared to standard analyses that use function value contraction e.g., Bottou et al. (2016, Theorem 4.6). To the best of our knowledge, all existing works establishing mini-batching thresholds in the stochastic optimization setting e.g., Dekel et al. (2012) work in the worst case (bounded noise) oracle model, with small step sizes, and draw conclusions on mini-batch thresholds and effects by comparing weak upper bounds on the excess risk.

Mini-Batched Tail-Averaged SGD for the mis-specified case: We present our main result, which is the error bound for mini-batch tail-averaged SGD for the general mis-specified LSR problem.

Theorem 1 *Consider the general mis-specified case of the LSR problem 1. Running Algorithm 1 with a batch size $b \geq 1$, step size $\gamma \leq \gamma_{b,max}/2$, number of unaveraged iterations s, total number of samples n, we obtain an iterate $\overline{\mathbf{w}}$ satisfying the following excess risk bound:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \frac{2}{\gamma^2\mu^2}\cdot\frac{(1-\gamma\mu)^s}{\left(\frac{n}{b}-s\right)^2}\cdot\left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + 4\cdot\frac{\widehat{\sigma^2_{MLE}}}{b\cdot(\frac{n}{b}-s)}. \tag{4}$$

In particular, with $\gamma = \gamma_{b,max}/2$, we have the following excess risk bound:

$$L(\overline{\mathbf{w}}) - L(\mathbf{w}^*) \leq \underbrace{\frac{2\kappa_b^2}{\left(\frac{n}{b}-s\right)^2}\exp\left(-\frac{s}{\kappa_b}\right)\left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right)}_{\mathfrak{T}_1} + \underbrace{4\cdot\frac{\widehat{\sigma^2_{MLE}}}{b(\frac{n}{b}-s)}}_{\mathfrak{T}_2},$$

with $\kappa_b = \frac{R^2\cdot\rho_m + (b-1)\|\mathbf{H}\|_2}{b\lambda_{min}(\mathbf{H})}$.

Note that the above theorem indicates that the excess risk is composed of two terms, namely the bias ($\mathfrak{T}_1$), which represents the dependence on the initial conditions $\mathbf{w}_0$ and the variance ($\mathfrak{T}_2$), which depends on the statistical noise ($\widehat{\sigma^2_{\text{MLE}}}$); the bias decays geometrically during the "s" unaveraged iterations while the variance is minimax optimal (up to constants) provided $s = \mathcal{O}(n)$. We will understand this geometric decay on the bias more precisely.

Effect of tail-averaging SGD's iterates: To understand tail-averaging, we specialize theorem 1 with a batch size 1 to the well-specified case, i.e., where, $\mathbf{\Sigma} = \sigma^2\mathbf{H}$, $\widehat{\sigma^2_{\text{MLE}}} = d\sigma^2$ and $\rho_{\text{m}} = 1$.

Corollary 2 *Consider the well-specified (additive noise) case of the streaming LSR problem ($\mathbf{\Sigma} = \sigma^2\mathbf{H}$), with a batch size $b = 1$. With a learning rate $\gamma = \frac{\gamma_{1,max}}{2} = \frac{1}{R^2}$, unaveraged iterations s and total samples n, we have the following excess risk bound:*

$$L(\overline{\mathbf{w}}) - L(\mathbf{w}^*) \leq \underbrace{\frac{2\kappa_1^2}{(n-s)^2}\exp\left(-\frac{s}{\kappa_1}\right)\{L(\mathbf{w}_0) - L(\mathbf{w}^*)\}}_{\mathfrak{T}_1} + \underbrace{4\cdot\frac{d\sigma^2}{n-s}}_{\mathfrak{T}_2}, \text{where, } \kappa_1 = R^2/\mu.$$

Tail-averaging allows for a geometric decay of the initial error $\mathfrak{T}_1$, while tail-averaging over $s = c\cdot n$ (with $c < 1$), allows for the variance $\mathfrak{T}_2$ to be minimax optimal (up to constants). We note that the work of Merity et al. (2017), which studies empirical optimization for training non-convex sequence models (e.g. Long-Short term memory models (LSTMs)) also indicate the benefits of tail-averaging.

Note that this particular case (i.e. additive noise/well-specified case with batch size 1) with tail-averaging from start ($s = 0$) is precisely the setting considered in Défossez and Bach (2015), and their result (a) achieves a sub-linear $\mathcal{O}(1/n^2)$ rate on the bias and (b) their variance term is shown to be minimax optimal only with learning rates that approach zero (i.e. $\gamma \to 0$).

3.1 Effects Of Learning Rate, Batch Size and The Role of Mis-specified Models

We now consider the interplay of learning rate, batch size and how model mis-specification plays into the mix. Towards this, we split this section into three parts: (a) understanding learning rate versus mini-batch size in the well-specified case, (b) how model mis-specification leads to a significant difference in the behavior of SGD and (c) how model mis-specification manifests itself when considered in tradeoff between the learning rate versus batch-size.

Effects of mini-batching in the well-specified case: As mentioned previously, in the well-specified case, $\mathbf{\Sigma} = \sigma^2\mathbf{H}$ and $\rho_{\text{m}} = 1$. For this case, equation (3) can be specialized as:

$$\gamma_{b,\max} = \frac{2b}{R^2 + (b-1)\|\mathbf{H}\|_2}. \tag{5}$$

Observe that the learning rate $\gamma_{b,\max}$ grows linearly as a function of the batch size b until a batch size $b = b_{\text{thresh}} = 1 + \frac{R^2}{\|\mathbf{H}\|_2}$. In the regime of batch sizes $1 < b \leq b_{\text{thresh}}$, the resulting mini-batch SGD updates offer near-linear parallelization speedups over SGD with a batch size of 1. Furthermore, increasing batch sizes beyond b_{thresh} leads to sub-linear increase in the learning rate, and this implies that we lose the linear parallelization speedup offered by mini-batching with a batch-size $b \leq b_{\text{thresh}}$. Losing the linear parallelization is indicative of the following: consider the case when we double batch-size from $b > b_{\text{thresh}}$ to $2b$. Suppose the bias error $\mathfrak{T}_1$ is larger than the variance $\mathfrak{T}_2$, we require performing the same number of updates with a batch size $2b$ as we did with a batch size b to achieve a similar excess risk bound; this implies we are inefficient in terms of number of samples (or, number of gradient computations) used to achieve a given excess risk. When the estimation error ($\mathfrak{T}_2$) dominates the approximation error ($\mathfrak{T}_1$), we note that larger batch sizes b (with $b > b_{\text{thresh}}$) serves to improve the variance term, thus allowing linear parallelization speedups via mini-batching.

Note that with a batch size of $b = b_{\text{thresh}}$, the learning rate of $\mathcal{O}(1/\lambda_{\max}(\mathbf{H}))$ employed by mini-batch SGD resembles ones used by batch gradient descent. This mini-batching characterization thus allows for understanding tradeoffs of learning rate versus batch size. This behavior is noted in practice (empirically, but with no underlying rigorous theory) for a variety of problems (going beyond linear regression/convex optimization), in the deep learning context (Goyal et al., 2017).

SGD's behaviour with mis-specified models: Next, this paper attempts to shed light on some fundamental differences in the behavior of SGD when dealing with the mis-specified case (as against the well-specified case, which is the focus of existing results (Polyak and Juditsky, 1992; Bach and Moulines, 2013; Dieuleveut and Bach, 2015; Défossez and Bach, 2015)) of the LSR problem. This paper's results in general mis-specified case with batch sizes $b > 1$ specialize to existing results additive noise/well-specified case with batch size 1 (Bach and Moulines, 2013; Dieuleveut and Bach, 2015). To understand these issues better, we consider $\gamma_{b,\max}$ in equation 3 with a batch size 1:

$$\gamma_{1,\max} = \frac{2}{R^2\cdot\rho_{\text{m}}}. \tag{6}$$

Recounting that $\rho_{\text{m}} \geq 1$, observe that the mis-specified case admits a maximal learning rate (with a view of achieving minimax rates) that is at most as large as the additive noise/well-specified case, where $\rho_{\text{m}} = 1$. Note that when $\text{Tr}\left(\mathcal{H}_{\mathcal{L}} + \mathcal{H}_{\mathcal{R}}\right)^{-1}\mathbf{\Sigma}\big)$ is nearly the same (say, upto constants) as the spectral norm $\left\|\mathcal{H}_{\mathcal{L}} + \mathcal{H}_{\mathcal{R}}\right)^{-1}\mathbf{\Sigma}\right\|_2$, then $\rho_{\text{m}} = \mathcal{O}(d)$ and $\gamma_{1,\max} = \mathcal{O}(\frac{1}{R^2 d})$. This implies that there exist mis-specified models whose noise properties (captured through the noise covariance matrix $\mathbf{\Sigma}$) prevents SGD from working with large learning rates of $\mathcal{O}(1/R^2)$ used in the well-specified case.

This notion is formalized in the following lemma, which presents an instance working with the mis-specified case, wherein, SGD *cannot* employ large learning rates used by the well-specified variant of the problem, while *retaining minimax optimality*. This behavior is in stark contrast to algorithms such as streaming SVRG (Frostig et al. (2015b)), which work with the same large learning rates in the mis-specified case as in the well-specified case, while guaranteeing minimax optimal rates. The proof of lemma 3 can be found in the appendix A.5.6.

Lemma 3 *Consider a Streaming LSR example with Gaussian covariates (i.e. $\mathbf{x} \sim \mathcal{N}(0, \mathbf{H})$) with a diagonal second moment matrix $\mathbf{H}$ that is defined by:*

$$\mathbf{H}_{ii} = \begin{cases} 1 & \text{if } i = 1 \\ 1/d & \text{if } i > 1 \end{cases}.$$

Further, let the noise covariance matrix $\mathbf{\Sigma}$ be diagonal as well, with the following entries:

$$\mathbf{\Sigma}_{ii} = \begin{cases} 1 & \text{if } i = 1 \\ 1/[(d-1)d] & \text{if } i > 1 \end{cases}.$$

For this problem instance, $\gamma_{1,max} \leq \frac{4}{(d+2)(1+\frac{1}{d})}$ is necessary for retaining minimax rates, while the well-specified variant of this problem permits a maximal learning rate $\leq \frac{d}{(d+2)(1+\frac{1}{d})}$, thus implying an $\mathcal{O}(d)$ separation in learning rates between the well-specified and mis-specified case.

Learning rate versus mini-batch size issues in the mis-specified case: Noting that for the batch size 1, as mentioned in equation 6, the learning rate for the mis-specified case in the most optimistic situation (when $\rho_{\text{m}} = \text{constant}$) can be atmost as large as the learning rate for the well-specified case. Furthermore, we also know from the observations in the mis-specified case that the learning rate tends to grow linearly as a function of the batch size until it hits the limit of $\mathcal{O}(1/\lambda_{\max}(\mathbf{H}))$. Combining these observations, we will revisit equation 3, which says:

$$\gamma_{b,\max} \overset{\text{def}}{=} \frac{2b}{R^2\cdot\rho_{\text{m}} + (b-1)\|\mathbf{H}\|_2}.$$

This implies that the mini-batching size threshold b_{thresh} can be expressed as:

$$b_{\text{thresh}} \stackrel{\text{def}}{=} 1 + \frac{R^2}{\|\mathbf{H}\|_2} \cdot \rho_{\text{m}}. \tag{7}$$

When $1 < b \leq b_{\text{thresh}}$, we achieve near linear parallelization speedups over running SGD with a batch size 1. Note that this characterization specializes to the batch size threshold b_{thresh} presented in the well-specified case (i.e. where $\rho_{\text{m}} = 1$). Furthermore, this batch size threshold (in the mis-specified case) could be much larger than the threshold in the well-specified case, which is expected since the learning rate for a batch size 1 in the mis-specified case can potentially be much smaller than ones used in the well specified case. Furthermore, with a batch size b_{thresh}, note that the learning rate is $\mathcal{O}(1/\lambda_{\max}(\mathbf{H}))$, resembling ones used with batch gradient descent.

Behavior of the final-iterate: We now present the excess risk bound offered by the final iterate of a stochastic gradient scheme. This result is of much practical relevance in the context of modern machine learning and deep learning, where final iterate is often used, and where the tradeoffs between learning rate and batch sizes are discussed in great detail (Smith et al., 2017). For this discussion, we consider the well-specified case to present our results owing to its ease in presentation. Our framework and results are generic for translating these observations to the mis-specified case.

Lemma 4 *Consider the well-specified case of the LSR problem. Running Algorithm 1 with a step size $\gamma \leq \frac{\gamma_{b,max}}{2} = \frac{b}{R^2+(b-1)\|\mathbf{H}\|_2}$, batch size b, total samples n and with no iterate averaging (i.e. with $s = n-1$) yields a result $\mathbf{w}_{\lfloor n/b \rfloor}$ that satisfies the following excess risk bound:*

$$\mathbb{E}\left[L(\mathbf{w}_{\lfloor n/b \rfloor})\right] - L(\mathbf{w}^*) \leq \kappa_b (1-\gamma\mu)^{\lfloor n/b \rfloor} \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + \frac{\gamma}{b}\sigma^2 \operatorname{Tr}(\mathbf{H}), \tag{8}$$

where $\kappa_b \stackrel{\text{def}}{=} \frac{R^2+(b-1)\|\mathbf{H}\|_2}{b\mu}$. In particular, with a step size $\gamma = \frac{\gamma_{b,max}}{2} = \frac{b}{R^2+(b-1)\|\mathbf{H}\|_2}$, we have:

$$\mathbb{E}\left[L(\mathbf{w}_{\lfloor n/b \rfloor})\right] - L(\mathbf{w}^*) \leq \kappa_b \cdot e^{-\frac{\lfloor n/b \rfloor}{\kappa_b}} \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + \frac{\sigma^2 \operatorname{Tr}(\mathbf{H})}{R^2 + (b-1)\|\mathbf{H}\|_2}. \tag{9}$$

Remarks: Noting that $\operatorname{Tr}(\mathbf{H}) \leq R^2$, the variance of the final iterate with batch size 1 is $\leq \sigma^2$. Next, with a batch size $b = b_{\text{thresh}}$, the final iterate has a variance $\leq \sigma^2/2$; at cursory glance this may appear interesting, in that by mini-batching, we do not appear to gain much in terms of the variance. This is unsurprising given that in the regime of $b \leq b_{\text{thresh}}$, the $\gamma_{b,\max}$ grows linearly, thus nullifying the effect of averaging multiple stochastic gradients. Furthermore, this follows in accordance with the linear parallelization speedups offered by a batch size $1 < b \leq b_{\text{thresh}}$. Note however, once $b > b_{\text{thresh}}$, any subsequent increase in batch sizes allows the variance of the final iterate to behave as $\mathcal{O}(\sigma^2/b)$. Finally, we note that once $b > b_{\text{thresh}}$, doubling batch sizes b (in equation 9) possesses the same effect as halving the learning rate from γ to $\gamma/2$ (as seen from equation 8), providing theoretical rigor to issues explored in training practical deep models (Smith et al., 2017).

3.2 Parallelization via Doubling Batch Sizes and Model Averaging

We now elaborate on a highly parallelizable stochastic gradient method, which is epoch based and relies on doubling batch sizes across epochs to yield an algorithm that offers the same generalization error as that of offline (batch) gradient descent in nearly the same number of serial updates as

Algorithm 2 MinibatchDoublingPartialAveragingSGD

Input: Initial point $\mathbf{w}_0$, stepsize γ, initial minibatch size b, number of iterations in each epoch s, number of samples n.

/*Run logarithmic number of epochs where each epoch runs t iterations of minibatch SGD (with out averaging). Double minibatch size after each epoch.*/

for $\ell = 1, 2, \cdots, \log \frac{n}{bt} - 1$ **do**

  $b_\ell \leftarrow 2^{\ell-1} b$

  $\mathbf{w}_\ell \leftarrow$ Minibatch-TailAveraging-SGD$(\mathbf{w}_{\ell-1}, \gamma, b_\ell, t-1, t \cdot b_\ell)$

/*For the last epoch, run tail averaged minibatch SGD with initial point $\mathbf{w}_t$, stepsize γ, mini-batch size $2^{\log \frac{n}{bt}-1} \cdot b = n/2t$, number of initial iterations $t/2$ and number of samples $n/2$.*/

$\overline{\mathbf{w}} \leftarrow$ Minibatch-TailAveraging-SGD$(\mathbf{w}_s, \gamma, n/2t, t/2, n/2)$

Output: $\overline{\mathbf{w}}$

batch gradient descent, while being a streaming algorithm that does not require storing the entire dataset in memory. Following this, we present a non-asymptotic bound for parameter mixing/model averaging, which is a communication efficient parallelization scheme that has favorable properties when the estimation error (i.e. variance) is the dominating term of the excess risk.

(Nearly) Matching the depth of Batch Gradient Descent: The result of theorem 1 establishes a scalar generalization error bound of Algorithm 1 for the general mis-specified case of LSR and showed that the depth (number of sequential updates in our algorithm) is decreased to n/b. This section builds upon this result to present a simple and intuitive doubling based streaming algorithm that works in epochs and processes a total of $n/2$ points. In each epoch, the minibatch size is increased by a factor of 2 while applying Algorithm 1 (with no tail-averaging) with twice as many samples as the previous epoch. After running over $n/2$ samples using this epoch based approach, we run Algorithm 1 (with tail-averaging) with the remaining $n/2$ points. Intuitively, each of the epoch decays the bias of the previous epoch linearly and halves the statistical error (owing to doubling of mini-batch sizes). The final tail-averaging phase ensures that the variance is small.

The next theorem formalizes this intuition and shows Algorithm 2 improves the depth exponentially from n/b_{thresh} to $\mathcal{O}\left(\kappa \log(d\kappa) \log(n\{L(\mathbf{w}_0) - L(\mathbf{w}^*)\}/\widehat{\sigma^2_{\text{MLE}}})\right)$ in the presence of an error oracle that provides us with the initial excess risk $L(\mathbf{w}_0) - L(\mathbf{w}^*)$ and the noise level $\widehat{\sigma^2_{\text{MLE}}}$.

Theorem 5 *Consider the general mis-specified case of LSR. Suppose in Algorithm 2, we use initial batchsize of $b = b_{thresh}$, stepsize $\gamma = \frac{\gamma_{b,max}}{2}$ and number of iterations in each epoch being $t \geq 24\kappa \log(\kappa)$, we obtain the following excess risk bound on $\overline{\mathbf{w}}$:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \left(\frac{2bt}{n}\right)^{\frac{t}{12\kappa \log(\kappa)}} \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + 80\frac{\widehat{\sigma^2_{MLE}}}{n}.$$

Remarks: The final error again has two parts: the bias term that depends on the initial error $L(\mathbf{w}_0) - L(\mathbf{w}^*)$ and the variance term that depends on the statistical noise $\widehat{\sigma^2_{\text{MLE}}}$. Note that the variance error decays at a rate of $\mathcal{O}\left(\widehat{\sigma^2_{\text{MLE}}}/n\right)$ which is minimax optimal up to constant factors.

Algorithm 2 decays the bias at a superpolynomial rate by choosing t large enough. If Algorithm 2 has access to an initial error oracle that provides $L(\mathbf{w}_0) - L(\mathbf{w}^*)$ and $\widehat{\sigma^2_{\text{MLE}}}$, we can run

Algorithm 2 with a batch size b_{thresh} until the excess risk drops to the noise level $\widehat{\sigma^2_{\text{MLE}}}$ and subsequently begin doubling the batch size. Such an algorithm indeed gives geometric convergence with a generalization error bound as:

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \exp\left(-(\frac{n\lambda_{\min}}{R^2 \cdot \log(\kappa)}) \cdot \frac{1}{\rho_{\text{m}}}\right)\{L(\mathbf{w}_0) - L(\mathbf{w}^*)\} + 80\frac{\widehat{\sigma^2_{\text{MLE}}}}{n},$$

with a depth of $\mathcal{O}\left(\kappa \log(d\kappa) \log \frac{n\{L(\mathbf{w}_0)-L(\mathbf{w}^*)\}}{\widehat{\sigma^2_{\text{MLE}}}}\right)$. The proof of this claim follows relatively straightforwardly from the proof of Theorem 5. We note that this depth nearly matches (up to $\log$ factors), the depth of standard offline gradient descent despite being a streaming algorithm. This algorithm (aside from tail-averaging in the final epoch) resembles empirically effective schemes proposed in the context of training deep models (Smith et al., 2017).

Parameter Mixing/Model-Averaging: We consider a communication efficient method for distributed optimization which involves running mini-batch tail-averaged SGD independently on P separate machines (each containing their own independent samples) and averaging the resulting solution estimates. This is a well studied scheme for distributed optimization (Mann et al., 2009; Zinkevich et al., 2011; Rosenblatt and Nadler, 2014; Zhang et al., 2015). As mentioned in Rosenblatt and Nadler (2014), these schemes do not appear to offer improvements in the bias error while offering near linear parallelization speedups on the variance. We provide here a non-asymptotic characterization of the behavior of model averaging for the general mis-specified LSR problem.

Theorem 6 *Consider running Algorithm (1), i.e., mini-batch tail-averaged SGD (for the mis-specified LSR problem (1)) independently in P machines, each of which contains N/P samples. Let algorithm (1) be run with a batch size b, learning rate $\gamma \leq \gamma_{b,max}/2$, tail-averaging begun after $s-$iterations, and let each of these machines output $\{\overline{\mathbf{w}}_i\}_{i=1}^P$. The excess risk of the model-averaged estimator $\overline{\mathbf{w}} = \frac{1}{P}\sum_{i=1}^P \overline{\mathbf{w}}_i$ is upper bounded as:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \frac{(1-\gamma\mu)^s}{\gamma^2\mu^2\left(\frac{n}{P\cdot b} - s\right)^2} \cdot \frac{2 + (P-1)(1-\gamma\mu)^s}{P} \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + 4 \cdot \frac{\widehat{\sigma^2_{MLE}}}{P \cdot b \cdot \left(\frac{n}{P\cdot b} - s\right)}.$$

In particular, with $\gamma = \gamma_{b,max}/2$, we have the following excess risk bound:

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \exp\left(-\frac{s}{\kappa_b}\right) \cdot \frac{\kappa_b^2}{\left(\frac{n}{P\cdot b} - s\right)^2} \cdot \frac{2 + (P-1)\cdot\exp(-s/\kappa_b)}{P} \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + 4 \cdot \frac{\widehat{\sigma^2_{MLE}}}{P \cdot b \cdot \left(\frac{n}{P\cdot b} - s\right)}.$$

Remarks: We note that during the iterate-averaged phase (i.e. $t > s$), there is no reduction of the bias, whereas, during the (initial) unaveraged iterations, once $s > \kappa_b \log(P)$, we achieve linear speedups on the bias. We note that model averaging offers linear parallelization speedups on the variance error. Furthermore, when the bias reduces to the noise level, model averaging offers linear parallelization speedups on the overall excess risk. Note that if $s = c \cdot n/(P \cdot b)$, with $c < 1$, then the excess risk is minimax optimal. Finally, we note that the theorem can be generalized in a straightforward manner to the situation when each machine has different number of examples.

4. Proof Outline

We present here the framework for obtaining the results described in this paper; the framework has been introduced in the work of Défossez and Bach (2015). Towards this purpose, we begin by introducing some notations. We begin by defining the centered estimate $\boldsymbol{\eta}_t$ as:

$$\boldsymbol{\eta}_t \stackrel{\text{def}}{=} \mathbf{w}_t - \mathbf{w}^*.$$

Mini-batch SGD (with a batch size b) moves $\boldsymbol{\eta}_{t-1}$ to $\boldsymbol{\eta}_t$ using the following update:

$$\boldsymbol{\eta}_t = \left(\mathbf{I} - \frac{\gamma}{b}\cdot\sum_{i=1}^b \mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\right)\boldsymbol{\eta}_{t-1} + \frac{\gamma}{b}\sum_{i=1}^b \epsilon_{ti}\mathbf{x}_{ti} = (\mathbf{I} - \gamma\widehat{\mathbf{H}}_{tb})\boldsymbol{\eta}_{t-1} + \gamma\cdot\boldsymbol{\xi}_{tb},$$

where, $\widehat{\mathbf{H}}_{tb} = \frac{1}{b}\sum_{i=1}^b \mathbf{x}_{ti}\otimes\mathbf{x}_{ti}$ and $\boldsymbol{\xi}_{tb} = \frac{1}{b}\sum_{i=1}^b \epsilon_{ti}\mathbf{x}_{ti}$. Next, the tail-averaged iterate $\bar{\mathbf{x}}_{s,n}$ is associated with its own centered estimate $\bar{\boldsymbol{\eta}}_{s,n} = \frac{1}{n-s}\sum_{i=s+1}^n \boldsymbol{\eta}_i$. The analysis proceeds by tracking the covariance of the centered estimates $\boldsymbol{\eta}_t$, i.e. by tracking $\mathbb{E}\left[\boldsymbol{\eta}_t\otimes\boldsymbol{\eta}_t\right]$.

Bias-Variance decomposition: The main results of this paper are derived by going through the bias-variance decomposition, which is well known in the context of Stochastic Approximation (Bach and Moulines, 2011, 2013; Frostig et al., 2015b). The bias-variance decomposition allows for us to bound the generalization error by analyzing two sub-problems, namely, (i) The *bias* sub-problem, which analyzes the noiseless/realizable (or the consistent linear system) problem, by setting the noise $\epsilon_{ti} = 0\ \forall\ t, i$, $\boldsymbol{\eta}_0^{\text{bias}} = \boldsymbol{\eta}_0$ and (ii) the *variance* sub-problem, which involves starting at the solution, i.e., $\boldsymbol{\eta}_0^{\text{variance}} = 0$ and allowing the noise ϵ_{ti} to drive the resulting process. The corresponding tail-averaged iterates are associated with their centered estimates $\bar{\boldsymbol{\eta}}_{s,n}^{\text{bias}}$ and $\bar{\boldsymbol{\eta}}_{s,n}^{\text{variance}}$ respectively. The bias-variance decomposition for the square loss establishes the following relation:

$$\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}\otimes\bar{\boldsymbol{\eta}}_{s,n}\right] \preceq 2\cdot\left(\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}^{\text{bias}}\otimes\bar{\boldsymbol{\eta}}_{s,n}^{\text{bias}}\right] + \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}^{\text{variance}}\otimes\bar{\boldsymbol{\eta}}_{s,n}^{\text{variance}}\right]\right). \tag{10}$$

Using the bias-variance decomposition, we obtain an estimate of the generalization error as

$$\begin{aligned}\mathbb{E}\left[L(\bar{\mathbf{x}}_{s,n})\right] - L(\mathbf{x}^*) &= \tfrac{1}{2}\cdot\langle\mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}\otimes\bar{\boldsymbol{\eta}}_{s,n}\right]\rangle \\ &\leq \mathrm{Tr}\left(\mathbf{H}\cdot\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}^{\text{bias}}\otimes\bar{\boldsymbol{\eta}}_{s,n}^{\text{bias}}\right]\right) + \mathrm{Tr}\left(\mathbf{H}\cdot\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s,n}^{\text{variance}}\otimes\bar{\boldsymbol{\eta}}_{s,n}^{\text{variance}}\right]\right).\end{aligned}$$

We now provide a few lemmas that help us bound the behavior of the bias and variance error.

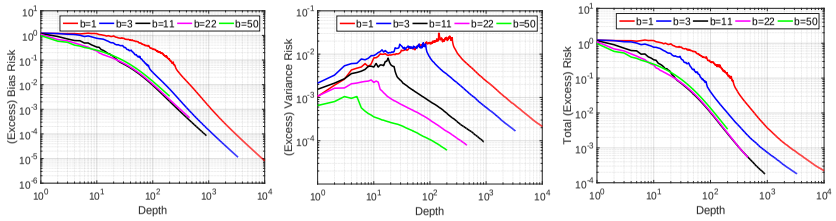
Lemma 7 *With a batch size b, step size $\gamma = \gamma_{b,max}/2$, the centered bias estimate $\boldsymbol{\eta}_t^{bias}$ exhibits the following per step contraction:*

$$\langle\mathbf{I}, \mathbb{E}\left[\boldsymbol{\eta}_t^{bias}\otimes\boldsymbol{\eta}_t^{bias}\right]\rangle \leq c_{\kappa_b}\langle\mathbf{I}, \mathbb{E}\left[\boldsymbol{\eta}_{t-1}^{bias}\otimes\boldsymbol{\eta}_{t-1}^{bias}\right]\rangle,$$

where, $c_{\kappa_b} = 1 - 1/\kappa_b$, where $\kappa_b = \frac{R^2\cdot\rho_m + (b-1)\|\mathbf{H}\|_2}{b\mu}$.

Lemma (7) ensures that the bias decays at a geometric rate during the burn-in iterations when the iterates are not averaged; this rate holds only when the excess risk is larger than the noise level σ^2.

We now turn to bounding the variance error. It turns out that it suffices to understand the behavior of limiting centered variance $\mathbb{E}\left[\boldsymbol{\eta}_\infty^{\text{variance}}\otimes\boldsymbol{\eta}_\infty^{\text{variance}}\right]$.



(a) Bias Risk (b) Variance Risk (c) Total Risk

Figure 1: Effect of increased batch sizes on the Algorithm's generalization error. The variance decreases monotonically with increasing batch size. The bias indicates that the rate of decay increases till the optimal b_{thresh}. With $b = b_{\text{thresh}}$, mini-batch SGD obtains the same generalization error as batchsize 1 using smaller number of iterations (i.e. smaller depth) compared to larger batch sizes.

Lemma 8 *Consider the well-specified case of the streaming LSR problem. With a batch size b, step size $\gamma = \gamma_{b,max}/2$, the limiting centered variance $\boldsymbol{\eta}_\infty^{variance}$ has an expected covariance that is upper bounded in a psd sense as:*

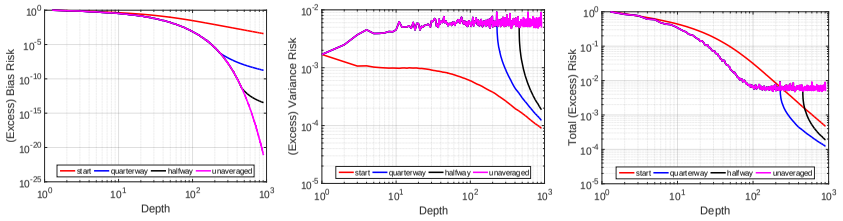
$$\mathbb{E}\left[\boldsymbol{\eta}_\infty^{variance} \otimes \boldsymbol{\eta}_\infty^{variance}\right] \preceq \frac{1}{R^2 + (b-1)\|\mathbf{H}\|_2} \cdot \sigma^2 \cdot \mathbf{I}.$$

Characterizing the behavior of the final iterate is crucial towards obtaining bounds on the behavior of the tail-averaged iterate. In particular, the final iterate having a excess variance risk $\mathcal{O}(\sigma^2)$ (as is the case with lemma (8)) appears crucial towards achieving minimax rates of the averaged iterate.

5. Experimental Simulations

We conduct experiments using a synthetic example to illustrate the implications of our theoretical results on mini-batching and tail-averaging. The data is sampled from a $50-$ dimensional Gaussian with eigenvalues decaying as $\{\frac{1}{k}\}_{k=1}^{50}$ (condition number $\kappa = 50$), and the variance σ^2 of the (additive noise) noise is 0.01. In this case, our estimated batch size according to Theorem 1 is $b_{\text{thresh}} = 11$. Our results are presented by averaging over 100 independent runs of the Algorithm, and each run employs 200κ samples. All plots are log-log with x-axis being the depth, and y-axis the excess risk. For our plots, we assume that each iteration takes constant time for all batch sizes; this is done to present evidence regarding the tightness of our mini-batching characterization limits that yield linear parallelization speedups over SGD with mini-batch size of 1.

We consider the effect of mini-batching (in figure 1) with batch sizes of 1, 3, $b_{\text{thresh}} = 11$, $2 \cdot b_{\text{thresh}} = 22$ and $d = 50$. Averaging begins after observing a fixed number of samples (set as 5κ). We see that the rate of bias decay (figure 1a) increases until reaching a mini-batch size of b_{thresh}, saturating thereafter; this implies we are inefficient in terms of sample size. As expected, the rate of decay of variance (figure 1b) is monotonic as a function of mini-batch size. Finally, the overall error (figure 1c) shows the tightness of our mini-batching characterization: with a batch size of b_{thresh}, we obtain a generalization error that is the *same* as using batch size of 1 with the number of (serial) iterations (i.e. depth) that is an order of magnitude smaller. Subsequently, we note that larger batch sizes worsen generalization error thus depicting the tightness of our characterization of b_{thresh}.



(a) Bias Risk (b) Variance Risk (c) Total Risk

Figure 2: [Zoom in to see detail] Effect of tail-averaging with mini-batch size of $b_{thresh} = 11$.

In the next experiment, we fix batch size $= b_{\text{thresh}}$ and consider the effect of when tail-averaging begins (figure 2). We consider averaging iterates from the start (as prescribed by Défossez and Bach (2015)), after a quarter/half of total number of iterations, and unaveraged SGD as well. We see that the bias (figure 2a) exhibits a geometric decay in the unaveraged phase while switching to an slower $\mathcal{O}(\frac{1}{t^2})$ rate with averaging. The variance (figure 2b) tends to increase and stabilize at $\mathcal{O}(\frac{\sigma^2}{b_{\text{thresh}}})$ in the absence of averaging, while switching to a $\mathcal{O}(\frac{1}{N})$ decay rate when averaging begins. The overall generalization error (figure 2c) shows the superiority of the scheme where averaging after a burn-in period allows the bias to decay towards the noise level at a geometric rate, following which tail-averaging allows us to decay the variance term, providing credence to our theoretical results that tail-averaged SGD allows us to obtain better generalization error as a function of sample size.

6. Concluding Remarks

This paper analyzes several algorithmic primitives often used in practice in conjunction with vanilla SGD for the stochastic approximation problem. In particular, this paper provides a sharp non-asymptotic treatment of (a) mini-batching, (b) tail-averaging, (c) effects of model mismatch, (d) behaviour of the final iterate, (e) highly parallel SGD method based on doubling batch sizes and (f) model-averaging/parameter mixing schemes for the strongly convex streaming LSR problem.

The effect of mini-batching and other algorithmic primitives mentioned above can be understood for a variety of models and/or algorithms. In particular, future directions could include understanding these issues for stochastic approximation with the Logistic Loss (Bach, 2014), streaming PCA (Jain et al., 2016a), and other algorithms such as streaming SVRG (Frostig et al., 2015b).

Appendix A. Appendix

We begin with a note on the organization:

- Section A.1 introduces notations necessary for the rest of the appendix.
- Section A.2 derives the mini-batch SGD update and provides the bias-variance decomposition and reasons about its implication in bounding the generalization error.
- Section A.3 provides lemmas that are used to bound the bias error.
- Section A.4 provides lemmas that are used to bound the variance error.
- Section A.5 uses the results of the previous sections to obtain the main results of this paper.

A.1 Notations

We begin by introducing the centered iterate $\boldsymbol{\eta}_t$ i.e.:

$$\boldsymbol{\eta}_t \stackrel{\text{def}}{=} \mathbf{w}_t - \mathbf{w}^*.$$

In a manner similar to $\mathbf{w}_t$, the tail-averaged iterate $\overline{\mathbf{w}}_{t,N}$ is associated with its corresponding centered estimate $\bar{\boldsymbol{\eta}}_{t,N} \stackrel{\text{def}}{=} \overline{\mathbf{w}}_{t,N} - \mathbf{w}^* = \frac{1}{N}\sum_{s=t}^{t+N-1}(\mathbf{w}_s - \mathbf{w}^*) = \frac{1}{N}\sum_{s=t}^{t+N-1}\boldsymbol{\eta}_s$. Next, let $\boldsymbol{\Phi}_t$ denote the expected covariance of the centered estimate $\boldsymbol{\eta}_t$, i.e.

$$\boldsymbol{\Phi}_t \stackrel{\text{def}}{=} \mathbb{E}\left[\boldsymbol{\eta}_t \otimes \boldsymbol{\eta}_t\right],$$

and in a similar way as the final iterate $\mathbf{w}_t$, the tail-averaged estimate $\overline{\mathbf{w}}_{t,N}$ is associated with its expected covariance, i.e. $\bar{\boldsymbol{\Phi}}_{t,N} \stackrel{\text{def}}{=} \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{t,N} \otimes \bar{\boldsymbol{\eta}}_{t,N}\right]$.

A.2 Mini-Batch Tail-Averaged SGD: Bias-Variance Decomposition

In section A.2.1, we derive the basic recursion governing the evolution of the iterates $\mathbf{w}_t$ and the tail-averaged iterate $\overline{\mathbf{w}}_{s+1,N}$. In section A.2.2 we provide the bias-variance decomposition of the final iterate. In section A.2.3, we provide the bias-variance decomposition of the tail-averaged iterate.

A.2.1 THE BASIC RECURSION

At each iteration t of Algorithm 1, we are provided with b fresh samples $\{(\mathbf{x}_{ti}, y_{ti})\}_{i=1}^b$ drawn i.i.d. from the distribution $\mathcal{D}$. We start by recounting the mini-batch gradient descent update rule that allows us to move from iterate $\mathbf{w}_{t-1}$ to $\mathbf{w}_t$:

$$\mathbf{w}_t = \mathbf{w}_{t-1} - \frac{\gamma}{b}\sum_{i=1}^{b}(\langle \mathbf{w}_{t-1}, \mathbf{x}_{ti}\rangle - y_{ti})\mathbf{x}_{ti},$$

where, $0 < \gamma < \gamma_{b,\max}$ is the constant step size that is set to a value less than the maximum allowed learning rate $\gamma_{b,\max}$. We also recount the definition of $\overline{\mathbf{w}}_{t,N}$ which is the iterate obtained by averaging for N iterations starting from the t^{th} iteration, i.e.,

$$\overline{\mathbf{w}}_{t,N} = \frac{1}{N}\sum_{s=t}^{t+N-1}\mathbf{w}_s.$$

Let us first denote the residual error term by $\epsilon_i = y_i - \langle \mathbf{w}^*, \mathbf{x}_i\rangle$. By the first order optimality conditions of $\mathbf{w}^*$, we observe that ϵ and $\mathbf{x}$ are orthogonal, i.e, $\mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}[\epsilon \cdot \mathbf{x}] = 0$. For any estimate $\mathbf{w}$, the excess risk/generalization error can be written as:

$$L(\mathbf{w}) - L(\mathbf{w}^*) = \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}\cdot(\boldsymbol{\eta}\otimes\boldsymbol{\eta})\right), \text{ with } \boldsymbol{\eta} = \mathbf{w} - \mathbf{w}^*. \tag{11}$$

We now write out the main recursion governing the mini-batch SGD updates in terms of $\boldsymbol{\eta}_\cdot$:

$$\begin{aligned}
\boldsymbol{\eta}_t &= \Big(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^{b}\mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\Big)\boldsymbol{\eta}_{t-1} + \frac{\gamma}{b}\sum_{i=1}^{b}\epsilon_{ti}\mathbf{x}_{ti} \\
&= \Big(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^{b}\mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\Big)\boldsymbol{\eta}_{t-1} + \frac{\gamma}{b}\sum_{i=1}^{b}\boldsymbol{\xi}_{ti} \\
&= \mathbf{P}_{tb}\boldsymbol{\eta}_{t-1} + \gamma\boldsymbol{\zeta}_{tb},
\end{aligned} \tag{12}$$

where, $\mathbf{P}_{tb} \stackrel{\text{def}}{=} \Big(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^{b}\mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\Big)$ and $\boldsymbol{\zeta}_{tb} \stackrel{\text{def}}{=} \frac{1}{b}\sum_{i=1}^{b}\boldsymbol{\xi}_{ti} = \frac{1}{b}\sum_{i=1}^{b}\epsilon_{ti}\mathbf{x}_{ti}$. Equation 12 automatically brings out the "operator" view of analyzing the (expected) covariance of the centered estimate $\boldsymbol{\Phi}_t = \mathbb{E}\left[\boldsymbol{\eta}_t\otimes\boldsymbol{\eta}_t\right]$ to provide an estimate of the generalization error. We now note the following about the covariance of $\boldsymbol{\zeta}_{tb}$:

$$\begin{aligned}
\mathbb{E}[\boldsymbol{\zeta}_{tb}\otimes\boldsymbol{\zeta}_{t'b}] &= \frac{1}{b^2}\sum_{i,j}\mathbb{E}[\boldsymbol{\xi}_{ti}\otimes\boldsymbol{\xi}_{t'j}] \\
&= \Big[\frac{1}{b^2}\sum_{i=1}^{b}\mathbb{E}[\boldsymbol{\xi}_{ti}\otimes\boldsymbol{\xi}_{ti}]\Big]\mathbb{1}[t=t'] = \frac{1}{b}\boldsymbol{\Sigma}\ \mathbb{1}[t=t'],
\end{aligned} \tag{13}$$

where, $\mathbb{1}[.]$ is the indicator function, and equals 1 if the argument inside $[.]$ is true and 0 otherwise. We note that the expectation of the cross terms in equation 13 is zero owing to independence of the samples $\{\mathbf{x}_{ti}, y_{ti}\}_{i=1}^b$ as well as between $\{\mathbf{x}_{ti}, y_{ti}\}_{i=1}^b$, $\{\mathbf{x}_{t'i}, y_{t'i}\}_{i=1}^b$ $\forall\, t \neq t'$ and owing to the first order optimality conditions. Owing to the invariance of $\boldsymbol{\zeta}_{tb}$ on the iteration t, context permitting, we sometimes drop the iteration index t from $\boldsymbol{\zeta}_{tb}$ and simply refer to it as $\boldsymbol{\zeta}_b$.

Next we expand out the recurrence (12). Let $\mathbf{Q}_{j,t} = (\prod_{k=j}^{t}\mathbf{P}_{kb})^T$ with the convention that $\mathbf{Q}_{t',t} = \mathbf{I}\ \forall\, t' > t$. With this notation we have:

$$\begin{aligned}
\boldsymbol{\eta}_t &= \mathbf{P}_{tb}\boldsymbol{\eta}_{t-1} + \gamma\boldsymbol{\zeta}_{tb} \\
&= \mathbf{P}_{tb}\mathbf{P}_{t-1,b}\ldots\mathbf{P}_{1,b}\boldsymbol{\eta}_0 + \gamma\sum_{j=0}^{t-1}\{\mathbf{P}_{tb}\ldots\mathbf{P}_{t-j+1,b}\}\boldsymbol{\zeta}_{t-j,b} \\
&= \mathbf{Q}_{1,t}\boldsymbol{\eta}_0 + \gamma\sum_{j=0}^{t-1}\mathbf{Q}_{t-j+1,t}\boldsymbol{\zeta}_{t-j,b} \\
&= \mathbf{Q}_{1,t}\boldsymbol{\eta}_0 + \gamma\sum_{j=1}^{t}\mathbf{Q}_{j+1,t}\boldsymbol{\zeta}_{j,b} \\
&= \boldsymbol{\eta}_t^{\text{bias}} + \boldsymbol{\eta}_t^{\text{variance}},
\end{aligned} \tag{14}$$

where, we note that

$$\boldsymbol{\eta}_t^{\text{bias}} \stackrel{\text{def}}{=} \mathbf{Q}_{1,t}\boldsymbol{\eta}_0 \tag{15}$$

relates to understanding the behavior of SGD on the noiseless problem (i.e. $\boldsymbol{\zeta}_{\cdot,\cdot} = 0$ a.s.) and aims to quantify the dependence on the initial conditions. Further,

$$\boldsymbol{\eta}_t^{\text{variance}} \stackrel{\text{def}}{=} \gamma \sum_{j=1}^{t} \mathbf{Q}_{j+1,t}\boldsymbol{\zeta}_{j,b} \tag{16}$$

relates to the behavior of SGD when begun at the solution (i.e. $\boldsymbol{\eta}_0 = 0$) and allowing the noise $\boldsymbol{\zeta}_{\cdot,\cdot}$ to drive the process.

Furthermore, considering the tail-averaged iterate obtained by averaging the iterates of the SGD procedure for N iterations starting from a certain number of iterations "s", i.e., we examine the quantity $\bar{\boldsymbol{\eta}}_{s+1,N} = \overline{\mathbf{w}}_{s+1,N} - \mathbf{w}^*$, where $\overline{\mathbf{w}}_{s+1,N} = \frac{1}{N}\sum_{t=s+1}^{s+N} \mathbf{w}_t$. We write out the expression for $\bar{\boldsymbol{\eta}}_{s+1,N}$ starting out from equation 14:

$$\begin{aligned}
\bar{\boldsymbol{\eta}}_{s+1,N} &= \frac{1}{N}\sum_{t=s+1}^{s+N} \boldsymbol{\eta}_t \\
&= \frac{1}{N}\sum_{t=s+1}^{s+N} \left(\boldsymbol{\eta}_t^{\text{bias}} + \boldsymbol{\eta}_t^{\text{variance}}\right) \qquad \text{(from equation 14)} \\
&= \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{bias}} + \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{variance}}.
\end{aligned} \tag{17}$$

A.2.2 THE FINAL ITERATE: BIAS-VARIANCE DECOMPOSITION

The behavior of the final iterate is considered to be of great practical interest and we hope to shed light on the behavior of this final iterate and the tradeoffs between the learning rate and batch size. Since the generalization error of any iterate $\mathbf{w}_N$ obtained by running mini-batch SGD with a batch size b for a total of N iterations can be estimated by tracking $\mathbb{E}\left[\boldsymbol{\eta}_N \otimes \boldsymbol{\eta}_N\right]$, where, $\boldsymbol{\eta}_N = \mathbf{w}_N - \mathbf{w}^*$, we provide a simple psd upper bound on the outer product of interest, i.e.:

$$\begin{aligned}
\mathbb{E}\left[\boldsymbol{\eta}_N \otimes \boldsymbol{\eta}_N\right] &= \mathbb{E}\left[\left(\boldsymbol{\eta}_N^{\text{bias}} + \boldsymbol{\eta}_N^{\text{variance}}\right) \otimes \left(\boldsymbol{\eta}_N^{\text{bias}} + \boldsymbol{\eta}_N^{\text{variance}}\right)\right] \qquad \text{(by substituting equation 14)} \\
&\preceq 2 \cdot \left(\mathbb{E}\left[\left(\boldsymbol{\eta}_N^{\text{bias}} \otimes \boldsymbol{\eta}_N^{\text{bias}}\right)\right] + \mathbb{E}\left[\left(\boldsymbol{\eta}_N^{\text{variance}} \otimes \boldsymbol{\eta}_N^{\text{variance}}\right)\right]\right).
\end{aligned}$$

Using this expression, we now write out the expression for the excess risk of the final iterate:

$$\begin{aligned}
\mathbb{E}\left[L(\mathbf{w}_N)\right] - L(\mathbf{w}^*) &= \frac{1}{2}\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_N \otimes \boldsymbol{\eta}_N\right]\rangle \\
&\leq \frac{1}{2}\langle \mathbf{H}, 2 \cdot \left(\mathbb{E}\left[\boldsymbol{\eta}_N^{\text{bias}} \otimes \boldsymbol{\eta}_N^{\text{bias}}\right] + \mathbb{E}\left[\boldsymbol{\eta}_N^{\text{variance}} \otimes \boldsymbol{\eta}_N^{\text{variance}}\right]\right)\rangle \\
&\leq 2 \cdot \left(\frac{1}{2}\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_N^{\text{bias}} \otimes \boldsymbol{\eta}_N^{\text{bias}}\right]\rangle + \frac{1}{2}\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_N^{\text{variance}} \otimes \boldsymbol{\eta}_N^{\text{variance}}\right]\rangle\right) \\
&= 2 \cdot \left(\left(\mathbb{E}\left[L(\mathbf{w}_N^{\text{bias}})\right] - L(\mathbf{w}^*)\right) + \left(\mathbb{E}\left[L(\mathbf{w}_N^{\text{variance}})\right] - L(\mathbf{w}^*)\right)\right).
\end{aligned} \tag{18}$$

A.2.3 THE TAIL-AVERAGED ITERATE: BIAS-VARIANCE DECOMPOSITION

Now, considering the fact that the excess risk/generalization error (equation 11) involves tracking $\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right]$, we see that the quantity of interest can be bounded by considering the behavior of SGD on bias and variance sub-problem. In particular, writing out the outerproduct of equation 17, we see the following inequality holds through a straightforward application of Cauchy-Shwartz inequality:

$$\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right] \preceq 2 \cdot \left(\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N}^{\text{bias}} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{bias}}\right] + \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N}^{\text{variance}} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{variance}}\right]\right). \tag{19}$$

The above equation is referred to as the bias-variance decomposition and is well known from previous work on Stochastic Approximation (Bach and Moulines, 2013; Frostig et al., 2015b; Défossez and Bach, 2015). This implies that an upper bound on the generalization error (equation 11) is:

$$\begin{aligned}
L(\overline{\mathbf{w}}_{s+1,N}) - L(\mathbf{w}^*) &= \frac{1}{2}\langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right]\rangle \\
&\leq \langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N}^{\text{bias}} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{bias}}\right]\rangle + \langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N}^{\text{variance}} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}^{\text{variance}}\right]\rangle.
\end{aligned} \tag{20}$$

Here, we adopt the proof approach of Jain et al. (2017a). In particular, Jain et al. (2017a) provide a clean way to simplify the expression corresponding to the tail-averaged iterate. Let us consider $\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right]$ and simplify the resulting expression: in particular,

$$\begin{aligned}
\mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N}\bar{\boldsymbol{\eta}}_{s+1,N}^\top\right] &= \frac{1}{N^2}\sum_{l=s+1}^{s+N}\sum_{k=s+1}^{s+N} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right] \\
&= \frac{1}{N^2} \cdot \left(\sum_{l \geq k} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right] + \sum_{l<k} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right]\right) \\
&\preceq \frac{1}{N^2} \cdot \left(\sum_{l \geq k} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right] + \sum_{l \leq k} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right]\right) \qquad (*) \\
&= \frac{1}{N^2} \cdot \left(\sum_{l \geq k} (\mathbf{I} - \gamma\mathbf{H})^{l-k}\mathbb{E}\left[\boldsymbol{\eta}_k \otimes \boldsymbol{\eta}_k\right] + \sum_{l \leq k} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\mathbf{I} - \gamma\mathbf{H})^{k-l}\right) \quad (**) \\
&= \frac{1}{N^2} \cdot \sum_{l \leq k}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\mathbf{I} - \gamma\mathbf{H})^{k-l} + (\mathbf{I} - \gamma\mathbf{H})^{k-l}\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right) \\
&= \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N}\sum_{k=l}^{s+N}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\mathbf{I} - \gamma\mathbf{H})^{k-l} + (\mathbf{I} - \gamma\mathbf{H})^{k-l}\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right) \\
&= \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N}\sum_{k=l}^{\infty}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\mathbf{I} - \gamma\mathbf{H})^{k-l} + (\mathbf{I} - \gamma\mathbf{H})^{k-l}\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right) \\
&\quad - \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N}\sum_{k=s+N+1}^{\infty}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\mathbf{I} - \gamma\mathbf{H})^{k-l} + (\mathbf{I} - \gamma\mathbf{H})^{k-l}\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right) \\
&= \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right](\gamma\mathbf{H})^{-1} + (\gamma\mathbf{H})^{-1}\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right)
\end{aligned}$$

$$- \frac{1}{N^2} \sum_{l=s+1}^{s+N} \sum_{k=s+N+1}^{\infty} \left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} + \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right) \tag{21}$$
$$(***),$$

where, $(*)$ is a valid PSD upper bound as we add and subtract the diagonal terms $\{\mathbb{E}\left[\boldsymbol{\eta}_k \boldsymbol{\eta}_k^\top\right]\}_{k=s+1}^{s+N}$. $(**)$ follows because of the following (assume $l > k$; the other case follows similarly):

$$\begin{aligned}
\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_k\right] &= \mathbb{E}\left[\left(\mathbf{P}_{lb}\boldsymbol{\eta}_{l-1} + \gamma \boldsymbol{\zeta}_{lb}\right) \otimes \boldsymbol{\eta}_k\right] \\
&= \mathbb{E}\left[\mathbb{E}\left[\left(\mathbf{P}_{lb}\boldsymbol{\eta}_{l-1} + \gamma \boldsymbol{\zeta}_{lb}\right) \otimes \boldsymbol{\eta}_k | \mathcal{F}_{l-1}\right]\right] \\
&= \mathbb{E}\left[\mathbb{E}\left[\left(\mathbf{P}_{lb}\boldsymbol{\eta}_{l-1} + \gamma \boldsymbol{\zeta}_{lb}\right) | \mathcal{F}_{l-1}\right] \otimes \boldsymbol{\eta}_k\right] \\
&= \left(\mathbf{I} - \gamma \mathbf{H}\right) \mathbb{E}\left[\boldsymbol{\eta}_{l-1} \otimes \boldsymbol{\eta}_k\right],
\end{aligned}$$

where, the final equation follows since $\mathbb{E}\left[\mathbf{P}_{lb} | \mathcal{F}_{l-1}\right] = \mathbb{E}\left[\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^{b} \mathbf{x}_{li} \otimes \mathbf{x}_{li} | \mathcal{F}_{l-1}\right] = \mathbf{I} - \gamma \mathbf{H}$ and $\mathbb{E}\left[\boldsymbol{\zeta}_{lb} | \mathcal{F}_{l-1}\right] = 0$ from first order optimality conditions. Recursing over l yields the result. $(***)$ follows from summing a (convergent) geometric series.

This implies that the excess risk corresponding to the bias/variance term can be obtained from equation 21 by taking an inner product with $\mathbf{H}$, i.e.:

$$\begin{aligned}
\left\langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right] \right\rangle &\leq \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N} \left(\left\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \left(\gamma \mathbf{H}\right)^{-1} + \left(\gamma \mathbf{H}\right)^{-1} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right\rangle \right) \\
&\quad - \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N} \sum_{k=s+N+1}^{\infty} \left(\left\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} \right.\right. \\
&\qquad \left.\left. + \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right\rangle \right) \\
&\leq \frac{1}{N^2} \cdot \sum_{l=s+1}^{s+N} \left(\left\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \left(\gamma \mathbf{H}\right)^{-1} + \left(\gamma \mathbf{H}\right)^{-1} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right\rangle \right) \\
&= \frac{2}{\gamma N^2} \cdot \sum_{l=s+1}^{s+N} \operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right).
\end{aligned} \tag{22}$$

The upper bound on the final line follows because each term within the summation in the second line is negative owing to the following argument. Consider say,

$$\begin{aligned}
&\left\langle \mathbf{H}, \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} + \left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right\rangle \\
&= 2 \operatorname{Tr}\left[\mathbf{H}\left(\mathbf{I} - \gamma \mathbf{H}\right)^{k-l} \mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]\right] \geq 0.
\end{aligned}$$

Note that $\mathbf{H}$ and $(\mathbf{I} - \gamma \mathbf{H})$ commute and both are psd, implying that $\mathbf{H}(\mathbf{I} - \gamma \mathbf{H})^{k-l}$ is PSD. Finally, the trace of the product of two PSD matrices is positive with $\mathbf{H}(\mathbf{I} - \gamma \mathbf{H})^{k-l}$ being one of these PSD matrices and $\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right]$ being the other, thus yielding the claimed bound in equation 22.

This implies that the overall error (through equation 11) can be upperbounded as:

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N})\right] - L(\mathbf{w}^*) = \frac{1}{2} \cdot \left\langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}_{s+1,N} \otimes \bar{\boldsymbol{\eta}}_{s+1,N}\right] \right\rangle$$

$$\begin{aligned}
&\leq \frac{1}{\gamma N^2} \sum_{l=s+1}^{s+N} \operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l \otimes \boldsymbol{\eta}_l\right] \right) \\
&\leq \frac{2}{\gamma N^2} \cdot \sum_{l=s+1}^{s+N} \left(\operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l^{\text{bias}} \otimes \boldsymbol{\eta}_l^{\text{bias}}\right] \right) + \operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l^{\text{variance}} \otimes \boldsymbol{\eta}_l^{\text{variance}}\right] \right) \right),
\end{aligned} \tag{23}$$

where the final line follows from equation 19. We will now bound each of these terms to precisely characterize the excess risk of mini-batch tail-averaged SGD. We refer to the bias error of the tail-averaged iterate as the following:

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{\text{bias}})\right] - L(\mathbf{w}^*) \stackrel{\text{def}}{=} \frac{2}{\gamma N^2} \sum_{l=s+1}^{s+N} \operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l^{\text{bias}} \otimes \boldsymbol{\eta}_l^{\text{bias}}\right] \right). \tag{24}$$

Similarly, we refer to the variance error of the tail-averaged iterate as the following:

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{\text{variance}})\right] - L(\mathbf{w}^*) \stackrel{\text{def}}{=} \frac{2}{\gamma N^2} \sum_{l=s+1}^{s+N} \operatorname{Tr}\left(\mathbb{E}\left[\boldsymbol{\eta}_l^{\text{variance}} \otimes \boldsymbol{\eta}_l^{\text{variance}}\right] \right). \tag{25}$$

A.3 Lemmas For Bounding The Bias Error

Lemma 9 *With $\gamma \leq \frac{\gamma_{b,max}}{2} = \frac{b}{R^2 \cdot \rho_m + (b-1)\|\mathbf{H}\|_2}$, the following bound holds:*

$$\left\| \mathbb{E}\left[\left(\mathbf{I} - \frac{\gamma}{b}\sum_{j=1}^{b} \mathbf{x}_{li} \otimes \mathbf{x}_{li}\right)\left(\mathbf{I} - \frac{\gamma}{b}\sum_{j=1}^{b} \mathbf{x}_{li} \otimes \mathbf{x}_{li}\right) \right] \right\|_2 \leq 1 - \gamma\mu.$$

Proof This lemma generalizes one appearing in Jain et al. (2017a) to the mini-batch size b case. Denote by $\mathbf{U}$ the matrix of interest and consider the following:

$$\begin{aligned}
\mathbf{U} &= \mathbb{E}\left[\left(\mathbf{I} - \frac{\gamma}{b}\sum_{j=1}^{b} \mathbf{x}_{li} \otimes \mathbf{x}_{li}\right)\left(\mathbf{I} - \frac{\gamma}{b}\sum_{j=1}^{b} \mathbf{x}_{li} \otimes \mathbf{x}_{li}\right) \right] \\
&= \mathbf{I} - \gamma\mathbf{H} - \gamma\mathbf{H} + \left(\frac{\gamma}{b}\right)^2 \cdot \left(b\mathbb{E}\left[\|\mathbf{x}\|^2 \mathbf{x}\mathbf{x}^\top\right] + b(b-1)\mathbf{H}^2 \right) \\
&\preceq \mathbf{I} - 2\gamma\mathbf{H} + \frac{\gamma^2}{b} \cdot \left(R^2\mathbf{H} + (b-1)\|\mathbf{H}\|_2\right)\mathbf{H} \\
&= \mathbf{I} - \gamma\mathbf{H},
\end{aligned}$$

from which a spectral norm bound implied by the lemma naturally follows. ■

Lemma 10 *For any learning rate $\gamma \leq \gamma_{b,max}/2$, the bias error of the tail-averaged iterate $\overline{\mathbf{w}}_{s+1,N}^{bias}$ is upper bounded as:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{bias})\right] - L(\mathbf{w}^*) \leq \frac{2}{\gamma^2 N^2 \mu^2}(1 - \gamma\mu)^{s+1} \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right).$$

Proof Before writing out the proof of the bound in the lemma, we require to bound the per step contraction properties of an SGD update in the case of the bias error (i.e. $\boldsymbol{\zeta}_\cdot = 0$):

$$\begin{aligned}
\mathbb{E}\left[\|\boldsymbol{\eta}_l\|^2\right] &= \mathbb{E}\left[\boldsymbol{\eta}_{l-1}^\top (\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{li}\otimes\mathbf{x}_{li})(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{li}\otimes\mathbf{x}_{li})\boldsymbol{\eta}_{l-1}\right] \\
&= \mathbb{E}\left[\boldsymbol{\eta}_{l-1}^\top \mathbb{E}\left[(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{li}\otimes\mathbf{x}_{li})(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{li}\otimes\mathbf{x}_{li})\middle|\mathcal{F}_{l-1}\right]\boldsymbol{\eta}_{l-1}\right] \\
&\leq (1-\gamma\mu)\mathbb{E}\left[\|\boldsymbol{\eta}_{l-1}\|^2\right] \quad \text{(using lemma 9)}.
\end{aligned}$$

This implies that a recursive application of the above bound yields $\mathbb{E}\left[\|\boldsymbol{\eta}_l\|^2\right] \leq (1-\gamma\mu)^l\mathbb{E}\left[\|\boldsymbol{\eta}_0\|^2\right]$.

Next, we consider the bias error from equation 24:

$$\begin{aligned}
\mathbb{E}\left[L(\overline{\mathbf{w}}^{\text{bias}}_{s+1,N})\right] - L(\mathbf{w}^*) &= \frac{2}{\gamma N^2}\sum_{t=s+1}^{s+N}\mathbb{E}\left[\|\boldsymbol{\eta}_t\|^2\right] \\
&\leq \frac{2}{\gamma N^2}\sum_{t=s+1}^{\infty}\mathbb{E}\left[\|\boldsymbol{\eta}_t\|^2\right] \\
&\leq \frac{2}{\gamma N^2}\sum_{t=s+1}^{\infty}(1-\gamma\mu)^t\|\boldsymbol{\eta}_0\|^2 \\
&= \frac{2}{\gamma N^2}(\gamma\mu)^{-1}(1-\gamma\mu)^{s+1}\|\boldsymbol{\eta}_0\|^2 \\
&= \frac{2}{\gamma^2\mu N^2}(1-\gamma\mu)^{s+1}\|\boldsymbol{\eta}_0\|^2 \\
&= \frac{2}{\gamma^2\mu^2 N^2}(1-\gamma\mu)^{s+1}\cdot\left(\mu\cdot\|\boldsymbol{\eta}_0\|^2\right) \\
&\leq \frac{2}{\gamma^2\mu^2 N^2}(1-\gamma\mu)^{s+1}\cdot\left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right),
\end{aligned}$$

where in the final line, we use the fact that $\mu\mathbf{I} \preceq \mathbf{H}$. This proves the claimed bound. ■

Lemma 11 *For any learning rate $\gamma \leq \gamma_{b,max}/2$, the bias error of the* **final** *iterate $\mathbf{w}_N^{bias}$ is upper bounded as:*

$$\mathbb{E}\left[L(\mathbf{w}_N^{bias})\right] - L(\mathbf{w}^*) \leq \frac{\kappa}{2}\cdot(1-\gamma\mu)^N\cdot\big(L(\mathbf{w}_0) - L(\mathbf{w}^*)\big).$$

Proof Similar to the tail-averaged case, we require to bound the per step contraction properties of an SGD update in the case of the bias error (i.e. $\boldsymbol{\zeta}_\cdot = 0$):

$$\begin{aligned}
\mathbb{E}\left[\|\boldsymbol{\eta}_N\|^2\right] &= \mathbb{E}\left[\boldsymbol{\eta}_{N-1}^\top (\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{Ni}\otimes\mathbf{x}_{Ni})(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{Ni}\otimes\mathbf{x}_{Ni})\boldsymbol{\eta}_{N-1}\right] \\
&= \mathbb{E}\left[\boldsymbol{\eta}_{N-1}^\top \mathbb{E}\left[(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{Ni}\otimes\mathbf{x}_{Ni})(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{Ni}\otimes\mathbf{x}_{Ni})\middle|\mathcal{F}_{N-1}\right]\boldsymbol{\eta}_{N-1}\right]
\end{aligned}$$

$$\leq (1-\gamma\mu)\mathbb{E}\left[\|\boldsymbol{\eta}_{N-1}\|^2\right] \quad \text{(using lemma 9)}.$$

This implies that a recursive application of the above bound yields $\mathbb{E}\left[\|\boldsymbol{\eta}_N\|^2\right] \leq (1-\gamma\mu)^N\mathbb{E}\left[\|\boldsymbol{\eta}_0\|^2\right]$. Then,

$$\begin{aligned}
\mathbb{E}\left[L(\mathbf{w}_N^{\text{bias}})\right] - L(\mathbf{w}^*) &= \frac{1}{2}\operatorname{Tr}\left((\boldsymbol{\eta}_N^{\text{bias}})^\top\mathbf{H}\boldsymbol{\eta}_N^{\text{bias}}\right) \\
&\leq \frac{\lambda_{\max}(\mathbf{H})}{2}\operatorname{Tr}\left(\|\boldsymbol{\eta}_N^{\text{bias}}\|^2\right) \\
&\leq \frac{\lambda_{\max}(\mathbf{H})(1-\gamma\mu)^N}{2\lambda_{\min}(\mathbf{H})}\operatorname{Tr}\left(\lambda_{\min}(\mathbf{H})\|\boldsymbol{\eta}_0\|^2\right) \\
&\leq \frac{\lambda_{\max}(\mathbf{H})(1-\gamma\mu)^N}{2\lambda_{\min}(\mathbf{H})}\Big(L(\mathbf{w}_0) - L(\mathbf{w}^*)\Big) \qquad (\text{since, } \mathbf{w}_0 = \mathbf{w}_0^{\text{bias}}). \\
&\leq \frac{\kappa}{2}\cdot(1-\gamma\mu)^N\Big(L(\mathbf{w}_0) - L(\mathbf{w}^*)\Big).
\end{aligned}$$

■

A.4 Lemmas For Bounding The Variance Error

Now, we seek to understand the behavior of the variance error of the tail-averaged iterate $\overline{\mathbf{w}}_{s+1,N}$. We begin by noting here that the variance error is analyzed by beginning the optimization at the solution, i.e. $\boldsymbol{\eta}_0^{\text{variance}} = 0$ and allowing the noise to drive the process. In particular, we write out the recursive updates that characterize the variance error:

$$\boldsymbol{\eta}_t^{\text{variance}} = \mathbf{P}_{tb}\boldsymbol{\eta}_{t-1}^{\text{variance}} + \gamma\boldsymbol{\zeta}_{tb}, \text{ with } \boldsymbol{\eta}_0^{\text{variance}} = 0.$$

This implies that by defining $\boldsymbol{\Phi}_t^{\text{variance}} \stackrel{\text{def}}{=} \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{variance}}\otimes\boldsymbol{\eta}_t^{\text{variance}}\right]$, we have:

$$\begin{aligned}
\boldsymbol{\Phi}_t^{\text{variance}} &= \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{variance}}\otimes\boldsymbol{\eta}_t^{\text{variance}}\right] \\
&= \mathbb{E}\left[\mathbb{E}\left[\left(\mathbf{P}_{tb}\boldsymbol{\eta}_{t-1}^{\text{variance}} + \gamma\boldsymbol{\zeta}_{tb}\right)\otimes\left(\mathbf{P}_{tb}\boldsymbol{\eta}_{t-1}^{\text{variance}} + \gamma\boldsymbol{\zeta}_{tb}\right)|\mathcal{F}_{t-1}\right]\right] \\
&= \mathbb{E}\left[\mathbf{P}_{tb}\boldsymbol{\Phi}_{t-1}^{\text{variance}}\mathbf{P}_{tb}^\top\right] + \frac{\gamma^2}{b}\boldsymbol{\Sigma}. \qquad (26)
\end{aligned}$$

where, $\mathcal{F}_{t-1}$ is the filtration defined using the samples $\{\mathbf{x}_{ji}, y_{ji}\}_{j=1,i=1}^{j=t-1,i=b}$. Furthermore cross terms are zero since $\mathbb{E}\left[\boldsymbol{\zeta}_{tb}|\mathcal{F}_{t-1}\right] = 0$ owing to first order optimality conditions. Recounting that $\mathbf{P}_{tb} = \mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{ti}\otimes\mathbf{x}_{ti}$, we express equation 26 using a linear operator as follows:

$$\begin{aligned}
\mathbb{E}\left[\mathbf{P}_{tb}\boldsymbol{\Phi}_{t-1}^{\text{variance}}\mathbf{P}_{tb}^\top\right] &= \mathbb{E}\left[\left(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\right)\boldsymbol{\Phi}_{t-1}^{\text{variance}}\left(\mathbf{I} - \frac{\gamma}{b}\sum_{i=1}^b \mathbf{x}_{ti}\otimes\mathbf{x}_{ti}\right)\right] \\
&\stackrel{\text{def}}{=} (\mathcal{I} - \gamma\mathcal{T}_b)\boldsymbol{\Phi}_{t-1}^{\text{variance}},
\end{aligned}$$

with $\mathcal{T}_b$ representing the following linear operator:

$$\mathcal{T}_b = \mathcal{H}_{\mathcal{L}} + \mathcal{H}_{\mathcal{R}} - \frac{\gamma}{b}\mathcal{M} - \gamma\frac{b-1}{b}\mathcal{H}_{\mathcal{L}}\mathcal{H}_{\mathcal{R}},$$

with $\mathcal{M} = \mathbb{E}[\mathbf{x} \otimes \mathbf{x} \otimes \mathbf{x} \otimes \mathbf{x}]$, $\mathcal{H}_{\mathcal{L}} = \mathbf{H} \otimes \mathbf{I}$ and $\mathcal{H}_{\mathcal{R}} = \mathbf{I} \otimes \mathbf{H}$ representing the left and right multiplication linear operators corresponding to the matrix $\mathbf{H}$. Given this notation, we consider $\mathbf{\Phi}_t^{\text{variance}}$:

$$\begin{aligned}\mathbf{\Phi}_t^{\text{variance}} &= (\mathcal{I} - \gamma\mathcal{T}_b)\mathbf{\Phi}_{t-1}^{\text{variance}} + \frac{\gamma^2}{b}\mathbf{\Sigma} \\ &= \frac{\gamma^2}{b}\left(\sum_{k=0}^{t-1}(\mathcal{I} - \gamma\mathcal{T}_b)^k\right)\mathbf{\Sigma}. \end{aligned} \tag{27}$$

Before bounding the variance error, we will describe a lemma that shows that the expected covariance of the variance error $\mathbf{\Phi}_t^{\text{variance}}$ initialized at 0 grows monotonically to its steady state value (in a PSD sense).

Lemma 12 *The sequence of centered variance iterates $\boldsymbol{\eta}_t^{variance}$ have expected covariances that monotonically grow in a PSD sense, i.e.:*

$$0 = \mathbf{\Phi}_0^{variance} \preceq \mathbf{\Phi}_1^{variance} \preceq \mathbf{\Phi}_2^{variance} \ldots. \preceq \mathbf{\Phi}_\infty^{variance}.$$

Proof This lemma generalizes the lemma appearing in Jain et al. (2017a,b). We begin by recounting the t^{th} variance iterate, i.e.:

$$\boldsymbol{\eta}_t^{\text{variance}} = \gamma\sum_{j=1}^{t}\mathbf{Q}_{j+1,t}\boldsymbol{\zeta}_{j,b}.$$

This implies in particular that

$$\begin{aligned}\mathbf{\Phi}_t^{\text{variance}} &= \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{variance}} \otimes \boldsymbol{\eta}_t^{\text{variance}}\right] \\ &= \gamma^2\sum_{j=1}^{t}\sum_{l=1}^{t}\mathbb{E}\left[\mathbf{Q}_{j+1,t}\boldsymbol{\zeta}_{j,b} \otimes \boldsymbol{\zeta}_{l,b}\mathbf{Q}_{l+1,b}^\top\right] \quad \text{(from equation 14)} \\ &= \gamma^2\sum_{j=1}^{t}\sum_{l=1}^{t}\mathbb{E}\left[\mathbf{Q}_{j+1,t}\mathbb{E}\left[\boldsymbol{\zeta}_{j,b} \otimes \boldsymbol{\zeta}_{l,b}|\mathcal{F}_{j-1}\right]\mathbf{Q}_{l+1,b}^\top\right] \\ &= \gamma^2\sum_{j=1}^{t}\mathbb{E}\left[\mathbf{Q}_{j+1,t}\boldsymbol{\zeta}_{j,b} \otimes \boldsymbol{\zeta}_{j,b}\mathbf{Q}_{j+1,t}^\top\right] \\ &= \frac{\gamma^2}{b}\sum_{j=1}^{t}\mathbb{E}\left[\mathbf{Q}_{j+1,t}\mathbf{\Sigma}\mathbf{Q}_{j+1,t}^\top\right].\end{aligned}$$

where, the third line follows since $\mathbb{E}\left[\boldsymbol{\zeta}_{l,b} \otimes \boldsymbol{\zeta}_{j,b}\right] = 0$ for $j \neq l$, similar to arguments in equation 13. This immediately reveals that the sequence of covariances grows as a function of time, since,

$$\mathbf{\Phi}_{t+1}^{\text{variance}} - \mathbf{\Phi}_t^{\text{variance}} = \frac{\gamma^2}{b}\mathbb{E}\left[\mathbf{Q}_{2,t+1}\mathbf{\Sigma}\mathbf{Q}_{2,t+1}^\top\right] \succeq 0.$$

■

This lemma leads to a natural upper bound on the variance error, as expressed below:

Lemma 13 *With $\gamma < \frac{\gamma_{b,max}}{2}$, the variance error of the tail-averaged iterate $\overline{\mathbf{w}}_{s+1,N}^{variance}$ is upper bounded as:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{variance})\right] - L(\mathbf{w}^*) \leq \frac{2}{Nb}\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right).$$

Proof Considering the variance error of tail-averaged iterate from equation 25:

$$\begin{aligned}\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{\text{variance}})\right] - L(\mathbf{w}^*) &= \frac{2}{\gamma N^2}\cdot\sum_{l=s+1}^{s+N}\left(\operatorname{Tr}\left(\mathbb{E}\left[\mathbf{\Phi}_l^{\text{variance}}\right]\right)\right) \\ &\leq \frac{2}{\gamma N}\cdot\operatorname{Tr}\left(\mathbb{E}\left[\mathbf{\Phi}_\infty^{\text{variance}}\right]\right) \quad \text{(from lemma 12)} \\ &= \frac{2}{\gamma N}\cdot\frac{\gamma^2}{b}\cdot\operatorname{Tr}\left(\sum_{k=0}^{\infty}(\mathcal{I} - \gamma\mathcal{T}_b)^k\mathbf{\Sigma}\right) \quad \text{(from equation 14)} \\ &= \frac{2}{Nb}\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right).\end{aligned}$$

■

Lemma 14 *With $\gamma < \frac{\gamma_{b,max}}{2}$, the variance error of the* **final** *iterate $\mathbf{w}_N^{variance}$, obtained by running mini-batch SGD for N steps is upper bounded as:*

$$\mathbb{E}\left[L(\mathbf{w}_N^{variance})\right] - L(\mathbf{w}^*) \leq \frac{\gamma}{2b}\operatorname{Tr}\left(\mathbf{H}\mathcal{T}_b^{-1}\mathbf{\Sigma}\right).$$

Proof We note that since we deal with the square loss case,

$$\begin{aligned}\mathbb{E}\left[L(\mathbf{w}_N^{\text{variance}})\right] - L(\mathbf{w}^*) &= \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}\mathbf{\Phi}_N^{\text{variance}}\right) \\ &\leq \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}\mathbf{\Phi}_\infty^{\text{variance}}\right) \quad \text{(using lemma 12)} \\ &= \frac{\gamma^2}{2b}\operatorname{Tr}\left(\mathbf{H}\sum_{j=0}^{\infty}(\mathcal{I} - \gamma\mathcal{T}_b)^j\mathbf{\Sigma}\right) \\ &= \frac{\gamma}{2b}\operatorname{Tr}\left(\mathbf{H}\mathcal{T}_b^{-1}\mathbf{\Sigma}\right).\end{aligned}$$

■

Lemma 15 *Denoting the assumption (A) $\gamma \leq \gamma_{b,max}/2$,*

1. *With (A) in place, $\mathcal{T}_b \succeq 0$.*
2. *With (A) in place, $\mathcal{T}_b^{-1}\mathbf{W} \succeq 0$ for every $\mathbf{W} \in \mathcal{S}(d)$, $\mathbf{W} \succeq 0$.*
3. $\operatorname{Tr}\left((\mathcal{H}_{\mathcal{R}} + \mathcal{H}_{\mathcal{L}})^{-1}\mathbf{A}\right) = \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{A}\right)\ \forall\ \mathbf{A} \in \mathcal{S}^+(\mathbb{R}^d)$.

4. With (A) in place,

$$\operatorname{Tr}\left(\mathcal{T}_b^{-1}\boldsymbol{\Sigma}\right) \leq 2\operatorname{Tr}\left(\mathbf{H}^{-1}\boldsymbol{\Sigma}\right).$$

Proof

Proof of claim 1 in Lemma 15: $\mathcal{T}_b \succeq 0$ implies that for all symmetric matrices $\mathbf{A} \in \mathcal{S}(d)$, we have $\operatorname{Tr}(\mathbf{A}\mathcal{T}_b\mathbf{A}) \geq 0$, and this is true owing to the following inequalities:

$$\begin{aligned}
\langle \mathbf{A}, \mathcal{T}_b\mathbf{A}\rangle &= 2\operatorname{Tr}(\mathbf{AHA}) - \frac{\gamma}{b}\mathbb{E}\left[\langle \mathbf{x}, \mathbf{Ax}\rangle^2\right] - \frac{\gamma(b-1)}{b}\langle \mathbf{H}, \mathbf{AHA}\rangle \\
&\geq 2\operatorname{Tr}(\mathbf{AHA}) - \frac{\gamma}{b}\mathbb{E}\left[\|\mathbf{x}\|^2\|\mathbf{Ax}\|^2\right] - \frac{\gamma(b-1)}{b}\|\mathbf{H}\|\operatorname{Tr}(\mathbf{AHA}) \\
&\geq 2\operatorname{Tr}(\mathbf{AHA}) - \frac{\gamma}{b}R^2\mathbb{E}\left[\|\mathbf{Ax}\|^2\right] - \frac{\gamma(b-1)}{b}\|\mathbf{H}\|\operatorname{Tr}(\mathbf{AHA}) \\
&\geq \left(2 - \frac{\gamma}{b}\left(R^2 + (b-1)\|\mathbf{H}\|\right)\right)\operatorname{Tr}(\mathbf{AHA}).
\end{aligned}$$

Using the definition of $\gamma_{b,\max}$ completes the proof of the claim.

Proof of claim 2 in Lemma 15: We require to prove $\mathcal{T}_b^{-1}$ operating on a PSD matrix produces a PSD matrix, or in other words, $\mathcal{T}_b^{-1}$ is a PSD map.

$$\begin{aligned}
\mathcal{T}_b^{-1} &= [\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R} - \frac{\gamma}{b}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})]^{-1} \\
&= (\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{\frac{1}{2}}[\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R} - \frac{\gamma}{b}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})]^{-1} \cdot \\
&\qquad (\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{\frac{1}{2}}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}} \\
&= (\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}[\mathcal{I} - \frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}]^{-1}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}.
\end{aligned} \tag{28}$$

Now, we prove that $\|\frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}\| < 1$. Given $\gamma < \gamma_{b,\max}/2$, we employ claim 1 to note that $\mathcal{T}_b \succ 0$.

$$\begin{aligned}
&\mathcal{T}_b \succ 0 \\
&\Rightarrow \mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R} - \frac{\gamma}{b}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}) \succ 0 \\
&\Rightarrow \frac{\gamma}{b}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}) \prec \mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R} \\
&\Rightarrow \frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}} \prec \mathcal{I} \\
&\Rightarrow \|\frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}\| < 1.
\end{aligned}$$

With this fact in place, we employ Taylor series to expand $\mathcal{T}_b^{-1}$ in equation 28, i.e.:

$$\begin{aligned}
\mathcal{T}_b^{-1} &= (\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}\sum_{i=0}^{\infty}(\frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}})^i(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-\frac{1}{2}} \\
&= \sum_{i=0}^{\infty}(\frac{\gamma}{b}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-1}(\mathcal{M} + (b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}))^i(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-1}.
\end{aligned}$$

The proof completes by employing the following facts: Using Lyapunov's theorem (Bhatia (2007) proposition A 1.2.6), we know $(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-1}$ is a PSD map, i.e. if $(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})^{-1}(A) = B$, then, if A is PSD $\implies$ B is PSD. Furthermore, $\mathcal{M}$ is also a PSD map, i.e. if A_1 is PSD, $\mathcal{M}(A_1) = E[(x^TA_1x)x \otimes x]$ is PSD as well. Finally, $\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}$ is also a PSD map, since, if A_2 is PSD, then, $\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}(A_2) = HA_2H$ which is PSD as well. With all these facts in place, we note that each term in the Taylor's expansion above is a PSD map implying the overall map is PSD as well, thus rounding up the proof to claim 2 in Lemma 15.

Proof of claim 3 in Lemma 15:

We know that the operator $(\mathcal{H}_\mathcal{R} + \mathcal{H}_\mathcal{L})^{-1}$ is a PSD map, i.e, it maps PSD matrices to PSD matrices. Since $\mathbf{A} \succeq 0$, we replace this condition with $\mathbf{U} = (\mathcal{H}_\mathcal{R} + \mathcal{H}_\mathcal{L})^{-1}\mathbf{A} \succeq 0$ implying, we need to show the following:

$$\operatorname{Tr}(\mathbf{U}) = \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{A}\right) \ \forall\, \mathbf{U} \succeq 0.$$

Examining the right hand side, we see the following:

$$\begin{aligned}
\frac{1}{2}\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{A}\right) &= \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}^{-1}(\mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R})\mathbf{U}\right) \\
&= \frac{1}{2}\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{HU} + \mathbf{H}^{-1}\mathbf{UH}\right) \\
&= \operatorname{Tr}(\mathbf{U}).
\end{aligned}$$

thus wrapping up the proof of claim 4.

Proof of claim 4 in Lemma 15: Let $\mathcal{U} = \mathcal{H}_\mathcal{L} + \mathcal{H}_\mathcal{R} - \frac{\gamma}{b}\cdot(b-1)\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}$. Then,

$$\begin{aligned}
\mathcal{T}_b^{-1}\boldsymbol{\Sigma} &= \left(\mathcal{U} - \frac{\gamma}{b}\mathcal{M}\right)^{-1}\boldsymbol{\Sigma} \\
&= \sum_{i=0}^{\infty}\left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)^i\mathcal{U}^{-1}\boldsymbol{\Sigma}.
\end{aligned}$$

Let $\mathbf{A} = \mathcal{U}^{-1}\boldsymbol{\Sigma}$, $\mathbf{A}' = \mathcal{U}^{-1}\mathbf{H}$. Then,

$$\mathcal{T}_b^{-1}\boldsymbol{\Sigma} = \sum_{i=1}^{\infty}\left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)^i\mathbf{A}.$$

The $i = 0$ term is just $= \mathbf{A}$. Now, considering $i = 1$, we have:

$$\begin{aligned}
\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\mathbf{A} &\preceq \frac{\gamma}{b}\|\mathbf{A}\|_2\mathcal{U}^{-1}\mathcal{M}\mathbf{I} \\
&\preceq \frac{\gamma}{b}\|\mathbf{A}\|_2R^2\mathcal{U}^{-1}\mathbf{H} = \frac{\gamma}{b}\|\mathbf{A}\|_2R^2\mathbf{A}'.
\end{aligned}$$

Next, considering $i = 2$, we have:

$$\left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)^2\mathbf{A} = \left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)\cdot\left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)\mathbf{A}$$

$$\preceq \left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right) \cdot \left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)\mathbf{A}'$$
$$\preceq \left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right) \cdot \left(\frac{\gamma}{b}\mathcal{U}^{-1}\right) \cdot \|\mathbf{A}'\|_2 \cdot R^2\mathbf{H}$$
$$\preceq \left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right) \cdot \left(\frac{\gamma}{b}\|\mathbf{A}'\|_2 R^2\right) \cdot \mathbf{A}'.$$

Noting this recursive structure, we see that:

$$\begin{aligned}\mathcal{T}_b^{-1}\mathbf{\Sigma} &= \sum_{i=0}^{\infty}\left(\frac{\gamma}{b}\mathcal{U}^{-1}\mathcal{M}\right)^i \mathbf{A} \\ &\preceq \mathbf{A} + \sum_{i=1}^{\infty}\left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right)\cdot\left(\frac{\gamma}{b}\|\mathbf{A}'\|_2 R^2\right)^{i-1}\cdot\mathbf{A}' \\ &= \mathbf{A} + \frac{\left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right)}{1-\left(\frac{\gamma}{b}\|\mathbf{A}'\|_2 R^2\right)}\cdot\mathbf{A}'.\end{aligned}$$

Note that this summation is finite iff $\gamma \leq \frac{b}{R^2\|\mathbf{A}'\|_2}$. Further, applying the trace operator on both sides, we have:

$$\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right) \leq \operatorname{Tr}\left(\mathbf{A}\right) + \frac{\left(\frac{\gamma}{b}\|\mathbf{A}\|_2 R^2\right)}{1-\left(\frac{\gamma}{b}\|\mathbf{A}'\|_2 R^2\right)}\operatorname{Tr}\left(\mathbf{A}'\right). \tag{29}$$

Now, for any psd matrix $\mathbf{B} \succeq 0$, let us upperbound $\mathcal{U}^{-1}\mathbf{B}$:

$$\mathcal{U}^{-1}\mathbf{B} = \sum_{j=0}^{\infty}\left(\gamma\cdot\frac{b-1}{b}\cdot(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\cdot\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}\right)^i(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}.$$

The recursion can be bounded by analyzing $i = 1$:

$$\begin{aligned}&\gamma\cdot\frac{b-1}{b}\cdot(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\cdot\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}\cdot(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B} \\ &\preceq \|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B}\|_2\cdot\gamma\cdot\frac{b-1}{b}\cdot(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\cdot\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R}\cdot\mathbf{I} \\ &\preceq \|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B}\|_2\cdot\gamma\cdot\frac{b-1}{b}\cdot(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\cdot\|\mathbf{H}\|_2\mathbf{H} \\ &= \|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B}\|_2\cdot\gamma\cdot\frac{b-1}{2b}\cdot\|\mathbf{H}\|_2\cdot\mathbf{I}.\end{aligned}$$

This indicates the means to recurse for bounding terms $i \geq 2$:

$$\mathcal{U}^{-1}\mathbf{B} \preceq \sum_{j=0}^{\infty}\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B}\|_2\left(\gamma\cdot\frac{b-1}{2b}\cdot\|\mathbf{H}\|_2\right)^j\cdot\mathbf{I}$$

$$= \frac{\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{B}\|_2}{1-\gamma\cdot\frac{(b-1)\|\mathbf{H}\|_2}{2b}}\cdot\mathbf{I}.$$

The upperbound above is true as long as $\gamma < \frac{2b}{(b-1)\|\mathbf{H}\|_2}$. This now allows us to obtain bounds on $\|\mathbf{A}\|_2, \|\mathbf{A}'\|_2, \operatorname{Tr}(\mathbf{A}')$:

$$\|\mathbf{A}\|_2 \leq \frac{\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\|_2}{1-\gamma\cdot\frac{b-1}{2b}\cdot\|\mathbf{H}\|_2}$$
$$\|\mathbf{A}'\|_2 \leq \frac{1/2}{1-\gamma\cdot\frac{b-1}{2b}\cdot\|\mathbf{H}\|_2}$$
$$\operatorname{Tr}\left(\mathbf{A}'\right) \leq \frac{d/2}{1-\gamma\cdot\frac{b-1}{2b}\cdot\|\mathbf{H}\|_2}.$$

Substituting these in equation 29:

$$\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right) \leq \operatorname{Tr}\left(\mathbf{A}\right) + \frac{\frac{\gamma R^2}{2b}\cdot d\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\|_2}{\left(1-\frac{\gamma}{2b}\cdot(R^2+(b-1)\|\mathbf{H}\|_2)\right)\cdot\left(1-\gamma\cdot\frac{b-1}{2b}\|\mathbf{H}\|_2\right)}. \tag{30}$$

with the conditions on γ being: $\gamma \leq \frac{2b}{(b-1)\|\mathbf{H}\|_2}$, $\gamma \leq \frac{2b}{R^2+(b-1)\|\mathbf{H}\|_2}$, $\gamma \leq \frac{2b}{R^2}$. These are combined using $\gamma \leq \frac{2b}{R^2+(b-1)\|\mathbf{H}\|_2}$. Once this condition is satisfied, the denominator of the second term can be upperbounded by atmost a constant. Next, looking at the numerator of the second term, we see that $\gamma \leq \frac{2b}{R^2\cdot\frac{d\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\|_2}{\operatorname{Tr}((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma})}} = \frac{2b}{R^2\rho_\mathrm{m}}$ allows for the second term to be upperbounded by $\mathcal{O}(\operatorname{Tr}((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}))$. This is clearly satisfied if $\gamma \leq \frac{2b}{R^2\cdot\rho_\mathrm{m}+(b-1)\|\mathbf{H}\|_2}$. In particular, setting γ to be half of this maximum, we have:

$$\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right) \leq \operatorname{Tr}\left(\mathbf{A}\right) + 2\operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right). \tag{31}$$

Denoting $\hat{\mathbf{\Sigma}} = (\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R}-\gamma\cdot\frac{b-1}{b}\cdot\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}$, in order to bound $\operatorname{Tr}(\mathbf{A})$, we require comparing $\operatorname{Tr}\left(\hat{\mathbf{\Sigma}}\right)$ with $\operatorname{Tr}\left(\tilde{\mathbf{\Sigma}}\right) = \operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right)$. For this, without loss of generality, we can consider $\mathbf{H}$ to be diagonal, and this implies that comparing the diagonal elements of $\hat{\mathbf{\Sigma}}_{ii} = \mathbf{\Sigma}_{ii}/(2\lambda_i - \gamma\frac{b-1}{b}\lambda_i^2)$ while $\tilde{\mathbf{\Sigma}}_{ii} = \mathbf{\Sigma}_{ii}/2\lambda_i$. Comparing these, we see that

$$\begin{aligned}\operatorname{Tr}\left(\hat{\mathbf{\Sigma}}\right) = \operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R}-\gamma\cdot\frac{b-1}{b}\cdot\mathcal{H}_\mathcal{L}\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right) &\leq \frac{1}{1-\gamma\frac{b-1}{2b}\|\mathbf{H}\|_2}\operatorname{Tr}\left(\tilde{\mathbf{\Sigma}}\right) \\ &= \frac{1}{1-\gamma\frac{b-1}{2b}\|\mathbf{H}\|_2}\operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right).\end{aligned}$$

Noting that $\operatorname{Tr}(\mathbf{A}) = \operatorname{Tr}\left(\hat{\mathbf{\Sigma}}\right)$, we see that substituting the above in equation 31, we have:

$$\begin{aligned}\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right) &\leq \frac{1}{1-\gamma\frac{b-1}{2b}\|\mathbf{H}\|_2}\operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right) + 2\operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right) \\ &\leq 4\operatorname{Tr}\left((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right) = 2\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{\Sigma}\right).\end{aligned}$$

■

Corollary 16 *Consider the mis-specified case of the streaming LSR problem. With* $\gamma \leq \frac{\gamma_{b,max}}{2}$, *the variance error of the tail-averaged iterate* $\overline{\mathbf{w}}_{s+1,N}^{variance}$ *is upper bounded as:*

$$\mathbb{E}\left[L(\overline{\mathbf{w}}_{s+1,N}^{variance})\right] - L(\mathbf{w}^*) \leq \frac{4}{Nb} \cdot \widehat{\sigma^2_{MLE}}.$$

Proof The result follows in a straightforward manner by noting that $\gamma \leq \frac{\gamma_{b,\max}}{2}$ implying that $\operatorname{Tr}\left(\mathcal{T}_b^{-1}\mathbf{\Sigma}\right) \leq 2\operatorname{Tr}\left(\mathbf{H}^{-1}\mathbf{\Sigma}\right)$ and by substituting into the result of lemma 13. ■

Corollary 17 *With* $\gamma \leq \frac{\gamma_{b,max}}{2}$, $\mathbf{\Sigma} = \sigma^2\mathbf{H}$ *the variance error of the* **final** *iterate* $\mathbf{w}_N^{variance}$, *obtained by running mini-batch SGD for* N *steps is upper bounded as:*

$$\mathbb{E}\left[L(\mathbf{w}_N^{variance})\right] - L(\mathbf{w}^*) \leq \frac{\gamma\sigma^2}{2b}\operatorname{Tr}\mathbf{H}.$$

Proof This follows from the fact that $\mathcal{T}_b^{-1}\mathbf{\Sigma} \preceq \sigma^2\mathbf{I}$, implying that $\mathbf{H}\mathcal{T}_b^{-1}\mathbf{\Sigma} \preceq \sigma^2\mathbf{H}$ and then applying the trace operator on the result of lemma 14. ■

A.5 Main Results

A.5.1 Derivation of Divergent Learning Rate

A necessary condition for the convergence of Stochastic Gradient Updates is $\mathcal{T}_b \succeq 0$, and this by definition implies,

$$\begin{aligned}
&\langle \mathbf{W}, \mathcal{T}_b\mathbf{W}\rangle \geq 0, \quad \mathbf{W} \in \mathcal{S}(d) \\
\implies &2\operatorname{Tr}(\mathbf{WHW}) - \frac{\gamma}{b}\operatorname{Tr}(\mathbf{W}\mathcal{M}\mathbf{W}) - \gamma\left(\frac{b-1}{b}\right)\operatorname{Tr}(\mathbf{WHWH}) \geq 0 \\
\implies &\frac{2}{\gamma} \geq \frac{\operatorname{Tr}(\mathbf{W}\mathcal{M}\mathbf{W}) + (b-1)\operatorname{Tr}(\mathbf{WHWH})}{b\operatorname{Tr}(\mathbf{WHW})} \\
\implies &\frac{2}{\gamma_{b,\max}^{div}} = \sup_{\mathbf{W}\in\mathcal{S}(d)} \frac{\operatorname{Tr}(\mathbf{W}\mathcal{M}\mathbf{W}) + (b-1)\operatorname{Tr}(\mathbf{WHWH})}{b\operatorname{Tr}(\mathbf{WHW})}.
\end{aligned}$$

A.5.2 Proof of Theorem 1

Proof [proof of Theorem 1] The proof of theorem 1 follows from characterizing bias-variance decomposition for the tail-averaged iterate in section A.2.3 with equation 23.

The bias error of the tail-averaged iterate (equation 24) is bounded with lemma 9 and lemma 10 in section A.3.

The variance error of the tail-averaged iterate (equation 25) is bounded with lemma 12, lemma 13, lemma 15 and corollary 16 in section A.4.

The final expression follows through substituting the result of lemma 10 and corollary 16 into equation 23, with appropriate parameters of the problem, i.e., with a batch size b, number of burn-in iterations s, number of tail-averaged iterations $n/b - s$ to provide the claimed excess risk bound of

Algorithm 1:

$$\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) \leq \frac{2}{\gamma^2\mu^2(\frac{n}{b}-s)^2} \cdot (1-\gamma\mu)^s \cdot \left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + 4 \cdot \frac{\widehat{\sigma^2_{\text{MLE}}}}{b\cdot(\frac{n}{b}-s)}.$$

■

A.5.3 Proof of Lemma 4

Proof [proof of Lemma 4] The proof of lemma 4 follows from characterizing bias-variance decomposition for the final iterate in section A.2.2 with equation 18.

The bias error of the final iterate is bounded with lemma 9 and lemma 11 in section A.3.

The variance error of the final iterate is bounded with lemma 12, lemma 14, lemma 15 and corollary 17 in section A.4.

The final expression follows through substituting the result of lemma 11 and corollary 17 into equation 18, with appropriate parameters of the problem, i.e., with a batch size b, number of samples n and number of iterations $\lfloor n/b \rfloor$, to provide the claimed excess risk bound:

$$\mathbb{E}\left[L(\mathbf{w}_{\lfloor n/b\rfloor})\right] - L(\mathbf{w}^*) \leq \kappa_b(1-\gamma\mu)^{\lfloor n/b\rfloor}\left(L(\mathbf{w}_0) - L(\mathbf{w}^*)\right) + \frac{\gamma}{b}\sigma^2\operatorname{Tr}(\mathbf{H}).$$

■

A.5.4 Proof of Theorem 5

Proof Let $\widetilde{L_e} = \mathbb{E}\left[L(\mathbf{w}_e)\right] - L(\mathbf{w}^*)$. We will first provide a recursive bound for $\widetilde{L_e}$ for $e \leq \log\left(\frac{n}{bt}\right) - 1$ using theorem 1, with a mini-batch size of $b_e = 1 + 2^{e-1}b$, where, $b = b_{\text{thresh}} - 1$, $n_e = b_e \cdot t$, $s = t - 1$:

$$\begin{aligned}
\widetilde{L_e} &\leq 2\kappa_{b_e}^2 \exp\left(-\frac{n_e}{b_e\cdot\kappa_{b_e}}\right)\widetilde{L_{e-1}} + 4\frac{\widehat{\sigma^2_{\text{MLE}}}}{b_e} \\
&\leq \exp\left(-\frac{n_e}{3b_e\kappa_e\log(\kappa_e)}\right)\cdot\widetilde{L_{e-1}} + 4\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{b_e}.
\end{aligned}$$

Next, denote $\kappa = \|\mathbf{H}\|_2/\mu$; now, let us bound κ_{b_e}:

$$\begin{aligned}
\kappa_{b_e} &= \frac{R^2\cdot\frac{d\left\|(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma}\right\|_2}{\operatorname{Tr}((\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathbf{\Sigma})} + (b_e-1)\|\mathbf{H}\|_2}{b_e\mu} \\
&= \kappa\cdot\frac{b_{\text{thresh}}-1+b_e-1}{b_e} = \kappa\cdot\frac{b_{\text{thresh}}-1+2^{e-1}(b_{\text{thresh}}-1)}{2^{e-1}(b_{\text{thresh}}-1)} \\
&= \kappa\cdot\frac{1+2^{e-1}}{2^{e-1}} \leq 2\kappa.
\end{aligned}$$

This implies $\kappa_{b_e}\log(\kappa_{b_e}) \le 4\kappa\log(\kappa)$. This implies, revisiting the recursion on $\widetilde{L_e}$, we have:

$$\begin{aligned}
\widetilde{L_e} &\le \exp\left(-\frac{n_e}{12b_e\kappa\log(\kappa)}\right)\cdot\widetilde{L_{e-1}} + 4\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{b_e}\\
&\le \exp\left(-\frac{t}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_{e-1}} + 4\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{2^{e-1}b}\\
&\le \exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + \frac{4\widehat{\sigma^2_{\text{MLE}}}}{b}\cdot\sum_{j=1}^{e}\frac{\exp\left(-\frac{t(j-1)}{12\kappa\log(\kappa)}\right)}{2^{e-j}}\\
&\le \exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + \frac{4\widehat{\sigma^2_{\text{MLE}}}}{b}\cdot\frac{1/2^{e-1}}{1-2\cdot\exp\left(-\frac{t}{12\kappa\log\kappa}\right)}\\
&\le \exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + \frac{12\widehat{\sigma^2_{\text{MLE}}}}{2^e b} \quad (\text{since } t > 24\kappa\log(\kappa))\\
&= \exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + \frac{12\widehat{\sigma^2_{\text{MLE}}}}{b\cdot n}\cdot(4bt) \quad (\text{since } 2^e = n/(4bt))\\
&= \exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + 48\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}t}{n}. \qquad (32)
\end{aligned}$$

Next, for the final epoch, we have $b = n/2t$, $s = t/2$, and a total of $n/2$ samples, implying:

$$\begin{aligned}
\widetilde{L_{e+1}} &\le \frac{2\kappa_b^2}{\left(t/2\right)^2}\cdot\exp\left(-\frac{t}{2\kappa_b}\right)\widetilde{L_e} + 4\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{b\cdot(n/4b)} = \frac{8\kappa_b^2}{t^2}\cdot\exp\left(-\frac{t}{2\kappa_b}\right)\cdot\widetilde{L_e} + 16\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}\\
&\le \frac{32\kappa^2}{t^2}\cdot\exp\left(-\frac{t}{4\kappa}\right)\cdot\widetilde{L_e} + 16\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n} \quad (\text{since } \kappa_b \le 2\kappa)\\
&\le \frac{32\kappa^2}{t^2}\cdot\exp\left(-\frac{t}{4\kappa}\right)\cdot\left(\exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + 48\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}t}{n}\right) + 16\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}\\
&\le \frac{32\kappa^2}{t^2}\cdot\exp\left(-\frac{t}{4\kappa}\right)\cdot\exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + 64\kappa\exp\left(-t/4\kappa\right)\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n} + 16\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}\\
&\le \frac{32\kappa^2}{t^2}\cdot\exp\left(-\frac{t}{4\kappa}\right)\cdot\exp\left(-\frac{te}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + 80\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}\\
&\le \exp\left(-\frac{t(e+1)}{12\kappa\log(\kappa)}\right)\cdot\widetilde{L_0} + 80\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}\\
&= \left(\frac{2bt}{n}\right)^{\frac{t}{12\kappa\log(\kappa)}}\widetilde{L_0} + 80\cdot\frac{\widehat{\sigma^2_{\text{MLE}}}}{n}, \qquad (33)
\end{aligned}$$

which rounds up the proof of the theorem. ■

A.5.5 PROOF OF THEOREM 6

Proof For analyzing the parameter mixing scheme, we require tracking the progress of the i^{th} machine's SGD updates using its centered estimate $\boldsymbol{\eta}_k^{(i)}$. Furthermore, the tail-averaged iterate for the i^{th} machine is represenetead as $\bar{\boldsymbol{\eta}}^{(i)} \stackrel{\text{def}}{=} \frac{1}{N}\sum_{k=s+1}^{s+N}\boldsymbol{\eta}_k^{(i)}$. Finally, the model averaged estimate is represented with its own centered estimate defined as $\bar{\boldsymbol{\eta}} = \frac{1}{P}\sum_{i=1}^{P}\bar{\boldsymbol{\eta}}^{(i)}$. Now, in a manner similar to standard mini-batch tail-averaged SGD on a single machine, the model averaged iterate admits its own bias variance decomposition, through which $\bar{\boldsymbol{\eta}} = \bar{\boldsymbol{\eta}}^{\text{bias}} + \bar{\boldsymbol{\eta}}^{\text{variance}}$ and an upperbound on the excess risk is written as:

$$\begin{aligned}
\mathbb{E}\left[L(\overline{\mathbf{w}})\right] - L(\mathbf{w}^*) &= \mathbb{E}\left[\frac{1}{2}\langle(\overline{\mathbf{w}}-\mathbf{w}^*),\mathbf{H}(\overline{\mathbf{w}}-\mathbf{w}^*)\rangle\right] = \mathbb{E}\left[\frac{1}{2}\langle\bar{\boldsymbol{\eta}},\mathbf{H}\bar{\boldsymbol{\eta}}\rangle\right]\\
&\le \mathbb{E}\left[\langle\bar{\boldsymbol{\eta}}^{\text{bias}},\mathbf{H}\bar{\boldsymbol{\eta}}^{\text{bias}}\rangle\right] + \mathbb{E}\left[\langle\bar{\boldsymbol{\eta}}^{\text{variance}},\mathbf{H}\bar{\boldsymbol{\eta}}^{\text{variance}}\rangle\right].
\end{aligned}$$

We will first handle the variance since it is straightforward given that the noise $\boldsymbol{\zeta}$ is independent for different machines SGD runs. What this implies is the following:

$$\begin{aligned}
\bar{\boldsymbol{\eta}}^{\text{variance}} &= \frac{1}{P}\sum_{i=1}^{P}\bar{\boldsymbol{\eta}}^{(i),\text{variance}}\\
\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{\text{variance}}\right] &= \frac{1}{P^2}\sum_{i,j}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{(j),\text{variance}}\right]\\
&= \frac{1}{P^2}\left(\sum_{i}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{(i),\text{variance}}\right] + \sum_{i\neq j}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{(j),\text{variance}}\right]\right)\\
&= \frac{1}{P}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(1),\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{(1),\text{variance}}\right]. \qquad (34)
\end{aligned}$$

Where, the final line follows because $\forall\ i \neq j$, the terms are in expectation equal to zero since in expectation each of the noise terms is zero (from first order optimality conditions). The other observation is that the only terms left are P independent runs of tail-averaged SGD in each of the machine, whose risk is straightforward to bound from corollary 16. This implies

$$\langle\mathbf{H},\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{\text{variance}}\otimes\bar{\boldsymbol{\eta}}^{\text{variance}}\right]\rangle \le \frac{4}{PNb}\cdot\widehat{\sigma^2_{\text{MLE}}}. \quad (\text{using corollary 16}) \qquad (35)$$

Next, let us consider the bias error:

$$\begin{aligned}
\bar{\boldsymbol{\eta}}^{\text{bias}} &= \frac{1}{P}\sum_{i=1}^{P}\bar{\boldsymbol{\eta}}^{(i),\text{bias}}\\
\implies \mathbb{E}\left[\bar{\boldsymbol{\eta}}^{\text{bias}}\otimes\bar{\boldsymbol{\eta}}^{\text{bias}}\right] &= \frac{1}{P^2}\sum_{i,j}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}}\otimes\bar{\boldsymbol{\eta}}^{(j),\text{bias}}\right]\\
&= \frac{1}{P^2}\left(\sum_{i=1}^{P}\underbrace{\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}}\otimes\bar{\boldsymbol{\eta}}^{(i),\text{bias}}\right]}_{\text{independent runs of tail-averaged SGD}} + \sum_{i\neq j}\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}}\otimes\bar{\boldsymbol{\eta}}^{(j),\text{bias}}\right]\right),
\end{aligned}$$

(36)

which implies that we require bounding $\forall\, i \neq j, \mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}} \otimes \bar{\boldsymbol{\eta}}^{(j),\text{bias}}\right]$.

$$\begin{aligned}
\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}} \otimes \bar{\boldsymbol{\eta}}^{(j),\text{bias}}\right] &= \frac{1}{N^2}\sum_{k,l=s+1}^{s+N} \mathbb{E}\left[\boldsymbol{\eta}_k^{(i),\text{bias}} \otimes \boldsymbol{\eta}_l^{(j),\text{bias}}\right] \\
&= \frac{1}{N^2}\sum_{k,l=s+1}^{s+N} \mathbb{E}\left[\boldsymbol{\eta}_k^{(i),\text{bias}}\right] \otimes \mathbb{E}\left[\boldsymbol{\eta}_l^{(j),\text{bias}}\right] \\
&= \frac{1}{N^2}\sum_{k,l=s+1}^{s+N} \mathbb{E}\left[\mathbf{Q}_{1:k}^{(i)}\boldsymbol{\eta}_0\right] \otimes \mathbb{E}\left[\mathbf{Q}_{1:l}^{(j)}\boldsymbol{\eta}_0\right] \quad \text{(from equation 15)} \\
&= \frac{1}{N^2}\left(\sum_{k=s+1}^{s+N}(\mathbf{I}-\gamma\mathbf{H})^k\right)\boldsymbol{\eta}_0 \otimes \boldsymbol{\eta}_0\left(\sum_{l=s+1}^{s+N}(\mathbf{I}-\gamma\mathbf{H})^l\right) \\
&\preceq \frac{1}{N^2}\left(\sum_{k=s+1}^{\infty}(\mathbf{I}-\gamma\mathbf{H})^k\right)\boldsymbol{\eta}_0 \otimes \boldsymbol{\eta}_0\left(\sum_{l=s+1}^{\infty}(\mathbf{I}-\gamma\mathbf{H})^l\right) \\
&= \frac{1}{\gamma^2N^2}\mathbf{H}^{-1}(\mathbf{I}-\gamma\mathbf{H})^{s+1}\boldsymbol{\eta}_0 \otimes \boldsymbol{\eta}_0(\mathbf{I}-\gamma\mathbf{H})^{s+1}\mathbf{H}^{-1}.
\end{aligned}$$

This implies that,

$$\begin{aligned}
\mathbb{E}\left[\bar{\boldsymbol{\eta}}^{(i),\text{bias}} \otimes \bar{\boldsymbol{\eta}}^{(j),\text{bias}}\right] &\leq \frac{1}{\gamma^2N^2}\cdot\langle \mathbf{H}, \mathbf{H}^{-1}(\mathbf{I}-\gamma\mathbf{H})^{s+1}\boldsymbol{\eta}_0 \otimes \boldsymbol{\eta}_0(\mathbf{I}-\gamma\mathbf{H})^{s+1}\mathbf{H}^{-1}\rangle \\
&= \frac{1}{\gamma^2N^2}\cdot\boldsymbol{\eta}_0^\top(\mathbf{I}-\gamma\mathbf{H})^{s+1}\mathbf{H}^{-1}\mathbf{H}\mathbf{H}^{-1}(\mathbf{I}-\gamma\mathbf{H})^{s+1}\boldsymbol{\eta}_0 \\
&\leq \frac{(1-\gamma\mu)^{2s+2}}{\mu\gamma^2N^2}\|\boldsymbol{\eta}_0\|^2 \leq \frac{(1-\gamma\mu)^{2s+2}}{\mu^2\gamma^2N^2}\cdot\Big(L(\mathbf{w}_0)-L(\mathbf{w}^*)\Big). \qquad (37)
\end{aligned}$$

Combining the bound for the cross terms in equation 37 and lemma 10 for the self-terms, we get:

$$\langle \mathbf{H}, \mathbb{E}\left[\bar{\boldsymbol{\eta}}^{\text{bias}} \otimes \bar{\boldsymbol{\eta}}^{\text{bias}}\right]\rangle \leq \frac{(1-\gamma\mu)^{s+1}}{\mu^2\gamma^2N^2}\cdot\frac{2+(1-\gamma\mu)^{s+1}\cdot(P-1)}{P}\cdot\Big(L(\mathbf{w}_0)-L(\mathbf{w}^*)\Big). \qquad (38)$$

The proof wraps up by substituting the relation $N = n/(P\cdot b) - s$ in equations 35 and 38. ■

A.5.6 PROOF OF LEMMA 3

For this problem instance, we begin by noting that $(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}$ is diagonal as well, with entries:

$$\{(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}\}_{ii} = \frac{1}{2}\{\mathbf{H}^{-1}\boldsymbol{\Sigma}\}_{ii} = \begin{cases} 1/2 & \text{if } i=1 \\ 1/2(d-1) & \text{if } i>1 \end{cases}.$$

Let us consider the case with batch size $b=1$. With the appropriate choice of step size γ that ensure contracting operators, we require considering $\operatorname{Tr}\left(\mathcal{T}_b^{-1}\boldsymbol{\Sigma}\right)$ as in equation 29, which corresponds to bounding the leading order term in the variance. We employ the taylor's expansion (just as in claim 2 of lemma 15) to expand the term of interest $\mathcal{T}_b^{-1}\boldsymbol{\Sigma}$:

$$\mathcal{T}_b^{-1}\boldsymbol{\Sigma} = \sum_{i=0}^{\infty}\left(\gamma(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathcal{M}\right)^i(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}$$

$$\begin{aligned}
&= (\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma} + \sum_{i=1}^{\infty}\left(\gamma(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathcal{M}\right)^i(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma} \\
\Rightarrow \operatorname{Tr}\mathcal{T}_b^{-1}\boldsymbol{\Sigma} &= \operatorname{Tr}(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma} + \sum_{i=1}^{\infty}\operatorname{Tr}\left[\left(\gamma(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathcal{M}\right)^i(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}\right] \\
\operatorname{Tr}\mathcal{T}_b^{-1}\boldsymbol{\Sigma} &= \frac{1}{2}\operatorname{Tr}\mathbf{H}^{-1}\boldsymbol{\Sigma} + \sum_{i=1}^{\infty}\operatorname{Tr}\left[\left(\gamma(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathcal{M}\right)^i(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}\right].
\end{aligned}$$

We observe that the term corresponding to $i=0$ works out regardless of the choice of stepsize γ; we then switch our attention to the second term, i.e., the term corresponding to $i=1$:

$$\operatorname{Tr}\left(\gamma(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\mathcal{M}\right)(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma} = \frac{d+2}{4}\cdot\operatorname{Tr}(\boldsymbol{\Sigma}).$$

We require that this term should be $\leq \operatorname{Tr}(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}$, implying,

$$\gamma < \frac{4\operatorname{Tr}(\mathcal{H}_\mathcal{L}+\mathcal{H}_\mathcal{R})^{-1}\boldsymbol{\Sigma}}{(d+2)\operatorname{Tr}(\boldsymbol{\Sigma})}.$$

For this example, we observe that this yields $\gamma < \frac{4}{(d+2)(1+\frac{1}{d})}$, which clearly is off by a factor d compared to the well-specified case which requires $\gamma < \frac{d}{(d+2)(1+\frac{1}{d})}$, establishing a clear separation between the step sizes required by SGD for the well-specified and mis-specified cases.

A.5.7 PROOFS OF SUPPORTING LEMMAS

Proof of lemma 7

Proof [Proof of lemma 7] We begin by considering $\langle \mathbf{I}, \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{bias}} \otimes \boldsymbol{\eta}_t^{\text{bias}}\right]\rangle$:

$$\begin{aligned}
\langle \mathbf{I}, \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{bias}} \otimes \boldsymbol{\eta}_t^{\text{bias}}\right]\rangle &= \mathbb{E}\left[\|\boldsymbol{\eta}_t^{\text{bias}}\|^2\right] \\
&= \mathbb{E}\left[(\boldsymbol{\eta}_{t-1}^{\text{bias}})^\top\left(\mathbf{I}-\frac{\gamma}{b}\sum_{i=1}^{b}\mathbf{x}_{ti}\mathbf{x}_{ti}^\top\right)\left(\mathbf{I}-\frac{\gamma}{b}\sum_{i=1}^{b}\mathbf{x}_{ti}\mathbf{x}_{ti}^\top\right)\boldsymbol{\eta}_{t-1}^{\text{bias}}\right] \\
&\leq (1-\gamma\mu)\cdot\mathbb{E}\left[\|\boldsymbol{\eta}_{t-1}^{\text{bias}}\|^2\right] \qquad \text{(from lemma 9)},
\end{aligned}$$

from where the lemma follows through substitution of $\gamma = \gamma_{b,\max}/2$. ■

Proof of lemma 8

Proof [Proof of lemma 8] From equation 27, we have that:

$$\begin{aligned}
\boldsymbol{\Phi}_t^{\text{variance}} &= \mathbb{E}\left[\boldsymbol{\eta}_t^{\text{variance}} \otimes \boldsymbol{\eta}_t^{\text{variance}}\right] \\
&= \frac{\gamma^2}{b}\left(\sum_{k=0}^{t-1}(\mathcal{I}-\gamma\mathcal{T}_b)^k\right)\boldsymbol{\Sigma}.
\end{aligned}$$

Allowing $t\to\infty$, we have:

$$\boldsymbol{\Phi}_\infty^{\text{variance}} = \frac{\gamma}{b}\mathcal{T}_b^{-1}\boldsymbol{\Sigma} \preceq \frac{\gamma}{b}\cdot\sigma^2\mathbf{I} \quad \text{(from claim 4 in lemma 15 since } \gamma \leq \gamma_{b,\max}/2,\ \boldsymbol{\Sigma} = \sigma^2\mathbf{H}).$$

Substituting $\gamma = \gamma_{b,\max}/2$, the result follows. ■

Abstract

Learning DAG or Bayesian network models is an important problem in multi-variate causal inference. However, a number of challenges arises in learning large-scale DAG models including model identifiability and computational complexity since the space of directed graphs is huge. In this paper, we address these issues in a number of steps for a broad class of DAG models where the noise or variance is signal-dependent. Firstly we introduce a new class of identifiable DAG models, where each node has a distribution where the variance is a quadratic function of the mean (QVF DAG models). Our QVF DAG models include many interesting classes of distributions such as Poisson, Binomial, Geometric, Exponential, Gamma and many other distributions in which the noise variance depends on the mean. We prove that this class of QVF DAG models is identifiable, and introduce a new algorithm, the OverDispersion Scoring (ODS) algorithm, for learning large-scale QVF DAG models. Our algorithm is based on firstly learning the moralized or undirected graphical model representation of the DAG to reduce the DAG search-space, and then exploiting the quadratic variance property to learn the ordering. We show through theoretical results and simulations that our algorithm is statistically consistent in the high-dimensional $p > n$ setting provided that the degree of the moralized graph is bounded and performs well compared to state-of-the-art DAG-learning algorithms. We also demonstrate through a real data example involving multi-variate count data, that our ODS algorithm is well-suited to estimating DAG models for count data in comparison to other methods used for discrete data.

Keywords: Bayesian Networks, Directed Acyclic Graph, Identifiability, Multi-variate Count Distribution, Overdispersion

1. Introduction

Probabilistic directed acyclic graphical (DAG) models or Bayesian networks provide a widely used framework for representing causal or directional dependence relationships amongst multiple variables. DAG models have applications in various areas including genomics, neuroimaging, statistical physics, spatial statistics and many others (see e.g., Doya 2007; Friedman et al. 2000; Kephart and White 1991). One of the fundamental problems associated with DAG models or Bayesian networks is structure learning from observational data.

If the number of variables is large, a number of challenges arise that make learning large-scale DAG models extremely difficult even when variables have a natural causal or directional structure. These challenges include: (1) identifiability since inferring causal directions from only observational data is in general not possible in the absence of additional assumptions; (2) computational complexity since it is NP-hard to search over the space of DAGs (Chickering, 1996); (3) providing sample size guarantee in the setting where the number of nodes p is large. In this paper we develop a general framework and algorithm for learning large-scale DAG models that addresses these challenges in a number of steps: Firstly, we introduce a new class of provably identifiable DAG models where each node has a conditional distribution where the variance is a quadratic function of the mean, which we refer to as QVF (quadratic variance function) distributions; secondly, we introduce a general OverDispersion Scoring (ODS) algorithm for learning large-scale QVF DAG models; thirdly, we provide theoretical guarantees for our ODS algorithm which proves that our algorithm is consistent in the high-dimensional setting $p > n$ provided that the moralized graph of the DAG is sparse; and finally, we show through a simulation study that our ODS algorithm supports our theoretical result has favorable performance to a number of state-of-the-art algorithms for learning both low-dimensional and high-dimensional DAG models.

Our algorithm is based on combining two ideas: *overdispersion* and *moralization*. Overdispersion is a property of Poisson and other random variables where the variance depends on the mean and we use overdispersion to address the identifiability issue. While overdispersion is a known phenomena used and exploited in many applications (see e.g., Dean 1992; Zheng et al. 2006), overdispersion has never been exploited for learning DAG models aside from our prior work (Park and Raskutti, 2015) which focuses on Poisson DAG models. In this paper, we show that overdispersion applies much more broadly and is used to prove identifiability for a broad class of DAG models. To provide a scalable algorithm with statistical guarantees, even in the high-dimensional setting, we exploit the moralized graph, that is the undirected representation of the DAG. Learning the moralized graph allows us to exploit sparsity and considerably reduces the DAG search-space which has both computational and statistical benefits. Furthermore, moralization allows us to use existing scalable algorithms and theoretical guarantees for learning large-scale undirected graphical models (e.g., Friedman et al. 2009; Yang et al. 2012).

A number of approaches have been used to address the identifiability challenge by imposing additional assumptions. For example ICA-based methods for learning ordering requires independent noise and non-Gaussianity (see e.g., Shimizu et al. 2006), structural equation models with Gaussian noise with equal or known variances (Peters et al., 2012), and non-parametric structural equation models with independent noise (see e.g., Peters and Bühlmann 2013). These approaches are summarized elegantly in an information-theoretic framework in Janzing and Scholkopf (2010). Our approach is along similar lines in that we impose overdispersion as an additional assumption which induces asymmetry and guarantees identifiability. However by exploiting overdispersion, our approach applies when the noise distribution of each node depends on its mean whereas prior approaches apply when

the additive noise variance is independent of the mean. Additionally, we exploit graph sparsity which has also been exploited in prior work by Loh and Bühlmann (2014); Raskutti and Uhler (2013); van de Geer and Bühlmann (2013) for various DAG models with independent additive noise components. Furthermore, sparsity allows us to develop a tractable algorithm where we reduce the DAG space by learning the moralized graph, an idea which has been used in prior work in Tsamardinos and Aliferis (2003).

1.1 Our Contributions

We summarize the major contributions of the paper as follows:

- We introduce the class of QVF DAG models, that include many interesting classes of multi-variate distributions and provide conditions under which QVF DAG models are identifiable.
- Using QVF DAG models, we develop the reliable and scalable generalized ODS algorithm which learns any large-scale QVF DAG model. Our algorithm combines two key ideas, moralization and overdispersion. Moralization significantly reduces computational complexity by exploiting sparsity of the moralized graph, while overdispersion exploits properties of QVF DAG models to estimate the causal ordering. The generalized ODS algorithm adapts the algorithm developed in Park and Raskutti (2015) to general QVF DAG models whilst the algorithm in Park and Raskutti (2015) focuses exclusively on Poisson DAG models.
- We provide statistical guarantees to show that our ODS algorithm is consistent for learning QVF DAG models, even in the high-dimensional $p > n$ setting, provided that the degree of the moralized graph is bounded. To the best of our knowledge, this is the only theoretical result that applies to the high-dimensional setting when the variables at each node model counts.
- We demonstrate through simulation studies and a real data application involving multi-variate count data that our ODS algorithm performs favorably compared to the state-of-the-art GES and MMHC algorithms. In our simulation study, we consider both the low-dimensional and high-dimensional setting. Our real data example involving NBA player statistics for 2009/10 season shows that our ODS algorithm is applicable to multi-variate count data while the GES and MMHC algorithms tend to select very few edges when variables represent counts.

The remainder of the paper is organized as follows: In Section 2, we define QVF DAG models and prove identifiability for this class of models. In Section 3, we introduce our polynomial-time DAG learning algorithm which we refer to as the generalized OverDispersion Scoring (ODS). Statistical guarantees for learning QVF DAG models using our ODS algorithm are provided in Section 3.2, and we provide numerical experiments on both small DAGs and large-scale DAGs with node-size up to 5000 nodes in Section 4. Our theoretical guarantees in Section 3.2 prove that even in the setting where the number of nodes p is larger than the sample size n, it is possible to learn the DAG structure under the assumption that the degree d of the so-called moralized graph of the DAG is small. Our numerical experiments in Section 4 support the theoretical results and show that our algorithm performs

well compared to other state-of-the-art DAG learning methods. Our numerical experiments confirm that our algorithm is one of the few DAG-learning algorithms that performs well in terms of statistical and computational complexity in high-dimensional $p > n$ settings, provided that the degree of the moralized graph d is bounded. Finally in Section 5 we show that our ODS algorithm performs well in terms of the eye test compared to state-of-the-art algorithms for a multi-variate count data set that involves basketball statistics.

2. Quadratic Variance Function (QVF) DAG Models and Identifiability

A DAG $G = (V, E)$ consists of a set of nodes V and a set of directed edges $E \in V \times V$ where each $e \in E$ is an ordered pair of distinct nodes. Hence our graphs are *simple*, i.e., there are no directed cycles or multiple edges between any pair of nodes. A directed edge from node j to k is denoted by (j, k) or $j \to k$. The set of *parents* of node k denoted by $\text{pa}(k)$ consists of all nodes j such that $(j, k) \in E$. If there is a directed path $j \to \cdots \to k$, then k is called a *descendant* of j and j is an *ancestor* of k. The set $\text{de}(k)$ denotes the set of all descendants of node k. The *non-descendants* of node k are $\text{nd}(k) := V \setminus (\{k\} \cup \text{de}(k))$. An important property of DAGs is that there exists an (possibly non-unique) *ordering* π^* of a directed graph that represents directions of edges such that for every directed edge $(j, k) \in E$, j comes before k in the ordering. Without loss of generality, we set $V = \{1, 2, \cdots, p\}$ and assume the true ordering is $\pi^* = (1, 2, \cdots, p)$.

We consider a set of random variables $X := (X_j), j \in V$ with probability distribution $\mathbb{P}$ taking values in probability space $\mathcal{X}_v$ over the nodes in G. Suppose that a random vector X has joint probability density function $f_G(X)$. For any subset S of V, let $X_S := \{X_s : s \in S \subset V\}$ and $\mathcal{X}(S) := \times_{j \in S} \mathcal{X}_j$. For $j \in V$, $f_j(X_j \mid X_S)$ denotes the conditional distribution of a random variable X_v given a random vector X_S. Then, a probabilistic DAG model has the following factorization (Lauritzen, 1996):

$$f_G(X) = \prod_{j \in V} f_j(X_j \mid X_{\text{pa}(j)}), \tag{1}$$

where $f_j(X_j \mid X_{\text{pa}(j)})$ refers to the conditional distribution of a random variable X_j in terms of its parents $X_{\text{pa}(j)} := \{X_s : s \in \text{pa}(j)\}$.

A core concept in this paper is *identifiability* for a family of probability distributions defined by the DAG factorization provided above. Intuitively identifiability addresses the question of what assumption we make on the conditional distributions $f_j(X_j \mid X_{\text{pa}(j)})$ allows us to uniquely determine the structure of that DAG G given the joint PDF $f_G(X)$.

To define identifiability precisely, let $\mathcal{P}$ denote the set of *conditional distributions* $f_j(X_j \mid X_{\text{pa}(j)})$ for all $j \in V$. Further for a graph $G = (V, E)$, define the class of *joint distributions* with respect to graph G and class of distributions $\mathcal{P}$ by

$$\mathcal{F}(G; \mathcal{P}) := \{f_G(X) = \prod_{j \in V} f_j(X_j \mid X_{\text{pa}(j)}) \text{ ; where } f_j(X_j \mid X_{\text{pa}(j)}) \in \mathcal{P} \; \forall \; j \in V\}.$$

Next let $\mathcal{G}_p$ denote the set of p-node directed acyclic graphs. Now we define identifiability for the class $\mathcal{P}$ over the space of DAGs $\mathcal{G}_p$.

Definition 1 (Identifiability) *A class of conditional distributions $\mathcal{P}$ is* identifiable *over $\mathcal{G}_p$ if $G \neq G'$ where $G, G' \in \mathcal{G}_p$, there exists no $f_G \in \mathcal{F}(G;\mathcal{P})$ and $f_{G'} \in \mathcal{F}(G';\mathcal{P})$ such that $f_G = f_{G'}$.*

Prior work has addressed the question of identifiability for different classes of $\mathcal{P}$. For example ICA-based methods make the assumption that $\mathcal{P}$ are independent error with non-Gaussian components (Shimizu et al., 2006) and prove that this class is identifiable as well as $\mathcal{P}$ corresponding to a non-parametric model with additive independent noise (Peters and Bühlmann, 2013), $\mathcal{P}$ represents structural linear equation models with Gaussian errors with equal or known variances (Peters et al., 2012). On the other hand, if $\mathcal{P}$ represents structural linear equation models with Gaussian errors with general variance is not identifiable and only the Markov equivalence class of DAG models is identifiable (Heckerman et al., 1995).

The main results of our paper give another class of identifiable graphical models. In our setting, $\mathcal{P}$ is a setting where the variance is a linear function of the mean so we deal with signal-dependent noise or variance, and more importantly is applicable for discrete distributions. We define $\mathcal{P}$ more precisely in the next section.

2.1 Quadratic Variance Function (QVF) DAG Models

Now we define quadratic variance function (QVF) DAG models. For QVF DAG models each node has a conditional distribution $\mathcal{P}$ given its parents with the property that the variance is a quadratic function of the mean. More precisely,

Definition 2 (QVF DAG models) *Quadratic variance function (QVF) DAG models are DAG models where conditional distribution of each node given its parents satisfies the* quadratic variance function property*: for all $j \in V$, there exist $\beta_{j0}, \beta_{j1} \in \mathbb{R}$ such that*

$$Var(X_j \mid X_{pa(j)}) = \beta_{j0}\mathbb{E}(X_j \mid X_{pa(j)}) + \beta_{j1}\mathbb{E}(X_j \mid X_{pa(j)})^2. \tag{2}$$

To the best of our knowledge, quadratic variance function (QVF) probability distributions were first introduced in the context of natural parameter exponential families (NEF) (Morris, 1982) which include Poisson, Binomial, Negative Binomial and Gamma distributions. In the directed graphical model framework, each node distribution is influenced by its parents. Hence for natural exponential families with quadratic variance functions (NEF-QVF), we provide an explicit form of joint distributions for DAG models.

For NEF-QVF, the conditional distribution of each node given its parents takes the simple form:

$$P(X_j \mid X_{\mathrm{pa}(j)}) = \exp\left(\theta_{jj}X_j + \sum_{(k,j)\in E}\theta_{jk}X_kX_j - B_j(X_j) - A_j\left(\theta_{jj} + \sum_{(k,j)\in E}\theta_{jk}X_k\right)\right)$$

where $A_j(\cdot)$ is the log-partition function, $B_j(\cdot)$ is determined by a chosen exponential family, and $\theta_{jk} \in \mathbb{R}$ is a parameter corresponding to a node j. By the factorization property (1), the joint distribution of a NEF-QVF DAG model takes the following form:

$$P(X) = \exp\left(\sum_{j\in V}\theta_{jj}X_j + \sum_{(k,j)\in E}\theta_{jk}X_kX_j - \sum_{j\in V}B_j(X_j) - \sum_{j\in V}A_j\left(\theta_{jj} + \sum_{(k,j)\in E}\theta_{jk}X_k\right)\right). \tag{3}$$

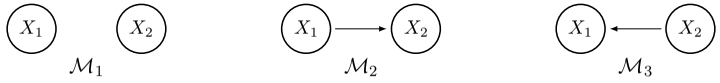

Figure 1: Directed graphical models of $\mathcal{M}_1$, $\mathcal{M}_2$ and $\mathcal{M}_3$

From Equation (3), we provide examples of classes of NEF-QVF DAG models. For Poisson DAG models studied in Park and Raskutti (2015) the log-partition function $A_j(\cdot) = \exp(\cdot)$, and $B_j(\cdot) = \log(\cdot!)$. Similarly, Binomial DAG models can be derived as an example of QVF DAG models where the conditional distribution for each node is binomial with known parameter N_j and the log-partition function $A_j(\cdot) = N_j\log(1+\exp(\cdot))$, and $B_j(\cdot) = -\log\binom{N_j}{\cdot}$. Another interesting instance is Exponential DAG models where each node conditional distribution given its parents is Exponential. Then, $A_j(\cdot) = -\log(-\cdot)$ and $B_j(\cdot) = 0$.

Our framework also naturally extends to mixed DAG models, where the conditional distributions have different distributions which incorporates different data types. In addition, our models extend to nonlinear and nonparametric DAG models depending on the data as long as the node distribution $\mathcal{P}$ satisfies the QVF property in Equation (2). This means our model is identifiable without information on how a node and its parents are related. In Section 4, we will provide numerical experiments on Poisson and Binomial DAG models.

2.2 Identifiability of QVF DAG Models

In this section we prove that QVF DAG models are identifiable. To provide intuition, we prove identifiability for the two-node Poisson DAG model in Park and Raskutti (2015). Consider all three models illustrated in Figure 1: $\mathcal{M}_1 : X_1 \sim \mathrm{Poisson}(\lambda_1)$, $X_2 \sim \mathrm{Poisson}(\lambda_2)$, where X_1 and X_2 are independent; $\mathcal{M}_2 : X_1 \sim \mathrm{Poisson}(\lambda_1)$ and $X_2 \mid X_1 \sim \mathrm{Poisson}(g_2(X_1))$; and $\mathcal{M}_3 : X_2 \sim \mathrm{Poisson}(\lambda_2)$ and $X_1 \mid X_2 \sim \mathrm{Poisson}(g_1(X_2))$ for arbitrary positive functions $g_1, g_2 : \mathbb{N}\cup\{0\} \to \mathbb{R}^+$. Our goal is to determine whether the underlying DAG model is $\mathcal{M}_1, \mathcal{M}_2$ or $\mathcal{M}_3$.

We exploit the equidispersion property that for a Poisson random variable X, $\mathrm{Var}(X) = \mathbb{E}(X)$, while for a distribution which is conditionally Poisson, the marginal variance is overdispersed relative to the marginal expectation, $\mathrm{Var}(X) > \mathbb{E}(X)$. Hence for $\mathcal{M}_1$, $\mathrm{Var}(X_1) = \mathbb{E}(X_1)$ and $\mathrm{Var}(X_2) = \mathbb{E}(X_2)$. For $\mathcal{M}_2$, $\mathrm{Var}(X_1) = \mathbb{E}(X_1)$, while

$$\mathrm{Var}(X_2) = \mathbb{E}(\mathrm{Var}(X_2 \mid X_1)) + \mathrm{Var}(\mathbb{E}(X_2 \mid X_1)) = \mathbb{E}(\mathbb{E}(X_2 \mid X_1)) + \mathrm{Var}(g_2(X_1)) > \mathbb{E}(X_2),$$

as long as $\mathrm{Var}(g_2(X_1)) > 0$. The first equality follows from the total variance decomposition and the second equality follows from the equidispersion property of Poisson distribution.

Similarly under $\mathcal{M}_3$, $\mathrm{Var}(X_2) = \mathbb{E}(X_2)$ and $\mathrm{Var}(X_1) > \mathbb{E}(X_1)$ as long as $\mathrm{Var}(g_1(X_2)) > 0$. Hence we can distinguish models $\mathcal{M}_1$, $\mathcal{M}_2$, and $\mathcal{M}_3$ by testing whether the variance is greater than or equal to the expectation. With finite samples, the quantities $\mathbb{E}(\cdot)$ and $\mathrm{Var}(\cdot)$ can be estimated from data and we describe this more precisely in Sections 3 and 3.2.

For general QVF DAG models, the variance for each node distribution is not necessarily equal to the mean. Hence we introduce a linear transformation $T_j(X_j)$ such that

Distribution	$\mathcal{P}$	β_0	β_1	ω
Binomial	Bin(N,p)	1	$-\frac{1}{N}$	$\frac{N}{N-\mu}$
Poisson	Poi(λ)	1	0	1
Geometric	Geo(p)	1	1	$\frac{1}{1+\mu}$
Negative Binomial	NB(R,p)	1	$\frac{1}{R}$	$\frac{R}{R+\mu}$
Exponential	Exp(λ)	0	1	$\frac{1}{\mu}$
Gamma	Gamma(α,β)	0	$\frac{1}{\alpha}$	$\frac{\alpha}{\mu}$

Table 1: Examples of distributions for QVF DAG models with β_0, β_1 and ω where μ is its expectation

$\mathrm{Var}(T_j(X_j) \mid X_{\mathrm{pa}(j)}) = \mathbb{E}(T_j(X_j) \mid X_{\mathrm{pa}(j)})$ in Proposition 3. This transformation enables us to use the notion of *overdispersion* for recovering QVF DAG models. We present examples of distributions $\mathcal{P}$ for QVF DAG models with the triple $(\beta_0, \beta_1, \omega)$ in Table 1.

Proposition 3 *Let $X = (X_1, X_2, \cdots, X_p)$ be a random vector associated with a QVF DAG model with quadratic variance coefficients $(\beta_{j0}, \beta_{j1})_{j=1}^p$ specified in Equation (2). Then, there exists a transformation $T_j(X_j) = \omega_j X_j$ for any node $j \in V$ where $\omega_j = (\beta_{j0} + \beta_{j1}\mathbb{E}(X_j \mid X_{pa(j)}))^{-1}$ such that*

$$Var(T_j(X_j) \mid X_{pa(j)}) = \mathbb{E}(T_j(X_j) \mid X_{pa(j)}).$$

Proof For any node $j \in V$,

$$\begin{aligned} \mathrm{Var}(\omega_j X_j \mid X_{\mathrm{pa}(j)}) &= \omega_j^2 \mathrm{Var}(X_j \mid X_{\mathrm{pa}(j)}) \\ &\overset{(a)}{=} \omega_j^2(\beta_{j0}\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)}) + \beta_{j1}\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)})^2) \\ &\overset{(b)}{=} \omega_j \mathbb{E}(X_j \mid X_{\mathrm{pa}(j)}) \\ &= \mathbb{E}(\omega_j X_j \mid X_{\mathrm{pa}(j)}). \end{aligned}$$

Equality (a) follows from the quadratic variance property (2), and (b) follows from the definition of ω_j. ■

Now we extend to general p-variate QVF DAG models. The key idea to extending identifiability from the bivariate to multivariate scenario involves conditioning on parents of each node, and then testing overdispersion.

Assumption 4 *For all $j \in V$ and any $pa_0(j) \subset pa(j)$ where $pa_0(j) \neq \emptyset$ and $S \subset nd(j) \setminus pa_0(j)$:*

(a) $Var(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_S) > 0$, and

(b) $\beta_{j0} + \beta_{j1}\mathbb{E}(X_j \mid X_S) \neq 0$.

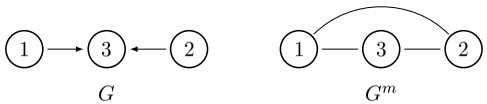

Figure 2: Moralized graph G^m for DAG G

Assumption 4(a) ensures that all parents of node j contribute to its variability, hence a conditional variance is bigger than the conditional expectation. Assumption 4(b) rules out the extremely skewed distributions. For example, Binomial distribution with a parameter N has $\beta_0 = 1$ and $\beta_1 = -\frac{1}{N}$. Then, the assumption is satisfied as long as the conditional expectation is less than N. Similarly Exponential distribution has $\beta_0 = 0$ and $\beta_1 = 1$, hence the assumption is satisfied as long as the conditional expectation is positive. Poisson distribution has $\beta_0 = 1$ and $\beta_1 = 0$, so the assumption is always satisfied.

Theorem 5 (Identifiability for p-variate QVF DAG models) *Consider the class of QVF DAG models (1) with quadratic variance coefficients $(\beta_{j0}, \beta_{j1})_{j=1}^p$ (2). If for all $j \in V$, $\beta_{j1} > -1$ and Assumption 4 is satisfied, then the class of QVF DAG models is identifiable according to Def. 1.*

The proof is provided in Appendix A. Theorem 5 shows that any QVF DAG model is identifiable under the assumption that all parents of node j contribute to its variability. The condition $\beta_{j1} > -1$ rules out DAG models with Bernoulli and multinomial distributions which are known to be non-identifiable (Heckerman et al., 1995) with $\beta_{j1} = -1$.

3. OverDispersion Scoring (ODS) Algorithm

In this section, we present our generalized OverDispersion Scoring (ODS) algorithm. The ODS algorithm is introduced by Park and Raskutti (2015) for Poisson DAG models, however it does not cover other QVF distributions. In this paper, we generalize the ODS algorithm for recovering QVF DAG models. An important concept we need to introduce for the generalized ODS algorithm is the *moral* graph or undirected graphical model representation of a DAG (see e.g., Cowell et al. 1999). The moralized graph G^m for a DAG $G = (V, E)$ is an undirected graph where $G^m = (V, E^m)$ where E^m includes the edge set E for the DAG G with directions removed plus edges between any nodes that are parents of a common child. Figure 2 represents the moralized graph for a simple 3-node example where $E = \{(1,3),(2,3)\}$ for the DAG G. Since nodes 1 and 2 are parents with a common child 3, the additional edge $(1,2)$ arises, and therefore $E^m = \{(1,2),(1,3),(2,3)\}$. Finally, the *neighborhood* for a node j refers to the adjacent nodes to j in the moralized graph, and is denoted by $\mathcal{N}(j) := \{k \in V \mid (j,k) \text{ or } (k,j) \in E^m\}$.

Our generalized ODS algorithm (Algorithm 1) has three main steps: 1) estimate the moralized graph G^m for the DAG G; 2) estimate the ordering of the DAG G using overdispersion scoring based on the moralized graph from step 1); and 3) estimate the DAG structure, given the ordering from step 2). Although Steps 2) and 3) are sufficient to recover

Algorithm 1: Generalized OverDispersion Scoring (ODS)

Input : n i.i.d. samples from a QVF-DAG model

Output: Estimated ordering $\widehat{\pi} \in \mathbb{N}^p$ and an edge structure, $\widehat{E} \in V \times V$

Step 1: Estimate the undirected edges $\widehat{E}^m = \cup_{j \in V} \cup_{k \in \widehat{\mathcal{N}}(j)} (j,k)$ where $\widehat{\mathcal{N}}(j)$ is estimated neighborhood set of a node j in the moralized graph;

Step 2: Estimate the ordering using overdispersion scores;

for $j \in \{1, 2, \cdots, p\}$ **do**

  Calculate overdispersion scores $\widehat{\mathcal{S}}(1, j)$ using Equation (4);

end

The first element of the ordering $\widehat{\pi}_1 = \arg\min_j \widehat{\mathcal{S}}(1, j)$;

for $m = \{2, 3, \cdots, p-1\}$ **do**

  for $j \in \{1, 2, \cdots, p\} \setminus \{\widehat{\pi}_1, \widehat{\pi}_2, \cdots, \widehat{\pi}_{m-1}\}$ **do**

    Find candidate parents set $\widehat{C}_{mj} = \widehat{\mathcal{N}}(j) \cap \{\widehat{\pi}_1, \widehat{\pi}_2, \cdots, \widehat{\pi}_{m-1}\}$;

    Calculate overdispersion scores $\widehat{\mathcal{S}}(m, j)$ using Equation (5);

  end

  The m^{th} element of an ordering $\widehat{\pi}_m = \arg\min_j \widehat{\mathcal{S}}(m, j)$;

  Step 3: Estimate the directed edges toward $\widehat{\pi}_m$, denoted by $\widehat{D}_m$;

end

The last element of the ordering $\widehat{\pi}_p = \{1, 2, \cdots, p\} \setminus \{\widehat{\pi}_1, \widehat{\pi}_2, \cdots, \widehat{\pi}_{p-1}\}$;

The directed edges toward $\widehat{\pi}_p$, denoted by $\widehat{D}_p = \{(j, \widehat{\pi}_p) \mid j \in \widehat{\mathcal{N}}(\widehat{\pi}_p)\}$;

Return: $\widehat{\pi} = (\widehat{\pi}_1, \widehat{\pi}_2, \cdots, \widehat{\pi}_p)$, and $\widehat{E} = \cup_{m=\{2,3,\cdots,p\}} \widehat{D}_m$

DAG structures, Step 1) is performed because it reduces both computational and sample complexity by exploiting the sparsity of the moralized graph for the DAG.

The main purpose of Step 1) is to reduce the search-space by exploiting sparsity of the moralized graph. The moralized graph provides a *candidate parents* set for each node. Similar ideas of reducing the search-space by utilizing the moralized graph or different undirected graphs are applied in existing algorithms (e.g., Tsamardinos and Aliferis 2003; Friedman et al. 1999; Loh and Bühlmann 2014). The concept of candidate parents set exploits two properties; (i) the neighborhood of a node is a superset of its parents, and (ii) a node should appear later than its parents in the ordering. Hence, the candidate parents set for a given node j is the intersection of its neighborhood and elements of the ordering which appear before that node j, and is denoted by $C_{mj} := \mathcal{N}(j) \cap \{\pi_1, \pi_2, ..., \pi_{m-1}\}$ where m^{th} element of the ordering is j (i.e., $\pi_m = j$). The estimated candidate parents set is $\widehat{C}_{mj} := \widehat{\mathcal{N}}(j) \cap \{\widehat{\pi}_1, \widehat{\pi}_2, ..., \widehat{\pi}_{m-1}\}$ that is also specified in Algorithm 1.

This candidate parents set is used as a conditioning set for the overdispersion score in Step 2). In principle, the size of the conditioning set for an overdispersion score could be $p-1$ if the moralized graph is not used. Since Step 2) requires computation of a conditional mean and variance, both the computational complexity and sample complexity depend significantly on the number of variables we condition on as illustrated in Sections 3.1

and 3.2. Therefore by making the conditioning set for the overdispersion score of each node as small as possible, we gain significant computational and statistical improvements.

A number of choices are available for estimation of the moralized graph. Since the moralized graph is an undirected graph, standard undirected graph learning algorithms such as HITON (Aliferis et al., 2003) and MMPC algorithms (Tsamardinos and Aliferis, 2003) as well as ℓ_1-penalized likelihood regression for generalized linear models (GLM) (Friedman et al., 2009). In addition, standard DAG learning algorithms such as PC (Spirtes et al., 2000), GES (Chickering, 2003) and MMHC algorithms (Tsamardinos and Aliferis, 2003) can be applied to estimate the Markov equivalence class and then the moralized graph is generated from the Markov equivalence class.

Step 2) of the generalized ODS algorithm involves learning the ordering by comparing overdispersion scores of nodes using Equations (4) and (5). The basic idea is to determine which nodes are overdispersed based on the sample conditional mean and conditional variance after the transformation in Proposition 3. The ordering is determined one node at a time by selecting the node with the smallest overdispersion score which is representative of a node that is least likely to be overdispersed.

Regarding the overdispersion scores, suppose that there are n i.i.d. samples $X^{1:n} := (X^{(i)})_{i=1}^n$ where $X^{(i)} := (X_1^{(i)}, X_2^{(i)}, \cdots, X_p^{(i)})$ is a p-variate random vector drawn from an underlying QVF DAG model with quadratic variance coefficients $(\beta_{j0}, \beta_{j1})_{j=1}^p$. We use the notation $\widehat{\cdot}$ to denote an estimate based on $X^{1:n}$. In addition, we use $n(x_S) := \sum_{i=1}^n \mathbf{1}(X_S^{(i)} = x_S)$ for $x_S \in \mathcal{X}(S)$ to denote the conditional sample size, and $n_S := \sum_{x_S} n(x_S)\mathbf{1}(n(x_S) \geq c_0 \cdot n)$ for an arbitrary $c_0 \in (0,1)$ to denote a truncated conditional sample size. We discuss the choice of c_0 shortly.

More precisely the overdispersion scores in Step 2) of Algorithm 1 involves the following equations:

$$\widehat{\mathcal{S}}(1,j) \;:=\; \widehat{\omega}_j^2 \cdot \widehat{\mathrm{Var}}(X_j) - \widehat{\omega}_j \cdot \widehat{\mathbb{E}}(X_j) \quad \text{where} \quad \widehat{\omega}_j := (\beta_{10} + \beta_{11}\widehat{\mathbb{E}}(X_j))^{-1}, \tag{4}$$

$$\widehat{\mathcal{S}}(m,j) \;:=\; \sum_{x \in \mathcal{X}_{\widehat{C}_{mj}}} \frac{n(x)}{n_{\widehat{C}_{mj}}} \Big[\widehat{\omega}_{mj}(x)^2 \widehat{\mathrm{Var}}(X_j \mid X_{\widehat{C}_{mj}} = x) - \widehat{\omega}_{mj}(x)\widehat{\mathbb{E}}(X_j \mid X_{\widehat{C}_{mj}} = x)\Big] \tag{5}$$

where $\widehat{\omega}_{mj}(x) := (\beta_{j0} + \beta_{j1}\widehat{\mathbb{E}}(X_j \mid X_{\widehat{C}_{mj}} = x))^{-1}$. $\widehat{C}_{mj}$ is the estimated candidate parents set of node j for the m^{th} element of the ordering and $\mathcal{X}_{\widehat{C}_{mj}} := \{x_{\widehat{C}_{mj}} \in \mathcal{X}(\widehat{C}_{mj}) : n(x_{\widehat{C}_{mj}}) \geq c_0 \cdot n\}$ to ensure we have enough samples for each element of an overdispersion score. c_0 is a tuning parameter of our algorithm that we specify in Theorem 14 and our numerical experiments. $\widehat{\omega}_{mj}(x)$ is an empirical version of the transformation in Proposition 3 assuming $\widehat{C}_{mj}$ is the parents of a node j. Since there are many conditional distributions, our overdispersion score is the weighted average of differences between conditional sample means and variances after the estimated transformation $\widehat{\omega}_{mj}(x)$. Then, the score is a measure of the level of overdispersion. As demonstrated in Section 2.2, the correct elements of an ordering achieve zero overdispersion score, otherwise positive in population.

Finding the set of parents of a node j boils down to selecting the parents out of all elements before a node j in the ordering. Hence given the estimated ordering from Step 2),

Step 3) can be reduced to p neighborhood selection problems which can be performed using ℓ_1-penalized likelihood regression for GLMs (Friedman et al., 2009) as well as standard DAG learning algorithms such as the PC (Spirtes et al., 2000), GES (Chickering, 2003), and MMHC algorithms (Tsamardinos and Aliferis, 2003).

3.1 Computational Complexity

For Steps 1) and 3) of the generalized ODS algorithm, we use off-the-shelf algorithms and the computational complexity depends on the choice of algorithm. For example, if we use the neighborhood selection ℓ_1-penalized likelihood regression for GLMs (Friedman et al., 2009) as is used in Yang et al. (2012), the worst-case complexity is $O(\min(n,p)np)$ for a single ℓ_1-penalized likelihood regression, but since there are p nodes, the total worst-case complexity is $O(\min(n,p)np^2)$. Similarly, if we use ℓ_1-penalized likelihood regression for Step 3) the worst-case complexity is also $O(\min(n,p)np^2)$ but maybe less if the degree d of the moralized graph is small.

For Step 2) where we estimate the ordering, there are $(p-1)$ iterations and each iteration has a number of overdispersion scores $\widehat{\mathcal{S}}(m,j)$ to be computed which is bounded by $O(p)$. Hence the total number of overdispersion scores that need to be computed is $O(p^2)$. Since the time for calculating each overdispersion score is proportional to the sample size n, the complexity is $O(np^2)$.

Hence, Step 1) is the main computational bottleneck of the generalized ODS algorithm. The addition of Step 2) which estimates the ordering does not significantly add to the computational bottleneck. Consequently, the generalized ODS algorithm, which is designed for learning DAGs is almost as computationally efficient as standard methods for learning undirected graphical models. As we show in numerical experiments, the ODS algorithm using ℓ_1-penalized likelihood regression for GLMs in both Steps 1) and 3) is faster than the state-of-the-art GES algorithm.

3.2 Statistical Guarantees

In this section, we provide theoretical guarantees for our generalized ODS algorithm. We provide sample complexity guarantees for the algorithm in the high-dimensional setting in three steps, by proving consistency of Steps 1), 2) and 3) in Sections 3.2.1, 3.2.2 and 3.2.3, respectively. All three main results are expressed in terms of the triple (n,p,d).

Although any off-the-shelf algorithms can be used in Steps 1) and 3), our theoretical guarantees focus on the case when we use the R package glmnet (Friedman et al., 2009) for neighborhood selection. We focus on glmnet since there exist provable theoretical guarantees for neighborhood selection for graphical model learning in the high-dimensional setting (see e.g., Yang et al. 2012; Ravikumar et al. 2010) and performs well in our simulation study. The glmnet package involves minimizing the ℓ_1-penalized generalized linear model loss.

Without loss of generality, assume that $(1,2,\cdots,p)$ is the true ordering and for ease of notation let $[\cdot]_k$ and $[\cdot]_S$ denotes parameter(s) corresponding to the variable X_k and random vector X_S, respectively. Suppose that $\theta^*_{D_j} \in \Theta_{D_j}$ denotes the solution of the following GLM problem where $\Theta_{D_j} := \{\theta \in \mathbb{R}^p : [\theta]_k = 0 \text{ for } k \notin \text{pa}(j)\}$.

$$\theta^*_{D_j} := \arg\min_{\theta\in\Theta_{D_j}} \mathbb{E}\left(-X_j([\theta]_j + \langle [\theta]_{\text{pa}(j)}, X_{\text{pa}(j)}\rangle) + A_j([\theta]_j + \langle [\theta]_{\text{pa}(j)}, X_{\text{pa}(j)}\rangle)\right), \quad (6)$$

where $A_j(\cdot)$ is the log-partition function determined by the GLM family (3), and $\langle\cdot,\cdot\rangle$ represents the inner product. In the special case where X_j has an NEF-QVF distribution (3) with log-partition function $A_j(\cdot)$, $\theta^*_{D_j}$ corresponds exactly to the set of true parameters, that is θ^*_{jk} is the coefficient $k \in \text{pa}(j)$ which represents the influence of node k on node j. However our results apply more generally and we do not require that X_j belongs to an NEF-QVF DAG model.

Similar definitions are required for parameters associated with the moralized graph G^m. Define $\theta^*_{M_j} \in \Theta_{M_j}$ as the solution of the following GLM problem for a node j over its neighbors where $\Theta_{M_j} := \{\theta \in \mathbb{R}^p : [\theta]_k = 0 \text{ for } k \notin \mathcal{N}(j)\}$.

$$\theta^*_{M_j} := \arg\min_{\theta\in\Theta_{M_j}} \mathbb{E}\left(-X_j([\theta]_j + \langle [\theta]_{\mathcal{N}(j)}, X_{\mathcal{N}(j)}\rangle) + A_j([\theta]_j + \langle [\theta]_{\mathcal{N}(j)}, X_{\mathcal{N}(j)}\rangle)\right). \quad (7)$$

We impose the following identifiability assumptions on $\theta^*_{D_j}$ and $\theta^*_{M_j}$ for ensuring each parents and each neighbor has non-zero influence on a node j, respectively.

Assumption 6 *(a) For any node $j \in V$ and $k \in pa(j)$,*

$$Cov(X_j, X_k) \neq Cov(X_k, \triangledown A_j([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{pa(j)\setminus k}, X_{pa(j)\setminus j}\rangle)).$$

(b) For any node $j \in V$ and $k \in \mathcal{N}(j)$,

$$Cov(X_j, X_k) \neq Cov(X_k, \triangledown A_j([\theta^*_{M_j}]_j + \langle [\theta^*_{M_j}]_{\mathcal{N}(j)\setminus k}, X_{\mathcal{N}(j)\setminus j}\rangle)).$$

Assumption 6 can be understood as a notion of restricted faithfulness only for neighbors and parents for each node. To provide intuition consider the special case of Gaussian DAG models. The log-partition function is $A_j(\eta) = \frac{\eta^2}{2}$, so that $\triangledown A_j(\eta) = \eta$. Then, the condition boils down to $\text{Cov}(X_j, X_k) \neq \sum_{m\in\text{pa}(j)\setminus k}[\theta^*_{D_j}]_m \text{Cov}(X_k, X_m)$, meaning the directed path from X_k to X_j does not exactly cancel the sum of paths from other parents of X_k. For general exponential families, the right-hand side involves non-linear functions of the variables of X corresponding to sets of measure 0. Under Assumption 6, the following result holds.

Lemma 7 *(a) Under Assumption 6(a), for all $1 \le j \le p$, $supp(\theta^*_{D_j}) = pa(j)$.*

(b) Under Assumption 6(b), for all $1 \le j \le p$, $supp(\theta^*_{M_j}) = \mathcal{N}(j)$.

Using the parameters $(\theta^*_{M_j})_{j=1}^p$ and $(\theta^*_{D_j})_{j=1}^p$ and their relationships to $\text{pa}(j)$ and $\mathcal{N}(j)$ respectively, we provide consistency guarantees for Steps 1) and 3) respectively.

3.2.1 Step 1): Recovery of the Moralized Graph via ℓ_1-penalized Likelihood Regression for GLMs

We first focus on the theoretical guarantee for recovering the moralized graph G^m. As we mentioned earlier, we approach this problem by solving an empirical version of the ℓ_1-penalized likelihood regression. Given n i.i.d. samples $X^{1:n} = (X^{(i)})_{i=1}^n$ where $X^{(i)} =$

$(X_1^{(i)}, X_2^{(i)} \cdots, X_p^{(i)})$ is a p-variate random vector drawn from the underlying DAG model, we define the conditional negative log-likelihood for a variable X_j:

$$\ell_j(\theta; X^{1:n}) := \frac{1}{n}\sum_{i=1}^{n}\left(-X_j^{(i)}([\theta]_j + \langle [\theta]_{V\setminus j}, X_{V\setminus j}^{(i)}\rangle) + A_j([\theta]_j + \langle [\theta]_{V\setminus j}, X_{V\setminus j}^{(i)}\rangle)\right) \quad (8)$$

where $\theta \in \mathbb{R}^p$ and $A_j(\cdot)$ is the log-partition function determined based on the chosen GLM family (3).

We analyze the ℓ_1-penalized log-likelihood for each node $j \in V$:

$$\hat{\theta}_{M_j} := \arg\min_{\theta\in\mathbb{R}^p} \ell_j(\theta; X^{1:n}) + \lambda_n \|[\theta]_{V\setminus j}\|_1 \quad (9)$$

where $\lambda_n > 0$ is the regularization parameter. Based on $\hat{\theta}_{M_j}$, the estimated neighborhood of node j is $\widehat{\mathcal{N}}(j) := \{k \in V \setminus j : [\hat{\theta}_M]_k \neq 0\}$. Based on Lemma 7, $\mathrm{supp}(\theta^*_{M_j}) = \mathcal{N}(j)$ where $\theta^*_{M_j}$ is defined by (7). Hence if for each j, $\hat{\theta}_{M_j}$ in (9) is sufficiently close to $\theta^*_{M_j}$, we conclude that $\widehat{\mathcal{N}}(j) = \mathcal{N}(j)$.

We begin by discussing the assumptions we impose on the DAG G. Since we apply the neighborhood selection strategy in Steps 1) and 3), we will present assumptions for both steps here. Most of the assumptions are similar to those imposed in Yang et al. (2012) where neighborhood selection is used for graphical model learning. Important quantities are the Hessian matrices of the negative conditional log-likelihood of a variable X_j given either the rest of the nodes $Q^{M_j} = \bigtriangledown^2 \ell_j(\theta^*_{M_j}; X^{1:n})$, and the nodes before j in the ordering $Q^{D_j} = \bigtriangledown^2 \ell_j^D(\theta^*_{D_j}; X^{1:n})$ which we discuss in Section 3.2.3. Let A_{SS} be the $|S| \times |S|$ submatrix of the matrix A_j corresponding to variables X_S.

Assumption 8 (Dependence assumption) *There exists a constant $\rho_{\min} > 0$ such that*

$$\min_{j\in V} \min\left(\lambda_{\min}(Q^{M_j}_{\mathcal{N}(j)\mathcal{N}(j)}), \lambda_{\min}(Q^{D_j}_{pa(j)pa(j)})\right) \geq \rho_{\min}.$$

Moreover, there exists a constant $\rho_{\max} < \infty$ such that

$$\max_{j\in V}\left(\lambda_{\max}\left(\frac{1}{n}\sum_{i=1}^{n} X^{(i)}_{\mathcal{N}(j)}(X^{(i)}_{\mathcal{N}(j)})^T\right)\right) \leq \rho_{\max}$$

where $\lambda_{\min}(A)$ and $\lambda_{\max}(A)$ are the smallest and largest eigenvalues of the matrix A, respectively.

Assumption 9 (Incoherence assumption) *There exists a constant $\alpha \in (0, 1]$ such that*

$$\max_{j\in V} \max\left(\max_{t\in\mathcal{N}(j)^c} \|Q^{M_j}_{t\mathcal{N}(j)}(Q^{M_j}_{\mathcal{N}(j)\mathcal{N}(j)})^{-1}\|_1, \max_{t'\in pa(j)^c} \|Q^{D_j}_{t'pa(j)}(Q^{D_j}_{pa(j)pa(j)})^{-1}\|_1\right) \leq 1-\alpha.$$

The dependence assumption 8 can be interpreted as ensuring that the variables in both $\mathcal{N}(j)$ and $\mathrm{pa}(j)$ are not too dependent. In addition, the incoherence assumption 9 ensures that variables that are not in the set of true variables are not highly correlated with

variables in the true variable set. These two assumptions are standard in all neighborhood regression approaches for variable selection involving ℓ_1-based methods and these conditions have imposed in proper work both for high-dimensional regression and graphical model learning (Yang et al., 2012; Meinshausen and Bühlmann, 2006; Wainwright et al., 2006; Ravikumar et al., 2011).

To ensure suitable concentration bounds hold, we impose two further technical assumptions. Firstly we require a boundedness assumption on the moment generating function to control the tail behavior.

Assumption 10 (Concentration bound assumption) *There exists a constant $M > 0$ such that*

$$\max_{j\in V} \mathbb{E}(exp(|X_j|)) < M.$$

We also require conditions on the first and third derivatives on the log-partition functions $A_j(.)$ for $1 \leq j \leq p$ in Equations (8) and (10). Let $A'_j(.)$ and $A'''_j(.)$ are the first and third derivatives of $A_j(.)$ respectively.

Assumption 11 (Log-partition assumption) *For the log-partition functions $A_j(\cdot)$ in Equation (8) or (10), there exist constants κ_1 and κ_2 such that $\max_{j\in V}\{|A'_j(a)|, |A'''_j(a)|\} \leq n^{\kappa_2}$ for $a \in [0, \kappa_1 \max\{\log(n), \log(p)\})$, $\kappa_1 \geq 6\max(\|\theta^*_{M_j}\|_1, \|\theta^*_{D_j}\|_1)$ and $\kappa_2 \in [0, 1/4]$.*

Prior work in Yang et al. (2012); Ravikumar et al. (2011); Jalali et al. (2011) impose similar technical conditions that control the tail behavior of $(X_j)_{j=1}^p$. It is important to note that there exist many distributions and associated parameters that satisfy these assumptions. For example the Binomial, Multinomial or Exponential distributions, the log-partition assumption 11 is satisfied with $\kappa_2 = 0$ because the log-partition function $A_j(\cdot)$ is bounded. For the Poisson distribution which has one of the steepest log-partition function, $A_j(\cdot) = \exp(\cdot)$. Hence, in order to satisfy Assumption 11, we require $\|\theta^*_{M_j}\|_1 \leq \frac{\log n}{48 \log p}$ with $\kappa_2 = \frac{1}{8}$.

Putting together Assumptions 8 9, 10, and 11, we have the following main result that the moralized graph can be recovered via ℓ_1-penalized likelihood regression for GLMs in high-dimensional settings.

Theorem 12 (Learning the moralized graph) *Consider the DAG model (1) satisfying the QVF property (2) and d is the maximum degree of the moralized graph. Suppose that Assumptions 6(b), 8, 9, 10 and 11 are satisfied. Assume $\hat{\theta}_{M_j}$ is any solution to the optimization problem (9) and $\frac{9\log^2(\max\{n,p\})}{n^a} \leq \lambda_n \leq \frac{\rho^2_{\min}}{30n^{\kappa_2}\log(\max\{n,p\})d\rho_{\max}}$ for some $a \in (2\kappa_2, 1/2)$, and $\min_{j\in V}\min_{t\in\mathcal{N}(j)}|[\theta^*_M]_t| \geq \frac{10}{\rho_{\min}}\sqrt{d}\lambda_n$. Then for any constant $\epsilon > 0$, there exists a positive constant C_ϵ such that if $n \geq C_\epsilon(d\log^3\max\{n,p\})^{\frac{1}{a-\kappa_2}}$,*

$$\mathbb{P}(supp(\hat{\theta}_{M_j}) = \mathcal{N}(j)) \geq 1-\epsilon,$$

for all $j \in V$.

We defer the proof to Appendix C. The key technique for the proof is that standard *primal-dual witness* method used in Wainwright et al. (2006); Ravikumar et al. (2011); Jalali et al. (2011); and Yang et al. (2012). Theorem 12 shows that the moralized graph G^m can be recovered via ℓ_1-penalized likelihood regression if sample size $n = \Omega((d\log^3(\max\{n,p\}))^{\frac{1}{a-\kappa_2}})$ with high probability.

3.2.2 Step 2): Recovering the Ordering using OverDispersion Scores

In this section, we provide theoretical guarantees for recovering the ordering for the DAG G via our generalized ODS algorithm. The first required condition is a stronger version of the identifiability assumption (Assumption 4) since we move from the population distribution to the finite sample setting.

Assumption 13 *For all $j \in V$ and any $pa_0(j) \subset pa(j)$ where $pa_0(j) \neq \emptyset$ and $S \subset nd(j) \setminus pa_0(j)$:*

(a) There exists an $M_{\min} > 0$ such that $Var(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_S) > M_{\min}$.

(b) There exists an $\omega_{\min} > 0$ such that $|\beta_{j0} + \beta_{j1}\mathbb{E}(X_j \mid X_S)| > \omega_{\min}$.

Assumption 10 is required since the overdispersion score is sensitive to the accuracy of the sample conditional mean and conditional variance. Since the true ordering π^* may not be unique, we use $\mathcal{E}(\pi^*)$ to denote the set of all the orderings that are consistent with the true DAG G.

Theorem 14 (Recovery of the ordering) *Consider the DAG model (1) satisfying the QVF property (2) with co-efficients $(\beta_{j0}, \beta_{j1})_{j=1}^p$ and d is the maximum degree of the moralized graph. Suppose that $\beta_{j1} > -1$ for all $j \in V$, and the structure of the moralized graph G^m is known. Suppose also that Assumptions 10 and 13 are satisfied. Then for any $\epsilon > 0$ and $c_0 \geq \log^d(\max\{n,p\})$, there exists a positive constant K_ϵ such that for $n \geq K_\epsilon \log^{5+d}(\max\{n,p\})$,*

$$P(\widehat{\pi} \in \mathcal{E}(\pi^*)) \geq 1 - \epsilon.$$

The detail of the proof is provided in Appendix D. The proof is novel and involves the combination of the transformation and overdispersion property exploited in Theorem 5. Intuitively, the estimated overdispersion scores $\widehat{\mathcal{S}}(m,j)$ converge to the true overdispersion scores $\mathcal{S}(m,j)$ as the sample size n increases which is where we exploit Assumption 10. This allows us to recover a true ordering for the DAG G. Assuming the moralized graph G^m is known is essential to exploiting the degree condition on the moralized graph and emphasizes the importance of Step 1) and Theorem 12.

Theorem 14 claims that if the triple (n,d,p) satisfies $n = \Omega(\log^{5+d} p)$, our generalized ODS algorithm correctly estimates the true ordering. Therefore if the moralized graph is sparse (i.e., $d = \Omega(\log p)$), our generalized ODS algorithm recovers the true casual ordering in the high-dimensional settings. Note that if the moralized graph is not sparse and $d = \Omega(p)$, the generalized ODS algorithm requires an extremely large sample size. Prior work on DAG learning algorithms in the high-dimensional setting has been based on learning the Markov equivalence class in settings with additive independent noise (see e.g., Loh and Bühlmann 2014; van de Geer and Bühlmann 2013).

3.2.3 Step 3): Recovery of the DAG via ℓ_1-penalized Likelihood Regression

Similar to Step 1), we provide a theoretical guarantee for Step 3) using ℓ_1-penalized likelihood regression where we estimate the parents of each node $\text{pa}(j)$. Importantly, we assume that Step 2) of the ODS algorithm has occurred and using Theorem 14, a true ordering has been learned. Recall that we impose the assumption that the true ordering is $\pi^* = (1, 2, \cdots, p)$. Then, we estimate the parents of a node j over the possible parents $\{1, 2, \cdots, j-1\}$.

For notational convenience, we use $X_{1:j} = (X_1, X_2, \cdots, X_j)$. Then for any variable X_j, the conditional negative log-likelihood for a given GLM is as follows:

$$\ell_j^D(\theta; X^{1:n}) := \frac{1}{n}\sum_{i=1}^n \left(-X_j^{(i)}([\theta]_j + \langle [\theta]_{1:j-1}, X_{1:j-1}^{(i)}\rangle) + A_j([\theta]_j + \langle [\theta]_{1:j-1}, X_{1:j-1}^{(i)}\rangle)\right) \quad (10)$$

where $\theta \in \mathbb{R}^j$, and $A_j(\cdot)$ is the log-partition function determined by a chosen GLM family.

We solve the negative conditional log-likelihood with ℓ_1 norm penalty for each variable X_j:

$$\hat{\theta}_{D_j} := \arg\min_{\theta \in \mathbb{R}^j} \ell_j^D(\theta; x) + \lambda_n^D \|[\theta]_{1:j-1}\|_1. \quad (11)$$

Recall that under Assumption 6(a), Lemma 7(a) shows that $\text{supp}(\theta^*_{D_j}) = \text{pa}(j)$. Hence if the solution of Equation (11) for each node $j \in V$ is close to $\theta^*_{D_j}$ in Equation (6), ℓ_1-penalized likelihood regression successfully recovers the parents of node j.

Theorem 15 (Learning DAG structure) *Consider the DAG model (1) satisfying the QVF property (2) and d is the maximum degree of the moralized graph. Suppose that Assumptions 6(a), 8, 9, 10 and 11 are satisfied. Assume $\hat{\theta}_{D_j}$ is any solution to the optimization problem (11) and $\frac{9\log^2(\max\{n,p\})}{n^a} \leq \lambda_n^D \leq \frac{\rho_{\min}^2}{30n^{\kappa_2}\log(\max\{n,p\})d\rho_{\max}}$ for some $a \in (2\kappa_2, 1/2)$, and $\min_{j\in V}\min_{t\in\mathcal{N}(j)}|[\theta^*_D]_t| \geq \frac{10}{\rho_{\min}}\sqrt{d}\lambda_n$. Then for any $\epsilon > 0$, there exists a positive constant C_ϵ such that if $n \geq C_\epsilon(d\log^3(\max\{n,p\}))^{\frac{1}{a-\kappa_2}}$,*

$$\mathbb{P}(supp(\hat{\theta}_{D_j}) = pa(j)) \geq 1 - \epsilon,$$

for all $j \in V$.

The details of the proof are provided in Appendix E. The proof technique is again based on the primal-dual technique as is used for the proof of Theorem 12. Theorem 15 shows that ℓ_1-penalized likelihood regression successfully recovers the structure of G if the sample size is $n = \Omega((d\log^3(\max\{n,p\}))^{\frac{1}{a-\kappa_2}})$ given the true ordering. Note once again that we exploit the sparsity d of the moralized graph.

So far, we have provided sample complexity guarantees for all three steps of the generalized ODS algorithm. Combining Theorems 12, 14, and 15, we reach our final main result that the generalized ODS algorithm successfully recovers the true structure of a QVF DAG with high probability. Furthermore if G is sparse (i.e., $d = \Omega(\log p)$), the generalized ODS algorithm recovers the structure of QVF DAG models in the high-dimensional setting.

Corollary 16 (Learning QVF DAG models) *Consider the DAG model* (1) *satisfying the QVF property* (2) *and d is the maximum degree of the moralized graph. Suppose that Assumptions 6, 8, 9, 10 and 11 are satisfied and all other conditions of Theorems 12, 14, and 15 are satisfied and $\widehat{G}$ is the output of the ODS algorithm. Then for any $\epsilon > 0$, there exists a positive constant C_ϵ such that if $n \geq C_\epsilon \max(d\log^3(\max\{n,p\}))^{\frac{1}{a-\kappa_2}}, \log^{5+d} p)$,*

$$\mathbb{P}(\widehat{G} = G) \geq 1 - \epsilon.$$

Concretely, we apply Corollary 16 to popular examples for our class of QVF DAG models. As we discussed earlier, Poisson DAG models have $(\beta_{j0}, \beta_{j1}) = (1, 0)$, the steepest log-partition function $A_j(\cdot) = \exp(\cdot)$, and $\kappa_2 = \frac{1}{8}$ if $\|\theta^*_{M_j}\|_1 \leq \frac{\log n}{48\log(\max\{n,p\})}$. Then, our generalized ODS algorithm recovers Poisson DAG models with high probability if $n = \Omega(\max\{(d\log^3 p)^4, \log^{5+d} p\})$ and $a = \frac{3}{8}$. Binomial DAG models have $(\beta_{0j}, \beta_{1j}) = (0, -\frac{1}{N})$ where N is a binomial distribution parameter, the log-partition function $A_j(\cdot) = N\log(1 + \exp(\cdot))$, $\kappa_2 = 0$. Then, the generalized ODS algorithm recover Binomial DAG models with high probability if $n = \Omega(\max\{(d\log^3 p)^3, \log^{5+d} p\})$ and $a = \frac{1}{3}$.

4. Simulation Experiments

In this section, we support our theoretical guarantees with numerical experiments and show that our generalized ODS algorithm 1 performs favorably compared to state-of-the-art DAG learning algorithms when applied to QVF DAG models. In order to validate Theorems 12, 14, and 15, we conduct a simulation study using 50 realizations of p-node Poisson and Binomial DAG models (3). That is, the conditional distribution for each node given its parents is either Poisson and Binomial. For all our simulation results, we generate DAG models (see Figure 3) that ensure a unique ordering $\pi^* = (1, 2, \cdots, p)$ with edges randomly generated while respecting the desired maximum number of parents constraints for the DAG. In our experiments, we always set the number of parents to two (the number of neighbors of each node is at least three, and therefore $d \in [3, p-1]$).

The set of parameters (θ_{jk}) for our GLM DAG models (3) encodes the DAG structure as follows: if there is no directed edge from node k to j, $\theta_{jk} = 0$, otherwise $\theta_{jk} \neq 0$. Non-zero parameters $\theta_{jk} \in E$ were generated uniformly at random in the range $\theta_{jk} \in [-1, -0.5]$ for Poisson DAG models and $\theta_{jk} \in [0.5, 1]$ for Binomial DAG models. In addition, we fixed parameters $N_1, N_2, \cdots, N_p = 4$ for Binomial DAG models. These parameter values were chosen to ensure Assumptions 10 and 11 are satisfied and most importantly, the count values do not blow up. Lastly, we set the thresholding constant for computing the ODS score to $c_0 = 0.005$ although any value below 0.01 seems to work well in practice. We consider more general parameter choices but for brevity, focus on these parameter settings.

To validate Theorems 12 and 14, we plot the proportion (out of 50) of simulations in which our generalized ODS algorithm recovers the correct ordering to validate π^* in Figure 4. We plot the accuracy rates in recovering the true ordering $\mathbf{1}(\hat{\pi} = \pi^*)$ as a function of the sample size ($n \in \{100, 500, 1000, 2500, 5000, 10000\}$) for different node sizes ($p = 10$ for (a) and (c), and $p = 100$ for (b) and (d)) and different distributions (Poisson for (a) and (b) and Binomial for (c) and (d)). In each sub-figure, two different choices for off-the-shelf algorithms for Step 1) are used; (i) ℓ_1 penalized likelihood regression (Friedman et al., 2009) where we chose the regularization parameter $\lambda = \frac{0.75}{\log(\max\{n,p\})}$ for Poisson DAG models and

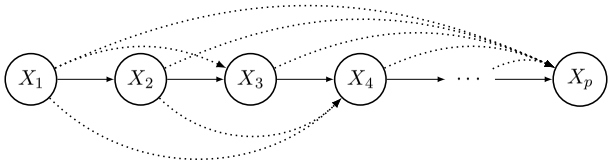

Figure 3: Structure of the DAG we used in numerical experiments. Solid directed edges are always present and dotted directed edges are randomly chosen based on the given number of parents of each node constraints

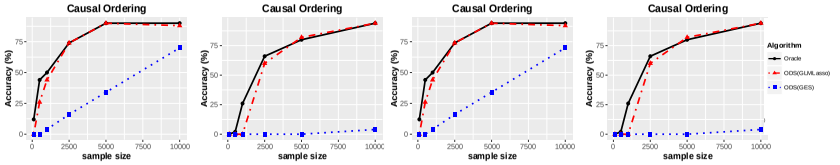


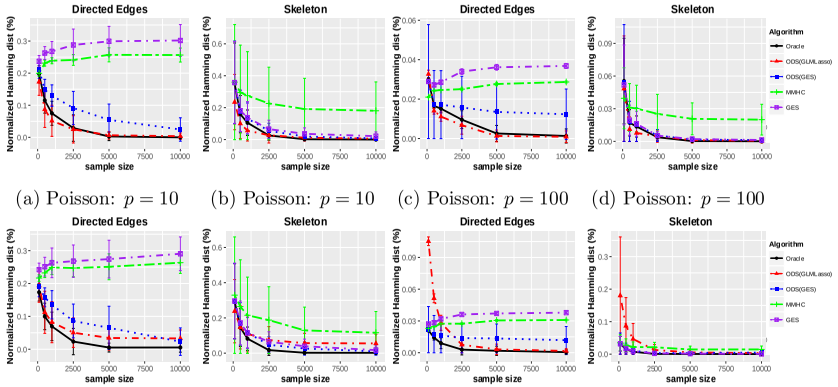
(a) Poisson: $p = 10$ (b) Poisson: $p = 100$ (c) Binomial: $p = 10$ (d) Binomial: $p = 100$

Figure 4: Probability of recovering the ordering of a DAG via our generalized ODS algorithm using two different algorithms (ℓ_1-penalized likelihood regression and GES algorithm) in Step 1)

$\lambda = \frac{.10}{\log(\max\{n,p\})}$ for Binomial DAG models; and (ii) the GES algorithm (Chickering, 2003) is applied for Step 1) where we used the mBDe (modified Bayesian Dirichlet equivalent, Heckerman et al. 1995) score and then the moralized graph is generated by moralizing the estimated DAG.

Figure 4 shows that our generalized ODS algorithm recovers the true ordering π^* well if the sample size is large, which supports our theoretical results. In addition, we can see that the ℓ_1-penalized based generalized ODS algorithm seems to perform substantially better than the GES-based ODS algorithm. Furthermore, since ℓ_1-penalized likelihood regression is the only algorithm that scales to the high-dimensional setting ($p \geq 1000$), we used ℓ_1-penalized likelihood regression in Steps 1) and 3) of the generalized ODS algorithm for large-scale DAG models.

Figure 5 provides a comparison of how accurately our generalized ODS algorithm performs in terms of recovering the full DAG model. We use two comparison metrics related to how many edges and directions are incorrect. First, we measured the Hamming distance between the skeleton (edges without directions) of the true DAG and the estimated DAG in (a), (c), (e) and (g). In addition, we measured the Hamming distance between the estimated and true DAG models (with directions) in (b), (d), (f), and (h). We normalized the Hamming distances by dividing by the maximum number of errors $\binom{p}{2}$ for the skeleton and



(a) Poisson: $p = 10$ (b) Poisson: $p = 10$ (c) Poisson: $p = 100$ (d) Poisson: $p = 100$

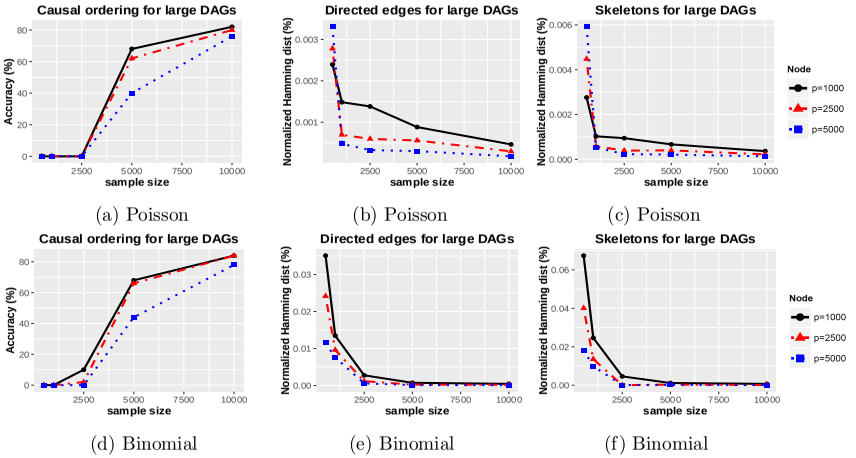
(e) Binomial: $p = 10$ (f) Binomial: $p = 10$ (g) Binomial: $p = 100$ (h) Binomial: $p = 100$

Figure 5: Comparison of the generalized ODS algorithms using ℓ_1-penalized likelihood regression (in Steps 1) and 3)) and the GES algorithm (in Steps 1) and 3)) to two state-of-the-art DAG learning algorithms (the MMHC and the GES algorithms) in terms of Hamming distance to skeletons and directed edges of Poisson and Binomial DAG models.

$p(p-1)$ for the full DAG respectively meaning the maximum normalized distance is 1. We compare to two state-of-the-art directed graphical model learning algorithms, the MMHC and GES algorithms for both Poisson and Binomial DAG models. Similar to learning the ordering, we used two generalized ODS algorithms exploiting ℓ_1-penalization in both Steps 1) and 3) and the GES algorithm in both Steps 1) and 3). We considered small-scale DAG models with $p = 10$ in (a), (b), (e) and (f), and $p = 100$ in (c), (d), (g) and (h).

As we see in Figure 5, the ODS algorithms significantly out-perform state-of-the-art MMHC and GES algorithms in terms of directed edges and skeleton. For small sample sizes, the generalized ODS algorithms have poor performance because they fail to recover the ordering, however we can see that the GES-based generalized ODS algorithm always performs better than the GES algorithm. This is because the generalized ODS algorithm adds directional information to the estimated skeleton via the GES algorithm, and hence the GES-based generalized ODS algorithm cannot be worse than the GES algorithm in terms of recovering both directed edges and skeleton. Furthermore Figure 5 shows that as sample size increases, our generalized ODS algorithms recovers the true directed edges and the skeleton for the DAG more accurately than state-of-the-art methods, which is consistent with our theoretical results.

Next we consider the performance for large-scale DAG models to show that the ODS algorithm works in the high-dimensional setting. In all experiments, we used the ℓ_1-penalized likelihood regression for GLMs in Steps 1) and 3) for the generalized ODS algorithm since it is the only graph-learning algorithm that scales. Figure 6 plots the statistical performance



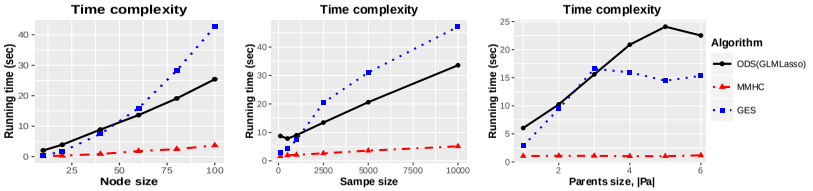
(a) Poisson (b) Poisson (c) Poisson

(d) Binomial (e) Binomial (f) Binomial

Figure 6: Performance of the generalized ODS algorithm using ℓ_1-penalized likelihood regression in both Steps 1) and 3) for large-scale DAG models with the node size $p = \{1000, 2500, 5000\}$

of the generalized ODS algorithm for large-scale Poisson DAGs in (a), (b), and (c) and Binomial DAGs in (d), (e), and (f). Furthermore, (a) and (d) represent the accuracy rates of the recovering the ordering, (b) and (e) show the normalized Hamming distance to the true skeleton, and (c) and (f) show the normalized Hamming distance for the true edge set of the DAG. Accuracies vary as a function of sample size ($n \in \{500, 1000, 2500, 5000, 10000\}$) for each node size ($p = \{1000, 2500, 5000\}$). Similar to small-scale DAG models, Figure 6 shows that the generalized ODS algorithm recovers the ordering and the skeleton of the DAG in the high-dimensional settings.

In Figure 7, we compared the run-time of the generalized ODS algorithms using ℓ_1-penalized likelihood regression for GLMs in Steps 1) and 3) to the run-time of the MMHC and the GES algorithms. We measured the run-time for Poisson DAG models by varying (a) node size $p \in \{10, 20, 40, 60, 80, 100\}$ with fixed sample size $n = 10000$ and exactly two parents of each node, (b) sample size $n \in \{100, 500, 1000, 2500, 5000, 10000\}$ with the fixed node size $p = 100$ and two parents of each node, and (c) the number of parents of each node $\in \{1, 2, 3, 4, 5, 6\}$ with the fixed sample size $n = 10000$ and node size $p = 20$. The results of (a) and (b) show that the generalized ODS algorithm is not always slower than the GES algorithm. In addition, (c) also shows that the run-time of the generalized ODS algorithm depends significantly on the number of parents for each node. Figure 7 shows that the generalized ODS algorithm is significantly slower than the MMHC algorithm, however this is because the MMHC algorithm often stops earlier before they reach the true DAG (see Figure 5).



(a) Poisson: $n = 10^4, d \geq 3$ (b) Poisson: $p = 100, d \geq 3$ (c) Poisson: $n = 10^4, p = 20$

Figure 7: Comparison of the generalized ODS algorithms using ℓ_1-penalized likelihood regression in Steps 1) and 3) to two standard DAG learning algorithms (the MMHC and the GES algorithms) in terms of running time with respect to (a) node size p, (b) sample size n, and (c) number of parents of each node

5. Real Multi-variate Count Data: 2009/2010 NBA Player Statistics

In terms of real data applications, one of the advantages of our ODS algorithm is that it provides a scalable approach for learning DAG models when variables are counts. In particular other approaches such as GES, MMHC and approaches based on conditional independence testing suffer severely from the fact that we are dealing with discrete variables where the number of discrete states is potentially large or infinite and represents counts. In this section, we demonstrate this advantage using a simple data set that involves multi-variate count data which models basketball statistics for NBA players during the 2009/10 season. To the best of our knowledge, our ODS algorithm is the only algorithm that provides a reliable and scalable approach for DAG learning with multi-variate count data, albeit under strong assumptions.

Our data set consists of 441 NBA player statistics from season 2009/2010 (see R package SportsAnalytics for detailed information). The original data set contains 24 covariates: player name, team name, players position (PG, SG, SF, PF or C), total minutes played, total number of field goals made, field goals attempted, threes made, threes attempted, free throws made, free throws attempted, offensive rebounds, rebounds, assists, steals, turnovers, blocks, personal fouls, disqualifications, technicals fouls, ejections, flagrant fouls, games started and total points. We eliminated player name, team name, number of games played, and players position, because our focus is to find the directional or causal relationships between statistics. We also eliminated ejections and flagrant fouls because both did not occur in our data set. Therefore the data set we consider contains 18 variables.

As we see in Figure 8 (left), all 18 variables are positively correlated. This makes sense because the total minutes played is likely to be positively correlated with other statistics, and some statistics have causal relationships (e.g., the more shooting attempt implies the more shooting made). The box plots in Figure 8 (right) show that the NBA statistics are significantly different depending on the player position. This is also makes sense because each position takes a different role. C and PF are expected to play near the baseline, hence they have more rebounds, blocks, and fouls. PG is expected to pass a ball and play far

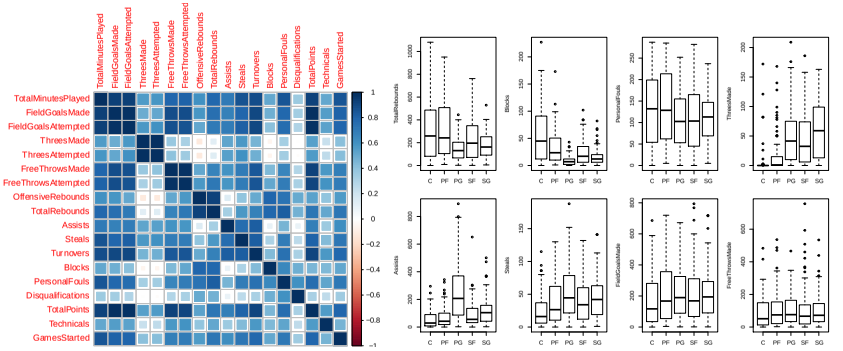


Figure 8: Correlation Plots for NBA statistics (left). Blue represents a high correlation and white represents a small correlation. Box plots for some NBA statistics depending on positions (right). Box plots consider the total number of rebounds, blocks, personal fouls, assists, steals, three points made, field goals made, and free throws made.

from the basket, hence PG has more steals, assists, turnover and the number of three points made. Hence the directed graph for each position may not be the same. For example, the directed graph for the position C and PF may not have an edge between total points and three points made because those positions players usually make a very small number of three points made while the directed graph for other positions may have an edge between total points and three points made. We also plotted DAG models for different positions, but for ease of presentation we combined all positions.

We assumed each node conditional distribution given its parents is Poisson because most of NBA statistics we consider are the number of successes or attempts counted in the season. Hence we applied the ODS algorithm 1 for Poisson DAG models where ℓ_1-penalized likelihood regression is used in Steps 1) and 3). We used leave-one-out cross validation to choose the tuning parameters, and chose the largest value where mean squared error is within 1 standard error of the minimum mean squared of error because we prefer a sparse graph containing only legitimate edges.

Figure 9 (left) shows the directed graph estimated by our method. The estimated graph reveals clear causal/directional relationships between statistics. A large number of shootings attempted implies a large number of shootings made that implies large total points. Moreover, a large number of rebounds implies a large number of offensive rebounds, and a large number of fouls implies more frequent disqualifications. Lastly, the more total minutes played, the more number of games started, total points and other statistics.

We also find the two clusters related to positions; (i) C and PF related nodes (blocks, offensive rebounds, rebounds, personal fouls, technical fouls, and disqualification) (ii) PG related nodes (steals, assists, turnover, and the number of three points attempts and made). Within the clusters, the nodes are highly connected although there may be no causal or

Eliminated Edge 2	TotalPoints → ThreesMade
Added Edge	Steals → TotalMinutesPlayed

Table 2: The differences between the estimated DAGs in Figure 9.

directional relationships. It can be understood that position variable is a latent variables, and if the position variable is considered in the graph, some false directed edges may be eliminated. However, we do not add the position variable in the graph because Multinomial distribution does not belong to the class of QVF distribution.

There are many unexplainable edges in Figure 9 (left) due to the assumptions made which are not completely satisfied by the real data. In order to obtain a sparser graph with legitimate edges, we applied the ODS algorithm with the same procedures except that we chose a larger tuning parameter where mean squared of error is within 2.5 standard error of the minimum mean squared of error.

Figure 9 (right) shows the estimated directed graph using large tuning parameters. Compared to Figure 9 (left), the estimated DAG has fewer edges as expected. Specifically, the estimated DAG in Figure 9 (right) excludes unrealistic edges (Eliminated Edges 1 in Table. 2). However the estimated DAG also loses a legitimate edge (Eliminated Edge 2 in Table. 2) because C and PF have fewer number of three points made. Lastly, the estimated DAG includes explainable additional edge (Added Edge in Table. 2) because Step 1) of the ODS algorithm reduces the search-space of DAGs well, and improves the accuracy of the graph structure learning.

We acknowledge that our estimated DAG model makes many errors due to the restrictive assumption. However the benefit is best seen by comparing to other DAG learning approaches and an undirected graphical model. In particular, we applied Poisson undirected graphical models (Yang et al., 2013) which is the same procedure of Step 1) of our algorithm. The estimated undirected graph in Figure 10 (left) shows that a lot of nodes are connected by edges, and many edges are not explainable because the Poisson undirected graphical model only permits negative conditional relationships while all 18 variables are positively correlated. Hence it is not useful to understand the relationships between NBA statistics. We provide the estimated undirected graph with larger tuning parameter where mean squared of error is within 2.5 standard error of the minimum mean squared of error.

We also compare to the GES and MMHC algorithms. In particular, the estimated graphs in Figure 10 (right) are the same and both algorithms use the Bayesian Dirichlet score for count data which prefers a sparse graph when the positivity assumption is violated (i.e., $\widehat{P}(X_j = x_j \mid \mathrm{pa}(X_j)) \approx 0$). Since all statistics have high cardinality, which means each variable has almost no repeats in its data range, the positivity assumption is not satisfied. Hence the estimated directed graphs are extremely sparse which have a single directed edge between technical fouls and disqualification.

Since our method is the first identifiability result for the count data to the best of our knowledge, our method more reliably recovers the directional/causal relationships between

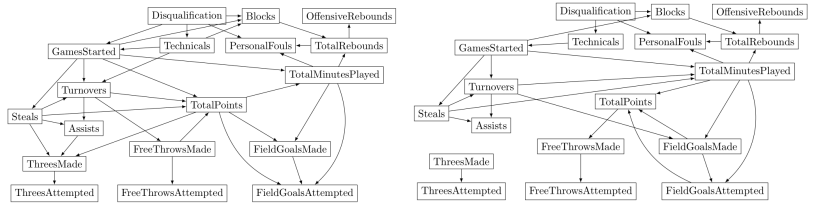

Figure 9: NBA players statistics directed graph estimated by the ODS algorithm for Poisson DAG models using ℓ_1-penalized likelihood regression in Steps 1) and 3) with small tuning parameters (left) and large tuning parameters (right).

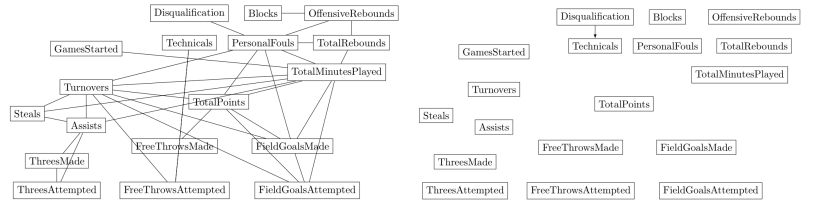

Figure 10: NBA players statistics undirected graph estimated by ℓ_1-penalized likelihood regression (left) and directed acyclic graph estimated by GES and MMHC algorithms (right).

NBA statistics. However we acknowledge that like most other DAG-learning approaches, very strong assumptions are required fore reliable recovery.

Appendix A. Proof for Theorem 5

Proof Without loss of generality, we assume the ordering is $\pi^* = (1, 2, \cdots, p)$. For notational convenience, we define $X_{1:j} = \{X_1, X_2, \cdots, X_j\}$ and $X_{1:0} = \emptyset$. For $m \in \{1, 2, ..., p-1\}$ and $j \in \{m, m+1, \cdots, p\}$, let $\omega_{jm} = (\beta_0 + \beta_1 \mathbb{E}(X_j \mid X_{1:m-1}))^{-1}$ and $\omega_{j1} = (\beta_0 + \beta_1 \mathbb{E}(X_j))^{-1}$. Recall that the overdispersion score of node j for m^{th} element of the ordering is Equation (5):

$$\mathcal{S}(m, j) = \omega_{jm}^2 \mathrm{Var}(X_j \mid X_{1:m-1}) - \omega_{jm} \mathbb{E}(X_j \mid X_{1:m-1}).$$

We now prove identifiability of our class of DAG models by induction. For the first element of the ordering ($m = 1$),

$$\begin{aligned}
\mathcal{S}(1, j) &= \omega_{j1}^2 \mathrm{Var}(X_j) - \omega_{j1} \mathbb{E}(X_j) \\
&\overset{(a)}{=} \omega_{j1}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)})) + \mathbb{E}(\mathrm{Var}(X_j \mid X_{\mathrm{pa}(j)})) - \omega_{j1}^{-1} \mathbb{E}(X_j) \big\} \\
&\overset{(b)}{=} \omega_{j1}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)})) + \mathbb{E}(\beta_0 \mathbb{E}(X_j \mid X_{\mathrm{pa}(j)}) + \beta_1 \mathbb{E}(X_j \mid X_{\mathrm{pa}(j)})^2) \\
&\qquad - (\beta_0 + \beta_1 \mathbb{E}(X_j)) \mathbb{E}(X_j) \big\} \\
&= \omega_{j1}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)})) + \beta_1 \mathbb{E}(\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)})^2) - \beta_1 \mathbb{E}(X_j)^2 \big\} \\
&= \omega_{j1}^2 (1 + \beta_1) \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)})).
\end{aligned}$$

(a) follows from the variance decomposition formula $\mathrm{Var}(Y) = \mathbb{E}(\mathrm{Var}(Y \mid X)) + \mathrm{Var}(\mathbb{E}(Y \mid X))$ for some random variables X and Y. In addition (b) follows from the quadratic variance property (2) of our class of distributions and the definition of ω_{j1}. Note that the score of the first element of the ordering is $\mathcal{S}(1, 1) = 0$ because $\mathrm{Var}(E(X_1)) = 0$, and other scores are strictly positive $\mathcal{S}(j, 1) > 0$ by the assumption $\beta_1 > -1$. Therefore 1 is the first element of the ordering.

For the $(m-1)^{th}$ element of the ordering, assume that the first $m-1$ elements of the ordering are correctly estimated. Now, we consider the m^{th} element of the ordering. Then, for $j \in \{m, m+1, \cdots, p\}$,

$$\begin{aligned}
\mathcal{S}(m, j) &= \omega_{jm}^2 \mathrm{Var}(X_j \mid X_{1:m-1}) - \omega_{jm} \mathbb{E}(X_j \mid X_{1:m-1}) \\
&\overset{(a)}{=} \omega_{jm}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)}) \mid X_{1:m-1}) + \mathbb{E}(\mathrm{Var}(X_j \mid X_{\mathrm{pa}(j)}) \mid X_{1:m-1}) - \omega_{jm}^{-1} \mathbb{E}(X_j \mid X_{1:m-1}) \big\} \\
&\overset{(b)}{=} \omega_{jm}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_{1:m-1}) + \mathbb{E}(\beta_0 \mathbb{E}(X_j \mid X_{\mathrm{pa}(j)} \mid X_{1:m-1}) \\
&\qquad + \beta_1 \mathbb{E}(X_j \mid X_{\mathrm{pa}(j)} \mid X_{1:m-1})^2) - (\beta_0 + \beta_1 \mathbb{E}(X_j \mid X_{1:m-1})) \mathbb{E}(X_j \mid X_{1:m-1}) \big\} \\
&= \omega_{jm}^2 \big\{ \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_{1:m-1}) + \beta_1 \mathbb{E}(\mathbb{E}(X_j \mid X_{\mathrm{pa}(j)})^2 \mid X_{1:m-1}) - \beta_1 \mathbb{E}(X_j \mid X_{1:m-1})^2 \big\} \\
&= \omega_{jm}^2 (1 + \beta_1) \mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_{1:m-1}).
\end{aligned}$$

Again (a) follows from the variance decomposition formula, and (b) follows from the quadratic variance property (2) of our class of distributions and the definition of ω_{jm}. If $\mathrm{pa}(j) \backslash \{1, 2, \cdots, m-1\}$ is empty, $\mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_{1:m-1}) = 0$, and hence $\mathcal{S}(m, m) = 0$. On the other hand, for any node j in which $\mathrm{pa}(j) \backslash \{1, 2, \cdots, m-1\}$ is non-empty, $\mathcal{S}(m, j) > 0$ by the assumption $\beta_{j1} > -1$, which excludes it from being next in the ordering. Therefore, we can estimate a valid m^{th} component of the ordering, $\widehat{\pi}_m = m$. By induction this completes the proof. ■

Appendix B. Proof for Lemma 7

Proof We begin with part (a). By the construction $\theta^*_{D_j}$ in Equation (6), $[\theta^*_{D_j}]_k = 0$ for any node $k \notin \mathrm{pa}(j)$. Hence, it is sufficient to show that for any $k \in \mathrm{pa}(j)$, $[\theta^*_{D_j}]_k \neq 0$. Assume for the sake of contradiction that $[\theta^*_{D_j}]_k = 0$. Applying the first order optimality condition to Equation (6), we have

$$\begin{aligned}
\mathbb{E}(X_j) &= \mathbb{E}(A_j'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle)) \\
\mathbb{E}(X_j X_k) &= \mathbb{E}(A_j'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle) X_k).
\end{aligned} \tag{12}$$

By the definition of the covariance, we obtain

$$\begin{aligned}
\mathbb{E}(X_j X_k) &= \mathrm{Cov}(A'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle), X_k), \\
&\quad + \mathbb{E}(A'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle)) \mathbb{E}(X_k).
\end{aligned}$$

By Equation (12),

$$\mathbb{E}(X_j X_k) = \mathrm{Cov}(A'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle), X_k) + \mathbb{E}(X_j) \mathbb{E}(X_k).$$

Therefore,

$$\mathrm{Cov}(X_j, X_k) = \mathrm{Cov}(A'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j)}, X_{\mathrm{pa}(j)} \rangle), X_k).$$

By Assumption 6 (a), we have $[\theta^*_{D_j}]_k = 0$, and

$$\mathrm{Cov}(X_j, X_k) = \mathrm{Cov}(D'([\theta^*_{D_j}]_j + \langle [\theta^*_{D_j}]_{\mathrm{pa}(j) \backslash k}, X_{\mathrm{pa}(j) \backslash j} \rangle), X_k),$$

which is a contradiction by our earlier assumption. Therefore $[\theta^*_{D_j}]_k \neq 0$. Furthermore since $k \in \mathrm{pa}(j)$ is arbitrary, the proof is complete. The proof for part (b) follows exactly the same line of reasoning. ■

Appendix C. Proof for Theorem 12

In this section, we provide the proof for Theorem 12 using the *primal-dual witness method* that also used many works (see e.g., Yang et al. 2012; Meinshausen and Bühlmann 2006; Wainwright et al. 2006; Ravikumar et al. 2011). We begin by introducing propositions to control the tail behavior for the distribution of each node:

Proposition 17 *Define*

$$\xi_1 := \{ \max_{j \in V} \max_{i \in \{1, \cdots, n\}} |X_j^{(i)}| < 4 \log(\eta) \}.$$

Under Assumption 10, $P(\xi_1^c) \leq M \cdot \eta^{-2}$.

Proposition 18 *Suppose that X is a random vector according to the DAG model* (1)*, and Assumption 10 is satisfied. Then, for any vector $u \in \mathbb{R}^p$ such that $\|u\|_1 \leq c'$, for any positive constant δ,*

$$P(|\langle u, X \rangle| \geq \delta \log \eta) \leq M \cdot p \cdot \eta^{-\delta / c'}. \tag{13}$$

Using these concentration results, we show that ℓ_1-penalized regression recovers the neighborhood for a fixed node $j \in V$ with high probability. For ease of notation, we define a new parameter $\theta \in \mathbb{R}^{p-1}$ without the node j since the node j is not penalized in regression problem (9). Then, the conditional negative log-likelihood of the GLM (8) is:

$$\ell_j(\theta; X^{1:n}) := \frac{1}{n}\sum_{i=1}^{n}\left(-X_j^{(i)}\langle\theta, X_{V\setminus j}^{(i)}\rangle + A_j(\langle\theta, X_{V\setminus j}^{(i)}\rangle)\right).$$

The main goal of the proof is to find the unique minimizer of the following convex problem:

$$\widehat{\theta}_{M_j} := \arg\min_{\theta\in\mathbb{R}^{p-1}} \mathcal{L}_j(\theta, \lambda_n) = \arg\min_{\theta\in\mathbb{R}^{p-1}} \{\ell_j(\theta; X^{1:n}) + \lambda_n\|\theta\|_1\}. \tag{14}$$

By setting the *sub-differential* to 0, $\widehat{\theta}_{M_j}$ must satisfy the following condition:

$$\bigtriangledown_\theta \mathcal{L}_j(\widehat{\theta}_{M_j}, \lambda_n) = \bigtriangledown_\theta \ell_j(\widehat{\theta}_{M_j}; X^{1:n}) + \lambda_n \widehat{Z} = 0 \tag{15}$$

where $\widehat{Z} \in \mathbb{R}^{p-1}$ and $\widehat{Z}_t = \text{sign}([\widehat{\theta}_{M_j}]_t)$ if $t \in \mathcal{N}(j)$, otherwise $|\widehat{Z}_t| < 1$.

The following Lemma 19 directly follows from prior works in Ravikumar et al. (2010) and Yang et al. (2012) where each node conditional distribution is in the form of a generalized linear model. For notational convenience, let $S = \mathcal{N}(j)$.

Lemma 19 *Suppose that $|\widehat{Z}_t| < 1$ for $t \notin S$. Then, the solution $\widehat{\theta}_{M_j}$ of (14) satisfies $[\widehat{\theta}_{M_j}]_t = 0$ for $t \notin S$. Furthermore, if the sub-matrix of the Hessian matrix $Q_{SS}^{M_j}$ is invertible, then $\widehat{\theta}_{M_j}$ is unique.*

The remainder of the proof is to show $|\widetilde{Z}_t| < 1$ for all $t \notin S$. Note that the restricted solution in Equation (19) is $(\widetilde{\theta}_{M_j}, \widetilde{Z})$. Equation (15) with the dual solution can be represented by

$$\bigtriangledown^2 \ell_j(\theta^*_{M_j}; X^{1:n})(\widetilde{\theta}_{M_j} - \theta^*_{M_j}) = -\lambda_n \widetilde{Z} - W_j^n + R_j^n$$

where:

(a) W_j^n is the sample score function.

$$W_j^n := -\bigtriangledown \ell_j(\theta^*_{M_j}; X^{1:n}). \tag{16}$$

(b) $R_j^n = (R_{j1}^n, R_{j2}^n, \cdots, R_{jp-1}^n)$ and R_{jk}^n is the remainder term by applying the coordinate-wise mean value theorem.

$$R_{jk}^n := [\bigtriangledown^2 \ell_j(\theta^*_{M_j}; X^{1:n}) - \bigtriangledown^2 \ell_j(\bar{\theta}^{(k)}_{M_j}; X^{1:n})]_k^T(\widetilde{\theta}^{(k)}_{M_j} - \theta^*_{M_j}). \tag{17}$$

Here $\bar{\theta}^{(k)}_{M_j}$ is a vector on the line between $\widetilde{\theta}$ and $\theta^*_{M_j}$ and $[\cdot]_k^T$ is the k^{th} row of a matrix.

Then, the following proposition provides a sufficient condition to control $\widetilde{Z}$.

Proposition 20 *Suppose that* $\max(\|W_j^n\|_\infty, \|R_j^n\|_\infty) \le \frac{\lambda_n\alpha}{4(2-\alpha)}$. *Then $|\widetilde{Z}_t| < 1$ for all $t \notin S$.*

Next we introduce the following three lemmas to show that conditions in Proposition 20 hold. For ease of notation, let $\eta = \max\{n, p\}$ and $\widetilde{\theta}_S = [\widetilde{\theta}_{M_j}]_S$ and $\widetilde{\theta}_{S^c} = [\widetilde{\theta}_{M_j}]_{S^c}$. Suppose that Assumptions 8, 9, 10, and 11 are satisfied.

Lemma 21 *Suppose that $\lambda_n \ge \frac{16\max\{n^{\kappa_2}\log\eta, \log^2\eta)\}}{n^a}$ for some $a \in \mathbb{R}$. Then,*

$$P\left(\frac{\|W_j^n\|_\infty}{\lambda_n} \le \frac{\alpha}{4(2-\alpha)}\right) \ge 1 - 2d\cdot exp(-\frac{\alpha^2}{8(2-\alpha)^2}\cdot n^{1-2a}) - M\cdot\eta^{-2}.$$

Lemma 22 *Suppose that $\|W_j^n\|_\infty \le \frac{\lambda_n}{4}$. For $\lambda_n \le \frac{1}{40}\frac{\rho^2_{\min}}{\rho_{\max}}\frac{1}{n^{\kappa_2} d\log\eta}$,*

$$P\left(\|\widetilde{\theta}_S - \theta^*_S\|_2 \le \frac{5}{\lambda_{\min}}\sqrt{d}\lambda_n\right) \ge 1 - 2M\cdot\eta^{-2}.$$

Lemma 23 *Suppose that $\|W_j^n\|_\infty \le \frac{\lambda_n}{4}$. For $\lambda_n \le \frac{\alpha}{400(2-\alpha)}\frac{\rho^2_{\min}}{\rho_{\max}}\frac{1}{n^{\kappa_2} d\log\eta}$,*

$$P\left(\frac{\|R_j^n\|_\infty}{\lambda_n} \le \frac{\alpha}{4(2-\alpha)}\right) \ge 1 - 2M\cdot\eta^{-2}.$$

The rest of the proof is straightforward using Lemmas 21, 22, and 23. Consider the choice of regularization parameter $\lambda_n = \frac{16\max\{n^{\kappa_2}\log\eta, \log^2\eta\}}{n^a}$ for a constant $a \in (2\kappa_2, 1/2)$ where κ_2 is determined by Assumption 11. Then, the condition for Lemma 21 is satisfied, and therefore $\|W_n\|_\infty \le \frac{\lambda_n}{4}$. Moreover, the conditions for Lemmas 22 and 23 are satisfied for $n \ge C'\max\{(d\log^2\eta)^{\frac{1}{a-2\kappa_2}}, (d\log^3\eta)^{\frac{1}{a-\kappa_2}}\}$ for some positive constant C'. Then,

$$\|\widetilde{Z}_{S^c}\|_\infty \le (1-\alpha) + (2-\alpha)\left[\frac{\|W_j^n\|_\infty}{\lambda_n} + \frac{\|R_j^n\|_\infty}{\lambda_n}\right] \le (1-\alpha) + \frac{\alpha}{4} + \frac{\alpha}{4} < 1, \tag{18}$$

with probability of at least $1 - C_1 d\exp(-C_2 n^{1-2a}) - C_3\eta^{-2}$ for positive constants C_1, C_2 and C_3.

To prove sign consistency, it is sufficient to show that $\|\widehat{\theta}_{M_j} - \theta^*_{M_j}\|_\infty \le \frac{\|\theta^*_{M_j}\|_{\min}}{2}$. By Lemma 22, we have $\|\widehat{\theta}_{M_j} - \theta^*_{M_j}\|_\infty \le \|\widehat{\theta}_{M_j} - \theta^*_{M_j}\|_2 \le \frac{5}{\lambda_{\min}}\sqrt{d}\ \lambda_n \le \frac{\|\theta^*_{M_j}\|_{\min}}{2}$ as long as $\|\theta^*_{M_j}\|_{\min} \ge \frac{10}{\lambda_{\min}}\sqrt{d}\ \lambda_n$.

Lemma 7(b) guarantees that ℓ_1-penalized likelihood regression recovers the true neighborhood for each node with high probability. Because we have p likelihood regression problems, if $n \ge C'(d\log^2\eta)^{\frac{1}{a-2\kappa_2}})$, it follows that:

$$P(\widehat{G^m} = G^m) \ge 1 - C_1 d\cdot p\cdot\exp(-C_2 n^{1-2a}) - C_3\eta^{-1}.$$

C.1 Proof for Proposition 17

Proof Applying the union bound and the Chernoff bound,

$$P(\xi_1^c) \le n.p.\max_{j\in V}\max_{i\in\{1,\cdots,n\}} P\left(|X_j^{(i)}| > 4\log\eta\right) \le \eta^{-2}\max_{i,j}\mathbb{E}[\exp(|X_j^{(i)}|)].$$

By Assumption 10, we obtain $\max_{i,j}\mathbb{E}(\exp(|X_j|^{(i)})) < M$, which completes the proof. ■

C.2 Proof for Proposition 18

Proof We exploit Hölder's inequality $\langle u, X\rangle \leq \|u\|_1 \max_{j\in V}|X_j|$. Therefore, we have

$$P(|\langle u, X\rangle)| \geq \delta \log \eta) \leq P(\max_{j\in V}|X_j| \geq \frac{\delta}{\|u\|_1}\log\eta).$$

Using the union bound, we have

$$P(\max_{j\in V}|X_j| \geq \frac{\delta}{\|u\|_1}\log\eta) \leq p\cdot\max_{j\in V}P(|X_j| \geq \frac{\delta}{\|u\|_1}\log\eta).$$

Applying the Chernoff bounding technique and Assumption 10 $\max_j \mathbb{E}(\exp(|X_j|) < M$, we obtain

$$p\cdot\max_{j\in V}P(|X_j| \geq \frac{\delta}{\|u\|_1}\log\eta) \leq M\cdot p\cdot\eta^{-\frac{\delta}{\|u\|_1}}.$$

By the assumption $\|u\|_1 \leq c'$, we compete the proof. ■

C.3 Proof for Proposition 20

Proof Since $\widetilde{\theta}_{S^c} = (0, 0, ..., 0) \in \mathbb{R}^{|S^c|}$ in our primal-dual construction, we can re-state condition (15) in block form as follows. For notational simplicity, $Q := Q^{M_j}$.

$$\begin{aligned} Q_{S^cS}[\widetilde{\theta}_S - \theta_S] &= W^n_{S^c} - \lambda_n\widetilde{Z}_{S^c} + R^n_{S^c}, . \\ Q_{SS}[\widetilde{\theta}_S - \theta^*_S] &= W^n_S - \lambda_n\widetilde{Z}_S + R^n_S, \end{aligned}$$

where W^n_S and R^n_S are sub-vectors of W^n_j and R^n_j indexed by S, respectively.

Since the matrix Q_{SS} is invertible, the above equations can be rewritten as

$$Q_{S^cS}Q^{-1}_{SS}[W^n_S - \lambda_n\widetilde{Z}_S - R^n_S] = W^n_{S^c} - \lambda_n\widetilde{Z}_{S^c} - R^n_{S^c}.$$

Therefore

$$[W^n_{S^c} - R^n_{S^c}] - Q_{S^cS}Q^{-1}_{SS}[W^n_S - R^n_S] + \lambda_n Q_{S^cS}Q^{-1}_{SS}\widetilde{Z}_S = \lambda_n\widetilde{Z}_{S^c}.$$

Taking the ℓ_∞ norm of both sides yields

$$\|\widetilde{Z}_{S^c}\|_\infty \leq |||Q_{S^cS}Q^{-1}_{SS}|||_\infty\left[\frac{\|W^n_S\|_\infty}{\lambda_n} + \frac{\|R^n_S\|_\infty}{\lambda_n} + 1\right] + \frac{\|W^n_{S^c}\|_\infty}{\lambda_n} + \frac{\|R^n_{S^c}\|_\infty}{\lambda_n}.$$

Recalling Assumption (9), we obtain $|||Q_{S^cS}Q^{-1}_{SS}|||_\infty \leq (1-\alpha)$, hence we have

$$\begin{aligned} \|\widetilde{Z}_{S^c}\|_\infty &\leq (1-\alpha)\left[\frac{\|W^n_S\|_\infty}{\lambda_n} + \frac{\|R^n_S\|_\infty}{\lambda_n} + 1\right] + \frac{\|W^n_{S^c}\|_\infty}{\lambda_n} + \frac{\|R^n_{S^c}\|_\infty}{\lambda_n} \\ &\leq (1-\alpha) + (2-\alpha)\left[\frac{\|W^n_j\|_\infty}{\lambda_n} + \frac{\|R^n\|_\infty}{\lambda_n}\right]. \end{aligned}$$

If $\|W^n_j\|_\infty$ and $\|R^n_j\|_\infty \leq \frac{\lambda_n\alpha}{4(2-\alpha)}$ as assumed,

$$\|\widetilde{Z}_{S^c}\|_\infty \leq (1-\alpha) + \frac{\alpha}{2} \leq 1.$$

■

C.4 Proof for Lemma 19

Proof The main idea of the proof is the *primal-dual-witness* method which asserts that there is a solution to the dual problem $\widetilde{\theta}_{M_j} = \widehat{\theta}_{M_j}$ if the following KKT conditions are satisfied:

(a) We define $\widetilde{\theta}_{M_j} \in \Theta_{M_j}$ where $\Theta_{M_j} = \{\theta \in \mathbb{R}^{p-1} : \theta_{S^c} = 0\}$ as the solution to the following optimization problem.

$$\widetilde{\theta}_{M_j} := \arg\min_{\theta\in\Theta_{M_j}} \mathcal{L}(\theta, \lambda_n) = \arg\min_{\theta\in\Theta_{M_j}} \{\ell_j(\theta; X^{1:n}) + \lambda_n\|\theta\|_1\}. \tag{19}$$

(b) Define $\widetilde{Z}$ to be a sub-differential for the regularizer $\|\cdot\|_1$ evaluated at $\widetilde{\theta}_{M_j}$. For any $t \in S$, $\widetilde{Z}_t = \text{sign}([\widetilde{\theta}_{M_j}]_t)$.

(c) For any $t \notin S$, $|\widetilde{Z}_t| < 1$.

If conditions (a), (b), and (c) are satisfied, $\widehat{\theta}_{M_j} = \widetilde{\theta}_{M_j}$, meaning that the solution of the unrestricted problem (14) is the same as the solution of the restricted problem (19). Conditions (a), (b) and (c) suffice to obtain a pair $(\widetilde{\theta}_{M_j}, \widetilde{Z})$ that satisfies the optimality condition (15), but do not guarantee that $\widetilde{Z}$ is an element of the sub-differential $\|\widetilde{\theta}_{M_j}\|_1$ (see details in Ravikumar et al. 2010, 2011). Since the sub-matrix of the Hessian $Q^{M_j}_{SS}$ is invertible, the restricted problem (19) is strictly convex, $\widetilde{\theta}_{M_j}$ is unique. ■

C.5 Proof for Lemma 21

Proof Each entry of the sample score function W^n_j in Equation (16) has the form $W^n_{jt} = \frac{1}{n}\sum_{i=1}^n W^{(i)}_{jt}$ for any $t \in S$. In addition, $W^n_{jt} = 0$ for all $t \notin S$ since $[\theta^*_{M_j}]_t = 0$ by the construction of $\theta^*_{M_j}$ in Equation (7). For any $t \in S$ and $i \in \{1, 2, \cdots, n\}$, $W^{(i)}_{jt} = X^{(i)}_t X^{(i)}_j - A'_j(\langle\theta^*_S, X^{(i)}_S\rangle)X^{(i)}_t$ are independent and have mean 0.

Now, we show that $(|W^{(i)}_{jt}|)^n_{i=1}$ are bounded with high probability given the following event ξ_1 using Hoeffding's inequality. Event ξ_1 is defined as follows:

$$\xi_1 := \left\{\max_{j\in V}\max_{i\in\{1,\cdots,n\}}|X^{(i)}_j| < 4\log\eta\right\}.$$

Conditioning on ξ_1, it follows that $\langle\theta^*_S, X^{(i)}_S\rangle < 4\log(\eta)\cdot\|\theta^*_S\|_1$, Assumption 11 is satisfied. Hence $\max_i|A'_j(\langle\theta^*_S, X^{(i)}_S\rangle)| \leq n^{\kappa_2}$. Furthermore given ξ_1, $\max_i X^{(i)}_t X^{(i)}_j < 16\log^2\eta$. Therefore there exists a constant $C_{\max}(\eta, \kappa_2) := 16\max\{n^{\kappa_2}\log\eta, \log^2\eta\}$ such that $\max_{i,j,t}|W^{(i)}_{jt}| \leq C_{\max}(\eta, \kappa_2)$.

Recall that d is the maximum degree of the moralized graph, therefore $|S| \leq d$. Applying the union bound,

$$P(\|W^n_j\|_\infty > \delta, \xi_1) \leq d\cdot\max_{t\in S}P(|W^n_{jt}| > \delta, \xi_1).$$

Using Hoeffding's inequality,

$$d \cdot \max_{t \in S} P(|W_{jt}^n| > \delta, \xi_1) \leq 2d \cdot \exp(-\frac{2n\delta^2}{C_{\max}(\eta,\kappa_2)^2}).$$

Suppose that $\delta = \frac{\lambda_n \alpha}{4(2-\alpha)}$ and $\lambda_n \geq \frac{C_{\max}(\eta,\kappa_2)}{n^a}$ for some $a \in [0, 1/2)$. Then

$$\begin{aligned} P(\frac{\|W_j^n\|_\infty}{\lambda_n} > \frac{\alpha}{4(2-\alpha)}, \xi_1) &\leq 2d \cdot \exp\Big(- \frac{\alpha^2}{8(2-\alpha)^2} \frac{n\lambda_n^2}{C_{\max}(\eta,\kappa_2)^2}\Big) \\ &\leq 2d \cdot \exp\Big(- \frac{\alpha^2}{8(2-\alpha)^2} n^{1-2a}\Big). \end{aligned} \tag{20}$$

Since $P(A) = P(A \cap B) + P(A \cap B^c) \leq P(A \cap B) + P(B^c)$,

$$P(\frac{\|W_j^n\|_\infty}{\lambda_n} > \frac{\alpha}{4(2-\alpha)}) \quad \leq \quad P(\frac{\|W_j^n\|_\infty}{\lambda_n} > \frac{\alpha}{4(2-\alpha)}, \xi_1) + P(\xi_1^c).$$

Then, the probability bound in Equation (20) and Proposition 17 $P(\xi_1^c) \leq M \cdot \eta^{-2}$ directly implies that

$$P(\frac{\|W_j^n\|_\infty}{\lambda_n} > \frac{\alpha}{4(2-\alpha)}) \leq 2d \cdot \exp\Big(- \frac{\alpha^2}{8(2-\alpha)^2} n^{1-2a}\Big) + M \cdot \eta^{-2}.$$

■

C.6 Proof for Lemma 22

Proof In order to establish the error bound $\|\widetilde{\theta}_S - \theta_S^*\| \leq B$ for some radius B, several works (Yang et al., 2012; Ravikumar et al., 2010, 2011) already proved that it suffices to show $F(u_S) > 0$ for all $u_S := \widetilde{\theta}_S - \theta_S^*$ such that $\|u_S\|_2 = B$ where

$$F(a) := \ell_j(\theta_S^* + a; X^{1:n}) - \ell_j(\theta_S^*; X^{1:n}) + \lambda_n(\|\theta_S^* + a\|_1 - \|\theta_S^*\|_1). \tag{21}$$

More specifically, since $u_S = \widetilde{\theta}_S - \theta_S^*$ is the minimizer of F and $F(0) = 0$ by the construction of Equation (21), $F(u_S) \leq 0$. Note that F is convex, and therefore we have $F(u_S) < 0$. Next we claim that $\|u_S\|_2 \leq B$. In fact, if u_S lies outside the ball of radius B, then the convex combination $v \cdot u_S + (1-v) \cdot 0$ would lie on the boundary of the ball, for an appropriately chosen $v \in (0, 1)$. By convexity,

$$F(v \cdot u_S + (1-v) \cdot 0) \leq v \cdot F(u_S) + (1-v) \cdot 0 \leq 0 \tag{22}$$

contradicting the assumed strict positivity of F on the boundary.

Thus it suffices to establish strict positivity of F on the boundary of the ball with radius $B := M_1 \lambda_n \sqrt{d}$ where $M_1 > 0$ is a parameter to be chosen later in the proof. Let $u_S \in \mathbb{R}^{|S|}$ be an arbitrary vector with $\|u_S\|_2 = B$. By the Taylor series expansion of F (21),

$$F(u_S) = (W_S^n)^T u_S + u_S^T [\nabla^2 \ell_j(\theta_M^* + v u_S; x)] u_S + \lambda_n(\|\theta_S^* + u_S\|_1 - \|\theta_S^*\|_1), \tag{23}$$

for some $v \in [0, 1]$. Since $\|W_S^n\|_\infty \leq \frac{\lambda_n}{4}$ by assumption and $\|u_S\|_1 \leq \sqrt{d}\|u_S\|_2 \leq \sqrt{d} \cdot B$, the first term in Equation (23) has the following bound:

$$|(W_S^n)^T u_S| \leq \|W_S^n\|_\infty \|u_S\|_1 \leq \|W_S^n\|_\infty \sqrt{d}\|u_S\|_2 \leq (\lambda_n \sqrt{d})^2 \frac{M_1}{4}.$$

Applying the triangle inequality to the last part of Equation (23), we have the following bound.

$$\lambda_n(\|\theta_S^* + u_S\|_1 - \|\theta_S^*\|_1) \geq -\lambda_n \|u_S\|_1 \geq -\lambda_n \sqrt{d}\|u_S\|_2 = -M_1(\lambda_n \sqrt{d})^2.$$

Next we bound $\lambda_{\min}\left(\nabla^2 \ell_j(\theta_S^* + v u_S)\right)$ where $\lambda_{\min}(\cdot)$ is the minimum eigenvalue of a matrix:

$$\begin{aligned} q^* &:= \lambda_{\min}\left(\nabla^2 \ell_j(\theta_S^* + v u_S)\right) \\ &\geq \min_{v \in [0,1]} \lambda_{\min}\left(\nabla^2 \ell_j(\theta_S^* + v u_S)\right) \\ &\geq \lambda_{\min}\left(\nabla^2 \ell_j(\theta_S^*)\right) - \max_{v \in [0,1]} \|\frac{1}{n} \sum_{i=1}^n A_j'''(\langle \theta_S^* + v u_S, X_S \rangle) u_S^T X_S^{(i)} X_S^{(i)} (X_S^{(i)})^T\|_2 \\ &\geq \rho_{\min} - \max_{v \in [0,1]} \max_{y : \|y\|_2 = 1} \frac{1}{n} \sum_{i=1}^n |A_j'''(\langle \theta_S^* + v u_S, X_S \rangle)| \cdot |u_S^T X_S^{(i)}| \cdot (y^T X_S^{(i)})^2. \end{aligned} \tag{24}$$

Next we define the event ξ_2 in order to bound $A_j'''(\langle \theta_S^* + v u_S, X_S \rangle)$.

$$\xi_2 := \{ \max_{i \in \{1, \cdots, n\}} \langle \theta_S^* + v u_S, X_S^{(i)} \rangle < \kappa_1 \log \eta \}.$$

On ξ_2, Assumption 11 is satisfied and

$$A_j'''(\langle \theta_S^* + v u_S, X_S \rangle) \leq n^{\kappa_2}. \tag{25}$$

In addition, we bound the second term in Equation (24). Recall that $\|X_S^{(i)}\|_\infty \leq 4 \log \eta$ for all $i \in \{1, 2, \cdots, n\}$ on ξ_1. Since $\|u_S\|_1 \leq \sqrt{d}\|u_S\|_2 \leq \sqrt{d} \cdot B$,

$$|u_S^T X_S^{(i)}| \leq 4 \log(\eta) \sqrt{d} \|u_S\|_2 \leq 4 \log(\eta) \cdot M_1 \lambda_n d. \tag{26}$$

Lastly, it is clear that $\max_{y : \|y\|_2 = 1} (y^T X_S^{(i)})^2 \leq \rho_{\max}$ by the definition of the maximum eigenvalue and Assumption 8. Together with the bounds of Equations (25) and (26) on the events ξ_1 and ξ_2,

$$q^* \leq \rho_{\min} - 4n^{\kappa_2} \log(\eta) \cdot M_1 \lambda_n d \ \rho_{\max}.$$

For $\lambda_n \leq \frac{\rho_{\min}}{8n^{\kappa_2} \log(\eta) M_1 d \rho_{\max}}$, we have $q^* \leq \frac{\rho_{\min}}{2}$. Therefore,

$$F(u) \geq (\lambda_n \sqrt{n})^2 \Big\{ - \frac{1}{4} M_1 + \frac{\rho_{\min}}{2} M_1^2 - M_1 \Big\},$$

which is strictly positive for $M_1 = \frac{5}{\rho_{\min}}$. Therefore for $\lambda_n \leq \frac{\rho_{\min}^2}{40 n^{\kappa_2} \log(\eta) d \rho_{\max}}$ given ξ_1 and ξ_2,

$$\|\widetilde{\theta}_S - \theta_S^*\|_2 \leq \frac{5}{\rho_{\min}} \sqrt{d} \lambda_n.$$

Since $P(A) = P(A \cap B \cap C) + P(A \cap (B \cap C)^c) \leq P(A \cap B \cap C) + P(B^c) + P(C^c)$,

$$P\left(\|\widetilde{\theta}_S - \theta^*_S\|_2 > \frac{5}{\rho_{\min}}\sqrt{d}\lambda_n\right) \leq P\left(\|\widetilde{\theta}_S - \theta^*_S\|_2 > \frac{5}{\rho_{\min}}\sqrt{d}\lambda_n, \xi_1, \xi_2\right) + P(\xi_1^c) + P(\xi_2^c).$$

Here the probability of ξ_2^c is upped bounded as follows.

$$\begin{aligned} P(\xi_2^c) &\overset{(a)}{\leq} n \max_i P(\langle \theta^*_{M_j} + v u_S, X_S^{(i)} \rangle > \kappa_1 \log \eta) \\ &\overset{(b)}{\leq} n \cdot M \cdot \eta^{-\frac{\kappa_1}{2\|\theta^*_{M_j}\|_1}} \\ &\overset{(c)}{\leq} M \cdot \eta^{-2}. \end{aligned}$$

(a) follows from the union bound, and (b) follows from Proposition 18, and $\|u_S\|_1 \leq \sqrt{d}\|u_S\|_2 \leq dM_1\lambda_n \leq \|\theta^*_{M_j}\|_1$ and $\min_{j\in V} \min_{t\in S} |[\theta^*_M]_t| \geq \frac{10}{\rho_{\min}}\sqrt{d}\lambda_n$. Lastly (c) follows from Assumption 11 that $\kappa_1 \geq 6\|\theta^*_{M_j}\|_1$.

In addition the probability bound of ξ_1^c is provided in Proposition 17. Therefore

$$P\left(\|\widetilde{\theta}_S - \theta^*_S\|_2 \leq \frac{5}{\lambda_{\min}}\sqrt{d}\ \lambda_n\right) \geq 1 - 2M \cdot \eta^{-2}.$$

■

C.7 Proof for Lemma 23

Proof According to Equation (17), R^n_{jt} for any $t \in S$ can be expressed as

$$\begin{aligned} R^n_{jt} &= \frac{1}{n}\sum_{i=1}^n [\bigtriangledown^2 \ell_j(\theta^*_{M_j}; X^{1:n}) - \bigtriangledown^2 \ell_j(\bar{\theta}^{(t)}_{M_j}; X^{1:n})]^T_t (\widetilde{\theta} - \theta^*_{M_j}) \\ &= \frac{1}{n}\sum_{i=1}^n [A''_j(\langle \theta^*_S, X^{(i)}_{V\setminus j}\rangle) - A''_j(\langle \bar{\theta}^{(t)}_{M_j}, X^{(i)}_{V\setminus j}\rangle)][X^{(i)}_{V\setminus j}(X^{(i)}_{V\setminus j})^T]^T_t (\widetilde{\theta} - \theta^*_{M_j}) \end{aligned}$$

for $\bar{\theta}^{(t)}_{M_j}$ which is some point in the line between $\widetilde{\theta}_{M_j}$ and $\theta^*_{M_j}$ (i.e., $\bar{\theta}^{(t)}_{M_j} = v\cdot\widetilde{\theta}_{M_j} + (1-v)\cdot\theta^*_{M_j}$ for some $v \in [0,1]$).

By the mean value theorem,

$$R^t_{jt} = \frac{1}{n}\sum_{i=1}^n \left\{A'''_j(\langle \bar{\bar{\theta}}^{(t)}_{M_j}, X^{(i)}_{V\setminus j}\rangle) X^{(i)}_t\right\}\left\{v(\widetilde{\theta}_{M_j} - \theta^*_{M_j})^T X^{(i)}_{V\setminus j}(X^{(i)}_{V\setminus j})^T(\widetilde{\theta}_{M_j} - \theta^*_{M_j})\right\}$$

for $\bar{\bar{\theta}}^{(t)}_{M_j}$ which is a point on the line between $\bar{\theta}^{(t)}_{M_j}$ and $\theta^*_{M_j}$.

By Proposition 17, $\max_{i,j} |X^{(i)}_j| \leq 4\log\eta$ given ξ_1. Furthermore in Section C.6, we showed that $A'''_j(\langle \bar{\bar{\theta}}^{(t)}_{M_j}, X_{M\setminus j}\rangle) \leq n^{\kappa_2}$ given ξ_2 . Therefore, on ξ_1 and ξ_2, it follows that:

$$|R^n_{jt}| \leq 4n^{\kappa_2}\log(\eta)\rho_{\max}\|\widetilde{\theta} - \theta^*_M\|_2^2.$$

We showed that $\|\widetilde{\theta} - \theta^*_M\|_2 \leq \frac{5}{\rho_{\min}}\sqrt{d}\lambda_n$ for $\lambda_n \leq \frac{\alpha}{400(2-\alpha)}\frac{\rho^2_{\min}}{\rho_{\max}}\frac{1}{dn^{\kappa_2}\log(\eta)}$ given ξ_1 and ξ_2 in the proof of Lemma 22. Therefore we obtain

$$\|R^n\|_\infty \leq \frac{100\rho_{\max}}{\rho^2_{\min}} d\ n^{\kappa_2}\log(\eta)\ \lambda_n^2 \leq \frac{\alpha\lambda_n}{4(2-\alpha)}.$$

Since $P(A) = P(A \cap B \cap C) + P(A \cap (B \cap C)^c) \leq P(A \cap B \cap C) + P(B^c) + P(C^c)$,

$$P\left(\|R^n\|_\infty > \frac{\alpha\lambda_n}{4(2-\alpha)}\right) \leq P\left(\|R^n\|_\infty > \frac{\alpha\lambda_n}{4(2-\alpha)}, \xi_1, \xi_2\right) + P(\xi_1^c) + P(\xi_2^c).$$

Putting the probability bounds for ξ_1^c and ξ_2^c specified in Proposition 17 and Section C.6 together, we have

$$P\left(\|R^n_j\|_\infty \leq \frac{\alpha\lambda_n}{4(2-\alpha)}\right) \geq 1 - 2M \cdot \eta^{-2}.$$

■

Appendix D. Proof for Theorem 14

Proof Without loss of generality, assume that the true ordering is $\pi^* = (1, 2, \cdots, p)$. Let $T_j(X_j) := \omega_j X_j$ where $\omega_j = (\beta_0 + \beta_1 \mathbb{E}(X_j \mid X_{\text{pa}(j)}))^{-1}$ (specified in Proposition 3). For any node $j \in V$ and $S \subset V \setminus \{j\}$, let $\mu_{j|S}$ and $\sigma^2_{j|S}$ represent $\mathbb{E}(T_j(X_j) \mid X_S)$ and $\text{Var}(T_j(X_j) \mid X_S)$ respectively. For realizations x_S, let $\mu_{j|S}(x_S)$ and $\sigma^2_{j|S}(x_S)$ denote $\mathbb{E}(T_j(X_j) \mid X_S = x_S)$ and $\text{Var}(T_j(X_j) \mid X_S = x_S)$, respectively. Let $n(x_S) = \sum_{i=1}^n \mathbf{1}(X_S^{(i)} = x_S)$ denote the total conditional sample size, and $n_S = \sum_{x_S} n(x_S)\mathbf{1}(n(x_S) \geq c_0 \cdot n)$ for an arbitrary $c_0 \in (0,1)$ to denote the truncated conditional sample size.

Let E^m denote the set of undirected edges corresponding to the *moralized* graph. Recall the definitions $\mathcal{N}(j) = \{k \in V : (j,k) \text{ or } (k,j) \in E^m\}$ denote the neighborhood set of node j in the moralized graph, $C_{jk} = \mathcal{N}(k) \cap \{\pi_1, \pi_2, \cdots, \pi_{j-1}\}$. Since we assume the structure of the moralized graph is provided, $\widehat{C}_{jk} = C_{jk}$. Hence C_{jk} is used instead of an estimated set $\widehat{C}_{jk}$.

The overdispersion score of node $k \in V \setminus \{\pi_1, ..., \pi_{j-1}\}$ for the j^{th} component of the ordering π_j only depends on $\mathcal{X}(C_{jk}) = \{x \in \{X^{(1)}_{C_{jk}}, X^{(2)}_{C_{jk}}, \cdots, X^{(n)}_{C_{jk}}\} : n(x) \geq c_0 \cdot n\}$, so we only count up elements that occur sufficiently frequently.

According to the generalized ODS algorithm, the truncated sample conditional mean and variance of $T_j(X_j)$ given $X_S = x_S$ are:

$$\begin{aligned} \widehat{\mu}_{j|S}(x_S) &:= \frac{1}{n_S(x_S)}\sum_{i=1}^n T_j(X_j^{(i)})\mathbf{1}(X_S^{(i)} = x_S), \\ \widehat{\sigma}^2_{j|S}(x_S) &:= \frac{1}{n_S(x_S) - 1}\sum_{i=1}^n (T_j(X_j^{(i)}) - \widehat{\mu}_{j|S}(x_S))^2\mathbf{1}(X_S^{(i)} = x_S). \end{aligned}$$

We rewrite the overdispersion score (5) of node $k \in V \setminus \{\pi_1, ..., \pi_{j-1}\}$ for π_j as follows:

$$\begin{aligned}
\widehat{\mathcal{S}}(1,k) &:= \left[\left(\frac{\widehat{\sigma}_k}{\beta_0+\beta_1\widehat{\mu}_k}\right)^2 - \frac{\widehat{\mu}_k}{\beta_0+\beta_1\widehat{\mu}_k}\right], \\
\widehat{\mathcal{S}}(m,k) &:= \sum_{x\in\mathcal{X}(C_{mk})} \frac{n(x)}{n_{C_{mk}}}\left[\left(\frac{\widehat{\sigma}_{k|C_{mk}}(x)}{\beta_0+\beta_1\widehat{\mu}_{k|C_{mk}}(x)}\right)^2 - \frac{\widehat{\mu}_{k|C_{mk}}(x)}{\beta_0+\beta_1\widehat{\mu}_{k|C_{mk}}(x)}\right].
\end{aligned}$$

For notational convenience, let each entry of the overdispersion score $\widehat{\mathcal{S}}(m,k)$ for $x \in \mathcal{X}(C_{mk})$ be defined as:

$$\widehat{\mathcal{S}}(m,k)(x) := \left(\frac{\widehat{\sigma}_{k|C_{mk}}(x)}{\beta_0+\beta_1\widehat{\mu}_{k|C_{mk}}(x)}\right)^2 - \frac{\widehat{\mu}_{k|C_{mk}}(x)}{\beta_0+\beta_1\widehat{\mu}_{k|C_{mk}}(x)}. \tag{27}$$

The true overdispersion scores are:

$$\begin{aligned}
\mathcal{S}^*(1,k) &:= \left[\left(\frac{\sigma_k}{\beta_0+\beta_1\mu_k}\right)^2 - \frac{\mu_k}{\beta_0+\beta_1\mu_k}\right], \\
\mathcal{S}^*(m,k) &:= \sum_{x\in\mathcal{X}(C_{mk})} \frac{n(x)}{n_{C_{mk}}}\left[\left(\frac{\sigma_{k|C_{mk}}(x)}{\beta_0+\beta_1\mu_{k|C_{mk}}(x)}\right)^2 - \frac{\mu_{k|C_{mk}}(x)}{\beta_0+\beta_1\mu_{k|C_{mk}}(x)}\right], \\
\mathcal{S}^*(m,k)(x) &:= \left(\frac{\sigma_{k|C_{mk}}(x)}{\beta_0+\beta_1\mu_{k|C_{mk}}(x)}\right)^2 - \frac{\mu_{k|C_{mk}}(x)}{\beta_0+\beta_1\mu_{k|C_{mk}}(x)} \quad \text{for } x \in \mathcal{X}(C_{mk}).
\end{aligned}$$

Next we introduce Proposition 24 which ensures the each component of the true overdispersion score $\mathcal{S}^*(m,k)(x)$ for $k \neq \pi_m$ is bounded away from $m_{\min} > 0$.

Proposition 24 *For all $j \in V$, $pa_0(j) \subset pa(j)$, $pa_0(j) \neq \emptyset$ and $S \subset nd(j) \setminus pa_0(j)$, there exists $m_{\min} > 0$ such that*

$$Var(T_j(X_j) \mid X_S) - \mathbb{E}(T_j(X_j) \mid X_S) > m_{\min}.$$

Now we define the following two events: For any $j \in V$, $k \in V \setminus \{\pi_1, ..., \pi_{j-1}\}$ and $m \in \{1, 2, ..., p-1\}$

$$\begin{aligned}
\xi_1 &:= \{\max_j \max_{i\in\{1,2,\cdots,n\}} |X_j^{(i)}| < 4\log\eta\} \\
\xi_3 &:= \{\max_{m,k} |\widehat{\mathcal{S}}(m,k) - \mathcal{S}^*(m,k)| < \frac{m_{\min}}{2}\}.
\end{aligned}$$

Then,

$$\begin{aligned}
P(\widehat{\pi} \neq \pi^*) &\overset{(a)}{\leq} P(\widehat{\pi} \neq \pi^*, \xi_3) + P(\xi_3^c, \xi_1) + P(\xi_1^c) \\
&\overset{(b)}{\leq} P(\widehat{\pi}_1 \neq \pi_1^*, \xi_3) + P(\widehat{\pi}_2 \neq \pi_2^*, \xi_3 \mid \widehat{\pi}_1 = \pi_1^*) + \cdots \\
&\quad + P(\widehat{\pi}_p \neq \pi_p^*, \xi_3 \mid \widehat{\pi}_1 = \pi_1^*, \cdots, \widehat{\pi}_{p-1} = \pi_{p-1}^*) + P(\xi_3^c, \xi_1) + P(\xi_1^c). \quad (28)
\end{aligned}$$

(a) follows from $P(A) \leq P(A \cap B) + P(B^c)$, and (b) follows from the induction and the fact $P(A \cup B) = P(A) + P(B \cap A^c) = P(A) + P(B \mid A^c)P(A^c) \leq P(A) + P(B \mid A^c)$.

We prove the probability bound (28) by induction. For the first step ($m = 1$), overdispersion scores of π_1 in Equation (4) are used where a set of candidate element of π_1 is $\{1, 2, \cdots, p\}$. Then,

$$\begin{aligned}
P(\widehat{\pi}_1 \neq \pi_1^*, \xi_3) &= P\left(\exists k' \in V \setminus \{\pi_1^*\} \text{ such that } \widehat{\mathcal{S}}(1,\pi_1^*) > \widehat{\mathcal{S}}(1,k'), \xi_3\right) \\
&\overset{(a)}{\leq} (p-1) \max_{k'\in V\setminus\{\pi_1^*\}} P\left(\mathcal{S}^*(1,\pi_1^*) + \frac{m_{\min}}{2} > \mathcal{S}^*(1,k') - \frac{m_{\min}}{2}, \xi_3\right) \\
&\overset{(b)}{=} (p-1) \max_{k'\in V\setminus\{\pi_1^*\}} P\left(m_{\min} > \mathcal{S}^*(1,k), \xi_3\right) \\
&\overset{(c)}{=} 0.
\end{aligned}$$

(a) follows from the union bound and the definition of ξ_3. (b) follows from that $\mathcal{S}^*(1,\pi_1^*) = 0$ by the property of the transformation $T_j(\cdot)$ specified in Proposition 3, and (c) follows from Proposition 24.

For the $m = (j-1)^{th}$ step, assume that the first $j-1$ elements of the estimated ordering are correct $(\widehat{\pi}_1, \widehat{\pi}_2, \cdots, \widehat{\pi}_{j-1}) = (\pi_1^*, \cdots, \pi_{j-1}^*)$. Then for the $m = j^{th}$ step, we consider the probability of a false recovery of π_j^* given $(\pi_1^*, \cdots, \pi_{j-1}^*)$. Using the same argument as the first step, the following result is straightforward.

$$\begin{aligned}
P(\widehat{\pi}_j \neq \pi_j^*, \xi_3 \mid \pi_1^*, \cdots, \pi_{j-1}^*) &= P\left(\exists k \in V \setminus \{\pi_j^*\} \text{ such that } \widehat{\mathcal{S}}(j,\pi_j^*) > \widehat{\mathcal{S}}(j,k), \xi_3\right) \\
&\overset{(a)}{\leq} p \max_{k\in V\setminus\{\pi_j^*\}} P\left(\mathcal{S}^*(j,\pi_j^*) + \frac{m_{\min}}{2} > \mathcal{S}^*(j,k) - \frac{m_{\min}}{2}, \xi_3\right) \\
&\overset{(b)}{=} p \max_{k\in V\setminus\{\pi_j^*\}} P\left(m_{\min} > \mathcal{S}^*(j,k), \xi_3\right) \\
&\overset{(c)}{=} 0.
\end{aligned}$$

Therefore, for any $j \in V$,

$$P(\widehat{\pi}_j \neq \pi_j^*, \xi_3 \mid \widehat{\pi}_1 = \pi_1^*, \cdots, \widehat{\pi}_{j-1} = \pi_{j-1}^*) = 0.$$

Then, the probability bound (28) is reduced to $P(\widehat{\pi} \neq \pi^*) \leq P(\xi_3^c, \xi_1) + P(\xi_1^c)$. Note that $P(\xi_1^c) \leq M \cdot \eta^{-2}$ by Proposition 17. The following lemma provides the upper bound of $P(\xi_3^c, \xi_1)$.

Lemma 25 *There exist positive constants C_1 and C_2 such that*

$$P(\xi_3^c, \xi_1) \leq C_1 p^2 c_0^{-1} exp\left(-C_2 \frac{c_0 \cdot n}{\log^4 \eta}\right).$$

where c_0 is the sample cut-off parameter.

Lastly, we define a condition on the sample cut-off parameter c_0. Intuitively if c_0 is too small, the estimated overdispersion scores may be biased due to the lack of samples.

In contrast, if c_0 is too large, all components of the conditioning set C_{mk} may not have enough samples size ($> c_0 \cdot n$), and therefore overdispersion scores cannot be calculated. The following proposition provides a maximum value of c_0 ensuring that overdispersion scores exist.

Proposition 26 *On the event ξ_1, if $c_0 \leq (3\log(\eta))^{-d}$ then the conditioning set C_{mk} has at least $c_0 \cdot n$ samples.*

The combination of Lemma 25 and Proposition 26 imply that for some C_1 and C_2

$$P(\xi_3^c, \xi_1) \leq C_1 p^2 \log^d(\eta) \exp\left(-C_2 \frac{n}{(\log(\eta))^{4+d}}\right).$$

Therefore,

$$P(\widehat{\pi} \neq \pi^*) \leq C_1 p^2 \log^d(\eta) \exp\left(-C_2 \frac{n}{\log^{4+d}\eta}\right) + \frac{M}{\eta^2}.$$

■

D.1 Proof for Proposition 24

Proof In the proof of the identifiability theorem in Appendix A, we obtain

$$\mathrm{Var}(T_j(X_j) \mid X_S) - \mathbb{E}(T_j(X_j) \mid X_S) = \frac{(1+\beta_1)\mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_S)}{(\beta_0 + \beta_1 \mathbb{E}(X_j \mid X_S))^2}.$$

By Assumption 13, $\mathrm{Var}(\mathbb{E}(X_j \mid X_{pa(j)}) \mid X_S) > M_{\min}$ and $|\beta_{j0} + \beta_{j1}\mathbb{E}(X_j \mid X_S)| > \omega_{\min}$. Then,

$$\mathrm{Var}(T_j(X_j) \mid X_S) - \mathbb{E}(T_j(X_j) \mid X_S) \geq \frac{(1+\beta_1)M_{\min}}{\omega_{\min}^2}.$$

Since $\beta_1 > -1$, the proof is complete. ■

D.2 Proof for Proposition 26

Proof Let $|X_S|$ denote the cardinality of a set $\{X_S^{(1)}, X_S^{(2)}, \cdots, X_S^{(n)}\}$ and $|\mathcal{X}(S)|$ denote the cardinality of the truncated set $\mathcal{X}(S) := \{x \in \{X_S^{(1)}, X_S^{(2)}, \cdots, X_S^{(n)}\} : n(x) \geq c_0 \cdot n\}$.

If $|\mathcal{X}(S)| = 1$, for all $x \in \{X_S^{(1)}, X_S^{(2)}, \cdots, X_S^{(n)}\}$, $n_S(x) = c_0 \cdot n - 1$ except for a single $z \in \mathcal{X}(S)$ where $n_S(z) \geq c_0.n$. In this case, the total sample size $n = n_S(z) + (|X_S| - 1)(c_0 \cdot n - 1)$. Hence

$$n_S(z) = n - (|X_S| - 1)(c_0.n - 1) = n - c_0 \cdot n \cdot |X_S| + c_0 \cdot n + |X_S| - 1.$$

Since $c_0 \cdot n \leq n_S(z)$,

$$c_0 \leq \frac{n + |X_S| - 1}{n \cdot |X_S|}.$$

Note that $\frac{1}{|X_S|} \leq \frac{n+|X_S|-1}{n \cdot |X_S|}$ and $|X_j^{(i)}| \leq 4\log(\eta)$ for all $j \in V$ and $i \in \{1, 2, \cdots, n\}$ given ξ_1. Then the maximum cardinality of X_S is $(4\log(\eta))^{|S|}$. Hence if $c_0 \leq (4\log(\eta))^{-|S|}$ there exists a $z \in \mathcal{X}(S)$.

Recall that the size of a candidate parents set C_{mk} is bounded by the maximum degree of the moralized graph d. Therefore if $c_0 \leq 4\log(\eta)^{-d}$, there exists at least one $z \in \mathcal{X}(C_{mk})$. ■

D.3 Proof for Lemma 25

Proof For ease of notation, let $n_{mk} = n_{C_{mk}}$ and $n_{mk}(x) = n_{C_{mk}}(x)$ for $x \in \mathcal{X}(C_{mk})$. Using the union bound, for $m \in \{1, 2, ..., p-1\}$ and $k \in V \setminus \{\pi_1, ..., \pi_{j-1}\}$

$$\begin{aligned} P(\xi_3^c, \xi_1) &= P(\max_{m,k} |\widehat{\mathcal{S}}(m,k) - \mathcal{S}^*(m,k)| > \frac{m_{\min}}{2}, \xi_1) \\ &\leq p^2 \max_{m,k} P(|\widehat{\mathcal{S}}(m,k) - \mathcal{S}^*(m,k)| > \frac{m_{\min}}{2}, \xi_1). \end{aligned}$$

Since overdispersion scores have an additive form,

$$P(|\widehat{\mathcal{S}}(m,k) - \mathcal{S}^*(m,k)| > \frac{m_{\min}}{2}, \xi_1) \leq P(\sum_{x \in \mathcal{X}(C_{mk})} \frac{n_{mk}(x)}{n_{mk}} |\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1).$$

Applying $P(\sum_i Y_i > \delta) \leq \sum_i P(Y_i > \omega_i \delta)$ for any $\delta \in \mathbb{R}$ and $\omega_i \in \mathbb{R}^+$ such that $\sum_i \omega_i = 1$, we have

$$\begin{aligned} P(\sum_{x \in \mathcal{X}(C_{mk})} \frac{n_{mk}(x)}{n_{mk}} |\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1) \\ \leq \sum_{x \in \mathcal{X}(C_{mk})} P(|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1). \end{aligned}$$

Applying the union bound,

$$\begin{aligned} \sum_{x \in \mathcal{X}(C_{mk})} P(|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1) \\ \leq |\mathcal{X}(C_{mk})| \max_{x \in \mathcal{X}(C_{mk})} P(|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}(m,k)^*(x)| > \frac{m_{\min}}{2}, \xi_1). \end{aligned}$$

Since we only consider $x \in \mathcal{X}(C_{mk})$, it follows that $n_{mk}(x) \geq c_0 \cdot n$. Further since the total truncated sample size is less than total sample size, $c_0 \cdot n \cdot |\mathcal{X}(C_{mk})| \leq n$, and therefore the cardinality of C_{mk} is at most c_0^{-1}. Hence

$$\begin{aligned} |\mathcal{X}(C_{mk})| \max_{x \in \mathcal{X}(C_{mk})} P(|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1) \\ \leq c_0^{-1} \max_{x \in \mathcal{X}(C_{mk})} P(|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1). \end{aligned}$$

Since the overdispersion score is the difference between the conditional mean and conditional variance, the remainder of the proof is reduced to finding the sample complexity for

the sample conditional mean and variance. Suppose that $\epsilon := \widehat{\mu}_{k|C_{mk}}(x) - \mu_{k|C_{mk}}(x)$ and $\kappa \cdot \epsilon := \widehat{\sigma}^2_{k|C_{mk}}(x) - \sigma^2_{k|C_{mk}}(x)$ for some $\kappa \in \mathbb{R}$. By the definition of the overdispersion scores in Equation (27), we have

$$
\begin{aligned}
&\{\epsilon : |\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}\} \\
&\subset \left\{\epsilon : \left| \left(\frac{\sigma_{k|C_{mk}}(x) + \kappa\epsilon}{\beta_0 + \beta_1 \mu_{k|C_{mk}}(x) + \epsilon}\right)^2 - \frac{\mu_{k|C_{mk}}(x) + \epsilon}{\beta_0 + \beta_1 \mu_{k|C_{mk}}(x) + \epsilon} \right.\right. \\
&\qquad \left.\left. - \left(\frac{\sigma_{k|C_{mk}}(x)}{\beta_0 + \beta_1 \mu_{k|C_{mk}}(x)}\right)^2 - \frac{\mu_{k|C_{mk}}(x)}{\beta_0 + \beta_1 \mu_{k|C_{mk}}(x)} \right| > \frac{m_{\min}}{2} \right\} \\
&= \{\epsilon : \epsilon \in (\epsilon_1, \epsilon_2) \cup (\epsilon_3, \epsilon_4)\}\,.
\end{aligned}
$$

where $\epsilon_1, \epsilon_2, \epsilon_3, \epsilon_4$ are constants that depend on $\mu, \sigma^2, \beta_0, \beta_1, m_{\min}$, and κ and are constructed as follows:

$$
\begin{aligned}
\zeta_1(\mu,\sigma^2,\beta_0,\beta_1,m_{\min},\kappa) &:= \beta_0^3(1+\beta_1 m_{\min}) - \beta_1^4 m_{\min}\mu^3 + 2\beta_1^2\mu^2\kappa\sigma^2 - 2\beta_1^2\mu\sigma^4 \\
&\quad + \beta_0^2(-2\beta_1\mu - 3\beta_1^2 m_{\min}\mu + 2\kappa\sigma^2) - \beta_0\beta_1\{\beta_1\mu^2 + 3\beta_1^2 m_{\min}\mu^2 + 2\sigma^2(-2\kappa\mu + \sigma^2)\}, \\
\zeta_2(\mu,\sigma^2,\beta_0,\beta_1,m_{\min},\kappa) &:= (\beta_0+\beta_1\mu)^2\Big[\beta_0^4(1+2\kappa\mu) + 2\beta_1^2(\kappa\mu - \sigma^2)^2(\beta_1^2\mu^2 m_{\min} + 2\sigma^4) \\
&\quad + 4\beta_0\beta_1(\kappa\mu - \sigma^2)\{\beta_1^2\mu m_{\min}(2\kappa\mu - \sigma^2) + \beta_1\mu\sigma^2 - 2\kappa\sigma^2\} \\
&\quad + 2\beta_0^3\{-2\kappa\sigma^2 + \beta_1(\mu + 4m_{\min}\kappa^2\mu - 2m_{\min}\kappa\sigma^2)\} \\
&\quad + \beta_0^2\{4\kappa^2\sigma^4 + 4\beta_1\sigma^2(-2\kappa\mu + \sigma^2) + \beta_1^2(\mu^2 + 12m_{\min}\kappa^2\mu^2 - 12m_{\min}\mu\kappa\sigma^2 + 2m_{\min}\sigma^4)\}\Big], \\
\zeta_3(\mu,\sigma^2,\beta_0,\beta_1,m_{\min},\kappa) &:= \beta_0^2(-2\kappa^2 + 2\beta_1 + \beta_1^2 m_{\min}) + 2\beta_0\beta\mu(\beta_1 + \beta_1^2 m_{\min} - \kappa^2) \\
&\quad + \beta_1^2(\beta_1^2 m_{\min}\mu^2 + 2\sigma^4 - 2\kappa^2\mu^2).
\end{aligned}
$$

Given $\zeta_1, \zeta_2, \zeta_3$,

$$
\begin{aligned}
\epsilon_1' &= \frac{\zeta_1(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa) + \sqrt{\zeta_2(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa)}}{\zeta_3(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa)}, \\
\epsilon_2' &= \frac{-\zeta_1(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa) + \sqrt{\zeta_2(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa)}}{\zeta_3(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, m_{\min}, \kappa)}, \\
\epsilon_3' &= \frac{\zeta_1(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa) + \sqrt{\zeta_2(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa)}}{\zeta_3(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa)}, \\
\epsilon_4' &= \frac{-\zeta_1(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa) + \sqrt{\zeta_2(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa)}}{\zeta_3(\mu_{k|C_{mk}}(x), \sigma^2_{k|C_{mk}}(x), \beta_0, \beta_1, -m_{\min}, \kappa)}.
\end{aligned}
$$

Let $(\epsilon_1, \epsilon_2, \epsilon_3, \epsilon_4)$ be the ordered values of $(\epsilon_1', \epsilon_2', \epsilon_3', \epsilon_4')$ from smallest to largest. Since $m_{\min} > 0$ it follows that $\epsilon_1, \epsilon_2 < 0$ and $\epsilon_3, \epsilon_4 > 0$.

For ease of notation, $\epsilon_{\min} = \min\{|\epsilon_2|, |\epsilon_3|\}$. Then,

$$
\{\epsilon : |\widehat{\mathcal{S}}(j,k)(x) - \mathcal{S}^*(j,k)(x)| > \frac{m_{\min}}{2}\} \subset (-\infty, -\epsilon_{\min}) \cup (\epsilon_{\min}, \infty).
$$

Hence

$$
\begin{aligned}
&P\{|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}\} \\
&\qquad \le P\left(|\widehat{\mu}_{k|C_{mk}}(x) - \mu_{k|C_{mk}}(x)| > \epsilon_{\min}\right) + P\left(|\widehat{\sigma}^2_{k|C_{mk}}(x) - \sigma^2_{k|C_{mk}}(x)| > \kappa\epsilon_{\min}\right).
\end{aligned}
$$

On ξ_1, $\max_{i,j} |X_j^{(i)}| \le 4\log(\eta)$. Furthermore recall that $n_{mk}(x) \ge c_0 \cdot n$. By applying Hoeffding's inequality,

$$
P(|\widehat{\mu}_{k|C_{mk}}(x) - \mu_{k|C_{mk}}(x)| > \epsilon_{\min}, \xi_1) \le 2\exp\left(-\frac{\epsilon^2_{\min} c_0.n}{8\log^2\eta}\right).
$$

Note that sample variance can be decomposed as follows:

$$
\frac{1}{n-1}\left(\sum_i^n X_i^2 - \frac{1}{n}(\sum_i^n X_i)^2\right) = \frac{1}{n}\sum_i^n X_i^2 - \frac{1}{n(n-1)}\sum_{i\neq j} X_i X_j.
$$

Using Hoeffding's inequality for the decomposed sample variance,

$$
P(|\widehat{\sigma}^2_{k|C_{mk}}(x) - \sigma^2_{k|C_{mk}}(x)| > |\kappa| \cdot \epsilon_{\min}, \xi_1) \le 2\exp\left(-\frac{\kappa^2\epsilon^2_{\min} c_0 \cdot n}{128\log^4\eta}\right) + 2\exp\left(-\frac{\kappa^2\epsilon^2_{\min} c_0 \cdot n}{256\log^4\eta}\right).
$$

Therefore,

$$
\begin{aligned}
&P\{|\widehat{\mathcal{S}}(m,k)(x) - \mathcal{S}^*(m,k)(x)| > \frac{m_{\min}}{2}, \xi_1\} \\
&\qquad \le 2\left(\exp\left(-\frac{\epsilon^2_{\min} c_0.n}{8\log^2\eta}\right) + \exp\left(-\frac{\kappa^2\epsilon^2_{\min} c_0 \cdot n}{128\log^4\eta}\right) + \exp\left(-\frac{\kappa^2\epsilon^2_{\min} c_0 \cdot n}{256\log^4\eta}\right)\right).
\end{aligned}
$$

This completes the proof since there exist constants C_1 and C_2 such that

$$
P(\xi_3^c, \xi_1) \le C_1 p^2 c_0^{-1} \exp\left(-C_2 \frac{c_0 \cdot n}{\log^4\eta}\right).
$$

■

Appendix E. Proof for Theorem 15

Proof Once again we use the *primal-dual witness* method used in the the proof for Theorem 12. The only difference is the conditioning set. In this proof, the conditioning set is all elements of the ordering before node j rather than j is $V \setminus \{j\}$. Without loss of generality, we assume the true ordering is $\pi^* = (1, 2, \cdots, p)$. Then the conditioning set is $\{1, 2, \cdots, j-1\}$.

For ease of notation, we define the parameter $\theta \in \mathbb{R}^{j-1}$ since the node j is not penalized in (11). Then, the conditional negative log-likelihood of a GLM (10) for X_j given $X_{1:j-1}$ is:

$$\ell_j^D(\theta; X^{1:n}) = \frac{1}{n}\sum_{i=1}^{n}\left(-X_j^{(i)}\langle\theta, X_{1:j-1}^{(i)}\rangle + A_j(\langle\theta, X_{1:j-1}^{(i)}\rangle)\right).$$

Recall that for any node $j \in V$:

$$\widehat{\theta}_{D_j} := \arg\min_{\theta\in\mathbb{R}^{j-1}} \mathcal{L}_j^D(\theta, \lambda_n^D) = \arg\min_{\theta\in\mathbb{R}^{j-1}} \{\ell_j^D(\theta; X^{1:n}) + \lambda_n^D\|\theta\|_1\}.$$

Using the *sub-differential*, $\widehat{\theta}_{D_j}$ should satisfy the following condition. For notational simplicity, let $S = \mathrm{pa}(j)$ for node $j \in V$.

$$\bigtriangledown_\theta \mathcal{L}_j^D(\widehat{\theta}_{D_j}, \lambda_n^D) = \bigtriangledown_\theta \ell_j^D(\widehat{\theta}_{D_j}; X^{1:n}) + \lambda_n^D \widehat{Z} = 0 \tag{29}$$

where $\widehat{Z} \in \mathbb{R}^{j-1}$ and $\widehat{Z}_t = \mathrm{sign}([\widehat{\theta}_{D_j}]_t)$ if a node $t \in S$, otherwise $|\widehat{Z}_t| < 1$.

By Lemma 19, it is sufficient the show that $|\widehat{Z}_t| < 1$ for all $t \in S$. We note that the restricted solution is $(\widetilde{\theta}_{D_j}, \widetilde{Z})$. Equation (29) with the dual solution $(\widetilde{\theta}_{D_j}, \widetilde{Z})$ can be represented as $\bigtriangledown^2\ell_j^D(\theta^*_{D_j}; X^{1:n})(\widetilde{\theta}_{D_j} - \theta^*_{D_j}) = -\lambda_n^D\widetilde{Z} - W_{Dj}^n + R_{Dj}^n$ by using the mean value theorem where:

(a) W_{Dj}^n is the sample score function,

$$W_{Dj}^n := -\bigtriangledown \ell_j^D(\theta^*_{D_j}; X^{1:n}). \tag{30}$$

(b) $R_{Dj}^n = (R_{Dj1}^n, R_{Dj2}^n, \cdots, R_{Djj-1}^n)$ and R_{Djk}^n is the remainder term by applying coordinate-wise mean value theorem,

$$R_{Djk}^n := [\bigtriangledown^2\ell_j^D(\theta^*_{D_j}; X^{1:n}) - \bigtriangledown^2\ell_j^D(\bar{\theta}_{D_j}^{(k)}; X^{1:n})]_k^T(\widetilde{\theta}_{D_j}^{(k)} - \theta^*_{D_j}) \tag{31}$$

where $\bar{\theta}_{D_j}^{(j)}$ is a vector on the line between $\widetilde{\theta}_{D_j}$ and $\theta^*_{D_j}$ and $[\cdot]_k^T$ is the k^{th} row of a matrix.

Similar to Proposition 20, the following corollary provides a sufficient condition to control $\widetilde{Z}$.

Corollary 27 *Suppose that* $\max(\|W_{Dj}^n\|_\infty, \|R_{Dj}^n\|_\infty) \le \frac{\lambda_n\alpha}{4(2-\alpha)}$. *Then,* $|\widetilde{Z}_t| < 1$ *for all* $t \notin pa(j)$.

Now we introduce the following three corollaries, to verify that the conditions in Proposition 27 hold, and the deviation $\widetilde{\theta}_{M_j} - \theta^*_{D_j}$ is sufficiently small to conclude $\widehat{\mathrm{pa}}(j) = \mathrm{pa}(j)$ with high probability. For ease of notation, let $\eta = \max\{n, p\}$ and For notational convenience, we use $\widetilde{\theta}_S = [\widetilde{\theta}_{D_j}]_S$ and $\widetilde{\theta}_{S^c} = [\widetilde{\theta}_{D_j}]_{S^c}$. Suppose that Assumptions 8, 9, 10, and 11 are satisfied.

Corollary 28 *Suppose that* $\lambda_n^D \ge \frac{16\max\{n^{\kappa_2}\log\eta, \log^2\eta\}}{n^a}$ *for some* $a \in \mathbb{R}$. *Then,*

$$P(\frac{\|W_{Dj}^n\|_\infty}{\lambda_n^D} \le \frac{\alpha}{4(2-\alpha)}) \ge 1 - 2d\cdot exp(-\frac{\alpha^2}{8(2-\alpha)^2}\cdot n^{1-2a}) - M\cdot\eta^{-2}.$$

Corollary 29 *Suppose that* $\|W_{Dj}^n\|_\infty \le \frac{\lambda_n^D}{4}$. *For* $\lambda_n^D \le \frac{\rho_{\min}^2}{40\rho_{\max}}\frac{1}{n^{\kappa_2}\log\eta d}$,

$$P\left(\|\widetilde{\theta}_S - \theta_S^*\|_2 \le \frac{5}{\lambda_{\min}}\sqrt{d}\lambda_n^D\right) \ge 1 - 2M\cdot\eta^{-2}.$$

Corollary 30 *Suppose that* $\|W_{Dj}^n\|_\infty \le \frac{\lambda_n^D}{4}$. *For* $\lambda_n^D \le \frac{\alpha}{400(2-\alpha)}\frac{\rho_{\min}^2}{\rho_{\max}}\frac{1}{n^{\kappa_2}d\log\eta}$,

$$P\left(\|R_{Dj}^n\|_\infty \le \frac{\alpha\lambda_n^D}{4(2-\alpha)}\right) \ge 1 - 2M\cdot\eta^{-2}.$$

Consider the choice of regularization parameter $\lambda_n^D = \frac{16\max\{n^{\kappa_2}\log\eta, \log^2\eta\}}{n^a}$ where $a \in (2\kappa_2, 1/2)$. Then, the condition for Corollary 28 is satisfied, and therefore $\|W_{Dj}^n\|_\infty \le \frac{\lambda_n^D}{4}$. Moreover, the conditions for Corollaries 29 and 30 are satisfied for a sufficiently large sample size $n \ge D'\max\{(d\log^2\eta)^{\frac{1}{a-2\kappa_2}}, (d\log^3\eta)^{\frac{1}{a-\kappa_2}}\}$ for a positive constant D'. Therefore, there exist some positive constants D_1, D_2 and D_3 such that

$$\|\widetilde{Z}_{S^c}\|_\infty \le (1-\alpha) + (2-\alpha)\left[\frac{\|W_{Dj}^n\|_\infty}{\lambda_n^D} + \frac{\|R_{Dj}^n\|_\infty}{\lambda_n^D}\right] \le (1-\alpha) + \frac{\alpha}{4} + \frac{\alpha}{4} < 1, \tag{32}$$

with probability of at least $1 - D_1 d\exp(-D_2 n^{1-2a}) - D_3\eta^{-2}$.

For sign consistency, it is sufficient to show that $\|\widehat{\theta}_{D_j} - \theta^*_{D_j}\|_\infty \le \frac{\|\theta^*_{D_j}\|_{\min}}{2}$. By Corollary 29, we have $\|\widehat{\theta}_{D_j} - \theta^*_{D_j}\|_\infty \le \|\widehat{\theta}_{D_j} - \theta^*_{D_j}\|_2 \le \frac{5}{\lambda_{\min}}\sqrt{d}\ \lambda_n^D \le \frac{\|\theta^*_{D_j}\|_{\min}}{2}$ as long as $\|\theta^*_{D_j}\|_{\min} \ge \frac{10}{\lambda_{\min}}\sqrt{d}\ \lambda_n^D$.

Lastly, Lemma 7(a) guarantees that ℓ_1-penalized likelihood regression recovers the parent set for each node with high probability. Because we have p regression problems if $n \ge D'\max\{(d\log^2\eta)^{\frac{1}{a-2\kappa_2}}, (d\log^3\eta)^{\frac{1}{a-\kappa_2}}\}$, the full DAG model is recovered with high probability:

$$P(\widehat{G} = G) \ge 1 - D_1 d\cdot p\cdot\exp(-D_2 n^{1-2a}) - D_3\eta^{-1}.$$

Abstract

In this article, we propose and study the performance of spectral community detection for a family of "α-normalized" adjacency matrices $\mathbf{A}$, of the type $\mathbf{D}^{-\alpha}\mathbf{A}\mathbf{D}^{-\alpha}$ with $\mathbf{D}$ the degree matrix, in heterogeneous dense graph models. We show that the previously used normalization methods based on $\mathbf{A}$ or $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}^{-1}$ are in general suboptimal in terms of correct recovery rates and, relying on advanced random matrix methods, we prove instead the existence of an optimal value α_{opt} of the parameter α in our generic model; we further provide an online estimation of α_{opt} only based on the node degrees in the graph. Numerical simulations show that the proposed method outperforms state-of-the-art spectral approaches on moderately dense to dense heterogeneous graphs.

Keywords: community detection, random networks, heterogeneous graphs, random matrix theory, spectral clustering.

1. Introduction and Motivations

The advent of the big data era is creating an unprecedented need for automating large network analysis. Community detection is among the most important tasks in automated network mining (Fortunato, 2010). Given a network graph, detecting communities consists in retrieving hidden clusters of nodes based on some similarity metric (the edges are dense inside communities and sparse across communities). While quite simple to define, community detection is usually not an easy task and many methods arising from different fields have been proposed to carry it out. The most important of them are statistical inference, modularity maximization and graph partitioning methods. Statistical inference methods consist in fitting the observed network to a structured network model and infer its parameters (among which the assignment of the nodes to the communities) (Hastings, 2006; Newman and Leicht, 2007). Modularity maximization algorithms rely instead on the modularity metric which quantifies the subdivision of networks into communities (Fortunato, 2010).[1] However, retrieving the modularity maximizing graph partition is generally an NP-hard problem and many polynomial-time approximation methods have been proposed: greedy methods (Newman, 2004), simulated annealing (Guimera et al., 2004), extremal optimization (Duch and Arenas, 2005) and spectral methods (Newman, 2006b). Spectral algorithms consist in retrieving the communities from the eigenvectors associated with the dominant eigenvalues of some matrix representation of the graph structure (adjacency matrix, modularity matrix, Laplacian matrix). By relaxing the modularity optimization problem from binary values of the community memberships to continuous scores, it is shown that approximate modularity maximization and even statistical inference methods can be performed via a low dimensional clustering of the entries of the dominant eigenvectors of the representation matrix (Ng et al., 2002; Newman, 2016) in polynomial time. Precisely, the steps of spectral methods for community detection are described in the following algorithm.

Algorithm 1: Spectral algorithm

1: Compute the, say, ℓ eigenvectors $\mathbf{u}_1, \ldots, \mathbf{u}_\ell \in \mathbb{R}^n$ corresponding to the dominant (largest or smallest) eigenvalues of one of the matrix representations of the network (adjacency, modularity, Laplacian) of size $n \times n$.
2: Stack the vectors $\mathbf{u}_i$'s columnwise in a matrix $\mathbf{W} = [\mathbf{u}_i, \ldots, \mathbf{u}_\ell] \in \mathbb{R}^{n \times \ell}$.
3: Let $\mathbf{r}_1, \ldots, \mathbf{r}_n \in \mathbb{R}^\ell$ be the rows of $\mathbf{W}$. Cluster $\mathbf{r}_i \in \mathbb{R}^\ell$, $1 \leq i \leq n$ in one of K groups using any low-dimensional classification algorithm (e.g., k-means (Hartigan and Wong, 1979) or Expectation Maximization (EM) (Ng et al., 2012)). The label assigned to $\mathbf{r}_i$ then corresponds to the label of node i.

Most of the works proposing statistical analysis of the performance of community detection (for dense as well as sparse networks) consider the basic Stochastic Block Model (SBM) as a model for networks decomposable into communities. Denoting $\mathcal{G}$ a K-class graph of n vertices with communities $\mathcal{C}_1, \ldots, \mathcal{C}_K$ with g_i the group assignment of node i, the SBM assumes an adjacency matrix $\mathbf{A} \in \{0,1\}^{n \times n}$ with A_{ij} independent Bernoulli random variables with parameter $P_{g_i g_j}$ where P_{ab} represents the probability that any node of class $\mathcal{C}_a$ is connected to any node of class $\mathcal{C}_b$. The main limitation of this model is that it is only suited to homogeneous graphs where all nodes have the same average degree in each community (besides, class sizes are often taken equal). As suggested in the practical case of the popular Political Blogs graph (Adamic and Glance, 2005) (see Figure 4), a more realistic model, the Degree-Corrected SBM (DCSBM), was proposed in (Coja-Oghlan and Lanka, 2009; Karrer and Newman, 2011) to account for degree heterogeneity inside communities. For the same graph $\mathcal{G}$ defined above, by letting q_i, $1 \leq i \leq n$, be some intrinsic weights which affect the probability for node i to connect to any other network node, the adjacency matrix $\mathbf{A} \in \{0,1\}^{n \times n}$ of the graph generated by the DCSBM is such that A_{ij} are independent Bernoulli random variables with parameter $q_i q_j C_{g_i g_j}$, where $C_{g_i g_j}$ is a class-wise correction factor.

Community detection in DCSBMs has recently been studied, providing "consistent"[2] algorithms ranging from modularity/likelihood based approaches to spectral clustering methods.

1. Precisely, the modularity is defined as the difference between the total number of edges inside the communities for a given partition and the total number of edges if the partition were created randomly in the graph.
2. Consistency is mainly defined in two forms. Informally, a community detection algorithm is **weakly** consistent whenever the fraction of misclassified nodes vanishes asymptotically with high probability and

JMLR 18(225):1-49, 2018

Sufficient conditions under which likelihood based approaches (Karrer and Newman, 2011) and modularity optimization methods (Newman, 2006b) are weakly and strongly consistent, have been provided in (Zhao et al., 2012). The so-called CMM (Convexified Modularity Maximization) algorithm was proposed in (Chen et al., 2015) to cope with the computational expensiveness of modularity/likelihood methods (Karrer and Newman, 2011; Newman, 2006b) by solving a convex programming relaxation of the modularity optimization. Asymptotic minimax risks for misclassification loss under the DCSBM have been established in (Gao et al., 2016). There a consistent algorithm achieving the minimax optimal rates was derived, which is similar to spectral methods but proceeds without the explicit computation of eigenvectors and is hence computationally less expensive. As far as spectral clustering methods are concerned, (Lyzinski et al., 2014) and (Lei et al., 2015) show consistency of the classical spectral clustering procedure for community detection applied to the adjacency matrix of moderately sparse DCSBM (for not too irregular degree distributions) where the expected degree is as small as $\log n$. Later, its has been shown (Coja-Oghlan and Lanka, 2009; Qin and Rohe, 2013; Jin et al., 2015; Gulikers et al., 2015) that when the degrees are highly heterogeneous, the classical spectral methods fail to detect the genuine communities. To illustrate those limitations of spectral methods under the DCSBM, the two graphs of Figure 1 provide 2D representations of dominant eigenvector 1 versus eigenvector 2 for the standard modularity matrix and the Bethe Hessian matrix[3], when three quarters of the nodes connect with low weight $q_{(1)}$ and one quarter of the nodes with high weight $q_{(2)}$. For both methods, it is clear that k-means or EM alike would erroneously induce the detection of extra communities and even a confusion of genuine communities in the Bethe Hessian approach. Those extra communities are produced by some biases created by the intrinsic weights q_i's; intuitively, nodes sharing the same intrinsic connection weights tend to create their own sub-cluster inside each community, thereby forming additionnal sub-communities inside the genuine communities. To overcome this issue, a number of regularized spectral clustering techniques have been proposed to normalize either the adjacency matrix or the leading eigenvectors by the degrees. In (Coja-Oghlan and Lanka, 2009; Gulikers et al., 2015), the authors have proposed to cluster the nodes based on the eigenvectors of a normalized adjacency matrix $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}^{-1}$ with $\mathbf{D}$ the diagonal matrix containing the observed degrees on the main diagonal. The SCORE algorithm devised in (Jin et al., 2015) consists instead in using the leading eigenvectors of the adjacency matrix (pre-normalized by the dominant eigenvector which, as shown subsequently, is equivalent to normalizing by the inverse degree matrix $\mathbf{D}^{-1}$) and (Qin and Rohe, 2013) proposed to use the eigenvectors of the Laplacian matrix $\mathbf{D}^{-\frac{1}{2}}\mathbf{A}\mathbf{D}^{-\frac{1}{2}}$.

As previously stated, the aforementioned works have shown that under some regularity (or regularization) conditions, an almost perfect or perfect reconstruction of the nodes labels can be achieved asymptotically. Our motivation in this article is to go beyond mere consistency results by understanding the performances of the different regularized spectral clustering algorithms for large but finite network sizes n. To this end, we place ourselves in a regime where communities are too close to induce perfect reconstructions. In order to encompass most aforementioned methods, we study here a generalized regularization of the adjacency

a community detection algorithm is **strongly** consistent whenever the labels estimated by the algorithm match exactly the true labelling asymptotically with high probability.

3. The Bethe Hessian (BH) spectral method (Saade et al., 2014) is based on the union of the eigenvectors associated to the negative eigenvalues of $H(r_c)$ and $H(-r_c)$ respectively where $H(r) = (r^2-1)\mathbf{I}_n - r\mathbf{A} + \mathbf{D}$ for $r_c = \frac{\sum_i d_i^2}{\sum_i d_i} - 1$ with d_i the degree of node i ($\mathbf{D}$ and d_i are defined subsequently).

matrix[4] given, for any $\alpha \in \mathbb{R}$, by

$$\mathbf{L}_\alpha = (2m)^\alpha \frac{1}{\sqrt{n}} \mathbf{D}^{-\alpha} \left[\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{2m} \right] \mathbf{D}^{-\alpha}$$

where $\mathbf{d}$ is the vector of degrees ($d_i = \sum_{j=1}^n A_{ij}$), $\mathbf{D}$ is the diagonal matrix of degrees (containing $\mathbf{d}$ on the main diagonal) and $m = \frac{1}{2}\mathbf{d}^\mathsf{T}\mathbf{1}_n$ is the number of edges in the network. In particular, $\mathbf{L}_0$ is the modularity matrix (Newman, 2006b; Jin et al., 2015), $\mathbf{L}_{\frac{1}{2}}$ is a modularity equivalent to the normalized Laplacian matrix (Qin and Rohe, 2013; Chung, 1997) and $\mathbf{L}_1$ is the form used in (Coja-Oghlan and Lanka, 2009; Gulikers et al., 2015; Tiomoko Ali and Couillet, 2016).

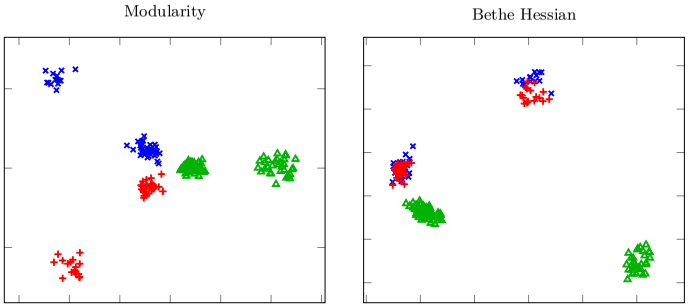

Figure 1: Two dominant eigenvectors (x-y axes) for $n = 2000$, $K = 3$ classes $\mathcal{C}_1$, $\mathcal{C}_2$ and $\mathcal{C}_3$ of sizes $|\mathcal{C}_1| = |\mathcal{C}_2| = \frac{n}{4}$, $|\mathcal{C}_3| = \frac{n}{2}$, $\frac{3}{4}$ of the nodes having $q_i = 0.1$ and $\frac{1}{4}$ of the nodes having $q_i = 0.5$, matrix of weights $\mathbf{C} = \mathbf{1}_3\mathbf{1}_3^\mathsf{T} + \frac{100}{\sqrt{n}}\mathbf{I}_3$. Colors and shapes correspond to ground truth classes.

Besides, while we believe (up to more involved mathematical treatment) that our results essentially hold true in moderately sparse graphs (of average degree of order $\Omega(\log n)$), we focus here on a *dense* DCSBM model where $q_i = \Omega(1)$. In this regime, when the correction factors $C_{g_i g_j}$ differ by a rate greater than $\mathcal{O}(n^{-\frac{1}{2}})$, weak consistency is shown for all regularized spectral algorithms. Instead, we induce a regime where clusters remain at an asymptotically "constant" distance. This is ensured by letting $C_{g_i g_j} = \Omega(1)$ individually but with the $C_{g_i g_j}$'s differing by $\mathcal{O}(n^{-\frac{1}{2}})$. Under this regime, we are able to fully study the dominant eigenvalues and associated eigenvectors (used for classification) of $\mathbf{L}_\alpha$ for large dimensional dense graphs following the DCSBM, thus allowing one to assess the performances for very large but finite-size graphs.

In a nutshell, our main findings are as follows.

4. The leading term $\frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{2m}$ (not providing any information about the communities) is shown in simulations to have asymptotically no impact on the clustering performance. It is discarded here mostly for mathematical simplicity. Note in passing that $\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{2m}$ corresponds to the so-called modularity matrix (Newman, 2006a), therefore $\mathbf{L}_\alpha$ may be seen as a "α-normalized" modularity matrix.

- We prove the existence of and obtain an expression for an optimal value α_{opt} of α for which the community detectability threshold[5] is maximally achievable.This value needs not be either 0 or 1 and its proper choice is of utmost importance in highly heterogeneous graphs.
- We provide a consistent estimator $\hat{\alpha}_{\text{opt}}$ of α_{opt} based on $\mathbf{d}$ alone.
- We show that to achieve consistent clustering in the DCSBM model, the dominant eigenvectors used for clustering should be pre-multiplied by $\mathbf{D}^{\alpha-1}$ prior to the low dimensional classification (step 3 of Algorithm 1), thereby recovering the SCORE algorithm (Jin et al., 2015) for $\alpha = 0$ and the algorithm in (Gulikers et al., 2015) for $\alpha = 1$, as special cases.
- Our proposed method is summarized under the form of Algorithm 2. As the estimation of α_{opt} is essentially linear with n, Algorithm 2 does not impair the computational cost of the underlying spectral method. A Python implementation of the algorithm is available in (Tiomoko Ali and Couillet, 2017).
- A deeper study of the regularized eigenvectors allows us to improve the initial setting of the EM algorithm (in the step 3 of the spectral algorithm described above) in comparison with a random setting.
- Numerical simulations (throughout the article) show that our methods outperform state-of-the-art spectral methods both on synthetic graphs and on real world networks.

All proofs are deferred to a separate section while sketches are provided for the main results of the article.

Notations: Vectors (matrices) are denoted by lowercase (uppercase) boldface letters. $\{\mathbf{v}_a\}_{a=1}^n$ is the column vector $\mathbf{v}$ with (scalar or vector) entries v_a and $\{\mathbf{V}_{ab}\}_{a,b=1}^n$ is the matrix $\mathbf{V}$ with (scalar or matrix) entries V_{ab}. For a vector $\mathbf{v}$, the operator $\mathcal{D}(\mathbf{v}) = \mathcal{D}\left(\{v_a\}_{a=1}^n\right)$ is the diagonal matrix having the scalars v_a down its diagonal and for a matrix $\mathbf{V}$, $\mathcal{D}(\mathbf{V})$ is the vector containing the diagonal entries of $\mathbf{V}$. The vector $\mathbf{1}_n \in \mathbb{R}^n$ stands for the column vector filled with ones. The Dirac measure at x is δ_x. The vector $\mathbf{j}_a$ is the canonical vector of class $\mathcal{C}_a$ defined by $(\mathbf{j}_a)_i = \delta_{i\in\mathcal{C}_a}$ and $\mathbf{J} = [\mathbf{j}_1, \ldots, \mathbf{j}_K] \in \{0,1\}^{n\times K}$. The set $\mathbb{C}^+$ is $\{z \in \mathbb{C},\ \Im[z] > 0\}$. We denote $\mathbf{x} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ to indicate that $\mathbf{x}$ is a Gaussian distributed random vector with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$.

2. Preliminaries

This section describes the network model under study, which is based on the DCSBM defined in the previous section, and provides preliminary technical results.

Consider an n-node random graph with K classes $\mathcal{C}_1, \ldots, \mathcal{C}_K$ of sizes $|\mathcal{C}_k| = n_k$. Each node is characterized by an intrinsic connexion weight q_i which affects the probability that this node gets attached to another node in the graph. A null model would consider that the existence of an edge between i and j has probability $q_i q_j$. In order to take into account the

5. The community detectability threshold is the point beyond which there exists a clustering algorithm which can do better than a random guess.

membership of the nodes to some group, we define $\mathbf{C} \in \mathbb{R}^{K\times K}$ as a matrix of class weights C_{ab}, independent of the q_i's, affecting the connection probability between nodes in $\mathcal{C}_a$ and nodes in $\mathcal{C}_b$. Following (Karrer and Newman, 2011), the adjacency matrix $\mathbf{A}$ of the graph generated from a DCSBM model has independent entries (up to symmetry) which are Bernoulli random variables with parameter $P_{ij} = q_i q_j C_{g_i g_j} \in (0,1)$ where g_i is the group assignment of node i. We set $A_{ii} = 0$ for all i. For convenience of exposition and without loss of generality, we assume that node indices are sorted by clusters, i.e nodes 1 to n_1 constitutes $\mathcal{C}_1$, nodes n_1+1 to n_1+n_2 form $\mathcal{C}_2$, and so on.

The matrix under study is given by

$$\mathbf{L}_\alpha = (2m)^\alpha \frac{1}{\sqrt{n}} \mathbf{D}^{-\alpha} \left[\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{2m}\right] \mathbf{D}^{-\alpha} \tag{1}$$

where $\mathbf{d} = \mathbf{A}\mathbf{1}_n$, $\mathbf{D} = \mathcal{D}(\mathbf{d})$ and $m = \frac{1}{2}\mathbf{d}^\mathsf{T}\mathbf{1}_n$.

We are mainly interested in a dense network regime where clustering is not asymptotically trivial. This regime is ensured by the following growth rate conditions.

Assumption 1 *As $n \to \infty$, K remains fixed and, for all $i, j \in \{1, \ldots, n\}$*

1. *$C_{g_i g_j} = 1 + \frac{M_{g_i g_j}}{\sqrt{n}}$, where $M_{g_i g_j} = \Omega(1)$; we shall denote $\mathbf{M} = \{M_{ab}\}_{a,b=1}^K$.*
2. *q_i are i.i.d. random variables with measure μ having compact support in $(0,1)$.*
3. *$\frac{n_i}{n} \to c_i > 0$ and we will denote $\mathbf{c} = \{c_k\}_{k=1}^K$.*

The goal of the article is to study deeply the eigenstructure of $\mathbf{L}_\alpha$ in order to understand the different mechanisms into play when performing spectral clustering on $\mathbf{L}_\alpha$. As can be observed, $\mathbf{L}_\alpha$ has non independent entries as $\mathbf{D}$ (and $\mathbf{d}$) depend on $\mathbf{A}$, and it thus does not follow a standard random matrix model. Our strategy is to approximate $\mathbf{L}_\alpha$ by a more tractable random matrix $\tilde{\mathbf{L}}_\alpha$ which asymptotically preserves the eigenvalue distribution and isolated eigenvectors of $\mathbf{L}_\alpha$. We obtain the corresponding approximate of $\mathbf{L}_\alpha$ as follows.

Theorem 2 *Let Assumption 1 hold and let $\mathbf{L}_\alpha$ be given by (1). Then, for $\mathbf{D}_q \triangleq \mathcal{D}(\mathbf{q})$, as $n \to \infty$, $\|\mathbf{L}_\alpha - \tilde{\mathbf{L}}_\alpha\| \to 0$ in operator norm, almost surely, where*

$$\begin{aligned}
\tilde{\mathbf{L}}_\alpha &= \frac{1}{\sqrt{n}} \mathbf{D}_q^{-\alpha} \mathbf{X} \mathbf{D}_q^{-\alpha} + \mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^\mathsf{T}, \\
\mathbf{U} &= \begin{bmatrix} \frac{\mathbf{D}_q^{1-\alpha}\mathbf{J}}{\sqrt{n}} & \frac{\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \end{bmatrix}, \\
\boldsymbol{\Lambda} &= \begin{bmatrix} \left(\mathbf{I}_K - \mathbf{1}_K \mathbf{c}^T\right) \mathbf{M} \left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right) & -\mathbf{1}_K \\ -\mathbf{1}_K^T & 0 \end{bmatrix},
\end{aligned}$$

with $\mathbf{X} = \{X_{ij}\}_{i,j=1}^n$ symmetric with independent entries (up to the symmetry), X_{ij} having zero mean and variance $q_i q_j (1 - q_i q_j)$, and $\mathbf{J} = [\mathbf{j}_1, \ldots, \mathbf{j}_K] \in \{0,1\}^{n\times K}$ with $(\mathbf{j}_a)_i = \delta_{\{g_i = a\}}$.

Proof [Sketch] The proof relies on the fact that we may write $A_{ij} = q_i q_j + q_i q_j \frac{M_{g_i g_j}}{\sqrt{n}} + X_{ij}$ where X_{ij} is a zero mean random variable with variance $q_i q_j (1 - q_i q_j) + \Theta(n^{-\frac{1}{2}})$, since A_{ij} is a Bernoulli random variable with parameter $q_i q_j (1 + \frac{M_{g_i g_j}}{\sqrt{n}})$. From there, the terms: $\mathbf{d} = \mathbf{A}\mathbf{1}_n$,

$\mathbf{d}^\mathsf{T}\mathbf{1}_n$, $\mathbf{d}\mathbf{d}^\mathsf{T}$ and $\mathbf{D} = \mathcal{D}(\mathbf{d})$ composing $\mathbf{L}_\alpha$ can be evaluated. Notably, $\mathbf{D}$ and $\mathbf{d}^\mathsf{T}\mathbf{1}_n$ can be decomposed as the sum of dominant terms (with higher spectral norms with respect to n) and trailing terms (vanishing spectral norms with respect to n), so that we can write a Taylor expansion of $\mathbf{D}^{-\alpha}$ and $(\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha$ for $\alpha \in \mathbb{R}$. By computing $\mathbf{L}_\alpha$ using the asymptotic approximations of $\mathbf{D}^{-\alpha}$, $(\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha$, $\mathbf{A}$, $\mathbf{d}\mathbf{d}^\mathsf{T}$, we obtain $\tilde{\mathbf{L}}_\alpha$. The complete proof is provided in Section 6.1. ■

This result immediately implies the following Corollary.

Corollary 3 *Under Assumption 1, let $\lambda_i(\mathbf{L}_\alpha)$ (resp., $\lambda_i(\tilde{\mathbf{L}}_\alpha)$) be the eigenvalues of $\mathbf{L}_\alpha$ (resp., $\tilde{\mathbf{L}}_\alpha$) with associated eigenvectors $\mathbf{u}_i(\mathbf{L}_\alpha)$ (resp., $\mathbf{u}_i(\tilde{\mathbf{L}}_\alpha)$). We have*

$$\max_{1\le i\le n} \left|\lambda_i(\mathbf{L}_\alpha) - \lambda_i(\tilde{\mathbf{L}}_\alpha)\right| \xrightarrow{\text{a.s.}} 0$$

and, if $\liminf_n \min_{j\neq i} |\lambda_i(\mathbf{L}_\alpha) - \lambda_j(\tilde{\mathbf{L}}_\alpha)| > 0$,

$$\left\|\mathbf{u}_i(\mathbf{L}_\alpha) - \mathbf{u}_i(\tilde{\mathbf{L}}_\alpha)\right\| \xrightarrow{\text{a.s.}} 0.$$

Thus, for large enough n, the spectral analysis of $\mathbf{L}_\alpha$ can be performed through that of $\tilde{\mathbf{L}}_\alpha$.

The matrix $\tilde{\mathbf{L}}_\alpha$ is essentially a classical random matrix model and the study of its eigenvalues and dominant eigenvectors can be performed using standard random matrix theory (RMT) approaches (Benaych-Georges and Nadakuditi, 2012; Hachem et al., 2013).

3. Main Results

3.1 Spike model and dominant eigenvector regularization

The matrix $\tilde{\mathbf{L}}_\alpha$ is an additive spiked random matrix (Baik et al., 2005) as it is the sum of the standard full rank symmetric random matrix $n^{-\frac{1}{2}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$ having independent zero mean entries and a low rank matrix $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$. As shown in Figure 2, the spectrum (eigenvalue distribution) of spiked random matrices is generally composed of (one or several) bulks of concentrated eigenvalues and, when a phase transition is met, of additionnal eigenvalues which isolate from the aforementioned bulks. The eigenvectors corresponding to the isolated eigenvalues of the spiked random matrix become more correlated to the eigenvectors of the low rank matrix when the corresponding eigenvalues are far away from the rest of the eigenvalues.

From Theorem 2, the low rank matrix $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$ contains the matrix $\mathbf{D}_q^{1-\alpha}\mathbf{J}$; so, when the phase transition is met, the eigenvectors of $\tilde{\mathbf{L}}_\alpha$ will be correlated to some extent to $\mathbf{D}_q^{1-\alpha}\mathbf{J}$ as long as the corresponding informative eigenvalues are isolated from the bulk of eigenvalues. This is well illustrated in Figure 2 where the eigenvectors associated to non-isolated eigenvalues are noisy, i.e., classes can be barely distinguished from those eigenvectors. On the other hand, the eigenvectors associated to isolated eigenvalues consist of noisy plateaus characterizing the classes and thus a consistent classification can be expected using those eigenvectors. However, for a better clustering, one expects instead the vectors used for classification to be correlated to the canonical vectors $\mathbf{j}_a$, $1 \le a \le K$, instead of $\mathbf{D}_q^{1-\alpha}\mathbf{j}_a$.

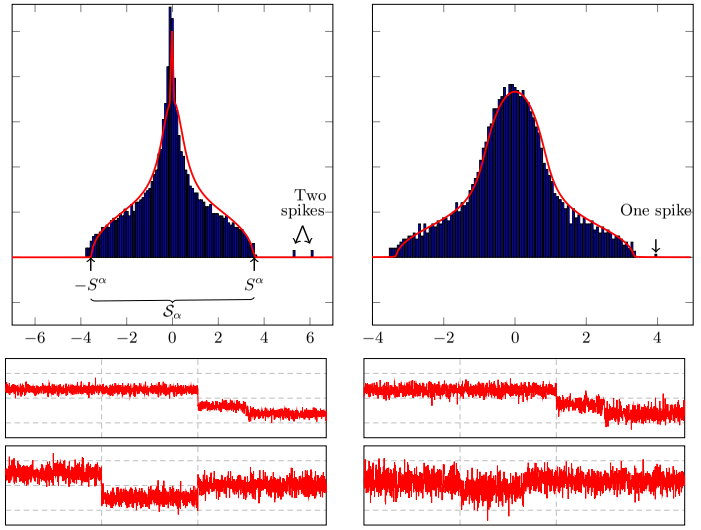

Figure 2: Two graphs generated upon the DCSBM with $K = 3$, $n = 2000$, $c_1 = 0.3, c_2 = 0.3, c_3 = 0.4$, $\mu = \frac{1}{2}\delta_{q_{(1)}} + \frac{1}{2}\delta_{q_{(2)}}$, $q_{(1)} = 0.4$, $q_{(2)} = 0.9$ and two different affinity matrices $\mathbf{M}$. **(Left)** $M_{ii} = 12$, $M_{ij} = -4, i \neq j$, **(Right)**: $M_{ii} = -3$, $M_{ij} = -10, i \neq j$, **(Top)**: Eigenvalue distribution of $\mathbf{L}_\alpha$, $\alpha = 0$. **(Bottom)**: First and second leading eigenvectors of $\mathbf{L}_\alpha$, $\alpha = 0$.

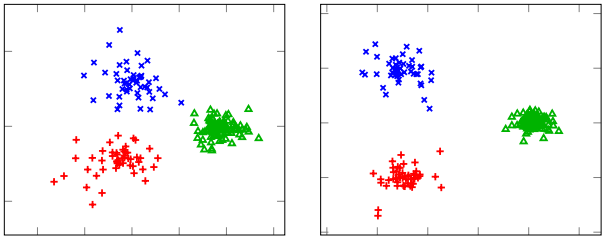
As a consequence, we claim that, letting $\mathbf{u}_1, \ldots, \mathbf{u}_l$ be the eigenvectors associated to the ℓ isolated eigenvalues of $\mathbf{L}_\alpha$, the vectors $\mathbf{v}_i = \mathbf{D}^{\alpha-1}\mathbf{u}_1$ for $1 \le i \le \ell$ should be the ones used for the classification instead of the $\mathbf{u}_i$'s.[6]

This important observation helps correcting the biases (creation of artificial classes) introduced by the degree heterogeneity observed earlier in Figure 1. As shown in Figure 3, which assumes the same setting as Figure 1, when the aforementioned eigenvector regularization is performed prior to EM or k-means classification, the genuine communities are correctly recovered.

As mentionned earlier, the eigenvectors corresponding to eigenvalues in the bulk are asymptotically of no use for clustering. It is thus important to characterize the phase transition point beyond which eigenvalues isolate from the bulk and determine which α best ensures this transition. To this end, we will first determine the support $\mathcal{S}^\alpha$ of the limiting spectral

6. As far as the eigenvectors are concerned, we may freely replace $\mathbf{D}_q$ (unknown in practice) by $\mathbf{D}$ (which can be computed from the observed graph) since, from Lemma 11 in the subsequent section 3.4, the vector of degrees $\mathbf{d}$ is, up to a scale factor β, a consistent estimator of the vector of intrinsic weights $\mathbf{q}$ and thus $\|\beta\mathbf{D} - \mathbf{D}_q\| \to 0$ almost surely.



$(\alpha = 1)$ $(\alpha = \hat{\alpha}_{\text{opt}})$

Figure 3: Two dominant eigenvectors of $\mathbf{L}_\alpha$ pre-multiplied by $\mathbf{D}^{\alpha-1}$(x-y axes) for $n = 2000$, $K = 3$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$, $q_{(1)} = 0.1$, $q_{(2)} = 0.5$, $c_1 = c_2 = \frac{1}{4}$, $c_3 = \frac{1}{2}$, $\mathbf{M} = 100\mathbf{I}_3$ with $\hat{\alpha}_{\text{opt}}$ defined in Section 3.4. Same setting as Figure 1.

distribution of $\mathbf{L}_\alpha$. Then, following popular spiked model tools, we will find conditions for the existence of isolated eigenvalues. This is the objective of the next sections.

3.2 Limiting support

In this section, we characterize the limiting eigenvalue distribution of $\mathbf{L}_\alpha$ where most eigenvalues concentrate. This in turn shall allow to determine the transition point beyond which informative eigenvalues isolate from the main bulk of eigenvalues and consistent clustering can thus be achieved by using the corresponding eigenvectors associated to those eigenvalues. The limiting eigenvalue distribution of $\mathbf{L}_\alpha$ is given in the following result.

Theorem 4 (Limiting spectrum) *Let $\pi_n^\alpha = \frac{1}{n}\sum_{i=1}^n \delta_{\lambda_i(\mathbf{L}_\alpha)}$ be the empirical spectral distribution (e.s.d.) of $\mathbf{L}_\alpha$. Then, as $n \to \infty$, $\pi_n^\alpha \to \bar{\pi}^\alpha$ almost surely where $\bar{\pi}^\alpha$ is a probability measure with compact symmetric support $\mathcal{S}^\alpha = [-S_\alpha, S_\alpha]$ defined, for $z \in \mathbb{C}^+ \setminus \mathcal{S}^\alpha$, by its Stieltjes transform*

$$m^\alpha(z) \equiv \int (t-z)^{-1}\, \mathrm{d}\bar{\pi}^\alpha(t) = \int \frac{1}{-z - f^\alpha(z) q^{1-2\alpha} + g^\alpha(z) q^{2-2\alpha}} \mu(dq)$$

where $(f^\alpha(z), g^\alpha(z)) \in (\mathbb{C}^+)^2$ (resp., $(\mathbb{R}^-)^2$) is the unique solution for $z \in \mathbb{C}^+$ (resp., $\mathbb{R}^+$), of

$$f^\alpha(z) = \int \frac{q^{1-2\alpha}\mu(dq)}{-z - f^\alpha(z) q^{1-2\alpha} + g^\alpha(z) q^{2-2\alpha}}$$
$$g^\alpha(z) = \int \frac{q^{2-2\alpha}\mu(dq)}{-z - f^\alpha(z) q^{1-2\alpha} + g^\alpha(z) q^{2-2\alpha}}. \tag{2}$$

Proof [Sketch] Since $\tilde{\mathbf{L}}_\alpha = \frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha} + \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$ is a spiked random matrix, the e.s.d. π_n^α of $\mathbf{L}_\alpha$ converges weakly to the the e.s.d. $\tilde{\pi}_n^\alpha$ of $\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$ (by Weyl interlacing lemma) since $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$ is a low rank matrix. We thus find an asymptotic limit $\bar{\pi}^\alpha$ for $\tilde{\pi}_n^\alpha$ so that $\pi_n^\alpha \to \bar{\pi}^\alpha$ almost surely. To do so, we show that the Stieltjes transform of $\tilde{\pi}_n^\alpha$ converges to $m^\alpha(z)$ for

$z \in \mathbb{C}^+$, which is the Stieltjes transform of the probability measure $\bar{\pi}^\alpha$ so that the convergence also holds for the probability measures (the e.s.d.). The Stieltjes transform of the e.s.d. $\tilde{\pi}_n^\alpha$ is $n^{-1}\operatorname{tr}(\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha} - z\mathbf{I}_n)^{-1}$ (where $(\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha} - z\mathbf{I}_n)^{-1}$ is the so-called resolvent of the random matrix $\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$), the deterministic limit of which gives $m^\alpha(z)$, computed using classical random matrix theory (RMT) tools (Pastur et al., 2011). The calculus details are provided in Section 6.2. ■

Remark 5 (Stochastic Block Model) *Particularizing Theorem 4 to the Stochastic Block Model (SBM) (where $q_i = q_0$ for all i), the limiting probability measure $\bar{\pi}^\alpha$ is the popular semi-circle distribution with density $\bar{\pi}^\alpha(dt) = \frac{2}{\pi(S^\alpha)^2}\sqrt{\max\{(S^\alpha)^2 - t^2, 0\}}dt$ with $S^\alpha = 2q_0^{1-2\alpha}\sqrt{1-q_0^2}$. The associated Stieljes transform $m^\alpha(z)$ is explicit with in particular*

$$q_0^{1-2\alpha} m^\alpha(z q_0^{1-2\alpha}) = q_0^{\frac{1}{2}-\alpha} f^\alpha(z q_0^{\frac{1}{2}-\alpha}) = q_0^{-1} g^\alpha(z q_0^{1-2\alpha}) = -\frac{z}{2(1-q_0^2)} - \sqrt{\left(\frac{z}{2(1-q_0^2)}\right)^2 - \frac{1}{1-q_0^2}}.$$

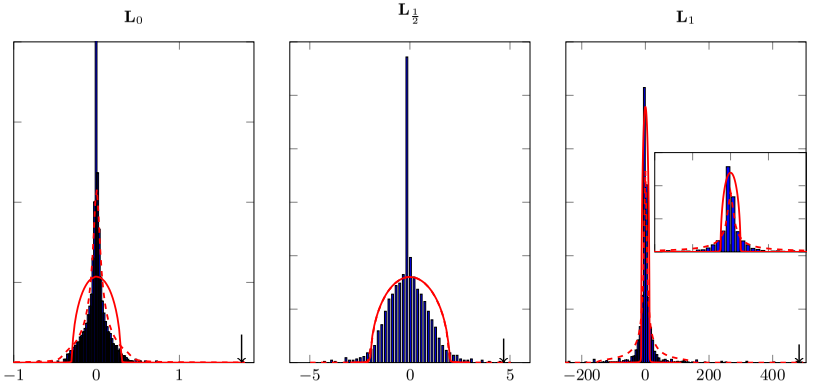


Figure 4: Political blogs (Adamic and Glance, 2005) network. Empirical versus Theoretical law of the eigenvalues of $\mathbf{L}_{\hat{\alpha}_{\text{opt}}}$ when fitting this network with the DCSBM (dashed) and the SBM (solid). Here $\hat{\alpha}_{\text{opt}} = 0$. The arrow shows the position of the largest eigenvalue.

The top of Figure 2, already discussed above, shows the density of the limiting $\bar{\pi}^\alpha$, for $\alpha = 0$, superimposed over the histogram of π_n^α. Figure 4 similarly displays the histogram π^α of the empirical eigenvalues of $\mathbf{L}_\alpha$ corresponding to the real network of Political blogs (Adamic and Glance, 2005) versus the theoretical limiting distribution $\bar{\pi}^\alpha$ obtained by fitting the network to the DCSBM (from Theorem 4, with μ the actual degree distribution of the graph) and the theoretical limiting distribution obtained by fitting the network to the SBM instead

(in solid lines).[7] We note importantly that the DCSBM is a good fit for the political blogs network except possibly for $L_{\frac{1}{2}}$ while the SBM does not fit the network in any case. This suggests that the DCSBM is a more appropriate model when studying real world networks.

3.3 Phase transition

We also observe in Figure 4 (and more obviously in the synthetic case of Figure 2) that different choices of α lead to different behaviors in the position of the dominant eigenvalues. We shall determine here when separation of one or several eigenvalues from the bulk occurs. To this end, we follow popular spiked model techniques (Benaych-Georges and Nadakuditi, 2012; Hachem et al., 2013) for phase transition characterization. This entails the following result.

Theorem 6 (Phase transition) *Let Assumption 1 hold and let $\lambda(\bar{\mathbf{M}})$ be a non zero eigenvalue with multiplicity η of $\bar{\mathbf{M}} \equiv \left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}$. Then, for $\alpha \in \mathbb{R}$, there exists corresponding isolated eigenvalues $\lambda_i(\mathbf{L}_\alpha), \ldots, \lambda_{i+\eta-1}(\mathbf{L}_\alpha) \in \mathbb{R}\backslash\mathcal{S}^\alpha$ of $\mathbf{L}_\alpha$ all converging to $\rho \in \mathbb{R} \setminus \mathcal{S}^\alpha$, as $n \to \infty$, almost surely, if and only if* [8]

$$\left|\lambda(\bar{\mathbf{M}})\right| > \tau^\alpha \triangleq -\lim_{x \downarrow \mathcal{S}^\alpha} \frac{1}{g^\alpha(x)},$$

with $g^\alpha(x)$ defined in Theorem 4. In this case, ρ is defined by

$$\rho = (g^\alpha)^{-1}\left(-\frac{1}{\lambda(\bar{\mathbf{M}})}\right).$$

Proof [Sketch] From Theorem 4, the e.s.d. of $\mathbf{L}_\alpha$ converges weakly to the e.s.d. of $\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$ with support $\mathcal{S}^\alpha$ (defined in Theorem 4) but since $\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$ and $\mathbf{L}_\alpha$ only differ by a finite rank matrix $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$, some eigenvalues of $\mathbf{L}_\alpha$ may isolate from the support $\mathcal{S}^\alpha$. To find those isolated eigenvalues, we solve for $\rho \notin \mathcal{S}^\alpha$, $\det(\mathbf{L}_\alpha - \rho\mathbf{I}_n) = 0$. This leads to find the ρ's for which $0 = \det(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda})$ where $\mathbf{Q}_\rho^\alpha = (\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha} - \rho\mathbf{I}_n)^{-1}$ is the resolvent of $\frac{1}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{D}_q^{-\alpha}$. By using standard RMT calculus (Benaych-Georges and Nadakuditi, 2012), we obtain a deterministic approximation of $\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}$ which leads to the phase transition condition in Theorem 6. ∎

Remark 7 (τ^α in SBM setting) *From Remark 5, in the SBM setting, τ^α no longer depends on α and is given by $\tau^\alpha = \frac{\sqrt{1-q_0^2}}{q_0}$.*

Remark 8 (Number of isolated eigenvalues) *From Theorem 6, there is a one-to-one mapping between the limiting isolated eigenvalues ρ of $\mathbf{L}_\alpha$ and non zero eigenvalues of $\bar{\mathbf{M}} = \left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}$. As $\mathbf{1}_K^\mathsf{T}\bar{\mathbf{M}} = 0$, $\bar{\mathbf{M}}$ has a maximum of $K-1$ non zero eigenvalues which means that at most $K-1$ eigenvalues of $\mathbf{L}_\alpha$ can be found at macroscopic distance from $\mathcal{S}^\alpha$. Thus, at most $K-1$ eigenvectors of $\mathbf{L}_\alpha$ can be used in the first step of the spectral algorithm described in the introduction.*

7. The SBM assumes here $q_i = q_0$ for all i.
8. The limit $\lim_{x \downarrow \mathcal{S}^\alpha} g^\alpha(x)$ is well defined in $(-\infty, 0]$ as $x \mapsto g^\alpha(x)$ can be shown to be a continuous growing negative function on the right side of $\mathcal{S}^\alpha$.

Remark 9 (The complete spectrum of $\mathbf{L}_\alpha$) *Strictly speaking, the aforementioned statements are somewhat inaccurate. An exhaustive analysis of $\mathbf{L}_\alpha$ indeed reveals that, under some conditions on μ, and irrespective of the clustering matrix $\mathbf{M}$, extra isolated eigenvalues can be found in the spectrum of $\mathbf{L}_\alpha$, the eigenvectors of which do not contain any structural information about the classes. This rather unfamiliar scenario has also been evidenced in the context of spectral kernel clustering in (Couillet et al., 2016). Since this hypothetical eigenvalue and eigenvector pair is of no value for the interest of clustering, it shall no longer be discussed in the following. Besides, most settings of practical interest do not present this singular behavior. A thorough discussion of this peculiarity is provided in Section 6.5.*

The value τ^α defined in Theorem 6 is a community detectability threshold which in the dense regime for the SBM case was shown to split the community detectability into two regions: a region where no algorithm can succed better than a random guess in classifying the nodes and a region where a non trivial detection is possible (Decelle et al., 2011; Nadakuditi and Newman, 2012). When the separability condition of Theorem 6 is ensured, the alignment between the properly normalized eigenvectors of $\mathbf{L}_\alpha$ and linear combinations of the class vectors $\mathbf{j}_a$'s (defined in Theorem 2) is away from zero, thus ensuring a non trivial classification performance. The larger $\lambda(\bar{\mathbf{M}})$, the closer are the vectors used for classification to the class vectors $\mathbf{j}_a$'s.

Theorem 10 *Under Assumption 1, let $\lambda(\bar{\mathbf{M}})$ and $\lambda(\mathbf{L}_\alpha)$ be an eigenvalue pair as defined in Theorem 6. We further assume $\lambda(\bar{\mathbf{M}})$ of unit multiplicity and denote $\mathbf{u}$ the eigenvector associated to the eigenvalue $\lambda(\mathbf{L}_\alpha)$. Then, letting $\bar{\mathbf{v}} = \frac{\mathbf{D}^{\alpha-1}\mathbf{u}}{\|\mathbf{D}^{\alpha-1}\mathbf{u}\|}$ and $\mathbf{\Pi} = \sum_{a=1}^K \frac{\mathbf{j}_a\mathbf{j}_a^\mathsf{T}}{n_a}$, for all $\epsilon > 0$, there exists $\gamma_-, \gamma_+ > 0$ such that, for all n large, almost surely,*

$$0 < \left|\lambda(\bar{\mathbf{M}})\right| - \tau^\alpha < \gamma_- \Rightarrow \bar{\mathbf{v}}^\mathsf{T}\mathbf{\Pi}\bar{\mathbf{v}} < \epsilon$$
$$\left|\lambda(\bar{\mathbf{M}})\right| - \tau^\alpha > \gamma_+ \Rightarrow \bar{\mathbf{v}}^\mathsf{T}\mathbf{\Pi}\bar{\mathbf{v}} > 1 - \epsilon.$$

This result is a direct corrolary of Theorem 15 which is introduced later in Section 3.5.

Figure 5 illustrates Theorem 10, which confirms that, below the phase transition threshold τ^α, there is asymptotically no correlation between the vectors $\bar{\mathbf{v}}$ and the class canonical vectors $\mathbf{j}_a$'s and thus no consistent clustering can be achieved in this regime. The theoretical curve is obtained by using the deterministic asymptotic approximation of $\bar{\mathbf{v}}^\mathsf{T}\mathbf{\Pi}\bar{\mathbf{v}}$ which is explicitely given in Section 6.4.

3.4 Optimal α

In this section, we determine the values of α for which the community detectability threshold is maximally achieved. This, in turn, is expected to allow for the optimal extraction of information about the classes from the extreme eigenvectors although this is not easily proved (and in our opinion, most likely not always true).

From Theorem 6, since $\bar{\mathbf{M}}$ does not depend on α, the smaller τ^α the more likely the detectability condition $\left|\lambda(\bar{\mathbf{M}})\right| > \tau^\alpha$ is met. We then seek α for which τ^α is minimal. For any compact set $\mathcal{A} \subset \mathbb{R}$, we may thus define

$$\alpha_{\text{opt}} \triangleq \text{argmin}_{\alpha \in \mathcal{A}}\{\tau^\alpha\}$$

which we shall assume is unique (if $q_i = q_0$ is constant, τ^α is constant across α; this case is thus excluded). The estimation of α_{opt} however requires the knowledge of $g^\alpha(x)$ for each

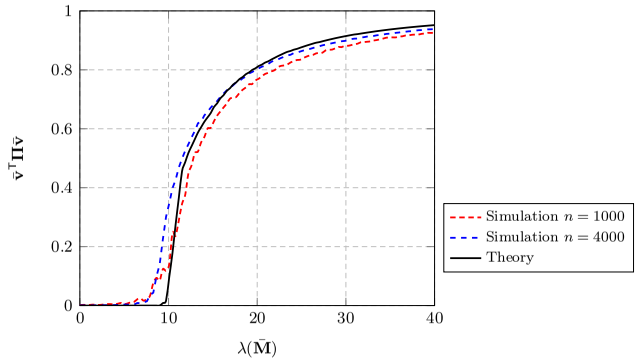

Figure 5: Simulated versus empirical $\bar{\mathbf{v}}^\mathsf{T}\mathbf{\Pi}\bar{\mathbf{v}}$ for $K = 3$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$, $q_{(1)} = 0.1$, $q_{(2)} = 0.2$, $c_1 = c_2 = \frac{1}{4}$, $c_3 = \frac{1}{2}$, $\mathbf{M} = \Delta\mathbf{I}_3$ with Δ ranging from 0 to 100.

$\alpha \in \mathcal{A}$. The estimation of $g^\alpha(x)$ can be done numerically by solving the fixed point equation defined in Theorem 4 provided μ is known. As a direct consequence of Assumption 1-(1), μ can in fact be estimated from the empirical graph degrees irrespective of the class matrix $\mathbf{C}$, according to the following result.

Lemma 11 *Let $\hat{q}_i = \frac{d_i}{\sqrt{\mathbf{d}^\mathsf{T}\mathbf{1}_n}}$. Then, under Assumption 1,*

$$\max_{1\le i\le n} |q_i - \hat{q}_i| \to 0 \tag{3}$$

almost surely.

We thus have all the ingredients to estimate α_{opt}.[9]

Proposition 12 *Define $\hat{\mu} \triangleq \frac{1}{n}\sum_{i=1}^n \delta_{\hat{q}_i}$ with $\hat{q}_i = \frac{d_i}{\sqrt{\mathbf{d}^\mathsf{T}\mathbf{1}_n}}$ and $\hat{\mathcal{S}}^\alpha$, $\hat{f}^\alpha(z)$, $\hat{g}^\alpha(z)$, as in Theorem 4 but for μ replaced by $\hat{\mu}$. Then, as $n \to \infty$,*

$$\hat{\alpha}_{\text{opt}} \to \alpha_{\text{opt}}$$

almost surely, where $\hat{\alpha}_{\text{opt}} \triangleq \text{argmin}_{\alpha\in\mathcal{A}}\{\hat{\tau}^\alpha\}$ with

$$\hat{\tau}_\alpha \equiv -\frac{1}{\lim_{x\downarrow\hat{S}^\alpha} \hat{g}^\alpha(x)}.$$

Remark 13 (Numerical evaluation of S^α) *Estimating $\hat{\tau}_\alpha$ requires to determine $\hat{\mathcal{S}}^\alpha$. To this end, we use the fact that $\hat{g}^\alpha(x)$ is only defined for $x \notin \hat{\mathcal{S}}^\alpha$. We thus evaluate $\hat{\mathcal{S}}^\alpha$ by an iterative dichotomic search in intervals of the type $[l, r]$ for which $\hat{g}^\alpha(l)$ is undefined (and thus the algorithm in Equation 2 does not converge) and $\hat{g}^\alpha(r)$ is defined (the algorithm converges), starting from e.g., $l = 0$ and r quite large.*

9. Note here that imposing $\mathcal{A}$ to be a compact set ensures the uniform validity of Theorem 4.

Remark 14 (Relevance of the choice of α) *Following Remarks 5 and 7, note that the choice of α is only relevant to heterogeneous graphs, as in the SBM case, the phase transition threshold τ^α is constant irrespective of α. This suggests that the more heterogeneous the graph the more important an appropriate setting of α.*

The aforementionned importance of choosing $\alpha = \hat{\alpha}_{\text{opt}}$ along with the need to pre-multiply the dominant eigenvectors of $\mathbf{L}_\alpha$ by $\mathbf{D}^{\alpha-1}$ before classification, as discussed after exposing Theorem 2, naturally bring us to an improved version of Algorithm 1 provided below. The

Algorithm 2: Improved spectral algorithm

1: Evaluate $\alpha = \hat{\alpha}_{\text{opt}} = \text{argmin}_{\alpha\in\mathcal{A}} \lim_{x\downarrow\hat{S}^\alpha} \hat{g}^\alpha(x)$ as per Proposition 12.
2: Retrieve the ℓ eigenvectors corresponding to the ℓ largest eigenvalues of $\mathbf{L}_\alpha = (2m)^\alpha \frac{1}{\sqrt{n}}\mathbf{D}^{-\alpha}\left[\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{2m}\right]\mathbf{D}^{-\alpha}$. Denote $\mathbf{u}_1^\alpha, \ldots, \mathbf{u}_\ell^\alpha$ those eigenvectors.
3: Letting $\mathbf{v}_i^\alpha = \mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha$ and $\bar{\mathbf{v}}_i^\alpha = \frac{\mathbf{v}_i^\alpha}{\|\mathbf{v}_i^\alpha\|}$, stack the vectors $\bar{\mathbf{v}}_i^\alpha$'s columnwise in a matrix $\mathbf{W} = [\bar{\mathbf{v}}_1^\alpha, \ldots, \bar{\mathbf{v}}_\ell^\alpha] \in \mathbb{R}^{n\times\ell}$.
4: Let $\mathbf{r}_1, \ldots, \mathbf{r}_n \in \mathbb{R}^\ell$ be the rows of $\mathbf{W}$. Cluster $\mathbf{r}_i \in \mathbb{R}^\ell$, $1 \le i \le n$ in one of the K groups using any low-dimensional classification algorithm (e.g., k-means or EM). The label assigned to $\mathbf{r}_i$ then corresponds to the label of node i.

performances of Algorithm 2 mainly depend on the content of the eigenvectors $\bar{\mathbf{v}}_i^\alpha$'s. These regularized eigenvectors happen to be shapped like noisy "plateaus" (step functions), each plateau characterizing a class. The objective of the next section is to provide deterministic limits of the parameters of those noisy plateaus from which the asymptotic performances of Algorithm 2 unfold.

3.5 Eigenvectors and improvement of Expectation Maximization (EM) algorithm

In this section, we provide a precise characterization of the asymptotic class means and class covariances of the dominant eigenvectors entries (used for clustering) which in turn allows to improve the classical EM algorithm used in the last step of spectral clustering procedures. The eigenvectors of $\mathbf{L}_\alpha$ have the property of remaining "stable" in the large dimensional limit, thereby allowing for a precise characterization of their content. This behavior (classical in the spike model analysis of random matrices) however only holds for eigenvectors associated to strictly isolated eigenvalues (in the sense that the latter remain at macroscopic distance of all other eigenvalues). In the remainder, we thus assume that the normalized eigenvector $\bar{\mathbf{v}}_i^\alpha$ under study is associated with such a strictly isolated eigenvalue.

As one can see in Figure 3, the different clusters of points (rows of $\mathbf{W}$ in Algorithm 2) have different dispersions (variances) in the DCSBM model under consideration. The most appropriate algorithm to use in step 4 of Algorithm 2 is the expectation maximization (EM) method. EM considers each point $\mathbf{r}_i \in \mathbb{R}^\ell$ arising from $[\bar{\mathbf{v}}_1^\alpha, \ldots, \bar{\mathbf{v}}_\ell^\alpha]$ as a mixture of K Gaussian random vectors with means $\boldsymbol{\nu}_{EM}^a$ and covariances $\mathbf{\Sigma}_{EM}^a \in \mathbb{R}^{\ell\times\ell}$, $a \in \{1, \ldots, K\}$. Starting from initial means and covariances, they are sequentially updated until convergence. To identify $\boldsymbol{\nu}_{EM}^a$, $\mathbf{\Sigma}_{EM}^a$ and thus understand the performance of Algorithm 2, we may write $\bar{\mathbf{v}}_i^\alpha$ [10] as the

10. Recall that the graph nodes were assumed labeled by class, and thus the entries of $\bar{\mathbf{v}}_i^\alpha$ are similarly sorted by class.

"noisy plateaus" vector

$$\bar{\mathbf{v}}_i^\alpha = \sum_{a=1}^{K} \nu_i^a \frac{\mathbf{j}_a}{\sqrt{n_a}} + \sqrt{\sigma_{ii}^a}\mathbf{w}_i^a \tag{4}$$

where $\mathbf{w}_i^a \in \mathbb{R}^n$ is a random vector orthogonal to $\mathbf{j}_a$, of norm $\sqrt{n_a}$ and supported on the indices of $\mathcal{C}_a$ and

$$\nu_i^a = \frac{1}{\sqrt{n_a}} (\bar{\mathbf{v}}_i^\alpha)^\mathsf{T} \mathbf{j}_a = \frac{1}{\sqrt{n_a}} \frac{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{j}_a}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i^\alpha}} \tag{5}$$

$$\sigma_{ij}^a = \frac{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathcal{D}_a \mathbf{D}^{\alpha-1} \mathbf{u}_j^\alpha}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i} \sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_j^\alpha}} - \nu_i^a \nu_j^a \tag{6}$$

with $\mathcal{D}_a = \mathcal{D}(\mathbf{j}_a)$. The vector $\boldsymbol{\nu}^a = (\nu_i^a)_{i=1}^\ell \in \mathbb{R}^\ell$ and the matrix $\boldsymbol{\Sigma}^a = (\sigma_{ij}^a)_{i,j=1}^\ell \in \mathbb{R}^{\ell \times \ell}$ represent respectively the empirical means and empirical covariances of the points $\mathbf{r}_i$ (defined in Algorithm 2) belonging to class $\mathcal{C}_a$. Thus, provided that EM converges to the correct solution, $(\boldsymbol{\nu}_{EM}^a)_i$ and $(\boldsymbol{\Sigma}_{EM}^a)_{ij}$ shall converge asymptotically to the limiting values of $\nu_i^a \in \mathbb{R}$ and σ_{ij}^a respectively. Clearly, for small values of $\boldsymbol{\Sigma}^a$ compared to $\boldsymbol{\nu}^a$, clustering the vectors $\bar{\mathbf{v}}_i^\alpha$ shall lead to good performances.

We find the asymptotic limits of the class means ν_i^a and the class covariances σ_{ij}^a. The explicit expressions of those limits are provided in the proof section (Theorems 22 and 23) for readability reasons.

Theorem 15 *For ν_i^a, σ_{ij}^a defined in* (26), (27)*respectively, there exist deterministic limits $\nu_i^{a,\infty}$ and $\sigma_{ij}^{a,\infty}$ (explicitely defined in Theorems 22 and 23 in Section 6.4) such that, as $n \to \infty$, almost surely*

$$\left|(\nu_i^a)^2 - (\nu_i^{a,\infty})^2\right| \to 0$$
$$\left|\sigma_{ij}^a - \sigma_{ij}^{a,\infty}\right| \to 0.$$

Proof [Sketch] Technically, the standard tools used in spiked random matrix analysis do not allow for an immediate assessment of the quantities ν_i^a and σ_{ij}^a. As a workaround, we follow the approach used in (Couillet et al., 2016) which relies on the possibility to estimate bilinear forms of the type $\mathbf{a}^\mathsf{T}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{b}$ for given vectors $\mathbf{a}, \mathbf{b} \in \mathbb{R}^n$ and unit multiplicity eigenvectors $\mathbf{u}_i^\alpha$ of $\mathbf{L}_\alpha$ since we have from Cauchy formula, as $n \to \infty$ almost surely, (since $\lambda_i(\mathbf{L}_\alpha) \to \rho$)

$$\mathbf{a}^\mathsf{T}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{b} = -\frac{1}{2\pi i} \oint_{\Gamma_\rho} \mathbf{a}^\mathsf{T} (\mathbf{L}_\alpha - z\mathbf{I}_n)^{-1} \mathbf{b} \mathrm{d}z$$

and for a given matrix $\mathbf{D}$

$$(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}\mathbf{u}_i^\alpha = \mathrm{tr}\, \mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D} = -\frac{1}{2\pi i} \oint_{\Gamma_\rho} \mathrm{tr}\, (\mathbf{L}_\alpha - z\mathbf{I}_n)^{-1} \mathbf{D} \mathrm{d}z$$

where Γ_ρ is a positively oriented contour circling around the limiting eigenvalue ρ of $\lambda_i(\mathbf{L}_\alpha)$ associated to the eigenvector $\mathbf{u}_i^\alpha$ of $\mathbf{L}_\alpha$. The calculus details are provided in Section 6.4. ■

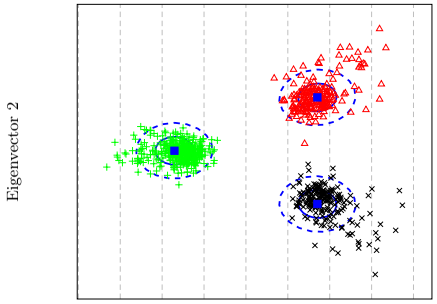

Figure 6: $n = 800$, $K = 3$ classes $\mathcal{C}_1$, $\mathcal{C}_2$ and $\mathcal{C}_3$ of sizes $|\mathcal{C}_1| = |\mathcal{C}_2| = \frac{n}{4}$, $|\mathcal{C}_3| = \frac{n}{2}$, $\frac{3}{4}$ of the nodes having $q_i = 0.3$ and the others having $q_i = 0.8$, matrix of weights $\mathbf{C} = \mathbf{1}_3\mathbf{1}_3^\mathsf{T} + \frac{30}{\sqrt{n}}\mathbf{I}_3$. Two dimensional representation of the dominant eigenvectors 1 and 2 of $\mathbf{L}_\alpha$. In blue, theoretical means and one- and two- standard deviations.

Using the asymptotic results in Theorem 15, we display in Figures 6 and 7 the theoretical means and standard deviations versus ground truths for each class-wise block of the eigenvectors entries. The good fit between the ground truths and the theoretical findings of the class means and class covariances, calls for the improvement of the random initialization of the EM procedure in the last step of spectral clustering.

The performances of EM highly depend on the chosen starting parameters; a first natural choice is to set them randomly, which as we shall see leads to poor performances especially in cases where the clusters are not easily separable. Since the theoretical limiting means $\boldsymbol{\nu}^{a,\infty}$ and covariances $\boldsymbol{\Sigma}^{a,\infty}$ are respectively the limiting values of $\boldsymbol{\nu}_{EM}^a$ and covariances $\boldsymbol{\Sigma}_{EM}^a$ provided EM converges to the correct solution, we may set as initial parameters of EM our findings $\boldsymbol{\nu}^{a,\infty}$ (Theorem 22) and $\boldsymbol{\Sigma}^{a,\infty}$ (Theorem 23) for $a \in \{1, \ldots, K\}$ provided those can be estimated. In most scenarios, the many unknowns prevent such an estimation. Nonetheless, from Corollary 25 (Section 6.4), provided the class proportions (or the sizes of each class) are (more or less) known, we can consistently estimate $\boldsymbol{\nu}^\infty$ and $\boldsymbol{\Sigma}^\infty$ in a 2-class scenario. As we shall see, this new setting of initial parameters is much better than other initializations approaches.

To show the effect of our setting of initial parameters of EM based on the findings $\boldsymbol{\nu}^\infty$ and $\boldsymbol{\Sigma}^\infty$, Figure 8 compares the empirical performances of our new spectral algorithm based on the regularized eigenvector of $\mathbf{L}_{0.5}$ for different initial settings of the EM parameters *i)* random setting (Random EM) *ii)* our theoretical setting (by assuming that the class proportions are known) and *iii)* the ground truth setting (oracle EM where we set the initial points to the empirically evaluated means and covariances of each cluster based on ground truth). Below the transition point, no consistent clustering can be achieved for large n using the eigenvectors associated to highest eigenvalues since the clusters are not separable and our theoretical limiting means and covariances are not defined since there is no isolated eigenvalues

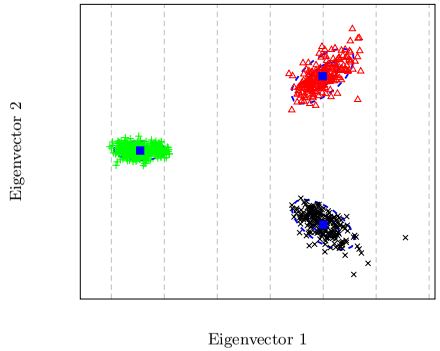

Figure 7: $n = 800$, $K = 3$ classes $\mathcal{C}_1$, $\mathcal{C}_2$ and $\mathcal{C}_3$ of sizes $|\mathcal{C}_1| = |\mathcal{C}_2| = \frac{n}{4}$, $|\mathcal{C}_3| = \frac{n}{2}$, q_i's uniformly distributed over $[0.1, 0.9]$, matrix of weights $\mathbf{C} = \mathbf{1}_3\mathbf{1}_3^\mathsf{T} + \frac{100}{\sqrt{n}}\mathbf{I}_3$. Two dimensional representation of the dominant eigenvectors 1 and 2 of $\mathbf{L}_\alpha$. In blue, theoretical means and one- and two- standard deviations

in that case. We have thus initialized EM at random in this non interesting regime (as for Random EM). The EM algorithm may in that regime set all the nodes to the same cluster, which will then result to a classification rate close to the proportion of the nodes in the cluster of largest size. In the interesting regime (after the transition point), we see that the performances (in terms of correct classification rate) of the algorithm using our theoretical setting of EM closely match the performances of an ideal setting with ground truth (oracle EM). The performances of the algorithm using a random initialization (Random EM) are completely degraded especially around critical cases (small values of Δ). Random EM becomes reliable only for very large values of Δ where clustering is somewhat trivial.

4. Numerical simulations

We restrict ourselves to $\alpha \in \mathcal{A} = [0, 1]$ for the numerical simulations. To illustrate the importance of the choice of α_{opt}, Figure 9 presents the theoretical (asymptotic) ratio between the limiting largest eigenvalue ρ of $\mathbf{L}_\alpha$ and the right edge S^α of the limiting support $\mathcal{S}^\alpha$ with respect to the amplitude of the eigenvalues of $\bar{\mathbf{M}}$. Although α_{opt} only ensures in theory to have the best isolation of the eigenvalues only in "worst cases scenarios"(i.e., when $\lambda(\bar{\mathbf{M}})$ is slighty larger than $\tau^{\alpha_{\text{opt}}}$), Figure 9 shows that taking $\alpha = \alpha_{\text{opt}}$ provides the largest gap $\frac{\rho}{S^\alpha}$ for all values of $\lambda(\bar{\mathbf{M}})$. This suggests (again, without any theoretical support) best performances with $\alpha = \alpha_{\text{opt}}$ in all cases (for any value of $\mathbf{M}$).

In the sequel, to compare the different algorithms, we will use the performance evaluation measure known as *overlap to ground truth communities*, defined in (Krzakala et al., 2013) as

$$\text{Overlap} \equiv \frac{\frac{1}{n}\sum_{i=1}^n \delta_{g_i \hat{g}_i} - \frac{1}{K}}{1 - \frac{1}{K}},$$

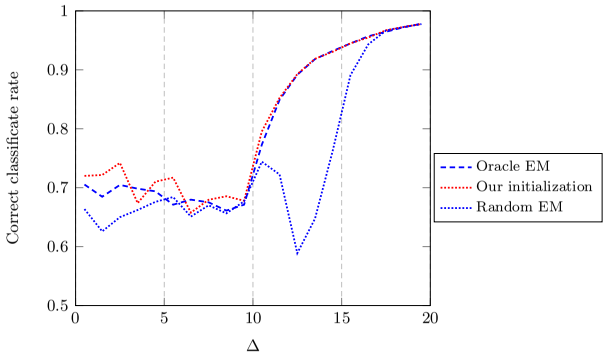

Figure 8: Probability of correct recovery for $\alpha = 0.5$, $n = 4000$, $K = 2$, $c_1 = 0.8$, $c_2 = 0.2$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$ with $q_{(1)} = 0.2$ and $q_{(2)} = 0.8$, $\mathbf{M} = \Delta\mathbf{I}_2$, for $\Delta \in [0, 20]$.

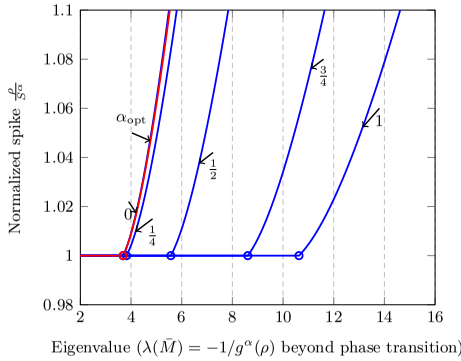

Figure 9: Ratio between the limiting largest eigenvalue ρ of $\mathbf{L}_\alpha$ and the right edge of the support $\mathcal{S}^\alpha$, as a function of the largest eigenvalue $\lambda(\bar{\mathbf{M}})$ of $\bar{\mathbf{M}}$, $\mathbf{M} = \Delta\mathbf{I}_3$, $c_i = \frac{1}{3}$, for $\Delta \in [10, 150]$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$ with $q_{(1)} = 0.1$ and $q_{(2)} = 0.5$, for $\alpha \in \{0, \frac{1}{4}, \frac{1}{2}, \frac{3}{4}, 1, \alpha_{\text{opt}}\}$ (indicated on the curves of the graph). Here, $\alpha_{\text{opt}} = 0.07$. Circles indicate phase transition.

where g_i and $\hat{g}_i$ are the true and estimated labels of node i, respectively. Figure 10 subsequently shows the overlap performance under the setting of Figure 9 for a simulated graph of $n = 3000$ nodes. Note that the empirically observed phase transitions closely match the theoretical ones (drawn in circles and the same as in Figure 9). We then consider in Fig-

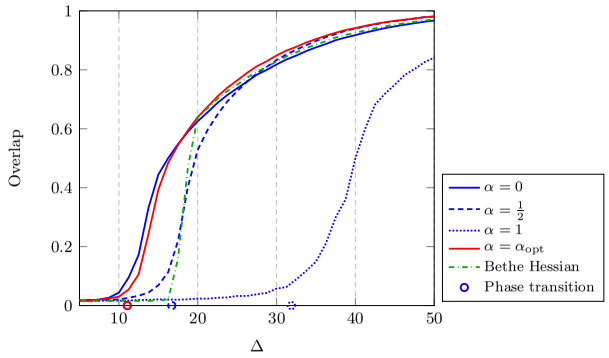

Figure 10: Overlap performance for $n = 3000$, $K = 3$, $c_i = \frac{1}{3}$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$ with $q_{(1)} = 0.1$ and $q_{(2)} = 0.5$, $\mathbf{M} = \Delta\mathbf{I}_3$, for $\Delta \in [5, 50]$. Here $\alpha_{\text{opt}} = 0.07$.

ure 11 a DCSBM graph where $\mathbf{M}$ is fixed and three quarters of the nodes connect with a fixed intrinsic low weight $q_{(1)} = 0.1$ and we vary the intrinsic weights $q_{(2)}$ of the remaining quarter of the nodes from low to high weights. We observe a sudden drop of the BH overlap for large $q_{(2)} - q_{(1)}$. This phenomenon is consistent with the fact, observed earlier in Figure 1, that BH creates artificial communities out of nodes with the same q_i parameter. This is a practical demonstration of the need for a proper eigenvector normalization to avoid degree biases. This observation has recently led (Newman, 2013) to consider a regularization for the non-backtracking operator on which the BH method is based, which still awaits for proper analysis.

In Figure 12, we consider a more realistic synthetic graph where the q_i's assume a power law of support $[0.05, 0.3]$ which simulates a sparse graph characteristic of real world networks. Although this is not the regime we study in this article, our method for $\alpha = \hat{\alpha}_{\text{opt}}$ still competes with the BH method which was developped for sparse homogeneous graphs. However, it is seen that the theoretical phase transitions do not closely match the empirical ones especially for the case $\alpha = 1$. This mismatch is likely due to the fact that our theoretical results in this article require $P_{ij} = \Omega(1)$ which is not always the case in this scenario.

We finally confront the performances (in terms of overlap and modularity [11]) of the different spectral algorithms on the Political blogs graph (Adamic and Glance, 2005) in Table 1. We should note that while $\alpha_{\text{opt}} = 0$ in this case, it achieves the best performance both in terms of the overlap to the ground truth and of the modularity. [12] Likely, the reason why

11. The modularity Q for a given graph partition with class labels g_i's is defined as : $Q = \frac{1}{2m}\sum_{i,j=1}^{n}\left(A_{ij} - \frac{d_i d_j}{2m}\right)\delta_{g_i=g_j}$ where $\mathbf{d} = \mathbf{A}\mathbf{1}_n$ is the degree vector and $m = \frac{1}{2}\mathbf{d}^{\mathsf{T}}\mathbf{1}_n$ is the total number of edges.

12. We should note here that the scores for the BH are different from the ones found in the article (Saade et al., 2014) since here we are running k-means algorithm in the last step of the spectral algorithm while the authors of (Saade et al., 2014) have instead used a sign classification of the eigenvector components for networks with two communities.

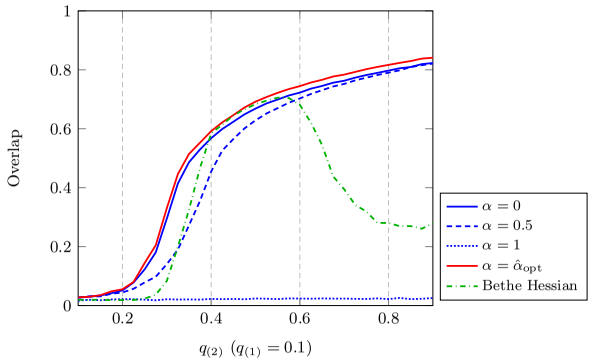

Figure 11: Overlap for $n = 3000$, $K = 3$, $\mu = \frac{3}{4}\delta_{q_{(1)}} + \frac{1}{4}\delta_{q_{(2)}}$ with $q_{(1)} = 0.1$ and $q_{(2)} \in [0.1, 0.9]$, $\mathbf{M}$ defined by $M_{ii} = 10$, $M_{ij} = -10, i \neq j$, $c_i = \frac{1}{3}$.

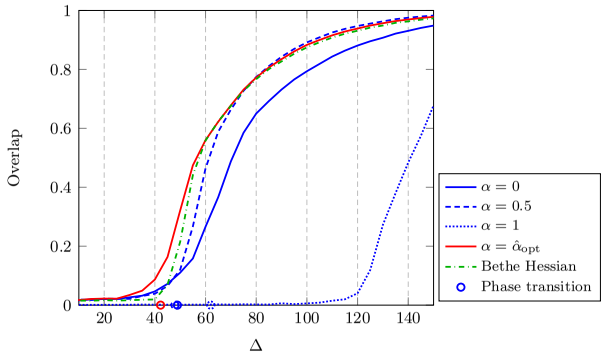

Figure 12: Overlap for $n = 3000$, $K = 3$, $c_i = \frac{1}{3}$, μ a power law with exponent 3 and support $[0.05, 0.3]$, $\mathbf{M} = \Delta\mathbf{I}_3$, for $\Delta \in [10, 150]$. Here $\hat{\alpha}_{\text{opt}} = 0.28$.

$\alpha = 0$ is optimal on the Political blogs dataset can be seen in Figure 4, where $\mathbf{L}_0$ is the similarity matrix for which the isolated eigenvalue is the farthest from the bulk of the other eigenvalues and thus the associated eigenvector is more aligned to the classes compared to the eigenvectors of $\mathbf{L}_{\frac{1}{2}}$ and $\mathbf{L}_1$.

Algo	Overlap	Modularity
$\hat{\alpha}_{\text{opt}}$ ($\simeq 0$)	**0.897**	**0.4246**
$\alpha = 0.5$	0.035	$\simeq 0$
$\alpha = 1$	0.040	$\simeq 0$
BH	0.304	0.2723

Table 1: Overlap performance and Modularity after applying the different spectral algorithms on the Political blogs graph (Adamic and Glance, 2005).

5. Concluding Remarks

The thorough study of $\mathbf{L}_\alpha$ performed in this article allows us to go further than the observation of (Gulikers et al., 2015) and (Jin et al., 2015) which state that it is important to use the eigenvectors of $\mathbf{L}_1$ or a normalization of the eigenvectors of $\mathbf{L}_0$ rather than the eigenvectors of $\mathbf{L}_0$ themselves for community detection when the network has an heterogeneous degree distribution (to avoid misclassifications induced by degree biases). Our main finding in particular is to show that there exists an optimal α, denoted here α_{opt}, for which taking the eigenvectors of $\mathbf{L}_{\alpha_{\text{opt}}}$ pre-multiplied by $\mathbf{D}^{\alpha_{\text{opt}}-1}$ ensures best performances (or to be more precise best asymptotic cluster detectability).

The results and methods in this article are all based on the strong assumption that the average node degree is of order $\mathcal{O}(n)$ and that the class-wise correction factors $C_{g_ig_j}$ differ by $\mathcal{O}(n^{-\frac{1}{2}})$ since $\forall i,j \in \{1,\dots,n\}$, $C_{g_ig_j} = 1 + \frac{M_{g_ig_j}}{\sqrt{n}}$. Previous works (Lyzinski et al., 2014; Lei et al., 2015; Gulikers et al., 2015) suggest that the present analysis, which only considers "first order spectral statistics", should naturally extend to moderately sparse graphs (of as little as $\Omega(\log n)$ average degree). Under the sparse DCSBM graph assumption, strikingly different tools are required, opening up a challenging area of improved algorithm research. Similarly, if the $C_{g_ig_j}$'s differ at a rate $n^{-\frac{1}{2}} \ll r_n \ll 1$, mere refinements of our analysis ensure asymptotic weak consistency for all values of α based on the present tools. In passing, this shows that identifiability considerations are equivalent to those delineated for any α, as in (Gulikers et al., 2015) for $\alpha = 1$. Formally, the case where $r_n = \Omega(1)$ breaks Lemma 11 and therefore the validity of our present analysis but this scenario is also by and far covered by previous works.

6. Proofs

Preliminaries

The random matrix under study $\mathbf{L}_\alpha$ is not a classically studied matrix in random matrix theory. We will thus first find in Section 6.1 an approximate tractable random matrix $\tilde{\mathbf{L}}_\alpha$ which asymptotically preserves the eigenvalue distribution and the extreme eigenvectors of $\mathbf{L}_\alpha$. In Section 6.2, we study the empirical distribution of the eigenvalues of $\mathbf{L}_\alpha$ and in Section 6.3, we characterize the exact localizations of those eigenvalues. Finally, a thorough study of the eigenvectors associated to the aforementioned eigenvalues is investigated in Sections 6.4 and 6.5.

We follow here the proof technique of (Couillet et al., 2016). In the sequel, we will make some approximations of random variables in the asymptotic regime where $n \to \infty$. For

the sake of random variables comparisons, we give the following stochastic definitions. For $x \equiv x_n$ a random variable and $u_n \geq 0$, we write $x = \mathcal{O}(u_n)$ if for any $\eta > 0$ and $D > 0$, $n^D \mathbb{P}(x \geq n^\eta u_n) \to 0$ as $n \to \infty$. For $\mathbf{v}$ a vector or a diagonal matrix with random entries, $\mathbf{v} = \mathcal{O}(u_n)$ means that the maximal entry of $\mathbf{v}$ in absolute value is $\mathcal{O}(u_n)$ in the sense defined previously. When $\mathbf{M}$ is a square matrix, $\mathbf{M} = \mathcal{O}(u_n)$ means that the operator norm of $\mathbf{M}$ is $\mathcal{O}(u_n)$. For $\mathbf{x}$ a vector or a matrix with random entries, $\mathbf{x} = o(u_n)$ means that there is $\kappa > 0$ such that $\mathbf{x} = \mathcal{O}(n^{-\kappa}u_n)$.

Most of the proofs here are classical in random matrix theory (see e.g., (Baik and Silverstein, 2006)) but require certain controls inherent to our model. The goal of the article not being an exhaustive development of the proofs techniques, we will admit a number of technical results already studied in the literature. However, we will exhaustively develop the calculus to obtain our final results which are not trivial.

6.1 Random equivalent for $\mathbf{L}_\alpha$

The matrix $\mathbf{L}_\alpha = (\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha \frac{1}{\sqrt{n}} \mathbf{D}^{-\alpha} \left[\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{\mathbf{d}^\mathsf{T}\mathbf{1}_n}\right] \mathbf{D}^{-\alpha}$ has non independent entries and is not a classical random matrix model. The idea is thus to approximate $\mathbf{L}_\alpha$ by a more tractable random matrix model $\tilde{\mathbf{L}}_\alpha$ in such a way that they share asymptotically the same set of outlying eigenvalues/eigenvectors which are of interest in our clustering scenario. We recall that the entries A_{ij} of the adjacency matrix is defined from the DCSBM model as independent Bernoulli random variables with parameter $q_iq_j\left(1 + \frac{M_{g_ig_j}}{\sqrt{n}}\right)$; one may thus write

$$A_{ij} = q_iq_j + q_iq_j\frac{M_{g_ig_j}}{\sqrt{n}} + X_{ij}$$

where X_{ij}, $1 \leq i,j \leq n$, are independent (up to the symmetry) zero mean random variables of variance $q_iq_j(1-q_iq_j) + \mathcal{O}(n^{-\frac{1}{2}})$, since A_{ij} has mean $q_iq_j + q_iq_j\frac{M_{g_ig_j}}{\sqrt{n}}$ and variance $q_iq_j(1-q_iq_j) + \mathcal{O}(n^{-\frac{1}{2}})$. We can then write the normalized adjacency matrix as follows

$$\frac{1}{\sqrt{n}}\mathbf{A} = \frac{1}{\sqrt{n}}\mathbf{q}\mathbf{q}^\mathsf{T} + \frac{1}{n}\left\{\mathbf{q}_{(a)}\mathbf{q}_{(b)}^\mathsf{T}M_{ab}\right\}_{a,b=1}^K + \frac{1}{\sqrt{n}}\mathbf{X} \tag{7}$$

$$= \underbrace{\frac{\mathbf{q}\mathbf{q}^\mathsf{T}}{\sqrt{n}}}_{\mathbf{A}_{d,\sqrt{n}}} + \underbrace{\frac{1}{n}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}_{\mathbf{A}_{d,1}} + \underbrace{\frac{\mathbf{X}}{\sqrt{n}}}_{\mathbf{A}_{r,1}}, \tag{8}$$

where[13] $\mathbf{q}_{(i)} = [q_{n_1+\ldots+n_{i-1}+1}, \ldots, q_{n_1+\ldots+n_i}]^\mathsf{T} \in \mathbb{R}^{n_i}$ ($n_0 = 0$) , $\mathbf{X} = \{X_{ij}\}_{i,j=1}^n$ and $\mathbf{D}_q = \mathcal{D}(\mathbf{q})$. The idea of the proof is to write all the terms of $\mathbf{L}_\alpha$ based on Equation (8), since all those terms depend on $\mathbf{A}$. To this end, we will evaluate successively $\mathbf{d} = \mathbf{A}\mathbf{1}_n$, $\mathbf{D} = \mathcal{D}(\mathbf{d})$, $\mathbf{d}\mathbf{d}^\mathsf{T}$ and $2m = \mathbf{d}^\mathsf{T}\mathbf{1}_n$. It will appear that $\mathbf{D}$ and $\mathbf{d}^\mathsf{T}\mathbf{1}_n$ are composed of dominant terms (with higher operator norm) and vanishing terms (with smaller operator norm); we may then proceed to writing a Taylor expansion of $\mathbf{D}^{-\alpha}$ and $(2m)^\alpha = (\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha$ for any α around their dominant terms to finally retrieve a Taylor expansion of $\mathbf{L}_\alpha$.

13. We recall that subscript 'd, n^k' stands for deterministic term whose operator norm is of order n^k and 'r, n^k' for random term with operator norm of order n^k.

Let us start by developing the degree vector $\mathbf{d} = \mathbf{A}\mathbf{1}_n$. We have

$$\mathbf{d} = \mathbf{q}\mathbf{q}^\mathsf{T}\mathbf{1}_n + \frac{1}{\sqrt{n}}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n + \mathbf{X}\mathbf{1}_n = \mathbf{q}^\mathsf{T}\mathbf{1}_n\Big(\underbrace{\mathbf{q}}_{\mathcal{O}(n^{\frac{1}{2}})} + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(n^{-\frac{1}{2}})} + \underbrace{\frac{\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(n^{-\frac{1}{2}})} \Big). \quad (9)$$

Let us then write the expansions of $\mathbf{d}^\mathsf{T}\mathbf{1}_n$, $(\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha$, $\mathbf{d}\mathbf{d}^\mathsf{T}$ and $\frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{(\mathbf{d}^\mathsf{T}\mathbf{1}_n)}$ respectively. From (9), we obtain

$$\mathbf{d}^\mathsf{T}\mathbf{1}_n = (\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2\Big[1 + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(n^{-\frac{1}{2}})} + \underbrace{\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(n^{-\frac{1}{2}})}\Big]. \quad (10)$$

Thus for any α, proceeding to a 1^{st} order Taylor expansion, we may write

$$(\mathbf{d}^\mathsf{T}\mathbf{1}_n)^\alpha = (\mathbf{q}^\mathsf{T}\mathbf{1}_n)^{2\alpha}\Big[1 + \frac{\alpha}{\sqrt{n}}\underbrace{\frac{\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(n^{-\frac{1}{2}})} + \alpha\underbrace{\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(n^{-\frac{1}{2}})} + o(n^{-\frac{1}{2}})\Big]. \quad (11)$$

Besides, from (9) we have

$$\begin{aligned}\mathbf{d}\mathbf{d}^\mathsf{T} = (\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2\Big[&\underbrace{\mathbf{q}\mathbf{q}^\mathsf{T}}_{\mathcal{O}(n)} + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(\sqrt{n})} + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(\sqrt{n})} + \underbrace{\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{X}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(\sqrt{n})} + \underbrace{\frac{\mathbf{X}\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}}_{\mathcal{O}(\sqrt{n})} \\ &+ \underbrace{\frac{1}{n}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(1)} + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{X}}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(1)} + \underbrace{\frac{1}{\sqrt{n}}\frac{\mathbf{X}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(1)} \\ &+ \underbrace{\frac{\mathbf{X}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{X}}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}}_{\mathcal{O}(1)} + o(1)\Big]. \end{aligned} \quad (12)$$

Keeping in mind that we shall only need terms with non vanishing operator norms asymptotically, we will require $\frac{1}{\sqrt{n}}\left[\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{\mathbf{d}^\mathsf{T}\mathbf{1}_n}\right]$ to have terms with spectral norms of order at least $\mathcal{O}(1)$. We get from multiplying (12) and (11) (with $\alpha = -1$)

$$\begin{aligned}\frac{1}{\sqrt{n}}\frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{\mathbf{d}^\mathsf{T}\mathbf{1}_n} = &\frac{\mathbf{q}\mathbf{q}^\mathsf{T}}{\sqrt{n}} + \frac{1}{n}\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} + \frac{1}{n}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} + \frac{1}{\sqrt{n}}\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{X}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} + \frac{1}{\sqrt{n}}\frac{\mathbf{X}\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \\ &- \frac{1}{n}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{q}\mathbf{q}^\mathsf{T} - \frac{1}{\sqrt{n}}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{q}\mathbf{q}^\mathsf{T} + \mathcal{O}(n^{-\frac{1}{2}}). \end{aligned} \quad (13)$$

By subtracting (13) from (8), we obtain

$$\begin{aligned}\frac{1}{\sqrt{n}}\left(\mathbf{A} - \frac{\mathbf{d}\mathbf{d}^\mathsf{T}}{\mathbf{d}^\mathsf{T}\mathbf{1}_n}\right) = &\frac{1}{n}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q - \frac{1}{n}\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} - \frac{1}{n}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \\ &+ \frac{1}{n}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{q}\mathbf{q}^\mathsf{T} + \frac{\mathbf{X}}{\sqrt{n}} - \frac{1}{\sqrt{n}}\frac{\mathbf{q}\mathbf{1}_n^\mathsf{T}\mathbf{X}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} - \frac{1}{\sqrt{n}}\frac{\mathbf{X}\mathbf{1}_n\mathbf{q}^\mathsf{T}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \\ &+ \frac{1}{\sqrt{n}}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{q}\mathbf{q}^\mathsf{T} + \mathcal{O}(n^{-\frac{1}{2}}). \end{aligned} \quad (14)$$

It then remains to evaluate $\mathbf{D}^{-\alpha}$. From (9), we may write $\mathbf{D} = \mathcal{D}(\mathbf{d})$ as

$$\mathbf{D} = \mathbf{q}^\mathsf{T}\mathbf{1}_n\Big(\underbrace{\mathbf{D}_q}_{\mathcal{O}(1)} + \underbrace{\mathcal{D}\left(\frac{1}{\sqrt{n}}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\right)}_{\mathcal{O}(n^{-\frac{1}{2}})} + \underbrace{\mathcal{D}\left(\frac{\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\right)}_{\mathcal{O}(n^{-\frac{1}{2}})}\Big).$$

The right hand side of $\mathbf{D}$ (in brackets) having a leading term in $\mathcal{O}(1)$ and residual terms in $\mathcal{O}(n^{-\frac{1}{2}})$, the Taylor expansion of the $(-\alpha)$-power of $\mathbf{D}$ is then retrieved

$$\mathbf{D}^{-\alpha} = \left(\mathbf{q}^\mathsf{T}\mathbf{1}_n\right)^{-\alpha}\Big(\underbrace{\mathbf{D}_q^{-\alpha}}_{\mathcal{O}(1)} - \alpha\mathbf{D}_q^{-(\alpha+1)}\underbrace{\mathcal{D}\left(\frac{1}{\sqrt{n}}\frac{\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\right)}_{\mathcal{O}(n^{-\frac{1}{2}})} - \alpha\mathbf{D}_q^{-(\alpha+1)}\underbrace{\mathcal{D}\left(\frac{\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\right)}_{\mathcal{O}(n^{-\frac{1}{2}})} + \mathcal{O}(n^{-1})\Big). \quad (15)$$

By combining the expressions (11), (14) and (15), we obtain a Taylor approximation of $\mathbf{L}_\alpha$ as follows

$$\begin{aligned}\mathbf{L}_\alpha = &\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} + \frac{1}{n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} - \frac{1}{n}\frac{\mathbf{D}_q^{1-\alpha}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \\ &- \frac{1}{n}\frac{\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{1-\alpha}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} + \frac{1}{n}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{D}_q\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{D}_q^{1-\alpha}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{1-\alpha} - \frac{1}{\sqrt{n}}\frac{\mathbf{D}_q^{1-\alpha}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{D}_q^{-\alpha}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \\ &- \frac{1}{\sqrt{n}}\frac{\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{1-\alpha}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} + \frac{1}{\sqrt{n}}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{D}_q^{1-\alpha}\mathbf{1}_n\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{1-\alpha} + \mathcal{O}(n^{-\frac{1}{2}}). \end{aligned}$$

The three following arguments allow to complete the proof

- $\mathbf{1}_n = \mathbf{J}\mathbf{1}_K$ and $\mathbf{D}_q\mathbf{1}_n = \mathbf{q}$.
- We may write $(\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{q})_i = \frac{n_i}{n}\left(\frac{1}{n_i}\sum_{a\in\mathcal{C}_i} q_a\right)$. For classes of large sizes n_i, from the law of large numbers, $\left(\frac{1}{n_i}\sum_{a\in\mathcal{C}_i} q_a\right) \xrightarrow{\text{a.s.}} m_\mu$ and so, $\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{q} \xrightarrow{\text{a.s.}} m_\mu\mathbf{c}$ where we recall that $m_\mu = \int t\mu(\mathrm{d}t)$.
- As $\mathbf{X}$ is a symmetric random matrix having independent entries of zero mean and finite variance, from the law of large numbers, we have $\frac{1}{n}\frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n}{\sqrt{n}} \xrightarrow{\text{a.s.}} 0$.

Using those three arguments, $\mathbf{L}_\alpha$ may be further rewritten

$$\begin{aligned}\mathbf{L}_\alpha = &\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} + \frac{1}{n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} - \frac{1}{n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{1}_K\mathbf{c}^\mathsf{T}\mathbf{M}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} \\ &- \frac{1}{n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{M}\mathbf{c}\mathbf{1}_K^\mathsf{T}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} + \frac{1}{n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{1}_K\mathbf{c}^\mathsf{T}\mathbf{M}\mathbf{c}\mathbf{1}_K^\mathsf{T}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} \\ &- \frac{1}{\sqrt{n}\mathbf{q}^\mathsf{T}\mathbf{1}_n}\mathbf{D}_q^{1-\alpha}\mathbf{J}\mathbf{1}_K\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{D}_q^{-\alpha} - \frac{1}{\sqrt{n}\mathbf{q}^\mathsf{T}\mathbf{1}_n}\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n\mathbf{1}_K^\mathsf{T}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha} + \mathcal{O}(n^{-\frac{1}{2}}). \end{aligned} \quad (16)$$

By rearranging the terms of (16), we obtain the expected result

$$\begin{aligned}\mathbf{L}_\alpha = &\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} \\ &+ \begin{bmatrix}\frac{\mathbf{D}_q^{1-\alpha}\mathbf{J}}{\sqrt{n}} & \frac{\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\end{bmatrix}\begin{bmatrix}\left(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^T\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right) & -\mathbf{1}_K \\ -\mathbf{1}_K^T & 0\end{bmatrix}\begin{bmatrix}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}}{\sqrt{n}} \\ \frac{\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{D}_q^{-\alpha}}{\mathbf{q}^\mathsf{T}\mathbf{1}_n}\end{bmatrix} + \mathcal{O}(n^{-\frac{1}{2}}). \end{aligned}$$

This proves Theorem 2.

6.2 Limiting spectral distribution of $\mathbf{L}_\alpha$

It follows from Theorem 2 that $\tilde{\mathbf{L}}_\alpha = \mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} + \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$ is equivalent to an additive spiked random matrix (Chapon et al., 2012) where

$$\mathbf{U} = \begin{bmatrix} \frac{\mathbf{D}_q^{1-\alpha}\mathbf{J}}{\sqrt{n}} & \frac{\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n}{\mathbf{q}^\mathsf{T}\mathbf{1}_n} \end{bmatrix},$$
$$\mathbf{\Lambda} = \begin{bmatrix} \left(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^T\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right) & -\mathbf{1}_K \\ -\mathbf{1}_K^T & 0 \end{bmatrix},$$

with the difference that the deterministic part $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$ is not independent of the random part $\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha}$ (an issue that we solve here) and $\mathbf{U}$ is not composed of orthonormal vectors. Let us then study $\bar{\mathbf{X}} = \mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha}$ (having entries $\bar{X}_{ij}$ with zero mean and variance σ_{ij}^2/n with $\sigma_{ij}^2 = q_iq_j(1-q_iq_j) + \mathcal{O}(n^{-\frac{1}{2}})$) and show that its empirical spectral distribution (e.s.d.) $\tilde{\pi}^\alpha$ converges weakly to $\bar{\pi}^\alpha$ with Stieljes transform $e_{00}^\alpha(z) = \int (t-z)^{-1}\,\mathrm{d}\bar{\pi}^\alpha(t)$ for $z \in \mathbb{C}^+$. This will imply (By Weyl interlacing formula) that the empirical spectral measure $\pi^\alpha \equiv \frac{1}{n}\sum_{i=1}^n \delta_{\lambda_i(\tilde{\mathbf{L}}_\alpha)}$ (with $\lambda_i(\tilde{\mathbf{L}}_\alpha)$ eigenvalues of $\tilde{\mathbf{L}}_\alpha$) will also converge to $\bar{\pi}^\alpha$.

The matrix $\bar{\mathbf{X}}$ is a classical random matrix model in RMT already studied in similar cases (Pastur et al., 2011). It is well known for those random matrix models (having entries with given means, variances and bounded first order moments) that the law of the $\bar{X}_{ij}$'s does not change the results on the limiting law of the e.s.d. $\tilde{\pi}^\alpha$: this property is kwown as *universality* (e.g., (Silverstein and Bai, 1995)). For technical reasons, we can thus assume that the $\bar{X}_{ij}$'s are Gaussian random variables with the same means and variances in order to use standard Gaussian calculus, introduced in (Pastur et al., 2011). The objective of the proof is to find the deterministic limit $e_{00}^\alpha(z)$ for the random quantity $\frac{1}{n}\operatorname{tr}\left(\bar{\mathbf{X}} - z\mathbf{I}_n\right)^{-1}$ which is the Stieljes transform of the e.s.d. $\tilde{\pi}^\alpha$. Deterministic equivalents for the Stieljes transform of empirical spectral measures associated with centered and symmetric random matrix models with a variance profile have already been studied in for example (Ajanki et al., 2015; Hachem et al., 2007). We give in Appendix C an exhaustive development of the Gaussian calculus to obtain $e_{00}^\alpha(z)$. The final result is as follows.

Lemma 16 (A first deterministic equivalent) *Let $\mathbf{Q} = (\bar{\mathbf{X}} - z\mathbf{I}_n)^{-1}$. Then, for all $z \in \mathbb{C}^+$,*

$$\mathbf{Q} \leftrightarrow \bar{\mathbf{Q}} = \left(-z\mathbf{I}_n - \mathcal{D}\left(e_i(z)\right)_{i=1}^n\right)^{-1} \tag{17}$$

where $e_i(z)$ the unique solution of $e_i(z) = \frac{1}{n}\operatorname{tr}\mathcal{D}\left(\sigma_{ij}^2\right)_{j=1}^n\left(-z\mathbf{I}_n - \mathcal{D}\left(e_j(z)\right)_{j=1}^n\right)^{-1}$ and the notation $\mathbf{A} \leftrightarrow \mathbf{B}$ stands for $\frac{1}{n}\operatorname{tr}\mathbf{C}\mathbf{A} - \frac{1}{n}\operatorname{tr}\mathbf{C}\mathbf{B} \to 0$ and $\mathbf{d}_1^\mathsf{T}(\mathbf{A}-\mathbf{B})\mathbf{d}_2 \to 0$ almost surely, for all deterministic Hermitian matrix $\mathbf{C}$ and deterministic vectors $\mathbf{d}_i$ of bounded norms (spectral norm for matrices and Euclidian norm for vectors).

From Lemma 16, we get directly $\frac{1}{n}\operatorname{tr}\mathbf{Q} - e_{00}^\alpha(z) \xrightarrow{\text{a.s.}} 0$ with $e_{00}^\alpha(z) = \frac{1}{n}\sum_{i=1}^n \frac{1}{-z-e_i(z)}$. Observe now that

$$\begin{aligned} e_i(z) &= \frac{1}{n}\sum_{j=1}^n \frac{q_i^{1-2\alpha}q_j^{1-2\alpha} - q_i^{2-2\alpha}q_j^{2-2\alpha}}{-z - e_j(z)} \\ &= q_i^{1-2\alpha}e_{11}^\alpha(z) - q_i^{2-2\alpha}e_{21}^\alpha(z) \end{aligned} \tag{18}$$

where

$$\begin{aligned} e_{11}^\alpha(z) &= \frac{1}{n}\sum_{j=1}^n \frac{q_j^{1-2\alpha}}{-z - q_j^{1-2\alpha}e_{11}^\alpha(z) + q_j^{2-2\alpha}e_{21}^\alpha(z)} \\ e_{21}^\alpha(z) &= \frac{1}{n}\sum_{j=1}^n \frac{q_j^{2-2\alpha}}{-z - q_j^{1-2\alpha}e_{11}^\alpha(z) + q_j^{2-2\alpha}e_{21}^\alpha(z)} \end{aligned} \tag{19}$$

from which we get

$$e_{00}^\alpha(z) = \int \frac{1}{-z - e_{11}^\alpha(z)q^{1-2\alpha} + e_{21}^\alpha(z)q^{2-2\alpha}}\mu(dq).$$

where for $z \in \mathbb{C}^+$ and $a, b \in \mathbb{Z}$ we define

$$e_{ab}^\alpha(z) = \int \frac{q^{a-2b\alpha}\mu(dq)}{-z - e_{11}^\alpha(z)q^{1-2\alpha} + e_{21}^\alpha(z)q^{2-2\alpha}}. \tag{20}$$

with $\mu(\mathrm{d}q) = \lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^n \delta_{q_i}$. From this, we have that $e_{00}^\alpha(z)$ does not depend on n, so that $\frac{1}{n}\operatorname{tr}\mathbf{Q} \xrightarrow{\text{a.s.}} E_0^\alpha(z)$, $\tilde{\pi}^\alpha \to \bar{\pi}^\alpha$, and thus $\pi^\alpha \to \bar{\pi}^\alpha$ since $\tilde{\mathbf{L}}_\alpha$ and $\bar{\mathbf{X}}$ only differ by a finite rank matrix. This proves Theorem 4.

In the main core of the article, we have defined $e_{00}^\alpha(z) \triangleq m^\alpha(z)$, $e_{11}^\alpha(z) \triangleq f^\alpha(z)$ and $e_{21}^\alpha(z) \triangleq g^\alpha(z)$ for readability reasons. For future use, we define for $z, \tilde{z} \in \mathbb{C}\setminus\mathcal{S}^\alpha$

$$e_{ab;2}^\alpha(z,\tilde{z}) = \int \frac{q^{a-2b\alpha}\mu(dq)}{(-z - E_1^\alpha(z)q^{1-2\alpha} + E_2^\alpha(z)q^{2-2\alpha})(-\tilde{z} - E_1^\alpha(\tilde{z})q^{1-2\alpha} + E_2^\alpha(\tilde{z})q^{2-2\alpha})} \tag{21}$$

and

$$e_{ab;3}^\alpha(z,\tilde{z}) = \int \frac{q^{a-2b\alpha}\mu(dq)}{(-z - E_1^\alpha(z)q^{1-2\alpha} + E_2^\alpha(z)q^{2-2\alpha})^2(-\tilde{z} - E_1^\alpha(\tilde{z})q^{1-2\alpha} + E_2^\alpha(\tilde{z})q^{2-2\alpha})}. \tag{22}$$

Convergence of the e_i's

Similar results to Lemma 16 have been derived for example in (Hachem et al., 2007) and the fixed point algorithm (17) which consists of iterating the e_i's is shown to converge. Since the calcultation of the e_{ab}'s is an intermediary step of (17) from (18), the fixed point algorithm (19) also converges. From the analyticity of the Stieljes transform outside its support, Lemma 16 extends naturally to $\mathbb{C}\setminus\mathcal{S}^\alpha$. This proves Theorem 4.

Remark 17 *Similarly to (Hachem et al., 2007), when none of the $(\mathbf{D}_q^{-\alpha})_{ii}$'s is isolated, the random matrix $\bar{\mathbf{X}}$ does not produce isolated eigenvalues outside the support $\mathcal{S}^\alpha$ of $\bar{\pi}^\alpha$. Here, for large n, this property is verified since from Assumption 1, the q_i's are i.i.d. arising from a law with compact support (the probability that a $(\mathbf{D}_q^{-\alpha})_{ii}$ gets isolated tends to 0 asymptotically). This gives Proposition 18 which we will not prove here; similar proofs are provided for example in (Bai and Silverstein, 1998).*

Proposition 18 (No eigenvalues outside the support) *Following the statement of Theorem 4, let S_-^α and S_+^α be respectively the left and right edges of $\mathcal{S}^\alpha$. Then, for any $\epsilon > 0$, by letting $\mathcal{S}_\epsilon^\alpha = [S_-^\alpha - \epsilon; S_+^\alpha + \epsilon]$, for all large n almost surely,*

$$\left\{\lambda_i\Big(\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha}\Big), 1 \le i \le n\right\} \cap (\mathbb{R} \setminus \mathcal{S}_\epsilon^\alpha) = \emptyset.$$

Remark 19 *The support $\mathcal{S}^\alpha$ is symmetric i.e., $\bar\pi^\alpha([a,b]) = \bar\pi^\alpha([-b,-a])$. We have in particular $S_-^\alpha = -S_+^\alpha = -S^\alpha$ where we denote $S_+^\alpha \triangleq \sup \mathcal{S}^\alpha$ and $S_-^\alpha \triangleq \inf \mathcal{S}^\alpha$.*

6.3 Isolated eigenvalues of $\mathbf{L}_\alpha$ and phase transition.

In the previous section, we have shown that the e.s.d. of $\mathbf{L}_\alpha$ converges weakly to the limiting law of the eigenvalues of $\bar{\mathbf{X}}$ since they only differ by a finite rank matrix. We shall have in addition isolated eigenvalues of $\mathbf{L}_\alpha$ induced by the aforementionned low rank matrix. We are interested here in the localization of eigenvalues of $\mathbf{L}_\alpha$ isolated from the support $\mathcal{S}^\alpha$ of the limiting law of its e.s.d. According to Proposition 18, there is almost surely no eigenvalue of $\bar{\mathbf{X}}$ at non-vanishing distance from $\mathcal{S}^\alpha$ asymptotically as $n \to \infty$ and hence the plausible isolated eigenvalues of $\mathbf{L}_\alpha$ are only due to the matrix $\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}$. We follow classical random matrix approaches used for the study of the spectrum of spiked random matrices (Benaych-Georges and Nadakuditi, 2012; Chapon et al., 2012). From Theorem 2, the eigenvalues ρ of $\mathbf{L}_\alpha$ falling at non-vanishing distance from the limiting support $\mathcal{S}^\alpha$ solve for large n, $0 = \det(\mathbf{L}_\alpha - \rho\mathbf{I}_n)$ almost surely for $\rho \notin \mathcal{S}^\alpha$. Since $\|\mathbf{L}_\alpha - \tilde{\mathbf{L}}_\alpha\| \xrightarrow{\text{a.s.}} 0$, $\rho_i(\mathbf{L}_\alpha) - \rho_i(\tilde{\mathbf{L}}_\alpha) \xrightarrow{\text{a.s.}} 0$ for all eigenvalues $\rho_i(\mathbf{L}_\alpha)$. We may then just solve $0 = \det(\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} + \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T} - \rho\mathbf{I}_n)$. Now, as from Proposition 18, the random matrix $\bar{\mathbf{X}}$ does not have eigenvalues at non-vanishing distance from $\mathcal{S}^\alpha$ asymptotically, for $\rho \notin \mathcal{S}^\alpha$, we can thus factor and cancel out $\det(\bar{\mathbf{X}} - \rho\mathbf{I}_n)$ from the previous determinant equation, so that we are left to solve

$$0 = \det(\mathbf{I}_n + \mathbf{Q}_\rho^\alpha \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T}) = \det(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha \mathbf{U}\mathbf{\Lambda})$$

where $\mathbf{Q}_\rho^\alpha = (\bar{\mathbf{X}} - \rho\mathbf{I}_n)^{-1}$. As we will show next, the matrix $\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda}$ converges to a deterministic matrix, almost surely for large n. By the argument principle (similar to e.g., (Chapon et al., 2012)), the roots of $\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda}$ are asymptotically those of the limiting matrix, with same multiplicity and it suffices to study the latter.

We then proceed to retrieving a limit for $\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda}$. From Theorem 2, we have

$$\mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U} = \begin{pmatrix} \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\mathbf{Q}_\rho^\alpha\mathbf{D}_q^{1-\alpha}\mathbf{J} & \frac{1}{\sqrt{n}(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\mathbf{Q}_\rho^\alpha\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n \\ \frac{1}{\sqrt{n}(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{D}_q^{-\alpha}\mathbf{Q}_\rho^\alpha\mathbf{D}_q^{1-\alpha}\mathbf{J} & \frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{D}_q^{-\alpha}\mathbf{Q}_\rho^\alpha\mathbf{D}_q^{-\alpha}\mathbf{X}\mathbf{1}_n \end{pmatrix}.$$

The entries $(1,2)$, $(2,1)$ and $(2,2)$ of $\mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}$ are random as they contain the random matrix $\mathbf{X}$ but tend to be deterministic in the limit. In fact, using the resolvent identity, we have that $\mathbf{Q}_\rho^\alpha\mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} = \mathbf{I}_n + \rho\mathbf{Q}_\rho^\alpha$, the entry $(1,2)$ becomes $\frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n + \rho\frac{1}{\sqrt{n}(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\mathbf{Q}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n$ and the entry $(2,2)$ is equal to $\frac{n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\Big(\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n + \rho\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{2\alpha}\mathbf{1}_n + \rho^2\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^\alpha\mathbf{Q}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n\Big)$. Now, we can freely use Lemma 16 to evaluate the limits of the entries of $\mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}$ since all the terms are of the form $\mathbf{a}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{b}$ with $\mathbf{a}$ and $\mathbf{b}$ deterministic vectors. From Lemma 16, the entries $(1,1)$, $(1,2)$ and $(2,2)$ converge almost surely respectively to $\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^{1-\alpha}\mathbf{J}$, $\frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n + \rho\frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n$ and $\frac{n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\Big(\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n + \rho\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{2\alpha}\mathbf{1}_n + \rho^2\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^\alpha\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n\Big)$ for large n.

Now, using the fact that for any bounded continuous function f, from the law of large numbers,

$$\frac{1}{n}\sum_{j\in\mathcal{C}_i} f(q_j) = \frac{n_i}{n}\frac{1}{n_i}\sum_{j\in\mathcal{C}_i} f(q_j) \xrightarrow{\text{a.s.}} c_i \int f(q)\mu(dq). \tag{23}$$

After some algebra, we obtain $\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^{1-\alpha}\mathbf{J} \xrightarrow{\text{a.s.}} e_{21}^\alpha(\rho)\mathcal{D}(\mathbf{c})$ where the e_{ij}'s are given in Theorem 4. Similarly for the terms $(1,2)$ and $(2,2)$, we obtain respectively

$$\frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q\mathbf{1}_n + \rho\frac{1}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{J}^\mathsf{T}\mathbf{D}_q^{1-\alpha}\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n \xrightarrow{\text{a.s.}} \left(1 + \frac{\rho}{m_\mu}e_{10}^\alpha(\rho)\right)\mathbf{c}$$

and

$$\frac{n}{(\mathbf{q}^\mathsf{T}\mathbf{1}_n)^2}\Big(\mathbf{1}_n^\mathsf{T}\mathbf{X}\mathbf{1}_n + \rho\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^{2\alpha}\mathbf{1}_n + \rho^2\mathbf{1}_n^\mathsf{T}\mathbf{D}_q^\alpha\bar{\mathbf{Q}}_\rho^\alpha\mathbf{D}_q^\alpha\mathbf{1}_n\Big) \xrightarrow{\text{a.s.}} \frac{1}{m_\mu^2}\left(\rho v_\mu + \rho^2 e_{0;-1}^\alpha(\rho)\right)$$

with $v_\mu = \int q^{2\alpha}\mu(\mathrm{d}q)$ and where we have also used the fact that $\frac{1}{n}\mathbf{1}_n^\mathsf{T}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{1}_n \xrightarrow{\text{a.s.}} 0$ again from the law of large numbers.

The limit of $\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda}$ is then obtained as

$$\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda} \xrightarrow{\text{a.s.}} \begin{pmatrix} \mathbf{I}_K + e_{21}^\alpha(\rho)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \left(1 + \frac{\rho}{m_\mu}e_{10}^\alpha(\rho)\right)\mathbf{c}\mathbf{1}_K^\mathsf{T} & -e_{21}^\alpha(\rho)\mathbf{c} \\ \frac{\rho}{m_\mu^2}\left(v_\mu + \rho e_{0;-1}^\alpha(\rho)\right)\mathbf{1}_K^\mathsf{T} & -\rho\frac{e_{10}^\alpha(\rho)}{m_\mu} \end{pmatrix}.$$

Using the Schur complement formula for the determinant of block matrices, we have that the determinant of the RHS matrix is zero whenever

$$-\rho\frac{e_{10}^\alpha(\rho)}{m_\mu}\det\Big[\mathbf{I}_K + e_{21}^\alpha(\rho)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \left(1 + \frac{\rho}{m_\mu}e_{10}^\alpha(\rho)\right)\mathbf{c}\mathbf{1}_K^\mathsf{T} + \frac{\left(v_\mu + \rho e_{0;-1}^\alpha(\rho)\right)e_{21}^\alpha(\rho)}{m_\mu e_{10}^\alpha(\rho)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\Big] = 0$$

or equivalently $\det(\underline{\mathbf{G}}_\rho^\alpha) = 0$ where

$$\underline{\mathbf{G}}_\rho^\alpha = \mathbf{I}_K + e_{21}^\alpha(\rho)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) + \theta^\alpha(\rho)\mathbf{c}\mathbf{1}_K^\mathsf{T}$$
$$\theta^\alpha(\rho) = -1 + \frac{\rho}{m_\mu}e_{10}^\alpha(\rho) + \frac{\left(v_\mu + \rho e_{0;-1}^\alpha(\rho)\right)e_{21}^\alpha(\rho)}{m_\mu e_{10}^\alpha(\rho)}.$$

The isolated eigenvalues ρ of $\mathbf{L}_\alpha$, which are the ρ for which $\det(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_\rho^\alpha\mathbf{U}\mathbf{\Lambda}) = 0$, are then asymptotically the ρ such that $\det(\underline{\mathbf{G}}_\rho^\alpha) = 0$.

Remark 20 (Two types of isolated eigenvalues) *From the previous paragraph, $1+\theta^\alpha(\rho)$ is an eigenvalue of $\underline{\mathbf{G}}_\rho^\alpha$ with associated left eigenvector $\mathbf{1}_K$ and right eigenvector $\mathbf{c}$ since $\mathbf{1}_K^T\underline{\mathbf{G}}_\rho^\alpha = (1+\theta^\alpha(\rho))\,\mathbf{1}_K^T$ and $\underline{\mathbf{G}}_\rho^\alpha\mathbf{c} = (1+\theta^\alpha(\rho))\,\mathbf{c}$.*

Letting ρ be such that $\det(\underline{\mathbf{G}}_\rho^\alpha) = 0$, we can discriminate two cases

- *$1+\theta^\alpha(\rho) = 0$: isolated eigenvalues are found for those $\rho \in \mathbb{R}\setminus\mathcal{S}^\alpha$ such that $1+\theta^\alpha(\rho) = 0$. We shall denote by $\tilde\rho$ such eigenvalues when they exist.*

- $1+\theta^\alpha(\rho)\neq 0$*: the left and right eigenvectors associated to the zero eigenvalues of* $\underline{\mathbf{G}}_\rho^\alpha$ *are respectively orthogonal to the right and left eigenvectors associated to the non-zero eigenvalues. So, by letting* $\mathbf{V}_l$, $\mathbf{V}_r$ *be matrices containing in columns the respectively left and right eigenvectors of* $\underline{\mathbf{G}}_\rho^\alpha$ *associated with the zero eigenvalues, we have* $\mathbf{V}_l^\mathsf{T}\mathbf{c}=\mathbf{0}$ *and* $\mathbf{1}_K^\mathsf{T}\mathbf{V}_r=\mathbf{0}$ *since* $1+\theta^\alpha(\rho)\neq 0$*. It is thus immediate that* $(\mathbf{V}_l,\mathbf{V}_r)$ *is also a pair of eigenvectors (with multiplicity) of* $\mathbf{I}_K+e_{21}^\alpha(\rho)\left(\mathcal{D}\left(\mathbf{c}\right)-\mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K-\mathbf{c}\mathbf{1}_K^T\right)$ *associated to the zero eigenvalues.*

As we show in Section 6.5, for $1+\theta^\alpha(\tilde\rho)=0$, the eigenvectors associated to the aforementioned isolated eigenvalues $\tilde\rho$ will not contain information about the classes. This case is thus of no interest for clustering. It is nevertheless important from a practical viewpoint to note that, even in the absence of communities, spurious isolated eigenvalues may be found that may deceive the experimenter in suggesting the presence of node clusters. From now on, we will only consider the isolated eigenvalues ρ for which $1+\theta^\alpha(\rho)\neq 0$.

We now have all the ingredients to determine the conditions under which we may have eigenvalues of $\mathbf{L}_\alpha$ which isolate from $\mathcal{S}^\alpha$. Let l be a non zero eigenvalue of $\mathbf{G}_\rho^\alpha=(\mathcal{D}\left(\mathbf{c}\right)-\mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K-\mathbf{c}\mathbf{1}_K^T)$. Since $\det((\mathcal{D}(\mathbf{c})-\mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K-\mathbf{c}\mathbf{1}_K^\mathsf{T}))=\det((\mathbf{I}_K-\mathbf{c}\mathbf{1}_K^\mathsf{T})(\mathcal{D}(\mathbf{c})-\mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M})=\det((\mathcal{D}(\mathbf{c})-\mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M})$, l is also a non zero eigenvalue of $\bar{\mathbf{M}}=(\mathcal{D}(\mathbf{c})-\mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}$. For each isolated eigenvalue ρ of $\mathbf{L}_\alpha$ we have a one-to-one mapping with a non zero eigenvalue l of $\bar{\mathbf{M}}$ such that $l=-\frac{1}{E_2^\alpha(\rho)}$. Hence, to show the existence of isolated eigenvalues of $\mathbf{L}_\alpha$, we need to solve for $\rho\in\mathbb{R}\setminus\mathcal{S}^\alpha$, $l=-\frac{1}{E_2^\alpha(\rho)}$ for each non zero eigenvalue l of $\bar{\mathbf{M}}$. Precisely, let us write $\mathcal{S}^\alpha=\bigcup_{m=1}^M[S_{m,-}^\alpha,S_{m,+}^\alpha]$ with $S_{1,-}^\alpha\leq S_{1,+}^\alpha<S_{2,-}^\alpha\leq\ldots<S_{M,+}^\alpha$ and define $S_{0,+}=-\infty$ and $S_{M+1,-}=+\infty$. Then, recalling that the Stieltjes transform of a real supported measure is necessarily increasing on $\mathbb{R}$, there exist isolated eigenvalues of $\mathbf{L}^\alpha$ in $(S_{m,+}^\alpha,S_{m+1,-}^\alpha)$, $m\in\{0,\ldots,M\}$, for all large n almost surely, if and only if there exists eigenvalues ℓ of $\bar{\mathbf{M}}$ such that

$$\lim_{x\downarrow S_{m,+}^\alpha}E_2^\alpha(x)<-\ell^{-1}<\lim_{x\uparrow S_{m+1,-}^\alpha}E_2^\alpha(x). \tag{24}$$

In particular, when $\mathcal{S}^\alpha=[S_-^\alpha,S_+^\alpha]$ is composed of a single connected component (as when $\mathcal{S}^\alpha$ is the support of the semi-circle law as well as most cases met in practice), then isolated eigenvalues of $\mathbf{L}^\alpha$ may only be found beyond S_+^α if $\ell>\lim_{x\downarrow S_+^\alpha}-\frac{1}{E_2^\alpha(x)}$ ($l>0$) or below S_-^α if $\ell<\lim_{x\uparrow S_-^\alpha}-\frac{1}{E_2^\alpha(x)}$ ($l<0$), for some non-zero eigenvalue ℓ of $\bar{\mathbf{M}}$. From the asymptotic spectrum of $\mathbf{L}_\alpha$, $S_-^\alpha=-S_+^\alpha$ as one can show that for any $z\in\mathbb{R}\setminus\mathcal{S}^\alpha$, $E_2^\alpha(-z)=-E_2^\alpha(z)$ so that both previous conditions reduce to $\mid\ell\mid>\lim_{x\downarrow S_+^\alpha}-\frac{1}{E_2^\alpha(x)}$. This proves Theorem 6.

The next section is advocated to the study of the eigenvectors associated to isolated eigenvalues of $\mathbf{L}_\alpha$.

6.4 Informative eigenvectors

In this section, in order to fully characterize the performances of Algorithm 2, we study in depth the normalized eigenvectors $\bar{\mathbf{v}}_i^\alpha$ used for the classification in the algorithm (step 3 of Algorithm2). We consider here the eigenvectors corresponding to the eigenvalues for which $1+\theta^\alpha(\rho)\neq 0$ (when $1+\theta^\alpha(\rho)=0$, the corresponding eigenvectors do not contain any structural information about the classes; this case is treated in Section 6.5). For technical

reasons, we restrict ourselves here to those eigenpairs $(\lambda_i,\bar{\mathbf{v}}_i^\alpha)$'s for which there exists no $\lambda_j\neq\lambda_i$ such that, if $\lambda_i\to\rho$, $\lambda_j\to\rho$.

We recall that we may write $\bar{\mathbf{v}}_i^\alpha$ [14] as the "noisy plateaus" vector

$$\bar{\mathbf{v}}_i^\alpha=\sum_{a=1}^K\nu_i^a\frac{\mathbf{j}_a}{\sqrt{n_a}}+\sqrt{\sigma_{ii}^a}\mathbf{w}_i^a \tag{25}$$

where $\mathbf{w}_i^a\in\mathbb{R}^n$ is a random vector orthogonal to $\mathbf{j}_a$, of norm $\sqrt{n_a}$ and supported on the indices of $\mathcal{C}_a$ and

$$\nu_i^a=\frac{1}{\sqrt{n_a}}\left(\bar{\mathbf{v}}_i^\alpha\right)^\mathsf{T}\mathbf{j}_a=\frac{1}{\sqrt{n_a}}\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_a}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}} \tag{26}$$

$$\sigma_{ij}^a=\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathcal{D}_a\mathbf{D}^{\alpha-1}\mathbf{u}_j^\alpha}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i}\sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha}}-\nu_i^a\nu_j^a \tag{27}$$

with $\mathcal{D}_a=\mathcal{D}(\mathbf{j}_a)$.

- We estimate the ν_i^a's by obtaining an estimator of the $K\times K$ matrix

$$\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha},$$

  the diagonal entries of which allow to estimate $|\nu_i^a|$ while the off-diagonal entries are used to decide on the signs of the ν_i^a's (up to a convention in the sign of $\mathbf{u}_i^\alpha$).

- Similarly, we first estimate the more involved object

$$\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathcal{D}_a\mathbf{D}^{\alpha-1}\mathbf{u}_j^\alpha(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{\left((\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha\right)\left((\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha\right)}$$

  from which $\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathcal{D}_a\mathbf{D}^{\alpha-1}\mathbf{u}_j^\alpha}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}\sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha}}$ is retrieved by dividing any entry e,f of the former quantity by non-vanishing quantities $\nu_i^e\nu_i^f$. For the eigenvectors $\mathbf{u}_i^\alpha$ used for clustering, there is always at least one index f such that ν_i^f is non zero (otherwise, this eigenvector is of no use for clustering).

6.4.1 Evaluation of the class means ν_i^a's

The estimation of the ν_i^a's requires the evaluation of $\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}$ for $\mathbf{u}_i^\alpha$ eigenvector associated to a limiting isolated eigenvalue ρ with unit multiplicity of $\mathbf{L}_\alpha$. By residue calculus, we have that

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}=-\frac{1}{2\pi i}\oint_{\Gamma_\rho}\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\left(\mathbf{L}_\alpha-z\mathbf{I}_n\right)^{-1}\mathbf{D}^{\alpha-1}\mathbf{J}\mathrm{d}z \tag{28}$$

14. Recall that the graph nodes were assumed labeled by class, and thus the entries of $\bar{\mathbf{v}}_i^\alpha$ are similarly sorted by class.

for large n almost surely, where Γ_ρ is a complex (positively oriented) contour circling around the limiting eigenvalue ρ only. As from Theorem 2, $\mathbf{L}_\alpha = \mathbf{D}_q^{-\alpha}\frac{\mathbf{X}}{\sqrt{n}}\mathbf{D}_q^{-\alpha} + \mathbf{U}\mathbf{\Lambda}\mathbf{U}^\mathsf{T} + o(1)$, we apply the Woodburry identity to the inverse in the previous integrand and we get

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\left(\mathbf{L}_\alpha - z\mathbf{I}_n\right)^{-1}\mathbf{D}^{\alpha-1}\mathbf{J} = \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{Q}_z^\alpha\mathbf{D}^{\alpha-1}\mathbf{J} + \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\left(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1}\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{\alpha-1}\mathbf{J} + o(1).$$

The first right-hand side has asymptotically no residue when we integrate over the contour Γ_ρ (as per Proposition 18 there is no eigenvalues of $\bar{\mathbf{X}}$ in Γ_ρ for all large n almost surely). We are then left with the second right-most term. Using the block structure used in Section 6.3, we may write

$$\left(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1} \xrightarrow{\text{a.s.}} \begin{pmatrix} \mathbf{I}_K + e_{21}^\alpha(z)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \left(1 + \frac{z}{m_\mu}e_{10}^\alpha(z)\right)\mathbf{c}\mathbf{1}_K^\mathsf{T} & -e_{21}^\alpha(z)\mathbf{c} \\ \frac{z}{m_\mu^2}\left(v_\mu + ze_{0;-1}^\alpha(z)\right)\mathbf{1}_K^\mathsf{T} & -z\frac{e_{10}^\alpha(z)}{m_\mu} \end{pmatrix}^{-1}.$$

Let us write $\gamma(z) = \frac{z}{m_\mu^2}\left(v_\mu + ze_{0;-1}^\alpha(z)\right)$. We can now use a block inversion formula to write

$$\left(\mathbf{I}_{K+1} + \mathbf{U}^T\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1} \xrightarrow{\text{a.s.}} \begin{pmatrix} (\underline{\mathbf{G}}_z^\alpha)^{-1} & -\frac{e_{10}^\alpha(z)\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{21}^\alpha(z)}{ze_{10}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]^{-1}\mathbf{c}}{-\frac{ze_{21}^\alpha(z)}{m_\mu} + \gamma(z)e_{10}^\alpha(z)\mathbf{1}_K^\mathsf{T}\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{21}^\alpha(z)}{ze_{10}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]^{-1}\mathbf{c}} \\ \frac{\gamma(z)m_\mu}{ze_{21}^\alpha(z)}\mathbf{1}_K^\mathsf{T}(\underline{\mathbf{G}}_z^\alpha)^{-1} & \frac{1}{-\frac{ze_{21}^\alpha(z)}{m_\mu} + \gamma(z)e_{10}^\alpha(z)\mathbf{1}_K^\mathsf{T}\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{21}^\alpha(z)}{ze_{10}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]^{-1}\mathbf{c}} \end{pmatrix} \tag{29}$$

with $\underline{\mathbf{G}}_z^\alpha = \mathbf{I}_K + e_{21}^\alpha(z)\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right) + \theta^\alpha(z)\mathbf{c}\mathbf{1}_K^T$. The entries of the previous matrix seem to be cumbersome but as we will see, the residue calculus will greatly simplify. In fact, we have that $\mathbf{1}_K^T\underline{\mathbf{G}}_z^\alpha = (1+\theta^\alpha(z))\mathbf{1}_K^T$ so that $\mathbf{1}_K^T(\underline{\mathbf{G}}_z^\alpha)^{-1} = \frac{1}{1+\theta^\alpha(z)}\mathbf{1}_K^T$ which is well defined since we are considering the case $1 + \theta^\alpha(z) \neq 0$. Similarly, we have that

$$\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{10}^\alpha(z)}{ze_{21}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]\mathbf{c} = \left(-z\frac{e_{10}^\alpha(z)}{m_\mu}\right)\mathbf{c}$$

meaning that $\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{21}^\alpha(z)}{ze_{10}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]^{-1}\mathbf{c} = -\frac{m_\mu}{ze_{10}^\alpha(z)}\mathbf{c}$. So finally, the terms $(1,2)$, $(2,1)$ and $(2,2)$ of $\left(\mathbf{I}_{K+1} + \mathbf{U}^T\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1}$ do no longer depend on $(\underline{\mathbf{G}}_z^\alpha)^{-1}$ and thus do not have poles in the contour Γ_ρ. We can then write

$$\left(\mathbf{I}_{K+1} + \mathbf{U}^T\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1} = \begin{pmatrix} (\underline{\mathbf{G}}_z^\alpha)^{-1} & 0 \\ 0 & 0 \end{pmatrix} + \mathbf{R}_1(z)$$

with $\mathbf{R}_1(z)$ having no residue in the contour Γ_ρ. Thus, to perform the contour integration of the integrand in (28) around Γ_ρ, we just need to evaluate the top-left entries of $\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}$ and $\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{\alpha-1}\mathbf{J}$. Those are easily retrieved from the calculus in Section 6.3.

We have in particular $(\frac{1}{\sqrt{n}}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda})_{11} \xrightarrow{\text{a.s.}} e_{00}^\alpha(z)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \beta^\alpha(z)\mathbf{c}\mathbf{1}_K^\mathsf{T}$ where $\beta^\alpha(z) = \frac{1}{m_\mu}\left[\int t^{2\alpha-1}\mu(\mathrm{d}t) + e_{-1;-1}^\alpha(z)\right]$ and similarly $(\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{\alpha-1}\mathbf{J})_{11} \xrightarrow{\text{a.s.}} e_{00}^\alpha(z)\mathcal{D}(\mathbf{c})$, so that finally

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J} \xrightarrow{\text{a.s.}} -\frac{1}{2\pi i}\oint_{\Gamma_\rho}\left[\left(e_{00}^\alpha(z)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \beta^\alpha(z)\mathbf{c}\mathbf{1}_K^\mathsf{T}\right)(\underline{\mathbf{G}}_z^\alpha)^{-1} \times e_{00}^\alpha(z)\mathcal{D}(\mathbf{c}) + \mathbf{R}_2(z)\mathrm{d}z\right]$$

where $\mathbf{R}_2(z)$ is a matrix having no residue in the considered contour. Now, we are ready to compute the integral. From the Cauchy integral formula,

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J} \xrightarrow{\text{a.s.}} \lim_{z\to\rho}(z-\rho)\left[e_{00}^\alpha(z)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \beta^\alpha(z)\mathbf{c}\mathbf{1}_K^\mathsf{T}\right](\underline{\mathbf{G}}_z^\alpha)^{-1} \times e_{00}^\alpha(z)\mathcal{D}(\mathbf{c}).$$

By writing $\underline{\mathbf{G}}_z^\alpha = \rho_z\mathbf{v}_{r,z}\mathbf{v}_{l,z}^T + \tilde{\mathbf{V}}_{r,z}\tilde{\mathbf{\Sigma}}_z\tilde{\mathbf{v}}_{l,z}^T$ where $\mathbf{v}_{r,z}$ and $\mathbf{v}_{l,z}$ are respectively right and left eigenvectors associated with the vanishing eigenvalue ρ_z of $\underline{\mathbf{G}}_z^\alpha$ when $z \to \rho$; $\tilde{\mathbf{V}}_{r,z} \in \mathbb{R}^{n\times\eta_\rho}$ and $\tilde{\mathbf{V}}_{l,z}\mathbb{R}^{n\times\eta_\rho}$ are respectively sets of right and left eigenspaces associated with non vanishing eigenvalues, we then have

$$\lim_{z\to\rho}(z-\rho)(\underline{\mathbf{G}}_z^\alpha)^{-1} \overset{(1)}{=} \lim_{z\to\rho}(z-\rho)\frac{\mathbf{v}_{r,z}\mathbf{v}_{l,z}^T}{\rho_z'}$$

where we have used the l'Hopital rule and the fact that the non vanishing eigenvalue part of $\underline{\mathbf{G}}_z^\alpha$ will produce zero in the limit $z \to \rho$. Using $\rho_z = \mathbf{v}_{l,z}^\mathsf{T}\underline{\mathbf{G}}_z^\alpha\mathbf{v}_{r,z}$, we obtain

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J} \xrightarrow{\text{a.s.}} \left[e_{00}^\alpha(\rho)(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \beta^\alpha(\rho)\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]\frac{\mathbf{v}_{r,\rho}\mathbf{v}_{l,\rho}^\mathsf{T}}{\left(\mathbf{v}_{l,z}^\mathsf{T}\underline{\mathbf{G}}_z^\alpha\mathbf{v}_{r,z}\right)'_{z=\rho}} \times e_{00}^\alpha(\rho)\mathcal{D}(\mathbf{c}).$$

Since $(\mathbf{v}_{l,\rho})^\mathsf{T}\underline{\mathbf{G}}_\rho^\alpha = \underline{\mathbf{G}}_\rho^\alpha\mathbf{v}_{r,\rho} = 0$,

$$\begin{aligned}\left((\mathbf{v}_{l,z})^T\underline{\mathbf{G}}_z^\alpha\mathbf{v}_{r,z}\right)'_{z=\rho} &= \left((\mathbf{v}_{l,z})^T\right)'_{z=\rho}\underline{\mathbf{G}}_\rho^\alpha\mathbf{v}_{r,\rho} + (\mathbf{v}_{l,\rho})^T\left(\underline{\mathbf{G}}_z^\alpha\right)'_{z=\rho}\mathbf{v}_{r,\rho} + (\mathbf{v}_{l,\rho})^T\underline{\mathbf{G}}_\rho^\alpha(\mathbf{v}_{r,z})'_{z=\rho} \\ &= (\mathbf{v}_{l,\rho})^T\left(\underline{\mathbf{G}}_z^\alpha\right)'_{z=\rho}\mathbf{v}_{r,\rho} \\ &= (e_{21}^\alpha(\rho))'(\mathbf{v}_{l,\rho})^T\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)\mathbf{v}_{r,\rho}\end{aligned}$$

where the subscript $'$ denotes the first derivative with respect to z. Using the fact that $\mathbf{v}_{r,\rho}$ is orthogonal to $\mathbf{1}_K^T$, and $(\mathbf{v}_{r,\rho}, \mathbf{v}_{l,\rho})$ is also a pair of eigenvectors of $\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)$ associated with eigenvalue $-\frac{1}{e_{21}^\alpha(\rho)}$, we get

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J} \xrightarrow{\text{a.s.}} \frac{(e_{00}^\alpha(\rho))^2}{e_{21}^\alpha(\rho)'}\frac{\mathbf{v}_{r,\rho}(\mathbf{v}_{l,\rho})^T}{\mathbf{v}_{l,\rho}^T\mathbf{v}_{r,\rho}}\mathcal{D}(\mathbf{c}). \tag{30}$$

By introducing $\mathbf{v}_\rho = \mathcal{D}(\mathbf{c})^{\frac{1}{2}}\mathbf{v}_{l,\rho} = \mathcal{D}(\mathbf{c})^{-\frac{1}{2}}\mathbf{v}_{r,\rho}$ eigenvector of the symmetric matrix $\mathcal{D}(\mathbf{c})^{\frac{1}{2}}\left(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)\mathcal{D}(\mathbf{c})^{\frac{1}{2}}$, we obtain the final result

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J} \xrightarrow{\text{a.s.}} \frac{\left(e_{00}^\alpha(\rho)\right)^2}{e_{21}^\alpha(\rho)'}\mathcal{D}\left(\mathbf{c}\right)^{1/2}\mathbf{v}_\rho(\mathbf{v}_\rho)^T\mathcal{D}\left(\mathbf{c}\right)^{1/2}. \tag{31}$$

Next, we need to estimate the denominator term $(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha$ of $\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}$ of ν_i^α.For $\mathbf{u}_i^\alpha$ an eigenvector of $\mathbf{L}_\alpha$ associated to an isolated eigenvalue converging to ρ asymptotically, we have

$$\begin{aligned}(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha &= \operatorname{tr}(\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}) \\ &= \operatorname{tr}\left(-\frac{1}{2\pi i}\oint_{\Gamma_\rho}\left(\mathbf{L}_\alpha - z\mathbf{I}_n\right)\mathbf{D}^{2(\alpha-1)}\mathrm{d}z\right).\end{aligned}$$

As in the previous section, by applying Woodburry idendity, this is equivalent to evaluating

$$\operatorname{tr}\left(-\frac{1}{2\pi i}\oint_{\Gamma_\rho}\left[\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\begin{pmatrix}(\underline{\mathbf{G}}_z^\alpha)^{-1} & 0\\ 0 & 0\end{pmatrix} + \mathbf{R}_3(z)\right]\mathrm{d}z\right),$$

where $\mathbf{R}_3(z)$ is a matrix having no residue in the considered contour.

Again here, we just need the top left entry of $\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}$ which is given from Theorem 2 by

$$(\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda})_{11} = \underbrace{\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{1-\alpha}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{D}^{1-\alpha}\mathbf{J}(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^\mathsf{T})\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T})}_{(\mathbf{I})} \tag{32}$$

$$\underbrace{-\frac{1}{\sqrt{n}(\mathbf{q}^\mathsf{T}\mathbf{1}_n)}\mathbf{D}^{1-\alpha}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{D}^{-\alpha}\mathbf{X}\mathbf{1}_n\mathbf{1}_K^\mathsf{T}}_{(\mathbf{II})}. \tag{33}$$

We can get rid of the term (**II**) since after residue calculus, we will get (similar to Equation (30)) $\mathbf{1}_K^\mathsf{T}\mathbf{v}_{r,\rho} = 0$ which cancels out the whole term. Let us now concentrate on the term (**I**). At this point, we need to introduce the following result which, for any deterministic vectors of bounded Euclidean norm $\mathbf{a}$, $\mathbf{b}$ and any deterministic diagonal matrix $\mathbf{\Xi}$, approximates the random quantity $\mathbf{a}^\mathsf{T}\mathbf{Q}_{z_1}^\alpha\mathbf{\Xi}\mathbf{Q}_{z_2}^\alpha\mathbf{b}$ by a deterministic equivalent.

Lemma 21 (Second deterministic equivalents) *For all $z \in \mathbb{C}\backslash\mathcal{S}^\alpha$, we have the following deterministic equivalent*

$$\mathbf{Q}_{z_1}^\alpha\mathbf{\Xi}\mathbf{Q}_{z_2}^\alpha \leftrightarrow \bar{\mathbf{Q}}_{z_1}^\alpha\mathbf{\Xi}\bar{\mathbf{Q}}_{z_2}^\alpha + \bar{\mathbf{Q}}_{z_1}^\alpha\mathcal{D}\left[\left(\mathbf{I}_n - \mathbf{\Upsilon}_{z_1,z_2}\right)^{-1}\mathbf{\Upsilon}_{z_1,z_2}\operatorname{diag}\left(\mathbf{\Xi}\right)\right]\bar{\mathbf{Q}}_{z_2}^\alpha$$

where $\mathbf{\Xi}$ is any diagonal matrix, $\bar{\mathbf{Q}}_z^\alpha$ is given in Lemma 16 and

$$\Upsilon_{z_1,z_2}(i,j) = \frac{1}{n}\frac{q_i^{1-2\alpha}q_j^{1-2\alpha}\left(1-q_iq_j\right)}{\left(-z_1 - e_{11}^\alpha(z_1)q_i^{1-2\alpha} + e_{21}^\alpha(z_1)q_i^{2-2\alpha}\right)\left(-z_2 - e_{11}^\alpha(z_2)q_j^{1-2\alpha} + e_{21}^\alpha(z_2)q_j^{2-2\alpha}\right)}.$$

The equivalence relation $\leftrightarrow$ is as defined in Lemma 16.

Thanks to Lemma 21 (proof provided in Appendix D), a deterministic approximation of the term (**I**) in Equation (32) can be obtained. We get in particular

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{1-\alpha}\mathbf{Q}_z^\alpha\mathbf{D}^{2(\alpha-1)}\mathbf{Q}_z^\alpha\mathbf{D}^{1-\alpha}\mathbf{J} = \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{1-\alpha}\bar{\mathbf{Q}}_z^\alpha\mathbf{D}^{2(\alpha-1)}\bar{\mathbf{Q}}_z^\alpha\mathbf{D}^{1-\alpha}\mathbf{J} \tag{34}$$

$$+\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{1-\alpha}\bar{\mathbf{Q}}_z^\alpha\mathcal{D}\left[\left(\mathbf{I}_n - \mathbf{\Upsilon}_{z,z}\right)^{-1}\mathbf{\Upsilon}_{z,z}\mathbf{d}^\alpha\right]\bar{\mathbf{Q}}_z^\alpha\mathbf{D}^{1-\alpha}\mathbf{J} \tag{35}$$

where $\mathbf{d}^\alpha = \{q_i^{2(\alpha-1)}\}_{i=1}^n$ and $\mathbf{\Upsilon}_{z_1,z_2}$ was defined in Lemma 21. Using similar argument as in Equation (23), we can easily show that the first right hand side term of (34) converges almost surely to $e_{00;2}^\alpha\mathcal{D}(\mathbf{c})$. It then remains to estimate the second right-most term of (34). $\mathbf{\Upsilon}_{z_1,z_2}$ (as defined in Lemma 21) may be written as the sum of two rank-one matrices

$$\mathbf{\Upsilon}_{z_1,z_2} = \frac{1}{n}\left(\mathbf{a}_{z_1}\mathbf{a}_{z_2}^\mathsf{T} - \mathbf{b}_{z_1}\mathbf{b}_{z_2}^\mathsf{T}\right)$$

where $\mathbf{a}_z = \left\{\frac{q_j^{1-2\alpha}}{-z-q_j^{1-2\alpha}e_{11}^\alpha(z)+q_j^{2-2\alpha}e_{21}^\alpha(z)}\right\}_{j=1}^n$ and $\mathbf{b}_z = \left\{\frac{q_j^{2-2\alpha}}{-z-q_j^{1-2\alpha}e_{11}^\alpha(z)+q_j^{2-2\alpha}e_{21}^\alpha(z)}\right\}_{j=1}^n$.

The matrix $\mathbf{\Upsilon}_{z,z}$ can thus be further written $\mathbf{\Upsilon}_{z,z} = \frac{1}{n}\begin{pmatrix}\mathbf{a}_z & \mathbf{b}_z\end{pmatrix}\mathbf{I}_2\begin{pmatrix}\mathbf{a}_z^\mathsf{T}/n\\ -\mathbf{b}_z^\mathsf{T}/n\end{pmatrix}$. Using matrix inversion lemmas, we have

$$\left(\mathbf{I}_n - \mathbf{\Upsilon}_{z,z}\right)^{-1}\mathbf{\Upsilon}_{z,z}\mathbf{d}^\alpha = \begin{pmatrix}\mathbf{a}_z & \mathbf{b}_z\end{pmatrix}\begin{pmatrix}1-\frac{\mathbf{a}_z^\mathsf{T}\mathbf{a}_z}{n} & -\frac{\mathbf{a}_z^\mathsf{T}\mathbf{b}_z}{n}\\ \frac{\mathbf{b}_z^\mathsf{T}\mathbf{a}_z}{n} & 1+\frac{\mathbf{b}_z^\mathsf{T}\mathbf{b}_z}{n}\end{pmatrix}^{-1}\begin{pmatrix}\frac{\mathbf{a}_z^\mathsf{T}\mathbf{d}^\alpha}{n}\\ -\frac{\mathbf{b}_z^\mathsf{T}\mathbf{d}^\alpha}{n}\end{pmatrix}.$$

Using again the argument in Equation (23) , we can easily show that $\frac{\mathbf{a}_z^\mathsf{T}\mathbf{a}_z}{n}$, $\frac{\mathbf{a}_z^\mathsf{T}\mathbf{b}_z}{n}$, $\frac{\mathbf{b}_z^\mathsf{T}\mathbf{b}_z}{n}$, $\frac{\mathbf{a}_z^\mathsf{T}\mathbf{d}^\alpha}{n}$ and $\frac{\mathbf{b}_z^\mathsf{T}\mathbf{d}^\alpha}{n}$ converge for large n almost surely respectively to $e_{22;2}^\alpha(z)$, $e_{32;2}^\alpha(z)$, $e_{42;2}^\alpha(z)$, $e_{-1;0}^\alpha(z)$ and $e_{00}^\alpha(z)$ with $e_{ij;2}^\alpha$ defined in Equation (21). This given, we can show that

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{D}^{1-\alpha}\bar{\mathbf{Q}}_z^\alpha\mathcal{D}\left[\left(\mathbf{I}_n - \mathbf{\Upsilon}_{z,z}\right)^{-1}\mathbf{\Upsilon}_{z,z}\mathbf{d}^\alpha\right]\bar{\mathbf{Q}}_z^\alpha\mathbf{D}^{1-\alpha}\mathbf{J} \xrightarrow{\text{a.s.}} \chi^\alpha(z)\mathcal{D}(\mathbf{c})$$

with

$$\chi^\alpha(z) = \frac{\left[\left(1+e_{42;2}^\alpha(z)\right)e_{-1,0}^\alpha(z) - e_{32;2}^\alpha(z)e_{00}^\alpha(z)\right]e_{32;3}^\alpha(z) - \left[e_{22;2}^\alpha(z)e_{-1,0}^\alpha(z) + \left(1-e_{22;2}^\alpha(z)\right)e_{00}^\alpha(z)\right]e_{42;3}^\alpha(z)}{\left(1+e_{42;2}^\alpha(z)\right)\left(1-e_{22;2}^\alpha(z)\right) + \left[e_{32;2}^\alpha(z)\right]^2}.$$

We thus have

$$(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha \xrightarrow{\text{a.s.}} \operatorname{tr}\left(\lim_{z\to\rho}\left(e_{00;2}^\alpha(z) + \chi^\alpha(z)\right)\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T})(\underline{\mathbf{G}}_z^\alpha)^{-1}\right).$$

By applying l'Hopital rule to evaluate this limit as in the previous section, we obtain

$$(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha \xrightarrow{\text{a.s.}} \frac{e_{00;2}(\rho) + \chi^\alpha(\rho)}{\left(e_{21}^\alpha(\rho)\right)'}.$$

Finally,

$$\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha} \xrightarrow{\text{a.s.}} \frac{\left(e_{00}^\alpha(\rho)\right)^2}{e_{00;2}(\rho) + \chi^\alpha(\rho)}\mathcal{D}\left(\mathbf{c}\right)^{1/2}\mathbf{v}_\rho(\mathbf{v}_\rho)^T\mathcal{D}\left(\mathbf{c}\right)^{1/2}. \tag{36}$$

We recall that one goal of this section is to estimate $\nu_i^a = \frac{1}{\sqrt{n_a}} \frac{\mathbf{u}_i^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{j}_a}{\sqrt{\mathbf{u}_i^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i}}$, the square of which is $\frac{n}{n_a} \left[\frac{1}{n} \frac{\mathcal{D}(\mathbf{c})^{-\frac{1}{2}} \mathbf{J}^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{u}_i^\alpha (\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{J} \mathcal{D}(\mathbf{c})^{-\frac{1}{2}}}{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i^\alpha} \right]_{aa}$. From Equation (36), the former quantity is easily retrieved and we have

$$|\nu_i^a|^2 = \frac{(e_{00}^\alpha(\rho_i))^2}{e_{00;2}^\alpha(\rho_i) + \chi^\alpha(\rho_i)} \left| v_a^i \right|^2. \tag{37}$$

This proves the following theorem giving the limit of the empirical class means ν_i^a's.

Theorem 22 (Means) *For each eigenpair $(\lambda(\bar{\mathbf{M}}), \mathbf{v})$ of $\mathcal{D}(\mathbf{c})^{\frac{1}{2}} \left(\mathbf{I}_K - \mathbf{1}_K \mathbf{c}^\mathsf{T} \right) \mathbf{M} \left(\mathbf{I}_K - \mathbf{c} \mathbf{1}_K^T \right) \mathcal{D}(\mathbf{c})^{\frac{1}{2}}$ of unit multiplicity, mapped to eigenpair $(\rho, \mathbf{u}_i^\alpha)$ of $\mathbf{L}_\alpha$ as defined in Corollary 6, under the conditions of Assumption 1 and for ν_i^a defined in (26), we have almost surely as $n \to \infty$, $\left| (\nu_i^a)^2 - (\nu_i^{a,\infty})^2 \right| \to 0$ where*

$$(\nu_i^{a,\infty})^2 \equiv \frac{\left[e_{00}^\alpha(\rho) \right]^2}{e_{00;2}^\alpha(\rho, \rho) + \chi^\alpha(\rho)} (v_a)^2$$

with
$\chi^\alpha(\rho) = \frac{\left[\left(1 + e_{42;2}^\alpha(\rho)\right) e_{-1,0}^\alpha(\rho) - e_{32;2}^\alpha(\rho) e_{00}^\alpha(\rho) \right] e_{32;3}^\alpha(\rho) - \left[e_{22;2}^\alpha(\rho) e_{-1,0}^\alpha(\rho) + \left(1 - e_{22;2}^\alpha(\rho)\right) e_{00}^\alpha(\rho) \right] e_{42;3}^\alpha(\rho)}{\left(1 + e_{42;2}^\alpha(\rho)\right)\left(1 - e_{22;2}^\alpha(\rho)\right) + \left[e_{32;2}^\alpha(\rho) \right]^2}$ *and v_a is the component a of $\mathbf{v}$.*

Using the definition of ν_a^i in (26) and of $\bar{\mathbf{v}}$, $\mathbf{\Pi}$ in Theorem 10, Theorem 10 unfolds easily since $\bar{\mathbf{v}}^\mathsf{T} \mathbf{\Pi} \bar{\mathbf{v}} = \sum_{a=1}^K (\nu_a^i)^2 = \frac{\left[e_{00}^\alpha(\rho) \right]^2}{e_{00;2}^\alpha(\rho,\rho) + \chi^\alpha(\rho)} (v_a)^2$.

6.4.2 Evaluation of the class covariances σ_{ij}^a's

We have shown at the beginning of this section that to estimate the σ_{ij}^a's, we need to evaluate the more involved object

$$\frac{1}{n} \frac{\mathbf{J}^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{u}_i^\alpha (\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathcal{D}_a \mathbf{D}^{\alpha-1} \mathbf{u}_j^\alpha (\mathbf{u}_j^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{J}}{\left((\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i^\alpha \right) \left((\mathbf{u}_j^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_j^\alpha \right)}.$$

Similarly to what was done previously for the estimation of $\frac{1}{n} \frac{\mathbf{J}^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{u}_i^\alpha (\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{J}}{(\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i^\alpha}$, we need here to evaluate

$$\left(\frac{1}{2\pi i} \right)^2 \oint_{\Gamma_{\rho 1}} \oint_{\Gamma_{\rho 2}} \frac{1}{n} \mathbf{J}^\mathsf{T} \mathbf{D}^{\alpha-1} \left(\mathbf{L}_\alpha - z_1 \mathbf{I}_n \right)^{-1} \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \left(\mathbf{L}_\alpha - z_2 \mathbf{I}_n \right)^{-1} \mathbf{D}^{\alpha-1} \mathbf{J} \mathrm{d}z_1 \mathrm{d}z_2$$

where Γ_{ρ_1} and Γ_{ρ_2} are two positively oriented contours circling around some limiting isolated eigenvalues ρ_1 and ρ_2 respectively. We will use the same technique as in the proof of Theorem 22 to evaluate this integrand. Namely, by applying the Woodburry identity to each of the inverse in the integrand, we get

$$\left(\frac{1}{2\pi i} \right)^2 \oint_{\Gamma_{\rho 1}} \oint_{\Gamma_{\rho 2}} \frac{1}{n} \mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \left(\mathbf{I}_{K+1} + \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \right)^{-1} \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U}$$
$$\times \mathbf{\Lambda} \left(\mathbf{I}_{K+1} + \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{U} \mathbf{\Lambda} \right)^{-1} \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J} \mathrm{d}z_1 \mathrm{d}z_2$$

where we have used the fact that the cross-terms $\frac{1}{n} \mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_i}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J}$, $i = 1, 2$ will vanish asymptotically as the latter do not have poles in the considered contours. By using the identity $\mathbf{\Lambda} \left(\mathbf{I}_{K+1} + \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \right)^{-1} \mathbf{U}^T = \left(\mathbf{I}_{K+1} + \mathbf{\Lambda} \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{U} \right)^{-1} \mathbf{\Lambda} \mathbf{U}^T$, the previous integral writes

$$\left(\frac{1}{2\pi i} \right)^2 \oint_{\Gamma_{\rho 1}} \oint_{\Gamma_{\rho 2}} \frac{1}{n} \mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \left(\mathbf{I}_{K+1} + \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \right)^{-1} \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U}$$
$$\times \left(\mathbf{I}_{K+1} + \mathbf{\Lambda} \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{U} \right)^{-1} \mathbf{\Lambda} \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J} \mathrm{d}z_1 \mathrm{d}z_2$$

Most of those quantities have been evaluated in the evaluation of the ν_i^a's. We thus obtain

$$\left(\frac{1}{2\pi i} \right)^2 \oint_{\Gamma_{\rho 1}} \oint_{\Gamma_{\rho 2}} \left[\frac{1}{n} \mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda} \begin{pmatrix} (\underline{\mathbf{G}}_{z_1}^\alpha)^{-1} & 0 \\ 0 & 0 \end{pmatrix} \mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U} \right.$$
$$\left. \times \begin{pmatrix} \left((\underline{\mathbf{G}}_{z_2}^\alpha)^{-1} \right)^T & 0 \\ 0 & 0 \end{pmatrix} \mathbf{\Lambda} \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J} + \mathbf{R}_4(z_1, z_2) \right] \mathrm{d}z_1 \mathrm{d}z_2$$

where $\mathbf{R}_4(z_1, z_2)$ has no poles in the considered contours. It is then sufficient to evaluate the top left entry of each of the matrices $\mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_1}^\alpha \mathbf{U} \mathbf{\Lambda}$, $\mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U}$ and $\mathbf{\Lambda} \mathbf{U}^T \mathbf{Q}_{z_2}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J}$ to compute the whole integrand. The first and the third of the latter matrices have been evaluated in the proof of Theorem 22. We are then left with the top left entry of $\mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U}$ which is $\frac{1}{n} \mathbf{J}^T \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{D}^{\alpha-1} \mathbf{J}$ from Theorem 2. The former quantity has already been evaluated in the previous section but for (z, z) replaced by (z_1, z_2) and the diagonal matrix between $\mathbf{Q}_{z_1}^\alpha$ and $\mathbf{Q}_{z_2}^\alpha$ being here $\mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1}$ instead of $\mathbf{D}^{2(\alpha-1)}$. We thus have

$$\left(\mathbf{U}^T \mathbf{Q}_{z_1}^\alpha \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{Q}_{z_2}^\alpha \mathbf{U} \right)_{11} \xrightarrow{\text{a.s.}} c_a \left(e_{00;2}^\alpha(z_1, z_2) \mathcal{D} \left(\boldsymbol{\delta}_{i=a} \right)_{i=1}^K + \chi^\alpha(z_1, z_2) \mathcal{D}(\mathbf{c}) \right).$$

Finally, we are left to evaluate

$$\left(\frac{1}{2\pi i} \right)^2 \oint_{\Gamma_{\rho 1}} \oint_{\Gamma_{\rho 2}} \frac{1}{n} \left[e_{00}^\alpha(z_1) (\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}) \mathbf{M} (\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^\mathsf{T}) - \beta^\alpha(z_1) \mathbf{c}\mathbf{1}_K^\mathsf{T} \right] (\underline{\mathbf{G}}_{z_1}^\alpha)^{-1}$$
$$\times c_a \left(e_{00;2}^\alpha(z_1, z_2) \mathcal{D} \left(\boldsymbol{\delta}_{i=a} \right)_{i=1}^K + \chi^\alpha(z_1, z_2) \mathcal{D}(\mathbf{c}) \right)$$
$$\times \left((\underline{\mathbf{G}}_{z_2}^\alpha)^{-1} \right)^\mathsf{T} \left[e_{00}^\alpha(z_2) (\mathbf{I}_K - \mathbf{1}_K \mathbf{c}^\mathsf{T}) \mathbf{M} (\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}) - \beta^\alpha(z_2) \mathbf{1}_K \mathbf{c}^\mathsf{T} \right] \mathrm{d}z_1 \mathrm{d}z_2.$$

We can then perform a residue calculus similar to what was done in the proof of Theorem 22. Additionnaly, we use the fact that the eigenvectors $\mathbf{v}_{\rho_1}$ and $\mathbf{v}_{\rho_2}$ corresponding to distinct eigenvalues ρ_1 and ρ_2 of the symmetric matrix $\mathcal{D}(\mathbf{c})^{\frac{1}{2}} \left(\mathbf{I}_K - \mathbf{1}_K \mathbf{c}^\mathsf{T} \right) \mathbf{M} \left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T \right) \mathcal{D}(\mathbf{c})^{\frac{1}{2}}$ are orthogonals. All calculus done, we get

$$\left(\frac{1}{n} \frac{\mathbf{J}^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{u}_i^\alpha (\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{D}_a \mathbf{D}^{\alpha-1} \mathbf{u}_j^\alpha (\mathbf{u}_j^\alpha)^\mathsf{T} \mathbf{D}^{\alpha-1} \mathbf{J}}{\left((\mathbf{u}_i^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_i^\alpha \right) \left((\mathbf{u}_j^\alpha)^\mathsf{T} \mathbf{D}^{2(\alpha-1)} \mathbf{u}_j^\alpha \right)} \right)_{ef} \xrightarrow{\text{a.s.}}$$
$$\frac{e_{00}^\alpha(\rho_i) e_{00}^\alpha(\rho_j)}{\left(e_{00;2}^\alpha(\rho_i, \rho_i) + \chi^\alpha(\rho_i) \right) \left(e_{00;2}^\alpha(\rho_j, \rho_j) + \chi^\alpha(\rho_j) \right)}$$
$$\times \left[e_{00;2}^\alpha(\rho_i, \rho_j) \sqrt{c_e c_f} v_e^i v_f^j v_a^i v_a^j + \delta_{\rho_i = \rho_j} c_a \chi^\alpha(\rho_i) \sqrt{c_e c_f} v_e^i v_f^j \right]. \tag{38}$$

We are thus now ready to evaluate the σ_{ij}^a's. By definition,

$$\sigma_{ij}^a = \left[\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{D}_a\mathbf{D}^{\alpha-1}\mathbf{u}_j^\alpha}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}\sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha}} - \frac{1}{n_a}\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_a}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}}\frac{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_a}{\sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha}} \right]. \tag{39}$$

The first right hand side term is estimated by dividing $\left(\frac{1}{n}\frac{\mathbf{J}^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{u}_i^\alpha(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{D}_a\mathbf{D}^{\alpha-1}\mathbf{u}_j^\alpha(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{J}}{((\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha)((\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha)}\right)_{ef}$ (Equation (38)) by $\frac{1}{\sqrt{n}}\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_e}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}} \neq 0$ and $\frac{1}{\sqrt{n}}\frac{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_f}{\sqrt{(\mathbf{u}_j^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_j^\alpha}} \neq 0$ for any couple of indexes (e, f) such that the aforementioned quantities are non zeros. Indeed from the definition of ν_i^a and Equation 37, we get

$$\frac{1}{\sqrt{n}}\frac{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{\alpha-1}\mathbf{j}_e}{\sqrt{(\mathbf{u}_i^\alpha)^\mathsf{T}\mathbf{D}^{2(\alpha-1)}\mathbf{u}_i^\alpha}} \xrightarrow{\text{a.s.}} \sqrt{c_e}\frac{e_{00}^\alpha(\rho)}{\sqrt{e_{00;2}^\alpha(\rho,\rho)+\chi^\alpha(\rho)}}\left|v_e^i\right|. \tag{40}$$

The covariances σ_{ij}^a's are then found by combining the previous estimates (38) and (40) as per the Definition (39) of the σ_{ij}^a's. This proves the following theorem giving the limit of the empirical class covariances σ_{ij}^a's.

Theorem 23 (Covariances) *For two unit multiplicity eigenpairs $(\lambda_1(\bar{\mathbf{M}}), \mathbf{v}^1)$ and $(\lambda_2(\bar{\mathbf{M}}), \mathbf{v}^2)$ of $\mathcal{D}(\mathbf{c})^{\frac{1}{2}}\left(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)\mathcal{D}(\mathbf{c})^{\frac{1}{2}}$ mapped respectively to $(\rho_1, \mathbf{u}_i^\alpha)$ and $(\rho_2, \mathbf{u}_j^\alpha)$ eigenpairs of $\mathbf{L}_\alpha$ and for σ_{ij}^a defined in (27), we have almost surely as $n \to \infty$, $\left|\sigma_{ij}^a - \sigma_{ij}^{a,\infty}\right| \to 0$ where*

$$\sigma_{ij}^{a,\infty} \equiv \frac{\left[\left(e_{00;2}^\alpha(\rho_1,\rho_2) - e_{00}^\alpha(\rho_1)e_{00}^\alpha(\rho_2)\right)v_a^{\rho_1}v_a^{\rho_2} + \delta_{\rho_1}^{\rho_2}c_a\chi^\alpha(\rho_1)\right]}{\sqrt{e_{00;2}^\alpha(\rho_1)+\chi^\alpha(\rho_1)}\sqrt{e_{00;2}^\alpha(\rho_2)+\chi^\alpha(\rho_2)}}$$

where $\chi^\alpha(\rho)$ is defined in Theorem 22.

From Theorems 22 and 23, $\nu_i^{a,\infty}$ and $\sigma_{ij}^{a,\infty}$ depend on the e_{ij}'s (defined in Theorem 4), the normalized eigenvectors $\mathbf{v}$ of $\mathcal{D}(\mathbf{c})^{\frac{1}{2}}\left(\mathbf{I}_K - \mathbf{1}_K\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)\mathcal{D}(\mathbf{c})^{\frac{1}{2}}$ and the proportions c_a's of classes. Thanks to Lemma 11, the e_{ij}'s can consistently be estimated similarly to what was described in Proposition 12. Namely, the q_i's can be estimated using $\hat{q}_i = \frac{d_i}{\sqrt{\mathbf{d}^\mathsf{T}\mathbf{1}_n}}$ and replaced in Equations (20), (21), (22) to obtain consistent estimates for the e_{ij}'s. However, the eigenvectors $\mathbf{v}$ and the class proportions are not directly accessible in practice. Nevertheless, in the particular case of $K = 2$ classes, we know exactly $\mathbf{v}$.

Remark 24 ($K = 2$ classes) *Here, only one isolated eigenvector is used for the classification. Since $\mathbf{v}_r$ (right eigenvector of $\bar{\mathbf{M}}$) is orthogonal to $\mathbf{1}_2$, $\mathbf{v}_r$ is necessarily the vector $[1, -1]^\mathsf{T}$. Hence, the normalized eigenvector $\mathbf{v} = \frac{\mathcal{D}(\mathbf{c})^{-\frac{1}{2}}\mathbf{v}_r}{\|\mathcal{D}(\mathbf{c})^{-\frac{1}{2}}\mathbf{v}_r\|}$ is $\frac{1}{\sqrt{1/c_1+1/c_2}}\left[\frac{1}{\sqrt{c_1}}, -\frac{1}{\sqrt{c_2}}\right]^\mathsf{T}$.*

We thus obtain from Theorems 22 and 23 along with Remark 24,

Corollary 25 (Means and covariances for $K = 2$ classes) *For $a = 1, 2$*

$$(\nu^{a,\infty})^2 = \frac{\left[e_{00}^\alpha(\rho)\right]^2}{\left(e_{00;2}^\alpha(\rho,\rho)+\chi^\alpha(\rho)\right)\left(1+\frac{c_a}{1-c_a}\right)}$$

$$(\sigma^{a,\infty})^2 = \frac{\left[\frac{\left(e_{00;2}^\alpha(\rho,\rho)-e_{00}^\alpha(\rho)^2\right)}{\left(1+\frac{c_a}{1-c_a}\right)} + c_a\chi^\alpha(\rho)\right]}{e_{00;2}^\alpha(\rho,\rho)+\chi^\alpha(\rho)}$$

for ρ the unique isolated eigenvalue of $\mathbf{L}_\alpha$ (if it exists).

6.5 Non informative eigenvectors

The objective of this section is to show that the eigenvectors $\tilde{\mathbf{u}}^\alpha$ of $\mathbf{L}_\alpha$ associated to the limiting eigenvalue $\tilde{\rho}$ for which $1+\theta^\alpha(\tilde{\rho}) = 0$ (Remark 20) are not useful for the classification.

Let us write as in Section 6.4

$$\tilde{\mathbf{u}}^\alpha = \sum_{a=1}^K \tilde{\nu}^a\mathbf{j}_a + \sqrt{\tilde{\sigma}_{ii}^a}\mathbf{w}^a \tag{41}$$

where $\mathbf{w}^a \in \mathbb{R}^n$ is a random vector orthogonal to $\mathbf{j}_a$ of norm $\sqrt{n_a}$, supported on the indices of $\mathcal{C}_a$ with identically distributed entries. We shall show that $\tilde{\nu}^a$ is independent of class $\mathcal{C}_a$ and thus, any correct classification cannot be done using $\tilde{\mathbf{u}}^\alpha$. From (41), $\tilde{\nu}^a = \frac{(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{j}_a}{n_a}$ which can be retrieved from the diagonal elements of $\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J}$. We will evaluate this object by using the same technique as in Section 6.4. By the residue formula, we have

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} = -\frac{1}{2\pi i}\oint_{\Gamma_{\tilde{\rho}}}\frac{1}{n}\mathbf{J}^\mathsf{T}\left(\mathbf{L}_\alpha - z\mathbf{I}_n\right)^{-1}\mathbf{J}\mathrm{d}z \tag{42}$$

$$= -\frac{1}{2\pi i}\oint_{\Gamma_{\tilde{\rho}}}\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{J}\mathrm{d}z + \frac{1}{2\pi i}\oint_{\Gamma_{\tilde{\rho}}}\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\left(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda}\right)^{-1}\mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{J} \tag{43}$$

for large n almost surely, where $\Gamma_{\tilde{\rho}}$ is a complex (positively oriented) contour circling around the limiting eigenvalue $\tilde{\rho}$ only. The first integral $-\frac{1}{2\pi i}\oint_{\Gamma_{\tilde{\rho}}}\frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{J}\mathrm{d}z$ is asymptotically zero since, from Proposition 18, the integrand has no poles in the contour $\Gamma_{\tilde{\rho}}$. We thus obtain similarly as in Section 6.4

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} = \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{U}\mathbf{\Lambda}\left[\lim_{z\to\tilde{\rho}}(z-\tilde{\rho})(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda})^{-1}\right]\mathbf{U}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{J}. \tag{44}$$

From (29), the entries $(1, 2)$ and $(2, 2)$ of $(\mathbf{I}_{K+1} + \mathbf{U}^\mathsf{T}\mathbf{Q}_z^\alpha\mathbf{U}\mathbf{\Lambda})^{-1}$ do not contain $(\underline{\mathbf{G}}_z^\alpha)^{-1}$ since $\left[\underline{\mathbf{G}}_z^\alpha - \frac{\gamma(z)m_\mu e_{21}^\alpha(z)}{ze_{10}^\alpha(z)}\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]^{-1}\mathbf{c} = -\frac{m_\mu}{ze_{10}^\alpha(z)}\mathbf{c}$ and thus, the above limit will give zero for those entries. We thus get

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} = \frac{1}{n}\mathbf{J}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{U}\mathbf{\Lambda}\left[\lim_{z\to\tilde{\rho}}(z-\tilde{\rho})\begin{pmatrix}(\underline{\mathbf{G}}_z^\alpha)^{-1} & 0\\ \frac{\gamma(z)m_\mu}{ze_{21}^\alpha(z)}\mathbf{1}_K^\mathsf{T}(\underline{\mathbf{G}}_z^\alpha)^{-1} & 0\end{pmatrix}\right]\mathbf{U}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{J}. \tag{45}$$

We recall that in the case under study ($1 + \theta^\alpha(\tilde{\rho}) = 0$), $\mathbf{1}_K$ and $\mathbf{c}$ are respectively left and right eigenvectors of $\underline{\mathbf{G}}_z^\alpha$ associated to the vanishing eigenvalue. We can thus write

$\underline{\mathbf{G}}_z^\alpha = \rho_z \mathbf{c}\mathbf{1}_K^\mathsf{T} + \tilde{\mathbf{V}}_{r,z}\tilde{\mathbf{\Sigma}}_z\tilde{\mathbf{V}}_{l,z}^T$ where ρ_z is the vanishing eigenvalue when $z \to \tilde{\rho}$ and $\tilde{\mathbf{V}}_{r,z}$ and $\tilde{\mathbf{V}}_{l,z}$ are respectively sets of right and left eigenspaces associated with non vanishing eigenvalues. Hence, we have

$$\lim_{z\to\tilde{\rho}}(z-\tilde{\rho})(\underline{\mathbf{G}}_z^\alpha)^{-1} \overset{(1)}{=} \lim_{z\to\tilde{\rho}} \frac{\mathbf{c}\mathbf{1}_K^\mathsf{T}}{\rho_z'} \overset{(2)}{=} \lim_{z\to\tilde{\rho}} \frac{\mathbf{c}\mathbf{1}_K^\mathsf{T}}{\mathbf{1}_K^\mathsf{T}(\underline{\mathbf{G}}_z^\alpha)'\mathbf{c}} \overset{(3)}{=} \lim_{z\to\tilde{\rho}} \frac{\mathbf{c}\mathbf{1}_K^\mathsf{T}}{(\theta^\alpha(z))'} \overset{(4)}{=} \frac{\mathbf{c}\mathbf{1}_K^\mathsf{T}}{(\theta^\alpha(\tilde{\rho}))'} \tag{46}$$

where in (1) we have used the l'Hopital rule, in (2) we used the fact that ρ_z can be written $\rho_z = \mathbf{1}_K^\mathsf{T}\underline{\mathbf{G}}_z^\alpha\mathbf{c}$ and in (3) we have used $(\underline{\mathbf{G}}_{\tilde{\rho}}^\alpha)' = (e_{21}^\alpha(\tilde{\rho}))'\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right) + (\theta^\alpha(\tilde{\rho}))'\mathbf{c}\mathbf{1}_K^T$ and $\mathbf{1}_K^\mathsf{T}\mathbf{c} = 1$. We then have

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} = \frac{1}{n}(\mathbf{J}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{U}\mathbf{\Lambda})_{11}\frac{\mathbf{c}\mathbf{1}_K^\mathsf{T}}{(\theta^\alpha(\tilde{\rho}))'}(\mathbf{U}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{J})_{11} \tag{47}$$

$$+ \frac{1}{n}(\mathbf{J}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{U}\mathbf{\Lambda})_{12}\frac{\gamma(\tilde{\rho})m_\mu\mathbf{1}_K^\mathsf{T}}{\tilde{\rho}e_{21}^\alpha(\tilde{\rho})(\theta^\alpha(\tilde{\rho}))'}(\mathbf{U}^\mathsf{T}\mathbf{Q}_{\tilde{\rho}}^\alpha\mathbf{J})_{11}. \tag{48}$$

All calculus done similarly as in Section 6.4, we get

$$\begin{aligned}\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} \xrightarrow{\text{a.s.}} \frac{e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})}{(\theta^\alpha(\tilde{\rho}))'}&\left[e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})\left(\mathcal{D}(\mathbf{c}) - \mathbf{c}\mathbf{c}^\mathsf{T}\right)\mathbf{M}\left(\mathbf{I}_K - \mathbf{c}\mathbf{1}_K^T\right)\right.\\ &\left. - \frac{1}{m_\mu}\left(\int t^\alpha\mu(\mathrm{d}t) + e_{0,\frac{1}{2}}^\alpha(\tilde{\rho})\right)\mathbf{c}\mathbf{1}_K^\mathsf{T}\right]\mathbf{c}\mathbf{c}^\mathsf{T}\\ &- (e_{1,\frac{1}{2}}^\alpha(\tilde{\rho}))^2\frac{\gamma(\tilde{\rho})m_\mu}{\tilde{\rho}e_{21}^\alpha(\tilde{\rho})(\theta^\alpha(\tilde{\rho}))'}\mathbf{c}\mathbf{c}^\mathsf{T}.\end{aligned}$$

Finally,

$$\frac{1}{n}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J} \xrightarrow{\text{a.s.}} -\frac{e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})}{m_\mu(\theta^\alpha(\tilde{\rho}))'}\left[\int t^\alpha\mu(\mathrm{d}t) + e_{0,\frac{1}{2}}^\alpha(\tilde{\rho}) + \frac{e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})\gamma(\tilde{\rho})m_\mu^2}{\tilde{\rho}e_{21}^\alpha(\tilde{\rho})}\right]\mathbf{c}\mathbf{c}^\mathsf{T}. \tag{49}$$

By recalling that $\tilde{\nu}^a = \frac{(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{j}_a}{n_a} = \sqrt{\frac{1}{n_a}\left[\frac{1}{n}\mathcal{D}(\mathbf{c})^{-\frac{1}{2}}\mathbf{J}^\mathsf{T}\tilde{\mathbf{u}}^\alpha(\tilde{\mathbf{u}}^\alpha)^\mathsf{T}\mathbf{J}\mathcal{D}(\mathbf{c})^{-\frac{1}{2}}\right]_{aa}}$, from (49) we deduce that

$$\tilde{\nu}^a \xrightarrow{\text{a.s.}} -\frac{1}{\sqrt{n}}\frac{e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})}{m_\mu(\theta^\alpha(\tilde{\rho}))'}\left[\int t^\alpha\mu(\mathrm{d}t) + e_{0,\frac{1}{2}}^\alpha(\tilde{\rho}) + \frac{e_{1,\frac{1}{2}}^\alpha(\tilde{\rho})\gamma(\tilde{\rho})m_\mu^2}{\tilde{\rho}e_{21}^\alpha(\tilde{\rho})}\right]$$

which is independent of the class information (class proportions or inter-class affinities). This concludes the proof.

Appendix A. Stein Lemma and Nash Poincare inequality

Lemma 26 *Let x be a standard real Gaussian random variable and $f : \mathbb{R} \to \mathbb{R}$ be a $\mathbb{C}^1$ function with first derivative $f'(x)$ having at most polynomial growth. Then,*

$$\mathbb{E}[xf(x)] = \mathbb{E}[f'(x)].$$

Lemma 27 *Let x be a standard real Gaussian random variable and $f : \mathbb{R} \to \mathbb{R}$ be a $\mathbb{C}^1$ function with first derivative $f'(x)$. Then, we have*

$$\mathrm{Var}[f(x)] \leq \mathbb{E}[|f'(x)|^2].$$

The proofs of those lemma can be found in (Pastur et al., 2011).

Appendix B. Consistent estimates of the averages connectivity weights q_i's

Lemma 28 *Under Assumption 1,*

$$\max_{1\leq i\leq n}|q_i - \hat{q}_i| \to 0 \tag{50}$$

almost surely, where $\hat{q}_i = \frac{d_i}{\sqrt{\mathbf{d}^\mathsf{T}\mathbf{1}_n}}$.

We need to prove that $\sum_{n=1}^\infty \mathbb{P}\left(\max_{1\leq i\leq n}|q_i - \hat{q}_i| > \eta\right) < \infty$ for any $\eta > 0$ so that we can conclude from the first Borel Cantelli lemma (Theorem 4.3 in (Billingsley, 1995)) that $\mathbb{P}\left(\limsup_n \max_{1\leq i\leq n}|q_i - \hat{q}_i| > \eta\right) = 0$ from which Lemma 28 unfolds. We have that

$$\begin{aligned}\mathbb{P}\left(\max_{1\leq i\leq n}|q_i - \hat{q}_i| > \eta\right) &\leq \sum_{i=1}^n \mathbb{P}(|q_i - \hat{q}_i| > \eta)\\ &\leq \sum_{i=1}^n \mathbb{P}(\hat{q}_i - q_i > \eta) + \mathbb{P}(q_i - \hat{q}_i > \eta).\end{aligned} \tag{51}$$

Let us treat for instance the term $\mathbb{P}(\hat{q}_i - q_i > \eta)$ in the following. Since $A_{ij} = q_iq_j + q_iq_j\frac{M_{g_ig_j}}{\sqrt{n}} + X_{ij}$ with X_{ij} a zero mean random variable, we have $\frac{1}{n}\sum_{j=1}^n \mathbb{E}A_{ij} \to q_im_\mu$ and $\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij} \to m_\mu^2$ in the limit $n \to \infty$. For $\hat{q}_i = \frac{\sum_{j=1}^n A_{ij}}{\sqrt{\sum_{i,j}A_{ij}}}$, we can write

$$\hat{q}_i - q_i = \underbrace{\frac{\frac{1}{n}\sum_{j=1}^n(A_{ij} - \mathbb{E}A_{ij})}{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}}}}_{A} + \underbrace{\frac{\frac{1}{n}\sum_{j=1}^n A_{ij}}{\sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}} - \frac{\frac{1}{n}\sum_{j=1}^n A_{ij}}{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}}}}_{B} + \underbrace{\frac{\frac{1}{n}\sum_{j=1}^n \mathbb{E}A_{ij}}{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}}} - q_i}_{C}$$

Since A, B and C tend to zero in the limit $n \to \infty$, we will next use the fact that $\mathbb{P}(\hat{q}_i - q_i > \eta) \leq \mathbb{P}(A > \eta/3) + \mathbb{P}(B > \eta/3) + \mathbb{P}(C > \eta/3)$ and show that all those individual probabilities vanish asymptotically. Since the term C is deterministic and tends to zero in the limit $n \to \infty$, we have $\mathbb{P}(C > \eta/3) = 0$ for all large n. Let us then control $\mathbb{P}(A > \eta/3)$ and $\mathbb{P}(B > \eta/3)$. We have

$$\begin{aligned}\mathbb{P}(A > \eta/3) &= \mathbb{P}\left(\frac{1}{n}\sum_{j=1}^n(A_{ij} - \mathbb{E}A_{ij}) > \frac{\eta m_\mu}{3} + o(1)\right)\\ &\leq \exp\left[-\frac{n\eta^2m_\mu^2}{18\left(\sigma^2 + \eta m_\mu/9\right))} + o(1)\right]\end{aligned} \tag{52}$$

with $\sigma^2 = \limsup_n \max_{1\leq i\leq n} q_i(\sum_j q_j) - q_i^2(\sum_j q_j^2)$ and where in the last inequality of (52), we have used Bernstein's inequality (Theorem 3 in (Boucheron et al., 2013)) since the A_{ij}'s

are independent Bernoulli random variables with variance $\sigma_{ij}^2 = q_i q_j(1-q_i q_j) + \mathcal{O}(n^{-\frac{1}{2}})$. For the term B we have

$$\begin{aligned}
\mathbb{P}(B > \eta/3) &= \mathbb{P}\left(\frac{1}{n}\sum_{j=1}^n A_{ij} \frac{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}}{\sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}} > \frac{\eta m_\mu}{3} + o(1) \right) \\
&\overset{(1)}{\leq} \mathbb{P}\left(\left| \frac{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}}{\sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}} \right| > \frac{\eta m_\mu}{3} + o(1) \right) \\
&\overset{(2)}{\leq} \mathbb{P}\left(\left| \sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}} \right| > \frac{\eta(m_\mu + o(1))\sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}}{3}, \frac{1}{n^2}\sum_{i,j}A_{ij} > \psi \right) \\
&+ \mathbb{P}\left(\left| \sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}} \right| > \frac{\eta m_\mu \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}}{3} + o(1), \frac{1}{n^2}\sum_{i,j}A_{ij} \leq \psi \right) \\
&\overset{(3)}{\leq} \underbrace{\mathbb{P}\left(\left| \sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}} \right| > \frac{\eta m_\mu \sqrt{\psi}}{3} + o(1) \right)}_{B_1} + \underbrace{\mathbb{P}\left(\frac{1}{n^2}\sum_{i,j}A_{ij} \leq \psi \right)}_{B_2}
\end{aligned} \tag{53}$$

where in the inequality (1) we have used the fact that $n^{-1}\sum_{j=1}^n A_{ij} \leq 1$; in the inequality (2) $\psi > 0$ is any constant smaller than m_μ^2 and in the inequality (3) we have used $\sqrt{n^{-2}\sum_{i,j}A_{ij}} > \sqrt{\psi}$ and the fact that the probability of the intersection between two events is always smaller than the probability of one of those events. It then remains to control B_1 and B_2. For B_2 we have

$$\mathbb{P}\left(\frac{1}{n^2}\sum_{i,j}A_{ij} \leq \psi \right) \leq \exp\left[-\frac{n(m_\mu^2 - \psi)^2}{2\left(\sigma^2 + (m_\mu^2 - \psi)/3\right)} + o(1) \right] \tag{54}$$

where the inequality follows from Bernstein's inequality with the similar arguments as previously. Finally for the term B_1 we have

$$\begin{aligned}
&\mathbb{P}\left(\left| \sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} - \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}} \right| > \frac{\eta m_\mu \sqrt{\psi}}{3} + o(1) \right) \\
&= \mathbb{P}\left(\left| \frac{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij} - \frac{1}{n^2}\sum_{i,j}A_{ij}}{\sqrt{\frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij}} + \sqrt{\frac{1}{n^2}\sum_{i,j}A_{ij}}} \right| > \frac{\eta m_\mu \sqrt{\psi}}{3} + o(1) \right) \\
&\overset{(1)}{\leq} \mathbb{P}\left(\left| \frac{1}{n^2}\sum_{i,j}\mathbb{E}A_{ij} - \frac{1}{n^2}\sum_{i,j}A_{ij} \right| > \frac{\eta m_\mu \sqrt{\psi}(m_\mu + \sqrt{\psi})}{3} + o(1) \right) + \mathbb{P}\left(\frac{1}{n^2}\sum_{i,j}A_{ij} \leq \psi \right) \\
&\overset{(2)}{\leq} \exp\left[-\frac{n\psi\left[\eta m_\mu(m_\mu + \sqrt{\psi})\right]^2}{18\left(\sigma^2 + \eta m_\mu\sqrt{\psi}(m_\mu + \sqrt{\psi})/9\right)} + o(1) \right] + \exp\left[-\frac{n(m_\mu^2 - \psi)^2}{2\left(\sigma^2 + (m_\mu^2 - \psi)/3\right)} + o(1) \right]
\end{aligned} \tag{55}$$

where in the inequality (1) of Equation (55) we have used the same arguments as in the inequalities (2)−(3) of Equation (52) and in the inequality (2) we have used Bernstein's inequality along with Equation (54). From Equations (52)(54)(55), we conclude that $\sum_{n=1}^\infty \sum_{i=1}^n \mathbb{P}(\hat{q}_i - q_i > \eta) < \infty$ since $m_\mu^2 - \psi > 0$. It follows the same lines to show that $\sum_{n=1}^\infty \sum_{i=1}^n \mathbb{P}(q_i - \hat{q}_i > \eta) < \infty$ which concludes the proof.

Appendix C. First deterministic equivalents

Let $\mathbf{Q}_z^\alpha = \left(\bar{\mathbf{X}} - z\mathbf{I}_n\right)^{-1}$ with $\bar{\mathbf{X}}$ a symmetric random matrix having independent entries $\bar{X}_{ij}$ which are Gaussian random variables with zero mean and variance $\frac{\sigma_{ij}^2}{n}$. For short, we shall denote $\mathbf{Q}_z^\alpha$ by $\mathbf{Q}$. We want to find a deterministic equivalent $\bar{\mathbf{Q}}$ of $\mathbf{Q}$ in the sense that $\frac{1}{n}\operatorname{tr}\mathbf{C}\mathbf{Q} - \frac{1}{n}\operatorname{tr}\mathbf{C}\bar{\mathbf{Q}} \to 0$ and $\mathbf{d}_1^\mathsf{T}(\mathbf{Q} - \bar{\mathbf{Q}})\mathbf{d}_2 \to 0$ almost surely, for all deterministic Hermitian matrix $\mathbf{C}$ and deterministic vectors $\mathbf{d}_i$ of bounded norms (spectral norm for matrices and Euclidian norm for vectors). To this end, we will evaluate $\mathbb{E}(\mathbf{Q})$ since using Lemma 27, one can show that $n^{-1}\operatorname{tr}(\mathbf{C}\mathbf{Q})$ and $\mathbf{a}^\mathsf{T}\mathbf{Q}\mathbf{b}$ concentrate respectively around $n^{-1}\operatorname{tr}(\mathbf{A}\mathbb{E}Q)$ and $\mathbf{d}_1^\mathsf{T}\mathbb{E}\mathbf{Q}\mathbf{d}_2$ for all bounded norm matrix $\mathbf{C}$ and vectors $\mathbf{d}_1, \mathbf{d}_2$. For the computations, we use standard Gaussian calculus introduced in (Pastur et al., 2011). Using the resolvent identity (for two invertible matrices $\mathbf{A}$ and $\mathbf{B}$, $\mathbf{A}^{-1} - \mathbf{B}^{-1} = -\mathbf{A}^{-1}(\mathbf{A} - \mathbf{B})\mathbf{B}^{-1}$), one has

$$\mathbf{Q} = \frac{1}{z}\bar{\mathbf{X}}\mathbf{Q} - \frac{1}{z}\mathbf{I}_n. \tag{56}$$

We then first compute $\mathbb{E}(\bar{\mathbf{X}}\mathbf{Q})$. By writing $\bar{X}_{il} = \frac{\sigma_{il}}{\sqrt{n}}Z_{il}$ where Z_{il} is a random variable with zero mean and unit variance, we thus have

$$\mathbb{E}(\bar{\mathbf{X}}\mathbf{Q})_{ij} = \sum_{l=1}^n \frac{\sigma_{il}}{\sqrt{n}}\mathbb{E}(Z_{il}Q_{lj}).$$

By applying Stein's Lemma (Lemma 26 in Section A), we have

$$\begin{aligned}
\mathbb{E}(Z_{il}Q_{lj}) &= \mathbb{E}\left(\frac{\partial(\bar{\mathbf{X}} - z\mathbf{I})^{-1}_{lj}}{\partial Z_{il}} \right) \\
&= \mathbb{E}\left(-(\bar{\mathbf{X}} - z\mathbf{I})^{-1}\frac{\partial\bar{\mathbf{X}}}{\partial Z_{il}}(\bar{\mathbf{X}} - z\mathbf{I})^{-1} \right)_{lj} \\
&= \mathbb{E}\left(-(\bar{\mathbf{X}} - z\mathbf{I})^{-1}\frac{\sigma_{il}}{\sqrt{n}}(\mathbf{E}_{il} + \mathbf{E}_{li})(\bar{\mathbf{X}} - z\mathbf{I})^{-1} \right)_{lj}
\end{aligned}$$

where $\mathbf{E}_{il}$ is the matrix with all entries equal to 0 but the entry (i,l) which is equal to 1. Using simple algebra, we have

$$\left((\bar{\mathbf{X}} - z\mathbf{I})^{-1}\mathbf{E}_{il}(\bar{\mathbf{X}} - z\mathbf{I})^{-1}\right)_{lj} = (\bar{\mathbf{X}} - z\mathbf{I})^{-1}_{li}(\bar{\mathbf{X}} - z\mathbf{I})^{-1}_{lj}$$

and

$$\left((\bar{\mathbf{X}} - z\mathbf{I})^{-1}\mathbf{E}_{li}(\bar{\mathbf{X}} - z\mathbf{I})^{-1}\right)_{lj} = (\bar{\mathbf{X}} - z\mathbf{I})^{-1}_{ll}(\bar{\mathbf{X}} - z\mathbf{I})^{-1}_{ij}.$$

We thus get

$$\mathbb{E}(\bar{\mathbf{X}}\mathbf{Q})_{ij} = \sum_{l=1}^n -\frac{\sigma_{il}^2}{n}\left(\mathbb{E}\left[Q_{li}Q_{lj}\right] + \mathbb{E}\left[Q_{ll}Q_{ij}\right]\right).$$

Going back to (56), we thus have

$$\begin{aligned}\mathbb{E}(Q_{ij}) &= -\frac{1}{z}\sum_{l=1}^{n}\frac{\sigma_{il}^2}{n}\mathbb{E}\left[Q_{li}Q_{lj}\right] - \frac{1}{z}\sum_{l=1}^{n}\frac{\sigma_{il}^2}{n}\mathbb{E}\left[Q_{ll}Q_{ij}\right] - \frac{1}{z}\delta_{ij} \\ &= -\frac{1}{z}\mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij} - \frac{1}{z}\mathbb{E}\left[Q_{ij}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right] - \frac{1}{z}\delta_{ij} \end{aligned} \tag{57}$$

where $\mathbf{\Sigma}_i = \mathcal{D}\left(\sigma_{ij}^2\right)_{j=1}^n$. Since the goal is to retrieve $\mathbb{E}(Q_{ij})$, the following lemma allows to split $\mathbb{E}\left[Q_{ij}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right]$ into $\mathbb{E}\left[Q_{ij}\right]$ and $\mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right]$.

Lemma 29 *For $\mathbf{Q} = (\bar{\mathbf{X}} - z\mathbf{I}_n)^{-1}$ and $\mathbf{\Sigma}_i = \mathcal{D}(\sigma_{ij}^2)_{j=1}^n$, where $\bar{\mathbf{X}}$ is a symmetric random matrix having independent entries (up to the symmetry) of zero mean and variance $\frac{\sigma_{ij}^2}{n}$, we have*

$$\mathbb{E}\left[Q_{ij}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\boldsymbol{Q}}{n}\right)\right] = \mathbb{E}\left[Q_{ij}\right]\mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\boldsymbol{Q}}{n}\right)\right] + o(1).$$

Proof For two real random variables x and y, by Cauchy-Shwarz's inequality,

$$\left|\mathbb{E}\left[(x-\mathbb{E}(x))(y-\mathbb{E}(y))\right]\right| \leq \sqrt{\operatorname{Var}(x)}\sqrt{\operatorname{Var}(y)}$$

which, for $x = \operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)$ and $y = Q_{ij} - \mathbb{E}(Q_{ij})$ gives

$$\left|\mathbb{E}\left[Q_{ij}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right] - \mathbb{E}\left[Q_{ij}\right]\mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right]\right| \leq \sqrt{\operatorname{Var}(x)}\sqrt{\operatorname{Var}(y)}$$

since $\mathbb{E}(y)$ is equal to 0 in that case. Using Nash Poincaré inequality (Lemma 27 in Section A), one can show that $\operatorname{Var}(x) = \mathcal{O}\left(\frac{1}{n^2}\right)$(Hachem et al., 2007). Additionally, $\forall i,j$ and $z \in \mathbb{C}^+$, $|Q_{ij}| \leq \frac{1}{|\Im(z)|}$. This finally implies that $\mathbb{E}\left[Q_{ij}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right] - \mathbb{E}\left[Q_{ij}\right]\mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right] = \mathcal{O}(n^{-1})$. ■

Since $\Im(-z-\mathbb{E}\operatorname{tr}(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n})) < -\Im(z)$ for $z \in \mathbb{C}^+$, $-z-\mathbb{E}\operatorname{tr}(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n})$ does not vanish asymptotically. Going back to $\mathbb{E}(Q_{ij})$ in Equation (57), we may then write

$$\mathbb{E}(Q_{ij}) = \frac{\mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij} + \delta_{ij}}{-z - \mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right]} + \mathcal{O}(n^{-1}). \tag{58}$$

Multiplying Equation (58) by $\frac{\sigma_{ki}^2}{n}$, taking $j = i$, summing over i and scaling by n, we get

$$\operatorname{tr}\mathbb{E}\left(\frac{\mathbf{\Sigma}_k\mathbf{Q}}{n}\right) = \sum_{i=1}^{n}\left(\frac{\mathbb{E}\left[\frac{\mathbf{\Sigma}_k}{n}\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ii} + \frac{\sigma_{ki}^2}{n}}{-z - \mathbb{E}\left[\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)\right]}\right) + \mathcal{O}(n^{-1}).$$

Using a similar approach to the proof of Lemma 29, we can show that $\sum_{i=1}^n \mathbb{E}\left[\frac{\mathbf{\Sigma}_k}{n}\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ii} = \mathcal{O}(n^{-1})$. We thus have

$$\frac{1}{n}\operatorname{tr}\mathbb{E}\left(\mathbf{\Sigma}_k\mathbf{Q}\right) = \sum_{i=1}^{n}\frac{\frac{\sigma_{ki}^2}{n}}{-z - \frac{1}{n}\mathbb{E}\left[\operatorname{tr}\left(\mathbf{\Sigma}_i\mathbf{Q}\right)\right]} + o(1).$$

By using standard techniques (Hachem et al., 2007), one can show that the unique solution $e_i(z)$ to $e_i(z) = \frac{1}{n}\sum_{j=1}^n \frac{\sigma_{ij}^2}{-z-e_j(z)}$ is such that $\frac{1}{n}\operatorname{tr}\mathbb{E}\left(\mathbf{\Sigma}_i\mathbf{Q}\right) - e_i(z) \xrightarrow{\text{a.s.}} 0$. Going back to Equation (58), we can thus write for large n

$$\mathbb{E}\left[(-z\mathbf{I} - \mathcal{D}(e_i(z)))\mathbf{Q}\right]_{ij} = \mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij} + \delta_{ij} + o(1). \tag{59}$$

Let us denote $\mathbf{\Xi} = -z\mathbf{I} - \mathcal{D}(e_i(z))$. Since $-z - \mathbb{E}\operatorname{tr}\left(\frac{\mathbf{\Sigma}_i\mathbf{Q}}{n}\right)$ is away from zero for $z \in \mathbb{C}^+$ so is $-z - e_i(z)$ and thus $\mathbf{\Xi}$ is invertible and bounded. For large n, we can write for a given deterministic matrix $\mathbf{C}$ of bounded norm

$$\begin{aligned}\mathbb{E}\left[\frac{1}{n}\operatorname{tr}\mathbf{C}\mathbf{Q}\right] &= \frac{1}{n}\sum_{i,j}(\mathbf{C}\mathbf{\Xi}^{-1})_{ji}\mathbb{E}\left(\mathbf{\Xi}\mathbf{Q}\right)_{ij} \\ &\overset{(1)}{=} \frac{1}{n}\sum_{i,j}(\mathbf{C}\mathbf{\Xi}^{-1})_{ji}\left(\mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij} + \delta_{ij}\right) + o(1) \\ &= \frac{1}{n}\operatorname{tr}\mathbb{E}\left(\mathbf{C}\mathbf{\Xi}^{-1}\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right) + \frac{1}{n}\operatorname{tr}(\mathbf{C}\mathbf{\Xi}^{-1}) + o(1)\end{aligned}$$

where (1) follows from Equation (59). We can then prove that $\frac{1}{n}\operatorname{tr}\mathbb{E}\left(\mathbf{C}\mathbf{\Xi}^{-1}\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right) = \mathcal{O}(n^{-1})$ using a similar approach to the proof of Lemma 29. Hence for large n

$$\mathbb{E}\left[\frac{1}{n}\operatorname{tr}\mathbf{C}\mathbf{Q}\right] = \frac{1}{n}\operatorname{tr}(\mathbf{C}\mathbf{\Xi}^{-1}) + o(1). \tag{60}$$

Similarly, for any vectors $\mathbf{a}$, $\mathbf{b}$ of bounded norms, we may write

$$\begin{aligned}\mathbb{E}\left[\mathbf{a}^*\mathbf{Q}\mathbf{b}\right] &= \sum_{i,j}(\mathbf{a}^*\mathbf{\Xi}^{-1})_i\mathbb{E}\left(\mathbf{\Xi}\mathbf{Q}\right)_{ij}\mathbf{b}_j \\ &= \sum_{i,j}(\mathbf{a}^*\mathbf{\Xi}^{-1})_i\mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij}\mathbf{b}_j + \mathbf{a}^*\mathbf{\Xi}^{-1}\mathbf{b} + o(1).\end{aligned}$$

We also have that $\sum_{i,j}(\mathbf{a}^*\mathbf{\Xi}^{-1})_i\mathbb{E}\left[\mathbf{Q}\frac{\mathbf{\Sigma}_i}{n}\mathbf{Q}\right]_{ij}\mathbf{b}_j = \mathcal{O}(n^{-1})$. This can be proved similarly to the proof of Lemma 29. Hence,

$$\mathbb{E}\left[\mathbf{a}^*\mathbf{Q}\mathbf{b}\right] = \mathbf{a}^*\mathbf{\Xi}^{-1}\mathbf{b} + o(1). \tag{61}$$

Appendix D. Second deterministic equivalents

Our goal is to find a deterministic equivalent to the random quantity $\mathbf{Q}_{z_1}^{\alpha}\mathbf{\Xi}\mathbf{Q}_{z_2}^{\alpha}$ for any diagonal deterministic matrix $\mathbf{\Xi}$ where we recall that $\mathbf{Q}_{z_1}^{\alpha} = \left(\frac{\bar{\mathbf{X}}}{\sqrt{n}} - z_1\mathbf{I}_n\right)^{-1}$ with $\bar{\mathbf{X}}$ defined previously in Appendix C. The proof follows the same techniques as the proof of the first deterministic equivalent $\mathbf{Q}_z^{\alpha}$ in Appendix C but here, the resolvent identity is either applied on $\mathbf{Q}_{z_1}^{\alpha}$ or $\mathbf{Q}_{z_2}^{\alpha}$. The technical details will be omitted as the key techniques have already been developped in

Appendix C. For the sake of readability, we will denote $\mathbf{Q}^{\alpha}_{z_1} \equiv \mathbf{Q}_1$ and $\mathbf{Q}^{\alpha}_{z_2} \equiv \mathbf{Q}_2$. As in Appendix C, we will evaluate $\mathbb{E}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)$. By the resolvent identity, we have

$$\begin{aligned}\mathbb{E}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij} &= -\frac{1}{z_1}\mathbb{E}(\mathbf{\Xi}\mathbf{Q}_2)_{ij} + \frac{1}{z_1}\mathbb{E}(\mathbf{X}\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij} \\ &= -\frac{1}{z_1}\Xi_{ii}\mathbb{E}(\mathbf{Q}_2)_{ij} + \frac{1}{z_1}\mathbb{E}\sum_{k,l} X_{ik}(Q_1)_{kl}\Xi_{ll}(Q_2)_{lj}.\end{aligned}$$

We have from Lemma 26, $\mathbb{E}\sum_{k,l} X_{ik}(Q_1)_{kl}\Xi_{ll}(Q_2)_{lj} = \sum_{k,l}\frac{\sigma_{ik}}{\sqrt{n}}\Xi_{ll}\mathbb{E}\frac{\partial[(Q_1)_{kl}(Q_2)_{lj}]}{\partial Z_{ik}}$. By expanding all terms and all calculus done, we obtain

$$\begin{aligned}\mathbb{E}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij} = -\frac{1}{z_1}\mathbb{E}(\mathbf{\Xi}\mathbf{Q}_2)_{ij} - \frac{1}{z_1}\sum_{k,l}\frac{\sigma^2_{ik}}{n}\Xi_{ll}\mathbb{E}\Bigg[&\underbrace{(Q_1)_{ki}(Q_1)_{kl}(Q_2)_{lj}}_{(1)} + \underbrace{(Q_1)_{kk}(Q_1)_{il}(Q_2)_{lj}}_{(2)} \\ &+ \underbrace{(Q_1)_{kl}(Q_2)_{li}(Q_2)_{kj}}_{(3)} + \underbrace{(Q_1)_{kl}(Q_2)_{lk}(Q_2)_{ij}}_{(4)}\Bigg].\end{aligned}$$

Asymptotically, the non vanishing terms are (2) and (4) so that

$$\begin{aligned}\mathbb{E}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij} &= -\frac{1}{z_1}\mathbb{E}(\mathbf{\Xi}\mathbf{Q}_2)_{ij} - \frac{1}{z_1}\sum_{k,l}\frac{\sigma^2_{ik}}{n}\Xi_{ll}\mathbb{E}\left[(Q_1)_{kk}(Q_1)_{il}(Q_2)_{lj} + (Q_1)_{kl}(Q_2)_{lk}(Q_2)_{ij}\right] \\ &\quad + o(1) \\ &= -\frac{1}{z_1}\mathbb{E}(\mathbf{\Xi}\mathbf{Q}_2)_{ij} - \frac{1}{z_1}\frac{1}{n}\mathbb{E}\left[\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_1)(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij}\right] - \frac{1}{z_1}\frac{1}{n}\mathbb{E}\left[\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)(\mathbf{Q}_2)_{ij}\right] \\ &\quad + o(1). \qquad (62)\end{aligned}$$

Similarly to what was done in the proof of of Lemma 29, we can show that $\mathbb{E}\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_1)\mathbb{E}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij} = \mathbb{E}\left(\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_1)\right)\mathbb{E}\left((\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)_{ij}\right)+o(1)$. We can then write from (62)

$$\begin{aligned}&\mathbb{E}\left(\left(\mathbf{I}_n + \frac{1}{z_1}\mathcal{D}\left(\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_1)\right)_{i=1}^n\right)\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2\right) = \\ &-\frac{1}{z_1}\mathbb{E}\left(\mathbf{\Xi} + \mathcal{D}\left(\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)\right)_{i=1}^n\right)\mathbf{Q}_2 + o(1). \qquad (63)\end{aligned}$$

From (63) and the result of Lemma 16, this entails

$$\mathbb{E}\left(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2\right) \longleftrightarrow \bar{\mathbf{Q}}_1\mathbf{\Xi}\bar{\mathbf{Q}}_2 + \bar{\mathbf{Q}}_1\mathcal{D}\left(\mathbb{E}\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)\right)_{i=1}^n\bar{\mathbf{Q}}_2. \qquad (64)$$

Every object in (64) is known but $\mathbb{E}\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)$ which we need to evaluate now. By left-multiplying (64) by $\mathbf{\Sigma}_i$ and taking the normalized trace, we get

$$\mathbb{E}\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1) = \frac{1}{n}\mathrm{tr}\left(\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\mathbf{\Xi}\bar{\mathbf{Q}}_2\right) + \mathbb{E}\frac{1}{n}\mathrm{tr}\left(\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\mathcal{D}\left(\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)\right)_{i=1}^n\bar{\mathbf{Q}}_2\right). \qquad (65)$$

By denoting $f_i = \frac{1}{n}\mathbb{E}\left(\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)\right)$, Equation (65) leads to

$$\mathbf{f} = \left\{\frac{1}{n}\mathrm{tr}\left(\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\mathbf{\Xi}\bar{\mathbf{Q}}_2\right)\right\}_{i=1}^n + \frac{1}{n}\left\{\left(\bar{\mathbf{Q}}_2\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\right)_{jj}\right\}_{i,j=1}^n\mathbf{f}$$

which finally entails

$$\mathbf{f} = \left(\mathbf{I}_n - \frac{1}{n}\left\{\left(\bar{\mathbf{Q}}_2\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\right)_{jj}\right\}_{i,j=1}^n\right)^{-1}\frac{1}{n}\left\{\bar{\mathbf{Q}}_2\mathbf{\Sigma}_i\bar{\mathbf{Q}}_1\right\}_{i,j=1}^n\mathrm{diag}(\mathbf{\Xi}).$$

To complete the proof of Lemma 21, we need to show that $\mathrm{Var}\left(\frac{1}{n}\mathrm{tr}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)\right)$ and $\mathrm{Var}\left(\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)\right)$ are asymptotically summable so that by the Borell Cantelli Lemma, $\frac{1}{n}\mathrm{tr}(\mathbf{Q}_1\mathbf{\Xi}\mathbf{Q}_2)$ and $\frac{1}{n}\mathrm{tr}(\mathbf{\Sigma}_i\mathbf{Q}_2\mathbf{\Xi}\mathbf{Q}_1)$ converge respectively almost surely to their expectations. Those follow directly by using Nash Poincare inequality (Lemma 27) similarly to what was done in the proof of Lemma 29.

Abstract

The random dot product graph (RDPG) is an independent-edge random graph that is analytically tractable and, simultaneously, either encompasses or can successfully approximate a wide range of random graphs, from relatively simple stochastic block models to complex latent position graphs. In this survey paper, we describe a comprehensive paradigm for statistical inference on random dot product graphs, a paradigm centered on spectral embeddings of adjacency and Laplacian matrices. We examine the graph-inferential analogues of several canonical tenets of classical Euclidean inference. In particular, we summarize a body of existing results on the consistency and asymptotic normality of the adjacency and Laplacian spectral embeddings, and the role these spectral embeddings can play in the construction of single- and multi-sample hypothesis tests for graph data. We investigate several real-world applications, including community detection and classification in large social networks and the determination of functional and biologically relevant network properties from an exploratory data analysis of the *Drosophila* connectome. We outline requisite background and current open problems in spectral graph inference.

Keywords: Random dot product graph, adjacency spectral embedding, Laplacian spectral embedding, multi-sample graph hypothesis testing, semiparametric modeling

1. Introduction

Random graph inference is an active, interdisciplinary area of current research, bridging combinatorics, probability, statistical theory, and machine learning, as well as a wide spectrum of application domains from neuroscience to sociology. Statistical inference on random graphs and networks, in particular, has witnessed extraordinary growth over the last decade: see, for example, Goldenberg et al. (2010) and Kolaczyk (2009) for a discussion of the considerable applications in recent network science of several canonical random graph models.

Of course, combinatorial graph theory itself is centuries old—indeed, in his resolution to the problem of the bridges of Königsberg, Leonard Euler first formalized graphs as mathematical objects consisting of vertices and edges. The notion of a random graph, however, and the modern theory of inference on such graphs, is comparatively new, and owes much to the pioneering work of Erdős, Rényi, and others in the late 1950s. E.N. Gilbert's short 1959 paper (Gilbert, 1959) considered a random graph for which the existence of edges between vertices are independent Bernoulli random variables with common probability p; roughly concurrently, Erdős and Rényi provided the first detailed analysis of the probabilities of the emergence of certain types of subgraphs within such graphs (Erdős and Rényi, 1960), and today, graphs in which the edges arise independently and with common probability p are known as *Erdős-Rényi* (or ER) graphs.

The Erdős-Rényi (ER) model is one of the simplest generative models for random graphs, but this simplicity belies astonishingly rich behavior (see Alon and Spencer, 2008; Bollobás et al., 2007). Nevertheless, in many applications, the requirement of a common connection probability is too stringent: graph vertices often represent heterogeneous entities, such as different people in a social network or cities in a transportation graph, and the connection probability p_{ij} between vertex i and j may well change with i and j or depend on underlying attributes of the vertices. Moreover, these heterogeneous vertex attributes may not be observable; for example, given the adjacency matrix of a Facebook community, the specific interests of the individuals may remain hidden. To more effectively model such real-world

networks, we consider *latent position* random graphs (Hoff et al., 2002). In a latent position graph, to each vertex i in the graph there is associated an element x_i of the so-called *latent space* $\mathcal{X}$, and the probability of connection p_{ij} between any two edges i and j is given by a *link* or *kernel* function $\kappa : \mathcal{X} \times \mathcal{X} \to [0, 1]$. That is, the edges are generated independently (so the graph is an *independent-edge* graph) and $p_{ij} = \kappa(x_i, x_j)$.

The *random dot product graph* (RDPG) of Young and Scheinerman (Young and Scheinerman, 2007) is an especially tractable latent position graph; here, the latent space is an appropriately constrained subspace of Euclidean space $\mathbb{R}^d$, and the link function is simply the dot or inner product of the pair of d-dimensional latent positions. Thus, in a d-dimensional random dot product graph with n vertices, the latent positions associated to the vertices can be represented by an $n \times d$ matrix $\mathbf{X}$ whose rows are the latent positions, and the matrix of connection probabilities $\mathbf{P} = (\mathbf{P}_{ij})$ is given by $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$. Conditional on this matrix $\mathbf{P}$, the RDPG has an adjacency matrix $\mathbf{A} = (\mathbf{A}_{ij})$ whose entries are Bernoulli random variables with probability $\mathbf{P}_{ij}$. For simplicity, we will typically consider symmetric, *hollow* RDPG graphs; that is, undirected, unweighted graphs in which $\mathbf{A}_{ii} = 0$, so there are no self-edges. In our real data analysis of a neural connectome in Section 6.3, however, we describe how to adapt our results to weighted and directed graphs.

In any latent position graph, the latent positions associated to graph vertices can themselves be random; for instance, the latent positions may be independent, identically distributed random variables with some distribution F on $\mathbb{R}^d$. The well-known *stochastic blockmodel* (SBM), in which each vertex belongs to one of K subsets known as *blocks*, with connection probabilities determined solely by block membership (Holland et al., 1983), can be represented as a random dot product graph in which all the vertices in a given block have the same latent positions (or, in the case of random latent positions, an RDPG for which the distribution F is supported on a finite set). Despite their structural simplicity, stochastic block models are the building blocks for all independent-edge random graphs; in Wolfe and Olhede (2013), the authors demonstrate that any independent-edge random graph can be well-approximated by a stochastic block model with a sufficiently large number of blocks. Since stochastic block models can themselves be viewed as random dot product graphs, we see that suitably high-dimensional random dot product graphs can provide accurate approximations of latent position graphs (Tang et al., 2013), and, in turn, independent-edge graphs. Thus, the architectural simplicity of the random dot product graph makes it particularly amenable to analysis, and its near-universality in graph approximation renders it expansively applicable. In addition, the cornerstone of our analysis of random dot product graphs is a set of classical probabilistic and linear algebraic techniques that are useful in much broader settings, such as random matrix theory. As such, the random dot product graph is both a rich and interesting object of study in its own right and a natural point of departure for wider graph inference.

A classical inference task for Euclidean data is to estimate, from sample data, certain underlying distributional parameters. Similarly, for a latent position graph, a classical graph inference task is to infer the graph parameters from an observation of the adjacency matrix $\mathbf{A}$. Indeed, our overall paradigm for random graph inference is inspired by the fundamental tenets of classical statistical inference for Euclidean data. Namely, our goal

is to construct methods and estimators of graph parameters or graph distributions; and, for these estimators, to analyze their (1) consistency; (2) asymptotic distributions; (3) asymptotic relative efficiency; (4) robustness to model misspecification; and (5) implications for subsequent inference including one- and multi-sample hypothesis testing. In this paper, we summarize and synthesize a considerable body of work on spectral methods for inference in random dot product graphs, all of which not only advance fundamental tenets of this paradigm, but do so within a unified and parsimonious framework. The random graph estimators and test statistics we discuss all exploit the *adjacency spectral embedding* (ASE) or the *Laplacian spectral embedding* (LSE), which are eigendecompositions of the adjacency matrix $\mathbf{A}$ and *normalized* Laplacian matrix $\mathbf{L} = \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$, where $\mathbf{D}$ is the diagonal degree matrix $\mathbf{D}_{ii} = \sum_{j \neq i} \mathbf{A}_{ij}$.

The ambition and scope of our approach to graph inference means that mere upper bounds on discrepancies between parameters and their estimates will not suffice. Such bounds are legion. In our proofs of consistency, we improve several bounds of this type, and in some cases improve them so drastically that concentration inequalities and asymptotic limit distributions emerge in their wake. We stress that aside from specific cases (see Füredi and Komlós, 1981; Tao and Vu, 2012; Lei, 2016), limiting distributions for eigenvalues and eigenvectors of random graphs are notably elusive. For the adjacency and Laplacian spectral embedding, we discuss not only consistency, but also asymptotic normality, robustness, and the use of the adjacency spectral embedding in the nascent field of multi-graph hypothesis testing. We illustrate how our techniques can be meaningfully applied to thorny and very sizable real data, improving on previously state-of-the-art methods for inference tasks such as community detection and classification in networks. What is more, as we now show, spectral graph embeddings are relevant to many complex and seemingly disparate aspects of graph inference.

A bird's-eye view of our methodology might well start with the stochastic blockmodel. For an SBM with a finite number of blocks of stochastically equivalent vertices, in Sussman et al. (2012) and Fishkind et al. (2013), we establish that k-means clustering of the rows of the adjacency spectral embedding accurately partitions the vertices into the correct blocks, even when the embedding dimension is misspecified or the number of blocks is unknown. Furthermore, in Lyzinski et al. (2014) and Lyzinski et al. (2017) we give a significant improvement in the misclassification rate, by exhibiting an almost-surely perfect clustering in which, in the limit, no vertices whatsoever are misclassified. For random dot product graphs more generally, we show in Sussman et al. (2014) that the latent positions are consistently estimated by the embedding, which then allows for accurate learning in a supervised vertex classification framework. In Tang et al. (2013), these results are extended to more general latent position models, establishing a powerful universal consistency result for vertex classification in general latent position graphs, and also exhibiting an efficient embedding of vertices which were not observed in the original graph. In Athreya et al. (2016) and Tang and Priebe (2018), we supply distributional results, akin to a central limit theorem, for both the adjacency and Laplacian spectral embedding, respectively; the former leads to a nontrivially superior algorithm for the estimation of block memberships in a stochastic block model (Suwan et al., 2016), and the latter resolves, through an elegant

comparison of Chernoff information, a long-standing open question of the relative merits of the adjacency and Laplacian graph representations.

Morever, graph embedding plays a central role in the foundational work on hypothesis testing of Tang et al. (2017a) and Tang et al. (2017b) for two-sample graph comparison: these papers provide theoretically justified, valid and consistent hypothesis tests for the semiparamatric problem of determining whether two random dot product graphs have the same latent positions and the nonparametric problem of determining whether two random dot product graphs have the same underlying distributions. This, then, yields a systematic framework for determining statistical similarity across graphs, which in turn underpins yet another provably consistent algorithm for the decomposition of random graphs with a hierarchical structure Lyzinski et al. (2017). In Levin et al. (2017), distributional results are given for an omnibus embedding of multiple random dot product graphs on the same vertex set, and this embedding performs well both for latent position estimation and for multi-sample graph testing. For the critical inference task of vertex nomination, in which the inference goal is to produce an ordering of vertices of interest (see, for instance Coppersmith, 2014), we find in Fishkind et al. (2015a) an array of principled vertex nomination algorithms —-the canonical, maximum likelihood and spectral vertex nomination schemes—and a demonstration of the algorithms' effectiveness on both synthetic and real data. In Lyzinski et al. (2016b) the consistency of the maximum likelihood vertex nomination scheme is established, a scalable restricted version of the algorithm is introduced, and the algorithms are adapted to incorporate general vertex features.

Overall, we stress that these principled techniques for random dot product graphs exploit the Euclidean nature of graph embeddings but are general enough to yield meaningful results for a wide variety of random graphs. Because our focus is, in part, on spectral methods, and because the adjacency matrix $\mathbf{A}$ of an independent-edge graph can be regarded as a noisy version of the matrix of probabilities $\mathbf{P}$ (Oliveira, 2009), we rely on several classical results on matrix perturbations, most prominently the Davis-Kahan Theorem (see Bhatia (1997) for the theorem itself, Rohe et al. (2011) for an illustration of its role in graph inference, and Yu et al. (2015) for a very useful variant). We also depend on the aforementioned spectral bounds in Oliveira (2009) and a more recent sharpening due to Lu and Peng (Lu and Peng, 2013). We leverage probabilistic concentration inequalities, such as those of Hoeffding and Bernstein (Tropp, 2015). Finally, several of our results do require suitable eigengaps for $\mathbf{P}$ and lower bounds on graph density, as measured by the maximum degree and the size of the smallest eigenvalue of $\mathbf{P}$. It is important to point out that in our analysis, we assume that the embedding dimension d of our graphs is known and fixed. In real data applications, such an embedding dimension is not known, and in Section 6.3, we discuss approaches (see Chatterjee, 2015; Zhu and Ghodsi, 2006) to estimating the embedding dimension. Robustness of our procedures to errors in embedding dimension is a problem of current investigation.

In the study of stochastic blockmodels, there has been a recent push to understand the fundamental information-theoretic limits for community detection and graph partitioning (see Mossel et al., 2018, 2014; Abbe and Sandon, 2015; Abbe et al., 2016). These bounds are typically algorithm-free and focus on stochastic blockmodels with constant or logarithmic

average degree, in which differences between vertices in different blocks are assumed to be at the boundary of detectability. Our efforts have a somewhat different flavor, in that we seek to understand the precise behavior of a widely applicable procedure in a more general model. Additionally, we treat sparsity as a secondary concern, and typically do not broach the question of the exact limits of our procedures. Our spectral methods may not be optimal for all random graph models, of course (Krzakala et al., 2013; Kawamoto and Kabashima, 2015), but they are very useful, in that they rely on well-optimized computational methods, can be implemented quickly in many standard languages, extend readily to other models, and serve as a foundation for more complex analyses.

Finally, we would be remiss not to point out that while spectral decompositions and clusterings of the adjacency matrix are appropriate for graph inference, they are also of considerable import in combinatorial graph theory: readers may recall, for instance, the combinatorial *ratio-cut* problem, whose objective is to partition the vertex set of a graph into two disjoint sets in a way that minimizes the number of edges between vertices in the two sets. The minimizer of a relaxation to the ratio-cut problem (Fiedler, 1973) is the eigenvector associated to the second smallest eigenvalue of the graph Laplacian $\mathbf{L}$. While we do not pursue more specific combinatorial applications of spectral methods here, we note that Chung (1997) provides a comprehensive overview, and von Luxburg (2007) gives an accessible tutorial on spectral methods.

We organize the paper as follows. In Section 2, we define random dot product graphs and the adjacency spectral embedding, and we recall important linear algebraic background. In Section 4, we discuss consistency, asymptotic normality, and hypothesis testing, as well as inference for hierarchical models. In Section 6, we discuss applications of these results to real data. Finally, in Section 7 we discuss current theoretical and computational difficulties and open questions, including issues of optimal embedding dimension, model limitations, robustness to errorful observations, and joint graph inference. Finally, in A, we provide further details in the proofs of our main results.

2. Definitions, notation, and background

2.1 Preliminaries and notation

We begin by establishing notation. For a positive integer n, we let $[n] = \{1, 2, \cdots, n\}$. For a vector $\mathbf{v} \in \mathbb{R}^n$, we let $\|\mathbf{v}\|$ denote the Euclidean norm of $\mathbf{v}$. We denote the identity matrix, zero matrix, and the square matrix of all ones by, $\mathbf{I}$, $\mathbf{0}$, and $\mathbf{J}$, respectively. We use $\otimes$ to denote the Kronecker product. For an $n_1 \times n_2$ matrix $\mathbf{H}$, we let $\mathbf{H}_{ij}$ denote its i, jth entry; we denote by $\mathbf{H}_{\cdot j}$ the column vector formed by the j-th column of $\mathbf{H}$; and we denote by $\mathbf{H}_{i\cdot}$ the row vector formed by the i-th row of $\mathbf{H}$. For a slight abuse of notation, we also let $\mathbf{H}_i \in \mathbb{R}^{n_2}$ denote the *column* vector formed by transposing the i-th row of $\mathbf{H}$. That is, $\mathbf{H}_i = (\mathbf{H}_{i\cdot})^\top$. Given any suitably specified ordering on eigenvalues of a square matrix $\mathbf{H}$, we let $\lambda_i(\mathbf{H})$ denote the i-th eigenvalue (under such an ordering) of $\mathbf{H}$ and $\sigma_i(\mathbf{H}) = \sqrt{\lambda_i(\mathbf{H}^\top\mathbf{H})}$ the i-th singular value of $\mathbf{H}$. We let $\|\mathbf{H}\|$ denote the spectral norm of $\mathbf{H}$ and $\|\mathbf{H}\|_F$ denote the Frobenius norm of $\mathbf{H}$. We let $\|\mathbf{H}\|_{2\to\infty}$ denote the maximum of the Euclidean norms of

the rows of $\mathbf{H}$, so that $\|\mathbf{H}\|_{2\to\infty} = \max_i \|\mathbf{H}_i\|$. We denote the trace of a matrix $\mathbf{H}$ by $\mathrm{tr}(\mathbf{H})$. For an $n \times n$ symmetric matrix $\mathbf{H}$ whose entries are all non-negative, we will frequently have to account for terms related to matrix sparsity, and we define $\delta(\mathbf{H})$ and $\gamma(\mathbf{H})$ as follows:

$$\delta(\mathbf{H}) = \max_{1\le i\le n} \sum_{j=1}^{n} \mathbf{H}_{ij} \qquad \gamma(\mathbf{H}) = \frac{\sigma_d(\mathbf{H}) - \sigma_{d+1}(\mathbf{H})}{\delta(\mathbf{H})} \tag{1}$$

(We remark that when H is a matrix of connection probabilities for a random graph, δ can be interpreted as the maximum expected degree, and γ relates this quantity to an eigengap that is especially useful in the case of probability matrices of suitably low rank.) In a number of cases, we need to consider a sequence of matrices. We will denote such a sequence by $\mathbf{H}_n$, where n is typically used to denote the index of the sequence. The distinction between a particular element $\mathbf{H}_n$ in a sequence of matrices and a particular row $\mathbf{H}_i$ of a matrix will be clear from context, and our convention is typically to use n to denote the index of a sequence and i or h to denote a particular row of a matrix. In the case where we need to consider the ith row of a matrix that is itself the nth element of a sequence, we will use the notation $(\mathbf{H}_n)_i$.

We define a *graph* G to be an ordered pair of (V, E) where V is the so-called *vertex* or *node* set, and E, the set of *edges*, is a subset of the Cartesian product of $V \times V$. In a graph whose vertex set has cardinality n, we will usually represent V as $V = \{1, 2, \cdots, n\}$, and we say there *is an edge between* i and j if $(i, j) \in E$. The *adjacency* matrix $\mathbf{A}$ provides a compact representation of such a graph:

$$\mathbf{A}_{ij} = 1 \text{ if } (i, j) \in E, \text{ and } \mathbf{A}_{ij} = 0 \text{ otherwise.}$$

Where there is no danger of confusion, we will often refer to a graph G and its adjacency matrix $\mathbf{A}$ interchangeably.

Our focus is random graphs, and thus we will let Ω denote our sample space, $\mathcal{F}$ the σ-algebra of subsets of Ω and $\mathbb{P}$ our probability measure $\mathbb{P} : \mathcal{F} \to [0, 1]$. We will denote the expectation of a (potentially multi-dimensional) random variable X with respect to this measure by $\mathbb{E}$. Given an event $F \in \mathcal{F}$, we denote its complement by F^c, and we let $\Pr(F)$ denote the probability of F. As we will see, in many cases we can choose Ω to be subset of Euclidean space. Because we are interested in large-graph inference, we will frequently need to demonstrate that probabilities of certain events decay at specified rates. This motivates the following definition.

Definition 1 (Convergence a.a.s. and w.h.p.) *Given a sequence of events $\{F_n\} \in \mathcal{F}$, where $n = 1, 2, \cdots$, we say that F_n occurs* asymptotically almost surely *(a.a.s.) if $\Pr(F_n) \to 1$ as $n \to \infty$. We say that F_n* occurs with high probability *(w.h.p.), and write F_n w.h.p. , if for any $c_0 > 1$, there exists finite positive constant C_0 depending on c_0 such that $\Pr[F_n^c] \le C_0 n^{-c_0}$ for all n. We note that F_n occurring w.h.p. is stronger than F_n occurring asymptotically almost surely. Morever, F_n occurring with high probability implies, by the Borel-Cantelli Lemma Chung (2001), that with probability 1 there exists an n_0 such that F_n holds for all $n \ge n_0$.*

Moreover, since our goal is often to understand large-graph inference, we need to consider asymptotics as a function of graph size n. As such, we recall familiar asymptotic notation:

Definition 2 (Asymptotic notation) *If $w(n)$ is a quantity depending on n, we will say that w* is of order $\alpha(n)$ *and use the notation $w(n) \sim \Theta(\alpha(n))$ to denote that there exist positive constants c, C such that for n sufficiently large,*

$$c\alpha(n) \le w(n) \le C\alpha(n).$$

When the quantity $w(n)$ is clear and $w(n) \sim \Theta(\alpha(n))$, we sometimes simply write "w is of order $\alpha(n)$". We write $w(n) \sim O(n)$ if there exists a constant C such that for n sufficiently large, $w(n) \le Cn$. We write $w(n) \sim o(n)$ if $w(n)/n \to 0$ as $n \to \infty$, and $w(n) \sim o(1)$ if $w(n) \to 0$ as $n \to \infty$. We write $w(n) \sim \Omega(n)$ if there exists a constant C such that for all n sufficiently large, $w(n) \ge Cn$.

Throughout, we will use $C > 0$ to denote a constant, not depending on n, which may vary from one line to another.

2.2 Models

Since our focus is on d-dimensional random dot product graphs, we first define an *an inner product distribution* as a probability distribution over a suitable subset of $\mathbb{R}^d$, as follows:

Definition 3 (d-dimensional inner product distribution) *Let F be a probability distribution whose support is given by $\operatorname{supp} F = \mathcal{X}_d \subset \mathbb{R}^d$. We say that F is a* d-dimensional inner product distribution *on $\mathbb{R}^d$ if for all $\mathbf{x}, \mathbf{y} \in \mathcal{X}_d = \operatorname{supp} F$, we have $\mathbf{x}^\top \mathbf{y} \in [0, 1]$.*

Next, we define a random dot product graph as an independent-edge random graph for which the edge probabilities are given by the dot products of the latent positions associated to the vertices. We restrict our attention here to graphs that are undirected and in which no vertex has an edge to itself.

Definition 4 (RDPG with distribution F) *Let F be a d-dimensional inner product distribution with $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n \overset{i.i.d.}{\sim} F$, collected in the rows of the matrix*

$$\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n]^\top \in \mathbb{R}^{n\times d}.$$

Suppose $\mathbf{A}$ is a random adjacency matrix given by

$$\Pr[\mathbf{A}|\mathbf{X}] = \prod_{i<j} (\mathbf{X}_i^\top \mathbf{X}_j)^{\mathbf{A}_{ij}} (1 - \mathbf{X}_i^\top \mathbf{X}_j)^{1-\mathbf{A}_{ij}} \tag{2}$$

We then write $(\mathbf{A}, \mathbf{X}) \sim \mathrm{RDPG}(F, n)$ and say that $\mathbf{A}$ is the adjacency matrix of a random dot product graph (RDPG) of dimension or rank at most d *and with* latent positions *given by the rows of $\mathbf{X}$. If $\mathbf{X}\mathbf{X}^\top$ is, in fact, a rank d matrix, we say $\mathbf{A}$ is the adjacency matrix of a rank d random dot product graph.*

Next, for such random dot product graphs, we frequently need to consider the $d \times d$ *second moment matrix* Δ, defined as follows:

Definition 5 (Second moment matrix) *Suppose A is an adjacency matrix from the random dot product graph model with distribution F. Let $X_1 \sim F$ be one of the i.i.d vectors of latent positions. Define the* second moment matrix Δ *via the expectation*

$$\Delta = E[\mathbf{X}_1 \mathbf{X}_1^\top]$$

While our notation for a random dot product graph with distribution F is $(\mathbf{A}, \mathbf{X}) \sim \text{RDPG}(F)$, we emphasize that in this paper the latent positions $\mathbf{X}$ are always assumed to be unobserved. An almost identical definition holds for random dot product graphs with fixed but unobserved latent positions:

Definition 6 (RDPG with fixed latent positions) *In the definition 4 given above, the latent positions are themselves random. If, instead, the latent positions are given by a fixed matrix $\mathbf{X}$ and, given this matrix, the graph is generated according to Eq.(2), we say that $\mathbf{A}$ is a realization of a random dot product graph with latent positions $\mathbf{X}$, and we write $\mathbf{A} \sim \text{RDPG}(\mathbf{X})$.*

Remark 7 (Nonidentifiability) *Given a graph distributed as an RDPG, the natural task is to recover the latent positions $\mathbf{X}$ that gave rise to the observed graph. However, the RDPG model has an inherent nonidentifiability: let $\mathbf{X} \in \mathbb{R}^{n \times d}$ be a matrix of latent positions and let $\mathbf{W} \in \mathbb{R}^{d \times d}$ be a unitary matrix. Since $\mathbf{X}\mathbf{X}^\top = (\mathbf{X}\mathbf{W})(\mathbf{X}\mathbf{W})^\top$, it is clear that the latent positions $\mathbf{X}$ and $\mathbf{X}\mathbf{W}$ give rise to the same distribution over graphs in Equation (2). Note that most latent position models, as defined below, also suffer from similar types of non-identifiability as edge-probabilities may be invariant to various transformations.*

As we mentioned, the random dot product graph is a specific instance of the more general *latent position random graph* with *link* or *kernel* function κ. Indeed, the latent positions themselves need not belong to Euclidean space per se, and the link function need not be an inner product.

Definition 8 (Latent position random graph with kernel κ) *Let $\mathcal{X}$ be a set and $\kappa : \mathcal{X} \times \mathcal{X} \to [0,1]$ a symmetric function. Suppose to each $i \in [n]$ there is associated a point $\mathbf{X}_i \in \mathcal{X}$. Given $\mathbf{X} = \{\mathbf{X}_1, \cdots, \mathbf{X}_n\}$ consider the graph with adjacency matrix $\mathbf{A}$ defined by*

$$\Pr[\mathbf{A}|\mathbf{X}] = \prod_{i<j} \kappa(\mathbf{X}_i, \mathbf{X}_j)^{\mathbf{A}_{ij}} (1 - \kappa(\mathbf{X}_i, \mathbf{X}_j))^{1-\mathbf{A}_{ij}} \tag{3}$$

Then $\mathbf{A}$ is the adjacency matrix of a latent position random graph with latent position $\mathbf{X}$ and link function κ.

Similarly, we can define independent edge graphs for which latent positions need not play a role.

Definition 9 (Independent-edge graphs) *For a matrix symmetric matrix $\mathbf{P}$ of probabilities, we say that $\mathbf{A}$ is distributed as an independent edge graph with probabilities $\mathbf{P}$ if*

$$\Pr[\mathbf{A}|\mathbf{X}] = \prod_{i<j} \mathbf{P}_{ij}^{\mathbf{A}_{ij}} (1 - \mathbf{P}_{ij})^{1-\mathbf{A}_{ij}} \tag{4}$$

By their very structure, latent position random graphs, for fixed latent positions, are independent-edge random graphs. In general, for any latent position graph the matrix of edge probabilities $\mathbf{P}$ is given by $\mathbf{P}_{ij} = \kappa(\mathbf{X}_i, \mathbf{X}_j)$ Of course, in the case of an random dot product graph with latent position matrix $\mathbf{X}$, the probability $\mathbf{P}_{ij}$ of observing an edge between vertex i and vertex j is simply $\mathbf{X}_i^\top \mathbf{X}_j$. Thus, for an RDPG with latent positions $\mathbf{X}$, the matrix $\mathbf{P} = [p_{ij}]$ is given by $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$.

In order to more carefully relate latent position models and RDPGs, we can consider the set of positive semidefinite latent position graphs. Namely, we will say that a latent position random graph is positive semidefinite if the matrix $\mathbf{P}$ is positive semidefinite. In this case, we note that an RDPG can be used to approximate the latent position random graph distribution. (In fact, as we describe further below, new work of Rubin-Delanchy, Tang, and Priebe (Rubin-Delanchy et al., 2017) presents a generalization of the RDPG which allows us to drop the positive semidefiniteness requirement.) The best rank-d approximation of $\mathbf{P}$, in terms of the Frobenius norm (Eckart and Young, 1936), will correspond to a RDPG with d-dimensional latent positions. In this sense, by allowing d to be as large as necessary, any positive semi-definite latent position random graph distribution can be approximated by a RDPG distribution to arbitrary precision (Tang et al., 2013).

While latent position models generalize the random dot product graph, RDPGs can be easily related to the more limited *stochastic blockmodel* (SBM) graph (Holland et al., 1983). The stochastic block model is also an independent-edge random graph whose vertex set is partitioned into K groups, called *blocks*, and the stochastic blockmodel is typically parameterized by (1) a $K \times K$ matrix of probabilities $\mathbf{B}$ of adjacencies between vertices in each of the blocks, and (2) a *block-assignment vector* $\tau : [n] \to [K]$ which assigns each vertex to its block. That is, for any two vertices i, j, the probability of their connection is

$$\mathbf{P}_{ij} = \mathbf{B}_{\tau(i),\tau(j)},$$

and we typically write $\mathbf{A} \sim \text{SBM}(\mathbf{B}, \tau)$. Here we present an alternative definition in terms of the RDPG model.

Definition 10 (Positive semidefinite k-block SBM) *We say an RDPG with latent positions $\mathbf{X}$ is an SBM with K blocks if the number of distinct rows in $\mathbf{X}$ is K, denoted $\mathbf{X}_{(1)}, \cdots, \mathbf{X}_{(K)}$ In this case, we define the block membership function $\tau : [n] \mapsto [K]$ to be a function such that $\tau(i) = \tau(j)$ if and only if $\mathbf{X}_i = \mathbf{X}_j$. We then write*

$$\mathbf{A} \sim \text{SBM}(\tau, \{\mathbf{X}_{(i)}\}_{i=1}^K)$$

In addition, we also consider the case of a stochastic block model in which the block memberships of each vertex is randomly assigned. More precisely, let $\pi \in (0,1)^K$ with $\sum_{k=1}^n \pi_k = 1$ and suppose that $\tau(1), \tau(2), \ldots, \tau(n)$ are now i.i.d. random variables with distribution Categorical(π)*; that is,* $\Pr(\tau(i) = k) = \pi_k$ *for all k. Then we say $\mathbf{A}$ is an* SBM with i.i.d block memberships*, and we write*

$$\mathbf{A} \sim \text{SBM}(\pi, \{X_{(i)}\}).$$

We also consider the *degree-corrected* stochastic block model (Karrer and Newman, 2011):

Definition 11 (Degree Corrected SBM) *We say an RDPG is a degree-corrected stochastic block model (DCSBM) with K blocks if there exist K unit vectors $y_1, \ldots, y_K \in \mathbb{R}^d$ such that for each $i \in [n]$, there exists $k \in [K]$ and $c_i \in (0,1)$ such that $X_i = c_i y_k$.*

Remark 12 *The degree-corrected stochastic blockmodel model is inherently more flexible than the standard SBM because it allows for vertices within each block/community to have different expected degrees. This flexibility has made it a popular choice for modeling network data (again, see Karrer and Newman, 2011).*

For an important generalization that offers more flexibility in block memberships, we consider the *mixed-membership stochastic block model* (MMSBM) of Airoldi et al. (2008):

Definition 13 (Mixed Membership SBM) *We say an RDPG is a mixed membership stochastic block model (MMSBM) with K blocks if there exists K unit vectors $y_1, \dots, y_K \in \mathbb{R}^d$ such that for each $i \in [n]$, there exists $\alpha_1, \dots, \alpha_K > 0$ such that $\sum_{k=1}^K \alpha_k = 1$ and $X_i = \sum_{k=1}^K \alpha_k y_k$.*

Remark 14 *The mixed membership SBM allows for each vertex to be in a mixture of different blocks. Additionally, note that every RDPG is a MMSBM for some choice of K.*

Our next theorem summarizes the relationship between these models.

Theorem 15 *Considered as statistical models for graphs—to wit, sets of probability distributions on graphs—the positive-semidefinite K-block SBM is a subset of the K-block DCSBM and the K-block MMSBM. Both the positive semidefinite K-block DCSBM and K-block MMSBM are subsets of the RDPG model with K-dimensional latent positions. Finally, the union of all possible RDPG models, without restriction of latent position dimension, is dense in the set of positive semidefinite latent position models.*

We emphasize that, as mentioned previously, very recent work of Rubin-Delanchy, Priebe, and Tang (Rubin-Delanchy et al., 2017) on the *generalized random dot product graph* (gRDPG) extends the essential construction of the random dot product graph to encompass non-positive-semidefinite stochastic block models and mixed membership block models, and the gRDPG possesses an elegant uniqueness property that permits the representation of mixed membership as a convex combination of extreme points in a simplex. So, while we impose some restrictions on positive-definiteness here, these are primarily for ease of exposition. Our methodology is general enough to encompass networks that exhibit both homophily and heterophily (see, for example, Hoff, 2007). Moreoever, when considering normalized latent positions for random dot product graphs, our requirement of positive definiteness is, in effect, a degree-corrected "affinity." Also, as we show in Section 6.3, our techniques have proven empirically appropriate in the analysis of certain directed graphs, wherein we consider right- and left-singular vectors in a singular value decomposition of the adjacency matrix.

2.3 Embeddings

Since we rely on spectral decompositions, we begin with describing the notations for the spectral decomposition of the rank d positive semidefinite matrix $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$.

Definition 16 (Spectral Decomp. of P) *Since $\mathbf{P}$ is symmetric and positive semidefinite, let $\mathbf{P} = \mathbf{U_P}\mathbf{S_P}\mathbf{U_P}^\top$ denote its spectral decomposition, with $\mathbf{U_P} \in \mathbb{R}^{n\times d}$ having orthonormal columns and $\mathbf{S_P} \in \mathbb{R}^{d\times d}$ a diagonal matrix with nonincreasing entries*

$$(\mathbf{S_P})_{1,1} \geq (\mathbf{S_P})_{2,2} \geq \cdots \geq (\mathbf{S_P})_{d,d} > 0.$$

As with the spectral decomposition of the matrix $\mathbf{P}$, given an adjancency matrix $\mathbf{A}$, we define its adjacency spectral embedding as follows;

Definition 17 (Adjacency spectral embedding (ASE)) *Given a positive integer $d \geq 1$, the* adjacency spectral embedding *(ASE) of $\mathbf{A}$ into $\mathbb{R}^d$ is given by $\hat{\mathbf{X}} = \mathbf{U_A}\mathbf{S_A}^{1/2}$ where*

$$|\mathbf{A}| = [\mathbf{U_A}|\mathbf{U_A^\perp}][\mathbf{S_A} \bigoplus \mathbf{S_A^\perp}][\mathbf{U_A}|\mathbf{U_A^\perp}]^\top$$

is the spectral decomposition of $|\mathbf{A}| = (\mathbf{A^T A})^{1/2}$ and $\mathbf{S_A}$ is the diagonal matrix of the d largest eigenvalues of $|\mathbf{A}|$ and $\mathbf{U_A}$ is the $n \times d$ matrix whose columns are the corresponding eigenvectors.

The intuition behind the notion of adjacency spectral embedding is as follows. Our goal is to estimate the latent position matrix $\mathbf{X}$. Now, if the matrix $\mathbf{P}$ were actually observable, then the spectral embedding of $\mathbf{P}$, given by $\mathbf{U_P}\mathbf{S_P}^{1/2}$, is simply some orthogonal transformation of $\mathbf{X}$. Of course, $\mathbf{P}$ is typically not observable; instead we observe $\mathbf{A}$, a noisy version of $\mathbf{P}$. The ASE will be a good estimate of $\mathbf{X}$ provided that the noise does not greatly impact the embedding—that is, if $\mathbf{A}$ and $\mathbf{P}$ are suitably close. As we will see shortly, one can show that $\|\mathbf{A} - \mathbf{X}\mathbf{X}^\top\| = O(\|\mathbf{X}\|) = o(\|\mathbf{X}\mathbf{X}^\top\|)$ with high probability (Oliveira, 2009; Lu and Peng, 2013; Tropp, 2015; Lei and Rinaldo, 2015). That is to say, $\mathbf{A}$ can be viewed as a comparatively small perturbation of $\mathbf{X}\mathbf{X}^\top$. Weyl's inequality or the Kato-Temple inequality (Cape et al., 2017a; Kato, 1950) guarantee that the eigenvalues of $\mathbf{A}$ are "close" to the eigenvalues of $\mathbf{X}\mathbf{X}^\top$. In addition, by the Davis-Kahan theorem (Davis and Kahan, 1970), the subspace spanned by the top d eigenvectors of $\mathbf{X}\mathbf{X}^\top$ is well-approximated by the subspace spanned by the top d eigenvectors of $\mathbf{A}$.

Having defined the adjacency spectral embedding, we next define the analogous Laplacian spectral embedding, which uses the spectral decomposition of the normalized Laplacian matrix.

Definition 18 (Laplacian Spectral Embedding (LSE)) *Let $\mathcal{L}(\mathbf{A}) = \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$ denote the normalized Laplacian of $\mathbf{A}$ where $\mathbf{D}$ is the diagonal matrix whose diagonal entries $\mathbf{D}_{ii} = \sum_{j\neq i} \mathbf{A}_{ij}$. Given a positive integer $d \geq 1$, the* Laplacian spectral embedding *(LSE) of $\mathbf{A}$ into $\mathbb{R}^d$ is given by $\check{\mathbf{X}} = \mathbf{U}_{\mathcal{L}(\mathbf{A})}\tilde{\mathbf{S}}_{\mathbf{A}}^{1/2}$ where*

$$|\mathcal{L}(\mathbf{A})| = \left[\mathbf{U}_{\mathcal{L}(\mathbf{A})}|\mathbf{U}^\perp_{\mathcal{L}(\mathbf{A})}\right]\left[\mathbf{S}_{\mathcal{L}(\mathbf{A})} \bigoplus \mathbf{S}^\perp_{\mathcal{L}(\mathbf{A})}\right]\left[\mathbf{U}_{\mathcal{L}(\mathbf{A})}|\mathbf{U}^\perp_{\mathcal{L}(\mathbf{A})}\right]^\top$$

is the spectral decomposition of $|\mathcal{L}(\mathbf{A})| = (\mathcal{L}(\mathbf{A})^\top\mathcal{L}(\mathbf{A}))^{1/2}$ and $\mathbf{S}_{\mathcal{L}(\mathbf{A})}$ is the diagonal matrix containg the d largest eigenvalues of $|\mathcal{L}(\mathbf{A})|$ on the diagonal and $\mathbf{U}_{\mathcal{L}(\mathbf{A})}$ is the $n \times d$ matrix whose columns are the corresponding eigenvectors.

Finally, there are a variety other matrices for which spectral decompositions may be applied to yield an embedding of the graph (Le et al., 2017). These are often dubbed as "regularized" embeddings, and many such embeddings are constructed with the aim of improving robustness of spectral decompositions to graph sparsity. While we do not analyze these embeddings directly, a number of our approaches can be adapted to these other embeddings.

3. Core proof techniques: probabilistic and linear algebraic bounds

In this section, we give an overview of the core background results used in our proofs. While we defer to the appendix the proofs of our primary results on consistency and normality for spectral graph estimates, we provide key background here to allow the reader a consolidated, accessible guide to the essential linear algebraic foundations of our approach. The key tools to several of our results on consistency and normality of the adjacency spectral embedding depend on a triumvirate of matrix concentration inequalities, the Davis-Kahan Theorem, and detailed bounds via the power method.

3.1 Concentration inequalities

Concentration inequalities for real- and matrix-valued data are a critical component to our proofs of consistency for spectral estimates. We make use of classical inequalities, such as Hoeffding's inequality, for real-valued random variables, and we also exploit more recent work on the concentration of sums of random matrices and matrix martingales around their expectation. For a careful study of several important matrix concentration inequalities, see Tropp (2015).

We begin by recalling Hoeffding's inequality, which bounds the deviations between a sample mean of independent random variables and the expected value of that sample mean.

Theorem 19 *Let X_i, $1 \leq i \leq n$, be independent, bounded random variables defined on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Suppose a_i, b_i are real numbers such that $a_i \leq X_i \leq b_i$. Let $\bar{X}$ be their sample mean:*

$$\bar{X} = \frac{1}{n}\sum_{i=1}^{n} X_i$$

Then

$$\Pr\left(\bar{X} - \mathbb{E}(\bar{X}) \geq t\right) \leq \exp\left(\frac{[-2n^2t^2]}{\sum_{i=1}^{n}(b_i - a_i)^2}\right) \tag{5}$$

and

$$\Pr\left(|\bar{X} - \mathbb{E}(\bar{X})| \geq t\right) \leq 2\exp\left(\frac{[-2n^2t^2]}{\sum_{i=1}^{n}(b_i - a_i)^2}\right) \tag{6}$$

For an undirected, hollow RDPG with probability matrix $\mathbf{P}$, $\mathbb{E}(\mathbf{A}_{ij}) = \mathbf{P}_{ij}$ for all $i \neq j$. As such, one can regard $\mathbf{A}$ as a "noisy" version of $\mathbf{P}$. It is tempting to believe that $\mathbf{A}$ and $\mathbf{P}$ are close in terms of the Frobenius norm, but this is sadly not true; indeed, it is easy to see that

$$\|\mathbf{A} - \mathbf{P}\|_F^2 = \Theta(\|\mathbf{P}\|_F^2)$$

To overcome this using only Hoeffding's inequality, we can instead consider the difference $(\mathbf{A}^2 - \mathbf{P}^2)_{ij}$, which is a sum of independent random variables. Hence, Hoeffding's inequality implies that

$$|(\mathbf{A}^2 - \mathbf{P}^2)_{ij}|^2 = o(|\mathbf{P}^2{}_{ij}|^2)$$

Since the eigenvectors of $\mathbf{A}$ and $\mathbf{A}^2$ coincide, this is itself sufficient to show concentration of the adjacency spectral embedding (Sussman et al., 2012; Rohe et al., 2011). However,

somewhat stronger and more elegant results can be shown by considering the spectral norm instead. In particular, a nontrivial body of recent work on matrix concentration implies that, under certain assumptions on the sparsity of $\mathbf{P}$, the spectral norm of $\mathbf{A} - \mathbf{P}$ can be well-controlled. We focus on the following important results of Oliveira (2009) and Tropp (2015) and further improvements of Lu and Peng (2013) and Lei and Rinaldo (2015), all of which establish that the $\mathbf{A}$ and $\mathbf{P}$ are close in spectral norm.

Theorem 20 (Spectral norm control of $\mathbf{A} - \mathbf{P}$) *Suppose Let $\mathbf{A}$ be the adjacency matrix of an independent-edge random graph on $[n]$ with matrix of edge probabilities $\mathbf{P}$. For any constant c, there exists another constant C, independent of n and $\mathbf{P}$, such that if $\delta(\mathbf{P}) > C \ln n$, then for any $n^{-c} < \eta < 1/2$,*

$$\Pr\left(\|\mathbf{A} - \mathbf{P}\| \leq 4\sqrt{\delta(P)\ln(n/\eta)}\right) \geq 1 - \eta. \tag{7}$$

In Lu and Peng (2013), the authors give an improvement under slightly stronger density assumptions[1]:

Theorem 21 (Refined spectral norm control of $\mathbf{A} - \mathbf{P}$) *With notation as above, suppose there exist positive constants such that for n sufficiently large, $\delta(\mathbf{P}) > (\log n)^{4+a}$. Then for any $c > 0$ there exists a constant C depending on c such that*

$$\mathbb{P}\left(\|\mathbf{A} - \mathbf{P}\| \leq 2\sqrt{\delta(\mathbf{P})} + C\delta^{1/4}(\mathbf{P})\ln n\right) \geq 1 - n^{-c}. \tag{8}$$

3.2 Matrix perturbations and spectral decompositions

The above results formalize our intuition that $\mathbf{A}$ provides a "reasonable" estimate for $\mathbf{P}$. Moreover, in the RDPG case, where $\mathbf{P}$ is of low rank and is necessarily positive semidefinite, these results have implications about the nonnegativity of the eigenvalues of $\mathbf{A}$. Specifically, we use Weyl's Theorem to infer bounds on the differences between the eigenvalues of $\mathbf{A}$ and $\mathbf{P}$ from the spectral norm of their difference, and the Gerschgorin Disks Theorem to infer lower bounds on the maximum row sums of $\mathbf{P}$ from assumptions on the eigengap of $\mathbf{P}$ (since both $\mathbf{P}$ and $\mathbf{A}$ are nonnegative matrices, one could also obtain the same lower bounds by invoking the Perron-Frobenius Theorem). For completeness, we recall the Gerschgorin Disks Theorem and Weyl's Theorem (these can be found, for example, in Horn and Johnson, 1985). The former relates the eigenvalues of a matrix to the sums of the absolute values of the entries in each row, and the latter establishes bounds on the differences in eigenvalues between a matrix and a perturbation.

Theorem 22 (Gerschgorin Disks) *Let $\mathbf{H}$ be a complex $n \times n$ matrix, with entries $\mathbf{H}_{ij}$. For $i \in \{1, \cdots, n\}$ let $R_i = \sum_{j \neq i} |\mathbf{H}_{ij}|$. Let the ith Gerschgorin disk $D(\mathbf{H}_{ii}, R_i)$ be the closed disk centered at $\mathbf{H}_{ii}$ with radius R_i. Then every eigenvalue of $\mathbf{H}$ lies within at least one of the Gershgorin discs $D(\mathbf{H}_{ii}, R_i)$.*

1. A similar bound is provided in Lei and Rinaldo (2015), but with $\delta(\mathbf{P})$ defined as $\delta(\mathbf{P}) = n\max_{ij}\mathbf{P}_{ij}$ and a density assumption of the form $(n\max_{ij}\mathbf{P}_{ij}) > (\log n)^{1+a}$.

Theorem 23 (Weyl) *Let $\mathbf{M}, \mathbf{H}$, and $\mathbf{R}$ be $n \times n$ Hermitian matrices, and suppose $\mathbf{M} = \mathbf{H} + \mathbf{R}$. Suppose $\mathbf{H}$ and $\mathbf{R}$ have eigenvalues $\nu_1 \geq \cdots \geq \nu_n$ and $r_1 \geq \cdots \geq r_n$, respectively. Suppose the eigenvalues of $\mathbf{M}$ are given by $\mu_1 \geq \cdots \geq \mu_n$. Then*

$$\nu_i + r_n \leq \mu_i \leq \nu_i + r_1$$

From our random graph model assumptions and our graph density assumptions, we can conclude that with for sufficiently large n, the top d eigenvalues of $\mathbf{A}$ will be nonnegative:

Remark 24 (Nonnegativity of the top d eigenvalues of A) *Suppose $\mathbf{A} \sim \mathrm{RDPG}(\mathbf{X})$. Since $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$, it is necessarily positive semidefinite, and thus has nonnegative eigenvalues. If we now assume that $\gamma(\mathbf{P}) > c_0$ for some constant c_0, then along with the Gershgorin Disks Theorem, guarantee that the top d eigenvalues of $\mathbf{P}$ are all of order $\delta(\mathbf{P})$, and our rank assumption on $\mathbf{P}$ mandates that the remaining eigenvalues be zero. If $\delta(\mathbf{P}) > \log^{4+a'} n$, the spectral norm bound in (8) applies, ensuring that for n sufficiently large, $\|A - P\|_2 \sim O(\sqrt{\delta(\mathbf{P})})$ with high probability. Thus, by Weyl's inequality, we see that the top d eigenvalues of $\mathbf{A}$ are, with high probability, of order δ, and the remaining are, with high probability, within $\sqrt{\delta}$ of zero.*

Since $\mathbf{P} = \mathbf{X}\mathbf{X}^\top = \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}(\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2})^\top$ and $\mathbf{A}$ is close to $\mathbf{P}$, it is intuitively appealing to conjecture that, in fact, $\hat{\mathbf{X}} = \mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2}$ should be close to some rotation of $\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}$. That is, if $\mathbf{X}$ is the matrix of true latent positions—-so $\mathbf{X}\mathbf{W} = \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}$ for some orthogonal matrix $\mathbf{W}$—then it is plausible that $\|\hat{\mathbf{X}} - \mathbf{X}\mathbf{W}\|_F$ ought to be comparatively small. To make this precise, however, we need to understand how both eigenvalues and eigenvectors of a matrix behave when the matrix is perturbed. Weyl's inequality addresses the former. The impact of matrix perturbations on associated eigenspaces is significantly more complicated, and the Davis-Kahan Theorem (Davis and Kahan, 1970; Bhatia, 1997) provides one approach to the latter. The Davis-Kahan has a significant role in several approaches to spectral estimation for graphs: for example, Rohe, Chatterjee, and Yu leverage it in Rohe et al. (2011) to prove the accuracy of spectral estimates (specifically, the graph Laplacian) in high-dimensional stochastic blockmodels. The version we give below is from Yu et al. (2015), which is a user-friendly guide to the the Davis-Kahan Theorem and its statistical implications.

The Davis-Kahan Theorem is often stated as a result on canonical angles between subspaces. To that end, we recall that if $\mathbf{U}$ and $\mathbf{V}$ are two $n \times d$ matrices with orthonormal columns, then we define the vector of d *canonical* or *principal* angles between their column spaces to be the vector Θ such that

$$\Theta = (\theta_1 = \cos^{-1}\sigma_1, \cdots, \theta_d = \cos^{-1}\sigma_d)^\top$$

where $\sigma_1, \cdots, \sigma_d$ are the singular values of $\mathbf{U}^\top\mathbf{V}$. We define the matrix $\sin(\Theta)$ to be the $d \times d$ diagonal matrix for which $\sin(\theta)_{ii} = \sin\theta_i$.

Theorem 25 (A variant of Davis-Kahan) *Suppose $\mathbf{H}$ and $\mathbf{H}'$ are two symmetric $n \times n$ matrices with real entries with spectrum given by $\lambda_1 \geq \lambda_2 \cdots \geq \lambda_n$ and $\lambda_1' \geq \lambda_2' \cdots \geq \lambda_n'$, respectively; and let $\mathbf{v}_1, \cdots, \mathbf{v}_n$ and $\mathbf{v}_1', \cdots, \mathbf{v}_n'$ denote their corresponding orthonormal eigenvectors.*

Let $0 < d \leq n$ be fixed, and let $\mathbf{V}$ be the matrix of whose columns are the eigenvectors $v_1, \cdots, v_d$, and similarly $\mathbf{V}'$ the matrix whose columns are the eigenvectors $\mathbf{v}_1', \cdots \mathbf{v}_n'$. Then

$$\|\sin(\Theta)\|_F \leq \frac{2\sqrt{d}\|\mathbf{V} - \mathbf{V}'\|}{\lambda_d(\mathbf{H}) - \lambda_{d+1}(\mathbf{H})}.$$

Observe that if we assume that $\mathbf{P}$ is of rank d and has a sufficient eigengap, the Davis-Kahan Theorem gives us an immediate bound on the spectral norm of the difference between $\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^\top$ and $\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top$ in terms of this eigengap and the spectral norm difference of $\mathbf{A} - \mathbf{P}$, namely:

$$\|\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^\top - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\| = \max_i \|\sin(\theta_i)\| \leq \frac{C\|\mathbf{A} - \mathbf{P}\|}{\lambda_d(\mathbf{P})}.$$

Recall that the Frobenius norm of a matrix $\mathbf{H}$ satisfies

$$(\|\mathbf{H}\|_F)^2 = \sum_{i,j} \mathbf{H}_{ij}^2 = \mathrm{tr}(\mathbf{H}^\top\mathbf{H}) \geq \|\mathbf{H}\|^2$$

and further that if $\mathbf{H}$ is of rank d, then

$$(\|\mathbf{H}\|_F)^2 \leq d\|\mathbf{H}\|^2$$

and hence for rank d matrices, spectral norm bounds are easily translated into bounds on the Frobenius norm. It is worth noting that Rohe et al. (2011) guarantees that a difference in projections can be transformed into a difference between eigenvectors themselves: namely, given the above bound for $\|\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^\top - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\|_F$, there is a constant C and an orthonormal matrix $W \in \mathbb{R}^{d \times d}$ such that

$$\|\mathbf{U}_\mathbf{P}\mathbf{W} - \mathbf{U}_\mathbf{A}\|_F \leq C\sqrt{d}\frac{\|\mathbf{A} - \mathbf{P}\|}{\lambda_d(\mathbf{P})}. \tag{9}$$

While these important results provide the backbone for much of our theory, the detailed bounds and distributional results described in the next section rely on a decomposition of $\hat{\mathbf{X}}$ in terms of $(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}$ and a remainder. This first term can be viewed as an application of the power method for finding eigenvectors. Additionally, standard univariate and multivariate concentration inequalities and distributional results can be readily applied to this term. On the other hand, the remainder term can be shown to be of smaller order than the first, and much of the technical challenges of this work rely on carefully bounding the remainder term.

4. Spectral embeddings and estimation for RDPGs

There is a wealth of literature on spectral methods for estimating model parameters in random graphs, dating back more than half a century to estimation in simple Erdős-Rényi models. More specifically, for Erdős-Rényi graphs, we would be remiss not to point to Furedi and Komlos's classic work (Füredi and Komlós, 1981) on the eigenvalues and eigenvectors

of the adjacency matrix of an ER graph. Again, despite their model simplicity, Erdős-Rényi graphs veritably teem with open questions; to cite but one example, in a very recent manuscript, Arias-Castro and Verzhelen (Arias-Castro and Verzelen, 2014) address, in the framework of hypothesis testing, the question of subgraph detection within an ER graph.

Moving up to the slightly more heterogeneous stochastic block model, we again find a rich literature on consistent block estimation in stochastic block models. Fortunato (Fortunato, 2010) provides an overview of partitioning techniques for graphs in general, and consistent partitioning of stochastic block models for two blocks was accomplished by Snijders and Nowicki (Snijders and K.Nowicki, 1997) and for equal-sized blocks by Condon and Karp in 2001. For the more general case, Bickel and Chen (Bickel and Chen, 2009) demonstrate a stronger version of consistency via maximizing Newman-Girvan modularity (Newman, 2006) and other modularities. For a growing number of blocks, Choi et al. (Bickel et al., 2013) prove consistency of likelihood based methods, and Bickel et al. (Bickel et al., 2011) provide a method to consistently estimate the stochastic block model parameters using subgraph counts and degree distributions. This work and the work of Bickel and Chen (Bickel and Chen, 2009) both consider the case of very sparse graphs. In Airoldi et al. (2008), Airoldi et al. define the important generalization of a *mixed-membership* stochastic blockmodel, in which block membership may change depending on vertex-to-vertex interactions, and the authors demonstrate methods of inference for the mixed membership and block probabilities.

Rohe, Chatterjee and Yu show in Rohe et al. (2011) that spectral embeddings of the Laplacian give consistent estimates of block memberships in a stochastic block model, and they also demonstrate how to deploy spectral approaches to estimate block memberships even in strongly heterophilic block models. One of the earliest corresponding results on the consistency of the adjacency spectral embedding the estimation of block memberships is given by Sussman and coauthors in Sussman et al. (2012), where it is proved that for a stochastic block model with K blocks and a rank d block probability matrix B, clustering the rows of the adjacency spectral embedding via k-means clustering (see Pollard, 1981) results in at most $\log n$ vertices being misclassified. An improvement to this can be found in Fishkind et al. (2013), where consistency recovery is possible even if the rank of the embedding dimension is unknown.

In Lyzinski et al. (2014), under the assumption of distinct eigenvalues for the second moment matrix Δ (recall we defined this in 5) of a random dot product graph, it is shown that clustering the rows of the adjacency spectral embedding results in asymptotically almost surely perfect recovery of the block memberships in a stochastic blockmodel—that is, for sufficiently large n, the probability of all vertices being correctly assigned is close to 1. An especially strong recovery is exhibited here: it is shown that in the $2 \to \infty$ norm, $\hat{\mathbf{X}}$ is sufficiently close to a rotation of the the true latent positions. In fact, each *row* in $\hat{\mathbf{X}}$ is within $C \log n/\sqrt{n}$ of the corresponding row in $\mathbf{X}$. Unlike a Frobenius norm bound, in which it is possible that some rows of $\hat{\mathbf{X}}$ may be close to the true positions but others may be significantly farther away, this $2 \to \infty$ bound implies that the adjacency spectral embedding has a *uniform* consistency.

Furthermore, in Tang et al. (2017a), one finds a nontrivial tightening of the Frobenius norm bound for the difference between the (rotated) true and estimated latent positions: in fact the Frobenius norm is not merely bounded from above by a term of order $\log n$, but rather concentrates around a *constant*. This constant-order Frobenius bound forms the basis of a principled two-sample hypothesis test for determining whether two random dot product graphs have the same generating latent positions (see Section 5.2).

In Lyzinski et al. (2017), the $2 \to \infty$-norm bound is extended even to the case when the second moment matrix Δ does not have distinct eigenvalues. This turns out to be critical in guaranteeing that the adjacency spectral embedding can be effectively deployed for community detection in hierarchical block models. We present this bound for the $2 \to \infty$ norm in some detail here; it illustrates the confluence of our key techniques and provides an effective roadmap for several subsequent results on asymptotic normality and two-sample testing.

4.1 Consistency of latent position estimates

We state here one of our lynchpin results on consistency, in the $2 \to \infty$ norm, of the adjacency spectral embedding for latent position estimation of a random dot product graph. We given an outline of the proof here, and refer the reader to the Appendix A for the details, which essentially follow the proof given in Lyzinski et al. (2017). We emphasize our setting is a sequence of random dot product graphs $\mathbf{A}_n \sim \text{RDPG}(\mathbf{X}_n)$ for increasing n and thus we make the following density assumption on $\mathbf{P}_n$ as n increases:

Assumption 1 *Let $\mathbf{A}_n \sim \text{RDPG}(\mathbf{X}_n)$ for $n \geq 1$ be a sequence of random dot product graphs with $\mathbf{A}_n$ being a $n \times n$ adjacency matrix. Suppose that $\mathbf{X}_n$ is of rank d for all n sufficiently large. Suppose also that there exists constants $a > 0$ and $c_0 > 0$ such that for all n sufficiently large,*

$$\delta(\mathbf{P}_n) = \max_i \sum_{j=1}^{n} (\mathbf{P}_n)_{ij} \geq \log^{4+a}(n); \quad \gamma(\mathbf{P}_n) = \frac{\lambda_d(\mathbf{P}_n)}{\delta(\mathbf{P}_n)} \geq c_0.$$

We remark that this assumption is, in essence, a restriction on graph sparsity, and not a particular onerous one; d-dimensional random dot product graphs with i.i.d latent positions that are not "too" degenerate will meet these requirements, and bounds on δ of the polylogarithmic order given above are quite common (see Oliveira, 2009; Lu and Peng, 2013).

Our consistency result for the $2 \to \infty$ norm is Theorem 26 below. In the proof of this particular result, we consider a particular random dot product graph with non-random (that is, fixed) latent positions, but our results apply also to the case of random latent positions. In Section 4.2, where we provide a central limit theorem, we focus on the case in which the latent positions are themselves random. Similarly, in Section 5.2, in our analysis of the semiparametric two-sample hypothesis test for the equality of latent positions in a pair of random dot product graphs, we return to the setting in which the latent positions are fixed, and in the nonparametric hypothesis test of equality of distributions, we analyze again the case when the latent positions are random. It is convenient to be able to move

fluidly between the two versions of a random dot product graph, adapting our results as appropriate in each case.

In the Appendix, we give a detailed proof of Theorem 26 and we point out the argument used therein also sets the stage for the central limit theorem for the rows of the adjacency spectral embedding given in Subsection 4.2.

Theorem 26 *Let $\mathbf{A}_n \sim \text{RDPG}(\mathbf{X}_n)$ for $n \geq 1$ be a sequence of random dot product graphs where the $\mathbf{X}_n$ is assumed to be of rank d for all n sufficiently large. Denote by $\hat{\mathbf{X}}_n$ the adjacency spectral embedding of $\mathbf{A}_n$ and let $(\hat{\mathbf{X}}_n)_i$ and $(\mathbf{X}_n)_i$ be the i-th row of $\hat{\mathbf{X}}_n$ and $\mathbf{X}_n$, respectively. Let E_n be the event that there exists an orthogonal transformation $\mathbf{W}_n \in \mathbb{R}^{d\times d}$ such that*

$$\max_i \|(\hat{\mathbf{X}}_n)_i - \mathbf{W}_n(\mathbf{X}_n)_i\| \leq \frac{Cd^{1/2}\log^2 n}{\delta^{1/2}(\mathbf{P}_n)}$$

where $C > 0$ is some fixed constant and $\mathbf{P}_n = \mathbf{X}_n\mathbf{X}_n^\top$. Then E_n occurs asymptotically almost surely; that is, $\Pr(E_n) \to 1$ as $n \to \infty$.

Under the stochastic blockmodel, previous bounds on $\|\mathbf{X} - \hat{\mathbf{X}}\|_F$ implied that k-means applied to the rows of $\hat{\mathbf{X}}$ would approximately correctly partition the vertices into their the true blocks with up to $O(\log n)$ errors. However, this Frobenius norm bound does not preclude the possibility of large outliers in the individual rows of $\mathbf{X} - \hat{\mathbf{X}}$. The improvements provided by Theorem 26 overcome this hurdle and, as shown in Lyzinski et al. (2014), under suitable sparsity and eigengap assumptions, k-means applied to $\hat{\mathbf{X}}$ will *exactly correctly* partition the vertices into their true blocks. This implication demonstrates the importance of improving the overall bounds and in focusing on the correct metrics for a given task—in this case, for instance, block identification.

While we defer the proof of this result to the Appendix, in A.1, we provide a brief outline and note several key ingredients here. First is a lemma guaranteeing the existence of an orthogonal matrix $\mathbf{W}^*$ such that

$$\|\mathbf{W}^*\mathbf{S}_\mathbf{A} - \mathbf{S}_\mathbf{P}\mathbf{W}^*\|_F = O((\log n)\delta^{1/2}(P)$$

That is, there is an approximate commutativity between right and left multiplication of the corresponding matrices of eigenvalues by this orthogonal transformation. The second essential component is, at heart, a bound inspired by the power method. Specifically, we show that there exists an orthogonal matrix

$$\|\hat{\mathbf{X}} - \mathbf{X}\mathbf{W}\| = \|(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\|_F + O((\log n)\delta^{-1/2})$$

Finally, from this point, establishing the bound on the $2 \to \infty$ norm is a consequence of Hoeffding's inequality applied to sums of the form

$$\sum_k (\mathbf{A}_{ik} - \mathbf{P}_{ik}\mathbf{U}_{kj})$$

.

The $2 \to \infty$ bound in Theorem 26 has several important implications. As we mentioned, the results in Lyzinski et al. (2014) establish an earlier form of this bound, with more

restrictive assumptions on the the second moment matrix, and illustrate how this can be used to cluster vertices in an SBM perfectly; that is, with no vertices misclassified. In addition, in Lyzinski et al. (2014), we show that clustering the rows of the ASE can be useful for inference in a degree-corrected stochastic block model as well. In Section 6, we see that because of Theorem 26, the adjacency spectral embedding and a novel angle-based clustering procedure can be used for accurately identifying subcommunities in an affinity-structured, hierarchical stochastic blockmodel (Lyzinski et al., 2017). In the next section, we see how our proof technique here can be used to obtain distributional results for the rows of the adjacency spectral embedding.

4.2 Distributional results for the ASE

In the classical statistical task of parametric estimation, one observes a collection of i.i.d observations $X_1, \cdots, X_n$ from some family of distributions $F_\theta : \theta \in \Theta$, where Θ is some subset of Euclidean space, and one seeks to find a consistent estimator $T(X_1, \cdots, X_n)$ for θ. As we mentioned in Section 1, often a next task is to determine the asymptotic distribution, as $n \to \infty$, of a suitable normalization of this estimator T. Such distributional results, in turn, can be useful for generating confidence intervals and testing hypotheses.

We adopt a similar framework for random graph inference. In the previous section, we demonstrate the consistency of the adjacency spectral embedding for the true latent position of a random dot product graph. In this section, we establish the asymptotic normality of the rows of this embedding and the Laplacian spectral embedding. In the subsequent section, we examine how our methodology can be deployed for multisample graph hypothesis testing.

We emphasize that distributional results for spectral decompositions of random graphs are comparatively few. The classic results of Füredi and Komlós (Füredi and Komlós, 1981) describe the eigenvalues of the Erdős-Rényi random graph and the work of Tao and Vu (Tao and Vu, 2012) is focused on distributions of eigenvectors of more general random matrices under moment restrictions, but Athreya et al. (2016) and Tang and Priebe (2018) are among the only references for central limit theorems for spectral decompositions of adjacency and Laplacian matrices for a wider class of independent-edge random graphs than merely the Erdős-Rényi model. Apart from their inherent interest, these limit theorems point us to current open questions on efficient estimation and the relative merits of different estimators and embeddings, in part by rendering possible a comparison of asymptotic variances and allowing us to quantify relative efficiency (see Tang et al. (2016) and to precisely conjecture a decomposition of the sources of variance in different spectral embeddings for multiple graphs (see Levin et al., 2017).

Specifically, we show that for a d-dimensional random dot product graph with i.i.d latent positions, there exists a sequence of $d \times d$ orthogonal matrices $\mathbf{W}_n$ such that for any row index i, $\sqrt{n}(\mathbf{W}_n(\hat{\mathbf{X}}_n)_i - (\mathbf{X}_n)_i)$ converges as $n \to \infty$ to a mixture of multivariate normals.

Theorem 27 (Central Limit Theorem for rows of ASE) *Let $(\mathbf{A}_n, \mathbf{X}_n) \sim \text{RDPG}(F)$ be a sequence of adjacency matrices and associated latent positions of a d-dimensional random dot product graph according to an inner product distribution F. Let $\Phi(\mathbf{x}, \mathbf{\Sigma})$ denote*

the cdf of a (multivariate) Gaussian with mean zero and covariance matrix $\mathbf{\Sigma}$*, evaluated at* $\mathbf{x} \in \mathbb{R}^d$*. Then there exists a sequence of orthogonal* d*-by-*d *matrices* $(\mathbf{W}_n)_{n=1}^{\infty}$ *such that for all* $\boldsymbol{z} \in \mathbb{R}^d$ *and for any fixed index* i*,*

$$\lim_{n\to\infty} \Pr\left[n^{1/2}\left(\hat{\mathbf{X}}_n\mathbf{W}_n - \mathbf{X}_n\right)_i \le \boldsymbol{z}\right] = \int_{\operatorname{supp} F} \Phi\left(\boldsymbol{z}, \mathbf{\Sigma}(\mathbf{x})\right) dF(\mathbf{x}),$$

where

$$\mathbf{\Sigma}(\mathbf{x}) = \Delta^{-1}\mathbb{E}\left[(\mathbf{x}^\top\mathbf{X}_1 - (\mathbf{x}^\top\mathbf{X}_1)^2)\mathbf{X}_1\mathbf{X}_1^\top\right]\Delta^{-1}; \quad \textit{and } \Delta = \mathbb{E}[\mathbf{X}_1\mathbf{X}_1^\top]. \tag{10}$$

We also note the following important corollary of Theorem 27 for when F is a mixture of K point masses; that is, $(\mathbf{X}, \mathbf{A}) \sim \text{RDPG}(F)$ is a K-block stochastic blockmodel graph. Then for any fixed index i, the event that $\mathbf{X}_i$ is assigned to block $k \in \{1, 2, \ldots, K\}$ has non-zero probability and hence one can condition on the block assignment of $\mathbf{X}_i$ to show that the conditional distribution of $\sqrt{n}(\mathbf{W}_n(\hat{\mathbf{X}}_n)_i - (\mathbf{X}_n)_i)$ converges to a multivariate normal. This is in contrast to the unconditional distribution being a mixture of multivariate normals as given in Theorem 27.

Corollary 28 (SBM) *Assume the setting and notations of Theorem 27 and let*

$$F = \sum_{k=1}^{K} \pi_k \delta_{\nu_k}, \quad \pi_1, \cdots, \pi_K > 0, \sum_k \pi_k = 1$$

be a mixture of K *point masses in* $\mathbb{R}^d$ *where* δ_{ν_k} *is the Dirac delta measure at* ν_k*. Then there exists a sequence of orthogonal matrices* $\mathbf{W}_n$ *such that for all* $\boldsymbol{z} \in \mathbb{R}^d$ *and for any fixed index* i*,*

$$\mathbb{P}\left\{\sqrt{n}(\mathbf{W}_n\hat{\mathbf{X}}_n - \mathbf{X}_n)_i \le \boldsymbol{z} \mid \mathbf{X}_i = \nu_k\right\} \longrightarrow \Phi(\boldsymbol{z}, \Sigma_k) \tag{11}$$

where $\Sigma_k = \Sigma(\nu_k)$ *is as defined in Eq.* (52)*.*

We relegate the full details of the proof of this central limit theorem to the Appendix, in Section A.2, but a few points bear noting here. First, both Theorem 27 and Corollary 28 are very similar to results proved in Athreya et al. (2016), but with the crucial difference being that we no longer require that the second moment matrix $\Delta = \mathbb{E}[\mathbf{X}_1\mathbf{X}_1^\top]$ of $\boldsymbol{X}_1 \sim F$ have distinct eigenvalues (for more details, see Tang and Priebe (2018)). As in Athreya et al. (2016), our proof here depends on writing the difference between a row of the adjacency spectral embedding and its corresponding latent position as a pair of summands: the first, to which a classical Central Limit Theorem can be applied, and the second, essentially a combination of residual terms, which we show, using techniques similar to those in the proof of Theorem 26, converges to zero. The weakening of the assumption of distinct eigenvalues necessitates significant changes from Athreya et al. (2016) in how to bound the residual terms, because the arguments in Athreya et al. (2016) require an adaptation of a result of Bickel and Sarkar (2015)—the latter of which depends on the assumption of distinct eigenvalues—to control these terms. Here, we resort to somewhat different methodology: we prove instead that analogous bounds to those in Lyzinski et al. (2017) and in Tang and Priebe (2018) hold for the estimated latent positions. This enables us to establish that here, too, the rows of the adjacency spectral embedding are also approximately normally distributed.

We stress that this central limit theorem depends on a delicate bounding of a sequence of so-called residual terms, but its essence is straightforward. Specifically, there exists an orthogonal transformation $\mathbf{W}^*$ such that we can write the ith row of the matrix

$$\sqrt{n}(\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^*)$$

as

$$\sqrt{n}(\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^*)_i = \sqrt{n}(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*)_i + \text{Residual terms} \tag{12}$$

where the residual terms are all of order $O(n^{-1/2}\log n)$ in probability. Now, to handle the first term in Eq.(12), we can condition on a fixed latent position $\mathbf{X}_i = \mathbf{x}_i$, and when this is fixed, the classical Lindeberg-Feller Central Limit Theorem establishes the asymptotic normality of this term. The order of the residual terms then guarantees, by Slutsky's Theorem, the desired asymptotic normality of the gap between estimated and true latent positions, and finally we need only integrate over the possible latent positions to obtain a mixture of normals.

4.3 An example under the stochastic block model

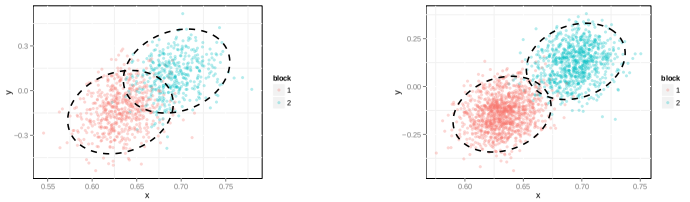
To illustrate Theorem 27, we refer the reader to Athreya et al. (2016), from which we reproduce the following simulation. Consider random graphs generated according to a stochastic block model with parameters

$$B = \begin{bmatrix} 0.42 & 0.42 \\ 0.42 & 0.5 \end{bmatrix} \quad \text{and} \quad \pi = (0.6, 0.4). \tag{13}$$

In this model, each node is either in block 1 (with probability 0.6) or block 2 (with probability 0.4). Adjacency probabilities are determined by the entries in B based on the block memberships of the incident vertices. The above stochastic blockmodel corresponds to a random dot product graph model in $\mathbb{R}^2$ where the distribution F of the latent positions is a mixture of point masses located at $x_1 \approx (0.63, -0.14)$ (with probability 0.6) and $x_2 \approx (0.69, 0.13)$ (with probability 0.4).

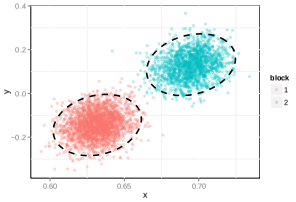
We sample an adjacency matrix $\mathbf{A}$ for graphs on n vertices from the above model for various choices of n. For each graph G, let $\hat{\mathbf{X}} \in \mathbb{R}^{n\times 2}$ denote the embedding of A and let $\hat{\mathbf{X}}_{i\cdot}$ denote the ith row of $\hat{\mathbf{X}}$. In Figure 1, we plot the n rows of $\hat{\mathbf{X}}$ for the various choices of n. The points are denoted by symbols according to the block membership of the corresponding vertex in the stochastic blockmodel. The ellipses show the 95% level curves for the distribution of $\hat{X}_i$ for each block as specified by the limiting distribution.

We estimate the covariance matrices for the residuals. The theoretical covariance matrices are given in the last column of Table 1, where Σ_1 and Σ_2 are the covariance matrices for the residual $\sqrt{n}(\hat{\mathbf{X}}_i - \mathbf{X}_i)$ when X_i is from the first block and second block, respectively. The empirical covariance matrices, denoted $\hat{\Sigma}_1$ and $\hat{\Sigma}_2$, are computed by evaluating the sample covariance of the rows of $\sqrt{n}\hat{\mathbf{X}}_i$ corresponding to vertices in block 1 and 2 respectively. The estimates of the covariance matrices are given in Table 1. We see that as n increases, the sample covariances tend toward the specified limiting covariance matrix given in the last column.

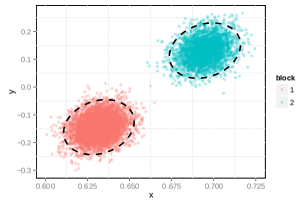


(a) $n = 1000$

(b) $n = 2000$



(c) $n = 4000$



(d) $n = 8000$

Figure 1: Plot of the estimated latent positions in a two-block stochastic blockmodel graph on n vertices. The points are denoted by symbols according to the block membership of the corresponding vertices. Dashed ellipses give the 95% level curves for the distributions as specified in Theorem 27. Figure duplicated from Athreya et al. (2016).

n	2000	4000	8000	16000	∞
$\hat{\Sigma}_1$	$\begin{bmatrix} .58 & .54 \\ .54 & 16.56 \end{bmatrix}$	$\begin{bmatrix} .58 & .63 \\ .63 & 14.87 \end{bmatrix}$	$\begin{bmatrix} .60 & .61 \\ .61 & 14.20 \end{bmatrix}$	$\begin{bmatrix} .59 & .58 \\ .58 & 13.96 \end{bmatrix}$	$\begin{bmatrix} .59 & .55 \\ .55 & 13.07 \end{bmatrix}$
$\hat{\Sigma}_2$	$\begin{bmatrix} .58 & .75 \\ .75 & 16.28 \end{bmatrix}$	$\begin{bmatrix} .59 & .71 \\ .71 & 15.79 \end{bmatrix}$	$\begin{bmatrix} .58 & .54 \\ .54 & 14.23 \end{bmatrix}$	$\begin{bmatrix} .61 & .69 \\ .69 & 13.92 \end{bmatrix}$	$\begin{bmatrix} .60 & .59 \\ .59 & 13.26 \end{bmatrix}$

Table 1: The sample covariance matrices for $\sqrt{n}(\hat{X}_i - X_i)$ for each block in a stochastic blockmodel with two blocks. Here $n \in \{2000, 4000, 8000, 16000\}$. In the last column are the theoretical covariance matrices for the limiting distribution. Table reproduced from Athreya et al. (2016).

We also investigate the effects of the multivariate normal distribution as specified in Theorem 27 on inference procedures. It is shown in Sussman et al. (2012, 2014) that the approach of embedding a graph into some Euclidean space, followed by inference (for example, clustering or classification) in that space can be consistent. However, these consistency results are, in a sense, only first-order results. In particular, they demonstrate only that the error of the inference procedure converges to 0 as the number of vertices in the graph increases. We now illustrate how Theorem 27 may lead to a more refined error analysis.

We construct a sequence of random graphs on n vertices, where n ranges from 1000 through 4000 in increments of 250, following the stochastic blockmodel with parameters as given above in Eq. (13). For each graph G_n on n vertices, we embed G_n and cluster the embedded vertices of G_n via Gaussian mixture model and K-means clustering. Gaussian mixture model-based clustering is done using the MCLUST implementation of (Fraley and Raftery, 1999). We then measure the classification error of the clustering solution. We repeat this procedure 100 times to obtain an estimate of the misclassification rate. The results are plotted in Figure 2. For comparison, we plot the Bayes optimal classification error rate under the assumption that the embedded points do indeed follow a multivariate normal mixture with covariance matrices Σ_1 and Σ_2 as given in the last column of Table 1. We also plot the misclassification rate of $(C \log n)/n$ as given in Sussman et al. (2012) where the constant C was chosen to match the misclassification rate of K-means clustering for $n = 1000$. For the number of vertices considered here, the upper bound for the constant C from Sussman et al. (2012) will give a vacuous upper bound of the order of 10^6 for the misclassification rate in this example. Finally, we recall that the $2 \to \infty$ norm bound of Theorem 26 implies that, for large enough n, even the k-means algorithm will exactly recover the true block memberships with high probability (Lyzinski et al., 2016a).

For yet another application of the central limit theorem, we refer the reader to Suwan et al. (2016), where the authors discuss the assumption of multivariate normality for estimated latent positions and how this can lead to a significantly improved empirical-Bayes framework for the estimation of block memberships in a stochastic blockmodel.

4.4 Distributional results for Laplacian spectral embedding

We now present the analogous central limit theorem results of Section 4.2 for the normalized *Laplacian spectral embedding* (see Definition 18). We first recall the definition of the Laplacian spectral embedding.

Theorem 29 (Central Limit Theorem for rows of LSE) *Let* $(\mathbf{A}_n, \mathbf{X}_n) \sim \text{RDPG}(F)$ *for* $n \geq 1$ *be a sequence of* d*-dimensional random dot product graphs distributed according to some inner product distribution* F*. Let* $\boldsymbol{\mu}$ *and* $\tilde{\Delta}$ *denote the quantities*

$$\boldsymbol{\mu} = \mathbb{E}[\mathbf{X}_1] \in \mathbb{R}^d; \quad \tilde{\Delta} = \mathbb{E}\Big[\frac{\mathbf{X}_1\mathbf{X}_1^\top}{\mathbf{X}_1^\top\boldsymbol{\mu}}\Big] \in \mathbb{R}^{d\times d}. \tag{14}$$

Also denote by $\tilde{\Sigma}(\mathbf{x})$ *the* $d \times d$ *matrix*

$$\mathbb{E}\Big[\Big(\frac{\tilde{\Delta}^{-1}\mathbf{X}_1}{\mathbf{X}_1^\top\boldsymbol{\mu}} - \frac{\mathbf{x}}{2\mathbf{x}^\top\boldsymbol{\mu}}\Big)\Big(\frac{\mathbf{X}_1^\top\tilde{\Delta}^{-1}}{\mathbf{X}_1^\top\boldsymbol{\mu}} - \frac{\mathbf{x}^\top}{2\mathbf{x}^\top\boldsymbol{\mu}}\Big)\frac{(\mathbf{x}^\top\mathbf{X}_1 - \mathbf{x}^\top\mathbf{X}_1\mathbf{X}_1^\top\mathbf{x})}{\mathbf{x}^\top\boldsymbol{\mu}}\Big]. \tag{15}$$

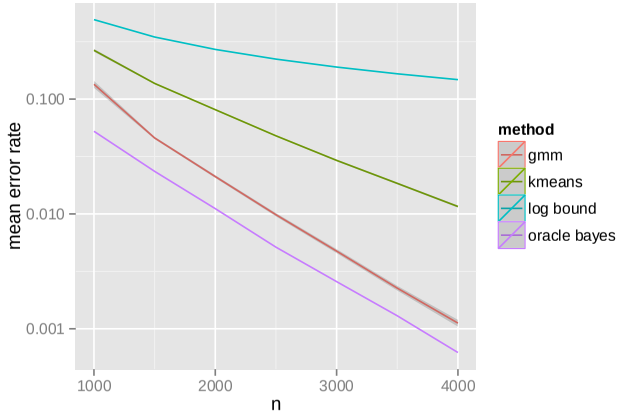


Figure 2: Comparison of classification error for Gaussian mixture model (red curve), K-Means (green curve), and Bayes classifier (cyan curve). The classification errors for each $n \in \{1000, 1250, 1500, \ldots, 4000\}$ were obtained by averaging 100 Monte Carlo iterations and are plotted on a $\log_{10}$ scale. The plot indicates that the assumption of a mixture of multivariate normals can yield non-negligible improvement in the accuracy of the inference procedure. The log-bound curve (purple) shows an upper bound on the error rate as derived in Sussman et al. (2012). Figure duplicated from Athreya et al. (2016).

Then there exists a sequence of $d \times d$ orthogonal matrices $(\mathbf{W}_n)$ such that for each fixed index i and any $\boldsymbol{x} \in \mathbb{R}^d$,

$$\Pr\Big\{n\big(\mathbf{W}_n(\breve{\mathbf{X}}_n)_i - \tfrac{(\mathbf{X}_n)_i}{\sqrt{\sum_j (\mathbf{X}_n)_i^\top (\mathbf{X}_n)_j}}\big) \le \boldsymbol{x}\Big\} \longrightarrow \int \Phi(\boldsymbol{x}, \tilde{\Sigma}(\boldsymbol{y}))dF(\boldsymbol{y}) \tag{16}$$

When F is a mixture of point masses—specifically, when $\mathbf{A} \sim \mathrm{RDPG}(F)$ is a stochastic blockmodel graph—we also have, below, the following limiting conditional distribution for

$$n\left(\mathbf{W}_n(\breve{\mathbf{X}}_n)_i - \frac{(\mathbf{X}_n)_i}{\sqrt{\sum_j (\mathbf{X}_n)_i^\top (\mathbf{X}_n)_j}}\right).$$

Theorem 30 *Assume the setting and notations of Theorem 29 and let*

$$F = \sum_{k=1}^{K} \pi_k \delta_{\nu_k}, \quad \pi_1, \cdots, \pi_K > 0, \sum_k \pi_k = 1$$

be a mixture of K point masses in $\mathbb{R}^d$. Then there exists a sequence of $d \times d$ orthogonal matrices $\mathbf{W}_n$ such that for any fixed index i,

$$\mathbb{P}\Big\{n\big(\mathbf{W}_n(\breve{\mathbf{X}}_n)_i - \tfrac{\nu_k}{\sqrt{\sum_l n_l \nu_k^\top \nu_l}}\big) \le \boldsymbol{z} \mid (\mathbf{X}_n)_i = \nu_k\Big\} \longrightarrow \boldsymbol{\Phi}(\boldsymbol{z}, \tilde{\Sigma}_k) \tag{17}$$

where $\tilde{\Sigma}_k = \tilde{\Sigma}(\nu_k)$ is as defined in Eq. (15) and n_k for $k \in \{1, 2, \ldots, K\}$ denote the number of vertices in $\mathbf{A}$ that are assigned to block k.

Remark 31 *As a special case of Theorem 30, we note that if $\mathbf{A}$ is an Erdős-Rényi graph on n vertices with edge probability p^2 – which corresponds to a random dot product graph where the latent positions are identically p – then for each fixed index i, the normalized Laplacian embedding satisfies*

$$n\big(\breve{\mathbf{X}}_i - \tfrac{1}{\sqrt{n}}\big) \xrightarrow{\mathrm{d}} \mathcal{N}\big(0, \tfrac{1-p^2}{4p^2}\big).$$

Recall that $\breve{\mathbf{X}}_i$ is proportional to $1/\sqrt{d_i}$ where d_i is the degree of the i-th vertex. On the other hand, the adjacency spectral embedding satisfies

$$\sqrt{n}(\hat{\mathbf{X}}_i - p) \xrightarrow{\mathrm{d}} \mathcal{N}(0, 1 - p^2).$$

As another example, let $\mathbf{A}$ be sampled from a stochastic blockmodel with block probability matrix $\mathbf{B} = \left[\begin{smallmatrix} p^2 & pq \\ pq & q^2 \end{smallmatrix}\right]$ and block assignment probabilities $(\pi, 1-\pi)$. Since $\mathbf{B}$ has rank 1, this model corresponds to a random dot product graph where the latent positions are either p with probability π or q with probability $1-\pi$. Then for each fixed index i, the normalized Laplacian embedding satisfies

$$n\big(\breve{\mathbf{X}}_i - \tfrac{p}{\sqrt{n_1 p^2 + n_2 pq}}\big) \xrightarrow{\mathrm{d}} \mathcal{N}\Big(0, \tfrac{\pi p(1-p^2) + (1-\pi)q(1-pq)}{4(\pi p + (1-\pi)q)^3}\Big) \text{ if } \mathbf{X}_i = p, \tag{18}$$

$$n\big(\breve{\mathbf{X}}_i - \tfrac{q}{\sqrt{n_1 pq + n_2 q^2}}\big) \xrightarrow{\mathrm{d}} \mathcal{N}\Big(0, \tfrac{\pi p(1-pq) + (1-\pi)q(1-q^2)}{4(\pi p + (1-\pi)q)^3}\Big) \text{ if } \mathbf{X}_i = q. \tag{19}$$

where n_1 and $n_2 = n - n_1$ are the number of vertices of $\mathbf{A}$ with latent positions p and q. The adjacency spectral embedding, meanwhile, satisfies

$$\sqrt{n}(\hat{\mathbf{X}}_i - p) \xrightarrow{\text{d}} \mathcal{N}\Big(0, \tfrac{\pi p^4(1-p^2)+(1-\pi)pq^3(1-pq)}{(\pi p^2+(1-\pi)q^2)^2}\Big) \text{ if } \mathbf{X}_i = p, \tag{20}$$

$$\sqrt{n}(\hat{\mathbf{X}}_i - q) \xrightarrow{\text{d}} \mathcal{N}\Big(0, \tfrac{\pi p^3q(1-pq)+(1-\pi)q^4(1-q^2)}{(\pi p^2+(1-\pi)q^2)^2}\Big) \text{ if } \mathbf{X}_i = q. \tag{21}$$

We present a sketch of the proof of Theorem 29 in the Appendix, in Section A.3. Due to the intricacy of the proof, however, even in the Appendix we do not provide full details; we instead refer the reader to Tang and Priebe (2018) for the complete proof. Moving forward, we focus on the important implications of these distributional results for subsequent inference, including a mechanism by which to assess the relative desirability of ASE and LSE, which *vary depending on inference task.*

5. Implications for subsequent inference

The previous sections are devoted to establishing the consistency and asymptotic normality of the adjacency and Laplacian spectral embeddings for the estimation of latent positions in an RDPG. In this section, we describe several subsequent graph inference tasks, all of which depend on this consistency: specifically, nonparametric clustering, semiparametric and nonparametric two-sample graph hypothesis testing, and multi-sample graph inference.

5.1 Nonparametric clustering: a comparison of ASE and LSE via Chernoff information

We now discuss how the limit results of Section 4.2 and Section 4.4 can provide insight into subsequent inference. In a recent pioneering work, the authors of Bickel and Sarkar (2015) analyze, in the context of stochastic blockmodel graphs, how the choice of spectral embedding by either the adjacency matrix or the normalized Laplacian matrix impacts subsequent recovery of the block assignments. In particular, they show that a metric constructed from the average distance between the vertices of a block and its cluster centroid for the spectral embedding can be used as a surrogate measure for the performance of the subsequent inference task: namely, the metric is a surrogate measure for the error rate in recovering the vertices to block assignments using the spectral embedding. It is shown in Bickel and Sarkar (2015) that for a large regime of parameters in a two-block stochastic block model, the normalized Laplacian spectral embedding reduces the within-block variance (occasionally by a factor of four) while preserving the between-block variance, as compared to that of the adjacency spectral embedding. This suggests that for a large region of the parameter space for two-block stochastic blockmodels, the spectral embedding of the Laplacian is preferable to the spectral embedding of the adjacency matrix for subsequent inference. However, we observe that the metric in Bickel and Sarkar (2015) is intrinsically tied to the use of K-means as the clustering procedure: specifically, a smaller value of the metric for the Laplacian spectral embedding as compared to that for the adjacency spectral embedding

only implies that clustering the Laplacian spectral embedding using K-means is possibly better than clustering the adjacency spectral embedding using K-means.

Motivated by the above observation, in Tang and Priebe (2018), we propose a metric that is *independent* of any specific clustering procedure, a metric that characterizes the minimum error achievable by *any* clustering procedure that uses only the spectral embedding for the recovery of block assignments in stochastic blockmodel graphs. For a given embedding method, the metric used in Tang and Priebe (2018) is based on the notion of statistical information between the limiting distributions of the blocks. Roughly speaking, smaller statistical information implies less information to discriminate between the blocks of the stochastic blockmodel. More specifically, the limit result in Section 4.2 and Section 4.4 state that, for stochastic blockmodel graphs, conditional on the block assignments the entries of the scaled eigenvectors corresponding to the few largest eigenvalues of the adjacency matrix and the normalized Laplacian matrix converge to a multivariate normal as the number of vertices increases. Furthermore, the associated covariance matrices are not spherical, so K-means clustering for the adjacency spectral embedding or Laplacian spectral embedding does not yield minimum error for recovering the block assignment. Nevertheless, these limiting results also facilitate comparison between the two embedding methods via the classical notion of Chernoff information (Chernoff, 1952).

We now recall the notion of the Chernoff α-divergences (for $\alpha \in (0,1)$) and Chernoff information. Let F_0 and F_1 be two absolutely continuous multivariate distributions in $\Omega = \mathbb{R}^d$ with density functions f_0 and f_1, respectively. Suppose that $Y_1, Y_2, \ldots, Y_m$ are independent and identically distributed random variables, with Y_i distributed either F_0 or F_1. We are interested in testing the simple null hypothesis $\mathbb{H}_0: F = F_0$ against the simple alternative hypothesis $\mathbb{H}_1: F = F_1$. A test T can be viewed as a sequence of mappings $T_m: \Omega^m \mapsto \{0,1\}$ such that given $Y_1 = y_1, Y_2 = y_2, \ldots, Y_m = y_m$, the test rejects $\mathbb{H}_0$ in favor of $\mathbb{H}_1$ if $T_m(y_1, y_2, \ldots, y_m) = 1$; similarly, the test favors $\mathbb{H}_0$ if $T_m(y_1, y_2, \ldots, y_m) = 0$.

The Neyman-Pearson lemma states that, given $Y_1 = y_1, Y_2 = y_2, \ldots, Y_m = y_m$ and a threshold $\eta_m \in \mathbb{R}$, the likelihood ratio test which rejects $\mathbb{H}_0$ in favor of $\mathbb{H}_1$ whenever

$$\Big(\sum_{i=1}^{m} \log f_0(y_i) - \sum_{i=1}^{m} \log f_1(y_i)\Big) \leq \eta_m$$

is the most powerful test at significance level $\alpha_m = \alpha(\eta_m)$, so that the likelihood ratio test minimizes the Type II error β_m subject to the constraint that the Type I error is at most α_m. Assuming that $\pi \in (0,1)$ is a prior probability that $\mathbb{H}_0$ is true. Then, for a given $\alpha_m^* \in (0,1)$, let $\beta_m^* = \beta_m^*(\alpha_m^*)$ be the Type II error associated with the likelihood ratio test when the Type I error is at most α_m^*. The quantity

$$\inf_{\alpha_m^* \in (0,1)} \pi\alpha_m^* + (1-\pi)\beta_m^*$$

is the Bayes risk in deciding between $\mathbb{H}_0$ and $\mathbb{H}_1$ given the m independent random variables $Y_1, Y_2, \ldots, Y_m$. A classical result of Chernoff (Chernoff, 1952, 1956) states that the Bayes risk is intrinsically linked to a quantity known as the *Chernoff information*. More specifically,

let $C(F_0, F_1)$ be the quantity

$$\begin{aligned} C(F_0, F_1) &= -\log\Big[\inf_{t\in(0,1)} \int_{\mathbb{R}^d} f_0^t(\boldsymbol{x}) f_1^{1-t}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}\Big] \\ &= \sup_{t\in(0,1)} \Big[-\log \int_{\mathbb{R}^d} f_0^t(\boldsymbol{x}) f_1^{1-t}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}\Big]. \end{aligned} \tag{22}$$

Then we have

$$\lim_{m\to\infty} \frac{1}{m} \inf_{\alpha_m^*\in(0,1)} \log(\pi\alpha_m^* + (1-\pi)\beta_m^*) = -C(F_0, F_1). \tag{23}$$

Thus $C(F_0, F_1)$, the Chernoff information between F_0 and F_1, is the *exponential* rate at which the Bayes error $\inf_{\alpha_m^*\in(0,1)} \pi\alpha_m^* + (1-\pi)\beta_m^*$ decreases as $m \to \infty$; we note that the Chernoff information is independent of π. We also define, for a given $t \in (0,1)$ the Chernoff divergence $C_t(F_0, F_1)$ between F_0 and F_1 by

$$C_t(F_0, F_1) = -\log \int_{\mathbb{R}^d} f_0^t(\boldsymbol{x}) f_1^{1-t}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}.$$

The Chernoff divergence is an example of a f-divergence as defined in, for example, the work of Csizár (1967) and Ali and Shelvey (1966). When $t = 1/2$, $C_t(F_0, F_1)$ is the Bhattacharyya distance between F_0 and F_1. Recall that any f-divergence satisfies the Information Processing Lemma and is invariant with respect to invertible transformations (Liese and Vadja, 2006). Therefore, any f-divergence such as the Kullback-Liebler divergence can also be used to compare the two embedding methods; the Chernoff information is particularly attractive because of its explicit relationship with the Bayes risk.

The characterization of Chernoff information in Eq. (23) can be extended to $K + 1 \geq 2$ hypotheses. Let $F_0, F_1, \ldots, F_K$ be distributions on $\mathbb{R}^d$ and suppose that $Y_1, Y_2, \ldots, Y_m$ are independent and identically distributed random variables with Y_i distributed $F \in \{F_0, F_1, \ldots, F_K\}$. We are thus interested in determining the distribution of the Y_i among the $K+1$ hypothesis $\mathbb{H}_0 : F = F_0, \ldots, \mathbb{H}_K : F = F_K$. Suppose also that hypothesis $\mathbb{H}_k$ has *a priori* probability π_k. Then for any decision rule δ, the risk of δ is $r(\delta) = \sum_k \pi_k \sum_{l\neq k} \alpha_{lk}(\delta)$ where $\alpha_{lk}(\delta)$ is the probability of accepting hypothesis $\mathbb{H}_l$ when hypothesis $\mathbb{H}_k$ is true. Then we have, from Leang and Johnson (1997),

$$\inf_{\delta} \lim_{m\to\infty} \frac{r(\delta)}{m} = -\min_{k\neq l} C(F_k, F_l). \tag{24}$$

where the infimum is over all decision rules δ. That is, for any δ, $r(\delta)$ decreases to 0 as $m \to \infty$ at a rate no faster than $\exp(-m \min_{k\neq l} C(F_k, F_l))$. It is also shown in Leang and Johnson (1997) that the *Maximum A Posterior* decision rule achieves this rate.

Finally, if $F_0 = \mathcal{N}(\mu_0, \Sigma_0)$ and $F_1 = \mathcal{N}(\mu_1, \Sigma_1)$, then denoting by $\Sigma_t = t\Sigma_0 + (1-t)\Sigma_1$, the Chernoff information $C(F_0, F_1)$ between F_0 and F_1 is given by

$$C(F_0, F_1) = \sup_{t\in(0,1)} \Big(\frac{t(1-t)}{2}(\mu_1 - \mu_2)^\top \Sigma_t^{-1}(\mu_1 - \mu_2) + \frac{1}{2}\log\frac{|\Sigma_t|}{|\Sigma_0|^t|\Sigma_1|^{1-t}}\Big).$$

Comparison of the performance of the Laplacian spectral embedding and the adjacency spectral embedding for recovering the block assignments now proceeds as follows. Let $\mathbf{B} \in [0,1]^{K\times K}$ and $\boldsymbol{\pi} \in \mathbb{R}^K$ be the matrix of block probabilities and the vector of block assignment probabilities for a K-block stochastic blockmodel. We shall assume that $\mathbf{B}$ is positive semidefinite. Then given an n vertex instantiation of the SBM graph with parameters $(\boldsymbol{\pi}, \mathbf{B})$, for sufficiently large n, the large-sample optimal error rate for recovering the block assignments when adjacency spectral embedding is used as the initial embedding step can be characterized by the quantity $\rho_{\mathrm{A}} = \rho_{\mathrm{A}}(n)$ defined by

$$\rho_{\mathrm{A}} = \min_{k\neq l} \sup_{t\in(0,1)} \frac{1}{2}\log\frac{|\Sigma_{kl}(t)|}{|\Sigma_k|^t|\Sigma_l|^{1-t}} + \frac{nt(1-t)}{2}(\nu_k - \nu_l)^\top \Sigma_{kl}^{-1}(t)(\nu_k - \nu_l) \tag{25}$$

where $\Sigma_{kl}(t) = t\Sigma_k + (1-t)\Sigma_l$; $\Sigma_k = \Sigma(\nu_k)$ and $\Sigma_l = \Sigma(\nu_l)$ are as defined in Theorem 27. We recall Eq. (24), in particular the fact that as ρ_{A} increases, the large-sample optimal error rate decreases. Similarly, the large-sample optimal error rate when Laplacian spectral embedding is used as the pre-processing step can be characterized by the quantity $\rho_{\mathrm{L}} = \rho_{\mathrm{L}}(n)$ defined by

$$\rho_{\mathrm{L}} = \min_{k\neq l} \sup_{t\in(0,1)} \frac{1}{2}\log\frac{|\tilde{\Sigma}_{kl}(t)|}{|\tilde{\Sigma}_k|^t|\tilde{\Sigma}_l|^{1-t}} + \frac{nt(1-t)}{2}(\tilde{\nu}_k - \tilde{\nu}_l)^\top \tilde{\Sigma}_{kl}^{-1}(t)(\tilde{\nu}_k - \tilde{\nu}_l) \tag{26}$$

where $\tilde{\Sigma}_{kl}(t) = t\tilde{\Sigma}_k + (1-t)\tilde{\Sigma}_l$ with $\tilde{\Sigma}_k = \tilde{\Sigma}(\nu_k)$ and $\tilde{\Sigma}_l = \tilde{\Sigma}(\nu_l)$ as defined in Theorem 30, and $\tilde{\nu}_k = \nu_k/(\sum_{k'} \pi_{k'} \nu_k^\top \nu_{k'})^{1/2}$. Note that ρ_{A} and ρ_{L} are similar to a weighted Mahalanobis distance. We emphasize that we have made the simplifying assumption that $n_k = n\pi_k$ in our expression for $\tilde{\nu}_k$ in Eq. (26). This is for ease of comparison between ρ_{A} and ρ_{L} in our subsequent discussion.

The ratio $\rho_{\mathrm{A}}/\rho_{\mathrm{L}}$ is a surrogate measure of the relative large-sample performance of the adjacency spectral embedding as compared to the Laplacian spectral embedding for subsequent inference, at least in the context of stochastic blockmodel graphs. That is to say, for given parameters $\boldsymbol{\pi}$ and $\mathbf{B}$, if $\rho_{\mathrm{A}}/\rho_{\mathrm{L}} > 1$, then adjacency spectral embedding is preferred over Laplacian spectral embedding when n, the number of vertices in the graph, is sufficiently large; similarly, if $\rho_{\mathrm{A}}/\rho_{\mathrm{L}} < 1$, then Laplacian spectral embedding is preferred over adjacency spectral embedding.

As an illustration of the ratio $\rho_{\mathrm{A}}/\rho_{\mathrm{L}}$, we first consider the collection of 2-block stochastic blockmodels where $\mathbf{B} = \left[\begin{smallmatrix} p^2 & pq \\ pq & q^2 \end{smallmatrix}\right]$ for $p, q \in (0,1)$ and $\boldsymbol{\pi} = (\pi_1, \pi_2)$ with $\pi_1 + \pi_2 = 1$. We note that these $\mathbf{B}$ also have rank 1 and thus the Chernoff information can be computed explicitly. Then for sufficiently large n, ρ_{A} is approximately

$$\rho_{\mathrm{A}} \approx \sup_{t\in(0,1)} \frac{nt(1-t)}{2}(p-q)^2(t\sigma_1^2 + (1-t)\sigma_2^2)^{-1}$$

where σ_1 and σ_2 are as specified in Eq. (20) and Eq. (21), respectively. Simple calculations yield

$$\rho_{\mathrm{A}} \approx \frac{n(p-q)^2(\pi_1 p^2 + \pi_2 q^2)^2}{2\Big(\sqrt{\pi_1 p^4(1-p^2) + \pi_2 pq^3(1-pq)} + \sqrt{\pi_1 p^3 q(1-pq) + \pi_2 q^4(1-q^2)}\Big)^2}$$

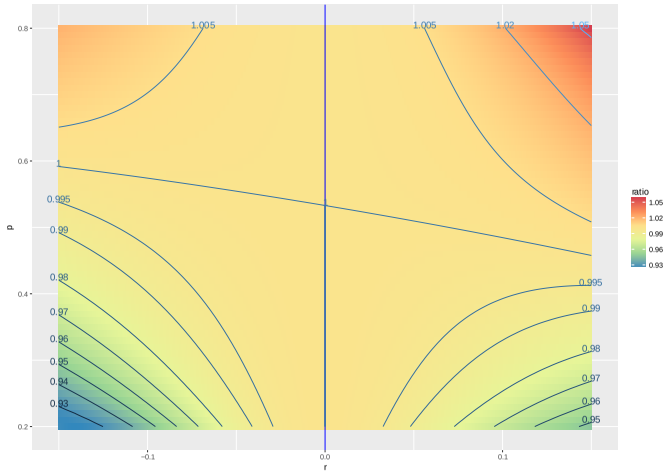

Figure 3: The ratio ρ_A/ρ_L displayed for various values of $p \in [0.2, 0.8]$ and $r = q - p \in [-0.15, 0.15]$. The labeled lines are the contour lines for ρ_A/ρ_L. Figure duplicated from Tang and Priebe (2018).

for sufficiently large n. Similarly, denoting by $\tilde{\sigma}_1^2$ and $\tilde{\sigma}_2^2$ the variances specified in Eq. (18) and Eq. (19), we have

$$\begin{aligned}\rho_L &\approx \sup_{t\in(0,1)} \frac{nt(1-t)}{2}\Big(\frac{p}{\sqrt{\pi_1 p^2+\pi_2 pq}} - \frac{q}{\sqrt{\pi_1 pq+\pi_2 q^2}}\Big)^2 (t\tilde{\sigma}_1^2 + (1-t)\tilde{\sigma}_2^2)^{-1} \\ &\approx \frac{2n(\sqrt{p}-\sqrt{q})^2(\pi_1 p+\pi_2 q)^2}{\Big(\sqrt{\pi_1 p(1-p^2)+\pi_2 q(1-pq)}+\sqrt{\pi_1 p(1-pq)+\pi_2 q(1-q^2)}\Big)^2} \\ &\approx \frac{2n(p-q)^2(\pi_1 p+\pi_2 q)^2}{(\sqrt{p}+\sqrt{q})^2\Big(\sqrt{\pi_1 p(1-p^2)+\pi_2 q(1-pq)}+\sqrt{\pi_1 p(1-pq)+\pi_2 q(1-q^2)}\Big)^2}\end{aligned}$$

for sufficiently large n. Fixing $\boldsymbol{\pi} = (0.6, 0.4)$, we compute the ratio ρ_A/ρ_L for a range of p and q values, with $p \in [0.2, 0.8]$ and $q = p + r$ where $r \in [-0.15, 0.15]$. The results are plotted in Figure 3. The y-axis of Figure 3 denotes the values of p and the x axis are the values of r. We see from the above figure that, in general, neither of the methods, namely adjacency spectral clustering or normalized Laplacian spectral embedding followed by clustering via Gaussian mixture models, dominates over the whole (p, r) parameter space. However, in general, one can easily show that LSE is preferable over ASE whenever the block probability matrix $\mathbf{B}$ becomes sufficiently sparse. Determination of similarly intuitive conditions for which ASE dominates over LSE is considerably more subtle and is the topic of current research. But in general, we observe that ASE dominates over LSE whenever the entries of $\mathbf{B}$ are relatively large.

Finally we consider the collection of stochastic blockmodels with parameters $\boldsymbol{\pi}$ and $\mathbf{B}$ where

$$\mathbf{B} = \begin{bmatrix} p & q & q \\ q & p & q \\ q & q & p \end{bmatrix}, \quad p, q \in (0,1), \text{ and } \boldsymbol{\pi} = (0.8, 0.1, 0.1). \tag{27}$$

First we compute the ratio ρ_A/ρ_L for $p \in [0.3, 0.9]$ and $r = q - p$ with $r \in [-0.2, -0.01]$. The results are plotted in Figure 4, with the y-axis of Figure 4 being the values of p and the x-axis being the values of r. Once again we see that for the purpose of subsequent inference, neither embedding methods dominates over the whole parameter space and that LSE is still preferable to ASE for smaller values of p and q and that ASE is preferable to LSE for larger values of p and q.

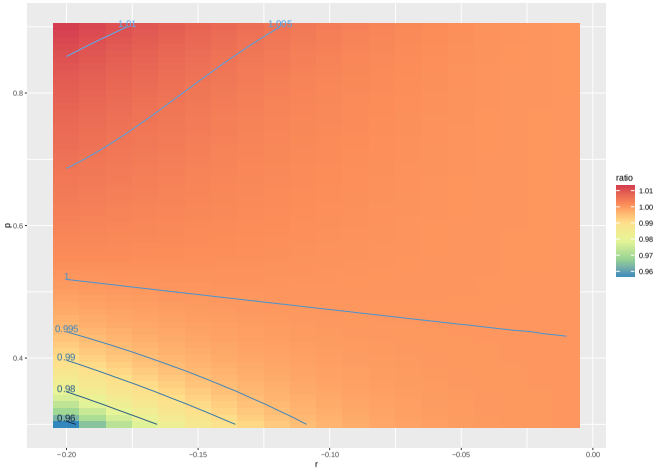

Figure 4: The ratio ρ_A/ρ_L displayed for various values of $p \in [0.2, 0.8]$ and $r = q - p \in [-0.2, -0.01]$ for the 3-block stochastic blockmodel of Eq. (27). The labeled lines are the contour lines for ρ_A/ρ_L. Figure duplicated from Tang and Priebe (2018).

5.2 Hypothesis testing

The field of multi-sample graph inference is comparatively new, and the development of a comprehensive machinery for two-sample hypothesis testing for random graphs is of both theoretical and practical importance. The test procedures in Tang et al. (2017a) and Tang et al. (2017b), both of which leverage the adjacency spectral embedding to test hypotheses of equality or equality in distribution for random dot product graphs, are among the only principled methodologies currently available. In both cases, the accuracy of the adjacency spectral embedding as an estimate of the latent positions is the key to constructing a

test statistic. Specifically, in Tang et al. (2017a), we give a new and improved bound, Theorem 32 below, for the Frobenius norm of the difference between the original latent positions and the estimated latent positions obtained from the embedding. This bound is then used to establish a valid and consistent test for the semiparameteric hypothesis test of equality for latent positions in a pair of vertex-aligned random dot product graphs. In the nonparametric case, in Tang et al. (2017b), we demonstrate how the adjacency spectral embedding can be integrated with a kernel density estimator to accurately estimate the underlying distribution F for in a random dot product graph with i.i.d latent positions.

We reproduce here several important points from Tang et al. (2017a,b). To begin our summary of two-sample hypothesis testing for graphs, we first consider the problem of developing a test for the hypothesis that two random dot product graphs on the same vertex set, with known vertex correspondence, have the same generating latent position or have generating latent positions that are scaled or diagonal transformations of one another, modulo a possible (non-identifiable) orthogonal transformation. This framework includes, as a special case, a test for whether two stochastic blockmodels have the same or related block probability matrices. In this two-sample testing problem, though, the parameter dimension grows as the sample size grows. Therefore, the problem is not precisely analogous to classical two-sample tests for, say, the difference of two parameters belonging to some fixed Euclidean space, in which an increase in data has no effect on the dimension of the parameter. The problem is also not nonparametric, since we view our latent positions as fixed and impose specific distributional requirements on the data—that is, on the adjacency matrices. Indeed, we regard the problem as semiparametric, and Tang et al. (2017a) adapts the traditional definition of consistency to this setting. In particular, for the test procedure we describe, power will increase to one for alternatives in which the difference between the two latent positions grows with the sample size.

Our test procedure is, at first glance, deceptively simple: given a pair of adjacency matrices $\mathbf{A}$ and $\mathbf{B}$ for two d-dimensional random dot product graphs, we generate their adjacency spectral embeddings, denoted $\hat{\mathbf{X}}$ and $\hat{\mathbf{Y}}$, respectively, and compute an appropriately normalized version of the so-called *Procrustes fit* or *Procrustes distance* between the two embeddings:

$$\min_{\mathbf{W}\in\mathcal{O}^{d\times d}} \|\hat{\mathbf{X}} - \hat{\mathbf{Y}}\mathbf{W}\|_F$$

(Recall that such a fit is necessary because of the inherent nonidentifiability of the random dot product model.)

Understanding the limiting distribution of this test statistic is more complicated, however, and appropriately framing the set of null and alternative hypothesis for which the test is valid and consistent (that is, a level α-test with power converging to 1 as $n \to \infty$) is delicate. To that end, we first state the key concentration inequality for $\min_{\mathbf{W}\in\mathcal{O}^{d\times d}} \|\hat{\mathbf{X}} - \hat{\mathbf{Y}}\mathbf{W}\|_F$.

Theorem 32 *Suppose $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$ is an $n \times n$ probability matrix of rank d. Suppose also that there exists $\epsilon > 0$ such that $\delta(\mathbf{P}) > (\log n)^{2+\epsilon}$. Let $c > 0$ be arbitrary but fixed. Then there exists a $n_0(c)$ and a universal constant $C \geq 0$ such that if $n \geq n_0$ and $n^{-c} < \eta < 1/2$, then*

there exists a deterministic $\mathbf{W} \in \mathcal{O}(d)$ such that, with probability at least $1 - 3\eta$,

$$\left| \|\hat{\mathbf{X}} - \mathbf{X}\mathbf{W}\|_F - C(\mathbf{X}) \right| \leq \frac{Cd\log(n/\eta)}{C(\mathbf{X})\sqrt{\gamma^5(\mathbf{P})\delta(\mathbf{P})}} \tag{28}$$

where $C(\mathbf{X})$ is a function of $\mathbf{X}$ given by

$$C(\mathbf{X}) = \sqrt{\operatorname{tr}\, \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{U}_\mathbf{P}^\top \mathbb{E}[(\mathbf{A}-\mathbf{P})^2]\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}} \tag{29}$$

where $\mathbb{E}[(\mathbf{A}-\mathbf{P})^2]$ is taken with respect to $\mathbf{A}$ and conditional on $\mathbf{X}$.

We note that the proof of this theorem consists of two pieces: it is straightforward to show that the Frobenius norm bound of Lemma 50 implies that

$$\|\hat{\mathbf{X}} - \mathbf{X}\mathbf{W}\|_F = \|(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\|_F + O(d\log(n)\delta^{-1/2}(\mathbf{P})\gamma^{-5/2}(\mathbf{P}))$$

To complete the theorem, then, in Tang et al. (2017a) we provide a concentration inequality for $\|(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\|_F^2$, showing that

$$\left| \|(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\|_F^2 - C^2(\mathbf{X}) \right| \leq \frac{14\sqrt{2d}\log(n/\eta)}{\gamma(\mathbf{P})\sqrt{\delta(\mathbf{P})}}. \tag{30}$$

where $C(\mathbf{X})$ is as defined in (29). We do not go into the details of this concentration inequality here, but rather point the reader to Tang et al. (2017a). We observe, however, that this inequality has immediate consequences for two-sample testing for random dot product graphs. For two random dot product graphs with probability matrices $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$ and $\mathbf{Q} = \mathbf{Y}\mathbf{Y}^\top$, consider the null hypothesis $\mathbf{X} = \mathbf{Y}\mathbf{W}$ for some orthogonal $\mathbf{W}$. It can be shown that $\min_{\mathbf{W}\in\mathcal{O}^{d\times d}} \|\hat{\mathbf{X}} - \hat{\mathbf{Y}}\mathbf{W}\|_F$ is the basis for a valid and consistent test. We emphasize, though, that as the graph size n increases, the $n \times d$ matrix of latent positions also increases in size. As a consequence of this, we consider the following notion of consistency in this semiparametric setting. As an aside on the notation, in this section, we consider a sequence of graphs with latent positions, all indexed by n; thus, as we noted in our preliminary remarks on notation, $\mathbf{X}_n$ and $\hat{\mathbf{X}}_n$ refer to the *matrices* of true and estimated latent positions in this sequence. We let

$$\mathbf{X}_n =_W \mathbf{Y}_n$$

denote that $\mathbf{X}_n$ and $\mathbf{Y}_n$ are equivalent up to orthogonal transformation; that is

$$\mathbf{X}_n = \mathbf{Y}_n\mathbf{W}$$

for some orthogonal $\mathbf{W} \in \mathbb{R}^{d\times d}$.

Definition 33 *Let $(\mathbf{X}_n, \mathbf{Y}_n)_{n\in\mathbb{N}}$, be a given sequence of latent positions, where $\mathbf{X}_n$ and $\mathbf{Y}_n$ are both in $\mathbb{R}^{n\times d}$. A test statistic T_n and associated rejection region R_n to test the null hypothesis*

$$H_0^n : \mathbf{X}_n =_W \mathbf{Y}_n \quad \text{against} \quad H_a^n : \mathbf{X}_n \neq_W \mathbf{Y}_n$$

is a consistent, asymptotically level α test *if for any $\eta > 0$, there exists $n_0 = n_0(\eta)$ such that*

(i) If $n > n_0$ and H_a^n is true, then $P(T_n \in R_n) > 1 - \eta$

(ii) If $n > n_0$ and H_0^n is true, then $P(T_n \in R_n) \leq \alpha + \eta$

With this definition of consistency, we obtain the following theorem on two-sample testing for random dot products on the same vertex set and with known vertex correspondence.

Theorem 34 *For each fixed n, consider the hypothesis test*

$$H_0^n : \mathbf{X}_n =_W \mathbf{Y}_n \quad \text{versus} \quad H_a^n : \mathbf{X}_n \neq_W \mathbf{Y}_n$$

where $\mathbf{X}_n$ and $\mathbf{Y}_n \in \mathbb{R}^{n \times d}$ are matrices of latent positions for two random dot product graphs. Let $\hat{\mathbf{X}}_n$ and $\hat{\mathbf{Y}}_n$ be the adjacency spectral embeddings of $\mathbf{A}_n \sim \text{Bernoulli}(\mathbf{X}_n\mathbf{X}_n^\top)$ and $\mathbf{B}_n \sim \text{Bernoulli}(\mathbf{Y}_n\mathbf{Y}_n^\top)$, respectively. Define the test statistic T_n as follows:

$$T_n = \frac{\min_{\mathbf{W} \in \mathcal{O}(d)} \|\hat{\mathbf{X}}_n\mathbf{W} - \hat{\mathbf{Y}}_n\|_F}{\sqrt{d\gamma^{-1}(\mathbf{A}_n)} + \sqrt{d\gamma^{-1}(\mathbf{B}_n)}}. \tag{31}$$

Let $\alpha \in (0,1)$ be given. Then for all $C > 1$, if the rejection region is $R := \{t \in \mathbb{R} : t \geq C\}$, then there exists an $n_1 = n_1(\alpha, C) \in \mathbb{N}$ such that for all $n \geq n_1$, the test procedure with T_n and rejection region R is an at most level α test, that is, for all $n \geq n_1$, if $\mathbf{X}_n =_W \mathbf{Y}_n$, then $\mathbb{P}(T_n \in R) \leq \alpha$. Furthermore, suppose the sequence of latent positions $\{\mathbf{X}_n\}$ and $\{\mathbf{Y}_n\}$, $n \in \mathbb{N}$, adhere to the following requirements:

(i) The latent positions satisfy the eigengap assumptions in Assumption 1;

(ii) With d_n denoting the quantity $d_n := \min_{\mathbf{W} \in \mathcal{O}(d)} \|\mathbf{X}_n\mathbf{W} - \mathbf{Y}_n\|$, suppose $d_n \neq 0$ for infinitely many n. Let $t_1 = \min\{k > 0 : d_k > 0\}$ and sequentially define $t_n = \min\{k > t_{n-1} : d_k > 0\}$. Let $b_n = d_{t_n}$. Suppose $\liminf b_n = \infty$.

Then this test procedure is consistent in the sense of Definition 33 over this sequence of latent positions.

Remark 35 *This result does not require that $\mathbf{A}_n$ and $\mathbf{B}_n$ be independent for any fixed n, nor that the sequence of pairs $(\mathbf{A}_n, \mathbf{B}_n)$, $n \in \mathbb{N}$, be independent. Further, with regard to requirement (ii) above, we note that Theorem 34 is written to emphasize consistency in the sense of Definition 33, even in a case when, for example, the latent position sequence is such that $\mathbf{X}_n =_W \mathbf{Y}_n$ for all even n, but $\mathbf{X}_n$ and $\mathbf{Y}_n$ are sufficiently far apart for odd n. In addition, the insistence that $\liminf b_k = \infty$ can also be relaxed somewhat. Specifically, consistency is achieved as long as*

$$\liminf_{n \to \infty} \Big(\|\mathbf{X}_n\mathbf{W} - \mathbf{Y}_n\|_F - C(\mathbf{X}_n) - C(\mathbf{Y}_n) \Big) > 0.$$

It also possible to construct analogous tests for latent positions related by scaling factors, or, in the case of the degree-corrected stochastic block model, by projection. We summarize these below, beginning with the case of scaling.

For the scaling case, let $\mathcal{C} = \mathcal{C}(\mathbf{Y}_n)$ denote the class of all positive constants c for which all the entries of $c^2\mathbf{Y}_n\mathbf{Y}_n^\top$ belong to the unit interval. We wish to test the null hypothesis

$H_0 : \mathbf{X}_n =_W c_n\mathbf{Y}_n$ for some $c_n \in \mathcal{C}$ against the alternative $H_a : \mathbf{X}_n \neq_W c_n\mathbf{Y}_n$ for any $c_n \in \mathcal{C}$. Recall, again, that our notation denotes equivalence up to $d \times d$ orthogonal transformation $\mathbf{W}$. In what follows below, we will only write $c_n > 0$, but will always assume that $c_n \in \mathcal{C}$, since the problem is ill-posed otherwise. The test statistic T_n is now a simple modification of the one used in Theorem 34: for this test, we compute a Procrustes distance between scaled adjacency spectral embeddings for the two graphs.

Theorem 36 *For each fixed n, consider the hypothesis test*

$$H_0^n : \mathbf{X}_n =_W c_n\mathbf{Y}_n \quad \text{for some } c_n > 0 \quad \text{versus} \quad H_a^n : \mathbf{X}_n \neq_W c_n\mathbf{Y}_n \quad \text{for all } c_n > 0$$

where $\mathbf{X}_n$ and $\mathbf{Y}_n \in \mathbb{R}^{n \times d}$ are latent positions for two random dot product graphs with adjacency matrices $\mathbf{A}_n$ and $\mathbf{B}_n$, respectively. Define the test statistic T_n as follows:

$$T_n = \frac{\min_{\mathbf{W} \in \mathcal{O}(d)} \|\hat{\mathbf{X}}_n\mathbf{W}/\|\hat{\mathbf{X}}_n\|_F - \hat{\mathbf{Y}}_n/\|\hat{\mathbf{Y}}_n\|_F\|_F}{2\sqrt{d\gamma^{-1}(\mathbf{A}_n)}/\|\hat{\mathbf{X}}_n\|_F + 2\sqrt{d\gamma^{-1}(\mathbf{B}_n)}/\|\hat{\mathbf{Y}}_n\|_F}. \tag{32}$$

Let $\alpha \in (0,1)$ be given. Then for all $C > 1$, if the rejection region is $R := \{t \in \mathbb{R} : t \geq C\}$, then there exists an $n_1 = n_1(\alpha, C) \in \mathbb{N}$ such that for all $n \geq n_1$, the test procedure with T_n and rejection region R is an at most level α test. Furthermore, consider the sequence of latent position $\{\mathbf{X}_n\}$ and $\{\mathbf{Y}_n\}$, $n \in \mathbb{N}$, satisfying Assumption 1 and denote by d_n the quantity

$$d_n := \frac{\min_{\mathbf{W} \in \mathcal{O}(d)} \|\mathbf{X}_n\mathbf{W}/\|\mathbf{X}_n\|_F - \mathbf{Y}_n/\|\mathbf{Y}_n\|_F\|_F}{1/\|\mathbf{X}_n\|_F + 1/\|\mathbf{Y}_n\|_F} = \frac{\min_{\mathbf{W} \in \mathcal{O}(d)} \|\mathbf{X}_n\|\mathbf{Y}_n\|_F\mathbf{W} - \mathbf{Y}_n\|\mathbf{X}_n\|_F\|_F}{\|\mathbf{X}_n\|_F + \|\mathbf{Y}_n\|_F} \tag{33}$$

Suppose $d_n \neq 0$ for infinitely many n. Let $t_1 = \min\{k > 0 : d_k > 0\}$ and sequentially define $t_n = \min\{k > t_{n-1} : d_k > 0\}$. Let $b_n = d_{t_n}$. If $\liminf b_n = \infty$, then this test procedure is consistent in the sense of Definition 33 over this sequence of latent positions.

We next consider the case of testing whether the latent positions are related by a diagonal transformation: that is, whether $H_0 : \mathbf{X}_n =_W \mathbf{D}_n\mathbf{Y}_n$ for some diagonal matrix $\mathbf{D}_n$. We proceed analogously to the scaling case, above, by defining the class $\mathcal{E} = \mathcal{E}(\mathbf{Y}_n)$ to be all positive diagonal matrices $\mathbf{D}_n \in \mathbb{R}^{n \times n}$ such that $\mathbf{D}_n\mathbf{Y}_n\mathbf{Y}_n^\top\mathbf{D}_n$ has all entries in the unit interval.

As before, we will always assume that $\mathbf{D}_n$ belongs to $\mathcal{E}$, even if this assumption is not explicitly stated. The test statistic T_n in this case is again a simple modification of the one used in Theorem 34. However, for technical reasons, our proof of consistency requires an additional condition on the minimum Euclidean norm of each row of the matrices $\mathbf{X}_n$ and $\mathbf{Y}_n$. To avoid certain technical issues, we impose a slightly stronger density assumption on our graphs for this test. These assumptions can be weakened, but at the cost of interpretability. The assumptions we make on the latent positions, which we summarize here, are moderate restrictions on the sparsity of the graphs.

Assumption 2 *We assume that there exists $d \in \mathbb{N}$ such that for all n, $\mathbf{P}_n$ is of rank d. Further, we assume that there exist constants $\epsilon_1 > 0$, $\epsilon_2 \in (0,1)$, $c_0 > 0$ and $n_0(\epsilon_1, \epsilon_2, c) \in \mathbb{N}$*

such that for all $n \geq n_0$:

$$\gamma(\mathbf{P}_n) \geq c_0; \qquad \delta(\mathbf{P}_n) \geq (\log n)^{2+\epsilon_1}; \qquad \min_i \|X_i\| > \left(\frac{\log n}{\sqrt{\delta(\mathbf{P}_n)}}\right)^{1-\epsilon_2} \tag{34}$$

We then have the following result.

Theorem 37 *For each fixed n, consider the hypothesis test*

$$H_0^n: \mathbf{X}_n =_W \mathbf{D}_n\mathbf{Y}_n \quad \text{for some } \mathbf{D}_n \in \mathcal{E} \quad \text{versus} \quad H_a^n: \mathbf{X}_n \neq_W \mathbf{D}_n\mathbf{Y}_n \quad \text{for any } \mathbf{D}_n \in \mathcal{E}$$

where $\mathbf{X}_n$ and $\mathbf{Y}_n \in \mathbb{R}^{n\times d}$ are matrices of latent positions for two random dot product graphs. For any matrix $\mathbf{Z} \in \mathbb{R}^{n\times d}$, let $\mathcal{D}(\mathbf{Z})$ be the diagonal matrix whose diagonal entries are the Euclidean norm of the rows of $\mathbf{Z}$ and let $\mathcal{P}(\mathbf{Z})$ be the matrix whose rows are the projection of the rows of $\mathbf{Z}$ onto the unit sphere. We define the test statistic as follows:

$$T_n = \frac{\min_{\mathbf{W}\in\mathcal{O}(d)} \|\mathcal{P}(\hat{\mathbf{X}}_n)\mathbf{W} - \mathcal{P}(\hat{\mathbf{Y}}_n)\|_F}{2\sqrt{d\gamma^{-1}(\mathbf{A})}\|\mathcal{D}^{-1}(\hat{\mathbf{X}}_n)\| + 2\sqrt{d\gamma^{-1}(\mathbf{B}_n)}\|\mathcal{D}^{-1}(\hat{\mathbf{Y}}_n)\|}. \tag{35}$$

where we write $\mathcal{D}^{-1}(\mathbf{Z})$ for $(\mathcal{D}(\mathbf{Z}))^{-1}$. Note that $\|\mathcal{D}^{-1}(\mathbf{Z})\| = 1/(\min_i \|Z_i\|)$.

Let $\alpha \in (0,1)$ be given. Then for all $C > 1$, if the rejection region is $R := \{t \in \mathbb{R} : t \geq C\}$, then there exists an $n_1 = n_1(\alpha, C) \in \mathbb{N}$ such that for all $n \geq n_1$, the test procedure with T_n and rejection region R is an at most level-α test. Furthermore, consider the sequence of latent position $\{\mathbf{X}_n\}$ and $\{\mathbf{Y}_n\}$, $n \in \mathbb{N}$, satisfying Assumption 2 and denote by d_n the quantity

$$d_n := \frac{\min_{\mathbf{W}\in\mathcal{O}(d)} \|\mathcal{P}(\mathbf{X}_n)\mathbf{W} - \mathcal{P}(\mathbf{Y}_n)\|_F}{\|\mathcal{D}^{-1}(\mathbf{X})\| + \|\mathcal{D}^{-1}(\mathbf{Y})\|} = D_{\mathcal{P}}(\mathbf{X}_n, \mathbf{Y}_n) \tag{36}$$

Suppose $d_n \neq 0$ for infinitely many n. Let $t_1 = \min\{k > 0 : d_k > 0\}$ and sequentially define $t_n = \min\{k > t_{n-1} : d_k > 0\}$. Let $b_n = d_{t_n}$. If $\liminf b_n = \infty$, then this test procedure is consistent in the sense of Definition 33 over this sequence of latent positions.

This collection of semiparametric tests has numerous applications in graph comparison; in Section 6 , we describe its use in connectomics and brain scan data. We stress, though, that the Procrustes transformations are rather cumbersome, and they limit our ability to generalize these procedures to graph comparisons involving more than two graphs. As a consequence, it can be useful to consider *joint* or *omnibus* embeddings, in which adjacency matrices for multiple graphs on the same vertex set are jontly embedded into a single (larger-dimensional) space, but *with a distinct representation for each graph.* For an illuminating joint graph inference study on the *C. elegans* connectome that addresses somewhat different questions from semiparametric testing, see Chen et al. (2016). Simultaneously embedding multiple graphs into a shared space allows comparison of graphs without the need to perform pairwise alignments of graph embeddings. Further, a distinct representation of each graph renders the omnibus embedding especially useful for subsequent comparative graph inference.

5.3 Omnibus embedding

In Levin et al. (2017), we show that an omnibus embedding—that is, an embedding of multiple graphs into a single shared space—can yield consistent estimates of underlying latent positions. Moreover, like the adjacency spectral embedding for a single graph, the rows of this omnibus embedding, suitably-scaled, are asymptotically normally distributed. As might be anticipated, the use of multiple independent graphs generated from the same latent positions, as opposed just a single graph, yields a reduction in variance for the estimated latent positions, and since the omnibus embedding provides a distinct representation for each graph, subsequently averaging these estimates reduces the variance further still. Further, the omnibus embedding allows us to compare graphs without cumbersome Procrustes alignments, but with nevertheless very similar empirical power, at least in certain simple cases, as that of the Procrustes-centered semiparametric test decribed earlier. In sum, the omnibus embedding can deliver nearly-optimal estimation of latent positions, and improvements in testing. Finally, when embedding m d-dimensional random dot product graphs, each with n vertices, the omnibus embedding provides a matrix in $\mathbb{R}^{nm\times d}$, with a separate representation in $\mathbb{R}^d$ for each vertex *in each graph.* We surmise that this distinct representation may be especially helpful for inference tasks such as graph regression, estimation of additional vertex covariates, or changepoint detection in a time series of graphs, and the impact of the omnibus embedding on such problems is a topic of curren investigation.

The discussion we give here is condensed and reproduced in significant parts from Levin et al. (2017). To construct the omnibus embedding, we consider a collection of m random dot product graphs, all with the same generating latent positions. This motivates the following definition:

Definition 38 (Conditionally independent, identically distributed joint RDPG) *Let F be a d-dimensional inner product distribution on $\mathbb{R}^d$. We say that random graphs $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}$ are distributed as a* conditionally independent, identically distributed joint random dot product graph (ciJRDPG) *and write*

$$(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, \mathbf{X}) \sim \text{ciJRDPG}(F, n, m)$$

if $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n]^\top \in \mathbb{R}^{n\times d}$ has its (transposed) rows distributed i.i.d. as $\mathbf{X}_i \sim F$, and we have marginal distributions $(\mathbf{A}^{(k)}, \mathbf{X}) \sim \text{RDPG}(F, n)$ for each $k = 1, 2, \ldots, m$. That is, the $\mathbf{A}^{(k)}$ are conditionally independent given $\mathbf{X}$, with edges independently distributed as $\mathbf{A}^{(k)}_{i,j} \sim \text{Bernoulli}((\mathbf{X}\mathbf{X}^\top)_{ij})$ for all $1 \leq i < j \leq n$ and all $k \in [m]$.

Remark 39 *We observe that the notion of a* joint *random dot product graph can be much more general than this definition alone, and indeed can allow for different mechanisms of dependence across graphs. Here, however, we are interested in the simple case in which the graphs are all on the same vertex set, and latent positions for the graphs have the same distribution; given the latent position matrix, the m graphs are generated independently of one another from the same latent positions.*

Given a set of m adjacency matrices distributed as

$$(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, \mathbf{X}) \sim \text{ciJRDPG}(F, n, m)$$

for distribution F on $\mathbb{R}^d$, a natural inference task is to recover the n latent positions $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n \in \mathbb{R}^d$ shared by the vertices of the m graphs. To estimate the underlying latent postions from these m graphs, Tang et al. (2016) provides justification for the estimate $\bar{\mathbf{X}} = \text{ASE}(\bar{\mathbf{A}}, d)$, where $\bar{\mathbf{A}}$ is the sample mean of the adjacency matrices $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}$. However, $\bar{\mathbf{X}}$ is ill-suited to any task that requires comparing latent positions across the m graphs, since the $\bar{\mathbf{X}}$ estimate collapses the m graphs into a single set of n latent positions. This motivates the *omnibus embedding*, which still yields a single spectral decomposition, but with a separate d-dimensional representation for each of the m graphs. This makes the omnibus embedding useful for *simultaneous* inference across all m observed graphs.

Definition 40 (Omnibus embedding) *Let $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)} \in \mathbb{R}^{n \times n}$ be adjacency matrices of a collection of m undirected graphs. We define the mn-by-mn omnibus matrix of $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}$ by*

$$\mathbf{M} = \begin{bmatrix} \mathbf{A}^{(1)} & \frac{1}{2}(\mathbf{A}^{(1)} + \mathbf{A}^{(2)}) & \ldots & \frac{1}{2}(\mathbf{A}^{(1)} + \mathbf{A}^{(m)}) \\ \frac{1}{2}(\mathbf{A}^{(2)} + \mathbf{A}_2^{(1)}) & \mathbf{A}^{(2)} & \ldots & \frac{1}{2}(\mathbf{A}^{(2)} + \mathbf{A}^{(m)}) \\ \vdots & \vdots & \ddots & \vdots \\ \frac{1}{2}(\mathbf{A}^{(m)} + \mathbf{A}^{(1)}) & \frac{1}{2}(\mathbf{A}^{(m)} + \mathbf{A}^{(2)}) & \ldots & \mathbf{A}^{(m)} \end{bmatrix}, \tag{37}$$

and the d-dimensional omnibus embedding *of $\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}$ is the adjacency spectral embedding of $\mathbf{M}$:*

$$\text{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, d) = \text{ASE}(\mathbf{M}, d).$$

where *ASE* is the d-dimensional adjacency spectral embedding. Under the ciJRDPG model, given the latent positions $\mathbf{X}$, the omnibus matrix has expected value

$$\mathbb{E}\mathbf{M} = \tilde{\mathbf{P}} = \mathbf{J}_m \otimes \mathbf{P} = \mathbf{U}_{\tilde{\mathbf{P}}} \mathbf{S}_{\tilde{\mathbf{P}}} \mathbf{U}_{\tilde{\mathbf{P}}}^\top$$

for $\mathbf{U}_{\tilde{\mathbf{P}}} \in \mathbb{R}^{mn \times d}$ having d orthonormal columns and $\mathbf{S}_{\tilde{\mathbf{P}}} \in \mathbb{R}^{d \times d}$ diagonal. Since $\mathbf{M}$ is a reasonable estimate for $\tilde{\mathbf{P}} = \mathbb{E}\mathbf{M}$, the matrix $\hat{\mathbf{Z}} = \text{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, d)$ is a natural estimate of the mn latent positions collected in the matrix $\mathbf{Z} = [\mathbf{X}^\top \mathbf{X}^\top \ldots \mathbf{X}^\top]^\top \in \mathbb{R}^{mn \times d}$. Here again, as in Remark 7, $\hat{\mathbf{Z}}$ only recovers the true latent positions $\mathbf{Z}$ up to an orthogonal rotation. The matrix

$$\mathbf{Z}^* = \begin{bmatrix} \mathbf{X}^* \\ \mathbf{X}^* \\ \vdots \\ \mathbf{X}^* \end{bmatrix} = \mathbf{U}_{\tilde{\mathbf{P}}} \mathbf{S}_{\tilde{\mathbf{P}}}^{1/2} \in \mathbb{R}^{mn \times d}, \tag{38}$$

provides a reasonable canonical choice of latent positions, so that $\mathbf{Z} = \mathbf{Z}^* \mathbf{W}$ for some suitably-chosen orthogonal matrix $\mathbf{W} \in \mathbb{R}^{d \times d}$; again, just as for a single random dot product graph, spectral embedding of the omnibus matrix is a consistent estimator for the latent positions (up to rotation).

Below, we state precise results on consistency and asymptotic normality of the embedding of the omnibus matrix $\mathbf{M}$. The proofs are similar to, but somewhat more involved than, the aforementioned analogues for the adjacency spectral embedding for one graph. We also demonstrate from simulations that the omnibus embedding can be successfully leveraged for subsequent inference, specifically two-sample testing.

First, Lemma 41 shows that the omnibus embedding provides uniformly consistent estimates of the true latent positions, up to an orthogonal transformation, roughly analogous to Lemma 5 in Lyzinski et al. (2014). Lemma 41 shows consistency of the omnibus embedding under the $2 \to \infty$ norm, implying that all mn of the estimated latent positions are near (a rotation of) their corresponding true positions.

Lemma 41 *With $\tilde{\mathbf{P}}$, $\mathbf{M}$, $\mathbf{U}_{\mathbf{M}}$, and $\mathbf{U}_{\tilde{\mathbf{P}}}$ defined as above, there exists an orthogonal matrix $\tilde{\mathbf{W}} \in \mathbb{R}^{d \times d}$ such that with high probability,*

$$\|\mathbf{U}_{\mathbf{M}} \mathbf{S}_{\mathbf{M}}^{1/2} - \mathbf{U}_{\tilde{\mathbf{P}}} \mathbf{S}_{\tilde{\mathbf{P}}}^{1/2} \tilde{\mathbf{W}}\|_{2 \to \infty} \leq \frac{C m^{1/2} \log mn}{\sqrt{n}}. \tag{39}$$

As with the adjacency spectral embedding, we once again can show the asymptotic normality of the individual rows of the omnibus embedding. Note that the covariance matrix does change with m, and for m large, this results in a nontrivial variance reduction.

Theorem 42 *Let $(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, \mathbf{X}) \sim \text{ciJRDPG}(F, n, m)$ for some d-dimensional inner product distribution F and let $\mathbf{M}$ denote the omnibus matrix as in (37). Let $\mathbf{Z} = \mathbf{Z}^* \mathbf{W}$ with $\mathbf{Z}^*$ as defined in Equation (38), with estimate $\hat{\mathbf{Z}} = \text{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, d)$. Let $h = m(s-1) + i$ for $i \in [n], s \in [m]$, so that $\hat{\mathbf{Z}}_h$ denotes the estimated latent position of the i-th vertex in the s-th graph $\mathbf{A}^{(s)}$. That is, $\hat{\mathbf{Z}}_h$ is the column vector formed by transposing the h-th row of the matrix $\hat{\mathbf{Z}} = \mathbf{U}_{\mathbf{M}} \mathbf{S}_{\mathbf{M}}^{1/2} = \text{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, d)$. Let $\Phi(\mathbf{x}, \mathbf{\Sigma})$ denote the cumulative distribution function of a (multivariate) Gaussian with mean zero and covariance matrix $\mathbf{\Sigma}$, evaluated at $\mathbf{x} \in \mathbb{R}^d$. There exists a sequence of orthogonal d-by-d matrices $(\tilde{\mathbf{W}}_n)_{n=1}^\infty$ such that for all $\mathbf{x} \in \mathbb{R}^d$,*

$$\lim_{n \to \infty} \Pr\left[n^{1/2} \left(\hat{\mathbf{Z}} \tilde{\mathbf{W}}_n - \mathbf{Z} \right)_h \leq \mathbf{x} \right] = \int_{\text{supp } F} \Phi\left(\mathbf{x}, \mathbf{\Sigma}(\mathbf{y})\right) dF(\mathbf{y}),$$

where $\mathbf{\Sigma}(\mathbf{y}) = (m+3) \mathbf{\Delta}^{-1} \tilde{\mathbf{\Sigma}}(\mathbf{y}) \mathbf{\Delta}^{-1} / (4m)$, $\mathbf{\Delta} = \mathbb{E}[\mathbf{X}_1 \mathbf{X}_1^\top]$ and

$$\tilde{\mathbf{\Sigma}}(\mathbf{y}) = \mathbb{E}\left[(\mathbf{y}^\top \mathbf{X}_1 - (\mathbf{y}^\top \mathbf{X}_1)^2) \mathbf{X}_1 \mathbf{X}_1^\top \right].$$

Next, we summarize from Levin et al. (2017) experiments on synthetic data exploring the efficacy of the omnibus embedding described above. If we merely wish to estimate the latent positions $\mathbf{X}$ of a set of m graphs $(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, \ldots, \mathbf{A}^{(m)}, \mathbf{X}) \sim \text{ciJRDPG}(F, n, m)$, the estimate $\bar{\mathbf{X}} = \text{ASE}(\sum_{i=1}^m \mathbf{A}^{(i)}/m, d)$, the embedding of the sample mean of the adjacency matrices performs well asymptotically (see Tang et al., 2016). Indeed, all else equal, the embedding $\bar{\mathbf{X}}$ is preferable to the omnibus embedding if only because it requires an eigendecomposition of an n-by-n matrix rather than the much larger mn-by-mn omnibus matrix.

Of course, the omnibus embedding can still be used to to estimate the latent positions, potentially at the cost of increased variance. Figure 5 compares the mean-squared error of various techniques for estimating the latent positions for a random dot product graph. The figure plots the (empirical) mean squared error in recovering the latent positions of a 3-dimensional ciJRDPG as a function of the number of vertices n. Each point in the plot is the empirical mean of 50 independent trials; in each trial, the latent positions are

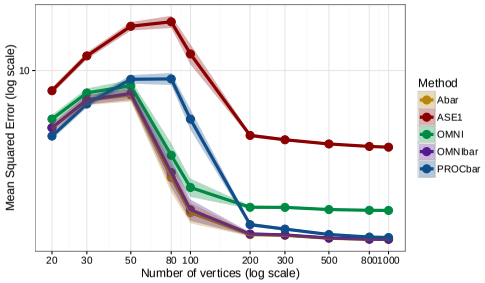

Figure 5: Mean squared error (MSE) in recovery of latent positions (up to rotation) in a 2-graph joint RDPG model as a function of the number of vertices. Performance of ASE applied to a single graph (red), ASE embedding of the mean graph (gold), the Procrustes-based pairwise embedding (blue), the omnibus embedding (green) and the mean omnibus embedding (purple). Each point is the mean of 50 trials; error bars indicate $\pm 2(SE)$. Mean omnibus embedding (OMNIbar) is competitive with $\mathrm{ASE}(\bar{\mathbf{A}}, d)$; Procrustes alignment estimation is notably inferior to the other two-graph techniques for graphs of size between 80 and 200 vertices (note that the gap appears to persist at larger graph sizes, though it shrinks). Figure duplicated from Levin et al. (2017).

drawn i.i.d. from a Dirichlet with parameter $[1, 1, 1]^\top \in \mathbb{R}^3$. Once the latent positions are so obtained, we independently generate two random dot product graphs, $\mathbf{A}^{(1)}, \mathbf{A}^{(2)} \in \mathbb{R}^{n \times n}$ with these latent positions. The figure is interpreted as follows:

1. **ASE1 (red)**: we embed only one of the two observed graphs, and use only the ASE of that graph to estimate the latent positions in $\mathbf{X}$, ignoring entirely the information present in $\mathbf{A}^{(2)}$. This condition serves as a baseline for how much additional information is provided by the second graph $\mathbf{A}^{(2)}$.

2. **Abar (gold)**: we embed the average of the two graphs, $\bar{\mathbf{A}} = (\mathbf{A}^{(1)} + \mathbf{A}^{(2)})/2$ as $\hat{\mathbf{X}} = \mathrm{ASE}(\bar{\mathbf{A}}, 3)$.

3. **OMNI (green)**: We apply the omnibus embedding to obtain $\hat{\mathbf{Z}} = \mathrm{ASE}(\mathbf{M}, 3)$, where $\mathbf{M}$ is as in Equation (37). We then use only the first n rows of $\hat{\mathbf{Z}} \in \mathbb{R}^{2n \times d}$ as our estimate of $\mathbf{X}$. This embedding incorporates information available in both graphs $\mathbf{A}^{(1)}$ and $\mathbf{A}^{(2)}$, but does not weight them equally, since the first rows of $\hat{\mathbf{Z}}$ are based primarily on the information contained in $\mathbf{A}^{(1)}$.

4. **OMNIbar (purple)**: We again apply the omnibus embedding to obtain estimated latent positions $\hat{\mathbf{Z}} = \mathrm{ASE}(\mathbf{M}, 3)$, but this time we use all available information by averaging the first n rows and the second n rows of $\hat{\mathbf{Z}}$.

5. **PROCbar (blue)**: We separately embed the graphs $\mathbf{A}^{(1)}$ and $\mathbf{A}^{(2)}$, perform a Procrustes alignment between the two embeddings, and average the aligned embeddings to obtain our final estimate of the latent positions.

First, let us note that ASE applied to a single graph (red) lags all other methods, as expected, since this discards all information from the second graph. For very small graphs, the dearth of signal is such that no method will recover the latent positions accurately.

Crucially, however, we see that the OMNIbar estimate (purple) performs nearly identically to the Abar estimate (gold), the natural choice among spectral methods for the estimation latent positions The Procrustes estimate (in blue) provides a two-graph analogue of ASE (red): it combines two ASE estimates via Procrustes alignment, but does not enforce an *a priori* alignment of the estimated latent positions. As predicted by the results in Lyzinski et al. (2014) and Tang et al. (2017a), the Procrustes estimate is competitive with the Abar (gold) estimate for suitably large graphs. The OMNI estimate (in green) serves, in a sense, as an intermediate, since it uses information available from both graphs, but in contrast to Procrustes (blue), OMNIbar (purple) and Abar (gold), it does not make complete use of the information available in the second graph. For this reason, it is noteworthy that the OMNI estimate outperforms the Procrustes estimate for graphs of 80-100 vertices. That is, for certain graph sizes, the omnibus estimate appears to more optimally leverage the information in both graphs than the Procrustes estimate does, despite the fact that the information in the second graph has comparatively little influence on the OMNI embedding.

The omnibus embedding can also be applied to testing the semiparametric hypothesis that two observed graphs are drawn from the same underlying latent positions. Consider a collection of latent positions $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n, \mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_n \in \mathbb{R}^d$. Let the graph G_1 with adjacency matrix $\mathbf{A}^{(1)}$ have edges distributed independently as $\mathbf{A}^{(1)}_{ij} \sim \mathrm{Bernoulli}(\mathbf{X}_i^\top \mathbf{X}_j)$. Similarly, let G_2 have adjacency matrix $\mathbf{A}^{(2)}$ with edges distributed independently as $\mathbf{A}^{(2)}_{ij} \sim \mathrm{Bernoulli}(\mathbf{Y}_i^\top \mathbf{Y}_j)$. Consider the following null hypothesis:

$$H_0 : \mathbf{X} =_W \mathbf{Y} \tag{40}$$

where $\mathbf{X}$ and $\mathbf{Y}$ are the matrices whose rows are the latent positions $\mathbf{X}_i$, $\mathbf{Y}_i$, respectively. The omnibus embedding provides a natural test of this null hypothesis (40) by comparing the first n and last n rows of a lower-dimensional embedding of the omnibus matrix

$$\mathbf{M} = \begin{bmatrix} \mathbf{A}^{(1)} & (\mathbf{A}^{(1)} + \mathbf{A}^{(2)})/2 \\ (\mathbf{A}^{(1)} + \mathbf{A}^{(2)})/2 & \mathbf{A}^{(2)} \end{bmatrix}.$$

Intuitively, when H_0 holds, the distributional result in Theorem 42 holds, and the i-th and $(n+i)$-th rows of $\mathrm{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, d)$ are equidistributed (though they are not independent). On the other hand, when H_0 fails to hold, there exists at least one $i \in [n]$ for which the i-th and $(n+i)$-th rows of $\mathbf{M}$ are *not* identically distributed, and thus the corresponding embeddings are also distributionally distinct. This suggests a test that compares the first n rows of $\mathrm{OMNI}(\mathbf{A}^{(1)}, \mathbf{A}^{(2)}, d)$ against the last n rows. That is, our omnibus test statistic simply considers the Frobenius norm of the difference between the top $n \times d$ submatrix of the omnibus embedding and the bottom $n \times d$ submatrix of the omnibus embedding, *with no Procrustes alignment*. Here, we empirically explore the power this test against its Procrustes-based alternative from Tang et al. (2017a).

We draw $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n \in \mathbb{R}^3$ i.i.d. according to a Dirichlet distribution F with parameter $\vec{\alpha} = [1, 1, 1]^\top$. With $\mathbf{X}$ defined as the matrix $\mathbf{X} = [\mathbf{X}_1 \mathbf{X}_2 \ldots \mathbf{X}_n]^\top \in \mathbb{R}^{n \times 3}$, let graph G_1 have

adjacency matrix $\mathbf{A}^{(1)}$, where $\mathbf{A}^{(1)}_{ij} \sim \text{Bernoulli}((\mathbf{X}\mathbf{X}^\top)_{ij})$. We generate a second graph G_2 by first drawing random points $\mathbf{Z}_1, \mathbf{Z}_2, \ldots, \mathbf{Z}_n \overset{\text{i.i.d.}}{\sim} F$. Selecting a set of indices $I \subset [n]$ of size $k < n$ uniformly at random from among all such $\binom{n}{k}$ sets, we let G_2 have latent positions

$$\mathbf{Y}_i = \begin{cases} \mathbf{Z}_i & \text{if } i \in I \\ \mathbf{X}_i & \text{otherwise.} \end{cases}$$

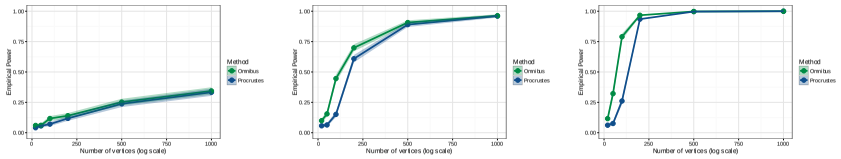
With $\mathbf{Y}$ the matrix $\mathbf{Y} = [\mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_n]^\top \in \mathbb{R}^{n\times 3}$, we generate graph G_2 with adjacency matrix $\mathbf{A}^{(2)}$, where $\mathbf{A}^{(2)}_{ij} \sim \text{Bernoulli}((\mathbf{Y}\mathbf{Y}^\top)_{ij})$. We wish to test

$$H_0 : \mathbf{X} =_W \mathbf{Y}. \tag{41}$$

Consider two different tests, one based on a Procrustes alignment of the adjacency spectral embeddings of G_1 and G_2, as in Tang et al. (2017a), and the other based on the omnibus embedding. Both approaches are based on estimates of the latent positions of the two graphs. In both cases we use a test statistic that is some variant of the form $T = \sum_{i=1}^n \|\hat{\mathbf{X}}_i - \hat{\mathbf{Y}}_i\|_F^2$, and accept or reject based on a Monte Carlo estimate of the critical value of T under the null hypothesis, in which $\mathbf{X}_i = \mathbf{Y}_i$ for all $i \in [n]$. In each trial, we use 500 Monte Carlo iterates to estimate the distribution of T.

We note that in the experiments presented here, we assume that the latent positions $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n$ of graph G_1 are known for sampling purposes, so that the matrix $\mathbf{P} = \mathbb{E}\mathbf{A}^{(1)}$ is known exactly, rather than estimated from the observed adjacency matrix $\mathbf{A}^{(1)}$. This allows us to sample from the true null distribution. As proved in Lyzinski et al. (2014), the estimated latent positions $\hat{\mathbf{X}}_1 = \text{ASE}(\mathbf{A}^{(1)})$ and $\hat{\mathbf{X}}_2 = \text{ASE}(\mathbf{A}^{(2)})$ recover the true latent positions $\mathbf{X}_1$ and $\mathbf{X}_2$ (up to rotation) to arbitrary accuracy in $(2, \infty)$-norm for suitably large n (Lyzinski et al., 2014). Without using this known matrix $\mathbf{P}$, we would require that our matrices have tens of thousands of vertices before the variance associated with estimating the latent positions would no longer overwhelm the signal present in the few altered latent positions.

Three major factors influence the complexity of testing the null hypothesis in Equation (41): the number of vertices n, the number of changed latent positions $k = |I|$, and the distances $\|\mathbf{X}_i - \mathbf{Y}_i\|_F$ between the latent positions. The three plots in Figure 6 illustrate the first two of these three factors. These three plots show the power of two different approaches to testing the null hypothesis (41) for different sized graphs and for different values of k, the number of altered latent positions. In all three conditions, both methods improve as the number of vertices increases, as expected, especially since we do not require estimation of the underlying expected matrix $\mathbf{P}$ for Monte Carlo estimation of the null distribution of the test statistic. We see that when only one vertex is changed, neither method has power much above 0.25. However, in the case of $k = 5$ and $k = 10$, is it clear that the omnibus-based test achieves higher power than the Procrustes-based test, especially in the range of 30 to 250 vertices. A more detailed examination of the relative impact of these factors in testing is given in Levin et al. (2017). We note that our present power analysis is limited to an empirical study in a few special cases, and a more detailed analysis of theoretical power guarantees for this embedding is ongoing.



(a) (b) (c)

Figure 6: Power of the ASE-based (blue) and omnibus-based (green) tests to detect when the two graphs being testing differ in (a) one, (b) five, and (c) ten of their latent positions. Each point is the proportion of 1000 trials for which the given technique correctly rejected the null hypothesis, and error bars denote two standard errors of this empirical mean in either direction. Figure duplicated from Levin et al. (2017).

In sum, our omnibus embedding provides a natural mechanism for the simultaneous embedding of multiple graphs into a single vector space. This eliminates the need for multiple Procrustes alignments, which were required in previously-explored approaches to multiple-graph testing (see Tang et al., 2017a). In the Procrustes-based approach, each graph is embedded separately, yielding estimates $\mathbf{X}_1$ and $\mathbf{X}_2$, and the test statistic is

$$\min_{\mathbf{W}\in\mathcal{O}_d} \|\hat{\mathbf{X}}_1 - \hat{\mathbf{X}}_2\mathbf{W}\|_F, \tag{42}$$

Under the null hypothesis, a suitable rescaling of this converges as $n \to \infty$. The effect of this Procrustes alignment on subsequent inference is ill-understood; it has the potential to introduce variance, and our simulations results suggest that it negatively impacts performance in both estimation and testing settings. Furthermore, when the matrix $\mathbf{P} = \mathbf{X}\mathbf{X}^\top$ does not have distinct eigenvalues (and is thus not uniquely diagonalizable), this Procrustes step is unavoidable, since the difference $\|\hat{\mathbf{X}}_1 - \hat{\mathbf{X}}_2\|_F$ need not converge at all.

In contrast, our omnibus embedding builds an alignment of the graphs into its very structure. To see this, consider, for simplicity, the $m = 2$ case. Let $\mathbf{X} \in \mathbb{R}^{n\times d}$ be the matrix whose rows are the latent positions of both graphs G_1 and G_2, and let $\mathbf{M} \in \mathbb{R}^{2n\times 2n}$ be their omnibus matrix. Then

$$\mathbb{E}\mathbf{M} = \tilde{\mathbf{P}} = \begin{bmatrix} \mathbf{P} & \mathbf{P} \\ \mathbf{P} & \mathbf{P} \end{bmatrix} = \begin{bmatrix} \mathbf{X} \\ \mathbf{X} \end{bmatrix} \begin{bmatrix} \mathbf{X} \\ \mathbf{X} \end{bmatrix}^\top.$$

Suppose now that we wish to factorize $\tilde{\mathbf{P}}$ as

$$\tilde{\mathbf{P}} = \begin{bmatrix} \mathbf{X} \\ \mathbf{X}\mathbf{W}^* \end{bmatrix} \begin{bmatrix} \mathbf{X} \\ \mathbf{X}\mathbf{W}^* \end{bmatrix}^\top = \begin{bmatrix} \mathbf{P} & \mathbf{X}(\mathbf{W}^*)^\top\mathbf{X}^\top \\ \mathbf{X}\mathbf{W}^*\mathbf{X}^\top & \mathbf{P} \end{bmatrix}.$$

That is, we want to consider graphs G_1 and G_2 as being generated from the same latent positions, but in one case, say, under a *different* rotation. This possibility necessitates the Procrustes alignment in the case of separately-embedded graphs. In the case of the omnibus matrix, the structure of the $\tilde{\mathbf{P}}$ matrix implies that $\mathbf{W}^* = \mathbf{I}_d$. In contrast to the Procrustes alignment, the omnibus matrix incorporates an alignment *a priori*. Simulations show

that the omnibus embedding outperforms the Procrustes-based test for equality of latent positions, especially in the case of moderately-sized graphs.

To further illustrate the utility of this omnibus embedding, consider the case of testing whether three different random dot product graphs have the same generating latent positions. The omnibus embedding gives us a *single* canonical representation of all three graphs: Let $\hat{\mathbf{X}}_1^O$, $\hat{\mathbf{X}}_2^O$, and $\hat{\mathbf{X}}_3^O$ be the estimates for the three latent position matrices generated from the omnibus embedding. To test whether any two of these random graphs have the same generating latent positions, we merely have to compare the Frobenius norms of their differences, as opposed to computing three separate Procrustes alignments. In the latter case, in effect, we do not have a canonical choice of coordinates in which to compare our graphs simultaneously.

5.4 Nonparametric graph estimation and testing

The semiparametric and omnibus testing procedures we describe both focus on the estimation of the latent positions themselves. But a very natural concern, for a random dot product graph with distribution F, is the estimation of the *distribution* F. We next address how the adjacency spectral embedding, judiciously integrated with kernel density estimation, can be used for nonparametric estimation and testing in random graphs.

Throughout our discussion on nonparametric estimation, we shall always assume that the distributions of the latent positions satisfy the following distinct eigenvalues assumption. The assumption implies that the estimates of the latent position obtained by the adjacency spectral embedding will, in the limit, be uniquely determined.

Assumption 3 *The distribution F for the latent positions $X_1, X_2, \ldots, \sim F$ is such that the second moment matrix $\mathbb{E}[X_1 X_1^\top]$ has d distinct eigenvalues and d is known.*

We realize that Assumption 3 is restrictive – in particular, it is not satisfied by the stochastic block model with $K > 2$ blocks of equal size and edge probabilities p within communities and q between communities – it is a necessary technical condition for us to obtain the limiting results of Theorem 3. The motivation behind this assumption is as follows: the matrix $\mathbb{E}[X_1 X_1^\top]$ is of rank d with d known so that given a graph $\mathbf{A} \sim \mathrm{RDPG}(F)$, one can construct the adjacency spectral embedding of $\mathbf{A}$ into the "right" Euclidean space. The requirement that $\mathbb{E}[X_1 X_1^\top]$ has d distinct eigenvalues is—once again—due to the intrinsic property of non-identifiability of random dot product graphs. As always, for any random dot product graph $\mathbf{A}$, the latent position $\mathbf{X}$ associated with $\mathbf{A}$ can only be estimated up to some true but unknown orthogonal transformation. Because we are concerned with two-sample hypothesis testing, we must guard against the scenario in which we have two graphs $\mathbf{A}$ and $\mathbf{B}$ with latent positions $\mathbf{X} = \{X_i\}_{i=1}^n \overset{\text{i.i.d}}{\sim} F$ and $\mathbf{Y} = \{Y_k\}_{k=1}^m \overset{\text{i.i.d}}{\sim} F$ but whose estimates $\hat{\mathbf{X}}$ and $\hat{\mathbf{Y}}$ lie in different, incommensurate subspaces of $\mathbb{R}^d$. That is to say, the estimates $\hat{\mathbf{X}}$ and $\hat{\mathbf{Y}}$ satisfy $\hat{\mathbf{X}} \approx \mathbf{X}\mathbf{W}_1$ and $\hat{\mathbf{Y}} \approx \mathbf{Y}\mathbf{W}_2$, but $\|\mathbf{W}_1 - \mathbf{W}_2\|_F$ does not converge to 0 as $n, m \to \infty$. See also Fishkind et al. (2015b) for exposition of a related so-called "incommensurability phenomenon."

Our main point of departure for this subsection compared to Section 5.2 is the assumption that, given a sequence of pairs of random dot product graphs with adjacency matrices $\mathbf{A}_n$ and $\mathbf{B}_n$, the rows of the latent positions $\mathbf{X}_n$ and $\mathbf{Y}_n$ are independent samples from some fixed distributions F and G, respectively. The corresponding tests are therefore tests of equality between F and G. More formally, we consider the following two-sample nonparametric testing problems for random dot product graphs. Let F and G be two inner product distributions. Given $\mathbf{A} \sim \mathrm{RDPG}(F)$ and $\mathbf{B} \sim \mathrm{RDPG}(G)$, we consider the tests:

1. *(Equality, up to orthogonal transformation)*

$$H_0 \colon F \doteq G \quad \text{against} \quad H_A \colon F \not\doteq G,$$

   where $F \doteq G$ denotes that there exists a unitary operator U on $\mathbb{R}^d$ such that $F = G \circ U$ and $F \not\doteq G$ denotes that $F \neq G \circ U$ for any unitary operator U on $\mathbb{R}^d$.

2. *(Equality, up to scaling)*

$$H_0 \colon F \doteq G \circ c \quad \text{for some } c > 0 \quad \text{against} \quad H_A \colon F \not\doteq G \circ c \quad \text{for any } c > 0,$$

   where $Y \sim F \circ c$ if $cY \sim F$.

3. *(Equality, up to projection)*

$$H_0 \colon F \circ \pi^{-1} \doteq G \circ \pi^{-1} \quad \text{against} \quad H_A \colon F \circ \pi^{-1} \not\doteq G \circ \pi^{-1},$$

   where π is the projection $x \mapsto x/\|x\|$; hence $Y \sim F \circ \pi^{-1}$ if $\pi^{-1}(Y) \sim F$.

We note that the above null hypotheses are nested; $F \doteq G$ implies $F \doteq G \circ c$ for $c = 1$ while $F \doteq G \circ c$ for some $c > 0$ implies $F \circ \pi^{-1} \doteq G \circ \pi^{-1}$.

We shall address the above hypothesis testing problem by combining the framework of adjacency spectral embedding and the kernel-based hypothesis testing framework of Gretton et al. (2012). The testing procedure in Gretton et al. (2012) is based on the following notion of the maximum mean discrepancy between distributions. Let Ω be a compact metric space and $\kappa \colon \Omega \times \Omega \mapsto \mathbb{R}$ a continuous, symmetric, and positive definite kernel on Ω. Denote by $\mathcal{H}$ the reproducing kernel Hilbert space associated with κ. Now let F be a probability distribution on Ω. Under mild conditions on κ, the map $\mu[F]$ defined by

$$\mu[F] := \int_\Omega \kappa(\omega, \cdot)\, \mathrm{d}F(\omega)$$

belongs to $\mathcal{H}$. Now, for given probability distributions F and G on Ω, the *maximum mean discrepancy* between F and G with respect to $\mathcal{H}$ is the measure

$$\mathrm{MMD}(F, G; \mathcal{H}) := \|\mu[F] - \mu[G]\|_{\mathcal{H}}.$$

We now summarize some important properties of the maximum mean discrepancy from Gretton et al. (2012).

Theorem 43 *Let $\kappa\colon \mathcal{X}\times\mathcal{X}\mapsto\mathbb{R}$ be a positive definite kernel and denote by $\mathcal{H}$ the reproducing kernel Hilbert space associated with κ. Let F and G be probability distributions on Ω; X and X' independent random variables with distribution F, Y and Y' independent random variables with distribution G, and X is independent of Y. Then*

$$\begin{aligned}\|\mu[F]-\mu[G]\|_{\mathcal{H}}^2 &= \sup_{h\in\mathcal{H}:\|h\|_{\mathcal{H}}\le 1}|\mathbb{E}_F[h]-\mathbb{E}_G[h]|^2\\ &= \mathbb{E}[\kappa(X,X')]-2\mathbb{E}[\kappa(X,Y)]+\mathbb{E}[\kappa(Y,Y')].\end{aligned} \tag{43}$$

Given $\mathbf{X}=\{X_i\}_{i=1}^n$ and $\mathbf{Y}=\{Y_k\}_{k=1}^m$ with $\{X_i\}\overset{\text{i.i.d}}{\sim}F$ and $\{Y_i\}\overset{\text{i.i.d}}{\sim}G$, the quantity $U_{n,m}(\mathbf{X},\mathbf{Y})$ defined by

$$\begin{aligned}U_{n,m}(\mathbf{X},\mathbf{Y}) = &\frac{1}{n(n-1)}\sum_{j\neq i}\kappa(X_i,X_j)-\frac{2}{mn}\sum_{i=1}^n\sum_{k=1}^m\kappa(X_i,Y_k)\\ &+\frac{1}{m(m-1)}\sum_{l\neq k}\kappa(Y_k,Y_l)\end{aligned} \tag{44}$$

is an unbiased consistent estimate of $\|\mu[F]-\mu[G]\|_{\mathcal{H}}^2$. Denote by $\tilde{\kappa}$ the kernel

$$\tilde{\kappa}(x,y)=\kappa(x,y)-\mathbb{E}_z\kappa(x,z)-\mathbb{E}_{z'}\kappa(z',y)+\mathbb{E}_{z,z'}\kappa(z,z')$$

where the expectation is taken with respect to $z,z'\sim F$. Suppose that $\frac{m}{m+n}\to\rho\in(0,1)$ as $m,n\to\infty$. Then under the null hypothesis of $F=G$,

$$(m+n)U_{n,m}(\mathbf{X},\mathbf{Y})\xrightarrow{d}\frac{1}{\rho(1-\rho)}\sum_{l=1}^{\infty}\lambda_l(\chi_{1l}^2-1) \tag{45}$$

where $\{\chi_{1l}^2\}_{l=1}^{\infty}$ is a sequence of independent χ^2 random variables with one degree of freedom, and $\{\lambda_l\}$ are the eigenvalues of the integral operator $\mathcal{I}_{F,\tilde{\kappa}}:\mathcal{H}\mapsto\mathcal{H}$ defined as

$$I_{F,\tilde{\kappa}}(\phi)(x)=\int_{\Omega}\phi(y)\tilde{\kappa}(x,y)dF(y).$$

Finally, if κ is a universal or characteristic kernel (Sriperumbudur et al., 2011; Steinwart, 2001), then μ is an injective map: that is, $\mu[F]=\mu[G]$ if and only if $F=G$.

Remark 44 *A kernel $\kappa\colon\mathcal{X}\times\mathcal{X}\mapsto\mathbb{R}$ is universal if κ is a continuous function of both its arguments and if the reproducing kernel Hilbert space $\mathcal{H}$ induced by κ is dense in the space of continuous functions on $\mathcal{X}$ with respect to the supremum norm. Let $\mathcal{M}$ be a family of Borel probability measures on $\mathcal{X}$. A kernel κ is characteristic for $\mathcal{M}$ if the map $\mu\in\mathcal{M}\mapsto\int\kappa(\cdot,z)\mu(dz)$ is injective. If κ is universal, then κ is characteristic for any $\mathcal{M}$ (Sriperumbudur et al., 2011). As an example, let $\mathcal{X}$ be a finite dimensional Euclidean space and define, for any $q\in(0,2)$, $k_q(x,y)=\frac{1}{2}(\|x\|^q+\|y\|^q-\|x-y\|^q)$. The kernels k_q are then characteristic for the collection of probability distributions with finite second moments (Lyons, 2013; Sejdinovic et al., 2013). In addition, by Eq. (43), the maximum mean discrepancy with reproducing kernel k_q can be written as*

$$\mathrm{MMD}^2(F,Q;k_q)=2\mathbb{E}\|X-Y\|^q-\mathbb{E}\|X-X'\|^q-\mathbb{E}\|Y-Y'\|^q.$$

where X,X' are independent with distribution F, Y,Y' are independent with distribution G, and X,Y are independent. This coincides with the notion of the energy distances of Székely and Rizzo (2013), or, when $q=1$, a special case of the one-dimensional interpoint comparisons of Maa et al. (1996). Finally, we note that $(m+n)U_{n,m}(\mathbf{X},\mathbf{Y})$ under the null hypothesis of $F=G$ in Theorem 43 depends on the $\{\lambda_l\}$ which, in turn, depend on the distribution F; thus the limiting distribution is not distribution-free. Moreover the eigenvalues $\{\lambda_l\}$ can, at best, be estimated; for finite n, they cannot be explicitly determined when F is unknown. In practice, generally the critical values are estimated through a bootstrap resampling or permutation test.

We focus on the nonparametric two-sample hypothesis test of $\mathbb{H}_0\colon F\doteq G$ against $\mathbb{H}_A\colon F\not\doteq G$. For our purposes, we shall assume henceforth that κ is a twice continuously-differentiable radial kernel and that κ is also universal. To justify this assumption on our kernel, we point out that in Theorem 45 below, we show that the test statistic $U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})$ based on the estimated latent positions converges to the corresponding statistic $U_{n,m}(\mathbf{X},\mathbf{Y})$ for the true but unknown latent positions. Due to the non-identifiability of the random dot product graph under unitary transformation, *any* estimate of the latent positions is close, only up to an appropriate orthogonal transformation, to $\mathbf{X}$ and $\mathbf{Y}$. For a radial kernel κ, this implies the approximations $\kappa(\hat{X}_i,\hat{X}_j)\approx\kappa(X_i,X_j)$, $\kappa(\hat{Y}_k,\hat{Y}_l)\approx\kappa(Y_k,Y_l)$ and the convergence of $U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})$ to $U_{n,m}(\mathbf{X},\mathbf{Y})$. If κ is not a radial kernel, the above approximations might not hold and $U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})$ need not converge to $U_{n,m}(\mathbf{X},\mathbf{Y})$. The assumption that κ is twice continuously-differentiable is technical. Finally, the assumption that κ is universal allows the test procedure to be consistent against a large class of alternatives.

Theorem 45 *Let $(\mathbf{X},\mathbf{A})\sim\mathrm{RDPG}(F)$ and $(\mathbf{Y},\mathbf{B})\sim\mathrm{RDPG}(G)$ be independent random dot product graphs with latent position distributions F and G. Furthermore, suppose that both F and G satisfies the distinct eigenvalues condition in Assumption 3. Consider the hypothesis test*

$$H_0\colon F\doteq G\quad\textit{against}\quad H_A\colon F\not\doteq G.$$

Denote by $\hat{\mathbf{X}}=\{\hat{X}_1,\dots,\hat{X}_n\}$ and $\hat{\mathbf{Y}}=\{\hat{Y}_1,\dots,\hat{Y}_m\}$ the adjacency spectral embedding of $\mathbf{A}$ and $\mathbf{B}$, respectively. Let κ be a twice continuously-differentiable radial kernel and $U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})$ be defined as

$$U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})=\frac{1}{n(n-1)}\sum_{j\neq i}\kappa(\hat{X}_i,\hat{X}_j)-\frac{2}{mn}\sum_{i=1}^n\sum_{k=1}^m\kappa(\hat{X}_i,\hat{Y}_k)+\frac{1}{m(m-1)}\sum_{l\neq k}\kappa(\hat{Y}_k,\hat{Y}_l).$$

Let $\mathbf{W}_1$ and $\mathbf{W}_2$ be $d\times d$ orthogonal matrices in the eigendecomposition $\mathbf{W}_1\mathbf{S}_1\mathbf{W}_1^\top=\mathbf{X}^\top\mathbf{X}$, $\mathbf{W}_2\mathbf{S}_2\mathbf{W}_2=\mathbf{Y}^\top\mathbf{Y}$, respectively. Suppose that $m,n\to\infty$ and $m/(m+n)\to\rho\in(0,1)$. Then under the null hypothesis of $F\doteq G$, the sequence of matrices $\mathbf{W}_{n,m}=\mathbf{W}_2\mathbf{W}_1^\top$ satisfies

$$(m+n)(U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})-U_{n,m}(\mathbf{X},\mathbf{Y}\mathbf{W}_{n,m}))\xrightarrow{\text{a.s.}}0. \tag{46}$$

Under the alternative hypothesis of $F\not\doteq G$, the sequence of matrices $\mathbf{W}_{n,m}$ satisfies

$$\frac{m+n}{\log^2(m+n)}(U_{n,m}(\hat{\mathbf{X}},\hat{\mathbf{Y}})-U_{n,m}(\mathbf{X},\mathbf{Y}\mathbf{W}_{n,m}))\xrightarrow{\text{a.s.}}0. \tag{47}$$

Eq.(46) and Eq.(47) state that the test statistic $U_{n,m}(\hat{\mathbf{X}}, \hat{\mathbf{Y}})$ using the *estimated* latent positions is almost identical to the statistic $U_{n,m}(\mathbf{X}, \mathbf{Y}\mathbf{W}_{n,m})$ using the true latent positions, under both the null and alternative hypothesis. If we assume that κ is a universal kernel, then $U_{n,m}(\mathbf{X}, \mathbf{Y}\mathbf{W}_{n,m})$ converges to 0 under the null and converges to a positive number under the alternative. The test statistic $U_{n,m}(\hat{\mathbf{X}}, \hat{\mathbf{Y}})$ therefore yields a test procedure that is consistent against any alternative, provided that both F and G satisfy Assumption 3, namely that the second moment matrices have d distinct eigenvalues.

We next consider the case of testing the hypothesis that the distributions F and G are equal up to scaling or equal up to projection. For the test of equality up to scaling,

$$H_0 \colon F \doteq G \circ c \quad \text{for some } c > 0 \quad \text{against} \quad H_A \colon F \not\doteq G \circ c \quad \text{for any } c > 0,$$

where $Y \sim F \circ c$ if $cY \sim F$, we modified Theorem 45 by first scaling the adjacency spectral embeddings by the norm of the empirical means before computing the kernel test statistic. In particular, let

$$\hat{s}_X = n^{-1/2}\|\hat{\mathbf{X}}\|_F, \quad \hat{s}_Y = m^{-1/2}\|\hat{\mathbf{Y}}\|_F, \quad s_X = n^{-1/2}\|\mathbf{X}\|_F, \quad s_Y = m^{-1/2}\|\mathbf{Y}\|_F,$$

then the conclusions of Theorem 45 hold when we replace $U_{n,m}(\hat{\mathbf{X}}, \hat{\mathbf{Y}})$ and $U_{n,m}(\mathbf{X}, \mathbf{Y}\mathbf{W}_{n,m})$ with $U_{n,m}(\hat{\mathbf{X}}/\hat{s}_X, \hat{\mathbf{Y}}/\hat{s}_Y)$ and $U_{n,m}(\mathbf{X}/s_X, \mathbf{Y}\mathbf{W}_{n,m}/s_Y)$, respectively.

For the test of equality up to projection,

$$H_0 \colon F \circ \pi^{-1} \doteq G \circ \pi^{-1} \quad \text{against} \quad H_A \colon F \circ \pi^{-1} \not\doteq G \circ \pi^{-1},$$

where π is the projection $x \mapsto x/\|x\|$ that maps x onto the unit sphere in $\mathbb{R}^d$, the conclusions of Theorem 45 hold when we replace $U_{n,m}(\hat{\mathbf{X}}, \hat{\mathbf{Y}})$ and $U_{n,m}(\mathbf{X}, \mathbf{Y}\mathbf{W}_{n,m})$ with $U_{n,m}(\pi(\hat{\mathbf{X}}), \pi(\hat{\mathbf{Y}}))$ and $U_{n,m}(\pi(\mathbf{X}), \pi(\mathbf{Y})\mathbf{W}_{n,m})$, respectively, provided that that 0 is not an atom of either F or G (and hence that $F(\{0\}) = G(\{0\}) = 0$). The assumption that 0 is not an atom is necessary, because otherwise the problem is possibly ill-posed: specifically, $\pi(0)$ is undefined. To contextualize the test of equality up to projection, consider the very specific case of the degree-corrected stochastic blockmodel of Karrer and Newman (2011). As mentioned earlier, the degree-corrected stochastic blockmodel can be regarded as a random dot product graph whose latent position X_v for an arbitrary vertex v is of the form $X_v = \theta_v \nu_v$ where ν_v is sampled from a mixture of point masses and θ_v (the degree-correction factor) is sampled from a distribution on $(0, 1]$. Thus, given two degree-corrected stochastic blockmodel graphs, equality up to projection tests whether the underlying mixtures of point masses (that is, the distribution of the ν_v) are the same modulo the distribution of the degree-correction factors θ_v.

6. Applications

We begin this section by first presenting an application of the two-sample semiparametric test procedure in Section 5.2, demonstrating how it can be applied to compare data from a collection of neural images.

Algorithm 1 Bootstrapping procedure for the test $\mathbb{H}_0 \colon \mathbf{X} =_W \mathbf{Y}$.

procedure Bootstrap($\mathbf{X}, T, bs$) ▷ Returns the p-value associated with T.
  $d \leftarrow \text{ncol}(\mathbf{X})$; $\mathcal{S}_X \leftarrow \varnothing$ ▷ Set d to be the number of columns of $\mathbf{X}$.
  for $b \leftarrow 1{:}bs$ **do**
    $\mathbf{A}_b \leftarrow \text{RDPG}(\hat{\mathbf{X}})$; $\mathbf{B}_b \leftarrow \text{RDPG}(\hat{\mathbf{X}})$
    $\hat{\mathbf{X}}_b \leftarrow \text{ASE}(\mathbf{A}_b, d)$; $\hat{\mathbf{Y}}_b \leftarrow \text{ASE}(\mathbf{B}_b, d)$
    $T_b \leftarrow \min_{\mathbf{W}} \|\hat{\mathbf{X}}_b - \hat{\mathbf{Y}}_b\mathbf{W}\|_F$; $\mathcal{S}_X \leftarrow \mathcal{S}_X \cup T_b$
  end for
  return $p \leftarrow (|\{s \in \mathcal{S}_X \colon s \geq T\}| + 0.5)/bs$ ▷ Continuity correction.
end procedure

$\hat{\mathbf{X}} \leftarrow \text{ASE}(\mathbf{A}, d)$; $\hat{\mathbf{Y}} \leftarrow \text{ASE}(\mathbf{B}, d)$ ▷ The embedding dimension d is assumed given.
$T \leftarrow \min_{\mathbf{W}} \|\hat{\mathbf{X}} - \hat{\mathbf{Y}}\mathbf{W}\|_F$
$p_X \leftarrow \text{Bootstrap}(\hat{\mathbf{X}}, T, bs)$ ▷ The number of bootstrap samples bs is assumed given.
$p_Y \leftarrow \text{Bootstrap}(\hat{\mathbf{Y}}, T, bs)$
$p = \max\{p_X, p_Y\}$ ▷ Returns the maximum of the two p-values.

6.1 Semiparametric testing for brain scan data

We consider neural imaging graphs obtained from the test-retest diffusion MRI and magnetization-prepared rapid acquisition gradient echo (MPRAGE) data of Landman et al. (2011). The raw data consist of 42 images: namely, one pair of neural images from each of 21 subjects. These images are generated, in part, for the purpose of evaluating scan-rescan reproducibility of the MPRAGE image protocol. Table 5 from Landman et al. (2011) indicates that the variability of MPRAGE is quite small; specifically, the cortical gray matter, cortical white matter, ventricular cerebrospinal fluid, thalamus, putamen, caudate, cerebellar gray matter, cerebellar white matter, and brainstem were identified with mean volume-wise reproducibility of 3.5%, with the largest variability being that of the ventricular cerebrospinal fluid at 11%.

We use the MIGRAINE pipeline of Roncal et al. (2013) to convert these scans into spatially-aligned graphs, in which each vertex corrresponds to a particular voxel in a reference coordinate system to which the image is registered. We first consider a collection of small graphs on seventy vertices that are generated from an atlas of seventy brain regions and the fibers connecting them. Given these graphs, we proceed to investigate the similarities and dissimilarities between the scans. We first embed each graph into $\mathbb{R}^4$. We then test the hypothesis of equality up to rotation between the graphs. Since Theorem 34 is a large-sample result, the rejection region specified therein might be excessively conservative for the graphs on $n = 70$ vertices in our current context. We remedy this issue by using the rejection region and p-values reported by the parametric bootstrapping procedure presented in Algorithm 1.

The pairwise comparisons between the 42 graphs are presented in Figure 7. Figure 7 indicates that, in general, the test procedure fails to reject the null hypothesis when the two graphs are for the same subject. This is consistent with the reproducibility finding of Landman et al. (2011). Furthermore, this outcome is also intuitively plausible; in addition

to failing to reject when two scans are from the same subject, we also frequently *do* reject the null hypothesis when the two graphs are from scans of different subjects. Note that our analysis is purely exploratory; as such, we do not grapple with issues of multiple comparisons here.

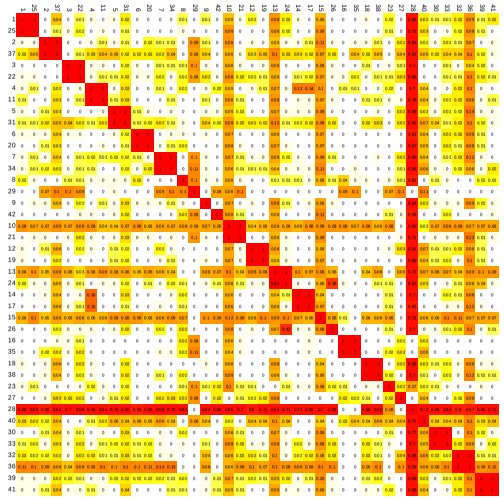


Figure 7: Matrix of p-values (uncorrected) for testing the hypothesis $\mathbb{H}_0: \mathbf{X} =_W \mathbf{Y}$ for the $42 \times 41/2$ pairs of graphs generated from the KKI test-retest dataset Landman et al. (2011). The labels had been arranged so that the pair $(2i-1, 2i)$ correspond to scans from the same subject. The p-values are color coded to vary in intensity from white (p-value of 0) to dark red (p-value of 1). Figure duplicated from Tang et al. (2017a).

Finally, we note that similar results also hold when we consider the large graphs generated from these test-retest data through the MIGRAINE pipeline. In particular, for each magnetic resonance scan, the MIGRAINE pipeline can generates graphs with upto 10^7 vertices and 10^{10} edges with the vertices of all the graphs aligned. Bootstrapping the test statistics for these large graphs present some practical difficulties; one procedure proposed in Tang et al. (2017a) is based on bootstrapping disjoint induced subgraphs of the original graphs using the bootstrapping procedure in Algorithm 1 and combining the resulting p-values using Fisher's combined probability tests (Mosteller and Fisher, 1948).

6.2 Community detection and classification in hierarchical models

In disciplines as diverse as social network analysis and neuroscience, many large graphs are believed to be composed of loosely connected communities and/or smaller graph primitives, whose structure is more amenable to analysis. We emphasize that while the problem of community detection is very well-studied and there are an abundance of community detection algorithms, these algorithms have focused mostly on uncovering the subgraphs. Recently, however, the characterization and further *classification* of these subgraphs into stochastically similar motifs has emerged as an important area of ongoing research The nonparametric two-sample hypothesis testing procedure in Section 5.4 can be used in conjunction with spectral community detection algorithms to yield a robust, scalable, integrated methodology for *community detection* and *community comparison* in graphs (Lyzinski et al., 2017).

The notion of *hierarchical stochastic block model*—namely, a graph consisting of densely connected subcommunities which are themselves stochastic block models, with this structure iterated repeatedly—is precisely formulated in Lyzinski et al. (2017). In that work, a novel angle-based clustering method is introduced, and this clustering method allows us to isolate appropriate subgraphs. We emphasize that the angle-based clustering procedure in Lyzinski et al. (2017) is designed to identify a particular affinity structure within our hierarchical block model graph. Figure 8 illustrates how an angle-based clustering may differ from a k-means clustering.

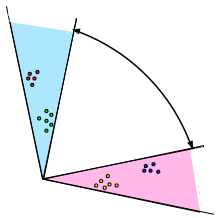

Figure 8: Subgraphs vs. angle-based clustering: Note that if the fraction of points in the pink cone is sufficiently large, K-means clustering (with $K = 2$) will not cluster the vertices in the hierarchical SBM affinity model of Lyzinski et al. (2017) into the appropriate subgraphs. Figure duplicated from Lyzinski et al. (2017).

Our overall community detection algorithm is summarized in Algorithm 2. As an illustrative example of this methodology, we present an analysis of the communities in the Friendster social network. The Friendster social network contains roughly 60 million users and 2 billion connections/edges. In addition, there are roughly 1 million communities at the local scale. Because we expect the social interactions in these communities to inform the function of the different communities, we expect to observe distributional repetition among the graphs associated with these communities.

Algorithm 2 Detecting hierarchical structure for graphs

Input: Adjacency matrix $A \in \{0,1\}^{n\times n}$ for a latent position random graph.
Output: Subgraphs and characterization of their dissimilarity
while Cluster size exceeds threshold **do**
Step 1: Compute the adjacency spectral embedding $\hat{\mathbf{X}}$ of A into $\mathbb{R}^D$;
Step 2: Cluster $\hat{\mathbf{X}}$ to obtain subgraphs $\hat{H}_1, \cdots, \hat{H}_R$ using a novel angle-based clustering procedure given in Lyzinski et al. (2017).
Step 3: For each $i \in [R]$, compute the adjacency spectral embedding for each subgraph $\hat{H}_i$ into $\mathbb{R}^d$, obtaining $\hat{\mathbf{X}}_{\hat{H}_i}$;
Step 4: Compute $\widehat{S} := [U_{\hat{n}_r,\hat{n}_s}(\hat{\mathbf{X}}_{\hat{H}_r}, \hat{\mathbf{X}}_{\hat{H}_s})]$, where U is the test statistic in Theorem 45, producing a pairwise dissimilarity matrix on induced subgraphs;
Step 5: Cluster induced subgraphs into motifs using the dissimilarities given in $\widehat{S}$; for example, use a hierarchical clustering algorithm to cluster the rows of $\widehat{S}$ or the matrix of associated p-values.
Step 6: Recurse on a representative subgraph from each motif (for example, the largest subgraph), embedding into $\mathbb{R}^d$ in Step 1 (not $\mathbb{R}^D$);
end while

Implementing Algorithm 2 on the very large Friendster graph presents several computational challenges and model selection quagmires. To overcome the computational challenge in scalability, we use the specialized SSD-based graph processing engine `FlashGraph` (Zheng et al., 2015), which is designed to analyze graphs with billions of nodes. With `FlashGraph`, we adjacency spectral embed the Friendster adjacency matrix into $\mathbb{R}^{14}$—where $\widehat{D} = 14$ is chosen using universal singular value thresholding on the partial SCREE plot (Chatterjee, 2015). We next cluster the embedded points into $\widehat{R} = 15$ large-scale/coarse-grained clusters ranging in size from 10^6 to 15.6 million vertices (note that to alleviate sparsity concerns, we projected the embedding onto the sphere before clustering); After re-embedding the induced subgraphs associated with these 15 clusters, we use a linear time estimate of the test statistic U to compute $\widehat{S}$, the matrix of estimated pairwise dissimilarities among the subgraphs. See Figure 9 for a heat map depicting $\widehat{S} \in \mathbb{R}^{15\times 15}$. In the heat map, the similarity of the communities is represented on the spectrum between white and red, with white representing highly similar communities and red representing highly dissimilar communities. From the figure, we can see clear repetition in the subgraph distributions; for example, we see a repeated motif including subgraphs $\{\hat{H}_5, \hat{H}_4, \hat{H}_3, \hat{H}_2\}$ and a clear motif including subgraphs $\{\hat{H}_{10}, \hat{H}_{12}, \hat{H}_9\}$.

Formalizing the motif detection step, we employ hierarchical clustering to cluster $\widehat{S}$ into motifs; see Figure 9 for the corresponding hierarchical clustering dendrogram, which suggests that our algorithm does in fact uncover repeated motif structure at the coarse-grained level in the Friendster graph. While it may be difficult to draw meaningful inference from repeated motifs at the scale of hundreds of thousands to millions of vertices, if these motifs are capturing a common HSBM structure within the subgraphs in the motif, then we can employ our algorithm recursively on each motif to tease out further hierarchical structure.

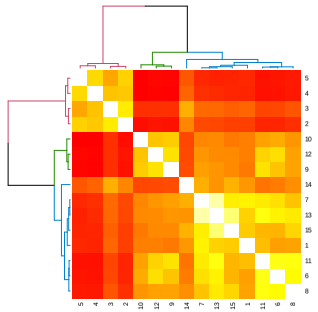

Figure 9: Heat map depiction of the level one Friendster estimated dissimilarity matrix $\widehat{S} \in \mathbb{R}^{15\times 15}$. In the heat map, the similarity of the communities is represented on the spectrum between white and red, with white representing highly similar communities and red representing highly dissimilar communities. In addition, we cluster $\widehat{S}$ using hierarchical clustering and display the associated hierarchical clustering dendrogram. Figure duplicated from Lyzinski et al. (2017).

Exploring this further, we consider three subgraphs $\{\hat{H}_2, \hat{H}_8, \hat{H}_{15}\}$, two of which are in the same motif (8 and 15) and both differing significantly from subgraph 2 according to $\widehat{S}$. We embed these subgraphs into $\mathbb{R}^{26}$ (26 were chosen once again using the universal singular value thresholding of Chatterjee (2015)) perform a Procrustes alignment of the vertex sets of the three subgraphs, cluster each into 4 clusters (4 chosen to optimize silhouette width in k-means clustering), and estimate both the block connection probability matrices,

$$\hat{P}_2 = \begin{bmatrix} 0.000045 & 0.00080 & 0.00056 & 0.00047 \\ 0.00080 & 0.025 & 0.0096 & 0.0072 \\ 0.00057 & 0.0096 & 0.012 & 0.0067 \\ 0.00047 & 0.0072 & 0.0067 & 0.023 \end{bmatrix},$$

$$\hat{P}_8 = \begin{bmatrix} 0.0000022 & 0.000031 & 0.000071 & 0.000087 \\ 0.000031 & 0.0097 & 0.00046 & 0.00020 \\ 0.000071 & 0.00046 & 0.0072 & 0.0030 \\ 0.000087 & 0.00020 & 0.003 & 0.016 \end{bmatrix},$$

$$\hat{P}_{15} = \begin{bmatrix} 0.0000055 & 0.00011 & 0.000081 & 0.000074 \\ 0.00011 & 0.014 & 0.0016 & 0.00031 \\ 0.000081 & 0.0016 & 0.0065 & 0.0022 \\ 0.000074 & 0.00031 & 0.0022 & 0.019 \end{bmatrix},$$

and the block membership probabilities $\hat{\pi}_2$, $\hat{\pi}_8$, $\hat{\pi}_{15}$, for each of the three graphs. We calculate

$$\|\hat{P}_2 - \hat{P}_8\|_F = 0.033; \quad \|\hat{\pi}_2 - \hat{\pi}_8\| = 0.043;$$
$$\|\hat{P}_8 - \hat{P}_{15}\|_F = 0.0058; \quad \|\hat{\pi}_8 - \hat{\pi}_{15}\| = 0.0010;$$
$$\|\hat{P}_2 - \hat{P}_{15}\|_F = 0.027; \quad \|\hat{\pi}_2 - \hat{\pi}_{15}\| = 0.043;$$

which suggests that the repeated structure our algorithm uncovers is *SBM substructure*, thus ensuring that we can proceed to apply our algorithm recursively to the subsequent motifs.

As a final point, we recursively apply Algorithm 2 to the subgraph $\hat{H}_{11}$. We first embed the graph into $\mathbb{R}^{26}$ (again, with 26 chosen via universal singular value thresholding). We then cluster the vertices into $\widehat{R} = 13$ large-scale clusters of sizes ranging from 500K to 2.7M vertices. We then use a linear time estimate of the test statistic T to compute $\widehat{S}$ (see Figure 10), and note that there appear to be clear repeated motifs (for example, subgraphs 8 and 12) among the $\widehat{H}$'s. We run hierarchical clustering to cluster the 13 subgraphs, and note that the associated dendrogram—as shown in Figure 10—shows that our algorithm again uncovered some repeated level-2 structure in the Friendster network. We can, of course, recursively apply our algorithm still further to tease out the motif structure at increasingly fine-grained scale.

Ideally, when recursively running Algorithm 2, we would like to simultaneously embed and cluster all subgraphs in the motif. In addition to potentially reducing embedding variance, being able to efficiently simultaneously embed all the subgraphs in a motif could greatly increase algorithmic scalability in large networks with a very large number of communities at local-scale. In order to do this, we need to understand the nature of the repeated structure within the motifs. This repeated structure can inform an estimation of a motif average (an averaging of the subgraphs within the motif), which can then be embedded into an appropriate Euclidean space in lieu of embedding all of the subgraphs in the motif separately. However, this averaging presents several novel challenges, as these subgraphs may be of very different orders and may be errorfully obtained, which could lead to compounded errors in the averaging step.

6.3 Structure discovery in the *Drosophila* connectome

In this subsection, we address a cutting-edge application of our techniques to neuroscience: structure discovery in the larval Drosophila connectome, comprehensively described in Priebe et al. (2017), and from which significant portions are reproduced here, with permission. This is a first-of-its-kind exploratory data analysis of a newly-available wiring diagram, and although the connectome graph we analyze is directed, weighted, and also of unknown embedding dimension, our statistical techniques can nonetheless be adapted to this setting.

Specifically, we introduce the *latent structure model* (LSM) for network modeling and inference. The LSM is a generalization of the stochastic block model (SBM) in that the latent

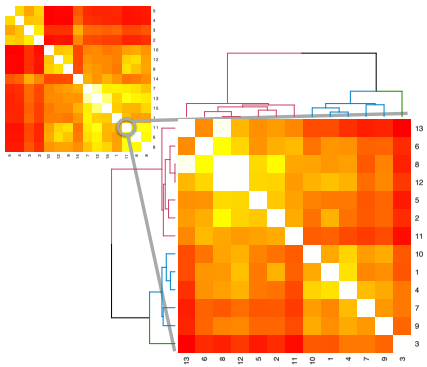

Figure 10: Heat map depiction of the level two Friendster estimated dissimilarity matrix $\widehat{S} \in \mathbb{R}^{13\times 13}$ of $\widehat{H}_{11}$. In the heat map, the similarity of the communities is represented on the spectrum between white and red, with white representing highly similar communities and red representing highly dissimilar communities. In addition, we cluster $\widehat{S}$ using hierarchical clustering and display the associated hierarchical clustering dendrogram. Figure duplicated from Lyzinski et al. (2017).

positions are allowed to lie on a lower-dimensional curve, and this model is amenable to semiparametric Gaussian mixture modeling (GMM) applied to the adjacency spectral embedding (ASE). The resulting *connectome code* derived via semiparametric GMM composed with ASE, which we denote, in shorthand, by $GMM \circ ASE$, captures latent connectome structure and elucidates biologically relevant neuronal properties.

HHMI Janelia has recently reconstructed the complete wiring diagram of the higher order parallel fiber system for associative learning in the larval *Drosophila* brain, the mushroom body (MB). Memories are thought to be stored as functional and structural changes in connections between neurons, but the complete circuit architecture of a higher-order learning center involved in memory formation or storage has not been known in any organism—until now, that is. Our MB connectome was obtained via serial section transmission electron microscopy of an entire larval *Drosophila* nervous system (Ohyama et al., 2015; Schneider-Mizell et al., 2016). This connectome contains the entirety of MB intrinsic neurons, called Kenyon cells, and all of their pre- and post-synaptic partners (Eichler et al., 2017).

We consider the right hemisphere MB. The connectome consists of four distinct types of neurons – Kenyon Cells (KC), Input Neurons (MBIN), Output Neurons (MBON), Projection Neurons (PN) – with directed connectivity illustrated in Figure 11. There are $n = 213$ neurons[2], with $n_{KC} = 100$, $n_{MBIN} = 21$, $n_{MBON} = 29$, and $n_{PN} = 63$. Figure 12 displays the

2. There are 13 isolates, all are KC; removing these isolates makes the (directed) graph one (weakly, but not strongly) connected component with 213 vertices and 7536 directed edges.

observed MB connectome as an adjacency matrix. Note that, in accordance with Figure 11, Figure 12 shows data (edges) in only eight of the 16 blocks.

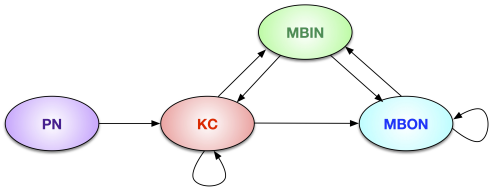

Figure 11: Illustration of the larval *Drosophila* mushroom body connectome as a directed graph on four neuron types. Figure duplicated from Priebe et al. (2017).

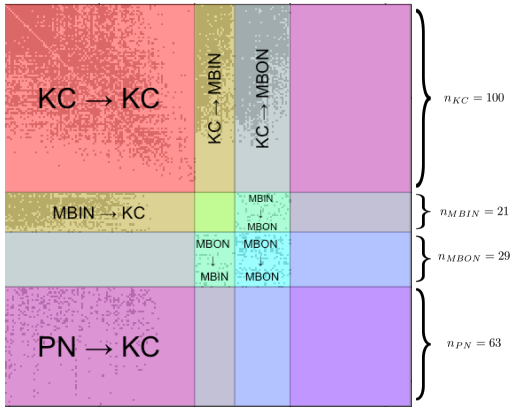

Figure 12: Observed data for our MB connectome as a directed adjacency matrix on four neuron types with 213 vertices ($n_{KC} = 100$, $n_{MBIN} = 21$, $n_{MBON} = 29$, and $n_{PN} = 63$) and 7536 directed edges. (This data matrix is available at `<http://www.cis.jhu.edu/~parky/MBstructure.html>`.) Figure duplicated from Priebe et al. (2017).

Due to its undeniable four-neuron-type connectivity structure, we might think of our MB connectome, to first order, as an observation from a $(K = 4)$-block directed stochastic block model (SBM) (Wang and Wong, 1987) on n vertices. This model is parameterized by (i) a block membership probability vector $\rho = [\rho_1, \cdots, \rho_K]$ such that $\rho_k \geq 0$ for all k and $\sum_k \rho_k = 1$ and (ii) a $K \times K$ block connectivity probability matrix B with entries $B_{k_1,k_2} \in [0, 1]$ governing the probability of directed edges from vertices in block k_1 to vertices in block k_2. For this

model of our MB connectome we have

$$B = \begin{bmatrix} B_{11} & B_{12} & B_{13} & 0 \\ B_{21} & 0 & B_{23} & 0 \\ 0 & B_{32} & B_{33} & 0 \\ B_{41} & 0 & 0 & 0 \end{bmatrix}$$

where the 0 in the B_{31} entry, for example, indicates that there are no directed connections from any MBON neuron to any KC neuron (as seen in Figures 11 and 12).

Theoretical results and methodological advances suggest that Gaussian mixture modeling (see, for example, Fraley and Raftery, 2002) composed with adjacency spectral embedding, denoted $GMM \circ ASE$, can be instructive in analysis of the (directed) SBM.

Since this graph is directed, we adapt our embedding technique just slightly. Given $d \geq 1$, the adjacency spectral embedding (ASE) of a *directed* graph on n vertices employs the singular value decomposition to represent the $n \times n$ adjacency matrix via $\mathbf{A} = \left[\mathbf{U} \mid \mathbf{U}^{\perp}\right]\left[\mathbf{S} \oplus \mathbf{S}^{\perp}\right]\left[\mathbf{V} \mid \mathbf{V}^{\perp}\right]^{\top}$ where $\mathbf{S}$ is the $d \times d$ diagonal matrix of the d largest singular values and $\mathbf{U}$ and $\mathbf{V}$ are the matrix of corresponding left and right singular vectors, and we embed the graph as n points in $\mathbb{R}^{2d}$ via the concatenation

$$\hat{\mathbf{X}} = \left[\mathbf{U}\mathbf{S}^{1/2} \mid \mathbf{V}\mathbf{S}^{1/2}\right] \in \mathbb{R}^{n \times 2d}.$$

(The scaled left-singular vectors $\mathbf{U}\mathbf{S}^{1/2}$ are interpreted as the "out-vector" representation of the digraph, modeling vertices' propensity to originate directed edges; similarly, $\mathbf{V}\mathbf{S}^{1/2}$ are interpreted as the "in-vectors".) Gaussian mixture modeling (GMM) then fits a K-component $2d$-dimensional Gaussian mixture model to the points $\hat{\mathbf{X}}_1, \cdots, \hat{\mathbf{X}}_n$ given by the rows of $\hat{\mathbf{X}}$. If the graph is a stochastic block model, then as we have discussed previously in Section 4.2, clustering the rows of the adjacency spectral embedding via Gaussian mixture modeling gives us consistent estimates for the latent positions.

Applying this procedure to our MB connectome yields the clustered embedding depicted via the pairs plot presented in Figure 13, with the associated cluster confusion matrix with respect to true neuron types presented in Table 2. The clusters are clearly coincident with the four true neuron types. (For ease of illustration, Figure 13 presents just the Out1 vs. Out2 subspace.)

There are two model selection problems inherent in spectral clustering in general, and in obtaining our clustered embedding (Figure 13) in particular: choice of embedding dimension $(\hat{d})$, and choice of mixture complexity $(\hat{K})$. A ubiquitous and principled method for choosing the number of dimensions in eigendecompositions and singular value decompositions is to examine the so-called *scree plot* and look for "elbows" or "knees" defining the cut-off between the top signal dimensions and the noise dimensions. Identifying a "best" method is, in general, impossible, as the bias-variance tradeoff demonstrates that, for small n, subsequent inference may be optimized by choosing a dimension *smaller than* the true signal dimension; see Section 3 of Jain et al. (2000) for a clear and concise illustration of this phenomenon. There are a plethora of variations for automating this singular value thresholding (SVT); Section 2.8 of Jackson (2004) provides a comprehensive discussion in

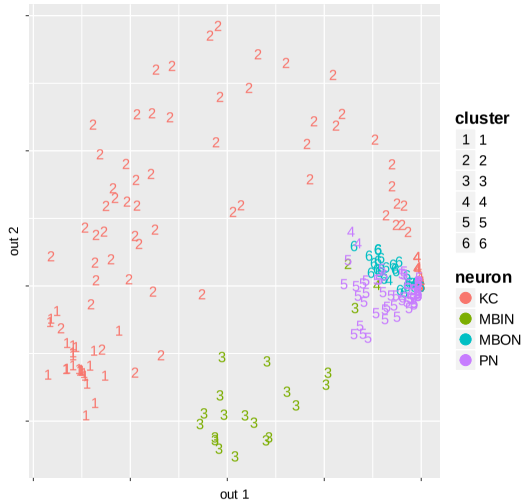

Figure 13: Plot for the clustered embedding of our MB connectome in the Out1 vs. Out2 dimensions. For ease of illustration, we present embedding results in this two-dimensional subspace. Recall that this is a two-dimensional visualization of six-dimensional structure. Figure duplicated from Priebe et al. (2017).

the context of principal components, and Chatterjee (2015) provides a theoretically-justified (but perhaps practically suspect, for small n) universal SVT. Using the profile likelihood SVT method of Zhu and Ghodsi (2006) yields a cut-off at three singular values, as depicted in Figure 14. Because this is a directed graph, we have both left- and right-singular vectors for each vertex; thus the SVT choice of three singular values results in $\hat{d} = 6$.

Similarly, a ubiquitous and principled method for choosing the number of clusters in, for example, Gaussian mixture models, is to maximize a fitness criterion penalized by model complexity. Common approaches include Akaike Information Criterion (AIC) (Akaike, 1974), Bayesian Information Criterion (BIC) (Schwarz, 1978), and Minimum Description Length (MDL) (Rissanen, 1978), to name a few. Again, identifying a "best" method is, in general, impossible, as the bias-variance tradeoff demonstrates that, for small n, inference performance may be optimized by choosing a number of clusters *smaller than* the true cluster complexity. The MCLUST algorithm of Fraley and Raftery (2002), as implemented in `R`, and its associated BIC applied to our MB connectome embedded via ASE into $\mathbb{R}^{\hat{d}=6}$, is maximized at six clusters, as depicted in Figure 15, and hence $\hat{K} = 6$.

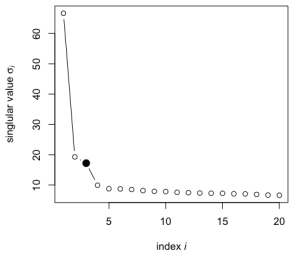

Figure 14: Model Selection: embedding dimension $\hat{d} = 6$ – the top 3 singular values and their associated left- and right-singular vectors – is chosen by SVT. Figure duplicated from Priebe et al. (2017).

	1	2	3	4	5	6
KC	**25**	**57**	0	**16**	2	0
MBIN	0	1	**19**	1	0	0
MBON	0	0	0	1	0	**28**
PN	0	0	0	2	**61**	0

Table 2: $GMM \circ ASE$ for our MB connectome yields $\hat{K} = 6$ clusters. The clusters are clearly coherent with but not perfectly aligned with the four true neuron types, as presented in this confusion matrix. Table duplicated from Priebe et al. (2017).

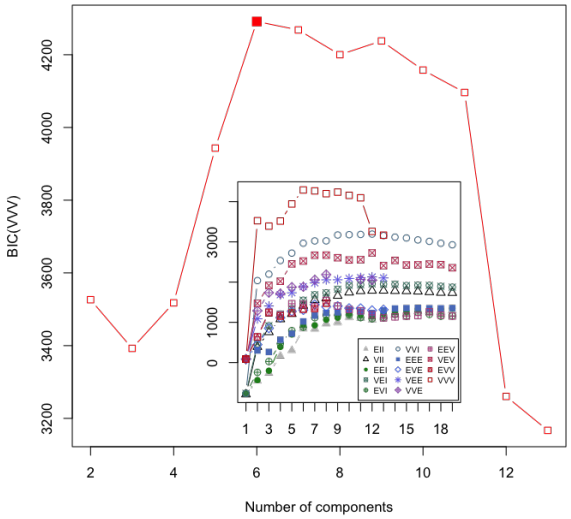

Figure 15: Model Selection: mixture complexity $\hat{K} = 6$ is chosen by BIC. (The inset shows that the main curve – BIC for dimensions 2 through 13 for MCLUST's most general covariance model, in red – dominates all other dimensions and all other models.) Figure duplicated from Priebe et al. (2017).

While BIC chooses $\hat{K} = 6$ clusters, it is natural to ask whether the distribution of KC across multiple clusters is an artifact of insufficiently parsimonious model selection. However, choosing four or five clusters not only (substantially) decreases BIC, but in fact leaves KC distributed across multiple clusters while splitting and/or merging other neuron types. In the direction of less parsimony, Figure 15 suggests that any choice from 7 to 11 clusters is competitive, in terms of BIC, with the maximizer $\hat{K} = 6$. Moreover, any of these choices only slightly decreases BIC, while leaving PN, MBIN, and MBON clustered (mostly) singularly and (mostly) purely and distributing KC across more clusters. Tables 3, 4, and 5 show cluster confusion matrices for other choices of K.

	1	2	3	4
KC	26	56	16	2
MBIN	0	20	1	0
MBON	0	28	1	0
PN	0	0	16	47

Table 3: Cluster confusion matrix for $GMM \circ ASE$ with 4 clusters. Choosing four or five clusters not only (substantially) decreases BIC (compared to $\hat{K} = 6$), but in fact leaves KC distributed across multiple clusters while splitting and/or merging other neuron types.

	1	2	3	4	5
KC	26	56	16	2	0
MBIN	0	20	1	0	0
MBON	0	0	1	0	28
PN	0	0	16	47	0

Table 4: Cluster confusion matrix for $GMM \circ ASE$ with 5 clusters. Choosing four or five clusters not only (substantially) decreases BIC (compared to $\hat{K} = 6$), but in fact leaves KC distributed across multiple clusters while splitting and/or merging other neuron types.

	1	2	3	4	5	6	7
KC	25	42	15	0	16	2	0
MBIN	0	0	1	19	1	0	0
MBON	0	0	0	0	1	0	28
PN	0	0	0	0	2	61	0

Table 5: Cluster confusion matrix for $GMM \circ ASE$ with 7 clusters. Any choice from 7 to 11 clusters only slightly decreases BIC (compared to $\hat{K} = 6$), while leaving PN, MBIN, and MBON clustered (mostly) singularly and (mostly) purely and distributing KC across more clusters. All tables reproduced from Priebe et al. (2017).

We see that our spectral clustering of the MB connectome via $GMM \circ ASE$, with principled model selection for choosing embedding dimension and mixture complexity, yields meaningful results: a single Gaussian cluster for each of MBIN, MBON, and PN, and multiple clusters for KC. That is, we have one substantial revision to Figure 11's illustration of the larval *Drosophila* mushroom body connectome as a directed graph on four neuron types:

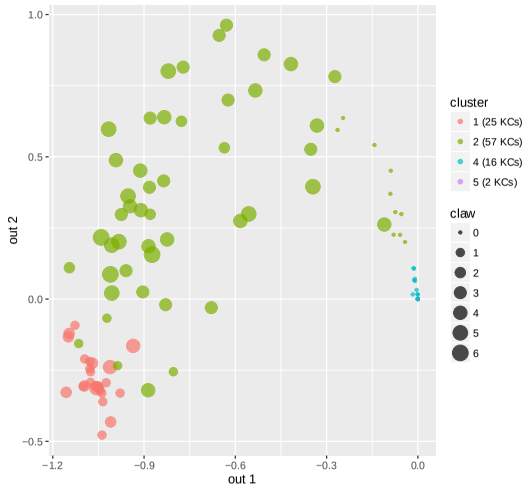

Figure 16: The multiple clusters for the KC neurons are capturing neuron age. Depicted are the first two dimensions for the KC neuron out-vectors, with color representing $\hat{K} = 6$ cluster membership – recall from Table 2 that the $n_{KC} = 100$ KCs are distributed across multiple clusters, with 25 neurons in cluster #1, 57 in #2, 0 in #3, 16 in #4, 2 in #5, and 0 in #6. The size of the dots represent the number of claws associated with the neurons. We see from the scatter plot that the embedded KC neurons arc from oldest (one-claw, lower left, cluster 1, in red), up and younger (more claws) through cluster 2 in green, and back down to youngest (zero-claw, clusters 4 and 5). See also Table 6. Recall that this is a two-dimensional visualization of six-dimensional structure. Figure duplicated from Priebe et al. (2017).

cluster	1	2	3	4	5	6
#KCs	25	57	0	16	2	0
claw: 1 (oldest)	15	4	—	0	0	—
claw: 2	7	4	—	0	0	—
claw: 3	0	15	—	0	0	—
claw: 4	3	13	—	0	0	—
claw: 5	0	8	—	0	0	—
claw: 6	0	3	—	0	0	—
claw: 0 (youngest)	0	10	—	16	2	—

Table 6: The multiple clusters for the KC neurons are capturing neuron age via the number of claws associated with the neuron. We see from the $\hat{K} = 6$ clustering table, for the $n_{KC} = 100$ KC neurons, that cluster 1 captures predominantly older neurons, cluster 2 captures both old and young neurons, and clusters 4 and 5 capture only the youngest neurons. See also Figure 16. Table reproduced from Priebe et al. (2017).

significant *substructure* associated with the KC neurons. Indeed, this hints at the possibility of a continuous, rather than discrete, structure for the KC. The paper Eichler et al. (2017) describes so-called "claws" associated with each KC neuron, and posits that KCs with only 1 claw are the oldest, followed in decreasing age by multi-claw KCs (from 2 to 6 claws), with finally the youngest KCs being those with 0 claws.

Figure 16 and Table 6 use this additional neuronal information to show that the multiple clusters for the KC neurons are capturing neuron age – and in a seemingly coherent geometry. Indeed, precisely because the clusters for the KC neurons are capturing neuron age – a continuous vertex attribute – again, in a seemingly coherent geometry, we define a "latent structure model" (LSM), a generalization of the SBM, together with a principled semiparametric spectral clustering methodology $SemiparGMM \circ ASE$ associated thereto. Specifically, we fit a continuous curve to (the KC subset of) the data in latent space and show that traversal of this curve corresponds monotonically to neuron age. To make this precise, we begin with a directed stochastic block model:

Definition 46 (Directed Stochastic Blockmodel (SBM)) *Let $d_{\text{out}} = d_{\text{in}}$, with $d = d_{\text{out}} + d_{\text{in}}$. We say that an n vertex graph $(\mathbf{A}, \mathbf{X}) \sim \text{RDPG}(F)$ is a directed stochastic blockmodel (SBM) with K blocks if the distribution F is a mixture of K point masses,*

$$dF = \sum_{k=1}^{K} \rho_k \delta_{x_k},$$

with block membership probability vector $\vec{\rho}$ in the unit $(K-1)$-simplex and distinct latent positions given by $\boldsymbol{\nu} = [\nu_1, \nu_2, \ldots, \nu_K]^\top \in \mathbb{R}^{K \times d}$. The first d_{out} entries of each latent position ν_k are the out-vectors, denoted $\xi_k \in \mathbb{R}^{d_{\text{out}}}$, and the remaining d_{in} elements are the in-vectors ζ_k. We write $G \sim SBM(n, \vec{\rho}, \boldsymbol{\xi}\boldsymbol{\zeta}^\top)$, and we refer to $\boldsymbol{\xi}\boldsymbol{\zeta}^\top \in \mathbb{R}^{K \times K}$ as the block connectivity probability matrix for the model.

We model the MB connectome as a four-component latent structure model (LSM), where LSM denotes the "generalized SBM" where each "block" may be generalized from point mass latent position distribution to latent position distribution with support on some curve (with the "block" curves disconnected, as (of course) are SBM's point masses). So LSM does have block structure, albeit not as simple as an SBM; and LSM will exhibit clustering, albeit just as transparently as an SBMs. As such, it is similar to other generalizations of SBMs, including the degree-corrected and hierarchical variants.

Definition 47 (Directed Latent Structure Model (LSM)) *Let $d_{\text{out}} = d_{\text{in}}$, and let F be a distribution on a set $\mathcal{X} = \mathcal{Y} \times \mathcal{Z} \subset \mathbb{R}^{d_{\text{out}}} \times \mathbb{R}^{d_{\text{in}}}$ such that $\langle y, z \rangle \in [0, 1]$ for all $y \in \mathcal{Y}$ and $z \in \mathcal{Z}$. We say that an n vertex graph $(\mathbf{A}, \mathbf{X}) \sim \text{RDPG}(F)$ is a directed latent structure model (LSM) with K "structure components" if the support of distribution F is a mixture of K (disjoint) curves,*

$$dF = \sum_{k=1}^{K} \rho_k dF_k(x),$$

with block membership probability vector $\vec{\rho}$ in the unit $(K-1)$-simplex and F_k supported on $\mathcal{C}_k$ and $\mathcal{C}_1, \cdots, \mathcal{C}_K$ disjoint. We write $G \sim LSM(n, \vec{\rho}, (F_1, \cdots, F_K))$.

We now investigate our MB connectome as an LSM with latent positions $X_i \overset{\text{i.i.d.}}{\sim} F$ where F is no longer a mixture of four point masses with one point mass per neuron type but instead supp(F) is three points and a continuous curve $\mathcal{C}_{KC}$.

Motivated by approximate normality of the adjacency spectral embedding of an RDPG, we consider estimating F via a semiparametric Gaussian mixture model for the $\hat{\mathbf{X}}_i$'s. Let H be a probability measure on a parameter space $\Theta \subset \mathbb{R}^d \times S_{d\times d}$, where $S_{d\times d}$ is the space of d-dimensional covariance matrices, and let $\{\varphi(\cdot;\theta) : \theta \in \Theta\}$ be a family of normal densities. Then the function given by

$$\alpha(\cdot; H) = \int_\Theta \varphi(\cdot;\theta) dH(\theta)$$

is a semiparametric GMM. $H \in \mathcal{M}$ is referred to as the mixing distribution of the mixture, where $\mathcal{M}$ is the class of all probability measures on Θ. If H consists of a finite number of atoms, then $\alpha(\cdot; H)$ is a finite normal mixture model with means, variances and proportions determined by the locations and weights of the point masses, and in Lindsay (1983), the author provides theory for maximum likelihood estimation (MLE) in this context.

Thus (ignoring covariances for presentation simplicity, so that $\theta \in \mathbb{R}^d$ is the component mean vector) we see that the central limit theorem suggests that we estimate the probability density function of the embedded MB connectome $\hat{\mathbf{X}}_1, \cdots, \hat{\mathbf{X}}_{n=213}$, under the LSM assumption, as the semiparametric GMM $\alpha(\cdot; H)$ with $\Theta = \mathbb{R}^6$ and where $H = F$ is supported by three points and a continuous curve $\mathcal{C}_{KC}$. Note that in the general case, where Θ includes both means and covariance matrices, we have $H = H_{F,n}$. The central limit theorem for the adjacency spectral embedding provides a large-sample approximation for $H_{F,n}$, and provides a mean-covariance constraint so that if we knew the latent position distribution F we would have no extra degrees of freedom (though perhaps a more challenging MLE optimization problem). As it is, we do our fitting in the general case, with simplifying constraints on the covariance structure associated with $\mathcal{C}_{KC}$.

Our MLE (continuing to ignore covariances for presentation simplicity) is given by

$$d\hat{H}(\theta) = \sum_{k=1}^{3} \widehat{\rho}_k I\{\theta = \widehat{\theta}_k\} + \left(1 - \sum_{k=1}^{3} \widehat{\rho}_k\right) \widehat{\rho}_{KC}(\theta) I\{\theta \in \widehat{\mathcal{C}}_{KC}\}$$

where $\widehat{\theta}_1, \widehat{\theta}_2, \widehat{\theta}_3$ are given by the means of the $GMM \circ ASE$ Gaussian mixture components for MBIN, MBON, and PN, and $\widehat{\mathcal{C}}_{KC} \subset \mathbb{R}^d$ is a one-dimensional curve. Figure 17 displays the MLE results from an EM optimization for the curve $\widehat{\mathcal{C}}_{KC}$ constrained to be quadratic, as detailed in the Appendix. (Model testing for $\mathcal{C}_{KC}$ in $\mathbb{R}^6$ does yield quadratic: testing the null hypothesis of linear against the alternative of quadratic yields clear rejection ($p < 0.001$), while there is insufficient evidence to favor H_A cubic over H_0 quadratic ($p \approx 0.1$).) That is, (continuing to ignore covariances for presentation simplicity) our structure discovery via $SemiparGMM \circ ASE$ yields an $\mathbb{R}^6$ latent position estimate for the MB connectome – a *connectome code* for the larval *Drosophila* mushroom body – as a semiparametric Gaussian mixture of three point masses and a continuous parameterized curve $\widehat{\mathcal{C}}_{KC}$; the three Gaussians correspond to three of the four neuron types, and the curve corresponds to the fourth neuron type (KC) with the parameterization capturing neuron age (see Figure 18). We note that in Eichler et al. (2017) , the authors suggest distance-to-neuropile δ_i – the

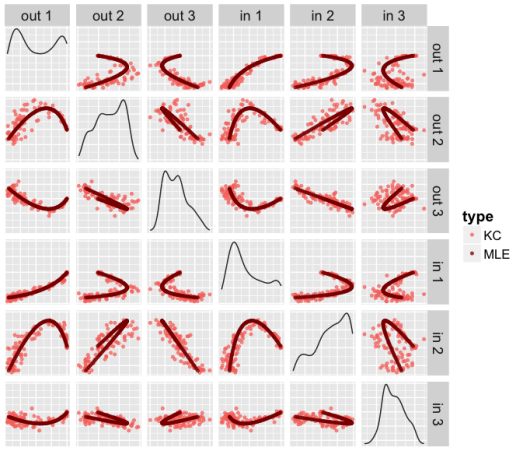

Figure 17: Semiparametric MLE $\widehat{\mathcal{C}}_{KC}$ for the KC latent-space curve in $\mathbb{R}^6$. Figure duplicated from Priebe et al. (2017).

distance to the MB neuropile from the bundle entry point of each KC neuron i – as a proxy for neuron age, and analyzes this distance in terms of number of claws for neuron i (see Figure 19). We now demonstrate that the correlation of this distance with the KC neurons' projection onto the parameterized curve $\widehat{\mathcal{C}}_{KC}$ is highly significant – this semiparametric spectral model captures neuroscientifically important structure in the connectome. To wit, we project each KC neuron's embedding onto our parameterized $\widehat{\mathcal{C}}_{KC}$ and study the relationship between the projection's position on the curve, t_i, and the neuron's age through the distance proxy δ_i (see Figures 20 and 21). We find significant correlation of δ_i with t_i – Spearman's $s = -0.271$, Kendall's $\tau = -0.205$, Pearson's $\rho = -0.304$, with $p < 0.01$ in each case – demonstrating that our semiparametric spectral modeling captures biologically relevant neuronal properties.

In summary, motivated by the results of a spectral clustering investigation of the recently-reconstructed synapse-level larval *Drosophila* mushroom body structural connectome, which demonstrate conclusively that modeling the Kenyon Cells (KC) demands additional latent space structure, we have developed semiparametric spectral modeling. Exploratory data analysis suggests that the MB connectome can be productively approximated by a four-component latent structure model (LSM), and the resulting MB connectome code derived via $SemiparGMM \circ ASE$ captures biologically relevant neuronal properties. Data and code for all our analyses are available at `http://www.cis.jhu.edu/~parky/MBstructure.html`.

Of course, the true connectome code is more elaborate, and cannot be completely encompassed by any simple latent position model – such a model precludes the propensity for transitivity, for example – but our semiparametric spectral modeling provides another step

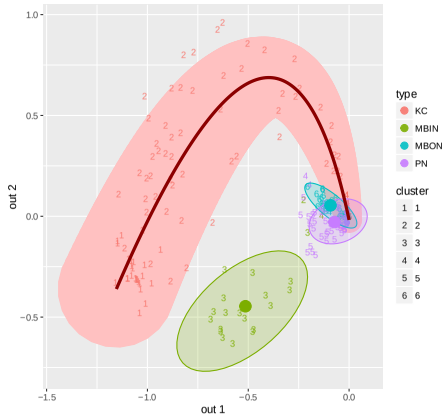

Figure 18: Semiparametric spectral latent space estimate of our MB connectome as three Gaussians and a KC curve: colors distinguish the four neuron types and numbers distinguish the original $\hat{K} = 6$ clusters. Figure 21: The correlation between the projection points t_i on the quadratic curve $\widehat{\mathcal{C}}_{KC}$ and distance δ_i (a proxy for age) for the KC neurons is highly significant, demonstrating that our semiparametric spectral modeling captures biologically relevant neuronal properties. Figure duplicated from Priebe et al. (2017).

along the path. In terms of a (partial) ladder of biological scales – for example, *C. elegans*, *Drosophila*, zebrafish, mouse, primate, and humans – this works moves us off the first rung for analysis of a complete neurons-as-vertices and synapses-as-edges connectome.

7. Conclusion: complexities, open questions, and future work

Our paradigm for statistical inference on random graphs is anchored by the familiar pillars of classical Euclidean inference. We exhibit estimates for graph parameters that satisfy (uniform) consistency and asymptotic normality, and we demonstrate how these estimates can be exploited in a bevy of subsequent inference tasks: community detection in heterogeneous networks, multi-sample graph hypothesis testing, and exploratory data analysis in connectomics. The random dot product graph model in which we ground our techniques has both linear algebraic transparency and wide applicability, since a hefty class of independent-edge graphs is well-approximated by RDPGs. The lynchpins of our approach are spectral decompositions of adjacency and Laplacian matrices, but many of our results and proof techniques can be applied to more general random matrices. In recent work, for example, we examine eigenvalue concentration for certain classes of random matrices (Cape et al., 2017a), and accurate estimation of covariance matrices (Cape et al., 2017b). As such, our methodology is a robust edifice from which to explore questions in graph inference, data analysis, and random matrix theory.

The results we summarize here are but the tip of the iceberg, though, and there persist myriad open problems in spectral graph inference—for random dot product graphs in particular, of course, but also for random graphs writ large. In this section, we outline some current questions of interest and describe future directions for research.

Our consistency results for the adjacency spectral embedding depend on knowing the correct embedding dimension. In real data, this optimal embedding dimension is typically not only not known, but, since the RDPG model is only an approximation to any true model, may well depend on the desired subsequent inference task. As we have pointed out in Section 6.3, multiple methods exist for estimating embedding dimension, and the universal singular value thresholding of Chatterjee (2015) and other thresholding methods (such as Fishkind et al., 2013) are theoretically justified in the large-n limit. For finite n, however, model selection is considerably trickier. Underestimation of the embedding dimension can markedly—and provably—bias subsequent inference. While we do not address it here, we remark that asymptotic results can be shown for the adjacency spectral embedding of a d-dimensional RDPG when the chosen embedding dimension is $d' < d$. On the other hand, if the embedding dimension is overestimated, no real signal is lost; therefore, most embedding methods continue to perform well, albeit with some loss of efficiency due to increased variance. Precisely quantifying this loss of efficiency is very much an open question and is related to analogous classical questions in random matrix theory (see Tao and Vu, 2012).

In our RDPG model, an important assumption is that the $\mathbf{P}$ matrix be positive semidefinite. While this limits the model, as we mentioned in the introduction, the *generalized random dot product graph model* (gRDPG) of Rubin-Delanchy et al. (2017) is not similarly restricted, but nevertheless shares many important useful properties of the RDPG. Considering a matrix

of latent positions $\mathbf{X} \in \mathbb{R}^{p+q}$, one can set $\mathbf{P} = \mathbf{X}\mathbf{I}_{p,q}\mathbf{X}^\top$ where $\mathbf{I}_{p,q}$ is the diagonal matrix of size $(p+q)\times(p+q)$ with p diagonal entries being 1 and q diagonal entries being -1. Under this generalization, any $\mathbf{P}$ can be obtained, provided that $p+q$ is appropriately chosen. This then implies that any latent position graph model, even a non-positive-semidefinite one, can be approximated arbitrarily closely by this generalized RDPG. We are currently investigation extensions of our results on consistency, distributional limits, and testing for estimates of gRDPGs parameters, including, for instance, suitable reformulations of the two-sample hypothesis tests for, say, mixed membership stochastic blockmodels.

We also wish to adapt our procedures to weighted graphs. For simple weighting, such as Poisson-distributed weights, our existing methodology applies quite naturally to the weighted adjacency matrix. More intricate questions arise when the weights are contaminated or their distribution is heavily skewed. In such cases, one can "pass to ranks"; that, is replace the nonzero weight by its normalized rank among all the edge weights. This mitigates skew and works well in many examples, but a deeper theoretical analysis of this procedure, as well as other approaches to weighted graph inference, remain open.

To address graphs with self-edges, note that the random dot product graph model does not preclude such edges. Indeed, since $\mathbf{P}$ is not constrained to be hollow, the adjacency matrix $\mathbf{A}$ thus generated need not be hollow, either. However, the generative mechanism for self-edges in a graph may be different from the mechanism for edges between two different vertices. One approach to addressing this is to set the diagonal entries of $\mathbf{A}$ to zero and then *augment* the diagonal artificially with imputed values. In fact, even when there are no self loops, such procedures can improve finite-sample inferential performance. In Marchette et al. (2011), it is demonstrated that augmenting the diagonal via $\mathbf{A}_{ii} = d_i/(n+1)$, where d_i is the degree of vertex i, can improve inference in certain cases. Similarly, in Scheinerman and Tucker (2010), we find an iterative procedure to find a diagonal augmentation consistent with the low-rank structure of $\mathbf{P}$. It is still unclear exactly what augmentation of the diagonal, if any, might be optimal for each particular inference task.

In the case when the vertices or edges are corrupted by occlusion or noise, the work of Priebe et al. (2015) and Levin and Lyzinski (2017) consider approaches to vertex classification and graph recovery, demonstrating that spectral embeddings are robust to certain sources of graph error. Violations of the independent edge assumption, though, can lead to more significant hurdles, both theoretical practical, since it is a requirement for a number of the concentration inequalities on which we depend.

For joint graph inference and testing, open problems abound. We mention, for instance, the analysis of the omnibus embedding when the m graphs are correlated, or when some are corrupted; a closer examination of the impact of the Procrustes alignment on power; the development of an analogue to a Tukey test for determining which graphs differ when we test for the equality of distribution for more than two graphs; the comparative efficiency of the omnibus embedding relative to other spectral decompositions; and a quantification of the trade-off for subsequent inference between a large number of independent graphs and large graph size (Tang et al., 2016).

In sum, the random dot product graph is a compact, manageable, and applicable model. The Euclidean nature of the adjacency and Laplacian spectral embedding for a random dot product graph allows us to approach statistical inference in this setting from a familiar Euclidean perspective. Both the adjacency spectral embedding and the Laplacian spectral embedding can be profitably leveraged for latent position estimation and single- and multi-sample graph hypothesis testing. Moreover, our distributional results for these spectral embeddings provide reassuring classical analogues of asymptotic normality for estimators, and in current ongoing work, we consider how to compare asymptotic relative efficiency of different estimators for graph parameters. While spectral methods may not always be optimal for a given task, they are often feasible and can provide a way to accurately initialize more complex procedures. Moreover, these Euclidean representations of graph data render possible the application of techniques for analysis of Euclidean data—clustering, classification, and density estimation, for instance—to graphs. As we have outlined above, while many important theoretical and practical challenges remain, spectral embeddings for random dot product graphs constitute an important piece of the greater puzzle of random graph inference.

Acknowledgments

We would like to acknowledge support for this project from the Johns Hopkins University Human Language Technology Center of Excellence (JHU HLT COE); the XDATA, SIMPLEX, and D3M programs of the Defense Advanced Research Projects Agency (DARPA) administered through contract FA8750-12-2-0303, contract N66001-15-C-4041, and contract FA8750-17-2-0112, respectively; and the Acheson J. Duncan Fund.

Appendix A. Appendix

In the appendix, we provide details for the proofs of our results on consistency and asymptotic normality of the adjacency spectral embedding, as well as an outline of the proof of the central limit theorem for the Laplacian spectral embedding. Our notation remains as stated in Section 4. We begin with a detailed proof of our result on the consistency, in the $2 \to \infty$ norm, of the ASE for latent position recovery in RDPGs.

A.1 Proof of Theorem 26

Let us recall **Theorem 26**: Let $\mathbf{A}_n \sim \text{RDPG}(\mathbf{X}_n)$ for $n \geq 1$ be a sequence of random dot product graphs where the $\mathbf{X}_n$ is assumed to be of rank d for all n sufficiently large. Denote by $\hat{\mathbf{X}}_n$ the adjacency spectral embedding of $\mathbf{A}_n$ and let $(\hat{\mathbf{X}}_n)_i$ and $(\mathbf{X}_n)_i$ be the i-th row of $\hat{\mathbf{X}}_n$ and $\mathbf{X}_n$, respectively. Let E_n be the event that there exists an orthogonal transformation $\mathbf{W}_n \in \mathbb{R}^{d\times d}$ such that

$$\max_i \|(\hat{\mathbf{X}})_i - \mathbf{W}_n(\mathbf{X}_n)_i\| \leq \frac{Cd^{1/2}\log^2 n}{\delta^{1/2}(\mathbf{P}_n)}$$

where $C > 0$ is some fixed constant and $\mathbf{P}_n = \mathbf{X}_n\mathbf{X}_n^\top$. Then E_n occurs asymptotically almost surely; that is, $\Pr(E_n) \to 1$ as $n \to \infty$.

The proof of Theorem 26 will follow from a succession of supporting results. We note that Theorem 50, which deals with the accuracy of spectral embedding estimates in Frobenius norm, may be of independent interest. We begin with the following simple but essential proposition, in which we show that $\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A}$ is close to an orthogonal transformation. For ease of exposition, in the remainder of this subsection we shall suppress the subscript index n from our matrices $\mathbf{X}_n$, $\mathbf{A}_n$ and $\hat{\mathbf{X}}_n$.

Proposition 48 *Let $\mathbf{A} \sim \text{RDPG}(\mathbf{X})$ and let $\mathbf{W}_1\mathbf{\Sigma}\mathbf{W}_2^\top$ be the singular value decomposition of $\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A}$. Then with high probability,*

$$\|\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} - \mathbf{W}_1\mathbf{W}_2^\top\| = O(\delta^{-1}(\mathbf{P})).$$

Proof Let $\sigma_1, \sigma_2, \ldots, \sigma_d$ denote the singular values of $\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A}$ (the diagonal entries of $\mathbf{\Sigma}$). Then $\sigma_i = \cos(\theta_i)$ where the θ_i are the principal angles between the subspaces spanned by $\mathbf{U}_\mathbf{A}$ and $\mathbf{U}_\mathbf{P}$. Furthermore, by the Davis-Kahan Theorem,

$$\|\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^\top - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\| = \max_i |\sin(\theta_i)| \leq \frac{C\sqrt{d}\|\mathbf{A}-\mathbf{P}\|}{\lambda_d(\mathbf{P})}$$

for sufficiently large n. Recall here $\lambda_d(\mathbf{P})$ denotes the d-th largest eigenvalue of $\mathbf{P}$. The spectral norm bound for $\mathbf{A}-\mathbf{P}$ from Theorem 21 along with the assumption that $\lambda_d(\mathbf{P})/\delta(\mathbf{P}) \geq c_0$ for some constant c_0 in Assumption 1 yield

$$\|\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^\top - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\| \leq \frac{C\sqrt{d}}{\delta^{1/2}(\mathbf{P})}.$$

We thus have

$$\begin{aligned}\|\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} - \mathbf{W}_1\mathbf{W}_2^\top\| &= \|\mathbf{\Sigma} - I\| = \max_i|1-\sigma_i| \leq \max_i(1-\sigma_i^2)\\ &= \max_i \sin^2(\theta_i) = \|\mathbf{U}_\mathbf{A}\mathbf{U}_\mathbf{A}^T - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\|^2 = O(\delta^{-1}(\mathbf{P}))\end{aligned}$$

as desired. ■

Denote by $\mathbf{W}^*$ the orthogonal matrix $\mathbf{W}_1\mathbf{W}_2^\top$ as defined in the above proposition. We now establish the following key lemma. The lemma allows us to exchange the order of the orthogonal transformation $\mathbf{W}^*$ and the diagonal scaling transformation $\mathbf{S}_\mathbf{A}$ or $\mathbf{S}_\mathbf{P}$.

Lemma 49 *Let $(\mathbf{A}, \mathbf{X}) \sim \text{RDPG}(F)$ with sparsity factor ρ_n. Then asymptotically almost surely,*

$$\|\mathbf{W}^*\mathbf{S}_\mathbf{A} - \mathbf{S}_\mathbf{P}\mathbf{W}^*\|_F = O(\log n) \tag{48}$$

and

$$\|\mathbf{W}^*\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^*\|_F = O((\log n)\,\delta^{-1/2}(\mathbf{P})) \tag{49}$$

Proof Let $\mathbf{R} = \mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}$. We note that $\mathbf{R}$ is the residual after projecting $\mathbf{U_A}$ orthogonally onto the column space of $\mathbf{U_P}$, and thus

$$\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F \le \min_{\mathbf{W}} \|\mathbf{U_A} - \mathbf{U_P}\mathbf{W}\|_F$$

where the minimization is over all orthogonal matrices $\mathbf{W}$. The variant of the Davis-Kahan Theorem given in Eq. (9) then implies

$$\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F \le O(\delta^{-1/2}(\mathbf{P})).$$

We next derive that

$$\begin{aligned}
\mathbf{W}^*\mathbf{S_A} &= (\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A} + \mathbf{U_P}^\top\mathbf{U_A}\mathbf{S_A} = (\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A} + \mathbf{U_P}^\top\mathbf{A}\mathbf{U_A} \\
&= (\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A} + \mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_A} + \mathbf{U_P}^\top\mathbf{P}\mathbf{U_A} \\
&= (\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A} + \mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{R} + \mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A} + \mathbf{U_P}^\top\mathbf{P}\mathbf{U_A} \\
&= (\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A} + \mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{R} + \mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A} + \mathbf{S_P}\mathbf{U_P}^\top\mathbf{U_A}
\end{aligned}$$

Writing $\mathbf{S_P}\mathbf{U_P}^\top\mathbf{U_A} = \mathbf{S_P}(\mathbf{U_P}^\top\mathbf{U_A} - \mathbf{W}^*) + \mathbf{S_P}\mathbf{W}^*$ and rearranging terms, we obtain

$$\begin{aligned}
\|\mathbf{W}^*\mathbf{S_A} - \mathbf{S_P}\mathbf{W}^*\|_F &\le \|\mathbf{W}^* - \mathbf{U_P}^\top\mathbf{U_A}\|_F(\|\mathbf{S_A}\| + \|\mathbf{S_P}\|) + \|\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{R}\|_F \\
&\quad + \|\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F \\
&\le O(1) + O(1) + \|\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\|_F\|\mathbf{U_P}^\top\mathbf{U_A}\|
\end{aligned}$$

asymptotically almost surely. Now, $\|\mathbf{U_P}^\top\mathbf{U_A}\| \le 1$. Hence we can focus on the term $\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}$, which is a $d \times d$ matrix whose ij-th entry is of the form

$$\begin{aligned}
(\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P})_{ij} &= \sum_{k=1}^{n}\sum_{l=1}^{n}(\mathbf{A}_{kl} - \mathbf{P}_{kl})\mathbf{U}_{ki}\mathbf{U}_{lj} \\
&= 2\sum_{k,l:k<l}(\mathbf{A}_{kl} - \mathbf{P}_{kl})\mathbf{U}_{ki}\mathbf{U}_{lj} - \sum_k \mathbf{P}_{kk}\mathbf{U}_{ki}\mathbf{U}_{kj}
\end{aligned}$$

where $\mathbf{U}_{\cdot i}$ and $\mathbf{U}_{\cdot j}$ are the i-th and j-th columns of $\mathbf{U_P}$. Thus, conditioned on $\mathbf{P}$, $(\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P})_{ij}$ is a sum of independent mean 0 random variables and a term of order $O(1)$. Now, by Hoeffding's inequality,

$$\Pr\left[\left|\sum_{k,l:k<l} 2(\mathbf{A}_{kl} - \mathbf{P}_{kl})\mathbf{U}_{ki}u_{lj}\right| \ge t\right] \le 2\exp\Big(\frac{-2t^2}{\sum_{k,l:k<l}(2\mathbf{U}_{ki}\mathbf{U}_{lj})^2}\Big) \le 2\exp(-t^2).$$

Therefore, each entry of $\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}$ is of order $O(\log n)$ with high probability, and as a consequence, since $\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}$ is a $d \times d$ matrix,

$$\|\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\|_F = O(\log n) \tag{50}$$

with high probability. We establish that

$$\|\mathbf{W}^*\mathbf{S_A}^{1/2} - \mathbf{S_P}^{1/2}\mathbf{W}^*\|_F = O((\log n)\lambda_d^{-1/2}(\mathbf{P}))$$

by noting that the ij-th entry of $\mathbf{W}^*\mathbf{S_A}^{1/2} - \mathbf{S_P}^{1/2}\mathbf{W}^*$ can be written as

$$\mathbf{W}^*_{ij}(\lambda_i^{1/2}(\mathbf{A}) - \lambda_j^{1/2}(\mathbf{P})) = \mathbf{W}^*_{ij}\frac{\lambda_i(\mathbf{A}) - \lambda_j(\mathbf{P})}{\lambda_i^{1/2}(\mathbf{A}) + \lambda_j^{1/2}(\mathbf{P})},$$

and the desired bound follows from the above after bounding $\lambda_i(\mathbf{A})$, either by Weyl's inequality and Theorem 21, or, alternatively, by a Kato-Temple inequality from Cape et al. (2017a). ■

We next present Theorem 50, which allows us to write the Frobenius norm difference of the adjacency spectral embedding $\hat{\mathbf{X}}$ and the true latent position $\mathbf{X}$ in terms of the Frobenius norm difference of $\mathbf{A}-\mathbf{P}$ and smaller order terms.

Theorem 50 *Let $\mathbf{A} \sim \mathrm{RDPG}(\mathbf{X})$. Then there exists an orthogonal matrix $\mathbf{W}$ such that, with high probability,*

$$\|\hat{\mathbf{X}} - \mathbf{X}\mathbf{W}\|_F = \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\|_F + O((\log n)\delta^{-1/2}(\mathbf{P}))$$

Proof Let

$$\begin{aligned}
\mathbf{R}_1 &= \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A} - \mathbf{U_P}\mathbf{W}^* \\
\mathbf{R}_2 &= (\mathbf{W}^*\mathbf{S_A}^{1/2} - \mathbf{S_P}^{1/2}\mathbf{W}^*).
\end{aligned}$$

We deduce that

$$\begin{aligned}
\hat{\mathbf{X}} - \mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^* &= \mathbf{U_A}\mathbf{S_A}^{1/2} - \mathbf{U_P}W^*\mathbf{S_A}^{1/2} + \mathbf{U_P}(\mathbf{W}^*\mathbf{S_A}^{1/2} - \mathbf{S_P}^{1/2}W^*) \\
&= (\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A})\mathbf{S_A}^{1/2} + \mathbf{R}_1\mathbf{S_A}^{1/2} + \mathbf{U_P}\mathbf{R}_2 \\
&= \mathbf{U_A}\mathbf{S_A}^{1/2} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\mathbf{S_A}^{1/2} + \mathbf{R}_1\mathbf{S_A}^{1/2} + \mathbf{U_P}\mathbf{R}_2
\end{aligned}$$

Observe that $\mathbf{U_P}\mathbf{U_P}^\top\mathbf{P} = \mathbf{P}$ and $\mathbf{U_A}\mathbf{S_A}^{1/2} = \mathbf{A}\mathbf{U_A}\mathbf{S_A}^{-1/2}$. Hence

$$\hat{\mathbf{X}} - \mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^* = (\mathbf{A}-\mathbf{P})\mathbf{U_A}\mathbf{S_A}^{-1/2} - \mathbf{U_P}\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_A}\mathbf{S_A}^{-1/2} + \mathbf{R}_1\mathbf{S_A}^{1/2} + \mathbf{U_P}\mathbf{R}_2$$

Writing

$$\mathbf{R}_3 = \mathbf{U_A} - \mathbf{U_P}\mathbf{W}^* = \mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A} + \mathbf{R}_1,$$

we derive that

$$\begin{aligned}
\hat{\mathbf{X}} - \mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^* &= (\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{W}^*\mathbf{S_A}^{-1/2} - \mathbf{U_P}\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{W}^*\mathbf{S_A}^{-1/2} \\
&\quad + (\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A}-\mathbf{P})\mathbf{R}_3\mathbf{S_A}^{-1/2} + \mathbf{R}_1\mathbf{S_A}^{1/2} + \mathbf{U_P}\mathbf{R}_2
\end{aligned}$$

Recalling that $\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F = O(\delta^{-1/2}(\mathbf{P}))$ with high probability, we have

$$\|\mathbf{R}_1\|_F = O(\delta^{-1}(\mathbf{P})), \quad \|\mathbf{R}_2\|_F = O((\log n)\,\delta^{-1/2}(\mathbf{P})), \quad \text{and } \|\mathbf{R}_3\|_F = O(\delta^{-1/2}(\mathbf{P}))$$

with high probability. Furthermore, a similar application of Hoeffding's inequality to that in the proof of Lemma 49, along with an application of Weyl's inequality and Theorem 21 to bound $\lambda_i(\mathbf{A})$, ensures that

$$\|\mathbf{U_P}\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{W}^*\mathbf{S_A}^{-1/2}\|_F \leq \|\mathbf{U_P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U_P}\|_F\|\mathbf{S_A}^{-1/2}\|_F = O(\log n\delta^{-1/2}(\mathbf{P}))/$$

As a consequence, with high probability

$$\begin{aligned}\|\hat{\mathbf{X}}-\mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^*\|_F &= \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{W}^*\mathbf{S_A}^{-1/2}\|_F + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\\ &= \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\mathbf{W}^* - (\mathbf{A}-\mathbf{P})\mathbf{U_P}(\mathbf{S_P}^{-1/2}\mathbf{W}^* - \mathbf{W}^*\mathbf{S_A}^{-1/2})\|_F\\ &\quad + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\end{aligned}$$

A very similar argument to that employed in the proof of Lemma 49 implies that

$$\|\mathbf{S_P}^{-1/2}\mathbf{W}^* - \mathbf{W}^*\mathbf{S_A}^{-1/2}\|_F = O((\log n)\,\delta^{-3/2}(\mathbf{P}))$$

with high probability. We thus obtain

$$\begin{aligned}\|\hat{\mathbf{X}}-\mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^*\|_F &= \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\mathbf{W}^*\|_F + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\\ &= \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\|_F + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\end{aligned} \tag{51}$$

with high probability. Finally, to complete the proof, we note that $\mathbf{X} = \mathbf{U_P}\mathbf{S_P}^{1/2}\tilde{\mathbf{W}}$ for some orthogonal matrix $\mathbf{W}$. Since $\mathbf{W}^*$ is also orthogonal, we conclude that there exists some orthogonal $\mathbf{W}$ for which $\mathbf{X}\mathbf{W} = \mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}^*$, as desired. ■

We are now ready to prove the $2\to\infty$ consistency we assert in Theorem 26.

Proof

To establish Theorem 26, we note that from Theorem 50

$$\|\hat{\mathbf{X}}-\mathbf{X}\mathbf{W}\|_F = \|(\mathbf{A}-\mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\|_F + O((\log n)\,\delta^{-1/2}(\mathbf{P}))$$

and hence

$$\begin{aligned}\max_i\|\hat{\mathbf{X}}_i-\rho_n^{1/2}\mathbf{W}\mathbf{X}_i\| &\leq \frac{1}{\lambda_d^{1/2}(\mathbf{P})}\max_i\|((\mathbf{A}-\mathbf{P})\mathbf{U_P})_i\| + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\\ &\leq \frac{d^{1/2}}{\lambda_d^{1/2}(\mathbf{P})}\max_j\|(\mathbf{A}-\mathbf{P})\mathbf{U}_{\cdot j}\|_\infty + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\end{aligned}$$

where $\mathbf{U}_{\cdot j}$ denotes the j-th column of $\mathbf{U_P}$. Now, for a given j and a given index i, the i-th element of the vector $(\mathbf{A}-\mathbf{P})\mathbf{U}_{\cdot j}$ is of the form

$$\sum_k(\mathbf{A}_{ik}-\mathbf{P}_{ik})\mathbf{U}_{kj}$$

and once again, by Hoeffding's inequality, the above term is $O(\log n)$ asymptotically almost surely. Taking the union bound over all indices i and all columns j of $\mathbf{U_P}$, we conclude that with high probability,

$$\begin{aligned}\max_i\|\hat{\mathbf{X}}_i-\rho_n^{1/2}\mathbf{W}\mathbf{X}_i\| &\leq \frac{Cd^{1/2}}{\lambda_d^{1/2}(P)}\log^2 n + O((\log n)\,\delta^{-1/2}(\mathbf{P}))\\ &\leq \frac{Cd^{1/2}\log^2 n}{\delta^{1/2}(\mathbf{P})}\end{aligned}$$

as desired. ■

Now, we move to our distributional results.

A.2 Proof of the central limit theorem for the adjacency spectral embedding

.

Recall **Theorem 27**: Let $(\mathbf{A}_n,\mathbf{X}_n)\sim\text{RDPG}(F)$ be a sequence of adjacency matrices and associated latent positions of a d-dimensional random dot product graph according to an inner product distribution F. Let $\Phi(\mathbf{x},\mathbf{\Sigma})$ denote the cdf of a (multivariate) Gaussian with mean zero and covariance matrix $\mathbf{\Sigma}$, evaluated at $\mathbf{x}\in\mathbb{R}^d$. Then there exists a sequence of orthogonal d-by-d matrices $(\mathbf{W}_n)_{n=1}^\infty$ such that for all $\boldsymbol{z}\in\mathbb{R}^d$ and for any fixed index i,

$$\lim_{n\to\infty}\Pr\left[n^{1/2}\left(\hat{\mathbf{X}}_n\mathbf{W}_n-\mathbf{X}_n\right)_i\leq\boldsymbol{z}\right] = \int_{\text{supp}\,F}\Phi\left(\boldsymbol{z},\mathbf{\Sigma}(\mathbf{x})\right)dF(\mathbf{x}),$$

where

$$\mathbf{\Sigma}(\mathbf{x}) = \Delta^{-1}\mathbb{E}\left[(\mathbf{x}^\top\mathbf{X}_1-(\mathbf{x}^\top\mathbf{X}_1)^2)\mathbf{X}_1\mathbf{X}_1^\top\right]\Delta^{-1};\quad\text{and }\Delta=\mathbb{E}[\mathbf{X}_1\mathbf{X}_1^\top]. \tag{52}$$

To prove this, we begin with the following simple lemma which indicates that when the rows of $\mathbf{X}$ are sampled i.i.d. from some distribution F, that the eigenvalues of $\mathbf{X}$ grows proportionally with n.

Lemma 51 *With notation as above, let F be an inner product distribution and suppose $\mathbf{X}_1,\cdots,\mathbf{X}_n,\mathbf{Y}$ be i.i.d F. Suppose also that $\Delta=\mathbb{E}[\mathbf{X}_1\mathbf{X}_1^\top]$ is of rank d. Then for $1\leq i\leq d$, $\lambda_i(\mathbf{P})=\Omega(n\lambda_i(\Delta))$ almost surely.*

Proof Recall that for any matrix $\mathbf{H}$, the nonzero eigenvalues of $\mathbf{H}^\top\mathbf{H}$ are the same as those of $\mathbf{H}\mathbf{H}^\top$, so $\lambda_i(\mathbf{X}\mathbf{X}^\top)=\lambda_i(\mathbf{X}^\top\mathbf{X})$. In what follows, we remind the reader that $\mathbf{X}$ is a matrix whose rows are the tranposes of the column vectors $\mathbf{X}_i$, and $\mathbf{Y}$ is a d-dimensional vector that is independent from and has the same distribution as that of the $\mathbf{X}_i$. We observe that $(\mathbf{X}^\top\mathbf{X}-n\mathbb{E}\mathbf{Y}\mathbf{Y}^\top)_{ij}=\sum_{k=1}^n(\mathbf{X}_{ki}\mathbf{X}_{kj}-\mathbb{E}\mathbf{Y}_i\mathbf{Y}_j)$ is a sum of n independent zero-mean random variables, each contained in $[-1,1]$. Thus, Hoeffding's inequality yields, for all $i,j\in[d]$,

$$\Pr\left[|(\mathbf{X}^\top\mathbf{X})-n\mathbb{E}\mathbf{Y}\mathbf{Y}^\top|_{ij}\geq 2\sqrt{n\log n}\right]\leq\frac{2}{n^2}.$$

A union bound over all $i, j \in [d]$ implies that $\|\mathbf{X}^\top\mathbf{X} - n\mathbb{E}\mathbf{Y}\mathbf{Y}^\top\|_F^2 \leq 4d^2 n \log n$ with probability at least $1 - 2d^2/n^2$. Taking square roots and noting that the Frobenius norm is an upper bound on the spectral norm, we have that $\|\mathbf{X}^\top\mathbf{X} - n\mathbb{E}(\mathbf{Y}\mathbf{Y}^\top)\| \leq 2d\sqrt{n\log n}$ with probability at least $1 - 2d^2/n^2$, and Weyl's inequality yields that for all $1 \leq i \leq d$, $|\lambda_i(\mathbf{X}\mathbf{X}^\top) - n\lambda_i(\mathbb{E}(\mathbf{Y}\mathbf{Y}^\top)| \leq 2d\sqrt{n\log n}$ with probability at least $1 - 2d^2/n^2$. Of course, since the vector $\mathbf{Y}$ has the same distribution as any of the latent positions $\mathbf{X}_i$, we see that $\mathbb{E}(\mathbf{Y}\mathbf{Y}^\top) = \Delta$. By the reverse triangle inequality, for any $1 \leq i \leq d$, we have

$$\lambda_i(\mathbf{X}\mathbf{X}^\top) \geq \lambda_d(\mathbf{X}\mathbf{X}^\top) \geq |n\lambda_d(\Delta) - 2d\sqrt{n\log n}| = \Omega(n).$$

Multiplying through by ρ_n, we find that there exists some constant C so that for all n sufficiently large, $\lambda_d(\rho_n\mathbf{X}\mathbf{X}^\top) \geq n\rho_n\lambda_d(\Delta)$ with probability at least $1 - 2d^2/n^2$. ■

As described previously, to prove our central limit theorem, we require somewhat more precise control on certain residual terms, which we establish in the following key lemma. In the lemmas and proofs that follow, we frequently suppress the dependence of the sequence of graphs and embeddings on n.

Lemma 52 *Let $\mathbf{R}_1, \mathbf{R}_2, \mathbf{R}_3$ be defined, as above, by*

$$\begin{aligned}
\mathbf{R}_1 &= \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{W}^* \\
\mathbf{R}_2 &= \mathbf{W}^*\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^* \\
\mathbf{R}_3 &= \mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} + \mathbf{R}_1 = \mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{W}^*.
\end{aligned}$$

where, as before, $\mathbf{W}^*$ is the orthogonal transformation $\mathbf{W}^* = \mathbf{W}_1\mathbf{W}_2^\top$ with $\mathbf{W}_1\Sigma\mathbf{W}_2$ being the singular value decomposition of $\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A}$. Then the following convergences in probability hold:

$$\sqrt{n}\Big[(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*)\Big]_h \xrightarrow{P} \mathbf{0}, \tag{53}$$

$$\sqrt{n}\Big[\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2}\Big]_h \xrightarrow{P} \mathbf{0}, \tag{54}$$

$$\sqrt{n}\Big[(\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{R}_3\mathbf{S}_\mathbf{A}^{-1/2}\Big]_h \xrightarrow{P} \mathbf{0}, \tag{55}$$

and with high probability,

$$\|\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2} + \mathbf{U}_\mathbf{P}\mathbf{R}_2\|_F \leq \frac{C\log n}{n^{1/2}}.$$

Proof We begin by observing that

$$\|\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2} + \mathbf{U}_\mathbf{P}\mathbf{R}_2\|_F \leq \|\mathbf{R}_1\|_F\|\mathbf{S}_\mathbf{A}^{1/2}\| + \|\mathbf{R}_2\|_F.$$

Proposition 48 and the trivial upper bound on the eigenvalues of $\mathbf{A}$ ensures that

$$\|\mathbf{R}_1\|_F\|\mathbf{S}_\mathbf{A}^{1/2}\| \leq \frac{C\log n}{n^{1/2}} \text{ w.h.p. },$$

Combining this with Eq. (49) in Lemma 49, we conclude that

$$\|\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2} + \mathbf{U}_\mathbf{P}\mathbf{R}_2\|_F \leq \frac{C\log n}{n^{1/2}} \text{ w.h.p.}$$

We will establish (53), (54) and (55) order. To see (53), observe that

$$\sqrt{n}\|(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*)\|_F \leq \sqrt{n}\|(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\|\|\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*\|_F,$$

and Lemma 49 imply that with high probability

$$\sqrt{n}\|(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*)\|_F \leq \frac{C\log n}{\sqrt{n}},$$

which goes to 0 as $n \to \infty$.

To show the convergence in (54), we recall that $\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W} = \mathbf{X}$ for some orthogonal matrix $\mathbf{W}$ and observe that since the rows of the latent position matrix $\mathbf{X}$ are necessarily bounded in Euclidean norm by 1, and since the top d eigenvalues of $\mathbf{P}$ are of order n (recall Lemma 51), it follows that

$$\|\mathbf{U}_\mathbf{P}\|_{2\to\infty} \leq Cn^{-1/2} \text{ w.h.p.} \tag{56}$$

Next, (50) and Lemma 51 imply that

$$\begin{aligned}
\|(\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2})_h\| &\leq \|\mathbf{U}_\mathbf{P}\|_{2\to\infty}\|\mathbf{U}_\mathbf{P}^\top(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}\|\|\mathbf{S}_\mathbf{A}^{-1/2}\| \\
&\leq \frac{C\log n}{n} \text{ w.h.p.},
\end{aligned}$$

which implies (54). Finally, to establish (55), we must bound the Euclidean norm of the vector

$$\Big[(\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{R}_3\mathbf{S}_\mathbf{A}^{-1/2}\Big]_h, \tag{57}$$

where, as defined above, $\mathbf{R}_3 = \mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{W}^*$. Let $\mathbf{B}_1$ and $\mathbf{B}_2$ be defined as follows:

$$\begin{aligned}
\mathbf{B}_1 &= (\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{-1/2} \\
\mathbf{B}_2 &= (\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} - \mathbf{W}^*)\mathbf{S}_\mathbf{A}^{-1/2}
\end{aligned} \tag{58}$$

Recalling that $\mathbf{R}_3 = \mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{W}^*$, we have

$$\begin{aligned}
(\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{R}_3\mathbf{S}_\mathbf{A}^{-1/2} &= (\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A})\mathbf{S}_\mathbf{A}^{-1/2} \\
&\quad + (\mathbf{I} - \mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top\mathbf{U}_\mathbf{A} - \mathbf{U}_\mathbf{P}\mathbf{W}^*)\mathbf{S}_\mathbf{A}^{-1/2} \\
&= \mathbf{B}_1 + \mathbf{B}_2.
\end{aligned}$$

We will bound the Euclidean norm of the h-th row of each of these two matrices on the right-hand side, from which a triangle inequality will yield our desired bound on the quantity in Equation (57). Recall that we use C to denote a positive constant, independent of n and m, which may change from line to line.

Let us first consider $\mathbf{B}_2 = (\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{U_P}(\mathbf{U_P}^\top\mathbf{U_A} - \mathbf{W}^*)\mathbf{S_A}^{-1/2}$. We have

$$\|\mathbf{B}_2\|_F \leq \|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{U_P}\|\|\mathbf{U_P}^\top\mathbf{U_A} - \mathbf{W}^*\|_F\|\mathbf{S_A}^{-1/2}\|.$$

By submultiplicativity of the spectral norm and Theorem20, $\|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})\mathbf{U_P}\| \leq Cn^{1/2}\log^{1/2} n$ with high probability (and indeed, under our degree assumptions and Theorem 21, the $\log n$ factor can be dropped). From Prop. 48 and Lemma 51, respectively, we have with high probability

$$\|\mathbf{U_P}^\top\mathbf{U_A} - \mathbf{W}^*\|_F \leq Cn^{-1}\log n \quad \text{and} \quad \|\mathbf{S_A}^{-1/2}\| \leq Cn^{-1/2}$$

Thus, we deduce that with high probability,

$$\|\mathbf{B}_2\|_F \leq \frac{C\log^{3/2} n}{n} \tag{59}$$

from which it follows that $\|\sqrt{n}\mathbf{B}_2\|_F \xrightarrow{P} 0$, and hence $\|\sqrt{n}(\mathbf{B}_2)_h\| \xrightarrow{P} 0$.

Turning our attention to $\mathbf{B}_1$, and recalling that $\mathbf{U_A}^\top\mathbf{U_A} = \mathbf{I}$, we note that

$$\begin{aligned}
\|(\mathbf{B}_1)_h\| &= \left\|\left[(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{S_A}^{-1/2}\right]_h\right\| \\
&= \left\|\left[(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\mathbf{U_A}\mathbf{S_A}^{-1/2}\right]_h\right\| \\
&\leq \left\|\mathbf{U_A}\mathbf{S_A}^{-1/2}\right\|\left\|\left[(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right]_h\right\|.
\end{aligned}$$

Let $\epsilon > 0$ be a constant. We will show that

$$\lim_{n\to\infty} \Pr\left[\|\sqrt{n}(\mathbf{B}_1)_h\| > \epsilon\right] = 0. \tag{60}$$

For ease of notation, define

$$\mathbf{E}_1 = (\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top.$$

We will show that

$$\lim_{n\to\infty} \Pr\left[\sqrt{n}\,\|[\mathbf{E}_1]_h\| > n^{1/4}\right] = 0, \tag{61}$$

which will imply (60) since, by Lemma 51, $\|\mathbf{U_A}\mathbf{S_A}^{-1/2}\| \leq Cn^{-1/2}$ with high probability. Let $\mathbf{Q} \in \mathbb{R}^{n\times n}$ be any permutation matrix. We observe that

$$\mathbf{Q}\mathbf{U_P}\mathbf{U_P}^\top\mathbf{Q}^\top\mathbf{Q}\mathbf{P}\mathbf{Q}^\top = \mathbf{Q}\mathbf{P}\mathbf{Q}^\top,$$

and thus $\mathbf{Q}\mathbf{U_P}\mathbf{U_P}^\top\mathbf{Q}^\top$ is a projection matrix for $\mathbf{Q}\mathbf{P}\mathbf{Q}^\top$ if and only if $\mathbf{U_P}\mathbf{U_P}^\top$ is a projection matrix for $\mathbf{P}$. A similar argument applies to the matrix $\mathbf{U_A}\mathbf{U_A}^\top$. Combining this with the exchangeability structure of the matrix $\mathbf{A} - \mathbf{P}$, it follows that the Frobenius norms of the rows of $\mathbf{E}_1$ are equidistributed. This row-exchangeability for $\mathbf{E}_1$ implies that $n\mathbb{E}\|(\mathbf{E}_1)_h\|^2 = \|\mathbf{E}_1\|_F^2$. Applying Markov's inequality,

$$\begin{aligned}
\Pr\left[\left\|\sqrt{n}\,[\mathbf{E}_1]_h\right\| > t\right] &\leq \frac{n\mathbb{E}\left\|\left[(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right]_h\right\|^2}{t^2} \\
&= \frac{\mathbb{E}\left\|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right\|_F^2}{t^2}.
\end{aligned} \tag{62}$$

We will proceed by showing that with high probability,

$$\left\|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right\|_F \leq C\log n, \tag{63}$$

whence choosing $t = n^{1/4}$ in (62) yields that

$$\lim_{n\to\infty} \Pr\left[\left\|\sqrt{n}\left[(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right]_h\right\| > n^{1/4}\right] = 0,$$

and (60) will follow. We have

$$\left\|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right\|_F \leq \|\mathbf{A} - \mathbf{P}\|\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F\|\mathbf{U_A}\|$$

Theorem 21 and Lemma 51 implies that the first term in this product is at most $Cn^{1/2}$ high probability, and the final term in this product is, trivially, at most 1. To bound the second term, we will follow reasoning similar to that in Lemma 49, combined with the Davis-Kahan theorem. The Davis-Kahan Theorem implies that for a suitable constant $C > 0$,

$$\|\mathbf{U_A}\mathbf{U_A}^\top - \mathbf{U_P}\mathbf{U_P}^\top\| \leq \frac{C\|\mathbf{A} - \mathbf{P}\|}{\lambda_d(\mathbf{P})}.$$

By Theorem 2 in Yu et al. (2015), there exists orthonormal $\mathbf{W} \in \mathbb{R}^{d\times d}$ such that

$$\|\mathbf{U_A} - \mathbf{U_P}\mathbf{W}\|_F \leq C\|\mathbf{U_A}\mathbf{U_A}^\top - \mathbf{U_P}\mathbf{U_P}^\top\|_F.$$

We observe further that the multivariate linear least squares problem

$$\min_{\mathbf{T}\in\mathbb{R}^{d\times d}} \|\mathbf{U_A} - \mathbf{U_P}\mathbf{T}\|_F^2$$

is solved by $\mathbf{T} = \mathbf{U_P}^\top\mathbf{U_A}$. Combining all of the above, we find that

$$\begin{aligned}
\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F^2 \leq \|\mathbf{U_A} - \mathbf{U_P}\mathbf{W}\|_F^2 &\leq C\|\mathbf{U_A}\mathbf{U_A}^\top - \mathbf{U_P}\mathbf{U_P}^\top\|_F^2 \\
&\leq C\|\mathbf{U_A}\mathbf{U_A}^\top - \mathbf{U_P}\mathbf{U_P}^\top\|^2 \leq \left(\frac{C\|\mathbf{A} - \mathbf{P}\|}{\lambda_d(\mathbf{P})}\right)^2 \leq \frac{C}{n} \quad \text{w.h.p.}
\end{aligned}$$

We conclude that

$$\begin{aligned}
\left\|(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)(\mathbf{A} - \mathbf{P})(\mathbf{I} - \mathbf{U_P}\mathbf{U_P}^\top)\mathbf{U_A}\mathbf{U_A}^\top\right\|_F &\leq C\|\mathbf{A} - \mathbf{P}\|\|\mathbf{U_A} - \mathbf{U_P}\mathbf{U_P}^\top\mathbf{U_A}\|_F\|\mathbf{U_A}\|_S \\
&\leq C\log n \text{ w.h.p. ,}
\end{aligned}$$

which implies (63), as required, and thus the convergence in (55) is established, completing the proof. ■

Next, recall the inherent nonidentifiability in the RDPG model: suppose the "true" latent positions are some matrix $\mathbf{X}$. Then $\mathbf{X} = \mathbf{U_P}\mathbf{S_P}^{1/2}\mathbf{W}$ for some suitably-chosen orthogonal matrix $\mathbf{W}$. We now consider the asymptotic distribution of

$$n^{1/2}\mathbf{W}_n^\top\left[(\mathbf{A} - \mathbf{P})\mathbf{U_P}\mathbf{S_P}^{-1/2}\right]_h$$

conditional on $\mathbf{X}_i = \mathbf{x}_i$. Because we can write suitable terms of $\mathbf{A} - \mathbf{P}$ as the sum of independent random variables, we can invoke the Lindeberg-Feller Central Limit Theorem to establish the asymptotic normality of

$$n^{1/2}\mathbf{W}_n^\top \Big[(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\Big]_h$$

as follows.

Lemma 53 *Fix some $i \in [n]$. Conditional on $\mathbf{X}_i = \mathbf{x}_i \in \mathbb{R}^d$, there exists a sequence of d-by-d orthogonal matrices $\{\mathbf{W}_n\}$ such that*

$$n^{1/2}\mathbf{W}_n^\top \Big[(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\Big]_h \xrightarrow{\mathcal{L}} \mathcal{N}(0, \mathbf{\Sigma}(\mathbf{x}_i)),$$

where $\mathbf{\Sigma}(\mathbf{x}_i) \in \mathbb{R}^{d\times d}$ is a covariance matrix that depends on $\mathbf{x}_i$.

Proof For each n, choose orthogonal $\mathbf{W}_n \in \mathbb{R}^{d\times d}$ so that $\mathbf{X} = \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}_n$. At least one such $\mathbf{W}_n$ exists for each value of n, since, as discussed previously, the true latent positions $\mathbf{X}$ are specified only up to some orthogonal transformation. We then have

$$\begin{aligned}
n^{1/2}\mathbf{W}_n^\top \Big[(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\Big]_i &= n^{1/2}\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\left[\mathbf{A}\mathbf{X}-\mathbf{P}\mathbf{X}\right]_i \\
&= n^{1/2}\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\left(\sum_{j=1}^n (\mathbf{A}_{ij}-\mathbf{P}_{ij})\,\mathbf{X}_j\right) \\
&= n^{1/2}\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\left(\sum_{j\neq i} (\mathbf{A}_{ij}-\mathbf{P}_{ij})\,\mathbf{X}_j\right) - n^{1/2}\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\mathbf{P}_{ii}\mathbf{X}_i \\
&= \big(n\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\big)\left[n^{-1/2}\sum_{j\neq i} (\mathbf{A}_{ij}-\mathbf{P}_{ij})\,\mathbf{X}_j\right] - n\mathbf{W}_n^\top\mathbf{S}_\mathbf{P}^{-1}\mathbf{W}_n\frac{\mathbf{P}_{ii}\mathbf{X}_i}{n^{1/2}}.
\end{aligned}$$

Conditioning on $\mathbf{X}_i = \mathbf{x}_i \in \mathbb{R}^d$, we first observe that $\frac{\mathbf{P}_{ii}}{n^{1/2}}\mathbf{X}_i = \frac{\mathbf{x}_i^\top\mathbf{x}_i}{n^{1/2}}x_i \to 0$ almost surely. Furthermore,

$$n^{-1/2}\sum_{j\neq i}(\mathbf{A}_{ij}-\mathbf{P}_{ij})\,\mathbf{X}_j = n^{-1/2}\sum_{j\neq i}\big(\mathbf{A}_{ij}-\mathbf{X}_j^\top\mathbf{x}_i\big)\mathbf{X}_j$$

is a scaled sum of $n-1$ independent 0-mean random variables, each with covariance matrix given by

$$\tilde{\mathbf{\Sigma}}(\mathbf{x}_i) = \mathbb{E}\left[\big(\mathbf{x}_i^\top\mathbf{X}_j - (\mathbf{x}_i^\top\mathbf{X}_j)^2\big)\,\mathbf{X}_j\mathbf{X}_j^\top\right].$$

The multivariate central limit theorem thus implies that

$$n^{-1/2}\sum_{j\neq i}\big(\mathbf{A}_{ij}-\mathbf{X}_j\mathbf{x}_i^\top)\mathbf{X}_j\big) \xrightarrow{\mathcal{L}} \mathcal{N}(\mathbf{0}, \tilde{\mathbf{\Sigma}}(\mathbf{x}_i)). \tag{64}$$

Finally, by the strong law of large numbers,

$$n^{-1}\mathbf{W}_n^\top\mathbf{S}_{\mathbf{P}_n}\mathbf{W}_n = \frac{1}{n}\mathbf{X}^\top\mathbf{X} \to \mathbf{\Delta} \text{ a.s.}$$

and thus $(n\mathbf{W}_n^\top\mathbf{S}_{\mathbf{P}_n}^{-1}\mathbf{W}_n) \to \mathbf{\Delta}^{-1}$ almost surely. Combining this fact with (64), the multivariate version of Slutsky's theorem yields

$$n^{1/2}\mathbf{W}_n^\top\Big[(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\Big]_h \xrightarrow{\mathcal{L}} \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}(\mathbf{x}_i))$$

where $\mathbf{\Sigma}(\mathbf{x}_i) = \mathbf{\Delta}^{-1}\tilde{\mathbf{\Sigma}}(\mathbf{x}_i)\mathbf{\Delta}^{-1}$. Integrating over the possible values of $\mathbf{x}_i$ with respect to distribution F completes the proof. ■

Lemmas 52 and 53 are the main ingredients in the proof of Theorem 27, whose proof now follows easily:

Proof [Proof of Theorem 27]. We start with the following decomposition that was originally used in the proof of Theorem 50.

$$\begin{aligned}
\sqrt{n}\left(\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^*\right) &= \sqrt{n}(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^* + \sqrt{n}(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*) \\
&\quad - \sqrt{n}\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} \\
&\quad + \sqrt{n}(\mathbf{I}-\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A}-\mathbf{P})\mathbf{R}_3\mathbf{S}_\mathbf{A}^{-1/2} + \sqrt{n}\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2} + \sqrt{n}\mathbf{U}_\mathbf{P}\mathbf{R}_2.
\end{aligned} \tag{65}$$

Now given any index i, Lemma 52 can be used to bound the Euclidean norms of the i-th rows of

$$(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}(\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2} - \mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*),$$
$$\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top(\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{W}^*\mathbf{S}_\mathbf{A}^{-1/2}$$

and

$$(\mathbf{I}-\mathbf{U}_\mathbf{P}\mathbf{U}_\mathbf{P}^\top)(\mathbf{A}-\mathbf{P})\mathbf{R}_3\mathbf{S}_\mathbf{A}^{-1/2}.$$

The Euclidean norms of the i-th row of $\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2}$ and $\mathbf{U}_\mathbf{P}\mathbf{R}_2$ can be bounded from above by the bounds on $\|\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2}\|_{2\to\infty}$ and $\|\mathbf{U}_\mathbf{P}\mathbf{R}_2\|_{2\to\infty}$. Since

$$\|\mathbf{U}_\mathbf{P}\|_{2\to\infty} = O(n^{-1/2})$$

by Eq. (56), we conclude that

$$\sqrt{n}\|\mathbf{R}_1\mathbf{S}_\mathbf{A}^{1/2}\|_{2\to\infty} = O(n^{-1/2}\log^{1/2} n)$$

and

$$\sqrt{n}\|\mathbf{U}_\mathbf{P}\mathbf{R}_2\|_{2\to\infty} = O(n^{-1/2}\log^{1/2} n)$$

Therefore, for any fixed index i, we have

$$\sqrt{n}\left(\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2} - \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}^*\right)_i = \sqrt{n}((\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W}^*)_i + O(n^{-1/2}\log^{1/2} n)$$

with high probability. Since $\mathbf{X} = \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}\mathbf{W}$, we can rewrite the above expression as

$$\sqrt{n}\left(\mathbf{U}_\mathbf{A}\mathbf{S}_\mathbf{A}^{1/2}(\mathbf{W}^*)^\top\mathbf{W} - \mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{1/2}\mathbf{W}\right)_i = \sqrt{n}((\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W})_i + O(n^{-1/2}\log^{1/2} n).$$

Lemma 53 then establishes the asymptotic normality of $\sqrt{n}((\mathbf{A}-\mathbf{P})\mathbf{U}_\mathbf{P}\mathbf{S}_\mathbf{P}^{-1/2}\mathbf{W})_i$ as desired. ■

We now turn out attention a brief sketch of the proof of the central limit theorem for the Laplacian spectral embedding.

A.3 Sketch of proof of Theorem 29

We present in this subsection a sketch of the main ideas in the proof of Theorem 29; detailed proofs are given in Tang and Priebe (2018). We first introduce some additional notation. For $(\mathbf{X}_n, \mathbf{A}_n) \sim \text{RDPG}(F)$, let $\mathbf{T}_n = \text{diag}(\mathbf{P}_n\mathbf{1})$ be the $n \times n$ diagonal matrices whose diagonal entries are the *expected* vertex degrees. Then defining $\tilde{\mathbf{X}}_n = \mathbf{T}_n^{-1/2}\mathbf{X}_n$, and noting that $\tilde{\mathbf{X}}_n\tilde{\mathbf{X}}_n^\top = \mathcal{L}(\mathbf{P}_n) = \mathbf{T}_n^{-1/2}\mathbf{P}_n\mathbf{T}_n^{-1/2}$, Theorem 29 depends on showing that there exists an orthogonal matrix $\mathbf{W}_n$ such that

$$\check{\mathbf{X}}_n\mathbf{W}_n - \tilde{\mathbf{X}}_n = \mathbf{T}_n^{-1/2}(\mathbf{A}_n - \mathbf{P}_n)\mathbf{T}_n^{-1/2}\tilde{\mathbf{X}}_n(\tilde{\mathbf{X}}_n^\top\tilde{\mathbf{X}}_n)^{-1} + \tfrac{1}{2}(\mathbf{I} - \mathbf{D}_n\mathbf{T}_n^{-1})\tilde{\mathbf{X}}_n + \mathbf{R}_n \tag{66}$$

where $\|\mathbf{R}_n\|_F = O(n^{-1})$ with high probability. The motivation behind Eq. (66) is as follows. Given $\tilde{\mathbf{X}}_n$, the entries of the right hand side of Eq. (66), except for the term $\mathbf{R}_n$, can be expressed explicitly in terms of linear combinations of the entries $a_{ij} - p_{ij}$ of $\mathbf{A}_n - \mathbf{P}_n$. This is in contrast with the left hand side of Eq. (66), which depends on the quantities $\mathbf{U}_{\mathcal{L}(\mathbf{A}_n)}$ and $\mathbf{S}_{\mathcal{L}(\mathbf{A}_n)}$ (recall Definition 18). Since the quantities $\mathbf{U}_{\mathcal{L}(\mathbf{A}_n)}$ and $\mathbf{S}_{\mathcal{L}(\mathbf{A}_n)}$ can not be expressed explicitly in terms of the entries of $\mathbf{A}_n$ and $\mathbf{P}_n$, we conclude that the right hand side of Eq. (66) is simpler to analyze.

Once Eq. (66) is established, we can derive Theorem 29 as follows. Let ξ_i denote the i-th row of $n(\check{\mathbf{X}}_n\mathbf{W}_n - \tilde{\mathbf{X}}_n)$ and let r_i denote the i-th row of $\mathbf{R}_n$. Eq. (66) then implies

$$\begin{aligned}
\xi_i &= (\tilde{\mathbf{X}}_n^\top\tilde{\mathbf{X}}_n)^{-1}\frac{n}{\sqrt{t_i}}\Big(\sum_j \frac{a_{ij} - p_{ij}}{\sqrt{t_j}}(\tilde{\mathbf{X}}_n)_j\Big) + \frac{n(t_i - d_i)}{2t_i}(\tilde{\mathbf{X}}_n)_i + nr_i \\
&= (\tilde{\mathbf{X}}_n^\top\tilde{\mathbf{X}}_n)^{-1}\frac{\sqrt{n}}{\sqrt{t_i}}\Big(\sum_j \frac{\sqrt{n\rho_n}(a_{ij} - p_{ij})(\mathbf{X}_n)_j}{t_j}\Big) - \frac{n(\mathbf{X}_n)_i}{2t_i^{3/2}}\sum_j(a_{ij} - p_{ij}) + nr_i \\
&= \frac{\sqrt{n}}{\sqrt{t_i}}\sum_j \frac{(a_{ij} - p_{ij})}{\sqrt{n}}\Big(\frac{(\tilde{\mathbf{X}}_n^\top\tilde{\mathbf{X}}_n)^{-1}(\mathbf{X}_n)_j}{t_j/n} - \frac{(\mathbf{X}_n)_i}{2t_i/n}\Big) + nr_i
\end{aligned}$$

where a_{ij} and p_{ij} are the ij-th entries of $\mathbf{A}$ and $\mathbf{P}$, respectively, and t_i is the i-th diagonal entry of $\mathbf{T}_n$. We can then show that $nr_i \xrightarrow{\text{d}} 0$. Indeed, there are n rows in $\mathbf{R}_n$ and $\|\mathbf{R}_n\|_F = O(n^{-1})$; hence, on average, for each index i, $\|r_i\|^2 = O(n^{-3})$ with high probability (a more precise argument similar to that used in proving Lemma 52 is needed to establish this rigorously). Furthermore,

$$t_i/n = \sum_j (\mathbf{X}_n)_i^\top(\mathbf{X}_n)_j/n \xrightarrow{\text{a.s.}} (\mathbf{X}_n)_i^\top\boldsymbol{\mu}$$

as $n \to \infty$. Finally,

$$\tilde{\mathbf{X}}_n^\top\tilde{\mathbf{X}}_n = \sum_i\big((\mathbf{X}_n)_i(\mathbf{X}_n)_i^\top/(\sum_j (\mathbf{X}_n)_i^\top(\mathbf{X}_n)_j)\big),$$

and this can be shown to converge to $\tilde{\Delta} = \mathbb{E}\big[\frac{\mathbf{X}_1\mathbf{X}_1^\top}{\mathbf{X}_1^\top\boldsymbol{\mu}}\big]$ as $n \to \infty$. We therefore have, after additional algebraic manipulations, that

$$\begin{aligned}
\xi_i &= \frac{\sqrt{n}}{\sqrt{t_i}}\sum_j \frac{(a_{ij} - p_{ij})}{\sqrt{n}}\Big(\frac{\tilde{\Delta}^{-1}(\mathbf{X}_n)_j}{(\mathbf{X}_n)_j^\top\boldsymbol{\mu}} - \frac{(\mathbf{X}_n)_i}{2(\mathbf{X}_n)_i^\top\boldsymbol{\mu}}\Big) + o(1) \\
&= \frac{\sqrt{n}}{\sqrt{t_i}}\sum_j \frac{(a_{ij} - (\mathbf{X}_n)_i^\top(\mathbf{X}_n)_j)}{\sqrt{n}}\Big(\frac{\tilde{\Delta}^{-1}(\mathbf{X}_n)_j}{(\mathbf{X}_n)_j^\top\boldsymbol{\mu}} - \frac{(\mathbf{X}_n)_i}{2(\mathbf{X}_n)_i^\top\boldsymbol{\mu}}\Big) + o(1)
\end{aligned}$$

with high probability. Conditioning on $(\mathbf{X}_n)_i = \boldsymbol{x}$, the above expression for ξ_i is roughly a sum of independent and identically distributed mean 0 random variables. The multivariate central limit theorem can then be applied to the above expression for ξ_i, thereby yielding Theorem 29.

We now sketch the derivation of Eq. (66). For simplicity of notation, we shall ignore the subscript n in the matrices $\mathbf{A}_n$, $\mathbf{X}_n$, $\mathbf{P}_n$ and related matrices. First, consider the following expression.

$$\begin{aligned}
\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{1/2} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} &= \mathcal{L}(\mathbf{A})\tilde{\mathbf{U}}_{\mathcal{L}(\mathbf{A})}\tilde{\mathbf{S}}_{\mathcal{L}(\mathbf{A})}^{-1/2} - \mathcal{L}(\mathbf{P})\tilde{\mathbf{U}}_{\mathcal{L}(\mathbf{P})}\tilde{\mathbf{S}}_{\mathcal{L}(\mathbf{P})}^{-1/2}\tilde{\mathbf{U}}_{\mathcal{L}(\mathbf{P})}^\top\tilde{\mathbf{U}}_{\mathcal{L}(\mathbf{A})} \\
&= \mathcal{L}(\mathbf{A})\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{U}_{\mathcal{L}(\mathbf{A})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2} - \mathcal{L}(\mathbf{P})\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}
\end{aligned} \tag{67}$$

Now $\mathcal{L}(\mathbf{A})$ is concentrated around $\mathcal{L}(\mathbf{P})$: namely, in the current setting,

$$\|\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P})\| = O(n^{-1/2})$$

with high probability (see Theorem 2 in Lu and Peng, 2013). Since $\|\mathcal{L}(\mathbf{P})\| = \Theta(1)$ and the non-zero eigenvalues of $\mathcal{L}(\mathbf{P})$ are all of order $\Theta(1)$, this again implies, by the Davis-Kahan theorem, that the eigenspace spanned by the d largest eigenvalues of $\mathcal{L}(\mathbf{A})$ is "close" to that spanned by the d largest eigenvalues of $\mathcal{L}(\mathbf{P})$. More precisely, $\|\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}\| = O(n^{-1/2})$ with high probability, and

$$\begin{aligned}
\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{1/2} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} &= \mathcal{L}(\mathbf{A})\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2} \\
&\quad - \mathcal{L}(\mathbf{P})\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} + \mathbf{R}_n
\end{aligned}$$

where $\|\mathbf{R}_n\| = O(n^{-1})$ with high probability. In addition, $\|\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}\| = O(n^{-1/2})$ also implies that there exists an orthogonal matrix $\mathbf{W}^*$ such that $\|\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{W}^*\| = O(n^{-1})$ with high probability.

We next consider the terms $\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}$ and $\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2}$. Note that the both are $d \times d$ matrices; furthermore, since $\mathbf{S}_{\mathcal{L}(\mathbf{A})}$ and $\mathbf{S}_{\mathcal{L}(\mathbf{P})}$ are diagonal matrices, the ij-th entry of $\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2}$ can be written as the $\zeta_{ij} \times h_{ij}$ where ζ_{ij} is the ij-th entry of $\mathbf{S}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}$ and the h_{ij} are functions of $\lambda_i(\mathcal{L}(\mathbf{A}))$

and $\lambda_j(\mathcal{L}(\mathbf{P}))$. In particular, $|h_{ij}| < C$ for some positive constant C for all n. We then have that

$$\begin{aligned}\mathbf{S}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})} &= \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top(\mathcal{L}(\mathbf{P}) - \mathcal{L}(\mathbf{A}))\mathbf{U}_{\mathcal{L}(\mathbf{A})} \\ &= \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top(\mathcal{L}(\mathbf{P}) - \mathcal{L}(\mathbf{A}))\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} \\ &+ \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top((\mathcal{L}(\mathbf{P}) - \mathcal{L}(\mathbf{A}))(\mathbf{I} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top)\mathbf{U}_{\mathcal{L}(\mathbf{A})}\end{aligned}$$

Now, conditioning on $\mathbf{P}$, the ij-th entry of $\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top(\mathcal{L}(\mathbf{P}) - \mathcal{L}(\mathbf{A}))\mathbf{U}_{\mathcal{L}(\mathbf{P})}$ can be written as a linear combination of the entries of $\mathbf{A} - \mathbf{P}$ (which are independent) and the rows of $\mathbf{X}$; hence, it can be bounded using Hoeffding's inequality. Meanwhile, the term

$$\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top((\mathcal{L}(\mathbf{P}) - \mathcal{L}(\mathbf{A}))(\mathbf{I} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top)\mathbf{U}_{\mathcal{L}(\mathbf{A})}$$

can be bounded by the Davis-Kahan Theorem and the spectral norm difference of $\|\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P})\|$. We therefore arrive at the important fact that

$$\|\mathbf{S}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}\|_F = O(n^{-1})$$

with high probability, and hence

$$\|\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2}\| = O(n^{-1})$$

with high probability.

We can juxtapose $\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}$ and $\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{-1/2}$ in the expression for Eq. (67) and then replace $\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top\mathbf{U}_{\mathcal{L}(\mathbf{A})}$ by the orthogonal matrix $\mathbf{W}^*$, thereby obtaining

$$\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{1/2} - \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{1/2}\mathbf{W}^* = (\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P}))\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{W}^* + \tilde{\mathbf{R}}_n$$

where $\|\tilde{\mathbf{R}}_n\| = O(n^{-1})$ with high probability. Since

$$\tilde{\mathbf{X}}\tilde{\mathbf{X}}^\top = \mathcal{L}(\mathbf{P}) = \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}\mathbf{U}_{\mathcal{L}(\mathbf{P})}^\top,$$

we have $\tilde{\mathbf{X}} = \mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{1/2}\tilde{\mathbf{W}}$ for some orthogonal matrix $\tilde{\mathbf{W}}$. Therefore,

$$\begin{aligned}\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{1/2} - \tilde{\mathbf{X}}\tilde{\mathbf{W}}^\top\mathbf{W}^* &= (\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P}))\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1/2}\mathbf{W}^* + \tilde{\mathbf{R}}_n \\ &= (\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P}))\mathbf{U}_{\mathcal{L}(\mathbf{P})}\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{1/2}\tilde{\mathbf{W}}\tilde{\mathbf{W}}^\top\mathbf{S}_{\mathcal{L}(\mathbf{P})}^{-1}\tilde{\mathbf{W}}\tilde{\mathbf{W}}^\top\mathbf{W}^* + \tilde{\mathbf{R}}_n \\ &= (\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P}))\tilde{\mathbf{X}}(\tilde{\mathbf{X}}^\top\tilde{\mathbf{X}})^{-1}\tilde{\mathbf{W}}^\top\mathbf{W}^* + \tilde{\mathbf{R}}_n.\end{aligned}$$

Equivalently,

$$\mathbf{U}_{\mathcal{L}(\mathbf{A})}\mathbf{S}_{\mathcal{L}(\mathbf{A})}^{1/2}(\mathbf{W}^*)^\top\tilde{\mathbf{W}} - \tilde{\mathbf{X}} = (\mathcal{L}(\mathbf{A}) - \mathcal{L}(\mathbf{P}))\tilde{\mathbf{X}}(\tilde{\mathbf{X}}^\top\tilde{\mathbf{X}})^{-1} + \tilde{\mathbf{R}}_n(\mathbf{W}^*)^\top\tilde{\mathbf{W}}. \tag{68}$$

The right hand side of Eq. (68) — except for the residual term $\tilde{\mathbf{R}}_n(\mathbf{W}^*)^\top\tilde{\mathbf{W}}$ which has norm of order $O(n^{-1})$ with high probability — can now be written explicitly in terms of the entries of $\mathbf{A}$ and $\mathbf{P}$. However, since

$$\mathcal{L}(\mathbf{A}) = \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2},$$

the entries of the right hand side of Eq. (68) are neither linear nor affine combinations of the entries of $\mathbf{A} - \mathbf{P}$. Nevertheless, a Taylor-series expansion of the entries of $\mathbf{D}^{-1/2}$ allows us to conclude that

$$\|\mathbf{D}^{-1/2} - \mathbf{T}^{-1/2} - \tfrac{1}{2}\mathbf{T}^{-3/2}(\mathbf{T} - \mathbf{D})\| = O(n^{-3/2})$$

with high probability. Substituting this into Eq. (68) yields, after a few further algebraic simplifications, Eq. (66).

Abstract

A binary classification problem is considered. The excess error probability of the k-nearest-neighbor classification rule according to the error probability of the Bayes decision is revisited by a decomposition of the excess error probability into approximation and estimation errors. Under a weak margin condition and under a modified Lipschitz condition or a local Lipschitz condition, tight upper bounds are presented such that one avoids the condition that the feature vector is bounded. The concept of modified Lipschitz condition is applied for discrete distributions, too. As a consequence of both concepts, we present the rate of convergence of L_2 error for the corresponding nearest neighbor regression estimate.

Keywords: rate of convergence, classification, error probability, k-nearest-neighbor rule

1. Introduction

Let the feature vector X take values in $\mathbb{R}^d$, and let its label Y be ± 1 valued. If g is an arbitrary decision function then its error probability is denoted by

$$L(g) = \mathbb{P}\{g(X) \neq Y\}.$$

Put

$$D(x) = \mathbb{E}\{Y \mid X = x\},$$

then the Bayes decision g^* minimizes the error probability:

$$g^*(x) = sign\, D(x),$$

where $sign(z) = 1$ for $z > 0$ and $sign(z) = -1$ for $z \leq 0$, and

$$L^* = \mathbb{P}\{g^*(X) \neq Y\}$$

denotes its error probability.

In the standard model of pattern recognition, we are given training labeled samples, which are independent and identical copies of (X, Y):

$$\mathcal{D}_n = \{(X_1, Y_1), \ldots, (X_n, Y_n)\}.$$

Based on these labeled samples, one can estimate the regression function D by $\tilde{D}$, and the corresponding plug-in classification rule g derived from $\tilde{D}$ is defined by

$$g(x) = sign\, \tilde{D}(x).$$

Then for any plug-in rule g derived from the regression estimate $\tilde{D}$ we have

$$L(g) - L^* = \mathbb{E}\left\{\mathbb{I}_{\{g(X) \neq g^*(X)\}} |D(X)|\right\} = \mathbb{E}\left\{\mathbb{I}_{\{sign\, \tilde{D}(X) \neq sign\, D(X)\}} |D(X)|\right\}, \tag{1}$$

where $\mathbb{I}$ denotes the indicator function (compare Theorem 2.2 in Devroye, Györfi and Lugosi 1996).

In the sequel our focus lies on the rate of convergence of the excess error probability $\mathbb{E}\{L(g_{n,k})\} - L^*$, where $g_{n,k}$ is the k-nearest-neighbor rule defined as follows. We fix $x \in \mathbb{R}^d$, and reorder the data $(X_1, Y_1), \ldots, (X_n, Y_n)$ according to increasing values of $\|X_i - x\|$, where $\|\cdot\|$ denotes the Euclidean norm. The reordered data sequence is denoted by

$$(X_{(n,1)}(x), Y_{(n,1)}(x)), \ldots, (X_{(n,n)}(x), Y_{(n,n)}(x)).$$

$X_{(n,k)}(x)$ is the k-th nearest neighbor of x. In this paper we assume that tie happens with probability 0. For instance when the distribution μ of X has a density f, this assumption is satisfied. In any case, by adding a randomizing component to X one can ensure that this assumption holds. Choose an integer k less than n, then the k-nearest-neighbor estimate of D is

$$D_{n,k}(x) = \frac{1}{k} \sum_{i=1}^{k} Y_{(n,i)}(x),$$

and the k-nearest-neighbor classification rule is

$$g_{n,k}(x) = sign\, D_{n,k}(x).$$

Concerning the properties of k-nearest-neighbor rule and the related literature see Biau and Devroye (2015).

The main aim of this paper is to show tight upper bounds on the excess error probability $\mathbb{E}\{L(g_{n,k})\} - L^*$ of the k-nearest-neighbor classification rule $g_{n,k}$. Given the plug-in classification rule g derived from $\tilde{D}$, (1) implies that

$$\mathbb{E}\{L(g)\} - L^* \leq \mathbb{E}\{|D(X) - \tilde{D}(X)|\}.$$

Therefore we may get an upper bound on the rate of convergence of the excess error probability $\mathbb{E}\{L(g_{n,k})\} - L^*$ via the L_1 rate of convergence of the corresponding regression estimation. Then

$$\mathbb{E}\{L(g_{n,k})\} - L^* \leq \mathbb{E}\{|D(X) - D_{n,k}(X)|\}.$$

Under some smoothness assumptions on D one could further upper bound the L_1 rate. For instance we may assume that D satisfies the *Lipschitz condition*: there is a constant C such that for any $x, z \in \mathbb{R}^d$

$$|D(x) - D(z)| \leq C\|x - z\|.$$

If D is Lipschitz continuous and X is bounded with the diameter M of the support of μ, then

$$\mathbb{E}\{|D(X) - D_{n,k}(X)|^2\} \leq c_1 M^2 (k/n)^{2/d} + c_2/k \tag{2}$$

with $d \geq 2$ (compare Chapter 6 in Györfi et al. 2002 and Liitiäinen, Corona and Lendasse 2010), so for $k = \lfloor c_3 n^{2/(d+2)} \rfloor$,

$$\mathbb{E}\{L(g_{n,k})\} - L^* \leq \sqrt{\mathbb{E}\{|D(X) - D_{n,k}(X)|^2\}} \leq c_4 n^{-1/(d+2)}. \tag{3}$$

However, according to Section 6.7 in Devroye, Györfi and Lugosi (1996) the classification is easier than L_1 regression function estimation, since the rate of convergence of the error probability depends on the behavior of the function D in the neighborhood of the decision boundary

$$B_0 = \{x; D(x) = 0\}. \tag{4}$$

This phenomenon has been discovered and investigated by Mammen and Tsybakov (1999); Tsybakov (2004); Audibert and Tsybakov (2007) and Kohler and Krzyżak (2007), who introduced the (weak) margin condition:

- The *weak margin condition* means that for all $0 < t \leq 1$,

$$\mathbb{P}\{0 < |D(X)| \leq t\} \leq c^* \cdot t^\alpha,$$

  where $\alpha > 0$ and $c^* > 0$.

Denote by

$$B_{0,r} = \left\{ x; \min_{z \in B_0} \|x - z\| \leq r \right\}, \; r > 0,$$

the closed r-neighborhood of the decision boundary B_0 defined by (4). Let λ be the Lebesgue measure and let $M^*(B_0)$ be the outer surface (Minkowski content) of the decision boundary B_0 defined by

$$M^*(B_0) = \lim_{r \downarrow 0} \frac{\lambda(B_{0,r} \setminus B_0)}{r}.$$

If D satisfies the Lipschitz condition, X has a density f, the density f is bounded by f_{max} and $M^*(B_0)$ is finite, then Lemma 2 in Döring, Györfi and Walk (2015) implies that the weak margin condition holds with $\alpha = 1$. Notice that the Lipschitz condition implies $\alpha \leq 1$.

In the analysis of classification rule one may use conditions on the density f of X:

- The *strong density condition* means that for $f(x) > 0$,

$$f(x) \geq f_{min} > 0.$$

The strong density condition implies that the support of the density f has finite Lebesgue measure, and so this assumption is close to the condition that X is bounded. It is a very restrictive condition, excluding important densities like Gaussian densities.

Kohler and Krzyżak (2007) proved that under the margin condition, Lipschitz condition and strong density assumption, for choice

$$k_n = \lfloor (\log n)^2 n^{2/(d+2)} \rfloor,$$

the order of the upper bound is smaller than (3):

$$(\log n)^{\frac{2(1+\alpha)}{d}} n^{-\frac{1+\alpha}{d+2}}.$$

Gadat, Klein and Marteau (2016) (comprehending also some classes of distributions with unbounded support) extended this bound such that under the margin condition, Lipschitz condition and the so called strong minimal mass assumption, for choice

$$k_n = \lfloor n^{2/(d+2)} \rfloor, \tag{5}$$

one has the order

$$n^{-\frac{1+\alpha}{d+2}}. \tag{6}$$

Audibert and Tsybakov (2007) showed that, under the margin condition and the strong density assumption, (6) is the minimax optimal rate of convergence for the class of Lipschitz continuous D, that is, (6) is the lower bound for *any* classifier.

Let $S_{x,r} = \{x' \in \mathbb{R}^d : \|x' - x\| \leq r\}$ and $S^o_{x,r} = \{x' \in \mathbb{R}^d : \|x' - x\| < r\}$ be the closed and open Euclidean ball, respectively, centered at $x \in \mathbb{R}^d$ with radius $r > 0$. In Chaudhuri and Dasgupta (2014) distribution-dependent rates of convergence are provided for the nearest neighbor classification rule in the framework of metric spaces. Therein a smoothness condition with respect to the distribution μ is introduced: For positive constants κ and L it is assumed that

$$\left| D(x) - \frac{1}{\mu(S_{x,r})} \int_{S_{x,r}} D(z)\mu(dz) \right| \leq L\mu(S^o_{x,r})^\kappa$$

for all $r > 0$ and x in the support of μ. Then the regression function D is called (κ, L)-smooth. Chaudhuri and Dasgupta (2014) revisited the order (6) using such a smoothness condition.

For higher order smoothness, one gets better rates of convergence. For weighted nearest neighbor classification including non-weighted k-nearest-neighbor classification, Samworth (2012a,b), with further references, considered the case when X is bounded, D is continuously differentiable with gradient $\nabla D(x) \neq 0$ for $x \in B_0$, the conditional densities of X given Y are twice differentiable and the density f of X satisfies the strong density assumption. Under some additional conditions on B_0, Samworth (2012b) derives the margin condition with $\alpha = 1$ and shows

$$\mathbb{E}\{L(g_{n,k})\} - L^* \leq \frac{c_5}{k} + c_6 (k/n)^{4/d},$$

which implies the order

$$n^{-\frac{4}{d+4}}.$$

In Cannings, Berett and Samworth (2017) the order $n^{-\frac{4}{d+4}}$ is revisited combining tail and smoothness conditions. For the feature vector a moment condition instead of boundedness is required. Further it is assumed that in a neighborhood of the decision boundary the function D and the marginal feature density are twice continuously differentiable and that the latter density allows to control the error of a Taylor approximation even in this region. For feature values away from the decision boundary it is assumed that the marginal feature distribution fulfills the strong minimal mass assumption, see Gadat, Klein and Marteau (2016), and that the function D does not approach the decision boundary too fast:

$$\sup_{x\in\mathbb{R}^d\setminus B_{0,r}:f(x)\geq\delta} |D(x)|^{-1} = o(\delta^{-\tau}) \text{ as } \delta\to 0 \text{ for some } r>0 \text{ and for every } \tau>0.$$

Interestingly, the analysis of empirical error minimization rules can avoid the condition that X is bounded, see Binev, Cohen, Dahmen and DeVore (2014) and Blaschzyk and Steinwart (2018).

Under the margin condition with $\alpha \leq 1$ ($d \geq 2$) and the strong density assumption, Audibert and Tsybakov (2007) showed that the order

$$n^{-\frac{2(1+\alpha)}{d+4}}$$

is the minimax optimal rate of convergence for the class of regression functions D, which have Lipschitz continuous gradients, that is, they are differentiable and the partial derivatives are Lipschitz continuous. Samworth (2012b) showed that under the assumptions together with Lipschitz continuity of the density function f several weighted nearest neighbor classifiers, particularly the non-weighted k-nearest-neighbor classifiers, attain this minimax rate.

2. Rate of Convergence of the Error Probability for k-NN Classifier

For most of the above cited results, the feature vector X is assumed to be bounded. Whenever the strong density assumption is used, it is implicitly assumed that the feature vector is bounded. They exclude the classical parametric discrimination problem, where the conditional distribution of X given Y are multidimensional Gaussian distributions. Next, we revisit these bounds such that our main aim is to avoid the condition that X is bounded and the strong density assumption.

In order to have non-trivial rate of convergence of the classification error probability, one has to assume tail and smoothness conditions. We treat two concepts of combined tail and smoothness condition, under which we get the known minimax rate of convergence.

- The *modified Lipschitz condition* means that there is a constant C^* such that for any $x, z \in \mathbb{R}^d$
$$|D(x) - D(z)| \leq C^* \mu(S^o_{x,\|x-z\|})^{1/d}.$$

Obviously, this definition is equivalent to the corresponding symmetric definition, i.e.,

$$|D(x) - D(z)| \leq C^* \min\{\mu(S^o_{x,\|x-z\|})^{1/d}, \mu(S^o_{z,\|x-z\|})^{1/d}\}.$$

In fact, for (κ, L)-smooth regression function D, Chaudhuri and Dasgupta (2014) already introduced the modified Lipschitz condition, where $\kappa = 1/d$ and $L = C^*$. The modified

Lipschitz condition is a universal condition not assuming the existence of a density, it holds for any pair of distribution μ and function D of practical interest.

The main result (Theorem 1) establishes rate of convergence under the modified Lipschitz condition by a decomposition of the excess error into approximation and estimation errors such that it extends and sharpens the result of Kohler and Krzyżak (2007) by avoiding the use of the strong density assumption. Furthermore, Theorem 7b in Chaudhuri and Dasgupta (2014) is closely related to Theorem 1 below.

Theorem 1 *Assume that tie happens with probability* 0*, D satisfies the weak margin condition with $0 < \alpha \leq 1$ and the modified Lipschitz condition. Then*

$$\mathbb{E}\{L(g_{n,k})\} - L^* = O(1/k^{(1+\alpha)/2}) + O((k/n)^{(\alpha+1)/d}),$$

and the choice (5) yields the order (6).

Because of (1), we have the following decomposition of the excess error probability:

$$\begin{aligned}\mathbb{E}\{L(g_{n,k})\} - L^* &= \mathbb{E}\left\{\int_{\{sign\, D_{n,k}(x)\neq sign\, D(x)\}} |D(x)|\mu(dx)\right\}\\ &\leq \mathbb{E}\left\{\int_{\{|D_{n,k}(x)-D(x)|\geq|D(x)|\}} |D(x)|\mu(dx)\right\}\\ &\leq I_{n,k} + J_{n,k},\end{aligned}$$

where

$$I_{n,k} = \mathbb{E}\left\{\int_{\{|\overline{D}_{n,k}(x)-D(x)|\geq|D(x)|/2\}} |D(x)|\mu(dx)\right\}$$

and

$$J_{n,k} = \mathbb{E}\left\{\int_{\{|D_{n,k}(x)-\overline{D}_{n,k}(x)|\geq|D(x)|/2\}} |D(x)|\mu(dx)\right\}$$

with

$$\overline{D}_{n,k}(x) = \mathbb{E}\{D_{n,k}(x) \mid X_1, \ldots, X_n\} = \frac{1}{k}\sum_{i=1}^{k} D(X_{(n,i)}(x)). \tag{7}$$

$I_{n,k}$ is called *approximation error*, while $J_{n,k}$ is the *estimation error*.

We split Theorem 1 into two lemmas such that Lemma 2 is on the estimation error, while Lemma 3 is on the approximation error.

Lemma 2 *If D satisfies the weak margin condition with $0 < \alpha \leq 1$, then*

$$J_{n,k} = O(1/k^{(1+\alpha)/2}). \tag{8}$$

Lemma 3 *Assume that tie happens with probability* 0*. If D satisfies the weak margin condition with $0 < \alpha \leq 1$ and the modified Lipschitz condition holds, then*

$$I_{n,k} \leq e^{-(1-\log 2)k} + O((k/n)^{(\alpha+1)/d}). \tag{9}$$

The proofs of these lemmas are in Section 4.

The concept of modified Lipschitz condition can be applied for discrete distributions, too. As an example, assume that the values of X are positive integers:

$$\mathbb{P}\{X = j\} = p_j.$$

For the classical example for slow rate of convergence, put $Y = D(X)$, that means the function D takes ± 1 values. Then $L^* = 0$ and D satisfies the Lipschitz condition with $C = 2$. As in the proof of Theorem 7.2 in Devroye, Györfi and Lugosi (1996), for any classifier g_n, the rate of convergence of $\mathbb{E}\{L(g_n)\}$ to zero can be arbitrarily slow by appropriate choice of the distribution $\{p_i\}$ of large tail.

Consider this discrete case with arbitrary function D such that the modified Lipschitz condition has the form

$$|D(j) - D(j')| \le C^* \mu([j - |j - j'| + 1, j + |j - j'| - 1]). \tag{10}$$

Next we show that under (10) and for any distribution $\{p_i\}$, even with large tail, the slow rate of convergence is excluded. Apply the k-NN rule with tie-breaking by indices, such that the k-NN estimate of D has the form

$$D_{n,k}(j) = \frac{1}{k} \sum_{i=1}^{k} Y_{(n,i)}(j).$$

Proposition 4 *Under the modified Lipschitz condition (10),*

$$\mathbb{E}\{L(g_{n,k})\} - L^* \le \frac{2 \max_{\{0 \le z\}} z e^{-z^2/8}}{\sqrt{k}} + e^{-3k/14} + 4C^* k/n.$$

The modified Lipschitz condition is an implicit condition, it is used in the proof of Lemma 3 in Section 4. We show how to extend this proof starting from a second concept such that we avoid the boundedness of X again. One can check that the Lipschitz condition and the strong density condition imply both concepts. However, as we mentioned earlier, the strong density condition is close to the condition, that X is bounded.

In the framework of the second concept we assume that μ has a density f satisfying a mild condition:

- The *weak density condition* means that there exist $c_{min} > 0$ and $\delta > 0$ such that for $f(x) r^d \le \delta^d$,
$$\mu(S_{x,r}) \ge c_{min}^d f(x) r^d.$$

If v_d denotes the volume of the unit ball $S_{0,1}$, then the Lebesgue density theorem implies that for all f and for almost all x with respect to the Lebesgues measure,

$$\lim_{r \downarrow 0} \frac{\mu(S_{x,r})}{v_d r^d} = f(x),$$

therefore, for small $r > 0$,

$$\mu(S_{x,r}) \approx f(x) v_d r^d.$$

Thus, the weak density condition requires a bit more than the Lebesgue density theorem.

- The *local Lipschitz condition* means that there exists a constant $\bar{C}$ such that for any $x, z \in \mathbb{R}^d$ with $f(x) > 0$
$$|D(x) - D(z)| \le \overline{C} f(x)^{1/d} \|x - z\|.$$

For the local Lipschitz condition the Lipschitz factor is proportional to $f(x)^{1/d}$. Thus, the fluctuation of D is small if the density is small. One may have a symmetric definition meaning that there exists a constant $\bar{C}$ such that for $\min\{f(x), f(z)\} > 0$

$$|D(x) - D(z)| \le \overline{C} \min\{f(x), f(z)\}^{1/d} \|x - z\|.$$

However, this definition has no additional advantage, just makes the derivation more involved. Because all three sets $\{(x,z); f(x) = 0\}$, $\{(x,z); f(z) = 0\}$, $\{(x,z); f(x) = 0 or f(z) = 0\}$ have zero product measure $\mu \otimes \mu$, both definitions are equivalent. Notice that the local Lipschitz condition is satisfied for any pair of density f and function D of practical interest.

Theorem 5 below states that under the local Lipschitz condition together with the weak density condition instead of the modified Lipschitz condition, the assertion of Theorem 1 remains valid. It will be shown in Section 4 by a modification of the proof of Lemma 3.

Theorem 5 *Assume that μ has a density such that the weak density condition holds. Furthermore, suppose that D satisfies the weak margin condition with $0 < \alpha \le 1$ and the local Lipschitz condition. Then*

$$\mathbb{E}\{L(g_{n,k})\} - L^* = O(1/k^{(1+\alpha)/2}) + O((k/n)^{(\alpha+1)/d}),$$

and the choice (5) yields the order (6).

On the one hand, note that the conditions of Theorem 1 don't imply the conditions of Theorem 5, because for Theorem 1, even the existence of a density is not required. On the other hand, the local Lipschitz and the weak density conditions imply that the modified Lipschitz condition holds in a neighborhood of x. It means that for all $x, z \in \mathbb{R}^d$ with $f(x) > 0$ and with $\|x - z\| \le \delta f(x)^{-1/d}$, one has

$$|D(x) - D(z)| \le \overline{C} f(x)^{1/d} \|x - z\| \le \overline{C} \mu(S^o_{x,\|x-z\|})^{1/d} / c_{min}.$$

3. Rate of Convergence of the L_2 Error for k-NN Regression Estimator

In this section we summarize the consequences of the previous section for k-NN regression estimation such that we prove (2) without assuming that X is bounded. Usually, (2) is proved such that after applying the Lipschitz condition one investigates

$$\mathbb{E}\{\|X_{(n,k)}(X) - X\|^2\},$$

which involves the condition that X is bounded. Compare Theorem 14.5 in Biau and Devroye (2015), Theorem 6.2 in Györfi et al. (2002) and Theorem 3.2 in Liitiäinen, Corona and Lendasse (2010), also Theorem 2 in Kohler, Krzyżak and Walk (2006), where a moment condition on X is assumed.

Theorem 6 *Put*

$$\sigma^2(x) = \mathbb{E}\left\{(Y - D(X))^2 \mid X = x\right\}.$$

If tie happens with probability 0*, D satisfies the modified Lipschitz condition and $k/n \to 0$, then*

$$\int \mathbb{E}\{(D_{n,k}(x) - D(x))^2\}\mu(dx) \le (\mathbb{E}\{\sigma^2(X)\} + o(1))/k + 2C^{*2}(k/n)^{2/d}.$$

The proof of Theorem 6 is at the end of Section 4. Similarly to Theorem 5, in Theorem 6 the modified Lipschitz condition can be replaced by the local Lipschitz condition together with the weak density condition.

4. Proofs

In this section we present the proofs of Lemmas 2 and 3, hence Theorem 1, and of Proposition 4, and of Theorems 5 and 6.

Proof of Lemma 2. For a fixed x, Proposition 8.1 in Biau and Devroye (2015) says the following: given $X_1, \dots, X_n$, the random pairs

$$(X_{(n,1)}(x), Y_{(n,1)}(x)), \dots, (X_{(n,k)}(x), Y_{(n,k)}(x))$$

are independent, and

$$\mathbb{E}\{Y_{(n,i)}(x) - D(X_{(n,i)}(x)) \mid X_1, \dots, X_n\} = 0.$$

Therefore, the Hoeffding inequality implies that

$$\begin{aligned}
&\mathbb{P}\{|D_{n,k}(x) - \overline{D}_{n,k}(x)| \ge |D(x)|/2 \mid X_1, \dots, X_n\} \\
&= \mathbb{P}\left\{\left|\frac{1}{k}\sum_{i=1}^{k}(Y_{(n,i)}(x) - D(X_{(n,i)}(x)))\right| \ge |D(x)|/2 \mid X_1, \dots, X_n\right\} \\
&\le 2e^{-k|D(x)|^2/8}.
\end{aligned}$$

Thus,

$$J_{n,k} \le 2\int |D(x)|e^{-k|D(x)|^2/8}\mu(dx).$$

The weak margin condition

$$G(t) := \mathbb{P}\{0 < |D(X)| \le t\} \le c^* \cdot t^\alpha,$$

implies by use of partial integration with respect to $G(s)$ that

$$\begin{aligned}
\int |D(x)|e^{-k|D(x)|^2/8}\mu(dx) &= \int_0^1 se^{-ks^2/8}G(ds) \\
&= e^{-k/8} - \int_0^1 e^{-ks^2/8}[1 - ks^2/4]G(s)ds \\
&\le e^{-k/8} + \frac{c^*}{4}\int_0^1 e^{-ks^2/8}ks^{2+\alpha}ds \\
&\le e^{-k/8} + \frac{c^*}{4}k^{-(\alpha+1)/2}\int_0^\infty e^{-u^2/8}u^{2+\alpha}du \\
&= O(k^{-(\alpha+1)/2}).
\end{aligned}$$

Thus, (8) is obtained. ■

Proof of Lemma 3. For $U_1, \dots, U_n$ i.i.d. uniformly distributed on $[0,1]$, let $U_{(1,n)}, \dots, U_{(n,n)}$ denote the corresponding order statistic. If tie happens with probability 0, then for any fixed x, $\mu(S_{x,r})$ is continuous in r, which implies that $\mu(S_{x,\|x-X\|})$ is uniformly distributed on $[0,1]$. From Section 1.2 in Biau and Devroye (2015) for any fixed x we have that

$$\mu(S_{x,\|x-X_{(n,k)}(x)\|}) \stackrel{\mathcal{D}}{=} U_{(k,n)}. \tag{11}$$

Because of

$$\begin{aligned}
|D(x) - \overline{D}_{n,k}(x)| &= \left|D(x) - \frac{1}{k}\sum_{i=1}^{k}D(X_{(n,i)}(x))\right| \\
&\le \frac{1}{k}\sum_{i=1}^{k}|D(x) - D(X_{(n,i)}(x))|
\end{aligned}$$

the modified Lipschitz condition together with (11) implies that

$$\begin{aligned}
&\mathbb{P}\left\{|D(x)|/2 < |D(x) - \overline{D}_{n,k}(x)|\right\} \\
&\le \mathbb{P}\left\{|D(x)|/2 < C^*\frac{1}{k}\sum_{i=1}^{k}\mu(S_{x,\|x-X_{(n,i)}(x)\|})^{1/d}\right\} \\
&\le \mathbb{P}\left\{|D(x)|/2 < C^*\mu(S_{x,\|x-X_{(n,k)}(x)\|})^{1/d}\right\} \\
&= \mathbb{P}\left\{|D(x)|/2 < C^*U_{(k,n)}^{1/d}\right\} \\
&= \mathbb{P}\left\{|D(x)|^d/(2C^*)^d < U_{(k,n)}\right\}.
\end{aligned} \tag{12}$$

Without loss of generality, assume that $C^* \geq 1/2$. Then

$$\begin{aligned}
&\mathbb{P}\left\{|D(x)|/2 < |D(x) - \overline{D}_{n,k}(x)|\right\} \\
&\leq \mathbb{P}\left\{\sum_{i=1}^{n} \mathbb{I}_{\{U_i \leq |D(x)|^d/(2C^*)^d\}} < k\right\} \\
&\leq \mathbb{I}_{\{|D(x)|^d/(2C^*)^d \geq 2k/n\}} \mathbb{P}\left\{\sum_{i=1}^{n} \mathbb{I}_{\{U_i \leq |D(x)|^d/(2C^*)^d\}} < \frac{n}{2}|D(x)|^d/(2C^*)^d\right\} \\
&+ \mathbb{I}_{\{|D(x)|^d/(2C^*)^d < 2k/n\}} \\
&\leq \mathbb{I}_{\{|D(x)|^d/(2C^*)^d \geq 2k/n\}} e^{-\frac{1-\log 2}{2} n|D(x)|^d/(2C^*)^d} + \mathbb{I}_{\{|D(x)|^d/(2C^*)^d < 2k/n\}} \\
&\leq e^{-(1-\log 2)k} + \mathbb{I}_{\{|D(x)|^d/(2C^*)^d < 2k/n\}}, \qquad (13)
\end{aligned}$$

where the third inequality follows from Chernoff's exponential inequality. Applying the weak margin condition, we get (9) by

$$\begin{aligned}
I_{n,k} &= \int |D(x)| \mathbb{P}\left\{|D(x)|/2 < |D(x) - \overline{D}_{n,k}(x)|\right\} \mu(dx) \\
&\leq e^{-(1-\log 2)k} + O((k/n)^{(\alpha+1)/d}). \qquad (14)
\end{aligned}$$

■

Proof of Proposition 4. The Hoeffding inequality implies

$$\begin{aligned}
&\mathbb{P}\{|D_{n,k}(j) - \overline{D}_{n,k}(j)| \geq |D(j)|/2 \mid X_1, \ldots, X_n\} \\
&= \mathbb{P}\left\{\left|\frac{1}{k}\sum_{i=1}^{k}(Y_{(n,i)}(j) - D(X_{(n,i)}(j)))\right| \geq |D(j)|/2 \mid X_1, \ldots, X_n\right\} \\
&\leq 2e^{-k|D(j)|^2/8}, \quad j \in \mathbb{N},
\end{aligned}$$

from which one gets a rough non-trivial upper bound on the estimation error:

$$\begin{aligned}
\mathbb{E}\left\{\int_{\{|D_{n,k}(x) - \overline{D}_{n,k}(x)| \geq |D(x)|/2\}} |D(x)|\mu(dx)\right\} &\leq 2\sum_{j=1}^{\infty} p_j |D(j)| e^{-k|D(j)|^2/8} \\
&\leq \frac{2\max_{\{0 \leq z\}} z e^{-z^2/8}}{\sqrt{k}}.
\end{aligned}$$

Concerning the approximation error, the modified Lipschitz condition (10) implies

$$\begin{aligned}
|\overline{D}_{n,k}(j) - D(j)| &\leq \frac{1}{k}\sum_{i=1}^{k} |D(X_{(n,i)}(j)) - D(j)| \\
&\leq C^* \frac{1}{k}\sum_{i=1}^{k} \mu\left([j - |X_{(n,i)}(j) - j| + 1, j + |X_{(n,i)}(j) - j| - 1]\right) \\
&\leq C^* \mu\left([j - |X_{(n,k)}(j) - j| + 1, j + |X_{(n,k)}(j) - j| - 1]\right).
\end{aligned}$$

Without loss of generality assume that $C^* > 1/2$ and $|D(j)| > 0$. Introduce the notation

$$\ell_j^* := \min\left\{\ell \in \mathbb{N}; \mu\left([j - \ell + 1, j + \ell - 1]\right) \geq \frac{|D(j)|}{2C^*}\right\}.$$

Because of

$$0 < \frac{|D(j)|}{2C^*} < 1,$$

ℓ_j^* is well defined. Put

$$A_j = \left[j - \ell_j^* + 1, j + \ell_j^* - 1\right].$$

Thus

$$\begin{aligned}
&\mathbb{E}\left\{\int_{\{|\overline{D}_{n,k}(x) - D(x)| \geq |D(x)|/2\}} |D(x)|\mu(dx)\right\} \\
&\leq \sum_{j=1}^{\infty} p_j |D(j)| \mathbb{P}\left\{\mu\left([j - |X_{(n,k)}(j) - j| + 1, j + |X_{(n,k)}(j) - j| - 1]\right) \geq \frac{|D(j)|}{2C^*}\right\} \\
&= \sum_{j=1}^{\infty} p_j |D(j)| \mathbb{P}\left\{|X_{(n,k)}(j) - j| \geq \ell_j^*\right\}.
\end{aligned}$$

If μ_n denotes the empirical distribution for $X_1, \ldots, X_n$, then

$$\begin{aligned}
\mathbb{E}\left\{\int_{\{|\overline{D}_{n,k}(x) - D(x)| \geq |D(x)|/2\}} |D(x)|\mu(dx)\right\} &\leq \sum_{j=1}^{\infty} p_j |D(j)| \mathbb{P}\left\{\sum_{i=1}^{n} \mathbb{I}_{|X_i - j| < \ell_j^*} \leq k\right\} \\
&= \sum_{j=1}^{\infty} p_j |D(j)| \mathbb{P}\left\{\mu_n(A_j) \leq k/n\right\}.
\end{aligned}$$

For the decomposition

$$\mathbb{P}\left\{\mu_n(A_j) \leq k/n\right\} \leq \mathbb{I}_{\mu(A_j) \leq 2k/n} + \mathbb{I}_{\mu(A_j) > 2k/n} \mathbb{P}\left\{\mu_n(A_j) \leq k/n\right\},$$

apply the Bernstein inequality:

$$\begin{aligned}
\mathbb{I}_{\mu(A_j) > 2k/n} \mathbb{P}\left\{\mu_n(A_j) \leq k/n\right\} &= \mathbb{I}_{\mu(A_j) > 2k/n} \mathbb{P}\left\{\mu_n(A_j) - \mu(A_j) \leq k/n - \mu(A_j)\right\} \\
&\leq \mathbb{I}_{\mu(A_j) > 2k/n} \mathbb{P}\left\{\mu_n(A_j) - \mu(A_j) \leq -\mu(A_j)/2\right\} \\
&\leq \mathbb{I}_{\mu(A_j) > 2k/n} e^{-\frac{n\mu(A_j)^2/4}{2(\mu(A_j) + \mu(A_j)/6)}} \\
&= \mathbb{I}_{\mu(A_j) > 2k/n} e^{-3n\mu(A_j)/28} \\
&\leq e^{-3k/14}.
\end{aligned}$$

The definition of A_j implies

$$\mu(A_j) \geq \frac{|D(j)|}{2C^*}.$$

Therefore,

$$\sum_{j=1}^{\infty} p_j |D(j)| \mathbb{I}_{\mu(A_j) \le 2k/n} \le \sum_{j=1}^{\infty} p_j |D(j)| \mathbb{I}_{|D(j)|/(2C^*) \le 2k/n} \le 4C^* k/n.$$

These bounds imply the bound on the approximation error:

$$\mathbb{E}\left\{ \int_{\{|\overline{D}_{n,k}(x) - D(x)| \ge |D(x)|/2\}} |D(x)| \mu(dx) \right\} \le e^{-3k/14} + 4C^* k/n.$$

■

Proof of Theorem 5. Again we use the decomposition (7). Lemma 2 with unchanged proof yields (8). Under the local Lipschitz condition and the weak density condition, we have to prove (9), i.e., (14). Let $\delta > 0$ be from the definition of weak density assumption. We have that

$$\begin{aligned}
&\int |D(x)| \mathbb{P}\left\{ |D(x)|/2 < |D(x) - \overline{D}_{n,k}(x)| \right\} \mu(dx) \\
&\le \int |D(x)| \mathbb{P}\left\{ |D(x)|/2 < \overline{C} f(x)^{1/d} \frac{1}{k} \sum_{i=1}^{k} \|x - X_{(n,i)}(x)\| \right\} \mu(dx) \\
&\le \int |D(x)| \mathbb{P}\left\{ |D(x)|/2 < \overline{C} f(x)^{1/d} \|x - X_{(n,k)}(x)\| \right\} \mu(dx) \\
&\le \int |D(x)| \mathbb{P}\left\{ |D(x)|/2 < \overline{C} \mu(S_{x,\|x - X_{(n,k)}(x)\|})^{1/d} / c_{min} \right\} \mu(dx) \\
&+ \int |D(x)| \mathbb{P}\left\{ f(x)^{1/d} \|x - X_{(n,k)}(x)\| > \delta \right\} \mu(dx).
\end{aligned}$$

The first term of the right hand side is

$$e^{-(1-\log 2)k} + O((k/n)^{(\alpha+1)/d})$$

by the weak margin condition according to (12) and (13). For the second term, we note

$$\begin{aligned}
&\mathbb{P}\left\{ f(x)^{1/d} \|x - X_{(n,k)}(x)\| > \delta \right\} \\
&= \mathbb{P}\left\{ \|x - X_{(n,k)}(x)\| > \delta / f(x)^{1/d} \right\} \\
&= \mathbb{P}\left\{ \sum_{i=1}^{n} \mathbb{I}_{\left\{X_i \in S_{x,\delta/f(x)^{1/d}}\right\}} < k \right\} \\
&\le \mathbb{I}_{\left\{\mu(S_{x,\delta/f(x)^{1/d}}) \ge 2k/n\right\}} \mathbb{P}\left\{ \sum_{i=1}^{n} \mathbb{I}_{\left\{X_i \in S_{x,\delta/f(x)^{1/d}}\right\}} < \frac{n}{2} \mu(S_{x,\delta/f(x)^{1/d}}) \right\} \\
&+ \mathbb{I}_{\left\{\mu(S_{x,\delta/f(x)^{1/d}}) < 2k/n\right\}} \\
&\le \mathbb{I}_{\left\{\mu(S_{x,\delta/f(x)^{1/d}}) \ge 2k/n\right\}} e^{-\frac{1-\log 2}{2} n \mu(S_{x,\delta/f(x)^{1/d}})} + \mathbb{I}_{\left\{\mu(S_{x,\delta/f(x)^{1/d}}) < 2k/n\right\}},
\end{aligned}$$

the latter by Chernoff's exponential inequality. The weak density assumption yields

$$\mathbb{I}_{\left\{\mu(S_{x,\delta/f(x)^{1/d}}) < 2k/n\right\}} \le \mathbb{I}_{\left\{c_{min}^d \delta^d < 2k/n\right\}}.$$

Thus the second term is bounded by

$$e^{-(1-\log 2)k} + \mathbb{I}_{\left\{c_{min}^d \delta^d < 2k/n\right\}} = e^{-(1-\log 2)k},$$

as soon as

$$c_{min}^d \delta^d \ge 2k/n.$$

■

Proof of Theorem 6. With the notation (7), we have

$$\mathbb{E}\{(D_{n,k}(x) - D(x))^2\} = \mathbb{E}\{(D_{n,k}(x) - \overline{D}_{n,k}(x))^2\} + \mathbb{E}\{(\overline{D}_{n,k}(x) - D(x))^2\}.$$

We show that

$$\int \mathbb{E}\left\{ \left(D_{n,k}(x) - \overline{D}_{n,k}(x)\right)^2 \right\} \mu(dx) = (\mathbb{E}\{\sigma^2(X)\} + o(1))/k \tag{15}$$

and

$$\mathbb{E}\left\{ \left(\overline{D}_{n,k}(x) - D(x)\right)^2 \right\} \le 2C^{*2}(k/n)^{2/d}, \tag{16}$$

which imply the assertion of the theorem.

In the proof of Lemma 2 we mentioned that for given $X_1, \ldots, X_n$, the random variable $D_{n,k}(x) - \overline{D}_{n,k}(x)$ is an average of independent random variables with mean zero, therefore

$$\begin{aligned}
&\mathbb{E}\left\{ (D_{n,k}(x) - \overline{D}_{n,k}(x))^2 \mid X_1, \ldots, X_n \right\} \\
&= \mathbb{E}\left\{ \left(\frac{1}{k} \sum_{i=1}^{k} (Y_{(n,i)}(x) - D(X_{(n,i)}(x))) \right)^2 \mid X_1, \ldots, X_n \right\} \\
&= \frac{1}{k^2} \sum_{i=1}^{k} \mathbb{E}\left\{ \left(Y_{(n,i)}(x) - D(X_{(n,i)}(x))\right)^2 \mid X_1, \ldots, X_n \right\} \\
&= \frac{1}{k^2} \sum_{i=1}^{k} \sigma^2(X_{(n,i)}(x)).
\end{aligned}$$

Problems 6.3 and 6.4 in Györfi et al. (2002) together with $k/n \to 0$ imply that

$$\int \mathbb{E}\{(D_{n,k}(x) - \overline{D}_{n,k}(x))^2\} \mu(dx) = \frac{\mathbb{E}\{\sigma^2(X)\} + o(1)}{k},$$

and so (15) is verified. Concerning (16), the modified Lipschitz condition implies that

$$\begin{aligned}\left(\overline{D}_{n,k}(x) - D(x)\right)^2 &= \left(\frac{1}{k}\sum_{i=1}^{k}(D(x) - D(X_{(n,i)}(x)))\right)^2 \\ &\leq \left(\frac{1}{k}\sum_{i=1}^{k}|D(x) - D(X_{(n,i)}(x))|\right)^2 \\ &\leq C^{*2}\left(\frac{1}{k}\sum_{i=1}^{k}\mu(S_{x,\|x-X_{(n,i)}(x)\|})^{1/d}\right)^2 \\ &\leq C^{*2}\mu(S_{x,\|x-X_{(n,k)}(x)\|})^{2/d}.\end{aligned}$$

Thus,

$$\mathbb{E}\left\{\left(\overline{D}_{n,k}(x) - D(x)\right)^2\right\} \leq C^{*2}\mathbb{E}\left\{U_{(k,n)}^{2/d}\right\}.$$

If $d \geq 2$, then the Jensen inequality implies

$$\mathbb{E}\left\{U_{(k,n)}^{2/d}\right\} \leq (k/n)^{2/d},$$

while for $d = 1$, one has

$$\mathbb{E}\left\{U_{(k,n)}^{2}\right\} = \mathbb{V}ar(U_{(k,n)}) + \mathbb{E}\left\{U_{(k,n)}\right\}^2 \leq k/n^2 + (k/n)^2.$$

Abstract

It is usual in machine learning theory to assume that the training and testing sets comprise of draws from the same distribution. This is rarely, if ever, true and one must admit the presence of corruption. There are many different types of corruption that can arise and as of yet there is no general means to compare the relative ease of learning in these settings. Such results are necessary if we are to make informed economic decisions regarding the acquisition of data.

Here we begin to develop an abstract framework for tackling these problems. We present a generic method for learning from a fixed, known, *reconstructible* corruption, along with an analyses of its statistical properties. We demonstrate the utility of our framework via concrete novel results in solving supervised learning problems wherein the labels are corrupted, such as learning with noisy labels, semi-supervised learning and learning with partial labels.

Keywords: Supervised Learning, Generalized Supervision, Decision Theory, Minimax Bounds, Data Processing, Noise

1. Introduction

The goal of supervised learning is to find,

$$\arg\min_{f\in\mathcal{F}} \mathbb{E}_{(x,y)\sim P}\ell(y, f(x)),$$

where $\mathcal{F}$ is a hypothesis class of functions and ℓ is loss function. Usually the decision maker is not given direct access to P, but rather a training set comprising n iid samples $\{(x_i, y_i)\}_{i=1}^n$ from P. There are many algorithms for solving this problem, for example empirical risk minimization (ERM), and this problem is well understood.

There are many other types of data one could learn from. For example in semi-supervised learning (Chapelle et al., 2010) the decision maker is given n instance label pairs and m instances devoid of labels. In learning with noisy labels (Angluin and Laird, 1988; Kearns, 1998; Natarajan et al., 2013), the decision maker observes instance label pairs where the observed labels have been corrupted by some noise process. There are many variants including, but not limited to, learning with label proportions (Quadrianto et al., 2009), learning with partial labels (Cour et al., 2011), multiple instance learning (Maron and Lozano-Pérez, 1998) as well as combinations of the above.

Abstractly, all of these problems can be understood as corrupted learning problems, in that the "ideal" clean training set is contaminated by a fixed and in general unknown noise process. What is currently lacking is a general theory of learning from corrupted data, as well as means to *compare* the relative usefulness of different data types. Such a theory is required if one wishes to make informed economic decisions on which data sets to acquire.

To make progress, we consider abstract prediction problems that have been contaminated by a fixed, known corruption. We demonstrate a generic method for learning from corrupted data, if the corruption is *reconstructible*. We show the utility of this framework via concrete novel results in supervised learning problems wherein the label has been corrupted, as in learning with label noise, semi-supervised learning and learning with partial labels.

We do not explicitly consider corruption of the instance nor corruption of the label that depends on the instance. While certain examples of these problems are reconstructible, they are not our interest here. We also do not consider non-reconstructible problems such as multiple instance learning/learning with label proportions.

The concrete contributions of this paper are:

- A general method for learning from corrupted labels based on a generalization of the method of unbiased estimators presented in Natarajan et al. (2013) and implicit in the earlier work of Kearns (1998) (theorems 5 and 6).
- Upper and lower bounds on the risk of learning from combinations of corrupted labels, with some analyses of their tightness (theorems 7 and 16). Our results greatly extend the state of the art of Crammer et al. (2005), both in scope and in completeness.
- Demonstration of the computational feasibility of our approach via the preservation of convexity (theorem 29).

Elements of our framework have appeared elsewhere, for example in Crammer et al. (2005); Cid-Sueiro et al. (2014); Blanchard et al. (2016); Natarajan et al. (2013). While not the complete story for *all* problems, the contributions outlined above make progress toward the final goal of informed economic decisions. The end result is a collection of general tools that allow one to *learn from* and *compare* the usefulness of various corrupted labels.

2. Basic Notation

Let $\mathbb{R}_+$ be the set of non-negative real numbers. Let Y^X be the set of functions with domain X and range Y. For a set X define the functions $\mathrm{id}_X(x) = x$, and $\mathbf{1}_X(x) = 1$. For a function $f \in \mathbb{R}^{X\times Y}$ and $y \in Y$, we denote the *partial* function $f(-, y) \in \mathbb{R}^X$, with $f(-, y)(x) = f(x, y)$, with similar notation for fixing the first argument. We denote the *dual space* of $\mathbb{R}^X$, the set of linear maps $\mathbb{R}^X \to \mathbb{R}$, by $(\mathbb{R}^X)^*$. We take the general view that a probability distribution is an element of the dual.

Definition 1 *A* probability distribution *on a set X is an element of $(\mathbb{R}^X)^*$, i.e. a linear function $\langle P, -\rangle : \mathbb{R}^X \to \mathbb{R}$, such that:*

1. $\langle P, \mathbf{1}_X \rangle = 1$.
2. *If* $f(x) \leq g(x),\ \forall x \in X$ *then* $\langle P, f \rangle \leq \langle P, g \rangle$.

The linear function $\langle P, - \rangle$ is called an expectation. For a large class of general topological spaces, this definition is equivalent to the usual one in terms of measures on sigma algebras (Rudin, 1991). If X is finite, a distribution is nothing more than a vector.

At times we use the standard prefix notation, with $\mathbb{E}_P f = \langle P, f \rangle$. Define the set of all distributions on a set X to be $\mathbb{P}(X)$. For any $x \in X$ define the point mass distribution δ_x, with $\langle \delta_x, f \rangle = f(x)$ for all functions f. Finally, for a boolean predicate $p : X \to \{\mathsf{True}, \mathsf{False}\}$, let $[\![p(x)]\!] = 1$ if $p(x)$ is true and 0 otherwise. Other notation will be developed as necessary.

3. The General Decision Problem

Consider the problem faced by a scientist in a laboratory. In front of them is a beaker, containing an unknown substance. Available to them are a myriad of experiments that can be performed to ascertain its identity. The scientist could attempt to ignite it, mix a bit of it with a known substance and see what happens, x-ray a sample, throw some of it at high velocity toward an oncoming beam of electrons and so on. Due to time and budget constraints, only a limited number of experiments can be performed to ascertain the substance's true identity. Therefore the scientist should focus their effort on the "most informative" experiments. Of course, what is informative depends on how the substance is to be *used*. For example, if the scientist wishes to sprinkle some of it on their food to enhance its flavor, misidentifying arsenic as table salt is a very bad idea. However, if they want to sprinkle it on the snails in their garden, this distinction is less important. The focus of this section is the abstract formulation of this problem. We consider the problem of how a decision maker, or scientist, uses observations from experiments to inform their actions.

Let Θ be a set of possible values of some unknown quantity, and A the set of actions available to the decision maker. The consequence of an action is measured by a loss function $L : \Theta \times A \to \mathbb{R}$. A negative loss represents a gain to the decision maker. In light of our previous example, Θ are the possible substances that could be in the beaker, A is what the decision maker can *do* with the substance (eat it, put it on snails and so on), and L measures the consequence of an action to the scientist ($L(\text{arsenic}, \text{eat})$ should be high). The norm of a loss function is given by its largest possible consequence (positive or negative), $\|L\|_\infty = \max_{\theta,a} |L(\theta, a)|$.

Unknown to the decision maker is the *exact* value of θ. To *discover* this, the decision maker is guided by experiments. Let $\mathcal{Z}$ be the set of possible outcomes of an experiment. We will assume that $\mathcal{Z}$ has enough mathematical structure so as to make sense of the theorems. As is standard in machine learning, the reader can assume that $\mathcal{Z}$ is of the form $X \times Y$ where X is a compact subset of $\mathbb{R}^d$ and Y is a finite set. All of the key ideas can be gleaned from assuming $\mathcal{Z}$ *finite*. This places no restrictions whatsoever one the usefulness of the theory in application to computer science problems. After all, computers work perfectly well with finite state spaces. The outcome of the experiment, $z \in \mathcal{Z}$, is assumed related to the unknown, certain outcomes are more strongly linked to certain values of θ. The relationship between the unknown and the outcome of the experiment is modeled by a *transition*.

3.1 Transitions

Definition 2 *A* transition *from a set X to a set Y is a linear map $T : (\mathbb{R}^X)^* \to (\mathbb{R}^Y)^*$.*

While abstract in appearance, we remark that when X and Y are *finite*, a transition is nothing more than a *matrix*. In general, a transition is an integral operator. Denote the set of all transitions from X to Y by $\mathbb{T}(X, Y)$. We call a transition *Markov* if $T(\mathbb{P}(X)) \subseteq \mathbb{P}(Y)$, ie it maps distributions over X to distributions over Y. When X and Y are finite, Markov transitions are represented by column stochastic matrices.

Markov transitions constitute a modern approach to conditional probability (Chang and Pollard, 1997; Torgersen, 1991; Le Cam, 1964; Chentsov, 1982). The distribution,

$$T(x) := T(\delta_x)$$

is how the decision maker summarizes their uncertainty about Y if the true value of X is x. In fact a transition is *completely determined* by its value on point masses. Every function $\phi \in Y^X$ defines a transition with,

$$\langle \phi(\alpha), f \rangle_Y := \langle \alpha, f \circ \phi \rangle_X\,,\ \forall f \in \mathbb{R}^Y,\ \forall \alpha \in (\mathbb{R}^X)^*.$$

Such a transition is called *deterministic*. Transitions can be combined in *series* and in *parallel*.

For transitions $T \in \mathbb{T}(X, Y)$ and $S \in \mathbb{T}(Y, Z)$ we can define $S \circ T \in \mathbb{T}(X, Z)$ by usual function composition. If X, Y and Z are finite, then this is just matrix multiplication. If T and S are Markov, this is just iterated expectation. Intuitively, this can be seen as "marginalizing" over Y in the Markov chain,

$$X \to Y \to Z.$$

Combination of transitions in series models corruptions that are performed one after another.

Transitions can be combined in *parallel*. For $\alpha, \beta \in (\mathbb{R}^X)^*$, denote the product by $\alpha \otimes \beta \in (\mathbb{R}^{X \times X})^*$. If $T_i \in \mathbb{T}(X_i, Y_i)$, $i \in [1; k]$, are transitions then denote,

$$\otimes_{i=1}^k T_i \in \mathbb{T}(\times_{i=i}^k X_i, \times_{i=1}^k Y_i)$$

with $\otimes_{i=1}^k T_i(x) = T_1(x_1) \otimes \cdots \otimes T_k(x_k)$, where $\times$ denotes the Cartesian product and $\otimes$ denotes products of duals. Transitions can also be *replicated*. For any transition $T \in \mathbb{T}(X, Y)$ we denote the *replicated transition* $T_n \in \mathbb{T}(X, Y^n),\ n \in \{1, 2, \dots\}$, with,

$$T_n(x) := \underbrace{T(x) \otimes \cdots \otimes T(x)}_{n \text{ times}} := T(x)^n,$$

the n-fold product of $T(x)$.

Parallel composition of transitions models performing two different experiments as well as the repeated performance of the same experiment.

3.2 Experiments and Risk

An *experiment* is a Markov transition $e \in \mathbb{T}(\Theta, \mathcal{Z})$. We call $\mathcal{Z}$ the observation space of the experiment. The distribution $e(\theta)$ summarizes uncertainty in the observation when θ is the value of the unknown. After observing the results of an experiment, the decision maker is tasked with choosing a suitable action. They do this via a *learning algorithm*.

In our language, a *learning algorithm* is a Markov transition $\mathcal{A} \in \mathbb{T}(\mathcal{Z}, A)$ [1]. $\mathcal{A}(z)$ summarizes the decision makers uncertainty in which action to choose. We define the *risk*,

$$\text{Risk}_L(\theta, e, \mathcal{A}) := \mathbb{E}_{z\sim e(\theta)}\mathbb{E}_{a\sim\mathcal{A}(z)}L(\theta, a) = \langle \mathcal{A} \circ e(\theta), L(\theta, -)\rangle\,.$$

The risk measures the quality of the final action chosen by the decision maker when they use the learning algorithm $\mathcal{A}$, after performing experiment e, assuming θ is the true value of the unknown. The risk does not provide a single number for the comparison of experiments, rather it provides an entire risk profile. To compare experiments directly we use the *minimax risk*,

$$\underline{\text{Risk}}_L(e) := \inf_{\mathcal{A}} \sup_{\theta} \text{Risk}_L(\theta, e, \mathcal{A}),$$

3.3 The Standard Prediction Problem

The preceding framework for defining and measuring the value of different experiments was largely conceived in the field of theoretical statistics, in the works of von Neumann and Morgenstern (1947); Blackwell (1951); DeGroot (1962) and Le Cam (1964). There is a perceived tension between the goals of statistics, that is to *discover* θ, versus the goals of machine learning, that is to *predict* the outcomes of the experiment e. As we now show, this distinction is only superficial. Let $\ell : \mathcal{Z} \times A \to \mathbb{R}$ be a "predictive" loss, that measures how well the action a predicts the outcome of the experiment e. Common examples include:

	Observations $\mathcal{Z}$	Actions A	Loss ℓ
Density Estimation	$X \subseteq \mathbb{R}^d$	Model $\Theta \subseteq P(X)$	$-\log(P_\theta(x))$
Classification	$X \times \{\pm 1\}$	Function class $\mathcal{F} \subseteq \{\pm 1\}^X$	$[\![y = f(x)]\!]$
Regression	$X \times \mathbb{R}$	Function class $\mathcal{F} \subseteq \mathbb{R}^X$	$(y - f(x))^2$
Supervised Learning	$X \times Y$	Function class $\mathcal{F} \subseteq \mathbb{P}(Y)^X$	$\ell(y, f(x))$

Due to the frequency with which we take expectations we overload our notation and define,

$$\ell(P, Q) := \mathbb{E}_{z\sim P}\mathbb{E}_{a\sim Q}\ell(z, a).$$

In learning theory, $\ell(P, Q)$ as defined above is refered to as the *risk*, here we reserve the term *risk* for its more classical statistical definition. Let $\Theta = \mathbb{P}(\mathcal{Z})$, the set of all possible distributions on the observation space. The loss function $L : \mathbb{P}(\mathcal{Z}) \times \mathbb{P}(A) \to \mathbb{R}$ of interest is the *regret*,

$$L(P, Q) := \ell(P, Q) - \inf_{a\in A} \ell(P, a),$$

Let e_n be the experiment that maps each $P \in \mathbb{P}(\mathcal{Z})$ to its n-fold product P^n. Then,

$$\underline{\text{Risk}}_L(e_n) = \inf_{\mathcal{A}} \sup_{P} \mathbb{E}_{S\sim P^n}\ell(P, \mathcal{A}(S)) - \inf_{a\in A} \ell(P, a),$$

1. We adopt the common terminology of algorithm, while not addressing computational issues.

is the minimax regret, a central object in learning theory. Therefore, the *prediction* problem of machine learning can be understood in the more general language of experiments. It is these problems that are of central interest in this paper. For the remainder L will represent the regret for a loss ℓ.

4. Corrupted Prediction Problems

Due to limitations in the measurement apparatus available to the decision maker, rather than observing $z \in \mathcal{Z}$, it is often the case that the decision maker observes a corrupted $\tilde{z}$ in a potentially different observation space $\tilde{\mathcal{Z}}$. We model the corruption process via a Markov transition $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$.

Definition 3 *A* corruption *is a Markov transition* $\mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$.

For example, we may wish to learn a relationship between measured symptoms and a medical diagnosis, as provided to us by an expert. To do so, rather than access to the expert's data, we are given data from one of their apprentices. Here T models the hypothesized link between the expert's and apprentice's data. The goal of predicting as well as the expert remains.

More concretely, we are interested in supervised learning problems wherein,

$$\mathcal{Z} = X \times Y \text{ and } \tilde{\mathcal{Z}} = X \times \tilde{Y},$$

with T corrupting only the label Y and acting as the identity on the instance X,

$$T = id_X \otimes T_Y.$$

Prominent examples include:

- **Learning with Label Noise**:

$$T_Y = \begin{pmatrix} 1 - \sigma_{-1} & \sigma_1 \\ \sigma_{-1} & 1 - \sigma_1 \end{pmatrix}.$$

- **Semi Supervised Learning**:

$$T_Y = \begin{pmatrix} \sigma_{-1} & 0 \\ 0 & \sigma_1 \\ 1 - \sigma_{-1} & 1 - \sigma_1 \end{pmatrix}$$

- **Learning with partial labels**: We assume that a partial label always includes the true label as one of the possibilities and furthermore that spurious labels are added with probability σ.

$$T_Y = \begin{pmatrix} (1-\sigma)^2 & 0 & 0 \\ 0 & (1-\sigma)^2 & 0 \\ 0 & 0 & (1-\sigma)^2 \\ (1-\sigma)\sigma & (1-\sigma)\sigma & 0 \\ (1-\sigma)\sigma & 0 & (1-\sigma)\sigma \\ 0 & (1-\sigma)\sigma & (1-\sigma)\sigma \\ \sigma^2 & \sigma^2 & \sigma^2 \end{pmatrix}.$$

For convenience we define the corrupted experiment $\tilde{e} = T \circ e$. We order the utility of different corruptions via the minimax risk,

$$\underline{\text{Risk}}_L(\tilde{e}_n) := \min_{\mathcal{A}} \max_{P} \text{Risk}_L(P, \tilde{e}_n, \mathcal{A}).$$

Note that the domain of $\mathcal{A}$ is now $\tilde{\mathcal{Z}}^n$. Ideally we wish to compare $\underline{\text{Risk}}_L(\tilde{e}_n)$ with $\underline{\text{Risk}}_L(e_n)$, the minimum risk of the corrupted and the clean experiments. By the general data processing theorem, $\underline{\text{Risk}}_L(\tilde{e}_n) \geq \underline{\text{Risk}}_L(e_n)$, however this does not allow one to *rank* the utility of *different* T.

Even after many years of directed research, in general we can not compute $\underline{\text{Risk}}_L(e_n)$ exactly, let alone $\underline{\text{Risk}}_L(\tilde{e}_n)$ for general corruptions. Consequently our effort for the remaining turns to upper and lower bounds of $\underline{\text{Risk}}_L(\tilde{e}_n)$.

4.1 Corruption Corrected Losses

When convenient we use the shorthand $T(P) = \tilde{P}$. Natarajan et al. (2013) introduced a method of learning classifiers from data subjected to label noise, called the "method of unbiased estimators". Here we show that this method can be generalized to other corruptions.

Recall that a transition $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ is a linear map $T : (\mathbb{R}^{\mathcal{Z}})^* \to (\mathbb{R}^{\tilde{\mathcal{Z}}})^*$. Associated with *any* transition is a *dual* or *adjoint* linear map $T^* : \mathbb{R}^{\tilde{\mathcal{Z}}} \to \mathbb{R}^{\mathcal{Z}}$ with,

$$\left\langle \alpha, T^*(\tilde{f}) \right\rangle_{\mathcal{Z}} := \left\langle T(\alpha), \tilde{f} \right\rangle_{\tilde{\mathcal{Z}}}, \ \forall \tilde{f} \in \mathbb{R}^{\tilde{\mathcal{Z}}}, \ \forall \alpha \in (\mathbb{R}^{\mathcal{Z}})^*,$$

In words, T^* "pulls back" functions of the corrupted sample to functions of the clean sample. When T is a matrix, T^* is the *transpose* of T. We wish to go in the other direction, to *transfer* functions of clean samples to those of corrupted samples.

Definition 4 *A transition $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ is* reconstructible *if T has a left inverse; that is there exists a transition $R \in \mathbb{T}(\tilde{\mathcal{Z}}, \mathcal{Z})$ such that $R \circ T = \text{id}_{(\mathbb{R}^{\mathcal{Z}})^*}$.*

Intuitively, T is reconstructible if there is some transformation that "undoes" the effects of T. Note that R need not be Markov for Markov T. We denote the set of all reconstructible transitions by $\mathbb{T}_{\leftarrow}(\mathcal{Z}, \tilde{\mathcal{Z}})$.

Many forms of corrupted learning are reconstructible, including semi-supervised learning, learning with label noise and learning with partial labels for all but a few pathological cases. Appendix A contains several worked examples.

We call a left inverse of T a *reconstruction*. For concreteness one can always take,

$$R = (T^*T)^{-1}T^*,$$

the Moore-Penrose pseudo inverse of T. For *invertible* T, R is given by the standard inverse. In general it will be useful to consider other reconstructions. In particular, for the proof of theorem 29, we use reconstructions with,

$$R^*(\mathbf{1}_{\mathcal{Z}}) = \mathbf{1}_{\tilde{\mathcal{Z}}},$$

ie those which preserve the *constant* loss function. This condition is *always* satisfied when T is invertible. More broadly, there is no loss in generality working with such reconstructions.

Reconstructible transitions are exactly those where we can *transfer* a function of the clean z to one of the corrupted $\tilde{z}$ while preserving expectations. By properties of adjoints,

$$\langle P, f \rangle = \langle R \circ T(P), f \rangle = \langle T(P), R^*(f) \rangle .$$

In words, to take expectations of f with samples from $\tilde{P}$, we use the *corruption corrected* $\tilde{f} = R^*(f)$. Recall the partial loss function $\ell(-, a) \in \mathbb{R}^{\mathcal{Z}}$. Using R we can reconstruct the partial loss from corrupted examples.

Theorem 5 (Corruption Corrected Loss) *For all reconstructible corruptions $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ and loss functions $\ell : \mathcal{Z} \times A \to \mathbb{R}$ define the* corruption corrected *loss $\ell_R : \tilde{\mathcal{Z}} \times A \to \mathbb{R}$ with,*

$$\ell_R(-, a) = R^*(\ell(-, a)), \ \forall a \in A.$$

Then for all distributions $P \in \mathbb{P}(\mathcal{Z})$, $\mathbb{E}_{z \sim P} \ell(z, a) = \mathbb{E}_{\tilde{z} \sim \tilde{P}} \ell_R(\tilde{z}, a)$.

4.1.1 USES OF CORRUPTION CORRECTED LOSSES IN SUPERVISED LEARNING

In supervised learning $\mathcal{Z} = X \times Y$ and the goal is to find a function that predicts $y \in Y$ from $x \in X$ with low expected loss. Given a suitable function class $\mathcal{F} \subseteq A^X$ and a loss $\ell : Y \times A \to \mathbb{R}$ one attempts to find,

$$f^* = \arg\min_{f \in \mathcal{F}} \mathbb{E}_{(x,y) \sim P} \ell(y, f(x)).$$

If the labels have been corrupted by $T_Y \in \mathbb{T}(Y, \tilde{Y})$, we can correct for the corruption and find,

$$f^* = \arg\min_{f \in \mathcal{F}} \mathbb{E}_{(x,\tilde{y}) \sim \tilde{P}} \ell_{R_Y}(\tilde{y}, f(x)) = \arg\min_{f \in \mathcal{F}} \mathbb{E}_{(x,y) \sim P} \ell(y, f(x)).$$

4.1.2 A WORKED EXAMPLE: LEARNING WITH SYMMETRIC LABEL NOISE

When learning under symmetric label noise, the decision maker is required to predict a binary label $y \in \{-1, 1\}$, where $y \sim P$. Rather than observing the true y, the decision maker observes $\tilde{y}$, where $\tilde{y} = y$ with probability $1 - \sigma$ and $\tilde{y} = -y$ with probability σ. This process can be modeled by the following corruption and reconstruction respectively;

$$T = \begin{pmatrix} 1-\sigma & \sigma \\ \sigma & 1-\sigma \end{pmatrix}, \ R^* = \frac{1}{1-2\sigma} \begin{pmatrix} 1-\sigma & -\sigma \\ -\sigma & 1-\sigma \end{pmatrix}.$$

Note that R is *not* Markov, as some of the entries of R are negative. For a loss $\ell : \{-1, 1\} \times A \to \mathbb{R}$ we have,

$$\begin{pmatrix} \ell_R(-1, a) \\ \ell_R(1, a) \end{pmatrix} = \frac{1}{1-2\sigma} \begin{pmatrix} 1-\sigma & -\sigma \\ -\sigma & 1-\sigma \end{pmatrix} \begin{pmatrix} \ell(-1, a) \\ \ell(1, a) \end{pmatrix},$$

or more compactly,

$$\ell_R(y, a) = \frac{(1-\sigma)\ell(y, a) - \sigma\ell(-y, a)}{1-2\sigma}.$$

This is equivalent to the "method of unbiased estimators" of Natarajan et al. (2013). Several examples of corruption corrected losses are given in appendix A.

4.1.3 WHEN TO APPEAL TO A SURROGATE LOSS

Many loss functions in machine learning are non convex, the zero one loss a prime example. Rather than minimizing one of these losses directly, it is common to instead minimize a convex surrogate loss function, such as the hinge loss. When learning in the presence of corruption we face a dilemma; when does one appeal to a surrogate? The method of unbiased estimators *first* appeals to a surrogate loss before correcting for noise. The method of label dependent costs (Natarajan et al., 2013) first corrects for noise before appealing to a surrogate.

4.2 Similarities with Other Frameworks

The framework here shares common points with two other broad directions in the literature, in the line of working of Cid-Sueiro et al. (2014) and Blanchard et al. (2016).

Cid-Sueiro et al. (2014); Cid-Sueiro (2012) consider the problem of learning when the corruption is only partially known. They also use transitions (stochastic matrices) and their reconstructions to construct loss functions that "correct for" noise in the labeling process. Their development closely mirrors that of section 11, with subtle differences (see section 11.3).

Blanchard et al. (2016) consider the closely related problem of learning under mutually contaminated distributions. For example, in binary classification many performance measures can be optimized with access to samples from $P_1, P_{-1} \in \mathbb{P}(X)$, the distribution over instances given a positive or negative label respectively. In practice however the samples can be *mixed*, yielding distributions,

$$\tilde{P}_{\pm 1} = (1 - \pi_{\pm 1})P_1 + \pi_{\pm 1}P_{-1}.$$

In general the mixing constants $\pi_{\pm 1}$ are unknown. Under the assumption that P_1 and P_{-1} are *mutually irreducible*, Blanchard et al. (2016) shows that one can reconstruct the clean distributions together with the mixing coefficients, providing means to estimate the corruption. Their framework has been extended to other problems (Katz-Samuels and Scott, 2016).

5. Upper Bounds for Corrupted Learning

In this section we develop upper bounds on the risk of any algorithm that learns from a corrupted sample, in terms of the *sample risk*, $\tilde{S} \sim \tilde{P}^n$. For simplicity we assume that A is finite. This assumption can be removed by PAC-Bayesian bounds (as we do in the appendix), via covering number arguments (Bartlett et al., 1997) or via more refined bounds from empirical process theory (Bartlett and Mendelson, 2006).

By an application of the PAC-Bayes bound (Zhang, 2006), one has for all algorithms $\mathcal{A} \in \mathbb{T}(\tilde{\mathcal{Z}}^n, A)$ and distributions $P \in \mathbb{P}(\mathcal{Z})$,

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell_R(\tilde{P}, \mathcal{A}(\tilde{S})) \leq \mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell_R(\tilde{S}, \mathcal{A}(\tilde{S})) + \|\ell_R\|_\infty\sqrt{\frac{2\log(|A|)}{n}}.$$

By the construction of ℓ_R, $\ell_R(\tilde{P}, \mathcal{A}(\tilde{S})) = \ell(P, \mathcal{A}(\tilde{S}))$, and the above bound yields the following theorem.

Theorem 6 *For all reconstructible $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$, algorithms $\mathcal{A} \in \mathbb{T}(\tilde{\mathcal{Z}}^n, A)$, distributions $P \in \mathbb{P}(\mathcal{Z})$ and bounded loss functions ℓ,*

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell(P, \mathcal{A}(\tilde{S})) \leq \mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell_R(\tilde{S}, \mathcal{A}(\tilde{S})) + \|\ell_R\|_\infty\sqrt{\frac{2\log(|A|)}{n}}.$$

A similar result also holds with high probability on draws from $\tilde{P}^n$. This bound motivates the following algorithm for learning from corrupted data,

$$\mathcal{A}_{ERM}(\tilde{S}) = \arg\min_{a\in A} \ell_R(\tilde{S}, a).$$

As this algorithm minimizes the loss on the sample,

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell_R(\tilde{S}, \mathcal{A}_{ERM}(\tilde{S})) \leq \mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell_R(\tilde{S}, a) = \ell(P, a),\ \forall a \in A.$$

Together with theorem 6 we have,

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}^n}\ell(P, \mathcal{A}_{ERM}(\tilde{S})) \leq \inf_a \ell(P, a) + \|\ell_R\|_\infty\sqrt{\frac{2\log(|A|)}{n}},\ \forall P$$

yielding,

$$\underline{\text{Risk}}_L(\tilde{e}_n) \leq \|\ell_R\|_\infty\sqrt{\frac{2\log(|A|)}{n}}.$$

Similarly,

$$\underline{\text{Risk}}_L(e_n) \leq \|\ell\|_\infty\sqrt{\frac{2\log(|A|)}{n}}.$$

Therefore, the ratio $\frac{\|\ell_R\|_\infty}{\|\ell\|_\infty}$ measures the relative difficulty of corrupted versus clean learning, as judged solely by our upper bound.

5.1 Upper Bounds for Combinations of Corrupted Data

Recall that our final goal is to quantify the utility of a data set comprising different corrupted data. For example in learning with noisy labels out of n data, there could be n_1 clean, n_2 slightly noisy and n_3 very noisy samples and so on. More generally we assume access to a corrupted sample $\tilde{S}$, made up of k different types of corrupted data, with $\tilde{S}_i \sim \tilde{P}^{n_i}$, $i \in [1; k]$.

Theorem 7 *Let $T_i \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}}_i)$ be a collection of k reconstructible corruptions. Let $\tilde{P} = \otimes_{i=i}^k \tilde{P}_i^{n_i}$, $\tilde{\mathcal{Z}} = \times_{i=1}^k \tilde{\mathcal{Z}}_i^{n_i}$, $n = \sum_{i=1}^k n_i$ and $r_i = \frac{n_i}{n}$. Then for all algorithms $\mathcal{A} \in \mathbb{T}(\tilde{\mathcal{Z}}, A)$, distributions $P \in \mathbb{P}(\mathcal{Z})$ and bounded loss functions ℓ,*

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}}\ell(P, \mathcal{A}(\tilde{S})) \leq \mathbb{E}_{\tilde{S}\sim\tilde{P}}\sum_{i=1}^k r_i\ell_{R_i}(\tilde{S}_i, \mathcal{A}(\tilde{S})) + K\sqrt{\frac{2\log(|A|)}{n}},$$

where $K = \sqrt{\sum_{i=1}^k r_i\|\ell_{R_i}\|_\infty^2}$.

A similar result also holds with high probability on draws from $\tilde{P}$. Theorem 7 is a generalization of the final bound appearing in Crammer et al. (2005) that only pertains to symmetric label noise and binary classification. Theorem 7 suggests the following means of choosing n_i examples from each of the corrupted experiments. Let c_i be the cost of acquiring data corrupted by T_i. First, choose data from the T_i with lowest $c_i \|\ell_{R_i}\|_\infty^2$ until picking more violates the budget constraint. Then choose data from the second lowest and so on.

One must be careful when comparing upper bounds, as there may exist alternate methods for learning from the corrupted sample with better properties. In the next section we present arguments indicating this is not the case.

6. Lower Bounds for Corrupted Learning

Thus far we have developed upper bounds for ERM algorithms. In particular we have found that reconstructible corruption does not affect the *rate* at which learning occurs, it only affects constants in the upper bound. Can we do better? Are these constants *tight*? To answer this question we develop lower bounds for corrupted learning.

Here we review Le Cam's method (see Yu (1997) for a more detailed account), a powerful technique for generating lower bounds for decision problems that very often gives the correct rate and dependence on constants (including being able to reproduce the standard VC dimension lower bounds for classification presented in Massart and Nédélec (2006)). In recent times it has been used to establish lower bounds for: differentially private learning (Duchi et al., 2013), learning in a distributed set up (Zhang et al., 2013), function evaluations required in convex optimization (Agarwal et al., 2012) as well as generic lower bounds in statistical estimation problems (Yang and Barron, 1999). We show how this method can be extended using the strong data processing theorem (Cohen and Kempermann, 1998) to provide a general tool for lower bounding the possible performance attainable in corrupted prediction problems.

We stress that these techniques apply to general experiments $e \in \mathbb{T}(\Theta, \mathcal{Z})$, and general loss functions $L : \Theta \times A \to \mathbb{R}$, and not only the predictive problems of interest here.

6.1 Le Cam's Method and Minimax Lower Bounds

Le Cam's method proceeds by reducing a general decision problem to an easier binary classification problem, before relating the best possible performance on this classification problem to the minimax risk. Let Θ be a set of unknowns, $e \in \mathbb{T}(\Theta, \mathcal{Z})$ an experiment and $L : \Theta \times A \to \mathbb{R}$ a loss. We assume further that $\inf_a L(\theta, a) = 0$ for all $\theta \in \Theta$. Define the *separation* $\rho : \Theta \times \Theta \to \mathbb{R}$,

$$\rho(\theta_1, \theta_2) := \inf_a L(\theta_1, a) + L(\theta_2, a).$$

The separation measures how hard it is to act well against both θ_1 and θ_2 simultaneously. Furthermore define the *variational divergence*,

$$V(P, Q) := \sup_{f \in [-1,1]^{\mathcal{Z}}} \mathbb{E}_P f - \mathbb{E}_Q f, \ \forall P, Q \in \mathbb{P}(\mathcal{Z}),$$

The variational divergence measures how hard to is to distinguish two distributions P and Q and is deeply related to binary classification.

Lemma 8 *For all experiments $e \in \mathbb{T}(\Theta, \mathcal{Z})$ and loss functions L,*

$$\underline{\text{Risk}}_L(e) \geq \frac{1}{4} \sup_{\theta_1, \theta_2 \in \Theta} \rho(\theta_1, \theta_2) \left(1 - V\left(e(\theta_1), e(\theta_2)\right)\right).$$

A compact proof is given in appendix B. This lower bound is a trade off between distances measured by ρ and statistical distances measured by the variational divergence. A decision problem is easy if proximity in variational divergence of $e(\theta_1)$ and $e(\theta_2)$ (hard to distinguish θ_1 and θ_2 statistically) implies proximity of θ_1 and θ_2 in ρ (hard to distinguish θ_1 and θ_2 with actions).

Lemma 8 suggests that to *rank* the difficulty of various experiments, one should work with their *Le Cam function.*

Definition 9 *Let e be an experiment and L a loss. The* Le Cam *function of e is,*

$$\text{Le Cam}_L(e, \gamma) = \frac{1}{4} \sup_{\theta_1, \theta_2 \in \Theta} \rho(\theta_1, \theta_2) \left(1 - \gamma V\left(e(\theta_1), e(\theta_2)\right)\right), \ \forall \gamma \geq 0.$$

Lemma 8 can be restated as,

$$\underline{\text{Risk}}_L(e) \geq \text{Le Cam}_L(e, 1).$$

REPLICATION AND RATES

We wish to lower bound how the risk decreases as n, the number of times the experiment is replicated, grows. The following lemma provides a simple way to do this.

Lemma 10 *For all collections of distributions $P_i, Q_i \in \mathbb{P}(\mathcal{Z}_i)$, $i \in [1; k]$,*

$$V(\otimes_{i=1}^k P_i, \otimes_{i=1}^k Q_i) \leq \sum_{i=1}^k V(P_i, Q_i).$$

We make use of the specific case where $P_i = P$ and $Q_i = Q$ for all i. Lemma 8 and lemma 10 yield the following.

Lemma 11 *For all experiments $e \in \mathbb{T}(\Theta, \mathcal{Z})$, loss functions L and n,*

$$\underline{\text{Risk}}_L(e_n) \geq \text{Le Cam}_L(e_n, 1) \geq \text{Le Cam}_L(e, n).$$

OTHER METHODS FOR OBTAINING MINIMAX LOWER BOUNDS

There are many other techniques for constructing lower bounds in terms of functions of pairwise KL divergences (Yu, 1997) as well as functions of pairwise f-divergences (Guntuboyina, 2011). Ultimately these methods replace the Variational divergence and separation in lemma 11 with a more general function of the experiment. While such methods are often required to get tighter lower bounds, all of what follows can be applied to these more intricate techniques. For the sake of conceptual clarity we proceed with Le Cam's method.

6.2 Measuring the Amount of Corruption

Rather than the experiment e, in corrupted learning we work with the corrupted experiment $\tilde{e}$. The data processing theorem for f-divergences states that,

$$V(T(P), T(Q)) \leq V(P, Q), \ \forall P, Q \in \mathbb{P}(\mathcal{Z}).$$

Thus any lower bound achieved by Le Cam's method for e can be directly transferred to one for $\tilde{e}$. However, this provides us with no means to rank different T. For some T, the data processing theorem can be *strengthened.*

Definition 12 *The* Clarity *of a Markov transitions $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ is,*

$$\text{Clarity}(T) := \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{V(T(P), T(Q))}{V(P, Q)}.$$

One has,

$$V(T(P), T(Q)) \leq \text{Clarity}(T) V(P, Q), \ \forall P, Q \in \mathbb{P}(\mathcal{Z}).$$

$\text{Clarity}(T)$ measures how much T corrupts. For example, if T is constant and maps all P to the same distribution, then $\text{Clarity}(T) = 0$. If T is an invertible function, then $\text{Clarity}(T) = 1$. When $\mathcal{Z}$ and $\tilde{\mathcal{Z}}$ are finite,

$$\text{Clarity}(T) = \sup_{v \in \Omega} \frac{\|T(v)\|_1}{\|v\|_1},$$

where $\Omega = \{v : \sum v_i = 0, v \neq 0\}$. Hence $\text{Clarity}(T)$ is the operator 1-norm of T when restricted to Ω. Clarity behaves as expected under composition.

Lemma 13 *For all transitions $T_1 \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}}_1)$ and $T_2 \in \mathbb{T}(\tilde{\mathcal{Z}}_1, \tilde{\mathcal{Z}}_2)$,*

$$\text{Clarity}(T_2 \circ T_1) \leq \text{Clarity}(T_2)\text{Clarity}(T_1) \leq \min(\text{Clarity}(T_2), \text{Clarity}(T_1)).$$

Hence $T_2 \circ T_1$ is at least as corrupt as either of the T_i.

$\text{Clarity}(T)$ was first used by Dobrushin (1956), where it is called the coefficient of ergodicity and is used to prove rates of convergence of Markov chains to their stationary distribution.

6.3 Lower bounds Relative to the Amount of Corruption

Together with lemma 11, the Clarity leads to meaningful lower bounds that allow the comparison of different corrupted experiments.

Theorem 14 *For all experiments e, loss functions L, corruptions $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ and $\gamma \geq 0$,*

$$\text{Le Cam}_L\left(T \circ e, \gamma\right) \geq \text{Le Cam}_L\left(e, \text{Clarity}(T)\gamma\right).$$

The proof is a simple application of the strong data processing theorem. Together with lemma 11, the above lemma yields the following corollary.

Corollary 15 *For all experiments e, loss functions L, corruptions $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ and n,*

$$\underline{\text{Risk}}_L(\tilde{e}_n) \geq \text{Le Cam}_L\left(e, \text{Clarity}(T)n\right)$$

In particular if Le Cam's method yields a lower bound of $\frac{C}{\sqrt{n}}$ for the clean problem, as is usual for many machine learning problems, theorem 15 yields a lower bound of $\frac{C}{\sqrt{\text{Clarity}(T)n}}$ for the corrupted problem. The *rate* at which one learns is unaffected, only the constants. A penalty of $\text{Clarity}(T)$ is unavoidable no matter what learning algorithm is used.

6.4 Lower Bounds for Combinations of Corrupted Data

As in section 5.1 we present lower bounds for combinations of corrupted data. For example in learning with noisy labels out of n data, there could be n_1 clean, n_2 slightly noisy and n_3 very noisy samples and so on.

Theorem 16 *Let $T_i \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}}_i)$, $i \in [1; k]$, be k corruptions. Let $T = \otimes_{i=1}^k T_i^{n_i}$ with $n = \sum_{i=1}^k n_k$. Then,*

$$\text{Le Cam}_L\left(T \circ e_n, \gamma\right) \geq \text{Le Cam}_L\left(e, \left(\sum_{i=1}^n n_i \text{Clarity}(T_i)\right)\gamma\right).$$

Furthermore,

$$\underline{\text{Risk}}_L(T \circ e_n) \geq \text{Le Cam}_L\left(e, \left(\sum_{i=1}^n n_i \text{Clarity}(T_i)\right)\right).$$

As in section 5.1, this bound suggests means of choosing data sets via the following integer program,

$$\arg\max_{n_1, n_2 \ldots n_k} \sum_{i=1}^k \text{Clarity}(T_i) n_i \ \text{ subject to } \sum_{i=1}^k c_i n_i \leq C,$$

where c_i is the cost of acquiring data corrupted by T_i and C is the maximum total cost. This is exactly the unbounded knapsack problem (Dantzig, 1957) which admits the following near optimal greedy algorithm. First, choose data from the T_i with highest $\frac{\text{Clarity}(T_i)}{c_i}$ until picking more violates the constraints. Then pick from the second highest and so on.

6.5 The Generality of Clarity

In light of section 6.1, it is often the case that more complicated lower bounding techniques based on pairwise f-divergences are required to produce *tight* lower bounds. Recall the definition of an f-divergence (Ali and Silvey, 1966).

Definition 17 *Let $f : \mathbb{R}_+ \to \mathbb{R}$ be a convex function with $f(1) = 0$. For all distributions $P, Q \in \mathbb{P}(\mathcal{Z})$ the* f-divergence *between P and Q is,*

$$D_f(P, Q) := \mathbb{E}_P f\left(\frac{dQ}{dP}\right),$$

if P and Q are absolutely continuous*, and is infinite otherwise.*

Both the variational and KL divergence are examples of f divergences. Following on from the reasoning of section 6.2, we seek a $\text{Clarity}_f(T)$ such that,

$$D_f(T(P), T(Q)) \leq \text{Clarity}_f(T) D_f(P, Q) \ \forall P, Q, f.$$

On the surface the choice of f matters. However, the clarity as we have defined is *generic*.

Theorem 18 (Strong Data Processing(Theorem 4.1 of Cohen et al. (1993))) *Let $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ be a Markov transition. Then for all P, Q, f,*

$$D_f(T(P), T(Q)) \leq \text{Clarity}(T) D_f(P, Q).$$

7. Measuring the Tightness of the Upper Bounds and Lower Bounds

In the previous sections we have shown upper bounds that depend on $\|\ell_R\|_\infty$ as well as lower bounds that depend on $\text{Clarity}(T)$. Here we compare these bounds.

Recall from theorem 5, $\ell_R(-, a) = R^*(\ell(-, a))$. The worst case ratio $\frac{\|\ell_R\|_\infty}{\|\ell\|_\infty}$ is determined by the *operator norm* of R^*. For a linear map $R : \mathbb{R}^X \to \mathbb{R}^Y$ define,

$$\|R\|_1 := \sup_{v \in \mathbb{R}^X} \frac{\|Rv\|_1}{\|v\|_1} \text{ and } \|R\|_\infty := \sup_{v \in \mathbb{R}^X} \frac{\|Rv\|_\infty}{\|v\|_\infty}$$

which are two operator norms of R. They are equal to the maximum absolute column and row sum of R respectively (Bernstein, 2009). Hence $\|R\|_1 = \|R^*\|_\infty$.

Lemma 19 *For all losses ℓ, $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ and reconstructions R, $\frac{\|\ell_R\|_\infty}{\|\ell\|_\infty} \leq \|R^*\|_\infty$.*

Lemma 20 *If $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ is reconstructible, with reconstruction R, then,*

$$\frac{1}{\text{Clarity}(T)} \leq 1 / \left(\inf_{u \in \mathbb{R}^X} \frac{\|Tu\|_1}{\|u\|_1} \right) \leq \|R^*\|_\infty.$$

Note that for lower bounds we look at the *best* case separation of columns of T, for upper bounds we essentially use the *worst*. We also get the following compositional theorem.

Lemma 21 *If $T_1 \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}}_1)$ and $T_2 \in \mathbb{T}(\tilde{\mathcal{Z}}_1, \tilde{\mathcal{Z}}_2)$ are reconstructible, with reconstructions R_1 and R_2, then $T_2 \circ T_1$ is reconstructible with reconstruction $R_1 \circ R_2$. Furthermore,*

$$\frac{1}{\text{Clarity}(T_1)\text{Clarity}(T_2)} \leq \|R_1 \circ R_2\|_1 \leq \|R_1\|_1 \|R_2\|_1.$$

Proof The first statement is obvious. For the first inequality simply use lemma 20 followed by lemma 13. The second inequality is an easy to prove property of operator norms. ■

7.1 Comparing Theorems 6 and 15

We have shown the following implication,

$$\frac{C_1}{\sqrt{n}} \leq \underline{\text{Risk}}_L(e_n) \leq \frac{C_2 \|\ell\|_\infty}{\sqrt{n}} \Rightarrow \frac{C_1}{\sqrt{\text{Clarity}(T) n}} \leq \underline{\text{Risk}}_L(\tilde{e}_n) \leq \frac{C_2 \|\ell_R\|_\infty}{\sqrt{n}},$$

for all reconstructible T. By lemma 20, in the worst case $\|\ell_R\|_\infty \geq \frac{\|\ell\|_\infty}{\text{Clarity}(T)}$. Thus in the worst case over all losses, we arrive at upper and lower bounds for the corrupted problem that are at least

factor of $\sqrt{\text{Clarity}(T)}$ apart. We do not know if this is the fault of our upper or lower bounding techniques. However, for *specific* ℓ and T this gap can be smaller.

For example, in the problem of learning with symmetric label noise discussed in section 4.1.2, with misclassification loss ℓ_{01},

$$\text{Clarity}(T) = 1 - 2\sigma \text{ and } \|\ell_{01,T}\| = \frac{1 - \sigma}{1 - 2\sigma},$$

respectively. The worst case ratio of upper and lower bounds over all losses is of order $\frac{1}{\sqrt{1-2\sigma}}$. For misclassification loss the actual ratio is $\frac{1-\sigma}{\sqrt{1-2\sigma}}$. For all $\sigma \in [0, \frac{2}{10}]$, i.e. up to 0.2 flip probability, this ratio is never larger than $\frac{4}{\sqrt{15}} \approx 1.03$.

7.2 Comparing Theorems 7 and 16

Let $\text{Cost}(T)$ be the cost of acquiring data corrupted by T. Theorem 7 prefers corruptions with low $\|\ell_R\|_\infty^2 \text{Cost}(T)$, or equivalently those with high,

$$\frac{1}{\|\ell_R\|_\infty \text{Cost}(T)}$$

Theorem 16 prefers corruptions with high,

$$\frac{\text{Clarity}(T)}{\text{Cost}(T)} \approx \frac{\|\ell\|_\infty}{\|\ell_R\|_\infty \text{Cost}(T)}.$$

In theorems 16 and 7 we have, respectively, best case and a worst case loss specific method for choosing data sets. Theorem 7 combined with 1emma 19 provides a worst case loss insensitive method for choosing data sets.

8. Corrupted Learning when Clean Learning is Fast

The contents of this paper largely solve the problem of learning from data with corrupted labels, when learning on the original problem occurs at the *standard* $\frac{1}{\sqrt{n}}$ rate. There are many conditions under which clean learning is fast, here we focus on the Bernstein condition presented in Bartlett and Mendelson (2006); van Erven et al. (2012).

Definition 22 *Let $P \in \mathbb{P}(\mathcal{Z})$, ℓ a loss and $a_P = \arg\min_a \mathbb{E}_{z \sim P} \ell(z, a)$. A pair (ℓ, P) satisfies the* Bernstein condition *with constant K if for all $a \in A$,*

$$\mathbb{E}_{z \sim P}(\ell(z, a) - \ell(z, a_P))^2 \leq K \, \mathbb{E}_{z \sim P} \ell(z, a) - \ell(z, a_P)$$

When A is finite, such a condition leads to $\frac{1}{n}$ rates of convergence for empirical risk minimization (ERM).

Theorem 23 *Let $\mathcal{A}$ be ERM with A finite. If (ℓ, P) satisfies the Bernstein condition then for some constant $C > 0$,*

$$\mathbb{E}_{S \sim P^n} \ell(P, \mathcal{A}(S)) - \ell(P, a_P) \leq \frac{C \log(|A|)}{n}.$$

Furthermore with probability at least $1-\delta$ *on a draw from* P^n *one has,*

$$\ell(P, \mathcal{A}(S)) - \ell(P, a_P) \leq \frac{C\left(\log(|A|) + \log\left(\frac{1}{\delta}\right)\right)}{n}.$$

While our lower bounding techniques will turn a lower bound of $\frac{1}{n}$ for clean learning to one of $\frac{1}{\alpha(T)n}$ for corrupted learning, it may be the case that this bound is too optimistic, there may be no algorithm that gives a $\frac{1}{n}$ rate of convergence.

A natural question to ask is when using the ERM algorithm for the loss ℓ_R converges quickly from samples drawn from $\tilde{P}$. Here we ask the simpler question: when does $(\ell_R, \tilde{P})$ satisfy the Bernstein condition?

Lemma 24 *If* $(\ell_R, \tilde{P})$ *satisfies the Bernstein condition with constant* K *then* (ℓ, P) *also satisfies the Bernstein condition with the same constant.*

This theorem (almost) rules out pathological behavior where ERM learns quickly from corrupted data and yet slowly for clean data. The converse of lemma 24 is not true, for example consider the case of PAC learning versus PAC learning with arbitrary instance dependent noise. In some cases the Bernstein condition can be transfered from the clean problem to the corrupted problem, as we now explore.

Definition 25 *Let* $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$*be a corruption and* ℓ *a loss. A pair* (ℓ, T) *are* η-compatible *if for all* $z \in \mathcal{Z}$ *and* $a_1, a_2 \in A$*,*

$$\mathbb{E}_{\tilde{z}\sim T(z)}(\ell_R(\tilde{z}, a_1) - \ell_R(\tilde{z}, a_2))^2 \leq \eta(\ell(z, a_1) - \ell(z, a_2))^2.$$

Theorem 26 *If the pair* (ℓ, P) *satisfies the Bernstein condition with constant* K *and the pair* (ℓ, T) *are* η*-compatible then* $(\ell_R, \tilde{P})$ *satisfies the Bernstein condition with constant* ηK*.*

While by no means the final word on fast corrupted learning, this theorem does allow one to prove interesting results in the binary classification setting.

Theorem 27 *Let* T *be label noise,* $T = \begin{pmatrix} 1-\sigma_{-1} & \sigma_1 \\ \sigma_{-1} & 1-\sigma_1 \end{pmatrix}$*, then the pair* (ℓ_{01}, T) *is* η*-compatible with* $\eta = \left(\frac{1+|\sigma_{-1}-\sigma_1|}{1-\sigma_{-1}-\sigma_1}\right)^2$*.*

One very useful example of a pair (P, ℓ) satisfying the Bernstein condition with constant 1 is when P is separable, ℓ is 01 loss and the Bayes optimal classifier is in the function class. Theorem 27 guarantees that as long as $\sigma_{-1} + \sigma_1 \neq 1$ (i.e. it is possible to learn from noisy labels), one learns at a fast rate from noisy examples.

9. Canonical Losses and Convexity

Thus far we have focused on the statistical properties of corrected loss minimization procedures. However, performing our correction may incur a computational penalty. Even if the loss ℓ is convex, there is no guarantee that the corrected loss remains so. Here we show that a large and useful class of loss functions remain convex when corrected.

Recall the constant function, $\mathbf{1}_{\mathcal{Z}}(z)$ and define,

$$\mathbf{1}_{\mathcal{Z}}^{\perp} := \left\{ v \in \mathbb{R}^{\mathcal{Z}} : \sum_{z\in\mathcal{Z}} v(z) = 0 \right\},$$

those functions that are orthogonal to $\mathbf{1}_{\mathcal{Z}}$. Proper losses and the closely related canonical losses form a large class of loss functions that provide means of attacking prediction problems.

Definition 28 *A loss* $\mathcal{L} : \mathcal{Z} \times A \to \mathbb{R}$ *is* canonical *if* A *is a convex subset of* $\mathbf{1}_{\mathcal{Z}}^{\perp}$ *and,*

$$\mathcal{L}(z, v) = -\langle \delta_z, v\rangle + \Psi(v),$$

for some convex function $\Psi : A \to \mathbb{R}$*.*

Intuitively, minimizing a canonical loss reduces to "lining up" with the average observed label, with "over confident" predictions penalized by the function Ψ. In appendix C we show that all losses are essentially canonical losses in disguise (theorem 49). Note that canonical losses split into two terms, one convex in v and unaffected by the observation, and a term linear in v. These losses are particular easy to correct for corruption, as only the linear term needs to be corrected.

Theorem 29 (Correcting Canonical Losses) *Let* $\mathcal{L} : \mathcal{Z} \times A \to \mathbb{R}$ *be a canonical loss. For all reconstructible corruptions* $T \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ *there exists a reconstruction* R *such that,*

$$\mathcal{L}_R(\tilde{z}, v) = -\langle \delta_{\tilde{z}}, R^*(v)\rangle + \Psi(v)$$

Furthermore R *can be calculated efficiently via Gaussian elimination.*

We develop the necessary representation results needed to prove this theorem in appendix C.

Theorem 29 extends results presented in Natarajan et al. (2013) concerning when losses used for learning binary classifiers remain convex when corrected for asymmetric label noise. Therefore we need not abandon the framework of convex surrogates when the corruption is known.

9.1 Comparison with Natarajan et al. (2013)

Recall in the problem of learning with label noise,

$$T = \begin{pmatrix} 1-\sigma_{-1} & \sigma_1 \\ \sigma_{-1} & 1-\sigma_1 \end{pmatrix},$$

where σ_y is the probability of label y being flipped. For this problem, the corrected loss is,

$$\ell_R(y,a) = \frac{(1-\sigma_{-y})\ell(y,a) - \sigma_y \ell(-y,a)}{1-\sigma_{-1}-\sigma_1}.$$

If $\ell : \{\pm 1\} \times \mathbb{R} \to \mathbb{R}$ is convex, smooth and satisfies,

$$\ell''(y,a) = \ell''(-y,a),$$

then lemma 4 of Natarajan et al. (2013) guarantees that ℓ_R is convex. Integrating twice yields,

$$\ell(y,a) = b_y + c_y v + g(a),$$

For some convex function g. Rearranging one has,

$$\ell(y,a) = \left(\frac{b_{-1} - b_1 + (c_1 - c_{-1})\,a}{2}\right) y + \underbrace{\frac{b_1 + b_{-1} + (c_1 + c_{-1})\,a}{2} + g(a)}_{\text{convex in } a}.$$

For canonical losses, corollary 50 states that any binary canonical loss is of the form $\mathcal{L} : \{\pm 1\} \times I \to \mathbb{R}$,

$$\mathcal{L}(y,v) = -yv + \Psi(v),\ v \in I,$$

where I is a convex subset of $\mathbb{R}$ and $\Psi : I \to \mathbb{R}$ a convex function. Letting,

$$\nu = -\left(\frac{b_{-1} - b_1 + (c_1 - c_{-1})\,a}{2}\right),$$

one can see that the losses considered in Natarajan et al. (2013) are affine re-parametrizations of canonical losses. Theorem 29 is therefore a generalization of lemma 4 of Natarajan et al. (2013).

9.2 Comparison with Cid-Sueiro et al. (2014)

Section 5 of Cid-Sueiro et al. (2014) provides some discussion of the convexity of corruption corrected losses. They state, without proof, that a requirement for the preservation of convexity is that the reconstruction have *non negative* entries. Theorem 29 shows that this is not the case, one can *always* preserve convexity as long as the correct reconstruction and parametrization of the loss function are used.

10. Learning when the Corruption Process is Partially Known

Thus far we have considered the problem of learning when T is known. Here we consider the problem of when T lies in a subset $\mathcal{C} \subset \mathbb{T}_{\leftarrow}(\mathcal{Z}, \tilde{\mathcal{Z}})$. For example when learning classifiers under symmetric label noise (Angluin and Laird, 1988), the corruption is of the form,

$$T_\sigma = \begin{pmatrix} 1-\sigma & \sigma \\ \sigma & 1-\sigma \end{pmatrix},$$

where $\sigma \neq \frac{1}{2}$. There are three ways in which one can proceed.

If we assume access to a "gold standard" sample $S \sim P^n$ as well as a corrupted sample $\tilde{S}$, we can use methods akin to those in Kearns (1998). One covers the set $\mathcal{C}$ to some tolerance ϵ with a finite cover $\{T_i\}_{i=1}^k$. For each T_i in the cover, estimate an action a_i using ℓ_{R_i} and the corrupted sample. Finally, choose the a_i that best predicts the gold standard sample. Using theorem 6, we know that for a large enough corrupted sample, one of the a_i has performance close to that of the optimal a.

One can attempt to *estimate* T from the corrupted sample. Under certain distributional assumptions (such as separability and mutual irreducibility), Menon et al. (2015) surveys methods for estimating T for the problem of learning under asymmetric label noise. Blanchard et al. (2016) gives theory for these estimators. There is a growing literature extending these estimates to other problems as well as new, computational efficient estimates (Blanchard and Scott, 2014; Katz-Samuels and Scott, 2016; Ramaswamy et al., 2016). We believe these methods can be extended to general corruptions.

In both of the above methods, operator norms can provide suitable losses/metrics that can guide their use.

Lemma 30 *Let $T, T' \in \mathbb{T}_{\leftarrow}(\mathcal{Z}, \tilde{\mathcal{Z}})$. Then,*

$$\|\ell_R - \ell_{R'}\|_\infty \leq \left\|R - R'\right\|_1 \|\ell\|_\infty.$$

The quantity $\|R - R'\|_1$ is a statistically motivated distance that can be used when covering $\mathcal{C}$. Furthermore, it can be used when designing loss functions for estimating T.

Finally, one can look for loss functions that are "invariant" to $\mathcal{C}$. This approach is explored further in section 11 and in van Rooyen et al. (2017).

11. Corruption Invariant Loss Functions

While exact knowledge of $T \in \mathcal{C} \subset \mathbb{T}_{\leftarrow}(\mathcal{Z}, \tilde{\mathcal{Z}})$ is required to estimate the *expected loss* from a corrupted distribution, in certain situations this is unnecessary for estimating optimal actions and *any* reconstruction will suffice. In this section we formalize this notion and *characterize* when exact knowledge of T is unnecessary. We assume for each $T \in \mathcal{C}$ an explicit reconstruction R, ie a function,

$$\mathrm{Rec} : \mathcal{C} \to \mathbb{T}(\tilde{\mathcal{Z}}, \mathcal{Z}),$$

with $\mathrm{Rec}(T)T = \mathrm{id}_{\mathcal{Z}}$. As in theorem 29, we will assume that,

$$\mathrm{Rec}(T)^*(\mathbf{1}_{\mathcal{Z}}) = \mathbf{1}_{\tilde{\mathcal{Z}}},\ \forall T \in \mathcal{C}.$$

We focus on the problem of prediction. Let $\ell : \mathcal{Z} \times A \to \mathbb{R}$ be a loss. ℓ provides an *ordering* on $\mathbb{P}(\mathcal{Z} \times A)$. $P_1 \leq_\ell P_2$ if,

$$\mathbb{E}_{(z,a)\sim P_1} \ell(z,a) \leq \mathbb{E}_{(z,a)\sim P_2} \ell(z,a).$$

In words, P_1 is making better decisions than P_2. One can think of P_1 and P_2 being the output of a learning algorithm, although exactly how they came to be is of no concern in this section.

Let $T \in \mathcal{C}$ be the true corruption and $T_0 \in \mathcal{C}$ the assumed corruption. By properties of adjoints,

$$\langle T(P), \mathrm{Rec}(T_0)^* \ell(-,a) \rangle = \langle P, (\mathrm{Rec}(T_0)T)^* \ell(-,a) \rangle.$$

When using the wrong reconstruction the decision maker is effectively using the loss,

$$\tilde{\ell}_T(-,a) := (\mathrm{Rec}(T_0)T)^* \ell(-,a),$$

in place of ℓ. In general there is no guarantee,

$$P_1 \leq_\ell P_2 \Leftrightarrow P_1 \leq_{\tilde{\ell}_T} P_2.$$

In words, assuming the *wrong* corruption may lead to the *wrong* ordering. Corruption immune losses are precisely those where the ordering is *unaltered.*

The reader may wonder why we focus on preserving *order* rather than preserving only the optimal action. Invariably in machine learning we make approximations, be it via working with a finite simple, or a restricted function class. What is key therefore is preserving what is *better* and not only what is *best.*

Definition 31 (Order Equivalence) *Let $\ell, \ell' : \mathcal{Z} \times A \to \mathbb{R}$ be loss functions. ℓ is* order equivalent *to ℓ' if for all $P_1, P_2 \in \mathbb{P}(A \times \mathcal{Z})$,*

$$P_1 \leq_\ell P_2 \Leftrightarrow P_1 \leq_{\ell'} P_2.$$

The lemma below *characterizes* when losses are order equivalent.

Lemma 32 (Theorem 2, Section 7.9 of DeGroot (1962)) *ℓ is order equivalent to ℓ' if and only if there exists a constants $\alpha > 0$ and β such that,*

$$\ell(z,a) = \alpha \ell'(z,a) + \beta,\ \forall z \in \mathcal{Z},\ \forall a \in A.$$

Definition 33 *Let $\mathcal{C} \subset \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}})$ be a set of reconstructible transitions. A loss ℓ is* immune to $\mathcal{C}$ *if for all $T \in \mathcal{C}$, ℓ is order equivalent to $\tilde{\ell}_T$.*

Losses that are immune to $\mathcal{C}$ are precisely those where exact knowledge of the corruption is unnecessary, assuming *any* $T \in \mathcal{C}$ and using its corresponding reconstruction is sufficient.

Theorem 34 *Fix $T_0 \in \mathcal{C}$. A loss ℓ is* immune to $\mathcal{C} \subset \mathbb{T}_\leftarrow(\mathcal{Z}, \tilde{\mathcal{Z}})$ *if and only if for all $T \in \mathcal{C}$.*

$$(\mathrm{Rec}(T_0)T)^* \ell(-,a) = \alpha(T)\ell(-,a) + \beta(T)\mathbf{1}_{\mathcal{Z}},\ \forall a \in A,$$

for functions $\alpha : \mathcal{C} \to \mathbb{R}_+$ and $\beta : \mathcal{C} \to \mathbb{R}$.

The proof follows directly from the definition and lemma 32. The operator $(\mathrm{Rec}(T_0)T)$ measures the effect of reconstructing incorrectly.

11.1 Constructing Corruption Immune Loss Functions

Theorem 34 provides means to *test* when a loss function is immune to $\mathcal{C}$. Here we show how to *construct* such losses. Immune losses arise from the *persistent eigenvectors* of $(\mathrm{Rec}(T_0)T)^*$.

Let $S \subset \mathbb{T}(\mathcal{Z}, \mathcal{Z})$. We call v a *persistent eigenvector* of S if,

$$Mv = \lambda(M)v,\ \forall M \in S,$$

ie, v is an eigenvector *for all* $M \in S$, albeit with differing eigenvalue. We call the function $\lambda : S \to \mathbb{R}$ a *persistent eigenvalue*. Much like normal eigenspaces, we define *persistent eigenspaces* as subspaces of $\mathbb{R}^{\mathcal{Z}}$ with the same persistent eigenvalue,

$$E_{\lambda,S} = \left\{ v \in \mathbb{R}^{\mathcal{Z}} : Mv = \lambda(M)v,\ \forall T \in S \right\}.$$

Persistent eigenspaces provide an alternative statement of theorem 34.

Corollary 35 *Let $\mathcal{C} \subset \mathbb{T}_\leftarrow(\mathcal{Z}, \tilde{\mathcal{Z}})$, with $T_0 \in \mathcal{C}$. Let,*

$$S = \left\{ (\mathrm{Rec}(T_0)T)^* : T \in \mathcal{C} \right\}.$$

and let $\alpha : S \to \mathbb{R}_+$ be a persistent eigenvalue of S. Any loss ℓ of the form,

$$\ell(-,a) = v(a) + \gamma \mathbf{1}_{\mathcal{Z}},$$

where $v(a) \in E_{\alpha,S}\ \forall a \in A$ and $\gamma \in \mathbb{R}$ is immune to $\mathcal{C}$.

Therefore the search for losses that are immune to $\mathcal{C}$ reduces to the calculation of the persistent eigenspaces of $\{(\mathrm{Rec}(T_0)T)^* : T \in \mathcal{C}\}$.

11.2 Examples of Corruption Immune Losses

Here we show how to apply corollary 35 to find losses that are immune to families of corruptions.

11.2.1 SYMMETRIC LABEL NOISE AND THE LINEAR LOSS

We proceed as in van Rooyen et al. (2017). In the problem of symmetric label noise $\mathcal{Z} = \{-1, +1\}$ with,

$$T = \begin{pmatrix} 1-\sigma & \sigma \\ \sigma & 1-\sigma \end{pmatrix} \text{ and } R = \frac{1}{1-2\sigma} \begin{pmatrix} 1-\sigma & -\sigma \\ -\sigma & 1-\sigma \end{pmatrix},$$

for $\sigma \neq \frac{1}{2}$. Let $\mathcal{C}$ be all such T with $\sigma \neq \frac{1}{2}$. Define the *linear* loss function,

$$\ell(y,v) = -yv,\ v \in \mathbb{R},$$

or in partial form,

$$\ell(-,v) = \begin{pmatrix} v \\ -v \end{pmatrix}.$$

We can quickly verify that the linear loss is immune to $\mathcal{C}$. Let $T_0 = \mathrm{id}_{\mathcal{Z}}$. As $\begin{pmatrix} 1 \\ -1 \end{pmatrix}$ is an eigenvector of T^* with eigenvalue of $1 - 2\sigma$ we have,

$$T^*\ell(-, v) = (1 - 2\sigma)\,\ell(-, v),\ \forall v \in \mathbb{R},\ \forall \sigma \neq \frac{1}{2}.$$

Therefore the linear loss is immune to $\mathcal{C}$.

11.2.2 MULTI-CLASS IMMUNE LOSSES

Here we consider the three-class generalization of linear loss with $\mathcal{Z} = \{1, 2, 3\}$ and,

$$\ell(-, v) = v, v \in \mathbf{1}_{\mathcal{Z}}^{\perp},$$

with,

$$v = v_1 \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} + v_2 \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \end{pmatrix},\ v_1, v_2 \in \mathbb{R}.$$

We consider two classes of corruption, firstly three-class symmetric noise, secondly symmetric partial label noise.

For three-class symmetric noise,

$$T = \begin{pmatrix} 1-\sigma & \frac{\sigma}{2} & \frac{\sigma}{2} \\ \frac{\sigma}{2} & 1-\sigma & \frac{\sigma}{2} \\ \frac{\sigma}{2} & \frac{\sigma}{2} & 1-\sigma \end{pmatrix} \text{ and } R = \begin{pmatrix} \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} \end{pmatrix},$$

for $\sigma \neq \frac{2}{3}$. Fix $T_0 = \mathrm{id}_{\mathcal{Z}}$. Both,

$$v = v_1 \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} \text{ and } \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \end{pmatrix},$$

are eigenvalues of T^* with eigenvalue $\frac{2-3\sigma}{2}$. Therefore,

$$T^*\ell(-, v) = \frac{2 - 3\sigma}{2}\ell(-, v),\ \forall v \in \mathbf{1}_{\mathcal{Z}}^{\perp},\ \forall \sigma \neq \frac{2}{3},$$

Hence linear loss is immune to three-class symmetric noise. Note that general losses are *not* immune to symmetric three-class label noise.

In learning under symmetric partial label noise,

$$T = \begin{pmatrix} (1-\sigma)^2 & 0 & 0 \\ 0 & (1-\sigma)^2 & 0 \\ 0 & 0 & (1-\sigma)^2 \\ (1-\sigma)\sigma & (1-\sigma)\sigma & 0 \\ (1-\sigma)\sigma & 0 & (1-\sigma)\sigma \\ 0 & (1-\sigma)\sigma & (1-\sigma)\sigma \\ \sigma^2 & \sigma^2 & \sigma^2 \end{pmatrix} \text{ and } R = \begin{pmatrix} 1 & 0 & 0 & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & -\frac{\sigma-3}{3(\sigma-1)} & \frac{1}{3} \\ 0 & 1 & 0 & \frac{3-2\sigma}{3-3\sigma} & -\frac{\sigma-3}{3(\sigma-1)} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \\ 0 & 0 & 1 & -\frac{\sigma-3}{3(\sigma-1)} & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \end{pmatrix},$$

for $\sigma \neq 1$. Taking,

$$T_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

ie $\sigma = 0$, one has,

$$(RT_1)^* = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \forall \sigma \neq 1.$$

This means that *all* losses are immune to symmetric partial label noise.

11.3 Comparison with Cid-Sueiro et al. (2014)

The development here closely mirrors that of Cid-Sueiro et al. (2014) with one key exception. While we look for *losses* with,

$$(\mathrm{Rec}(T_0)T)^*\ell(-, a) \cong \ell(-, a),\ \forall T \in \mathcal{C},$$

Cid-Sueiro et al. (2014) looks for classes of losses $\ell : \mathcal{Z} \times \mathbb{R}^{\mathcal{Z}} \to \mathbb{R}$ that are closed under the action of $(\mathrm{Rec}(T_0)T)$. In particular they consider strictly proper and classification calibrated (Bartlett et al., 2006) loss functions. They show (theorem 2) that if,

$$(\mathrm{Rec}(T_0)T)^* = \alpha(T)\mathrm{id}_{\mathcal{Z}},\ \forall T \in \mathcal{C},$$

for $\alpha(T) > 0$, then proper losses are mapped to proper losses by $(\mathrm{Rec}(T_0)T)^*$. By theorem 34 this would guarantee,

$$(\mathrm{Rec}(T_0)T)^*\ell(-, a) = \alpha(T)\ell(-, a),\ \forall T \in \mathcal{C},\ \forall a \in A,\ \forall \ell,$$

ie *all* losses are immune to $\mathcal{C}$. We saw an example of this in section 11.2.2. They also show (theorem 5) that if,

$$(\mathrm{Rec}(T_0)T)^* = \alpha(T)\mathrm{id}_{\mathcal{Z}} + v(T) \otimes \mu,\ \forall T \in \mathcal{C},$$

for $\alpha(T) > 0$ and $v(T) \in \mathbb{R}^{\mathcal{Z}}$, where μ is the uniform distribution over the outcomes, then classification calibrated losses are mapped to classification calibrated losses. This yields,

$$(\text{Rec}(T_0)T)^*\ell(-,a) = \alpha(T)\ell(-,a) + \left(\sum_{z\in\mathcal{Z}} \ell(z,a)\right) v(T),\ \forall T \in \mathcal{C},\ \forall a \in A,\ \forall \ell,$$

or in expectation,

$$\langle P, (\text{Rec}(T_0)T)^*\ell(-,a)\rangle = \alpha(T)\ell(P,a) + \langle P, v(T)\rangle\, \ell(\mu,a),$$

ie the effect of reconstructing incorrectly is to add a distribution dependent multiple of $\ell(\mu,a)$ to the loss.

The virtue of our approach is the identification of loss functions with *stronger* robustness properties over standard classification calibrated losses. We direct the reader to van Rooyen et al. (2017) for an in depth discussion.

12. Summary and a Guide to the Practitioner

Real world data sets are amalgamations of data of variable quality and type. Understanding how to *learn from* and *compare* different corrupted data sets is therefore a problem of great practical importance. Theorem 7, Appendix C and theorem 29 yield powerful means to do this. In concert, they provide the following framework to the practitioner:

1. Identify the appropriate loss function for the problem at hand.
2. Acquire data in accordance with theorem 7, and any relevant financial constraints.
3. Correct for any noise present in the data, and solve for,

$$\arg\min_{f\in\mathcal{F}} \sum_{i=1}^{n} \ell_{R_i}(y_i, f(x_i)).$$

As long as the decision maker is willing to work with *linear* and *kernelized* function classes, this is a convex problem with *many* available algorithmic solutions.

Acknowledgments

This work was completed while Brendan van Rooyen was with NICTA, The Australian National University, ACEMS and The Queensland University of Technology. The work was partially supported by the Australian Research Council. Many thanks go to Aditya Menon for many interesting conversations and providing some of the initial impetus for the paper. Thanks to Clayton Scott for providing detailed feedback.

Appendix A. Examples

Here we show examples of common corrupted machine learning problems.

A.1 Noisy Labels

We consider the problem of learning from noisy binary labels (Angluin and Laird, 1988; Natarajan et al., 2013). Here σ_i is the probability that class i is has its label flipped. We have,

$$T = \begin{pmatrix} 1-\sigma_{-1} & \sigma_1 \\ \sigma_{-1} & 1-\sigma_1 \end{pmatrix} \text{ and } R = \frac{1}{1-\sigma_{-1}-\sigma_1}\begin{pmatrix} 1-\sigma_1 & -\sigma_1 \\ -\sigma_{-1} & 1-\sigma_{-1} \end{pmatrix},$$

This yields,

$$\ell_R(y,a) = \frac{(1-\sigma_{-y})\ell(y,a) - \sigma_y\ell(-y,a)}{1-\sigma_{-1}-\sigma_1}.$$

The above loss is lemma 1 in Natarajan et al. (2013). Interestingly, even if ℓ is positive, ℓ_R can be negative. If the noise is symmetric with $\sigma_{-1} = \sigma_1 = \sigma$ and ℓ is 01 loss then,

$$\ell_R(y,a) = \frac{\ell_{01}(y,a) - \sigma}{1-2\sigma},$$

which is just a rescaled and shifted version of 01 loss. If we work in the realizable setting, i.e. there is some $f \in \mathcal{F}$ with,

$$\mathbb{E}_{(x,y)\sim P}\ell_{01}(y, f(x)) = 0,$$

then the above provides an interesting correspondence between learning with symmetric label noise and learning under distributions with large Tsybakov margin (Audibert and Tsybakov, 2007). Taking $\sigma = \frac{1}{2} - h$ with P *separable* in turn implies $\tilde{P}$ has Tsybakov margin h. This means bounds developed for this setting, such as in Massart and Nédélec (2006), can be transferred to the setting of learning with symmetric label noise. Our lower bound reproduces the results of Massart and Nédélec (2006).

Below is a table of the relevant parameters for learning with noisy binary labels. These results directly extend those presented in Kearns (1998) that considered only the case of symmetric label noise.

Learning with Label Noisy (Binary)

T	$\begin{pmatrix} 1-\sigma_{-1} & \sigma_1 \\ \sigma_{-1} & 1-\sigma_1 \end{pmatrix}$
R^*	$\frac{1}{1-\sigma_{-1}-\sigma_1}\begin{pmatrix} 1-\sigma_1 & -\sigma_1 \\ -\sigma_{-1} & 1-\sigma_{-1} \end{pmatrix}$
$\text{Clarity}(T)$	$\lvert 1-\sigma_{-1}-\sigma_1\rvert$
$\lVert R^*\rVert_\infty$	$\frac{1}{\lvert 1-\sigma_{-1}-\sigma_1\rvert}\max(1-\sigma_{-1}+\sigma_1, 1-\sigma_1+\sigma_{-1})$
$\lVert \ell_{01,T}\rVert_\infty$	$\frac{1}{\lvert 1-\sigma_{-1}-\sigma_1\rvert}\max(1-\sigma_{-1}, 1-\sigma_1, \sigma_{-1}, \sigma_1)$

We see that as long as $\sigma_{-1} + \sigma_1 \neq 1$, T is reconstructible. The pattern we see in this table is quite common. $\|R^*\|_\infty$ tends to be marginally greater than $\frac{1}{\alpha(T)}$, with $\|\ell_{01,T}\|_\infty$ less than both. In the symmetric case our lower bound reproduces that of Aslam and Decatur (1996).

Finally, when working with symmetric label noise ($\sigma_{-1} = \sigma_1 = \sigma$),

$$\|R_\sigma - R_{\sigma'}\|_1 = \frac{2|\sigma - \sigma'|}{|1 - 2\sigma||1 - 2\sigma'|}.$$

For fixed true noise rate σ, the presence of a factor $|1-2\sigma'|$ in the denominator means that underestimating σ is preferred to overestimating. Hence when designing estimates for σ, those with negative bias might perform better than those that are unbiased or are positively biased. Furthermore, when covering noise rates, as per the discussion in 10, more focus should be given to higher noise rates than to lower.

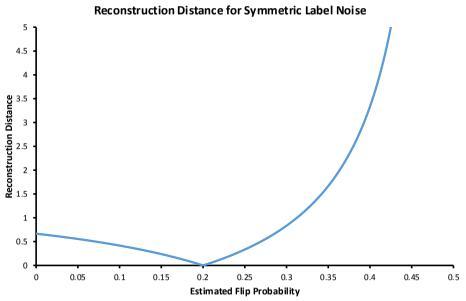

Figure 1: Plot of $\|R_\sigma - R_{\sigma'}\|_1$ for $\sigma = 0.2$. $\|R_\sigma - R_{\sigma'}\|_1$ is a measure of how far apart two corruptions are. This distance measure can be used when constructing estimators for the corruption process T. See text.

A.2 Semi-Supervised Learning

We consider the problem of semi-supervised learning (Chapelle et al., 2010). Here $1 - \sigma_i$ is the probability class i has a missing label. We consider the symmetric case where $\sigma_{-1} = \sigma_1 = \sigma$.

Symmetric Semi-Supervised Learning

T	$\begin{pmatrix} \sigma & 0 \\ 0 & \sigma \\ 1-\sigma & 1-\sigma \end{pmatrix}$
R^*	$\begin{pmatrix} \frac{1-2\sigma+2\sigma^2}{1-3\sigma+5\sigma^2-3\sigma^3} & \frac{-\sigma^2}{1-3\sigma+5\sigma^2-3\sigma^3} \\ \frac{-\sigma^2}{1-3\sigma+5\sigma^2-3\sigma^3} & \frac{1-2\sigma+2\sigma^2}{1-3\sigma+5\sigma^2-3\sigma^3} \\ \frac{\sigma}{1-2\sigma+3\sigma^2} & \frac{\sigma}{1-2\sigma+3\sigma^2} \end{pmatrix}$
$\text{Clarity}(T)$	σ
$\|R^*\|_\infty$	$\frac{1}{\sigma}$
$\|\ell_{01,T}\|_\infty$	$\frac{1-2\sigma+2\sigma^2}{2\sigma+3\sigma-5\sigma^2}$

Once again $\|\ell_{01,T}\|_\infty \leq \frac{1}{\text{Clarity}(T)}$. Our lower bound confirms that in general unlabelled data does not help (Balcan and Blum, 2010). Rather than using the method of unbiased estimators, one could simply throw away the unlabelled data leaving behind σn labelled instances on average. To make further progress in this problem, as noted elsewhere (Balcan and Blum, 2010), normally one assumes some form of compatibility between the marginal distribution of instances and the optimal classifier. In principle, restricted versions of Le Cams method and the strong data processing inequality could be used to give lower bounds under these different assumptions. As our interest here are minimax bounds, we do not pursue these methods.

A.3 Three Class Symmetric Label Noise

Here we present parameters for the three class variant of symmetric label noise. We have $\tilde{Y} = Y = \{1, 2, 3\}$ with $P(\tilde{Y} = \tilde{y}|Y = y) = 1 - \sigma$, if $y = \tilde{y}$ and $\frac{\sigma}{2}$ otherwise.

Learning with Symmetric Label Noisy (Multiclass)

T	$\begin{pmatrix} 1-\sigma & \frac{\sigma}{2} & \frac{\sigma}{2} \\ \frac{\sigma}{2} & 1-\sigma & \frac{\sigma}{2} \\ \frac{\sigma}{2} & \frac{\sigma}{2} & 1-\sigma \end{pmatrix}$
R^*	$\begin{pmatrix} \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} \end{pmatrix}$
$\text{Clarity}(T)$	$\lvert 1 - \frac{3}{2}\sigma \rvert$
$\|R^*\|_\infty$	$\frac{2+\sigma}{\lvert 2-3\sigma \rvert}$
$\|\ell_{01,T}\|_\infty$	$\frac{2}{\lvert 2-3\sigma \rvert} \max(\sigma, 1-\sigma)$

We see that as long as $\sigma \neq \frac{2}{3}$, T is reconstructible. Once again $\|\ell_{01,T}\|_\infty \leq \frac{1}{\alpha(T)}$.

A.4 Partial Labels

Here we follow Cour et al. (2011) with $Y = \{1, 2, 3\}$ and $\tilde{Y} = \{0, 1\}^Y$ the set of partial labels. A partial label of $(0, 1, 1)$ indicates that the true label is either 2 or 3 but not 1. We assume that a

partial label always includes the true label as one of the possibilities and furthermore that spurious labels are added with probability σ.

Learning with Partial Labels

T	$\begin{pmatrix} (1-\sigma)^2 & 0 & 0 \\ 0 & (1-\sigma)^2 & 0 \\ 0 & 0 & (1-\sigma)^2 \\ (1-\sigma)\sigma & (1-\sigma)\sigma & 0 \\ (1-\sigma)\sigma & 0 & (1-\sigma)\sigma \\ 0 & (1-\sigma)\sigma & (1-\sigma)\sigma \\ \sigma^2 & \sigma^2 & \sigma^2 \end{pmatrix}$
R	$\begin{pmatrix} 1 & 0 & 0 & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & -\frac{\sigma-3}{3(\sigma-1)} & \frac{1}{3} \\ 0 & 1 & 0 & \frac{3-2\sigma}{3-3\sigma} & -\frac{\sigma-3}{3(\sigma-1)} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \\ 0 & 0 & 1 & -\frac{\sigma-3}{3(\sigma-1)} & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \end{pmatrix}$
$\mathrm{Clarity}(T)$	$1-\sigma$
$\|R^*\|_\infty$	$\frac{\lvert 3-\sigma\rvert + 2\lvert 3-2\sigma\rvert}{3\lvert 1-\sigma\rvert}$
$\|\ell_{01,T}\|_\infty$	$\frac{6-4\sigma}{3-3\sigma}$

We see that as long as $\sigma \neq 1$, T is reconstructible. In this case $\|\ell_{01,T}\|_\infty$ and $\|R^*\|_\infty$ are given by more complicated expressions (however they are both available in closed form). We display their interrelation in a graph in below. To the best of our knowledge, no upper and lower bounds are present in the literature for this problem.

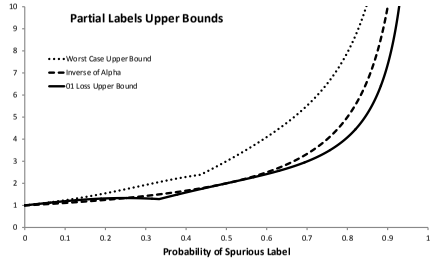

Figure 2: Upper and lower bounds for the problem of learning from partial labels, see text.

Appendix B. Le Cam's Method and Minimax Lower Bounds

The development here closely follows Duchi et al. (2013) with some streamlining. We consider a general decision problem with unknowns Θ, observation space $\mathcal{Z}$ and loss $L : \Theta \times A \to \mathbb{R}$, with $\inf_a L(\theta, a) = 0$. For any learning algorithm $\mathcal{A} \in \mathbb{T}(\mathcal{Z}, A)$ we wish to lower bound the minimax risk,

$$\underline{\mathrm{Risk}}_L(e) = \inf_{\mathcal{A}} \sup_{\theta} \mathbb{E}_{z\sim e(\theta)} L(\theta, \mathcal{A}(z)).$$

The method proceeds by reducing a general decision problem to an easier binary classification problem, by considering a supremum of the risk over a restricted set $\{\theta_1, \theta_2\}$. Using Markov's inequality we then relate this to the minimum 01 loss in a particular binary classification problem. Finally one finds a lower bound for this quantity. With $\theta\sim\{\theta_1, \theta_2\}$ meaning θ is drawn uniformly at random from the set $\{\theta_1, \theta_2\}$, we have,

$$\begin{aligned}
\sup_{\theta} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} L(\theta, a) &\geq \sup_{\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} L(\theta, a) \\
&\geq \mathbb{E}_{\theta\sim\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} L(\theta, a) \\
&\geq \delta \mathbb{E}_{\theta\sim\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} [\![L(\theta, a) \geq \delta]\!].
\end{aligned}$$

Recall the *separation* $\rho : \Theta\times\Theta \to \mathbb{R}$, $\rho(\theta_1, \theta_2) = \inf_a L(\theta_1, a) + L(\theta_2, a)$. The separation measures how hard it is to act well against both θ_1 and θ_2 simultaneously. We now assume $\rho(\theta_1, \theta_2) > 2\delta$. Define $f : A \to \{\theta_1, \theta_2, \text{error}\}$ where $f(a) = \theta_i$ if $L(\theta_i, a) < \delta$ and error otherwise. This function is well defined as if there exists an action a with $L(\theta_1, a) < \delta$ and $L(\theta_2, a) < \delta$ then $\rho(\theta_1, \theta_2) < 2\delta$, a contradiction. Let $\hat{\mathcal{A}}$ be the classifier that first draws $a\sim\mathcal{A}(z)$ and then outputs $f(a)$. We have,

$$\begin{aligned}
\sup_{\theta} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} L(\theta, a) &\geq \delta \mathbb{E}_{\theta\sim\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{\theta'\sim\hat{\mathcal{A}}(z)} [\![\theta \neq \theta']\!] \\
&\geq \delta \inf_{\hat{\mathcal{A}}\in\mathbb{T}(\mathcal{Z},\Theta)} \mathbb{E}_{\theta\sim\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{\theta'\sim\hat{\mathcal{A}}(z)} [\![\theta \neq \theta']\!] \\
&= \delta \left(\frac{1}{2} - \frac{1}{2} V(e(\theta_1), e(\theta_2)) \right),
\end{aligned}$$

where the first line is a rewriting of of the previous in terms of the classifier $\hat{\mathcal{A}}$, the second takes an infimum over all classifiers and the final line is a standard result in theoretical statistics (see Reid and Williamson (2011) for a modern treatment). Taking $\delta = \frac{\rho(\theta_1,\theta_2)}{2}$ yields lemma 8.

B.1 Extension of Le Cam's Method to Bayesian Risk

Rather than lower bounding $\sup_\theta \mathbb{E}_{z\sim e(\theta)} L(\theta, \mathcal{A}(z))$, a Bayesian with some knowledge about the unknown, given in the form of a prior $\pi \in \mathbb{P}(\Theta)$, wishes to lower bound the Bayesian risk,

$$\underline{\mathrm{Risk}}^{\pi}_L(e) := \inf_{\mathcal{A}} \mathbb{E}_{\theta\sim\pi} \mathbb{E}_{z\sim e(\theta)} L(\theta, \mathcal{A}(z)).$$

Following from the second line of the derivation of Le Cam's method, we have a lower bound,

$$\begin{aligned}
\mathbb{E}_{\theta\sim\{\theta_1,\theta_2\}} \mathbb{E}_{z\sim e(\theta)} \mathbb{E}_{a\sim\mathcal{A}(z)} L(\theta, a) &= \frac{1}{2}\mathrm{Risk}_L(\theta_1, e, \mathcal{A}) + \frac{1}{2}\mathrm{Risk}_L(\theta_2, e, \mathcal{A}) \\
&\geq \rho(\theta_1, \theta_2) \left(\frac{1}{4} - \frac{1}{4} V(e(\theta_1), e(\theta_2)) \right).
\end{aligned}$$

Let $\mu \in \mathbb{P}(\Theta \times \Theta)$ be any distribution with *both* marginals over Θ equal to π. Averaging over this distribution we have,

$$\mathbb{E}_{\theta\sim\pi}\text{Risk}_L(\theta, e, \mathcal{A}) \geq \mathbb{E}_{(\theta_1,\theta_2)\sim\mu}\rho(\theta_1, \theta_2)\left(\frac{1}{4} - \frac{1}{4}V(e(\theta_1), e(\theta_2))\right).$$

This insight leads to a Bayesian version of lemma 8.

Lemma 36 *Let $\mu \in \mathbb{P}(\Theta \times \Theta)$ be any distribution with* both *marginals over Θ equal to π. Then for all experiments e and loss functions ℓ,*

$$\underline{\text{Risk}}^{\pi}_L(e) \geq \mathbb{E}_{(\theta_1,\theta_2)\sim\mu}\rho(\theta_1, \theta_2)\left(\frac{1}{4} - \frac{1}{4}V(e(\theta_1), e(\theta_2))\right).$$

Using this in place of lemma 8 leads to Bayesian versions of theorems 15 and 16.

Appendix C. Canonical Loss Functions and their Convexification

Here we develop *general* representations of loss functions $L : \Theta \times A \to \mathbb{R}$. We assume that the set Θ is finite.

In many statistical problems, it is natural for the space of actions A to be the set of distributions over unknowns $\mathbb{P}(\Theta)$.

Definition 37 *A loss $L : \Theta \times \mathbb{P}(\Theta) \to \mathbb{R}$ is* proper *if for all distributions $P \in \mathbb{P}(\Theta)$,*

$$P \in \operatorname*{arg\,min}_{Q\in\mathbb{P}(\Theta)} \langle P, L(-, Q)\rangle_\Theta .$$

It is strictly proper *if P is the* unique *minimizer.*

A proper loss takes a prediction $Q \in \mathbb{P}(\Theta)$, and then penalizes the decision maker according to how much weight their prediction assigned to the unknown θ. Intuitively properness ensures that if the decision maker *knows* P, then they minimize their expected loss by *reporting* P. Proper losses constitute a well studied class of loss functions, that provide suitable surrogates for decision problems (Brier, 1950; Grünwald and Dawid, 2004; Zhang, 2004; Gneiting and Raftery, 2007; Dawid, 2007; Reid and Williamson, 2009a; Dawid, 2007; Ávila Pires et al., 2013).

As will be shown, all "sensible" losses are essentially re-parametrized proper losses. We show how to *construct* proper losses from their entropies. Furthermore, we show how to render any proper loss convex through a canonical re-parametrization. This allows the use of tools from convex analysis (Boyd and Vandenberghe, 2004; Lucchetti, 2006) to aid in calculating optimal actions.

C.1 Entropy from Loss

Rather than working with probability distributions, we take the route of Williamson (2014) and work with un-normalized distributions. Denote the set of all unnormalized distributions on Θ by $\mathbb{P}^+(\Theta)$. For any loss function L, define the *entropy* $\underline{L} : \mathbb{P}^+(\Theta) \to \mathbb{R}$,

$$\underline{L}(\mu) = \min_{a\in A}\langle \mu, L(-, a)\rangle_\Theta.$$

$\underline{L}(P)$ measures the uncertainty of the optimal action for the distribution P. The entropy is also called an *uncertainty function*, a *Bayes risk* or a *support function* (DeGroot, 1962; Williamson, 2014). It is concave and 1-homogeneous.

Definition 38 *A function $f : \mathbb{P}^+(\Theta) \to \mathbb{R}$ is 1-homogeneous if for all $x \in \mathbb{P}^+(\Theta)$ and for all $\lambda > 0$,*

$$f(\lambda x) = \lambda f(x).$$

C.2 Loss from Entropy

All loss functions give rise to an entropy. Conversely, the entropy encodes much information of its associated loss through its *super-gradients*, which include all the *Bayes* actions for the underlying loss.

C.2.1 Bayes Actions and Super-gradients

For any distribution P, define the *Bayes actions* for P as the set of minimizers,

$$A_P = \operatorname*{arg\,min}_{a\in A} \langle P, L(-, a)\rangle .$$

For any $a_P \in A_P$ we have $\underline{L}(P) = \langle P, L(-, a_P)\rangle$.

Definition 39 (Super-gradient of a concave function) *Let $f : \mathbb{P}^+(\Theta) \to \mathbb{R}$ be a concave function. $v \in \mathbb{R}^\Theta$ is a* super-gradient *of f at the point x if for all $y \in \mathbb{P}^+(\Theta)$,*

$$\langle y - x, v\rangle + f(x) \geq f(y).$$

Denote the set of all super-gradients at a point x by $\partial f(x)$, and the set of all super-gradients by $\partial f = \cup_x \partial f(x)$. For differentiable concave functions, super-gradients are the same as regular gradients (Lucchetti, 2006). 1-homogeneous functions afford a very simple representation via their super-gradients.

Theorem 40 (Generalized Euler's Homogeneous Function Theorem) *Let $f : \mathbb{P}^+(\Theta) \to \mathbb{R}$ be a concave 1-homogeneous function. Then for all x and for all $v \in \partial f(x)$,*

$$f(x) = \langle x, v\rangle.$$

Furthermore, $v \in \partial f(x) \implies v \in \partial f(\lambda x)$ for all $\lambda > 0$.

We include a simple proof of this theorem for completeness.
Proof Firstly, for all x and all $\lambda > 0$,

$$\langle \lambda x - x, v\rangle + f(x) \geq \lambda f(x),$$

which follows directly from the definition of a super-gradient at x and the 1-homogeneity of f. Re-arranging yields, $(1 - \lambda)(f(x) - \langle x, v\rangle) \geq 0$. Letting $\lambda \to 0^+$ yields $f(x) \geq \langle x, v\rangle$. Similarly, for all x and all $\lambda > 0$,

$$\langle x - \lambda x, v\rangle + \lambda f(x) \geq f(x),$$

which follows directly from the definition of a super-gradient at λx and the 1-homogeneity of f. Re-arranging yields, $(1-\lambda)(f(x)-\langle x,v\rangle)\leq 0$. Letting $\lambda\to 0^+$ yields $f(x)\leq\langle x,v\rangle$, therefore $f(x)=\langle x,v\rangle$.

To prove the second claim, we have for all y and $\lambda>0$,

$$\langle y-x,v\rangle+f(x)\geq f(y)$$
$$\langle \lambda y-\lambda x,v\rangle+f(\lambda x)\geq f(\lambda y),$$

where the first line is by definition, and the second is by 1-homogeneity. As y is arbitrary, the claim is proved.

■

This theorem provides a corollary, that shows the super-gradients of a 1-homogeneous function have a property similar to properness.

Corollary 41 *Let $f:\mathbb{P}^+(\Theta)\to\mathbb{R}$ be a concave 1-homogeneous function. Then for all $x,y\in\mathbb{P}^+(\Theta)$ and for all $v_x\in\partial f(x)$, $v_y\in\partial f(y)$,*

$$\langle x,v_y\rangle\geq\langle x,v_x\rangle\,.$$

We now show that the partial loss of a Bayes action is a super-gradient of $\underline{L}$.

Theorem 42 *For all loss functions L and distributions P, $a_P\in A_P\Leftrightarrow L(-,a_P)\in\partial\underline{L}(P)$.*

Proof For $a_P\in A_P$ we have for all $\mu\in\mathbb{P}^+(\Theta)$,

$$\langle\mu-P,L(-,a_P)\rangle+\underline{L}(P)=\langle\mu,L(-,a_P)\rangle\geq\min_{a\in A}\langle\mu,L(-,a)\rangle=\underline{L}(\mu).$$

Hence $L(-,a_P)\in\partial\underline{L}(P)$. For the converse, if $L(-,a_P)\in\partial\underline{L}(P)$ then,

$$\underline{L}(P)=\langle P,L(-,a_P)\rangle=\min_{a\in A}\langle P,L(-,a)\rangle\,,$$

meaning a is Bayes.

■

Therefore, once non-Bayes actions are discarded, we can identify a loss with a subset of $\partial\underline{L}$. Rather than working with a subset $\partial\underline{L}$, it is advantageous to consider *all* of $\partial\underline{L}$.

Definition 43 (Canonical Loss (Preliminary)) *Let $\underline{L}:\mathbb{P}^+(\Theta)\to\mathbb{R}$ be a concave, 1-homogeneous function. Then its* canonical loss, *$\mathcal{L}:\Theta\times\partial\underline{L}\to\mathbb{R}$ is given by, $\mathcal{L}(\theta,\zeta)=\zeta(\theta)$.*

As will be shown, canonical losses can always be convexified. Furthermore, they maintain all of the properties of L needed for assessing the quality of decisions.

C.2.2 THE BAYES SUPER PREDICTION SET

The process of *canonising* a loss, i.e. going from,

$$L\to\underline{L}\to\mathcal{L},$$

can create *extra* partial losses/actions that were not originally available to the decision maker. However, they gain no benefit from these extra actions. From any entropy define the *Bayes super prediction set*,

$$\mathcal{S}_{\underline{L}}:=\left\{\zeta\in\mathbb{R}^\Theta:\langle\mu,\zeta\rangle\geq\underline{L}(\mu),\ \forall\mu\in\mathbb{R}^\Theta_+\right\}.$$

By the definition,

$$\min_{a\in A}\langle P,L(-,a)\rangle=\min_{\zeta\in\mathcal{S}_{\underline{L}}}\langle P,\zeta\rangle\,,\ \forall P\in\mathbb{P}(\Theta).$$

The Bayes super prediction set is precisely those partial losses that the decision maker need not use over the actions available to them, no matter the distribution P. The super prediction set is convex. Furthermore, the Bayes actions for $\mathcal{L}$ are the lower boundary of the super prediction set.

Lemma 44 *Let $\underline{L}:\mathbb{P}^+(\Theta)\to\mathbb{R}$ be a concave, 1-homogeneous function. Then $\zeta\in\partial\underline{L}$ if and only if,*

$$\langle\mu,\zeta\rangle\geq\underline{L}(\mu),\ \forall\mu\in\mathbb{P}^+(\Theta),$$

with equality holding for at least one μ.

The proof is a straightforward application of 1-homogeneity and super-gradients.

Canonical losses use *all* super gradients of $\underline{L}$. Proper losses use some.

Corollary 45 (Loss from Entropy) *Let $\underline{L}:\mathbb{P}^+(\Theta)\to\mathbb{R}$ be a concave, 1-homogeneous function and let $\nabla\underline{L}:\mathbb{P}^+(\Theta)\to\mathbb{R}^\Theta$ be a super-gradient function, $\nabla\underline{L}(\mu)\in\partial\underline{L}(\mu)$, $\forall\mu$. Then,*

$$L(\theta,Q)=\mathcal{L}(\theta,\nabla\underline{L}(Q)),$$

is a proper loss. Furthermore if $\underline{L}$ is strictly concave then L is strictly proper.

C.3 Convexification of Losses in Canonical Form

The preceding shows how to *construct* losses, we begin with a concave 1-homogeneous function and take super-gradients. Focus now turns to their convexification. Once convexified, the decision maker gains access to the large and ever growing literature on the minimization of convex functions to aid in the calculation of optimal actions. We closely follow Dawid (2007), with a focus on canonical losses. This streamlines the development. For example, for some proper losses lemma 47 fails to hold. Furthermore, our result on convexification of canonical losses (theorem 49), is to the best of our knowledge novel.

Recall $\mathbf{1}_\Theta\in\mathbb{R}^\Theta$ is the function that always returns 1, and define $\mathbf{1}_\Theta^\perp$ to be its orthogonal complement in $\mathbb{R}^\Theta$, i.e. the functions $v\in\mathbb{R}^\Theta$ with,

$$\langle\mathbf{1}_\Theta,v\rangle=\sum_{z\in\Theta}v(z)=0.$$

Define,

$$\Gamma_{\underline{L}} = \{(\gamma, v) \in \mathbb{R} \times \mathbf{1}_\Theta^\perp : \gamma \mathbf{1}_\Theta + v \in \partial \underline{L}\}.$$

Lemma 46 *Let $(\gamma, v) \in \Gamma_{\underline{L}}$. Then γ is uniquely determined by v.*

Proof Fix v and suppose there exists γ_1 and γ_2 with $\gamma_1 < \gamma_2$ and $\gamma_1 \mathbf{1}_\Theta + v, \gamma_2 \mathbf{1}_\Theta + v \in \partial \underline{L}$. By assumption, $\gamma_2 \mathbf{1}_\Theta + v$ is Bayes for some distribution P. But,

$$\langle P, \gamma_1 \mathbf{1}_\Theta + v \rangle = \gamma_1 + \langle P, v \rangle < \gamma_2 + \langle P, v \rangle = \langle P, \gamma_2 \mathbf{1}_\Theta + v \rangle,$$

a contradiction. ■

Thus we lose nothing by working with projections of losses onto $\mathbf{1}_\Theta^\perp$. Define,

$$\hat{\Gamma}_{\underline{L}} = \mathrm{proj}_{\mathbf{1}_\Theta^\perp}(\partial \underline{L}) \subseteq \mathbf{1}_\Theta^\perp.$$

By lemma 46 $\hat{\Gamma}_{\underline{L}}$ is in 1-1 correspondence with $\partial \underline{L}$.

Lemma 47 *$\hat{\Gamma}_{\underline{L}}$ is a convex set.*

Proof To show $\hat{\Gamma}_{\underline{L}}$ is convex, we are required to show that for all $\zeta_1, \zeta_2 \in \partial \underline{L}$ and all $\lambda \in [0, 1]$ there is a constant γ such that,

$$\lambda \zeta_1 + (1 - \lambda)\zeta_2 - \gamma \mathbf{1}_\Theta \in \partial \underline{L}.$$

By lemma 44, this is equivalent to,

$$\underbrace{\lambda \langle P, \zeta_1 \rangle + (1 - \lambda) \langle P, \zeta_2 \rangle - \underline{L}(P)}_{\gamma(P)} - \gamma = \gamma(P) - \gamma \geq 0, \ \forall P \in \mathbb{P}(\Theta),$$

with equality holding for one P. Let $\gamma^* = \min_P \gamma(P)$, with P^* the distribution that achieves the minimum. Clearly $\gamma(P) - \gamma^* \geq 0$. Therefore,

$$\lambda \langle P, \zeta_1 \rangle + (1 - \lambda) \langle P, \zeta_2 \rangle - \gamma^* \geq \underline{L}(P), \ \forall P \in \mathbb{P}(\Theta),$$

with equality for P^*. Therefore by lemma 44, $\lambda \zeta_1 + (1 - \lambda)\zeta_2 - \gamma^* \mathbf{1}_\Theta \in \partial \underline{L}$. ■

Define the function $\Psi : \hat{\Gamma}_{\underline{L}} \to \mathbb{R}$ such that,

$$v + \Psi(v) \mathbf{1}_\Theta \in \partial \underline{L}.$$

By lemma 46, Ψ is well defined.

Lemma 48 *Ψ is a convex function.*

Proof Let $v_1, v_2 \in \hat{\Gamma}_{\underline{L}}$ with $v_\lambda = \lambda v_1 + (1 - \lambda) v_2$. Let their partial losses be,

$$\begin{aligned}
\zeta_1 &= v_1 + \Psi(v_1) \mathbf{1}_\Theta \\
\zeta_2 &= v_2 + \Psi(v_2) \mathbf{1}_\Theta \\
\zeta_\lambda &= \lambda v_1 + (1 - \lambda) v_2 + \Psi(\lambda v_1 + (1 - \lambda) v_2) \mathbf{1}_\Theta,
\end{aligned}$$

respectively. By assumption, for all $\lambda \in [0, 1]$ there exists a distribution P_λ such that,

$$\langle P_\lambda, \zeta_\lambda \rangle \leq \langle P_\lambda, \zeta \rangle, \ \forall \zeta \in \partial \underline{L}.$$

Assume there is a λ^* such that,

$$\lambda^* \Psi(v_1) + (1 - \lambda^*) \Psi(v_2) < \Psi(\lambda^* v_1 + (1 - \lambda^*) v_2).$$

But then,

$$\langle P_{\lambda^*}, \lambda^* \zeta_1 + (1 - \lambda^*) \zeta_2 \rangle < \langle P_{\lambda^*}, \zeta_{\lambda^*} \rangle,$$

a contradiction. ■

This gives the following representation theorem for canonical losses.

Theorem 49 (Representation of Canonical Losses) *Let $\underline{L} : \mathbb{P}^+(\Theta) \to \mathbb{R}$ be a concave, 1-homogeneous function. Then its canonical loss $\mathcal{L}$ can be represented as $\mathcal{L} : \Theta \times C \to \mathbb{R}$, with $C \subseteq \mathbf{1}_\Theta^\perp$ a convex set and,*

$$\mathcal{L}(\theta, v) = -\langle \delta_\theta, v \rangle + \Psi(v),$$

for a convex function Ψ.

The situation is particularly simple for binary problems.

Corollary 50 *Let $\Theta = \{\pm 1\}$. Then all canonical losses can be written as $\mathcal{L} : \{\pm 1\} \times I \to \mathbb{R}$,*

$$\mathcal{L}(\theta, v) = -\theta v + \Psi(v),$$

where I is a convex subset of $\mathbb{R}$ and $\Psi : I \to \mathbb{R}$ a convex function.

The proof comes from the observation that,

$$\mathbf{1}_\Theta^\perp = \mathrm{Span}((-1, 1)).$$

C.4 Illustrative Example: Binary Decisions and Square Loss

In binary problems, $\Theta = \{\pm 1\}$. An often used loss is the square or Brier loss. $L(\theta, \hat{\theta}) = \left(\theta - \hat{\theta}\right)^2$, where $\hat{\theta} \in [-1, 1]$. We plot this loss in figure 3. The partial losses are given by the red curve, the super prediction set in gray. The loss on negatives is plotted on the x-axis. In figure 4 we show geometrically how to produce canonical coordinates.

We seek to decompose,

$$L(-, \hat{\theta}) = \left((-1 - \hat{\theta})^2, (1 - \hat{\theta})^2\right) = \alpha \begin{pmatrix} 1 \\ -1 \end{pmatrix} + \beta \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Solving for α and β in terms of $\hat{\theta}$ gives,

$$\alpha = 2\hat{\theta} \text{ and } \beta = 1 + \hat{\theta}^2.$$

These equations can be easily solved for $\hat{\theta}$ giving,

$$\beta = \Psi(\alpha) = 1 + \frac{\alpha^2}{4}.$$

Therefore the canonical form of square loss is,

$$\mathcal{L}(\theta, \alpha) = -\theta\alpha + 1 + \frac{\alpha^2}{4}.$$

Notice that the only dependence on θ is via the "linear" term $-\theta\alpha$.

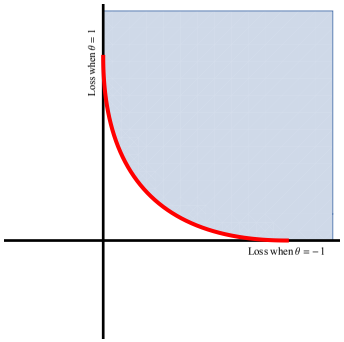

Figure 3: Plot of super prediction set and its lower boundary for square loss, see text.

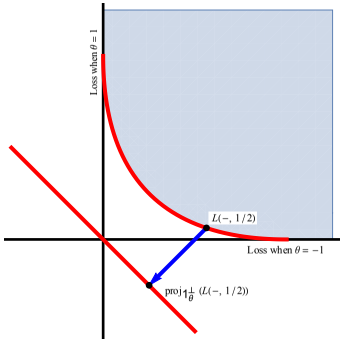

Figure 4: Construction of canonical coordinates for square loss, see text.

C.5 Illustrative Example: Hinge Loss

Hinge loss $L : \{-1, 1\} \times \mathbb{R} \to \mathbb{R}_+$,

$$L(\theta, \nu) = \max(0, 1 - \theta\nu),$$

is an often used, non-differentiable, loss function. Its minimization forms the basis of the support vector machine learning algorithm (Cortes and Vapnik, 1995; Schölkopf and Smola, 2002; Steinwart and Christmann, 2008), a popular method for learning classifiers. Here we show that the canonical form of hinge loss is the *linear loss*,

$$\mathcal{L}(\theta, \nu) = -\theta\nu, \ \nu \in [-1, 1].$$

Figure 5 is a plot of hinge loss and its super prediction set. Shown in orange are actions with $|\nu| \geq 1$. These actions are *inadmissible* and therefore not Bayes for any distribution over Θ. Figure 6 shows the projection of the Bayes actions for hinge loss unto $\mathbf{1}_\Theta^\perp$. As can be seen from the figure, linear loss is the result of "canonizing" hinge loss.

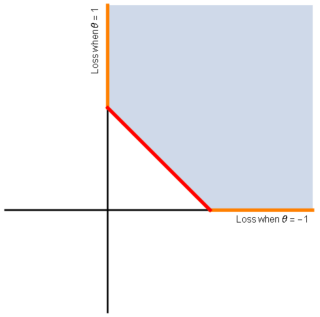

Figure 5: Plot of super prediction set and its lower boundary for hinge loss, see text (best viewed in color).

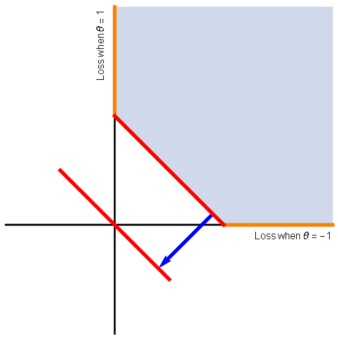

Figure 6: Construction of canonical coordinates for square loss, see text.

C.6 Proof of Theorem 29

Proof As $\mathcal{L}$ is canonical, its partial loss function is given by $\mathcal{L}(-,v) = v + \Psi(v)\mathbf{1}_{\mathcal{Z}}$. By definition,

$$\mathcal{L}_R(-,v) = R^*(\mathcal{L}(-,v)) = R^*(v) + \Psi(v)R^*(\mathbf{1}_{\mathcal{Z}}).$$

If $|\mathcal{Z}| = |\tilde{\mathcal{Z}}|$, then T is reconstructible if and only if T is invertible. As T is column stochastic,

$$\mathbf{1}_{\mathcal{Z}} = T^*(\mathbf{1}_{\tilde{\mathcal{Z}}}).$$

This yields,

$$R^*(\mathbf{1}_{\mathcal{Z}}) = R^*T^*(\mathbf{1}_{\tilde{\mathcal{Z}}}) = \mathbf{1}_{\tilde{\mathcal{Z}}}.$$

For the more general case where $|\mathcal{Z}| < |\tilde{\mathcal{Z}}|$, we have for all T and all $v \in \mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$,

$$\begin{aligned}\left\langle T(v), \mathbf{1}_{\tilde{\mathcal{Z}}}\right\rangle &= \left\langle v, T^*(\mathbf{1}_{\tilde{\mathcal{Z}}})\right\rangle \\ &= \langle v, \mathbf{1}_{\mathcal{Z}}\rangle \\ &= 0.\end{aligned}$$

Therefore $T(\mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}) \subseteq \mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$. As left inverses are not unique, we can further restrict R to those with $R(\mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}) \subseteq \mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$, or dually those with $R^*(\mathbf{1}_{\mathcal{Z}}) = \mathbf{1}_{\tilde{\mathcal{Z}}}$. There is always such an R, as the restriction of T to $\mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$ is also left invertible. Furthermore, $T(\mathbf{1}_{\mathcal{Z}}) \notin \mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$, as $T(\mathbf{1}_{\mathcal{Z}})$ nonnegative entries. Therefore, we can take R restricted to $\mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$ to be the left inverse of T restricted to $\mathbf{1}_{\tilde{\mathcal{Z}}}^{\perp}$, with $RT(\mathbf{1}_{\mathcal{Z}}) = \mathbf{1}_{\mathcal{Z}}$. Such an R can then be extended to all of $\mathbb{R}^{\tilde{\mathcal{Z}}}$. Finally, by definition, $\mathcal{L}_R(\tilde{z},v) = \langle \delta_{\tilde{z}}, \mathcal{L}_R(-,v)\rangle$, yielding,

$$\begin{aligned}\mathcal{L}_R(\tilde{z},v) &= \langle \delta_{\tilde{z}}, R^*(v)\rangle + \langle \delta_{\tilde{z}}, R^*(\mathbf{1}_{\mathcal{Z}})\rangle \Psi(v) \\ &= \langle R(\delta_{\tilde{z}}), v\rangle + \Psi(v),\end{aligned}$$

where the last line is by properties of adjoints. This function is the sum of two functions, one linear in v the other convex and is therefore convex in v. ■

C.7 Illustrative Example: Multi-class Logistic Loss and its Corrections

Here we show by example how to apply theorem 29 to construct losses for multiclass corrupted learning problems. We take $\Theta = \{1,2,3\}$, with L the log loss,

$$L(-,P) = (-\log(P_1), -\log(P_2), -\log(P_3))\,.$$

We express $v \in \mathbf{1}_{\Theta}^{\perp}$ as,

$$v = v_1 \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} + v_2 \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \end{pmatrix}.$$

Note that these basis vectors are the projections onto $\mathrm{id}_{\Theta}^{\perp}$ of the partial losses,

$$\begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix} \text{ and } \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix},$$

respectively. We have,

$$P = \left(\frac{e^{v_1}}{1+e^{v_1}+e^{v_2}}, \frac{e^{v_2}}{1+e^{v_1}+e^{v_2}}, \frac{1}{1+e^{v_1}+e^{v_2}}\right).$$

with,

$$\begin{aligned}\mathcal{L}(-,v) &= \begin{pmatrix} -v_1 + \log(1+e^{v_1}+e^{v_2}) \\ -v_2 + \log(1+e^{v_1}+e^{v_2}) \\ \log(1+e^{v_1}+e^{v_2}) \end{pmatrix} \\ &= v + \underbrace{\left(-\frac{1}{3}(v1+v2) + \log(1+e^{v_1}+e^{v_2})\right)}_{\Psi(v)} \mathbf{1}_{\Theta}.\end{aligned} \tag{1}$$

(1) is the usual form of multiclass logistic loss. For the case of symmetric noise,

$$T = \begin{pmatrix} 1-\sigma & \frac{\sigma}{2} & \frac{\sigma}{2} \\ \frac{\sigma}{2} & 1-\sigma & \frac{\sigma}{2} \\ \frac{\sigma}{2} & \frac{\sigma}{2} & 1-\sigma \end{pmatrix} \text{ and } R = \begin{pmatrix} \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} \\ \frac{-\sigma}{2-3\sigma} & \frac{-\sigma}{2-3\sigma} & \frac{2-\sigma}{2-3\sigma} \end{pmatrix},$$

respectively. All $v \in \mathbf{1}_{\Theta}^{\perp}$ are eigenvalues of R, with eigenvalue $\frac{2}{2-3\sigma}$, giving a corruption corrected loss of,

$$\mathcal{L}_R(-,v) = \frac{2}{2-3\sigma}v + \Psi(v)\mathrm{id}_{\Theta}.$$

Recall for the problem of learning partial labels $\tilde{\Theta} = \{0,1\}^{\Theta}$ the set of all partial labellings. Under the assumption that the partial label always includes the correct underlying label, and that spurious

labels are added with probability σ,

$$T = \begin{pmatrix} (1-\sigma)^2 & 0 & 0 \\ 0 & (1-\sigma)^2 & 0 \\ 0 & 0 & (1-\sigma)^2 \\ (1-\sigma)\sigma & (1-\sigma)\sigma & 0 \\ (1-\sigma)\sigma & 0 & (1-\sigma)\sigma \\ 0 & (1-\sigma)\sigma & (1-\sigma)\sigma \\ \sigma^2 & \sigma^2 & \sigma^2 \end{pmatrix}.$$

For this problem, there are several different alternatives for R. The reconstruction,

$$R = \begin{pmatrix} 1 & 0 & 0 & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & \frac{\sigma-3}{3(1-\sigma)} & \frac{1}{3} \\ 0 & 1 & 0 & \frac{3-2\sigma}{3-3\sigma} & \frac{\sigma-3}{3(1-\sigma)} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \\ 0 & 0 & 1 & \frac{\sigma-3}{3(1-\sigma)} & \frac{3-2\sigma}{3-3\sigma} & \frac{3-2\sigma}{3-3\sigma} & \frac{1}{3} \end{pmatrix}, \ \sigma \neq 1,$$

is a left inverse for T and satisfies the requirements of theorem 29. For this reconstruction one has,

$$R^* \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} = \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{2(2-\sigma)}{3(1-\sigma)} \\ 0 \end{pmatrix} \text{ and } R^* \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \end{pmatrix} = \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{2(2-\sigma)}{3(1-\sigma)} \\ \frac{\sigma-2}{3(1-\sigma)} \\ 0 \end{pmatrix},$$

leading to the loss,

$$\mathcal{L}_R(-, v) = v_1 \begin{pmatrix} -\frac{2}{3} \\ \frac{1}{3} \\ \frac{1}{3} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{2(2-\sigma)}{3(1-\sigma)} \\ 0 \end{pmatrix} + v_2 \begin{pmatrix} \frac{1}{3} \\ -\frac{2}{3} \\ \frac{1}{3} \\ \frac{\sigma-2}{3(1-\sigma)} \\ \frac{2(2-\sigma)}{3(1-\sigma)} \\ \frac{\sigma-2}{3(1-\sigma)} \\ 0 \end{pmatrix} + \Psi(v)\mathrm{id}_{\tilde{\Theta}}.$$

Appendix D. Proofs of Theorems in Main Text

D.1 Proof of Theorem 7

We actually prove a more general theorem, that works for infinite action sets.

Theorem 51 *Let $T_i \in \mathbb{T}(\mathcal{Z}, \tilde{\mathcal{Z}}_i)$ be a collection of k reconstructible corruptions. Let $\tilde{P} = \otimes_{i=i}^k \tilde{P}_i^{n_i}$, $\tilde{\mathcal{Z}} = \times_{i=1}^k \tilde{\mathcal{Z}}_i^{n_i}$, $n = \sum_{i=1}^k n_i$ and $r_i = \frac{n_i}{n}$. Then for all algorithms $\mathcal{A} \in \mathbb{T}(\tilde{\mathcal{Z}}, A)$, priors $\pi \in \mathbb{P}(A)$, distributions $P \in \mathbb{P}(\mathcal{Z})$ and bounded loss functions ℓ,*

$$\mathbb{E}_{\tilde{S}\sim\tilde{P}}\ell(P, \mathcal{A}(\tilde{S})) \leq \mathbb{E}_{\tilde{S}\sim\tilde{P}} \sum_{i=1}^k r_i \ell_{R_i}(\tilde{S}_i, \mathcal{A}(\tilde{S})) + K\sqrt{\frac{2\mathbb{E}_{S\sim P^n} D_{KL}(\mathcal{A}(\tilde{S}), \pi)}{n}}.$$

where $K = \sqrt{\sum_{i=1}^k r_i \|\ell_{R_i}\|_\infty^2}$.

Proof Define $L(\tilde{S}, a) = \sum_{i=1}^k \sum_{\tilde{z}\in\tilde{S}_i} \ell_{R_i}(z_i, a)$, the sum of the corrupted losses on the sample. By theorem 2.1 of Zhang (2006) for $\beta > 0$,

$$\mathbb{E}_{\tilde{S}\sim Q}\mathbb{E}_{a\sim\mathcal{A}(\tilde{S})} - \frac{1}{\beta}\log(\mathbb{E}_{\tilde{S}'\sim Q} e^{-\beta L(\tilde{S}', a)}) \leq \mathbb{E}_{\tilde{S}\sim Q}\left[L(\tilde{S}, \mathcal{A}(\tilde{S})) + \frac{D_{KL}(\mathcal{A}(\tilde{S}), \pi)}{\beta}\right]$$

$$\sum_{i=1}^k n_i \mathbb{E}_{\tilde{S}\sim Q}\mathbb{E}_{a\sim\mathcal{A}(\tilde{S})} - \frac{1}{\beta}\log(\mathbb{E}_{\tilde{z}\sim\tilde{P}_i} e^{-\beta\ell_{R_i}(\tilde{z}, a)}) \leq \mathbb{E}_{\tilde{S}\sim Q}\left[L(\tilde{S}, \mathcal{A}(\tilde{S})) + \frac{D_{KL}(\mathcal{A}(\tilde{S}), \pi)}{\beta}\right]$$

where the first line follows from the theorem and the second from properties of the cumulant generating function. Invoking lemma A.1 of Cesa-Bianchi and Lugosi (2006) yields,

$$\sum_{i=1}^k n_i \left(\mathbb{E}_{\tilde{S}\sim Q}\ell_{R_i}(\tilde{P}_i, \mathcal{A}(\tilde{S})) - \frac{\|\ell_{R_i}\|_\infty^2 \beta}{2}\right) \leq \mathbb{E}_{\tilde{S}\sim Q}\left[L(\tilde{S}, \mathcal{A}(\tilde{S})) + \frac{D_{KL}(\mathcal{A}(\tilde{S}), \pi)}{\beta}\right].$$

As the T_i are reconstructible,

$$\mathbb{E}_{\tilde{S}\sim Q}\ell(P, \mathcal{A}(\tilde{S})) \leq \frac{1}{n}\mathbb{E}_{\tilde{S}\sim Q}\left[L(\tilde{S}, \mathcal{A}(\tilde{S})) + \frac{D_{KL}(\mathcal{A}(\tilde{S}), \pi)}{\beta}\right] + \frac{\left(\sum_{i=1}^k r_i \|\ell_{R_i}\|_\infty^2\right)\beta}{2}.$$

Optimizing over β yields the desired result. ■

Theorem 7 is recovered by taking A finite, π uniform on A and upper bounding $D_{KL}(\mathcal{A}(S), \pi) \leq \log(|A|)$.

D.2 Proof of Lemma 10

Proof Firstly V is a *metric* on $\mathbb{P}(\times_{n=1}^k \mathcal{Z}_i)$ (Reid and Williamson, 2009b). Thus,

$$\begin{aligned} V(\otimes_{i=1}^k P_i, \otimes_{i=1}^k Q_i) &= V(P_1 \otimes (\otimes_{i=2}^k P_i), Q_1 \otimes (\otimes_{i=2}^k Q_i)) \\ &\leq V(P_1 \otimes (\otimes_{i=2}^k P_i), Q_1 \otimes (\otimes_{i=2}^k P_i)) + V(Q_1 \otimes (\otimes_{i=2}^k P_i), Q_1 \otimes (\otimes_{i=2}^k Q_i)) \\ &= V(P_1, Q_1) + V(\otimes_{i=2}^k P_i, \otimes_{i=2}^k Q_i), \end{aligned}$$

where the first line is by definition, the second as V is a metric and the third is easily verified from the definition of V. To complete the proof proceed inductively. ■

D.3 Proof of Theorem 16

Proof Let

$$T = \otimes_{i=i}^{k} T_i^{n_i} = \underbrace{T_1 \otimes \cdots \otimes T_1}_{n_1 \text{ times}} \otimes \underbrace{T_2 \otimes \cdots \otimes T_2}_{n_2 \text{ times}} \otimes \cdots \otimes \underbrace{T_k \otimes \cdots \otimes T_k}_{n_k \text{ times}}.$$

One has $T(e_n(\theta)) = T_1(e(\theta))^{n_1} \otimes T_2(e(\theta))^{n_2} \otimes \cdots \otimes T_k(e(\theta))^{n_k}$. By lemma 10,

$$\begin{aligned} V(T(e_n(\theta_1)), T(e_n(\theta_2)) &\leq \sum_{i=1}^{k} n_i V(T_i(e(\theta_1)), T_i(e(\theta_2))) \\ &\leq \underbrace{\left(\sum_{i=1}^{k} \text{Clarity}(T_i) n_i \right)}_{K} V(e(\theta_1), e(\theta_2)). \end{aligned}$$

Rearranging gives,

$$\rho(\theta_1, \theta_2) \left(1 - \gamma V(T(e_n(\theta_1), T(e_n(\theta_2))\right) \geq \rho(\theta_1, \theta_2) \left(1 - K\gamma V(T(e(\theta_1), T(e(\theta_2))\right), \ \forall \gamma > 0.$$

Taking supremum's over θ_1, θ_2 yields,

$$\text{Le Cam}_L \left(T \circ e_n, \gamma\right) \geq \text{Le Cam}_L \left(e, K\gamma\right)$$

Applying lemma 11 yields the result. ■

D.4 Proof of Lemma 13

Proof

$$\begin{aligned} \text{Clarity}(T_2 T_1) &= \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{\|T_2 \circ T_1(P) - T_2 \circ T_1(Q)\|_1}{\|P - Q\|_1} \\ &= \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{\|T_2 \circ T_1(P) - T_2 \circ T_1(Q)\|_1}{\|T_1(P) - T_2(Q)\|_1} \frac{\|T_1(P) - T_2(Q)\|_1}{\|P - Q\|_1} \\ &\leq \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{\|T_2 \circ T_1(P) - T_2 \circ T_1(Q)\|_1}{\|T_1(P) - T_2(Q)\|_1} \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{\|T_1(P) - T_2(Q)\|_1}{\|P - Q\|_1} \\ &\leq \sup_{P,Q \in \mathbb{P}(\tilde{\mathcal{Z}}_1)} \frac{\|T_2(P) - T_2(Q)\|_1}{\|P - Q\|_1} \sup_{P,Q \in \mathbb{P}(\mathcal{Z})} \frac{\|T_1(P) - T_2(Q)\|_1}{\|P - Q\|_1} \\ &= \text{Clarity}(T_2)\text{Clarity}(T_1), \end{aligned}$$

where the first line follows from the definitions, the second follows if $T_1(P) \neq T_2(Q)$ and the rest are simple rearrangements. For the final inequality, remember that $\text{Clarity}(T) \leq 1$. ■

D.5 Proof of Lemma 19

Proof By definition $\|\tilde{\ell}\|_\infty = \sup_{z,a} |\tilde{\ell}(z,a)| = \sup_a \|\tilde{\ell}_a\|_\infty$. Hence,

$$\begin{aligned} \|\tilde{\ell}\|_\infty &= \sup_a \|\tilde{\ell}_a\|_\infty \\ &\leq \sup_a \|R^*\|_\infty \|\ell_a\|_\infty \\ &= \|R^*\|_\infty \|\ell\|_\infty, \end{aligned}$$

where the second line follows from the definition of the operator norm $\|R^*\|_\infty$. ■

D.6 Proof of Lemma 20

Proof Firstly $\|R\|_1 = \|R^*\|_\infty$ (Bernstein, 2009). From the definition of $\|R\|_1$ we have,

$$\begin{aligned} \|R\|_1 &= \sup_{v \in \mathbb{R}^Y} \frac{\|Rv\|_1}{\|v\|_1} \\ &\geq \sup_{u \in \mathbb{R}^X} \frac{\|RTu\|_1}{\|Tu\|_1} \\ &= \sup_{u \in \mathbb{R}^X} \frac{\|u\|_1}{\|Tu\|_1} \\ &= 1 / \left(\inf_{u \in \mathbb{R}^X} \frac{\|Tu\|_1}{\|u\|_1} \right). \end{aligned}$$

This proves the first inequality. Recall,

$$\text{Clarity}(T) = \sup_{v \in \Omega} \frac{\|T(v)\|_1}{\|v\|_1},$$

where $\Omega = \{v \in \mathbb{R}^X : \sum v_i = 0, v \neq 0\}$. Hence $\inf_{u \in \mathbb{R}^X} \frac{\|Tu\|_1}{\|u\|_1} \leq \text{Clarity}(T)$. ■

D.7 Proof of Theorem 23

Proof First, define $\ell_P(z,a) = \ell(z,a) - \ell(z,a_P)$. ℓ_P measures the loss relative to the best action for the distribution P. It is easy to verify that for bounded ℓ, $\|\ell_P\|_\infty \leq 2\|\ell\|_\infty$. We now utilize theorem 2.1 of Zhang (2006), together with a lower bound presented in the appendix, with ℓ_P and π uniform on A. This yields,

$$\mathbb{E}_{S \sim P^n} \left[\ell_P(P, \mathcal{A}(S)) - \gamma \mathbb{E}_{z \sim P} \ell_P^2(z, \mathcal{A}(S)) \right] \leq \frac{1}{n} \mathbb{E}_{S \sim P^n} \left[\ell_P(S, \mathcal{A}(S)) + \|\ell_P, \|_\infty \left(\frac{\log(|A|)}{\beta} \right) \right],$$

with $\gamma = \frac{(e^\beta - 1 - \beta)}{\beta \|\ell_P\|_\infty}$. Firstly ERM minimizes the right hand side of the bound meaning,

$$\frac{1}{n} \mathbb{E}_{S \sim P^n} \left[\ell_P(S, \mathcal{A}(S)) + \|\ell_P\|_\infty \left(\frac{\log(|A|)}{\beta} \right) \right] \leq \frac{1}{n} \left[\|\ell_P\|_\infty \left(\frac{\log(|A|)}{\beta} \right) \right].$$

To see this consider the algorithm that always outputs a_P, this algorithm generalizes very well however it may be suboptimal on the sample. Secondly (ℓ, P) satisfies the Bernstein condition with constant K. Therefore,

$$(1-\gamma K)\mathbb{E}_{S\sim P^n}\ell_P(P,\mathcal{A}(S)) \leq \frac{1}{n}\left[\|\ell_P\|_\infty\left(\frac{\log(|A|)}{\beta}\right)\right].$$

Finally chose β small enough so that $\gamma K \leq 1$. This can always be done as $\gamma \to 0$ as $\beta \to 0_+$. The high probability version proceeds in a similar way.

■

D.8 Proof of Lemma 24

Proof

$$\begin{aligned}
K\mathbb{E}_{z\sim P}\ell(z,a) - \ell(z,a_P) &= K\mathbb{E}_{\tilde{z}\sim\tilde{P}}\ell_R(z,a) - \ell_R(z,a_P)\\
&\geq \mathbb{E}_{\tilde{z}\sim\tilde{P}}(\ell_R(\tilde{z},a) - \ell_R(\tilde{z},a_P))^2\\
&= \mathbb{E}_{z\sim P}\mathbb{E}_{\tilde{z}\sim T(z)}(\ell_R(\tilde{z},a) - \ell_R(\tilde{z},a_P))^2\\
&\geq \mathbb{E}_{z\sim P}(\mathbb{E}_{\tilde{z}\sim T(z)}\ell_R(\tilde{z},a) - \mathbb{E}_{\tilde{z}\sim T(z)}\ell_R(\tilde{z},a_P))^2\\
&= \mathbb{E}_{z\sim P}(\ell(z,a) - \ell(z,a_P))^2,
\end{aligned}$$

where the first line follows from the definition of ℓ and because $a_P = a_{\tilde{P}}$, the second as $(\ell_R, \tilde{P})$ satisfies the Bernstein condition and finally we have used the convexity of $f(x) = x^2$.

■

D.9 Proof of Theorem 26

Proof

$$\begin{aligned}
\mathbb{E}_{\tilde{z}\sim\tilde{P}}(\ell_R(\tilde{z},a) - \ell_R(\tilde{z},a_P))^2 &= \mathbb{E}_{z\sim P}\mathbb{E}_{\tilde{z}\sim T(z)}(\ell_R(\tilde{z},a) - \ell_R(\tilde{z},a_P))^2\\
&\leq \eta\mathbb{E}_{z\sim P}(\ell(z,a) - \ell(z,a_P))^2\\
&\leq \eta K\mathbb{E}_{z\sim P}\ell(z,a) - \ell(z,a_P)\\
&= \eta K\mathbb{E}_{\tilde{z}\sim\tilde{P}}\ell_R(\tilde{z},a) - \ell_R(\tilde{z},a_P),
\end{aligned}$$

where we have first used η-compatibility, then the fact that (ℓ, P) satisfies the Bernstein condition with constant K and finally the definition of ℓ_R.

■

D.10 Proof of Theorem 27

Proof Due to the symmetry of the left and right hand sides of the Bernstein condition, one only needs to check the case where $a_1 = 1$, $a_2 = -1$. Recall,

$$\begin{aligned}
\ell_{01,T}(\tilde{y},a) &= \frac{(1-\sigma_{-y})\ell_{01}(\tilde{y},a) - \sigma_y\ell_{01}(-\tilde{y},a)}{1-\sigma_{-1}-\sigma_1}\\
&= \frac{(1-\sigma_{-y}+\sigma_y)\ell_{01}(\tilde{y},a) - \sigma_y}{1-\sigma_{-1}-\sigma_1}.
\end{aligned}$$

For $y = 1$ it is easy to confirm $(\ell_{01}(1,1) - \ell_{01}(1,-1))^2 = 1$. We have,

$$\begin{aligned}
\ell_{01,T}(\tilde{y},1) - \ell_{01,T}(\tilde{y},-1) &= \frac{(1-\sigma_{-y}+\sigma_y)(\ell_{01}(\tilde{y},1) - \ell_{01}(\tilde{y},-1))}{1-\sigma_{-1}-\sigma_1}\\
&= \frac{-\tilde{y}(1-\sigma_{-y}+\sigma_y)}{1-\sigma_{-1}-\sigma_1}.
\end{aligned}$$

Squaring, taking maxima and finally expectations yields the desired result.

■

D.11 Proof of Corollary 35

Proof Let,

$$\ell(-,a) = v(a) + \gamma\mathbf{1}_{\mathcal{Z}},$$

where $v(a) \in E_{\alpha,S}\ \forall a \in A$ and $\gamma \in \mathbb{R}$. Therefore for all $M \in S$ and $\forall a \in A$,

$$\begin{aligned}
M\ell(-,a) &= Mv(a) + \gamma M\mathbf{1}_{\mathcal{Z}}\\
&= \alpha(M)v(a) + \gamma\mathbf{1}_{\mathcal{Z}}\\
&= \underbrace{\alpha(M)\left(v(a) + \gamma\mathbf{1}_{\mathcal{Z}}\right)}_{\alpha(M)\ell(-,a)} + \underbrace{\left(\gamma - \gamma\alpha(M)\right)\mathbf{1}_{\mathcal{Z}}}_{\beta(M)\mathbf{1}_{\mathcal{Z}}},
\end{aligned}$$

where the second line follows as by assumption $M\mathbf{1}_{\mathcal{Z}} = \mathbf{1}_{\mathcal{Z}}$ for all $M \in S$.

Abstract

We consider interactive algorithms in the pool-based setting, and in the stream-based setting. Interactive algorithms observe suggested elements (representing actions or queries), and interactively select some of them and receive responses. Pool-based algorithms can select elements at any order, while stream-based algorithms observe elements in sequence, and can only select elements immediately after observing them. We further consider an intermediate setting, which we term *precognitive stream*, in which the algorithm knows in advance the identity of all the elements in the sequence, but can select them only in the order of their appearance. For all settings, we assume that the suggested elements are generated independently from some source distribution, and ask what is the stream size required for emulating a pool algorithm with a given pool size, in the stream-based setting and in the precognitive stream setting. We provide algorithms and matching lower bounds for general pool algorithms, and for utility-based pool algorithms. We further derive nearly matching upper and lower bounds on the gap between the two settings for the special case of active learning for binary classification.

Keywords: interactive algorithms, active learning, pool-based, stream-based

1. Introduction

Interactive algorithms are algorithms which are presented with input in the form of suggested elements (representing actions or queries), and iteratively select elements, getting a response for each selected element. The reward of the algorithm, which is application-specific, is a function of the final set of selected elements along with their responses. Interactive algorithms are used in many application domains, including, for instance, active learning (McCallum and Nigam, 1998), interactive sensor placement (Golovin and Krause, 2011), summarization (Singla et al., 2016) and promotion in social networks (Guillory and Bilmes, 2010). As a specific motivating example, consider an application in which elements represent web users, and the algorithm should select up to q users to present with a free promotional item. For each selected user, the response is the observed behavior of the user after having received the promotion, such as the next link that the user clicked on. The final reward of the algorithm depends on the total amount of promotional impact it obtained, as measured by some function of the set of selected users and their observed responses. Note that the algorithm can use responses from previous selected users when deciding on the next user to select.

We consider two main interaction settings for interactive algorithms: The *pool-based* setting and the *stream-based* setting. In the pool-based setting, the entire set of suggested elements is provided in advance to the algorithm, which can then select any of the elements at any order. For instance, in the web promotion example, there might be a set of users who use the website for an extended period of time, and any of them can be approached with a promotion. In the stream-based setting, elements are presented to the algorithm in sequence, and the algorithm must decide immediately after observing an element, whether to select it or not. In the web promotion example, this is consistent with a setting where users access the website for single-page sessions, and so any promotion must be decided on immediately when the user is observed. Note that in the stream-based setting considered in this work, the only direct restriction is on the timing of selecting elements. We do not place restrictions on storage space or other resources.

The stream-based setting is in general weaker than the pool-based setting. Nonetheless, it is important and useful: In many real-life scenarios, it is not possible to postpone selection of elements, for instance due to storage and retrieval constraints, or because of timing constraints. This is especially pertinent when the data stream is real-time in nature, such as in streaming document classification (Bouguelia et al., 2013), in spam filtering (Chu et al., 2011), in web streams such as Twitter (Smailović et al., 2014), in video surveillance (Loy et al., 2012) and with active sensors (Krishnamurthy, 2002).

In this work, our goal is to study the relationship between these two important settings: the pool-based setting and the stream-based setting. Both of these settings have been widely studied in many contexts. In active learning, both the pool-based and the stream-based setting have been studied in classic works (Cohn et al., 1994; Lewis and Gale, 1994). Works that address mainly the stream-based setting include, for instance, Balcan et al. (2009); Hanneke (2011); Dasgupta (2012); Balcan and Long (2013); Sabato and Munos (2014). Some theoretical results hold for both the stream-based and the pool-based settings (e.g., Balcan and Long, 2013; Hanneke and Yang, 2015). Several near-optimal algorithms have been developed for the pool-based setting (Dasgupta, 2005; Golovin and Krause, 2011; Golovin et al., 2010b; Hanneke, 2007; Sabato et al., 2013; Gonen et al., 2013; Cuong et al., 2014). The pool-based setting is also heavily studied in various active learning applications (e.g., Tong and Koller, 2002; Tong and Chang, 2001; Mitra et al., 2004; Gosselin and Cord, 2008; Cebron and Berthold, 2009; Guo et al., 2013). General interactive algorithms have also been studied in both a pool-based setting (e.g., Golovin and Krause, 2011; Guillory and Bilmes, 2010; Deshpande et al., 2014) and in stream-based settings (e.g., Demaine et al., 2014; Arlotto et al., 2016; Streeter and Golovin, 2009; Golovin et al., 2010a).

To facilitate this study, we introduce a third setting, which we term the *precognitive stream-based* setting. This is an intermediate setting, which is weaker than the pool-based setting but stronger than the stream-based setting. In the precognitive setting, as in the standard stream-based setting, there is a sequence of elements and the algorithm must make a decision immediately after the item is presented to it. However, unlike the standard stream-based setting, in the precognitive setting the algorithm knows in advance the identity of items that will be presented in the future. This intermediate setting is of interest, since it has only one of the disadvantages of the standard stream-based setting: the requirement that elements are selected in order of their presentation in the sequence. On the other hand, it does not have the second disadvantage: the lack of knowledge of future possible items. Thus, studying this setting allows distinguishing the effect of the two issues on the performance of stream-based algorithms.

To study the relationship between the pool-based setting and the stream-based setting, as well as its precognitive variant, we assume that in all settings the suggested elements, along with their hidden responses, are drawn i.i.d. from some unknown source distribution. We then ask under what conditions, and at what cost, can a stream-based algorithm obtain the same output distribution as

a given black-box pool algorithm. Such an exact emulation is advantageous, as it allows direct application of methods and results developed for the pool-based setting, in the stream-based setting. Especially, if a pool-based algorithm succeeds in practice, but its analysis is unknown or limited, exact emulation guarantees that this success is reproduced in the streaming setting as well.

For discrete source distributions, any pool-based algorithm can be emulated in a stream-based setting, simply by waiting long enough, until the desired element shows up again. The challenge for stream-based interactive algorithms is thus to achieve the same output distribution as a pool-based algorithm, while observing as few suggested elements as possible. Clearly, there are many cases in which it is desirable to require less suggested elements, as this could save resources such as time, money, and communication. In active learning as well, while examples are usually assumed cheap, they are not usually completely free in all respects.

We study emulation of pool-based algorithms in two regimes. First, we consider the fully general case, of emulating some unrestricted pool algorithm. We provide a stream algorithm that can emulate any given black-box pool algorithm, and uses a uniformly bounded expected number of observed elements. The bound on the expected number of observed elements is exponential in the number of selected elements. We further prove a lower bound which indicates that this exponential dependence is necessary. We also study the precognitive stream-based setting and show the following: On the one hand, it can require a significantly smaller number of observed elements than the standard stream-based setting. On the other hand, its worst-case performance is also exponential in the number of selected elements, similarly to the stream-based setting. We conclude that while knowing the sequence in advance can be helpful, it does not improve the general performance of stream-based emulation.

Second, we consider *utility-based* interactive algorithm for the pool setting. We provide a stream algorithm that emulates such pool algorithms, using repeated careful applications of solutions of the well known "Secretary Problem" (Dynkin, 1963; Gilbert and Mosteller, 1966; Ferguson, 1989). The expected number of observed elements for this algorithm is only linear in the number of selected elements. In this case too we prove matching lower bounds. These results hold also for the precognitive stream setting. Our analysis shows a tradeoff between the number of observed elements and the number of selected elements, in cases where the stream algorithm is allowed to select extra elements over what the pool-algorithm selects.

Finally, we consider the special case of active learning for binary classification. We give nearly-matching upper and lower bounds for stream emulation in this setting. From the lower bound, we conclude that even in this well-studied setting, there are cases in which there exists a significant gap between the best pool-based algorithm and the best stream-based algorithm. This result generalizes a previous observation of Gonen et al. (2013) on the sub-optimality of CAL (Cohn et al., 1994), the classical stream-based active learning algorithm, compared to pool algorithms.

This paper is structured as follows: In Section 2 formal definitions and notations are provided. Section 3 discusses natural but suboptimal solutions. Section 4 considers emulating general pool algorithms, and Section 5 addresses the case of utility-based pool algorithms. In Section 6 we study active learning for binary classification. We conclude in Section 7.

2. Definitions

For a predicate p, denote by $\mathbb{I}[p]$ the indicator function which is 1 if p holds and zero otherwise. For an integer k, denote $[k] := \{1, \ldots, k\}$ and $[k]_0 = \{0, \ldots, k\}$. For a sequence S, $S(i)$ is the

i'th member of the sequence. Denote concatenation of sequences by $\circ$. Denote by Π_k the set of permutations over $[k]$.

For A, B which are both sequences, or one is a set and one a sequence, we use $A =_\pi B$ and $A \subseteq_\pi B$ to denote equality or inclusion on the unordered sets of elements in B and in A. We sometimes omit the π when no other interpretation is possible.

Let $\mathcal{X}$ be a measurable domain of elements, and let $\mathcal{Y}$ be a measurable domain of responses. A pool-based (or just pool) interactive algorithm $\mathcal{A}_p$ receives as input an integer $q \leq m$, and a pool of elements $(x_1, \ldots, x_m) \in \mathcal{X}^m$. We assume that for each x_i there is a response $y_i \in \mathcal{Y}$, which is initially hidden from $\mathcal{A}_p$. Denote $S = ((x_i, y_i))_{i \in [m]}$. We will assume throughout this work that S is drawn i.i.d. from a distribution over $\mathcal{X} \times \mathcal{Y}$. For a given S, S_X denotes the pool $(x_1, \ldots, x_m)$. At each round, $\mathcal{A}_p$ selects one of the elements i_t that have not been selected yet, and receives its response y_{i_t}. After q rounds, $\mathcal{A}_p$ terminates. Its output is the set $\{(x_{i_1}, y_{i_1}), \ldots, (x_{i_q}, y_{i_q})\}$. For a pool algorithm $\mathcal{A}_p$, denote by $\mathsf{sel}_p(S, t)$ the element that $\mathcal{A}_p$ selects at round t, if S is the pool it interacts with. $\mathsf{sel}_p(S, t)$, which can be random, can depend on S_X and on y_{i_k} for $k < t$. Denote by $\mathsf{sel}_p(S, [t])$ the sequence of elements selected by $\mathcal{A}_p$ in the first t rounds. $\mathsf{pairs}_p(S, t)$ and $\mathsf{pairs}_p(S, [t])$ similarly denote the selected elements along with their responses. The final output of $\mathcal{A}_p$ is the set of pairs in the sequence $\mathsf{pairs}_p(S, [q])$. We assume that $S \mapsto \mathsf{pairs}_p(S, [q])$ is measurable.

We assume for simplicity that the pool algorithm is permutation invariant. That is, for any $S, S' \subseteq (\mathcal{X} \times \mathcal{Y})^m$, if S' is a permutation of S then $\mathsf{sel}_p(S, [q]) = \mathsf{sel}_p(S', [q])$, or if $\mathcal{A}_p$ is randomized then the output distributions are the same. Since the pool S is drawn i.i.d. this does not lose generality.

A stream-based (or just stream) interactive algorithm $\mathcal{A}_s$ receives as input an integer q. We assume an infinite stream $S \subseteq (\mathcal{X} \times \mathcal{Y})^\infty$, where $S(t) = (x_t, y_t)$. We will assume that this stream is also an i.i.d. sample from a distribution over $\mathcal{X} \times \mathcal{Y}$. At iteration t, $\mathcal{A}_s$ observes x_t, and may select one of the following actions:

- Do nothing
- Select x_t and observe y_t
- Terminate.

At termination, the algorithm outputs a subset of size q of the set of pairs (x_t, y_t) it observed. Denote by $\mathsf{sel}_s(S, t)$ the t'th element that $\mathcal{A}_s$ selects and is also in the output set. Denote by $\mathsf{sel}_s(S, [t])$ the sequence of first t elements that $\mathcal{A}_s$ selects and are also in the output set. Use pairs_s to denote these elements along with their responses. The output of $\mathcal{A}_s$ when interacting with S is the set of the pairs in the sequence $\mathsf{pairs}_s(S, [q])$. We assume $S \mapsto \mathsf{pairs}_s(S, [q])$ is measurable. The total number of elements selected by $\mathcal{A}_s$ when interacting with S (including discarded elements) is denoted $N_{\mathsf{sel}}(\mathcal{A}_s, S, q)$. The number of iterations (observed elements) until $\mathcal{A}_s$ terminates is denoted $N_{\mathsf{iter}}(\mathcal{A}_s, S, q)$.

We would like to have stream algorithms that emulate pool algorithms, under the assumption that both the pool and the stream are drawn from the same distribution. We define an equivalence between a stream algorithm and a pool algorithm as follows.

Definition 1 *Let $\mathcal{D}$ be a distribution over $\mathcal{X} \times \mathcal{Y}$ and let q be an integer. Let $S \sim \mathcal{D}^m$, $S' \sim \mathcal{D}^\infty$. A pool algorithm $\mathcal{A}_p$ and a stream algorithm $\mathcal{A}_s$ are* $(q, \mathcal{D})$-equivalent*, if the total-variation distance between the distributions of $\mathsf{pairs}_p(S, [q])$ and $\mathsf{pairs}_s(S', [q])$ is zero.*

In the standard stream setting defined above, the algorithm can only make decisions based on data observed in the past, that is its decision at iteration t can depend on $x_1, \ldots, x_t$, as well as the responses for the elements it selected until iteration $t-1$. Thus, the stream setting is harder than the pool setting in two separate aspects:

- It must make decisions without knowing what elements will show up after the current iteration; and
- It must select elements in the order of their appearance in the stream.

We introduce an additional setting, which we term *precognitive stream*. A precognitive stream algorithm follows the same protocol as the standard stream algorithm defined above, but we assume that it knows the elements in the entire stream, including those in future iterations. Formally, its decisions in iteration t for an input stream $S \subseteq (\mathcal{X} \times \mathcal{Y})^\infty$ may depend on the full (infinite) sequence elements S_X.

Denote by $\mathcal{D}_X$ the marginal of $\mathcal{D}$ on $\mathcal{X}$. For a given distribution $\mathcal{D}_X$ over $\mathcal{X}$, let $\textsc{ds}(\mathcal{D}_X)$ be the set of distributions over $\mathcal{X} \times \mathcal{Y}$ such that their marginal over $\mathcal{X}$ is equal to $\mathcal{D}_X$. Below, unless specified otherwise, we assume that the probability under $\mathcal{D}_X$ of observing any single $x \in \mathcal{X}$ is zero. This does not lose generality, since if this is not the case, $\mathcal{D}_X$ can be replaced by the distribution $\mathcal{D}_X \times \mathrm{Unif}[0,1]$, with the interactive algorithms ignoring the second element in the pair.

In some of the proofs below we use the following lemma, proved in Appendix A. This lemma captures a relationship between the expected number of observed Bernoulli trials and the probability of success in the last trial.

Lemma 2 *Let $\alpha \in (0,1), p \in (0, \alpha^4/2)$. Let $X_1, X_2, \ldots$ be independent Bernoulli random variables with $\mathbb{P}[X_i = 1] \leq p$. Let I be a random integer, which can be dependent on the entire sequence $X_1, X_2, \ldots$. Suppose that $\mathbb{P}[X_I = 1] \geq \alpha$. Then $\mathbb{E}[I] \geq \frac{\alpha^2}{4p}$.*

3. Simple Equivalent Stream Algorithms

Algorithm 1 Algorithm $\mathcal{A}_{\text{wait}}$

In the first m iterations, observe $x_1, \ldots, x_m$ and do nothing.
$S \leftarrow ((x_1, \star), \ldots, (x_m, \star))$
$j \leftarrow 1, t \leftarrow m+1$
repeat
  In iteration t, observe element x_t
  if $x_t = \mathsf{sel}_p(S, j)$ **then**
    Select x_t and observe y_t
    $S(i) \leftarrow (x_t, y_t)$
    $j \leftarrow j + 1$
  end if
  $t \leftarrow t + 1$
until $j = q + 1$
Return the set of all the pairs (x, y) in S with $y \neq \star$.

Emulating a pool algorithm in a streaming setting can be naively done using two extremely simple approaches, which we discuss below. However, each of these approaches is wasteful, in either the number of iterations it requires, or the number of selections it makes.

For the first approach, let $\mathcal{A}_p$ be a pool algorithm. For any discrete distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, and any q, it is easy to define a stream algorithm which is $(q, \mathcal{D})$-equivalent to $\mathcal{A}_p$. Let "$\star$" be some value not in $\mathcal{Y}$, and define $\mathcal{A}_{\text{wait}}$ as in Alg. 1. $\mathcal{A}_{\text{wait}}$ first draws a pool of size m, and then replicates the selections that a pool algorithm would have done for this pool, by each time waiting until the requested element is observed again in the stream. This stream algorithm is clearly $(q, \mathcal{D})$ equivalent to $\mathcal{A}_p$ for any discrete distribution $\mathcal{D}$, and it has $N_{\mathsf{sel}}(\mathcal{A}_{\text{wait}}, S', q) = q$ for all $S' \in (\mathcal{X} \times \mathcal{Y})^\infty$. However, $\mathbb{E}_{S' \sim \mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_{\text{wait}}, S', q)]$ is not uniformly bounded, even for the class of discrete distributions. For instance, if the probability of observing any $x \in \mathcal{X}$ is some small p, then every selection that the algorithm makes would require observing $1/p$ elements in expectation.

In the second approach, one can simply select the first m elements observed by the stream, as done in the stream algorithm $\mathcal{A}_{\text{nowait}}$ defined in Alg. 2. This algorithm is also $(q, \mathcal{D})$ equivalent to $\mathcal{A}_p$, and it requires the smallest possible number of observed elements, since $N_{\mathsf{iter}}(\mathcal{A}_{\text{wait}}, S', q) = m$ for all $S' \in (\mathcal{X} \times \mathcal{Y})^\infty$, exactly the same as for the pool algorithm. However, in this case the number of selections is large, since $N_{\mathsf{sel}}(\mathcal{A}_{\text{nowait}}, S', q) = m > q$, regardless of q. This trivial algorithm is thus again unsatisfying.

Algorithm 2 Algorithm $\mathcal{A}_{\text{nowait}}$

input Pool size m, Black-box pool algorithm $\mathcal{A}_p$.
In each iteration $t \in [m]$, select x_t and observe y_t.
Return the pairs in $\mathsf{pairs}_p(S, q)$.

In the next section we consider the general pool emulation problem, and show that it is possible to have a uniform upper bound on the number of iterations, regardless of the distribution, and without selecting more than q elements. In addition, in Section 5, we show for utility-based pool algorithms, that there is a tradeoff between the number of additional selected elements and the expected number of observed elements. This tradeoff is evident also in the two simple algorithms shown above.

4. General Pool Algorithms

In this section we consider emulating general pool algorithms. In Section 4.1 we present a stream algorithm which can emulate any pool-based algorithm, using only black-box access to the pool algorithm. We prove a distribution-free upper bound on its expected number of iterations. In Section 4.2 we show that the number of iterations required by the proposed algorithm cannot be significantly improved. In Section 4.3, we study the precognitive stream setting and compare its guarantees to the standard stream setting.

4.1 Stream Emulation for General Pool Algorithms

The stream algorithm $\mathcal{A}_{\text{gen}}$, listed in Alg. 3, emulates any pool based algorithm $\mathcal{A}_p$ using only black-box access to $\mathcal{A}_p$. The algorithm emulates a general pool algorithm by making sure that in each iteration, its probability of selecting an element is identical to the conditional probability of the pool algorithm selecting the same element, conditioned on the history of elements and responses

selected and observed so far. This is achieved by repeatedly drawing the remaining part of the pool, and keeping it only if it is consistent with the elements that were already selected. The algorithm further uses the partial pool draw only if the element to be selected happens to have been observed last.

Algorithm 3 Algorithm $\mathcal{A}_{\text{gen}}$

input Original pool size m, budget $q < m$, black-box pool algorithm $\mathcal{A}_p$.

$S_0 \leftarrow ()$
for $i = 1 : q$ **do**
  repeat
    Draw $m - i + 1$ elements, denote them $\bar{x}_{i,i}, \ldots, \bar{x}_{i,m}$.
    $S'_i \leftarrow ((\bar{x}_{i,i}, \star), \ldots, (\bar{x}_{i,m}, \star))$.
  until $\mathsf{pairs}_p(S_{i-1} \circ S'_i, [i-1]) =_\pi S_{i-1}$ and $\mathsf{sel}_p(S_{i-1} \circ S'_i, i) = \bar{x}_{i,m}$.
  Select $\bar{x}_{i,m}$, get the response $\bar{y}_{i,m}$.
  $S_i \leftarrow S_{i-1} \circ ((\bar{x}_{i,m}, \bar{y}_{i,m}))$.
end for
Output S_q.

Below we show that $\mathcal{A}_{\text{gen}}$ improves over the two stream algorithms presented above, in that it selects exactly q elements, and has a uniform upper bound on the expected number of iterations, for any source distribution. First, we prove that $\mathcal{A}_{\text{gen}}$ indeed emulates any pool-based algorithm.

Theorem 3 *For any pool algorithm $\mathcal{A}_p$, any distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, any integer m and $q \le m$, $\mathcal{A}_s := \mathcal{A}_{gen}(\mathcal{A}_p)$ is $(q, \mathcal{D})$-equivalent to $\mathcal{A}_p$.*

Proof For simplicity of presentation, we prove the result for discrete distributions. The proof for continuous distribution is analogous. Consider the probability space defined by the infinite sequence $S' \sim \mathcal{D}^\infty$ which generates the input to the stream algorithm, and an independent sequence $S \sim \mathcal{D}^m$ which is the input to the pool algorithm. For $z_1, \ldots, z_q \in \mathcal{X} \times \mathcal{Y}$, denote $Z_j = \{z_1, \ldots, z_j\}$. We have, for every $i \in [q]$,

$$\mathbb{P}[\mathsf{pairs}_p(S, [i]) =_\pi Z_i] = \sum_{j=1}^{i} \mathbb{P}[(\mathsf{pairs}_p(S, i) = z_j) \wedge (\mathsf{pairs}_p(S, [i-1]) =_\pi Z_i \setminus \{z_j\})]$$

$$= \sum_{j=1}^{i} \mathbb{P}[\mathsf{pairs}_p(S, i) = z_j \mid \mathsf{pairs}_p(S, [i-1]) =_\pi Z_i \setminus \{z_j\}] \cdot \mathbb{P}[\mathsf{pairs}_p(S, [i-1]) =_\pi Z_i \setminus \{z_j\}].$$

The same holds for $\mathsf{pairs}_s(S', \cdot)$. To show the equivalence it thus suffices to show that for all $z_1, \ldots, z_q \in \mathcal{X} \times \mathcal{Y}, i \in [q]$,

$$\mathbb{P}[\mathsf{pairs}_s(S', i) = z_i \mid \mathsf{pairs}_s(S', [i-1]) =_\pi Z_{i-1}] = \mathbb{P}[\mathsf{pairs}_p(S, i) = z_i \mid \mathsf{pairs}_p(S, [i-1]) =_\pi Z_{i-1}].$$

From the definition of $\mathcal{A}_s$ we have

$$\begin{aligned}
&\mathbb{P}[\mathsf{pairs}_s(S', i) = z_i \mid \mathsf{pairs}_s(S', [i-1]) =_\pi Z_{i-1}] \\
&= \mathbb{P}[\mathsf{pairs}_p(S_{i-1} \circ S'_i, i) = z_i \mid S_{i-1} =_\pi Z_{i-1} \wedge \mathsf{pairs}_p(S_{i-1} \circ S'_i, [i-1]) =_\pi Z_{i-1}] \\
&= \mathbb{P}[\mathsf{pairs}_p(S, i) = z_i \mid \mathsf{pairs}_p(S, [i-1]) =_\pi Z_{i-1}].
\end{aligned}$$

The last equality follows since $\mathcal{A}_p$ is permutation invariant and never selects the same index twice. This proves the equivalence. ■

The next theorem provides an upper bound on the expected number of elements observed by $\mathcal{A}_{\text{gen}}$. Unlike $\mathcal{A}_{\text{wait}}$, this upper bound holds uniformly for all source distributions.

Theorem 4 *For any pool algorithm $\mathcal{A}_p$, any distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, any integer m and $q \le m$, if $\mathcal{A}_s := \mathcal{A}_{gen}(\mathcal{A}_p)$, $N_{\mathsf{sel}}(\mathcal{A}_s, S, q) = q$ for any $S \in (\mathcal{X} \times \mathcal{Y})^\infty$, and*

$$\mathbb{E}_{S \sim \mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s, S, q)] \le m^2 \left(\frac{em}{q-1}\right)^{q-1}.$$

Proof First, clearly $N_{\mathsf{sel}}(\mathcal{A}_s, S, q) = q$ for any $S \sim \mathcal{D}^\infty$. We now prove the upper bound on the expected number of iterations of $\mathcal{A}_s$. Let $S \sim \mathcal{D}^m$. For $i \ge 1$, $z_1, \ldots, z_{i-1} \in \mathcal{X}$, denote $Z_j = \{z_1, \ldots, z_j\}$, and let

$$p_i(z_1, \ldots, z_i) := \mathbb{P}[\mathsf{sel}_p(S, [i]) =_\pi Z_i \mid Z_i \subseteq_\pi S_X].$$

Suppose that $(S_{i-1})_X =_\pi Z_{i-1}$. The expected number of times that steps 3 to 6 are repeated for index i is the inverse of the probability that the condition in 6 holds. This condition, in our notation, is that $\mathsf{sel}_p(S_{i-1} \circ S'_i, [i-1]) =_\pi Z_{i-1}$ and $\mathsf{sel}_p(S_{i-1} \circ S'_i, i) = \bar{x}_{i,m}$. We have, from the permutation invariance of $\mathcal{A}_p$,

$$\mathbb{P}[\mathsf{sel}_p(S_{i-1} \circ S'_i, [i-1]) =_\pi Z_{i-1} \mid (S_{i-1})_X =_\pi Z_{i-1}] = p_{i-1}(z_1, \ldots, z_{i-1}).$$

In addition, for every draw of S'_i,

$$\mathbb{P}[\mathsf{sel}_p(S_{i-1} \circ S'_i, i) = \bar{x}_{i,m} \mid \mathsf{sel}_p(S_{i-1} \circ S'_i, [i-1]) =_\pi Z_{i-1} \wedge (S_{i-1})_X =_\pi Z_{i-1}] = \frac{1}{m-i+1}.$$

This is since under the conditional, one of the elements in S'_i must be selected by $\mathcal{A}_p$ in round i. Therefore, the probability that the condition in step 6 holds is $p_{i-1}(z_1, \ldots, z_{i-1})/(m-i+1)$. The expected number of times that steps 3 to 6 are repeated for index i is the inverse of that, and in each round $m-i+1$ elements are observed. Therefore the expected number of elements observed until selection i is made conditioned on $z_1, \ldots, z_{i-1}$ is $(m-i+1)^2/p_{i-1}(z_1, \ldots, z_{i-1})$. The unconditional expected number of elements observed until selection i is $(m-i+1)^2 \cdot \mathbb{E}[1/p_{i-1}(\mathsf{sel}_s(S', [i-1]))]$. For a set of indices J, denote $S|_J = \{S(j) \mid j \in J\}$. For simplicity of presentation we give the following derivation for discrete distributions, the proof for continuous distributions is analogous.

$$\begin{aligned}
\mathbb{E}[1/p_i(\mathsf{sel}_s(S', [i]))] &= \mathbb{E}[1/p_i(\mathsf{sel}_p(S, [i]))] \\
&= \sum_{\{z_1, \ldots, z_i\} \subseteq \mathcal{X} \times \mathcal{Y}} \mathbb{P}[\mathsf{sel}_p(S, [i]) =_\pi Z_i] \cdot \frac{1}{p_i(z_1, \ldots, z_i)} \\
&= \sum_{\{z_1, \ldots, z_i\} \subseteq \mathcal{X} \times \mathcal{Y}} \mathbb{P}[Z_i \subseteq_\pi S_X].
\end{aligned}$$

Hence

$$\begin{aligned}\mathbb{E}[1/p_i(\mathsf{sel}_s(S',[i])] &\leq \sum_{\{z_1,..,z_i\}\subseteq\mathcal{X}\times\mathcal{Y}} \sum_{J\subseteq[m],|J|=i} \mathbb{P}[(S|_J)_X = Z_i] \\ &= \sum_{J\subseteq[m],|J|=i} \sum_{\{z_1,..,z_i\}\subseteq\mathcal{X}\times\mathcal{Y}} \mathbb{P}[(S|_J)_X = Z_i] \\ &= \sum_{J\subseteq[m],|J|=i} 1 = \binom{m}{i}.\end{aligned}$$

It follows that the expected number of elements observed after the $i-1$'th selection and until selection i is at most $(m-i+1)^2\binom{m}{i-1}$. We conclude that

$$\mathbb{E}[N_{\mathsf{iter}}(\mathcal{A}_s,S,q)] \leq \sum_{i=0}^{q-1}(m-i)^2\binom{m}{i} \leq m^2\left(\frac{em}{q-1}\right)^{q-1}.$$

This completes the proof. ■

From the existence of $\mathcal{A}_{\text{gen}}$ we can conclude that the pool-based and the stream-based setting are essentially equivalent, up to the number of observed elements. However, the expected number of observed elements is exponential in q. In the next sections we show that this exponential dependence cannot be avoided when emulating general pool algorithms in a stream setting.

4.2 A Lower Bound for the Standard Stream Setting

The upper bound in Theorem 4 is exponential in q. We next show that this dependence cannot be eliminated in the general case for a standard stream algorithm. This result indicates that $\mathcal{A}_{\text{gen}}$ is close to optimal in terms of expected number of iterations. The lower bound holds for a standard stream algorithm, which does not know the identity of future elements in the stream. We consider precognitive stream algorithms in Section 4.3.

The lower bound is proved using a construction in which some of the elements represent base elements, and some represent permutations over base elements. The pool algorithm selects permutation elements that are consistent with the base elements it selected. Since the ranking of elements depends on the elements in the input pool, the same permutation can be consistent with different selections in different pools. The following lemma, which is used the proof of the lower bound, shows that nonetheless, once certain base elements have been selected, the set of permutations that are likely consistent with them is considerably limited. The lemma is also later used in a lower bound for the precognitive stream setting.

Lemma 5 *Let $t \leq t' \leq l$ be integers such that $l \geq 2t$. Let $Z = z_1,\ldots,z_t$ a set of values in $[0,1]$. Let X be l random values sampled i.i.d. from the uniform distribution on $[0,1]$. Denote $X = x_1,\ldots,x_l$ where $x_1 \leq x_2 \leq \ldots x_l$. Let $A_\sigma(Z,X) \subseteq \Pi_l$ be the set of permutations σ such that $\{x_{\sigma(1)},\ldots,x_{\sigma(t')}\} \supseteq \{z_1,\ldots,z_t\}$. For any $d \leq l-t$, there exists a set of permutations $\Phi(Z) \subseteq \Pi_l$, such that*

$$|\Phi(Z)|/|\Pi_l| \leq (4dt'/l)^t,$$

and

$$\mathbb{P}[A_\sigma(Z,X) \subseteq \Phi(Z) \mid Z \subseteq X] \geq 1 - 2t\exp(-2d^2/(l-t)),$$

Where the probability is over the randomness of X. Moreover, let $L(\sigma) := \cup_{Z:\sigma\in\Phi(Z)}\Phi(Z)$, then for all $\sigma \in \Pi_l$,

$$|L(\sigma)|/|\Pi_l| \leq (8dt'/l)^{2t}.$$

Proof Fix $d \leq l-t$. Denote the expected number of elements that are smaller than z_i in X, conditioned on $Z \subseteq X$, by $n_i := (l-t)z_i + \sum_{j=1}^t \mathbb{I}[z_j < z_i]$, and let

$$\Phi(Z) := \{\sigma \in \Pi_l \mid \exists f : [t] \to [t'] \text{ s.t. } f \text{ is one-to-one and } \forall i \in [t], |\sigma(f(i)) - n_i| < d\}. \quad (1)$$

These are the permutations such that the first t elements according to the permutation are mapped from elements with ranks in $[n_i - d, n_i + d]$. It is easy to see that

$$|\Phi(Z)|/|\Pi_l| \leq (t')^t \frac{(2d)^t}{\prod_{i=0}^{t-1}(l-i)} \leq \left(\frac{4dt'}{l}\right)^t,$$

where the last inequality follows since $l \geq 2t$. This proves the first part of the lemma. We now show the second part of the lemma. For $x \in X$, let $r(x)$ be its rank in X. By Hoeffding's inequality, for any $i \leq t$,

$$\mathbb{P}[|r(z_i) - n_i| \geq d \mid Z \subseteq X] \leq 2\exp(-2d^2/(l-t)).$$

Therefore,

$$\mathbb{P}[\forall i \leq t, |r(z_i) - n_i| < d \mid Z \subseteq X] \geq 1 - 2t\exp(-2d^2/(l-t)).$$

For any $\sigma \in A_\sigma$ we have that for each $i \leq t$, $z_i = x_{\sigma(j)}$ for some $j \leq t'$, that is $r(z_i) = \sigma(j)$. Moreover, different values of i are mapped to different values of j. Therefore there is some one-to-one function $f : [t] \to [t']$ such that for all $i \leq t$, $z_i = x_{\sigma(f(i))}$. Conditioned on the event $\forall i \leq t, |r(z_i) - n_i| < d$, it follows that $\forall i \leq t, |\sigma(f(i)) - n_i| < d$. Thus $\sigma \in \Phi(Z)$, which proves the second claim of the lemma.

To see the last claim, observe that if $\sigma, \sigma' \in \phi(Z)$ for some Z, then there are functions $f, g : [t] \to [t']$ such that for $i \in [t]$, $|\sigma(f(i)) - \sigma'(g(i))| < 2d$. Therefore,

$$L(\sigma) \subseteq \{\sigma' \in \Pi_l \mid \exists f, g : [t] \to [t'], \forall i \in [t], |\sigma(f(i)) - \sigma'(g(i))| < 2d\}.$$

The bound on the size of $L(\sigma)$ in the claim directly follows, similarly to the bound on $|\Phi(Z)|$. ■

The lower bound for the standard stream setting is provided below. It shows that for some pool algorithm, any equivalent stream algorithm has an expected number of observed elements which is exponential in q. The lower bound is worst-case over all source distributions $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, where the pool and the stream, as above, are drawn i.i.d. from the distribution. The proof involves constructing a pool-based algorithm in which the last selected element is significantly constrained by the identity of the previously selected elements, using the permutation construction. This type of constraint is not an issue in a pool setting, since the algorithm has advance knowledge of all the available elements. In a streaming setting, however, this requires a possibly long wait to obtain the matching last element. Because the stream algorithm is allowed to select elements in a different order than the pool algorithm, additional care is taken to make sure that in this construction, it is not possible to circumvent the problem this way.

Theorem 6 *There is an integer q_0, such that for $q \geq q_0$ and $m \geq 16q^2\log(4q)+1$, there exist a pool algorithm $\mathcal{A}_p$ and a marginal $\mathcal{D}_X$, such that any stream algorithm $\mathcal{A}_s$ which is $(q,\mathcal{D})$ equivalent to $\mathcal{A}_p$ for all $\mathcal{D} \in \text{DS}(\mathcal{D}_X)$, and selects only q elements, has*

$$\exists \mathcal{D} \in \text{DS}(\mathcal{D}_X), \mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s,S,q)] \geq \frac{1}{1{,}000}\left(\frac{m-1}{8q^2\log(4q)}\right)^{\frac{q-1}{2}}.$$

Proof Let the domain of elements be $\mathcal{X} = [0,2)$ and assume responses in $\mathcal{Y} = \{0,1\}$. Denote $\texttt{base} := [0,1]$ and $\texttt{perm} := (1,2)$. Call a pool S_X in which exactly one element in the pool is in $\texttt{perm}$ and the rest are in $\texttt{base}$ a "good pool".

We now define a pool algorithm as follows. On bad pools, $\mathcal{A}_p$ always selects only elements in $\texttt{base}$ or only elements in $\texttt{perm}$. In a good pool, denote for simplicity the single element from $\texttt{perm}$ by z_m, and the elements from $\texttt{base}$ by $z_1,\ldots,z_{m-1}$, where $z_{i-1} < z_i$ for $i \in [m-1]$. Define a mapping $\psi : \texttt{perm} \to \Pi_{m-1}$, such that if z_m is uniform over $\texttt{perm}$, then for $\psi(z_m)$ all permutations in the range are equally likely. Let $\sigma = \psi(z_m)$. On a good pool, $\mathcal{A}_p$ behaves as follows: The first $q-1$ elements that $\mathcal{A}_p$ selects are $z_{1+\sigma(1)},\ldots,z_{1+\sigma(q-1)}$. The last element that it selects is z_m if the response for all previous elements was 0, and z_1 otherwise.

Define the marginal $\mathcal{D}_X$ over $\mathcal{X}$ such that for $X \sim \mathcal{D}_X$, $\mathbb{P}[X \in \texttt{base}] = 1-1/m$, $\mathbb{P}[X \in \texttt{perm}] = 1/m$, and in each range $\texttt{base},\texttt{perm}$, X is uniform. The probability of a good pool under $\mathcal{D} \in \text{DS}(\mathcal{D}_X)$ is $(1-1/m)^{m-1} \geq 1/e^2 =: c_1$. We now show a lower bound on the expected number of iterations of a stream algorithm which is $(q,\mathcal{D})$-equivalent to any $\mathcal{D} \in \text{DS}(\mathcal{D}_X)$. Let $\mathcal{D}_0$ be the distribution over $\mathcal{X}\times\mathcal{Y}$ such that for $(X,Y) \sim \mathcal{D}_0$, $X \sim \mathcal{D}_X$ and $Y = 0$ with probability 1. Let $S \sim \mathcal{D}_0^m$ be the input to $\mathcal{A}_p$.

We apply Lemma 5 with $t = t' = q-1, l = m-1, d = \sqrt{(m-q)\log(4q)/2}$. By this lemma, for any set $Z = \{z_1,\ldots,z_{q-1}\} \subseteq \texttt{base}$, there exists a set of permutations $\Phi(Z) \subseteq \Pi_{m-1}$ such that

$$|\Phi(Z)|/|\Pi_{m-1}| \leq \left(\frac{8q^2(m-q)\log(4q)}{(m-1)^2}\right)^{(q-1)/2} \leq \left(\frac{8q^2\log(4q)}{m-1}\right)^{\frac{q-1}{2}}, \tag{2}$$

and also

$$\mathbb{P}[\psi(z_m) \in \Phi(Z) \mid \mathsf{sel}_p(S,[q-1]) =_\pi Z \wedge S \text{ is good}] \geq 1 - 2(q-1)\exp(-\log(4q)) \geq \frac{1}{2}. \tag{3}$$

The theorem follows from the following two claims:

1. When $\mathcal{A}_s$ emulates a good pool, it selects an element from $\texttt{perm}$ only after selecting $q-1$ elements from $\texttt{base}$.
2. Therefore, when $\mathcal{A}_s$ emulates a good pool, the expected number of observed elements until selecting the last element is lower bounded, and so the overall expected number is lower bounded.

We first prove claim 1. Consider a stream algorithm which is $(q,\mathcal{D})$-equivalent to $\mathcal{A}_p$ for any $\mathcal{D} \in \text{DS}(\mathcal{D}_X)$. Consider runs of $\mathcal{A}_s$ with input $S' \sim \mathcal{D}_0^\infty$. Denote by E_g the event that the output of $\mathcal{A}_s$ is equal to a possible output of $\mathcal{A}_p$ on a good pool with $S \sim \mathcal{D}_0^m$. Then $\mathbb{P}[E_g] \geq c_1$. Claim 1 is that

$$\mathbb{P}[\mathsf{sel}_s(S',[q-1]) \subseteq_\pi \texttt{base} \mid E_g] = 1. \tag{4}$$

In other words, when simulating a good pool, the elements in $\texttt{base}$ are all selected before the element in $\texttt{perm}$.

To show claim 1, note that by the definition of $\mathcal{A}_p$, for any source distribution over $\mathcal{X}\times\mathcal{Y}$, if $\mathcal{A}_p$ outputs a set with elements both in $\texttt{base}$ and in $\texttt{perm}$, then there is exactly one element in $\texttt{perm}$ in the output, and all the responses in the output for elements in $\texttt{base}$ are 0 with probability 1.

Now, suppose that $\mathbb{P}[\mathsf{sel}_s(S',[q-1]) \subseteq_\pi \texttt{base} \mid E_g] < 1$. Then $\mathbb{P}[\mathsf{sel}_s(S',q) \in \texttt{base} \mid E_g] > 0$, since there can be only one element in $\texttt{perm}$ in the output of a good pool. But, consider running $\mathcal{A}_s$ with a source distribution $\mathcal{D}' \in \text{DS}(\mathcal{D}_X)$ such that for $(X,Y) \sim \mathcal{D}'$, $X \sim \mathcal{D}_X$ and $\mathbb{P}_{\mathcal{D}'}[Y = 0|X = x] = \frac{1}{2}$ for all x. There is a positive probability that in the first $q-1$ selected elements all the responses are 0, just as for $\mathcal{D}_0$. Therefore, also for $S'' \sim \mathcal{D}'^\infty$, $\mathbb{P}[\mathsf{sel}_s(S'',q) \in \texttt{base} \mid E_g] > 0$. But then there is a positive probability that the response for the last element, which is in $\texttt{base}$, is 1, contradicting the $(q,\mathcal{D}')$-equivalence of the pool and $\mathcal{A}_s$. This proves claim 1.

We now show claim 2, which completes the proof. From claim 1 in Eq. (4), we conclude that $\mathbb{P}[\mathsf{sel}_s(S',q) \in \texttt{perm} \mid E_g] = 1$. Therefore, from Eq. (3), for any $Z \subseteq \texttt{base}$ with $|Z| = q-1$,

$$\mathbb{P}[\psi(\mathsf{sel}_s(S',q)) \in \Phi(\mathsf{sel}_s(S',[q-1])) \mid E_g] \geq 1/2.$$

Therefore

$$\mathbb{P}[\psi(\mathsf{sel}_s(S',q)) \in \Phi(\mathsf{sel}_s(S',[q-1]))] \geq \mathbb{P}[E_g]/2 \geq c_1/2.$$

Now, let $X_i \sim \mathcal{D}_X$ be the i'th element observed after selecting the first $q-1$ elements, and let $B_i = \mathbb{I}[\psi(X_i) \in \Phi(Z)]$, where Z is the set of $q-1$ selected elements. B_i are independent Bernoulli random variables, each with a probability of success at most p, where by Eq. (2)

$$p \leq \frac{|\Phi(Z)|}{|\Pi_{m-1}|} \leq \left(\frac{8q^2\log(4q)}{m-1}\right)^{\frac{q-1}{2}}.$$

Let I be the number of elements that $\mathcal{A}_s$ observes after selecting Z, until selecting element q. We have $\mathbb{P}[B_I = 1] \geq c_1/2$. From the assumption in the theorem statement that $m \geq 16q^2\log(4q)+1$, we have that for sufficiently large q, $p \leq c_1^4/32$. By Lemma 2, it follows that $\mathbb{E}[I] \geq c_1^2/(16p) \geq (1000p)^{-1}$. Hence

$$\mathbb{E}[I] \geq \frac{1}{1000}\left(\frac{m-1}{8q^2\log(4q)}\right)^{\frac{q-1}{2}}.$$

Since $\mathbb{E}[N_{\mathsf{iter}}(\mathcal{A},S,q)] \geq \mathbb{E}[I]$, this completes claim 2 and finalizes the proof. ■

The lower bound, as well as the upper bound in Theorem 4, both show an exponential dependence on q. However, the exponent in the lower bound is about half that of the upper bound. Some of this gap might be an artifact of the fact that in the lower bound, only a fixed marginal distribution is considered. Closing this gap remains an open problem, which we leave for future work.

4.3 Emulation with a Precognitive Stream Algorithm

We next consider the precognitive setting. In the precognitive setting, the stream algorithm has the advantage that it can plan ahead, since it knows in advance the identity of elements that will be available for selection from the entire stream. This breaks the construction used in the lower bound of Theorem 6, thus showing that in some cases there is a significant gap between standard stream algorithms and precognitive stream algorithms. We prove this in the following theorem.

Theorem 7 *There is an integer q_0, such that for $q \geq q_0$ and $m \geq 16q^2\log(4q)+1$, there exist a pool algorithm $\mathcal{A}_p$ and a marginal $\mathcal{D}_X$, such that any stream algorithm $\mathcal{A}_s$ which is $(q, \mathcal{D})$ equivalent to $\mathcal{A}_p$ for all $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$, and selects only q elements, requires an expected number of iterations of $\Omega\left(\left(\frac{m}{q^2\log(q)}\right)^{q/2}\right)$, while there exists a precognitive stream algorithm that satisfies the same equivalence, and requires only m^2 iterations in expectation.*

Proof Consider the same construction as in the proof of Theorem 6: the same $\mathcal{D}_X$, and the same behavior of the pool algorithm on "good pools", defined as in that proof. Assume further, consistently with the definition of $\mathcal{A}_p$ in that proof, that on bad pools, the pool algorithm checks if there are more `base` element or more `perm` elements in the pool, and then selects the first q elements in the pool that belong to the set with the larger number (in case of a tie, `base` is selected). Denote `base`, `perm`, ψ as in the proof of Theorem 6.

From Theorem 6 we have that the expected number of iterations of a standard stream algorithm on this problem is $\Omega\left(\left(\frac{m}{q^2\log(q)}\right)^{q/2}\right)$.

Now, consider the following precognitive stream algorithm: The algorithm checks, before the start of the iterations, whether the first m stream elements constitute a good pool. If they do not, it checks whether there are more `base` or more `perm` elements in the first m elements. Then it selects the first q elements in the stream that belong to the majority set (tie-breaking with preference to `base` as in the pool algorithm). Thus, for bad pools, the expected number of iterations by the precognitive stream algorithm is at most m.

Now, if the first m elements in the stream constitute a good pool, then the precognitive stream algorithm finds an integer t such that x_t is the smallest element from `base` among the previous $m-1$ `base` elements, using the following procedure:

1. Let $t_0 \leftarrow 1$; $t_1 \leftarrow m$.
2. Let A be the set of $m-1$ elements from `base` in $x_{t_0}, \ldots, x_{t_1}$.
3. If x_{t_1} is the minimum of A, set $t \leftarrow t_1$ and terminate.
4. Otherwise, set $t_0 \leftarrow t_1 + 1$, and $t_1 \leftarrow$ the smallest integer such that $x_{t_0}, \ldots, x_{t_1}$ has exactly $m-1$ elements from `base`. Go to 2

After setting t, the algorithm identifies the earliest iteration $t' > t$ such that $x_{t'} \in$ `perm`. The algorithm then ranks the $m-1$ elements from `base` that immediately precede x_t, denoting them $z_2 < \ldots < z_{m-1}$, and denotes $z_1 := x_t$.

The algorithm then selects $z_{1+\sigma(1)}, \ldots, z_{1+\sigma(q-1)}$ in the order of their appearance in the stream, where $\sigma := \psi(x_{t'})$. Then, if all of the responses to these elements were 0, it selects $x_{t'}$. Otherwise, it selects z_1.

It is easy to see that this algorithm is equivalent to the pool algorithm defined above. Also, the expected number of iterations of this algorithm is

$$\mathbb{E}[t'] = \mathbb{E}[t' - t] + \mathbb{E}[t].$$

Now, $\mathbb{E}[t'-t]$ is the expected wait time until observing an element from `perm`. Since for $X \sim \mathcal{D}_X$, $\mathbb{P}[X \in \texttt{perm}] = 1/m$, we have $\mathbb{E}[t'-t] = m$. In addition, by Wald's identity, $\mathbb{E}[t]$ is equal to the expected number of rounds of the procedure for setting t above, which is $m-1$, times the expected size

of $t_1 - t_0 + 1$ in each round, which is $\mathbb{P}[X \in \texttt{base}] \cdot (m-1)$. Thus, $\mathbb{E}[t] = (m-1)^3/m \leq (m-1)m$. It follows that the expected number of iterations of the precognitive stream algorithm is $\mathbb{E}[t'] \leq m^2$. ■

This result shows that the precognitive setting has a significant advantage in some cases. Nonetheless, we show a lower bound, indicating that its worst-case performance cannot be much better than the worst-case performance of a standard stream algorithm. The proof of the lower bound shares some techniques with the proof of Theorem 6, especially the use of permutations. It additionally relies on the observation that while the stream algorithm knows in advance what elements will be available for selection and when, it is still constrained to selecting the elements in the order that they are provided by the stream. It also must keep to a certain order of selections to emulate the pool algorithm, since the pool algorithm makes decisions based on previously observed responses. Thus, in the proof of the lower bound, we construct a pool algorithm that might select two permutation elements, but the order in which they would be selected depends on the responses to selected base elements. As a result, the precognitive algorithm cannot tell in advance in which order the two elements must be selected. The probability of both orders appearing early enough in the stream is low, so that even when the whole stream is taken into account, an exponential dependence cannot be avoided, though this dependence is weaker than the one shown in Theorem 6 for standard stream algorithms.

The proof of the lower bound employs the following lemma, which states that after partially observing two sequences of fair coin tosses, there is a positive probability that both sequences share the majority outcome, as well as a positive probability that their majority outcome is different. In the lower bound below, this lemma is used to show that the precognitive algorithm must commit to a small set of permutations before finding out in which order they must be selected.

Lemma 8 *Consider n i.i.d. tosses of two fair coins, where n is an odd number. Denote the tosses of the first coin by $A_1, \ldots, A_n \in \{0,1\}$, and the second by $B_1, \ldots, B_n \in \{0,1\}$. Let $K \in \{n/2, \ldots, n\}$ be a stopping time for the sequence $B_1, \ldots, B_n$, which can depend also on $\bar{A} := (A_1, \ldots, A_{n/2})$. Denote $\bar{B}(K) := (B_1, \ldots, B_K)$.*

There exists some integer n_0 and constants $c = 0.68$, $c' = 0.15$ such that for all odd $n > n_0$, with a probability at least c over the values of $\bar{A}, K, \bar{B}(K)$,

$$\mathbb{P}\left[\mathbb{I}[\sum_{i=1}^{n} A_i > n/2] = \mathbb{I}[\sum_{i=1}^{n} B_i > n/2] \;\middle|\; \bar{A}, K, \bar{B}(K)\right] \in [c', 1-c']$$

Proof Denote for brevity $A_j^l := \sum_{i=j}^{l} A_i$ and similarly for B_j^l. First note that

$$\begin{aligned}&\mathbb{P}\left[\mathbb{I}[A_1^n > n/2] = \mathbb{I}[B_1^n > n/2] \;\middle|\; K, \bar{A}, \bar{B}(K)\right] \\ &= \mathbb{P}[B_1^n > n/2 \mid K, \bar{B}(K)] \cdot \mathbb{P}[A_1^n > n/2 \mid \bar{A}] + \mathbb{P}[B_1^n \leq n/2 \mid K, \bar{B}(K)] \cdot \mathbb{P}[A_1^n \leq n/2 \mid \bar{A}]\end{aligned}$$

Thus it suffices to prove that with a probability at least c over the values of $\bar{A}$, $\mathbb{P}[A_1^n > n/2 \mid \bar{A}] \in [c', 1-c']$, which implies the same for $\mathbb{P}[A_1^n \leq n/2 \mid \bar{A}]$, leading to the claim of the lemma.

We first consider the limit case $n \to \infty$. In this case $A_1^{n/2} \sim N(n/4, \sqrt{n/8})$. Thus, with a probability of $\mathrm{erf}(1/\sqrt{2}) > 0.68 =: c$,

$$A_1^{n/2} \in [n/4 - \sqrt{n/8}, n/4 + \sqrt{n/8}].$$

If this is the case, then

$$A^n_{n/2+1} < n/4 - \sqrt{n/8} \quad \Longrightarrow \quad A^n_1 < n/2, \text{ and}$$
$$A^n_{n/2+1} > n/4 + \sqrt{n/8} \quad \Longrightarrow \quad A^n_1 > n/2.$$

Since $A^n_{n/2+1} \sim N(n/4, \sqrt{n/8})$, each of the above events occurs with a probability at least $\frac{1}{2} - \mathrm{erf}(1/\sqrt{2})/2 > 0.15 =: c'$. Thus, with a probability at least c over the values of $\bar{A}$,

$$\mathbb{P}[A^n_1 > n/2 \mid \bar{A}], \mathbb{P}[A^n_1 \leq n/2 \mid \bar{A}] \in [c', 1-c'].$$

The same holds for any large enough finite value of n. The statement of the lemma directly follows. ■

The lower bound for the precognitive setting is given below. It is exponential in q, like the lower bound for the standard stream setting in Theorem 6, however the dependence is slightly weaker.

Theorem 9 *There is an integer q_0 such that for any $q \geq q_0$ and $m \geq 2q+1$ there exist a pool algorithm $\mathcal{A}_p$ and a distribution $\mathcal{D}$, such that any precognitive stream algorithm $\mathcal{A}_s$ which is $(q, \mathcal{D})$ equivalent to $\mathcal{A}_p$ and selects only q elements, has*

$$\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s, S, q)] \geq \frac{1}{600}\left(\frac{m}{8q^2\log(2q)}\right)^{q/8}.$$

Proof Assume for simplicity that 4 divides q and m. Let the domain of elements be $\mathcal{X} = [0,4) \cup \{\star\}$ and assume responses in $\mathcal{Y} = \{0,1\}$. Denote $\texttt{base1} := [0,1]$, $\texttt{base2} := [2,3]$, $\texttt{perm1} := (1,2)$ and $\texttt{perm2} := (3,4)$. Denote $\texttt{base} = \texttt{base1} \cup \texttt{base2}$ and $\texttt{perm} = \texttt{perm1} \cup \texttt{perm2}$.

We define the pool algorithm $\mathcal{A}_p$ as follows. Call a pool S_X a "good pool" if it includes at least $m/4$ elements from each of $\texttt{base1}$ and $\texttt{base2}$, and at least one element from each of $\texttt{perm1}, \texttt{perm2}, \star$. In a good pool S_X, the pool algorithm $\mathcal{A}_p$ behaves as follows. For $i \in \{1,2\}$, let $X_i \subseteq S_X \cap \texttt{base}(i)$ be a subset of size $m/4$, selected uniformly at random from $S_X \cap \texttt{base}(i)$. Let $x_{p(i)}$ be a random element from $S_X \cap \texttt{perm}(i)$. Let $\sigma_1 = \psi(x_{p(1)} - 1)$, $\sigma_2 = \psi(x_{p(2)} - 3)$. For $j \in [m/4]$, let x^i_j be the j-th largest value in X_i. Define a mapping $\psi : (0,1) \to \Pi_{m/4}$, such that if Z is uniform over $(0,1)$, then for $\psi(Z)$ all permutations in the range are equally likely.

The first $q-2$ elements that $\mathcal{A}_p$ selects are $\bar{X}_i := x^i_{\sigma_i(1)}, \ldots, x^i_{\sigma_i(q/2-1)}$, for each of $i \in \{1,2\}$. The last 2 elements that $\mathcal{A}_p$ selects are determined as follows: Let $r_i \in \{0,1\}$ be the value of the majority of responses received for the elements in $\bar{X}_i$. Denote $s = 1 + \mathbb{I}[r_1 = r_2]$ and $\bar{s} = 1 + \mathbb{I}[r_1 \neq r_2]$. The second-to-last element that $\mathcal{A}_p$ selects is $x_{p(s)}$. The last element that $\mathcal{A}_p$ selects is $x_{p(\bar{s})}$ if the response for $x_{p(s)}$ is 0, and $\star$ otherwise. See illustration in Figure 1.

Define the distribution $\mathcal{D}$ such that its marginal $\mathcal{D}_X$ over $\mathcal{X}$ satisfies, for $X \sim \mathcal{D}_X$, $\mathbb{P}[X \in \texttt{base1}] = \mathbb{P}[X \in \texttt{base2}] = 1/3$, $\mathbb{P}[X \in \texttt{perm1}] = \mathbb{P}[X \in \texttt{perm2}] = \mathbb{P}[X = \star] = 1/9$, and in each range $\texttt{base1}, \texttt{base2}, \texttt{perm1}, \texttt{perm2}$, X is conditionally uniform. In addition, for $(X,Y) \sim \mathcal{D}$, $\mathbb{P}[Y = 0 | X = x] = \frac{1}{2}$ for all $x \in \mathcal{X}$. Assume a large enough m such that the probability of a good pool under $\mathcal{D}_X$ is at least $1-\epsilon$ for some very small $\epsilon > 0$. We set $\epsilon = 0$ below for simplicity, noting that any small enough choice will lead to the same lower bound due to rounding down of constants. Thus we assume all pools are good pools.

Consider running the $(q, \mathcal{D})$-equivalent algorithm $\mathcal{A}_s$ with the source distribution $\mathcal{D}$. We derive a lower bound on $\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s, S, q)]$ via the following sequence of arguments.

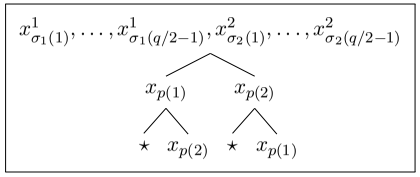

Figure 1: A tree describing the possible selections made by the pool algorithm on a good pool in the proof of Theorem 9.

1. We show that $\mathcal{A}_s$ selects at least $q/4$ elements from each of $\texttt{base1}$ and $\texttt{base2}$ before it selects any element from $\texttt{perm}$.

2. Using the previous claim, we show that there is a positive probability over runs of $\mathcal{A}_s$ on $S \sim D^\infty$ that there is an iteration in the run such that the following hold:

   - Before this iteration at least $q/4$ elements from each of $\texttt{base1}$ and $\texttt{base2}$ have been selected.
   - Conditioned on the run until this iteration, and on the entire S_X, the probability that at some time after this iteration an element from $\texttt{perm1}$ is selected, and an element from $\texttt{perm2}$ is selected at some time after that, is larger than a constant.
   - The same property holds for the reverse order: selecting first an element from $\texttt{perm2}$ and then an element from $\texttt{perm1}$.

3. We conclude that the expected number of iterations of $\mathcal{A}_s$ depends on the probability to have, in a single stream S_X, two elements that are both mapped to permutations in a single small subset. We then show that this implies a lower bound on the number of iterations of $\mathcal{A}_s$.

We start by showing the claim in item 1. Consider a run of $\mathcal{A}_s$ with input $S \sim \mathcal{D}^\infty$. Since the output must be equivalent to an output of $\mathcal{A}_p$ on a good pool, this implies that for $i \in \{1,2\}$, an element from $\texttt{perm}(i)$ is selected if and only if $s = i$ (where s is defined as done above for the pool algorithm) or the response for an element selected from $\texttt{perm}(\bar{s})$ is 0. Denote the iteration in which an element from $\texttt{perm}$ is first selected by I. Suppose for contradiction that before iteration I, less than $q/4$ elements from either $\texttt{base1}$ or $\texttt{base2}$ have been selected. Thus, for at least one of $\texttt{base1}, \texttt{base2}$, less than half of the elements to be selected from this set during this run are selected until iteration I. It follows that at iteration I the majority of the responses for at least one of the sets $\bar{X}_i$ is yet unknown. Therefore the value of s is also unknown and there is a positive probability that it will be each of $1,2$. There is also a positive probability that, if an additional element from $\texttt{perm}$ is selected later, its response will be 1. Thus, there is a positive probability that the output of this run does not correspond to any output of $\mathcal{A}_p$, contradicting the equivalence of $\mathcal{A}_s$ and $\mathcal{A}_p$. This proves the claim in item 1.

We now prove the claim in item 2. Let T be the smallest integer such that until iteration T (non-inclusive), at least $q/4$ elements from each of $\texttt{base1}$ and $\texttt{base2}$ have been selected, and no

element from $\texttt{perm}$ has been selected yet. T exists by item 1 above. An element from $\texttt{perm}(s)$, where s depends on the majority of responses in each of $\bar{X}_i$, must be selected before an element from $\texttt{perm}(\bar{s})$ is selected (if at all). Consider the distribution of s, conditioned on the run of $\mathcal{A}_s$ until iteration T and on S_X. We have $s = 2$ if the majority of responses on $\bar{X}_1$ is equal to the majority of responses on $\bar{X}_2$. Out of these responses, at least $q/4 - 1$ of at least one of $\bar{X}_1, \bar{X}_2$, are yet unknown at iteration T. Thus, by Lemma 8, for a large enough q we have that for any S_X, there is a probability of at least $c = 0.68$ over the responses until iteration T that

$$\mathbb{P}[s = 2 \mid \text{the responses until iteration } T, S_X] \in [c', 1 - c'],$$

where $c' = 0.15$. The same holds for $s = 1$.

To finalize the proof of the claim in item 2, observe that if the response for the element selected from $\texttt{perm}(s)$ is 0, then an element from $\texttt{perm}(\bar{s})$ will also be selected later. This occurs with a probability of $\frac{1}{2}$. Consider the event $B_1 :=$ "an element from $\texttt{perm}(1)$ is selected at some point in the run and an element from $\texttt{perm}(2)$ is selected some time later". Let B_2 be the symmetric event. We conclude that with a probability of at least c,

$$\forall i \in \{1, 2\}, \quad \mathbb{P}[B_i \mid \text{the responses until iteration } T, S_X] \geq c'/2. \tag{5}$$

This proves the claim in item 2. Denote the event that Eq. (5) holds by E_p.

We now turn to the third and last part of the proof. Denote by Z_i, for $i \in \{1, 2\}$, the first $q/4$ elements selected by $\mathcal{A}_s$ from $\texttt{base}(i)$. We apply Lemma 5 with $t = q/4, t' = q/2 - 1, l = m/4, d = \sqrt{m \log(q/c)/8}$, to obtain that if the pool algorithm has $Z_i \subseteq \bar{X}_i$ for $i \in \{1, 2\}$, then there is a probability of at least $1 - \frac{q}{2} \exp(-8d^2/(m-q)) \geq 1 - c/2$ that the element that $\mathcal{A}_p$ selects from $\texttt{perm}(i)$ for $i \in \{1, 2\}$ (if it exists) is in a given set of permutations $\Phi(Z_i)$ that satisfies[1]

$$\frac{|\Phi(Z_i)|}{|\Pi_{m/4}|} \leq \left(\frac{8dq}{m}\right)^{q/4}.$$

Thus, this holds also for $\mathcal{A}_s$. Since this holds with probability $1 - c/2$, and Eq. (5) holds with a probability at least c, there is a probability at least $c/2$ that both events hold simultaneously. That is, denoting the event $G_1 :=$ "an element from $\phi(Z_1)$ is selected at some point in the run and an element from $\phi(Z_2)$ is selected some time later" and symmetrically for G_2, we have that with a probability at least $c/2$ over the responses until iteration T and S_X,

$$\forall i \in \{1, 2\}, \quad \mathbb{P}[G_i \mid \text{the responses until iteration } T, S_X] \geq c'/2.$$

Denote the event that this holds E_G. Abbreviate $N_{\mathsf{iter}} := N_{\mathsf{iter}}(\mathcal{A}_s, S, q)$. It follows that

$$\begin{aligned}\mathbb{E}[N_{\mathsf{iter}} \mid S_X, E_G] &\geq c'/2 \cdot \left(\mathbb{E}_{Z_1,Z_2}\Big[\mathbb{E}[N_{\mathsf{iter}} \mid G_1, E_G, S_X, Z_1, Z_2] + \mathbb{E}[N_{\mathsf{iter}} \mid G_2, E_G, S_X, Z_1, Z_2]\Big]\right) \\ &\geq c'/2 \min_{Z_1,Z_2} \left(\mathbb{E}[N_{\mathsf{iter}} \mid G_1, E_G, S_X, Z_1, Z_2] + \mathbb{E}[N_{\mathsf{iter}} \mid G_2, E_G, S_X, Z_1, Z_2]\right)\end{aligned}$$

Letting $S_X = x_1, x_2, \ldots$, denote by $N_1 \equiv N_1(S_X, Z_1, Z_2)$ the length of the shortest prefix of $x_T, x_{T+1}, \ldots$ that includes an element from $\Phi(Z_1)$ and at some later point an element from $\Phi(Z_2)$, and by $N_2 \equiv N_2(S_X, Z_1, Z_2)$ the length of the shortest prefix that includes the reverse order. Clearly, the number of iterations under G_i is at least N_i. Therefore

$$\mathbb{E}[N_{\mathsf{iter}} \mid S_X, E_G] \geq c'/2 \min_{Z_1,Z_2} (N_1(S_X, Z_1, Z_2) + N_2(S_X, Z_1, Z_2)).$$

Let $N \equiv N(S_X, Z_1, Z_2) := \max(N_1(S_X, Z_1, Z_2), N_2(S_X, Z_1, Z_2))$. Observe that in the subsequence $x_T, \ldots, x_{T+N}$, there is an element from $\Phi(Z_1)$ followed by one from $\Phi(Z_2)$ some time later, and also the reverse order. It follows there are at least two elements from $\Phi(Z_i)$ for at least one of $i \in \{1, 2\}$ in this subsequence. Let $N' \equiv N'(S_X, Z_1, Z_2)$ be the smallest integer such that $x_T, \ldots, x_{T+N'}$ includes at least one of the two options. Then $N' \leq N$, and so

$$\mathbb{E}[N_{\mathsf{iter}} \mid S_X, E_G] \geq c'/2 \min_{Z_1,Z_2} (N'(S_X, Z_1, Z_2)).$$

Taking expectation over S_X conditioned on E_G, it follows that

$$\mathbb{E}[N_{\mathsf{iter}} \mid E_G] \geq c'/2 \cdot \mathbb{E}_{S_X}[\min_{Z_1,Z_2} (N'(S_X, Z_1, Z_2)) \mid E_G].$$

therefore, since $\mathbb{P}[E_G] \geq c/2$,

$$\mathbb{E}[N_{\mathsf{iter}}] \geq c' \cdot c/4 \cdot \mathbb{E}_{S_X}[\min_{Z_1,Z_2} (N'(S_X, Z_1, Z_2)) \mid \mathbb{E}_G]. \tag{6}$$

We now lower-bound the RHS of this inequality. Let K be an integer. We have

$$\mathbb{E}_{S_X}[\min_{Z_1,Z_2} N' \mid \mathbb{E}_G] \geq K(\mathbb{P}[\min_{Z_1,Z_2} N' \geq K] - (1 - \mathbb{P}[E_G])) \geq K(c/2 - \mathbb{P}[\min_{Z_1,Z_2} N' < K]). \tag{7}$$

We have left to upper-bound $\mathbb{P}[\min_{Z_1,Z_2} N' < K]$ for a non-trivial value of K. Denoting $S_X = x_1, x_2, \ldots$, we have

$$\begin{aligned}\mathbb{P}[\min_{Z_1,Z_2} N' < K] &= \mathbb{P}[\exists i \in \{1, 2\}, Z_i \subseteq \texttt{base}(i), j < j' < K, \text{ s.t. } |Z_i| = q/4, x_j, x_{j'} \in \Phi(Z_i)] \\ &\leq 2\mathbb{P}[\exists Z_1 \subseteq \texttt{base1}, j < j' < K, \text{ s.t. } |Z_1| = q/4, x_j, x_{j'} \in \Phi(Z_1)].\end{aligned}$$

The last inequality follows from a union bound and the symmetry between the cases $i = 1$, $i = 2$. For $x \in \texttt{perm1}$, denote $L(x) := \cup_{Z \subseteq \texttt{base1}: |Z| = q/4, x \in \Phi(Z))} \Phi(Z)$. For $x \notin \texttt{perm1}$, let $L(x) := \emptyset$. We have

$$\begin{aligned}&\mathbb{P}[Z_1 \subseteq \texttt{base1}, j < j' < K, \text{ s.t. } |Z_i| = q/4, x_j, x_{j'} \in \Phi(Z_1)] \\ &\leq \mathbb{P}[\exists j < j' < K \text{ s.t. } x_{j'} \in L(x_j)] \\ &\leq K^2 \max_{x \in \texttt{perm1}} \mathbb{P}_{X \sim \mathcal{D}_X}[X \in L(x)] \\ &\leq K^2 \max_{x \in \texttt{perm1}} |L(x)|/|\Pi_{m/4}| \\ &\leq K^2 (8dq/m)^{q/2},\end{aligned}$$

where the last inequality follows from the last part of Lemma 5. Substituting for the value of d, it follows that

$$\mathbb{P}[N < K] \leq K^2 \left(8q^2 \log(q/c)/m\right)^{q/4}.$$

1. We abuse notation and let Φ denote a mapping from $\texttt{base}(i)$ to $\texttt{perm}(i)$ for both of $i \in \{1, 2\}$, using the obvious isomorfisms.

Setting $K = \sqrt{c}/2 \cdot \left(\frac{m}{8q^2 \log(q/c)}\right)^{q/8}$, we get that $\mathbb{P}[N < K] \leq c/4$, therefore by Eq. (6) and Eq. (7),

$$\mathbb{E}[N_{\mathsf{iter}}] \geq c' \cdot c/4 \cdot K(c/4) \geq c' \cdot c^{5/2}/32 \cdot \left(\frac{m}{8q^2 \log(q/c)}\right)^{q/8}.$$

Substituting $c' = 0.15$, $c = 0.68$ and rounding downward, we get the statement of the lemma. ■

The lower bounds above indicate that to improve the dependence on q, one must consider a more restricted class of pool algorithms. This is the topic of the next section.

5. Utility-Based Pool Algorithms

In Section 4 we provided an algorithm with a uniform guarantee on the expected number of iterations. However, this guarantee was exponential q, and as our lower bounds show, this dependence cannot be removed for a general pool algorithm. We now consider a more restricted class of pool algorithms, which we term *utility-based* pool algorithms, and show that it allows stream emulation with an expected number of iterations linear in q. Utility-based pool algorithms are defined in Section 5.1. In Section 5.2 an algorithm that emulates utility-based pool algorithms in a streaming setting is proposed, and it is shown that for this algorithm, the expected number of iterations is at most linear in q, in contrast to the exponential dependence required in the general case. In Section 5.3 two lower bounds are proved, showing that a quasi-linear dependence of the number of iterations on q cannot be avoided when emulating utility-based pool algorithms.

5.1 Defining Utility-Based Algorithms

A common approach for designing pool-based interactive algorithms is to define a utility function that scores each element depending on the history of selected elements and their responses so far (e.g., Seung et al., 1992; Lewis and Gale, 1994; Tong and Koller, 2002; Guo and Greiner, 2007; Golovin et al., 2010b; Guillory and Bilmes, 2010; Golovin and Krause, 2011; Gonen et al., 2013; Cuong et al., 2014). In each round, the algorithm selects the element that maximizes the current utility function. For example, the score can estimate the marginal benefit of selecting an element based on the current information on the source distribution, as gleaned from the previous elements and their responses. We consider black-box emulation for this class of pool-based algorithms.

Formally, a utility-based interactive pool algorithm is defined by a utility function $\mathcal{U}$, of the form $\mathcal{U} : \cup_{n=0}^{\infty} \mathcal{X} \times (\mathcal{X} \times \mathcal{Y})^n \to \mathbb{R}_{>0}$. The value of $\mathcal{U}(x, S_{t-1})$ represents the score of element x given history S_{t-1}. The pool algorithm selects, in each round, the element that is assigned the maximal score by the utility function given the history. We assume for simplicity that there are no ties in $\mathcal{U}$ and that all its outputs are positive. The general form of a utility-based interactive pool algorithm for $\mathcal{U}$, denoted $\mathcal{A}_p^{\mathcal{U}}$, is given in Alg. 4.

Our goal when emulating a pool algorithm is not to maximize $\mathcal{U}$ on the selected elements, but to exactly emulate the behavior of the pool algorithm $\mathcal{A}_p^{\mathcal{U}}$. This is because we do not assume any specific relationship between the value of the utility function and the reward of the algorithm. For instance, the utility-based pool algorithm might be empirically successful, while its analysis is not fully understood (e.g. Tong and Koller, 2002).

Algorithm 4 $\mathcal{A}_p^{\mathcal{U}}$

input Elements $x_1, \ldots, x_m$, budget $q < m$.

$S_0 \leftarrow ()$
$M_0 \leftarrow [m]$
for $t = 1 : q$ **do**
  $i_t \leftarrow \operatorname{argmax}_{j \in M_{t-1}} \mathcal{U}(x_j, S_{t-1})$.
  Select x_{i_t}, get y_{i_t}.
  $S_t \leftarrow S_{t-1} \circ (x_{i_t}, y_{i_t})$.
  $M_t \leftarrow M_{t-1} \setminus \{i_t\}$.
end for
Output the set of all pairs in S_q.

5.2 Stream Emulation for Utility-Based Pool Algorithms

We propose a stream algorithm that emulates a utility-based pool algorithm using a black-box solution to the well-known *secretary problem* (Dynkin, 1963; Gilbert and Mosteller, 1966; Ferguson, 1989). We first present this classical riddle and discuss its possible solutions in Section 5.2.1. The stream algorithm and its analysis are presented in Section 5.2.2.

5.2.1 THE SECRETARY PROBLEM WITH A BI-CRITERION

In the classical formulation of the secretary problem, an algorithm sequentially observes a stream of n different real numbers, and selects a single number. The goal of the algorithm is to select the unique maximal number out of the n numbers, but it can only select a number immediately after it is observed, before observing the rest of the numbers. It is assumed that the n numbers in the stream are unknown and selected by an adversary, but their order of appearance is uniformly random.

The classical goal is to select the maximal number with a maximal probability, where n is known to the algorithm. This task can be optimally solved by a simple deterministic algorithm, achieving a success probability which approaches $1/e$ in the limit of $n \to \infty$ (Dynkin, 1963; Gilbert and Mosteller, 1966; Ferguson, 1989). The optimal algorithm observes the first $t(n)$ numbers, and then selects the next observed number which is at least as large as the maximal in the first $t(n)$. The limit of $t(n)/n$ for $n \to \infty$ is $1/e$.

In the next section we show how any secretary problem strategy can be used to emulate a utility-based pool algorithm in a streaming setting. However, while the classical formulation of the secretary problem is concerned only with the probability of success, in our context an additional criterion is important. Thus for a given strategy, we consider the following two criteria:

1. The probability of success—the probability that the strategy selects the maximal element out of n, assuming a random ordering of the input sequence. This is the single criterion of the classical secretary problem.

2. The *success/select ratio*—the conditional probability that a number is maximal, given that the strategy selected it.

For the second criterion to be meaningful, we allow the strategy to decide not to select any number. For instance, in the classical optimal solution to the secretary problem, the strategy should not select

any number if after the first $t(n)$ numbers, all the other numbers are smaller than the maximal in the first $t(n)$. As we see in Section 5.2.2, we would optimally like the strategy to have both a high success probability and a high success/select ratio. This is because a high success probability leads to a lower number of observed elements N_{iter} required by the stream algorithm, while a high success/select ratio leads to a lower number of selections of elements N_{sel}.

The classical solution maximizes the success probability, but does not optimize for the success/select ratio. Another extreme can be found in the following strategy, which sets the success/select ratio at one, at the expense of the success probability: Wait for the last number, and then select it only if it is the maximal out of all the observed items. This strategy never selects a non-maximal number, hence its success/select ratio is one, however its success probability is only $1/n$. Denote this strategy SecPr[last].

In general, consider strategies of the following form: For a given $M \geq 1$, observe the first $M-1$ numbers. Then select the first number which is larger than the maximal in the first $M-1$ numbers. If no such number is observed, avoid selecting a number. Denote this strategy SecPr$[M]$. Denote by $p_s(M)$ the success probability of this strategy, and by $\mathrm{sr}(M)$ its success/select ratio. The analysis of $p_s(M)$ (see Ferguson, 1989) gives $p_s(1) = 1/n$, and for $M > 1$,

$$p_s(M) = \frac{M-1}{n}(H_{n-1} - H_{M-1}),$$

where H_i is the i'th harmonic number $H_i := \sum_{j=1}^{i} \frac{1}{i}$.

To calculate $\mathrm{sr}(M)$, note that the event that some number is selected occurs exactly when the maximal number is in the last $n-(M-1)$ observed numbers. Therefore the probability of selecting a number is $1 - \frac{M-1}{n}$, and so

$$\mathrm{sr}(M) = \frac{p_s(M)}{1 - \frac{M-1}{n}}.$$

Setting $\alpha := \frac{M-1}{n}$ and considering large n, we have $H_{n-1} - H_{M-1} \approx \ln(\frac{n-1}{M-1}) \approx \ln(1/\alpha)$. Therefore

$$p_s(M) \approx \alpha \log(1/\alpha), \quad \text{and} \quad \mathrm{sr}(M) \approx \frac{\alpha \log(1/\alpha)}{1-\alpha}.$$

For $\alpha \in (0,1)$, $p_s(M)$ is concave with a single maximum at $\alpha = 1/e$, while $\mathrm{sr}(M)$ is monotonic increasing. Since we wish for both criteria to be large, the Pareto frontier includes only and all the solutions with $\alpha \geq 1/e$. See Figure 2 and Figure 3 for the trade-off between $p_s(M)$ and $\mathrm{sr}(M)$ as α changes between $1/e$ and 1.

In the implementation of the stream algorithm shown in the following section, the secretary problem strategy is executed multiple times, for sequences of different lengths. Given any secretary problem strategy for length m, we apply it for any length up to m, using the procedure in Alg. 5.

When running SecPrVar, the subset I should be drawn uniformly at random from all possible subsets. This way, clearly the success probability and the success/select ratio for SecPrVar, for any sequence of positive numbers of length $m' \leq m$, are at least as high as those for SecPr with a sequence of length m.

We also consider stream emulation using precognitive stream algorithms. In this case, the secretary problem can easily be perfectly solved: it may be assumed that the algorithm knows in advance all the numbers in the sequence and thus it can select the maximal number with probability 1. We

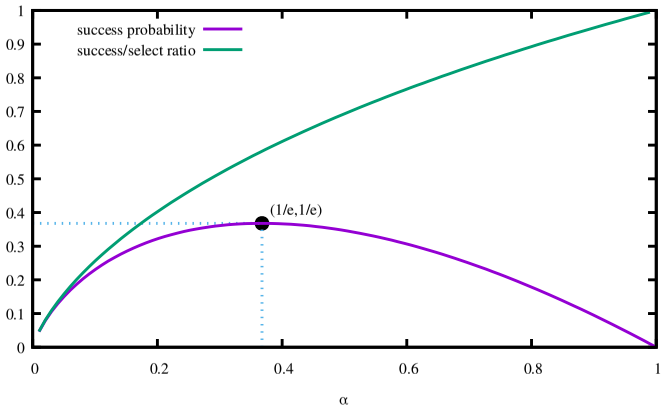

Figure 2: The success probability and the success/select ratio for large n, as a function of α.

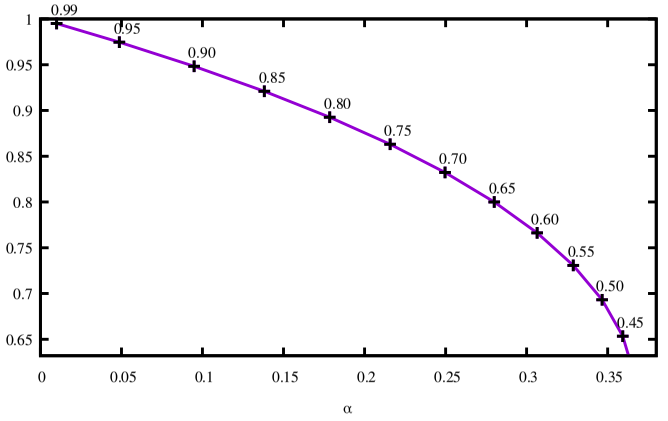

Figure 3: The trade-off between the success probability and the success/select ratio for large n, in the Pareto frontier of α values, for strategies of the form SecPr$[\alpha n]$. On the Pareto frontier α ranges between $1/e$ (largest success probability) and 1 (smallest success probability). The labels on the points indicate the value of α.

Algorithm 5 SecPrVar(m, m', I,SecPr): Secretary problem for sequences of variable length

input Integers $m, m' \leq m$, $I \subseteq [m]$, a secretary problem strategy SecPr for sequence length m.

$R \leftarrow ()$
for $i = 1 : m$ **do**
  if $i \notin I$ **then**
    $R \leftarrow R \circ (0)$ # Add a dummy zero to sequence
  else
    Get next number r from input
    $R \leftarrow R \circ (r)$
    if r should be selected according to SecPr on R **then**
      Select r and terminate.
    end if
  end if
end for

will denote this strategy $SecPr[\text{precog}]$. It has success probability and success/select ratio both equal to 1.

We next present and analyze the stream emulation algorithm for utility-based pool algorithms, which uses a secretary problem strategy via SecPrVar.

5.2.2 THE STREAM EMULATION ALGORITHM

We propose the stream emulation algorithm $\mathcal{A}_s^{\mathcal{U}}$, listed in Alg. 6. This algorithm repeatedly applies a secretary problem strategy to decide which elements to select. Because the secretary problem strategy might fail to select the maximal number, repeated applications of the strategy might be necessary. This trial-and-error approach means that $\mathcal{A}_s^{\mathcal{U}}$ might select more than q elements. However, the expected number of selected elements is a constant factor over q. The trade-off between the number of iterations and number of selected elements is controlled by the probability of success and the success/select ratio of the selected strategy SecPr, which is provided to $\mathcal{A}_s^{\mathcal{U}}$ as input.

$\mathcal{A}_s^{\mathcal{U}}$ is equivalent to $\mathcal{A}_p^{\mathcal{U}}$, as Theorem 10 below shows. In order to guarantee this equivalence, $\mathcal{A}_s^{\mathcal{U}}$ never selects an element that could not have been in a pool in which the previous elements were selected. This is achieved by discarding such elements in each round: The set $\mathcal{X}_i$ is the set of elements that are allowed in round i, and is defined to include only elements that could not have been selected by the pool algorithm before round i. To bound the expected number of iterations, we show in Theorem 11 that the probability mass of $\mathcal{X}_i$ can be controlled in expectation, which leads to a bound on the expected number of discarded elements.

Theorem 10 *For any utility function $\mathcal{U}$, any distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, any integer m and $q \leq m$, $\mathcal{A}_s^{\mathcal{U}}$ is $(q, \mathcal{D})$-equivalent to $\mathcal{A}_p^{\mathcal{U}}$.*

Proof Consider the probability space defined by $S \sim \mathcal{D}^m$ and $S' \sim \mathcal{D}^\infty$, where S, S' are independent. We prove the equivalence by showing that for any $j \in [q]$ and $L_j = ((x_{i,k_i}, y_{i,k_i}))_{i \in [j]}$ that could have been selected by the pool algorithm,

$$d\mathbb{P}[\mathsf{pairs}_p(S, j+1) \mid \mathsf{pairs}_p(S, [j]) = L_j] = d\mathbb{P}[\mathsf{pairs}_s(S', j+1) \mid \mathsf{pairs}_s(S', [j]) = L_j].$$

Algorithm 6 $\mathcal{A}_s^{\mathcal{U}}$ Stream-emulation for utility-based pool algorithms

input Integers $m, q \leq m$, a secretary problem strategy SecPr for sequences of length m.

$L_0 \leftarrow ()$
$\mathcal{X}_1 = \mathcal{X}$
for $i = 1 : q$ **do**
  repeat

    for $j = 1 : m - i + 1$ **do**
      Repeatedly draw elements from $\mathcal{D}_X$, until drawing an element in $\mathcal{X}_i$.
      Denote it $x_{i,j}$, and let $r_{i,j} \leftarrow \mathcal{U}(x_{i,j}, L_{i-1})$.
      if SecPrVar($m, m-i+1, I$,SecPr) would select the last element in the sequence prefix $r_{i,1}, \ldots, r_{i,j}$ **then**
        $k \leftarrow j$
        Select $x_{i,k}$, get its response $y_{i,k}$.
      end if
    end for
  until $r_{i,k} = \max\{r_{i,1}, \ldots, r_{i,m-i+1}\}$.
  $k_i \leftarrow k$
  $L_i \leftarrow L_{i-1} \circ (x_{i,k_i}, y_{i,k_i})$.
  $\mathcal{X}_{i+1} \leftarrow \{x \in \mathcal{X}_i \mid \mathcal{U}(x, L_{i-1}) < \mathcal{U}(x_{i,k_i}, L_{i-1})\}$
end for
Output the set of pairs in L_q.

For a given L_j, denote by $\mathcal{D}_{j+1}$ the distribution generated by drawing $(X, Y) \sim \mathcal{D}$ conditioned on $X \in \mathcal{X}_{j+1}$, where $\mathcal{X}_{j+1}$ depends on L_j. Denote by $\mathcal{G}$ all the finite sequences of pairs such that when the optimal secretary problem solution is applied to the sequence, it succeeds. That is, the optimal value under the score $(x, y) \to \mathcal{U}(x, L_j)$ is indeed selected. From the definition of $\mathcal{A}_{\mathcal{U}}^s$, we have

$$d\mathbb{P}[\mathsf{pairs}_s(S', j+1) \mid \mathsf{pairs}_s(S', [j]) = L_j] = d\mathbb{P}_{\bar{S} \sim \mathcal{D}_{j+1}^{m-j}}[\operatorname*{argmax}_{(x,y) \in \bar{S}} \mathcal{U}(x, L_j) \mid \bar{S} \in \mathcal{G}].$$

For a given sequence $\bar{S} = ((\bar{x}_i, y_i))_{i \in [m-j]}$, let $\sigma(\bar{S}) : [m-j] \to [m-j]$ be a permutation such that for all $i \leq m - j$, $\bar{x}_{\sigma(i)} \leq \bar{x}_{\sigma(i+1)}$. The success of the optimal secretary problem algorithm depends only on the ordering of ranks in its input sequence, hence there is a set of permutations $\mathcal{G}'$ such that $\bar{S} \in \mathcal{G}$ if and only if $\sigma(\bar{S}) \in \mathcal{G}'$. Now, $\operatorname{argmax}_{(x,y) \in \bar{S}} \mathcal{U}(x, L_j)$ depends only on the identity of pairs in $\bar{S}$, while $\sigma(\bar{S})$ depends only on their order. Since the elements in $\bar{S}$ are i.i.d., these two properties are independent. Therefore

$$d\mathbb{P}_{\bar{S} \sim \mathcal{D}_{j+1}^{m-j}}[\operatorname*{argmax}_{(x,y) \in \bar{S}} \mathcal{U}(x, L_j) \mid \bar{S} \in \mathcal{G}] = d\mathbb{P}_{\bar{S} \sim \mathcal{D}_{j+1}^{m-j}}[\operatorname*{argmax}_{(x,y) \in \bar{S}} \mathcal{U}(x, L_j)].$$

Therefore

$$\begin{aligned}
&d\mathbb{P}[\mathsf{pairs}_s(S', j+1) \mid \mathsf{pairs}_s(S', [j]) = L_j] \\
&= d\mathbb{P}_{\bar{S}\sim\mathcal{D}^{m-j}_{j+1}}[\operatorname*{argmax}_{(x,y)\in\bar{S}} \mathcal{U}(x, L_j)] \\
&= d\mathbb{P}_{\hat{S}\sim\mathcal{D}^{m-j}}[\operatorname*{argmax}_{(x,y)\in\hat{S}} \mathcal{U}(x, L_j) \mid \hat{S} \subseteq (\mathcal{X}_{j+1} \times \mathcal{Y})^{m-j}] \\
&= d\mathbb{P}_{\hat{S}\sim\mathcal{D}^{m-j}}[\operatorname*{argmax}_{(x,y)\in\hat{S}} \mathcal{U}(x, L_j) \mid \forall (x,y) \in \hat{S}, i \in [j],\ \mathcal{U}(x, L_{i-1}) < \mathcal{U}(x_{i,k_i}, L_{i-1})] \\
&= d\mathbb{P}_{\hat{S}\sim\mathcal{D}^{m-j}}[\operatorname*{argmax}_{(x,y)\in\hat{S}} \mathcal{U}(x, L_j) \mid \mathsf{pairs}_p(L_j \circ \hat{S}, [j]) = L_j] \\
&= d\mathbb{P}_{S\sim\mathcal{D}^{m}}[\operatorname*{argmax}_{(x,y)\in S\setminus L_j} \mathcal{U}(x, L_j) \mid \mathsf{pairs}_p(S, [j]) = L_j] \\
&= d\mathbb{P}_{S\sim\mathcal{D}^{m}}[\mathsf{pairs}_p(S)(j+1) \mid \mathsf{pairs}_p(S, [j]) = L_j].
\end{aligned}$$

Here L_i is the prefix of length i of L_j. Since this equality holds for all $j \in [q-1]$, $d\mathbb{P}[\mathsf{pairs}_s(S', [q])] = d\mathbb{P}[\mathsf{pairs}_p(S, [q])]$. ■

The following theorem gives the expected number of selected elements and the expected number of observed elements used by $\mathcal{A}^{\mathcal{U}}_s$. Both of these values depend on the properties of the secretary problem strategy SecPr that $\mathcal{A}^{\mathcal{U}}_s$ receives as input.

Theorem 11 *Suppose that $\mathcal{A}^{\mathcal{U}}_s$ is run with $m, q \leq m$ and a secretary problem strategy SecPr for sequences of size m with success probability p_s and success/select ratio* sr. *Then, for any utility function $\mathcal{U}$ and any distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$*

$$\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{sel}}(\mathcal{A}^{\mathcal{U}}_s, S, q)] = q/\mathrm{sr}$$

and

$$\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}^{\mathcal{U}}_s, S, q)] = mq/p_s.$$

To observe the implications of these upper bounds, consider for instance the classical secretary problem strategy SecPr$[t(n)]$, as defined in Section 5.2.1, which has $p_s \approx 1/e$ and $\mathrm{sr} \approx \frac{1}{e(1-1/e)}$ for large m. It follows that for $m \to \infty$, the expected number of selected elements by $\mathcal{A}^{\mathcal{U}}_s$ is eq, and the expected number of observed elements is eqm. Other choices of parameters for the secretary problem lead to other points on the Pareto frontier in Figure 3. All the points on the Pareto frontier give a constant factor over q for the expected number of selected elements, and a factor linear in q over m for the expected number of iterations. To get an algorithm that selects exactly q elements, one can use the strategy SecPr[last], which gives $p_s = 1/m$ and $\mathrm{sr} = 1$, leading to an expected number of iterations of qm^2. In the precognitive setting, one can use $SecPr$[precog], which gives an expected number of selections exactly q, and an expected number of iterations mq.

Proof [of Theorem 11] Call a full run of the loop starting at step 6 an attempt for the i'th element. In each attempt for the i'th element, $m - i + 1$ elements from $\mathcal{X}_i$ are observed. The expected number of element selection attempts for each successful element selection is $\frac{1}{\mathrm{sr}}$. Thus,

$$\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{sel}}(\mathcal{A}^{\mathcal{U}}_s, S, q)] = \frac{1}{\mathrm{sr}} \cdot q.$$

For the second part of the statement, we need to bound $\mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}^{\mathcal{U}}_s, S, q)]$. The total expected number of attempts of running the secretary problem for each successful selection of an element is $\frac{1}{p_s}$, and the expected number of elements from $\mathcal{X}_i$ observed in each attempt is $m - i + 1$. Thus the expected number of elements from $\mathcal{X}_i$ observed until x_i is selected is $\frac{1}{p_s} \cdot (m - i + 1)$. However, drawing a single element from $\mathcal{X}_i$ might require several draws from $\mathcal{X}$. To bound the total expected number of observed elements, we now consider the definition of $\mathcal{X}_i$.

Denote by f_i the utility function $\mathcal{U}(\cdot, L_{i-1})$. Let $x_i := x_{i,k_i}$, be the i'th element added to L_i. Then $\mathcal{X}_i = \{x \in \mathcal{X}_{i-1} \mid f_{i-1}(x) \leq f_{i-1}(x_{i-1})\}$. Consider the probability space defined by the input to the stream algorithm $S \sim \mathcal{D}^\infty$, and let $Z_i, Z'_i \sim \mathcal{D}_X$ for $i \in [q]$ such that these random variables and S are all independent. Denote

$$p(\alpha, i) := \mathbb{P}[f_i(Z_i) \leq \alpha \mid Z_i \in \mathcal{X}_i].$$

$p(\alpha, i)$ is a random variable since $\mathcal{X}_i$ depends on S. Let $U_i := p(f_i(Z'_i), i)$. Since we assume no ties in $\mathcal{U}$, and no single x has a positive probability in $\mathcal{D}_X$, then conditioned on $\mathcal{X}_i$, U_i is distributed uniformly in $[0, 1]$. Hence $U_1, \ldots, U_q$ are statistically independent.

For $i > 1$, define the random variable $M_i := p(f_{i-1}(x_{i-1}), i-1)$. Then $M_i = \mathbb{P}[\mathcal{X}_i]/\mathbb{P}[\mathcal{X}_{i-1}]$. The expected number of elements that need to be drawn from $\mathcal{D}$ to get a single element from $\mathcal{X}_i$ is $1/\mathbb{P}[\mathcal{X}_i] = (\prod_{j=1}^{i} M_j)^{-1}$. Therefore,

$$\mathbb{E}[N_{\mathsf{iter}}(\mathcal{A}^{\mathcal{U}}_s, S, q) \mid M_2, \ldots, M_q] = \sum_{i=1}^{q} \frac{p_s^{-1} \cdot (m - i + 1)}{\prod_{j=1}^{i} M_j}.$$

The element x_i maximizes the function $x \mapsto f_i(x)$ over $m-i+1$ independent draws of elements x from $\mathcal{D}_X$ conditioned on $x \in \mathcal{X}_i$, hence it also maximizes $x \mapsto p(f_i(x), i)$. Therefore, for $i > 1$, M_i is the maximum of $m - i + 2$ independent copies of U_i, hence $\mathbb{P}[M_i \leq p] = p^{m-i+2}$. Hence

$$d\mathbb{P}[M_2, \ldots, M_q](p_2, \ldots, p_q)/dp_2 \cdot \ldots \cdot dp_q = \prod_{i=2}^{q} d\mathbb{P}[M_i \leq p_i]/dp_i = \prod_{i=2}^{q} (m - i + 2) p_i^{m-i+1}.$$

We have

$$\begin{aligned}
\mathbb{E}[N_{\mathsf{iter}}(\mathcal{A}^{\mathcal{U}}_s, S, q)] &= \int_{M_2=0}^{1} \cdots \int_{M_q=0}^{1} \mathbb{E}[N_{\mathsf{iter}}(\mathcal{A}^{\mathcal{U}}_s, S, q) \mid M_1, \ldots, M_q] d\mathbb{P}[M_1, \ldots, M_q] \\
&= p_s^{-1} \int_{M_2=0}^{1} \cdots \int_{M_q=0}^{1} \sum_{i=1}^{q} \frac{m - i + 1}{\prod_{j=1}^{i} M_j} \prod_{l=2}^{q} (m - l + 2) M_l^{m-l+1} dM_l \\
&= p_s^{-1} \sum_{i=1}^{q} (m - i + 1) \int_{M_2=0}^{1} \cdots \int_{M_q=0}^{1} \prod_{l=2}^{i} (m - l + 2) M_l^{m-l} dM_l \\
&\qquad \cdot \prod_{l=i+1}^{q} (m - l + 2) M_l^{m-l+1} dM_l,
\end{aligned}$$

Therefore

$$\mathbb{E}[N_{\mathsf{iter}}(\mathcal{A}_s^{\mathcal{U}}, S, q)] = p_s^{-1} \sum_{i=1}^{q} (m-i+1) \prod_{l=2}^{i} \frac{m-l+2}{m-l+1}$$
$$= p_s^{-1} \sum_{i=1}^{q} (m-i+1) \cdot \frac{m}{m-i+1} = mq/p_s.$$

This concludes the proof. ■

5.3 Lower Bounds

The following lower bounds show that the number of iterations required by any stream emulator for utility-based algorithms must be at least quasi-linear in q. We provide two results. The first result considers a stream algorithm that selects exactly q elements, and it allows q to be large with respect to m. The second result considers stream algorithms that are allowed to select more than q elements. In this case, the lower bound is smaller, but it is reduced only linearly in the number of selections. It follows that a constant factor increase in the number of selections cannot overcome the quasi-linear dependence on q in the number of iterations. The proofs of the lower bounds are based on constructing a utility function which in effect allows only one set of selected elements for a given distribution, and forces the stream algorithm to select them in the same order as the pool algorithm. The first lower bound considers stream emulation with exactly q selections. The bound holds for both standard streaming algorithms and precognitive streaming algorithms.

Theorem 12 *For any integer m, $q \leq m/2$, there exists a utility-based pool algorithm, and a marginal $\mathcal{D}_X$, such that any stream algorithm $\mathcal{A}_s$ which is $(q, \mathcal{D})$ equivalent to the pool algorithm for all $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$, and selects only q elements, has*

$$\exists \mathcal{D} \in \mathrm{DS}(\mathcal{D}_X), \mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s, S, q)] \geq \frac{q}{32} \left\lfloor \frac{m}{2\log(4q)} \right\rfloor .$$

The result holds even if $\mathcal{A}_s$ is a precognitive stream algorithm.

Proof Let $n = \left\lfloor \frac{m}{2\log(4q)} \right\rfloor$, and let $\mathcal{D}_X$ be a uniform distribution over $\mathcal{X} = \{a_i \mid i \in [n]\}$. Assume $\mathcal{Y} = \{0,1\}$. A pool of size m then includes all elements in $A := \{a_i \mid i \in [2q-1]\}$ with a probability of at least $\alpha \geq 1 - (2q-1)\exp(-m/n) \geq 1 - \frac{1}{4q}$.

Consider a utility function $\mathcal{U}$ such that given a history of the form $((a_1, y_1), \ldots, (a_t, y_t))$ for $t \in [q-1]$, assigns a maximal score in $\mathcal{X}$ to a_{t+1} if $\forall i \leq t, y_i = 0$, and a maximal score to a_{q+t} if $\exists i \leq t, y_i = 1$. In addition, if the history is $((a_1, y_1), \ldots, (a_t, y_t), (a_{q+t}, y_{t+1}), \ldots, (a_{q+t'}, y_{t'+1}))$ for some $t \in [q-1], t' \in [q-2]$, then $\mathcal{U}$ assigns a maximal score to $a_{q+t'+1}$. Then, in a pool that includes all elements $a_1, \ldots, a_{2q-1}$, the pool algorithm based on $\mathcal{U}$ behaves as follows: In every round, if all selected elements so far received the response 0, it selects at round t the element a_t. Otherwise, it selects the element a_{q+t} and then continues to select $a_{q+t+1}, \ldots, a_{2q-1}$.

Let $\mathcal{D}_0$ be a distribution in which the response is deterministically zero. If the distribution is $\mathcal{D}_0$, $\mathcal{A}_s$ selects $Z_0 = \{a_1, \ldots, a_q\}$ with a probability at least α. Denote $\mathcal{D}_t$ for $t \in [q]$, in which the response is deterministically zero for $X \in \{a_1, \ldots, a_q\} \setminus \{a_t\}$ and 1 for a_t. For this distribution, the algorithm must select the elements in $Z_t = \{a_1, \ldots, a_t, a_{q+t}, \ldots, a_{2q-1}\}$ with a probability at least α.

Consider the probability space defined by the input sequence $S \sim \mathcal{D}_0^\infty$ and the randomness of $\mathcal{A}_s$. Let E_0 be the event in this space that $\mathcal{A}_s$ selects $\{a_1, \ldots, a_q\}$, and let $\bar{E}_0$ be the event in this space that $\mathcal{A}_s$ selects $(a_1 \ldots, a_q)$ in order. We have $\mathbb{P}[E_0] \geq \alpha$. Denote $\beta = \mathbb{P}[\bar{E}_0]$. We show a lower bound on β.

Let T be a random variable in the same probability space, such that $T = 0$ if E_0 does not hold. If E_0 does hold, then T is the smallest round in which the algorithm selects some $a_{t'}$, for $t' > T$, or $T = 0$ if no such round exists. If $\mathcal{A}_s$ selects $\{a_1, \ldots, a_q\}$ but not in order, then $T \in [q]$. Therefore, $\mathbb{P}[T \in [q]] \geq \alpha - \beta$, hence there exists some $t^* \in [q]$ such that $\mathbb{P}[T = t^*] \geq (\alpha - \beta)/q$. Now, consider the distribution $\mathcal{D}_{t^*}$. Define a sequence of pairs $\gamma(S)$ such that S and $\gamma(S)$ have the same elements in the same order, and the responses in $\gamma(S)$ are determined by $\mathcal{D}_{t^*}$ instead of by $\mathcal{D}_0$. Clearly, $\gamma(S)$ is distributed according to $\mathcal{D}_{t^*}^\infty$. Consider a run of the algorithm on S in which E_0 holds, and a parallel run (with the same random bits) on $\gamma(S)$. The algorithm selects the same elements for both sequences until the T'th selection, inclusive. By the definition of T, the T'th selection is some element in $\{a_{T+1}, \ldots, a_q\}$. If $T = t^*$, then an element not in Z_{t^*} is selected in round T. But this same element would be selected by $\mathcal{A}_s$ in the parallel run on $\gamma(S)$. Since under $\gamma(S) \sim \mathcal{D}_{t^*}^\infty$, $\mathcal{A}_s$ selects exactly the set Z_{t^*} with a probability of at least α, and so we have $\mathbb{P}[T = t^*] \leq 1 - \alpha$. This holds also for the precognitive stream algorithm since it is required from the emulation of the pool algorithm. It follows that $(\alpha - \beta)/q \leq \mathbb{P}[T = t^*] \leq 1 - \alpha$. Hence $\beta \geq \frac{1}{2}$.

Let W_i be the number of elements that $\mathcal{A}_s$ observes after selecting element $i-1$, until observing the next element. Let $X_1, X_2, \ldots$ be the sequence of elements observed after selecting the first $i-1$ elements, and for integers j, let $B_j = \mathbb{I}[X_j = a_i]$. $B_1, B_2, \ldots$ are independent Bernoulli random variables with $\mathbb{P}[B_j = 1] = 1/n$, and $\mathbb{P}[B_{W_i} = 1] \geq \mathbb{P}[\bar{E}_0] = \beta \geq \frac{1}{2}$. By Lemma 2, if $\frac{1}{n} \leq \frac{1}{32}$, $\mathbb{E}[W_i] \geq \frac{n}{16}$. It follows that the expected number of iterations for making q selections is at least $\frac{qn}{16}$ if $n \geq 32$. Since it is also at least q, a lower bound of $\frac{qn}{32} = \frac{q}{32}\left\lfloor \frac{m}{2\log(4q)} \right\rfloor$ holds for all n. This analysis holds also for the precognitive stream algorithm, since it also must select the same set of elements in the given order. ■

The second lower bound considers stream emulation with possibly more than q selections. This lower bound also holds for both standard and precognitive stream algorithms.

Theorem 13 *For any integers m, q such that $m \geq 2^{q+1}\log(2q)$ there exists a utility-based pool algorithm, and a marginal $\mathcal{D}_X$, such that for any $\beta \geq 1$, any stream algorithm $\mathcal{A}_s$ which is $(q, \mathcal{D})$ equivalent to the pool algorithm for all $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$, and selects at most βq elements, has*

$$\exists \mathcal{D} \in \mathrm{DS}(\mathcal{D}_X), \mathbb{E}_{S\sim\mathcal{D}^\infty}[N_{\mathsf{iter}}(\mathcal{A}_s, S, q)] \geq \frac{q}{256\beta} \cdot \left\lfloor \frac{m}{\log(2q)} \right\rfloor .$$

This result holds also for precognitive stream algorithms.

Proof Let $n = \left\lfloor \frac{m}{\log(2q)} \right\rfloor$, and let $\mathcal{D}_X$ be a uniform distribution over $\mathcal{X} = \{a_v \mid v \in \{0,1\}^t, t \in [q-1]_0\} \cup \mathcal{X}'$, where $\mathcal{X}'$ includes arbitrary elements so that $|\mathcal{X}| = n$. Note that $\mathcal{X}$ includes $a_()$, which stands for a zero-length vector. Assume $\mathcal{Y} = \{0,1\}$. Let $v \in \{0,1\}^q$ be a binary vector of length

q, and let $v(1:t)$ be its prefix of length $t \in [q-1]_0$. Consider distributions $\mathcal{D}_{v,f}$ for $v \in \{0,1\}^q$ and $f : \cup_{t\in[q-1]_0}\{0,1\}^t \to \{0,1\}$, such that $\mathcal{D}_v$ has a uniform marginal over $\mathcal{X}$, and for every $t \in [q-1]_0$, $\mathbb{P}[Y = v(t+1) \mid X = a_{v(1:t)}] = 1$. In other words, the label of any element which is a prefix of v is the next bit in v. In addition, for any other element a_b, $\mathbb{P}[Y = 1 \mid X = a_b] = f(a_b)$. Denote the elements representing prefixes of v by $A_v := \{a_{v(1:t)} \mid t \in [q-1]_0\}$.

Assume a utility function $\mathcal{U}$ such that for any $b \in \{0,1\}^t$ of length $t < q$, if the last element selected so far was a_b and its response was y, the function assigns the maximal score to $a_{b\circ y}$. Under this utility function, if the distribution is $\mathcal{D}_{v,f}$ and $A_v \subseteq_\pi S_X$, then the pool algorithm selects exactly the elements in A_v. This happens with probability at least $1 - q\exp(-m/n) \geq \frac{1}{2}$.

Let $\mathcal{A}_s$ be a stream-based algorithm which is equivalent to the pool algorithm $\mathcal{A}_p^{\mathcal{U}}$. Let V be a random variable drawn uniformly at random from $\{0,1\}^q$, and let F be a random variable drawn uniformly over all functions $f : \cup_{t\in[q-1]_0}\{0,1\}^t \to \{0,1\}$. Consider the probability space defined by $V, F, S \sim \mathcal{D}_{V,F}^{\infty}$, and the run of $\mathcal{A}_s$ on S. Let I_t be a random variable that is equal to 1 if the t'th selection of $\mathcal{A}_s$ is an element from A_V that has not been selected in previous rounds. Since $\mathcal{A}_s$ is equivalent to $\mathcal{A}_p^{\mathcal{U}}$, then $\mathbb{P}[\sum_{t=1}^{\beta q} I_t = q] \geq \frac{1}{2}$. By the reverse Markov's inequality, there are at least $q/4$ rounds t such that $\mathbb{E}[I_t] \geq \frac{1}{4\beta}$. This holds also for a precognitive stream algorithm due to its emulation of the pool algorithm.

Consider one such round t. Let $Z = \mathsf{pairs}_s(S, [t-1])$. We have $\frac{1}{4\beta} \leq \mathbb{E}[I_t] = \mathbb{E}_Z[\mathbb{E}[I_t \mid Z]]$. By the reverse Markov's inequality, with a probability of at least $\frac{1}{8\beta}$, the value of Z is some z that satisfies $\mathbb{E}[I_t \mid Z = z] \geq \frac{1}{8\beta}$. Let z such that $\mathbb{E}[I_t \mid Z = z] \geq \frac{1}{8\beta}$. Denote by B_t the (random) index of the element a_{B_t} selected in round t. By the reverse Markov's inequality, the probability that $B_t = b$ for some b such that $\mathbb{P}[I_t = 1 \mid Z = z, B_t = b] \geq \frac{1}{16\beta}$ is at least $\frac{1}{16\beta}$. In other words,

$$P(b,t) := \mathbb{P}[a_b \in A_V \mid Z = z, B_t = b] \geq \frac{1}{16\beta}.$$

We now upper bound the number of vectors b such that this inequality holds and they do not already appear in Z. Call such vectors "admissible".

Let Z', z' be the prefixes of length $t-2$ of Z, z respectively, and denote $P(b,t-1) := \mathbb{P}[a_b \in A_V \mid Z' = z']$. Let (w,y) be the last pair in z, and assume without loss of generality that (w,y) is absent from z'. The relationship between $P(b,t-1)$ and $P(b,t)$ can be described based on the relationships between w, y, b, by distinguishing into cases.

1. b is a (weak) prefix of w.
2. $w \circ y$ is a (weak) prefix of b.
3. $w \circ (1-y)$ is a (weak) prefix of b.
4. Neither of the cases above hold. In this case, b and w are incompatible.

In cases 1 and 4, the distribution of y is uniform on $\{0,1\}$ conditioned on b being a prefix of V. It is uniform also conditioned on b not being a prefix of V. Hence, in these cases conditioning on (w,y) does not affect the probability that b is a prefix of V, hence $P(b,t) = P(b,t-1)$. In case 3, $P(b,t) = 0$. We are left with case 2, in which $w \circ y$ is a (weak) prefix of b. In this case we have that $P(b,t) = 2P(b,t-1)$. By induction, we can conclude that if $P(b,t) \neq 0$, then $P(b,t) = 2^{-|b|} \cdot 2^{N(b)}$, where $N(b)$ is the number of pairs in Z of the form (w,y) where $w \circ y$ is a prefix of b.

To bound the number of admissible vectors, let us show a one-to-one mapping between such vectors and binary vectors with a bounded length. For any such b, we have $N(b) - |b| = \log_2(P(b,t)) \geq \log_2(\frac{1}{16\beta})$. Denote $k = \lceil \log_2(16\beta) \rceil$. Then $k \geq |b| - N(b)$. b can be encoded as a vector of length at most k as follows: Go over the bits in b from first to last. For each bit i in b, copy it to the output vector in the next available location only if the prefix $b(1:(i-1))$ does not match some w such that $(w,y) \in Z$. Clearly, $N(b)$ bits are skipped this way, so that the total number of bits in the output is no more than k. Moreover, the mapping is one-to-one, since the only possible ambiguity in decoding is how many bits to decode; but whenever $(w,y) \in Z$, b cannot be equal to w, since w has appeared in Z. Therefore the decoding should stop only when it is not possible to infer more bits. It follows that the number of admissible vectors is at most $2^{k+1} - 1 \leq 64\beta$.

Therefore, the probability of observing such an element in each iteration after round $t-1$ is at most $64\beta/|\mathcal{X}|$. Since there are $q/4$ such iterations, the expected total number of iterations is at least $\frac{qn}{256\beta} = \frac{q}{256\beta} \cdot \left\lfloor \frac{m}{\log(2q)} \right\rfloor$. This result holds also for a precognitive stream algorithm, since it also must select admissible vectors due to the same analysis. ■

6. Active Learning for Binary Classification

Lastly, we consider a special case of interactive algorithms, active learning for binary classification. Recent works provide for this setting relatively tight label complexity bounds, that hold for both the stream-based and the pool-based settings. In Balcan and Long (2013), tight upper and lower bounds for active learning of homogeneous linear separators under isotropic log-concave distributions are provided. The bounds hold for both the stream-based and the pool-based setting, and assume the same budget of unlabeled examples. In Hanneke and Yang (2015), tight minimax label complexity bounds for active learning are provided for several classes of distributions. These bounds also hold for both the stream-based and the pool-based setting. No explicit restriction is placed on the number of unlabeled examples.

The upper bound in Theorem 11 for utility-based pool algorithms can be applied to several pool-based active-learning algorithms which use a utility function (e.g., Golovin and Krause, 2011; Gonen et al., 2013; Cuong et al., 2014). The upper bound shows that when the label budget q is relatively small, the gap between the stream and the pool settings is not significant. For instance, consider an active learning problem in which a utility-based pool active learner achieves a label complexity close to the information-theoretic lower bound for the realizable setting (Kulkarni et al., 1993), so that $q \in \Theta(\log(1/\epsilon))$. The passive learning sample complexity in the realizable setting is at most $m \in \Theta(1/\epsilon)$. Therefore, a stream-based active learner with the same properties needs at most $O(\log(1/\epsilon)/\epsilon)$ unlabeled examples. Therefore, in this case the difference between the pool-based setting and the stream-based setting can be seen as negligible.

Here, we study the general question: what is the possible gap between pool-based and stream based active learning? We study this question in the realizable setting, where the distribution is consistent with some hypothesis in a given finite hypothesis class $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$. We give an upper bound and a lower bound on this gap, which hold for a large class of pool-based algorithms.

First, we show the upper bound. This upper bound is derived by showing that any pool-based active learner for the realizable setting with a finite hypothesis class can be approximated by a utility-based pool algorithm. This in turn implies, using Theorem 11, that a stream algorithm with

similar guarantees can emulate the pool-based algorithm with a bounded approximation factor on the number of iterations and queries.

To show that any pool-based active learner can be approximated by a utility-based pool algorithm, we use the machinery of submodular function maximization for active learning. The challenge is that a successful pool-based active learner might not fully identify the true hypothesis consistent with the distribution, since it suffices that it identifies a hypothesis which is ϵ-close to the true one. Thus, we define a submodular function that allows taking this into account. Our construction combines ideas from Guillory and Bilmes (2010); Golovin et al. (2010b); Dasgupta (2006).

Let $f : \cup_{i=0}^{\infty}(\mathcal{X} \times \mathcal{Y})^n \to \mathbb{N}$ be an objective function which maps any set of labeled examples to a non-negative value. For a given pool of examples, let OPT be the smallest number of queries that are required (in the worst-case over all possible labelings of the pool that are consistent with $\mathcal{H}$) to obtain an S such that $f(S) = Q$ for some fixed integer Q. Guillory and Bilmes (2010) show that if f is monotone non-decreasing and submodular, then there exists a utility-based active learning algorithm which requires at most $O(\log(Q|\mathcal{H}|)) \cdot \mathrm{OPT}$ queries in the worst case to obtain an S such that $f(S) = Q$.

We define a function f which will allow proving the existence of a utility-based pool active learner in our setting. For a given set of labeled examples $S \subseteq \mathcal{X} \times \mathcal{Y}$, the version space induced by S on $\mathcal{H}$ is defined by $\mathrm{VS}(S) := \{h \in \mathcal{H} \mid \forall (x, y) \in S, h(x) = y\}$. Define a fixed set of pairs of hypotheses $E \subseteq \mathcal{H} \times \mathcal{H}$. Let $E(S) := (\mathrm{VS}(S) \times \mathrm{VS}(S)) \cap E$. This is the set of pairs from E such that none of the hypotheses in the pair are disqualified by the labels in S.

Given E, define the objective function f by

$$f(S) := |E| - |E(S)|.$$

Let $Q = |E|$. The following lemma shows that the objective-function requirements above hold for this definition of f.

Lemma 14 *For any $E \subseteq \mathcal{H} \times \mathcal{H}$, f as defined above is monotone and submodular.*

Proof Monotonicity is trivial here since if $S \subseteq S'$ then $|E(S)| \leq |E(S')|$. f is submodular (see e.g., Fujishige 2005) if and only if for any S, S' such that $S \subseteq S'$, and any $(x, y) \notin S'$,

$$f(S \cup \{(x, y)\}) - f(S) \geq f(S' \cup \{(x, y)\}) - f(S'). \tag{8}$$

Denote $S_+ := S \cup \{(x, y)\}$ for brevity, and similarly for S'_+. It is easy to see that $\mathrm{VS}(S) \supseteq \mathrm{VS}(S')$. In addition, $\mathrm{VS}(S) \setminus \mathrm{VS}(S_+) \supseteq \mathrm{VS}(S') \setminus \mathrm{VS}(S'_+)$, since any $h \in \mathrm{VS}(S') \setminus \mathrm{VS}(S'_+)$ is consistent with all the pairs in S' but not with (x, y), implying that $h \in \mathrm{VS}(S) \setminus \mathrm{VS}(S_+)$.

It follows that

$$\mathrm{VS}(S) \times \mathrm{VS}(S) \setminus (\mathrm{VS}(S_+) \times \mathrm{VS}(S_+)) \supseteq \mathrm{VS}(S') \times \mathrm{VS}(S') \setminus (\mathrm{VS}(S'_+) \times \mathrm{VS}(S'_+)).$$

Therefore,

$$(\mathrm{VS}(S) \times \mathrm{VS}(S) \cap E) \setminus ((\mathrm{VS}(S_+) \times \mathrm{VS}(S_+)) \cap E) \supseteq (\mathrm{VS}(S') \times \mathrm{VS}(S') \cap E) \setminus ((\mathrm{VS}(S'_+) \times \mathrm{VS}(S'_+)) \cap E).$$

It follows that $|E(S)| - |E(S_+)| \geq |E(S')| - |E(S'_+)|$, which implies Eq. (8). ■

We use this construction in the proof of the upper bound on the gap between pool-based and stream-based active learning, which we presently state and prove.

A somewhat technical issue is that the results of Guillory and Bilmes (2010) hold only under the assumption that whenever the optimal pool-based algorithm succeeds, it knows that it has succeeded. In other words, it has "proof" that its answer is ϵ-good. This is known as a *self-certifying* algorithm Golovin et al. (2010b). Our results thus apply to pool-based active learning algorithm that have this property as well. This property is related, though not completely equivalent, to the concept of "verifiable active learning algorithms" studied in Balcan et al. (2010). In that work it is shown that non-verifiable active learning algorithms sometime require fewer labels than verifiable active learning algorithms. Characterizing the gap between pool-based and stream-based algorithms for non-verifiable active learning algorithms is an open question which we leave for future work.

For a fixed distribution $\mathcal{D}_X$ over $\mathcal{X}$, denote $\Delta(h, h') := \mathbb{P}[h(X) \neq h'(X)]$.

Theorem 15 *Let $\mathcal{X}$ be a finite instance domain and let $\mathcal{Y}$ be a finite label domain. Let $\mathcal{D}_X$ be a marginal distribution over $\mathcal{X}$. Let $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$ be a hypothesis class. Suppose that there is a pool-based active learning algorithm such that for any $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$ which is consistent with some $h^* \in \mathcal{H}$, with a probability at least $1 - \delta$ over i.i.d. pools of size m, it outputs $\hat{h} \in \mathcal{H}$ such that $\Delta(\hat{h}, h^*) < \epsilon$ for $(X, Y) \sim \mathcal{D}$, using q label queries. We also assume that the pool algorithm is self-certifying: the algorithm also outputs an indicator $I \in \{0, 1\}$ where $\mathbb{P}[\Delta(\hat{h}, h^*) < \epsilon \mid I = 1] = 1$, and $\mathbb{P}[I = 1] \geq 1 - \delta$.*

Under these assumptions, there exists a stream-based active learner that with a probability of at least $1 - |\mathcal{H}|\delta$ outputs a hypothesis $\hat{h}$ such that $\Delta(\hat{h}, h^*) \leq 2\epsilon$. The expected number of queries requested by the stream-based active learner is at most $O(\log(|\mathcal{H}|)) \cdot q$, and its expected number of iterations is at most $O(\log(|\mathcal{H}|)) \cdot mq$.

Proof Define $E := \{(h, h') \mid \Delta(h, h') \geq 2\epsilon\}$. Denote an ϵ-ball around a hypothesis $h \in \mathcal{H}$ by

$$B(h, \epsilon) := \{h' \in \mathcal{H} \mid \Delta(h, h') < \epsilon\}.$$

Fix a $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$ which is consistent with some $h^* \in \mathcal{H}$. Any pool algorithm with the guarantees assumed by the theorem statement, outputs an $I = 1$ with a probability at least $1 - \delta$, and has $\mathbb{P}[\hat{h} \in B(h^*, \epsilon) \mid I = 1] = 1$. Thus, for any pool with $I = 1$, $h^* \in B(\hat{h}, \epsilon)$. Let S be the set of labeled examples that the pool algorithm obtained during its entire run. Since any of the hypotheses in $\mathrm{VS}(S)$ could be the true h^*, it follows that for any $h \in \mathrm{VS}(S)$, $\Delta(\hat{h}, h) < \epsilon$, hence for any $h, h' \in \mathrm{VS}(S)$, $\Delta(h, h') \leq 2\epsilon$. Therefore, $(h, h') \notin E$. It follows that $E(S) = \emptyset$.

There are $|\mathcal{H}|$ possible distributions $\mathcal{D} \in \mathrm{DS}(\mathcal{D}_X)$ which are consistent with some $h^* \in \mathcal{H}$. It follows that with a probability of $1 - |\mathcal{H}|\delta$ over pools, at the end of the run $E(S) = \emptyset$. For any such pool, we have that q queries suffice to certifiably obtain $f(S) = Q$, thus $\mathrm{OPT} \leq q$.

We now apply the results cited above from Guillory and Bilmes (2010), which imply that there exists a utility-based pool algorithm that obtains $f(S) = Q$ with at most $O(\log(|\mathcal{H}|)q)$ queries. By Theorem 11, we conclude that there exists a stream algorithm which requires at most $O(\log(|\mathcal{H}|)) \cdot q$ queries and $O(\log(|\mathcal{H}|)) \cdot mq$ iterations to obtain $f(S) = Q$.

Since $f(S) = Q$ at the end of the run of the stream algorithm, then $E(S) = \emptyset$, which implies that for any (h, h') such that $\Delta(h, h') \geq 2\epsilon$, at least one of h, h' is not in $\mathrm{VS}(S)$. Therefore, the diameter of $\mathrm{VS}(S)$ is at most 2ϵ. The stream algorithm may therefore return any $\hat{h} \in \mathrm{VS}(S)$, and it holds that $\Delta(\hat{h}, h^*) \leq 2\epsilon$. ■

Next, we provide a lower bound, showing that in the general case $\tilde{\Omega}(mq)$ iterations are required for emulating pool-based active learning in a stream setting. The lower bound, which holds also for the precognitive setting, employs the following example and is presented in Theorem 16.

Example 1 *For given integers m and $q \leq m$, and $T \leq q$, define $\mathcal{X} = \{a_{k,j} \mid k \in [q], j \in \{0, \ldots, 2^{\min(k,T)-1} - 1\}\} \cup \mathcal{X}'$, where $\mathcal{X}'$ includes arbitrary elements so that $|\mathcal{X}| = n$, for some $n \geq q2^T/2$. Define the following hypothesis class $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$.*

$$\mathcal{H} := \{h_i \mid i \in \{0, \ldots, 2^q - 1\}\}, \text{ where } h_i(a_{k,j}) = \begin{cases} \mathbb{I}[i \bmod 2^k = j] & k \leq T, \\ \mathbb{I}[\lfloor i/2^{T-k} \rfloor \bmod 2^T = j]. & k > T. \end{cases} \quad (9)$$

Essentially, for $k \leq T$, $h_i(a_{k,j}) = 1$ if the k least significant bits in the binary expansion of i are equal to the binary expansion of j to T bits. For $k \geq T$, $h_i(a_{k,j}) = 1$ if T consecutive bits in i, starting from bit $T - k$, are equal to the binary expansion of j.

Theorem 16 *Let $q \geq 22$ and $m \geq 8 \log(2q) q^2$ be integers. Consider Example 1 with m, q, setting $T = \lceil \log_2(q) \rceil$ and $n = \lfloor m/7 \log(2q) \rfloor$. Consider $\mathcal{H}$ as defined in Eq. (9). There exist $\delta, \epsilon \in (0, 1)$ such that there is a pool-based active learning algorithm that uses a pool of m unlabeled examples and q labels, such that for any distribution $\mathcal{D}$ which is consistent with some $h^* \in \mathcal{H}$ and has a uniform marginal over $\mathcal{X}$, with a probability of at least $1 - \delta$, $\mathbb{P}[\hat{h}(X) \neq h^*(X)] \leq \epsilon$. On the other hand, for $q > 22$, any stream-based active learning algorithm with the same guarantee, including a precognitive stream algorithm, requires at least $\frac{q}{512} \left\lfloor \frac{m}{7 \log(2q)} \right\rfloor$ unlabeled examples in expectation.*

Proof Let $\mathcal{D}_X$ be uniform over $\mathcal{X}$. Let E be the event that $\mathcal{X} \not\subseteq_\pi S_X$, and define $\delta := \mathbb{P}_{S \sim \mathcal{D}_X^m}[E]$. Define $\epsilon = 1/n$, so that $\mathbb{P}[\hat{h}(X) \neq h^*(X)] < \epsilon$ if and only if $\hat{h} = h^*$. Let i^* such that $h^* = h_{i^*}$.

First, a pool-based algorithm can achieve the required accuracy as follows: Let $j_t := i^* \bmod 2^t$ for $t \leq T$, and $j_t := \lfloor i^*/2^{T-t} \rfloor \bmod 2^T$ for $t \geq T$. If E holds, then t'th element selected by the pool algorithm is $a_{t,j}$, where j is obtained as follows: If $t \leq T$, $j = j_{t-1}$. If $t > T$, $j = \lfloor j_{t-1}/2 \rfloor$. In round 1, $j = 0$ and the selected element is $a_{1,0}$. Inductively, in this strategy the algorithm finds the t'th least significant bit in the binary expansion of i^* in round t, thus it can use j_{t-1} to set j for round t. Under E, after q labels i^* is identified exactly. This happens with a probability of $1 - \delta$ for any $\mathcal{D}$ with the uniform marginal $\mathcal{D}_X$.

Now, let $\mathcal{D}_h$ be a distribution with a uniform marginal over $\mathcal{X}$ with labels consistent with $h \in \mathcal{H}$. Consider a stream-based algorithm $\mathcal{A}_s$ which is equivalent to the pool algorithm. Denote its output by $\bar{h}$ and its input by $S \sim \mathcal{D}_{h^*}^\infty$. Let I be a random variable drawn uniformly at random from $\{0, \ldots, 2^q - 1\}$. Let $H = h_I$ be a hypothesis chosen uniformly at random from $\mathcal{H}$. Consider the probability space defined by $I, S \sim \mathcal{D}_H^\infty$, and the run of $\mathcal{A}_s$ on S. Let $(Z_1, Y_1), \ldots, (Z_q, Y_q)$ be the examples that $\mathcal{A}_s$ receives and the labels it gets, in order. Let $Y = (Y_1, \ldots, Y_q)$. Let $\alpha = \mathbb{P}[Z_1 = a_{1,0} \mid S_X]$. If $Z_1 = a_{1,0}$, then $\mathbb{P}[Y_1 = 0 \mid S_X] = \frac{1}{2}$. If $Z_1 \neq a_{1,0}$, then $\mathbb{P}[Y_1 = 0 \mid S_X] \geq 3/4$. Let $\mathbb{H}$ be the base-2 entropy, and $\mathbb{H}_b$ be the binary entropy. Then $\mathbb{H}_b(Y_1 \mid S_X) = \mathbb{H}_b((\alpha + 1)/4)$, and so

$$\begin{aligned} \mathbb{H}(H \mid Y, S_X) &= \mathbb{H}(H, Y \mid S_X) - \mathbb{H}(Y_1 \mid S_X) - \mathbb{H}(Y_1, \ldots, Y_q \mid Y_1, S_X) \\ &\geq q - \mathbb{H}_b((\alpha + 1)/4) - (q - 1) \\ &= 1 - \mathbb{H}_b((\alpha + 1)/4). \end{aligned}$$

From the Taylor expansion of the binary entropy around $1/2$, $\mathbb{H}_b(p) \leq 1 - (1 - 2p)^2/2$, therefore $\mathbb{H}(H \mid Y, S_X) \geq (1 - \alpha)^2/8$. Since $\mathcal{A}_s$ is equivalent to $\mathcal{A}_p^{\mathcal{U}}$, we have $\mathbb{P}[\bar{h} \neq H] \leq \delta$, hence $\mathbb{P}_{S_X}[\mathbb{P}[\bar{h} \neq H \mid S_X] \leq 2\delta] \geq \frac{1}{2}$. By Fano's inequality, for any S_X such that $\mathbb{P}[\bar{h} \neq H \mid S_X] \leq 2\delta$,

$$(1 - \alpha)^2/8 \leq \mathbb{H}(H \mid Y, S_X) \leq \mathbb{H}_b(2\delta) + 2\delta q \leq 2\delta(\log_2(\frac{1}{2\delta}) + 2 + q).$$

Where the last inequality follows from $\mathbb{H}_b(p) \leq p \log_2(1/p) + 2p$. From the definition of δ, we have $\delta \leq |\mathcal{X}| \exp(-m/n)$. Setting $T = \lceil \log_2(q) \rceil$, and noting that $|\mathcal{X}| \leq q2^T/2 \leq q^2$ and so $m \geq n \log(128q^3|\mathcal{X}|)$, we have $\delta \leq \frac{1}{128q^3}$. Therefore, for $q \geq 22$, $1 - \alpha \leq \frac{1}{2q}$. It follows that $\mathbb{P}_{S_X}[\mathbb{P}[Z_1 \neq a_{1,0} \mid S_X] \leq \frac{1}{2q}] \geq 1/2$.

Now, the same argument holds for any round t conditioned on $I \bmod 2^t = 0$ and $Z_1 = a_{1,0}, \ldots, Z_t = a_{t,0}$, since in this case after t labels, the algorithm has $q - t$ queries left, and needs to select from $\mathcal{H}'$, which is equivalent to $\mathcal{H}$, with $q - t$ instead of q. Moreover, $\mathbb{P}[\bar{h} = H \mid I \bmod 2^t = 0] \leq 1 - \delta$ as well, since this holds for every H individually. We conclude that for every $t \leq q$, with a probability at least $\frac{1}{2}$ over S_X,

$$\mathbb{P}[Z_t \neq a_{t,0} \mid S_X, H = h_0] \leq \frac{1}{2q}.$$

It follows that with a probability at least $\frac{1}{2}$ over S_X, $\mathbb{P}[Z_1 = a_{1,0}, \ldots, Z_q = a_{q,0} \mid S_X, H = h_0] \geq 1/2$. Hence $\mathbb{P}[Z_1 = a_{1,0}, \ldots, Z_q = a_{q,0} \mid H = h_0] \geq 1/4$.

Finally, suppose $H = h_0$. Let W_t be the number of elements that $\mathcal{A}_s$ observes after selecting element $t - 1$, until observing the next element. Let $X_j \sim \mathcal{D}_X$ be the j'th element observed after selecting the first $t - 1$ elements, and let $B_j = \mathbb{I}[X_j = a_{t,0}]$. B_j are independent Bernoulli random variables with $\mathbb{P}[B_j = 1] = 1/n$, and $\mathbb{P}[B_{W_t} = 1] \geq \mathbb{P}[E] = \beta \geq \frac{1}{4}$. By Lemma 2, if $\frac{1}{n} \leq \frac{1}{512}$, then $\mathbb{E}[W_t] \geq \frac{n}{64}$. It follows that the expected number of iterations over q selections is at least $\frac{qn}{64}$ if $n \geq 512$. Since it is also at least q, a lower bound of $\frac{qn}{512}$ holds for all n. ■

This lower bound shows that a gap between the stream-based and the pool-based settings exists not only for general interactive algorithms, but also specifically for active learning for binary classification. The gap is the most significant when $q = \tilde{\Theta}(\sqrt{m})$, in which case the stream algorithm requires $\tilde{\Omega}(m^{3/2})$ unlabeled examples, compared to only m for the pool algorithm. It has been previously observed (Gonen et al., 2013) that in some cases, the ALuMA algorithm, which is a pool-based active learning algorithm for halfspaces, is superior to the classical stream-based algorithm CAL (Cohn et al., 1994). Theorem 16 shows that this is not a limitation specifically of CAL, but of any stream-based active learning algorithm. On the other hand, Theorem 15 shows that this gap cannot be very large, at least for self-certifying active learning algorithms.

7. Conclusions

In this work we studied the relationship between the stream-based and the pool-based interactive settings, by designing algorithms that emulate pool-based behavior in a stream-based setting, and proving upper and lower bounds on the stream sizes required for such emulation. Our results concern mostly the case where the budget of the stream algorithm is similar or identical to that of the pool algorithm. We expect that as the budget grows, there should be a smooth improvement in

the expected stream length, which should approach m as the budget approaches m. It is an open problem to quantify this tradeoff in the various settings we considered.

Appendix A. Proof of Lemma 2

The proof of Lemma 2, defined in Section 2, is provided below.

Proof [of Lemma 2] $\mathbb{E}[I]$ is minimized under the constraint when $\mathbb{P}[X_i = 1] = p$. Therefore assume this equality holds. Let W be the random variable whose value is the smallest integer such that $X_W = 1$. Let T be the largest integer such that $\mathbb{P}[W \leq T] \leq \alpha$.

The expectation of I is subject to $\mathbb{P}[X_I = 1] \geq \alpha$ is smallest if I is defined as follows: $\mathbb{P}[I = W \mid W \leq T] = 1$, $\mathbb{P}[I = W \mid W = T + 1] = \alpha - \mathbb{P}[W \leq T]$, and in all other cases, $I = 0$. Therefore,

$$\mathbb{E}[I] \geq \mathbb{E}[W \cdot \mathbb{I}[W \leq T]].$$

We have

$$\begin{aligned}\frac{1}{p} = \mathbb{E}[W] &= \mathbb{E}[W \cdot \mathbb{I}[W \leq T]] + \mathbb{E}[W \cdot \mathbb{I}[W > T]] \\ &= \mathbb{E}[W \cdot \mathbb{I}[W \leq T]] + (\frac{1}{p} + T)(1-p)^T.\end{aligned}$$

Therefore

$$\mathbb{E}[I] \geq \mathbb{E}[W \cdot \mathbb{I}[W \leq T]] = \frac{1}{p} - (\frac{1}{p} + T)(1-p)^T.$$

From the definition of T, T is the largest integer such that $1 - (1-p)^T \leq \alpha$. Hence $1 - \alpha \leq \exp(-pT)$, so $T \leq \frac{\log(1/(1-\alpha))}{p}$. In addition, since $1 - (1-p)^{T+1} \geq \alpha$, we have $(1-p)^T \leq (1-\alpha)/(1-p)$. Therefore

$$\mathbb{E}[I] \geq \frac{1}{p} - \left(\frac{1}{p} + \frac{\log(1/(1-\alpha))}{p}\right)\frac{1-\alpha}{1-p} = \frac{1}{p}\left(1 - \frac{(1-\alpha)(1+\log(1/(1-\alpha)))}{1-p}\right).$$

To show that $\mathbb{E}[I] \geq \alpha^2/(4p)$, for $p \leq \alpha^4/2$ and $\alpha \in (0,1)$, we show that

$$1 - \frac{(1-\alpha)(1+\log(1/(1-\alpha)))}{1-p} \geq \alpha^2/4. \tag{10}$$

It suffices to show that

$$1 - \alpha^2/4 - \frac{(1-\alpha)(1+\log(1/(1-\alpha)))}{1-\alpha^4/2} \geq 0.$$

Multiplying the LHS by $1 - \alpha^4/2$, we have

$$\begin{aligned}A(\alpha) &:= (1-\alpha^2/4)(1-\alpha^4/2) - (1-\alpha)(1+\log(1/(1-\alpha))) \\ &= \alpha - \alpha^2/4 - \alpha^4/2 + \alpha^6/8 - (1-\alpha)\log(1/(1-\alpha)).\end{aligned}$$

By the Taylor expansion of the natural logarithm around $1 - \alpha$,

$$(1-\alpha)\log(1/(1-\alpha)) = \sum_{n=1}^{\infty}\frac{\alpha^n}{n} - \sum_{n=1}^{\infty}\frac{\alpha^{n+1}}{n} = \alpha + \sum_{n=2}^{\infty}\alpha^n(\frac{1}{n} - \frac{1}{n-1}).$$

Therefore

$$\begin{aligned}A(\alpha) &= \alpha - \alpha^2/4 - \alpha^4/2 + \alpha^6/8 - \alpha + \sum_{n=2}^{\infty}\alpha^n(\frac{1}{n-1} - \frac{1}{n}) \\ &= \sum_{n=2}^{\infty}\alpha^n(\frac{1}{n-1} - \frac{1}{n}) - \alpha^2/4 - \alpha^4/2 + \alpha^6/8 \\ &= \sum_{n=3}^{\infty}\alpha^n(\frac{1}{n-1} - \frac{1}{n}) + (\alpha^2/4 - \alpha^4/2) + \alpha^6/4 \geq 0.\end{aligned}$$

It follows that $A(\alpha)/(1-\alpha^4/2) \geq 0$, implying Eq. (10), and concluding that $\mathbb{E}[I] \geq \alpha^2/(4p)$. ■

Abstract

The scale of modern datasets necessitates the development of efficient distributed optimization methods for machine learning. We present a general-purpose framework for distributed computing environments, CoCoA, that has an efficient communication scheme and is applicable to a wide variety of problems in machine learning and signal processing. We extend the framework to cover general non-strongly-convex regularizers, including L1-regularized problems like lasso, sparse logistic regression, and elastic net regularization, and show how earlier work can be derived as a special case. We provide convergence guarantees for the class of convex regularized loss minimization objectives, leveraging a novel approach in handling non-strongly-convex regularizers and non-smooth loss functions. The resulting framework has markedly improved performance over state-of-the-art methods, as we illustrate with an extensive set of experiments on real distributed datasets.

Keywords: Convex optimization, distributed systems, large-scale machine learning, parallel and distributed algorithms

1. Introduction

Distributed computing architectures have come to the fore in modern machine learning, in response to the challenges arising from a wide range of large-scale learning applications. Distributed architectures offer the promise of scalability by increasing both computational and storage capacities. A critical challenge in realizing this promise of scalability is to develop efficient methods for communicating and coordinating information between distributed machines, taking into account the specific needs of machine-learning algorithms.

On most distributed systems, the communication of data between machines is vastly more expensive than reading data from main memory and performing local computation. Moreover, the optimal trade-off between communication and computation can vary widely depending on the dataset being processed, the system being used, and the objective being optimized. It is therefore essential for distributed methods to accommodate flexible communication-computation profiles while still providing convergence guarantees.

Although numerous distributed optimization methods have been proposed, the mini-batch optimization approach has emerged as one of the most popular paradigms for tackling this communication-computation tradeoff (e.g., Dekel et al., 2012; Shalev-Shwartz and Zhang, 2013b; Shamir and Srebro, 2014; Qu et al., 2015; Richtárik and Takáč, 2016). Mini-batch methods are often developed by generalizing stochastic methods to process multiple data points at a time, which helps to alleviate the communication bottleneck by enabling more distributed computation per round of communication. However, while the need to reduce communication would suggest large mini-batch sizes, the theoretical convergence rates of these methods tend to degrade with increased mini-batch size, reverting to the rates of classical (batch) gradient methods. Empirical results corroborate these theoretical rates, and in practice, mini-batch methods have limited flexibility to adapt to the communication-computation tradeoffs that would maximally leverage parallel execution. Moreover, because mini-batch methods are typically derived from a specific single-machine solver, these methods and their associated analyses are often tailored to specific problem instances and can suffer both theoretically and practically when applied outside of their restricted setting.

In this work, we propose a framework, CoCoA[1], that addresses these two fundamental limitations. First, we allow arbitrary local solvers to be used on each machine in parallel. This allows the framework to directly incorporate state-of-the-art, application-specific single-machine solvers in the distributed setting. Second, the framework shares information between machines through a highly flexible communication scheme. This allows the amount of communication to be easily tailored to the problem and system at hand, in particular allowing for the case of significantly reduced communication in the distributed environment.

A key step in providing these features in the framework is to first define meaningful subproblems for each machine to solve in parallel, and to then combine updates from the subproblems in an efficient manner. Our method and convergence results rely on noting that, depending on the distribution of the data (e.g., by feature or by training point), and whether we solve the problem in the primal or the dual, certain machine learning objectives

1. CoCoA-v1 (Jaggi et al., 2014) and CoCoA$^+$ (Ma et al., 2017b, 2015a) are predecessors of this work. We continue to use the name CoCoA for the more general framework proposed here, and show how earlier work can be derived as a special case (Section 4). Portions of this newer work additionally appear in SF's master's thesis (Forte, 2015) and Smith et al. (2015).

can be more easily decomposed into subproblems in the distributed setting. In particular, we categorize common machine learning objectives into several cases, and use duality to help decompose these objectives. Using primal-dual information in this manner not only allows for efficient methods (achieving, e.g., up to 50x speedups compared to state-of-the-art), but also allows for strong primal-dual convergence guarantees and practical benefits such as computation of the duality gap for use as an accuracy certificate and stopping criterion.

1.1 Contributions

General framework. We develop a communication-efficient primal-dual framework that is applicable to a broad class of convex optimization problems. Notably, in contrast to earlier work of Yang (2013), Jaggi et al. (2014), Ma et al. (2017b) and Ma et al. (2015a), our generalized, cohesive framework: (1) specifically incorporates difficult cases of L_1 regularization and other non-strongly-convex regularizers; (2) allows for the flexibility of distributing the data by either feature or training point; and (3) can be run in either a primal or dual formulation, which we show to have significant theoretical and practical implications.

Flexible communication and local solvers. Two key advantages of the proposed framework are its communication efficiency and ability to employ off-the-shelf single-machine solvers internally. On real-world systems, the cost of communication versus computation can vary widely, and it is thus advantageous to permit a flexible amount of communication depending on the setting at hand. Our framework provides exactly such control. Moreover, we allow arbitrary solvers to be used on each machine, which permits the reuse of existing code and the benefits from multi-core or other optimizations therein. We note that beyond the selection of the local solver and communication vs. computation profile, there are no required hyperparameters to tune; the provided default parameters ensure convergence and are used throughout our experiments to achieve state-of-the-art performance.

Convergence guarantees. We derive convergence rates for the framework, guaranteeing, e.g., a $\mathcal{O}(1/t)$ rate of convergence in terms of communication rounds for convex objectives with Lipschitz continuous losses, and a faster linear rate for strongly convex losses. Importantly, our convergence guarantees do not degrade with the number of machines, K, and allow for subproblems to be solved to arbitrary accuracies, which allows for highly flexible computation vs. communication profiles. Additionally, we leverage a novel approach in the analysis of primal-dual rates for non-strongly-convex regularizers. The proposed technique is an improvement over simple smoothing techniques used in, e.g., Nesterov (2005), Shalev-Shwartz and Zhang (2014) and Zhang and Lin (2015) that enforce strong convexity by adding a small L_2 term to the objective. Our results include primal-dual rates and certificates for the general class of linear regularized loss minimization, and we show how earlier work can be derived as a special case of our more general approach.

Experimental comparison. The proposed framework yields order-of-magnitude speedups (as much as 50× faster) compared to state-of-the-art methods for large-scale machine learning. We demonstrate these gains with an extensive experimental comparison on real-world distributed datasets. We additionally explore properties of the framework itself, including the effect of running the framework in the primal or the dual, and the impact of subproblem accuracy on convergence. All algorithms for comparison are implemented in Apache Spark and run on Amazon EC2 clusters. Our code is available at: `gingsmith.github.io/cocoa/`.

2. Background and Setup

In this paper we develop a general framework for minimizing problems of the following form:

$$\ell(\mathbf{u}) + r(\mathbf{u})\,, \tag{I}$$

for convex functions ℓ and r. Frequently the term ℓ is a loss function, taking the form $\sum_i \ell_i(\mathbf{u})$, and the term r is a regularizer, e.g., $r(\mathbf{u}) = \lambda\|\mathbf{u}\|_p$. This formulation includes many popular methods in machine learning and signal processing, such as support vector machines, linear and logistic regression, lasso and sparse logistic regression, and many others.

2.1 Definitions

The following standard definitions will be used throughout the paper.

Definition 1 (L-Lipschitz Continuity). *A function $h : \mathbb{R}^m \to \mathbb{R}$ is* L-Lipschitz continuous *if $\forall \mathbf{u}, \mathbf{v} \in \mathbb{R}^m$, we have*

$$|h(\mathbf{u}) - h(\mathbf{v})| \leq L\|\mathbf{u} - \mathbf{v}\|\,. \tag{1}$$

Definition 2 (L-Bounded Support). *A function $h : \mathbb{R}^m \to \mathbb{R} \cup \{+\infty\}$ has* L-bounded support *if its effective domain is bounded by L, i.e.,*

$$h(\mathbf{u}) < +\infty \;\Rightarrow\; \|\mathbf{u}\| \leq L\,. \tag{2}$$

Definition 3 ($(1/\mu)$-Smoothness). *A function $h : \mathbb{R}^m \to \mathbb{R}$ is* $(1/\mu)$-smooth *if it is differentiable and its derivative is $(1/\mu)$-Lipschitz continuous, or equivalently*

$$h(\mathbf{u}) \leq h(\mathbf{v}) + \langle \nabla h(\mathbf{v}), \mathbf{u} - \mathbf{v}\rangle + \frac{1}{2\mu}\|\mathbf{u} - \mathbf{v}\|^2 \qquad \forall \mathbf{u}, \mathbf{v} \in \mathbb{R}^m\,. \tag{3}$$

Definition 4 (μ-Strong Convexity). *A function $h : \mathbb{R}^m \to \mathbb{R}$ is* μ-strongly convex *for $\mu \geq 0$ if*

$$h(\mathbf{u}) \geq h(\mathbf{v}) + \langle s, \mathbf{u} - \mathbf{v}\rangle + \frac{\mu}{2}\|\mathbf{u} - \mathbf{v}\|^2 \qquad \forall \mathbf{u}, \mathbf{v} \in \mathbb{R}^m\,, \tag{4}$$

for any $s \in \partial h(\mathbf{v})$, where $\partial h(\mathbf{v})$ denotes the subdifferential of h at $\mathbf{v}$.

2.2 Primal-Dual Setting

Numerous methods have been proposed to solve (I), and these methods generally fall into two categories: *primal methods*, which run directly on the primal objective, and *dual methods*, which instead run on the dual formulation of the primal objective. In developing our framework, we present an abstraction that allows for either a primal or a dual variant of our framework to be run. In particular, to solve the input problem (I), we consider mapping the problem to one of the following two general problems:

$$\min_{\boldsymbol{\alpha} \in \mathbb{R}^n} \quad \left[\; \mathcal{O}_A(\boldsymbol{\alpha}) := \quad f(A\boldsymbol{\alpha}) \;+\; g(\boldsymbol{\alpha}) \qquad\qquad \right] \tag{A}$$

$$\min_{\mathbf{w} \in \mathbb{R}^m} \quad \left[\; \mathcal{O}_B(\mathbf{w}) := \quad f^*(\mathbf{w}) \;+\; g^*(-A^\top \mathbf{w}) \qquad \right]. \tag{B}$$

In general, our aim will be to compute a minimizer of the problem (A) in a distributed fashion; the main difference will be whether we initially map the primal (I) to (A) or (B).

Here $\boldsymbol{\alpha} \in \mathbb{R}^n$ and $\mathbf{w} \in \mathbb{R}^m$ are parameter vectors, $A := [\mathbf{x}_1; \ldots; \mathbf{x}_n] \in \mathbb{R}^{m \times n}$ is a data matrix with column vectors $\mathbf{x}_i \in \mathbb{R}^m$, $i \in \{1, \ldots, n\}$, and the functions f^* and g_i^* are the *convex conjugates* of f and g_i, respectively.

The dual relationship between problems (A) and (B) is known as Fenchel-Rockafellar duality (Borwein and Zhu, 2005, Theorem 4.4.2). We provide a self-contained derivation of the duality in Appendix B. Note that while dual problems are typically presented as a pair of (min, max) problems, we have equivalently reformulated (A) and (B) to both be minimization problems in accordance with their roles in our framework.

Given $\boldsymbol{\alpha} \in \mathbb{R}^n$ in the context of (A), a corresponding vector $\mathbf{w} \in \mathbb{R}^m$ for problem (B) is obtained by:

$$\mathbf{w} = \mathbf{w}(\boldsymbol{\alpha}) := \nabla f(A\boldsymbol{\alpha}) \,. \tag{5}$$

This mapping arises from first-order optimality conditions on the f-part of the objective. The duality gap, given by:

$$G(\boldsymbol{\alpha}) := \mathcal{O}_A(\boldsymbol{\alpha}) - [-\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha}))] \,, \tag{6}$$

is always non-negative, and under strong duality, the gap will reach zero only for an optimal pair $(\boldsymbol{\alpha}^\star, \mathbf{w}^\star)$. The duality gap at any point provides a practically computable upper bound on the unknown primal as well as dual optimization error (suboptimality), since

$$\mathcal{O}_A(\boldsymbol{\alpha}) \geq \mathcal{O}_A(\boldsymbol{\alpha}^\star) \geq -\mathcal{O}_B(\mathbf{w}^\star) \geq -\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha})) \;.$$

In developing the proposed framework, noting the duality between (A) and (B) has many benefits, including the ability to compute the duality gap, which acts as a certificate of the approximation quality. It is also useful as an analysis tool, helping us to present a cohesive framework and relate this work to the prior work of Yang (2013), Jaggi et al. (2014) and Ma et al. (2015a, 2017b). As a word of caution, note that we avoid prescribing the name "primal" or "dual" directly to either of the problems (A) or (B), as we demonstrate below that their role as primal or dual can change depending on the application problem of interest.

2.3 Assumptions and Problem Cases

Assumptions. Our main assumptions on problem (A) are that f is $(1/\tau)$-smooth, and the function g is separable, i.e., $g(\boldsymbol{\alpha}) = \sum_i g_i(\alpha_i)$, with each g_i having L-bounded support. Given the duality between the problems (A) and (B), this can be equivalently stated as assuming that in problem (B), f^* is τ-strongly convex, and the function $g^*(-A^\top \mathbf{w}) = \sum_i g_i^*(-\mathbf{x}_i^\top \mathbf{w})$ is separable with each g_i^* being L-Lipschitz.

Problem cases. Suppose, as in equation (I), we would like to find a minimizer of the general objective $\ell(\mathbf{u}) + r(\mathbf{u})$. Depending on the smoothness of the function ℓ and the strong convexity of the function r, we will be able to map the input function (I) to one (or both) of the objectives (A) and (B) based on our assumptions. In particular, we outline three separate cases: Case I, in which the function ℓ is smooth and the function r is strongly convex; case II, in which ℓ is smooth, and r is non-strongly convex and separable; and case III, in which ℓ is non-smooth and separable, and r is strongly convex. These cases are summarized in Table 1. Note that the union of these cases captures most commonly-used applications of linear regularized loss minimization problems.

In Section 3, we will see that different variants of the framework may be realized depending on which of these three cases we consider when solving the input problem (I).

Table 1: Criteria for Objectives (A) and (B).

	Smooth ℓ	Non-smooth, separable ℓ
Strongly convex r	Case I: Obj (A) or (B)	Case III: Obj (B)
Non-strongly convex, separable r	Case II: Obj (A)	–

2.4 Running Examples

To illustrate the cases in Table 1, we consider several examples below. *Those interested in details of the framework itself may skip to Section 3.* These applications will serve as running examples throughout the paper, and we will revisit them in our experiments (Section 6). For further applications and details, see Section 5.

1. *Elastic Net Regression (Case I: map to either (A) or (B)).* We can map elastic-net regularized least squares regression,

$$\min_{\mathbf{u} \in \mathbb{R}^p} \; \tfrac{1}{2}\|A\mathbf{u} - \mathbf{b}\|_2^2 + \eta\lambda\|\mathbf{u}\|_1 + (1-\eta)\frac{\lambda}{2}\|\mathbf{u}\|_2^2 \,, \tag{7}$$

   to either objective (A) or (B). To map to objective (A), we let: $f(A\boldsymbol{\alpha}) = \frac{1}{2}\|A\boldsymbol{\alpha} - \mathbf{b}\|_2^2$ and $g(\boldsymbol{\alpha}) = \sum_i g_i(\alpha_i) = \sum_i \eta\lambda|\alpha_i| + (1-\eta)\frac{\lambda}{2}\alpha_i^2$, setting n to be the number of features and m the number of training points. To map to (B), we let: $g(-A^\top \mathbf{w}) = \sum_i g_i^*(-\mathbf{x}_i^\top \mathbf{w}) = \sum_i \frac{1}{2}(\mathbf{x}_i^\top \mathbf{w} - b_i)^2$ and $f^*(\mathbf{w}) = \eta\lambda\|\mathbf{w}\|_1 + (1-\eta)\frac{\lambda}{2}\|\mathbf{w}\|_2^2$, setting m to be the number of features and n the number of training points. We discuss in Section 3 how the choice of mapping to either (A) or to (B) can have implications on the distribution scheme and overall performance of the framework.

2. *Lasso (Case II: map to (A)).* We can represent L_1-regularized least squares regression by mapping the model:

$$\min_{\mathbf{u} \in \mathbb{R}^p} \; \tfrac{1}{2}\|A\mathbf{u} - \mathbf{b}\|_2^2 + \lambda\|\mathbf{u}\|_1 \tag{8}$$

   to objective (A), letting $f(A\boldsymbol{\alpha}) = \frac{1}{2}\|A\boldsymbol{\alpha} - \mathbf{b}\|_2^2$ and $g(\boldsymbol{\alpha}) = \sum_i g_i(\alpha_i) = \sum_i \lambda|\alpha_i|$. In this mapping, n represents the number of features, and m the number of training points. Note that we cannot map the lasso objective to (B) directly, as f^* must be τ-strongly convex and the L_1-norm is non-strongly convex.

3. *Support Vector Machine (Case III: map to (B)).* We can represent a hinge loss support vector machine (SVM) by mapping the model:

$$\min_{\mathbf{u} \in \mathbb{R}^p} \; \frac{1}{m}\sum_{i=1}^m \max\left\{0, 1 - y_i(\mathbf{x}_i^\top \mathbf{u})\right\} + \tfrac{\lambda}{2}\|\mathbf{u}\|_2^2 \,, \tag{9}$$

   to objective (B), letting $g^*(-A^\top \mathbf{w}) = \sum_i g_i^*(-\mathbf{x}_i^\top \mathbf{w}) = \sum_i \frac{1}{n}\max\{0, 1 - y_i\mathbf{x}_i^\top \mathbf{w}\}$ and $f^*(\mathbf{w}) = \frac{\lambda}{2}\|\mathbf{w}\|_2^2$. In this mapping, m represents the number of features, and n the number of training points. Note that we cannot map the hinge loss SVM primal to objective (A) directly, as f must be $(1/\tau)$-smooth and the hinge loss is non-smooth.

2.5 Data Partitioning

In this work, we are interested in the setting where the dataset at hand is distributed across multiple machines. We assume that the dataset A is distributed over K machines according to a partition $\{\mathcal{P}_k\}_{k=1}^K$ of the *columns* of $A \in \mathbb{R}^{m\times n}$. We denote the size of the partition on machine k by $n_k = |\mathcal{P}_k|$. For machine $k \in \{1,\dots,K\}$ and weight vector $\boldsymbol{\alpha} \in \mathbb{R}^n$, we define $\boldsymbol{\alpha}_{[k]} \in \mathbb{R}^n$ as the n-vector with elements $(\boldsymbol{\alpha}_{[k]})_i := \alpha_i$ if $i \in \mathcal{P}_k$ and $(\boldsymbol{\alpha}_{[k]})_i := 0$ otherwise. Analogously, we write $A_{[k]}$ for the corresponding group of columns of A, and zeros elsewhere (note that columns can correspond to either training examples or features, depending on the application). We discuss these distribution schemes in greater detail in Section 3.

3. The CoCoA Method

In the following sections, we describe the proposed framework, CoCoA, at a high level, and then discuss two approaches for using the framework in practice: CoCoA in the primal, where we consider (A) to be the primal objective and run the framework on this problem directly, and CoCoA in the dual, where we instead consider (B) to be the primal objective, and then run the framework on the dual (A).

Note that in both approaches, the aim will be to compute a minimizer of the problem (A) in a distributed fashion; the main difference will be whether we view (A) as the primal objective or as the dual objective.

3.1 The Generalized Framework

The goal of the CoCoA framework is to find a global minimizer of the objective (A), while distributing computation based on the partitioning of the dataset A across machines (Section 2.5). As a first step, note that distributing the update to the function g in objective (A) is straightforward, as we have required that this term is separable according to the partitioning of our data, i.e., $g(\boldsymbol{\alpha}) = \sum_{i=1}^n g_i(\alpha_i)$. However, the same does not hold for the term $f(A\boldsymbol{\alpha})$. To minimize this part of the objective in a distributed fashion, we propose minimizing a quadratic approximation of the function, which allows the minimization to separate across machines. We make this approximation precise in the following subsection.

Data-local quadratic subproblems. In the general CoCoA framework (Algorithm 1), we distribute computation by defining a data-local subproblem of the optimization problem (A) for each machine. This simpler problem can be solved on machine k and only requires accessing data which is already available locally, i.e., the columns $A_{[k]}$. More formally, each machine k is assigned the following local subproblem, which depends only on the previous shared vector $\mathbf{v} := A\boldsymbol{\alpha} \in \mathbb{R}^m$, and the local data $A_{[k]}$:

$$\min_{\Delta\boldsymbol{\alpha}_{[k]}\in\mathbb{R}^n} \ \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]})\,, \tag{10}$$

where

$$\mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) := \frac{1}{K} f(\mathbf{v}) + \mathbf{w}^\top A_{[k]}\Delta\boldsymbol{\alpha}_{[k]} + \frac{\sigma'}{2\tau}\left\|A_{[k]}\Delta\boldsymbol{\alpha}_{[k]}\right\|^2 + \sum_{i\in\mathcal{P}_k} g_i(\alpha_i + \Delta\boldsymbol{\alpha}_{[k]_i}),$$

Algorithm 1 Generalized CoCoA Distributed Framework

Input: Data matrix A distributed column-wise according to partition $\{\mathcal{P}_k\}_{k=1}^K$, aggregation parameter $\gamma \in (0,1]$, and parameter σ' for the local subproblems $\mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]})$. Starting point $\boldsymbol{\alpha}^{(0)} := \mathbf{0} \in \mathbb{R}^n$, $\mathbf{v}^{(0)} := \mathbf{0} \in \mathbb{R}^m$.
for $t = 0, 1, 2, \dots$ **do**
  for $k \in \{1, 2, \dots, K\}$ **in parallel over computers do**
    call local solver, returning a Θ-approximate solution $\Delta\boldsymbol{\alpha}_{[k]}$ of the local subproblem (10)
    update local variables $\boldsymbol{\alpha}_{[k]}^{(t+1)} := \boldsymbol{\alpha}_{[k]}^{(t)} + \gamma\,\Delta\boldsymbol{\alpha}_{[k]}$
    return updates to shared state $\Delta\mathbf{v}_k := A_{[k]}\Delta\boldsymbol{\alpha}_{[k]}$
  end for
  reduce $\mathbf{v}^{(t+1)} := \mathbf{v}^{(t)} + \gamma\sum_{k=1}^K \Delta\mathbf{v}_k$
end for

and $\mathbf{w} := \nabla f(\mathbf{v})$. Here we let $\Delta\boldsymbol{\alpha}_{[k]}$ denote the change of local variables α_i for indices $i \in \mathcal{P}_k$, and we set $(\Delta\boldsymbol{\alpha}_{[k]})_i := 0$ for all $i \notin \mathcal{P}_k$. It is important to note that the subproblem (10) is simple in the sense that it is always a quadratic objective (apart from the g_i term). The subproblem does not depend on the function f itself, but only its linearization at the fixed shared vector $\mathbf{v}$. This property additionally simplifies the task of the local solver, especially for cases of complex functions f.

Framework parameters γ and σ'. There are two parameters that must be set in the framework: γ, the aggregation parameter, which controls how the updates from each machine are combined, and σ', the subproblem parameter, which is a data-dependent term measuring the difficulty of the data partitioning $\{\mathcal{P}_k\}_{k=1}^K$. These terms play a crucial role in the convergence of the method, as we demonstrate in Section 4. In practice, we provide a simple and robust way to set these parameters: For a given aggregation parameter $\gamma \in (0,1]$, the subproblem parameter σ' will be set as $\sigma' := \gamma K$, but can also be improved in a data-dependent way as we discuss below. *In general, as we show in Section 4, setting $\gamma := 1$ and $\sigma' := K$ will guarantee convergence while delivering our fastest convergence rates.*

Definition 5 (Data-dependent aggregation parameter)**.** *In Algorithm 1, the aggregation parameter γ controls the level of adding ($\gamma := 1$) versus averaging ($\gamma := \frac{1}{K}$) of the partial solutions from all machines. For our convergence results (Section 4) to hold, the subproblem parameter σ' must be chosen not smaller than*

$$\sigma' \geq \sigma'_{min} := \gamma \max_{\boldsymbol{\alpha}\in\mathbb{R}^n} \frac{\|A\boldsymbol{\alpha}\|^2}{\sum_{k=1}^K \|A_{[k]}\boldsymbol{\alpha}_{[k]}\|^2}\,. \tag{11}$$

The simple choice of $\sigma' := \gamma K$ is valid for (11), i.e.,

$$\gamma K \geq \sigma'_{min}\,.$$

In some cases, it will be possible to give a better (data-dependent) choice for σ', closer to the actual bound given in σ'_{min}.

Subproblem interpretation. Here we provide further intuition behind the data-local subproblems (10). The local objective functions $\mathcal{G}_k^{\sigma'}$ are defined to closely approximate the global objective in (A) as the "local" variable $\Delta\boldsymbol{\alpha}_{[k]}$ varies, which we will see in the analysis (Appendix D, Lemma 1). In fact, if the subproblem were solved exactly, this could be interpreted as a data-dependent, block-separable proximal step, applied to the f part of the objective (A) as follows:

$$\sum_{k=1}^{K} \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) = R + f(\mathbf{v}) + \nabla f(\mathbf{v})^\top A\Delta\boldsymbol{\alpha} + \frac{\sigma'}{2\tau}\Delta\boldsymbol{\alpha}^\top \begin{bmatrix} A_{[1]}^\top A_{[1]} & & 0 \\ & \ddots & \\ 0 & & A_{[K]}^\top A_{[K]} \end{bmatrix} \Delta\boldsymbol{\alpha}, \quad (12)$$

where $R = \sum_{i\in[n]} g_i(-\alpha_i - \Delta\alpha_i)$.

However, note that in contrast to traditional proximal methods, CoCoA does *not* assume that this subproblem is solved to high accuracy, as we instead allow the use of local solvers of any approximation quality Θ.

Reusability of existing single-machine solvers. The local subproblems (10) have the appealing property of being very similar in structure to the global problem (A), with the main difference being that they are defined on a smaller (local) subset of the data, and are simpler because they are not dependent on the shape of f. For a user of CoCoA, this presents a significant advantage in that existing single machine-solvers can be directly re-used in our distributed framework (Algorithm 1) by employing them on the subproblems $\mathcal{G}_k^{\sigma'}$.

Therefore, problem-specific tuned solvers which have already been developed, along with associated speed improvements (such as multi-core implementations), can be easily leveraged in the distributed setting. We quantify the dependence on local solver performance with the following assumption and remark, and relate this performance to our global convergence rates in Section 4.

Assumption 1 (Θ-approximate solution)**.** *We assume that there exists $\Theta \in [0, 1)$ such that $\forall k \in [K]$, the local solver at any outer iteration t produces a (possibly) randomized approximate solution $\Delta\boldsymbol{\alpha}_{[k]}$, which satisfies*

$$\frac{\mathbb{E}\left[\mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) - \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}^\star; \mathbf{v}, \boldsymbol{\alpha}_{[k]})\right]}{\mathcal{G}_k^{\sigma'}(\ \mathbf{0}\ ; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) - \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}^\star; \mathbf{v}, \boldsymbol{\alpha}_{[k]})} \leq \Theta\,, \quad (13)$$

where

$$\Delta\boldsymbol{\alpha}_{[k]}^\star \in \arg\min_{\Delta\boldsymbol{\alpha}\in\mathbb{R}^n} \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}), \quad \forall k \in [K]\,. \quad (14)$$

Remark 1. *In practice, the time spent solving the local subproblems in parallel should be chosen comparable to the time of a communication round, for best overall efficiency on a given system. We study this trade-off in theory (Section 4) and experiments (Section 6).*

Remark 2. *Note that the accuracy parameter Θ does not have to be chosen* a priori*: Our convergence results (Section 4) are valid if Θ is an upper bound on the actual empirical values Θ in Algorithm 1. This allows for some of the K machines to at times deliver better or worse accuracy Θ (e.g., this would allow a slow local machine to be stopped early during a specific round in order to avoid stragglers). See (Smith et al., 2017) for more details.*

Remark 3. *From a theoretical perspective, the multiplicative notion of accuracy is advantageous over classical additive accuracy as existing convergence results for first- and second-order optimization methods typically appear in multiplicative form, i.e., relative to the error at the initialization point (here $\Delta\boldsymbol{\alpha}_{[k]} = \mathbf{0}$). This accuracy notion Θ is also useful beyond the distributed setting (see, e.g., Karimireddy et al., 2018a,b). We discuss local solvers and associated rates to achieve accuracy Θ for particular applications in Section 5.*

With this general framework in place, we next discuss two variants of our framework, CoCoA-Primal and CoCoA-Dual. In running either the primal or dual variant of the framework, the goal will always be to solve objective (A) in a distributed fashion. The main difference will be whether this objective is viewed as the primal or dual of the input problem (I). We make this mapping technique precise and discuss its implications in the following subsections (Sections 3.2–3.4).

3.2 Primal Distributed Optimization

In the primal distributed version of the framework (Algorithm 2), the framework is run by mapping the initial problem (I) directly to objective (A) and then applying the generalized CoCoA framework described in Algorithm 1. In other words, we view problem (A) as the primal objective, and solve this problem directly.

From a theoretical perspective, viewing (A) as the primal will allow us to consider non-strongly convex regularizers, since we allow the terms g_i to be non-strongly convex. This setting was not covered in earlier work of Yang (2013); Jaggi et al. (2014); Ma et al. (2015a); and Ma et al. (2017b), and we discuss it in detail in Section 4, as additional machinery must be introduced to develop primal-dual rates for this setting.

Running the primal version of the framework has important practical implications in the distributed setting, as it typically implies that the data is distributed by feature rather than by training point. In this setting, the amount of communication at every outer iteration will be $\mathcal{O}(\#$ of training points). When the number of features is high (as is common when using sparsity-inducing regularizers) this can help to reduce communication and improve overall performance, as we demonstrate in Section 6.

Algorithm 2 CoCoA-Primal (Mapping Problem (I) to (A))

1: **Map:** Input problem (I) to objective (A)
2: **Distribute:** Dataset A by columns (here typically features) according to partition $\{\mathcal{P}_k\}_{k=1}^K$
3: **Run:** Algorithm 1 with aggregation parameter γ and subproblem parameter σ'

3.3 Dual Distributed Optimization

In the dual distributed version of the framework (Algorithm 3), we run the framework by mapping the original problem (I) to objective (B), and then solve the problem by running Algorithm 1 on the dual (A). In other words, we view problem (B) as the primal, and solve this problem via the dual (A).

This version of the framework will allow us to consider non-smooth losses, such as the hinge loss or absolute deviation loss, since the terms g_i^* can be non-smooth. From a practical perspective, this version of the framework will typically imply that the data is distributed by training point, and for a vector $\mathcal{O}(\#$ of features) to be communicated at every outer iteration. This variant may therefore be preferable when the number of training points exceeds the number of features.

Algorithm 3 CoCoA-Dual (Mapping Problem (I) to (B))

1: **Map:** Input problem (I) to objective (B)
2: **Distribute:** Dataset A by columns (here typically training points) according to partition $\{\mathcal{P}_k\}_{k=1}^K$
3: **Run:** Algorithm 1 with aggregation parameter γ and subproblem parameter σ'

3.4 Primal vs. Dual

In Table 2, we revisit the three cases from Section 2, showing how the primal and dual variants of CoCoA can be applied to various input problems $\ell(\mathbf{u}) + r(\mathbf{u})$, depending on properties of the functions ℓ and r. In particular, in the setting where ℓ is smooth and r is strongly convex, the user may choose whether to run the framework in the primal (Algorithm 2), or in the dual (Algorithm 3).

Intuitively, Algorithm 2 will be preferable as r loses strong convexity, and Algorithm 3 will be preferable as ℓ loses smoothness. However, there are also systems-related aspects to consider. In Algorithm 2, we typically distribute the data by feature, and in Algorithm 3, by training point (this distribution depends on how the terms n and m are defined in our mapping; see Section 5). Depending on whether the number of features or number of training points is the dominating term, we may chose to run Algorithm 2 or Algorithm 3, respectively, in order to reduce communication costs. We validate these ideas empirically in Section 6 by comparing the performance of each variant (primal vs. dual) on real distributed datasets.

Table 2: Criteria for Running Algorithms 2 vs. 3.

	Smooth ℓ	Non-smooth and separable ℓ
Strongly convex r	Case I: Alg. 2 or 3	Case III: Alg. 3
Non-strongly convex and separable r	Case II: Alg. 2	–

In the following subsection, we provide greater insight into the CoCoA framework and its relation to prior work. An extended discussion on related work is available in Section 7.

3.5 Interpretations of CoCoA

There are numerous methods that have been developed to solve (A) and (B) in parallel and distributed environments. We describe related work in detail in Section 7, and here briefly position CoCoA and in relation to other widely-used parallel and distributed methods.

CoCoA in the context of classical parallelization schemes. We first contrast CoCoA with common distributed mini-batch and batch methods, such as mini-batch stochastic gradient descent or coordinate descent, gradient descent, and quasi-Newton methods.

CoCoA is similar to these methods in that they are all *iterative*, i.e., they make progress towards the optimal solution by updating the parameter vector $\boldsymbol{\alpha}$ according to some function h: $\mathbb{R}^n \to \mathbb{R}^n$ at each iteration t: $\boldsymbol{\alpha}^{(t+1)} = h(\boldsymbol{\alpha}^{(t)})$, $t = 0, 1, \ldots$, until convergence is reached. From a coordinate-wise perspective, two approaches to update $\boldsymbol{\alpha}$ iteratively include the Jacobi "all-at-once" and Gauss-Seidel "one-at-a-time" methods (Bersekas and Tsitsiklis, 1989):

$$\text{Jacobi:} \quad \alpha_i^{(t+1)} = h_i(\alpha_1^{(t)}, \ldots, \alpha_n^{(t)}), \quad i = 1, \ldots, n,$$
$$\text{Gauss-Seidel:} \quad \alpha_i^{(t+1)} = h_i(\alpha_1^{(t+1)}, \ldots, \alpha_{i-1}^{(t+1)}, \alpha_i^{(t)}, \ldots, \alpha_n^{(t)}), \quad i = 1, \ldots, n.$$

The Jacobi method does not require information from the other coordinates to update coordinate i, which makes this style of method well-suited for parallelization. However, the sequential Gauss-Seidel-style method tends to converge faster in terms of iterations, as it is able to incorporate information from the updates of other coordinates more quickly. This difference is well-known and evident in single machine solvers, where stochastic methods (benefiting from fresh updates) tend to outperform their batch counterparts.

Typical mini-batch methods, e.g., mini-batch coordinate descent, perform a Jacobi-style update on a subset of the coordinates at each iteration. This makes these methods amenable to high levels of parallelization. However, they are unable to incorporate information as quickly as their serial counterparts in terms of number of data points accessed, as synchronization is required before updating the coordinates. As the size of the mini-batch grows, this can increase the runtime and even lead to divergence (Richtárik and Takáč, 2016).

CoCoA instead aims to combine attractive properties of both of these update paradigms. In CoCoA, Jacobi-style updates are applied in parallel to *blocks* of the coordinates of $\boldsymbol{\alpha}$ to distribute the method, while allowing for (though not necessarily requiring) faster Gauss-Seidel-style updates on each machine. This change in parallelization scheme is one of the key reasons for improved performance over simpler mini-batch or batch style methods.

Two extremes: from distributed CD to one-shot communication. In addition to the parallel block-Jacobi updating scheme described above, CoCoA incorporates an additional level of flexibility by allowing for an *arbitrary number* of sequential Gauss-Seidel iterations (or any local solver for that matter) to be performed locally on each machine. This flexibility is critical in the distributed setting, as one of the key indicators of parallel efficiency is the time spent on local computation vs. communication. In particular, the flexibility to solve each subproblem to arbitrary accuracy, Θ, allows CoCoA to scale from low-communication environments, where more iterations can be performed before communicating, to high communication environments, where fewer local iterations are necessary.

In comparison with other distributed methods, this flexibility also affords an explanation of CoCoA as a method that can freely move between two extremes. On one extreme, if the subproblems (10) are solved exactly, CoCoA recovers block coordinate descent, where the coordinate updates are applied as part of a block-separable proximal step (12). If only one outer round of communication is performed, this is similar in spirit to one-shot communication schemes, which attempt to completely solve for and then combine locally-computed models (see, e.g., Mann et al., 2009; Zhang et al., 2013; Heinze et al., 2016). While

these one-shot communication schemes are ideal in terms of reducing communication, they are, in contrast to CoCoA, generally not guaranteed to converge to the optimal solution.

On the other extreme, if just a single update (i.e., with respect to one coordinate α_i) is performed at each communication round, this recovers traditional distributed coordinate descent. In comparison to CoCoA, vanilla distributed coordinate descent can suffer from a high communication bottleneck due to the low relative amount of local computation. Even in the case of mini-batch coordinate descent, the most amount of work that can be performed locally at each round includes a single pass through the data, whereas CoCoA has the flexibility to take multiple passes. We empirically compare to mini-batch distributed coordinate descent in Section 6 to demonstrate the effect of this issue in practice.

Comparison to ADMM. Finally, we provide a direct comparison between CoCoA and the alternating direction method of multipliers (ADMM), a well-established framework for distributed optimization (Boyd et al., 2010). Similar to CoCoA, ADMM defines a subproblem for each machine to solve in parallel, rather than parallelizing a mini-batch update. ADMM also leverages duality structure, similar to that presented in Section 2. For consensus ADMM (Mota et al., 2013), (B) is decomposed with a re-parameterization:

$$\max_{\mathbf{w}_1,\dots\mathbf{w}_K,\mathbf{w}} \quad \sum_{k=1}^{K}\sum_{i\in\mathcal{P}_k} g^*(-\mathbf{x}_i^\top\mathbf{w}_k) + f^*(\mathbf{w}) \quad \text{s.t. } \mathbf{w}_k = \mathbf{w},\ k=1,\dots,K.$$

This problem is then solved by constructing the augmented Lagrangian, which yields the following decomposable updates:

$$\begin{aligned}
\mathbf{w}_k^{(t+1)} &= \arg\min_{\mathbf{w}_k} \sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k) + \rho\mathbf{u}_k^{(t)^\top}(\mathbf{w}_k - \mathbf{w}^{(t)}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}^{(t)}\|^2,\\
\mathbf{w}^{(t+1)} &= \arg\min_{\mathbf{w}} \ f^*(\mathbf{w}) + \frac{\rho K}{2}\|\mathbf{w} - (\bar{\mathbf{w}}_k^{(t+1)} + \bar{\mathbf{u}}_k^{(t)})\|^2,\\
\mathbf{u}_k^{(t+1)} &= \mathbf{u}_k^{(t)} + \mathbf{w}_k^{(t+1)} - \mathbf{w}^{(t+1)},
\end{aligned}$$

where ρ is a penalty parameter that must be tuned for best performance. It can be shown that the update to $\mathbf{w}_k$ can be reformulated in terms of the conjugate functions g_i as:

$$\arg\min_{\boldsymbol{\alpha}_{[k]}} \sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{[k]_i}) + (\mathbf{w}^{(t)} - \mathbf{u}_k^{(t)})^\top A_{[k]}\boldsymbol{\alpha}_{[k]} + \frac{1}{2\rho}\|A_{[k]}\boldsymbol{\alpha}_{[k]}\|^2\,. \tag{15}$$

Thus, we see that the update to $\mathbf{w}_k$ closely matches the CoCoA subproblem (10), where $\rho := \frac{\tau}{\sigma'}$. This is intuitive as both methods use proximal steps to derive the subproblem, and a similar result can be shown when applying ADMM to the (A) formulation, which can be seen as an instantiation of the sharing variant of ADMM (Boyd et al., 2010, Section 7.3).

However, there remain major differences between the methods despite this connection. First, CoCoA has a more direct and simplified scheme for updating the global weight vector $\mathbf{w}$, as the additional proximal step is not required. Second, in CoCoA, there is no need to tune any parameters such as ρ, as the method can be run simply using $\sigma'{=}K$. Finally, in the CoCoA method and theory, the subproblem can be solved approximately to any accuracy Θ, rather than requiring a full batch update as in ADMM. We will see in our experiments that these differences have a substantial impact in practice (Section 6). We provide a full derivation of the comparison to ADMM for reference in Appendix C.

4. Convergence Analysis

In this section, we provide convergence rates for the proposed framework and introduce a key theoretical technique in analyzing non-strongly convex terms in the primal-dual setting.

For simplicity of presentation, we assume in the analysis that the data partitioning is balanced, i.e., $n_k = n/K$ for all k. Furthermore, we assume that the columns of A satisfy $\|\mathbf{x}_i\| \le 1$ for all $i \in [n]$, and $\mathcal{O}_B$ contains the average term $\frac{1}{n}\sum_{i=1}^n g_i^*(\cdot)$, as is common in ERM-type problems. We present rates for the case where $\gamma := 1$ in Algorithm 1, and where the subproblems (10) are defined using the corresponding safe bound $\sigma' := K$. This case will guarantee convergence while delivering our fastest rates in the distributed setting, which in particular do not degrade as the number of machines K increases and n remains fixed. More general rates and all proof details can be found in the appendix.

4.1 Proof Strategy: Relating Subproblem Approximation to Global Progress

To guarantee convergence, it is critical to show how progress made on the local subproblems (10) relates to the global objective $\mathcal{O}_A$. Our first lemma provides exactly this information. In particular, we see that if the aggregation and subproblem parameters are selected according to Definition 5, the sum of the subproblem objectives, $\sum_{k=1}^K \mathcal{G}_k^{\sigma'}$, will form a block-separable upper bound on the global objective $\mathcal{O}_A$.

Lemma 1. *For any weight vector $\boldsymbol{\alpha}, \Delta\boldsymbol{\alpha} \in \mathbb{R}^n$, $\mathbf{v} = \mathbf{v}(\boldsymbol{\alpha}) := A\boldsymbol{\alpha}$, and real values γ, σ' satisfying* (11)*, it holds that*

$$\mathcal{O}_A\Big(\boldsymbol{\alpha} + \gamma\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]}\Big) \le (1-\gamma)\mathcal{O}_A(\boldsymbol{\alpha}) + \gamma\sum_{k=1}^K \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]})\,. \tag{16}$$

A proof of Lemma 1 is provided in Appendix D. We use this main lemma, in combination with our measure of quality of the subproblem approximations (Assumption 1), to deliver global convergence rates.

4.2 Rates for General Convex g_i, L-Lipschitz g_i^*

Our first main theorem provides convergence guarantees for objectives with general convex g_i (or, equivalently, L-Lipschitz g_i^*), including models with non-strongly convex regularizers such as lasso and sparse logistic regression, or models with non-smooth losses, such as the hinge loss support vector machine.

Theorem 2. *Consider Algorithm 1 with $\gamma := 1$, and let Θ be the quality of the local solver as in Assumption 1. Let g_i have L-bounded support, and let f be $(1/\tau)$-smooth. Then after T iterations, where*

$$\begin{aligned}
T &\ge T_0 + \max\{\Big\lceil\frac{1}{1-\Theta}\Big\rceil, \frac{4L^2}{\tau\epsilon_G(1-\Theta)}\}\,, \\
T_0 &\ge t_0 + \Big\lceil\frac{2}{1-\Theta}\left(\frac{8L^2}{\tau\epsilon_G} - 1\right)\Big\rceil_+\,, \\
t_0 &\ge \max(0, \Big\lceil\tfrac{1}{(1-\Theta)}\log\Big(\tfrac{\tau n(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))}{2L^2K}\Big)\Big\rceil)\,,
\end{aligned} \tag{17}$$

we have that the expected duality gap satisfies

$$\mathbb{E}\big[\mathcal{O}_A(\overline{\boldsymbol{\alpha}}) - (-\mathcal{O}_B(\mathbf{w}(\overline{\boldsymbol{\alpha}})))\big] \leq \epsilon_G\,,$$

where $\overline{\boldsymbol{\alpha}}$ *is the averaged iterate:* $\frac{1}{T-T_0}\sum_{t=T_0+1}^{T-1}\boldsymbol{\alpha}^{(t)}$.

Providing primal-dual rates and globally defined primal-dual accuracy certificates for these objectives may require a theoretical technique that we introduce below, in which we show how to satisfy the notion of L-bounded support for g_i, as stated in Definition 2.

4.2.1 Bounded support modification

Additional work is necessary if Theorem 2 is to be applied to non-strongly convex regularizers such as the L_1 norm, which do not have L-bounded support for each g_i, and thus violate the main assumptions. Note for example that the conjugate function of $g_i = |\cdot|$, which is the indicator function of an interval, is not defined globally over $\mathbb{R}$, and thus (without further modification) the duality gap $G(\boldsymbol{\alpha})$:=$\mathcal{O}_A(\boldsymbol{\alpha})$-(-$\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha}))$) is not defined at all points $\boldsymbol{\alpha}$.

Smoothing. To address this problem, existing approaches typically use a simple smoothing technique (e.g., Nesterov, 2005; Shalev-Shwartz and Zhang, 2014): by adding a small amount of L_2 regularization, the functions g_i become strongly convex. Following this change, the methods are run on the dual instead of the original primal problem. While this modification satisfies the necessary assumptions for convergence, this smoothing technique is often undesirable in practice, as it changes the iterates, the algorithms at hand, the convergence rate, and the tightness of the resulting duality gap compared to the original objective. Further, the amount of smoothing can be difficult to tune and has a large impact on empirical performance. We perform experiments to highlight these issues in practice in Section 6.

Bounded support modification. In contrast to smoothing, our approach preserves all solutions of the original objective, leaves the iterate sequence unchanged, and allows for direct reusability of existing solvers for the original g_i objectives (such as L_1 solvers). It also removes the need for tuning a smoothing parameter. To achieve this, we modify the function g_i by imposing an additional weak constraint that is inactive in our region of interest. Formally, we replace $g_i(\alpha_i)$ by the following modified function:

$$\bar{g}_i(\alpha_i) := \begin{cases} g_i(\alpha_i) & : \alpha_i \in [-B, B] \\ +\infty & : \text{otherwise.} \end{cases} \tag{18}$$

For large enough B, this problem yields the same solution as the original objective. Note also that this only affects convergence theory, in that it allows us to present a strong primal-dual rate (Theorem 2 for L=B). The modification of g_i does not affect the algorithms for the original problems. Whenever a monotone optimizer is used, we will never leave the level set defined by the objective at the starting point.

Using the resulting modified function will allow us to apply the results of Theorem 2 for general convex functions g_i. This technique can also be thought of as "Lipschitzing" the dual g_i^*, because of the general result that g_i^* is L-Lipschitz if and only if g_i has L-bounded support (Rockafellar, 1997, Corollary 13.3.3). We derive the conjugate function $\bar{g}_i^*$ for completeness in Appendix B (Lemma 6). In Section 5, we show how to leverage this technique for a variety of application input problems. See also Dünner et al. (2016) for a follow-up discussion of this technique in the non-distributed case.

4.3 Rates for Strongly Convex g_i, Smooth g_i^*

For the case of objectives with strongly convex g_i (or, equivalently, smooth g_i^*), e.g., elastic net regression or logistic regression, we obtain the following faster *linear* convergence rate.

Theorem 3. *Consider Algorithm 1 with* $\gamma := 1$*, and let* Θ *be the quality of the local solver as in Assumption 1. Let* g_i *be* μ*-strongly convex* $\forall i \in [n]$*, and let* f *be* $(1/\tau)$*-smooth. Then after* T *iterations where*

$$T \geq \tfrac{1}{(1-\Theta)}\tfrac{\mu\tau+1}{\mu\tau}\log\tfrac{1}{\epsilon_{\mathcal{O}_A}}\,, \tag{19}$$

it holds that

$$\mathbb{E}\big[\mathcal{O}_A(\boldsymbol{\alpha}^{(T)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)\big] \leq \epsilon_{\mathcal{O}_A}\,.$$

Furthermore, after T *iterations with*

$$T \geq \tfrac{1}{(1-\Theta)}\tfrac{\mu\tau+1}{\mu\tau}\log\Big(\tfrac{1}{(1-\Theta)}\tfrac{\mu\tau+1}{\mu\tau}\tfrac{1}{\epsilon_G}\Big)\,,$$

we have the expected duality gap

$$\mathbb{E}\big[\mathcal{O}_A(\boldsymbol{\alpha}^{(T)}) - (-\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha}^{(T)}))\big] \leq \epsilon_G\,.$$

We provide proofs of both Theorem 2 and Theorem 3 in Appendix D.

4.4 Convergence Cases

Revisiting Table 1 from Section 2, we summarize our convergence guarantees for the three cases of input problems (I) in the following table. In particular, we see that for cases II and III, we obtain a sublinear convergence rate, whereas for case I we can obtain a faster linear rate, as provided in Theorem 3.

Table 3: Applications of Convergence Rates.

	Smooth ℓ	Non-smooth, separable ℓ
Strongly convex r	Case I: Theorem 3	Case III: Theorem 2
Non-strongly convex, separable r	Case II: Theorem 2	–

4.5 Recovering Earlier Work as a Special Case

As a special case, the proposed framework and rates directly apply to L_2-regularized loss-minimization problems, including those presented in the earlier work of Jaggi et al. (2014) and Ma et al. (2015a).

Remark 4. *If we run Algorithm 3 (mapping* (I) *to* (B)*) and restrict* $f^*(\cdot) := \frac{\lambda}{2}\|\cdot\|^2$ *(so that* $\tau = \lambda$*), Theorem 2 recovers as a special case the* CoCoA$^+$ *rates for general L-Lipschitz* ℓ_i^* *losses (see Ma et al., 2015a, Corollary 9). The earlier work of* CoCoA*-v1 (Jaggi et al., 2014) did not provide rates for L-Lipschitz* ℓ_i^* *losses.*

Remark 5. *If we run Algorithm 3 (mapping* (I) *to* (B)*) and restrict* $f^*(\cdot) := \frac{\lambda}{2}\|\cdot\|^2$ *(so that* $\tau = \lambda$*), Theorem 3 recovers as a special case the* CoCoA$^+$ *rates for* $(1/\ell_i^*)$*-smooth losses (see Ma et al., 2015a, Corollary 11). The earlier rates of* CoCoA*-v1 can be obtained by setting* $\gamma{:=}\frac{1}{K}$ *and* $\sigma'{=}1$ *in Algorithm 1 (Jaggi et al., 2014, Theorem 2).*

These cases follow since g_i^* is L-Lipschitz if and only if g_i has L-bounded support (Rockafellar, 1997, Corollary 13.3.3), and g_i^* is μ-strongly convex if and only if g_i is $(1/\mu)$-smooth (Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.2.2).

5. Applications

In this section we detail example applications that can be cast within the general CoCoA framework. For each example, we describe the primal-dual setup and algorithmic details, discuss the convergence properties our framework for the application, and include practical concerns such as information on state-of-the-art local solvers. We discuss examples according to the three cases defined in Table 1 of Section 2 for finding a minimizer of the general objective $\ell(\mathbf{u}) + r(\mathbf{u})$, and provide a summary of these common examples in Table 4.

Table 4: Common Losses and Regularizers.

(i) Losses

Loss	Obj	f / g^*
Least Squares	(A)	$f{=}\frac{1}{2}\|A\boldsymbol{\alpha} - \mathbf{b}\|_2^2$
	(B)	$g^*{=}\frac{1}{2}\|A^\top\mathbf{w} - \mathbf{b}\|_2^2$
Logistic Reg.	(A)	$f{=}\frac{1}{m}\sum_j \log(1{+}\exp(b_j\mathbf{x}_j^\top\boldsymbol{\alpha}))$
	(B)	$g^*{=}\frac{1}{n}\sum_i \log(1{+}\exp(b_i\mathbf{x}_i^\top\mathbf{w}))$
SVM	(B)	$g^*{=}\frac{1}{n}\sum_i \max(0, 1{-}y_i\mathbf{x}_i^\top\mathbf{w})$
Absolute Dev.	(B)	$g^* = \frac{1}{n}\sum_i \|\mathbf{x}_i^\top\mathbf{w} - y_i\|$

(ii) Regularizers

Regularizer	Obj	g / f^*
Elastic Net	(A)	$g{=}\lambda(\eta\|\boldsymbol{\alpha}\|_1{+}\frac{1-\eta}{2}\|\boldsymbol{\alpha}\|_2^2)$
	(B)	$f^*{=}\lambda(\eta\|\mathbf{w}\|_1{+}\frac{1-\eta}{2}\|\mathbf{w}\|_2^2)$
L_2	(A)	$g{=}\frac{\lambda}{2}\|\boldsymbol{\alpha}\|_2^2$
	(B)	$f^*{=}\frac{\lambda}{2}\|\mathbf{w}\|_2^2$
L_1	(A)	$g{=}\lambda\|\boldsymbol{\alpha}\|_1$
Group Lasso	(A)	$g{=}\lambda\sum_p\|\boldsymbol{\alpha}_{\mathcal{I}_p}\|_2$, $\mathcal{I}_p \subseteq [n]$

5.1 Case I: Smooth ℓ, Strongly convex r

For input problems (I) with smooth ℓ and strongly convex r, Theorem 3 from Section 4 gives a global linear (geometric) convergence rate. Smooth loss functions can be mapped either to the function f in objective (A), or g^* in (B). Similarly, strongly convex regularizers can be mapped either to function g in objective (A), or f^* in (B). To illustrate the role of f as a smooth loss function and g as a strongly convex regularizer in objective (A), contrasting with their traditional roles in prior work (Yang, 2013; Jaggi et al., 2014; Ma et al., 2015a, 2017b), we consider the following examples. Note that mapping to objective (B) instead will follow trivially assuming that the loss is separable across training points (see Table 4).

For the examples in this subsection, we use m to represent the number of training points and n the number of features. Note that these definitions may change in the following subsections: this flexibility is useful so that we can present both the primal and dual variations of our framework (Algorithms 2 and 3) via a single abstract method (Algorithm 1).

Smooth ℓ: least squares loss. Let $\mathbf{b} \in \mathbb{R}^m$ be labels or response values, and consider the least squares objective, $f(\mathbf{v}) := \frac{1}{2}\|\mathbf{v} - \mathbf{b}\|_2^2$, which is 1-smooth. We obtain the familiar least-squares regression objective in our optimization problem (A), using

$$f(A\boldsymbol{\alpha}) := \tfrac{1}{2}\|A\boldsymbol{\alpha} - \mathbf{b}\|_2^2 \,. \tag{20}$$

Observing that the gradient of f is $\nabla f(\mathbf{v}) = \mathbf{v}{-}\mathbf{b}$, the primal-dual mapping is given by: $\mathbf{w}(\boldsymbol{\alpha}) := A\boldsymbol{\alpha}{-}\mathbf{b}$, which is well known as the *residual vector* in least-squares regression.

Smooth ℓ: logistic regression loss. For classification, we consider a logistic regression model with m training examples, $\mathbf{y}_j \in \mathbb{R}^n$ for $j \in [m]$, collected as the rows of the data matrix A. For each training example, we are given a binary label, which we collect in the vector $\mathbf{b} \in \{-1, 1\}^m$. Formally, the objective is defined as $f(\mathbf{v}) := \sum_{j=1}^m \log\left(1 + \exp\left(-b_j v_j\right)\right)$, which is again a separable function. The classifier loss is given by

$$f(A\boldsymbol{\alpha}) := \sum_{j=1}^m \log\left(1 + \exp\left(-b_j \mathbf{y}_j^\top\boldsymbol{\alpha}\right)\right), \tag{21}$$

where $\boldsymbol{\alpha} \in \mathbb{R}^n$ is the parameter vector. It is not hard to show that f is 1-smooth if the labels satisfy $b_j \in [-1, 1]$. The primal-dual mapping is given by $w_j(\boldsymbol{\alpha}) := \frac{-b_j}{1+\exp\left(b_j \mathbf{y}_j^\top\boldsymbol{\alpha}\right)}$.

Strongly convex r: elastic net regularizer. An application we can consider for a strongly convex regularizer, g in (A) or f^* in (B), is elastic net regularization, $\eta\lambda\|\mathbf{u}\|_1 + (1-\eta)\frac{\lambda}{2}\|\mathbf{u}\|_2^2$, for fixed parameter $\eta \in (0, 1]$. This can be obtained in (A) by setting

$$g(\boldsymbol{\alpha}) = \sum_{i=1}^n g_i(\alpha_i) := \sum_{i=1}^n \eta\lambda|\alpha_i| + (1-\eta)\tfrac{\lambda}{2}\alpha_i^2. \tag{22}$$

For the special case $\eta = 1$, we obtain the L_1-norm, and for $\eta = 0$, we obtain the L_2-norm. The conjugate of g_i is given by: $g_i^*(x) := \frac{1}{2(1-\eta)}\left(\left[|x| - \eta\right]_+\right)^2$, where $[.]_+$ is the positive part operator, $[s]_+ = s$ for $s > 0$, and zero otherwise.

5.2 Case II: Smooth ℓ, Non-Strongly Convex Separable r

In case II, we consider mapping the input problem (I) to objective (A), where ℓ is assumed to be smooth, and r non-strongly convex and separable. For smooth losses in (A), we can consider as examples those provided in Subsection 5.1, e.g., the least squares loss or logistic loss. For an example of a non-strongly convex regularizer, we consider the important case of L_1 regularization below. Again, we note that this application cannot be realized by objective (B), where it is assumed that the regularization term f^* is strongly convex.

Non-strongly convex r: L_1 regularizer. L_1 regularization is obtained in objective (A) by letting $g_i(\cdot) := \lambda|\cdot|$. However, an additional modification is necessary to obtain primal-dual convergence and certificates for this setting. In particular, we employ the modification introduced in Section 4, which will guarantee L-bounded support. Formally, we replace $g_i(\cdot) = |\cdot|$ by

$$\bar{g}(\alpha) := \begin{cases} |\alpha| & : \alpha \in [-B, B], \\ +\infty & : \text{otherwise.} \end{cases}$$

For large enough B, this problem yields the same solution as the original L_1-regularized objective. Note that this only affects convergence theory, in that it allows us to present a strong primal-dual rate (Theorem 2 for L=B). With this modified L_1 regularizer, the optimization problem (A) with regularization parameter λ becomes

$$\min_{\boldsymbol{\alpha}\in\mathbb{R}^n} \; f(A\boldsymbol{\alpha}) + \lambda \sum_{i=1}^{n} \bar{g}(\alpha_i)\,. \tag{23}$$

For large enough choice of the value B, this problems yields the same solution as the original objective: $f(A\boldsymbol{\alpha}) + \lambda\sum_{i=1}^{n}|\alpha_i|$. The modified $\bar{g}$ is simply a constrained version of the absolute value to the interval $[-B, B]$. Therefore by setting B to a large enough value that the values of α_i will never reach it, $\bar{g}^*$ will be continuous and at the same time make (23) equivalent to the original objective.

Formally, a simple way to obtain a large enough value of B, so that all solutions are unaffected, is the following: If we start the algorithm at $\boldsymbol{\alpha} = \mathbf{0}$, for every point encountered during execution of a monotone optimizer, the objective values will never become worse than $\mathcal{O}_A(\mathbf{0})$. Formally, under the assumption that f is non-negative, we will have that (for each i):

$$\lambda|\alpha_i| \leq f(\mathbf{0}) = \mathcal{O}_A(\mathbf{0}) \implies |\alpha_i| \leq \frac{f(\mathbf{0})}{\lambda}.$$

We can therefore safely set the value of B as $\frac{f(\mathbf{0})}{\lambda}$. For the modified $\bar{g}_i$, the conjugate $\bar{g}_i^*$ is given by:

$$\bar{g}_i^*(x) := \begin{cases} 0 & : x \in [-1, 1], \\ B(|x| - 1) & : \text{otherwise.} \end{cases}$$

We provide a proof of this in Appendix B (Lemma 6).

Non-strongly convex r: group lasso. The group lasso penalty can be mapped to objective (A), with:

$$g(\boldsymbol{\alpha}) := \lambda \sum_{p=1}^{P} \|\boldsymbol{\alpha}_{\mathcal{I}_p}\|_2 \quad \text{with} \quad \bigcup_{p=1}^{P} \mathcal{I}_p = \{1, \ldots, n\}\,, \tag{24}$$

where the disjoint sets $\mathcal{I}_p \subseteq \{1, \ldots, n\}$ represent a partitioning of the total set of variables. This penalty can be viewed as an intermediate between a pure L_1 or L_2 penalty, performing variable selection only at the group level. The term $\boldsymbol{\alpha}_{\mathcal{I}_p} \in \mathbb{R}^{|\mathcal{I}_p|}$ denotes part of the vector $\boldsymbol{\alpha}$ with indices $\mathcal{I}_p$. The conjugate is given by:

$$g^*(\mathbf{w}) = I_{\{\mathbf{w} \mid \max_{\mathcal{I}_p \in [n]} \|\boldsymbol{\alpha}_{\mathcal{I}_p}\|_2 \leq \lambda\}}(\mathbf{w}).$$

For details, see, e.g., Dünner et al. (2016) or Boyd and Vandenberghe (2004, Example 3.26).

5.3 Case III: Non-Smooth Separable ℓ, Strongly Convex r

Finally, in case III, we consider mapping the input problem (I) to objective (B), where ℓ is assumed to be non-smooth and separable, and r strongly convex. We discuss two common cases of general non-smooth losses ℓ, including the the hinge loss for classification and

absolute deviation loss for regression. When paired with a strongly convex regularizer, the regularizer via f gives rise to the primal-dual mapping, and Theorem 2 provides a sublinear convergence rate for objectives of this form. We note that these losses cannot be realized directly by objective (A), where it is assumed that the loss term f is smooth.

Non-smooth ℓ: hinge loss. For classification problems, we can consider a hinge loss support vector machine model, on n training points in $\mathbb{R}^m$, given with the loss:

$$g^*(-A^\top \mathbf{w}) = \sum_{i=1}^{n} g_i^*(-\mathbf{x}_i^\top \mathbf{w}) := \frac{1}{n}\sum_{i=1}^{n} \max\{0, 1 - y_i \mathbf{x}_i^\top \mathbf{w}\}. \tag{25}$$

The conjugate function of the hinge loss $\phi(a) = \max\{0, 1 - b\}$ is given by $\phi^*(b) = \{b$ if $b \in [-1, 0]$, else $\infty\}$. When using the L_2 norm for regularization in this problem: $f^*(\mathbf{w}) := \lambda\|\mathbf{w}\|_2^2$, a primal-dual mapping is given by: $\mathbf{w}(\boldsymbol{\alpha}) := \frac{1}{\lambda n} A\boldsymbol{\alpha}$.

Non-smooth ℓ: absolute deviation loss. The absolute deviation loss, used, e.g., in quantile regression or least absolute deviation regression, can be realized in objective (B) by setting:

$$g^*(-A^\top \mathbf{w}) = \sum_{i=1}^{n} g_i^*(-\mathbf{x}_i^\top \mathbf{w}) := \frac{1}{n}\sum_{i=1}^{n} \left|\mathbf{x}_i^\top \mathbf{w} - y_i\right|. \tag{26}$$

The conjugate function of the absolute deviation loss $\phi(a) = |a - y_i|$ is given by $\phi^*(-b) = -by_i$, with $b \in [-1, 1]$.

5.4 Local Solvers

As discussed in Section 3, the subproblems solved on each machine in the CoCoA framework are appealing in that they are very similar in structure to the global problem (A), with the main difference being that they are defined on a smaller (local) subset of the data, and have a simpler dependence on the term f. Therefore, solvers which have already proven their value in the single machine or multicore setting can be easily leveraged within the framework. We discuss some specific examples of local solvers below, and point the reader to Ma et al. (2017b) for an empirical exploration of these choices.

Local solvers for Algorithm 2. In the primal setting (Algorithm 2), the local subproblem (10) becomes a simple quadratic problem on the local data, with regularization applied only to local variables $\boldsymbol{\alpha}_{[k]}$. For the L_1-regularized examples discussed, existing fast L_1-solvers for the single-machine case, such as GLMNET variants (Friedman et al., 2010) or BLITZ (Johnson and Guestrin, 2015) can be directly applied to each local subproblem $\mathcal{G}_k^{\sigma'}(\,\cdot\,; \mathbf{v}, \boldsymbol{\alpha}_{[k]})$ within Algorithm 1. The sparsity induced on the subproblem solutions of each machine naturally translates into the sparsity of the global solution, since the local variables $\boldsymbol{\alpha}_{[k]}$ will be concatenated.

In terms of the approximation quality parameter Θ for the local problems (Assumption 1), we can apply existing recent convergence results from the single machine case. For example, for randomized coordinate descent (as part of GLMNET), Lu and Xiao (2013, Theorem 1) gives a $\mathcal{O}(1/t)$ approximation quality for any separable regularizer, including L_1 and elastic net; see also Tappenden et al. (2015) and Shalev-Shwartz and Tewari (2011).

Local solvers for Algorithm 3. In the dual setting (Algorithm 3) for the discussed examples, the losses are applied only to local variables $\boldsymbol{\alpha}_{[k]}$, and the regularizer is approximated via a quadratic term. Current state of the art for the problems of the form in (B) are variants of randomized coordinate ascent—Stochastic Dual Coordinate Ascent (SDCA) (Shalev-Shwartz and Zhang, 2013a). This algorithm and its variants are increasingly used in practice (Wright, 2015), and extensions such as accelerated and parallel versions can directly be applied (Shalev-Shwartz and Zhang, 2014; Fan et al., 2008) in our framework. For non-smooth losses such as SVMs, the analysis of Shalev-Shwartz and Zhang (2013a) provides a $\mathcal{O}(1/t)$ rate, and for smooth losses, a faster linear rate. There have also been recent efforts to derive a linear convergence rate for problems like the hinge-loss support vector machine that could be applied, e.g., by using error bound conditions (Necoara and Nedelcu, 2014; Wang and Lin, 2014), weak strong convexity conditions (Ma et al., 2015b; Necoara, 2015) or by considering Polyak-Łojasiewicz conditions (Karimi et al., 2016).

6. Experiments

In this section we demonstrate the empirical performance of CoCoA in the distributed setting. We first compare CoCoA to competing methods for two common machine learning applications: lasso regression (Section 6.1) and support vector machine (SVM) classification (Section 6.2). We then explore the performance of CoCoA in the primal versus the dual directly by solving an elastic net regression model with both variants (Section 6.3). Finally, we illustrate general properties of the CoCoA method empirically in Section 6.4.

Experimental setup. We compare CoCoA to numerous state-of-the-art general-purpose methods for large-scale optimization, including:

- Mb-SGD: Mini-batch stochastic gradient. For our experiments with lasso, we compare against Mb-SGD with an L_1-prox.
- GD: Full gradient descent. For lasso we use the proximal version, Prox-GD.
- L-BFGS: Limited-memory quasi-Newton method. For lasso, we use OWL-QN (orthant-wise limited quasi-Newton).
- ADMM: Alternating direction method of multipliers. We use conjugate gradient internally for the lasso experiments, and SDCA for SVM experiments.
- Mb-CD: Mini-batch parallel coordinate descent. For SVM experiments, we implement Mb-SDCA (mini-batch stochastic dual coordinate ascent).

The first three methods are optimized and implemented in Apache Spark's MLlib (v1.5.0) (Meng et al., 2016). We test the performance of each method in large-scale experiments fitting lasso, elastic net regression, and SVM models to the datasets shown in Table 5. In comparing to other methods, we plot the distance to the optimal primal solution. This optimal value is calculated by running all methods for a large number of iterations (until progress has stalled), and then selecting the smallest primal value amongst the results. All code is written in Apache Spark and experiments are run on public-cloud Amazon EC2 m3.xlarge machines with one core per machine. Our code is publicly available at `gingsmith.github.io/cocoa/`.

Table 5: Datasets for Empirical Study.

Dataset	Training Size	Feature Size	Sparsity
url	2 M	3 M	3.5e-5
epsilon	400 K	2 K	1.0
kddb	19 M	29 M	9.8e-7
webspam	350 K	16 M	2.0e-4

We carefully tune each competing method in our experiments for best performance. ADMM requires the most tuning, both in selecting the penalty parameter ρ and in solving the subproblems. Solving the subproblems to completion for ADMM is prohibitively slow, and we thus use an iterative method internally and improve performance by allowing early stopping. We also use a varying penalty parameter ρ — practices described in Boyd et al. (2010, Sections 4.3, 8.2.3, 3.4.1). For Mb-SGD, we tune the step size and mini-batch size parameters. For Mb-CD and Mb-SDCA, we scale the updates at each round by $\frac{\beta}{b}$ for mini-batch size b and $\beta \in [1, b]$, and tune both parameters b and β. Further implementation details for all methods are given in Section 6.5. For simplicity of presentation and comparison, in all of the following experiments, we restrict CoCoA to only use simple coordinate descent as the local solver. We note that even stronger empirical results for CoCoA could be obtained by plugging in state-of-the-art local solvers for each application at hand.

6.1 CoCoA in the Primal: An Application to Lasso Regression

We first demonstrate the performance of CoCoA in the primal (Algorithm 2) by applying CoCoA to a lasso regression model (8) fit to the datasets in Table 5. We use stochastic coordinate descent as a local solver for CoCoA, and select the number of local iterations H (a proxy for subproblem approximation quality, Θ) from several options with best performance.

We compare CoCoA to the general methods listed above, including Mb-SGD with an L_1-prox, Prox-GD, OWL-QN, ADMM, and Mb-CD. We provide a comparison with Shotgun (Bradley et al., 2011), a popular method for solving L_1-regularized problems in the multicore environment, as an extreme case to highlight the detrimental effects of frequent communication in the distributed environment. For Mb-CD, Shotgun, and CoCoA in the primal, datasets are distributed by feature, whereas for Mb-SGD, Prox-GD, OWL-QN and ADMM they are distributed by training point.

In analyzing the performance of each algorithm (Figure 1), we measure the improvement to the primal objective given in (A) ($\mathcal{O}_A(\boldsymbol{\alpha})$) in terms of wall-clock time in seconds. We see that both Mb-SGD and Mb-CD are slow to converge, and come with the additional burden of having to tune extra parameters (though Mb-CD makes clear improvements over Mb-SGD). As expected, naively distributing Shotgun (single coordinate updates per machine) does not perform well, as it is tailored to shared-memory systems and requires communicating too frequently. OWL-QN performs the best of all compared methods, but is still much slower to converge than CoCoA, and converges, e.g., 50× more slowly for the webspam dataset. The optimal performance of CoCoA is particularly evident in datasets

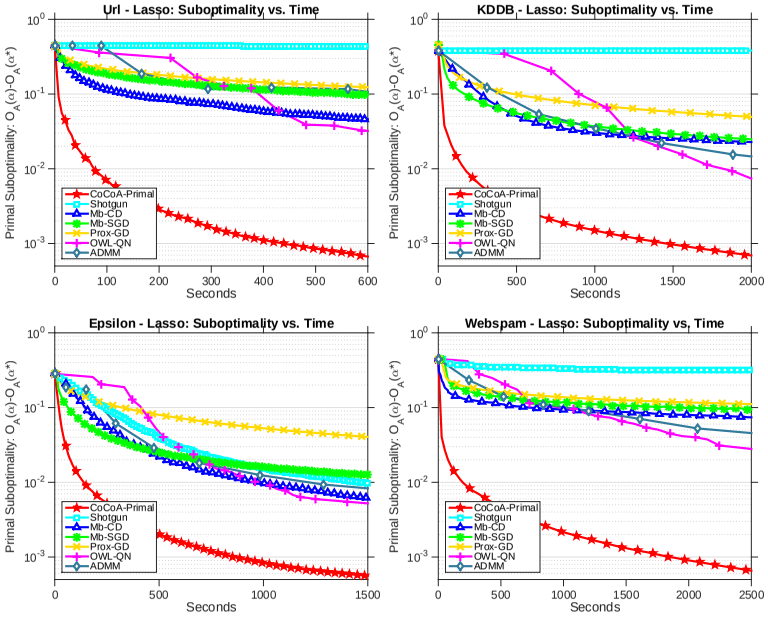

Figure 1: Suboptimality in terms of $\mathcal{O}_A(\boldsymbol{\alpha})$ for fitting a lasso regression model to four datasets: url (K=4, λ=1E-4), kddb (K=4, λ=1E-6), epsilon (K=8, λ=1E-5), and webspam (K=16, λ=1E-5) datasets. CoCoA applied to the primal formulation converges more quickly than all other compared methods in terms of the time in seconds.

with large numbers of features (e.g., url, kddb, webspam), which are exactly the datasets where L_1 regularization would most typically be applied.

Results are shown for regularization parameters λ such that the resulting weight vector $\boldsymbol{\alpha}$ is sparse. However, our results are robust to varying values of λ as well as to various problem settings, as we illustrate in Figure 2.

A case against smoothing. We additionally motivate the use of CoCoA in the primal by showing how it improves upon CoCoA in the dual (Yang, 2013; Jaggi et al., 2014; Ma et al., 2015a, 2017b) for non-strongly convex regularizers. First, CoCoA in the dual cannot be included in the set of experiments in Figure 1 because it cannot be directly applied to the lasso objective (recall that Algorithm 3 only allows for strongly convex regularizers).

To get around this requirement, previous work has suggested implementing the smoothing technique used in, e.g., Shalev-Shwartz and Zhang (2014); Zhang and Lin (2015) — adding a small amount of strong convexity $\delta\|\boldsymbol{\alpha}\|_2^2$ to the objective for lasso regression. In Figure 3 we demonstrate the issues with this approach, comparing CoCoA in the primal

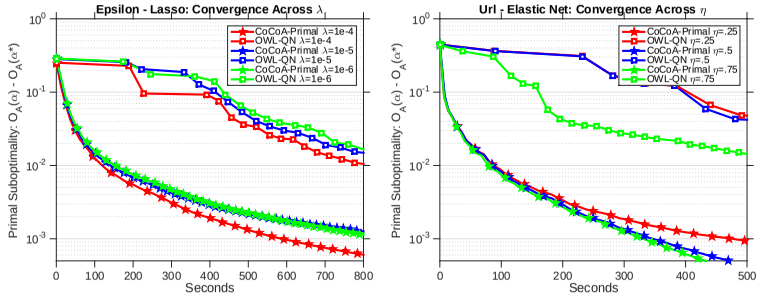

Figure 2: Suboptimality in terms of $\mathcal{O}_A(\boldsymbol{\alpha})$ for solving lasso for the epsilon dataset (left, K=8) and elastic net for the url dataset, (right, K=4, λ=1E-4). Speedups are robust over different regularizers λ (left), and across problem settings, including varying η parameters of elastic net regularization (right).

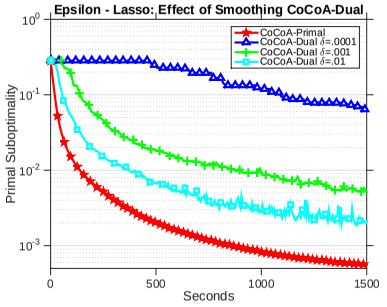

Table 6: Sparsity of Final Iterates.

Method	Sparsity
CoCoA-Primal	0.6030
CoCoA-Dual: $\delta = 0.0001$	0.6035
CoCoA-Dual: $\delta = 0.001$	0.6240
CoCoA-Dual: $\delta = 0.01$	0.6465

Figure 3 & Table 6: For pure L_1 regularization, smoothing is not an effective option for CoCoA in the dual. It either modifies the solution (Figure 3) or slows convergence (Table 6). This motivates running CoCoA instead on the primal for these problems.

on a pure L_1-regularized regression problem to CoCoA in the dual for decreasing levels of δ. The smaller we set δ, the less smooth the problem becomes. As δ decreases, the final sparsity of running CoCoA in the dual starts to match that of running pure L_1 (Table 6), but the performance also degrades (Figure 3). We note that by using CoCoA in the primal with the modification presented in Section 4, we can deliver strong rates without having to make any compromises in terms of the training speed or accuracy.

6.2 CoCoA in the Dual: An Application to SVM Classification

Next we present results on CoCoA in the dual against competing methods, for a hinge loss support vector machine model (9) on the datasets in Table 5. We use stochastic dual

coordinate ascent (SDCA) as a local solver for CoCoA in this setting, again selecting the number of local iterations H from several options with best performance. We compare CoCoA to the general methods listed above, including Mb-SGD, GD, L-BFGS, ADMM, and Mb-SDCA. All datasets are distributed by training point for these methods.

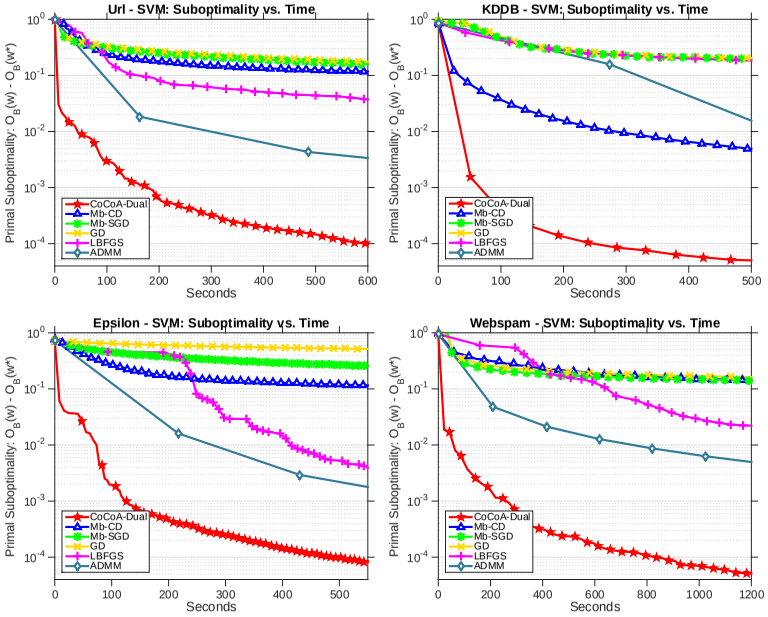

Figure 4: Suboptimality in terms of $\mathcal{O}_B(\mathbf{w})$ for solving a hinge-loss support vector machine model: url (K=4, λ=1e-4), kddb (K=4, λ=1e-6), epsilon (K=8, λ=1e-5), and webspam (K=16, λ=1e-5) datasets. CoCoA applied to the dual formulation converges more quickly than all other compared methods in terms of the time in seconds.

In comparing methods in this setting (Figure 4), we measure the improvement to the primal objective $\mathcal{O}_B(\mathbf{w})$ in terms of wall-clock time in seconds. We see again that Mb-SGD and Mb-CD are slow to converge, and come with the additional burden of having to tune extra parameters. ADMM performs the best of the methods other than CoCoA, followed by L-BFGS. However, both are still much slower to converge than CoCoA in the dual. ADMM in particular is affected by the fact that many internal iterations of SDCA are necessary in order to guarantee convergence. In contrast, CoCoA can incorporate arbitrary amounts of work locally and still converge. We note that although CoCoA, ADMM, and Mb-SDCA run in the dual, Figure 4 tracks progress towards the primal objective, $\mathcal{O}_B(\mathbf{w})$.

6.3 Primal vs. Dual: An Application to Elastic Net Regression

To compare primal vs. dual optimization for CoCoA, we explore both variants by fitting an elastic net regression model (7) to two datasets. We use coordinate descent (with closed-form updates) as the local solver in both variants. From the results in Figure 5, we see that CoCoA in the dual tends to perform better on datasets with a large number of training points (relative to the number of features), and that the performance deteriorates as the strong convexity in the problem disappears. In contrast, CoCoA in the primal performs well on datasets with a large number of features relative to training points, and is robust to changes in strong convexity. These changes in performance are to be expected, as we have discussed that CoCoA in the primal is more suited for non-strongly convex regularizers (Section 6.1), and that the feature size dominates communication for CoCoA in the dual, as compared to the training point size for CoCoA in the primal (Section 3.4).

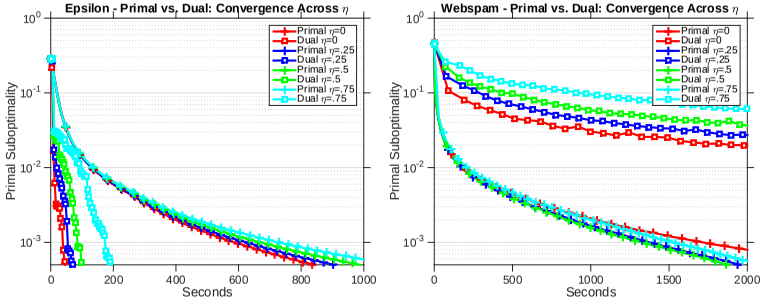

Figure 5: The convergence of CoCoA in the primal versus dual for various values of η in an elastic net regression model. CoCoA in dual performs better on the Epsilon dataset, where the training point size is the dominating term, and CoCoA in the primal performs better on the Webspam dataset, where the feature size is the dominating term. For both datasets, CoCoA in the dual is susceptible to changes in strong convexity—converging more quickly as the problem becomes more strongly convex ($\eta \to 0$), whereas CoCoA in the primal remains robust to changes in strong convexity.

6.4 General Properties: Effect of Communication

Finally, we note that in contrast to the compared methods from Sections 6.1 and 6.2, CoCoA comes with the benefit of having only a single parameter to tune: the subproblem approximation quality, Θ, which we control in our experiments via the number of local subproblem iterations, H, for the example of local coordinate descent. We further explore the effect of this parameter in Figure 6, and provide a general guideline for choosing it in practice (see Remark 1). In particular, we see that while increasing H always results in better performance in terms of the number of communication rounds, smaller or larger values of H may result in better performance in terms of wall-clock time, depending on the cost of communication and computation. The flexibility to fine-tune H is one of the reasons for CoCoA's significant performance gains.

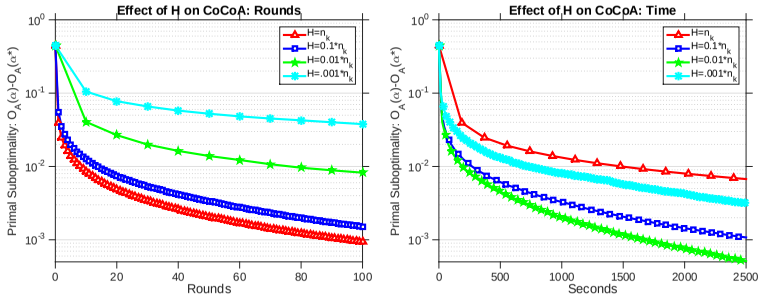

Figure 6: Suboptimality in terms of $\mathcal{O}_A(\boldsymbol{\alpha})$ for solving lasso for the webspam dataset (K=16, λ=1e-5). Here we illustrate how the work spent in the local subproblem (given by H) affects the total performance of CoCoA in terms of number of rounds as well as wall time.

6.5 Experiment Details

In this subsection we provide thorough details on the experimental setup and methods used in our comparison. All experiments are run on Amazon EC2 clusters of m3.xlarge machines, with one core per machine. The code for each method is written in Apache Spark, v1.5.0. Our code is open source and publicly available at `gingsmith.github.io/cocoa/`.

ADMM. ADMM (Boyd et al., 2010) is a popular method that lends itself naturally to the distributed environment. For lasso regression, implementing ADMM for the problems of interest requires solving a large linear system $C\mathbf{x} = \mathbf{d}$ on each machine, where $C \in \mathbb{R}^{n\times n}$ with n scaling beyond 10^7 for the datasets in Table 5, and with C being possibly dense. It is prohibitively slow to solve this directly on each machine, and we therefore employ conjugate gradient with early stopping (see, e.g., Boyd et al., 2010, Section 4.3). For SVM classification, we use stochastic dual coordinate ascent as an internal optimizer, which is shown in Zhang et al. (2012) to have superior performance. We further improve performance with a varying rather than constant penalty parameter, as suggested in Boyd et al., 2010, Section 3.4.1.

Mini-batch SGD and proximal GD. Mini-batch SGD is a standard and widely used method for parallel and distributed optimization. We use the optimized code provided in Spark's machine learning library, MLlib, v1.5.0 (Meng et al., 2016). We tune both the size of the mini-batch and SGD step size using grid search. For lasso, we use the proximal version of the method. Full gradient descent can be seen as a specific setting of mini-batch SGD, where the mini-batch size is equal to the total number of training points. We thus also use the implementation in MLlib for full GD, and tune the step size parameter using grid search.

Mini-batch CD and SDCA. Mini-batch CD (for lasso) and SDCA (for SVM) aim to improve mini-batch SGD by employing coordinate descent, which has theoretical and practical justifications (Shalev-Shwartz and Tewari, 2011; Takáč et al., 2013; Fercoq and Richtárik, 2015). We implement mini-batch CD and SDCA in Spark and scale the updates made at each round by $\frac{\beta}{b}$ for mini-batch size b and $\beta \in [1, b]$, tuning both parameters b and

β via grid search. For the case of lasso regression, we implement Shotgun (Bradley et al., 2011), which is a popular method for parallel optimization. Shotgun can be seen an extreme case of mini-batch CD where the mini-batch is set to K, i.e., there is a single update made by each machine per round. We see in the experiments that communicating this frequently becomes prohibitively slow in the distributed environment.

OWL-QN. OWN-QN (Yu et al., 2010) is a quasi-Newton method optimized in Spark's spark.ml package (Meng et al., 2016). Outer iterations of OWL-QN make significant progress towards convergence, but the iterations themselves can be slow as they require processing the entire dataset. CoCoA, the mini-batch methods, and ADMM with early stopping all improve on this by allowing the flexibility to process only a subset of the dataset at each iteration. CoCoA and ADMM have even greater flexibility by allowing internal methods to process the dataset more than once. CoCoA makes this approximation quality explicit, both in theoretical convergence rates and via guidelines for setting the parameter.

CoCoA. We implement CoCoA with coordinate descent as the local solver. We note that since the framework and theory allow any internal solver to be used, CoCoA could benefit even beyond the results shown, e.g., by using existing fast L_1-solvers for the single-machine case, such as glmnet variants (Friedman et al., 2010) or blitz (Johnson and Guestrin, 2015) or SVM solvers like liblinear (Fan et al., 2008). The only parameter influencing the overall performance of CoCoA is the level of approximation quality, which we parameterize in the experiments through H, the number of local iterations of the iterative method run locally. Our theory relates local approximation quality to global convergence (Section 4), and we provide a guideline for how to choose this value in practice that links the parameter to the systems environment at hand (Remark 1).

7. Related Work

There exist myriad optimization methods for the distributed setting; the following section is not meant to be wholly comprehensive, but to provide an overview of the most prevalent and related approaches. We additionally note that many new methods have been proposed since the time of submission of this manuscript in October 2016, including several extensions of the presented CoCoA framework—e.g., for federated learning (Smith et al., 2017), computing over heterogeneous systems (Dünner et al., 2017), second-order algorithm extensions (Gargiani, 2017; Lee and Chang, 2017; Dünner et al., 2018; Lee et al., 2018), and accelerated methods (Ma et al., 2017a; Zheng et al., 2017). We defer the readers to these follow-up works for the most current literature review.

Single-machine coordinate solvers. For strongly convex regularizers, state-of-the-art for empirical loss minimization is randomized coordinate ascent on the dual (SDCA) (Shalev-Shwartz and Zhang, 2013a) and accelerated variants (e.g., Shalev-Shwartz and Zhang, 2014). In contrast to primal stochastic gradient descent (SGD) methods, the SDCA family is often preferred as it is free of learning rate parameters and has faster (geometric) convergence guarantees. Interestingly, a similar trend in coordinate solvers exists in recent lasso literature, but with the roles of primal and dual reversed. For those problems, primal-based coordinate descent methods are state-of-the-art, as in glmnet (Friedman et al., 2010) and extensions (Yuan et al., 2012); see, e.g., the overview in Yuan et al. (2010). However, primal-

dual rates for unmodified coordinate methods have to our knowledge only been obtained for strongly convex regularizers to date (Shalev-Shwartz and Zhang, 2014; Zhang and Lin, 2015).

Coordinate descent on L_1-regularized problems (i.e., (A) with $g(\cdot) = \lambda\|\cdot\|_1$) can be interpreted as the iterative minimization of a quadratic approximation of the smooth part of the objective, followed by a shrinkage step. In the single-coordinate update case, this is at the core of GLMNET (Friedman et al., 2010; Yuan et al., 2010), and widely used in, e.g., solvers based on the primal formulation of L_1-regularized objectives (Shalev-Shwartz and Tewari, 2011; Yuan et al., 2012; Bian et al., 2013; Fercoq and Richtárik, 2015; Tappenden et al., 2015). When changing more than one coordinate at a time, again employing a quadratic upper bound on the smooth part, this results in a two-loop method as in GLMNET for the special case of logistic regression. In the distributed setting, when the set of active coordinates coincides with the ones on the local machine, these single-machine approaches closely resemble the distributed framework proposed here.

Parallel methods. For the general regularized loss minimization problems of interest, methods based on stochastic subgradient descent (SGD) are well-established. Several variants of SGD have been proposed for parallel computing, many of which build on the idea of asynchronous communication (Niu et al., 2011; Duchi et al., 2013). Despite their simplicity and competitive performance on shared-memory systems, the downside of this approach in the distributed environment is that the amount of required communication is equal to the amount of data read locally, since one data point is accessed per machine per round (e.g., mini-batch SGD with a batch size of one per worker). These variants are in practice not competitive with the more communication-efficient methods considered in this work, which allow more local updates per communication round.

For the specific case of L_1-regularized objectives, parallel coordinate descent (with and without using mini-batches) was proposed in Bradley et al. (2011) (Shotgun) and generalized in Bian et al. (2013) , and is among the best performing solvers in the parallel setting. Our framework reduces to Shotgun as a special case when the internal solver is a single-coordinate update on the subproblem (10), $\gamma = 1$, and for a suitable σ'. However, Shotgun is not covered by our convergence theory, since it uses a potentially unsafe upper bound of β instead of σ', which isn't guaranteed to satisfy our condition for convergence (11). We compare empirically with Shotgun in Section 6 to highlight the detrimental effects of running this high-communication method in the distributed environment.

One-shot communication schemes. At the other extreme, there are distributed methods that use only a single round of communication, such as Mann et al. (2009); Zinkevich et al. (2010); Zhang et al. (2013); McWilliams et al. (2014); and Heinze et al. (2016). These methods require additional assumptions on the partitioning of the data, which are usually not satisfied in practice if the data are distributed "as is", i.e., if we do not have the opportunity to distribute the data in a specific way beforehand. Furthermore, some cannot guarantee convergence rates beyond what could be achieved if we ignored data residing on all but a single computer, as shown in Shamir et al. (2014). Additional relevant lower bounds on the minimum number of communication rounds necessary for a given approximation quality are presented in Balcan et al. (2012) and Arjevani and Shamir (2015).

Mini-batch methods. Mini-batch methods (which use updates from several training points or features per round) are more flexible and lie within the two extremes of parallel and one-shot communication schemes. However, mini-batch versions of both SGD and coordinate descent (CD) (e.g., Dekel et al., 2012; Takáč et al., 2013; Shalev-Shwartz and Zhang, 2013b; Shamir and Srebro, 2014; Qu et al., 2015; Richtárik and Takáč, 2016; Défossez and Bach, 2017) suffer from their convergence rate degrading towards the rate of batch gradient descent as the size of the mini-batch is increased. This follows because mini-batch updates are made based on the outdated previous parameter vector $\mathbf{w}$, in contrast to methods that allow immediate local updates like CoCoA.

Another disadvantage of mini-batch methods is that the aggregation parameter is more difficult to tune, as it can lie anywhere in the order of mini-batch size. The optimal choice is often either unknown or too challenging to compute in practice. In the CoCoA framework there is no need to tune parameters, as the aggregation parameter and subproblem parameters can be set directly using the safe bound discussed in Section 3 (Definition 5).

Batch solvers. ADMM (Boyd et al., 2010), gradient descent, and quasi-Newton methods such as L-BFGS and are also often used in distributed settings because of their relatively low communication requirements. However, they require at least a full (distributed) batch gradient computation at each round, and therefore do not allow the gradual trade-off between communication and computation provided by CoCoA. In Section 6, we include experimental comparisons with ADMM, gradient descent, and L-BFGS variants, including orthant-wise limited memory quasi-Newton (OWL-QN) for the L_1 setting (Andrew and Gao, 2007).

Finally, we note that while the convergence rates provided for CoCoA mirror the convergence class of classical batch gradient methods in terms of the number of outer rounds, existing batch gradient methods come with a weaker theory, as they do not allow general inexactness Θ for the local subproblem (10). In contrast, our convergence rates incorporate this approximation directly, and, moreover, hold for arbitrary local solvers of much cheaper cost than batch methods (where in each round, every machine has to process exactly a full pass through the local data). This makes CoCoA more flexible in the distributed setting, as it can adapt to varied communication costs on real systems. We have seen in Section 6 that this flexibility results in significant performance gains over the competing methods.

Distributed solvers. By making use of the primal-dual structure in the line of work of Yu et al. (2012); Pechyony et al. (2011); Yang (2013); Yang et al. (2013) and Lee and Roth (2015), the CoCoA-v1 and CoCoA$^+$ frameworks (which are special cases of the presented framework, CoCoA) are the first to allow the use of any local solver—of weak local approximation quality—in each round in the distributed setting. The practical variant of the DisDCA (Yang, 2013), called DisDCA-p, allows for additive updates in a similar manner to CoCoA, but is restricted to coordinate decent (CD) being the local solver, and was initially proposed without convergence guarantees. DisDCA-p, CoCoA-v1, and CoCoA$^+$ are all limited to strongly convex regularizers, and therefore are not as general as the CoCoA framework discussed in this work.

In the L_1-regularized setting, an approach related to our framework includes distributed variants of GLMNET as in Mahajan et al. (2017). Inspired by GLMNET and Yuan et al. (2012), the works of Bian et al. (2013) and Mahajan et al. (2017) introduced the idea of a block-diagonal Hessian upper approximation in the distributed L_1 context. The later work of Trofimov and Genkin (2014, 2016) specialized this approach to sparse logistic regression.

If hypothetically each of our quadratic subproblems $\mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]})$ as defined in (10) were to be minimized exactly, the resulting steps could be interpreted as block-wise Newton-type steps on each coordinate block k, where the Newton-subproblem is modified to also contain the L_1-regularizer (Mahajan et al., 2017; Yuan et al., 2012; Qu et al., 2016). While Mahajan et al. (2017) allows a fixed accuracy for these subproblems, but not arbitrary approximation quality Θ as in our framework, the works of Trofimov and Genkin (2016); Yuan et al. (2012); and Yen et al. (2015) assume that the quadratic subproblems are solved exactly. Therefore, these methods are not able to freely trade off communication and computation. Also, they do not allow the re-use of arbitrary local solvers. On the theoretical side, the convergence rate results provided by Mahajan et al. (2017); Trofimov and Genkin (2016); and Yuan et al. (2012) are not explicit convergence rates but only asymptotic, as the quadratic upper bounds are not explicitly controlled for safety as with our σ'.

8. Discussion

To enable large-scale machine learning and signal processing, we have developed, analyzed, and evaluated a general-purpose framework for communication-efficient primal-dual optimization in the distributed environment. Our framework, CoCoA, takes a unique approach by using duality to derive subproblems for each machine to solve in parallel. These subproblems closely match the global problem of interest, which allows for state-of-the-art single-machine solvers to easily be re-used in the distributed setting. Further, by allowing the local solvers to find solutions of arbitrary approximation quality to the subproblems on each machine, our framework permits a highly flexible communication scheme. In particular, as the local solvers make updates directly to their local parameters, the need to communicate reduces and can be adapted to the system at hand, which helps to manage the communication bottleneck in the distributed setting.

We analyzed the impact of the local solver approximation quality and derived global primal-dual convergence rates for our framework that are agnostic to the specifics of the local solvers. We have taken particular care in extending our framework to the case of non-strongly convex regularizers, where we introduced a bounded-support modification technique to provide robust convergence guarantees. Finally, we demonstrated the efficiency of our framework in an extensive experimental comparison with state-of-the-art distributed solvers. Our framework achieves up to a 50× speedup over other widely-used methods on real-world distributed datasets.

Acknowledgments

We thank Michael P. Friedlander, Matilde Gargiani, Sai Praneeth Karimireddy, Jakub Konečný, Ching-pei Lee, and Peter Richtárik for their help and for fruitful discussions. We are additionally grateful to the reviewers for their valuable comments. Appendix A. Convex Conjugates

The convex conjugate of a function $f : \mathbb{R}^m \to \mathbb{R}$ is defined as

$$f^*(\mathbf{v}) := \max_{\mathbf{u}\in\mathbb{R}^m} \mathbf{v}^\top\mathbf{u} - f(\mathbf{u})\,. \tag{27}$$

Below we list several useful properties of conjugates (see, e.g., Boyd and Vandenberghe, 2004, Section 3.3.2):

- Double conjugate: $(f^*)^* = f$ if f is closed and convex.
- Value Scaling: (for $\alpha > 0$) $f(\mathbf{v}) = \alpha g(\mathbf{v}) \quad \Rightarrow \quad f^*(\mathbf{w}) = \alpha g^*(\mathbf{w}/\alpha)\,.$
- Argument Scaling: (for $\alpha \neq 0$) $f(\mathbf{v}) = g(\alpha\mathbf{v}) \quad \Rightarrow \quad f^*(\mathbf{w}) = g^*(\mathbf{w}/\alpha)\,.$
- Conjugate of a separable sum: $f(\mathbf{v}) = \sum_i \phi_i(v_i) \quad \Rightarrow \quad f^*(\mathbf{w}) = \sum_i \phi_i^*(w_i)\,.$

Lemma 4 (Duality between Lipschitzness and L-Bounded Support, (Rockafellar, 1997, Corollary 13.3.3)). *Given a proper convex function f, it holds that f is L-Lipschitz if and only if f^* has L-bounded support.*

Lemma 5 (Duality between Smoothness and Strong Convexity, (Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.2.2)). *Given a closed convex function f, it holds that f is μ strongly convex w.r.t. the norm $\|\cdot\|$ if and only if f^* is $(1/\mu)$-smooth w.r.t. the dual norm $\|\cdot\|_*$.*

Appendix B. Proofs of Primal-Dual Relationships

In the following subsections we provide derivations of the primal-dual relationship of the general objectives (A) and (B), and then show how to derive the conjugate of the modified L_1-norm, as an example of the bounded-support modification introduced in Section 4.

B.1 Primal-Dual Relationship

The relation of the original formulation (A) to its dual formulation (B) is standard in convex analysis. Using the linear map A as in our case, the relationship is an instance of Fenchel-Rockafellar Duality, see e.g. Borwein and Zhu (2005, Theorem 4.4.2) or Bauschke and Combettes (2011, Proposition 15.18). For completeness, we illustrate this correspondence with a self-contained derivation of the duality.

Starting with the original formulation (A), we introduce an auxiliary vector $\mathbf{v} \in \mathbb{R}^m$ representing $\mathbf{v} = A\boldsymbol{\alpha}$. Then optimization problem (A) becomes:

$$\min_{\boldsymbol{\alpha},\mathbf{v}} \quad f(\mathbf{v}) + g(\boldsymbol{\alpha}) \quad \text{such that } \mathbf{v} = A\boldsymbol{\alpha}\,. \tag{28}$$

Introducing Lagrange multipliers $\mathbf{w} \in \mathbb{R}^m$, the Lagrangian is given by:

$$L(\boldsymbol{\alpha}, \mathbf{v}; \mathbf{w}) := f(\mathbf{v}) + g(\boldsymbol{\alpha}) + \mathbf{w}^\top (A\boldsymbol{\alpha} - \mathbf{v})\,.$$

The dual problem of (A) follows by taking the infimum with respect to both $\boldsymbol{\alpha}$ and $\mathbf{v}$:

$$\begin{aligned}\inf_{\boldsymbol{\alpha},\mathbf{v}} L(\mathbf{w},\boldsymbol{\alpha},\mathbf{v}) &= \inf_{\mathbf{v}}\left\{f(\mathbf{v}) - \mathbf{w}^\top\mathbf{v}\right\} + \inf_{\boldsymbol{\alpha}}\left\{g(\boldsymbol{\alpha}) + \mathbf{w}^\top A\boldsymbol{\alpha}\right\}\\ &= -\sup_{\mathbf{v}}\left\{\mathbf{w}^\top\mathbf{v} - f(\mathbf{v})\right\} - \sup_{\boldsymbol{\alpha}}\left\{(-\mathbf{w}^\top A)\boldsymbol{\alpha} - g(\boldsymbol{\alpha})\right\}\\ &= -f^*(\mathbf{w}) - g^*(-A^\top\mathbf{w})\,. \end{aligned} \tag{29}$$

We change signs and turn the maximization of the dual problem (29) into a minimization, thereby arriving at the dual formulation (B) as claimed:

$$\min_{\mathbf{w}\in\mathbb{R}^m} \quad \Big[\ \mathcal{O}_B(\mathbf{w}) := f^*(\mathbf{w}) + g^*(-A^\top\mathbf{w})\ \Big]\,.$$

B.2 Continuous Conjugate Modification for Indicator Functions

Lemma 6 (Conjugate of the modified L_1-norm)**.** *The convex conjugate of the bounded support modification of the L_1-norm, as defined in* (18)*, is:*

$$\bar{g}_i^*(x) := \begin{cases} 0 & : x \in [-1,1],\\ B(|x|-1) & : \textit{otherwise,}\end{cases}$$

and is B-Lipschitz.

Proof. We start by applying the definition of convex conjugate:

$$\bar{g}_i(\alpha) = \sup_{x\in\mathbb{R}}\left[\alpha x - \bar{g}_i^*(x)\right]\,.$$

We begin by looking at the case in which $\alpha \geq B$; in this case it's easy to see that when $x \to +\infty$, we have:

$$\alpha x - B(|x|-1) = (\alpha - B)x - B \to +\infty\,,$$

as $\alpha - B \geq 0$. The case $\alpha \leq -B$ holds analogously. We'll now look at the case $\alpha \in [0,B]$; in this case it is clear we must have $x^\star \geq 0$. It also must hold that $x^\star \leq 1$, since

$$\alpha x - B(x-1) < \alpha x\,,$$

for every $x > 1$. Therefore the maximization becomes

$$\bar{g}_i(\alpha) = \sup_{x\in[0,1]} \alpha x\,,$$

which has maximum α at $x = 1$. The remaining $\alpha \in [-B,0]$ case follows in similar fashion.

Lipschitz continuity of $\bar{g}_i^*$ follows directly, or alternatively also from the general result that g_i^* is L-Lipschitz if and only if g_i has L-bounded support (Rockafellar, 1997, Corollary 13.3.3) or (Dünner et al., 2016, Lemma 5). □

Appendix C. Comparison to ADMM

C.1 ADMM Applied to the $\mathcal{O}_B(\cdot)$ Formulation

Here we compare consensus ADMM (Mota et al., 2013) applied to the problem (B) to the CoCoA framework, as discussed in Section 3.5. For consensus ADMM, the objective $\mathcal{O}_B(\cdot)$ can be decomposed using the following re-parameterization:

$$\begin{aligned}\min_{\mathbf{w}_1,\ldots\mathbf{w}_K,\mathbf{w}} \quad & \sum_{k=1}^K\sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k) + f^*(\mathbf{w})\\ s.t. \quad & \mathbf{w}_k = \mathbf{w},\ k = 1,\ldots,K.\end{aligned}$$

To solve this problem, we construct the augmented Lagrangian:

$$\begin{aligned}L_\rho(\mathbf{w}_1,\ldots,\mathbf{w}_k,\mathbf{w},\mathbf{u}_1,\ldots,\mathbf{u}_k) := &\sum_{k=1}^K\sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k)\\ &+ f^*(\mathbf{w}) + \sum_{k=1}^K\mathbf{u}_k^\top(\mathbf{w}_k - \mathbf{w}) + \frac{\rho}{2}\sum_{k=1}^K\|\mathbf{w}_k - \mathbf{w}\|^2\,,\end{aligned}$$

which yields the following decomposable updates:

$$\begin{aligned}\mathbf{w}_k^{(t+1)} &= \arg\min_{\mathbf{w}_k} \sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k) + \mathbf{u}_k^{(t)\top}(\mathbf{w}_k - \mathbf{w}^{(t)}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}^{(t)}\|^2,\\ \mathbf{w}^{(t+1)} &= \arg\min_{\mathbf{w}} f^*(\mathbf{w}) + \sum_{k=1}^K\mathbf{u}_k^{(t)\top}(\mathbf{w}_k^{(t+1)} - \mathbf{w}) + \frac{\rho}{2}\sum_{k=1}^K\|\mathbf{w}_k^{(t+1)} - \mathbf{w}\|^2,\\ \mathbf{u}_k^{(t+1)} &= \mathbf{u}_k^{(t)} + \rho(\mathbf{w}_k^{(t+1)} - \mathbf{w}^{(t+1)}).\end{aligned}$$

These updates can be further simplified by using the scaled form of $\mathbf{u}_k$ and combining terms for $\mathbf{w}$ using the averages $\bar{\mathbf{w}}_k$ and $\bar{\mathbf{u}}_k$:

$$\begin{aligned}\mathbf{w}_k^{(t+1)} &= \arg\min_{\mathbf{w}_k} \sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k) + \rho\mathbf{u}_k^{(t)\top}(\mathbf{w}_k - \mathbf{w}^{(t)}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}^{(t)}\|^2,\\ \mathbf{w}^{(t+1)} &= \arg\min_{\mathbf{w}} f^*(\mathbf{w}) + \frac{\rho K}{2}\|\mathbf{w} - (\bar{\mathbf{w}}_k^{(t+1)} + \bar{\mathbf{u}}_k^{(t)})\|^2,\\ \mathbf{u}_k^{(t+1)} &= \mathbf{u}_k^{(t)} + \mathbf{w}_k^{(t+1)} - \mathbf{w}^{(t+1)}.\end{aligned}$$

To compare this to the CoCoA subproblems (10), we will derive the dual form of the update to $\mathbf{w}_k$. Suppressing the iteration counter for simplicity, the minimization is of the form:

$$\begin{aligned}&\min_{\mathbf{w}_k} \sum_{i\in\mathcal{P}_k} g_i^*(-\mathbf{x}_i^\top\mathbf{w}_k) + \rho\mathbf{u}_k{}^\top(\mathbf{w}_k - \mathbf{w}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}\|^2\\ =&\min_{\mathbf{w}_k} \sum_{i\in\mathcal{P}_k} \max_{\alpha_i} -\mathbf{x}_i^\top\mathbf{w}_k\alpha_i - g_i(\alpha_i) + \rho\mathbf{u}_k{}^\top(\mathbf{w}_k - \mathbf{w}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}\|^2\\ =&\max_{\boldsymbol{\alpha}_{[k]}}\min_{\mathbf{w}_k} -\mathbf{w}_k^\top A_{[k]}\boldsymbol{\alpha}_{[k]} - \sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{[k]i}) + \rho\mathbf{u}_k{}^\top(\mathbf{w}_k - \mathbf{w}) + \frac{\rho}{2}\|\mathbf{w}_k - \mathbf{w}\|^2\,.\end{aligned}$$

Solving the minimization yields: $\mathbf{w}_k = \frac{1}{\rho} A_{[k]}\boldsymbol{\alpha}_{[k]} - \mathbf{u}_k + \mathbf{w}$. Plugging this back in, we have:

$$\begin{aligned}
&\max_{\boldsymbol{\alpha}_{[k]}} \sum_{i\in\mathcal{P}_k} -g_i(\boldsymbol{\alpha}_{[k]_i}) - (\frac{1}{\rho}A_{[k]}\boldsymbol{\alpha}_{[k]} - \mathbf{u}_k + \mathbf{w})^\top A_{[k]}\boldsymbol{\alpha}_{[k]} + \rho\mathbf{u}_k{}^\top(\frac{1}{\rho}A_{[k]}\boldsymbol{\alpha}_{[k]} - \mathbf{u}_k) + \frac{\rho}{2}\|\frac{1}{\rho}A_{[k]}\boldsymbol{\alpha}_{[k]} - \mathbf{u}_k\|^2 \\
=&\max_{\boldsymbol{\alpha}_{[k]}} \sum_{i\in\mathcal{P}_k} -g_i(\boldsymbol{\alpha}_{[k]_i}) + \mathbf{u}_k^\top A_{[k]}\boldsymbol{\alpha}_{[k]} - \mathbf{w}^\top A_{[k]}\boldsymbol{\alpha}_{[k]} - \frac{1}{2\rho}\|A_{[k]}\boldsymbol{\alpha}_{[k]}\|^2 \\
=&\min_{\boldsymbol{\alpha}_{[k]}} \sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{[k]_i}) + (\mathbf{w} - \mathbf{u}_k)^\top A_{[k]}\boldsymbol{\alpha}_{[k]} + \frac{1}{2\rho}\|A_{[k]}\boldsymbol{\alpha}_{[k]}\|^2 .
\end{aligned}$$

We therefore see that the update to $\mathbf{w}_k$ has a similar form to the CoCoA subproblem (10), where $\rho := \frac{\tau}{\sigma'}$.

C.2 ADMM Applied to the $\mathcal{O}_A(\cdot)$ Formulation

We can also compare CoCoA to ADMM as applied to the (A) problem. For consensus ADMM, the objective $\mathcal{O}_A(\cdot)$ can be decomposed using the following re-parametrization, which introduces local copies $\boldsymbol{\alpha}_k$ of the global variable $\boldsymbol{\alpha}$, and a set of consensus constraints to achieve the equality between them:

$$\begin{aligned}
\min_{\boldsymbol{\alpha},\boldsymbol{\alpha}_1,\dots\boldsymbol{\alpha}_K} \quad & f(A\boldsymbol{\alpha}) + \sum_{k=1}^K \sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{k,i}) \\
s.t. \quad & A_{[k]}\boldsymbol{\alpha} = A_{[k]}\boldsymbol{\alpha}_k,\ k = 1,\dots,K.
\end{aligned}$$

To solve this problem, we construct the augmented Lagrangian with a penalty parameter ρ:

$$\begin{aligned}
L_\rho(\tilde{\boldsymbol{\alpha}}, \boldsymbol{\alpha}_1, \dots, \boldsymbol{\alpha}_K, \mathbf{w}_1, \dots, \mathbf{w}_k) := f(A\tilde{\boldsymbol{\alpha}}) + \\
\sum_{k=1}^K \left[\sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{k,i}) + \mathbf{w}_k^\top A_{[k]}(\boldsymbol{\alpha}_k - \boldsymbol{\alpha}) + \frac{\rho}{2}\|A_{[k]}(\boldsymbol{\alpha}_k - \boldsymbol{\alpha})\|_2^2 \right]
\end{aligned}$$

which yields to the following decomposable updates:

$$\begin{aligned}
\boldsymbol{\alpha}_k^{(t)} &= \arg\min_{\boldsymbol{\alpha}_k} \sum_{i\in\mathcal{P}_k} g_i(\boldsymbol{\alpha}_{k,i}) + \mathbf{w}_k^{(t-1)\top} A_{[k]}(\boldsymbol{\alpha}_k - \boldsymbol{\alpha}^{(t-1)}) + \frac{\rho}{2}\|A_{[k]}(\boldsymbol{\alpha}_k - \boldsymbol{\alpha}^{(t-1)})\|_2^2, \\
\boldsymbol{\alpha}^{(t)} &= \arg\min_{\boldsymbol{\alpha}} f(A\boldsymbol{\alpha}) + \sum_{k=1}^K \left[\mathbf{w}_k^{(t-1)\top} A_{[k]}(\boldsymbol{\alpha}_k^{(t)} - \boldsymbol{\alpha}) + \frac{\rho}{2}\|A_{[k]}(\boldsymbol{\alpha}_k^{(t)} - \boldsymbol{\alpha})\|_2^2 \right], \\
\mathbf{w}_k^{(t)} &= \mathbf{w}_k^{(t-1)} + \rho A_{[k]}(\boldsymbol{\alpha}_k^{(t)} - \boldsymbol{\alpha}^{(t)}).
\end{aligned}$$

The first minimization is solved locally in a distributed manner by the K partitions. By setting $\rho := \frac{\sigma'}{\tau}$ and applying the change of variables $\Delta\boldsymbol{\alpha}_{[k]} = (\boldsymbol{\alpha}_k - \boldsymbol{\alpha}^{(t-1)})$, we can obtain the CoCoA local subproblems (10):

$$\Delta\boldsymbol{\alpha}_{[k]}{}^{(t)} = \arg\min_{\Delta\boldsymbol{\alpha}_{[k]}} \sum_{i\in\mathcal{P}_k} g(\alpha_i^{(t-1)} + \Delta\boldsymbol{\alpha}_{[k]_i}) + \mathbf{w}^{(t-1)\top} A_{[k]}\Delta\boldsymbol{\alpha}_{[k]} + \frac{\sigma'}{2\tau}\|A_{[k]}\Delta\boldsymbol{\alpha}_{[k]}\|^2$$

Note that the update to $\boldsymbol{\alpha}$ in its current form is not separable and must be solved via some distributed optimization procedure. The comparison to the $\mathcal{O}_B(\cdot)$ formulation is more natural in this sense, as it captures a setting and formulation in which distributed ADMM would more commonly be applied. However, the above formulation is closely related to the *sharing* variant of ADMM (Boyd et al., 2010, Section 7.3), where data for canonical regularized loss minimization problems is assumed to be distributed via features (see, e.g., Boyd et al., 2010, Section 8.3).

Appendix D. Convergence Proofs

In this section we provide proofs of our main convergence results. The arguments follow the reasoning in Ma et al. (2015a, 2017b), but where we have generalized them to be applicable directly to (A). We provide full details of Lemma 1 as a proof of concept, but omit details in later proofs that can be derived using the arguments in Ma et al. (2015a) or earlier work of Shalev-Shwartz and Zhang (2013a), and instead outline the proof strategy and highlight sections where the theory deviates.

D.1 Approximation of $\mathcal{O}_A(\cdot)$ by the Local Subproblems $\mathcal{G}_k^{\sigma'}(\cdot)$

Our first lemma in the overall proof of convergence helps to relate progress on the local subproblems to the global objective $\mathcal{O}_A(\cdot)$.

Lemma' 1. *For any dual variables $\boldsymbol{\alpha}, \Delta\boldsymbol{\alpha} \in \mathbb{R}^n$, $\mathbf{v} = \mathbf{v}(\boldsymbol{\alpha}) := A\boldsymbol{\alpha}$, and real values γ, σ' satisfying* (11)*, it holds that*

$$\mathcal{O}_A\Big(\boldsymbol{\alpha} + \gamma\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]}\Big) \le (1-\gamma)\mathcal{O}_A(\boldsymbol{\alpha}) + \gamma\sum_{k=1}^K \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) . \tag{30}$$

Proof. In this proof we follow the line of reasoning in Ma et al. (2015a, Lemma 4) with a more general $(1/\tau)$ smoothness assumption on $f(\cdot)$. An outer iteration of CoCoA performs the following update:

$$\mathcal{O}_A(\boldsymbol{\alpha} + \gamma\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]}) = \underbrace{f(\mathbf{v}(\boldsymbol{\alpha} + \gamma\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]}))}_{A} + \underbrace{\sum_{i=1}^n g_i(\alpha_i + \gamma(\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]})_i)}_{B} . \tag{31}$$

We bound A and B separately. First we bound A using $(1/\tau)$-smoothness of f:

$$\begin{aligned}
A &= f\Big(\mathbf{v}(\boldsymbol{\alpha} + \gamma\sum_{k=1}^K \Delta\boldsymbol{\alpha}_{[k]})\Big) = f\Big(\mathbf{v}(\boldsymbol{\alpha}) + \gamma\sum_{k=1}^K \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\Big) \\
&\overset{\text{smoothness of } f \text{ as in (3)}}{\le} f(\mathbf{v}(\boldsymbol{\alpha})) + \sum_{k=1}^K \gamma\nabla f(\mathbf{v}(\boldsymbol{\alpha}))^\top \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]}) + \frac{\gamma^2}{2\tau}\|\sum_{k=1}^K \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\|^2 \\
&\overset{\text{definition of } \mathbf{w} \text{ as in (5)}}{=} f(\mathbf{v}(\boldsymbol{\alpha})) + \sum_{k=1}^K \gamma\mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})^\top \mathbf{w}(\boldsymbol{\alpha}) + \frac{\gamma^2}{2\tau}\|\sum_{k=1}^K \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\|^2
\end{aligned}$$

$$\overset{\text{safe choice of } \sigma' \text{ as in (11)}}{\leq} f(\mathbf{v}(\boldsymbol{\alpha})) + \sum_{k=1}^{K} \gamma \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})^\top \mathbf{w}(\boldsymbol{\alpha}) + \frac{1}{2\tau}\gamma\sigma' \sum_{k=1}^{K} \|\mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\|^2 .$$

Next we use Jensen's inequality to bound B:

$$B = \sum_{k=1}^{K} \left(\sum_{i\in\mathcal{P}_k} g_i(\alpha_i + \gamma(\Delta\boldsymbol{\alpha}_{[k]})_i) \right) = \sum_{k=1}^{K} \left(\sum_{i\in\mathcal{P}_k} g_i((1-\gamma)\alpha_i + \gamma(\alpha_i + (\Delta\boldsymbol{\alpha}_{[k]})_i)) \right)$$
$$\leq \sum_{k=1}^{K} \left(\sum_{i\in\mathcal{P}_k} (1-\gamma) g_i(\alpha_i) + \gamma g_i(\alpha_i + (\Delta\boldsymbol{\alpha}_{[k]})_i) \right) .$$

Plugging A and B back into (31) yields:

$$\begin{aligned}
\mathcal{O}_A\Big(\boldsymbol{\alpha} + \gamma \sum_{k=1}^{K} \Delta\boldsymbol{\alpha}_{[k]}\Big) \leq\ & f(\mathbf{v}(\boldsymbol{\alpha})) \pm \gamma f(\mathbf{v}(\boldsymbol{\alpha})) + \sum_{k=1}^{K} \gamma \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})^\top \mathbf{w}(\boldsymbol{\alpha}) + \frac{1}{2\tau}\gamma\sigma' \sum_{k=1}^{K} \|\mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\|^2 \\
& + \sum_{k=1}^{K} \sum_{i\in\mathcal{P}_k} (1-\gamma) g_i(\alpha_i) + \gamma g_i(\alpha_i + (\Delta\boldsymbol{\alpha}_{[k]})_i) \\
=\ & \underbrace{(1-\gamma) f(\mathbf{v}(\boldsymbol{\alpha})) + \sum_{k=1}^{K} \left(\sum_{i\in\mathcal{P}_k} (1-\gamma) g_i(\alpha_i) \right)}_{(1-\gamma)\mathcal{O}_A(\boldsymbol{\alpha})} \\
& + \gamma \sum_{k=1}^{K} \left(\frac{1}{K} f(\mathbf{v}(\boldsymbol{\alpha})) + \mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})^\top \mathbf{w}(\boldsymbol{\alpha}) + \frac{\sigma'}{2\tau} \|\mathbf{v}(\Delta\boldsymbol{\alpha}_{[k]})\|^2 + \sum_{i\in\mathcal{P}_k} g_i(\alpha_i + (\Delta\boldsymbol{\alpha}_{[k]})_i) \right) \\
\overset{(10)}{=}\ & (1-\gamma)\mathcal{O}_A(\boldsymbol{\alpha}) + \gamma \sum_{k=1}^{K} \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}; \mathbf{v}, \boldsymbol{\alpha}_{[k]}) ,
\end{aligned}$$

where the last equality is by the definition of the subproblem objective $\mathcal{G}_k^{\sigma'}(.)$ as in (10). □

D.2 Proof of Main Convergence Result (Theorem 2)

Before proving the main convergence results, we introduce several useful quantities, and establish the following lemma, which characterizes the effect of iterations of Algorithm 1 on the duality gap for any chosen local solver of approximation quality Θ.

Lemma 7. *Let g_i be strongly convex [2] with convexity parameter $\mu \geq 0$ with respect to the norm $\|\cdot\|$, $\forall i \in [n]$. Then at each iteration of Algorithm 1 under Assumption 1, and any $s \in [0,1]$, it holds that*

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] \geq \gamma(1-\Theta)\Big(sG(\boldsymbol{\alpha}^{(t)}) - \frac{\sigma' s^2}{2\tau} R^{(t)} \Big) , \tag{32}$$

2. Note that the case of weakly convex $g_i(.)$ is explicitly allowed here as well, as the Lemma holds for the case $\mu = 0$.

where

$$R^{(t)} := -\tfrac{\tau\mu(1-s)}{\sigma' s} \|\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)}\|^2 + \textstyle\sum_{k=1}^{K} \|A_{[k]}(\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)})_{[k]}\|^2 , \tag{33}$$

for $\mathbf{u}^{(t)} \in \mathbb{R}^n$ with

$$u_i^{(t)} \in \partial g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha}^{(t)})) . \tag{34}$$

Proof. This proof is motivated by Shalev-Shwartz and Zhang (2013a, Lemma 19) and follows Ma et al. (2015a, Lemma 5), with a difference being the extension to our generalized subproblems $\mathcal{G}_k^{\sigma'}(\cdot; \mathbf{v}, \boldsymbol{\alpha}_{[k]})$ along with the mappings $\mathbf{w}(\boldsymbol{\alpha}) := \nabla f(\mathbf{v}(\boldsymbol{\alpha}))$ with $\mathbf{v}(\boldsymbol{\alpha}) := A\boldsymbol{\alpha}$.

For simplicity, we write $\boldsymbol{\alpha}$ instead of $\boldsymbol{\alpha}^{(t)}$, $\mathbf{v}$ instead of $\mathbf{v}(\boldsymbol{\alpha}^{(t)})$, $\mathbf{w}$ instead of $\mathbf{w}(\boldsymbol{\alpha}^{(t)})$ and $\mathbf{u}$ instead of $\mathbf{u}^{(t)}$. We can estimate the expected change of the objective $\mathcal{O}_A(\boldsymbol{\alpha})$ as follows. Starting from the definition of the update $\boldsymbol{\alpha}^{(t+1)} := \boldsymbol{\alpha}^{(t)} + \gamma \sum_k \Delta\boldsymbol{\alpha}_{[k]}$ from Algorithm 1, we apply Lemma 1, which relates the local approximation $\mathcal{G}_k^{\sigma'}(\boldsymbol{\alpha}; \mathbf{v}, \boldsymbol{\alpha}_{[k]})$ to the global objective $\mathcal{O}_A(\boldsymbol{\alpha})$, and then bound this using the notion of quality of the local solver (Θ), as in Assumption 1. This gives us:

$$\begin{aligned}
\mathbb{E}\big[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})\big] &= \mathbb{E}\Big[\mathcal{O}_A(\boldsymbol{\alpha}) - \mathcal{O}_A\Big(\boldsymbol{\alpha} + \gamma \sum_{k=1}^{K} \Delta\boldsymbol{\alpha}_{[k]}\Big)\Big] \\
&\geq \gamma(1-\Theta) \left(\underbrace{\mathcal{O}_A(\boldsymbol{\alpha}) - \sum_{k=1}^{K} \mathcal{G}_k^{\sigma'}(\Delta\boldsymbol{\alpha}_{[k]}^\star; \mathbf{v}, \boldsymbol{\alpha}_{[k]})}_{C} \right) .
\end{aligned} \tag{35}$$

We next upper bound the C term, denoting $\Delta\boldsymbol{\alpha}^\star = \sum_{k=1}^{K} \Delta\boldsymbol{\alpha}_{[k]}^\star$. We first plug in the definition of the objective $\mathcal{O}_A$ in (A) and the local subproblems (10), and then substitute $s(u_i - \alpha_i)$ for $\Delta\alpha_i^\star$ and apply the μ-strong convexity of the g_i terms. This gives us:

$$\begin{aligned}
C &= \sum_{i=1}^{n} (g_i(\alpha_i) - g_i(\alpha_i + \Delta\alpha_i^\star)) - (A\Delta\boldsymbol{\alpha}^\star)^\top \mathbf{w}(\boldsymbol{\alpha}) - \sum_{k=1}^{K} \frac{\sigma'}{2\tau} \Big\| A_{[k]} \Delta\boldsymbol{\alpha}_{[k]}^\star \Big\|^2 \\
&= \sum_{i=1}^{n} (g_i(\alpha_i) - g_i(su_i + (1-s)\alpha_i)) - A(s(\mathbf{u} - \boldsymbol{\alpha}))^\top \mathbf{w}(\boldsymbol{\alpha}) - \sum_{k=1}^{K} \frac{\sigma'}{2\tau} \Big\| A_{[k]} s(\mathbf{u} - \boldsymbol{\alpha})_{[k]} \Big\|^2 \\
&\geq \sum_{i=1}^{n} \Big(sg_i(\alpha_i) - sg_i(u_i) + \frac{\mu}{2}(1-s)s(u_i - \alpha_i)^2 \Big) \\
&\quad - A(s(\mathbf{u} - \boldsymbol{\alpha}))^\top \mathbf{w}(\boldsymbol{\alpha}) - \sum_{k=1}^{K} \frac{\sigma'}{2\tau} \Big\| A_{[k]} (s(\mathbf{u} - \boldsymbol{\alpha})_{[k]}) \Big\|^2 .
\end{aligned} \tag{36}$$

From the definition of the optimization problems (A) and (B), and definition of convex conjugates, we can write the duality gap as:

$$\begin{aligned} G(\boldsymbol{\alpha}) := \mathcal{O}_A(\boldsymbol{\alpha}) - (-\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha})) &\overset{\text{(A),(B)}}{=} \sum_{i=1}^n \left(g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + g_i(\alpha_i) \right) + f^*(\mathbf{w}(\boldsymbol{\alpha})) + f(A\boldsymbol{\alpha})) \\ &= \sum_{i=1}^n \left(g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + g_i(\alpha_i) \right) + (A\boldsymbol{\alpha})^\top \mathbf{w}(\boldsymbol{\alpha}) \\ &= \sum_{i=1}^n \left(g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + g_i(\alpha_i) + \alpha_i \mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha}) \right) . \end{aligned} \tag{37}$$

The convex conjugate maximal property from (34) implies that

$$g_i(u_i) = u_i(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) - g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) . \tag{38}$$

Using (38) and (37), we therefore have:

$$\begin{aligned} C &\overset{(38)}{\geq} \sum_{i=1}^n \left(s g_i(\alpha_i) - s u_i(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + s g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + \frac{\mu}{2}(1-s)s(u_i - \alpha_i)^2 \right) \\ &\quad - A(s(\mathbf{u}-\boldsymbol{\alpha}))^\top \mathbf{w}(\boldsymbol{\alpha}) - \sum_{k=1}^K \frac{\sigma'}{2\tau} \left\| A_{[k]}(s(\mathbf{u}-\boldsymbol{\alpha})_{[k]}) \right\|^2 \\ &= \sum_{i=1}^n \left[s g_i(\alpha_i) + s g_i^*(-\mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})) + s \mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha}) \alpha_i \right] - \sum_{i=1}^n \left[s \mathbf{x}_i^\top \mathbf{w}(\boldsymbol{\alpha})(\alpha_i - u_i) - \frac{\mu}{2}(1-s)s(u_i - \alpha_i)^2 \right] \\ &\quad - A(s(\mathbf{u}-\boldsymbol{\alpha}))^\top \mathbf{w}(\boldsymbol{\alpha}) - \sum_{k=1}^K \frac{\sigma'}{2\tau} \left\| A_{[k]}(s(\mathbf{u}-\boldsymbol{\alpha})_{[k]}) \right\|^2 \\ &\overset{(37)}{=} s G(\boldsymbol{\alpha}) + \frac{\mu}{2}(1-s)s\|\mathbf{u}-\boldsymbol{\alpha}\|^2 - \frac{\sigma' s^2}{2\tau} \sum_{k=1}^K \|A_{[k]}(\mathbf{u}-\boldsymbol{\alpha})_{[k]}\|^2 . \end{aligned} \tag{39}$$

The claimed improvement bound (32) then follows by plugging (39) into (35). □

The following Lemma provides a uniform bound on $R^{(t)}$.

Lemma 8. *If g_i^* are L-Lipschitz continuous for all $i \in [n]$, then*

$$\forall t : R^{(t)} \leq 4L^2 \underbrace{\sum_{k=1}^K \sigma_k n_k}_{=:\sigma} , \tag{40}$$

where

$$\sigma_k := \max_{\boldsymbol{\alpha}_{[k]} \in \mathbb{R}^n} \frac{\|A_{[k]}\boldsymbol{\alpha}_{[k]}\|^2}{\|\boldsymbol{\alpha}_{[k]}\|^2} . \tag{41}$$

Proof. (Ma et al., 2015a, Lemma 6). For general convex functions, the strong convexity parameter is $\mu = 0$, and hence the definition (33) of the complexity constant $R^{(t)}$ becomes

$$R^{(t)} = \sum_{k=1}^K \|A_{[k]}(\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)})_{[k]}\|^2 \overset{(41)}{\leq} \sum_{k=1}^K \sigma_k \|(\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)})_{[k]}\|^2 \leq \sum_{k=1}^K \sigma_k |\mathcal{P}_k| 4L^2 .$$

Here the last inequality follows from (Shalev-Shwartz and Zhang, 2013a, Lemma 21), which shows that for $g_i^* : \mathbb{R} \to \mathbb{R}$ being L-Lipschitz, it holds that for any real value a with $|a| > L$ one has that $g_i(a) = +\infty$. □

Remark 6. *(Ma et al., 2015a, Remark 7) If the data points $\mathbf{x}_i$ are normalized such that $\|\mathbf{x}_i\| \leq 1$, $\forall i \in [n]$, then $\sigma_k \leq |\mathcal{P}_k| = n_k$. Furthermore, if we assume that the data partition is balanced, i.e., that $n_k = n/K$ for all k, then $\sigma \leq n^2/K$. This can be used to bound the constants $R^{(t)}$, above, as $R^{(t)} \leq \frac{4L^2 n^2}{K}$.*

Theorem 9. *Consider Algorithm 1, using a local solver of quality Θ (See Assumption 1). Let $g_i^*(\cdot)$ be L-Lipschitz continuous, and $\epsilon_G > 0$ be the desired duality gap (and hence an upper-bound on suboptimality $\epsilon_{\mathcal{O}_A}$). Then after T iterations, where*

$$T \geq T_0 + \max\{ \left\lceil \frac{1}{\gamma(1-\Theta)} \right\rceil, \left\lceil \frac{4L^2 \sigma\sigma'}{\tau \epsilon_G \gamma(1-\Theta)} \right\rceil \} , \tag{42}$$

$$T_0 \geq t_0 + \left\lceil \frac{2}{\gamma(1-\Theta)} \left(\frac{8L^2\sigma\sigma'}{\tau\epsilon_G} - 1 \right) \right\rceil_+ , \quad t_0 \geq \max(0, \left\lceil \tfrac{1}{\gamma(1-\Theta)} \log\left(\tfrac{\tau(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))}{2L^2\sigma\sigma'} \right) \right\rceil) ,$$

we have that the expected duality gap satisfies

$$\mathbb{E}[\mathcal{O}_A(\overline{\boldsymbol{\alpha}}) - (-\mathcal{O}_B(\mathbf{w}(\overline{\boldsymbol{\alpha}})))] \leq \epsilon_G$$

at the averaged iterate

$$\overline{\boldsymbol{\alpha}} := \tfrac{1}{T-T_0} \textstyle\sum_{t=T_0}^{T-1} \boldsymbol{\alpha}^{(t)} . \tag{43}$$

Proof. We begin by estimating the expected change of feasibility for $\mathcal{O}_A$. We can bound this above by using Lemma 7 and the fact that the $\mathcal{O}_B(\cdot)$ is always a lower bound for $-\mathcal{O}_A(\cdot)$, and then applying (40) to find:

$$\begin{aligned} \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] &= \mathbb{E}[-\mathcal{O}_A(\boldsymbol{\alpha}^\star) + \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) + \mathcal{O}_A(\boldsymbol{\alpha}^{(t)})] \\ &\leq (1 - \gamma(1-\Theta)s) \left(\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \right) + \gamma(1-\Theta)\tfrac{\sigma' s^2}{2\tau} 4L^2\sigma . \end{aligned} \tag{44}$$

Using (44) recursively we have

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq (1 - \gamma(1-\Theta)s)^t \left(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \right) + s\frac{4L^2\sigma\sigma'}{2\tau} . \tag{45}$$

Choosing $s = 1$ and $t = t_0 := \max\{0, \lceil \frac{1}{\gamma(1-\Theta)} \log(2(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))/(4L^2\sigma\sigma')) \rceil\}$ leads to

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq (1 - \gamma(1-\Theta))^{t_0} \left(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \right) + \frac{4L^2\sigma\sigma'}{2\tau} \leq \frac{4L^2\sigma\sigma'}{\tau} . \tag{46}$$

Next, we show inductively that

$$\forall t \geq t_0 : \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq \frac{4L^2\sigma\sigma'}{\tau(1+\frac{1}{2}\gamma(1-\Theta)(t-t_0))}\,. \tag{47}$$

Clearly, (46) implies that (47) holds for $t = t_0$. Assuming that it holds for any $t \geq t_0$, we show that it must also hold for $t+1$. Indeed, using

$$s = \frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(t-t_0)} \in [0,1]\,, \tag{48}$$

we obtain

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq \frac{4L^2\sigma\sigma'}{\tau}\underbrace{\left(\frac{1+\frac{1}{2}\gamma(1-\Theta)(t-t_0)-\frac{1}{2}\gamma(1-\Theta)}{(1+\frac{1}{2}\gamma(1-\Theta)(t-t_0))^2}\right)}_{D}\,,$$

by applying the bounds (44) and (47), plugging in the definition of s (48), and simplifying. We upper bound the term D using the fact that geometric mean is less or equal to arithmetic mean:

$$\begin{aligned} D &= \frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(t+1-t_0)}\underbrace{\frac{(1+\frac{1}{2}\gamma(1-\Theta)(t+1-t_0))(1+\frac{1}{2}\gamma(1-\Theta)(t-1-t_0))}{(1+\frac{1}{2}\gamma(1-\Theta)(t-t_0))^2}}_{\leq 1} \\ &\leq \frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(t+1-t_0)}. \end{aligned}$$

If $\overline{\boldsymbol{\alpha}}$ is defined as (43), we apply the results of Lemma 7 and Lemma 8 to obtain

$$\begin{aligned} \mathbb{E}[G(\overline{\boldsymbol{\alpha}})] &= \mathbb{E}\left[G\left(\sum_{t=T_0}^{T-1}\tfrac{1}{T-T_0}\boldsymbol{\alpha}^{(t)}\right)\right] \leq \tfrac{1}{T-T_0}\mathbb{E}\left[\sum_{t=T_0}^{T-1} G\left(\boldsymbol{\alpha}^{(t)}\right)\right] \\ &\leq \frac{1}{\gamma(1-\Theta)s}\frac{1}{T-T_0}\mathbb{E}\left[\mathcal{O}_A(\boldsymbol{\alpha}^{(T_0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)\right] + \tfrac{4L^2\sigma\sigma' s}{2\tau}\,. \end{aligned} \tag{49}$$

If $T \geq \lceil \frac{1}{\gamma(1-\Theta)} \rceil + T_0$ such that $T_0 \geq t_0$ we have

$$\begin{aligned} \mathbb{E}[G(\overline{\boldsymbol{\alpha}})] &\overset{(49),(47)}{\leq} \frac{1}{\gamma(1-\Theta)s}\frac{1}{T-T_0}\left(\frac{4L^2\sigma\sigma'}{\tau(1+\frac{1}{2}\gamma(1-\Theta)(T_0-t_0))}\right) + \frac{4L^2\sigma\sigma' s}{2\tau} \\ &= \frac{4L^2\sigma\sigma'}{\tau}\left(\frac{1}{\gamma(1-\Theta)s}\frac{1}{T-T_0}\frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(T_0-t_0)} + \frac{s}{2}\right). \end{aligned} \tag{50}$$

Choosing

$$s = \frac{1}{(T-T_0)\gamma(1-\Theta)} \in [0,1] \tag{51}$$

gives us

$$\mathbb{E}[G(\overline{\boldsymbol{\alpha}})] \overset{(50),(51)}{\leq} \frac{4L^2\sigma\sigma'}{\tau}\left(\frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(T_0-t_0)} + \frac{1}{(T-T_0)\gamma(1-\Theta)}\frac{1}{2}\right). \tag{52}$$

To have right hand side of (52) smaller then ϵ_G it is sufficient to choose T_0 and T such that

$$\frac{4L^2\sigma\sigma'}{\tau}\left(\frac{1}{1+\frac{1}{2}\gamma(1-\Theta)(T_0-t_0)}\right) \leq \frac{1}{2}\epsilon_G\,, \tag{53}$$

$$\frac{4L^2\sigma\sigma'}{\tau}\left(\frac{1}{(T-T_0)\gamma(1-\Theta)}\frac{1}{2}\right) \leq \frac{1}{2}\epsilon_G\,. \tag{54}$$

Hence if $T_0 \geq t_0 + \frac{2}{\gamma(1-\Theta)}\left(\frac{8L^2\sigma\sigma'}{\tau\epsilon_G} - 1\right)$ and $T \geq T_0 + \frac{4L^2\sigma\sigma'}{\tau\epsilon_G\gamma(1-\Theta)}$ then (53) and (54) are satisfied. □

The following main theorem simplifies the results of Theorem 9 and is a generalization of Ma et al. (2015a, Corollary 9) for general $f^*(\cdot)$ functions:

Theorem' 2. *Consider Algorithm 1 with $\gamma := 1$, using a local solver of quality Θ (see Assumption 1). Let $g_i^*(\cdot)$ be L-Lipschitz continuous, and assume that the columns of A satisfy $\|\mathbf{x}_i\| \leq 1$, $\forall i \in [n]$ and g_i^* is of the form $\frac{1}{n}g_i^*$, as is common in ERM-type problems. Let $\epsilon_G > 0$ be the desired duality gap (and hence an upper-bound on primal sub-optimality). Then after T iterations, where*

$$\begin{aligned} T &\geq T_0 + \max\{\left\lceil \frac{1}{1-\Theta}\right\rceil, \frac{4L^2}{\tau\epsilon_G(1-\Theta)}\}\,, \\ T_0 &\geq t_0 + \left\lceil \frac{2}{1-\Theta}\left(\frac{8L^2}{\tau\epsilon_G} - 1\right)\right\rceil_+\,, \\ t_0 &\geq \max(0, \left\lceil \tfrac{1}{(1-\Theta)}\log\left(\tfrac{\tau n(\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))}{2L^2K}\right)\right\rceil)\,, \end{aligned} \tag{55}$$

we have that the expected duality gap satisfies

$$\mathbb{E}[\mathcal{O}_A(\overline{\boldsymbol{\alpha}}) - (-\mathcal{O}_B(\mathbf{w}(\overline{\boldsymbol{\alpha}})))] \leq \epsilon_G\,,$$

where $\overline{\boldsymbol{\alpha}}$ is the averaged iterate returned by Algorithm 1.

Proof. Plug in parameters $\gamma := 1$, $\sigma' := \gamma K = K$, $\tilde{L} := \frac{1}{n}L$ to the results of Theorem 9, and note that for balanced datasets with $g_i^* := \frac{1}{n}g_i^*$ we have $\sigma \leq \frac{n}{K}$ (see Remark 6). We can further simplify the rate by noting that $\tau = 1$ for the 1-smooth losses (least squares and logistic) given as examples in this work. □

D.3 Proof of Convergence Result for Strongly Convex g_i

Our second main theorem follows reasoning in Shalev-Shwartz and Zhang (2013a) and is a generalization of Ma et al. (2015a, Corollary 11). We first introduce a lemma to simplify the proof.

Lemma 10. *Assume that $g_i(0) \in [0,1]$ for all $i \in [n]$, then for the zero vector $\boldsymbol{\alpha}^{(0)} := \mathbf{0} \in \mathbb{R}^n$, we have*

$$\mathcal{O}_A(\boldsymbol{\alpha}^{(0)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) = \mathcal{O}_A(\mathbf{0}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \leq n\,. \tag{56}$$

Proof. Since $-\mathcal{O}_A(\cdot)$ is always a lower bound on $\mathcal{O}_B(\cdot)$, and by definition of the objectives $\mathcal{O}_A$ and $\mathcal{O}_B$ given in (A) and (B) respectively, for $\boldsymbol{\alpha} := \mathbf{0} \in \mathbb{R}^n$,

$$\begin{aligned} 0 \leq \mathcal{O}_A(\boldsymbol{\alpha}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \leq \mathcal{O}_A(\mathbf{0}) - (-\mathcal{O}_B(\mathbf{w}(\mathbf{0}))) &\overset{(A),(B)}{=} \\ \overset{(A),(B)}{=} f(\mathbf{0}) + f^*(\mathbf{w}(\mathbf{0})) + g(\mathbf{0}) + g^*(-A^\top \mathbf{w}(\mathbf{0}))\,. \end{aligned}$$

Since $f^*(\mathbf{w}(\mathbf{0})) = f^*(\nabla f(\mathbf{0})) = \mathbf{0}^\top \nabla f(\mathbf{0}) - f(\mathbf{0}) = -f(\mathbf{0})$, and given our initial assumption on $g(\mathbf{0})$, the duality gap reduces to:

$$0 \leq g(\mathbf{0}) + g^*(-A^\top \mathbf{w}(\mathbf{0})) \leq n. \qquad \square$$

Theorem 11. *Assume that g_i are μ-strongly convex $\forall i \in [n]$. We define $\sigma_{\max} = \max_{k\in[K]} \sigma_k$. Then after T iterations of Algorithm 1, with*

$$T \geq \tfrac{1}{\gamma(1-\Theta)} \tfrac{\mu\tau + \sigma_{\max}\sigma'}{\mu\tau} \log \tfrac{n}{\epsilon_{\mathcal{O}_A}}\,,$$

it holds that

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(T)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq \epsilon_{\mathcal{O}_A}\,.$$

Furthermore, after T iterations with

$$T \geq \tfrac{1}{\gamma(1-\Theta)} \tfrac{\mu\tau + \sigma_{\max}\sigma'}{\mu\tau} \log\left(\tfrac{1}{\gamma(1-\Theta)} \tfrac{\mu\tau + \sigma_{\max}\sigma'}{\mu\tau} \tfrac{n}{\epsilon_G}\right)\,,$$

we have the expected duality gap

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(T)}) - (-\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha}^{(T)})))] \leq \epsilon_G\,.$$

Proof. Given that $g_i(.)$ is μ-strongly convex, we can apply (33) and the definition of σ_k to find:

$$\begin{aligned} R^{(t)} &\leq -\tfrac{\tau\mu(1-s)}{\sigma' s}\|\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)}\|^2 + \sum\nolimits_{k=1}^K \sigma_k \|\mathbf{u}^{(t)} - \boldsymbol{\alpha}_{[k]}^{(t)}\|^2 \\ &\leq \left(-\tfrac{\tau\mu(1-s)}{\sigma' s} + \sigma_{\max}\right)\|\mathbf{u}^{(t)} - \boldsymbol{\alpha}^{(t)}\|^2\,, \end{aligned} \tag{57}$$

where $\sigma_{\max} = \max_{k\in[K]} \sigma_k$. If we plug the following value of s

$$s = \frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'} \in [0,1] \tag{58}$$

into (57) we obtain that $\forall t : R^{(t)} \leq 0$. Putting the same s into (32) will give us

$$\begin{aligned} \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] &\overset{(32),(58)}{\geq} \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'} G(\boldsymbol{\alpha}^{(t)}) \\ &\geq \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}(\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))\,. \end{aligned} \tag{59}$$

Using the fact that $\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] = \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^\star) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] + \mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)$ we have

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^\star) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] + \mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star) \overset{(59)}{\geq} \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}(\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))\,,$$

which is equivalent to

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)] \leq \left(1 - \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}\right)(\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star))\,. \tag{60}$$

Therefore if we denote $\epsilon_{\mathcal{O}_A}^{(t)} = \mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)$ we have recursively that

$$\begin{aligned} \mathbb{E}[\epsilon_{\mathcal{O}_A}^{(t)}] &\overset{(60)}{\leq} \left(1 - \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}\right)^t \epsilon_{\mathcal{O}_A}^{(0)} \overset{(56)}{\leq} \left(1 - \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}\right)^t n \\ &\leq \exp\left(-t\gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}\right) n\,. \end{aligned}$$

The right hand side will be smaller than some $\epsilon_{\mathcal{O}_A}$ if

$$t \geq \frac{1}{\gamma(1-\Theta)}\frac{\tau\mu + \sigma_{\max}\sigma'}{\tau\mu}\log\frac{n}{\epsilon_{\mathcal{O}_A}}\,.$$

Moreover, to bound the duality gap, we have

$$\gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'} G(\boldsymbol{\alpha}^{(t)}) \overset{(59)}{\leq} \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^{(t+1)})] \leq \mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(t)}) - \mathcal{O}_A(\boldsymbol{\alpha}^\star)]\,.$$

Thus, $G(\boldsymbol{\alpha}^{(t)}) \leq \frac{1}{\gamma(1-\Theta)}\frac{\tau\mu + \sigma_{\max}\sigma'}{\tau\mu}\epsilon_{\mathcal{O}_A}^{(t)}$. Hence if $\epsilon_{\mathcal{O}_A} \leq \gamma(1-\Theta)\frac{\tau\mu}{\tau\mu + \sigma_{\max}\sigma'}\epsilon_G$ then $G(\boldsymbol{\alpha}^{(t)}) \leq \epsilon_G$. Therefore after

$$t \geq \frac{1}{\gamma(1-\Theta)}\frac{\tau\mu + \sigma_{\max}\sigma'}{\tau\mu}\log\left(\frac{1}{\gamma(1-\Theta)}\frac{\tau\mu + \sigma_{\max}\sigma'}{\tau\mu}\frac{n}{\epsilon_G}\right)$$

iterations we have obtained a duality gap less than ϵ_G. $\square$

Theorem' 3. *Consider Algorithm 1 with $\gamma := 1$, using a local solver of quality Θ (see Assumption 1). Let $g_i(\cdot)$ be μ-strongly convex, $\forall i \in [n]$, and assume that the columns of A satisfy $\|\mathbf{x}_i\| \leq 1\ \forall i \in [n]$ and and g_i^* is of the form $\frac{1}{n}g_i^*$, as is common in ERM-type problems. Then we have that T iterations are sufficient for suboptimality $\epsilon_{\mathcal{O}_A}$, with*

$$T \geq \tfrac{1}{(1-\Theta)}\tfrac{\tau\mu+1}{\tau\mu}\log\tfrac{1}{\epsilon_{\mathcal{O}_A}}\,.$$

Furthermore, after T iterations with

$$T \geq \tfrac{1}{(1-\Theta)}\tfrac{\tau\mu+1}{\tau\mu}\log\left(\tfrac{1}{(1-\Theta)}\tfrac{\tau\mu+1}{\tau\mu}\tfrac{1}{\epsilon_G}\right)\,,$$

we have the expected duality gap

$$\mathbb{E}[\mathcal{O}_A(\boldsymbol{\alpha}^{(T)}) - (-\mathcal{O}_B(\mathbf{w}(\boldsymbol{\alpha}^{(T)})))] \leq \epsilon_G\,.$$

Proof. Plug in parameters $\gamma := 1$, $\sigma' := \gamma K = K$, $\tilde{\mu} = n\mu$ to the results of Theorem 11 and note that for balanced datasets with $g_i^* := \frac{1}{n}g_i^*$ we have $\sigma_{\max} \leq \frac{n}{K}$ (see Remark 6). We can further simplify the rate by noting that $\tau = 1$ for the 1-smooth losses (least squares and logistic) given as examples in this work. $\square$

Abstract

The paper considers suprema of empirical processes for linear time series indexed by functional classes. We derive an upper bound for the tail probability of the suprema under conditions on the size of the function class, the sample size, temporal dependence and the moment conditions of the underlying time series. Due to the dependence and heavy-tailness, our tail probability bound is substantially different from those classical exponential bounds obtained under the independence assumption in that it involves an extra polynomial decaying term. We allow both short- and long-range dependent processes. For empirical processes indexed by half intervals, our tail probability inequality is sharp up to a multiplicative constant.

Keywords: martingale decomposition, tail probability, heavy tail, MA(∞)

1. Introduction

Concentration inequalities for suprema of empirical processes play a fundamental role in statistical learning theory. They have been extensively studied in the literature; see for example Vapnik (1998), Ledoux (2001), Massart (2007), Boucheron et al. (2013) among others. To fix the idea, let $(\Omega, \mathcal{F}, \mathbb{P})$ be the probability space on which a sequence of random variables (X_i) is defined, $\mathcal{A}$ be a set of real-valued measurable functions. For a function g, denote $S_n(g) = \sum_{i=1}^n g(X_i)$. We are interested in studying the tail probability

$$T(z) := \mathbb{P}(\Delta_n \geq z), \text{ where } \Delta_n = \sup_{g\in\mathcal{A}} |S_n(g) - \mathbb{E}S_n(g)|. \tag{1}$$

When $\mathcal{A}$ is uncountable, $\mathbb{P}$ is understood as the outer probability (van der Vaart (1998)). In the special case in which $X_1, \ldots, X_n$ are independent and identically distributed (i.i.d.) random variables and $\mathcal{A} = \{\mathbf{1}_{(-\infty,t]}, t \in \mathbb{R}\}$ is the set of indicator functions of half intervals, the Dvoretzky-Kiefer-Wolfowitz-Massart (Dvoretzky et al. (1956); Massart (1990)) theorem asserts that for all $z \geq 0$,

$$T(z) \leq 2e^{-2z^2/n}. \tag{2}$$

Talagrand (1994) obtained a concentration inequality with $\mathcal{A} = \{\mathbf{1}_A, A \in \mathcal{C}\}$, where $\mathcal{C}$ is a VC class; cf Vapnik and Chervonenkis (1971). For empirical processes of independent random variables, a substantial theory has been developed and various powerful techniques have been invented; see Talagrand (1995, 1996), Ledoux (1997), Massart (2000), Boucheron et al. (2003), Klein and Rio (2005) and the monograph Boucheron et al. (2013).

In this paper we shall consider tail probability inequalities for temporally dependent data which are commonly encountered in economics, engineering, finance, geography, physics and other fields. It is considerably more challenging to deal with dependent data. Previous results include uniform laws of large numbers and central limit theorems; see, for example, Adams and Nobel (2012), Levental (1988), Arcones and Yu (1994), Kontorovich and Brockwell (2014) and Yu (1994). Various uniform deviation results have been derived for mixing processes, Markov chains and their variants; see Marton (1996, 1998), Samson (2000), Kontorovich and Ramanan (2008), Adamczak (2008), Kontorovich and Weiss (2014), Kontorovich and Raginsky (2017), Kuznetsov and Mohri (2014, 2015) and Agarwal and Duchi (2013) among others. In many of the aforementioned papers, exponentially decaying tail bounds have been obtained which are similar to those obtained under independence.

Here we shall consider the widely used linear or moving average (MA) process

$$X_i = \sum_{k\geq 0} a_k \epsilon_{i-k}, \tag{3}$$

where innovations $\epsilon_i, i \in \mathbb{Z}$, are i.i.d random variables with mean 0 and $a_k, k \geq 0$, are real numbers such that X_i is a proper random variable. Assume that $\epsilon_i \in \mathcal{L}^q$, $q \geq 1$, namely $\mu_q := \|\epsilon_i\|_q = (\mathbb{E}|\epsilon_i|^q)^{1/q} < \infty$ and coefficients $a_k = O(k^{-\beta})$, $\beta > 1/q$. Namely there exists a constant $C > 0$ such that $|a_k| \leq Ck^{-\beta}$ holds for all large k. Then by Kolmogorov's three-series theorem (Chow and Teicher (1997)), the sum in (3) exists and X_i is well-defined. If $q \geq 2$ and $1/2 < \beta < 1$, then the auto-covariances of the process (X_i) may not be summable, suggesting that the process is long-memory or long-range dependent (LRD). When $\beta > 1$, the process is short-range dependent (SRD). The linear or MA(∞) process (3) is very widely used in practice and it includes many important time series models such as the autoregressive moving average (ARMA) process

$$(1 - \sum_{j=1}^p \theta_j B^j) X_i = X_i - \sum_{j=1}^p \theta_j X_{i-j} = \sum_{k=0}^q \phi_k \epsilon_{i-k}, \tag{4}$$

where θ_j and ϕ_k are real coefficients such that the roots to the equation $1 - \sum_{j=1}^p \theta_j u^j = 0$ are all outside the unit disk and B is the backshift operator, and the fractional autoregressive integrated moving average (FARIMA) (cf. Granger and Joyeux (1980); Hosking (1981))

$$(1 - B)^d (X_i - \sum_{j=1}^p \theta_j X_{i-j}) = \sum_{k=0}^q \phi_k \epsilon_{i-k}, \tag{5}$$

where the fractional integration index $d \in (0, 1/2)$. For (4), the corresponding coefficients $|a_i| = O(\rho^i)$ for some $\rho \in (0, 1)$. While for (5) under suitable causality and invertibility conditions the limit $\lim_{i\to\infty} i^{1-d} a_i = c \neq 0$ exists (Granger and Joyeux (1980); Hosking (1981)). Hence $a_i \sim ci^{-\beta}$ with $\beta = 1 - d$.

The primary goal of the paper is to establish a concentration inequality for $T(z)$ in (1) for the linear process (3). Our theory allows both short- and long-range dependence and

heavy-tailed innovations. Heavy-tailed distributions have been substantially studied in the literature. For instance, Mandelbrot (1963) documented evidence of power-law behavior in asset prices. Rachev and Mittnik (2000) showed long memory and heavy tails in the high frequency asset return data. Recently researchers extended tail probability inequalities to independent heavy-tailed random variables. Lederer and van de Geer (2014) applied the truncation method to develop bounds for an envelope of functions with finite moment assumptions on the envelope. Based on the robust M-estimator introduced in Catoni (2012), Brownlees et al. (2015) proposed a risk minimization procedure using the generic chaining method. The case with both dependence and heavy tails is more challenging. Jiang (2009) introduced a triplex inequality to handle unbounded and dependent situations. Mohri and Rostamizadeh (2010) considered φ-mixing and β-mixing processes. It is generally not easy to verify that a process is strong mixing and computation of mixing coefficients can be very difficult. Some simple and widely used AR processes are not strong mixing (Andrews (1984)).

In the present paper, we propose a martingale approximation based method. An intuitive illustration is given in Section 6.2. Our tail probability bound is a combination of an exponential term and a polynomial term (cf. Theorems 4 and 8), whose order depends on both β and q, which quantify the dependence and the moment condition, respectively. Larger β or q implies thinner tails. Our tail inequality allows both short- and long- range dependent processes and can also be adapted to discontinuous function classes including empirical distribution functions, which is fundamental and is of independent interest. Our theorem implies that, if the innovation ϵ_0 has tail

$$\mathbb{P}(|\epsilon_0| \geq x) = O(\log^{-r_0}(x)x^{-q}), \quad \text{as } x \to \infty, \tag{6}$$

where $r_0 > 1$ and $q > 1$ signifies heaviness of the tail, namely there exists a constant $C > 0$ such that $\mathbb{P}(|\epsilon_0| \geq x) \leq C\log^{-r_0}(x)x^{-q}$ holds for all large x, and the coefficients

$$a_k = O(k^{-\beta}),\ \beta > 1 \text{ and } q\beta \geq 2, \tag{7}$$

where β quantifies the dependence with larger β implying weaker dependence, then for $z \geq \sqrt{n}\log(n)$, the tail probability

$$\mathbb{P}\Big(\sup_{t\in\mathbb{R}}\Big|\sum_{i=1}^{n}[\mathbf{1}_{X_i\leq t} - F(t)]\Big| > z\Big) \lesssim \frac{n}{z^{q\beta}\log^{r_0}(z)}, \tag{8}$$

where the constant in $\lesssim$ is independent of n and z, $F(t) = \mathbb{P}(X_i \leq t)$ is the cumulative distribution function (c.d.f.) for X_i. Note that the bound (8) involves both the dependence parameter β and the tail heaviness parameter q. In comparison with the sub-Gaussian bound $e^{-2z^2/n}$ in (2), the polynomial bound (8) is much larger. On the other hand, however, it turns out that the polynomial bound (8) is *sharp* and it is essentially not improvable. For example, let $F_\epsilon(t) = \mathbb{P}(\epsilon_0 \leq t)$ be the c.d.f. of ϵ_0, and assume that the innovation ϵ_i has a symmetric regularly varying tail: for some $r_0 > 1$,

$$F_\epsilon(-x) = 1 - F_\epsilon(x) \sim \log^{-r_0}(x)x^{-q} \text{ as } x \to \infty, \tag{9}$$

namely $\lim_{x\to\infty}(1 - F_\epsilon(x))\log^{r_0}(x)x^q = 1$, and that the coefficients

$$a_k = (k \vee 1)^{-\beta},\ \beta > 1. \tag{10}$$

Then by Theorem 14, when $n/\log^{\alpha_0}(n) \geq z \geq \sqrt{n}\log(n)$ for some $\alpha_0 > 0$, we can have the precise order of the tail probability

$$\mathbb{P}\Big(\sum_{i=1}^{n}[\mathbf{1}_{X_i\leq t} - F(t)] > z\Big) = C_1\frac{n}{z^{q\beta}\log^{r_0}(z)}(1 + o(1)), \quad n \to \infty,$$

and

$$\mathbb{P}\Big(\sum_{i=1}^{n}[\mathbf{1}_{X_i\leq t} - F(t)] < -z\Big) = C_2\frac{n}{z^{q\beta}\log^{r_0}(z)}(1 + o(1)), \quad n \to \infty,$$

where the constants C_1, C_2 are independent of z and n. Hence the bound in (8) is sharp up to a multiplicative constant.

On the technical side, to establish inequality (8) and more generally, a tail probability inequality for empirical processes indexed by function classes, we need to develop new approaches so that the two main challenges posed by dependence and heavy tails can be dealt with. Techniques developed for empirical processes with independent random variables are not directly applicable. Here, we apply the martingale approximation method, together with the Fuk-Nagaev inequalities for high-dimensional vectors recently obtained by Chernozhukov et al. (2017), projection techniques and martingale inequalities, so that an optimal bound can be derived. Intuitions are given in the proof of Theorem 4 in Section 6.2. As a result, we can allow short- and long-range dependent, and light- and heavy-tailed linear processes.

The remainder of the paper is organized as follows. Section 2 states the theoretical results: Subsections 2.1 and 2.2 show the tail probabilities for short- and long- range dependence situations respectively with heavy tailness, Subsection 2.3 presents results for light tailed innovations. In Section 3, we apply the concentration inequality to empirical distribution functions as an important special case. We also derive an exact order of decay speed under certain settings, which demonstrates the sharpness of our upper bound. Sections 4 and 5 present applications in kernel density estimation and empirical risk minimization, respectively. Detailed proofs are provided in Section 6.

We now introduce some notation. For a random variable X and $q > 0$, we write $X \in \mathcal{L}^q$ if $\|X\|_q := \mathbb{E}(|X|^q)^{1/q} < \infty$. Write $\|\cdot\| = \|\cdot\|_2$. For a function g, define $|g|_\infty := \sup_x |g(x)|$. Let $x \vee y = \max\{x, y\}$ and $x \wedge y = \min\{x, y\}$. For two sequences of positive numbers (a_n) and (b_n), write $a_n \lesssim b_n$ (resp. $a_n \ll b_n$, $a_n \asymp b_n$, $a_n \sim b_n$) if there exists a positive constant C such that $a_n/b_n \leq C$ for all large n (resp. $\lim_{n\to\infty} a_n/b_n = 0$, $1/C \leq a_n/b_n \leq C$ for all large n, $\lim_{n\to\infty} a_n/b_n = 1$). Denote by F_ϵ (resp. F) the c.d.f. of the innovation ϵ_i (resp. X_i) and by $f_\epsilon = F_\epsilon'$ (resp. $f = F'$) the probability density function (p.d.f.) of ϵ_i (resp. X_i).

2. Main results

Recall (3) for the MA(∞) process (X_i), where $\epsilon_j \in \mathcal{L}^q,\ j \in \mathbb{Z}$, are i.i.d. with c.d.f. F_ϵ and p.d.f. f_ϵ. Assume $a_0 \neq 0$ and without loss of generality, let $a_0 = 1$.

For a function class $\mathcal{A}$ of bounded functions, define the covering number

$$\mathcal{N}_{\mathcal{A}}(\delta) := \min\Big\{m :\ \text{there exist } g_1, \ldots, g_m \in \mathcal{A} \text{ such that } \sup_{g\in\mathcal{A}}\min_{1\leq j\leq m}|g - g_j|_\infty \leq \delta\Big\}. \tag{11}$$

Let $H_{\mathcal{A}}(\delta) := \log(\mathcal{N}_{\mathcal{A}}(\delta))$ be the metric entropy.

Before stating the main theorems, we shall introduce some assumptions.

(A) (Smoothness) For any $g \in \mathcal{A}$, g', g'' exist and $|g|, |g'|, |g''|$ are uniformly bounded, without loss of generality set the bound to be 1.

(A') Functions in $\mathcal{A}$ are uniformly bounded in $|\cdot|_\infty$ with $\sup_{g\in\mathcal{A}}|g|_\infty \le 1$. Assume that $f'_\epsilon, f''_\epsilon$ exist and the integrals $\int_{-\infty}^{\infty}|f'_\epsilon(x)|\mathrm{d}x, \int_{-\infty}^{\infty}|f''_\epsilon(x)|\mathrm{d}x$ are bounded by 1.

(B) (Algebraically Decaying Coefficients) For some $\gamma, \beta > 0$, $|a_k| \le \gamma k^{-\beta}$ holds for all $k \ge 1$.

(B') (Exponentially Decaying Coefficients) For some $\gamma > 0, 0 < \rho < 1$, $|a_k| \le \gamma\rho^k$ holds for all $k \ge 1$.

(D) (Exponential Class) For some constants $N, C, \theta > 0$, the covering number $\mathcal{N}_{\mathcal{A}}(\delta) \le N\exp(C\delta^{-\theta})$ holds for all $0 < \delta \le 1$.

(D') (Algebraical Class) For some constants $N, \theta > 0$, the covering number $\mathcal{N}_{\mathcal{A}}(\delta) \le N\delta^{-\theta}$ holds for all $0 < \delta \le 1$.

Remark 1 *Assumption (A) requires that functions in $\mathcal{A}$ have up to second order derivatives. This is relaxed in (A'), where an extra differentiability condition of f_ϵ is imposed. It holds for many commonly used distributions such as Gaussian and t distributions.*

Remark 2 *Assumption (B) specifies the decay rate of the MA(∞) coefficients to be at most polynomial. The parameter β controls the dependence strength, with larger β implying weaker dependence. By Theorem 4(v) in Chen and Wu (2016), the AR(∞) process*

$$X_t = \sum_{i\ge1} b_i X_{t-i} + \epsilon_t \tag{12}$$

with coefficients $|b_i| = O(i^{-\beta})$, $\beta > 1$, and $\sum_{i\ge1}|b_i| < 1$, can also be rewritten as an MA(∞) process with coefficients (a_i) decaying at the same polynomial rate. Assumption (B') allows ARMA processes (4).

Remark 3 *Assumptions (D) and (D') quantify the magnitudes of the class $\mathcal{A}$. They are satisfied for many function classes; see van der Vaart and Wellner (1996) and Kosorok (2008). For example, the former holds for Hölder or Sobolev classes, while the latter holds for VC classes.*

In the MA(∞) model described in (3), the parameter β controls the dependence: if $\beta > 1$, the covariances $\mathrm{Cov}(X_i, X_0)$, $i \ge 1$, are absolutely summable and the process (X_i) is short-range dependent; if $1/2 < \beta < 1$, then the covariances may not be absolutely summable and the process exhibits long-range dependence. The two cases are dealt with in Subsections 2.1 and 2.2, respectively. Subsection 2.3 deals linear processes with sub-exponential innovations.

2.1 Short-range dependent linear processes

We first consider the short-range dependence case with $\beta > 1$ in model (3). Recall (1) for Δ_n. Assume throughout the paper that $n \ge 2$. Let $q' := q \wedge 2$ and

$$c(n,q) = \begin{cases} n^{1/q'}, & \text{if } q > 2 \text{ or } 1 < q < 2, \\ n^{1/2}\log^{1/2}(n), & \text{if } q = 2. \end{cases} \tag{13}$$

Theorems 4 and 7 concern algebraically and exponentially decaying coefficients, respectively. In the statements of our theorems we use the notation $C_{\alpha,\beta,\gamma,\ldots}$ to denote constants that only depend on subscripts $\alpha, \beta, \gamma, \ldots$. Since $|g|_\infty \le 1$, we have $T(z) = 0$ if $z > n$ and thus assume throughout the paper that $z \le n$.

Theorem 4 (Algebraically decaying coefficients) *Assume (A) and (B), $\beta > 1, q > 1$ and $q\beta \ge 2$. Then there exist positive constants $C_q, C_{\beta,q,\gamma}$ and $C_{\beta,\gamma}$ such that for all $z > 0$,*

$$\begin{aligned}&\mathbb{P}\Big(\Delta_n \ge C_q a_* \mu_q c(n,q) + z\Big) \\ \le& C_{\beta,q,\gamma}\mu_q^q \frac{n}{z^{q\beta}} + 3\exp\Big(-\frac{z^2}{C_{\beta,\gamma}\mu_{q'}^{q'} n} + H_{\mathcal{A}}(z/(4n))\Big) + 2\exp\Big(-\frac{z^v}{8\mu_q^{v'}} + H_{\mathcal{A}}(z/(4n))\Big),\end{aligned} \tag{14}$$

where $\mu_q = (\mathbb{E}|\epsilon_i|^q)^{1/q}$, $a_* = \sum_{i=0}^{\infty}|a_i|$, and

$$v = v_{q,\beta} = (q'\beta - 1)(3q'\beta - 1)^{-1}, \quad v' = 2q'(3q'\beta - 1)^{-1}. \tag{15}$$

The specific values of the constants $C_q, C_{\beta,q,\gamma}$ and $C_{\beta,\gamma}$ will be given in Remark 25 (Section 6.2). The bound (14) is a combination of exponential and polynomial terms. For z relatively small, the exponential term contributes more, while for z relatively large, the polynomial term $n/z^{q\beta}$ dominates. Note that $0 < v < 1/3$. Comparing the last two terms in (14), if $n^{1/(2-v)} \lesssim z$, then the last term dominates, and vise versa.

In Theorem 4, under Assumption (A), the class $\mathcal{A}$ consists of differentiable functions. To incorporate non-continuous functions, we can impose Assumption (A'), which requires differentiability of f_ϵ; cf Proposition 5. Corollary 6 follows from Theorem 4 and Proposition 5.

Proposition 5 *Assume (A') and (B), $\beta > 1, q > 1$ and $q\beta \ge 2$. Then there exist positive constants $C_q, C_{\beta,q,\gamma}$ and $C_{\beta,\gamma}$ such that for all $z > 0$,*

$$\begin{aligned}&\mathbb{P}\Big(\Delta_n \ge C_q a_* \mu_q c(n,q) + z\Big) \\ \le& C_{\beta,q,\gamma}\mu_q^q \frac{n}{z^{q\beta}} + 5\exp\Big(-\frac{z^2}{C_{\beta,\gamma}(\mu_{q'}^{q'} \vee 1)n} + H_{\mathcal{A}}(z/(4n))\Big) + 2\exp\Big(-\frac{z^v}{8\mu_q^{v'}} + H_{\mathcal{A}}(z/(4n))\Big),\end{aligned}$$

where $c(n,q)$ is defined in (13) *and v, v' are defined in* (15).

Corollary 6 *Assume (A) (or (A')) and (B). Let $\beta > 1, q > 1$ and $q\beta \ge 2$. Define $c(n,q)$ and v as in* (13) *and* (15)*, respectively. If either (i) Assumption (D) holds, $\alpha = \max\{\theta/(\theta+$*

$2), (\theta - v)/(\theta + v)\}/2$, *and* $z \geq cn^{1/2+\alpha}$ *for a sufficiently large* c*; or (ii) for some* $N, \theta > 0$, *Assumption* (D') *holds and* $z \geq cn^{1/2}\log^{1/2}(n)$ *for a sufficiently large* c*, then we have*

$$\mathbb{P}\Big(\Delta_n \geq C_q a_* \mu_q c(n,q) + z\Big) \leq C\mu_q^q \frac{n}{z^{q\beta}}, \tag{16}$$

where the constant C *only depends on* $\beta, q, \gamma, \theta, c$ *and* N.

Observe that in (16), when $q > 2$, the term $C_q a_* \mu_q c(n,q) + z$ can actually be replaced by z by choosing a larger constant C at the right hand side of (16), since $z \geq cn^{1/2+\alpha}$ or $z \geq cn^{1/2}\log^{1/2}(n)$ for a sufficiently large c, under (i) or (ii), respectively. The tail bound depends on both the dependence parameter β and the moment q.

If the coefficients (a_k) decay exponentially (cf Assumption (B')), then the process is very weakly dependent. It turns out that the polynomial term can be removed and an exponential upper bound can be derived; cf Theorem 7. Note that the bound in Theorem 7 explicitly involves ρ, with larger ρ indicating stronger dependence. We emphasize that the constants C_q, $C_{q,\gamma}$ and $C'_{q,\gamma}$ in (17) does not depend on ρ and they are given in Remark 26 (Section 6.3). Concentration inequality of this form is useful in situations in which one needs to deal with the dependence on ρ.

Theorem 7 (Exponentially decaying coefficients) *Assume that the coefficients* (a_k) *of* (X_i) *defined in* (3) *satisfy* (B') *and* $\mu_q = \|\epsilon_i\|_q < \infty$, $q > 1$. *Let* $\mathcal{A} = \{g : \mathbb{R} \mapsto \mathbb{R}, |g|_\infty \leq 1, |g'|_\infty \leq 1\}$. *Then*

$$\mathbb{P}(\Delta_n \geq C_q \mu_q c^*(n,\rho,q) + z) \leq C_{q,\gamma}\frac{\exp\{-q(1-\rho)n\}\mu_q^q}{z^q(1-\rho)^{q+q/q'}} + \exp\Big\{-C'_{q,\gamma}\frac{z^2(1-\rho)^2}{n(\mu_q^q \vee 1)}\Big\}, \tag{17}$$

where $q' = \min\{q, 2\}$,

$$c^*(n,\rho,q) = \begin{cases} n^{1/q'}(1-\rho)^{-1-1/q'}, & \text{if } q \neq 2, \\ \sqrt{n}(1-\rho)^{-3/2}\log(n(1-\rho)^{-1}), & \text{if } q = 2. \end{cases}$$

2.2 Long-range dependent linear processes

The phenomenon of long-range dependence has been observed in various fields including economics, finance, hydrology, geophysics etc; see, for example, Beran (1994), Baillie (1996). This subsection considers $1/2 < \beta < 1$, the long-range dependence case in model (3). Weak convergence for empirical processes for long-memory time series was studied by Ho and Hsing (1996) and Wu (2003) among others. Under suitable conditions on the class $\mathcal{A}$, by Corollary 1 in Wu (2003), one has $\mathbb{E}(\Delta_n^2) \lesssim n^{3-2\beta}$, which by Markov's inequality implies

$$\mathbb{P}(\Delta_n \geq z) \leq \frac{\mathbb{E}(\Delta_n^2)}{z^2} \lesssim \frac{n^{3-2\beta}}{z^2}.$$

Here we shall derive a much sharper and more general bound; cf Theorem 8, which allows strong dependence with non-summable algebraically decaying coefficients since $\beta < 1$. In comparison the coefficients (a_k) in Theorem 4 are summable, since $\beta > 1$, and the process is weakly dependent. Proposition 9 is an analogous version of Proposition 5 which allows discontinuous functions. Corollary 10 provides an explicit upper bound under certain conditions on the bracketing numbers and it follows from Theorem 8 and Proposition 9.

Theorem 8 *Assume* (A) *and* (B), $q > 2$, $1/2 < \beta < 1$. *Then there exist positive constants* $C'_{\beta,q,\gamma}$, $C_{\beta,q,\gamma}$ *and* $C_{\beta,\gamma}$ *such that for all* $z > 0$,

$$\begin{aligned}&\mathbb{P}\Big(\Delta_n \geq C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z\Big) \\ \leq& C_{\beta,q,\gamma}(\mu_q^{2q} \vee \mu_q^q)\frac{n^{1+(1-\beta)q}}{z^q}\Big(1 + \frac{[H_{\mathcal{A}}(z/4n) + \log(n)]^q}{\tilde{c}^q(n,\beta)}\Big) + 3\exp\Big(-\frac{z^2}{C_{\beta,\gamma}n^{3-2\beta}\mu_2^2} + H_{\mathcal{A}}(z/(4n))\Big),\end{aligned} \tag{18}$$

where

$$\tilde{c}(n,\beta) = \begin{cases} n^{1/4-|3/4-\beta|} & \text{if } \beta \neq 3/4, \\ n^{1/4}/\log(n) & \text{if } \beta = 3/4. \end{cases} \tag{19}$$

Values of constants $C'_{\beta,q,\gamma}$, $C_{\beta,q,\gamma}$ and $C_{\beta,\gamma}$ in Theorem 8 are given in Remark 29 (Section 6.4). In comparison with the bound $nz^{-q\beta}$ in the short-range dependence case Theorem 4, the bound $n^{1+(1-\beta)q}z^{-q}$ in (18) of Theorem 8 is larger since $nz^{-q\beta} \leq n^{1+(1-\beta)q}z^{-q}$ and $n \geq z$.

Proposition 9 *Assume* (A') *and* (B), $q > 2$, $1/2 < \beta < 1$. *Recall* (19) *for* $\tilde{c}(n,q)$. *Then there exist positive constants* $C'_{\beta,q,\gamma}$, $C_{\beta,q,\gamma}$ *and* $C_{\beta,\gamma}$ *such that for all* $z > 0$,

$$\begin{aligned}\mathbb{P}\Big(\Delta_n \geq C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z\Big) \;\leq\; & C_{\beta,q,\gamma}(\mu_q^{2q} \vee \mu_q^q)\frac{n^{1+(1-\beta)q}}{z^q}\Big(1 + \frac{[H_{\mathcal{A}}(z/4n) + \log(n)]^q}{\tilde{c}^q(n,\beta)}\Big) \\ & + 5\exp\Big(-\frac{z^2}{C_{\beta,\gamma}n^{3-2\beta}(\mu_2^2 \vee 1)} + H_{\mathcal{A}}(z/(4n))\Big).\end{aligned}$$

Corollary 10 *Assume* (A) *(or* (A')*) and* (B). *Let* $q > 2$, $1/2 < \beta < 1$. *If either (i) for some* $N, \theta > 0$, *Assumption* (D) *holds and* $z \geq cn^{3/2-\beta+\alpha}$ *for* $\alpha = (\beta - 1/2)\theta/(\theta + 2)$ *and a sufficiently large* c *or (ii) for some* $N, \theta > 0$, *Assumption* (D') *holds and* $z \geq cn^{3/2-\beta}\log^{1/2}(n)$ *for a sufficiently large* c. *Then there exists a constant* $C'_{q,\beta,\gamma}$ *such that*

$$\mathbb{P}\Big(\Delta_n \geq C'_{q,\beta,\gamma}\mu_q n^{3/2-\beta} + z\Big) \lesssim \frac{n^{1+(1-\beta)q}}{z^q}(\mu_q^{2q} \vee \mu_q^q)\Big(1 + \frac{t_n^q}{\tilde{c}^q(n,\beta)}\Big), \tag{20}$$

where $t_n = n^{\theta(\beta-1/2-\alpha)}$ *and* $\log(n)$ *for* (i) *and* (ii) *respectively, and the constant in* $\lesssim$ *only depends on* $q, \beta, \gamma, \theta, c$ *and* N.

2.3 Linear processes with sub-exponential innovations

In this subsection, we shall consider concentration inequalities for linear processes with innovations having very light tails. In particular, we assume that innovations ϵ_i have sub-exponential tails. In this case for both short- and long-range dependent processes we have exponentially decaying tail probabilities, with different norming sequences.

Theorem 11 *Let* $\mathcal{G} = \{g : |g|_\infty \leq 1, |g'|_\infty \leq 1\}$. *Assume* (B) *and there exist constants* $c_0 > 0, f_* > 0$ *such that* $|f_\epsilon|_\infty \leq f_*$, *where* f_ϵ *is the p.d.f of* ϵ_0, *and* $\mu_e := \mathbb{E}(e^{c_0|\epsilon_0|}) < \infty$. *Then there exist constants* C_1, C_2, C_3 *and* C_4 *such that*

(a) for SRD case ($\beta > 1$), we have for all $z > 0$,

$$\mathbb{P}(\Delta_n \geq C_1\sqrt{n} + z) \leq 2e^{-C_2 z^2/n},$$

(b) for LRD case ($1/2 < \beta < 1$), we have for all $z > 0$,

$$\mathbb{P}(\Delta_n \geq C_3 n^{3/2-\beta} + z) \leq 2e^{-C_4 z^2/n^{3-2\beta}}.$$

Here the constants C_1 and C_3 only depend on $f_*, \beta, \gamma, c_0, \mu_e$, constants C_2, C_4 only depend on $\beta, \gamma, c_0, \mu, \mu_e$ and their values are given in Remark 30 (Section 6.5). Note that Theorem 11(a) implies $\mathbb{P}(\Delta \geq z) \leq 2e^{-C_5 z^2/n}$ for all $z > 0$, where constant C_5 depends on $f_*, \beta, \gamma, c_0, \mu$ and μ_e. A similar claim can be made for case (b).

In comparison with the results in Theorem 4 and Theorem 8, due to the light tails of the innovations, we do not encounter the polynomial terms $n/z^{q\beta}$ or $n^{3-2\beta}/z^{q\beta}$ here.

3. Empirical distribution functions

In this section we shall consider the important class of indicators indexed by half intervals. Let

$$S_n(t) = n[\hat{F}_n(t) - F(t)] = \sum_{i=1}^{n} [\mathbf{1}_{X_i \leq t} - F(t)]. \tag{21}$$

In Massart (1990)'s result (2), X_i are i.i.d. In Theorem 12, we present a concentration inequality for dependent and possibly heavy-tailed random variables, which has a very different upper bound that involves a polynomial decaying tail. Theorem 14 provides a lower bound for the deviation with regularly varying innovations. That lower bound assures the sharpness of Theorem 12: the polynomial decaying tail is unavoidable. Recall F_ϵ is the c.d.f. of ϵ_0 and f_ϵ its p.d.f. The values of constants in Theorem 12 are given in Remark 31 (Section 6.6). Following assumption states the boundedness of $|f_\epsilon|_\infty$ and $|f'_\epsilon|_\infty$.

(A_1) Let $f_* := \max(1, |f_\epsilon|_\infty, |f'_\epsilon|_\infty)$. Assume $f_* < \infty$.

Theorem 12 *Assume (A_1) and (B). Recall $c(n,q)$ and v, v' in (13) and (15) respectively.*

(i). Let $\beta > 1, q > 1$ (SRD case) and $q\beta \geq 2$. Then there exist constants C_0, C_1, C_2, C_3 such that

$$\begin{aligned}
&\mathbb{P}\left(\sup_{t\in\mathbb{R}} |S_n(t)|/f_* > C_0 a_* \mu_q c(n,q) + z\right) \\
\leq& C_1 \mu_q^q \frac{n}{z^{q\beta}} + 4\exp\Big\{ - C_2 \frac{z^2}{n(\mu_{q'}^{q'} \vee 1)} + C_3 \log(n\mu_q) \Big\} \\
&+ 2\exp\Big\{ - \frac{z^v}{2^{3+2v}\mu_q^{v'}} + C_3 \log(n\mu_q) \Big\},
\end{aligned}$$

In particular, if $z \geq cn^{1/2}\log^{1/2}(n)$, where c is a sufficiently large constant, then the above upper bound becomes $2C_1\mu_q^q n/z^{q\beta}$.

(ii). If $1/2 < \beta < 1$ (LRD case) and $q > 2$, then there exist constants C_0', C_1', C_2', C_3' such that

$$\begin{aligned}
&\mathbb{P}\left(\sup_{t\in\mathbb{R}} |S_n(t)|/f_* > C_0' \mu_q n^{3/2-\beta} + z\right) \\
\leq& C_1'(\mu_q^{2q} \vee \mu_q^q) \frac{n^{1+(1-\beta)q}}{z^q} + 4\exp\Big\{ - C_2' \frac{z^2}{n^{3-2\beta}(\mu_2^2 \vee 1)} + C_3' \log(n\mu_q) \Big\},
\end{aligned}$$

If $z \geq cn^{3/2-\beta}\log^{1/2}(n)$ for a sufficiently large c, then the above upper bound becomes $2C_1'(\mu_q^{2q} \vee \mu_q^q) n^{1+(1-\beta)q}/z^q$.

In (i) the constant C_0 only depends on q, C_1, C_3 only depend on β, q, γ and C_2 only depends on β, γ; In (ii) the constants C_0', C_1', C_3' only depend on β, q, γ and C_2' only depends on β, γ, their specific values can be found in Remark 31 (Section 6.6).

Under certain forms of tail probability of the innovations, we can have a more refined result.

Proposition 13 *Assume (A_1), (B), $\beta > 1$ and $q > 2$. Assume for any $x > 1$, $\mathbb{P}(|\epsilon_0| > x) \leq L\log^{-r_0}(x)x^{-q}$, with some constants $r_0 > 1, L > 0$. If $z \geq c\sqrt{n}\log^\alpha(n)$, $\alpha > 1/2$, then*

$$\mathbb{P}\left(\sup_{t\in\mathbb{R}} |S_n(t)|/f_* > z\right) \lesssim \frac{\mu_q^q n}{z^{q\beta}\log^{r_0}(z)},$$

where the constant in $\lesssim$ only depends on $\beta, q, \gamma, r_0, L, c$ and α.

To appreciate the sharpness of the upper bound in Proposition 13, we derive an exact decay rate when $a_k = (k \vee 1)^{-\beta}$ and ϵ_0 is symmetric with a regularly varying tail.

Theorem 14 *Assume (A_1), (B) with coefficients $a_k = (k \vee 1)^{-\beta}$, $k \geq 0$, and that ϵ_0 is symmetric with tail distribution*

$$\mathbb{P}(\epsilon_0 \geq x) \sim \log^{-r_0}(x)x^{-q}, \text{ as } x \to \infty, \tag{22}$$

where $r_0 > 1$ is a constant. Let $\beta > 1$, $q > 2$ and $\alpha > 1/2$. Then there exists a constant $\Gamma > 0$ such that for all z with $\sqrt{n}\log^\alpha(n) \leq z \leq n/\log^\Gamma(n)$,

$$\mathbb{P}\left(S_n(t) > z\right) = (1 + o(1))C_1 \frac{n}{\log^{r_0}(z)z^{q\beta}}, \tag{23}$$

and

$$\mathbb{P}\left(S_n(t) < -z\right) = (1 + o(1))C_2 \frac{n}{\log^{r_0}(z)z^{q\beta}}, \tag{24}$$

where the constants C_1, C_2 only depend on q, β, r_0, t and F.

Values of C_1 and C_2 are given in Lemma 34, and the constant Γ can be found in Remark 35 (Section 6.7). The asymptotic expressions (23) and (24) in Theorem 14 precisely depict the magnitude of the tail probability $\mathbb{P}\left(S_n(t) > z\right)$ and $\mathbb{P}\left(S_n(t) < -z\right)$. It asserts that the upper bound order in Proposition 13 is optimal within the range $\sqrt{n}\log^\alpha(n) \leq z \leq n/\log^\Gamma(n)$. Thus the polynomial $n/z^{q\beta}$ in Theorems 4 and 12 is sharp up to a multiplicative logarithmic term.

4. Kernel density estimation

Let (X_i) be a stationary sequence satisfying (3) with the marginal p.d.f. f. Given the observations $X_1, \ldots, X_n$, the kernel density estimator of f is

$$\hat{f}_n(x) = \frac{1}{n}\sum_{j=1}^{n} K_b(x - X_j), \quad K_b(\cdot) = b^{-1}K(\cdot/b),$$

where the bandwidth $b = b_n$ satisfies the natural condition $b_n \to 0$ and $nb_n \to \infty$. Wu and Mielniczuk (2002) established an asymptotic distribution theory for $A_n(\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x))$ for both short- and long-range dependent processes, where A_n is a proper norming sequence. In this section we shall derive a bound for the tail probability

$$\mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \geq z\Big).$$

Such a bound is useful for constructing non-asymptotic confidence bounds. Giné and Guillou (2002) and Giné and Nickl (2010) considered the latter problem for i.i.d. data. Einmahl and Mason (2005) derived uniform in bandwidth consistency result for kernel-type function estimators. Hang et al. (2016) studied consistency properties for observations generated by certain dynamical systems under mixing conditions. Rinaldo et al. (2012), Chen et al. (2016) and Arias-Castro et al. (2016) applied such bounds in clustering problem. Liu et al. (2011) and Lafferty et al. (2012) used it in forest density estimation. Here, we shall provide a polynomial decay bound for linear time series.

Corollary 15 *Assume (B), the kernel K is symmetric with support $[-1,1]$, $\max(|K|_\infty, |K'|_\infty) \leq K_*$ and $\max(1, |f_\epsilon|_\infty, |f'_\epsilon|_\infty, |f''_\epsilon|_\infty) \leq f_*$ for some constants $K_*, f_* > 0$.*

(a) In the SRD case with $\beta > 1, q > 1, q\beta \geq 2$, if $z \geq c(n/b_n)^{1/2}\log^{1/2}(n)$ for a sufficiently large c, then

$$\mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \geq \max(f_*, K_*)z\Big) \lesssim \mu_q^q n/z^{q\beta}, \tag{25}$$

where the constant in $\lesssim$ only depends on β, q, γ and c.

(b) In the LRD case with $1/2 < \beta < 1, q > 2$, if $z \geq c\max\{n^{3/2-\beta}, (n/b_n)^{1/2}\}\log^{1/2}(n)$ holds for a sufficiently large c, then

$$\mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \geq \max(f_*, K_*)z\Big) \lesssim (\mu_q^{2q} \vee \mu_q^q)\frac{n^{1+(1-\beta)q}}{z^q}, \tag{26}$$

where the constant in $\lesssim$ only depends on β, q, γ and c.

5. Empirical risk minimization

Empirical risk minimization is of fundamental importance in the statistical learning theory and it is studied in various contexts including classification, regression and clustering among others. To fix the notation, let (X, Y) be a random vector taking values in the space $\mathcal{X} \times \mathcal{Y}$

and $\mathcal{H}$ be a class of measurable functions $h : \mathcal{X} \to \mathcal{Y}$. For a function $h \in \mathcal{H}$, define the risk $R(h) = \mathbb{E}[L(X, Y, h(X))]$, where L is a loss function. Let $h^* = \mathrm{argmin}_{h\in\mathcal{H}} R(h)$. Based on the observations $(X_1, Y_1), \ldots, (X_n, Y_n)$ which are identically distributed as (X, Y), consider the empirical risk minimizer

$$\hat{h} = \mathrm{argmin}_{h\in\mathcal{H}} R_n(h), \text{ where } R_n(h) = n^{-1}\sum_{i=1}^{n} L(X_i, Y_i, h(X_i)) \tag{27}$$

is the empirical risk. Since $R_n(h^*) \geq R_n(\hat{h})$, it follows (cf. Devroye et al. (1996)) that

$$0 \leq R(\hat{h}) - R(h^*) \leq 2\Psi_n, \text{ where } \Psi_n = \sup_{h\in\mathcal{H}} |R_n(h) - R(h)|. \tag{28}$$

A primary goal in statistical learning theory is to bound the uniform deviation Ψ_n. The latter problem has been widely studied when (X_i, Y_i) are assumed to be i.i.d.; see, for example, Caponnetto and Rakhlin (2006), Vapnik (1998, 2000) and Gottlieb et al. (2017). In recent years various dependent processes have been considered; see Modha and Masry (1996), Guo and Shi (2011), Zou and Li (2007), Zou et al. (2009), Alquier and Wintenberger (2012), Mohri and Rostamizadeh (2010), Steinwart and Christmann (2009), Hang and Steinwart (2014, 2016), Shalizi and Kontorovich (2013) among others.

Here we shall provide an upper bound for Ψ_n with (X_i) being the MA(∞) process (3) and the regression model

$$Y_i = H_0(X_i, \eta_i),$$

where $\eta_i, i \in \mathbb{Z}$, are i.i.d. random errors independent of (ϵ_i) and H_0 is an unknown measurable function. Denote $\mathcal{A} = \{g(x, y) = L(x, y, h(x)), h \in \mathcal{H}\}$ and

$$\mathcal{N}_{\mathcal{A}}(\delta) = \min\{m : \text{there exist } g_1, \ldots, g_m \in \mathcal{A}, \text{such that } \sup_{g\in\mathcal{A}} \min_{1\leq j\leq m} |g - g_j|_\infty \leq \delta\},$$

where $|g|_\infty = \sup_{x,y} |g(x, y)|$. Assume that the loss function L take values in $[0, 1]$. Here for the sake of presentational clarity we do not seek the fullest generality but as an illustration on how to apply our main results. Recall that f_ϵ is the density function of ϵ_i.

Corollary 16 *Assume (B), the density $f_\epsilon \in \mathcal{C}^2(\mathbb{R})$ with $f_* := \max(\int_{-\infty}^{\infty} |f'_\epsilon(x)|\mathrm{d}x, \int_{-\infty}^{\infty} |f''_\epsilon(x)|\mathrm{d}x, 1)$. Under conditions (i) or (ii) in Corollary 6 on the function class $\mathcal{H}$, $q, \beta > 1$ and $q\beta \geq 2$ (resp. conditions (i) or (ii) in Corollary 10 on $\mathcal{H}$, $q > 2$ and $1/2 < \beta < 1$), we have* (16) *(resp.* (20)*) holds with Δ_n therein replaced by $n\Psi_n/f_*$.*

Remark 17 In literature, many concentration inequalities for time series are derived under various mixing conditions (see, for example, Mohri and Rostamizadeh (2010)). Since mixing and our model (3) cover different ranges of processes, our results are not directly comparable with theirs. Here we consider an example in which our result and Corollary 21 in Mohri and Rostamizadeh (2010) can be compared. Let $X_i = \sum_{k\geq 0} a_k\epsilon_{i-k}$, where ϵ_t are i.i.d. with finite qth moment, $q > 2$ and $a_0 = 1$, $a_k \asymp k^{-\alpha}$, $\alpha > 2 + 1/q$. Assume the p.d.f. of ϵ_i satisfies $\int_{x\in\mathbb{R}} |f'_\epsilon(x)|\mathrm{d}x < \infty$ and $\int_{x\in\mathbb{R}} |f''_\epsilon(x)|\mathrm{d}x < \infty$. By Theorem 2.1 in Pham and Tran (1985), X_i is β-mixing and its β-mixing coefficient $\beta(k) = O(k^{1-(\alpha-1)q/(1+q)})$.

Assume functions $h \in \mathcal{H}$ are bounded and the function class $\mathcal{H}$ satisfies condition (D'). Also assume that a $\hat{\beta}$-stable algorithm yields an estimate $\hat{h}_S$ with $\hat{\beta} = O(n^{-1})$ where the definition for $\hat{\beta}$-stable can be found in Definition 4 of Mohri and Rostamizadeh (2010).

Let $K = 1/4 - (q+1)/(2(\alpha-1)q)$. By Corollary 21 in Mohri and Rostamizadeh (2010), there exists a constant $C > 0$ such that for $\delta > n^{-K}$,

$$\mathbb{P}(n|R_n(\hat{h}) - R(\hat{h})| \geq Cz_\delta) \leq \delta, \text{ where } z_\delta = n^{1-K}(\log(\delta - n^{-K})^{-1})^{1/2}. \tag{29}$$

By our Corollary 17,

$$\mathbb{P}(\sup_{h\in\mathcal{H}} n|R_n(h) - R(h)| \geq Cz_\delta) \lesssim \frac{n}{z_\delta^{q\alpha}}. \tag{30}$$

Note that, if $\delta > n^{-K}$, $nz_\delta^{-q\alpha} = O(n^{1-(1-K)q\alpha})$, which is of order $o(n^{-K})$ since $1-(1-K)q\alpha < -K$. To give a numeric example, let $\alpha = 4$, $q = 4$. Then $K = 1/24$, $1-(1-K)q\alpha = -43/3$. So (30) gives a much smaller upper bound $O(n^{-43/3})$, while (29) leads to the bound $O(n^{-1/24})$. The latter phenomenon could be explained by the sharpness of our upper bounds.

6. Proofs

In this section we shall provide proofs for results stated in the previous sections. We shall first introduce some notation. For $k \geq 1$ define the functions

$$g_k(x) := \mathbb{E}\Big[g(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x)\Big], \quad g_\infty(x) := \mathbb{E}[g(X_0 + x)]. \tag{31}$$

Since $a_0 = 1$, $g_1(x) = \mathbb{E}g(\epsilon_0 + x)$. Write $g_0(\cdot) = g(\cdot)$. Define projection operator P_k, $k \in \mathbb{Z}$, by $P_k\cdot = \mathbb{E}(\cdot|\mathcal{F}_k) - \mathbb{E}(\cdot|\mathcal{F}_{k-1})$, where $\mathcal{F}_i = (\epsilon_i, \epsilon_{i-1}, \ldots)$, that is $P_k f = \mathbb{E}(f(X)|\mathcal{F}_k) - \mathbb{E}(f(X)|\mathcal{F}_{k-1})$. For $j \leq i$, let

$$X_{i,j} = \sum_{k\geq 0} a_{i-j+k}\epsilon_{j-k}$$

be the truncated process. Then $X_{i,j} = \mathbb{E}(X_i|\mathcal{F}_j)$ and $g_{i-j}(X_{i,j}) = \mathbb{E}(g(X_i)|\mathcal{F}_j)$.

Let $\lfloor x \rfloor = \max\{i \in \mathbb{Z}, i \leq x\}$ and $\lceil x \rceil = \min\{i \in \mathbb{Z}, i \geq x\}$. Recall $\mu_q = (\mathbb{E}|\epsilon_0|^q)^{1/q}$ and let $\mu = \mu_1$.

In Section 6.1 we shall first present some inequalities and lemmas that will be extensively used. Theorem 4 and Proposition 5 (resp. Theorem 8 and Proposition 9) are proved in Section 6.2 (resp. Section 6.4). Theorem 7 (resp. Theorem 11, Theorem 14) is shown in Section 6.3 (resp. Section 6.5, Section 6.7). Section 6.6 gives proofs of Theorem 12 and Proposition 13. Proofs of Corollaries 15 and 16 are provided in Section 6.8.

6.1 Some useful lemmas

Lemma 18 is a maximal form of Freedman's martingale inequality (cf Freedman (1975)) and it is a simple modified version of Lemma 1 in Haeusler (1984). Lemma 19 is Burkholder's martingale inequality for moments (Burkholder (1988)). Lemma 20 is a Fuk-Nagaev inequality for high dimensional vectors (Chernozhukov et al. (2017)).

Lemma 18 *Let $\mathcal{A}$ be an index set with $|\mathcal{A}| < \infty$. For each $a \in \mathcal{A}$, let $\{\xi_{a,i}\}_{i=1}^n$ be a martingale difference sequence with respect to the filtration $\{\mathcal{F}_i\}_{i=1}^n$. Let $M_a = \sum_{i=1}^n \xi_{a,i}$ and $V_a = \sum_{i=1}^n \mathbb{E}[\xi_{a,i}^2|\mathcal{F}_{i-1}]$. Then for all $z, u, v > 0$*

$$\mathbb{P}\Big(\max_{a\in\mathcal{A}} |M_a| \geq z\Big) \leq \sum_{i=1}^n \mathbb{P}\Big(\max_{a\in\mathcal{A}} |\xi_{a,i}| \geq u\Big) + 2\mathbb{P}\Big(\max_{a\in\mathcal{A}} V_a \geq v\Big) + 2|\mathcal{A}|e^{-z^2/(2zu+2v)}.$$

Lemma 19 (Burkholder (1988), Rio (2009)) *Let $q > 1$, $q' = \min\{q, 2\}$. Let $M_T = \sum_{t=1}^T \xi_t$, where $\xi_t \in \mathcal{L}^q$ are martingale differences. Then*

$$\|M_T\|_q^{q'} \leq K_q^{q'} \sum_{t=1}^T \|\xi_t\|_q^{q'}, \text{ where } K_q = \max((q-1)^{-1}, \sqrt{q-1}).$$

Lemma 20 (A Fuk-Nagaev type inequality) *Let $X_1, \ldots, X_n$ be independent mean 0 random vectors in $\mathbb{R}^p$ and $\sigma^2 = \max_{1\leq j\leq p} \sum_{i=1}^n \mathbb{E}(X_{i,j}^2)$. Then for every $s > 1$ and $t > 0$,*

$$\mathbb{P}\Big(\max_{1\leq j\leq p} |\sum_{i=1}^n X_{i,j}| \geq 2\mathbb{E}(\max_{1\leq j\leq p} |\sum_{i=1}^n X_{i,j}|) + t\Big) \leq e^{-t^2/(3\sigma^2)} + \frac{K_s}{t^s}\sum_{i=1}^n \mathbb{E}(\max_{1\leq j\leq p} |X_{i,j}|^s),$$

where K_s is a constant depending only on s.

Lemma 21 *Assume that function g has second order derivative and $|g|, |g'|, |g''|$ are all bounded by $M < \infty$. Then $g_k, k \geq 1$, and g_∞ also have second order derivatives and $|g_k|, |g_k'|, |g_k''|$, $|g_\infty|, |g_\infty'|, |g_\infty''|$ are all bounded by M, where g_k and g_∞ are defined in* (31).

Proof Since $|g'|$ is bounded by M, by the dominated convergence theorem,

$$\lim_{\delta\to 0} \mathbb{E}\Big(\frac{g(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x + \delta) - g(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x)}{\delta}\Big) = \mathbb{E}\Big(g'(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x)\Big).$$

Since $g_k(x) = \mathbb{E}g(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x)$, $g_k'(x)$ exists and equals to $\mathbb{E}(g'(\sum_{i=0}^{k-1} a_i\epsilon_{-i} + x))$ with $|g_k'| \leq M$. Similarly g_k'' exists and $|g_k''|_\infty \leq M$. Note that $g_\infty(x) = \mathbb{E}g(\sum_{i=0}^{\infty} a_i\epsilon_{-i} + x)$. Hence same arguments lead to the existence of g_∞' and g_∞'', and they are also bounded in absolute value by M. ∎

Lemma 22 *Let $\lambda > 0$, $\beta > 1$ and $G(y) = \sum_{k=0}^\infty \min\{\lambda, (k \vee 1)^{-\beta} y\}$, $y > 0$. Then for all $y > 0$, $G(y) \leq K_{\beta,\lambda} \min\{y, y^{1/\beta}\}$, where $K_{\beta,\lambda} = \max\{(\beta-1)^{-1}, \lambda\} + 2$.*

Proof Clearly $G(y) \leq \sum_{k=0}^\infty (k \vee 1)^{-\beta} y \leq (2 + (\beta-1)^{-1})y$. If $y \geq 1$, we have $y^{1/\beta} \leq y$ and

$$\begin{aligned} G(y) &\leq \sum_{k=0}^{\lceil y^{1/\beta}\rceil} \lambda + \sum_{k=\lceil y^{1/\beta}\rceil+1}^\infty k^{-\beta} y \leq \lambda(y^{1/\beta} + 2) + (\beta-1)^{-1} y^{(1-\beta)/\beta} y \\ &\leq \max\{(\lambda+2), (\beta-1)^{-1}\} y^{1/\beta}. \end{aligned}$$

So the lemma follows by considering two cases $0 < y < 1$ and $y \geq 1$ separately. ∎

6.2 Proof of Theorem 4 and Proposition 5

The proof of Theorem 4 is quite involved. Here we shall first provide intuitive ideas of our martingale approximation approach. Recall the projection operator $P_k\cdot = \mathbb{E}(\cdot|\mathcal{F}_k) - \mathbb{E}(\cdot|\mathcal{F}_{k-1})$ and (31) for g_k and g_∞. Then $P_k g(X_i) = 0$ if $k > i$. Note that $\phi_j(g) := P_j S_n(g)$, $j = \ldots, n-1, n$, are martingale differences. Since $g_{i-j}(X_{i,j}) = \mathbb{E}(g(X_i)|\mathcal{F}_j)$, $j \le i$,

$$S_n(g) - \mathbb{E}S_n(g) = \sum_{j\le n}\phi_j(g), \text{ where } \phi_j(g) = \sum_{i=1\vee j}^{n}(g_{i-j}(X_{i,j}) - g_{i-j+1}(X_{i,j-1})). \tag{32}$$

Let $\epsilon_i, \epsilon_j', \epsilon_k'', i, j, k \in \mathbb{Z}$ be i.i.d. Since $g_{i-j+1}(x) = \mathbb{E}(g_{i-j}(x + a_{i-j}\epsilon_j))$, $g_{i-j}(x + a_{i-j}\epsilon_j) - g_{i-j+1}(x) = \mathbb{E}(\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j} g_{i-j}'(x+t)\mathrm{d}t|\mathcal{F}_j)$. Note that $X_{i,j} - X_{i,j-1} = a_{i-j}\epsilon_j$. Then

$$g_{i-j}(X_{i,j}) - g_{i-j+1}(X_{i,j-1}) = \mathbb{E}\Big(\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j} g_{i-j}'(x + X_{i,j-1})\mathrm{d}x|\mathcal{F}_j\Big). \tag{33}$$

Let $X_{i,j}'' = \sum_{k\ge 0} a_{i-j+k}\epsilon_{j-k}''$. Then $g_\infty(x) = \mathbb{E}(g_{i-j}(X_{i,j}'' + x)) = \mathbb{E}(g_{i-j}(X_{i,j}'' + x)|\mathcal{F}_j)$ and

$$g_\infty(a_{i-j}\epsilon_j) - \mathbb{E}g_\infty(a_{i-j}\epsilon_j) = \mathbb{E}\Big(\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j} g_{i-j}'(x + X_{i,j}'')\mathrm{d}x|\mathcal{F}_j\Big). \tag{34}$$

Since $\|X_{i,j}\|_q \to 0$ as $j \to \infty$, intuitively we have $g_{i-j}'(x+X_{i,j-1}) \approx g_{i-j}'(x) \approx g_{i-j}'(x+X_{i,j}'')$. These relations (33) and (34) motivate us to approximate $S_n(g) - \mathbb{E}S_n(g)$ by

$$T_n(g) = \sum_{j\le n}\tilde{\phi}_j(g), \text{ where } \tilde{\phi}_j(g) = \sum_{i=1\vee j}^{n}\big(g_\infty(a_{i-j}\epsilon_j) - \mathbb{E}g_\infty(a_{i-j}\epsilon_j)\big). \tag{35}$$

Note that $\tilde{\phi}_j(g), j \le n$, are independent random variables. Hence we can apply corresponding inequalities. In Lemma 23 a Fuk-Nagaev type inequality for $T_n(g)$ is derived. Lemma 24 concerns the closeness of $S_n(g) - \mathbb{E}S_n(g)$ and $T_n(g)$. Similar arguments are also applied in the proofs of other theorems in the paper.

Proof We now proceed with the formal argument. By (11), there exists a set A_n such that for any $g \in \mathcal{A}$, $\min_{h\in A_n}|h-g|_\infty \le z/(4n)$ and $|A_n| = \mathcal{N}_{\mathcal{A}}(z/(4n))$. Then

$$\sup_{g\in\mathcal{A}}\Big|\sum_{i=1}^{n}\big[(g-\tau_n(g))(X_i) - \mathbb{E}(g-\tau_n(g))(X_i)\big]\Big| \le z/2,$$

where $\tau_n(g) := \mathrm{argmin}_{h\in A_n}|h-g|_\infty$. Hence $\Delta_n \le z/2 + \max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g)|$ and

$$\Delta_n \le \frac{z}{2} + \max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g) - T_n(g)| + \max_{g\in A_n}|T_n(g)| =: \frac{z}{2} + \Omega_n + U_n. \tag{36}$$

For $U_n = \max_{g\in A_n}|T_n(g)|$, by Lemma 23, we have

$$\mathbb{P}\Big(U_n \ge C_q a_* \mu_q c(n,q) + \frac{z}{4}\Big) \le \exp\Big(-\frac{z^2}{C_{\beta,\gamma}\mu_{q'}^{q'}n}\Big) + C_{\beta,q,\gamma,1}\mu_q^q\frac{n}{z^{q\beta}}. \tag{37}$$

For the difference term $\Omega_n = \max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g) - T_n(g)|$, by Lemma 24,

$$\mathbb{P}(\Omega_n \ge \frac{z}{4}) \le C_{\beta,q,\gamma,2}\mu_q^q\frac{n}{z^{q\beta}} + 2|A_n|\exp\Big(-\frac{z^2}{C_{\beta,\gamma}\mu_{q'}^{q'}n}\Big) + 2|A_n|\exp\Big(-\frac{z^v}{8\mu_q^{v'}}\Big), \tag{38}$$

where $C_{\beta,q,\gamma,1}$ and $C_{\beta,q,\gamma,2}$ are constants only depending on β, q, γ and $C_{\beta,q,\gamma} = C_{\beta,q,\gamma,1} + C_{\beta,q,\gamma,2}$. Combining (36), (37) and (38), we complete the proof. ■

Lemma 23 *Recall the definitions of $\tilde{\phi}_j(g)$ and $T_n(g)$ in* (32) *and* (35) *respectively. Under assumptions of Theorem 4, we have* (37).

Proof Recall $U_n = \max_{g\in A_n}|T_n(g)|$. The proof contains two parts:

(i). Apply the Fuk-Nagaev type inequality (Lemma 20) to bound $\mathbb{P}(U_n - 2\mathbb{E}U_n \ge z/4)$.

(ii). Show that $2\mathbb{E}U_n \le C_q a_* \mu_q c(n,q)$.

Part (i): For $g \in A_n$, since $|g|, |g'|$ are bounded by 1, by Lemma 21, $|g_\infty|$ and $|g_\infty'|$ are also bounded by 1. Then

$$|\tilde{\phi}_j(g)| = \Big|\sum_{i=1\vee j}^{n}\mathbb{E}\big(\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j} g_\infty'(x)\mathrm{d}x|\mathcal{F}_j\big)\Big| \le \sum_{i=1\vee j}^{n}\min\big\{|a_{i-j}|(|\epsilon_j| + \mu),\, 2\big\}. \tag{39}$$

Therefore for $j < -n$ and any $g \in A_n$, by (39),

$$|\tilde{\phi}_j(g)| \le \min\{\gamma n(-j)^{-\beta}(|\epsilon_j| + \mu), 2n\}, \tag{40}$$

for $-n \le j \le n$ and any $g \in A_n$, by Lemma 22 and (39),

$$|\tilde{\phi}_j(g)| \le \gamma K_{\beta,2/\gamma}(|\epsilon_j| + \mu)^{1/\beta}. \tag{41}$$

Denote $V = \max_{g\in A_n}\sum_{j\le n}\mathbb{E}\tilde{\phi}_j^2(g)$. Hence by (40) and (41),

$$\begin{aligned} V &\le \sum_{j<-n}(\gamma n(-j)^{-\beta})^{q'}\mathbb{E}(|\epsilon_0| + \mu)^{q'}(2n)^{2-q'} + (\gamma K_{\beta,2/\gamma})^2\sum_{-n\le j\le n}\mathbb{E}[(|\epsilon_j| + \mu)^{2/\beta}] \\ &\le \Big(\frac{4\gamma^2}{\beta-1} + 2^{1+2/\beta}(\gamma K_{\beta,2/\gamma})^2\Big)n\mu_{q'}^{q'}. \end{aligned} \tag{42}$$

By (40),

$$\sum_{j<-n}\mathbb{E}\big(\max_{g\in A_n}|\tilde{\phi}_j|^{q\beta}\big) \le \sum_{j<-n}(2n)^{q\beta-q}(\gamma n(-j)^{-\beta})^q\mathbb{E}[(|\epsilon_j| + \mu)^q] \le \frac{2^{q\beta}\gamma^q}{q\beta-1}n\mu_q^q. \tag{43}$$

By (41),

$$\sum_{-n\le j\le n}\mathbb{E}\big(\max_{g\in A_n}|\tilde{\phi}_j|^{q\beta}\big) \le 2n(\gamma K_{\beta,2/\gamma})^{q\beta}\mathbb{E}[(|\epsilon_j| + \mu)^q] \le 2^{q+1}(\gamma K_{\beta,2/\gamma})^{q\beta}n\mu_q^q. \tag{44}$$

Inserting the bounds (42), (43) and (44) into Lemma 20, we obtain

$$\begin{aligned}\mathbb{P}(U_n - 2\mathbb{E}U_n \geq z/4) \leq & e^{-z^2/(48V)} + \frac{4^{q\beta}K_{q\beta}}{z^{q\beta}}\sum_{j\leq n}\mathbb{E}\big(\max_{g\in A_n}|\tilde{\phi}_j|^{q\beta}\big) \\ \leq & \exp\Big(-\frac{z^2}{C_{\beta,\gamma}\mu_{q'}^{q'}n}\Big) + C_{\beta,q,\gamma,1}\mu_q^q\frac{n}{z^{q\beta}}, \end{aligned} \tag{45}$$

where $C_{\beta,\gamma} = 48(4\gamma^2/(\beta-1) + 2^{1+2/\beta}(\gamma K_{\beta,2/\gamma})^2)$ and $C_{\beta,q,\gamma,1} = 4^{q\beta}K_{q\beta}(2^{q\beta}\gamma^q/(q\beta-1) + 2^{q+1}(\gamma K_{\beta,2/\gamma})^{q\beta})$.

Part (ii): Recall $a_* = \sum_{k=0}^{\infty}|a_k|$. Note that $T_n(g)$ can be rewritten as

$$\begin{aligned}T_n(g) = & \sum_{j\leq n}\tilde{\phi}_j(g) = \sum_{k\geq 0}\sum_{i=1}^{n}\{g_\infty(a_k\epsilon_{i-k}) - \mathbb{E}g_\infty(a_k\epsilon_{i-k})\} \\ = & \sum_{k\geq 0}\int_{-\infty}^{\infty}\sum_{i=1}^{n}\big(\mathbf{1}_{a_k\epsilon_{i-k}\geq x} - \mathbb{P}(a_k\epsilon_{i-k}\geq x)\big)g_\infty'(x)\mathrm{d}x.\end{aligned}$$

Let $W_n(x) = \sum_{i=1}^{n}\big(\mathbf{1}_{\epsilon_i\geq x} - \mathbb{P}(\epsilon_i\geq x)\big)$. By Lemma 21, $|g_\infty'(x)|\leq 1$. Then

$$\begin{aligned}\mathbb{E}\Big[\max_{g\in A_n}|T_n(g)|\Big] \leq & \sum_{k\geq 0}\int_{-\infty}^{\infty}\mathbb{E}|\sum_{i=1}^{n}\big(\mathbf{1}_{a_k\epsilon_{i-k}\geq x} - \mathbb{P}(a_k\epsilon_{i-k}\geq x)\big)|\mathrm{d}x \\ = & \sum_{k\geq 0}\int_{-\infty}^{\infty}\mathbb{E}|W_n(x/a_k)|\mathrm{d}x = a_*\int_{-\infty}^{\infty}\mathbb{E}|W_n(y)|\mathrm{d}y, \end{aligned} \tag{46}$$

where the last equality is obtained by change of variables $y = x/a_k$ and $a_* = \sum_{k=0}^{\infty}|a_k|$. Let $T_F(x) = \mathbb{P}(|\epsilon_0|\geq|x|)$. Note that $\mathbb{E}|\mathbf{1}_{\epsilon_i\geq x} - \mathbb{P}(\epsilon_i\geq x)| = 2F_\epsilon(x)(1-F_\epsilon(x)) \leq 2T_F(x)$, and $\mathbb{E}(\mathbf{1}_{\epsilon_i\geq x} - \mathbb{P}(\epsilon_i\geq x))^2 = F_\epsilon(x)(1-F_\epsilon(x)) \leq T_F(x)$. Hence

$$\mathbb{E}|W_n(x)| \leq \min\{\|W_n(x)\|, 2nT_F(x)\} \leq \min\{\sqrt{n}T_F(x)^{1/2}, 2nT_F(x)\}. \tag{47}$$

We have different bounds for (46) when $q>2$, $1<q<2$ and $q=2$. By Markov's inequality,

$$T_F(x) \leq \min\{|x|^{-q}\mu_q^q, 1\}. \tag{48}$$

When $q>2$, we have

$$\int_{-\infty}^{\infty}T_F(x)^{1/2}\mathrm{d}y \leq 2\Big(\int_0^{\mu_q}1\mathrm{d}x + \int_{\mu_q}^{\infty}|x|^{-q/2}\mu_q^{q/2}\mathrm{d}x\Big) = q/(q/2-1)\mu_q.$$

Inserting above into (46) and (47), we obtain

$$\mathbb{E}U_n \leq a_*\int_{-\infty}^{\infty}\mathbb{E}|W_n(x)|\mathrm{d}x \leq q/(q/2-1)a_*\mu_q\sqrt{n}. \tag{49}$$

When $1<q<2$, by (47) and (48),

$$\begin{aligned}\int_{-\infty}^{\infty}\mathbb{E}|W_n(x)|\mathrm{d}x &\leq 2\Big(\int_0^{n^{1/q}\mu_q}\sqrt{n}x^{-q/2}\mu_q^{q/2}\mathrm{d}x + \int_{n^{1/q}\mu_q}^{\infty}2nx^{-q}\mu_q^q\mathrm{d}x\Big) \\ &\leq 4(1/(2-q)+1/(q-1))\mu_q n^{1/q}.\end{aligned}$$

When $q=2$, $\mathrm{I}_1 := \int_{|x|\leq\mu_2}\sqrt{n}T_F(x)^{1/2}\mathrm{d}x \leq 2\mu_2\sqrt{n}$. By (48), $\mathrm{I}_2 := \int_{|x|>n\mu_2}2nT_F(x)\mathrm{d}x \leq 4\int_{n\mu_2}^{\infty}n\mu_2^2x^{-2}\mathrm{d}x = 4\mu_2$. By the Cauchy-Schwarz inequality,

$$\begin{aligned}\mathrm{I}_3^2 &:= \Big[\int_{\mu_2<|x|\leq n\mu_2}\sqrt{n}T_F(x)^{1/2}\mathrm{d}x\Big]^2 \leq 4n\int_{\mu_2}^{n\mu_2}xT_F(x)\mathrm{d}x\int_{\mu_2}^{n\mu_2}x^{-1}\mathrm{d}x \\ &\leq 4n\int_0^{\infty}x\mathbb{P}(|\epsilon_0|\geq x)\mathrm{d}x(\log n) = 2\mathbb{E}(\epsilon_0^2)n\log(n) = 2\mu_2^2n\log(n).\end{aligned}$$

Then by (47), $\int_{-\infty}^{\infty}\mathbb{E}|W_n(x)|\mathrm{d}x \leq \mathrm{I}_1+\mathrm{I}_2+\mathrm{I}_3 \leq 2\mu_2\sqrt{n} + 4\mu_2 + \mu_2(2n\log n)^{1/2}$. Combining the three cases $q>2$, $1<q<2$ and $q=2$, by (46), we have $\mathbb{E}U_n \leq c_qa_*\mu_qc(n,q)$. where $c_q = \max\{q/(q/2-1), 4(1/(2-q)+1/(q-1)), 6+\sqrt{2}\}$. ■

Lemma 24 *Recall the definitions of $\phi_j(g)$, $\tilde{\phi}_j(g)$ and $T_n(g)$ in* (32) *and* (35). *Under conditions of Theorem 4, we have* (38).

Proof Since $S_n(g) - \mathbb{E}S_n(g) - T_n(g)$ is the sum of martingale differences $\phi_j(g) - \tilde{\phi}_j(g)$, $j\leq n$, we can apply Lemma 18 to bound the tail probability. To this end, we shall:

(i). Derive the upper bound for $\mathrm{I}_1 = \sum_{j\leq n}\mathbb{P}(\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)|\geq u)$.

(ii). Bound the term $\mathrm{I}_2 = \max_{g\in A_n}\sum_{j\leq n}\mathbb{E}[(\phi_j(g) - \tilde{\phi}_j(g))^2|\mathcal{F}_{j-1}]$.

First we derive some inequalities that will be used for I_1 and I_2. Let $\epsilon_i, \epsilon_j', \epsilon_k'', i,j,k\in\mathbb{Z}$, be i.i.d. and $X_{i,j}'' = \sum_{k\geq 0}a_{i-j+k}\epsilon_{j-k}''$. Write $\phi_j(g) - \tilde{\phi}_j(g) = \sum_{i=1\vee j}^{n}d_{i,j}(g)$, where

$$\begin{aligned}d_{i,j}(g) =& g_{i-j}(X_{i,j}) - g_{i-j+1}(X_{i,j-1}) - g_\infty(a_{i-j}\epsilon_j) + \mathbb{E}g_\infty(a_{i-j}\epsilon_j) && (D_1)\\ =& \mathbb{E}\Big[\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j}\big(g_{i-j}'(x+X_{i,j-1}) - g_{i-j}'(x+X_{i,j}'')\big)\mathrm{d}x\big|\mathcal{F}_j\Big] && (D_2)\\ =& \mathbb{E}\Big[\int_{X_{i,j}''}^{X_{i,j-1}}\big(g_{i-j}'(x+a_{i-j}\epsilon_j) - g_{i-j}'(x+a_{i-j}\epsilon_j')\big)\mathrm{d}x\big|\mathcal{F}_j\Big] && (D_3)\\ =& \mathbb{E}\Big[\int_{a_{i-j}\epsilon_j'}^{a_{i-j}\epsilon_j}\int_{X_{i,j}''}^{X_{i,j-1}}g_{i-j}''(x+y)\mathrm{d}y\mathrm{d}x\big|\mathcal{F}_j\Big]. && (D_4)\end{aligned}$$

By Lemma 21, $|g_j|, |g_j'|$ and $|g_j''|$ are bounded by 1. Hence by (D_1)-(D_4), we have

$$\begin{aligned}&\max_{g\in A_n}|d_{i,j}(g)| \\ \leq& \min\Big\{4, 2|a_{i-j}|(|\epsilon_j|+\mu), 2(|X_{i,j-1}| + \mathbb{E}|X_{i,j}|), |a_{i-j}|(|\epsilon_j|+\mu)(|X_{i,j-1}| + \mathbb{E}|X_{i,j}|)\Big\} \\ =& \min\Big\{|a_{i-j}|(|\epsilon_j|+\mu), 2\Big\}\min\Big\{(|X_{i,j-1}| + \mathbb{E}|X_{i,j}|), 2\Big\}. \end{aligned} \tag{50}$$

Part (i): Recall $q' = \min(q, 2)$. For $i > j$, by Lemma 19,

$$\|X_{i,j-1}\|_q^{q'} \le K_q^{q'} \sum_{k\ge 1} (|a_{i-j+k}|\|\epsilon_{j-k}\|_q)^{q'} \le \big(K_q^{q'}\gamma^{q'}(\beta q'-1)^{-1}\big)(i-j)^{-q'\beta+1}\mu_q^{q'}. \quad (51)$$

Let $r = (q'\beta - 1)/(2q')$, by Markov's inequality,

$$\mathrm{I}_1 \le \sum_{-n\le j\le n} u^{-q(\beta+r)}\mathbb{E}[\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|^{q(\beta+r)}] + \sum_{j<-n} u^{-q}\mathbb{E}[\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|^q]. \quad (52)$$

We shall consider the two cases $-n \le j \le n$ and $j < -n$ separately. For $-n \le j \le n$, by (50) and since ϵ_j and $X_{i,j-1}$ are independent,

$$\begin{aligned}
&\|\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|\|_{q(\beta+r)} \\
&\le \sum_{i=j\vee 1}^{n} \big\|\min\{|a_{i-j}|(|\epsilon_j|+\mu), 2\}\big\|_{q(\beta+r)} \big\|\min\{|X_{i,j-1}| + \mathbb{E}|X_{i,j}|, 2\}\big\|_{q(\beta+r)} \\
&\le \sum_{i=j\vee 1}^{n} \Big(|a_{i-j}|^q\mathbb{E}(|\epsilon_j|+\mu)^q 2^{q(\beta+r)-q}\Big)^{1/q(\beta+r)} \Big(\mathbb{E}(|X_{i,j-1}| + \mathbb{E}|X_{i,j}|)^q 2^{q(\beta+r)-q}\Big)^{1/q(\beta+r)}.
\end{aligned}$$

By (51) and $2\beta q' - 1 > (\beta + r)q'$, above inequality is further bounded by

$$\|\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|\|_{q(\beta+r)} \le c_1 \sum_{i=j\vee 1}^{n} ((i-j)\vee 1)^{\frac{-2\beta q'+1}{(\beta+r)q'}}\mu_q^{2/(\beta+r)} \le c_2\mu_q^{2/(\beta+r)}, \quad (53)$$

where $c_1 = (K_q\gamma(\beta q'-1)^{-1}2^{\beta+r})^{1/(\beta+r)}$ and $c_2 = 4(2\beta q'-1)(\beta q'-1)^{-1}c_1$.

For $j < -n$, again by (50) and the independence between ϵ_j and $X_{i,j-1}$,

$$\begin{aligned}
\|\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|\|_q &\le \sum_{i=1}^{n} |a_{i-j}|\||\epsilon_j| + \mu\|_q\|X_{i,j-1}| + \mathbb{E}|X_{i,j}|\|_q \\
&\le \big(4\gamma(\beta q'-1)^{1/q'}\big)n(-j)^{-\frac{2\beta q'-1}{q'}}\mu_q^2, \quad (54)
\end{aligned}$$

where the last inequality is due to (51).

Applying (53) and (54) to (52), we have

$$\mathrm{I}_1 \le c_3\mu_q^{2q}nu^{-\beta(q+r)}, \text{ where } c_3 = 2c_2^{q(\beta+r)} + (4\gamma(\beta q'-1)^{1/q'})^q.$$

Part (ii): We shall bound $\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)|$ for $-n \le j \le n$ and $j < -n$ seperately. For $-n \le j \le n$, by (50) and Lemma 22,

$$\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)| \le \sum_{i=1\vee j}^{n} \min\{|a_{i-j}|(|\epsilon_j|+\mu), 2\} \le \gamma K_{\beta,\gamma/2}(|\epsilon_j|+\mu)^{1/\beta},$$

Since ϵ_j is independent of $\mathcal{F}_{j-1}$, we have

$$\begin{aligned}
\mathrm{I}_{21} &:= \sum_{-n\le j\le n} \mathbb{E}\big[\max_{g\in A_n}(\phi_j(g) - \tilde\phi_j(g))^2|\mathcal{F}_{j-1}\big] \\
&\le \sum_{-n\le j\le n} (\gamma K_{\beta,\gamma/2})^2\mathbb{E}[(|\epsilon_j|+\mu)^{2/\beta}] \le \big(2^{1+2/\beta}(\gamma K_{\beta,\gamma/2})^2\big)n\mu_{q'}^{q'}.
\end{aligned}$$

For $j < -n$, by Lemma 22,

$$\max_{g\in A_n}|\phi_j(g) - \tilde\phi_j(g)| \le n\min\{\gamma(-j)^{-\beta}(|\epsilon_j|+\mu), 2\}.$$

Since ϵ_j is independent of $\mathcal{F}_{j-1}$, we have

$$\begin{aligned}
\mathrm{I}_{22} &:= \sum_{j<-n} \mathbb{E}\big[\max_{g\in A_n}(\phi_j(g) - \tilde\phi_j(g))^2|\mathcal{F}_{j-1}\big] \\
&\le n^2\sum_{j<-n} 2^{2-q'}\gamma^{q'}(-j)^{-q'\beta}\mathbb{E}[(|\epsilon_j|+\mu)^{q'}] \le \big(4\gamma^2/(\beta-1)\big)n\mu_{q'}^{q'},
\end{aligned}$$

Hence we have $\mathrm{I}_2 = \mathrm{I}_{21} + \mathrm{I}_{22} \le c_4 n\mu_{q'}^{q'}$, where $c_4 = 2^{1+2/\beta}(\gamma K_{\beta,\gamma/2})^2 + 4\gamma^{q'}/(q'\beta-1)$.

Inserting the bounds for I_1 and I_2 into Lemma 18 leads to

$$\mathbb{P}(\Omega_n \ge z/4) \le c_3 n\mu_q^{2q}u^{-q(\beta+r)} + 2|A_n|\exp\Big(-\frac{z^2}{32c_4\mu_{q'}^{q'}n}\Big) + 2|A_n|\exp\Big(-\frac{z^2}{8zu}\Big). \quad (55)$$

Take $u = z^{\beta/(\beta+r)}\mu_q^{1/(\beta+r)}$ and we complete the proof. ■

Remark 25 *Let $K_{q\beta}$ (resp. K_q and $K_{\beta,2/\gamma}$) be the constant in Lemma 20 (resp. Lemma 19 and Lemma 22). With a careful check of the proofs of Theorem 4, Lemmas 23 and 24, we can choose constants in Theorem 4 as follows:*

- $C_q = 2\max\{q/(q/2-1), 4(1/(2-q) + 1/(q-1)), 6+\sqrt{2}\}$.
- $C_{\beta,q,\gamma} = C_{\beta,q,\gamma,1} + C_{\beta,q,\gamma,2}$, *where* $C_{\beta,q,\gamma,1} = 4^{q\beta}K_{q\beta}(2^{q\beta}\gamma^q/(q\beta-1) + 2^{q+1}(\gamma K_{\beta,2/\gamma})^{q\beta})$ *and* $C_{\beta,q,\gamma,2} = 2c_2^{q(\beta+r)} + (4\gamma(\beta q'-1)^{1/q'})^q$ *with* $r = (q'\beta-1)/(2q')$, $c_1 = (K_q\gamma(\beta q'-1)^{-1}2^{\beta+r})^{1/(\beta+r)}$ *and* $c_2 = 4(2\beta q'-1)(\beta q'-1)^{-1}c_1$.
- $C_{\beta,\gamma} = 48\big(4\gamma^2/(\beta-1) + 2^{1+2/\beta}(\gamma K_{\beta,2/\gamma})^2\big)$.

Proof [Proof of Proposition 5] Construct A_n as in the proof of Theorem 4. Recall (31) for the function g_k. Note that $g_1(X_{i,i-1}) = \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}]$. By (36), we have

$$\begin{aligned}
\mathbb{P}(|\Delta_n| \ge a+z) \le&\mathbb{P}\Big(\max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g)| \ge a + z/2\Big) \\
\le&\mathbb{P}\Big(\max_{g\in A_n}\Big|\sum_{i=1}^{n}\big(g_1(X_{i,i-1}) - \mathbb{E}g_1(X_{i,i-1})\big)\Big| \ge a + z/4\Big) \\
&+ \sum_{g\in A_n}\mathbb{P}\Big(\Big|\sum_{i=1}^{n}(g(X_i) - \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}])\Big| \ge z/4\Big) =: \mathrm{I}_1 + \mathrm{I}_2,
\end{aligned}$$

where $a = C_q a_* \mu_q c(n,q)$.

Since $|g| \le 1$ and $g(X_i) - \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}]$, $1 \le i \le n$, are martingale differences, by Azuma's inequality, $\mathrm{I}_2 \le 2|A_n|\exp\{-z^2/(64n)\}$. For I_1, notice

$$g_1(x) = \int_{-\infty}^{\infty} g(x+y) f_\epsilon(y)\mathrm{d}y = \int_{-\infty}^{\infty} g(y) f_\epsilon(y-x)\mathrm{d}y.$$

By Assumption (A'), $\sup_{g\in\mathcal{A}}|g_1|_\infty$, $\sup_{g\in\mathcal{A}}|g_1'|_\infty$ and $\sup_{g\in\mathcal{A}}|g_1''|_\infty$ are all bounded by 1. Thus in the I_1 part, the function g_1 satisfies Assumption (A) and can be dealt with by Theorem 4. Combining I_1 and I_2, we complete the proof. ■

6.3 Proof of Theorem 7

Proof [Proof of Theorem 7] Recall the projection operator $P_k\cdot = \mathbb{E}(\cdot|\mathcal{F}_k) - \mathbb{E}(\cdot|\mathcal{F}_{k-1})$. Let $D_k = P_k\Delta_n$, $k \le n$. Then $\Delta_n - \mathbb{E}\Delta_n = \sum_{k\le n} D_k$ and

$$\mathbb{P}(\Delta_n - \mathbb{E}\Delta_n \ge z) \le \mathbb{P}\Big(\sum_{k\le -n} D_k \ge z/2\Big) + \mathbb{P}\Big(\sum_{-n<k\le n} D_k \ge z/2\Big) =: \mathrm{I}_1 + \mathrm{I}_2. \tag{56}$$

Then the theorem follows from the following three claims which will be proved in the sequel:

(i). $\mathrm{I}_1 \le C_{q,\gamma} e^{-qn(1-\rho)} \mu_q^q (z^q(1-\rho)^{q+q/q'})^{-1}$.

(ii). $\mathrm{I}_2 \le \exp\{-C'_{q,\gamma} z^2(1-\rho)^2((\mu_q^q \vee 1)n)^{-1}\}$.

(iii). $\mathbb{E}\Delta_n \le C_q \mu_q c^*(n,\rho,q)$.

To prove (i) and (ii), we need to apply coupling. Let $\epsilon_i, \epsilon'_j, i, j \in \mathbb{Z}$, be i.i.d. For a random variable $Z = H(\varepsilon)$, where H is a measurable function and $\varepsilon = (\epsilon_i)_{i\in\mathbb{Z}}$, we define the coupled version $Z_{\{j\}} = H(\varepsilon'_{\{j\}})$, where $\varepsilon'_{\{j\}} = (...,\epsilon_{j-1},\epsilon'_j,\epsilon_{j+1},...)$. We shall now derive an upper bound for $|D_k|$. Since $|g|, |g'|$ are bounded by 1, for any $k \le i$,

$$\mathbb{E}\big(\sup_{g\in\mathcal{A}} |g(X_i) - g(X_{i,\{k\}})|\big|\mathcal{F}_k\big) \le \mathbb{E}\big(|X_i - X_{i,\{k\}}|\big|\mathcal{F}_k\big) \le |a_{i-k}|(|\epsilon_k| + \mu). \tag{57}$$

Note $\mathbb{E}(\Delta_n|\mathcal{F}_{k-1}) = \mathbb{E}(\Delta_{n,\{k\}}|\mathcal{F}_k)$, thus $D_k = \mathbb{E}(\Delta_n - \Delta_{n,\{k\}}|\mathcal{F}_k)$ and by (57),

$$|D_k| \le \mathbb{E}\Big(\sup_{g\in\mathcal{A}}\Big|\sum_{i=1}^n [g(X_i) - g(X_{i,\{k\}})]\Big|\Big|\mathcal{F}_k\Big) \le \sum_{i=1\vee k}^n \min\{|a_{i-k}|(|\epsilon_k|+\mu), 2\}. \tag{58}$$

Part (i): Since D_k are martingale differences, by Lemma 19,

$$\mathrm{I}_1 \le (z/2)^{-q}\|\sum_{k\le -n} D_k\|_q^q \le K_q^q (z/2)^{-q}\Big(\sum_{k\le -n} \|D_k\|_q^{q'}\Big)^{q/q'}. \tag{59}$$

Since (58) implies $|D_k| \le \gamma\rho^{-k}(1-\rho)^{-1}(|\epsilon_k|+\mu)$ for any $k \le -n$, we further obtain from (59) and the elementary inequality $\log(\rho^{-1}) \ge 1-\rho$ that

$$\mathrm{I}_1 \le (4K_q\gamma)^q \frac{\rho^{nq}\mu_q^q}{z^q(1-\rho)^q(1-\rho^{q'})^{q/q'}} \le (4K_q\gamma)^q \frac{e^{-nq(1-\rho)}\mu_q^q}{z^q(1-\rho)^{q+q/q'}}. \tag{60}$$

Part (ii): Note for any $y \ge 1$, since $\log(\rho^{-1}) \ge 1-\rho$,

$$\begin{aligned}\sum_{i\ge 0}\min(\rho^i y, 1) &\le \sum_{i\ge -\log_\rho y} \rho^i y + (-\log_\rho y)\\ &\le (1-\rho)^{-1} - \log_\rho y \le (1-\rho)^{-1}[1+\log(y)].\end{aligned} \tag{61}$$

Hence for $k > -n$, by (58) and (61),

$$|D_k| \le (2\vee\gamma)(1-\rho)^{-1}\big[1 + \log(|\epsilon_k|+\mu)\mathbf{1}_{\{|\epsilon_k|+\mu\ge 1\}}\big]. \tag{62}$$

Let $h^* := (2\vee\gamma)^{-1}(1-\rho)q$. Since $\epsilon_k \in \mathcal{L}^q$, for any $0 < h \le h^*$, $\mathbb{E}(e^{D_k h}) < \infty$. Note $\mathbb{E}(D_k|\mathcal{F}_{k-1}) = 0$, then

$$\begin{aligned}\mathbb{E}(e^{D_k h}|\mathcal{F}_{k-1}) &= 1 + \mathbb{E}(e^{D_k h} - D_k h - 1|\mathcal{F}_{k-1})\\ &\le 1 + \mathbb{E}\Big[\frac{e^{|D_k|h} - |D_k|h - 1}{h^2(1-\rho)^{-2}}\Big|\mathcal{F}_{k-1}\Big]h^2(1-\rho)^{-2}\end{aligned} \tag{63}$$

in view of $e^x - x \le e^{|x|} - |x|$ for any x. Note that for any fixed $x > 0$, $(e^{tx} - tx - 1)/t^2$ is increasing on $t \in (0,\infty)$. Applying the upper bound of D_k in (62), we have

$$\begin{aligned}\mathbb{E}\Big[\frac{e^{|D_k|h} - |D_k|h - 1}{h^2(1-\rho)^{-2}}\Big|\mathcal{F}_{k-1}\Big] &\le \mathbb{E}\Big[\frac{e^{|D_k|h^*} - |D_k|h^* - 1}{h^{*2}(1-\rho)^{-2}}\Big|\mathcal{F}_{k-1}\Big]\\ &\le \mathbb{E}\Big[\frac{e^{q[1+\log(|\epsilon_k|+\mu)1_{\{|\epsilon_k|+\mu>1\}}]}}{h^{*2}(1-\rho)^{-2}}\Big|\mathcal{F}_{k-1}\Big] \le c_1\mu_q^q,\end{aligned} \tag{64}$$

where $c_1 = 2^q e^q (2\vee\gamma)^2 q^{-2}$. Hence for any $h \le h^*$,

$$\mathbb{E}(e^{D_k h}|\mathcal{F}_{k-1}) \le 1 + c_1\mu_q^q h^2(1-\rho)^{-2}. \tag{65}$$

By Markov's inequality we have $\mathrm{I}_2 \le e^{-zh/2}\mathbb{E}[\exp(\sum_{-n<k\le n} D_k h)]$. Then by recursively applying (65), let $h = z(1-\rho)^2[8c_1(\mu_q^q\vee 1)n]^{-1} \le h^*$, we further obtain

$$\begin{aligned}\mathrm{I}_2 \le& e^{-zh/2}\mathbb{E}\Big(e^{\sum_{k=-n+1}^{n-1} D_k h}\mathbb{E}(e^{D_n h}|\mathcal{F}_{n-1})\Big) \le e^{-zh/2}(1 + c_1\mu_q^q h^2/(1-\rho)^2)^{2n}\\ \le& \exp\big(-zh/2 + 2nc_1\mu_q^q h^2/(1-\rho)^2\big) \le \exp\Big(-\frac{z^2(1-\rho)^2}{32c_1(\mu_q^q\vee 1)n}\Big),\end{aligned} \tag{66}$$

where the third inequality is due to $1 + x \le e^x$ for $x > 0$.

Part (iii): Note

$$\begin{aligned}g(X_i) - \mathbb{E}g(X_i) &= \sum_{j\ge 0}(g_j(X_{i,i-j}) - g_{j+1}(X_{i,i-j-1}))\\ &= \sum_{j\ge 0}\int_{-\infty}^{\infty} g_j'(x)\big(\mathbf{1}_{x\le X_{i,i-j}} - \mathbb{E}(\mathbf{1}_{x\le X_{i,i-j}}|\mathcal{F}_{i-j-1})\big)\mathrm{d}x.\end{aligned}$$

By above inequality and that $|g_j'|$ are bounded by 1,

$$\mathbb{E}(\Delta_n) \le \sum_{j\ge 0}\int_{-\infty}^{\infty}\mathbb{E}\Big|\sum_{i=1}^{n}\big(\mathbf{1}_{x\le X_{i,i-j}} - \mathbb{E}(\mathbf{1}_{x\le X_{i,i-j}}|\mathcal{F}_{i-j-1})\big)\Big|\mathrm{d}x. \tag{67}$$

Let $H_j(x) = \mathbb{P}(|X_{0,-j}| \ge |x|)$. Since for any fixed j, $\mathbf{1}_{x\le X_{i,i-j}} - \mathbb{E}(\mathbf{1}_{x\le X_{i,i-j}}|\mathcal{F}_{i-j-1})$, $i = 1,\dots,n$, are martingale differences, by the same arguments as for (47), we have

$$\mathbb{E}\Big|\sum_{i=1}^{n}\big(\mathbf{1}_{x\le X_{i,i-j}} - \mathbb{E}(\mathbf{1}_{x\le X_{i,i-j}}|\mathcal{F}_{i-j-1})\big)\Big| \le \min\{\sqrt{n}H_j(x)^{1/2}, nH_j(x)\}. \tag{68}$$

For any $1 < r \le q$ and $r' = \min\{r, 2\}$, by Lemma 19,

$$H_j(x) \le \frac{\|X_{0,-j}\|_r^r}{|x|^r} \le \frac{K_r^r}{|x|^r}\Big(\sum_{k\ge j}|a_k|^{r'}\mu_r^{r'}\Big)^{r/r'} \le \frac{K_r^r}{|x|^r}\rho^{jr}(1-\rho)^{-r/r'}\mu_r^r. \tag{69}$$

We need to deal with the three cases separately: $q > 2$, $1 < q < 2$ and $q = 2$.
Case $q > 2$: Let $r = 3/2$. By (67) and (68),

$$\mathbb{E}(\Delta_n) \le \sum_{j\ge 0}\sqrt{n}\int_{-\infty}^{\infty}H_j(x)^{1/2}\mathrm{d}x.$$

Since $1-\rho^x \ge 1-\rho$ for $x \ge 1$ and $1-\rho^x \ge 1-\rho^{1/2} \ge (1-\rho)/2$ for $1/2 \le x < 1$, by (69),

$$\begin{aligned}\mathbb{E}(\Delta_n) &\le (K_r \vee K_q)^{q/2}\sum_{j\ge 0}\sqrt{n}\Big(\int_{|x|>\mu_q}\rho^{jq/2}(1-\rho)^{-q/4}|x|^{-q/2}\mu_q^{q/2}\mathrm{d}x \\ &\quad + \int_{|x|\le\mu_q}\rho^{jr/2}(1-\rho)^{-1/2}|x|^{-r/2}\mu_r^{r/2}\mathrm{d}x\Big) \\ &\le (K_r \vee K_q)^{q/2}(2/(q-2)+8)\sqrt{n}(1-\rho)^{-3/2}\mu_q.\end{aligned}$$

Case $1 < q < 2$: By (67) and (68), for $a = n^{1/q}(1-\rho)^{-1/q}K_q\mu_q$,

$$\mathbb{E}(\Delta_n) \le \sum_{j\ge 0}\Big(\int_{|x|>a} nH_j(x)\mathrm{d}x + \int_{|x|\le a} n^{1/2}H_j(x)^{1/2}\mathrm{d}x\Big).$$

By (69), we further obtain

$$\begin{aligned}\mathbb{E}(\Delta_n) &\le K_q^q n\sum_{j\ge 0}\int_{|x|>a}\frac{\rho^{jq}\mu_q^q}{(1-\rho)|x|^q}\mathrm{d}x + K_q^{q/2}n^{1/2}\sum_{j\ge 0}\int_{|x|\le a}\frac{\rho^{qj/2}\mu_q^{q/2}}{(1-\rho)^{1/2}|x|^{q/2}}\mathrm{d}x \\ &\le (1/(q-1)+2/(2-q))K_q n^{1/q}(1-\rho)^{-1/q-1}\mu_q.\end{aligned}$$

Case $q = 2$: Take $a = n^{1/2}(1-\rho)^{-1/2}\mu_2$, $b = \mu_2$, then by (67) and (68),

$$\mathbb{E}(\Delta_n) \le \sum_{j\ge 0}\Big(\int_{|x|>a} nF_j(x)\mathrm{d}x + \int_{b<|x|\le a} n^{1/2}F_j(x)^{1/2}\mathrm{d}x + \int_{|x|\le b} n^{1/2}F_j(x)^{1/2}\mathrm{d}x\Big)$$

By (69), for $r = 3/2$,

$$\begin{aligned}\mathbb{E}(\Delta_n) &\le n\sum_{j\ge 0}\int_{|x|>a}\frac{\rho^{2j}\mu_2^2}{(1-\rho)|x|^2}\mathrm{d}x + n^{1/2}\sum_{j\ge 0}\int_{b<|x|\le a}\frac{\rho^j\mu_2}{(1-\rho)^{1/2}|x|}\mathrm{d}x \\ &\quad + n^{1/2}\sum_{j\ge 0}\int_{|x|\le b}\frac{\rho^{jr/2}\mu_2^{r/2}}{(1-\rho)^{1/2}|x|^{r/2}}\mathrm{d}x \le \frac{10\sqrt{n}\mu_2}{(1-\rho)^{3/2}}\log(n(1-\rho)^{-1}).\end{aligned}$$

■

Remark 26 *Let $K_{3/2}$ and K_q be the constants defined in Lemma 19. With a careful check of the proof of Theorem 7, we can choose constants in Theorem 7 as follows:*

- $C_q = \max\{(K_{3/2}\vee K_q)^{q/2}(2/(q-2)+8), (1/(q-1)+2/(2-q))K_q, 10\}$,
- $C_{q,\gamma} = (4K_q\gamma)^q$,
- $C'_{q,\gamma} = 2^{q+5}e^q(2\vee\gamma)^2q^{-2}$.

6.4 Proofs of Theorem 8 and Proposition 9

Proof [Proof of Theorem 8] The idea of proving Theorem 8 is similar to the proof of Theorem 4. Recall the definitions of $\phi_j(g)$, $\tilde{\phi}_j(g)$, $T_n(g)$ in (32), (35) and definitions of Ω_n, U_n in (36). Then the same argument as in Theorem 4 leads to

$$\begin{aligned}\mathbb{P}(\Delta_n \ge C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z) &\le \mathbb{P}\Big(\max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g)| \ge C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z/2\Big). \\ &\le \mathbb{P}\Big(U_n \ge C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z/4\Big) + \mathbb{P}(\Omega_n \ge z/4).\end{aligned} \tag{70}$$

Again we shall use $T_n(g)$ to approximate $S_n(g) - \mathbb{E}S_n(g)$, and apply Fuk-Nagaev's inequality to deal with $T_n(g)$ part. By Lemma 27,

$$\mathbb{P}\Big(U_n \ge C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta} + z/4\Big) \le C_{\beta,q,\gamma,1}\mu_q^q\frac{n^{1+(1-\beta)q}}{z^q} + \exp\Big(-\frac{z^2}{C_{\beta,\gamma}n^{3-2\beta}\mu_2^2}\Big), \tag{71}$$

and by Lemma 28,

$$\mathbb{P}(\Omega_n \ge \frac{z}{4}) \le C_{\beta,q,\gamma,2}\mu_q^{2q}\frac{n^{1+(1-\beta)q}[\log|A_n| + \log(n)]^q}{\tilde{c}^q(n,\beta)z^q} + 2|A_n|\exp\Big(-\frac{z^2}{C_{\beta,\gamma}n^{3-2\beta}\mu_2^2}\Big). \tag{72}$$

Combining (70), (71) and (72) with $C_{\beta,q,\gamma} = C_{\beta,q,\gamma,1} + C_{\beta,q,\gamma,2}$, the result follows. ■

Lemma 27 *Recall the definitions of $\phi_j(g)$, $T_n(g)$ in (32), (35) and U_n in (36). Under assumptions of Theorem 8, we have (71).*

Proof The proof is similar to the one of Lemma 23. We shall

(i). Bound the probability $\mathbb{P}(U_n - 2\mathbb{E}U_n \geq z/4)$.

(ii). Bound the expectation $\mathbb{E}U_n$.

Part (i): For $j < -n$, by (39),

$$|\tilde{\phi}_j(g)| \leq \sum_{i=1}^{n} |a_{i-j}|(|\epsilon_j| + \mu) \leq \gamma n(-j)^{-\beta}(|\epsilon_j| + \mu). \tag{73}$$

For $-n \leq j \leq n$, by (39),

$$|\tilde{\phi}_j(g)| \leq \sum_{i=1\vee j}^{n} |a_{i-j}|(|\epsilon_j| + \mu) \leq 2(1-\beta)^{-1}\gamma n^{1-\beta}(|\epsilon_j| + \mu). \tag{74}$$

Denote $V = \max_{g\in A_n} \sum_{j\leq n} \mathbb{E}\tilde{\phi}_j^2(g)$. Hence by (73) and (74),

$$V \leq \max_{g\in A_n} \sum_{j<-n} \mathbb{E}|\tilde{\phi}_j|^2 + \max_{g\in A_n} \sum_{j=-n}^{n} \mathbb{E}|\tilde{\phi}_j|^2 \leq c_1\mu_2^2 n^{3-2\beta}, \tag{75}$$

where $c_1 = 4\gamma^2((2\beta-1)^{-1} + 8(1-\beta)^{-2})$. Also by (73) and (74), we have

$$\sum_{j\leq n} \mathbb{E}\big(\max_{g\in A_n} |\tilde{\phi}_j|^q\big) \leq \sum_{j<-n} \mathbb{E}\big(\max_{g\in A_n} |\tilde{\phi}_j|^q\big) + \sum_{j=-n}^{n} \mathbb{E}\big(\max_{g\in A_n} |\tilde{\phi}_j|^q\big) \leq c_2 n^{1+(1-\beta)q}\mu_q^q, \tag{76}$$

where $c_2 = \gamma^q 2^q(2^{1+q}(1-\beta)^{-q} + (q\beta-1)^{-1})$.

Using the bounds (75) and (76) in the Fuk-Nagaev inequality Lemma 20, we obtain

$$\mathbb{P}\Big(U_n - 2\mathbb{E}U_n \geq z/4\Big) \leq \exp\Big(-\frac{z^2}{C_{\beta,\gamma} n^{3-2\beta}\mu_2^2}\Big) + C_{\beta,q,\gamma,1}\mu_q^q \frac{n^{1+(1-\beta)q}}{z^q}. \tag{77}$$

Part (ii): By Lemma 21 the derivatives $|g'_\infty(x)| \leq 1$, thus

$$\begin{aligned}
\max_{g\in A_n} |T_n(g)| &= \max_{g\in A_n} \Big| \int_{-\infty}^{\infty} \sum_{j\leq n} \sum_{i=1\vee j}^{n} \big(\mathbf{1}_{a_{i-j}\epsilon_j \geq x} - \mathbb{P}(a_{i-j}\epsilon_j \geq x)\big) g'_\infty(x)\mathrm{d}x \Big| \\
&\leq \int_{-\infty}^{\infty} \Big| \sum_{j\leq -n} \sum_{i=1\vee j}^{n} \big(\mathbf{1}_{a_{i-j}\epsilon_j \geq x} - \mathbb{P}(a_{i-j}\epsilon_j \geq x)\big) \Big| \mathrm{d}x \\
&\quad + \int_{-\infty}^{\infty} \Big| \sum_{-n\leq j\leq n} \sum_{i=1\vee j}^{n} \big(\mathbf{1}_{a_{i-j}\epsilon_j \geq x} - \mathbb{P}(a_{i-j}\epsilon_j \geq x)\big) \Big| \mathrm{d}x =: \mathrm{I}_1 + \mathrm{I}_2.
\end{aligned}$$

For I_1 : since ϵ_j are independent,

$$\begin{aligned}
\mathbb{E}(\mathrm{I}_1) &\leq \sum_{i=1}^{n} \int_{-\infty}^{\infty} \Big\| \sum_{j<-n} \big(\mathbf{1}_{a_{i-j}\epsilon_j \geq x} - \mathbb{P}(a_{i-j}\epsilon_j \geq x)\big) \Big\| \mathrm{d}x \\
&= \sum_{i=1}^{n} \int_{-\infty}^{\infty} \Big[\sum_{j<-n} (1 - F_\epsilon(x/a_{i-j}))F_\epsilon(x/a_{i-j}) \Big]^{1/2} \mathrm{d}x.
\end{aligned} \tag{78}$$

Denote $F^*(x) = \mathbb{P}(|\epsilon_0| \geq |x|)$, then

$$\max\big\{F_\epsilon(x) \wedge (1 - F_\epsilon(x)), F_\epsilon(-x) \wedge (1 - F_\epsilon(-x))\big\} \leq F^*(x).$$

Since $F^*(x)$ decreases in $|x|$ and $|a_{i-j}| \leq \gamma(-j)^\beta$, (78) can be further bounded by

$$\begin{aligned}
\mathbb{E}(\mathrm{I}_1) &\leq 2\sum_{i=1}^{n} \int_0^{\infty} \Big[\sum_{j<-n} F^*(x/a_k) \Big]^{1/2} \mathrm{d}x \\
&\leq 2n \int_0^{\infty} \Big[\sum_{j<-n} F^*(x\gamma^{-1}(-j)^\beta) \Big]^{1/2} \mathrm{d}x \\
&\leq 2n \int_0^{\infty} \Big[\int_n^{\infty} F^*(\gamma^{-1}xy^\beta)\mathrm{d}y \Big]^{1/2} \mathrm{d}x \\
&= 2n^{3/2-\beta}\gamma \int_0^{\infty} \Big[\int_1^{\infty} F^*(xy^\beta)\mathrm{d}y \Big]^{1/2} \mathrm{d}x,
\end{aligned} \tag{79}$$

where the last equality is due to a change of variables: $x \mapsto n^\beta x/\gamma$, $y \mapsto y/n$.

Let $r = 1 + 1/(2\beta)$. Then $1/\beta < r < 2$. Since $r < q$, we have $F^*(x) \leq |x|^{-r}\mu_q^r$, $F^*(x) \leq |x|^{-q}\mu_q^q$ and

$$\begin{aligned}
\int_0^{\infty} \Big[\int_1^{\infty} F^*(xy^\beta)\mathrm{d}y \Big]^{1/2} \mathrm{d}x \;&\leq\; \int_0^{\mu_q} \Big[\int_1^{\infty} x^{-r}y^{-r\beta}\mu_q^r \mathrm{d}y \Big]^{1/2} \mathrm{d}x \\
&+ \int_{\mu_q}^{\infty} \Big[\int_1^{\infty} x^{-q}y^{-q\beta}\mu_q^q \mathrm{d}y \Big]^{1/2} \mathrm{d}x \leq c_3\mu_q,
\end{aligned}$$

where $c_3 = 2(2-r)^{-1}(r\beta-1)^{-1} + 2(q-2)^{-1}(q\beta-1)^{-1/2}$.

For I_2: Since ϵ_j are independent, we have

$$\begin{aligned}
\mathbb{E}(\mathrm{I}_2) &= \mathbb{E}\int_{-\infty}^{\infty} \Big| \sum_{k=0}^{2n} \sum_{i=(k-n)\vee 1}^{n} \big(\mathbf{1}_{a_k\epsilon_{i-k} \geq x} - \mathbb{P}(a_k\epsilon_{i-k} \geq x)\big) \Big| \mathrm{d}x \\
&\leq \sum_{k=0}^{2n} \int_{-\infty}^{\infty} \Big(\sum_{i=(k-n)\vee 1}^{n} (1 - F_\epsilon(x/a_k))F_\epsilon(x/a_k) \Big)^{1/2} \mathrm{d}x \\
&\leq \sum_{k=0}^{2n} |a_k| \int_{-\infty}^{\infty} [nF^*(x)]^{1/2} \mathrm{d}x \leq \gamma(1-\beta)^{-1}2^{1-\beta}n^{3/2-1} \int_{-\infty}^{\infty} F^*(x)^{1/2} \mathrm{d}x,
\end{aligned}$$

where the second inequality is by a change of variable and the last inequality is by $|a_k| \le \gamma k^{-\beta}$. Note by definition of $F^*(x)$,

$$\int_{-\infty}^{\infty} F^*(x)^{1/2}\mathrm{d}x = 2\int_0^{\mu_q} 1\mathrm{d}x + 2\int_{\mu_q}^{\infty} F^*(x)^{1/2}\mathrm{d}x \le 2q/(q-2)\mu_q.$$

Combining I_1 and I_2, $\mathbb{E}U_n \le c_4\mu_q n^{3/2-\beta}$, where $c_4 = 2\gamma c_3 + 4\gamma(1-\beta)^{-1}q(q-2)^{-1}$. ■

Lemma 28 *Recall the definitions of $\phi_j(g)$, $\tilde{\phi}_j(g)$, $T_n(g)$ in (32), (35) and definition of Ω_n in (36). Under assumptions of Theorem 8, we have (72).*

Proof The argument is similar to the proof of Lemma 24, that is, we shall apply Lemma 18 to bound the tail probability. To this aim, we need to:

(i). Derive the upper bound for $\mathrm{I}_1 = \sum_{j\le n}\mathbb{P}(\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)| \ge u)$.

(ii). Bound the term $\mathrm{I}_2 = \max_{g\in A_n}\sum_{j\le n}\mathbb{E}[(\phi_j(g) - \tilde{\phi}_j(g))^2|\mathcal{F}_{j-1}]$.

Part (i): By (50), we have

$$\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)| \le \sum_{i=1\vee j}^{n}|a_{i-j}|(|\epsilon_j| + \mu)(|X_{i,j-1}| + \mathbb{E}|X_{i,j}|).$$

Since ϵ_j are independent of $X_{i,j-1}$, above together with (51) leads to

$$\|\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)|\|_q \le c_1'\sum_{i=1\vee j}^{n}(i-j)^{-2\beta+1/2}\mu_q^2 \le \begin{cases} c_1' n(-j)^{-2\beta+1/2}, & \text{if } j < -n,\\ 2c_1' h(n,\beta)\mu_q^2, & \text{if } -n \le j \le n,\end{cases}$$

where $c_1' = 4(2\beta-1)^{-1/2}\gamma^2 K_q$, $h(n,\beta) = \log(n)$ if $\beta = 3/4$; $h(n,\beta) = (4\beta-1)/(4\beta-3)$ if $\beta > 3/4$; $h(n,\beta) = 2(3-4\beta)^{-1}n^{3/2-2\beta}$ if $\beta < 3/4$. Therefore by Markov's inequality

$$\begin{aligned}\mathrm{I}_1 &\le u^{-q}\Big(\sum_{-n\le j\le n}\|\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)|\|_q^q + \sum_{j<-n}\|\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)|\|_q^q\Big)\\ &\lesssim u^{-q}n^{1+(1-\beta)q}\tilde{c}^{-q}(n,\beta)\mu_q^{2q},\end{aligned}$$

where the constant in $\lesssim$ only depends on β, q, γ.
Part (ii): By (50) we obtain

$$\max_{g\in A_n}|\phi_j(g) - \tilde{\phi}_j(g)| \le \sum_{i=1\vee j}^{n}2|a_{i-j}|(|\epsilon_j| + \mu) \le \begin{cases} 2\gamma n(-j)^{-\beta}(|\epsilon_j| + \mu), & \text{if } j < -n,\\ 2\gamma n^{1-\beta}(|\epsilon_j| + \mu), & \text{if } -n \le j \le n.\end{cases}$$

Since ϵ_j is independent of $\mathcal{F}_{j-1}$, $\mathbb{E}(|\epsilon_j|^2|\mathcal{F}_{j-1}) = \mu_2^2$. Hence

$$\begin{aligned}\mathrm{I}_2 \le& \sum_{-n\le j\le n}\mathbb{E}\big[\max_{g\in A_n}(\phi_j(g) - \tilde{\phi}_j(g))^2|\mathcal{F}_{j-1}\big] + \sum_{j<-n}\mathbb{E}\big[\max_{g\in A_n}(\phi_j(g) - \tilde{\phi}_j(g))^2|\mathcal{F}_{j-1}\big]\\ \le& 16\gamma^2\sum_{-n\le j\le n}n^{2(1-\beta)}\mu_2^2 + 16\gamma^2\sum_{j<-n}n^2(-j)^{-2\beta}\mu_2^2 \le c_2' n^{3-2\beta}\mu_2^2,\end{aligned}$$

where $c_2' = 32\gamma^2\beta(2\beta-1)^{-1}$.

Combining two parts and applying them to Lemma 18, we have

$$\mathbb{P}\Big(\Omega_n \ge \frac{z}{4}\Big) \lesssim \frac{n^{1+(1-\beta)q}\tilde{c}^{-q}(n,\beta)\mu_q^{2q}}{u^q} + 2|A_n|\exp\Big(-\frac{z^2}{C_{\beta,\gamma}n^{3-2\beta}\mu_2^2}\Big) + 2|A_n|\exp\Big(-\frac{z^2}{2zu}\Big),$$

where the constant in $\lesssim$ only depends on β, q, γ. Let $R_n = 2|A_n|\tilde{c}^q(n,\beta)z^q/n^{1+(1-\beta)q}$ and $u = z/(4\log(R_n))$. Notice $\log(R_n) \lesssim \log|A_n| + \log(n)$, where constant in $\lesssim$ only depends on β, q, γ. Then the desired result follows. ■

Remark 29 *With a careful check of the proofs of Theorem 8, Lemmas 27 and 28, we can choose constants in Theorem 8 as follows:*

- $C_{\beta,\gamma} = 64\max\{3\gamma^2((2\beta-1)^{-1} + 8(1-\beta)^{-2}), 16\gamma^2\beta(2\beta-1)^{-1}\}$.
- $C_{\beta,q,\gamma} = \max\{C_{\beta,q,\gamma,1}, C_{\beta,q,\gamma,2}\}$, *where* $C_{\beta,q,\gamma,1} = 4^q K_q' c_2$, *with* $c_2 = \gamma^q 2^q(2^{1+q}(1-\beta)^{-q} + (q\beta-1)^{-1})$ *and* $C_{\beta,q,\gamma,2} = 1 + 8{c_1'}^q(2\beta q - q/2 - 1)^{-1} + 2^{q+3}{c_1'}^q\max^q\{1, (4\beta-1)/(4\beta-3), 2(3-4\beta)^{-1}\}$, *with* $c_1' = 4(2\beta-1)^{-1/2}\gamma^2 K_q$.
- $C'_{\beta,q,\gamma} = 2\gamma c_3 + 4\gamma(1-\beta)^{-1}q(q-2)^{-1}$, *where* $c_3 = 2(2-r)^{-1}(r\beta-1)^{-1} + 2(q-2)^{-1}(q\beta-1)^{-1/2}$ *with* $r = 1 + 1/(2\beta)$.

Here K_q (resp. K_q') is the constant given in Lemma 19 (resp. Lemma 20).

Proof [Proof of Proposition 9] Construct A_n as in the proof of Theorem 4. Recall (31) for the function g_k. Note that $g_1(X_{i,i-1}) = \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}]$. By (36), we have

$$\begin{aligned}\mathbb{P}(|\Delta_n| \ge a + z) \le& \mathbb{P}\Big(\max_{g\in A_n}|S_n(g) - \mathbb{E}S_n(g)| \ge a + z/2\Big)\\ \le& \mathbb{P}\Big(\max_{g\in A_n}\Big|\sum_{i=1}^{n}\big(g_1(X_{i,i-1}) - \mathbb{E}g_1(X_{i,i-1})\big)\Big| \ge a + z/4\Big)\\ &+ \sum_{g\in A_n}\mathbb{P}\Big(\Big|\sum_{i=1}^{n}(g(X_i) - \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}])\Big| \ge z/4\Big) =: \mathrm{I}_1 + \mathrm{I}_2,\end{aligned}$$

where $a = C_q a_* \mu_q c(n,q)$ and $a = C'_{\beta,q,\gamma}\mu_q n^{3/2-\beta}$ for Propositions 5 and 9, respectively.

Since $|g| \le 1$ and $g(X_i) - \mathbb{E}[g(X_i)|\mathcal{F}_{i-1}]$, $1 \le i \le n$, are martingale differences, by Azuma's inequality, $\mathrm{I}_2 \le 2|A_n|\exp\{-z^2/(64n)\}$. For I_1, notice

$$g_1(x) = \int_{-\infty}^{\infty}g(x+y)f_\epsilon(y)\mathrm{d}y = \int_{-\infty}^{\infty}g(y)f_\epsilon(y-x)\mathrm{d}y.$$

By Assumption (A'), $\sup_{g\in\mathcal{A}}|g_1|_\infty$, $\sup_{g\in\mathcal{A}}|g_1'|_\infty$ and $\sup_{g\in\mathcal{A}}|g_1''|_\infty$ are all bounded by 1. Thus in the I_1 part, the function g_1 satisfies Assumption (A) and can be dealt with by Theorem 4 and Theorem 8 for Propositions 5 and 9 respectively. Combining I_1 and I_2, we complete the proof. ■

6.5 Proof of Theorem 11

Proof [Proof of Theorem 11] We shall apply the argument in the proof of Theorem 7. Recall (56) for D_k, I_1 and I_2. Case (a) follows from the following three claims:
(a.i) $\mathrm{I}_1 \le e^{-C_2 z^2/n}$, (a.ii) $\mathrm{I}_2 \le e^{-C_2 z^2/n}$, (a.iii) $\mathbb{E}\Delta_n \le C_1\sqrt{n}$,
while Case (b) follows from the following three:
(b.i) $\mathrm{I}_1 \le e^{-C_4 z^2 n^{-(3-2\beta)}}$, (b.ii) $\mathrm{I}_2 \le e^{-C_4 z^2 n^{-(3-2\beta)}}$, (b.iii) $\mathbb{E}\Delta_n \le C_3 n^{3/2-\beta}$.
Part (a.i) and (b.i): By (58), for $k \le -n$,

$$|D_k| \le \sum_{i=1\vee k}^{n} |a_{i-k}|(|\epsilon_k|+\mu) \le \gamma n(-k)^{-\beta}(|\epsilon_k|+\mu). \tag{80}$$

Let $h^* = c_0/(2\gamma)$. By the same argument in (63) and (64), for $0 < h \le h^*$,

$$\mathbb{E}(e^{D_k h}|\mathcal{F}_{k-1}) \le 1 + \mathbb{E}\Big[\frac{e^{|D_k|h^*} - |D_k|h^* - 1}{h^{*2}}\Big|\mathcal{F}_{k-1}\Big]h^2. \tag{81}$$

Denote $\theta = n(-k)^{-\beta}/2$. Note that for any fixed $x > 0$, $e^{tx} - tx - 1$ is increasing on $t \in (0,\infty)$. Applying the upper bound for $|D_k|$ in (80), we have

$$\begin{aligned}
&\mathbb{E}(e^{|D_k|h^*} - |D_k|h^* - 1|\mathcal{F}_{k-1}) \le \mathbb{E}\big[e^{c_0\theta(|\epsilon_k|+\mu)} - c_0\theta(|\epsilon_k|+\mu) - 1\big] \\
&= \mathbb{E}\Big[\int_0^\infty \frac{\mathrm{d}}{\mathrm{d}x}(e^{\theta x} - \theta x - 1)\cdot \mathbf{1}_{\{c_0(|\epsilon_k|+\mu)\ge x\}}\mathrm{d}x\Big] = \int_0^\infty (\theta e^{\theta x} - \theta)\mathbb{P}(c_0(|\epsilon_k|+\mu) \ge x)\mathrm{d}x,
\end{aligned}$$

where the last equality is by Fubini's theorem. Note that $\mathbb{P}(c_0(|\epsilon_k|+\mu) \ge x) \le c_1 e^{-x}$, where $c_1 = e^{c_0\mu}\mu_e$. Then we further have

$$\mathbb{E}(e^{|D_k|h^*} - |D_k|h^* - 1|\mathcal{F}_{k-1}) \le \int_0^\infty c_1 e^{-x}(\theta e^{\theta x} - \theta)\mathrm{d}x = c_1\theta^2/(1-\theta) \le 2c_1\theta^2. \tag{82}$$

where the last inequality is due to $\theta \le 1/2$. Hence by (81) and (82) we have for any $h \le h^*$,

$$\mathbb{E}(e^{D_k h}|\mathcal{F}_{k-1}) \le 1 + c_2 n^2(-k)^{-2\beta}h^2 \le e^{c_2 n^2(-k)^{-2\beta}h^2}. \tag{83}$$

where $c_2 = 2c_1\gamma^2/c_0^2$ and the last inequality is due to $1 + x \le e^x$. By Markov's inequality

$$\mathrm{I}_1 \le e^{-zh/2}\mathbb{E}\Big(e^{\sum_{k\le -n} D_k h}\Big) \le e^{-zh/2}\mathbb{E}\Big(e^{\sum_{k\le -n-1} D_k h}\mathbb{E}(e^{D_{-n}h}|\mathcal{F}_{-n-1})\Big).$$

Hence recursively applying (83), we obtain

$$\mathrm{I}_1 \le \exp\Big(-zh/2 + c_2 n^2 \sum_{k\le -n}(-k)^{-2\beta}h^2\Big) \le \exp\Big(-zh/2 + c_2 c_3(2\beta-1)^{-1}n^{3-2\beta}h^2\Big),$$

where $c_3 = \max\{(2\beta-1)/(4c_2h^*), 1\}$. Take $h = (2\beta-1)(4c_2c_3)^{-1}z/n$ for (a.i) and $h = (2\beta-1)(4c_2c_3)^{-1}z/n^{3-2\beta}$ for (b.i) respectively, then $h \le h^*$ and we have $\mathrm{I}_1 \le e^{-C_{21}z^2/n}$ for (a.i) and $\mathrm{I}_1 \le e^{-C_{21}z^2/n^{3-2\beta}}$ for (b.i), where $C_{21} = (2\beta-1)/(16c_2c_3)$.

Part (a.ii): By (58), for $-n < k \le n$,

$$|D_k| \le \sum_{i=1\vee k}^{n} |a_{i-k}|(|\epsilon_k|+\mu) \le 2\beta(\beta-1)^{-1}\gamma(|\epsilon_k|+\mu). \tag{84}$$

Let $c_4 = 2\beta(\beta-1)^{-1}\gamma$ and $h^* = c_0 c_4^{-1}$. By the same argument as (83) in Part (a.i), we have for any $h \le h^*$,

$$\mathbb{E}(e^{D_k h}|\mathcal{F}_{k-1}) \le e^{c_5 h^2}, \tag{85}$$

where $c_5 = c_1 c_4^2/(2c_0^2)$. Similarly to Part (a.i), by Markov's inquality and recursively applying (85),

$$\mathrm{I}_2 \le e^{-zh/2}\mathbb{E}\Big(e^{\sum_{-n<k\le n} D_k h}\Big) \le \exp\Big(-zh/2 + 2c_5c_6nh^2\Big),$$

where $c_6 = \max\{c_4/(8c_0c_5), 1\}$. Let $h = (8c_5c_6)^{-1}z/n$. Then $h \le h^*$ and we have $\mathrm{I}_2 \le e^{-C_{22}z^2/n}$, where $C_{22} = (32c_5c_6)^{-1}$.
Part (b.ii): By (58), for $-n < k \le n$,

$$|D_k| \le (1-\beta)^{-1}\gamma n^{1-\beta}(|\epsilon_k|+\mu). \tag{86}$$

Let $c_7 = (1-\beta)^{-1}\gamma$, $h^* = c_0 c_7^{-1} n^{-1+\beta}$ and $c_8 = 2\max\{c_7/(8c_0), c_1c_7^2/(2c_0^2)\}$. By the same argument as in Part (a.ii) with the bound in (84) replaced by (86), we have for any $h \le h^*$,

$$\mathrm{I}_2 \le e^{-zh/2}\mathbb{E}\Big(e^{\sum_{-n<k\le n} D_k h}\Big) \le \exp\Big(-zh/2 + c_8 n^{3-2\beta}h^2\Big).$$

Take $h = (4c_8)^{-1}zn^{-(3-2\beta)}$, then $h \le h^*$ and we have $\mathrm{I}_2 \le e^{-C_{42}z^2 n^{-(3-2\beta)}}$.

Part (a.iii) and (b.iii): Applying Theorem 1 in Wu (2003) with $p = 0$, $k = 1$ and $\gamma = 2$ therein, we have $\mathbb{E}(\Delta_n) = C_1 n^{1/2}$ (resp. $\mathbb{E}(\Delta_n) = C_3 n^{3/2-\beta}$) for SRD (resp. LRD) processes, where the constants C_1 and C_3 only depend on $\beta, \gamma, f_*, \mu_e, c_0$. ■

Remark 30 *Based on the proof of Theorem 11, the constants can take the following values:* $C_2 = \max(C_{21}, C_{22})$, $C_4 = \max(C_{21}, C_{42})$, *where* $C_{21} = (2\beta-1)/(16c_2c_3)$, $C_{22} = (32c_5c_6)^{-1}$ *and* $C_{42} = (16c_8)^{-1}$, *with* $c_1 = e^{c_0\mu}\mu_e$, $c_2 = 2c_1\gamma^2/c_0^2$, $c_3 = \max\{(2\beta-1)\gamma/(2c_0c_2), 1\}$, $c_4 = 2\beta(\beta-1)^{-1}\gamma$, $c_5 = c_1c_4^2/(2c_0^2)$, $c_6 = \max\{c_4/(8c_0c_5), 1\}$, $c_7 = (1-\beta)^{-1}\gamma$ *and* $c_8 = 2\max\{c_7/(8c_0), c_1c_7^2/(2c_0^2)\}$. *Constants* C_1 *and* C_3 *only depend on* $\beta, \gamma, f_*, \mu_e, c_0$.

6.6 Proofs of Theorem 12 and Proposition 13

Proof [Proof of Theorem 12] Since F_ϵ is the c.d.f of ϵ_i and $a_0 = 1$, $\mathbb{E}(\mathbf{1}_{X_i\le t}|\mathcal{F}_{i-1}) = F_\epsilon(t - X_{i,i-1})$. The summation $S_n(t)$ can be decomposed into two parts:

$$S_n(t) = \sum_{i=1}^n [\mathbf{1}_{X_i\le t} - \mathbb{E}(\mathbf{1}_{X_i\le t}|\mathcal{F}_{i-1})] + \sum_{i=1}^n [F_\epsilon(t - X_{i,i-1}) - F(t)] =: Q_n(t) + R_n(t). \tag{87}$$

Note that summands of $Q_n(t)$ are martingale differences. We shall derive bounds for

(i). $\mathbb{P}(\sup_{t\in\mathbb{R}}|Q_n(t)|/f_*\geq z/2)$.

(ii). $\mathbb{P}\big(\sup_{t\in\mathbb{R}}|R_n(t)|/f_*\geq C_0a_*\mu_q c(n,q)+z/2\big)$, for SRD case;
$\mathbb{P}(\sup_{t\in\mathbb{R}}|R_n(t)|/f_*\geq C_0'\mu_q n^{3/2-\beta}+z/2)$, for LRD case.

We shall apply Azuma's inequality on $Q_n(t)$ since it is the sum of martingale differences. For $R_n(t)$, since F_ϵ is smooth, we apply Theorems 4 and 8 for SRD and LRD cases, respectively.
Part (i): Let $M=2\mu_q n^{2\beta}$, $H(t)=\sum_{i=1}^n\mathbf{1}_{X_i\leq t}$ and $\tilde{H}(t)=\sum_{i=1}^n F_\epsilon(t-X_{i,i-1})$. Then $Q_n(t)=H(t)-\tilde{H}(t)$ and

$$\mathbb{P}\Big(\sup_{t\in\mathbb{R}}|Q_n(t)|/f_*\geq z/2\Big)\leq \mathrm{I}_1+\mathrm{I}_2,\ \text{where}$$

$$\mathrm{I}_1=\mathbb{P}\Big(\sup_{t\in\mathbb{R}}|H(t)-\tilde{H}(t)|/f_*\geq z/2,\ \max_{i\leq n}|X_{i,i-1}|\leq M\Big),\ \mathrm{I}_2=\sum_{i=1}^n\mathbb{P}\Big(|X_{i,i-1}|\geq M\Big).$$

For I_1, let $t_k=-2M+\delta k,\ k=0,\ldots,\lceil 4M/\delta\rceil$, where $\delta=z/(4n)$. Since $|F_\epsilon'|\leq f_*$, under this construction, $|\tilde{H}(t_k)-\tilde{H}(t_{k+1})|/f_*\leq z/4$.

Moreover, since $n\mathbb{P}(|\epsilon_0|\geq M)\leq n^{1-2q\beta}\leq z/4$, $\tilde{H}(t_0)$ and $1-\tilde{H}(t_{\lceil 4M/\delta\rceil})$ are less than $z/4$ on the set $\{\max_{i\leq n}|X_{i,i-1}|\leq M\}$.

Since $H(t)$ and $\tilde{H}(t)$ are both non-decreasing, for $s_1\leq s_2$ and $t\in[s_1,s_2]$, we have

$$|H(t)-\tilde{H}(t)|\leq|\tilde{H}(s_1)-\tilde{H}(s_2)|+\max\big\{|H(s_1)-\tilde{H}(s_1)|,|H(s_2)-\tilde{H}(s_2)|\big\}.$$

Consequently,

$$\mathrm{I}_1\leq\sum_{k=0}^{\lceil 4M/\delta\rceil}\mathbb{P}\left(|H(t_k)-\tilde{H}(t_k)|/f_*>z/4\right).\tag{88}$$

For any $t\in\mathbb{R}$, since the martingale differences $\mathbf{1}_{X_i\leq t}-\mathbb{E}(\mathbf{1}_{X_i\leq t}|\mathcal{F}_{i-1}),i=1,\ldots,n$, are bounded in absolute value by 1, by Azuma's inequality,

$$\mathbb{P}\left(|H(t)-\tilde{H}(t)|>z\right)\leq 2\exp(-z^2/2n).\tag{89}$$

With (88) and (89), we obtain

$$\mathrm{I}_1\leq(64\mu_q)z^{-1}n^{2\beta+1}\exp(-z^2/(32n)).$$

For I_2, by (51) and Markov's inequality,

$$\mathrm{I}_2\leq M^{-q}\sum_{i=1}^n\|X_{i,i-1}\|_q^q\leq c_1n^{1-2q\beta},\tag{90}$$

where $c_1=(K_q\gamma/2)^q(\beta q'-1)^{-q/q'}$. Combining I_1 and I_2 we complete the proof for this part.

Part (ii): Let $M=c_2\mu_q n^{2\beta}$, where $c_2=2K_q\gamma q'\beta$, then for any $\tau>0$,

$$\begin{aligned}&\mathbb{P}(\sup_{t\in\mathbb{R}}|R_n(t)|/f_*\geq z/2+\tau)\\ \leq&\mathbb{P}\Big(\sup_{|t|\leq 2M}|R_n(t)|/f_*\geq z/4+\tau\Big)+\sum_{i=1}^n\mathbb{P}\big(|X_{i,i-1}|\geq M\big)\\ +&\mathbb{P}\Big(\sup_{|t|\geq 2M}|R_n(t)|/f_*\geq z/4,\ \max_{i\leq n}|X_{i,i-1}|\leq M\Big)=:\mathrm{I}_1'+\mathrm{I}_2'+\mathrm{I}_3'.\end{aligned}\tag{91}$$

For I_1', let

$$A_n=\{-2M+\delta k|\delta=z/(8n),k=0,1,\ldots,\lceil 4M/\delta\rceil\}.\tag{92}$$

Then $\sup_{|t|\leq 2M}\min_{s\in A_n}(|F_\epsilon(t-\cdot)-F_\epsilon(s-\cdot)|_\infty+|F(t)-F(s)|)/f_*\leq z/(4n)$, and the cardinal number $|A_n|\leq(32c_2\mu_q)n^{2\beta+1}/z$. Hence under short- (resp. long-) range dependence, take $\tau=C_qa_*\mu_qc(n,q)$ (resp. $\tau=C'_{\beta,q\gamma}\mu_qn^{3/2-\beta}$), then I_1' can be bounded by Theorem 4 (resp. Theorem 8), that is, for SRD case,

$$\mathrm{I}_1'\leq 2^{2q\beta}C_{\beta,q,\gamma}\mu_q^q\frac{n}{z^{q\beta}}+3\exp\Big(-\frac{z^2}{16C_{\beta,\gamma}\mu_{q'}^{q'}n}+\log(|A_n|)\Big)+2\exp\Big(-\frac{z^v}{2^{3+2v}\mu_q^{v'}}+\log(|A_n|)\Big),$$

and for LRD case,

$$\mathrm{I}_1'\leq 2^{2q}C_{\beta,q,\gamma}(\mu_q^{2q}\vee\mu_q^q)\frac{n^{1+(1-\beta)q}}{z^q}\Big(1+\frac{[\log(|A_n|)+\log(n)]^q}{\tilde{c}^q(n,\beta)}\Big)+3\exp\Big(-\frac{z^2}{16C_{\beta,\gamma}n^{3-2\beta}\mu_2^2}+\log(|A_n|)\Big),$$

where $C_{\beta,q,\gamma}$ and $C_{\beta,\gamma}$ take the same values as in Theorems 4 and 8, respectively.

For I_2', by (90) we have $\mathrm{I}_2'\leq n^{1-2q\beta}$.

For I_3', if $|X_{i,i-1}|\leq M$ and $t\leq -2M$, then $F_\epsilon(t-X_{i,i-1})\leq F_\epsilon(-M)\leq M^{-q}\mu_q^q$ and $F(t)\leq(2M)^{-q}\mathbb{E}|X_0|^q$. By a similar argument for $t\geq 2M$, we obtain $R_n(x)<z/4$ for $|X_{i,i-1}|\leq M$ and $|t|\geq 2M$, that is $\mathrm{I}_3'=0$. ■

Remark 31 *Recall Lemma 19 for K_q. We can choose constants in Theorem 12 as follows:*

SRD $C_0=C_q$, $C_1=(K_q\gamma/2)^q(\beta q'-1)^{-q/q'}+1+2^{q\beta}C_{\beta,q,\gamma}$, $C_2=(16C_{\beta,\gamma}\vee 32)^{-1}$, $C_3=64K_q\gamma q'\beta(2\beta+1)$, *where $C_{\beta,q,\gamma}$, $C_{\beta,\gamma}$ and C_q take same values as those in Theorem 4.*

LRD $C_0'=C'_{\beta,q,\gamma}$, $C_1'=(K_q\gamma/2)^q(\beta q'-1)^{-q/q'}+1+2^{2q}C_{\beta,q,\gamma}c_0$, $C_2'=(16C_{\beta,\gamma}\vee 32)^{-1}$, $C_3'=64K_q\gamma q'\beta(2\beta+1)$, *where $C'_{\beta,q,\gamma}$, $C_{\beta,q,\gamma}$, $C_{\beta,\gamma}$ take same values as those in Theorem 8,* $c_0=1+\max_{n\geq 1}\log^q(c_0'n^{2\beta+1})\tilde{c}^{-q}(n,\beta)$, *with* $c_0'=64K_q\gamma q'\beta$. *Since* $\tilde{c}(n,\beta)=n^\alpha$ *some* $\alpha>0$ *and* $\log(n)/n^\alpha\to 0$, *c_0' is a finite constant.*

The following lemma is a variant of the Fuk-Nagaev inequality which will be used in the proof of Proposition 13.

Lemma 32 *Let $X_i = (X_{i1}, \ldots, X_{ip})^\mathsf{T}$, $i \in \mathbb{Z}$, be independent mean 0 random vectors in $\mathbb{R}^p$ and $S_{nj} = \sum_{i\le n} X_{ij}$. Assume there exist constants $s, r, c > 0$ such that*

$$\sum_{i\le n} \mathbb{P}\big(\max_{1\le j\le p} |X_{ij}| \ge y\big) \le cn/(y^s \log^r(y)), \qquad \text{for all } y > e.$$

Let $\sigma_n^2 = \max_{1\le j\le p} \sum_{i\le n} \mathbb{E}(X_{ij}^2)$. Then for any $z \ge c' n^{1/2}$, where $c' > 0$,

$$\mathbb{P}\Big(\max_{1\le j\le p} |S_{nj}| \ge 2\mathbb{E}\big[\max_{1\le j\le p} |S_{nj}|\big] + z\Big) \le C_1 e^{-z^2/(3\sigma_n^2)} + C_2 n/(z^s \log^r(z)),$$

where C_1, C_2 are positive constants that only depend on c, c', s and r.

Proof We shall apply the argument in Theorem 3.1 of Einmahl and Li (2008) with $(B, \|\cdot\|) = (\mathbb{R}^p, |\cdot|_\infty)$, $\eta = \delta = 1$ and $\beta(y) = \beta_{sr}(y) = M/(y^s \log^r(y))$. Notice Λ_n^2 in Theorem 3.1 of Einmahl and Li (2008) is bounded by σ^2 in our settings (cf. proof of Lemma A.2 in Chernozhukov et al. (2017)). ■

Proof [Proof of Proposition 13] Recall the proof of Theorem 12 for I_1, I_2, I_1'-I_3' and A_n in (92). For $z \ge c\sqrt{n}\log^\alpha(n)$, where $\alpha > 1/2$, all terms except I_1' are of order $o\big(nz^{-q\beta}\log^{-r_0}(z)\big)$. Hence we only need to show that $\mathrm{I}_1' \lesssim z^{-q\beta}\log^{-r_0}(z) n\mu_q^q$ for $\tau = C_q a_* \mu_q \sqrt{n}$. Let

$$\phi_j(t) = \sum_{i=1}^n P_j F_\epsilon(t - X_{i,i-1}) = \sum_{i=1\vee(j+1)}^n \big(F_{i-j}(t - X_{i,j}) - F_{i-j+1}(t - X_{i,j-1})\big),$$

Then $R_n(t) = \sum_{j\le n-1} \phi_j(t)$. Define

$$\tilde\phi_j(t) = \sum_{i=1\vee(j+1)}^n \big(F(t - a_{i-j}\epsilon_j) - \mathbb{E}F(t - a_{i-j}\epsilon_j)\big) \text{ and } \tilde R_n(t) = \sum_{j\le n-1} \tilde\phi_j(t).$$

By the same argument for I_1' in the proof of Theorem 12, we have

$$\mathrm{I}_1' \le \mathbb{P}\Big(\max_{t\in A_n} |R_n(t)|/f_* \ge z/4 + C_q a_* \mu_q \sqrt{n}\Big).$$

The idea is similar to the proof of Theorem 4, that is, we shall show:

(i). $R_n(t)$ can be approximated by $\tilde R_n(t)$, specifically,

$$\mathbb{P}\Big(\max_{t\in A_n} |R_n(t) - \tilde R_n(t)|/f_* \ge z/8\Big) = o\big(nz^{-q\beta}\log^{-r_0}(z)\big). \tag{93}$$

(ii). The tail probability of $\tilde R_n(t)$,

$$\mathbb{P}\big(\max_{t\in A_n} |\tilde R_n(t)|/f_* \ge C_q a_* \mu_q \sqrt{n} + z/8\big) \lesssim \frac{\mu_q^q n}{z^{q\beta}\log^{r_0}(z)}.$$

Part (i): Note that $\log(|A_n|) \lesssim \log(n)$ (actually $\log(|A_n|) \asymp \log(n)$) and that F_ϵ/f_*, f_ϵ/f_*, f_ϵ'/f_* are all bounded in absolute value by 1. By the same argument as in the proof of Lemma 24, using $u = z/\log^{3/2}(z)$ in inequality (55), we obtain (93).

Part (ii): Denote $V = \max_{t\in A_n} \sum_{j\le n-1} \mathbb{E}[\tilde\phi_j^2(t)]$, then by (39), we have $V \lesssim n$, where the constant in $\lesssim$ only depends on β, q, γ. For $j \le -n$, by (40) and $f' \le f_*$, we have

$$\sum_{j\le -n} \mathbb{P}(\max_{t\in A_n} |\tilde\phi_j(t)|/f_* \ge z) \le \sum_{j\le -n} \mathbb{P}(\gamma n(-j)^{-\beta}(|\epsilon_j| + \mu) \ge z) \lesssim \mu_q^q n/(z^{q\beta}\log^{r_0}(z)),$$

where the constant in $\lesssim$ only depends on β, q, γ, r_0, L. For $-n < j \le n$, by (41),

$$\sum_{-n<j\le n} \mathbb{P}(\max_{t\in A_n} |\tilde\phi_j(t)|/f_* \ge z) \le \sum_{-n<j\le n} \mathbb{P}(c_\beta(|\epsilon_j| + \mu)^{1/\beta} \ge z) \lesssim \mu_q^q n/(z^{q\beta}\log^{r_0}(z)),$$

where the constant in $\lesssim$ only depends on β, q, γ, r_0, L. By Lemma 32 we have

$$\mathbb{P}\Big(\max_{t\in A_n} \big|\tilde R_n(t)\big|/f_* - 2\mathbb{E}\Big[\max_{t\in A_n} |\tilde R_n(t)|\Big]/f_* \ge z\Big) \lesssim e^{-z^2/(3V)} + \frac{\mu_q^q n}{z^{q\beta}\log^{r_0}(z)} \lesssim \frac{\mu_q^q n}{z^{q\beta}\log^{r_0}(z)}.$$

By (49), we have $\mathbb{E}[\max_{t\in A_n} |\tilde R_n(t)|] \le C_q a_* \mu_q \sqrt{n}$, which implies the desired result. ■

6.7 Proof of Theorem 14

Proof [Proof of Theorem 14] Define

$$W_n(t) = \sum_{j=0}^{n-1} \varphi_j(t), \text{ where } \varphi_j(t) = \sum_{k\ge 1} \big[F(t - k^{-\beta}\epsilon_j) - \mathbb{E}F(t - k^{-\beta}\epsilon_j)\big]. \tag{94}$$

We claim that:

(i). $S_n(t)$ can be approximated by $W_n(t)$, specifically for $\theta_0 = (2\alpha - 1)/4$,

$$\mathbb{P}\Big(|S_n(t) - W_n(t)| \ge z/\log^{\theta_0}(z)\Big) = o\big(nz^{-q\beta}/\log^{r_0}(z)\big). \tag{95}$$

(ii). The tail distribution of $\varphi_0(t)$ satisfies

$$\mathbb{P}(\varphi_0(t) > z) \sim \frac{C_1}{z^{q\beta}\log^{r_0}(z)} \text{ and } \mathbb{P}(\varphi_0(t) < -z) \sim \frac{C_2}{z^{q\beta}\log^{r_0}(z)}, \tag{96}$$

where C_1, C_2 only depend on q, β, r_0, t, F.

Proofs of (95) and (96) will be given in Lemmas 33 and 34, respectively. By (95),

$$\begin{aligned}\mathbb{P}(S_n(t) > z) \ge& \mathbb{P}(W_n(t) \ge z + z/\log^{\theta_0}(z)) - \mathbb{P}(|S_n(t) - W_n(t)| \ge z/\log^{\theta_0}(z)),\\ =& \mathbb{P}(W_n(t) \ge z + z/\log^{\theta_0}(z)) + o\big(nz^{-q\beta}/\log^{r_0}(z)\big),\end{aligned} \tag{97}$$

and similarly

$$\mathbb{P}(S_n(t) > z) \le \mathbb{P}(W_n(t) \ge z - z/\log^{\theta_0}(z)) + o\big(nz^{-q\beta}/\log^{r_0}(z)\big). \tag{98}$$

Since φ_j has a regularly varying tail (96), by Theorem 1.9 in Nagaev (1979),

$$\sup_{w \ge \sqrt{n}\log^{\alpha}(n)} \Big|\frac{\mathbb{P}(W_n(t) \ge w)}{n\mathbb{P}(\varphi_0(t) \ge w)} - 1\Big| \to 0, \text{ as } n \to \infty.$$

Hence we have $\mathbb{P}(S_n(t) \ge z) \sim C_1 n z^{-q\beta}\log^{-r_0}(z)$ by (96), (97) and (98) in view of

$$\mathbb{P}(W_n(t) \ge z + z/\log^{\theta_0}(z)) \sim C_1 \frac{n}{z^{q\beta}\log^{r_0}(z)} \sim \mathbb{P}(W_n(t) \ge z - z/\log^{\theta_0}(z)).$$

Similarly we can derive $\mathbb{P}(S_n(t) \le -z) \sim C_2 n z^{-q\beta}\log^{-r_0}(z)$. ■

Lemma 33 *Recall definitions of $S_n(t)$, $W_n(t)$ in (94). Under assumptions of Theorem 14, we have for $\theta_0 = (2\alpha-1)/4$, (95) holds.*

Proof Recall (87) for $Q_n(t)$ and $R_n(t)$. Let

$$\tilde{W}_n(t) = \sum_{j\le n-1}\sum_{i=1\vee(j+1)}^{n} [F(t-(i-j)^{-\beta}\epsilon_j) - \mathbb{E}F(t-(i-j)^{-\beta}\epsilon_j)].$$

Then

$$\begin{aligned}
&\mathbb{P}\big(|S_n(t) - W_n(t)| \ge z\log^{-\theta_0}(z)\big)\\
\le&\mathbb{P}\big(|Q_n(t)| \ge z\log^{-\theta_0}(z)/3\big) + \mathbb{P}\big(|R_n(t) - \tilde{W}_n(t)| \ge z\log^{-\theta_0}(z)/3\big)\\
+&\mathbb{P}\big(|W_n(t) - \tilde{W}_n(t)| \ge z\log^{-\theta_0}(z)/3\big) =: \mathrm{I}_1 + \mathrm{I}_2 + \mathrm{I}_3.
\end{aligned}$$

Part I_1: Since $Q_n(t)$ is the summation of martingale differences bounded in absolute value by 1, Azuma's inequality leads to

$$\mathbb{P}\big(|Q_n(t)| \ge z/\log^{\theta_0}(z)\big) \le 2\exp\Big\{-\frac{z^2}{2n\log^{2\theta_0}(z)}\Big\} = o\big(nz^{-q\beta}/\log^{r_0}(z)\big). \tag{99}$$

Part I_2: Note that

$$R_n(t) = \sum_{j\le n-1}\sum_{i=1\vee(j+1)}^{n} \big(F_{i-j}(t-X_{i,j}) - F_{i-j+1}(t-X_{i,j-1})\big).$$

Take $F_\epsilon(t-\cdot)$ as $g(\cdot)$ in Lemma 24, then $g_\infty(\cdot) = F(t-\cdot)$. By Lemma 24, but in inequality (55), take $u = z/\log^{\theta_0+2}(z)$ instead, we obtain

$$\mathbb{P}\big(|R_n(t) - \tilde{W}_n(t)| \ge z/\log^{\theta_0}(z)\big) = o\big(nz^{-q\beta}\log^{-r_0}(z)\big).$$

Part I_3: Since $\tilde{W}_n(t)$ can be rewritten as

$$\tilde{W}_n(t) = \sum_{j\le n-1}\sum_{k=1\vee(1-j)}^{n-j} [F(t-k^{-\beta}\epsilon_j) - \mathbb{E}F(t-k^{-\beta}\epsilon_j)].$$

Notice that

$$\begin{aligned}
&\tilde{W}_n(t) - W_n(t)\\
=&\sum_{j\le -1}\sum_{k=1-j}^{n-j} [F(t-k^{-\beta}\epsilon_j) - \mathbb{E}F(t-k^{-\beta}\epsilon_j)] - \sum_{j=0}^{n-1}\sum_{k\ge n-j+1} [F(t-k^{-\beta}\epsilon_j) - \mathbb{E}F(t-k^{-\beta}\epsilon_j)].
\end{aligned}$$

For $j<0$, let $\phi_j = \sum_{k=1-j}^{n-j}[F(t-k^{-\beta}\epsilon_j) - \mathbb{E}F(t-k^{-\beta}\epsilon_j)]$, then by Lemma 22,

$$\begin{aligned}
|\phi_j| &\le \sum_{k=1-j}^{n-j} \min\big\{f_* k^{-\beta}(|\epsilon_j| + \mu), 1\big\}\\
&\le f_* \min\Big\{2\beta(\beta-1)^{-1}(|\epsilon_j|+\mu)^{1/\beta}, n(-j)^{-\beta}(|\epsilon_j|+\mu)\Big\}.
\end{aligned} \tag{100}$$

Denote $V = \sum_{j\le -1}\mathbb{E}(|\phi_j|^2)$. By Corollary 1.8 in Nagaev (1979), for $x = \lfloor n/\log^{\Gamma_0}(n)\rfloor$ with $\Gamma_0 = r_0 + \theta_0 q\beta + 1/2$,

$$\begin{aligned}
\mathbb{P}\Big(\Big|\sum_{j\le -1}\phi_j\Big| \ge z/\log^{\theta_0}(z)\Big) \lesssim& \sum_{j=-x}^{-1}\frac{\log^{\theta_0 q}(z)}{z^q}\mathbb{E}(|\phi_j|^q) + \sum_{j<-x}\frac{\log^{\theta_0 q\beta}(z)}{z^{q\beta}}\mathbb{E}(|\phi_j|^{q\beta})\\
&+\exp\Big(-\frac{z^2}{\log^{2\theta_0}(z)V}\Big) = \mathrm{II}_1 + \mathrm{II}_2 + \mathrm{II}_3,
\end{aligned}$$

where the constant in $\lesssim$ only depends on q and β.

For II_1, by (100),

$$\mathrm{II}_1 \lesssim \frac{\log^{\theta_0 q\beta}(z)}{z^{q\beta}} x\mu_q^q = \frac{n}{z^{q\beta}\log^{r_0}(z)}\frac{x}{n}[\log(z)]^{\theta_0 q\beta + r_0}\mu_q^q = o\big(nz^{-q\beta}/\log^{r_0}(z)\big),$$

where the constant in $\lesssim$ only depends on μ_q, f_*, q and β.

For II_2, by (100),

$$\begin{aligned}
\mathrm{II}_2 &\lesssim \frac{\log^{\theta_0 q}(z)}{z^q}\sum_{j<-x} n^q(-j)^{q\beta}\mu_q^q\\
&\lesssim \frac{n}{z^{q\beta}\log^{r_0}(z)}\frac{[\log(z)]^{\theta_0 q + r_0} z^{q(\beta-1)} n^{q-1}}{x^{q\beta-1}}\mu_q^q = o\big(nz^{-q\beta}/\log^{r_0}(z)\big),
\end{aligned}$$

where the constants in $\lesssim$ only depend on μ_q, f_*, q and β.

For II_3, by (100),

$$V \lesssim \sum_{j<-n}(n(-j)^{-\beta})^{q'} n^{2-q'}\mu_q^{q'} + \sum_{-n\le j\le n}\mu_q^q \lesssim n\mu_q^q,$$

where the constants in $\lesssim$ only depends on f_*, q and β.

Combining II_1-II_3, we have $\mathbb{P}(|\sum_{j\le -1}\phi_j| \ge z/\log^{\theta_0}(z)) = o(nz^{-q\beta}/\log^{r_0}(z))$. A similar argument will lead to the same bound for $j \ge 0$ part, thus

$$\mathbb{P}\big(|\tilde{W}_n(t) - W_n(t)| \ge z/\log^{\theta_0}(z)\big) = o\big(nz^{-q\beta}/\log^{r_0}(z)\big).$$

Thus the lemma follows from I_1-I_3. ∎

Lemma 34 *Recall* (94) *for* $\varphi_0(t)$. *Under conditions of Theorem 14, we have*

$$\mathbb{P}\left(\varphi_0(t) > z\right) \sim \frac{C_1}{z^{q\beta}\log^{r_0}(z)} \quad \textit{and} \quad \mathbb{P}\left(\varphi_0(t) < -z\right) \sim \frac{C_2}{z^{q\beta}\log^{r_0}(z)}, \ \textit{as } z \to \infty,$$

where $C_1 = L_1^{q\beta}(t)\beta^{-r_0}$, $C_2 = L_2^{q\beta}(t)\beta^{-r_0}$, *and*

$$L_1(t) = \int_0^\infty \frac{F(t+u) - F(t)}{\beta u^{1+1/\beta}}\mathrm{d}u, \quad L_2(t) = \int_0^\infty \frac{F(t) - F(t-u)}{\beta u^{1+1/\beta}}\mathrm{d}u. \tag{101}$$

Proof Since $f_\epsilon \le 1$, by Lemma 21, f is bounded by 1. Let

$$\tilde{\varphi}_0(t) = \int_0^\infty \big[F(t - s^{-\beta}\epsilon_0) - F(t)\big]\mathrm{d}s. \tag{102}$$

Since $|F(t - s^{-\beta}\epsilon_0) - F(t)| \le \min\{1, s^{-\beta}|\epsilon_0|\}$, we have

$$|\tilde{\varphi}_0(t)| \le 1 + \int_1^\infty s^{-\beta}|\epsilon_0|\mathrm{d}s \le 1 + (\beta-1)^{-1}|\epsilon_0|.$$

Thus $\tilde{\varphi}_0(t)$ is well defined. Note that the lemma follows from the following two claims:

(i). $|\varphi_0(t) - \tilde{\varphi}_0(t)| \le f_*\mu\beta/(\beta-1) + 1$, which is bounded.

(ii). $\mathbb{P}(\tilde{\varphi}_0(t) > z) \sim C_1\log^{-r_0}(z)z^{-q\beta}$ and $\mathbb{P}(\tilde{\varphi}_0(t) < -z) \sim C_2\log^{-r_0}(z)z^{-q\beta}$ as $z \to \infty$.

Part (i): Since F is non-decreasing, for any $s \in [k-1, k]$,

$$|F(t - s^{-\beta}\epsilon_0) - F(t - k^{-\beta}\epsilon_0)| \le \mathrm{sign}(\epsilon_0)\Big\{F(t - k^{-\beta}\epsilon_0) - F(t - (k-1)^{-\beta}\epsilon_0)\Big\}.$$

Since $F(-\infty) = 0$ and $F(\infty) = 1$,

$$\mathrm{I}_1 := \sum_{k=1}^\infty \int_{k-1}^k |F(t - s^{-\beta}\epsilon_0) - F(t - k^{-\beta}\epsilon_0)|\mathrm{d}s \le 1.$$

Since f is bounded, we have

$$\mathrm{I}_2 := \sum_{k=1}^\infty |F(t) - \mathbb{E}F(t - k^{-\beta}\epsilon_0)| \le f_* \sum_{k=1}^\infty k^{-\beta}\mu \le f_*\mu\beta/(\beta-1).$$

Thus $|\varphi_0(t) - \tilde{\varphi}_0(t)| \le \mathrm{I}_1 + \mathrm{I}_2 \le f_*\mu\beta/(\beta-1) + 1$, a finite constant.

Part (ii): Let $u > 0$. Then $0 \le F(t+u) - F(t) \le \min\{f_*u, 1\}$. Hence $L_1(t)$ is bounded by $\int_0^\infty \min\{f_*u, 1\}/(\beta u^{1+1/\beta})\mathrm{d}u \le f_*\beta/(\beta-1)$. Similarly $L_2(t) \le f_*\beta/(\beta-1)$. Note that

$$\int_0^\infty \big[F(t - s^{-\beta}y) - F(t)\big]\mathrm{d}s = \begin{cases} L_1(t)|y|^{1/\beta}, & \text{if } y < 0, \\ -L_2(t)|y|^{1/\beta}, & \text{if } y > 0. \end{cases}$$

Since ϵ_0 is symmetric, by (22) and the definition of $\tilde{\varphi}_0(t)$ in (102), (ii) follows. ∎

Remark 35 *Values of* C_1 *and* C_2 *are given in Lemma 34. A careful check of the proof of Theorem 14 suggests that the constant* Γ *can be chosen as* $\Gamma = [\theta_0 q + r_0 + (q\beta-1)\Gamma']/(q\beta - q)$, *where* $\theta_0 = (2\alpha-1)/4$ *and* $\Gamma' = r_0 + \theta_0 q\beta + 1$.

6.8 Proof of Corollaries 15 and 16

Proof [Proof of Corollary 15] We shall first deal with the SRD case. Recall $\mathcal{F}_j = (\epsilon_j, \epsilon_{j-1}, \ldots)$. Write

$$M_n(x) = \sum_{j=1}^n \Big(K_b(x - X_j) - \mathbb{E}[K_b(x - X_j)|\mathcal{F}_{j-1}]\Big),$$

$$R_n(x) = \sum_{j=1}^n \Big(\mathbb{E}[K_b(x - X_j)|\mathcal{F}_{j-1}] - \mathbb{E}[K_b(x - X_j)]\Big) = n(\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)) - M_n(x).$$

Note that $M_n(x)$ is a martingale w.r.t. filter $\sigma(\mathcal{F}_n)$. Let $\tau_n = n^\beta$ and $l_* = K_* \vee f_*$. Then

$$\begin{aligned} \mathrm{I} :&= \mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \ge l_*z\Big) \\ &\le \sum_{j=1}^n \mathbb{P}(|X_j| \ge \tau_n) + \mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \ge l_*z, \max_{1\le j\le n}|X_j| < \tau_n\Big) \\ &=: \mathrm{I}_1 + \mathrm{I}_1'. \end{aligned} \tag{103}$$

Since K has support $[-1, 1]$, $K_b(x - X_j) = 0$ when $|X_j| < \tau_n$ and $|x| > \tau_n + b_n$. Hence if $\max_{j\le n}|X_j| < \tau_n$ and $|x| > \tau_n + b_n$, we have $\hat{f}_n(x) = 0$. Note that $\sup_{|x|\le\tau_n+b_n}|M_n(x)| + \sup_{|x|\le\tau_n+b_n}|R_n(x)| \ge \sup_{|x|\le\tau_n+b_n} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)|$, we have

$$\begin{aligned} \mathrm{I}_1' \le &\mathbb{P}\Big(\sup_{|x|>\tau_n+b_n} n|\mathbb{E}K_b(x - X_1)| \ge l_*z/4\Big) + \mathbb{P}\Big(\sup_{|x|\le\tau_n+b_n}|M_n(x)| \ge l_*z/2\Big) \\ &+ \mathbb{P}\Big(\sup_{|x|\le\tau_n+b_n}|R_n(x)| \ge l_*z/4\Big) =: \mathrm{I}_2 + \mathrm{I}_3 + \mathrm{I}_4. \end{aligned} \tag{104}$$

Hence by (103) and (104), we have $\mathrm{I} \le \mathrm{I}_1 + \mathrm{I}_2 + \mathrm{I}_3 + \mathrm{I}_4$. For I_1-I_3 we shall bound them through some basic inequalities, for I_4, we will apply Corollary 6.

For I_1: By Lemma 19, $\mathbb{E}(|X_0|^q) \le K_q^q(\sum_{j\ge 0}|a_j|^{q'})^{q/q'}\mu_q^q$. Hence by Markov's inequality $\mathrm{I}_1 \le n\tau_n^{-q}\mathbb{E}(|X_0|^q) \lesssim nz^{-q\beta}\mu_q^q$, where the constant in $\lesssim$ only depends on q, β and γ.

For I_2: Since $|K|_\infty$ is bounded by K_* with support $[-1,1]$, we have $|\mathbb{E}K_b(x-X_1)| \le K_* b_n^{-1}\mathbb{P}(|X_1-x|\le b_n)$. When $|x| > \tau_n + b_n$, $\mathbb{P}(|X_1-x|\le b_n) \le \mathbb{P}(|X_1|\ge \tau_n)$. Hence

$$n|\mathbb{E}K_b(x-X_1)| \le nK_*b_n^{-1}\mathbb{P}(|X_1|\ge\tau_n) \le K_*b_n^{-1}n^{1-q\beta}\mathbb{E}|X_0|^q = o(K_*z),$$

in view of $z \ge c(n/b_n)^{1/2}\log^{1/2}(n)$ and $nb_n \to \infty$. Thus $\mathrm{I}_2 = 0$ for all large n.

For I_3: Let $A_n = \{-(\tau_n+b_n)+\delta_n k, k = 0,1,\ldots,\lfloor 2(\tau_n+b_n)/\delta_n + 1\rfloor\}$, where $\delta_n = zb_n^2/(8n)$. Then

$$\sup_{|x|\le\tau_n+b_n}\min_{y\in A_n}|M_n(x)-M_n(y)| \le K_*z/4,$$

and $\mathrm{I}_3 \le \sum_{x\in A_n}\mathbb{P}(|M_n(x)|\ge l_*z/4)$. Since $|K|_\infty \le K_*$ and $|f_\epsilon|_\infty \le f_*$, for $X_{j,j-1} = \sum_{k\ge 1}a_k\epsilon_{j-k}$,

$$\begin{aligned}\mathbb{E}[K_b^2(x-X_j)|\mathcal{F}_{j-1}]| &= \int_{-\infty}^{\infty} b_n^{-2}K^2(\frac{x-X_{j,j-1}-u}{b_n})f_\epsilon(u)\mathrm{d}u\\ &= \int_{-\infty}^{\infty} b_n^{-1}K^2(y)f_\epsilon(x-b_ny-X_{j,j-1})\mathrm{d}y\\ &\le K_*f_*b_n^{-1}\int_{-\infty}^{\infty}K(y)\mathrm{d}y = K_*f_*b_n^{-1}.\end{aligned}$$

Therefore for $\xi_j(x) = K_b(x-X_j) - \mathbb{E}[K_b(x-X_j)|\mathcal{F}_{j-1}]$,

$$V(x) := \sum_{j=1}^n \mathbb{E}(\xi_j(x)^2|\mathcal{F}_{j-1}) \le nK_*f_*b_n^{-1}.$$

Note $|K_b| \le K_*/b_n$, therefore by Freedman's inequality (Lemma 18), we have

$$\begin{aligned}\mathrm{I}_3 &\le \sum_{x\in A_n}\mathbb{P}\big(|M_n(x)|\ge l_*z/4\big) \le 2\sum_{x\in A_n}\exp(-\frac{z^2}{2zb_n^{-1}+2nb_n^{-1}})\\ &\le \frac{32n(\tau_n+b_n)}{zb_n^2}\exp(-\frac{z^2b_n}{4n}).\end{aligned}$$

Since $z \ge c(n/b_n)^{1/2}\log^{1/2}(n)$, for c sufficiently large $\mathrm{I}_3 = o(n/z^{q\beta})$.

For I_4: Since $\mathbb{E}[K_{b_n}(x-X_j)|\mathcal{F}_{j-1}] = \int_{\mathbb{R}}K(u)f_\epsilon(x-b_nu-X_{j,j-1})\mathrm{d}u$, we have $R_n(x) = \sum_{j=1}^n N_n(x, X_{j,j-1})$, where

$$N_n(x,y) = \int_{-\infty}^{\infty}K(u)[f_\epsilon(x-b_nu-y) - f(x-b_nu)]\mathrm{d}u. \tag{105}$$

Let function class $\mathcal{A}_n = \{N_n(x,\cdot), |x| \le \tau_n + b_n\}$, then for any function in $\mathcal{A}_n$, its up to second order derivatives are bounded by f_* and $\mathcal{N}_{\mathcal{A}_n}(f_*z/n) \le 4n(\tau_n+b_n)/z$. Therefore by Corollary 6, we have $\mathrm{I}_4 \lesssim \mu_q^q nz^{-q\beta}$, where the constant in $\lesssim$ only depends on β, q and γ. Thus (25) follows from I_1-I_4.

For the LRD case, define $M_n(x)$ and $R_n(x)$ as in the SRD case and let $\tau_n = z$. Again we have

$$\begin{aligned}&\mathbb{P}\Big(\sup_{x\in\mathbb{R}} n|\hat{f}_n(x) - \mathbb{E}\hat{f}_n(x)| \ge l_*z\Big) \le \sum_{j=1}^n \mathbb{P}(|X_j|\ge z)\\ &+\mathbb{P}\Big(\sup_{|x|>z+b_n} n|\mathbb{E}K_b(x-X_1)| \ge l_*z/4\Big) + \mathbb{P}\Big(\sup_{|x|\le z+b_n}|M_n(x)| \ge l_*z/2\Big)\\ &+\mathbb{P}\Big(\sup_{|x|\le z+b_n}|R_n(x)| \ge l_*z/4\Big) =: \mathrm{I}_1+\mathrm{I}_2+\mathrm{I}_3+\mathrm{I}_4.\end{aligned}$$

Using same argument as for SRD case with τ_n replaced by z, we obtain $\mathrm{I}_1, \mathrm{I}_2, \mathrm{I}_3 \lesssim nz^{-q}\mu_q^q$, where the constants in $\lesssim$ only depend on q, β and γ. For I_4, we still have (105). Let $\mathcal{A}_n = \{N_n(x,\cdot), |x| \le z+b_n\}$. Then $\mathcal{N}_{\mathcal{A}_n}(f_*z/n) \le 4n(z+b_n)/z$. Therefore by Corollary 10, we have $\mathrm{I}_3 \lesssim (\mu_q^{2q}\vee\mu_q^q)n^{3/2-\beta}z^{-q}$, where the constant in $\lesssim$ only depends on β, q and γ. ■

Proof [Proof of Corollary 16] Let $\mathcal{G}_i = (\epsilon_i, \epsilon_{i-1}, \ldots; \eta_i, \eta_{i-1}, \ldots)$ and $X_{i,i-1} = \sum_{j=1}^\infty a_j\epsilon_{i-j}$. Then we have $\mathbb{E}[L(X_i, Y_i, h(X_i))|\mathcal{G}_{i-1}] = Q_h(X_{i,i-1})$, where

$$Q_h(w) = \int_{-\infty}^{\infty}\mathbb{E}[L(u, H_0(u,\eta_i), h(u))]f_\epsilon(u-w)\mathrm{d}u. \tag{106}$$

Let $J_h(x) = Q_h(x) - \mathbb{E}[L(X_i, Y_i, h(X_i))]$. Write

$$n(R_n(h) - R(h)) = \sum_{i=1}^n\Big[L(X_i,Y_i,h(X_i)) - Q_h(X_{i,i-1})\Big] + \sum_{i=1}^n J_h(X_{i,i-1}) =: \mathrm{I}_1(h) + \mathrm{I}_2(h).$$

For $h, g \in \mathcal{H}$, let $D(h,g) = \sup_{x,y\in\mathbb{R}}|L(x,y,h(x)) - L(x,y,g(x))|$. Let $\mathcal{H}_n$ be the subset of $\mathcal{H}$ such that $\sup_{h_1\in\mathcal{H}}\inf_{h_2\in\mathcal{H}_n}D(h_1,h_2) \le z/(4n)$ and $|\mathcal{H}_n| \le \mathcal{N}_{\mathcal{A}}(z/(4n))$. Then for $\tau > 0$,

$$\begin{aligned}\mathbb{P}(n\Psi_n/f_* \ge z+\tau) &\le \mathbb{P}\Big(\max_{h\in\mathcal{H}_n} n|R_n(h)-R(h)|/f_* \ge z/2+\tau\Big)\\ &\le \sum_{h\in\mathcal{H}_n}\mathbb{P}(|\mathrm{I}_1(h)|/f^* \ge z/4) + \mathbb{P}\Big(\max_{h\in\mathcal{H}_n}|\mathrm{I}_2(h)|/f_* \ge z/4+\tau\Big).\end{aligned}$$

Since $0 \le L \le 1$, $f^* \ge 1$ and the summands of $\mathrm{I}_1(h)$ are bounded martingale differences with respect to $\mathcal{G}_i$, by Azuma's inequality, we have $\sum_{h\in\mathcal{H}_n}\mathbb{P}(|\mathrm{I}_1(h)| \ge z) \le 2|\mathcal{H}_n|e^{-z^2/(32n)}$. Since both $\int_{-\infty}^\infty|f_\epsilon'(x)|\mathrm{d}x$ and $\int_{-\infty}^\infty|f_\epsilon''(x)|\mathrm{d}x$ are bounded by f_*, by (106), for $h \in \mathcal{H}$, Q_h, Q_h' and Q_h'' exist and are uniformly bounded by f_* in absolute value. Thus (16) (resp. (20)) follows from applying Corollary 6 to Q_h/f_* with $\tau = C_q a_*\mu_q c(n,q)$ (resp. Corollary 10 with $\tau = C_{\beta,q,\gamma}\mu_q n^{3/2-\beta}$). ■

Acknowledgments

We thank the reviewers and the editor for very helpful suggestions, which substantially improve the paper.

Abstract

We propose a method for simultaneously estimating regression coefficients and clustering response variables in a multivariate regression model, to increase prediction accuracy and give insights into the relationship between response variables. The estimates of the regression coefficients and clusters are found by using a penalized likelihood estimator, which includes a cluster fusion penalty, to shrink the difference in fitted values from responses in the same cluster, and an L_1 penalty for simultaneous variable selection and estimation. We propose a two-step algorithm, that iterates between k-means clustering and solving the penalized likelihood function assuming the clusters are known, which has desirable parallel computational properties obtained by using the cluster fusion penalty. If the response variable clusters are known *a priori* then the algorithm reduces to just solving the penalized likelihood problem. Theoretical results are presented for the penalized least squares case, including asymptotic results allowing for $p \gg n$. We extend our method to the setting where the responses are binomial variables. We propose a coordinate descent algorithm for the normal likelihood and a proximal gradient descent algorithm for the binomial likelihood, which can easily be extended to other generalized linear model (GLM) settings. Simulations and data examples from business operations and genomics are presented to show the merits of both the least squares and binomial methods.

Keywords: Multivariate Regression, Clustering, Fusion Penalty

1. Introduction

In this article we consider the pair $(\mathbf{x}_i, \mathbf{y}_i)_{i=1}^n$, with $\mathbf{x}_i^T = (x_{i1}, \ldots, x_{ip}) \in \mathcal{R}^p$ and $\mathbf{y}_i = (y_{i1}, \ldots, y_{ir})^T \in \mathcal{R}^r$. Define $X = (\mathbf{x}_1, \ldots, \mathbf{x}_n)^T \in \mathcal{R}^{n \times p}$ and $Y = (\mathbf{y}_1, \ldots, \mathbf{y}_n)^T \in \mathcal{R}^{n \times r}$. We initially assume the linear model

$$\mathbf{y}_i = B^{*T}\mathbf{x}_i + \boldsymbol{\epsilon}_i, \tag{1}$$

where $\boldsymbol{\epsilon}_i = (\epsilon_{i1}, \ldots, \epsilon_{ir})^T \in \mathcal{R}^r$ are realizations of an i.i.d. random variable with mean zero and covariance matrix Σ, $B^* = (\boldsymbol{\beta}_1^*, \ldots, \boldsymbol{\beta}_r^*) \in \mathcal{R}^{p \times r}$ and $\boldsymbol{\beta}_k^* = (\beta_{1k}^*, \ldots, \beta_{pk}^*)^T \in \mathcal{R}^p$. We will refer to the matrix of error as $E = (\boldsymbol{\epsilon}_1, \ldots, \boldsymbol{\epsilon}_n)^T \in \mathcal{R}^{n \times r}$. Under mild assumptions a consistent estimator of $\boldsymbol{\beta}_k^*$ is the ordinary least squares (OLS) estimator of

$$\tilde{\boldsymbol{\beta}}_k = \underset{\boldsymbol{\beta}_k}{\operatorname{argmin}} \sum_{i=1}^n (y_{ik} - \mathbf{x}_i^T \boldsymbol{\beta}_k)^2.$$

If $\boldsymbol{\epsilon}_i$ are i.i.d. and $\boldsymbol{\epsilon}_i \sim N(\mathbf{0}_r, \Sigma)$ the estimator $\tilde{\boldsymbol{\beta}}_k$ is the MLE. This estimator does not use the other responses, ignoring potentially useful information.

Throughout this paper for a vector $\mathbf{a}$ define $||\mathbf{a}||_q$ as the L_q norm and for a matrix A we define $||A||_q$ as the entrywise L_q norm. If there is *a priori* information that the fitted values of response k and m should be close then we could impose a penalty on the difference in the fitted values and consider the estimators

$$(\tilde{\boldsymbol{\beta}}_k, \tilde{\boldsymbol{\beta}}_m) = \underset{\boldsymbol{\beta}_k, \boldsymbol{\beta}_m}{\operatorname{argmin}} \sum_{i=1}^n \left\{ (y_{ik} - \mathbf{x}_i^T \boldsymbol{\beta}_k)^2 + (y_{im} - \mathbf{x}_i^T \boldsymbol{\beta}_m)^2 \right\} + \frac{\gamma}{n} ||X(\boldsymbol{\beta}_k - \boldsymbol{\beta}_m)||_2^2, \tag{2}$$

where γ is a tuning parameter controlling the amount of agreement between the two fitted values vectors. We propose an objective function that generalizes (2) for multiple responses from multiple clusters that may not be known *a priori*. The proposed objective function also includes an L_1 penalty for simultaneous estimation and variable selection, which allows our method to be used to increase prediction accuracy, select relevant variables for each response, and detect groupings of response variables without assuming or estimating a covariance structure. In our theory, simulations, and applied examples we consider cases where $p \gg n$. We extend the proposed method to the generalized linear model framework, specifically focusing on multiple binary responses. This extension allows the method to be used in many different contexts, such as understanding co-morbidities related to patient information recorded in electronic medical records, or product level purchasing habits of customers based on information obtained from a loyalty program. We propose a coordinate descent algorithm for the least squares case and proximal coordinate descent algorithm for the binomial GLM case, which provides a general framework for extending the method to other GLM or M-estimator settings.

Our work has been influenced by previous work in estimating high dimensional models. When $\frac{1}{n}X'X = I_p$ the penalty function is equivalent to a ridge penalty (Hoerl and Kennard, 1970) on the difference of the coefficient vectors for the two responses. We add the L_1 penalty as proposed in Tibshirani (1996) to do simultaneous variable selection and estimation. Similar to the work of Zou and Hastie (2005) we combine the ridge and L_1 penalties. The proposed estimator simultaneously estimates clusters of the response and fuses the fitted values of the clustered responses. Previous work has been done on clustering covariates for high dimensional regression with a univariate response. This work is most similar to the work of Witten et al. (2014) who proposed the cluster elastic net (CEN) that simultaneously estimates clusters of covariates and fuses the effects of covariates within the same cluster. Our proposed method is also similar to Grace estimators proposed in Li and Li (2008) and Li and Li (2010), which use regularization based on external network information to minimize the difference of coefficients for related predictors and use a lasso penalty for sparsity. Huang et al. (2011) proposed the sparse Laplacian shrinkage method, which preforms variable selection and promotes similarities among coefficients of correlated covariates. Zhao and Shojaie (2016) proposed the Grace Test, a testing framework for Grace estimators, that

allows for some uncertainty in the graph and showed that if the external graph is informative it increases the power of the Grace test. Bühlmann et al. (2013) proposed two different penalized methods for clustered covariates in high-dimensional regression: cluster representative lasso (CRL) and cluster group lasso (CGL). In CRL the covariates are clustered, dimension reduction is done by replacing the original covariates with the cluster centers and a lasso model is fit using the cluster centers as covariates. In CGL the group penalty of Yuan and Lin (2005) is applied using the previously found clusters as the groups. Zhou et al. (2017) demonstrated that averaging over models using different cluster centers for both responses and predictors can improve prediction accuracy of DNase I hypersensitivity using gene expression data. Kim et al. (2009) proposed graph-guided fused lasso (GGFL) to the specific problem of association analysis to quantitative trait networks. GGFL presents a fused lasso framework in multivariate regression that leverages correlated traits based on a network structure. Our work is related to the fused lasso literature as well, though we do not achieve exact fusion (Tibshirani et al., 2005; Rinaldo, 2009; Hoefling, 2010; Tibshirani, 2014). The proposed method differs from the works mentioned in this setting because it focuses on using correlation between the response variables to improve estimation, however all of the works mentioned were instrumental in helping us derive our final estimator.

The idea of using information from different responses to improve estimation in multivariate regression is not new and our work builds upon previous works in this area. Breiman and Friedman (1997) introduced the Curds and Whey method whose predictions are an optimal linear combination of least squares predictions. Rothman et al. (2010) proposed multivariate regression with covariance estimation (MRCE), which is a penalized likelihood approach to simultaneously estimate the regression coefficients and the inverse covariance matrix of the errors. MRCE leverages correlation in unexplained variation to improve estimation, while our proposed method leverages correlation in explained variation to improve estimation. Other estimators assume both the response and covariates are multivariate normal and exploit this structure to derive estimators (Lee and Liu, 2012; Molstad and Rothman, 2016). Rai et al. (2012) proposed a penalized likelihood method for multivariate regression that simultaneously estimates regression coefficients, the inverse covariance matrix of the errors, and the covariance matrix of the regression coefficients across responses using lasso type penalties. Peng et al. (2010) introduced regularized multivariate regression for identifying master predictors (remMap), which relies on *a priori* information about valuable predictors and imposes a group L_1 and L_2 norm, across responses, on all covariates not prespecified as being useful predictors. Kim and Xing (2012) proposed the tree guided group lasso, which uses an *a priori* hierarchical clustering of the responses to define overlapping group lasso penalties for the multivariate regression model. They propose a weighting method that ensures all coefficients are penalized equally, while using the hierarchical structure to impose a similar sparsity structure across highly correlated responses.

Another approach to improving efficiency is by doing dimension reduction on Y to find a smaller subspace that retains the material information needed for estimation of the regression coefficients (Cook et al., 2010; Cook and Zhang, 2015; Sun et al., 2015). Cook et al. (2010) introduced the envelope estimator for the multivariate linear model, which projects the maximum likelihood estimator onto the estimated subspace with the material information. Cook and Zhang (2015) provided envelope models for GLMs and weighted least squares. Sun et al. (2015) proposed a sparse regression model (SPReM) for estimating models where r is very large. SPReM projects the response variables into a lower-dimensional space while maintaining the structure needed for a specific hypothesis test. The key difference between our proposed method and these approaches is that we are interested in simultaneously estimating clustering of the response variables and fusing the fitted values from responses within the same cluster.

The proposed method simultaneously estimates clusters of the response and coefficients. Changes in cluster groups are discrete changes and as a result our objective function is discontinuous, similar to k-means clustering, thus making it difficult to derive an efficient algorithm that will find the optimal estimates for coefficients and groups. Witten et al. (2014) dealt with a similar difficulty for the CEN estimator, but noticed that if the groups are fixed then the problem is convex, while if the regression coefficients are fixed the problem becomes a k-means clustering problem. We modify the approach proposed in Witten et al. (2014) to our problem of grouping responses and extend the approach to the case of generalized linear models, specifically the binomial logistic model. In our theoretical results we assume the clustering groups are known, but the problem remains challenging as we are dealing with multiple responses, allow for $p \gg n$ and for p to increase with n.

In Section 2 we present our method for the multivariate linear regression model and provide theoretical results, including consistency of our estimator, to better understand the basic properties of the penalized likelihood solution. In Section 3 we provide details on the two-step iterative algorithm and show estimating the regression coefficients for the different clusters is an embarrassingly parallel problem, which is a property of our cluster fusion penalty that fuses within group fitted values. This avoids issues that would arise in fusing all possible combinations of regression coefficients, or having to specify a fusion set *a priori*. Examples of the issues that can arise can be found in Price et al. (2017), who discussed the importance of choosing the fusion set, and the original fused lasso paper which fused only consecutive coefficients (Tibshirani et al., 2005). In Section 4 we present the model for binomial responses along with an algorithm, demonstrating how the use of the cluster fusion penalty can exploit relationships of response variables beyond the traditional Gaussian problem. Simulations for both conditional Gaussian and binomial responses are presented in Section 5. The least squares version of our method is applied to model baby birth weight, placental weight and cotinine levels given maternal gene expression and demographic information. The binomial case is applied to model concession stand purchases using customer information as covariates. Both applied analysis are presented in Section 6. We conclude with a summary in Section 7.

2. Least Squares Model

2.1 Method

First, we consider estimating (1) when there are Q unknown clusters of the r responses. We further assume that $\sum_{i=1}^{n} y_{ik} = 0$ for all $k = 1, \ldots, r$, $\sum_{i=1}^{n} x_{ij} = 0$ and $\sum_{i=1}^{n} x_{ij}^2 \leq n$ for all $j = 1 \ldots, p$. The model requires rp parameters to be estimated for prediction, which is problematic when r or p are large. Let $D = (D_1, \ldots, D_Q)$ be a partition of the set $\{1, \ldots, r\}$. For a set A define $|A|$ as the cardinality of that set. We propose the multivariate cluster

elastic net (MCEN) estimator as

$$(\hat{B},\hat{D}) = \underset{B\in\mathcal{R}^{p\times r},D_1,\ldots,D_Q}{\arg\min} \frac{1}{2n}\sum_{i=1}^{n}\sum_{c=1}^{r}(y_{ic}-\mathbf{x}_i^T\boldsymbol{\beta}_c)^2+\delta||B||_1 \\ +\frac{\gamma}{2n}\sum_{q=1}^{Q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||X(\boldsymbol{\beta}_l-\boldsymbol{\beta}_m)||_2^2, \tag{3}$$

where Q is the number of clusters and γ and δ are non-negative user specified tuning parameters. In addition Q, the total number of clusters, can be considered a tuning parameter. The cluster fusion penalty, associated with tuning parameter γ, is used to exploit similarities in the fitted values. The lasso penalty, with tuning parameter δ, is used to perform simultaneous estimation and variable selection. When $\gamma = 0$ or $Q = r$, the optimization in (3) reduces to r independent lasso penalized least squares problems with tuning parameter δ. If $\hat{D}$ is known then the optimization in (3) can be split into Q independent optimizations that are similar to the optimizations presented in Li and Li (2008), Li and Li (2010), and Witten et al. (2014) and can be solved in parallel. We exploit this computational feature in our algorithm, which is a result of using the cluster fusion penalty.

The proposed method uses a combination of L_1 and L_2 penalties as proposed by Zou and Hastie (2005). Similar methods have been proposed for grouping the effects of predictors with a univariate response such as CEN (Witten et al., 2014) and Grace estimators (Li and Li, 2008, 2010; Zhao and Shojaie, 2016). Kim and Xing (2012) proposed a method that uses a predetermined hierarchical clustering of the responses that provides an L_1 penalty for all coefficients and a group L_2 penalty for responses that are grouped together. Chen et al. (2016) proposed a method using conjoint clustering to incorporate similarities in preferences between individuals in conjoint analysis. This method does not simultaneously estimate coefficients and groupings. It requires a two-step algorithm to estimate the number of clusters, and then estimates coefficients using regularization based on the estimated cluster. The proposed approach uses non-hierarchical clusters, allows for the clustering structure to be unknown before estimation of the coefficients and focuses more on imposing similar fitted values for grouped responses, compared to directly imposing a similar sparsity structure.

Selecting the triplet, (Q,γ,δ), of tuning parameters can be done by K-fold cross validation minimizing the squared prediction error. Let $\mathcal{F}_k$ be the set of indices in the kth fold, $k\in\{1,\ldots,K\}$, and $\hat{\boldsymbol{\beta}}_c^{(-\mathcal{F}_k)}(Q,\gamma,\delta)$ be the estimated regression coefficient vector using Q, γ and δ for response c produced from the training set with $\mathcal{F}_k$ removed. Then select the triplet, $(\hat{Q},\hat{\gamma},\hat{\delta})$, that minimizes

$$V(Q,\delta,\gamma)=\sum_{k=1}^{K}\sum_{c=1}^{r}\sum_{i\in\mathcal{F}_k}\left\{y_{ic}-x_i^T\hat{\boldsymbol{\beta}}_c^{(-\mathcal{F}_k)}(Q,\gamma,\delta)\right\}^2. \tag{4}$$

2.2 Theoretical Results

For theoretical discussions we assume that D is known for some fixed value of Q. This is because for D unknown the objective function in (3) is discontinuous because of the discrete changes in groups, however if D is known (3) is a convex function. In this section we will look at properties of the MCEN estimator for the special case of fixed n and p with $\delta = 0$. In addition, we present a consistency result that allows for $p \gg n$ when $\delta = o(1)$ and $\gamma = o(1)$.

Thus, the first two theorems refer to the following estimator

$$\bar{B} = \underset{B\in\mathcal{R}^{p\times r}}{\arg\min}\frac{1}{2n}\sum_{i=1}^{n}\sum_{c=1}^{r}(y_{ic}-\mathbf{x}_i^T\boldsymbol{\beta}_c)^2+\delta||B||_1 \\ +\frac{\gamma}{2n}\sum_{q=1}^{Q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||X(\boldsymbol{\beta}_l-\boldsymbol{\beta}_m)||_2^2. \tag{5}$$

The estimator $\bar{B}$ does not simultaneously estimate the groups, it assumes they are known *a priori*, and thus is different than $\hat{B}$. There are instances where the grouping structure is known before data analysis and thus using $\bar{B}$ would be preferable in practice. In addition $\bar{B}$ is a key component to the algorithm discussed in Section 3. We begin by relating the estimator in (5) to ordinary least squares (OLS), for the special case of $\delta = 0$. Removing the L_1 penalty allows us to derive a closed form for the estimator.

Theorem 1 *Assume $n > p$, $\delta = 0$, and Q and γ are fixed values. Define $\dot{B} = (\dot{\boldsymbol{\beta}}_1,\ldots,\dot{\boldsymbol{\beta}}_r)$ to be the OLS estimates for the r response variables and $\bar{B} = (\bar{\boldsymbol{\beta}}_1,\ldots,\bar{\boldsymbol{\beta}}_r)$ be the solution to (5) with tuning parameter γ. Given $l\in D_q$ then $\bar{\boldsymbol{\beta}}_l$ has the closed form solution of*

$$\bar{\boldsymbol{\beta}}_l = \dot{\boldsymbol{\beta}}_l + \frac{2\gamma}{(1+2\gamma)|D_q|}\sum_{c\in D_q c\neq l}(\dot{\boldsymbol{\beta}}_c-\dot{\boldsymbol{\beta}}_l). \tag{6}$$

Theorem 1 provides some intuition about the MCEN estimator. As γ increases the MCEN estimator approaches a weighted average of the OLS coefficients within a cluster. In addition the results from Theorem 1 can be used to calculate the bias and variance of $\bar{B}$, which are needed for proving Theorem 2. The proof of Theorem 1 and the following Theorems can be found in the appendix.

Theorem 2 *Assume $E(\epsilon_{ic}^2)=1$ for all $i\in\{1,\ldots,n\}$ and $c\in\{1,\ldots,r\}$ and $E(\epsilon_{ic}\epsilon_{ik})=\rho$ for $c\neq k$, where $\rho\in(0,1)$. Set $\delta=0$, then for a fixed n and p where $n>p$ there exists a positive γ such that*

$$E\left(\left|\left|\bar{B}-B^*\right|\right|_2^2\right) < E\left(\left|\left|\dot{B}-B^*\right|\right|_2^2\right), \tag{7}$$

where B^* are the true regression coefficients, $\dot{B}$ is as defined in Theorem 1 and $\bar{B}$ is as defined in (5).

Similar to ridge regression Theorem 2 shows that for some positive γ the estimator from (5) has a smaller mean squared error than OLS. Note, we are not assuming that for $l,s\in D_m$ that $\boldsymbol{\beta}_l^* = \boldsymbol{\beta}_m^*$ and unless this condition holds the estimator $\bar{B}$ is biased. Thus, there exists a value of γ for which there is a favorable bias-variance trade off.

Next we examine the asymptotic performance of the estimator with the L_1 penalty. At times it will be easier to refer to a vectorized version of a matrix and for any matrix $A\in\mathcal{R}^{a\times b}$, $\text{vec}(A)\in\mathcal{R}^{ab}$. Where $\text{vec}(A)$ is the vector formed by stacking the columns of A.

Define S as the set of active predictors. That is, S is a subset of $\{1,\ldots,rp\}$ where $m \in S$ if $\text{vec}(B^*)_m \neq 0$. The subspace for the active predictors is

$$\mathcal{M}(S) \equiv \{\boldsymbol{\theta} \in \mathcal{R}^{pr} | \theta_j = 0 \text{ if } j \notin S\}.$$

The parameter space will be separated using projections of vectors into orthogonal complements. We define a projection of a vector $\mathbf{u}$ into space $\mathcal{M}(S)$ as

$$\mathbf{u}_{\mathcal{M}(S)} \equiv \underset{\mathbf{v}\in\mathcal{M}(S)}{\arg\min} ||\mathbf{u}-\mathbf{v}||_2.$$

The orthogonal complement of space $\mathcal{M}(S) \subseteq \mathcal{R}^p$ is

$$\mathcal{M}^{\perp}(S) \equiv \{\mathbf{v} \in \mathcal{R}^{pr} | \langle \mathbf{u}, \mathbf{v}\rangle = 0 \text{ for all } \mathbf{u} \in \mathcal{M}(S)\}.$$

The following set is central to our proof of consistency,

$$\mathcal{C} \equiv \{\boldsymbol{\theta} \in \mathcal{R}^{pr} | \, ||\boldsymbol{\theta}_{\mathcal{M}^{\perp}(S)}||_1 \leq ||\boldsymbol{\theta}_{\mathcal{M}}||_1\}.$$

For our proof of the consistency of $\bar{B}$ we make the following six assumptions:

A1 Define $\mathbf{X}_j$ to be the jth column vector of X, then $\mathbf{X}_j \in \mathcal{R}^p$ has the condition that $\frac{||\mathbf{X}_j||_2^2}{n} \leq 1$.

A2 Define $\boldsymbol{\epsilon}_c = (\epsilon_{1c},\ldots,\epsilon_{nc})^T \in \mathcal{R}^n$ as the error vector for response c. The error vector $\boldsymbol{\epsilon}_c$ has a mean of zero and sub-Gaussian tails for all $c \in \{1,\ldots,r\}$. That is, there exists a constant σ_c such that for any $\mathbf{a} \in \mathcal{R}^n$, with $||\mathbf{a}||_2 = 1$,

$$P(|\langle \boldsymbol{\epsilon}_c, \mathbf{a}\rangle| > t) \leq 2\text{exp}\left(-\frac{t^2}{2\sigma_c^2}\right).$$

Define $\sigma = \max_c \sigma_c$.

A3 Define $\tilde{X} = I_r \otimes X \in \mathcal{R}^{rn\times rp}$, where $\otimes$ is the standard Kronecker product. There exists a positive constant κ such that

$$\kappa||\boldsymbol{\theta}||_2^2 \leq \min_{\boldsymbol{\theta}\in\mathcal{C}} n^{-1}||\tilde{X}\boldsymbol{\theta}||_2^2.$$

A4 There exists a positive constant $\acute{b}$ such that $\max_{q=1,\ldots,Q}\max_{(l,k)\in D_q}||\boldsymbol{\beta}_l^* - \boldsymbol{\beta}_k||_2 \leq \acute{b}$.

A5 Given $l,k \in D_q$, if $\beta_{lj}^* = 0$ then $\beta_{kj}^* = 0$, for all $j \in \{1,\ldots,p\}$ and $q \in \{1,\ldots,Q\}$.

A6 Define $\rho_{\max}(A)$ as the maximum eigenvalue of square matrix A and $X_{S_{D_q}}$ as the matrix of true predictors for cluster q, where the jth predictor is a true predictor if $\boldsymbol{\beta}_{lj}^* \neq 0$ for any $l \in D_q$. There exists a positive constant $\rho_{\max}$ such that

$$\max_{q=1,\ldots,q} \rho_{\max}\left(\frac{1}{n}X_{S_{D_q}}^T X_{S_{D_q}}\right) \leq \rho_{\max}.$$

Assumption A1 is a standard assumption for lasso-type penalties and can be achieved by appropriately scaling the covariates, which is commonly done in penalized regression. Assumption A2 is a generalization of the sub-Gaussian error assumption for penalized regression for a univariate response. Assumption A1 could be relaxed to allow for certain unbounded covariates, but then A2 would be replaced by assuming the errors are normally distributed (Candes and Tao, 2007; Meinshausen and Yu, 2009). Assumption A3 is a generalization of the common restricted eigenvalue assumption. Motivation for assumption A3 is discussed in great detail by Negahban et al. (2012) and a version for $r = 1$ has been used in several works analyzing asymptotic behaviors of the lasso estimator (Bickel et al., 2009; van de Geer and Bühlmann, 2009; Meinshausen and Yu, 2009). Assumptions A4 and A5 provide that the true coefficients are similar for responses in the same group. Assumption A5 provides that they have the same sparsity structure. While, assumption A4 ensures that the difference in the non-zero elements can be bounded by a finite constant, even if the number of predictors increases with n. Assumption A6 assumes the maximum eigenvalues of the sample covariance of the true predictors are bounded, a common assumption in high-dimensional work. Assumptions A4-A6 can be replaced by an assumption similar to assumption A2 from Witten et al. (2014) that if $b, c \in D_m$ then $\boldsymbol{\beta}_b^* = \boldsymbol{\beta}_c^*$, for all $m \in \{1,\ldots,Q\}$, thus the bias of the MCEN estimator only comes from the L_1 penalty.

Using assumptions A3 and A5 we can provide a closed form definition of the asymptotic bias when $\delta = 0$. This relationship will be central to our proof of consistency of $\bar{B}$.

Corollary 3 *Let B^* be an s-sparse matrix, whose column vectors are all sparse and $E[X^TX/n] \in \mathcal{R}^{p\times p}$ to be a positive definite matrix. Assume Q and γ are fixed values. Define,*

$$\acute{B} = \left(\acute{\beta}_1,\ldots\acute{\beta}_r\right) = \underset{\beta_1,\ldots,\beta_r\in\mathcal{R}^p}{\arg\min}\; E\left(\frac{1}{2n}\sum_{i=1}^{n}\sum_{c=1}^{r}(y_{ic} - \mathbf{x}_i^T\boldsymbol{\beta}_c)^2 + \frac{\gamma}{2n}\sum_{q=1}^{Q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||X(\boldsymbol{\beta}_l - \boldsymbol{\beta}_m)||_2^2\right),$$

Assume $l \in D_q$ then $\acute{\beta}_l$ has closed form solution,

$$\acute{\beta}_l = \beta_l^* + \frac{2\gamma}{(1+2\gamma)|D_q|}\sum_{c\in D_q, c\neq l}(\beta_c^* - \beta_l^*).$$

Corollary 3 provides insight into what $\bar{B}$ would converge to for a fixed γ. Knowing this exact relationship is used in our consistency proof because it allows us to understand the exact nature of the bias caused by the L_2 penalty and for γ going to zero at a given rate we can show that the bias is asymptotically negligible.

Theorem 4 *Let B^* be an s-sparse matrix, whose column vectors are all sparse and $E[X^TX/n] \in \mathcal{R}^{p\times p}$ to be a positive definite matrix. Given $\delta = 16\sigma\sqrt{\frac{\log(rp)}{n}}$, $\gamma \leq \frac{5}{4\rho_{\max}\acute{b}}\sigma\sqrt{\frac{\log(rp)}{n}}$ and assumptions A1-A6 hold then there exist constants c_1, c_2, c_3 and c_4 such that*

$$\left|\left|vec\left(\bar{B} - B^*\right)\right|\right|_2 \leq \sigma\sqrt{\frac{s\log(rp)}{n}}\left(\frac{c_3}{\kappa} + \frac{c_4}{\rho_{\max}}\right), \tag{8}$$

with probability at least $1 - c_1\exp(-c_2 n\delta^2)$.

The convergence rate derived is similar to rates found in lasso-type estimators with a univariate response, with $\log(rp)$ replacing $\log(p)$ to accommodate for the multiple responses (Bickel et al., 2009; Candes and Tao, 2007; Meinshausen and Yu, 2009; Negahban et al., 2012). Thus, under the conditions of Theorem 4 if $pr \to \infty$ then $||\text{vec}(\bar{B} - B^*)||_2 = O_p\left\{\sqrt{\frac{s\log(rp)}{n}}\right\}$. Our results prove consistency of our estimator when the group structure is known. Zhao and Shojaie (2016) propose the Grace test for an estimator with a similar penalty for grouping predictors with a univariate response and establish asymptotic results that allow for inference even if there is some uncertainty to the grouping structure.

3. Algorithm

The optimization in (3) is discontinuous because of the estimation of cluster assignments. To simplify the optimization we propose an iterative algorithm that alternates between estimating the groups with the regression coefficients fixed, and estimating the regression coefficients with the groups fixed. If the clusters are known (5) then it is a convex optimization problem that can be solved by a coordinate descent algorithm. Let $R = \frac{1}{n}X^TX$, define $\mathbf{R}_j$ as the jth column of R. The super script $(-h)$ denotes the hth element of the vector has been removed, and r_{jj} is jth diagonal element of R. Define $S(a,b) = \text{sign}(a)\max(0, |a| - b)$. To solve (5), we use a coordinate descent algorithm where each update is preformed by

$$\bar{\beta}_{jk} \leftarrow \frac{S\left[\frac{1}{n}y_k^T\mathbf{X}_j - \left\{1 + \frac{\gamma(|D_q|-1)}{|D_q|}\right\}\mathbf{R}_j^{(-j)T}\overline{\boldsymbol{\beta}}_k^{(-j)} + \frac{\gamma}{|D_q|}\sum_{s\in D_q, s\neq k}\mathbf{R}_j^T\overline{\boldsymbol{\beta}}_s, \delta/2\right]}{r_{jj}\left(1 + \gamma\frac{|D_q|-1}{|D_q|}\right)}. \quad (9)$$

Thus, (5) is solved by iterating through $j \in \{1,\ldots,p\}$ and $k \in \{1,\ldots,r\}$ until the solution converges, similar to other coordinate descent solutions (Witten et al., 2014; Li and Li, 2010, 2008; Friedman et al., 2008). If B is known then the solution to (3) reduces to the well studied k-means clustering problem. Recognizing this, we propose a two-step iterative procedure to obtain a local minimum. To start the algorithm an initial estimate of D or B is needed. We propose initializing the regression coefficients for the different responses separately with the elastic net estimator of response c of

$$\hat{\boldsymbol{\beta}}_c^1 = \underset{\boldsymbol{\beta}_c\in\mathcal{R}^p}{\arg\min}\frac{1}{2n}\sum_{i=1}^n(y_{ic} - \mathbf{x}_i^T\boldsymbol{\beta}_c)^2 + \delta||\boldsymbol{\beta}_c||_1 + \gamma||\boldsymbol{\beta}_c||_2^2, \quad (10)$$

where $\hat{B}^w = \left(\hat{\boldsymbol{\beta}}_1^w,\ldots,\hat{\boldsymbol{\beta}}_r^w\right)$ represents the wth iterative estimate of B^*. Given a fixed (Q,γ,δ) we propose the following algorithm.

1. Begin with initial estimates, $\hat{\boldsymbol{\beta}}_1^1,\ldots,\hat{\boldsymbol{\beta}}_r^1$.
2. For the wth step, where $w > 1$, repeat the steps below until the group estimates do not change:
   (a) Hold $\hat{B}^{w-1}$ fixed and minimize,

$$\left(\hat{D}_1^w,\ldots,\hat{D}_Q^w\right) = \underset{D_1,\ldots,D_Q}{\text{minimize}}\left\{\sum_{q=1}^Q\frac{1}{|D_q|}\sum_{l,m\in D_q}\left|\left|X\left(\hat{\boldsymbol{\beta}}_l^{w-1} - \hat{\boldsymbol{\beta}}_m^{w-1}\right)\right|\right|_2^2\right\}. \quad (11)$$

The above can be solved by performing K-means clustering on the r $n-$dimensional vectors $X\hat{\boldsymbol{\beta}}_1^{w-1},\ldots,X\hat{\boldsymbol{\beta}}_r^{w-1}$.

   (b) Holding $\hat{D}_1^w,\ldots,\hat{D}_Q^w$ fixed the wth estimate of B^* is

$$\begin{aligned}\hat{B}^w = \underset{B\in\mathcal{R}^{p\times r}}{\arg\min}\frac{1}{2n}\sum_{i=1}^n\sum_{c=1}^r(y_{ic} - \mathbf{x}_i^T\boldsymbol{\beta}_c)^2 + \delta||B||_1 \\ + \frac{\gamma}{2n}\sum_{q=1}^Q\frac{1}{|\hat{D}_q^w|}\sum_{l,m\in\hat{D}_q^w}||X(\boldsymbol{\beta}_l - \boldsymbol{\beta}_m)||_2^2.\end{aligned} \quad (12)$$

   Note that for the groups known, instead of estimated, $\hat{B}^w$ is equivalent to $\bar{B}$. Thus (12) can be solved using the coordinate descent solution from (9) using $\hat{B}^{w-1}$ as the initial estimates for the coordinate descent algorithm.

Convergence is reached once the groups at the wth and $(w-1)$th iteration are the same. The optimization in (5) is separable with respect to $\hat{D}$, and results in Q independent optimization problems that can be solved in parallel. The algorithm for (5) can be solved in solution path type form where we iterate across different values of δ in a similar fashion as proposed in the glmnet algorithm (Friedman et al., 2008). If all of the initial elastic net estimators are fully sparse, we set the solution to be a zero matrix and thus following Friedman et al. (2008), initialize the algorithm by beginning the sequence with $\delta_{\max}$ at

$$\delta_{\max} = 2\max_{j,k}\left|\frac{\sum_{i=1}^n y_{ik}x_{ij}}{n}\right|.$$

Our two-step approach is closely related to the CEN algorithm proposed by Witten et al. (2014), who proposed a two-step algorithm where the two steps are solved by coordinate descent and k-means algorithms. The major difference in our proposal is that we cluster the responses rather than the predictors, and have the ability to solve the optimization in parallel due to the nature of our regularization in a multiple response setting.

4. Binomial Model

4.1 Method

Next we extend the multivariate cluster elastic net to generalized linear models. We focus specifically on the binomial response case, but our discussion here will scale to other exponential families. A fusion penalty has been proposed for merging groups from a multinomial response (Price et al., 2017), but our method differs as it aims to leverage association between multiple binomial responses. Kasap et al. (2016) proposed an ensemble method that combines association rule mining and binomial logistic regression via a multiple linear regression model. Our method differs from this by simultaneously estimating the clusters of the response variables and estimating the regression coefficients. An example is n customers, with p covariates, such as demographic and historic purchasing variables, and r indicators of product purchasing statuses for each customer. You could run r independent models, but this would not allow for modeling the relationship between the different products. Extending the multivariate cluster elastic net to multiple binomial responses would

allow us to group products by purchase probabilities to identify and use relationships between products. This could also be used to create a probabilistic model for diseases based on patient demographic and medical information.

For the linear model we ignore the intercept term as it can be removed by appropriately scaling Y and X. This is not possible in logistic regression, therefore the model needs an intercept term. We define $\mathbf{u}_i = (1, \mathbf{x}_i^T)^T \in \mathcal{R}^{p+1}$, $U = (\mathbf{u}_1^T, \ldots, \mathbf{u}_n)^T \in \mathcal{R}^{n\times p+1}$, $\mathbf{U}_k \in \mathcal{R}^n$ as the kth column vector of U and $\tilde{R} = U^T U$. The true coefficients for response k is defined as $\boldsymbol{\theta}_k^* \in \mathcal{R}^{p+1}$, $\Theta^* = (\boldsymbol{\theta}_1^*, \ldots, \boldsymbol{\theta}_r^*) \in \mathcal{R}^{p+1\times r}$, $\Theta_{-1}^* \in \mathcal{R}^{p\times r}$ is the matrix with the first row, the row of intercept coefficients, of Θ^* removed and $\boldsymbol{\theta}_{(-1)k}^* \in \mathcal{R}^p$ is the kth column vector of Θ_{-1}^*. In this model y_{ik} is an independent draw from

$$Bin\left(1, \pi_{ik}^*\right), \tag{13}$$

where

$$\pi_{ik}^* = \frac{\exp(\mathbf{u}_i^T \boldsymbol{\theta}_k^*)}{1 + \exp(\mathbf{u}_i^T \boldsymbol{\theta}_k^*)}. \tag{14}$$

The penalized negative log-likelihood function is

$$\begin{aligned} &\sum_{k=1}^{r}\sum_{i=1}^{n} y_{ik}\mathbf{u}_i^T\boldsymbol{\theta}_k - \log\left\{1 + \exp(\mathbf{u}_i^T\boldsymbol{\theta}_k)\right\} \\ &+ \frac{\gamma}{2n}\sum_{q=1}^{q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||U(\boldsymbol{\theta}_l - \boldsymbol{\theta}_m)||_2^2 + \delta||\Theta_{-1}||_1. \end{aligned} \tag{15}$$

4.2 Algorithm

We propose solving (15) by approximating it with a penalized quadratic function similar to the glmnet algorithm proposed by Friedman et al. (2008). Define,

$$g(\pi_{ik}) = \log\left(\frac{\pi_{ik}}{1-\pi_{ik}}\right) = \mathbf{u}_i^T\boldsymbol{\theta}_k. \tag{16}$$

To implement this approximation we define

$$\begin{aligned} z_{ik} &= g(y_{ik}) = g(\pi_{ik}) + \frac{y_{ik} - \pi_{ik}}{\pi_{ik}(1-\pi_{ik})}, & (17)\\ w_{ik} &= \pi_{ik}(1-\pi_{ik}), & (18)\\ -l_{Ak}(\boldsymbol{\theta}_k) &= \sum_{i=1}^{n} w_{ik}(z_{ik} - \mathbf{u}_i^T\boldsymbol{\theta}_k)^2. & (19) \end{aligned}$$

Note that z_{ik} is just the first order Taylor approximation of $g(y_{ik})$, and that w_{ik} is the conditional variance of z_{ik} given $\mathbf{u}_i$. Define $\mathbf{Z}_k = (z_{1k}, \ldots, z_{nk})^T \in \mathcal{R}^n$ and $\mathbf{W} = (w_{1k}, \ldots, w_{nk})^T \in \mathcal{R}^n$.

The MCEN estimator for the binomial model is

$$\begin{aligned} (\hat{\Theta}, \hat{D}) = \underset{\Theta\in\mathcal{R}^{p+1\times r}, D_1,\ldots,D_Q}{\arg\min} &\sum_{k=1}^{r} -l_{Ak}(\boldsymbol{\theta}_k) + \delta||\Theta_{-1}||_1 \\ &+ \frac{\gamma}{2n}\sum_{q=1}^{q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||U(\boldsymbol{\theta}_r - \boldsymbol{\theta}_s)||_2^2. \end{aligned} \tag{20}$$

If the groups are known *a priori* the solution is

$$\begin{aligned} \bar{\Theta} = \underset{\Theta\in\mathcal{R}^{p+1\times r}}{\arg\min} &\sum_{k=1}^{r} -l_{Ak}(\boldsymbol{\theta}_k) + \delta||\Theta_{(-1)}||_1 \\ &+ \frac{\gamma}{2n}\sum_{q=1}^{q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||U(\boldsymbol{\theta}_r - \boldsymbol{\theta}_s)||_2^2. \end{aligned} \tag{21}$$

For same length vectors $\mathbf{a}$ and $\mathbf{b}$ let $\mathbf{a}\circ\mathbf{b}$ represent the component wise multiplication of the two vectors. To solve (21), we use a proximal coordinate descent algorithm where each update is performed by

$$\bar{\theta}_{jk} \leftarrow \frac{S\left\{(\mathbf{w}_k\circ\mathbf{z}_k)^T\mathbf{U}_j - M_{jk}, I(j\neq 0)\delta/2\right\}}{r_{jj}\gamma\frac{|D_q|-1}{n|D_q|} + \mathbf{U}_j^T(\mathbf{w}_k\circ\mathbf{U}_j)}, \tag{22}$$

where

$$\begin{aligned} M_{jk} &= \sum_{c=1,c\neq h}^{p}\mathbf{U}_j^T(\mathbf{w}_k\circ\mathbf{U}_c)\bar{\Theta}_{cj} + \frac{\gamma(|D_q|-1)}{n|D_q|}\tilde{\mathbf{R}}_j^{(-j)T}\bar{\boldsymbol{\theta}}_k^{(-j)} \\ &- \frac{\gamma}{n|D_q|}\sum_{s\in D_q, s\neq k}\tilde{\mathbf{R}}_j^T\bar{\boldsymbol{\theta}}_s. \end{aligned}$$

The final solution is found by iterating through $j \in \{1, \ldots, p\}$ and $k \in \{1, \ldots, r\}$ until convergence. Again this is a solution similar to the glmnet algorithm proposed by Friedman et al. (2008).

To solve (20), we propose an algorithm that is similar in nature to the penalized least squares solution proposed in Section 3. The main difference is that we solve (20) with $D_1, \ldots, D_Q$ fixed using an iteratively reweighed least squares (IRWLS) solution with a proximal coordinate descent algorithm. The initial estimator for each response is done separately with

$$\hat{\boldsymbol{\theta}}_k^1 = \underset{\boldsymbol{\theta}_k\in\mathcal{R}^{p+1}}{\arg\min} -l_{Ak}(\boldsymbol{\theta}_k) + \delta||\boldsymbol{\theta}_{(-1)k}||_1 + \gamma||\boldsymbol{\theta}_{(-1)k}||_2^2. \tag{23}$$

The following is our proposed algorithm for estimating (20).

1. Begin with initial estimates of $\hat{\Theta}^1 = \left(\hat{\boldsymbol{\theta}}_1^1, \ldots, \hat{\boldsymbol{\theta}}_r^1\right) \in \mathcal{R}^{p+1\times r}$.
2. For the wth step, where $w > 1$, repeat the steps below until the group estimates do not change:
   (a) Hold $\hat{\Theta}^{w-1}$ fixed and minimize

$$\left(\hat{D}_1^w, \ldots, \hat{D}_Q^w\right) = \underset{D_1,\ldots,D_Q}{\text{minimize}}\left\{\sum_{q=1}^{Q}\frac{1}{|D_q|}\sum_{l,m\in D_q}\left|\left|U\left(\boldsymbol{\theta}_l^{w-1} - \boldsymbol{\theta}_m^{w-1}\right)\right|\right|_2^2\right\}. \tag{24}$$

   The above can be solved by performing K-means clustering.

(2b) Holding $\hat{D}_1^w, \ldots, \hat{D}_Q^w$ fixed the wth update for the coefficients is

$$\begin{aligned}\hat{\Theta}^w = \underset{\Theta \in \mathcal{R}^{p+1\times r}}{\arg\min} \sum_{k=1}^{r} -l_{Ak}(\boldsymbol{\theta}_k) + \delta||\Theta_{-1}||_1 \\ + \frac{\gamma}{2n}\sum_{q=1}^{q}\frac{1}{|\hat{D}_q^w|}\sum_{l,m\in\hat{D}_q^w}||U(\boldsymbol{\theta}_r - \boldsymbol{\theta}_s)||_2^2.\end{aligned} \tag{25}$$

Where (25) can be solved using the proximal coordinate descent solution presented in (22), using $\hat{\Theta}^{w-1}$ as the initial estimates for the proximal coordinate descent algorithm.

The triplet (Q, γ, δ) can be selected using K-Fold cross validation maximizing the validation log-likelihood. Let $\mathcal{F}_k$ be the set of indices in the kth fold ($k \in \{1, \ldots, K\}$) and $\hat{\pi}_{ic}^{(-\mathcal{F}_k)}(Q, \gamma, \delta)$ be the estimated probability for observation i and response c produced from the model with $\mathcal{F}_k$ removed using Q, γ and δ. Specifically we select the triplet that maximizes

$$V(Q, \delta, \gamma) = \sum_{v=1}^{K}\sum_{c=1}^{r}\sum_{i\in\mathcal{F}_v}\left[y_{ic}\log\left\{\hat{\pi}_{ic}^{(-\mathcal{F}_k)}\right\} + (1-y_{ik})\log\left\{1-\hat{\pi}_{ic}^{(-\mathcal{F}_k)}\right\}\right]. \tag{26}$$

The quadratic approximation defined by (19), is a standard technique used to estimate parameters in generalized linear models, making this framework and our algorithm scalable to other exponential family settings (Faraway, 2006). Tuning parameter selection would then be done by updating (26) with the appropriate likelihood.

5. Simulations

5.1 Gaussian Simulations

In this section we compare the performances of the MCEN estimator (3), the true MCEN (TMCEN) (5), with clustering structure known *a priori*, the separate elastic net (SEN) estimator (10), the joint elastic net (JEN) estimator

$$\hat{B}_{\text{JEN}} = \underset{B}{\arg\min}\frac{1}{2n}\sum_{k=1}^{r}\sum_{i=1}^{n}(y_{ik} - \mathbf{x}_i^T\boldsymbol{\beta}_k)^2 + \delta\sum_{j=1}^{p}\sqrt{\beta_{j1}^2 + \ldots + \beta_{jr}^2} + \gamma\sum_{k=1}^{r}\sum_{j=1}^{p}\beta_{jk}^2, \tag{27}$$

and the tree-guided group lasso (TGL) (Kim and Xing, 2012). Define $\mathbf{B}_j \in \mathcal{R}^r$ as the jth row vector of matrix B. Given a tree T with vertices V, where each node $v \in V$ is associated with group G_v define $B_j^{G_v}$ as a vector of the jth predictors from responses in group G_v. The TGL estimator is

$$\hat{B}_{\text{TGL}} = \underset{B}{\arg\min}\frac{1}{2}\sum_{k=1}^{r}\sum_{i=1}^{n}(y_{ik} - \mathbf{x}_i^T\boldsymbol{\beta}_k)^2 + \delta\sum_{j=1}^{p}\sum_{v\in V}w_v||B_j^{G_v}||_2, \tag{28}$$

where w_v are weights that can vary with the nodes. See Kim and Xing (2012) for a detailed presentation of TGL, including how the weights, w_v, are derived.

The JEN and SEN models are fit using the `glmnet` package in R (Friedman et al., 2008). Tuning parameters for all methods are selected using 10-folds cross validation. For the MCEN and TMCEN methods cluster sizes of 2, 3 and 4 are considered. We include the TMCEN estimator for two reasons. First, in practice the TMCEN estimator could be used if the practitioner has a predetermined clustering of the responses. Second, the TMCEN is useful as a benchmark to compare with the MCEN estimator because if the grouping of responses is useful TMCEN provides the optimal grouping.In all of the simulations the sample size is 100 and the number of responses is 15. For the number of covariates we considered 12, 100 and 300. Next we define how the covariates are generated and then will present the generating process for the response variables.

Define $\tilde{\Sigma} \in \mathcal{R}^{12\times 12}$ with entries $\tilde{\sigma}_{ii} = 1$ and $\tilde{\sigma}_{ij} = \rho$, for $i \neq j$. Let $0_{a,b} \in \mathcal{R}^{a\times b}$ be a matrix with all entries equal to zero. The covariates are generated by $\mathbf{x}_i \sim N(\mathbf{0}_p, \Sigma_x)$, where $\Sigma_x = \tilde{\Sigma}$ for $p = 12$ and otherwise

$$\Sigma_x = \begin{pmatrix}\tilde{\Sigma} & 0_{p-12,p-12} \\ 0_{p-12,p-12} & I_{p-12}\end{pmatrix},$$

with $\rho = .7$.

For a group of responses we define the grouped coefficients as $\mathbf{b}_q(\eta, \lambda) = (\boldsymbol{\eta}_q - \lambda, \boldsymbol{\eta}_q^*, \boldsymbol{\eta}_q + \lambda, \boldsymbol{\eta}_q + 2\lambda, \boldsymbol{\eta} + 3\lambda) \in \mathcal{R}^{q\times 5}$, where λ is a constant and $\boldsymbol{\eta}_q \in \mathcal{R}^q$ with each element equal to η. In the case of $p = 12$ the matrix of coefficients is

$$B_{\eta,\lambda}^* = \begin{Bmatrix}\mathbf{b}_4(\eta,\lambda) & \mathbf{0}_{4,5} & \mathbf{0}_{4,5} \\ \mathbf{0}_{4,5} & \mathbf{b}_4(\eta,\lambda) & \mathbf{0}_{4,5} \\ \mathbf{0}_{4,5} & \mathbf{0}_{4,5} & \mathbf{b}_4(\eta,\lambda)\end{Bmatrix},$$

otherwise

$$B_{\eta,\lambda}^* = \begin{Bmatrix}\mathbf{b}_{10}(\eta,\lambda) & \mathbf{0}_{10,5} & \mathbf{0}_{10,5} \\ \mathbf{0}_{10,5} & \mathbf{b}_{10}(\eta,\lambda) & \mathbf{0}_{10,5} \\ \mathbf{0}_{10,5} & \mathbf{0}_{10,5} & \mathbf{b}_{10}(\eta,\lambda) \\ \mathbf{0}_{p-30,5} & \mathbf{0}_{p-30,5} & \mathbf{0}_{p-30,5}\end{Bmatrix}.$$

Define $\Sigma_\epsilon \in \mathcal{R}^{15\times 15}$ with $\sigma(\epsilon)_{ij}$ being the entry for the ith row and jth column of Σ_ϵ. The generating process for the response is

$$\mathbf{y}_i = {B_{\eta,\lambda}^*}^T\mathbf{x}_i + \boldsymbol{\epsilon}_i, \tag{29}$$

where $\boldsymbol{\epsilon}_i \sim N(\mathbf{0}_{15}, \Sigma_\epsilon)$, $\sigma(\epsilon)_{ii} = 1$ and $\sigma(\epsilon)_{ij} = 0$, for i not equal to j. In all simulations we set the sample size to 100, perform 50 replications and with p set consider the following 9 different combinations for the true coefficient matrix,

$$(\eta, \lambda) \in \{0.25, 0.5, 0.75, 1\} \times \{0.02, 0.05, 0.10\}.$$

Models are fit using the training data with a sample size of 100. The tree for TGL is defined by performing complete-linkage hierarchical clustering on the responses in the training data. In addition we generate 1000 additional testing samples to assess the prediction accuracies of the models. Let y_{ij}^* represent the ith training sample for the jth response and

$\hat{y}_{ij}$ represent a predicted value of that sample and response. The average squared prediction error (ASPE) is defined as

$$\frac{1}{15000}\sum_{i=1}^{1000}\sum_{j=1}^{15}\left(y_{ij}^{*}-\hat{y}_{ij}\right)^{2}. \tag{30}$$

We also report the mean squared error (MSE) of the estimators where for an estimator B

$$\text{MSE}\left(B\right)=\sum_{j=1}^{15}\left|\left|\boldsymbol{\beta}_{j}-\boldsymbol{\beta}_{j}^{*}\right|\right|_{2}^{2}. \tag{31}$$

In addition we report the number of true variables selected (TV), out of a maximum of 60 for $p = 12$ and 150 otherwise, and the number of false variables selected (FV). Box plots of the statistics for $p = 300$ and the different combinations of η and λ are reported in Figures 1–4. These results show that TMCEN generally outperforms all methods in terms of ASPE and MSE. The one exception being when $\eta = 1$, particularly for larger values of λ, TGL is competitive with or outperforms TMCEN. For larger values of λ we expect more bias in the MCEN and TMCEN solutions and our simulation setting is favorable to TGL because the sparsity structure is the same for responses in the same cluster. With regards to ASPE and MSE, MCEN generally does better than TGL when $\eta = .5$ or .75. This suggests that the MCEN approach is advantageous with several smaller signals, but the signals need to be strong enough to correctly identify the clustering of the responses. The MCEN method also outperforms JEN and SEN in terms of ASPE and MSE, except in the case of $\eta = .25$ where JEN outperforms MCEN. In this case the signal is too small resulting in the MCEN method not finding the true clustering structure, and thus the grouping penalty will not be optimal. The MCEN and TMCEN methods tend to pick a larger model than SEN, but a smaller model than JEN. This results in the MCEN and TMCEN methods correctly choosing more true predictors than SEN and fewer false positive predictors than JEN for weaker signal cases. In terms of variable selection MCEN and TMCEN tend to do better than TGL in terms of both true and false variable selection. For the stronger signal cases the SEN approach does the best in terms of variable selection, tending to have the maximum number of true covariates selected, while a smaller number of false covariates selected. Similar conclusions can be derived for the plots of $p = 12$ and $p = 100$, which are available in the supplementary material.

5.2 Binomial Simulations

In this setting we have a binomial response variable and compare performance of the MCEN estimator (20) to SEN (23), for $r = 15$ and $p = 12, 100$ or 300. The SEN models were fit using the `glmnet` package in R (Friedman et al., 2008). Similar to the previous section, the covariates are generated by $\mathbf{x}_i \sim N(\mathbf{0}_p, \Sigma_x)$, where Σ_x has the same structure provided in the Gaussian simulations with $\rho = .9$.

We use the same structure of B presented in Section 5.1, consider the same values of η and λ and again perform 50 replications with a sample size of 100. Tuning parameters for the models are estimated via 10-folds cross validation as explained in Section 4.2. For Q, the number of groups, we consider values of 2, 3, and 4. For the SEN method each response

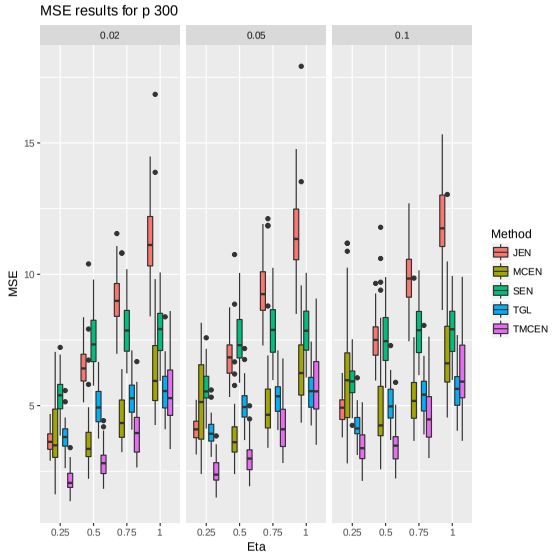

Figure 1: MSE results for the Gaussian simulations with p equal to 300. Different box plots correspond to different values of λ, while x-axis values are for different values of η.

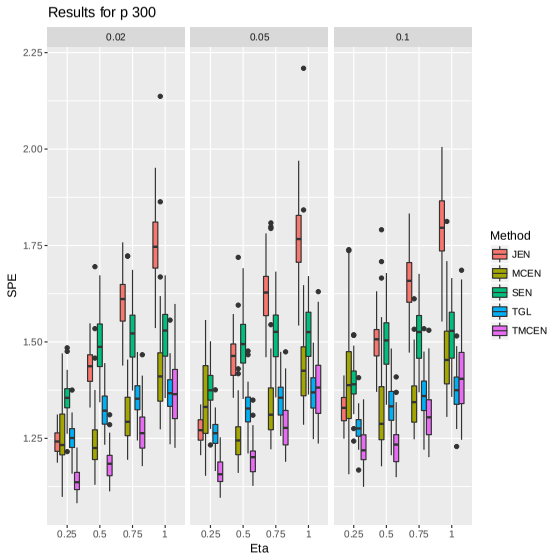

Figure 2: ASPE results for the Gaussian simulations with p equal to 300. Different box plots correspond to different values of λ, while x-axis values are for different values of η.

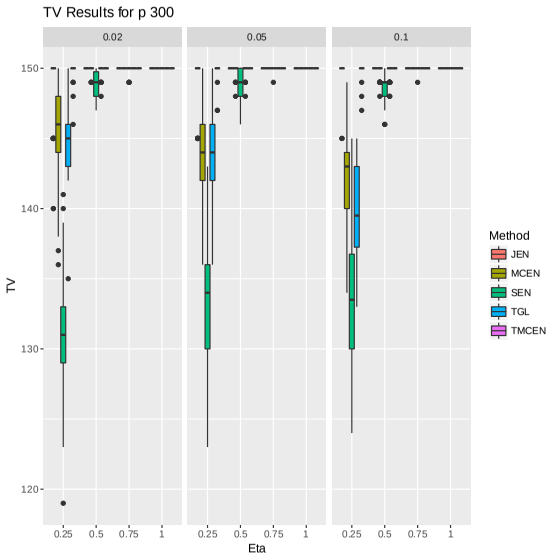

Figure 3: TV results for the Gaussian simulations with p equal to 300. Different box plots correspond to different values of λ, while x-axis values are for different values of η.

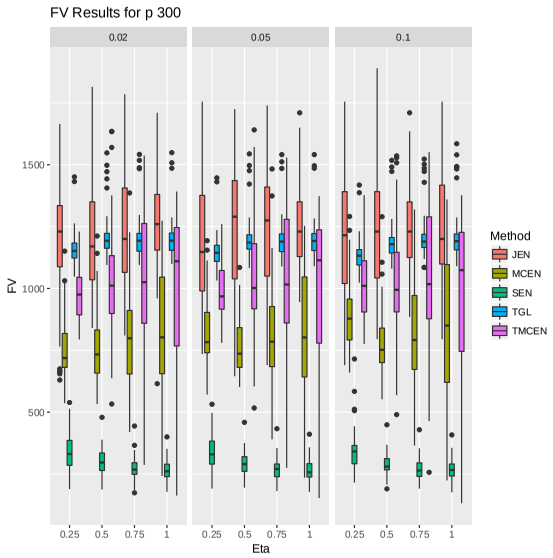

Figure 4: FV results for the Gaussian simulations with p equal to 300. Different box plots correspond to different values of λ, while x-axis values are for different values of η.

$c \in \{1, \ldots, r\}$ will be associated with its own tuning parameters of γ_c and δ_c that will be selected by maximizing the equivalent of (26) for only one response.

Define $\boldsymbol{\beta}^*_k(\eta, \lambda)$ as the kth column vector of $B^*_{\eta,\lambda}$. In all settings the kth response of the ith observation, y_{ik}, is an independent draw from $\text{Bin}(1, \pi^*_{ik})$ where

$$\pi^*_{ik} = \frac{\exp\left\{\mathbf{x}_i'\boldsymbol{\beta}^*_k(\eta,\lambda)\right\}}{1+\exp\left\{\mathbf{x}_i'\boldsymbol{\beta}^*_k(\eta,\lambda)\right\}}.$$

To evaluate the methods, 1000 validation observations are generated from the data generating model and the KL divergence is measured for each of the 50 replications. The KL divergence for a replication is defined as,

$$\frac{1}{1000}\sum_{i=1}^{1000}\sum_{k=1}^{15}\left\{\log\left(\frac{\widehat{\pi}_{ik}}{\pi^*_{ik}}\right)\widehat{\pi}_{ik} + \log\left(\frac{1-\widehat{\pi}_{ik}}{1-\pi^*_{ik}}\right)(1-\widehat{\pi}_{ik})\right\},$$

where π^*_{ik} is the true probability and $\widehat{\pi}_k(x_i, \delta, \gamma)$ is the estimated probability for response k for validation observation i.

Box plots are presented to compare the KL divergence of MCEN and SEN for the different settings in the case of $p = 300$. The results of simulation in cases where $p = 12$ and 100 are available in the supplementary material. Figure 5 presents the KL divergence results from the 50 replications for the different settings of η and λ. In terms of KL divergence MCEN outperforms SEN in all settings.

A comparison of MSE of coefficient estimates between methods is shown using box plots in Figure 6 and shows similar results to the cases of $p = 12$ and 100 available in the supplementary material. The results show that based on MSE binomial MCEN either outperforms or performs as well as binomial SEN. Figures 7 and 8 report the number of true positive and false positive predictors selected by each method for each combination of η and λ when $p = 300$, and MCEN outperforms SEN by generally selecting more true positive predictors, while the number of false predictors selected varies by the signal size. For smaller signals MCEN selects a smaller number of false predictors, but for larger signals MCEN tends to select more false predictors.

6. Data Example

6.1 Genomics Data

Votavova et al. (2011) collected gene expression profiles, demographic and birth information from 72 pregnant mothers. Using these data we modeled four response variables: placental weight, newborn weight, cotinine level from the mothers' peripheral blood sample and cotinine level from the umbilical cord blood sample. Smoking status, mother's age, mother's BMI, parity, gestational age and expression data for 24,526 gene probes from the mother's peripheral blood sample were used as covariates. Our analysis was limited to the 65 mothers with complete data. From a clinical perspective an accurate model for birth weight would be the primary interest as birth weight is associated with both short and long term negative health outcomes (Turan et al., 2012). Including placental weight as an additional response could potentially be helpful in the MCEN model because previous studies found placental and newborn weight are correlated (Molteni et al., 1978; Panti et al., 2012; Thame et al.,

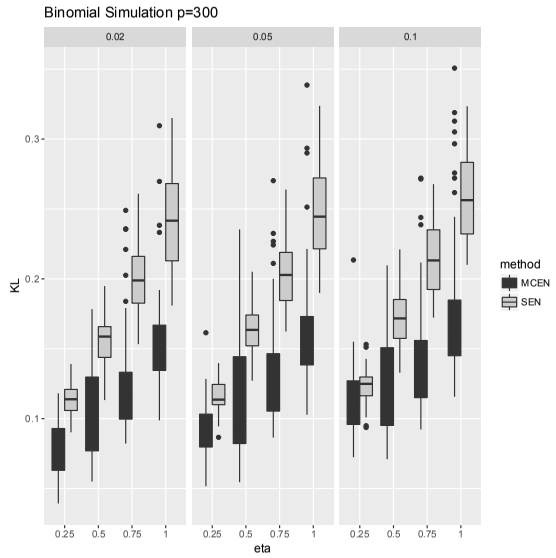

Figure 5: Simulation results comparing binomial SEN and binomial MCEN for p=300 at varying values of λ and η. Each box plot represents results for a different value of η, given at the top of the plot.

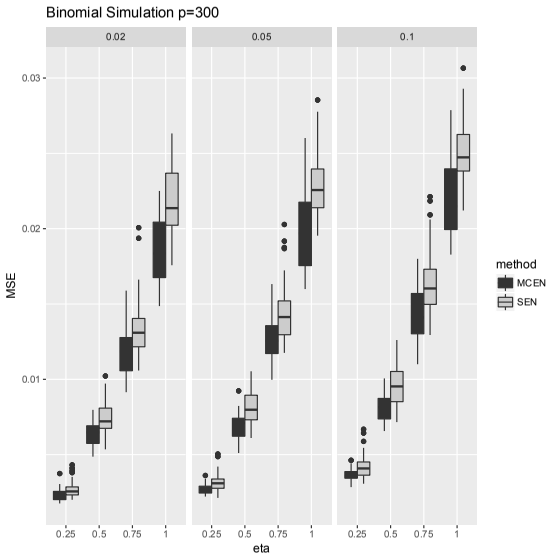

Figure 6: Simulation results comparing MSE of binomial SEN and binomial MCEN when p=300 at varying values of λ and η. Each box plot represents results for a different value of η, given at the top of the plot.

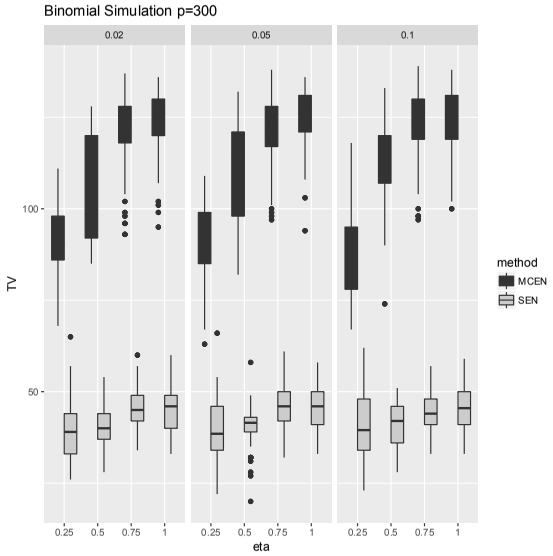

Figure 7: Simulation results comparing TV results by binomial SEN and binomial MCEN when p=300 at varying values of λ and η. Each box plot represents results for a different value of η, given at the top of the plot.

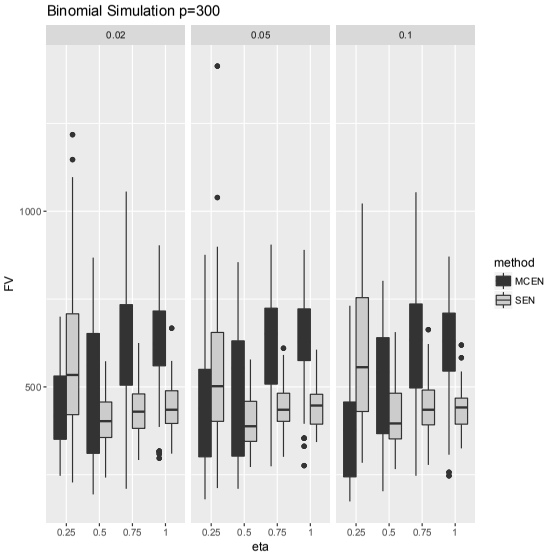

Figure 8: Simulation results comparing FV results by binomial SEN and binomial MCEN when p=300 at varying values of λ and η. Each box plot represents results for a different value of η, given at the top of the plot.

2004), but placental weight is hard to use as a predictor since it is observed at birth. The two measurements of cotinine levels are essentially measuring the same thing and are clearly related to smoking status. Thus we can test if these variables were correctly clustered and smoking status selected in the MCEN models.

The same methods used in Section 5.1 are used to fit the data, except we did not implement the TMCEN method as we did not assume to know the true clustering structure of the response variables. To evaluate the methods we randomly partitioned the data into 50 training and 15 testing samples. All four response variables are modeled on the log scale. In the training data all variables are centered and scaled to have mean zero and a standard deviation of one. We filter the gene expression data for each response by using the top 25 genes in terms of absolute value of correlation with a given response. For the joint modeling methods we use a union of the top 25 genes for each response. Models are fit using the training data, then predictions are evaluated on the testing samples. We compare the methods by looking at the ASPE, as defined in Section 5.1. For MCEN we consider clusters of size 1, 2 and 3. The process is repeated 100 times and the ASPE for all methods and responses are included in Figure 9. The MCEN method performs the best for modeling birth weight, the most clinically interesting variable, and is about the same as the other methods for modeling placenta weight. However, it does worse than the other three methods for modeling cotinine level. In all 100 random partitions the MCEN method correctly grouped the two cotinine responses together and selected smoking status as a predictor for those two responses.

6.2 Concession Data

We analyzed 2000 concession transactions from a major event venue. Each transaction is linked with the customer's information from the venue's loyalty program. These data are proprietary and cannot be made publicly available. Whether a customer purchases a specific item, 0 if they do and 1 if they do not, is the response and customer information from the loyalty program, such as seat identification and amount spent on previous concession sales, are treated as the covariates. The multiple response setting comes from there being multiple items available for sale at the concession stands. In total there are 34 predictor variables, stemming from purchase history from the venue, ticketing, and seating. The same customer may appear in the data more than once, but any correlation structure is ignored. We analyze two different sets of responses with the same covariates. The point-of-sale system records purchases in two different item set groupings; menu group (7 items) and food group (12 items). The different groups provide different insights into customer habits as the items form different groups.

Similar to the simulation section we compared SEN and MCEN, with tuning parameter selected as described in Section 5.2. For Q, the number of groups, we consider values of $\{1, 2, \ldots, 7\}$. We divide 2000 transactions into training and validation sets. There is a time component to our data, which we ignore, but use to evaluate the predictive performance of our models. The first 1000 transactions are used to train our models, with 3-fold cross validation used to select the tuning parameters for both MCEN and SEN. The predictive performance of the models are then compared using the next 1000 transactions.

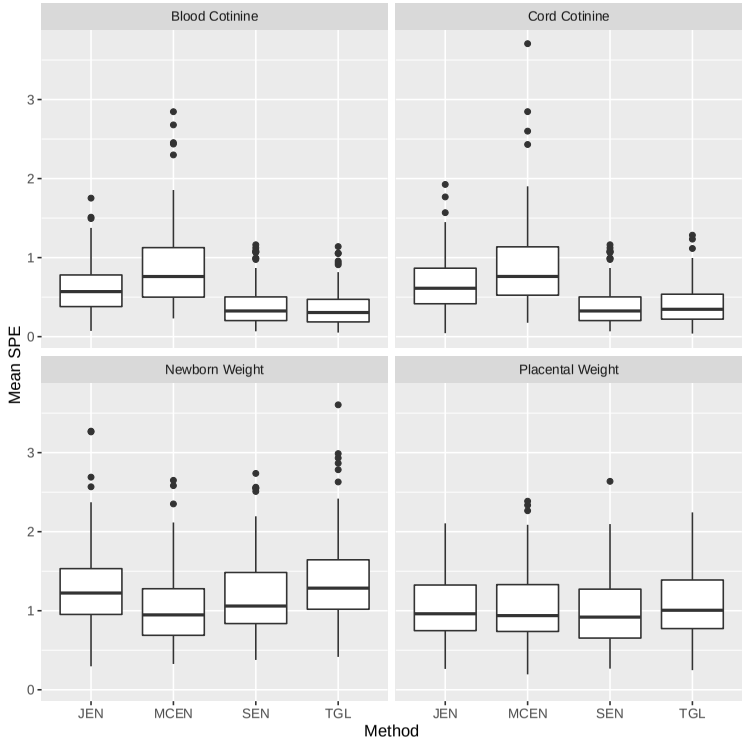

Figure 9: Mean SPE from 100 random partitions

For comparison of the methods we present the ROC curves as a metric for classification performance on the 1000 validation observations. Figure 10 presents the ROC curves and shows that in most situations the binomial logistic MCEN was competitive with SEN. In this analysis MCEN found 3 response clusters where the first cluster contained concession food, the second cluster contained both alcoholic and non-alcoholic beverages, and the third cluster contained all specialty item groups. For comparison we used k-means clustering on the predicted values of the independent elastic net, and selected the number of clusters based on the gap statistic. It selected 2 clusters. The first cluster had concession and both beverage types, while the second cluster contained all specialty items.

The resulting ROC curves for the food group analysis are presented in Figure 11. Five clusters were found by binomial logistic MCEN. The first cluster has popcorn, hamburger, french fires, bottled water, appetizers, and a chicken basket. These correspond to low selling non-alcoholic items. The second cluster consists of hot dogs, craft beer and misc sides, which represents a group of higher selling items. The last three clusters are singleton clusters consisting of non-alcoholic beverages, domestic beer, and liquor. These clusters represent high selling items with different demographics important in each. We also ran k-means clustering on the predicted values from the EN results, and found no distinct clustering using the gap statistic to select the number of clusters. Thus the MCEN method clusters all cold beverages together, while using k-means on fitted values from SEN does not find this clustering. The results of both analyses show that SEN outperforms MCEN using ROC curves. This could be due to the coarseness of MCEN framework, which assumes a similar sparsity structure for all responses. The grouping insights given from the resulting MCEN clusters provide a starting point for investigating each cluster individually with its own MCEN models. This procedure would allow for different levels of sparsity for different clusters. Flexibility such as this should be addressed in extensions of MCEN.

7. Discussion

We present a method for simultaneous estimation of regression coefficients and response clustering for a multivariate response model. The method is introduced for the case of continuous and binary responses. Future work could include extending the model to other GLM settings. Currently, our model imposes the same amount of sparsity on all response models, but this could be relaxed by allowing a sparsity tuning parameter for each individual response or each response group. The `mcen` R package that implements the methods outlined in this article is available on CRAN (Sherwood and Price, 2018).

Define $\ell(B)$ as a likelihood or convex objective function, $P(\boldsymbol{\beta}, D_q)$ as a distance function between all elements where $\sum_{q=1}^{Q} P(B, D_q)$ is an optimization problem to separate the r p-dimensional coefficient vectors into Q clusters and $p_\delta(B)$ as a penalty function with tuning parameter δ. Then the MCEN method could be generalized to a larger class of estimators where

$$(\hat{B}, \hat{D}) = \underset{B, D_1, \ldots, D_Q}{\arg\min} \; \ell(B) + \gamma \sum_{q=1}^{Q} P(B, D_q) + p_\delta(B). \tag{32}$$

One example would be to define $P(B, D_q)$ as an L_1 norm to penalize the difference between fitted values, similar to a fused lasso penalty (Tibshirani et al., 2005; Tibshirani, 2014). An

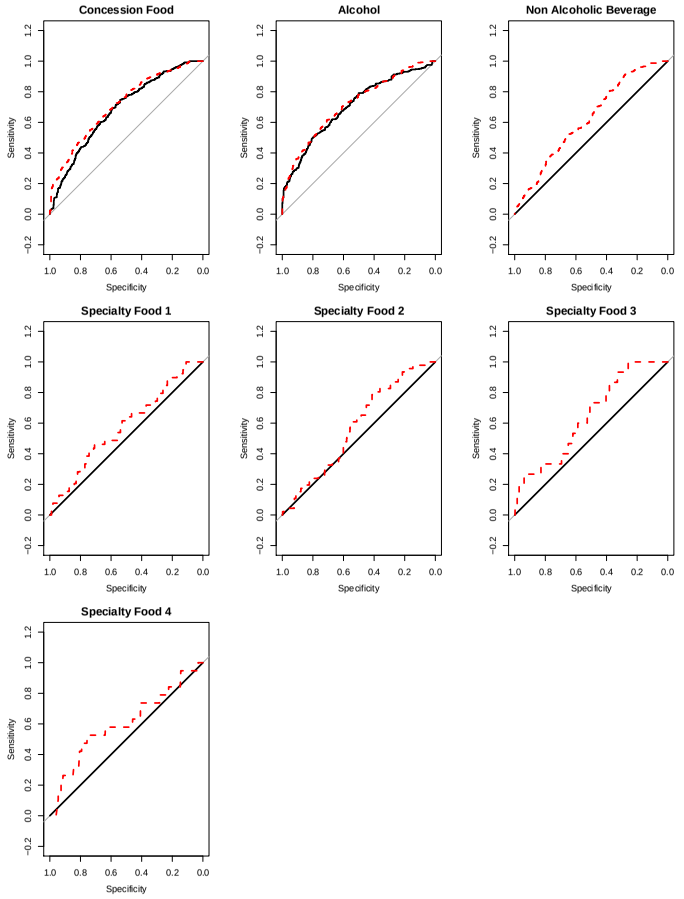

Figure 10: ROC curves for the 1000 validation observations for the menu group item responses. The black lines represent the ROC for MCEN and red for SEN.

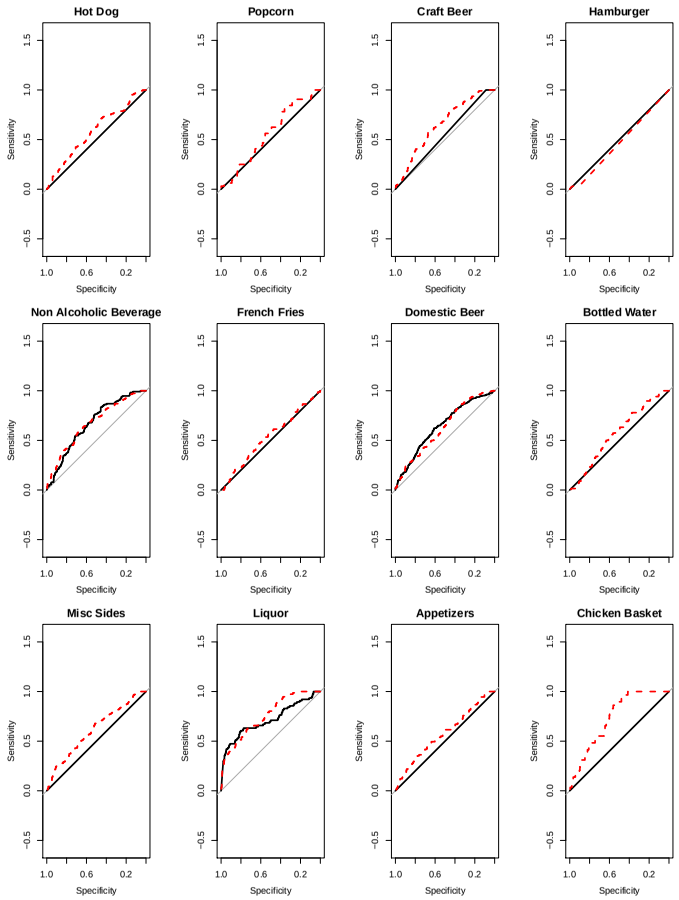

Figure 11: ROC curves for the 1000 validation observations for the food group item responses comparing EN and MCEN. The black lines represent the ROC for MCEN and red for SEN.

advantage of the estimator proposed in this paper is that by defining $P(B, D_q)$ as the L_2 norm squared, when the coefficients are fixed, the minimization problem is equivalent to a k-means problem. However, different definitions of $P(B, D_q)$ may not have well studied clustering algorithms to solve the optimization to define the groupings. One challenge of extending this work would be finding functions $P(B, D_q)$ that become well defined clustering problems when B is known or proposing new algorithms for solving $P(B, D_q)$. Otherwise the two-step algorithm proposed in this paper would not work.

The asymptotics in this paper are limited to consistency of the estimator when groups are known. Zhao and Shojaie (2016) presented an inference framework for a similar estimator that uses a fusion penalty and demonstrated that inference is still possible even if the structure of the graph that determines the fusion penalty is not correctly specified. Extending the results provided here to include inference would be of great use to practitioners and a good topic for future research.

Acknowledgments

We would like to thank Dr. Sara van de Geer and an anonymous reviewer for their insightful comments on early versions of this work. We would also like to thank Suzanna Emelio of the University of Kansas and Dr. Nancy McIntyre for their careful editing of our manuscript. This work was also partially sponsored by Big XII Faculty Fellowships from West Virginia University and the University of Kansas.

Appendix

A.1. Proof of Theorem 1

Proof Define

$$L(B) = \frac{1}{2n}\sum_{i=1}^{n}\sum_{c=1}^{r}(y_{ic} - \mathbf{x}_i^T\boldsymbol{\beta}_c)^2 + \frac{\gamma}{2n}\sum_{q=1}^{Q}\frac{1}{|D_q|}\sum_{l,m\in D_q}||X(\boldsymbol{\beta}_l - \boldsymbol{\beta}_m)||_2^2.$$

For $l \in D_q$

$$\frac{\partial}{\partial\boldsymbol{\beta}_l}L(B) = -\frac{1}{n}\left(X^TY - X^TX\boldsymbol{\beta}_l\right) + X^TX\frac{2\gamma}{n|D_q|}\sum_{c\in D_q, c\neq l}\boldsymbol{\beta}_l - \boldsymbol{\beta}_c.$$

Thus,

$$\bar{\boldsymbol{\beta}}_l\left\{1 + \frac{2\gamma(|D_q|-1)}{|D_q|}\right\} - \dot{\boldsymbol{\beta}}_l - \frac{2\gamma}{|D_q|}\sum_{c\in D_q, c\neq l}\bar{\boldsymbol{\beta}}_c = 0. \tag{33}$$

Therefore for $l, m \in D_q$

$$\begin{aligned}
&\bar{\boldsymbol{\beta}}_l\left\{1 + \frac{2\gamma(|D_q|-1)}{|D_q|}\right\} - \dot{\boldsymbol{\beta}}_l - \frac{2\gamma}{|D_q|}\sum_{c\in D_q, c\neq l}\bar{\boldsymbol{\beta}}_c \\
- \quad &\bar{\boldsymbol{\beta}}_m\left\{1 + \frac{2\gamma(|D_q|-1)}{|D_q|}\right\} - \dot{\boldsymbol{\beta}}_m - \frac{2\gamma}{|D_q|}\sum_{c\in D_q, c\neq m}\bar{\boldsymbol{\beta}}_c \\
= \quad &(\bar{\boldsymbol{\beta}}_l - \bar{\boldsymbol{\beta}}_m)(1+2\gamma) - \dot{\boldsymbol{\beta}}_l + \dot{\boldsymbol{\beta}}_m = 0.
\end{aligned}$$

Therefore for $l, m \in D_q$ and $l \neq m$

$$\bar{\boldsymbol{\beta}}_m = \bar{\boldsymbol{\beta}}_l + \frac{1}{1+2\gamma}\left(\dot{\boldsymbol{\beta}}_m - \dot{\boldsymbol{\beta}}_l\right). \tag{34}$$

Combining (33) and (34) gives

$$\begin{aligned}\bar{\boldsymbol{\beta}}_l\left\{1+\frac{2\gamma(|D_q|-1)}{|D_q|}\right\} &= \dot{\boldsymbol{\beta}}_l + \frac{2\gamma}{|D_q|}\sum_{c\in D_q, c\neq l}\bar{\boldsymbol{\beta}}_l + \frac{1}{1+2\gamma}\left(\dot{\boldsymbol{\beta}}_c - \dot{\boldsymbol{\beta}}_l\right)\\ &= \dot{\boldsymbol{\beta}}_l + \frac{2\gamma(|D_q|-1)}{|D_q|}\bar{\boldsymbol{\beta}}_l + \frac{2\gamma}{(1+2\gamma)|D_q|}\sum_{c\in D_q, c\neq l}\left(\dot{\boldsymbol{\beta}}_c - \dot{\boldsymbol{\beta}}_l\right),\end{aligned}$$

which completes the proof. ■

A.2. Proof of Theorem 2

Proof It is assumed that $E(\epsilon_{ic}^2) = 1$ and for $c \neq k$ that $E(\epsilon_{ic}\epsilon_{ik}) = \rho$. Thus, note that for any $v \in \{1, \ldots, r\}$

$$\begin{aligned}\text{Var}\left(\bar{\boldsymbol{\beta}}_v\right) &= \text{Var}\left\{\frac{|D_q|+2\gamma}{(1+2\gamma)|D_q|}\dot{\boldsymbol{\beta}}_v + \frac{2\gamma}{(1+2\gamma)|D_q|}\sum_{s\in D_q, s\neq v}\dot{\boldsymbol{\beta}}_s\right\}\\ &= (X^TX)^{-1}\left\{\frac{|D_q|\left(|D_q|+4\gamma+4\gamma^2\right)}{(1+2\gamma)^2|D_q|^2} + 4\rho\gamma(|D_q|-1)\frac{|D_q|+2\gamma|D_q|-2\gamma}{(1+2\gamma)^2|D_q|^2}\right\}.\end{aligned}$$

Define $\mathbf{b}_v = \sum_{s\in D_q, s\neq v}(\boldsymbol{\beta}_s^* - \boldsymbol{\beta}_v^*)$. The squared bias term is then

$$\begin{aligned}&E\left[\left\{E\left(\bar{\boldsymbol{\beta}}_v\right) - \boldsymbol{\beta}_v^*\right\}'\left\{E\left(\bar{\boldsymbol{\beta}}_v\right) - \boldsymbol{\beta}_v^*\right\}\right]\\ =\ &E\left[\left\{\boldsymbol{\beta}_v^* + \frac{2\gamma}{(1+2\gamma)|D_q|}\mathbf{b}_v - \boldsymbol{\beta}_v^*\right\}'\left\{\boldsymbol{\beta}_v^* + \frac{2\gamma}{(1+2\gamma)|D_q|}\mathbf{b}_v - \boldsymbol{\beta}_v^*\right\}\right]\\ =\ &\frac{4\gamma^2}{(1+2\gamma)^2|D_q|^2}||\mathbf{b}_v||_2^2.\end{aligned}$$

Let $\omega = \text{Trace}\left\{\left(X^TX\right)^{-1}\right\}$ then MSE of $\bar{\boldsymbol{\beta}}_v$ will be smaller than MSE of $\dot{\boldsymbol{\beta}}_v$ if

$$\begin{aligned}&\omega\left\{\frac{|D_q|\left(|D_q|+4\gamma+4\gamma^2\right)}{(1+2\gamma)^2|D_q|^2} + 4\rho\gamma(|D_q|-1)\frac{|D_q|+2\gamma|D_q|-2\gamma}{(1+2\gamma)^2|D_q|^2}\right\}\\ +\ &\frac{4\gamma^2}{(1+2\gamma)^2|D_q|^2}||\mathbf{b}_v||_2^2\\ <\ &\omega,\end{aligned}$$

which is equivalent to

$$\begin{aligned}\gamma||\mathbf{b}_v||_2^2 &< \omega\Big\{|D_q|(|D_q|-1) + \gamma|D_q|(|D_q|-1)\\ &\quad -\rho\left\{(|D_q|-1)|D_q| + 2\gamma(|D_q|-1)^2\right\}\Big\}.\end{aligned}$$

Note that, $\omega|D_q|(|D_q|-1)(1-\rho) > 0$ and thus if $||\mathbf{b}_v||_2^2 \leq \omega(|D_q|-1)\left\{|D_q| - 2\rho(|D_q|-1)\right\}$ then the MSE of $\bar{\boldsymbol{\beta}}_v$ is smaller than the MSE of $\dot{\boldsymbol{\beta}}_v$ for any $\gamma > 0$. Otherwise, the MSE of $\bar{\boldsymbol{\beta}}_v$ will be smaller for any $\gamma \in \left(0, \frac{\omega|D_q|(|D_q|-1)(1-\rho)}{||\mathbf{b}_v||_2^2 - \omega(|D_q|-1)\{|D_q|-2\rho(|D_q|-1)\}}\right)$. Thus for any $v \in \{1, \ldots, r\}$ then any $\gamma > 0$ or any γ sufficiently small will result in $\bar{\boldsymbol{\beta}}_v$ having a smaller MSE than $\dot{\boldsymbol{\beta}}_v$. The proof is complete because we can then find a γ sufficiently small that will result in $\bar{\boldsymbol{\beta}}_v$ having a smaller MSE than $\dot{\boldsymbol{\beta}}_v$ for all $v \in \{1, \ldots, r\}$. ■

A.3. Proof of Corollary 3

The proof of Corollary 3 is similar to the proof of Theorem 1 and only changes with respect to the expected loss rather than the observed loss.

A.4. Theorem 4

The proof of Theorem 4 will include some new definitions and an alternative formulation of (5). In our proof we use a vectorized version of many of the matrices. Let $\tilde{\mathbf{Y}} = \text{vec}(Y)$, $\tilde{\boldsymbol{\beta}} = \text{vec}(B)$, $\tilde{\boldsymbol{\beta}}' = \text{vec}(\acute{B})$ and $\tilde{\mathbf{E}} = \text{vec}(E)$. Define $\mathbf{A}_{m,s} \in \mathcal{R}^r$, where $(m,s) \in D_q$, with $\sqrt{\frac{1}{|D_q|}}$ in the mth element, $-\sqrt{\frac{1}{|D_q|}}$ in the sth element and 0 in all other elements, $A_{D_q} \in \mathcal{R}^{|D_q|(|D_q|-1)\times r}$ as the matrix with row vectors $\mathbf{A}_{m,s}$ where $(m,s) \in D_q$, and $A_D \equiv \left(A_{D_1}^T, \ldots, A_{D_Q}^T\right)^T \in \mathcal{R}^{\sum_{q=1}^Q |D_q|(|D_q|-1)\times r}$.

Then the objective function from (5) can be restated as

$$\begin{aligned}&\frac{1}{2n}\left[\tilde{\boldsymbol{\beta}}^T\left\{\tilde{X}^T\tilde{X} + \gamma(A_D\otimes X)^T(A_D\otimes X)\right\}\tilde{\boldsymbol{\beta}} - 2\tilde{\mathbf{Y}}^T\tilde{X}\tilde{\boldsymbol{\beta}}\right] + \delta||\tilde{\boldsymbol{\beta}}||_1\\ =\ &\ell(\tilde{\boldsymbol{\beta}}) + \delta g(\tilde{\boldsymbol{\beta}}).\end{aligned}$$

In addition define, $\tilde{\ell}(\boldsymbol{\Delta}, \tilde{\boldsymbol{\beta}}) \equiv \ell(\tilde{\boldsymbol{\beta}} + \boldsymbol{\Delta}) - \ell(\tilde{\boldsymbol{\beta}}) - \langle\nabla\ell(\tilde{\boldsymbol{\beta}}, \Delta)\rangle$.

First, we will present some lemmas that are helpful in proving Theorem 4. A general outline of the proof for Theorem 4 is by using the triangle inequality we have $||\text{vec}(\bar{B} - B*)||_2 \leq ||\text{vec}(\bar{B} - \acute{B})||_2 + ||\tilde{\boldsymbol{\beta}}' - \tilde{\boldsymbol{\beta}}^*||_2$. Completing the proof is done by establishing upper bounds for $||\text{vec}(\bar{B} - \acute{B})||_2$ and $||\tilde{\boldsymbol{\beta}}' - \tilde{\boldsymbol{\beta}}^*||_2$. Much of the proof will require working with $\tilde{\boldsymbol{\beta}}'$ and we introduce the following notation to easily relate $\tilde{\boldsymbol{\beta}}'$ and $\tilde{\boldsymbol{\beta}}^*$. For response l in group q define $\mathbf{H}_l = \frac{1}{\sqrt{|D_q|}}\sum_{c\in D_q, c\neq l}\mathbf{A}_{c,l}$ where $\mathbf{H}_l \in \mathcal{R}^r$ and $H = (\mathbf{H}_1, \ldots, \mathbf{H}_r)^T \in \mathcal{R}^{r\times r}$. Then we have

$$\tilde{\boldsymbol{\beta}}' = \left\{\left(I_r + \frac{2\gamma}{2\gamma+1}H\right)\otimes I_p\right\}\tilde{\boldsymbol{\beta}}^*.$$

For response l is in group q define $\mathbf{U}_l = \frac{1}{|D_q|}\sum_{k\in D_q}(\beta_k^* - \beta_l^*)$ where $\mathbf{U}_l \in \mathcal{R}^p$ and $U = (\mathbf{U}_1, \ldots, \mathbf{U}_r)$ with $U \in \mathcal{R}^{p\times r}$ and $\tilde{\mathbf{U}} = \text{vec}(U) \in \mathcal{R}^{pr}$, then

$$\left|\left|\text{vec}\left(\acute{B} - B^*\right)\right|\right|_2 = \frac{2\gamma}{1+2\gamma}\left|\left|(H\otimes I_p)\tilde{\boldsymbol{\beta}}^*\right|\right|_2 = \frac{2\gamma}{1+2\gamma}\left|\left|\tilde{\mathbf{U}}\right|\right|_2.$$

Lemma 5 *Under assumption A3*

$$\tilde{\ell}(\boldsymbol{\Delta}, \tilde{\boldsymbol{\beta}}') \geq \kappa||\boldsymbol{\Delta}||_2^2 \text{ for all } \boldsymbol{\Delta} \in \mathcal{C}.$$

Proof From the definition of $\tilde{\ell}(\boldsymbol{\Delta}, \tilde{\boldsymbol{\beta}})$, assumption A3 and that $\boldsymbol{\Delta} \in \mathcal{C}$ it follows that

$$\begin{aligned}\tilde{\ell}(\boldsymbol{\Delta}, \tilde{\boldsymbol{\beta}}') &= \frac{1}{2n}\boldsymbol{\Delta}^T\left\{\tilde{X}^T\tilde{X} + \gamma(A_D\otimes X)^T(A_D\otimes X)\right\}\boldsymbol{\Delta} \\ &\geq \frac{1}{2n}\boldsymbol{\Delta}^T\tilde{X}^T\tilde{X}\boldsymbol{\Delta} \\ &\geq \frac{\kappa}{2}||\boldsymbol{\Delta}||_2^2.\end{aligned}$$

■

For any vector $\mathbf{a} = (a_1, \ldots, a_{pr})^T \in \mathcal{R}^{pr}$ we define the $||\mathbf{a}||_\infty$ as the L_∞ norm of $\mathbf{a}$, that is $||\mathbf{a}||_\infty = \max_i |a_i|$.

Lemma 6 *For $\bar{B}$ from (5), under assumptions A1-A4 with $\delta \geq 2\left|\left|\nabla\ell(\tilde{\boldsymbol{\beta}}')\right|\right|_\infty$ then there exists a positive constant c_3 such that*

$$\left|\left|vec(\bar{B} - \acute{B})\right|\right|_2^2 \leq 9\frac{\delta^2}{\kappa^2}s.$$

Proof Define the set $\acute{S} = \{j \in \{1, \ldots, rp\}, \tilde{\boldsymbol{\beta}}_j' \neq 0\}$. By assumption A5 and Corollary 3 $\acute{S} = S$, that is $\tilde{\boldsymbol{\beta}}_j' = 0$ if and only if $\tilde{\boldsymbol{\beta}}_j^* = 0$. Define $\psi(\mathcal{M}) \equiv \sup_{\mathbf{u}\in\mathcal{M}\setminus\{\mathbf{0}\}}\frac{||\mathbf{u}||_1}{||\mathbf{u}||_2}$. Note that $\psi\{\mathcal{M}(S)\} = \sqrt{s}$. Also, note that the dual norm of the L_1 norm is the L_∞ norm. Results follow from Theorem 1 of Negahban et al. (2012) and Lemma 5. ■

Lemma 7 *Under the conditions of Theorem 4 there exists positive c_1, c_2 and c_3 such that*

$$\left|\left|vec\left(\bar{B} - \acute{B}\right)\right|\right|_2 \leq \frac{48\sigma}{\kappa}\sqrt{\frac{s\log(rp)}{n}},$$

with probability at least $1 - c_1 exp(-c_2 n\delta^2)$.

Proof If we can find positive constants c_1 and c_2 such that with probability at least $1 - c_1\exp(-c_2 n\delta^2)$ that $\delta \geq 2\left|\left|\nabla\ell(\tilde{\boldsymbol{\beta}}')\right|\right|_\infty$ then proof will be complete by Lemma 6 and by

the condition that $\delta = 16\sigma\sqrt{\frac{\log(rp)}{n}}$. Note that

$$\begin{aligned}2\left|\left|\nabla\ell(\tilde{\boldsymbol{\beta}}')\right|\right|_\infty &= 2\left|\left|\frac{1}{n}\left[\left\{\tilde{X}^T\tilde{X} + \gamma(A_D\otimes X)^T(A_D\otimes X)\right\}\tilde{\boldsymbol{\beta}}' - \tilde{X}^T\tilde{Y}\right]\right|\right|_\infty \\ &= 2\left|\left|\frac{1}{n}\left[\left\{\tilde{X}^T\tilde{X} + \gamma(A_D\otimes X)^T(A_D\otimes X)\right\}\left\{\left(I_r + \frac{2\gamma}{2\gamma+1}H\right)\otimes I_p\right\}\tilde{\boldsymbol{\beta}}^* - \tilde{X}^T\left(\tilde{X}\tilde{\boldsymbol{\beta}}^* + \tilde{\mathbf{E}}\right)\right]\right|\right| \\ &\leq 2\left|\left|\frac{2\gamma}{n(1+2\gamma)}\tilde{X}^T\tilde{X}\tilde{\mathbf{U}}\right|\right|_\infty + 2\left|\left|\frac{\gamma}{n}(A_D\otimes X)^T(A_D\otimes X)\tilde{\boldsymbol{\beta}}^*\right|\right|_\infty \\ &\quad + 2\left|\left|\frac{2\gamma^2}{n(1+2\gamma)}(A_D\otimes X)^T(A_D\otimes X)\tilde{\mathbf{U}}\right|\right|_\infty + 2\left|\left|\frac{1}{n}\tilde{X}^T\tilde{\mathbf{E}}\right|\right|_\infty.\end{aligned}$$

Next, we will establish upper bounds for the first three terms. Define $I(l \in D_q)$ to be 1 if $l \in D_q$ and zero otherwise. Using the definition of $\tilde{\mathbf{U}}$ and assumptions A4-A6,

$$\begin{aligned}2\left|\left|\frac{2\gamma}{n(1+2\gamma)}\tilde{X}^T\tilde{X}\tilde{\mathbf{U}}\right|\right|_\infty &= \frac{4\gamma}{1+2\gamma}\max_{l\in\{1,\ldots,r\}}\left|\left|\frac{1}{n}X^TX\sum_{q=1}^{Q}I(l\in D_q)\sum_{k\in D_q}\frac{1}{|D_q|}(\boldsymbol{\beta}_k^* - \boldsymbol{\beta}_l^*)\right|\right|_\infty \\ &\leq \frac{4\gamma}{1+2\gamma}\rho_{\max}\max_{l\in\{1,\ldots,r\}}\left|\left|\sum_{q=1}^{Q}I(l\in D_q)\sum_{k\in D_q}\frac{1}{|D_q|}(\boldsymbol{\beta}_k^* - \boldsymbol{\beta}_l^*)\right|\right|_2 \\ &\leq \frac{4\gamma}{1+2\gamma}\rho_{\max}\acute{b}.\end{aligned}$$

Using assumptions A4-A6,

$$\begin{aligned}2\left|\left|\frac{\gamma}{n}(A_D\otimes X)^T(A_D\otimes X)\tilde{\boldsymbol{\beta}}^*\right|\right|_\infty &= 2\gamma\max_{l\in\{1,\ldots,r\}}\left|\left|\frac{1}{n}X^TX\sum_{k,l\in D_q,k\neq l}\frac{1}{|D_q|}(\beta_k^* - \beta_l^*)\right|\right|_\infty \\ &\leq 2\gamma\rho_{\max}\max_{l\in\{1,\ldots,r\}}\left|\left|\sum_{k,l\in D_q}\frac{1}{|D_q|}(\beta_k^* - \beta_l^*)\right|\right|_2 \\ &\leq 2\gamma\rho_{\max}\acute{b}.\end{aligned}$$

Note that for $a \in D_q$ and $b \in D_q$ that

$$\begin{aligned}\mathbf{U}_a - \mathbf{U}_b &= \frac{1}{|D_q|}\left(\sum_{l\in D_q}\boldsymbol{\beta}_l^* - \boldsymbol{\beta}_a^* - \sum_{l\in D_q}\boldsymbol{\beta}_l^* - \boldsymbol{\beta}_b^*\right) \\ &= \frac{1}{|D_q|}\sum_{l\in D_q}\boldsymbol{\beta}_b^* - \boldsymbol{\beta}_a^* = \boldsymbol{\beta}_b^* - \boldsymbol{\beta}_a^*.\end{aligned}$$

Therefore

$$\begin{aligned}
2\left\|\frac{2\gamma^2}{n(1+2\gamma)}(A_D\otimes X)^T(A_D\otimes X)\tilde{\mathbf{U}}\right\|_\infty &= \frac{4\gamma^2}{1+2\gamma}\max_{l\in\{1,\ldots,r\}}\left\|\frac{1}{n}X^TX\sum_{q=1}^{Q}I(l\in D_q)\sum_{k\in D_q}\frac{1}{|D_q|}(\mathbf{U}_k-\mathbf{U}_l)\right\|_\infty \\
&= \frac{4\gamma^2}{1+2\gamma}\max_{l\in\{1,\ldots,r\}}\left\|\frac{1}{n}X^TX\sum_{q=1}^{Q}I(l\in D_q)\sum_{k\in D_q}\frac{1}{|D_q|}\boldsymbol{\beta}_l^*-\boldsymbol{\beta}_k^*\right\|_\infty \\
&\leq \frac{4\gamma^2}{1+2\gamma}\rho_{\max}\max_{l\in\{1,\ldots,r\}}\left\|\sum_{q=1}^{Q}I(l\in D_q)\sum_{k\in D_q}\frac{1}{|D_q|}\boldsymbol{\beta}_l^*-\boldsymbol{\beta}_k^*\right\|_2 \\
&\leq \frac{4\gamma^2}{1+2\gamma}\rho_{\max}\acute{b} \\
&\leq 2\gamma\rho_{\max}\acute{b}.
\end{aligned}$$

Under assumptions A1 and A2 it follows that

$$P\left(\left\|\frac{1}{n}\tilde{X}^T\tilde{\mathbf{E}}\right\|_\infty > t\right)\leq 2\exp\left\{\frac{-nt^2}{2\sigma^2}+\log(rp)\right\}. \tag{35}$$

Thus,

$$\begin{aligned}
P\left\{\delta\geq 2\left\|\nabla\ell(\tilde{\boldsymbol{\beta}}')\right\|_\infty\right\} &\geq P\left\{\delta\geq 2\left\|\frac{1}{n}\tilde{X}^T\tilde{\mathbf{E}}\right\|_\infty+\rho_{\max}\acute{b}\left(\frac{4\gamma}{1+2\gamma}+2\gamma+2\gamma\right)\right\} \\
&\geq P\left(\delta\geq 2\left\|\frac{1}{n}\tilde{X}^T\tilde{\mathbf{E}}\right\|_\infty+8\gamma\rho_{\max}\acute{b}\right) \\
&\geq P\left(\frac{3}{16}\delta\geq\left\|\frac{1}{n}\tilde{X}^T\tilde{\mathbf{E}}\right\|_\infty\right) \\
&\geq 1-2\exp\left\{\frac{-9n\delta^2}{16^2 2\sigma^2}+\log(rp)\right\} \\
&= 1-2\exp\left\{-\frac{7}{2}\log(rp)\right\}.
\end{aligned}$$

Set $c_1=2$ and $c_2=\frac{7}{2}$ and the proof is complete. ■

Proof of Theorem 4

Proof Applying the triangle inequality we have

$$\left\|\text{vec}\left(\hat{\beta}-\beta^*\right)\right\|_2\leq\left\|\text{vec}\left(\hat{\beta}-\acute{\beta}\right)\right\|_2+\left\|\tilde{\boldsymbol{\beta}}'-\tilde{\boldsymbol{\beta}}^*\right\|_2. \tag{36}$$

For the second term using the upper bound for γ stated in the conditions for Theorem 4 and assumptions A4 and A5 it follows that

$$\begin{aligned}
\left\|\tilde{\boldsymbol{\beta}}'-\tilde{\boldsymbol{\beta}}^*\right\|_2 &= \frac{2\gamma}{1+2\gamma}\left\|\tilde{\mathbf{U}}\right\|_2 \\
&\leq 2\gamma\sqrt{s}\acute{b}\leq\frac{5\sigma}{2\rho_{\max}}\sqrt{\frac{s\log(rp)}{n}}.
\end{aligned}$$

Combining the above inequality with (36) and Lemma 7 it follows that there exists positive constants c_1 and c_2 such that

$$\left|\left|\text{vec}\left(\bar{B}-B^*\right)\right|\right|_2\leq\frac{48\sigma}{\kappa}\sqrt{\frac{s\log(rp)}{n}}+\frac{5\sigma}{2\rho_{\max}}\sqrt{\frac{s\log(rp)}{n}},$$

with probability at least $1-c_1\exp(-c_2n\delta^2)$. To complete the proof set $c_3=48$ and $c_4=\frac{5}{2}$. ■

Abstract

Maximum mean discrepancy (MMD), also called energy distance or N-distance in statistics and Hilbert-Schmidt independence criterion (HSIC), specifically distance covariance in statistics, are among the most popular and successful approaches to quantify the difference and independence of random variables, respectively. Thanks to their kernel-based foundations, MMD and HSIC are applicable on a wide variety of domains. Despite their tremendous success, quite little is known about when HSIC characterizes independence and when MMD with tensor product kernel can discriminate probability distributions. In this paper, we answer these questions by studying various notions of characteristic property of the tensor product kernel.

Keywords: tensor product kernel, kernel mean embedding, characteristic kernel, $\mathcal{I}$-characteristic kernel, universality, maximum mean discrepancy, Hilbert-Schmidt independence criterion

1. Introduction

Kernel methods (Schölkopf and Smola, 2002) are among the most flexible and influential tools in machine learning and statistics, with superior performance demonstrated in a large number of areas and applications. The key idea in these methods is to map the data samples into a possibly infinite-dimensional feature space—precisely, a reproducing kernel Hilbert space (RKHS; Aronszajn, 1950)—and apply linear methods in the feature space, without the explicit need to compute the map. A generalization of this idea to probability measures, i.e., mapping probability measures into an RKHS (Berlinet and Thomas-Agnan, 2004, Chapter 4; Smola et al., 2007) has found novel applications in nonparametric statistics and machine learning. Formally, given a probability measure $\mathbb{P}$ defined on a measurable space $\mathcal{X}$ and an RKHS $\mathcal{H}_k$ with $k : \mathcal{X}\times\mathcal{X} \to \mathbb{R}$ as the reproducing kernel (which is symmetric and positive definite), $\mathbb{P}$ is embedded into $\mathcal{H}_k$ as

$$\mathbb{P} \mapsto \int_{\mathcal{X}} k(\cdot, x)\, \mathrm{d}\mathbb{P}(x) =: \mu_k(\mathbb{P}), \tag{1}$$

where $\mu_k(\mathbb{P})$ is called the *mean element* or *kernel mean embedding* of $\mathbb{P}$. The *mean embedding* of $\mathbb{P}$ has lead to a new generation of solutions in two-sample testing (Baringhaus and Franz, 2004; Székely and Rizzo, 2004, 2005; Borgwardt et al., 2006; Harchaoui et al., 2007; Gretton et al., 2012), goodness-of-fit testing (Chwialkowski et al., 2016; Liu et al., 2016; Jitkrittum et al., 2017b; Balasubramanian et al., 2017), domain adaptation (Zhang et al., 2013) and generalization (Blanchard et al., 2017), kernel belief propagation (Song et al., 2011), kernel Bayes' rule (Fukumizu et al., 2013), model criticism (Lloyd et al., 2014; Kim et al., 2016), approximate Bayesian computation (Park et al., 2016), probabilistic programming (Schölkopf et al., 2015), distribution classification (Muandet et al., 2011; Zaheer et al., 2017), distribution regression (Szabó et al., 2016; Law et al., 2018) and topological data analysis (Kusano et al., 2016). A recent survey on the topic is provided by Muandet et al. (2017).

Crucial to the success of the mean embedding based representation is whether it encodes all the information about the distribution, in other words whether the map in (1) is injective in which case the kernel is referred to as *characteristic* (Fukumizu et al., 2008; Sriperumbudur et al., 2010). Various characterizations for the characteristic property of k is known in the literature (Fukumizu et al., 2008, 2009; Sriperumbudur et al., 2010; Gretton et al., 2012) using which the popular kernels on $\mathbb{R}^d$ such as Gaussian, Laplacian, B-spline, inverse multiquadrics, and the Matérn class are shown to be characteristic. The characteristic property is closely related to the notion of *universality* (Steinwart, 2001; Micchelli et al., 2006; Carmeli et al., 2010; Sriperumbudur et al., 2011)—k is said to be universal if the corresponding RKHS $\mathcal{H}_k$ is dense in a certain target function class, for example, the class of continuous functions on compact domains—and the relation between these notions has recently been explored by Sriperumbudur et al. (2011); Simon-Gabriel and Schölkopf (2016).

Based on the mean embedding in (1), Smola et al. (2007) and Gretton et al. (2012) defined a semi-metric, called the maximum mean discrepancy (MMD) on the space of probability measures:

$$\mathrm{MMD}_k(\mathbb{P}, \mathbb{Q}) := \|\mu_k(\mathbb{P}) - \mu_k(\mathbb{Q})\|_{\mathcal{H}_k},$$

which is a metric iff k is characteristic. A fundamental application of MMD is in nonparametric hypothesis testing that includes two-sample (Gretton et al., 2012) and independence tests (Gretton et al., 2008). Particularly in independence testing, as a measure of independence, MMD measures the distance between the joint distribution $\mathbb{P}_{XY}$ and the product of marginals $\mathbb{P}_X \otimes \mathbb{P}_Y$ of two random variables X and Y which are respectively defined on measurable spaces $\mathcal{X}$ and $\mathcal{Y}$, with the kernel k being defined on $\mathcal{X}\times\mathcal{Y}$. As aforementioned, if k is characteristic, then $\mathrm{MMD}_k(\mathbb{P}_{XY}, \mathbb{P}_X \otimes \mathbb{P}_Y) = 0$ implies $\mathbb{P}_{XY} = \mathbb{P}_X \otimes \mathbb{P}_Y$, i.e., X and Y are independent. A simple way to define a kernel on $\mathcal{X}\times\mathcal{Y}$ is through the tensor product of kernels k_X and k_Y defined on $\mathcal{X}$ and $\mathcal{Y}$ respectively: $k = k_X \otimes k_Y$, i.e., $k\left((x, y), (x', y')\right) = k_X(x, x')k_Y(y, y')$, $x, x' \in \mathcal{X}$, $y, y' \in \mathcal{Y}$, with the corresponding RKHS $\mathcal{H}_k = \mathcal{H}_{k_X} \otimes \mathcal{H}_{k_Y}$ being the tensor product space generated by $\mathcal{H}_{k_X}$ and $\mathcal{H}_{k_Y}$. This means, when $k = k_X \otimes k_Y$,

$$\mathrm{MMD}_k(\mathbb{P}_{XY}, \mathbb{P}_X \otimes \mathbb{P}_Y) = \|\mu_{k_X\otimes k_Y}(\mathbb{P}_{XY}) - \mu_{k_X\otimes k_Y}(\mathbb{P}_X \otimes \mathbb{P}_Y)\|_{\mathcal{H}_{k_X}\otimes\mathcal{H}_{k_Y}}. \tag{2}$$

In addition to the simplicity of defining a joint kernel k on $\mathcal{X}\times\mathcal{Y}$, the tensor product kernel offers a principled way of combining inner products (k_X and k_Y) on domains that can

correspond to different modalities (say images, texts, audio). By exploiting the isomorphism between tensor product Hilbert spaces and the space of Hilbert-Schmidt operators[1], it follows from (2) that

$$\mathrm{MMD}_k(\mathbb{P}_{XY}, \mathbb{P}_X \otimes \mathbb{P}_Y) = \|C_{XY}\|_{\mathrm{HS}} =: \mathrm{HSIC}_k(\mathbb{P}_{XY}), \tag{3}$$

which is the Hilbert-Schmidt norm of the cross-covariance operator $C_{XY} := \mu_{k_X \otimes k_Y}(\mathbb{P}_{XY}) - \mu_{k_X}(\mathbb{P}_X) \otimes \mu_{k_Y}(\mathbb{P}_Y)$ and is known as the *Hilbert-Schmidt independence criterion* (HSIC) (Gretton et al., 2005a). HSIC has enjoyed tremendous success in a variety of applications such as independent component analysis (Gretton et al., 2005a), feature selection (Song et al., 2012), independence testing (Gretton et al., 2008; Jitkrittum et al., 2017a), post selection inference (Yamada et al., 2018) and causal detection (Mooij et al., 2016; Pfister et al., 2017; Strobl et al., 2017). Recently, MMD and HSIC (as defined in (3) for two components) have been shown by Sejdinovic et al. (2013b) to be equivalent to other popular statistical measures such as the energy distance (Baringhaus and Franz, 2004; Székely and Rizzo, 2004, 2005)—also known as N-distance (Zinger et al., 1992; Klebanov, 2005)—and distance covariance (Székely et al., 2007; Székely and Rizzo, 2009; Lyons, 2013) respectively. HSIC has been generalized to $M \geq 2$ components (Quadrianto et al., 2009; Sejdinovic et al., 2013a) to measure the joint independence of M random variables

$$\mathrm{HSIC}_k\left(\mathbb{P}\right) = \left\| \mu_{\otimes_{m=1}^M k_m}(\mathbb{P}) - \otimes_{m=1}^M \mu_{k_m}\left(\mathbb{P}_m\right) \right\|_{\otimes_{m=1}^M \mathcal{H}_{k_m}}, \tag{4}$$

where $\mathbb{P}$ is a joint measure on the product space $\mathcal{X} := \times_{m=1}^M \mathcal{X}_m$ and $(\mathbb{P}_m)_{m=1}^M$ are the marginal measures of $\mathbb{P}$ defined on $(\mathcal{X}_m)_{m=1}^M$ respectively. The extended HSIC measure has recently been analyzed in the context of independence testing (Pfister et al., 2017). In addition to testing, the extended HSIC measure is also useful in the problem of independent subspace analysis (ISA; Cardoso, 1998), wherein the latent sources are separated by maximizing the degree of independence among them. In all the applications of HSIC, the key requirement is that $k = \otimes_{m=1}^M k_m$ captures the joint independence of M random variables (with joint distribution $\mathbb{P}$)—we call this property as $\mathcal{I}$-characteristic—, which is guaranteed if k is characteristic. Since k is defined in terms of $(k_m)_{m=1}^M$, it is of fundamental importance to understand the characteristic and $\mathcal{I}$-characteristic properties of k in terms of the characteristic property of $(k_m)_{m=1}^M$, which is one of the main goals of this work.

For $M = 2$, the characterization of independence, i.e., the $\mathcal{I}$-characteristic property of k, is studied by Blanchard et al. (2011) and Gretton (2015) where it has been shown that if k_1 and k_2 are universal, then k is universal[2] and therefore HSIC captures independence. A stronger version of this result can be obtained by combining (Lyons, 2013, Theorem 3.11) and (Sejdinovic et al., 2013b, Proposition 29): if k_1 and k_2 are characteristic, then the HSIC associated with $k = k_1 \otimes k_2$ characterizes independence. Apart from these results, not much is known about the characteristic/$\mathcal{I}$-characteristic/universality properties of k in terms of the individual kernels. Our **goal** is to resolve this question and understand the characteristic, $\mathcal{I}$-characteristic and universal property of the product kernel $(\otimes_{m=1}^M k_m)$ in terms of the kernel components $((k_m)_{m=1}^M)$ for $M \geq 2$. Because of the relatedness of MMD and HSIC to energy distance and distance covariance, our results also contribute to the better understanding of these other measures that are popular in the statistical literature.

Specifically, our results shed light on the following **surprising phenomena** of the $\mathcal{I}$-characteristic property of $\otimes_{m=1}^M k_m$ for $M \geq 3$:

1. characteristic property of $(k_m)_{m=1}^M$ is not sufficient but necessary for $\otimes_{m=1}^M k_m$ to be $\mathcal{I}$-characteristic;
2. universality of $(k_m)_{m=1}^M$ is sufficient for $\otimes_{m=1}^M k_m$ to be $\mathcal{I}$-characteristic, and
3. if at least one of $(k_m)_{m=1}^M$ is only characteristic and not universal, then $\otimes_{m=1}^M k_m$ need not be $\mathcal{I}$-characteristic.

The paper is organized as follows. In Section 3, we conduct a comprehensive analysis about the above mentioned properties of k and $(k_m)_{m=1}^M$ for any positive integer M. To this end, we define various notions of characteristic property on the product space $\mathcal{X}$ (see Definition 1 and Figure 2(a) in Section 3) and explore the relation between them. In order to keep our presentation in this section to be non-technical, we relegate the problem formulation to Section 3, with the main results of the paper being presented in Section 4. A summary of the results is captured in Figure 1 while the proofs are provided in Section 5. Various definitions and notation that are used throughout the paper are collected in Section 2.

2. Definitions and Notation

$\mathbb{N} := \{1, 2, \ldots\}$ and $\mathbb{R}$ denotes the set of natural numbers and real numbers respectively. For $M \in \mathbb{N}$, $[M] := \{1, \ldots, M\}$. $\mathbf{1}_d := (1, 1, \ldots, 1) \in \mathbb{R}^d$ and $\mathbf{0}$ denotes the matrix of zeros. For $a := (a_1, \ldots, a_d) \in \mathbb{R}^d$ and $b := (b_1, \ldots, b_d) \in \mathbb{R}^d$, $\langle a, b\rangle = \sum_{i=1}^d a_i b_i$ is the Euclidean inner product. For sets A and B, $A \backslash B = \{a \in A : a \notin B\}$ is their difference, $|A|$ is the cardinality of A and $\times_{m=1}^M A_m = \{(a_1, \ldots, a_M) : a_m \in A_m\, m \in [M]\}$ is the Descartes product of sets $(A_m)_{m=1}^M$. $\mathcal{P}(\mathcal{X})$ denotes the power set of a set $\mathcal{X}$, i.e., all subsets of $\mathcal{X}$ (including the empty set and $\mathcal{X}$). The Kronecker delta is defined as $\delta_{a,b} = 1$ if $a = b$, and zero otherwise. χ_A is the indicator function of set A: $\chi_A(x) = 1$ if $x \in A$ and $\chi_A(x) = 0$ otherwise. $\mathbb{R}^{d_1 \times \ldots \times d_M}$ is the set of $d_1 \times \ldots \times d_M$-sized tensors.

For a topological space $(\mathcal{X}, \tau_{\mathcal{X}})$, $\mathcal{B}(\mathcal{X}) := \mathcal{B}(\tau_{\mathcal{X}})$ is the Borel sigma-algebra on $\mathcal{X}$ induced by the topology $\tau_{\mathcal{X}}$. Probability and finite signed measures in the paper are meant w.r.t. the measurable space $(\mathcal{X}, \mathcal{B}(\mathcal{X}))$. Given $\{(\mathcal{X}_i, \tau_i)\}_{i \in I}$ topological spaces, their product $\times_{i \in I} \mathcal{X}_i$ is enriched with the product topology; it is the coarsest topology for which the canonical projections $\pi_i : \times_{i \in I} \mathcal{X}_i \to (\mathcal{X}_i, \tau_i)$ are continuous for all $i \in I$. A topological space $(\mathcal{X}, \tau_{\mathcal{X}})$ is called second-countable if $\tau_{\mathcal{X}}$ has a countable basis.[3] $C(\mathcal{X})$ denotes the space of continuous functions on $\mathcal{X}$. $C_0(\mathcal{X})$ denotes the class of real-valued functions vanishing at infinity on a locally compact Hausdorff (LCH) space[4] $\mathcal{X}$, i.e., for any $\epsilon > 0$, the set $\{x \in \mathcal{X} : |f(x)| \geq \epsilon\}$

1. In the equivalence one assumes that $\mathcal{H}_{k_X}$, $\mathcal{H}_{k_Y}$ are separable; this holds under mild conditions, for example if $\mathcal{X}$ and $\mathcal{Y}$ are separable topological domains and k_X, k_Y are continuous (Steinwart and Christmann, 2008, Lemma 4.33).
2. Blanchard et al. (2011) deal with c-universal kernels while Gretton (2015) deals with c_0-universal kernels. A brief description of these notions are given in Section 3. Carmeli et al. (2010); Sriperumbudur et al. (2010) provide further details on these notions of universality.
3. Second-countability implies separability; in metric spaces the two notions coincide (Dudley, 2004, Proposition 2.1.4). By the Urysohn's theorem, a topological space is separable and metrizable if and only if it is regular, Hausdorff and second-countable. Any uncountable discrete space is *not* second-countable.
4. LCH spaces include $\mathbb{R}^d$, discrete spaces, and topological manifolds. Open or closed subsets, finite products of LCH spaces are LCH. Infinite-dimensional Hilbert spaces are *not* LCH.

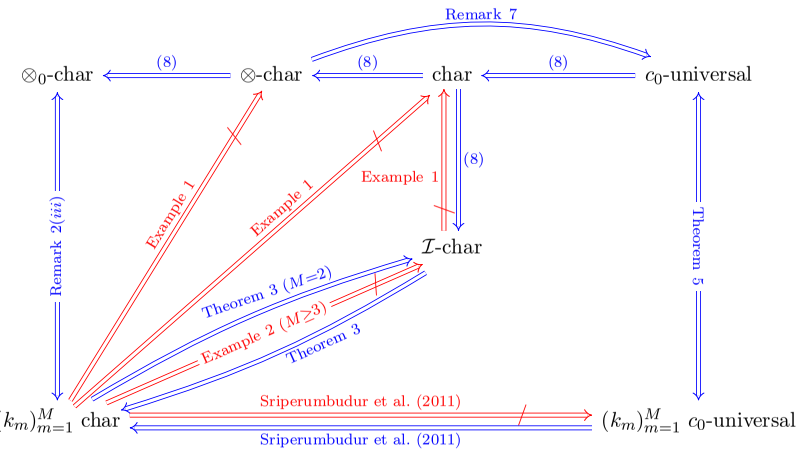

Figure 1: Summary of results: "char" denotes characteristic. In addition to the usual characteristic property, three new notions $\otimes_0$-characteristic, $\otimes$-characteristic and $\mathcal{I}$-characteristic are introduced in Definition 1 which along with c_0-universal (in the top right corner) correspond to the property of the tensor product kernel $\otimes_{m=1}^M k_m$, while the bottom part of the picture corresponds to the individual kernels $(k_m)_{m=1}^M$ being characteristic or c_0-universal. If $(k_m)_{m=1}^M$-s are continuous, bounded and translation invariant kernels on $\mathbb{R}^{d_m}$, $m \in [M]$, all the notions are equivalent (see Theorem 4).

is compact. $C_0(\mathcal{X})$ is endowed with the uniform norm $\|f\|_\infty = \sup_{x\in\mathcal{X}} |f(x)|$. $\mathcal{M}_b(\mathcal{X})$ and $\mathcal{M}_1^+(\mathcal{X})$ are the space of finite signed measures and probability measures on $\mathcal{X}$, respectively. For $\mathbb{P}_m \in \mathcal{M}_1^+(\mathcal{X}_m)$, $\otimes_{m=1}^M \mathbb{P}_m$ denotes the product probability measure on the product space $\times_{m=1}^M \mathcal{X}_m$, i.e., $\otimes_{m=1}^M \mathbb{P}_m \in \mathcal{M}_1^+(\times_{m=1}^M \mathcal{X}_m)$. δ_x is the Dirac measure supported on $x \in \mathcal{X}$. For $\mathbb{F} \in \mathcal{M}_b\left(\times_{m=1}^M \mathcal{X}_m\right)$, the finite signed measure $\mathbb{F}_m$ denotes its marginal on $\mathcal{X}_m$. $\mathcal{H}_{k_m}$ is the reproducing kernel Hilbert space (RKHS) associated with the reproducing kernel $k_m : \mathcal{X}_m \times \mathcal{X}_m \to \mathbb{R}$, which in this paper is assumed to be measurable and bounded. The tensor product of $(k_m)_{m=1}^M$ is a kernel, defined as

$$\otimes_{m=1}^M k_m\left((x_1,\ldots,x_M),(x'_1,\ldots,x'_M)\right) = \prod_{m=1}^M k_m\left(x_m,x'_m\right), \quad x_m,x'_m \in \mathcal{X}_m,$$

whose associated RKHS is denoted as $\mathcal{H}_{\otimes_{m=1}^M k_m} = \otimes_{m=1}^M \mathcal{H}_{k_m}$ (Berlinet and Thomas-Agnan, 2004, Theorem 13), where the r.h.s. is the tensor product of RKHSs $(\mathcal{H}_{k_m})_{m=1}^M$. For $h_m \in \mathcal{H}_m$, $m \in [M]$, the multi-linear operator $\otimes_{m=1}^M h_m \in \otimes_{m=1}^M \mathcal{H}_m$ is defined as

$$\left(\otimes_{m=1}^M h_m\right)(v_1,\ldots,v_M) = \prod_{m=1}^M \langle h_m, v_m\rangle_{\mathcal{H}_m}, \quad v_m \in \mathcal{H}_m.$$

A kernel $k : \mathcal{X}\times\mathcal{X} \to \mathbb{R}$ defined on a LCH space $\mathcal{X}$ is called a c_0-kernel if $k(\cdot,x) \in C_0(\mathcal{X})$ for all $x \in \mathcal{X}$. $k : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ is said to be a translation invariant kernel on $\mathbb{R}^d$ if $k(x,y) = \psi(x-y)$, $x,y \in \mathbb{R}^d$ for a positive definite function $\psi : \mathbb{R}^d \to \mathbb{R}$. $\mu_k(\mathbb{F})$ denotes the kernel mean embedding of $\mathbb{F} \in \mathcal{M}_b(\mathcal{X})$ to $\mathcal{H}_k$ which is defined as $\mu_k(\mathbb{F}) = \int_{\mathcal{X}} k(\cdot,x)\,\mathrm{d}\mathbb{F}(x)$, where the integral is meant in the Bochner sense.

3. Problem Formulation

In this section, we formally introduce the goal of the paper. To this end, we start with a definition. For simplicity, throughout the paper, we assume that all kernels are bounded. The definition is based on the observation (Sriperumbudur et al., 2010, Lemma 8) that a bounded kernel k on a topological space $(\mathcal{X},\tau_{\mathcal{X}})$ is characteristic if and only if

$$\int_{\mathcal{X}}\int_{\mathcal{X}} k(x,x')\,\mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x') > 0, \ \forall\, \mathbb{F} \in \mathcal{M}_b(\mathcal{X})\backslash\{0\} \text{ such that } \mathbb{F}(\mathcal{X}) = 0.$$

In other words, characteristic kernels are integrally strictly positive definite (ispd; see Sriperumbudur et al., 2010, p. 1523) w.r.t. the class of finite signed measures that assign zero measure to $\mathcal{X}$. The following definition extends this observation to tensor product kernels on product spaces.

Definition 1 **($\mathcal{F}$-ispd tensor product kernel)** *Suppose $k_m : \mathcal{X}_m \times \mathcal{X}_m \to \mathbb{R}$ is a bounded kernel on a topological space $(\mathcal{X}_m,\tau_{\mathcal{X}_m})$, $m \in [M]$. Let $\mathcal{F} \subseteq \mathcal{M}_b(\mathcal{X})$ be such that $0 \in \mathcal{F}$ where $\mathcal{X} := \times_{m=1}^M \mathcal{X}_m$. $k := \otimes_{m=1}^M k_m$ is said to be* $\mathcal{F}$-ispd *if*

$$\mu_k(\mathbb{F}) = 0 \Rightarrow \mathbb{F} = 0 \quad (\mathbb{F} \in \mathcal{F}), \text{ or equivalently}$$

$$\|\mu_k(\mathbb{F})\|_{\mathcal{H}_k}^2 = \int_{\times_{m=1}^M \mathcal{X}_m}\int_{\times_{m=1}^M \mathcal{X}_m} \left(\otimes_{m=1}^M k_m\right)(x,x')\ \mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x') > 0, \quad \forall\, \mathbb{F} \in \mathcal{F}\backslash\{0\}. \quad (5)$$

Specifically,

- *if k_m-s are c_0-kernels on locally compact Polish (LCP)* [5] *spaces $\mathcal{X}_m$-s and $\mathcal{F} = \mathcal{M}_b(\mathcal{X})$, then k is called c_0-universal.*
- *if*

$$\begin{aligned}
\mathcal{F} &= [\mathcal{M}_b(\mathcal{X})]^0 && := \{\mathbb{F} \in \mathcal{M}_b(\mathcal{X}) : \mathbb{F}(\mathcal{X}) = 0\},\\
\mathcal{F} &= \left[\otimes_{m=1}^M \mathcal{M}_b(\mathcal{X}_m)\right]^0 && := \left\{\mathbb{F} \in \otimes_{m=1}^M \mathcal{M}_b\left(\mathcal{X}_m\right), \mathbb{F}(\mathcal{X}) = 0\right\},\\
\mathcal{F} &= \mathcal{I} && := \left\{\mathbb{P} - \otimes_{m=1}^M \mathbb{P}_m : \mathbb{P} \in \mathcal{M}_1^+\left(\times_{m=1}^M \mathcal{X}_m\right)\right\}, \quad (M \geq 2)\\
\mathcal{F} &= \otimes_{m=1}^M \mathcal{M}_b^0(\mathcal{X}_m) && := \left\{\mathbb{F} = \otimes_{m=1}^M \mathbb{F}_m \ : \mathbb{F}_m \in \mathcal{M}_b\left(\mathcal{X}_m\right), \mathbb{F}_m(\mathcal{X}_m) = 0, \ \forall\, m \in [M]\right\},
\end{aligned}$$

then k is called characteristic, $\otimes$-characteristic, $\mathcal{I}$-characteristic *and* $\otimes_0$-characteristic, *respectively.*

5. A topological space is called Polish if it is complete, separable and metrizable. For example, $\mathbb{R}^d$ and countable discrete spaces are Polish. Open and closed subsets, products and disjoint unions of countably many Polish spaces are Polish. Every second-countable LCH space is Polish.

In Definition 1, k being characteristic matches the usual notion of characteristic kernels on a product space, i.e., there are no two distinct probability measures on $\mathcal{X} = \times_{m=1}^{M} \mathcal{X}_m$ such that the MMD between them is zero. The other notions such as $\otimes$-characteristic, $\mathcal{I}$-characteristic and $\otimes_0$-characteristic are typically weaker than the usual characteristic property since

$$\otimes_{m=1}^{M} \mathcal{M}_b^0(\mathcal{X}_m) \quad \subseteq \left[\otimes_{m=1}^{M} \mathcal{M}_b(\mathcal{X}_m)\right]^0 \quad \subseteq \quad \left[\mathcal{M}_b\left(\times_{m=1}^{M} \mathcal{X}_m\right)\right]^0 \subseteq \quad \mathcal{M}_b\left(\times_{m=1}^{M} \mathcal{X}_m\right). \qquad (6)$$

$$\cup\!| \quad \mathcal{I}$$

Below we provide further intuition on the $\mathcal{F}$ measure classes enlisted in Definition 1.

Remark 2 *(i)* $\boldsymbol{\mathcal{F} = \mathcal{M}_b(\mathcal{X})}$ **:** *If k_m-s are c_0-kernels on LCH spaces $\mathcal{X}_m$ for all $m \in [M]$, then k is also a c_0-kernel on LCH space $\mathcal{X}$ implying that if k satisfies* (5)*, then k is c_0-universal (Sriperumbudur et al., 2010, Proposition 2). It is well known (Sriperumbudur et al., 2010) that c_0-universality reduces to c-universality (i.e., the notion of universality proposed by Steinwart, 2001) if $\mathcal{X}$ is compact which is guaranteed if and only if each $\mathcal{X}_m$, $m \in [M]$ is compact.*

(ii) $\boldsymbol{\mathcal{F} = \mathcal{I}}$ **:** *This family is useful to describe the joint* independence *of M random variables—hence the name $\mathcal{I}$-characteristic—defined on kernel-endowed domains $(\mathcal{X}_m)_{m=1}^M$: If $\mathbb{P}$ denotes the joint distribution of random variables $(X_m)_{m=1}^M$ and $(\mathbb{P}_m)_{m=1}^M$ are the associated marginals on $(\mathcal{X}_m)_{m=1}^M$, then by definition $k = \otimes_{m=1}^M k_m$ is $\mathcal{I}$-characteristic iff*

$$\mathrm{HSIC}_k(\mathbb{P}) = 0 \Longleftrightarrow \mathbb{P} = \otimes_{m=1}^{M} \mathbb{P}_m.$$

In other words, HSIC captures joint independence exactly with $\mathcal{I}$-characteristic kernels. Similarly, the $\mathcal{I}$-characteristic property ensures that COCO (constrained covariance; Gretton et al., 2005b) is a joint independence measure as COCO is defined by replacing the Hilbert-Schmidt norm of the cross-covariance operator (see (3) *and* (4)*) with its spectral norm.*

(iii) $\boldsymbol{\mathcal{F} = \otimes_{m=1}^{M} \mathcal{M}_b^0(\mathcal{X}_m)}$ **:** *In this case $\mathcal{F}$ is chosen to be the product of finite signed measures on $\mathcal{X}$ such that each marginal measure $\mathbb{F}_m$ assigns zero to the corresponding space $\mathcal{X}_m$. This choice is relevant as the characteristic property of individual kernels $(k_m)_{m=1}^M$ need* not *imply the characteristic property of $\otimes_{m=1}^M k_m$, but is equivalent to the $\otimes_0$-characteristic property of $\otimes_{m=1}^M k_m$. The equivalence holds for bounded kernels $k_m : \mathcal{X}_m \times \mathcal{X}_m \to \mathbb{R}$ on topological spaces $\mathcal{X}_m$ ($m \in [M]$) since for any $\mathbb{F} = \otimes_{m=1}^M \mathbb{F}_m \in \otimes_{m=1}^M \mathcal{M}_b(\mathcal{X}_m)$, $\mathbb{F}_m(\mathcal{X}_m) = 0$ $(\forall\, m \in [M])$*

$$\|\mu_k(\mathbb{F})\|^2_{\mathcal{H}_{\otimes_{m=1}^M k_m}} = \prod_{m=1}^{M} \|\mu_{k_m}(\mathbb{F}_m)\|^2_{\mathcal{H}_{k_m}}, \qquad (7)$$

and the l.h.s. is positive iff each term on the r.h.s. is positive.

(iv) $\boldsymbol{\mathcal{F} = \left[\otimes_{m=1}^{M} \mathcal{M}_b(\mathcal{X}_m)\right]^0}$ **:** *This class is similar to the one discussed in (iii) above—i.e., class of product measures—with the slight difference that the joint measure $\mathbb{F}$ is restricted to assign zero measure to $\mathcal{X}$ without requiring all the marginal measures $\mathbb{F}_m$ to assign zero measure to the corresponding space $\mathcal{X}_m$. While the need for considering such a measure class may not be clear at this juncture, however, based on* (7)*, it turns out that this choice of $\mathcal{F}$ has quite surprising connections to the characteristic property and c_0-universality of the product kernel; for details see Remark 7.*

(v) ***$\mathcal{F}$-ispd relations:*** *Given the relations in* (6)*, it immediately follows that $k = \otimes_{m=1}^M k_m$ satisfies*

$$\otimes_0\text{-characteristic} \Longleftarrow \otimes\text{-characteristic} \Longleftarrow \begin{array}{c} \text{characteristic} \\ \Downarrow \\ \mathcal{I}\text{-characteristic} \end{array} \Longleftarrow c_0\text{-universal} \qquad (8)$$

when $\mathcal{X}_m$ for all $m \in [M]$ are LCP. A visual illustration of (6) *and* (8) *is provided in Figure 2.*

(vi) $\boldsymbol{\left[\otimes_{m=1}^{M} \mathcal{M}_b(\mathcal{X}_m)\right]^0 \cap \mathcal{I} = \{0\}}$ **:** *While it is clear that $\left[\otimes_{m=1}^M \mathcal{M}_b(\mathcal{X}_m)\right]^0$ and $\mathcal{I}$ are subsets of $\left[\mathcal{M}_b(\times_{m=1}^M \mathcal{X}_m)\right]^0$, it is interesting to note that $\left[\otimes_{m=1}^M \mathcal{M}_b(\mathcal{X}_m)\right]^0$ and $\mathcal{I}$ have a trivial intersection with 0 being the measure common to each of them, assuming that $\mathcal{X}_m$-s are second-countable for all $m \in [M]$; see Section 5.1.*

Having defined the $\mathcal{F}$-ispd property, our **goal** is to investigate whether the characteristic or c_0-universal property of k_m-s ($m \in [M]$) imply different $\mathcal{F}$-ispd properties of $\otimes_{m=1}^M k_m$, and vice versa.

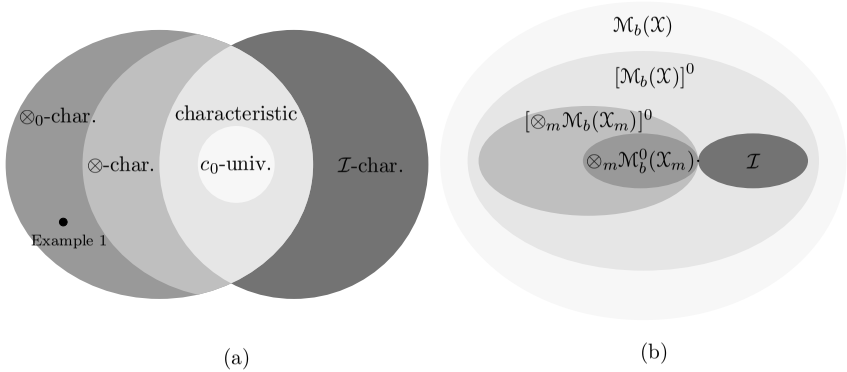

Figure 2: (a) $\mathcal{F}$-ispd $\otimes_{m=1}^M k_m$ kernels (see (8)); (b) $\mathcal{F} \subseteq \mathcal{M}_b(\mathcal{X})$, $\mathcal{X} = \times_{m=1}^M \mathcal{X}_m$. Example 1: $\otimes_{m=1}^M k_m$ is $\otimes_0$-characteristic but not $\otimes$-characteristic and therefore not characteristic.

4. Main Results

In this section, we present our main results related to the $\mathcal{F}$-ispd property of tensor product kernels, which are summarized in Figure 1. The results in this section will deal with various assumptions on $\mathcal{X}_m$, such as second-countability, Hausdorff, locally compact Hausdorff

(LCH) and locally compact Polish (LCP), so that they are presented in more generality. However, for simplicity, all these assumptions can be unified by simply assuming a stronger condition that $\mathcal{X}_m$'s are LCP.

Our first example illustrates that the characteristic property of k_m-s does not imply the characteristic property of the tensor product kernel. In light of Remark 2(iv) of Section 3, it follows that the class of $\otimes_0$-characteristic tensor product kernels form a *strictly* larger class than characteristic tensor product kernels; see also Figure 2.

Example 1 *Let $\mathcal{X}_1 = \mathcal{X}_2 = \{1,2\}$, $\tau_{\mathcal{X}_1} = \tau_{\mathcal{X}_2} = \mathcal{P}(\{1,2\})$, $k_1(x,x') = k_2(x,x') = 2\delta_{x,x'} - 1$. It is easy to verify that k_1 and k_2 are characteristic. However, it can be proved that $k_1 \otimes k_2$ is* not *$\otimes$-characteristic and therefore not characteristic. On the hand, interestingly, $k_1 \otimes k_2$ is $\mathcal{I}$-characteristic. We refer the reader to Section 5.2 for details.*

In the above example, we showed that the tensor product of k_1 and k_2 (which are characteristic kernels) is $\mathcal{I}$-characteristic. The following result generalizes this behavior for any bounded characteristic kernels. In addition, under a mild assumption, it shows the converse to be true for any M.

Theorem 3 *Let $k_m : \mathcal{X}_m \times \mathcal{X}_m \to \mathbb{R}$ be bounded kernels on topological spaces $\mathcal{X}_m$ for all $m \in [M]$, $M \geq 2$. Then the following holds.*

(i) Suppose $\mathcal{X}_m$ is second-countable for all $m \in [M]$ with $M = 2$. If k_1 and k_2 are characteristic, then $k_1 \otimes k_2$ is $\mathcal{I}$-characteristic.

(ii) Suppose $\mathcal{X}_m$ is Hausdorff and $|\mathcal{X}_m| \geq 2$ for all $m \in [M]$. If $\otimes_{m=1}^M k_m$ is $\mathcal{I}$-characteristic, then $k_1, \ldots, k_M$ are characteristic.

Lyons (2013) has showed an analogous result to Theorem 3(i) for distance covariances ($M = 2$) on metric spaces of negative type (Lyons, 2013, Theorem 3.11), which by Sejdinovic et al. (2013b, Proposition 29) holds for HSIC yielding the $\mathcal{I}$-characteristic property of $k_1 \otimes k_2$. Recently, Gretton (2015) presented a direct proof showing that HSIC corresponding to $k_1 \otimes k_2$ captures independence if k_1 and k_2 are translation invariant characteristic kernels on $\mathbb{R}^d$ (which is equivalent to c_0-universality). Blanchard et al. (2011) proved a result similar to Theorem 3(i) assuming that $\mathcal{X}_m$'s are compact and k_1, k_2 being c-universal. In contrast, Theorem 3(i) establishes the result for bounded kernels on general second-countable topological spaces. In fact, the results of Gretton (2015); Blanchard et al. (2011) are special cases of Theorems 4 and 5 below. Theorem 3(i) raises a pertinent question: whether $\otimes_{m=1}^M k_m$ is $\mathcal{I}$-characteristic if k_m-s are characteristic for all $m \in [M]$ where $M > 2$? The following example provides a negative answer to this question. On a positive side, however, we will see in Theorem 5 that the $\mathcal{I}$-characteristic property of $\otimes_{m=1}^M k_m$ can be guaranteed for any $M \geq 2$ if a stronger condition is imposed on k_m-s (and $\mathcal{X}_m$-s). Theorem 3(ii) generalizes Proposition 3.15 of Lyons (2013) for any $M > 2$, which states that every kernel k_m, $m \in [M]$ being characteristic is necessary for the tensor kernel $\otimes_{m=1}^M k_m$ to be $\mathcal{I}$-characteristic.

Example 2 *Let $M = 3$ and $\mathcal{X}_m := \{1,2\}$, $\tau_{\mathcal{X}_m} = \mathcal{P}(\mathcal{X}_m)$, $k_m(x,x') = 2\delta_{x,x'} - 1$ ($m = 1,2,3$). As mentioned in Example 1, $(k_m)_{m=1}^3$ are characteristic. However, it can be shown that $\otimes_{m=1}^3 k_m$ is not $\mathcal{I}$-characteristic. See Section 5.4 for details.*

In Remark 2(iii) and Example 1, we showed that in general, only the $\otimes_0$-characteristic property of $\otimes_{m=1}^M k_m$ is equivalent to the characteristic property of k_m-s. Our next result shows that all the various notions of characteristic property of $\otimes_{m=1}^M k_m$ *coincide* if k_m-s are translation-invariant, continuous bounded kernels on $\mathbb{R}^d$.

Theorem 4 *Suppose $k_m : \mathbb{R}^{d_m} \times \mathbb{R}^{d_m} \to \mathbb{R}$ are continuous, bounded and translation-invariant kernels for all $m \in [M]$. Then the following statements are equivalent:*

(i) k_m-s are characteristic for all $m \in [M]$;
(ii) $\otimes_{m=1}^M k_m$ is $\otimes_0$-characteristic;
(iii) $\otimes_{m=1}^M k_m$ is $\otimes$-characteristic;
(iv) $\otimes_{m=1}^M k_m$ is $\mathcal{I}$-characteristic;
(v) $\otimes_{m=1}^M k_m$ is characteristic.

The following result shows that on LCP spaces, the tensor product of $M \geq 2$ c_0-universal kernels is also c_0-universal, and vice versa.

Theorem 5 *Suppose $k_m : \mathcal{X}_m \times \mathcal{X}_m \to \mathbb{R}$ are c_0-kernels on LCP spaces $\mathcal{X}_m$ ($m \in [M]$). Then $\otimes_{m=1}^M k_m$ is c_0-universal iff k_m-s are c_0-universal for all $m \in [M]$.*

Remark 6 *(i) A special case of Theorem 5 for $M = 2$ is proved by Lyons (2013, Lemma 3.8) in the context of distance covariance which reduces to Theorem 5 through the equivalence established by Sejdinovic et al. (2013b). Another special case of Theorem 5 is proved by Blanchard et al. (2011, Lemma 5.2) for c-universality with $M = 2$ using the Stone-Weierstrass theorem: if k_1 and k_2 are c-universal then $k_1 \otimes k_2$ is c-universal.*

(ii) Since the notions of c_0-universality and characteristic property are equivalent for translation invariant c_0-kernels on $\mathbb{R}^d$ (Carmeli et al., 2010, Prop. 5.16, Sriperumbudur et al., 2010, Theorem 9), Theorem 4 can be considered as a special case of Theorem 5. In other words, requiring $(k_m)_{m=1}^M$ to be also c_0-kernels in Theorem 4(i)-(iv) is equivalent to

(v) k_m-s are c_0-universal for all $m \in [M]$;
(vi) $\otimes_{m=1}^M k_m$ is c_0-universal.

(iii) Since the c_0-universality of $\otimes_{m=1}^M k_m$ implies its $\mathcal{I}$-characteristic property (see (8)), Theorem 5 also provides a generalization of Theorem 3(i) to $M \geq 2$ under additional assumptions on k_m-s, while constraining $\mathcal{X}_m$-s to LCP-s instead of second-countable topological spaces.

In Example 2 and Theorem 5, we showed that for $M \geq 3$ components while the characteristic property of $(k_m)_{m=1}^M$ is not sufficient, their universality is enough to guarantee the $\mathcal{I}$-characteristic property of $\otimes_{m=1}^M k_m$. The next example demonstrates that these results are tight: If at least one k_m is not universal but only characteristic, then $\otimes_{m=1}^M k_m$ might not be $\mathcal{I}$-characteristic.

Example 3 *Let $M = 3$ and $\mathcal{X}_m := \{1,2\}$, $\tau_{\mathcal{X}_m} = \mathcal{P}(\mathcal{X}_m)$, for all $m \in [3]$, $k_1(x,x') = 2\delta_{x,x'} - 1$, and $k_m(x,x') = \delta_{x,x'}$ ($m = 2,3$). k_1 is characteristic (Example 1), k_2 and k_3 are universal since the associated Gram matrix $\mathbf{G} = [k_m(x,x')]_{x,x' \in \mathcal{X}_m}$ is an identity matrix,*

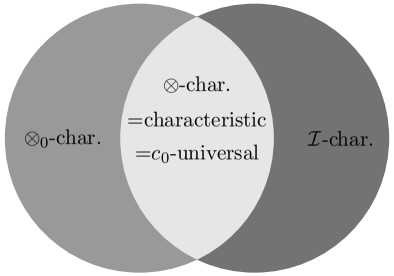

Figure 3: Simplification of the $\mathcal{F}$-ispd property of tensor product kernels; see Remark 7.

which is strictly positive definite ($m = 2, 3$). However, $\otimes_{m=1}^3 k_m$ is not *$\mathcal{I}$-characteristic. See Section 5.7 for details.*

Remark 7 *Note that the l.h.s. in* (7) *is positive if and only if each term on the r.h.s. is positive, i.e., if $k = \otimes_{m=1}^M k_m$ is $\otimes$-characteristic with k_m-s being c_0-kernels on LCP $\mathcal{X}_m$-s, then all k_m-s are c_0-universal. A similar result was also proved by Steinwart and Ziegel (2017, Lemma 3.4). Combining this with Theorem 5 yields that for tensor product c_0-kernels, the notions of $\otimes$-characteristic, characteristic and c_0-universality are equivalent, which is quite surprising as for a joint kernel k (that is not of product type), these notions need not necessarily coincide. In light of this discussion, Figure 2(a) can be simplified to Figure 3.*

5. Proofs

In this section, we provide the proofs of our results presented in Section 4.

5.1 Proof of Remark 2(iv)

By the second-countability of $\mathcal{X}_m$-s, $\mathcal{B}\left(\times_{m=1}^M \mathcal{X}_m\right) = \otimes_{m=1}^M \mathcal{B}(\mathcal{X}_m)$, where the r.h.s. is defined as the σ-field generated by the cylinder sets $A_m \times_{n\neq m} \mathcal{X}_n$ where $m \in [M]$ and $A_m \in \mathcal{B}(\mathcal{X}_m)$. Suppose there exists $\mathbb{F} \in \left[\otimes_{m=1}^M \mathcal{M}_b(\mathcal{X}_m)\right]^0 \cap \mathcal{I}$ such that $\mathbb{F} \neq 0$. This means there exists $\mathbb{P} \in \mathcal{M}_1^+\left(\times_{m=1}^M \mathcal{X}_m\right)$ with $(\mathbb{P}_m)_{m=1}^M$ being the marginals of $\mathbb{P}$ such that $\mathbb{F} = \otimes_{m=1}^M \mathbb{F}_m = \mathbb{P} - \otimes_{m=1}^M \mathbb{P}_m$. Since $\mathbb{F} \neq 0$ there exists $A_m \times_{n\neq m} \mathcal{X}_n$ for some $m \in [M]$ and $A_m \in \mathcal{B}(\mathcal{X}_m)$ such that $0 \neq \mathbb{F}(A_m \times_{n\neq m} \mathcal{X}_n) = \mathbb{F}_m(A_m) \prod_{n\neq m} \mathbb{F}_n(\mathcal{X}_n) = \mathbb{P}\left(A_m \times_{n\neq m} \mathcal{X}_n\right) - \mathbb{P}_m(A_m) \prod_{n\neq m} \mathbb{P}_n(\mathcal{X}_n) = \mathbb{P}_m(A_m) - \mathbb{P}_m(A_m) = 0$, leading to a contradiction.

5.2 Proof of Example 1

The proof is structured as follows.

1. First we show that $k := k_1 = k_2$ is a kernel and it is characteristic.
2. Next it is proved that $k_1 \otimes k_2$ is not $\otimes$-characteristic, which implies $k_1 \otimes k_2$ is not characteristic.
3. Finally, the $\mathcal{I}$-characteristic property of $k_1 \otimes k_2$ is established.

The individual steps are as follows:

k **is a kernel.** Assume w.l.o.g. that $x_1 = \ldots = x_N = 1$, $x_{N+1} = \ldots = x_n = 2$. Then it is easy to verify that the Gram matrix $\mathbf{G} = [k(x_i, x_j)]_{i,j=1}^n = \mathbf{a}\mathbf{a}^\top$ where $\mathbf{a} := \left(\mathbf{1}_N^\top, -\mathbf{1}_{n-N}^\top\right)^\top$ and $\mathbf{a}^\top$ is the transpose of $\mathbf{a}$. Clearly $\mathbf{G}$ is positive semidefinite and so k is a kernel.

k **is characteristic**. We will show that k satisfies (5). On $\mathcal{X} = \{1, 2\}$ a finite signed measure $\mathbb{F}$ takes the form $\mathbb{F} = a_1\delta_1 + a_2\delta_2$ for some $a_1, a_2 \in \mathbb{R}$. Thus,

$$\mathbb{F} \in \mathcal{M}_b(\mathcal{X})\backslash\{0\} \Leftrightarrow (a_1, a_2) \neq \mathbf{0} \qquad \text{and} \qquad \mathbb{F}(\mathcal{X}) = 0 \Leftrightarrow a_1 + a_2 = 0. \tag{9}$$

Consider

$$\begin{aligned}\int_{\mathcal{X}}\int_{\mathcal{X}} k(x, x')\,\mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x') &= a_1^2 k(1,1) + a_2^2 k(2,2) + 2a_1a_2k(1,2)\\ &= a_1^2 + a_2^2 - 2a_1a_2 = (a_1 - a_2)^2 = 4a_1^2 > 0,\end{aligned} \tag{10}$$

where we used (9) and the facts that $k(1,1) = k(2,2) = 1$, $k(1,2) = -1$.

$k_1 \otimes k_2$ **is not** $\otimes$**-characteristic**. We construct a witness $\mathbb{F} = \mathbb{F}_1 \otimes \mathbb{F}_2 \in \otimes_{m=1}^2 \mathcal{M}_b(\mathcal{X}_m)\backslash\{0\}$ such that

$$\mathbb{F}(\mathcal{X}_1 \times \mathcal{X}_2) = \mathbb{F}_1(\mathcal{X}_1)\mathbb{F}_2(\mathcal{X}_2) = 0, \tag{11}$$

and

$$\begin{aligned}0 &= \int_{\mathcal{X}_1\times\mathcal{X}_2}\int_{\mathcal{X}_1\times\mathcal{X}_2} \underbrace{(k_1 \otimes k_2)((i_1, i_2), (i_1', i_2'))}_{k_1(i_1,i_1')k_2(i_2,i_2')}\,\mathrm{d}\mathbb{F}(i_1, i_2)\,\mathrm{d}\mathbb{F}(i_1', i_2')\\ &= \prod_{m=1}^2 \int_{\mathcal{X}_m}\int_{\mathcal{X}_m} k_m(i_m, i_m')\,\mathrm{d}\mathbb{F}_m(i_m)\,\mathrm{d}\mathbb{F}_m(i_m').\end{aligned} \tag{12}$$

Finite signed measures on $\{1, 2\}$ take the form $\mathbb{F}_1 = \mathbb{F}_1(\mathbf{a}) = a_1\delta_1 + a_2\delta_2$, $\mathbb{F}_2 = \mathbb{F}_2(\mathbf{b}) = b_1\delta_1 + b_2\delta_2$ form, where $\mathbf{a} = (a_1, a_2) \in \mathbb{R}^2, \mathbf{b} = (b_1, b_2) \in \mathbb{R}^2$. With these notations, (11) and (12) can be rewritten as

$$\begin{aligned}0 &= (a_1 + a_2)(b_1 + b_2),\\ 0 &= \left[\sum_{i,i'=1}^2 k_1(i, i')a_ia_{i'}\right]\left[\sum_{j,j'=1}^2 k_2(j, j')b_jb_{j'}\right] = (a_1 - a_2)^2(b_1 - b_2)^2.\end{aligned}$$

Keeping the solutions where neither $\mathbf{a}$ nor $\mathbf{b}$ is the zero vector, there are 2 (symmetric) possibilities: (i) $a_1 + a_2 = 0$, $b_1 = b_2$ and (ii) $a_1 = a_2$, $b_1 + b_2 = 0$. In other words, for any $a, b \neq 0$, the possibilities are (i) $\mathbf{a} = (a, -a)$, $\mathbf{b} = (b, b)$ and (ii) $\mathbf{a} = (a, a)$, $\mathbf{b} = (b, -b)$. This establishes the non-$\left[\otimes_{m=1}^2 \mathcal{M}_b(\mathcal{X}_m)\right]^0$-ispd property of $k_1 \otimes k_2$.

$k_1 \otimes k_2$ **is $\mathcal{I}$-characteristic**. Our goal is to show that $k_1 \otimes k_2$ is $\mathcal{I}$-characteristic, i.e., for any $\mathbb{P} \in \mathcal{M}_1^+(\mathcal{X}_1 \times \mathcal{X}_2)$, $\mu_{k_1 \otimes k_2}(\mathbb{F}) = 0$ implies $\mathbb{F} = 0$, where $\mathbb{F} = \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2$. We divide the proof into two parts:

1. First we derive the equations of
$$\mathbb{F}(\mathcal{X}_1 \times \mathcal{X}_2) = 0 \quad \text{and} \quad \int\int_{(\mathcal{X}_1 \times \mathcal{X}_2)^2} (k_1 \otimes k_2)\left((i,j),(r,s)\right) \mathrm{d}\mathbb{F}(i,j)\, \mathrm{d}\mathbb{F}(r,s) = 0 \quad (13)$$
for general finite signed measures $\mathbb{F} = \sum_{i,j=1}^2 a_{ij}\delta_{(i,j)}$ on $\mathcal{X}_1 \times \mathcal{X}_2$.
2. Then, we apply the $\mathbb{F} = \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2$ parameterization and solve for $\mathbb{P}$ that satisfies (13) to conclude that $\mathbb{P} = \mathbb{P}_1 \otimes \mathbb{P}_2$, i.e., $\mathbb{F} = 0$. Note that in the chosen parametrization for $\mathbb{F}$, $\mathbb{F}(\mathcal{X}_1 \times \mathcal{X}_2) = 0$ holds automatically.

The details are as follows.

Step 1.

$$0 = \mathbb{F}(\mathcal{X}_1 \times \mathcal{X}_2) \Leftrightarrow 0 = a_{11} + a_{12} + a_{21} + a_{22}, \quad (14)$$

$$\begin{aligned}
0 &= \int_{\mathcal{X}_1 \times \mathcal{X}_2} \int_{\mathcal{X}_1 \times \mathcal{X}_2} \underbrace{(k_1 \otimes k_2)\left((i,j),(r,s)\right)}_{k_1(i,r)k_2(j,s)} \mathrm{d}\mathbb{F}(i,j)\, \mathrm{d}\mathbb{F}(r,s) \\
&= \sum_{i,j=1}^2 \sum_{r,s=1}^2 k_1(i,r)k_2(j,s)a_{ij}a_{rs} = \sum_{i,r=1}^2 k_1(i,r) \sum_{j,s=1}^2 k_2(j,s)a_{ij}a_{rs} \\
&= k_1(1,1)\left[k_2(1,1)a_{11}a_{11} + k_2(1,2)a_{11}a_{12} + k_2(2,1)a_{12}a_{11} + k_2(2,2)a_{12}a_{12}\right] \\
&\quad + k_1(1,2)\left[k_2(1,1)a_{11}a_{21} + k_2(1,2)a_{11}a_{22} + k_2(2,1)a_{12}a_{21} + k_2(2,2)a_{12}a_{22}\right] \\
&\quad + k_1(2,1)\left[k_2(1,1)a_{21}a_{11} + k_2(1,2)a_{21}a_{12} + k_2(2,1)a_{22}a_{11} + k_2(2,2)a_{22}a_{12}\right] \\
&\quad + k_1(2,2)\left[k_2(1,1)a_{21}a_{21} + k_2(1,2)a_{21}a_{22} + k_2(2,1)a_{22}a_{21} + k_2(2,2)a_{22}a_{22}\right] \\
&= \underbrace{\left(a_{11}^2 - 2a_{11}a_{12} + a_{12}^2\right)}_{(a_{11}-a_{12})^2} + \underbrace{\left(a_{21}^2 - 2a_{21}a_{22} + a_{22}^2\right)}_{(a_{21}-a_{22})^2} - 2\underbrace{\left(a_{11}a_{21} - a_{11}a_{22} - a_{12}a_{21} + a_{12}a_{22}\right)}_{(a_{11}-a_{12})(a_{21}-a_{22})} \\
&= (a_{11} - a_{12} - a_{21} + a_{22})^2. \quad (15)
\end{aligned}$$

Solving (14) and (15) yields

$$a_{11} + a_{22} = 0 \quad \text{and} \quad a_{12} + a_{21} = 0. \quad (16)$$

Step 2. Any $\mathbb{P} \in \mathcal{M}_1^+(\mathcal{X}_1 \times \mathcal{X}_2)$ can be parametrized as

$$\mathbb{P} = \sum_{i,j=1}^2 p_{ij}\delta_{(i,j)}, \quad p_{ij} \geq 0, \forall\,(i,j) \quad \text{and} \quad \sum_{i,j=1}^2 p_{ij} = 1. \quad (17)$$

Let $\mathbb{F} = \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2 = \sum_{i,j=1}^2 a_{ij}\delta_{(i,j)}$; for illustration see Table 1. It follows from step 1 that $\mathbb{F}$ satisfying (16) is equivalent to satisfying (13). Therefore, for the choice of $\mathbb{F} := \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2$, we obtain

$$p_{11} - (p_{11} + p_{12})(p_{11} + p_{21}) + p_{22} - (p_{21} + p_{22})(p_{12} + p_{22}) = 0, \quad (18)$$

$\mathbb{P}$: $y\backslash x$	1	2	$\mathbb{P}_2$
1	p_{11}	p_{21}	$q_1 = p_{11} + p_{21}$
2	p_{12}	p_{22}	$q_2 = p_{12} + p_{22}$
$\mathbb{P}_1$	$p_1 = p_{11} + p_{12}$	$p_2 = p_{21} + p_{22}$	

$\Rightarrow$

$\mathbb{F} := \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2$	1	2
1	$a_{11} = p_{11} - (p_{11} + p_{12})(p_{11} + p_{21})$	$a_{21} = p_{21} - (p_{21} + p_{22})(p_{11} + p_{21})$
2	$a_{12} = p_{12} - (p_{11} + p_{12})(p_{12} + p_{22})$	$a_{22} = p_{22} - (p_{21} + p_{22})(p_{12} + p_{22})$

Table 1: Joint ($\mathbb{P}$), joint minus product of the marginals ($\mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2$).

$\mathbb{P}$: $y\backslash x$	1	2	$\mathbb{P}_2$
1	$p_{11} = \frac{a[1-(a+b)]}{a+b}$	$p_{21} = a$	$q_1 = \frac{a}{a+b}$
2	$p_{12} = \frac{b[1-(a+b)]}{a+b}$	$p_{22} = b$	$q_2 = \frac{b}{a+b}$
$\mathbb{P}_1$	$p_1 = 1 - (a+b)$	$p_2 = a + b$	

Table 2: Family of probability distributions solving (17)–(19).

$$p_{12} - (p_{11} + p_{12})(p_{12} + p_{22}) + p_{21} - (p_{21} + p_{22})(p_{11} + p_{21}) = 0, \quad (19)$$

where $(p_{ij})_{i,j\in[2]}$ satisfy (17). Solving (17)–(19), we obtain

$$p_{11} = \frac{a[1-(a+b)]}{a+b}, \quad p_{12} = \frac{b[1-(a+b)]}{a+b}, \quad p_{21} = a \quad \text{and} \quad p_{22} = b,$$

with $0 \leq a, b \leq 1$, $a + b \leq 1$ and $(a, b) \neq \mathbf{0}$. The resulting distribution family with its marginals is summarized in Table 2. It can be seen that each member of this family (any a, b in the constraint set) factorizes: $\mathbb{P} = \mathbb{P}_1 \otimes \mathbb{P}_2$. In other words, $\mathbb{F} = \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2 = 0$; hence $k_1 \otimes k_2$ is $\mathcal{I}$-characteristic.

Remark. We would like to mention that while k_1 and k_2 are characteristic, they are not universal. Since $\mathcal{X}$ is finite, the usual notion of universality (also called c-universality) matches with c_0-universality. Therefore, from (10), we have $\int_{\mathcal{X}}\int_{\mathcal{X}} k(x,x')\,\mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x) = (a_1 - a_2)^2$ where $\mathbb{F} = a_1\delta_1 + a_2\delta_2$ for some $a_1, a_2 \in \mathbb{R}\backslash\{0\}$. Clearly, the choice of $a_1 = a_2$ establishes that there exists $\mathbb{F} \in \mathcal{M}_b(\mathcal{X})\backslash\{0\}$ such that $\int_{\mathcal{X}}\int_{\mathcal{X}} k(x,x')\,\mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x) = 0$. Hence k is not universal. Note that the constraint in (9), which is needed to verify the characteristic property of k is not needed to verify its universality.

5.3 Proof of Theorem 3

Define $\mathcal{H}_m := \mathcal{H}_{k_m}$.

(i) Suppose k_1 and k_2 are characteristic and that for some $\mathbb{F} = \mathbb{P} - \mathbb{P}_1 \otimes \mathbb{P}_2 \in \mathcal{I}$,

$$\mathcal{H}_1 \otimes \mathcal{H}_2 \ni \int_{\mathcal{X}_1 \times \mathcal{X}_2} (k_1 \otimes k_2)(\cdot, x) \, \mathrm{d}\mathbb{F}(x) = \int_{\mathcal{X}_1 \times \mathcal{X}_2} k_1(\cdot, x_1) \otimes k_2(\cdot, x_2) \, \mathrm{d}\mathbb{F}(x) = 0, \tag{20}$$

where $x = (x_1, x_2)$. We want to show that $\mathbb{F} = 0$. By the second-countability of $\mathcal{X}_m$-s, the product σ-field, i.e., $\otimes_{m=1}^2 \mathcal{B}(\mathcal{X}_m)$ generated by the cylinder sets $B_1 \times \mathcal{X}_2$ and $\mathcal{X}_1 \times B_2$ ($B_m \in \mathcal{B}(\mathcal{X}_m), m = 1, 2$), coincides with the Borel σ-field $\mathcal{B}(\mathcal{X}_1 \times \mathcal{X}_2)$ on the product space (Dudley, 2004, Lemma 4.1.7):

$$\otimes_{m=1}^2 \mathcal{B}(\mathcal{X}_m) = \mathcal{B}(\mathcal{X}_1 \times \mathcal{X}_2).$$

Hence, it is sufficient to prove that $\mathbb{F}(B_1 \times B_2) = 0$, $\forall B_m \in \mathcal{B}(\mathcal{X}_m)$, $m = 1, 2$. To this end, it follows from (20) that for all $h_2 \in \mathcal{H}_2$,

$$\mathcal{H}_1 \ni \int_{\mathcal{X}_1 \times \mathcal{X}_2} k_1(\cdot, x_1) h_2(x_2) \, \mathrm{d}\mathbb{F}(x) = \int_{\mathcal{X}_1} k_1(\cdot, x_1) \, \mathrm{d}\nu(x_1) = 0, \tag{21}$$

where

$$\nu(B_1) := \nu_{h_2}(B_1) = \int_{\mathcal{X}_1 \times \mathcal{X}_2} \chi_{B_1}(x_1) h_2(x_2) \, \mathrm{d}\mathbb{F}(x), \quad B_1 \in \mathcal{B}(\mathcal{X}_1).$$

Since k_1 is characteristic, (21) implies $\nu = 0$, provided that $|\nu|(\mathcal{X}_1) < \infty$ and $\nu(\mathcal{X}_1) = 0$. These two requirements hold:

$$\begin{aligned}
\nu(\mathcal{X}_1) &= \int_{\mathcal{X}_1 \times \mathcal{X}_2} h_2(x_2) \, \mathrm{d}\mathbb{F}(x) = \int_{\mathcal{X}_2} h_2(x_2) \, \mathrm{d}[\mathbb{P}_2 - \mathbb{P}_2](x_2) = 0, \\
|\nu|(\mathcal{X}_1) &\leq \int_{\mathcal{X}_1 \times \mathcal{X}_2} \underbrace{|h_2(x_2)|}_{\left|\langle h_2, k_2(\cdot, x_2) \rangle_{\mathcal{H}_2}\right|} \mathrm{d}[\mathbb{P} + \mathbb{P}_1 \otimes \mathbb{P}_2](x_1, x_2) \\
&\leq \|h_2\|_{\mathcal{H}_2} \int_{\mathcal{X}_1 \times \mathcal{X}_2} \sqrt{k_2(x_2, x_2)} \, \mathrm{d}[\mathbb{P} + \mathbb{P}_1 \otimes \mathbb{P}_2](x_1, x_2) \\
&\leq 2 \|h_2\|_{\mathcal{H}_2} \int_{\mathcal{X}_2} \sqrt{k_2(x_2, x_2)} \, \mathrm{d}\mathbb{P}_2(x_2) < \infty,
\end{aligned}$$

where the last inequality follows from the boundedness of k_2. The established $\nu = 0$ implies that for $\forall B_1 \in \mathcal{B}(\mathcal{X}_1)$ and $\forall h_2 \in \mathcal{H}_2$,

$$0 = \nu(B_1) = \left\langle h_2, \int_{\mathcal{X}_1 \times \mathcal{X}_2} \chi_{B_1}(x_1) k_2(\cdot, x_2) \, \mathrm{d}\mathbb{F}(x) \right\rangle_{\mathcal{H}_2},$$

and hence

$$0 = \int_{\mathcal{X}_1 \times \mathcal{X}_2} \chi_{B_1}(x_1) k_2(\cdot, x_2) \, \mathrm{d}\mathbb{F}(x) = \int_{\mathcal{X}_2} k_2(\cdot, x_2) \, \mathrm{d}\theta_{B_1}(x_2), \tag{22}$$

where

$$\theta_{B_1}(B_2) = \int_{\mathcal{X}_1 \times \mathcal{X}_2} \chi_{B_1}(x_1) \chi_{B_2}(x_2) \, \mathrm{d}\mathbb{F}(x), \quad B_2 \in \mathcal{B}(\mathcal{X}_2).$$

Using the characteristic property of k_2, it follows from (22) that $\theta_{B_1} = 0$ for $\forall B_1 \in \mathcal{B}(\mathcal{X}_1)$, i.e.,

$$0 = \theta_{B_1}(B_2) = \mathbb{F}(B_1 \times B_2), \quad \forall B_1 \in \mathcal{B}(\mathcal{X}_1), \forall B_2 \in \mathcal{B}(\mathcal{X}_2)$$

provided that $\theta_{B_1}(\mathcal{X}_2) = 0$ and $|\theta_{B_1}|(\mathcal{X}_2) < \infty$. Indeed, both these conditions hold:

$$\begin{aligned}
\theta_{B_1}(\mathcal{X}_2) &= \int_{\mathcal{X}_1 \times \mathcal{X}_2} \chi_{B_1}(x_1) \, \mathrm{d}\mathbb{F}(x) = \int_{\mathcal{X}_1} \chi_{B_1}(x_1) \, \mathrm{d}[\mathbb{P}_1 - \mathbb{P}_1](x_1) = 0, \\
|\theta_{B_1}|(\mathcal{X}_2) &\leq \int_{\mathcal{X}_1 \times \mathcal{X}_2} \mathrm{d}[\mathbb{P} + \mathbb{P}_1 \otimes \mathbb{P}_2](x) = 2.
\end{aligned}$$

(ii) Assume w.l.o.g. that k_1 is not characteristic. This means there exists $\mathbb{P}_1 \neq \mathbb{P}_1' \in \mathcal{M}_1^+(\mathcal{X}_1)$ such that $\mu_{k_1}(\mathbb{P}_1) = \mu_{k_1}(\mathbb{P}_1')$. Our goal is to construct an $\mathbb{F} \in \mathcal{M}_1^+\left(\times_{m=1}^M \mathcal{X}_m\right)$ such that

$$\mu_{\otimes_{m=1}^M k_m}\left(\mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m\right) = \int_{\times_{m=1}^M} \otimes_{m=1}^M k_m(\cdot, x_m) \, \mathrm{d}\left[\mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m\right] = 0, \text{ but } \mathbb{F} \neq \otimes_{m=1}^M \mathbb{F}_m.$$

Define $\mathbb{I} := \mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m \in \mathcal{I}$. In other words we want to get a witness $\mathbb{I} \in \mathcal{I}$ proving that $\otimes_{m=1}^M k_m$ is not $\mathcal{I}$-characteristic. Let us take $z \neq z' \in \mathcal{X}_2$, which is possible since $|\mathcal{X}_2| \geq 2$. Let us define $\mathbb{F}$ as[6]

$$\mathbb{F} = \frac{\mathbb{P}_1 \otimes \delta_z \otimes (\otimes_{m=3}^M \mathbb{Q}_m) + \mathbb{P}_1' \otimes \delta_{z'} \otimes (\otimes_{m=3}^M \mathbb{Q}_m)}{2} \in \mathcal{M}_1^+\left(\times_{m=1}^M \mathcal{X}_m\right).$$

It is easy to verify that

$$\mathbb{F}_1 = \frac{\mathbb{P}_1 + \mathbb{P}_1'}{2}, \; \mathbb{F}_2 = \frac{\delta_z + \delta_{z'}}{2} \text{ and } \mathbb{F}_m = \mathbb{Q}_m \quad (m = 3, \ldots, M),$$

where $\mathbb{Q}_3, \ldots, \mathbb{Q}_M$ are arbitrary probability measures on $\mathcal{X}_3, \ldots, \mathcal{X}_M$, respectively. First we check that $\mathbb{I} \neq 0$. Indeed it is the case since

- $z \neq z'$ and $\mathcal{X}_2$ is a Hausdorff space, there exists $B_2 \in \mathcal{B}(\mathcal{X}_2)$ such that $z \in B_2$, $z' \notin B_2$.
- $\mathbb{P}_1 \neq \mathbb{P}_1'$, $\mathbb{P}_1(B_1) \neq \mathbb{P}_1'(B_1)$ for some $B_1 \in \mathcal{B}(\mathcal{X}_1)$.

Let $S = B_1 \times B_2 \times \left(\times_{m=3}^M \mathcal{X}_m\right)$, and compare its measure under $\mathbb{F}$ and $\otimes_{m=1}^M \mathbb{F}_m$:

$$\begin{aligned}
\mathbb{F}(S) &= \frac{\mathbb{P}_1(B_1) \overbrace{\delta_z(B_2)}^{=1\,(z \in B_2)} \prod_{m=3}^M \overbrace{\mathbb{Q}_m(\mathcal{X}_m)}^{=1} + \mathbb{P}_1'(B_1) \overbrace{\delta_{z'}(B_2)}^{=0\,(z' \notin B_2)} \prod_{m=3}^M \overbrace{\mathbb{Q}_m(\mathcal{X}_m)}^{=1}}{2} \\
&= \frac{\mathbb{P}_1(B_1)}{2}, \\
\left(\otimes_{m=1}^M \mathbb{F}_m\right)(S) &= \prod_{m=1}^M \mathbb{F}_m(B_m) = \frac{\mathbb{P}_1(B_1) + \mathbb{P}_1'(B_1)}{2} \frac{\overbrace{\delta_z(B_2)}^{=1} + \overbrace{\delta_{z'}(B_2)}^{=0}}{2} \prod_{m=3}^M \overbrace{\mathbb{Q}_m(\mathcal{X}_m)}^{=1}
\end{aligned}$$

6. The $\mathbb{F}$ construction specializes to that of Lyons (2013, Proposition 3.15) in the $M = 2$ case; Lyons used it for distance covariances, which is known to be equivalent to HSIC (Sejdinovic et al., 2013b).

$$= \frac{\mathbb{P}_1(B_1) + \mathbb{P}'_1(B_1)}{4} \neq \frac{\mathbb{P}_1(B_1)}{2},$$

where the last equality holds since $\mathbb{P}_1(B_1) \neq \mathbb{P}'_1(B_1)$. This shows that $\mathbb{I} = \mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m \neq 0$ since $\mathbb{I}(S) \neq 0$.
Next we prove that $\mu_{\otimes_{m=1}^M k_m}\left(\mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m\right) = 0$. Indeed,

$$\begin{aligned}
\mu_{\otimes_{m=1}^M k_m}(\mathbb{I}) &= \int_{\times_{m=1}^M \mathcal{X}_m} \otimes_{m=1}^M k_m(\cdot, x_m)\, \mathrm{d}\left[\mathbb{F} - \otimes_{m=1}^M \mathbb{F}_m\right](x_1, \ldots, x_M) \\
&= \int_{\times_{m=1}^M \mathcal{X}_m} \otimes_{m=1}^M k_m(\cdot, x_m)\, \mathrm{d}\left(\left[\frac{\mathbb{P}_1 \otimes \delta_z + \mathbb{P}'_1 \otimes \delta_{z'}}{2} - \frac{\mathbb{P}_1 + \mathbb{P}'_1}{2} \otimes \frac{\delta_z + \delta_{z'}}{2}\right]\right. \\
&\qquad \left.\otimes \left(\otimes_{m=3}^M \mathbb{Q}_m\right)\right)(x_1, \ldots, x_M) \\
&= \int_{\times_{m=1}^M \mathcal{X}_m} \otimes_{m=1}^M k_m(\cdot, x_m)\, \mathrm{d}\left(\left[\frac{\mathbb{P}_1(x_1) \otimes \delta_z(x_2) + \mathbb{P}'_1(x_1) \otimes \delta_{z'}(x_2)}{2}\right.\right. \\
&\qquad - \frac{\mathbb{P}_1(x_1) \otimes \delta_z(x_2) + \mathbb{P}_1(x_1) \otimes \delta_{z'}(x_2)}{4} \\
&\qquad \left.\left. - \frac{\mathbb{P}'_1(x_1) \otimes \delta_z(x_2) + \mathbb{P}'_1(x_1) \otimes \delta_{z'}(x_2)}{4}\right] \otimes \left(\otimes_{m=3}^M \mathbb{Q}_m(x_m)\right)\right) \\
&\overset{(*)}{=} \left[\frac{\mu_{k_1}(\mathbb{P}_1) \otimes k_2(\cdot, z) + \mu_{k_1}(\mathbb{P}'_1) \otimes k_2(\cdot, z')}{2}\right. \\
&\qquad - \frac{\mu_{k_1}(\mathbb{P}_1) \otimes k_2(\cdot, z) + \mu_{k_1}(\mathbb{P}_1) \otimes k_2(\cdot, z')}{4} \\
&\qquad \left. - \frac{\mu_{k_1}(\mathbb{P}'_1) \otimes k_2(\cdot, z) + \mu_{k_1}(\mathbb{P}'_1) \otimes k_2(\cdot, z')}{4}\right] \otimes \left[\otimes_{m=3}^M \mu_{k_m}(\mathbb{Q}_m)\right] \\
&= \underbrace{0}_{\in \mathcal{H}_{k_1 \otimes k_2}} \otimes \left[\otimes_{m=3}^M \mu_{k_m}(\mathbb{Q}_m)\right] = 0,
\end{aligned}$$

where we used $\mu_{k_1}(\mathbb{P}_1) = \mu_{k_1}(\mathbb{P}'_1)$ in $(*)$.

5.4 Proof of Example 2

Let $M = 3$, $\times_{m=1}^M \mathcal{X}_m = \{(i_1, i_2, i_3) : i_m \in \{1, 2\},\, m \in [3]\}$, $k_m(x, x') = 2\delta_{x,x'} - 1$. Our goal is to show that $\otimes_{m=1}^3 k_m$ is *not* $\mathcal{I}$-characteristic. The structure of the proof is as follows:

1. First we describe the equations of the non-characteristic property of $\otimes_{m=1}^3 k_m$ with a general finite signed measure $\mathbb{F} = \sum_{i_1,i_2,i_3=1}^2 a_{i_1,i_2,i_3} \delta_{(i_1,i_2,i_3)}$ on $\times_{m=1}^3 \mathcal{X}_m$ where $a_{i_1,i_2,i_3} \in \mathbb{R}$ $(\forall\, i_1, i_2, i_3)$.
2. Next, we apply the $\mathbb{F} = \mathbb{P} - \otimes_{m=1}^3 \mathbb{P}_m$ parameterization and show that there exists $\mathbb{P}$ that satisfies the equations of step 1 to conclude that $\otimes_{m=1}^3 k_m$ is not $\mathcal{I}$-characteristic.

The details are as follows.

Step 1. The equations of non-characteristic property in terms of $\mathbf{A} = [a_{i_1,i_2,i_3}]_{(i_m)_{m=1}^3 \in [2]^3} \in \mathbb{R}^{2\times 2\times 2}$ are

$$\mathbb{F} \in \mathcal{M}_b\left(\times_{m=1}^3 \mathcal{X}_m\right) \setminus \{0\} \Leftrightarrow \mathbf{A} \neq \mathbf{0},$$

$$0 = \mathbb{F}(\times_{m=1}^3 \mathcal{X}_m) \Leftrightarrow 0 = \sum_{i_1,i_2,i_3=1}^2 a_{i_1,i_2,i_3}, \tag{23}$$

$$\begin{aligned}
0 &= \int_{\times_{m=1}^3 \mathcal{X}_m} \int_{\times_{m=1}^3 \mathcal{X}_m} \underbrace{\left(\otimes_{m=1}^3 k_m\right)\left((i_1, i_2, i_3), (i'_1, i'_2, i'_3)\right)}_{\Pi_{m=1}^3 k_m(i_m, i'_m)} \mathrm{d}\mathbb{F}(i_1, i_2, i_3)\, \mathrm{d}\mathbb{F}(i'_1, i'_2, i'_3) \\
&= \sum_{i_1,i_2,i_3=1}^2 \sum_{i'_1,i'_2,i'_3=1}^2 \prod_{m=1}^3 k_m(i_m, i'_m) a_{i_1,i_2,i_3} a_{i'_1,i'_2,i'_3}.
\end{aligned} \tag{24}$$

Solving (23) and (24) yields

$$a_{1,1,1} + a_{1,2,2} + a_{2,1,2} + a_{2,2,1} = 0 \quad \text{and} \quad a_{1,1,2} + a_{1,2,1} + a_{2,1,1} + a_{2,2,2} = 0.$$

Step 2. The equations of non $\mathcal{I}$-characteristic property can be obtained from step 1 by choosing $\mathbb{F} = \mathbb{P} - \otimes_{m=1}^M \mathbb{P}_m$, where

$$\mathbb{P} = \sum_{i_1,i_2,i_3=1}^2 p_{i_1,i_2,i_3} \delta_{(i_1,i_2,i_3)} \quad \text{and} \quad \mathbf{P} = [p_{i_1,i_2,i_3}]_{(i_m)_{m=1}^3 \in [2]^3} \in \mathbb{R}^{2\times 2\times 2}.$$

In other words, it is sufficient to obtain a $\mathbf{P}$ that solves the following system of equations for which $\mathbf{A} = \mathbf{A}(\mathbf{P}) \neq \mathbf{0}$:

$$\sum_{i_1,i_2,i_3=1}^2 p_{i_1,i_2,i_3} = 1, \tag{25}$$

$$p_{i_1,i_2,i_3} \geq 0,\ \forall\, (i_1, i_2, i_3) \in [2]^3, \tag{26}$$

$$a_{1,1,1} + a_{1,2,2} + a_{2,1,2} + a_{2,2,1} = 0, \tag{27}$$

$$a_{1,1,2} + a_{1,2,1} + a_{2,1,1} + a_{2,2,2} = 0, \tag{28}$$

where

$$a_{i_1,i_2,i_3} = p_{i_1,i_2,i_3} - p_{1,i_1} p_{2,i_2} p_{3,i_3}, \tag{29}$$

and

$$p_{1,i_1} = \sum_{i_2,i_3=1}^2 p_{i_1,i_2,i_3}, \quad p_{2,i_2} = \sum_{i_1,i_3=1}^2 p_{i_1,i_2,i_3}, \quad p_{3,i_3} = \sum_{i_1,i_2=1}^2 p_{i_1,i_2,i_3}. \tag{30}$$

One can get an analytical description for the solution of (25)–(30), where the solution $\mathbf{P}(\mathbf{z})$ is parameterized by $\mathbf{z} = (z_0, \ldots, z_5) \in \mathbb{R}^6$. For explicit expressions, we refer the reader to Appendix A. In the following, we present two examples of $\mathbf{P}$ that satisfy (25)–(30) such that $\mathbf{A} \neq \mathbf{0}$, thereby establishing the non $\mathcal{I}$-characteristic property of $\otimes_{m=1}^3 k_m$.

1. $\mathbf{P}$:

$$\begin{aligned}
p_{1,1,1} &= \frac{1}{5}, & p_{1,1,2} &= \frac{1}{10}, & p_{1,2,1} &= \frac{1}{10}, & p_{1,2,2} &= \frac{1}{10}, \\
p_{2,1,1} &= \frac{1}{5}, & p_{2,1,2} &= \frac{1}{10}, & p_{2,2,1} &= \frac{1}{10}, & p_{2,2,2} &= \frac{1}{10},
\end{aligned}$$

and **A**:

$$a_{1,1,1}=\frac{1}{50}, \quad a_{1,1,2}=-\frac{1}{50}, \quad a_{1,2,1}=-\frac{1}{50}, \quad a_{1,2,2}=\frac{1}{50}, \tag{31}$$
$$a_{2,1,1}=\frac{1}{50}, \quad a_{2,1,2}=-\frac{1}{50}, \quad a_{2,2,1}=-\frac{1}{50}, \quad a_{2,2,2}=\frac{1}{50}. \tag{32}$$

2. **P**:

$$p_{1,1,1}=0, \quad p_{1,1,2}=\frac{1}{10}, \quad p_{1,2,1}=\frac{1}{10}, \quad p_{1,2,2}=\frac{1}{10},$$
$$p_{2,1,1}=\frac{1}{10}, \quad p_{2,1,2}=\frac{1}{10}, \quad p_{2,2,1}=\frac{3}{10}, \quad p_{2,2,2}=\frac{1}{5},$$

and **A**:

$$a_{1,1,1}=-\frac{9}{200}, \quad a_{1,1,2}=\frac{11}{200}, \quad a_{1,2,1}=-\frac{1}{200}, \quad a_{1,2,2}=-\frac{1}{200},$$
$$a_{2,1,1}=-\frac{1}{200}, \quad a_{2,1,2}=-\frac{1}{200}, \quad a_{2,2,1}=\frac{11}{200}, \quad a_{2,2,2}=-\frac{9}{200}.$$

In fact these examples are obtained with the choices $\mathbf{z}=(\frac{1}{10},\frac{1}{10},\frac{1}{10},\frac{1}{10},\frac{1}{10},\frac{1}{10})$ and $\mathbf{z}=(\frac{3}{10},\frac{1}{10},\frac{1}{10},\frac{1}{10},\frac{1}{10},\frac{2}{10})$ respectively. See Appendix A for details.

5.5 Proof of Theorem 4

It follows from (8) and Remark 2(iii) that $(v)\Rightarrow(iii)\Rightarrow(ii)\Leftrightarrow(i)$. It also follows from (8) and Theorem 3(ii) that $(v)\Rightarrow(iv)\Rightarrow(i)$. We now show that $(i)\Rightarrow(v)$ which establishes the equivalence of (i)–(v). Suppose (i) holds. Then by Bochner's theorem (Wendland, 2005, Theorem 6.6), we have that for all $m\in[M]$,

$$k_m(x_m,y_m)=\int_{\mathbb{R}^{d_m}} e^{-\sqrt{-1}\langle\omega_m,x_m-y_m\rangle}\,\mathrm{d}\Lambda_m(\omega_m),\ x_m,y_m\in\mathbb{R}^{d_m},$$

where $(\Lambda_m)_{m=1}^M$ are finite non-negative Borel measures on $(\mathbb{R}^{d_m})_{m=1}^M$ respectively. This implies

$$\otimes_{m=1}^M k_m(x_m,y_m)=\otimes_{m=1}^M\int_{\mathbb{R}^{d_m}} e^{-\sqrt{-1}\langle\omega_m,x_m-y_m\rangle}\,\mathrm{d}\Lambda_m(\omega_m)=\int_{\mathbb{R}^d} e^{-\sqrt{-1}\langle\omega,x-y\rangle}\,\mathrm{d}\Lambda(\omega),$$

where $x=(x_1,\ldots,x_M)\in\mathbb{R}^d$, $y=(y_1,\ldots,y_M)\in\mathbb{R}^d$, $\omega=(\omega_1,\ldots,\omega_M)\in\mathbb{R}^d$, $d=\sum_{m=1}^M d_m$ and $\Lambda:=\otimes_{m=1}^M\Lambda_m$. Sriperumbudur et al. (2010, Theorem 9) showed that k_m is characteristic iff $\mathrm{supp}\,(\Lambda_m)=\mathbb{R}^{d_m}$, where $\mathrm{supp}(\cdot)$ denotes the support of its argument. Since $\mathrm{supp}(\Lambda)=\mathrm{supp}\left(\otimes_{m=1}^M\Lambda_m\right)=\times_{m=1}^M\mathrm{supp}\,(\Lambda_m)=\times_{m=1}^M\mathbb{R}^{d_m}=\mathbb{R}^d$, it follows that $\otimes_{m=1}^M k_m$ is characteristic.

5.6 Proof of Theorem 5

The c_0-kernel property of k_m-s $(m=1,\ldots,M)$ implies that of $\otimes_{m=1}^M k_m$. Moreover, $\mathcal{X}_m$-s are LCP spaces, hence $\times_{m=1}^M\mathcal{X}_m$ is also LCP.

($\Leftarrow$) Assume that $\otimes_{m=1}^M k_m$ is c_0-universal. Since $\otimes_{m=1}^M\mathcal{M}_b\left(\mathcal{X}_m\right)\subseteq\mathcal{M}_b\left(\times_{m=1}^M\mathcal{X}_m\right)$, we have that for all $\mathbb{F}=\otimes_{m=1}^M\mathbb{F}_m\in\otimes_{m=1}^M\mathcal{M}_b(\mathcal{X}_m)\backslash\{0\}$,

$$0<\int_{\times_{m=1}^M\mathcal{X}_m}\int_{\times_{m=1}^M\mathcal{X}_m}\underbrace{\left(\otimes_{m=1}^M k_m\right)(x,x')}_{\prod_{m=1}^M k_m(x_m,x'_m)}\mathrm{d}\mathbb{F}(x)\,\mathrm{d}\mathbb{F}(x')$$
$$=\prod_{m=1}^M\int_{\mathcal{X}_m\times\mathcal{X}_m} k_m(x_m,x'_m)\,\mathrm{d}\mathbb{F}_m(x_m)\,\mathrm{d}\mathbb{F}_m\left(x'_m\right),$$

where $x=(x_1,\ldots,x_M)$ and $x'=(x'_1,\ldots,x'_M)$. The above inequality implies

$$\int_{\mathcal{X}_m\times\mathcal{X}_m} k_m(x_m,x'_m)\,\mathrm{d}\mathbb{F}_m(x_m)\,\mathrm{d}\mathbb{F}_m\left(x'_m\right)>0,\ \forall\, m\in[M].$$

Since $\mathbb{F}\in\otimes_{m=1}^M\mathcal{M}_b\left(\mathcal{X}_m\right)\backslash\{0\}$ iff $\mathbb{F}_m\in\mathcal{M}_b(\mathcal{X}_m)\backslash\{0\}$ for all $m\in[M]$, the result follows.

($\Rightarrow$) Assume that k_m-s are c_0-universal. By the note above $\otimes_{m=1}^M k_m$ is c_0-kernel; its c_0-universality is equivalent to the injectivity of $\mu=\mu_{\otimes_{m=1}^M k_m}$ on $\mathcal{M}_b\left(\times_{m=1}^M\mathcal{X}_m\right)$. In other words, we want to prove that $\mu(\mathbb{F})=0$ implies $\mathbb{F}=0$, where $\mathbb{F}\in\mathcal{M}_b\left(\times_{m=1}^M\mathcal{X}_m\right)$. We will use the shorthand $\mathcal{H}_m=\mathcal{H}_{k_m}$ below.

Suppose there exists $\mathbb{F}\in\mathcal{M}_b\left(\times_{m=1}^M\mathcal{X}_m\right)$ such that

$$\mu_{\mathbb{F}}=\int_{\times_{m=1}^M\mathcal{X}_m}\underbrace{\left(\otimes_{m=1}^M k_m\right)(\cdot,x)}_{\otimes_{m=1}^M k_m(\cdot,x_m)}\mathrm{d}\mathbb{F}(x)=0\ (\in\otimes_{m=1}^M\mathcal{H}_m). \tag{33}$$

Since $\mathcal{X}_m$-s are LCP, $\otimes_{m=1}^M\mathcal{B}\left(\mathcal{X}_m\right)=\mathcal{B}\left(\times_{m=1}^M\mathcal{X}_m\right)$ (Steinwart and Christmann, 2008, page 480). Hence, in order to get $\mathbb{F}=0$ it is sufficient to prove that

$$\mathbb{F}\left(\times_{m=1}^M B_m\right)=0,\quad \forall\, B_m\in\mathcal{B}(\mathcal{X}_m), m\in[M].$$

We will prove by induction that for $m=0,\ldots,M$

$$\left(\otimes_{j=m+1}^M\mathcal{H}_j\ni\right)0=\int_{\times_{j=1}^M\mathcal{X}_j}\prod_{j=1}^m\chi_{B_j}(x_j)\otimes_{j=m+1}^M k_j(\cdot,x_j)\,\mathrm{d}\mathbb{F}(x)$$
$$=:o(B_1,\ldots,B_m,k_{m+1},\ldots,k_M),\forall\, B_j\in\mathcal{B}(\mathcal{X}_j),\ j\in[m], \tag{34}$$

which

- $(*)$ reduces to (33) when $m=0$ by defining $\prod_{j=1}^0\chi_{B_j}(x_j):=1$;
- $(\dagger)$ for $m=M$, $\otimes_{m=M+1}^M\mathcal{H}_m$ is defined to be equal to $\mathbb{R}$ and $\otimes_{m=M+1}^M k_m(\cdot,x_m):=1$, in which case $o(B_1,\ldots,B_M)=\mathbb{F}\left(\times_{j=1}^M B_j\right)=0\Rightarrow\mathbb{F}=0$, the result we want to prove.

From the above, it is clear that (34) holds for $m=0$. Assuming (34) holds for some m, we now prove that it holds for $m+1$. To this end, it follows from (34) that $\forall\, h_{m+2}\in\mathcal{H}_{m+2},\ldots,\forall\, h_M\in\mathcal{H}_M$,

$$\left(\mathcal{H}_{m+1}\ni\right)0=o(B_1,\ldots,B_m,k_{m+1},\ldots,k_M)\,(h_{m+2},\ldots,h_M)$$

$$= \left[\int_{\times_{j=1}^M \mathcal{X}_j} \left(\prod_{j=1}^m \chi_{B_j}(x_j)\right) \otimes_{j=m+1}^M k_j(\cdot, x_j)\,\mathrm{d}\mathbb{F}(x)\right](h_{m+2}, \ldots, h_M)$$
$$= \int_{\times_{j=1}^M \mathcal{X}_j} k_{m+1}(\cdot, x_{m+1}) \prod_{j=1}^m \chi_{B_j}(x_j) \prod_{j=m+2}^M h_j(x_j)\,\mathrm{d}\mathbb{F}(x)$$
$$= \int_{\mathcal{X}_{m+1}} k_{m+1}(\cdot, x_{m+1})\,\mathrm{d}\nu(x_{m+1}),$$

where

$$\nu(B) := \nu_{B_1,\ldots,B_m,h_{m+2},\ldots,h_M}(B)$$
$$= \int_{\times_{j=1}^M \mathcal{X}_j} \left[\prod_{j=1}^m \chi_{B_j}(x_j)\right] \chi_B(x_{m+1}) \left[\prod_{j=m+2}^M h_j(x_j)\right] \mathrm{d}\mathbb{F}(x),\ B \in \mathcal{B}(\mathcal{X}_{m+1}).$$

By the c_0-universality of k_{m+1},

$$\nu = 0 \text{ for } \forall\, h_{m+2} \in \mathcal{H}_{m+2}, \ldots, \forall\, h_M \in \mathcal{H}_M \tag{35}$$

provided that $\nu \in \mathcal{M}_b(\mathcal{X}_{m+1})$, in other words if $|\nu|(\mathcal{X}_{m+1}) < \infty$. This condition is met:

$$|\nu|(\mathcal{X}_{m+1}) \le \int_{\times_{j=1}^M \mathcal{X}_j} \prod_{j=m+2}^M \underbrace{\left|\langle h_j, k_j(\cdot, x_j)\rangle_{\mathcal{H}_j}\right|}_{\le \|h_j\|_{\mathcal{H}_j}\sqrt{k_j(x_j,x_j)}} \mathrm{d}|\mathbb{F}|(x)$$
$$\le |\mathbb{F}|\left(\times_{m=1}^M \mathcal{X}_m\right) \prod_{j=m+2}^M \|h_j\|_{\mathcal{H}_j} \sup_{x\in\mathcal{X}_j, x'\in\mathcal{X}_j} \sqrt{k_j(x,x')} < \infty,$$

where we used the boundedness of k_m-s in the last inequality. (35) implies that for $\forall\, B_1 \in \mathcal{B}(\mathcal{X}_1), \ldots, \forall\, B_{m+1} \in \mathcal{B}(\mathcal{X}_{m+1})$ and $\forall\, h_{m+2} \in \mathcal{H}_{m+2}, \ldots, \forall\, h_M \in \mathcal{H}_M$

$$0 = \nu(B_{m+1}) = \int_{\times_{j=1}^M \mathcal{X}_j} \left[\prod_{j=1}^{m+1} \chi_{B_j}(x_j)\right] \left[\prod_{j=m+2}^M h_j(x_j)\right] \mathrm{d}\mathbb{F}(x)$$
$$= \left\langle \otimes_{j=m+2}^M h_j, \int_{\times_{j=1}^M \mathcal{X}_j} \left[\prod_{j=1}^{m+1} \chi_{B_j}(x_j)\right] \otimes_{j=m+2}^M k_j(\cdot, x_j)\,\mathrm{d}\mathbb{F}(x)\right\rangle_{\otimes_{j=m+2}^M \mathcal{H}_j},$$

and therefore

$$o(B_1, \ldots, B_{m+1}, k_{m+2}, \ldots, k_M) = \int_{\times_{j=1}^M \mathcal{X}_j} \left[\prod_{j=1}^{m+1} \chi_{B_j}(x_j)\right] \otimes_{j=m+2}^M k(\cdot, x_j)\,\mathrm{d}\mathbb{F}(x)$$
$$= 0\left(\in \otimes_{j=m+2}^M \mathcal{H}_j\right)$$

for $\forall\, B_1 \in \mathcal{B}(\mathcal{X}_1), \ldots, \forall\, B_{m+1} \in \mathcal{B}(\mathcal{X}_{m+1})$, i.e., (34) holds for $m+1$. Therefore, by induction, (34) holds for $m = M$ and the result follows from (†). To justify the convention in (†), consider the case of $m = M-1$ in which case (34) can be written as

$$\int_{\mathcal{X}_M} k_M(\cdot, x_M)\,\mathrm{d}\nu(x_M) = 0,$$

where

$$\nu(B) = \int_{\times_{j=1}^M \mathcal{X}_j} \left[\prod_{j=1}^{M-1} \chi_{B_j}(x_j)\right] \chi_B(x_M)\,\mathrm{d}\mathbb{F}(x),\ B \in \mathcal{B}(\mathcal{X}_M).$$

Then by the c_0-universal property of k_M, since

$$|\nu|(\mathcal{X}_M) \le \int_{\times_{j=1}^M \mathcal{X}_j} 1\,\mathrm{d}|\mathbb{F}|(x) = |\mathbb{F}|\left(\times_{j=1}^M \mathcal{X}_j\right) < \infty$$

we obtain

$$\int_{\times_{j=1}^M \mathcal{X}_j} \prod_{j=1}^M \chi_{B_j}(x_j)\,\mathrm{d}\mathbb{F}(x) = \mathbb{F}\left(\times_{j=1}^M B_j\right) = 0, \forall\, B_1 \in \mathcal{B}(\mathcal{X}_1), \ldots, \forall\, B_M \in \mathcal{B}(\mathcal{X}_M).$$

5.7 Proof of Example 3

The proof follows by a simple modification of that of Example 2 (Section 5.4). The equations of a witness $\mathbf{A} = [a_{i_1,i_2,i_3}]_{(i_m)_{m=1}^3 \in [2]^3}$ (and corresponding $\mathbf{P} = [p_{i_1,i_2,i_3}]_{(i_m)_{m=1}^3 \in [2]^3}$) for the non-$\mathcal{I}$-characteristic property of $\otimes_{m=1}^3 k_m$ take the form:

$$\mathbf{A} \ne \mathbf{0},$$
$$0 = \sum_{i_1,i_2,i_3=1}^2 a_{i_1,i_2,i_3}, \tag{36}$$
$$0 = \sum_{i_1,i_2,i_3=1}^2 \sum_{i_1',i_2',i_3'=1}^2 \prod_{m=1}^3 k_m(i_m, i_m') a_{i_1,i_2,i_3} a_{i_1',i_2',i_3'}$$
$$= (a_{1,1,1} - a_{2,1,1})^2 + (a_{1,1,2} - a_{2,1,2})^2 + (a_{1,2,1} - a_{2,2,1})^2 + (a_{1,2,2} - a_{2,2,2})^2, \tag{37}$$

where (36) and (37) are equivalent to

$$0 = \sum_{i_1,i_2,i_3=1}^2 a_{i_1,i_2,i_3},\quad a_{1,1,1} = a_{2,1,1},\quad a_{1,1,2} = a_{2,1,2},\quad a_{1,2,1} = a_{2,2,1},\quad a_{1,2,2} = a_{2,2,2}. \tag{38}$$

While (38) is more restrictive than (27) and (28) (hence its solution set might even be empty), one can immediately see that the example of $\mathbf{A} \ne \mathbf{0}$ given in (31) and (32) fulfills (38) proving the non-$\mathcal{I}$-characteristic property of $\otimes_{m=1}^3 k_m$.

Acknowledgments

The authors profusely thank Ingo Steinwart for fascinating discussions on topics related to the paper and for contributing to Remark 7. The authors also thank the anonymous reviewers for their constructive comments that improved the manuscript. A part of the work was carried out while BKS was visiting ZSz at CMAP, École Polytechnique. BKS is supported by NSF-DMS-1713011 and also thanks CMAP and DSI for their generous support. ZSz is highly grateful for the Greek hospitality around the Aegean Sea; it greatly contributed to the development of the induction arguments.

Appendix A. Analytical Solution to (25)–(30) in Example 2

The solution of (25)–(30) takes the form

$$p_{1,1,1} = -\frac{\begin{array}{l} z_2+z_1+z_4+z_5-3z_2z_1-4z_2z_4-4z_1z_4-z_2z_3-2z_2z_0-2z_1z_3-3z_2z_5 \\ -2z_4z_3-z_1z_0-3z_1z_5-2z_4z_0-4z_4z_5-z_3z_0-z_3z_5-z_0z_5+2z_2z_1^2+2z_2^2z_1 \\ +4z_2z_4^2+2z_2^2z_4+4z_1z_4^2+2z_1^2z_4+2z_2^2z_0+2z_1^2z_3+2z_2z_5^2+2z_2^2z_5+2z_4^2z_3 \\ +2z_1z_5^2+2z_1^2z_5+2z_4^2z_0+2z_4z_5^2+4z_4^2z_5-z_2^2-z_1^2-3z_4^2+2z_4^3-z_5^2 \\ +6z_2z_1z_4+2z_2z_1z_3+2z_2z_4z_3+2z_2z_1z_0+4z_2z_1z_5+4z_2z_4z_0+4z_1z_4z_3 \\ +6z_2z_4z_5+2z_1z_4z_0+6z_1z_4z_5+2z_2z_3z_0+2z_2z_3z_5+2z_1z_3z_0+2z_2z_0z_5 \\ +2z_1z_3z_5+2z_4z_3z_0+2z_4z_3z_5+2z_1z_0z_5+2z_4z_0z_5 \end{array}}{\begin{array}{l} 2z_2z_1-z_1-2z_4-z_3-z_0-2z_5-z_2+2z_2z_4+2z_1z_4+2z_2z_0+2z_1z_3+2z_2z_5 \\ +2z_4z_3+2z_1z_5+2z_4z_0+4z_4z_5+2z_3z_0+2z_3z_5+2z_0z_5+2z_4^2+2z_5^2 \end{array}},$$

Abstract

We present the design and implementation of a custom discrete optimization technique for building rule lists over a categorical feature space. Our algorithm produces rule lists with optimal training performance, according to the regularized empirical risk, with a certificate of optimality. By leveraging algorithmic bounds, efficient data structures, and computational reuse, we achieve several orders of magnitude speedup in time and a massive reduction of memory consumption. We demonstrate that our approach produces optimal rule lists on practical problems in seconds. Our results indicate that it is possible to construct optimal sparse rule lists that are approximately as accurate as the COMPAS proprietary risk prediction tool on data from Broward County, Florida, but that are completely interpretable. This framework is a novel alternative to CART and other decision tree methods for interpretable modeling.

Keywords: rule lists, decision trees, optimization, interpretable models, criminal justice applications

1. Introduction

As machine learning continues to gain prominence in socially-important decision-making, the interpretability of predictive models remains a crucial problem. Our goal is to build models that are highly predictive, transparent, and easily understood by humans. We use rule lists, also known as decision lists, to achieve this goal. Rule lists are predictive models composed of if-then statements; these models are interpretable because the rules provide a reason for each prediction (Figure 1).

Constructing rule lists, or more generally, decision trees, has been a challenge for more than 30 years; most approaches use greedy splitting techniques (Rivest, 1987; Breiman et al., 1984; Quinlan, 1993). Recent approaches use Bayesian analysis, either to find a locally optimal solution (Chipman et al., 1998) or to explore the search space (Letham et al., 2015;

if $(age = 18-20)$ **and** $(sex = male)$ **then predict** *yes*
else if $(age = 21-23)$ **and** $(priors = 2-3)$ **then predict** *yes*
else if $(priors > 3)$ **then predict** *yes*
else predict *no*

Figure 1: An example rule list that predicts two-year recidivism for the ProPublica data set, found by CORELS.

Yang et al., 2017). These approaches achieve high accuracy while also managing to run reasonably quickly. However, despite the apparent accuracy of the rule lists generated by these algorithms, there is no way to determine either if the generated rule list is optimal or how close it is to optimal, where optimality is defined with respect to minimization of a regularized loss function.

Optimality is important, because there are societal implications for a lack of optimality. Consider the ProPublica article on the Correctional Offender Management Profiling for Alternative Sanctions (COMPAS) recidivism prediction tool (Larson et al., 2016). It highlights a case where a black box, proprietary predictive model is being used for recidivism prediction. The authors hypothesize that the COMPAS scores are racially biased, but since the model is not transparent, no one (outside of the creators of COMPAS) can determine the reason or extent of the bias (Larson et al., 2016), nor can anyone determine the reason for any particular prediction. By using COMPAS, users implicitly assumed that a transparent model would not be sufficiently accurate for recidivism prediction, *i.e.*, they assumed that a black box model would provide better accuracy. We wondered whether there was indeed no transparent and sufficiently accurate model. Answering this question requires solving a computationally hard problem. Namely, we would like to both find a transparent model that is optimal within a particular pre-determined class of models and produce a certificate of its optimality, with respect to the regularized empirical risk. This would enable one to say, for this problem and model class, with certainty and before resorting to black box methods, whether there exists a transparent model. While there may be differences between training and test performance, finding the simplest model with optimal training performance is prescribed by statistical learning theory.

To that end, we consider the class of rule lists assembled from pre-mined frequent itemsets and search for an optimal rule list that minimizes a regularized risk function, R. This is a hard discrete optimization problem. Brute force solutions that minimize R are computationally prohibitive due to the exponential number of possible rule lists. However, this is a worst case bound that is not realized in practical settings. For realistic cases, it is possible to solve fairly large cases of this problem to optimality, with the careful use of algorithms, data structures, and implementation techniques.

We develop specialized tools from the fields of discrete optimization and artificial intelligence. Specifically, we introduce a special branch-and bound algorithm, called Certifiably Optimal RulE ListS (CORELS), that provides the optimal solution according to the training objective, along with a certificate of optimality. The certificate of optimality means that we can investigate how close other models (*e.g.*, models provided by greedy algorithms) are to optimal.

Within its branch-and-bound procedure, CORELS maintains a lower bound on the minimum value of R that each incomplete rule list can achieve. This allows CORELS to prune an incomplete rule list (and every possible extension) if the bound is larger than the error of the best rule list that it has already evaluated. The use of careful bounding techniques leads to massive pruning of the search space of potential rule lists. The algorithm continues to consider incomplete and complete rule lists until it has either examined or eliminated every rule list from consideration. Thus, CORELS terminates with the optimal rule list and a certificate of optimality.

The efficiency of CORELS depends on how much of the search space our bounds allow us to prune; we seek a tight lower bound on R. The bound we maintain throughout execution is a maximum of several bounds that come in three categories. The first category of bounds are those intrinsic to the rules themselves. This category includes bounds stating that each rule must capture sufficient data; if not, the rule list is provably non-optimal. The second type of bound compares a lower bound on the value of R to that of the current best solution. This allows us to exclude parts of the search space that could never be better than our current solution. Finally, our last type of bound is based on comparing incomplete rule lists that capture the same data and allows us to pursue only the most accurate option. This last class of bounds is especially important—without our use of a novel *symmetry-aware map*, we are unable to solve most problems of reasonable scale. This symmetry-aware map keeps track of the best accuracy over all observed permutations of a given incomplete rule list.

We keep track of these bounds using a modified *prefix tree*, a data structure also known as a trie. Each node in the prefix tree represents an individual rule; thus, each path in the tree represents a rule list such that the final node in the path contains metrics about that rule list. This tree structure, together with a search policy and sometimes a queue, enables a variety of strategies, including breadth-first, best-first, and stochastic search. In particular, we can design different best-first strategies by customizing how we order elements in a priority queue. In addition, we are able to limit the number of nodes in the trie and thereby enable tuning of space-time tradeoffs in a robust manner. This trie structure is a useful way of organizing the generation and evaluation of rule lists.

We evaluated CORELS on a number of publicly available data sets. Our metric of success was 10-fold cross-validated prediction accuracy on a subset of the data. These data sets involve hundreds of rules and thousands of observations. CORELS is generally able to find an optimal rule list in a matter of seconds and certify its optimality within about 10 minutes. We show that we are able to achieve better or similar out-of-sample accuracy on these data sets compared to the popular greedy algorithms, CART and C4.5.

CORELS targets large (not massive) problems, where interpretability and certifiable optimality are important. We illustrate the efficacy of our approach using (1) the ProPublica COMPAS data set (Larson et al., 2016), for the problem of two-year recidivism prediction, and (2) stop-and-frisk data sets from the NYPD (New York Police Department, 2016) and the NYCLU (New York Civil Liberties Union, 2014), to predict whether a weapon will be found on a stopped individual who is frisked or searched. On these data, we produce certifiably optimal, interpretable rule lists that achieve the same accuracy as approaches such as random forests. This calls into question the need for use of a proprietary, black box algorithm for recidivism prediction.

Our work overlaps with the thesis of Larus-Stone (2017). We have also written a preliminary conference version of this article (Angelino et al., 2017), and a report highlighting systems optimizations of our implementation (Larus-Stone et al., 2018); the latter includes additional empirical measurements not presented here.

Our code is at `https://github.com/nlarusstone/corels`, where we provide the C++ implementation we used in our experiments (§6). Kaxiras and Saligrama (2018) have also created an interactive web interface at `https://corels.eecs.harvard.edu`, where a user can upload data and run CORELS from a browser.

2. Related Work

Since every rule list is a decision tree and every decision tree can be expressed as an equivalent rule list, the problem we are solving is a version of the "optimal decision tree" problem, though regularization changes the nature of the problem (as shown through our bounds). The optimal decision tree problem is computationally hard, though since the late 1990's, there has been research on building optimal decision trees using optimization techniques (Bennett and Blue, 1996; Dobkin et al., 1996; Farhangfar et al., 2008). A particularly interesting paper along these lines is that of Nijssen and Fromont (2010), who created a "bottom-up" way to form optimal decision trees. Their method performs an expensive search step, mining all possible leaves (rather than all possible rules), and uses those leaves to form trees. Their method can lead to memory problems, but it is possible that these memory issues can be mitigated using the theorems in this paper.[1] None of these methods used the tight bounds and data structures of CORELS.

Because the optimal decision tree problem is hard, there are a huge number of algorithms such as CART (Breiman et al., 1984) and C4.5 (Quinlan, 1993) that do not perform exploration of the search space beyond greedy splitting. Similarly, there are decision list and associative classification methods that construct rule lists iteratively in a greedy way (Rivest, 1987; Liu et al., 1998; Li et al., 2001; Yin and Han, 2003; Sokolova et al., 2003; Marchand and Sokolova, 2005; Vanhoof and Depaire, 2010; Rudin et al., 2013). Some exploration of the search space is done by Bayesian decision tree methods (Dension et al., 1998; Chipman et al., 2002, 2010) and Bayesian rule-based methods (Letham et al., 2015; Yang et al., 2017). The space of trees of a given depth is much larger than the space of rule lists of that same depth, and the trees within the Bayesian tree algorithms are grown in a top-down greedy way. Because of this, authors of Bayesian tree algorithms have noted that their MCMC chains tend to reach only locally optimal solutions. The RIPPER algorithm (Cohen, 1995) is similar to the Bayesian tree methods in that it grows, prunes, and then locally optimizes. The space of rule lists is smaller than that of trees, and has simpler structure. Consequently, Bayesian rule list algorithms tend to be more successful at escaping local minima and can introduce methods of exploring the search space that exploit this structure—these properties motivate our focus on lists. That said, the tightest bounds for the Bayesian lists (namely, those of Yang et al., 2017, upon whose work we build), are not nearly as tight as those of CORELS.

1. There is no public version of their code for distribution as of this writing.

Tight bounds, on the other hand, have been developed for the (immense) literature on building disjunctive normal form (DNF) models; a good example of this is the work of Rijnbeek and Kors (2010). For models of a given size, since the class of DNF's is a proper subset of decision lists, our framework can be restricted to learn optimal DNF's. The field of DNF learning includes work from the fields of rule learning/induction (*e.g.*, early algorithms by Michalski, 1969; Clark and Niblett, 1989; Frank and Witten, 1998) and associative classification (Vanhoof and Depaire, 2010). Most papers in these fields aim to carefully guide the search through the space of models. If we were to place a restriction on our code to learn DNF's, which would require restricting predictions within the list to the positive class only, we could potentially use methods from rule learning and associative classification to help order CORELS' queue, which would in turn help us eliminate parts of the search space more quickly.

Some of our bounds, including the minimum support bound (§3.7, Theorem 10), come from Rudin and Ertekin (2016), who provide flexible mixed-integer programming (MIP) formulations using the same objective as we use here; MIP solvers in general cannot compete with the speed of CORELS.

CORELS depends on pre-mined rules, which we obtain here via enumeration. The literature on association rule mining is huge, and any method for rule mining could be reasonably substituted.

CORELS' main use is for producing interpretable predictive models. There is a growing interest in interpretable (transparent, comprehensible) models because of their societal importance (see Rüping, 2006; Bratko, 1997; Dawes, 1979; Vellido et al., 2012; Giraud-Carrier, 1998; Holte, 1993; Shmueli, 2010; Huysmans et al., 2011; Freitas, 2014). There are now regulations on algorithmic decision-making in the European Union on the "right to an explanation" (Goodman and Flaxman, 2016) that would legally require interpretability of predictions. There is work in both the DNF literature (Rückert and Raedt, 2008) and decision tree literature (Garofalakis et al., 2000) on building interpretable models. Interpretable models must be so sparse that they need to be heavily optimized; heuristics tend to produce either inaccurate or non-sparse models.

Interpretability has many meanings, and it is possible to extend the ideas in this work to other definitions of interpretability; these rule lists may have exotic constraints that help with ease-of-use. For example, Falling Rule Lists (Wang and Rudin, 2015a) are constrained to have decreasing probabilities down the list, which makes it easier to assess whether an observation is in a high risk subgroup. In parallel to this paper, we have been working on an algorithm for Falling Rule Lists (Chen and Rudin, 2018) with bounds similar to those presented here, but even CORELS' basic support bounds do not hold for the falling case, which is much more complicated. One advantage of the approach taken by Chen and Rudin (2018) is that it can handle class imbalance by weighting the positive and negative classes differently; this extension is possible in CORELS but not addressed here.

The models produced by CORELS are predictive only; they cannot be used for policy-making because they are not causal models, they do not include the costs of true and false positives, nor the cost of gathering information. It is possible to adapt CORELS' framework for causal inference (Wang and Rudin, 2015b), dynamic treatment regimes (Zhang et al., 2015), or cost-sensitive dynamic treatment regimes (Lakkaraju and Rudin, 2017) to

if $(age = 18-20)$ **and** $(sex = male)$ **then predict** *yes*	**if** p_1 **then predict** q_1
else if $(age = 21-23)$ **and** $(priors = 2-3)$ **then predict** *yes*	**else if** p_2 **then predict** q_2
else if $(priors > 3)$ **then predict** *yes*	**else if** p_3 **then predict** q_3
else predict *no*	**else predict** q_0

Figure 2: The rule list $d = (r_1, r_2, r_3, r_0)$. Each rule is of the form $r_k = p_k \rightarrow q_k$, for all $k = 0, \ldots, 3$. We can also express this rule list as $d = (d_p, \delta_p, q_0, K)$, where $d_p = (p_1, p_2, p_3)$, $\delta_p = (1, 1, 1, 1)$, $q_0 = 0$, and $K = 3$. This is the same 3-rule list as in Figure 1, that predicts two-year recidivism for the ProPublica data set.

help with policy design. CORELS could potentially be adapted to handle these kinds of interesting problems.

3. Learning Optimal Rule Lists

In this section, we present our framework for learning certifiably optimal rule lists. First, we define our setting and useful notation (§3.1) and then the objective function we seek to minimize (§3.2). Next, we describe the principal structure of our optimization algorithm (§3.3), which depends on a hierarchically structured objective lower bound (§3.4). We then derive a series of additional bounds that we incorporate into our algorithm, because they enable aggressive pruning of our state space.

3.1 Notation

We restrict our setting to binary classification, where rule lists are Boolean functions; this framework is straightforward to generalize to multi-class classification. Let $\{(x_n, y_n)\}_{n=1}^N$ denote training data, where $x_n \in \{0,1\}^J$ are binary features and $y_n \in \{0,1\}$ are labels. Let $\mathbf{x} = \{x_n\}_{n=1}^N$ and $\mathbf{y} = \{y_n\}_{n=1}^N$, and let $x_{n,j}$ denote the j-th feature of x_n.

A rule list $d = (r_1, r_2, \ldots, r_K, r_0)$ of length $K \geq 0$ is a $(K+1)$-tuple consisting of K distinct association rules, $r_k = p_k \rightarrow q_k$, for $k = 1, \ldots, K$, followed by a default rule r_0. Figure 2 illustrates a rule list, $d = (r_1, r_2, r_3, r_0)$, which for clarity, we sometimes call a K-rule list. An association rule $r = p \rightarrow q$ is an implication corresponding to the conditional statement, "if p, then q." In our setting, an antecedent p is a Boolean assertion that evaluates to either true or false for each datum x_n, and a consequent q is a label prediction. For example, $(x_{n,1} = 0) \wedge (x_{n,3} = 1) \rightarrow (y_n = 1)$ is an association rule. The final default rule r_0 in a rule list can be thought of as a special association rule $p_0 \rightarrow q_0$ whose antecedent p_0 simply asserts true.

Let $d = (r_1, r_2, \ldots, r_K, r_0)$ be a K-rule list, where $r_k = p_k \rightarrow q_k$ for each $k = 0, \ldots, K$. We introduce a useful alternate rule list representation: $d = (d_p, \delta_p, q_0, K)$, where we define $d_p = (p_1, \ldots, p_K)$ to be d's prefix, $\delta_p = (q_1, \ldots, q_K) \in \{0,1\}^K$ gives the label predictions associated with d_p, and $q_0 \in \{0,1\}$ is the default label prediction. For example, for the rule list in Figure 1, we would write $d = (d_p, \delta_p, q_0, K)$, where $d_p = (p_1, p_2, p_3)$, $\delta_p = (1, 1, 1)$, $q_0 = 0$, and $K = 3$. Note that $((), (), q_0, 0)$ is a well-defined rule list with an empty prefix; it is completely defined by a single default rule.

Let $d_p = (p_1, \ldots, p_k, \ldots, p_K)$ be an antecedent list, then for any $k \leq K$, we define $d_p^k = (p_1, \ldots, p_k)$ to be the k-prefix of d_p. For any such k-prefix d_p^k, we say that d_p starts with d_p^k.

For any given space of rule lists, we define $\sigma(d_p)$ to be the set of all rule lists whose prefixes start with d_p:

$$\sigma(d_p) = \{(d'_p, \delta'_p, q'_0, K') : d'_p \text{ starts with } d_p\}. \tag{1}$$

If $d_p = (p_1, \ldots, p_K)$ and $d'_p = (p_1, \ldots, p_K, p_{K+1})$ are two prefixes such that d'_p starts with d_p and extends it by a single antecedent, we say that d_p is the parent of d'_p and that d'_p is a child of d_p.

A rule list d classifies datum x_n by providing the label prediction q_k of the first rule r_k whose antecedent p_k is true for x_n. We say that an antecedent p_k of antecedent list d_p captures x_n in the context of d_p if p_k is the first antecedent in d_p that evaluates to true for x_n. We also say that a prefix captures those data captured by its antecedents; for a rule list $d = (d_p, \delta_p, q_0, K)$, data not captured by the prefix d_p are classified according to the default label prediction q_0.

Let β be a set of antecedents. We define $\text{cap}(x_n, \beta) = 1$ if an antecedent in β captures datum x_n, and 0 otherwise. For example, let d_p and d'_p be prefixes such that d'_p starts with d_p, then d'_p captures all the data that d_p captures:

$$\{x_n : \text{cap}(x_n, d_p)\} \subseteq \{x_n : \text{cap}(x_n, d'_p)\}.$$

Now let d_p be an ordered list of antecedents, and let β be a subset of antecedents in d_p. Let us define $\text{cap}(x_n, \beta \,|\, d_p) = 1$ if β captures datum x_n in the context of d_p, *i.e.*, if the first antecedent in d_p that evaluates to true for x_n is an antecedent in β, and 0 otherwise. Thus, $\text{cap}(x_n, \beta \,|\, d_p) = 1$ only if $\text{cap}(x_n, \beta) = 1$; $\text{cap}(x_n, \beta \,|\, d_p) = 0$ either if $\text{cap}(x_n, \beta) = 0$, or if $\text{cap}(x_n, \beta) = 1$ but there is an antecedent α in d_p, preceding all antecedents in β, such that $\text{cap}(x_n, \alpha) = 1$. For example, if $d_p = (p_1, \ldots, p_k, \ldots, p_K)$ is a prefix, then

$$\text{cap}(x_n, p_k \,|\, d_p) = \left(\bigwedge_{k'=1}^{k-1} \neg \, \text{cap}(x_n, p_{k'}) \right) \wedge \text{cap}(x_n, p_k)$$

indicates whether antecedent p_k captures datum x_n in the context of d_p. Now, define $\text{supp}(\beta, \mathbf{x})$ to be the normalized support of β,

$$\text{supp}(\beta, \mathbf{x}) = \frac{1}{N} \sum_{n=1}^{N} \text{cap}(x_n, \beta), \tag{2}$$

and similarly define $\text{supp}(\beta, \mathbf{x} \,|\, d_p)$ to be the normalized support of β in the context of d_p,

$$\text{supp}(\beta, \mathbf{x} \,|\, d_p) = \frac{1}{N} \sum_{n=1}^{N} \text{cap}(x_n, \beta \,|\, d_p), \tag{3}$$

Next, we address how empirical data constrains rule lists. Given training data $(\mathbf{x}, \mathbf{y})$, an antecedent list $d_p = (p_1, \ldots, p_K)$ implies a rule list $d = (d_p, \delta_p, q_0, K)$ with prefix d_p, where the label predictions $\delta_p = (q_1, \ldots, q_K)$ and q_0 are empirically set to minimize the number of misclassification errors made by the rule list on the training data. Thus for $1 \leq k \leq K$, label prediction q_k corresponds to the majority label of data captured by antecedent p_k in the context of d_p, and the default q_0 corresponds to the majority label of data not captured by d_p. In the remainder of our presentation, whenever we refer to a rule list with a particular prefix, we implicitly assume these empirically determined label predictions.

Our method is technically an associative classification method since it leverages pre-mined rules.

3.2 Objective Function

We define a simple objective function for a rule list $d = (d_p, \delta_p, q_0, K)$:

$$R(d, \mathbf{x}, \mathbf{y}) = \ell(d, \mathbf{x}, \mathbf{y}) + \lambda K. \tag{4}$$

This objective function is a regularized empirical risk; it consists of a loss $\ell(d, \mathbf{x}, \mathbf{y})$, measuring misclassification error, and a regularization term that penalizes longer rule lists. $\ell(d, \mathbf{x}, \mathbf{y})$ is the fraction of training data whose labels are incorrectly predicted by d. In our setting, the regularization parameter $\lambda \geq 0$ is a small constant; *e.g.*, $\lambda = 0.01$ can be thought of as adding a penalty equivalent to misclassifying 1% of data when increasing a rule list's length by one association rule.

3.3 Optimization Framework

Our objective has structure amenable to global optimization via a branch-and-bound framework. In particular, we make a series of important observations, each of which translates into a useful bound, and that together interact to eliminate large parts of the search space. We discuss these in depth in what follows:

- Lower bounds on a prefix also hold for every extension of that prefix. (§3.4, Theorem 1)
- If a rule list is not accurate enough with respect to its length, we can prune all extensions of it. (§3.4, Lemma 2)
- We can calculate *a priori* an upper bound on the maximum length of an optimal rule list. (§3.5, Theorem 6)
- Each rule in an optimal rule list must have support that is sufficiently large. This allows us to construct rule lists from frequent itemsets, while preserving the guarantee that we can find a globally optimal rule list from pre-mined rules. (§3.7, Theorem 10)
- Each rule in an optimal rule list must predict accurately. In particular, the number of observations predicted correctly by each rule in an optimal rule list must be above a threshold. (§3.7, Theorem 11)
- We need only consider the optimal permutation of antecedents in a prefix; we can omit all other permutations. (§3.10, Theorem 15 and Corollary 16)
- If multiple observations have identical features and opposite labels, we know that any model will make mistakes. In particular, the number of mistakes on these observations will be at least the number of observations with the minority label. (§3.14, Theorem 20)

3.4 Hierarchical Objective Lower Bound

We can decompose the misclassification error in (4) into two contributions corresponding to the prefix and the default rule:

$$\ell(d, \mathbf{x}, \mathbf{y}) \equiv \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}),$$

where $d_p = (p_1, \ldots, p_K)$ and $\delta_p = (q_1, \ldots, q_K)$;

$$\ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{n=1}^{N} \sum_{k=1}^{K} \mathrm{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[q_k \neq y_n]$$

is the fraction of data captured and misclassified by the prefix, and

$$\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{n=1}^{N} \neg\, \mathrm{cap}(x_n, d_p) \wedge \mathbb{1}[q_0 \neq y_n]$$

is the fraction of data not captured by the prefix and misclassified by the default rule. Eliminating the latter error term gives a lower bound $b(d_p, \mathbf{x}, \mathbf{y})$ on the objective,

$$b(d_p, \mathbf{x}, \mathbf{y}) \equiv \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K \leq R(d, \mathbf{x}, \mathbf{y}), \tag{5}$$

where we have suppressed the lower bound's dependence on label predictions δ_p because they are fully determined, given $(d_p, \mathbf{x}, \mathbf{y})$. Furthermore, as we state next in Theorem 1, $b(d_p, \mathbf{x}, \mathbf{y})$ gives a lower bound on the objective of *any* rule list whose prefix starts with d_p.

Theorem 1 (Hierarchical objective lower bound) *Define $b(d_p, \mathbf{x}, \mathbf{y})$ as in (5). Also, define $\sigma(d_p)$ to be the set of all rule lists whose prefixes starts with d_p, as in (1). Let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix d_p, and let $d' = (d'_p, \delta'_p, q'_0, K') \in \sigma(d_p)$ be any rule list such that its prefix d'_p starts with d_p and $K' \geq K$, then $b(d_p, \mathbf{x}, \mathbf{y}) \leq R(d', \mathbf{x}, \mathbf{y})$.*

Proof Let $d_p = (p_1, \ldots, p_K)$ and $\delta_p = (q_1, \ldots, q_K)$; let $d'_p = (p_1, \ldots, p_K, p_{K+1}, \ldots, p_{K'})$ and $\delta'_p = (q_1, \ldots, q_K, q_{K+1}, \ldots, q_{K'})$. Notice that d'_p yields the same mistakes as d_p, and possibly additional mistakes:

$$\begin{aligned}
&\ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{n=1}^{N} \sum_{k=1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] \\
&= \frac{1}{N} \sum_{n=1}^{N} \left(\sum_{k=1}^{K} \mathrm{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[q_k \neq y_n] + \sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] \right) \\
&= \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N} \sum_{n=1}^{N} \sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] \geq \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}),
\end{aligned} \tag{6}$$

where in the second equality we have used the fact that $\mathrm{cap}(x_n, p_k \,|\, d'_p) = \mathrm{cap}(x_n, p_k \,|\, d_p)$ for $1 \leq k \leq K$. It follows that

$$\begin{aligned}
b(d_p, \mathbf{x}, \mathbf{y}) &= \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K \\
&\leq \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda K' = b(d'_p, \mathbf{x}, \mathbf{y}) \leq R(d', \mathbf{x}, \mathbf{y}).
\end{aligned} \tag{7}$$

Algorithm 1 Branch-and-bound for learning rule lists.

Input: Objective function $R(d, \mathbf{x}, \mathbf{y})$, objective lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, set of antecedents $S = \{s_m\}_{m=1}^{M}$, training data $(\mathbf{x}, \mathbf{y}) = \{(x_n, y_n)\}_{n=1}^{N}$, initial best known rule list d^0 with objective $R^0 = R(d^0, \mathbf{x}, \mathbf{y})$; d^0 could be obtained as output from another (approximate) algorithm, otherwise, $(d^0, R^0) = (\text{null}, 1)$ provide reasonable default values
Output: Provably optimal rule list d^* with minimum objective R^*

```
(d^c, R^c) ← (d^0, R^0)                          ▷ Initialize best rule list and objective
Q ← queue( [ ( ) ] )                             ▷ Initialize queue with empty prefix
while Q not empty do                             ▷ Stop when queue is empty
    d_p ← Q.pop( )                               ▷ Remove prefix d_p from the queue
    d ← (d_p, δ_p, q_0, K)   ▷ Set label predictions δ_p and q_0 to minimize training error
    if b(d_p, x, y) < R^c then                   ▷ Bound: Apply Theorem 1
        R ← R(d, x, y)                           ▷ Compute objective of d_p's rule list d
        if R < R^c then                          ▷ Update best rule list and objective
            (d^c, R^c) ← (d, R)
        end if

            if s not in d_p then
                Q.push( (d_p, s) )
            end if
        end for
    end if
end while
(d*, R*) ← (d^c, R^c)                            ▷ Identify provably optimal solution
```

■

To generalize, consider a sequence of prefixes such that each prefix starts with all previous prefixes in the sequence. It follows that the corresponding sequence of objective lower bounds increases monotonically. This is precisely the structure required and exploited by branch-and-bound, illustrated in Algorithm 1.

Specifically, the objective lower bound in Theorem 1 enables us to prune the state space hierarchically. While executing branch-and-bound, we keep track of the current best (smallest) objective R^c, thus it is a dynamic, monotonically decreasing quantity. If we encounter a prefix d_p with lower bound $b(d_p, \mathbf{x}, \mathbf{y}) \geq R^c$, then by Theorem 1, we do not need to consider *any* rule list $d' \in \sigma(d_p)$ whose prefix d'_p starts with d_p. For the objective of such a rule list, the current best objective provides a lower bound, *i.e.*, $R(d', \mathbf{x}, \mathbf{y}) \geq b(d'_p, \mathbf{x}, \mathbf{y}) \geq b(d_p, \mathbf{x}, \mathbf{y}) \geq R^c$, and thus d' cannot be optimal.

Next, we state an immediate consequence of Theorem 1.

Lemma 2 (Objective lower bound with one-step lookahead) *Let d_p be a K-prefix and let R^c be the current best objective. If $b(d_p, \mathbf{x}, \mathbf{y}) + \lambda \geq R^c$, then for any K'-rule list $d' \in \sigma(d_p)$ whose prefix d'_p starts with d_p and $K' > K$, it follows that $R(d', \mathbf{x}, \mathbf{y}) \geq R^c$.*

Proof By the definition of the lower bound (5), which includes the penalty for longer prefixes,

$$\begin{aligned} R(d'_p, \mathbf{x}, y) \geq b(d'_p, \mathbf{x}, \mathbf{y}) &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda K' \\ &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda K + \lambda(K' - K) \\ &= b(d_p, \mathbf{x}, \mathbf{y}) + \lambda(K' - K) \geq b(d_p, \mathbf{x}, \mathbf{y}) + \lambda \geq R^c. \end{aligned} \tag{8}$$

■

Therefore, even if we encounter a prefix d_p with lower bound $b(d_p, \mathbf{x}, \mathbf{y}) \leq R^c$, as long as $b(d_p, \mathbf{x}, \mathbf{y}) + \lambda \geq R^c$, then we can prune all prefixes d'_p that start with and are longer than d_p.

3.5 Upper Bounds on Prefix Length

In this section, we derive several upper bounds on prefix length:

- The simplest upper bound on prefix length is given by the total number of available antecedents. (Proposition 3)
- The current best objective R^c implies an upper bound on prefix length. (Theorem 4)
- For intuition, we state a version of the above bound that is valid at the start of execution. (Corollary 5)
- By considering specific families of prefixes, we can obtain tighter bounds on prefix length. (Theorem 6)

In the next section (§3.6), we use these results to derive corresponding upper bounds on the number of prefix evaluations made by Algorithm 1.

Proposition 3 (Trivial upper bound on prefix length) *Consider a state space of all rule lists formed from a set of M antecedents, and let $L(d)$ be the length of rule list d. M provides an upper bound on the length of any optimal rule list $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, i.e., $L(d) \leq M$.*

Proof Rule lists consist of distinct rules by definition. ■

At any point during branch-and-bound execution, the current best objective R^c implies an upper bound on the maximum prefix length we might still have to consider.

Theorem 4 (Upper bound on prefix length) *Consider a state space of all rule lists formed from a set of M antecedents. Let $L(d)$ be the length of rule list d and let R^c be the current best objective. For all optimal rule lists $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$*

$$L(d^*) \leq \min\left(\left\lfloor \frac{R^c}{\lambda} \right\rfloor, M\right), \tag{9}$$

where λ is the regularization parameter. Furthermore, if d^c is a rule list with objective $R(d^c, \mathbf{x}, \mathbf{y}) = R^c$, length K, and zero misclassification error, then for every optimal rule list $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, if $d^c \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, then $L(d^*) \leq K$, or otherwise if $d^c \notin \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, then $L(d^*) \leq K - 1$.

Proof For an optimal rule list d^* with objective R^*,

$$\lambda L(d^*) \leq R^* = R(d^*, \mathbf{x}, \mathbf{y}) = \ell(d^*, \mathbf{x}, \mathbf{y}) + \lambda L(d^*) \leq R^c.$$

The maximum possible length for d^* occurs when $\ell(d^*, \mathbf{x}, \mathbf{y})$ is minimized; combining with Proposition 3 gives bound (9).

For the rest of the proof, let $K^* = L(d^*)$ be the length of d^*. If the current best rule list d^c has zero misclassification error, then

$$\lambda K^* \leq \ell(d^*, \mathbf{x}, \mathbf{y}) + \lambda K^* = R(d^*, \mathbf{x}, \mathbf{y}) \leq R^c = R(d^c, \mathbf{x}, \mathbf{y}) = \lambda K,$$

and thus $K^* \leq K$. If the current best rule list is suboptimal, *i.e.*, $d^c \notin \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, then

$$\lambda K^* \leq \ell(d^*, \mathbf{x}, \mathbf{y}) + \lambda K^* = R(d^*, \mathbf{x}, \mathbf{y}) < R^c = R(d^c, \mathbf{x}, \mathbf{y}) = \lambda K,$$

in which case $K^* < K$, *i.e.*, $K^* \leq K - 1$, since K is an integer. ■

The latter part of Theorem 4 tells us that if we only need to identify a single instance of an optimal rule list $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, and we encounter a perfect K-rule list with zero misclassification error, then we can prune all prefixes of length K or greater.

Corollary 5 (Simple upper bound on prefix length) *Let $L(d)$ be the length of rule list d. For all optimal rule lists $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$,*

$$L(d^*) \leq \min\left(\left\lfloor \frac{1}{2\lambda} \right\rfloor, M\right). \tag{10}$$

Proof Let $d = ((), (), q_0, 0)$ be the empty rule list; it has objective $R(d, \mathbf{x}, \mathbf{y}) = \ell(d, \mathbf{x}, \mathbf{y}) \leq 1/2$, which gives an upper bound on R^c. Combining with (9) and Proposition 3 gives (10). ■

For any particular prefix d_p, we can obtain potentially tighter upper bounds on prefix length for the family of all prefixes that start with d_p.

Theorem 6 (Prefix-specific upper bound on prefix length) *Let $d = (d_p, \delta_p, q_0, K)$ be a rule list, let $d' = (d'_p, \delta'_p, q'_0, K') \in \sigma(d_p)$ be any rule list such that d'_p starts with d_p, and let R^c be the current best objective. If d'_p has lower bound $b(d'_p, \mathbf{x}, \mathbf{y}) < R^c$, then*

$$K' < \min\left(K + \left\lfloor \frac{R^c - b(d_p, \mathbf{x}, \mathbf{y})}{\lambda} \right\rfloor, M\right). \tag{11}$$

Proof First, note that $K' \geq K$, since d'_p starts with d_p. Now recall from (7) that

$$b(d_p, \mathbf{x}, \mathbf{y}) = \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K \leq \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda K' = b(d'_p, \mathbf{x}, \mathbf{y}),$$

and from (6) that $\ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) \leq \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y})$. Combining these bounds and rearranging gives

$$\begin{aligned} b(d'_p, \mathbf{x}, \mathbf{y}) &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda K + \lambda(K' - K) \\ &\geq \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K + \lambda(K' - K) = b(d_p, \mathbf{x}, \mathbf{y}) + \lambda(K' - K). \end{aligned} \tag{12}$$

Combining (12) with $b(d'_p, \mathbf{x}, \mathbf{y}) < R^c$ and Proposition 3 gives (11). ■

We can view Theorem 6 as a generalization of our one-step lookahead bound (Lemma 2), as (11) is equivalently a bound on $K' - K$, an upper bound on the number of remaining 'steps' corresponding to an iterative sequence of single-rule extensions of a prefix d_p. Notice that when $d = ((), (), q_0, 0)$ is the empty rule list, this bound replicates (9), since $b(d_p, \mathbf{x}, \mathbf{y}) = 0$.

3.6 Upper Bounds on the Number of Prefix Evaluations

In this section, we use our upper bounds on prefix length from §3.5 to derive corresponding upper bounds on the number of prefix evaluations made by Algorithm 1. First, we present Theorem 7, in which we use information about the state of Algorithm 1's execution to calculate, for any given execution state, upper bounds on the number of additional prefix evaluations that might be required for the execution to complete. The relevant execution state depends on the current best objective R^c and information about prefixes we are planning to evaluate, *i.e.*, prefixes in the queue Q of Algorithm 1. We define the number of *remaining prefix evaluations* as the number of prefixes that are currently in or will be inserted into the queue.

We use Theorem 7 in some of our empirical results (§6, Figure 18) to help illustrate the dramatic impact of certain algorithm optimizations. The execution trace of this upper bound on remaining prefix evaluations complements the execution traces of other quantities, *e.g.*, that of the current best objective R^c. After presenting Theorem 7, we also give two weaker propositions that provide useful intuition. In particular, Proposition 9 is a practical approximation to Theorem 7 that is significantly easier to compute; we use it in our implementation as a metric of execution progress that we display to the user.

Theorem 7 (Fine-grained upper bound on remaining prefix evaluations) *Consider the state space of all rule lists formed from a set of M antecedents, and consider Algorithm 1 at a particular instant during execution. Let R^c be the current best objective, let Q be the queue, and let $L(d_p)$ be the length of prefix d_p. Define $\Gamma(R^c, Q)$ to be the number of remaining prefix evaluations, then*

$$\Gamma(R^c, Q) \leq \sum_{d_p \in Q} \sum_{k=0}^{f(d_p)} \frac{(M - L(d_p))!}{(M - L(d_p) - k)!}, \tag{13}$$

where

$$f(d_p) = \min\left(\left\lfloor \frac{R^c - b(d_p, \mathbf{x}, \mathbf{y})}{\lambda} \right\rfloor, M - L(d_p)\right).$$

Proof The number of remaining prefix evaluations is equal to the number of prefixes that are currently in or will be inserted into queue Q. For any such prefix d_p, Theorem 6 gives an upper bound on the length of any prefix d'_p that starts with d_p:

$$L(d'_p) \leq \min\left(L(d_p) + \left\lfloor \frac{R^c - b(d_p, \mathbf{x}, \mathbf{y})}{\lambda} \right\rfloor, M\right) \equiv U(d_p).$$

This gives an upper bound on the number of remaining prefix evaluations:

$$\Gamma(R^c, Q) \leq \sum_{d_p \in Q} \sum_{k=0}^{U(d_p) - L(d_p)} P(M - L(d_p), k) = \sum_{d_p \in Q} \sum_{k=0}^{f(d_p)} \frac{(M - L(d_p))!}{(M - L(d_p) - k)!},$$

where $P(m, k)$ denotes the number of k-permutations of m. ■

Proposition 8 is strictly weaker than Theorem 7 and is the starting point for its derivation. It is a naïve upper bound on the total number of prefix evaluations over the course of Algorithm 1's execution. It only depends on the number of rules and the regularization parameter λ; *i.e.*, unlike Theorem 7, it does not use algorithm execution state to bound the size of the search space.

Proposition 8 (Upper bound on the total number of prefix evaluations) *Define $\Gamma_{\text{tot}}(S)$ to be the total number of prefixes evaluated by Algorithm 1, given the state space of all rule lists formed from a set S of M rules. For any set S of M rules,*

$$\Gamma_{\text{tot}}(S) \leq \sum_{k=0}^{K} \frac{M!}{(M - k)!},$$

where $K = \min(\lfloor 1/2\lambda \rfloor, M)$.

Proof By Corollary 5, $K \equiv \min(\lfloor 1/2\lambda \rfloor, M)$ gives an upper bound on the length of any optimal rule list. Since we can think of our problem as finding the optimal selection and permutation of k out of M rules, over all $k \leq K$,

$$\Gamma_{\text{tot}}(S) \leq 1 + \sum_{k=1}^{K} P(M, k) = \sum_{k=0}^{K} \frac{M!}{(M - k)!}.$$

■

Our next upper bound is strictly tighter than the bound in Proposition 8. Like Theorem 7, it uses the current best objective and information about the lengths of prefixes in the

queue to constrain the lengths of prefixes in the remaining search space. However, Proposition 9 is weaker than Theorem 7 because it leverages only coarse-grained information from the queue. Specifically, Theorem 7 is strictly tighter because it additionally incorporates prefix-specific objective lower bound information from prefixes in the queue, which further constrains the lengths of prefixes in the remaining search space.

Proposition 9 (Coarse-grained upper bound on remaining prefix evaluations) *Consider a state space of all rule lists formed from a set of M antecedents, and consider Algorithm 1 at a particular instant during execution. Let R^c be the current best objective, let Q be the queue, and let $L(d_p)$ be the length of prefix d_p. Let Q_j be the number of prefixes of length j in Q,*

$$Q_j = \left|\{d_p : L(d_p) = j, d_p \in Q\}\right|$$

and let $J = \operatorname{argmax}_{d_p \in Q} L(d_p)$ be the length of the longest prefix in Q. Define $\Gamma(R^c, Q)$ to be the number of remaining prefix evaluations, then

$$\Gamma(R^c, Q) \leq \sum_{j=1}^{J} Q_j \left(\sum_{k=0}^{K-j} \frac{(M-j)!}{(M-j-k)!} \right),$$

where $K = \min(\lfloor R^c/\lambda \rfloor, M)$.

Proof The number of remaining prefix evaluations is equal to the number of prefixes that are currently in or will be inserted into queue Q. For any such remaining prefix d_p, Theorem 4 gives an upper bound on its length; define K to be this bound: $L(d_p) \leq \min(\lfloor R^c/\lambda \rfloor, M) \equiv K$. For any prefix d_p in queue Q with length $L(d_p) = j$, the maximum number of prefixes that start with d_p and remain to be evaluated is:

$$\sum_{k=0}^{K-j} P(M-j, k) = \sum_{k=0}^{K-j} \frac{(M-j)!}{(M-j-k)!},$$

where $P(T, k)$ denotes the number of k-permutations of T. This gives an upper bound on the number of remaining prefix evaluations:

$$\Gamma(R^c, Q) \leq \sum_{j=0}^{J} Q_j \left(\sum_{k=0}^{K-j} P(M-j, k) \right) = \sum_{j=0}^{J} Q_j \left(\sum_{k=0}^{K-j} \frac{(M-j)!}{(M-j-k)!} \right).$$

■

3.7 Lower Bounds on Antecedent Support

In this section, we give two lower bounds on the normalized support of each antecedent in any optimal rule list; both are related to the regularization parameter λ.

Theorem 10 (Lower bound on antecedent support) *Let $d^* = (d_p, \delta_p, q_0, K)$ be any optimal rule list with objective R^*, i.e., $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$. For each antecedent p_k in prefix $d_p = (p_1, \ldots, p_K)$, the regularization parameter λ provides a lower bound on the normalized support of p_k,*

$$\lambda \leq \operatorname{supp}(p_k, \mathbf{x} \,|\, d_p). \tag{14}$$

Proof Let $d^* = (d_p, \delta_p, q_0, K)$ be an optimal rule list with prefix $d_p = (p_1, \ldots, p_K)$ and labels $\delta_p = (q_1, \ldots, q_K)$. Consider the rule list $d = (d'_p, \delta'_p, q'_0, K-1)$ derived from d^* by deleting a rule $p_i \to q_i$, therefore $d'_p = (p_1, \ldots, p_{i-1}, p_{i+1}, \ldots, p_K)$ and $\delta'_p = (q_1, \ldots, q_{i-1}, q'_{i+1}, \ldots, q'_K)$, where q'_k need not be the same as q_k, for $k > i$ and $k = 0$.

The largest possible discrepancy between d^* and d would occur if d^* correctly classified all the data captured by p_i, while d misclassified these data. This gives an upper bound:

$$\begin{aligned} R(d, \mathbf{x}, \mathbf{y}) = \ell(d, \mathbf{x}, \mathbf{y}) + \lambda(K-1) &\leq \ell(d^*, \mathbf{x}, \mathbf{y}) + \operatorname{supp}(p_i, \mathbf{x} \,|\, d_p) + \lambda(K-1) \\ &= R(d^*, \mathbf{x}, \mathbf{y}) + \operatorname{supp}(p_i, \mathbf{x} \,|\, d_p) - \lambda \\ &= R^* + \operatorname{supp}(p_i, \mathbf{x} \,|\, d_p) - \lambda \end{aligned} \tag{15}$$

where $\operatorname{supp}(p_i, \mathbf{x} \,|\, d_p)$ is the normalized support of p_i in the context of d_p, defined in (3), and the regularization 'bonus' comes from the fact that d is one rule shorter than d^*.

At the same time, we must have $R^* \leq R(d, \mathbf{x}, \mathbf{y})$ for d^* to be optimal. Combining this with (15) and rearranging gives (14), therefore the regularization parameter λ provides a lower bound on the support of an antecedent p_i in an optimal rule list d^*. ■

Thus, we can prune a prefix d_p if any of its antecedents captures less than a fraction λ of data, even if $b(d_p, \mathbf{x}, \mathbf{y}) < R^*$. Notice that the bound in Theorem 10 depends on the antecedents, but not the label predictions, and thus does not account for misclassification error. Theorem 11 gives a tighter bound by leveraging this additional information, which specifically tightens the upper bound on $R(d, \mathbf{x}, \mathbf{y})$ in (15).

Theorem 11 (Lower bound on accurate antecedent support) *Let d^* be any optimal rule list with objective R^*, i.e., $d^* = (d_p, \delta_p, q_0, K) \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$. Let d^* have prefix $d_p = (p_1, \ldots, p_K)$ and labels $\delta_p = (q_1, \ldots, q_K)$. For each rule $p_k \to q_k$ in d^*, define a_k to be the fraction of data that are captured by p_k and correctly classified:*

$$a_k \equiv \frac{1}{N} \sum_{n=1}^{N} \operatorname{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[q_k = y_n]. \tag{16}$$

The regularization parameter λ provides a lower bound on a_k:

$$\lambda \leq a_k. \tag{17}$$

Proof As in Theorem 10, let $d = (d'_p, \delta'_p, q'_0, K-1)$ be the rule list derived from d^* by deleting a rule $p_i \to q_i$. Now, let us define ℓ_i to be the portion of R^* due to this rule's misclassification error,

$$\ell_i \equiv \frac{1}{N} \sum_{n=1}^{N} \operatorname{cap}(x_n, p_i \,|\, d_p) \wedge \mathbb{1}[q_i \neq y_n].$$

The largest discrepancy between d^* and d would occur if d misclassified all the data captured by p_i. This gives an upper bound on the difference between the misclassification error of d and d^*:

$$\begin{aligned}\ell(d,\mathbf{x},\mathbf{y}) - \ell(d^*,\mathbf{x},\mathbf{y}) &\leq \text{supp}(p_i,\mathbf{x}\,|\,d_p) - \ell_i \\ &= \frac{1}{N}\sum_{n=1}^{N}\text{cap}(x_n,p_i\,|\,d_p) - \frac{1}{N}\sum_{n=1}^{N}\text{cap}(x_n,p_i\,|\,d_p)\wedge\mathbb{1}[q_i\neq y_n] \\ &= \frac{1}{N}\sum_{n=1}^{N}\text{cap}(x_n,p_i\,|\,d_p)\wedge\mathbb{1}[q_i= y_n] = a_i,\end{aligned}$$

where we defined a_i in (16). Relating this bound to the objectives of d and d^* gives

$$\begin{aligned}R(d,\mathbf{x},\mathbf{y}) = \ell(d,\mathbf{x},\mathbf{y}) + \lambda(K-1) &\leq \ell(d^*,\mathbf{x},\mathbf{y}) + a_i + \lambda(K-1) \\ &= R(d^*,\mathbf{x},\mathbf{y}) + a_i - \lambda \\ &= R^* + a_i - \lambda. \qquad (18)\end{aligned}$$

Combining (18) with the requirement $R^* \leq R(d,\mathbf{x},\mathbf{y})$ gives the bound $\lambda \leq a_i$. ■

Thus, we can prune a prefix if any of its rules correctly classifies less than a fraction λ of data. While the lower bound in Theorem 10 is a sub-condition of the lower bound in Theorem 11, we can still leverage both—since the sub-condition is easier to check, checking it first can accelerate pruning. In addition to applying Theorem 10 in the context of constructing rule lists, we can furthermore apply it in the context of rule mining (§3.1). Specifically, it implies that we should only mine rules with normalized support of at least λ; we need not mine rules with a smaller fraction of observations.[2] In contrast, we can only apply Theorem 11 in the context of constructing rule lists; it depends on the misclassification error associated with each rule in a rule list, thus it provides a lower bound on the number of observations that each such rule must correctly classify.

3.8 Upper Bound on Antecedent Support

In the previous section (§3.7), we proved lower bounds on antecedent support; in Appendix A, we give an upper bound on antecedent support. Specifically, Theorem 21 shows that an antecedent's support in a rule list cannot be too similar to the set of data not captured by preceding antecedents in the rule list. In particular, Theorem 21 implies that we should only mine rules with normalized support less than or equal to $1-\lambda$; we need not mine rules with a larger fraction of observations. Note that we do not otherwise use this bound in our implementation, because we did not observe a meaningful benefit in preliminary experiments.

3.9 Antecedent Rejection and its Propagation

In this section, we demonstrate further consequences of our lower (§3.7) and upper bounds (§3.8) on antecedent support, under a unified framework we refer to as antecedent rejection. Let $d_p = (p_1,\ldots,p_K)$ be a prefix, and let p_k be an antecedent in d_p. Define p_k to have

2. We describe our application of this idea in Appendix E, where we provide details on data processing.

insufficient support in d_p if it does not obey the bound in (14) of Theorem 10. Define p_k to have insufficient accurate support in d_p if it does not obey the bound in (17) of Theorem 11. Define p_k to have excessive support in d_p if it does not obey the bound in (37) of Theorem 21 (Appendix A). If p_k in the context of d_p has insufficient support, insufficient accurate support, or excessive support, let us say that prefix d_p rejects antecedent p_K. Next, in Theorem 12, we describe large classes of related rule lists whose prefixes all reject the same antecedent.

Theorem 12 (Antecedent rejection propagates) *For any prefix $d_p = (p_1,\ldots,p_K)$, let $\phi(d_p)$ denote the set of all prefixes d'_p such that the set of all antecedents in d_p is a subset of the set of all antecedents in d'_p, i.e.,*

$$\phi(d_p) = \{d'_p = (p'_1,\ldots,p'_{K'}) \text{ s.t. } \{p_k : p_k \in d_p\} \subseteq \{p'_\kappa : p'_\kappa \in d'_p\}, K' \geq K\}. \qquad (19)$$

Let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1,\ldots,p_{K-1},p_K)$, such that d_p rejects its last antecedent p_K, either because p_K in the context of d_p has insufficient support, insufficient accurate support, or excessive support. Let $d_p^{K-1} = (p_1,\ldots,p_{K-1})$ be the first $K-1$ antecedents of d_p. Let $D = (D_p, \Delta_p, Q_0, \kappa)$ be any rule list with prefix $D_p = (P_1,\ldots,P_{K'-1}, P_{K'},\ldots,P_\kappa)$ such that D_p starts with $D_p^{K'-1} = (P_1,\ldots,P_{K'-1}) \in \phi(d_p^{K-1})$ and antecedent $P_{K'} = p_K$. It follows that prefix D_p rejects $P_{K'}$ for the same reason that d_p rejects p_K, and furthermore, D cannot be optimal, i.e., $D \notin \text{argmin}_{d^\dagger} R(d^\dagger,\mathbf{x},\mathbf{y})$.

Proof Combine Proposition 13, Proposition 14, and Proposition 22. The first two are found below, and the last in Appendix A. ■

Theorem 12 implies potentially significant computational savings. We know from Theorems 10, 11, and 21 that during branch-and-bound execution, if we ever encounter a prefix $d_p = (p_1,\ldots,p_{K-1},p_K)$ that rejects its last antecedent p_K, then we can prune d_p. By Theorem 12, we can also prune *any* prefix d'_p whose antecedents contains the set of antecedents in d_p, in almost any order, with the constraint that all antecedents in $\{p_1,\ldots,p_{K-1}\}$ precede p_K. These latter antecedents are also rejected directly by the bounds in Theorems 10, 11, and 21; this is how our implementation works in practice. In a preliminary implementation (not shown), we maintained additional data structures to support the direct use of Theorem 12. We leave the design of efficient data structures for this task as future work.

Proposition 13 (Insufficient antecedent support propagates) *First define $\phi(d_p)$ as in (19), and let $d_p = (p_1,\ldots,p_{K-1},p_K)$ be a prefix, such that its last antecedent p_K has insufficient support, i.e., the opposite of the bound in (14): $\text{supp}(p_K,\mathbf{x}\,|\,d_p) < \lambda$. Let $d_p^{K-1} = (p_1,\ldots,p_{K-1})$, and let $D = (D_p,\Delta_p,Q_0,\kappa)$ be any rule list with prefix $D_p = (P_1,\ldots,P_{K'-1}, P_{K'},\ldots,P_\kappa)$, such that D_p starts with $D_p^{K'-1} = (P_1,\ldots,P_{K'-1}) \in \phi(d_p^{K-1})$ and $P_{K'} = p_K$. It follows that $P_{K'}$ has insufficient support in prefix D_p, and furthermore, D cannot be optimal, i.e., $D \notin \text{argmin}_d R(d,\mathbf{x},\mathbf{y})$.*

Proof The support of p_K in d_p depends only on the set of antecedents in $d_p^K = (p_1, \ldots, p_K)$:

$$\begin{aligned}\text{supp}(p_K, \mathbf{x} \,|\, d_p) = \frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, p_K \,|\, d_p) &= \frac{1}{N}\sum_{n=1}^{N} \left(\neg \text{cap}(x_n, d_p^{K-1})\right) \wedge \text{cap}(x_n, p_K) \\ &= \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K-1} \neg \text{cap}(x_n, p_k)\right) \wedge \text{cap}(x_n, p_K) < \lambda,\end{aligned}$$

and the support of $P_{K'}$ in D_p depends only on the set of antecedents in $D_p^{K'} = (P_1, \ldots, P_{K'})$:

$$\begin{aligned}\text{supp}(P_{K'}, \mathbf{x} \,|\, D_p) = \frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, P_{K'} \,|\, D_p) &= \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K'-1} \neg \text{cap}(x_n, P_k)\right) \wedge \text{cap}(x_n, P_{K'}) \\ &\leq \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K-1} \neg \text{cap}(x_n, p_k)\right) \wedge \text{cap}(x_n, P_{K'}) \\ &= \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K-1} \neg \text{cap}(x_n, p_k)\right) \wedge \text{cap}(x_n, p_K) \\ &= \text{supp}(p_K, \mathbf{x} \,|\, d_p) < \lambda. \qquad (20)\end{aligned}$$

The first inequality reflects the condition that $D_p^{K'-1} \in \phi(d_p^{K-1})$, which implies that the set of antecedents in $D_p^{K'-1}$ contains the set of antecedents in d_p^{K-1}, and the next equality reflects the fact that $P_{K'} = p_K$. Thus, P'_K has insufficient support in prefix D_p, therefore by Theorem 10, D cannot be optimal, *i.e.*, $D \notin \text{argmin}_d R(d, \mathbf{x}, \mathbf{y})$. ■

Proposition 14 (Insufficient accurate antecedent support propagates) *Let $\phi(d_p)$ denote the set of all prefixes d'_p such that the set of all antecedents in d_p is a subset of the set of all antecedents in d'_p, as in* (19)*. Let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1, \ldots, p_K)$ and labels $\delta_p = (q_1, \ldots, q_K)$, such that the last antecedent p_K has insufficient accurate support, i.e., the opposite of the bound in* (17)*:*

$$\frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, p_K \,|\, d_p) \wedge \mathbb{1}[q_K = y_n] < \lambda.$$

Let $d_p^{K-1} = (p_1, \ldots, p_{K-1})$ and let $D = (D_p, \Delta_p, Q_0, \kappa)$ be any rule list with prefix $D_p = (P_1, \ldots, P_\kappa)$ and labels $\Delta_p = (Q_1, \ldots, Q_\kappa)$, such that D_p starts with $D_p^{K'-1} = (P_1, \ldots, P_{K'-1}) \in \phi(d_p^{K-1})$ and $P_{K'} = p_K$. It follows that $P_{K'}$ has insufficient accurate support in prefix D_p, and furthermore, $D \notin \text{argmin}_{d^\dagger} R(d^\dagger, \mathbf{x}, \mathbf{y})$.

Proof The accurate support of $P_{K'}$ in D_p is insufficient:

$$\begin{aligned}&\frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, P_{K'} \,|\, D_p) \wedge \mathbb{1}[Q_{K'} = y_n] \\ &\qquad = \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K'-1} \neg \text{cap}(x_n, P_k)\right) \wedge \text{cap}(x_n, P_{K'}) \wedge \mathbb{1}[Q_{K'} = y_n] \\ &\qquad \leq \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K-1} \neg \text{cap}(x_n, p_k)\right) \wedge \text{cap}(x_n, P_{K'}) \wedge \mathbb{1}[Q_{K'} = y_n] \\ &\qquad = \frac{1}{N}\sum_{n=1}^{N} \left(\bigwedge_{k=1}^{K-1} \neg \text{cap}(x_n, p_k)\right) \wedge \text{cap}(x_n, p_K) \wedge \mathbb{1}[Q_{K'} = y_n] \\ &\qquad = \frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, p_K \,|\, d_p) \wedge \mathbb{1}[Q_{K'} = y_n] \\ &\qquad \leq \frac{1}{N}\sum_{n=1}^{N} \text{cap}(x_n, p_K \,|\, d_p) \wedge \mathbb{1}[q_K = y_n] < \lambda.\end{aligned}$$

The first inequality reflects the condition that $D_p^{K'-1} \in \phi(d_p^{K-1})$, the next equality reflects the fact that $P_{K'} = p_K$. For the following equality, notice that $Q_{K'}$ is the majority class label of data captured by $P_{K'}$ in D_p, and q_K is the majority class label of data captured by P_K in d_p, and recall from (20) that $\text{supp}(P_{K'}, \mathbf{x} \,|\, D_p) \leq \text{supp}(p_K, \mathbf{x} \,|\, d_p)$. By Theorem 11, $D \notin \text{argmin}_{d^\dagger} R(d^\dagger, \mathbf{x}, \mathbf{y})$. ■

Propositions 13 and 14, combined with Proposition 22 (Appendix A), constitute the proof of Theorem 12.

3.10 Equivalent Support Bound

If two prefixes capture the same data, and one is more accurate than the other, then there is no benefit to considering prefixes that start with the less accurate one. Let d_p be a prefix, and consider the best possible rule list whose prefix starts with d_p. If we take its antecedents in d_p and replace them with another prefix with the same support (that could include different antecedents), then its objective can only become worse or remain the same.

Formally, let D_p be a prefix, and let $\xi(D_p)$ be the set of all prefixes that capture exactly the same data as D_p. Now, let d be a rule list with prefix d_p in $\xi(D_p)$, such that d has the minimum objective over all rule lists with prefixes in $\xi(D_p)$. Finally, let d' be a rule list whose prefix d'_p starts with d_p, such that d' has the minimum objective over all rule lists whose prefixes start with d_p. Theorem 15 below implies that d' also has the minimum objective over all rule lists whose prefixes start with *any* prefix in $\xi(D_p)$.

Theorem 15 (Equivalent support bound) *Define $\sigma(d_p)$ to be the set of all rule lists whose prefixes start with d_p, as in* (1)*. Let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1, \ldots, p_K)$, and let $D = (D_p, \Delta_p, Q_0, \kappa)$ be a rule list with prefix $D_p = (P_1, \ldots, P_\kappa)$,*

such that d_p and D_p capture the same data, i.e.,

$$\{x_n : \text{cap}(x_n, d_p)\} = \{x_n : \text{cap}(x_n, D_p)\}.$$

If the objective lower bounds of d and D obey $b(d_p, \mathbf{x}, \mathbf{y}) \leq b(D_p, \mathbf{x}, \mathbf{y})$, then the objective of the optimal rule list in $\sigma(d_p)$ gives a lower bound on the objective of the optimal rule list in $\sigma(D_p)$:

$$\min_{d' \in \sigma(d_p)} R(d', \mathbf{x}, \mathbf{y}) \leq \min_{D' \in \sigma(D_p)} R(D', \mathbf{x}, \mathbf{y}). \tag{21}$$

Proof See Appendix B for the proof of Theorem 15. ■

Thus, if prefixes d_p and D_p capture the same data, and their objective lower bounds obey $b(d_p, \mathbf{x}, \mathbf{y}) \leq b(D_p, \mathbf{x}, \mathbf{y})$, Theorem 15 implies that we can prune D_p. Next, in Sections 3.11 and 3.12, we highlight and analyze the special case of prefixes that capture the same data because they contain the same antecedents.

3.11 Permutation Bound

If two prefixes are composed of the same antecedents, *i.e.*, they contain the same antecedents up to a permutation, then they capture the same data, and thus Theorem 15 applies. Therefore, if one is more accurate than the other, then there is no benefit to considering prefixes that start with the less accurate one. Let d_p be a prefix, and consider the best possible rule list whose prefix starts with d_p. If we permute its antecedents in d_p, then its objective can only become worse or remain the same.

Formally, let $P = \{p_k\}_{k=1}^K$ be a set of K antecedents, and let Π be the set of all K-prefixes corresponding to permutations of antecedents in P. Let prefix d_p in Π have the minimum prefix misclassification error over all prefixes in Π. Also, let d' be a rule list whose prefix d'_p starts with d_p, such that d' has the minimum objective over all rule lists whose prefixes start with d_p. Corollary 16 below, which can be viewed as special case of Theorem 15, implies that d' also has the minimum objective over all rule lists whose prefixes start with *any* prefix in Π.

Corollary 16 (Permutation bound) *Let π be any permutation of $\{1, \ldots, K\}$, and define $\sigma(d_p) = \{(d'_p, \delta'_p, q'_0, K') : d'_p \text{ starts with } d_p\}$ to be the set of all rule lists whose prefixes start with d_p. Let $d = (d_p, \delta_p, q_0, K)$ and $D = (D_p, \Delta_p, Q_0, K)$ denote rule lists with prefixes $d_p = (p_1, \ldots, p_K)$ and $D_p = (p_{\pi(1)}, \ldots, p_{\pi(K)})$, respectively, i.e., the antecedents in D_p correspond to a permutation of the antecedents in d_p. If the objective lower bounds of d and D obey $b(d_p, \mathbf{x}, \mathbf{y}) \leq b(D_p, \mathbf{x}, \mathbf{y})$, then the objective of the optimal rule list in $\sigma(d_p)$ gives a lower bound on the objective of the optimal rule list in $\sigma(D_p)$:*

$$\min_{d' \in \sigma(d_p)} R(d', \mathbf{x}, \mathbf{y}) \leq \min_{D' \in \sigma(D_p)} R(D', \mathbf{x}, \mathbf{y}).$$

Proof Since prefixes d_p and D_p contain the same antecedents, they both capture the same data. Thus, we can apply Theorem 15. ■

Thus if prefixes d_p and D_p have the same antecedents, up to a permutation, and their objective lower bounds obey $b(d_p, \mathbf{x}, \mathbf{y}) \leq b(D_p, \mathbf{x}, \mathbf{y})$, Corollary 16 implies that we can prune D_p. We call this symmetry-aware pruning, and we illustrate the subsequent computational savings next in §3.12.

3.12 Upper Bound on Prefix Evaluations with Symmetry-aware Pruning

Here, we present an upper bound on the total number of prefix evaluations that accounts for the effect of symmetry-aware pruning (§3.11). Since every subset of K antecedents generates an equivalence class of $K!$ prefixes equivalent up to permutation, symmetry-aware pruning dramatically reduces the search space.

First, notice that Algorithm 1 describes a breadth-first exploration of the state space of rule lists. Now suppose we integrate symmetry-aware pruning into our execution of branch-and-bound, so that after evaluating prefixes of length K, we only keep a single best prefix from each set of prefixes equivalent up to a permutation.

Theorem 17 (Upper bound on prefix evaluations with symmetry-aware pruning) *Consider a state space of all rule lists formed from a set S of M antecedents, and consider the branch-and-bound algorithm with symmetry-aware pruning. Define $\Gamma_{\text{tot}}(S)$ to be the total number of prefixes evaluated. For any set S of M rules,*

$$\Gamma_{\text{tot}}(S) \leq 1 + \sum_{k=1}^{K} \frac{1}{(k-1)!} \cdot \frac{M!}{(M-k)!},$$

where $K = \min(\lfloor 1/2\lambda \rfloor, M)$.

Proof By Corollary 5, $K \equiv \min(\lfloor 1/2\lambda \rfloor, M)$ gives an upper bound on the length of any optimal rule list. The algorithm begins by evaluating the empty prefix, followed by M prefixes of length $k = 1$, then $P(M, 2)$ prefixes of length $k = 2$, where $P(M, 2)$ is the number of size-2 subsets of $\{1, \ldots, M\}$. Before proceeding to length $k = 3$, we keep only $C(M, 2)$ prefixes of length $k = 2$, where $C(M, k)$ denotes the number of k-combinations of M. Now, the number of length $k = 3$ prefixes we evaluate is $C(M, 2)(M - 2)$. Propagating this forward gives

$$\Gamma_{\text{tot}}(S) \leq 1 + \sum_{k=1}^{K} C(M, k-1)(M-k+1) = 1 + \sum_{k=1}^{K} \frac{1}{(k-1)!} \cdot \frac{M!}{(M-k)!}.$$

■

Pruning based on permutation symmetries thus yields significant computational savings. Let us compare, for example, to the naïve number of prefix evaluations given by the upper bound in Proposition 8. If $M = 100$ and $K = 5$, then the naïve number is about 9.1×10^9, while the reduced number due to symmetry-aware pruning is about 3.9×10^8, which is smaller by a factor of about 23. If $M = 1000$ and $K = 10$, the number of evaluations falls from about 9.6×10^{29} to about 2.7×10^{24}, which is smaller by a factor of about 360,000.

While 10^{24} seems infeasibly enormous, it does not represent the number of rule lists we evaluate. As we show in our experiments (§6), our permutation bound in Corollary 16 and

our other bounds together conspire to reduce the search space to a size manageable on a single computer. The choice of $M = 1000$ and $K = 10$ in our example above corresponds to the state space size our efforts target. $K = 10$ rules represents a (heuristic) upper limit on the size of an interpretable rule list, and $M = 1000$ represents the approximate number of rules with sufficiently high support (Theorem 10) we expect to obtain via rule mining (§3.1).

3.13 Similar Support Bound

We now present a relaxation of Theorem 15, our equivalent support bound. Theorem 18 implies that if we know that no extensions of a prefix d_p are better than the current best objective, then we can prune all prefixes with support similar to d_p's support. Understanding how to exploit this result in practice represents an exciting direction for future work; our implementation (§5) does not currently leverage the bound in Theorem 18.

Theorem 18 (Similar support bound) *Define $\sigma(d_p)$ to be the set of all rule lists whose prefixes start with d_p, as in (1). Let $d_p = (p_1, \ldots, p_K)$ and $D_p = (P_1, \ldots, P_\kappa)$ be prefixes that capture nearly the same data. Specifically, define ω to be the normalized support of data captured by d_p and not captured by D_p, i.e.,*

$$\omega \equiv \frac{1}{N}\sum_{n=1}^{N} \neg \operatorname{cap}(x_n, D_p) \wedge \operatorname{cap}(x_n, d_p). \tag{22}$$

Similarly, define Ω to be the normalized support of data captured by D_p and not captured by d_p, i.e.,

$$\Omega \equiv \frac{1}{N}\sum_{n=1}^{N} \neg \operatorname{cap}(x_n, d_p) \wedge \operatorname{cap}(x_n, D_p). \tag{23}$$

We can bound the difference between the objectives of the optimal rule lists in $\sigma(d_p)$ and $\sigma(D_p)$ as follows:

$$\min_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y}) - \min_{d^\dagger \in \sigma(d_p)} R(d^\dagger, \mathbf{x}, \mathbf{y}) \geq b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \omega - \Omega, \tag{24}$$

where $b(d_p, \mathbf{x}, \mathbf{y})$ and $b(D_p, \mathbf{x}, \mathbf{y})$ are the objective lower bounds of d and D, respectively.

Proof See Appendix C for the proof of Theorem 18. ■

Theorem 18 implies that if prefixes d_p and D_p are similar, and we know the optimal objective of rule lists starting with d_p, then

$$\begin{aligned}\min_{D' \in \sigma(D_p)} R(D', \mathbf{x}, \mathbf{y}) &\geq \min_{d' \in \sigma(d_p)} R(d', \mathbf{x}, \mathbf{y}) + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \chi \\ &\geq R^c + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \chi,\end{aligned}$$

where R^c is the current best objective, and χ is the normalized support of the set of data captured either exclusively by d_p or exclusively by D_p. It follows that

$$\min_{D' \in \sigma(D_p)} R(D', \mathbf{x}, \mathbf{y}) \geq R^c + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \chi \geq R^c$$

if $b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) \geq \chi$. To conclude, we summarize this result and combine it with our notion of lookahead from Lemma 2. During branch-and-bound execution, if we demonstrate that $\min_{d' \in \sigma(d_p)} R(d', \mathbf{x}, \mathbf{y}) \geq R^c$, then we can prune all prefixes that start with any prefix D'_p in the following set:

$$\left\{ D'_p : b(D'_p, \mathbf{x}, \mathbf{y}) + \lambda - b(d_p, \mathbf{x}, \mathbf{y}) \geq \frac{1}{N}\sum_{n=1}^{N} \operatorname{cap}(x_n, d_p) \oplus \operatorname{cap}(x_n, D'_p) \right\},$$

where the symbol $\oplus$ denotes the logical operation, exclusive or (XOR).

3.14 Equivalent Points Bound

The bounds in this section quantify the following: If multiple observations that are not captured by a prefix d_p have identical features and opposite labels, then no rule list that starts with d_p can correctly classify all these observations. For each set of such observations, the number of mistakes is at least the number of observations with the minority label within the set.

Consider a data set $\{(x_n, y_n)\}_{n=1}^N$ and also a set of antecedents $\{s_m\}_{m=1}^M$. Define distinct observations to be equivalent if they are captured by exactly the same antecedents, *i.e.*, $x_i \neq x_j$ are equivalent if

$$\frac{1}{M}\sum_{m=1}^{M} \mathbb{1}[\operatorname{cap}(x_i, s_m) = \operatorname{cap}(x_j, s_m)] = 1.$$

Notice that we can partition a data set into sets of equivalent points; let $\{e_u\}_{u=1}^U$ enumerate these sets. Let e_u be the equivalent points set that contains observation x_i. Now define $\theta(e_u)$ to be the normalized support of the minority class label with respect to set e_u, *e.g.*, let

$$e_u = \{x_n : \forall m \in [M],\, \mathbb{1}[\operatorname{cap}(x_n, s_m) = \operatorname{cap}(x_i, s_m)]\},$$

and let q_u be the minority class label among points in e_u, then

$$\theta(e_u) = \frac{1}{N}\sum_{n=1}^{N} \mathbb{1}[x_n \in e_u]\, \mathbb{1}[y_n = q_u]. \tag{25}$$

The existence of equivalent points sets with non-singleton support yields a tighter objective lower bound that we can combine with our other bounds; as our experiments demonstrate (§6), the practical consequences can be dramatic. First, for intuition, we present a general bound in Proposition 19; next, we explicitly integrate this bound into our framework in Theorem 20.

Proposition 19 (General equivalent points bound) *Let $d = (d_p, \delta_p, q_0, K)$ be a rule list, then*

$$R(d, \mathbf{x}, \mathbf{y}) \geq \sum_{u=1}^{U} \theta(e_u) + \lambda K.$$

Proof Recall that the objective is $R(d, \mathbf{x}, \mathbf{y}) = \ell(d, \mathbf{x}, \mathbf{y}) + \lambda K$, where the misclassification error $\ell(d, \mathbf{x}, \mathbf{y})$ is given by

$$\begin{aligned}\ell(d, \mathbf{x}, \mathbf{y}) &= \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) + \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) \\ &= \frac{1}{N} \sum_{n=1}^{N} \left(\neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[q_0 \neq y_n] + \sum_{k=1}^{K} \operatorname{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[q_k \neq y_n] \right).\end{aligned}$$

Any particular rule list uses a specific rule, and therefore a single class label, to classify all points within a set of equivalent points. Thus, for a set of equivalent points u, the rule list d correctly classifies either points that have the majority class label, or points that have the minority class label. It follows that d misclassifies a number of points in u at least as great as the number of points with the minority class label. To translate this into a lower bound on $\ell(d, \mathbf{x}, \mathbf{y})$, we first sum over all sets of equivalent points, and then for each such set, count differences between class labels and the minority class label of the set, instead of counting mistakes:

$$\begin{aligned}&\ell(d, \mathbf{x}, \mathbf{y}) \\ &= \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \left(\neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[q_0 \neq y_n] + \sum_{k=1}^{K} \operatorname{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[q_k \neq y_n] \right) \mathbb{1}[x_n \in e_u] \\ &\geq \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \left(\neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[y_n = q_u] + \sum_{k=1}^{K} \operatorname{cap}(x_n, p_k \,|\, d_p) \wedge \mathbb{1}[y_n = q_u] \right) \mathbb{1}[x_n \in e_u].\end{aligned} \tag{26}$$

Next, we factor out the indicator for equivalent point set membership, which yields a term that sums to one, because every datum is either captured or not captured by prefix d_p.

$$\begin{aligned}\ell(d, \mathbf{x}, \mathbf{y}) &= \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \left(\neg \operatorname{cap}(x_n, d_p) + \sum_{k=1}^{K} \operatorname{cap}(x_n, p_k \,|\, d_p) \right) \wedge \mathbb{1}[x_n \in e_u] \, \mathbb{1}[y_n = q_u] \\ &= \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} (\neg \operatorname{cap}(x_n, d_p) + \operatorname{cap}(x_n, d_p)) \wedge \mathbb{1}[x_n \in e_u] \, \mathbb{1}[y_n = q_u] \\ &= \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \mathbb{1}[x_n \in e_u] \, \mathbb{1}[y_n = q_u] = \sum_{u=1}^{U} \theta(e_u),\end{aligned}$$

where the final equality applies the definition of $\theta(e_u)$ in (25). Therefore, $R(d, \mathbf{x}, \mathbf{y}) = \ell(d, \mathbf{x}, \mathbf{y}) + \lambda K \geq \sum_{u=1}^{U} \theta(e_u) + \lambda K$. ■

Now, recall that to obtain our lower bound $b(d_p, \mathbf{x}, \mathbf{y})$ in (5), we simply deleted the default rule misclassification error $\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y})$ from the objective $R(d, \mathbf{x}, \mathbf{y})$. Theorem 20 obtains a tighter objective lower bound via a tighter lower bound on the default rule misclassification error, $0 \leq b_0(d_p, \mathbf{x}, \mathbf{y}) \leq \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y})$.

Theorem 20 (Equivalent points bound) *Let d be a rule list with prefix d_p and lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, then for any rule list $d' \in \sigma(d)$ whose prefix d'_p starts with d_p,*

$$R(d', \mathbf{x}, \mathbf{y}) \geq b(d_p, \mathbf{x}, \mathbf{y}) + b_0(d_p, \mathbf{x}, \mathbf{y}), \tag{27}$$

where

$$b_0(d_p, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[x_n \in e_u] \, \mathbb{1}[y_n = q_u]. \tag{28}$$

Proof See Appendix D for the proof of Theorem 20. ■

4. Incremental Computation

For every prefix d_p evaluated during Algorithm 1's execution, we compute the objective lower bound $b(d_p, \mathbf{x}, \mathbf{y})$ and sometimes the objective $R(d, \mathbf{x}, \mathbf{y})$ of the corresponding rule list d. These calculations are the dominant computations with respect to execution time. This motivates our use of a highly optimized library, designed by Yang et al. (2017), for representing rule lists and performing operations encountered in evaluating functions of rule lists. Furthermore, we exploit the hierarchical nature of the objective function and its lower bound to compute these quantities incrementally throughout branch-and-bound execution. In this section, we provide explicit expressions for the incremental computations that are central to our approach. Later, in §5, we describe a cache data structure for supporting our incremental framework in practice.

For completeness, before presenting our incremental expressions, let us begin by writing down the objective lower bound and objective of the empty rule list, $d = ((), (), q_0, 0)$, the first rule list evaluated in Algorithm 1. Since its prefix contains zero rules, it has zero prefix misclassification error and also has length zero. Thus, the empty rule list's objective lower bound is zero, *i.e.*, $b((), \mathbf{x}, \mathbf{y}) = 0$. Since none of the data are captured by the empty prefix, the default rule corresponds to the majority class, and the objective corresponds to the default rule misclassification error, *i.e.*, $R(d, \mathbf{x}, \mathbf{y}) = \ell_0((), q_0, \mathbf{x}, \mathbf{y})$.

Now, we derive our incremental expressions for the objective function and its lower bound. Let $d = (d_p, \delta_p, q_0, K)$ and $d' = (d'_p, \delta'_p, q'_0, K+1)$ be rule lists such that prefix $d_p = (p_1, \ldots, p_K)$ is the parent of $d'_p = (p_1, \ldots, p_K, p_{K+1})$. Let $\delta_p = (q_1, \ldots, q_K)$ and $\delta'_p = (q_1, \ldots, q_K, q_{K+1})$ be the corresponding labels. The hierarchical structure of Algorithm 1 enforces that if we ever evaluate d', then we will have already evaluated both the objective and objective lower bound of its parent, d. We would like to reuse as much of these computations as possible in our evaluation of d'. We can write the objective lower bound of d' incrementally,

with respect to the objective lower bound of d:

$$\begin{aligned} b(d'_p, \mathbf{x}, \mathbf{y}) &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \lambda(K+1) \\ &= \frac{1}{N}\sum_{n=1}^{N}\sum_{k=1}^{K+1} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] + \lambda(K+1) \qquad (29) \\ &= \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K + \lambda + \frac{1}{N}\sum_{n=1}^{N} \mathrm{cap}(x_n, p_{K+1} \,|\, d'_p) \wedge \mathbb{1}[q_{K+1} \neq y_n] \\ &= b(d_p, \mathbf{x}, \mathbf{y}) + \lambda + \frac{1}{N}\sum_{n=1}^{N} \mathrm{cap}(x_n, p_{K+1} \,|\, d'_p) \wedge \mathbb{1}[q_{K+1} \neq y_n] \\ &= b(d_p, \mathbf{x}, \mathbf{y}) + \lambda + \frac{1}{N}\sum_{n=1}^{N} \neg\,\mathrm{cap}(x_n, d_p) \wedge \mathrm{cap}(x_n, p_{K+1}) \wedge \mathbb{1}[q_{K+1} \neq y_n]. \qquad (30) \end{aligned}$$

Thus, if we store $b(d_p, \mathbf{x}, \mathbf{y})$, then we can reuse this quantity when computing $b(d'_p, \mathbf{x}, \mathbf{y})$. Transforming (29) into (30) yields a significantly simpler expression that is a function of the stored quantity $b(d_p, \mathbf{x}, \mathbf{y})$. For the objective of d', first let us write a naïve expression:

$$\begin{aligned} &R(d', \mathbf{x}, \mathbf{y}) = \ell(d', \mathbf{x}, \mathbf{y}) + \lambda(K+1) = \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y}) + \lambda(K+1) \\ &= \frac{1}{N}\sum_{n=1}^{N}\sum_{k=1}^{K+1} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] + \frac{1}{N}\sum_{n=1}^{N} \neg\,\mathrm{cap}(x_n, d'_p) \wedge \mathbb{1}[q'_0 \neq y_n] + \lambda(K+1). \end{aligned} \qquad (31)$$

Instead, we can compute the objective of d' incrementally with respect to its objective lower bound:

$$\begin{aligned} R(d', \mathbf{x}, \mathbf{y}) &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y}) + \lambda(K+1) \\ &= b(d'_p, \mathbf{x}, \mathbf{y}) + \ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y}) \\ &= b(d'_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{n=1}^{N} \neg\,\mathrm{cap}(x_n, d'_p) \wedge \mathbb{1}[q'_0 \neq y_n] \\ &= b(d'_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{n=1}^{N} \neg\,\mathrm{cap}(x_n, d_p) \wedge (\neg\,\mathrm{cap}(x_n, p_{K+1})) \wedge \mathbb{1}[q'_0 \neq y_n]. \qquad (32) \end{aligned}$$

The expression in (32) is simpler to compute than that in (31), because the former reuses $b(d'_p, \mathbf{x}, \mathbf{y})$, which we already computed in (30). Note that instead of computing $R(d', \mathbf{x}, \mathbf{y})$ incrementally from $b(d'_p, \mathbf{x}, \mathbf{y})$ as in (32), we could have computed it incrementally from $R(d, \mathbf{x}, \mathbf{y})$. However, doing so would in practice require that we store $R(d, \mathbf{x}, \mathbf{y})$ in addition to $b(d_p, \mathbf{x}, \mathbf{y})$, which we already must store to support (30). We prefer the incremental approach suggested by (32) since it avoids this additional storage overhead.

We present an incremental branch-and-bound procedure in Algorithm 2, and show the incremental computations of the objective lower bound (30) and objective (32) as two separate functions in Algorithms 3 and 4, respectively. In Algorithm 2, we use a cache to

Algorithm 2 Incremental branch-and-bound for learning rule lists, for simplicity, from a cold start. We explicitly show the incremental objective lower bound and objective functions in Algorithms 3 and 4, respectively.

Input: Objective function $R(d, \mathbf{x}, \mathbf{y})$, objective lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, set of antecedents $S = \{s_m\}_{m=1}^{M}$, training data $(\mathbf{x}, \mathbf{y}) = \{(x_n, y_n)\}_{n=1}^{N}$, regularization parameter λ
Output: Provably optimal rule list d^* with minimum objective R^*

```
d^c ← ((), (), q_0, 0)                          ▷ Initialize current best rule list with empty rule list

```

store prefixes and their objective lower bounds. Algorithm 2 additionally reorganizes the structure of Algorithm 1 to group together the computations associated with all children of a particular prefix. This has two advantages. The first is to consolidate cache queries: all children of the same parent prefix compute their objective lower bounds with respect to the parent's stored value, and we only require one cache 'find' operation for the entire group of children, instead of a separate query for each child. The second is to shrink the queue's size: instead of adding all of a prefix's children as separate queue elements, we represent the entire group of children in the queue by a single element. Since the number of children associated with each prefix is close to the total number of possible antecedents, both of these effects can yield significant savings. For example, if we are trying to optimize over rule lists

Algorithm 3 Incremental objective lower bound (30) used in Algorithm 2.

Input: Bit vector $\mathbf{v} \in \{0,1\}^N$ indicating data captured by s, the last antecedent in D_p, bit vector of class labels $\mathbf{y} \in \{0,1\}^N$, number of observations N
Output: Component of D's misclassification error due to data captured by s

function IncrementalLowerBound($\mathbf{v}, \mathbf{y}, N$)
  $n_v = \text{sum}(\mathbf{v})$ ▷ Number of data captured by s, the last antecedent in D_p
  $\mathbf{w} \leftarrow \mathbf{v} \wedge \mathbf{y}$ ▷ Bit vector indicating data captured by s with label 1
  $n_w = \text{sum}(\mathbf{w})$ ▷ Number of data captured by s with label 1
  if $n_w/n_v > 0.5$ **then**
    return $(n_v - n_w)/N$ ▷ Misclassification error of the rule $s \to 1$
  else
    return n_w/N ▷ Misclassification error of the rule $s \to 0$
  end if
end function

Algorithm 4 Incremental objective function (32) used in Algorithm 2.

Input: Bit vector $\mathbf{u} \in \{0,1\}^N$ indicating data not captured by D_p's parent prefix, bit vector $\mathbf{v} \in \{0,1\}^N$ indicating data not captured by s, the last antecedent in D_p, bit vector of class labels $\mathbf{y} \in \{0,1\}^N$, number of observations N
Output: Component of D's misclassification error due to its default rule

function IncrementalObjective($\mathbf{u}, \mathbf{v}, \mathbf{y}, N$)
  $\mathbf{f} \leftarrow \mathbf{u} \wedge \neg\, \mathbf{v}$ ▷ Bit vector indicating data not captured by D_p
  $n_f = \text{sum}(\mathbf{f})$ ▷ Number of data not captured by D_p
  $\mathbf{g} \leftarrow \mathbf{f} \wedge \mathbf{y}$ ▷ Bit vector indicating data not captured by D_p with label 1
  $n_g = \text{sum}(\mathbf{g})$ ▷ Number of data not captued by D_p with label 1
  if $n_g/n_f > 0.5$ **then**
    return $(n_f - n_g)/N$ ▷ Misclassification error of the default label prediction 1
  else
    return n_g/N ▷ Misclassification error of the default label prediction 0
  end if
end function

formed from a set of 1000 antecedents, then the maximum queue size in Algorithm 2 will be smaller than that in Algorithm 1 by a factor of nearly 1000.

5. Implementation

We implement our algorithm using a collection of optimized data structures that we describe in this section. First, we explain how we use a prefix tree (§5.1) to support the incremental computations that we motivated in §4. Second, we describe several queue designs that implement different search policies (§5.2). Third, we introduce a symmetry-aware map (§5.3) to support symmetry-aware pruning (Corollary 16, §3.11). Next, we summarize how these data structures interact throughout our model of incremental execution (§5.4). In particular, Algorithms 5 and 6 illustrate many of the computational details from CORELS' inner loop, highlighting each of the bounds from §3 that we use to prune the search space. We additionally describe how we garbage collect our data structures (§5.5). Finally, we explore how our queue can be used to support custom scheduling policies designed to improve performance (§5.6).

5.1 Prefix Tree

Our incremental computations (§4) require a cache to keep track of prefixes that we have already evaluated and that are also still under consideration by the algorithm. We implement this cache as a prefix tree, a data structure also known as a trie, which allows us to efficiently represent structure shared between related prefixes. Each node in the prefix tree encodes an individual rule $r_k = p_k \to q_k$. Each path starting from the root represents a prefix, such that the final node in the path also contains metadata associated with that prefix. For a prefix $d_p = (p_1, \ldots, p_K)$, let $\varphi(d_p)$ denote the corresponding node in the trie. The metadata at node $\varphi(d_p)$ supports the incremental computation and includes:

- An index encoding p_K, the last antecedent.
- The objective lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, defined in (5), the central bound in our framework (Theorem 1).
- The lower bound on the default rule misclassification error $b_0(d_p, \mathbf{x}, \mathbf{y})$, defined in (28), to support our equivalent points bound (Theorem 20).
- An indicator denoting whether this node should be deleted (see §5.5).
- A representation of viable extensions of d_p, *i.e.*, length $K+1$ prefix that start with d_p and have not been pruned.

For evaluation purposes and convenience, we store additional information in the prefix tree; for a prefix d_p with corresponding rule list $d = (d_p, \delta_p, q_0, K)$, the node $\varphi(d_p)$ also stores:

- The length K; equivalently, node $\varphi(d_p)$'s depth in the trie.
- The label prediction q_K corresponding to antecedent p_K.
- The default rule label prediction q_0.
- N_{cap}, the number of samples captured by prefix d_p, as in (34).
- The objective value $R(d, \mathbf{x}, \mathbf{y})$, defined in (4).

Finally, we note that we implement the prefix tree as a custom C++ class.

5.2 Queue

The queue is a worklist that orders exploration over the search space of possible rule lists; every queue element corresponds to a leaf in the prefix tree, and vice versa. In our implementation, each queue element points to a leaf; when we pop an element off the queue, we use the leaf's metadata to incrementally evaluate the corresponding prefix's children.

We order entries in the queue to implement several different search policies. For example, a first-in-first-out (FIFO) queue implements breadth-first search (BFS), and a priority queue implements best-first search. In our experiments (§6), we use the C++ Standard Template Library (STL) queue and priority queue to implement BFS and best-first search, respectively. For CORELS, priority queue policies of interest include ordering by the lower bound, the objective, or more generally, any function that maps prefixes to real values; stably ordering by prefix length and inverse prefix length implement BFS and depth-first search (DFS), respectively. In our released code, we present a unified implementation, where we use the STL priority queue to support BFS, DFS, and several best-first search policies. As we demonstrate in our experiments (§6.8), we find that using a custom search strategy, such as ordering by the lower bound, usually leads to a faster runtime than BFS.

We motivate the design of additional custom search strategies in §5.6. In preliminary work (not shown), we also experimented with stochastic exploration processes that bypass the need for a queue by instead following random paths from the root to leaves; developing such methods could be an interesting direction for future work. We note that these search policies are referred to as node selection strategies in the MIP literature. Strategies such as best-first (best-bound) search and DFS are known as static methods, and the framework we present in §5.6 has the spirit of estimate-based methods (Linderoth and Savelsbergh, 1999).

5.3 Symmetry-aware Map

The symmetry-aware map supports the symmetry-aware pruning justified in §3.10. In our implementation, we specifically leverage our permutation bound (Corollary 16), though it is also possible to directly exploit the more general equivalent support bound (Theorem 15). We use the C++ STL unordered map to keep track of the best known ordering of each evaluated set of antecedents. The keys of our symmetry-aware map encode antecedents in canonical order, *i.e.*, antecedent indices in numerically sorted order, and we associate all permutations of a set of antecedents with a single key. Each key maps to a value that encodes the best known prefix in the permutation group of the key's antecedents, as well as the objective lower bound of that prefix.

Before we consider adding a prefix d_p to the trie and queue, we check whether the map already contains a permutation $\pi(d_p)$ of that prefix. If no such permutation exists, then we insert d_p into the map, trie, and queue. Otherwise, if a permutation $\pi(d_p)$ exists and the lower bound of d_p is better than that of $\pi(d_p)$, *i.e.*, $b(d_p, \mathbf{x}, \mathbf{y}) < b(\pi(d_p), \mathbf{x}, \mathbf{y})$, then we update the map and remove $\pi(d_p)$ and its entire subtree from the trie; we also insert d_p into the trie and queue. Otherwise, if there exists a permutation $\pi(d_p)$ such that $b(\pi(d_p), \mathbf{x}, \mathbf{y}) \leq b(d_p, \mathbf{x}, \mathbf{y})$, then we do nothing, *i.e.*, we do not insert d_p into any data structures.

5.4 Incremental Execution

Mapping our algorithm to our data structures produces the following execution strategy, which we also illustrate in Algorithms 5 and 6. We initialize the current best objective R^c and rule list d^c. While the trie contains unexplored leaves, a scheduling policy selects the next prefix d_p to extend; in our implementation, we pop elements from a (priority) queue, until the queue is empty. Then, for every antecedent s that is not in d_p, we construct a new prefix D_p by appending s to d_p; we incrementally calculate the lower bound $b(D_p, \mathbf{x}, \mathbf{y})$, the objective $R(D, \mathbf{x}, \mathbf{y})$, of the associated rule list D, and other quantities used by our algorithm, summarized by the metadata fields of the (potential) prefix tree node $\varphi(D_p)$.

If the objective $R(D, \mathbf{x}, \mathbf{y})$ is less than the current best objective R^c, then we update R^c and d^c. If the lower bound of the new prefix D_p is less than the current best objective, then as described in §5.3, we query the symmetry-aware map for D_p; if we insert d'_p into the symmetry-aware map, then we also insert it into the trie and queue. Otherwise, then by our hierarchical lower bound (Theorem 1), no extension of D_p could possibly lead to a rule list with objective better than R^c, thus we do not insert D_p into the tree or queue. We also leverage our other bounds from §3 to aggressively prune the search space; we highlight each of these bounds in Algorithms 5 and 6, which summarize the computations and data structure operations performed in CORELS' inner loop. When there are no more leaves to explore, *i.e.*, the queue is empty, we output the optimal rule list. We can optionally terminate early according to some alternate condition, *e.g.*, when the size of the prefix tree exceeds some threshold.

5.5 Garbage Collection

During execution, we garbage collect the trie. Each time we update the minimum objective, we traverse the trie in a depth-first manner, deleting all subtrees of any node with lower bound larger than the current minimum objective. At other times, when we encounter a node with no children, we prune upwards, deleting that node and recursively traversing the tree towards the root, deleting any childless nodes. This garbage collection allows us to constrain the trie's memory consumption, though in our experiments we observe the minimum objective to decrease only a small number of times.

In our implementation, we cannot immediately delete prefix tree leaves because each corresponds to a queue element that points to it. The C++ STL priority queue is a wrapper container that prevents access to the underlying data structure, and thus we cannot access elements in the middle of the queue, even if we know the relevant identifying information. We therefore have no way to update the queue without iterating over every element. We address this by marking prefix tree leaves that we wish to delete (see §5.1), deleting the physical nodes lazily, after they are popped from the queue. Later, in our section on experiments (§6), we refer to two different queues that we define here: the physical queue corresponds to the C++ queue, and thus all prefix tree leaves, and the logical queue corresponds only to those prefix tree leaves that have not been marked for deletion.

Algorithm 5 The inner loop of CORELS, which evaluates all children of a prefix d_p.

Define $\mathbf{z} \in \{0,1\}^N$, s.t. $z_n = \sum_{u=1}^{U} \mathbb{1}[x_n \in e_u][y_n = q_u]$
▷ e_u is the equivalent points set containing x_n and q_u is the minority class label of e_u (§3.14)
Define $b(d_p, \mathbf{x}, \mathbf{y})$ and $\mathbf{u} = \neg \operatorname{cap}(\mathbf{x}, d_p)$ ▷ $\mathbf{u}$ is a bit vector indicating data not captured by d_p
for s in S **if** s not in d_p **then do** ▷ Evaluate all of d_p's children
  $D_p \leftarrow (d_p, s)$ ▷ **Branch**: Generate child D_p

5.6 Custom Scheduling Policies

In our setting, an ideal scheduling policy would immediately identify an optimal rule list, and then certify its optimality by systematically eliminating the remaining search space. This motivates trying to design scheduling policies that tend to quickly find optimal rule lists. When we use a priority queue to order the set of prefixes to evaluate next, we are free to implement different scheduling policies via the ordering of elements in the queue. This motivates designing functions that assign higher priorities to 'better' prefixes that we believe are more likely to lead to optimal rule lists. We follow the convention that priority queue elements are ordered by keys, such that keys with smaller values have higher priorities.

We introduce a custom class of functions that we call *curiosity* functions. Broadly, we think of the curiosity of a rule list d as the expected objective value of another rule list d' that is related to d; different models of the relationship between d and d' lead to different curiosity functions. In general, the curiosity of d is, by definition, equal to the sum of the expected misclassification error and the expected regularization penalty of d':

$$\mathcal{C}(d_p, \mathbf{x}, \mathbf{y}) \equiv \mathbb{E}[R(d', \mathbf{x}, \mathbf{y})] = \mathbb{E}[\ell(d'_p, \delta'_p, \mathbf{x}, \mathbf{y})] + \lambda \mathbb{E}[K']. \tag{33}$$

Next, we describe a simple curiosity function for a rule list d with prefix d_p. First, let N_{cap} denote the number of observations captured by d_p, *i.e.*,

$$N_{\text{cap}} \equiv \sum_{n=1}^{N} \text{cap}(x_n, d_p). \tag{34}$$

We now describe a model that generates another rule list $d' = (d'_p, \delta'_p, q'_0, K')$ from d_p. Assume that prefix d'_p starts with d_p and captures all the data, such that each additional antecedent in d'_p captures as many 'new' observations as each antecedent in d_p, on average; then, the expected length of d'_p is

$$\mathbb{E}[K'] = \frac{N}{N_{\text{cap}}/K}. \tag{35}$$

Furthermore, assume that each additional antecedent in d'_p makes as many mistakes as each antecedent in d_p, on average, thus the expected misclassification error of d'_p is

$$\begin{aligned}\mathbb{E}[\ell(d'_p, \delta'_p, \mathbf{x}, \mathbf{y})] &= \mathbb{E}[\ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y})] + \mathbb{E}[\ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y})] \\ &= \mathbb{E}[\ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y})] = \mathbb{E}[K'] \left(\frac{\ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y})}{K} \right). \end{aligned} \tag{36}$$

Note that the default rule misclassification error $\ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y})$ is zero because we assume that d'_p captures all the data. Inserting (35) and (36) into (33) thus gives curiosity for this model:

$$\begin{aligned}\mathcal{C}(d_p, \mathbf{x}, \mathbf{y}) &= \left(\frac{N}{N_{\text{cap}}} \right) \left(\ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K \right) \\ &= \left(\frac{1}{N} \sum_{n=1}^{N} \text{cap}(x_n, d_p) \right)^{-1} b(d_p, \mathbf{x}, \mathbf{y}) = \frac{b(d_p, \mathbf{x}, \mathbf{y})}{\text{supp}(d_p, \mathbf{x})}, \end{aligned}$$

where for the second equality, we used the definitions in (34) of N_{cap} and in (5) of d_p's lower bound, and for the last equality, we used the definition in (2) of d_p's normalized support.

The curiosity for a prefix d_p is thus also equal to its objective lower bound, scaled by the inverse of its normalized support. For two prefixes with the same lower bound, curiosity gives higher priority to the one that captures more data. This is a well-motivated scheduling strategy if we model prefixes that extend the prefix with smaller support as having more 'potential' to make mistakes. We note that using curiosity in practice does not introduce new bit vector or other expensive computations; during execution, we can calculate curiosity as a simple function of already derived quantities.

In preliminary experiments, we observe that using a priority queue ordered by curiosity sometimes yields a dramatic reduction in execution time, compared to using a priority queue ordered by the objective lower bound. Thus far, we have observed significant benefits on specific small problems, where the structure of the solutions happen to render curiosity particularly effective (not shown). Designing and studying other 'curious' functions, that are effective in more general settings, is an exciting direction for future work.

Data set	Prediction problem	N	Positive fraction	Resample training set	Training set size	Test set size
ProPublica	Two-year recidivism	6,907	0.46	No	6,217	692
NYPD	Weapon possession	325,800	0.03	Yes	566,839	32,580
NYCLU	Weapon possession	29,595	0.05	Yes	50,743	2,959

Table 1: Summary of data sets and prediction problems. The last five columns report the total number of observations, the fraction of observations with the positive class label, whether we resampled the training set due to class imbalance, and the sizes of each training and test set in our 10-fold cross-validation studies.

6. Experiments

Our experimental analysis addresses five questions: How does CORELS' predictive performance compare to that of COMPAS scores and other algorithms? (§6.4, §6.5, and §6.6) How does CORELS' model size compare to that of other algorithms? (§6.6) How rapidly do the objective value and its lower bound converge, for different values of the regularization parameter λ? (§6.7) How much does each of the implementation optimizations contribute to CORELS' performance? (§6.8) How rapidly does CORELS prune the search space? (§6.7 and §6.8) Before proceeding, we first describe our computational environment (§6.1), as well as the data sets and prediction problems we use (§6.2), and then in Section 6.3 show example optimal rule lists found by CORELS.

6.1 Computational Environment

All timed results ran on a server with an Intel Xeon E5-2699 v4 (55 MB cache, 2.20 GHz) processor and 264 GB RAM, and we ran each timing measurement separately, on a single hardware thread, with nothing else running on the server. Except where we mention a memory constraint, all experiments can run comfortably on smaller machines, *e.g.*, a laptop with 16 GB RAM.

6.2 Data Sets and Prediction Problems

Our evaluation focuses on two socially-important prediction problems associated with recent, publicly-available data sets. Table 1 summarizes the data sets and prediction problems, and Table 2 summarizes feature sets extracted from each data set, as well as antecedent sets we mine from these feature sets. We provide some details next. For further details about data sets, preprocessing steps, and antecedent mining, see Appendix E.

6.2.1 Recidivism Prediction

For our first problem, we predict which individuals in the ProPublica COMPAS data set (Larson et al., 2016) recidivate within two years. This data set contains records for all offenders in Broward County, Florida in 2013 and 2014 who were given a COMPAS score pre-trial. Recidivism is defined as being charged with a new crime within two years

Data set	Feature set	Categorical attributes	Binary features	Mined antecedents	Max number of clauses	Negations
ProPublica	A	6	13	122	2	No
ProPublica	B	7	17	189	2	No
NYPD	C	5	28	28	1	No
NYPD	D	3	20	20	1	No
NYCLU	E	5	28	46	1	Yes

Table 2: Summary of feature sets and mined antecedents. The last five columns report the number of categorical attributes, the number of binary features, the average number of mined antecedents, the maximum number of clauses in each antecedent, and whether antecedents include negated clauses.

after receiving a COMPAS assessment; the article by Larson et al. (2016), and their code,[3] provide more details about this definition. From the original data set of records for 7,214 individuals, we identify a subset of 6,907 records without missing data. For the majority of our analysis, we extract a set of 13 binary features (Feature Set A), which our antecedent mining framework combines into $M = 122$ antecedents, on average (folds ranged from containing 121 to 123 antecedents). We also consider a second, similar antecedent set in §6.3, derived from a superset of Feature Set A that includes 4 additional binary features (Feature Set B).

6.2.2 Weapon Prediction

For our second problem, we use New York City stop-and-frisk data to predict whether a weapon will be found on a stopped individual who is frisked or searched. For experiments in Sections 6.3 and 6.5 and Appendix G, we compile data from a database maintained by the New York Police Department (NYPD) (New York Police Department, 2016), from years 2008-2012, following Goel et al. (2016). Starting from 2,941,390 records, each describing an incident involving a stopped person, we first extract 376,488 records where the suspected crime was criminal possession of a weapon (CPW).[4] From these, we next identify a subset of 325,800 records for which the individual was frisked and/or searched; of these, criminal possession of a weapon was identified in only 10,885 instances (about 3.3%). Resampling due to class imbalance, for 10-fold cross-validation, yields training sets that each contain 566,839 datapoints. (We form corresponding test sets without resampling.) From a set of 5 categorical features, we form a set of 28 single-clause antecedents corresponding to 28 binary features (Feature Set C). We also consider another, similar antecedent set, derived from a subset of Feature Set C that excludes 8 location-specific binary features (Feature Set D).

In Sections 6.3, 6.6, 6.7, and 6.8, we also use a smaller stop-and-frisk data set, derived by the NYCLU from the NYPD's 2014 data (New York Civil Liberties Union, 2014). From the

3. Data and code used in the analysis by Larson et al. (2016) can be found at `https://github.com/propublica/compas-analysis`.

4. We filter for records that explicitly match the string 'CPW'; we note that additional records, after converting to lowercase, contain strings such as 'cpw' or 'c.p.w.'

if $(age = 21 - 22)$ **and** $(priors = 2 - 3)$ **then predict** *yes*

Figure 3: Example optimal rule lists that predict two-year recidivism for the ProPublica data set (Feature Set B, $M = 189$), found by CORELS ($\lambda = 0.005$), across 10 cross-validation folds. While some input antecedents contain features for race, no optimal rule list includes such an antecedent. Every optimal rule list is the same or similar to one of these examples, with prefixes containing the same rules, up to a permutation, and same default rule.

original data set of 45,787 records, each describing an incident involving a stopped person, we identify a subset of 29,595 records for which the individual was frisked and/or searched. Of these, criminal possession of a weapon was identified in about 5% of instances. As with the larger NYPD data set, we resample the data to form training sets (but not to form test sets). From the same set of 5 categorical features as in Feature Set C, we form a set of $M = 46$ single-clause antecedents, including negations (Feature Set E).

6.3 Example Optimal Rule Lists

To motivate Feature Set A, described in Appendix E, which we used in most of our analysis of the ProPublica data set, we first consider Feature Set B, a larger superset of features.

Figure 3 shows optimal rule lists learned by CORELS, using Feature Set B, which additionally includes race categories from the ProPublica data set (African American, Caucasian, Hispanic, Other[5]). For Feature Set B, our antecedent mining procedure generated an average of 189 antecedents, across folds. None of the optimal rule lists contain antecedents that directly depend on race; this motivated our choice to exclude race, by using Feature Set A, in our subsequent analysis. For both feature sets, we replaced the original ProPublica age categories (<25, 25-45, >45) with a set that is more fine-grained for younger individuals (18-20, 21-22, 23-25, 26-45, >45). Figure 4 shows example optimal rule lists that CORELS learns for the ProPublica data set (Feature Set A, $\lambda = 0.005$), using 10-fold cross validation.

Figures 5 and 6 show example optimal rule lists that CORELS learns for the NYCLU ($\lambda = 0.01$) and NYPD data sets. Figure 6 shows optimal rule lists that CORELS learns for the larger NYPD data set.

While our goal is to provide illustrative examples, and not to provide a detailed analysis nor to advocate for the use of these specific models, we note that these rule lists are short and easy to understand. For the examples and regularization parameter choices in this section,

5. We grouped the original Native American (<0.003), Asian (<0.005), and Other (<0.06) categories.

if $(age = 18-20)$ **and** $(sex = male)$ **then predict** *yes*

else if $(age = 21-22)$ **and** $(priors = 2-3)$ **then predict** *yes*
else if $(age = 23-25)$ **and** $(priors = 2-3)$ **then predict** *yes*
else if $(priors > 3)$ **then predict** *yes*
else predict *no*

Figure 4: Example optimal rule lists that predict two-year recidivism for the ProPublica data set (Feature Set A, $M = 122$), found by CORELS ($\lambda = 0.005$), across 10 cross-validation folds. Feature Set A is a subset of Feature Set B (Figure 3) that excludes race features. Optimal rule lists found using the two feature sets are very similar. The upper and lower rule lists are representative of 7 and 3 folds, respectively. Each of the remaining 8 solutions is the same or similar to one of these, with prefixes containing the same rules, up to a permutation, and the same default rule. See Figure 20 in Appendix F for a complete listing.

if $(location = transit\ authority)$ **then predict** *yes*
else if $(stop\ reason = suspicious\ bulge)$ **then predict** *yes*
else if $(stop\ reason = suspicious\ object)$ **then predict** *yes*
else predict *no*

Figure 5: An example rule list that predicts whether a weapon will be found on a stopped individual who is frisked or searched, for the NYCLU stop-and-frisk data set. Across 10 cross-validation folds, the other optimal rule lists found by CORELS ($\lambda = 0.01$) contain the same or equivalent rules, up to a permutation. See also Figure 23 in Appendix F.

the optimal rule lists are relatively robust across cross-validation folds: the rules are nearly the same, up to permutations of the prefix rules. For smaller values of the regularization parameter, we observe less robustness, as rule lists are allowed to grow in length. For the sets of optimal rule lists represented in Figures 3, 4, and 5, each set could be equivalently expressed as a DNF rule; *e.g.*, this is easy to see when the prefix rules all predict the positive class label and the default rule predicts the negative class label. Our objective is not designed to enforce any of these properties, though some may be seen as desirable.

As we demonstrate in §6.6, optimal rule lists learned by CORELS achieve accuracies that are competitive with a suite of other models, including black box COMPAS scores. See Appendix F for additional listings of optimal rule lists found by CORELS, for each of our prediction problems, across cross-validation folds, for different regularization parameters λ.

Figure 6: Example optimal rule lists for the NYPD stop-and-frisk data set, found by CORELS. Feature Set C contains attributes for 'location' and 'city', while Feature Set D does not. For each choice of regularization parameter and feature set, the rule lists learned by CORELS, across all 10 cross-validation folds, contain the same or equivalent rules, up to a permutation, with the exception of a single fold (Feature Set C, $\lambda = 0.005$). For a complete listing, see Figures 21 and 22 in Appendix F.

6.4 Comparison of CORELS to the Black Box COMPAS Algorithm

The accuracies of rule lists learned by CORELS are competitive with scores generated by the black box COMPAS algorithm at predicting two-year recidivism for the ProPublica data set (Figure 9). Across 10 cross-validation folds, optimal rule lists learned by CORELS (Figure 4, $\lambda = 0.005$) have a mean test accuracy of 0.665, with standard deviation 0.018. The COMPAS algorithm outputs scores between 1 and 10, representing low (1-4), medium (5-7), and high (8-10) risk for recidivism. As in the analysis by Larson et al. (2016), we interpret a medium or high score as a positive prediction for two-year recidivism, and a low score as a negative prediction. Across the 10 test sets, the COMPAS algorithm scores obtain a mean accuracy of 0.660, with standard deviation 0.019.

Figure 7 shows that CORELS and COMPAS perform similarly across both black and white individuals. Both algorithms have much higher true positive rates (TPR's) and false positive rates (FPR's) for blacks than whites (left), and higher true negative rates (TNR's)

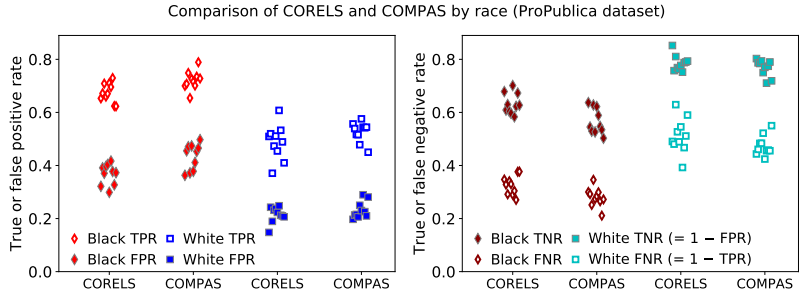

Figure 7: Comparison of TPR and FPR (left), as well as TNR and FNR (right), for different races in the ProPublica data set, for CORELS and COMPAS, across 10 cross-validation folds.

and false negative rates (FNR's) for whites than blacks (right). The fact that COMPAS has higher FPR's for blacks and higher FNR's for whites was a central observation motivating ProPublica's claim that COMPAS is racially biased (Larson et al., 2016). The fact that CORELS' models are so simple, with almost the same results as COMPAS, and contain only counts of past crimes, age, and gender, indicates possible explanations for the uneven predictions of both COMPAS and CORELS among blacks and whites. In particular, blacks evaluated within Broward County tend to be younger and have longer criminal histories within the data set, (on average, 4.4 crimes for blacks versus 2.6 crimes for whites) leading to higher FPR's for blacks and higher FNR's for whites. This aspect of the data could help to explain why ProPublica concluded that COMPAS was racially biased.

Similar observations have been reported for other datasets, namely that complex machine learning models do not have an advantage over simpler transparent models (Tollenaar and van der Heijden, 2013; Bushway, 2013; Zeng et al., 2017). There are many definitions of fairness, and it is not clear whether CORELS' models are fair either, but it is much easier to debate about the fairness of a model when it is transparent. Additional fairness constraints or transparency constraints can be placed on CORELS' models if desired, though one would need to edit our bounds (§3) and implementation (§5) to impose more constraints.

Regardless of whether COMPAS is racially biased (which our analysis does not indicate is necessarily true as long as criminal history and age are allowed to be considered as features), COMPAS may have many other fairness defects that might be considered serious. Many of COMPAS's survey questions are direct inquiries about socioeconomic status. For instance, a sample COMPAS survey[6] asks: "Is it easy to get drugs in your neighborhood?," "How often do you have barely enough money to get by?," "Do you frequently get jobs that don't pay more than minimum wage?," "How often have you moved in the last 12 months?" COMPAS's survey questions also ask about events that were not caused by the person who

6. A sample COMPAS survey contributed by Julia Angwin, ProPublica, can be found at `https://www.documentcloud.org/documents/2702103-Sample-Risk-Assessment-COMPAS-CORE.html`.

is being evaluated, such as: "If you lived with both parents and they later separated, how old were you at the time?," "Was one of your parents ever sent to jail or prison?," "Was your mother ever arrested, that you know of?"

The fact that COMPAS requires over 130 questions to be answered, many of whose answers may not be verifiable, means that the computation of the COMPAS score is prone to errors. Even the Arnold Foundation's "public-safety assessment" (PSA) score—which is completely transparent, and has only 9 factors—has been miscalculated in serious criminal trials, leading to a recent lawsuit (Westervelt, 2017). It is substantially more difficult to obtain the information required to calculate COMPAS scores than PSA scores (with over 14 times the number of survey questions). This significant discrepancy suggests that COMPAS scores are more fallible than PSA scores, as well as even simpler models, like those produced by CORELS. Some of these problems could be alleviated by using only data within electronic records that can be automatically calculated, instead of using information entered by hand and/or collected via subjective surveys.

The United States government pays Northpointe (now called Equivant) to use COMPAS. In light of our observations that CORELS is as accurate as COMPAS on a real-world data set where COMPAS is used in practice, CORELS predicts similarly to COMPAS for both blacks and whites, and CORELS' models are completely transparent, it is not clear what value COMPAS scores possess. Our experiments also indicate that the proprietary survey data required to compute COMPAS scores has not boosted its prediction accuracy above that of transparent models in practice.

Risk predictions are important for the integrity of the judicial system; judges cannot be expected to keep entire databases in their heads to calculate risks, whereas models (when used correctly) can help to ensure equity. Risk prediction models also have the potential to heavily impact how efficient the judicial system is, in terms of bail and parole decisions; efficiency in this case means that dangerous individuals are not released, whereas non-dangerous individuals are granted bail or parole. High stakes decisions, such as these, are ideal applications for machine learning algorithms that produce transparent models from high dimensional data.

Currently, justice system data does not support highly accurate risk predictions, but current risk models are useful in practice, and these risk predictions will become more accurate as more and higher quality data are made available.

6.5 Comparison of CORELS to a Heuristic Model for Weapon Prediction

CORELS generates simple, accurate models for the task of weapon prediction, using the NYPD stop-and-frisk data set. Our approach offers a principled alternative to heuristic models proposed by Goel et al. (2016), who develop a series of regression models to analyze racial disparities in New York City's stop-and-frisk policy for a related, larger data set. In particular, the authors arrive at a heuristic that they suggest could potentially help police officers more effectively decide when to frisk and/or search stopped individuals, *i.e.*, when such interventions are likely to discover criminal possession of a weapon (CPW). Starting from a full regression model with 7,705 variables, the authors reduce this to a smaller model with 98 variables; from this, they keep three variables with the largest coefficients. This gives

a heuristic model of the form $ax + by + cz \geq T$, where

$$x = \mathbb{1}[\textit{stop reason} = \textit{suspicious object}]$$
$$y = \mathbb{1}[\textit{stop reason} = \textit{suspicious bulge}]$$
$$z = \mathbb{1}[\textit{additional circumstances} = \textit{sights and sounds of criminal activity}],$$

and T is a threshold, such that the model predicts CPW when the threshold is met or exceeded. We focus on their approach that uses a single threshold, rather than precinct-specific thresholds. To increase ease-of-use, the authors round the coefficients to the nearest integers, which gives $(a, b, c) = (3, 1, 1)$; this constrains the threshold to take one of six values, $T \in \{0, 1, 2, 3, 4, 5\}$. To employ this heuristic model in the field, "...officers simply need to add at most three small, positive integers ... and check whether the sum exceeds a fixed threshold..." (Goel et al., 2016).

Figure 8 directly compares various models learned by CORELS to the heuristic models, using the same data set as Goel et al. (2016) and 10-fold cross-validation. Recall that we train on resampled data to correct for class imbalance; we evaluate with respect to test sets that have been formed without resampling. For CORELS, the models correspond to the rule lists illustrated in Figure 6 from Section 6.3, and Figures 21 and 22 in Appendix F, we consider both Feature Sets C and D and both regularization parameters $\lambda = 0.005$ and 0.01. The top panel plots the fraction of weapons recovered as a function of the fraction of stops where the individual was frisked and/or searched. Goel et al. (2016) target models that efficiently recover a majority of weapons (while also minimizing racial disparities, which we do not address here). Interestingly, the models learned by CORELS span a significant region that is not available to the heuristic model, which would require larger or non-integer parameters to access the region. The region is possibly desirable, since it includes models ($\lambda = 0.005$, bright red) that recover a majority ($\geq 50\%$) of weapons (that are known in the data set). More generally, CORELS' models all recover at least 40% of weapons on average, *i.e.*, more weapons than any of the heuristic models with $T \geq 2$, which recover less than 25% of weapons on average. At the same time, CORELS' models all require well under 25% of stops—significantly less than the heuristic model with $T = 1$, which requires over 30% of stops to recover a fraction of weapons comparable to the CORELS model that recovers the most weapons.

The bottom panel in Figure 8 plots both TPR and FPR and labels model size, for each of the models in the top panel. For the heuristic, we define model size as the number of model parameters; for CORELS, we use the number of rules in the rule list, which is equal to the number of leaves when we view a rule list as a decision tree. The heuristic models all have 4 parameters, while the different CORELS models have either 3 or approximately 5 rules. CORELS' models are thus approximately as small, interpretable, and transparent as the heuristic models; furthermore, their predictions are straightforward to compute, without even requiring arithmetic.

6.6 Predictive Performance and Model Size for CORELS and Other Algorithms

We ran a 10-fold cross validation experiment using CORELS and eight other algorithms: logistic regression, support vector machines (SVM), AdaBoost, CART, C4.5, random for-

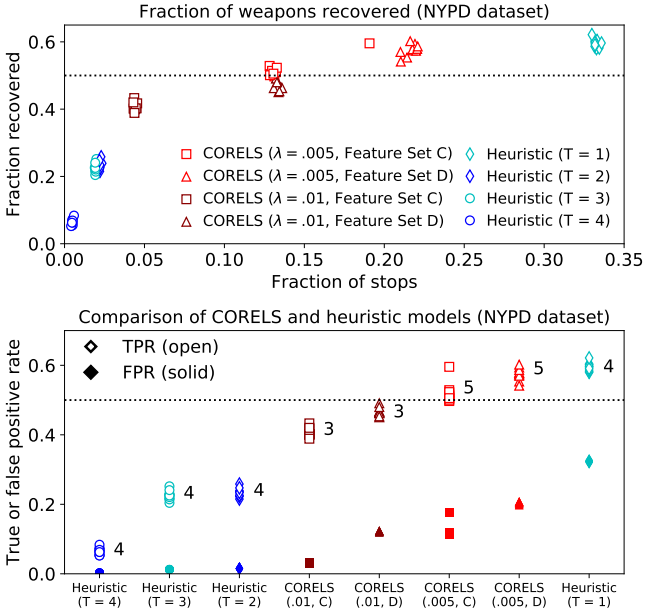

Figure 8: Weapon prediction with the NYPD stop-and-frisk data set, for various models learned by CORELS and the heuristic model by Goel et al. (2016), across 10 cross-validation folds. Note that the fraction of weapons recovered (top) is equal to the TPR (bottom, open markers). Markers above the dotted horizontal lines at the value 0.5 correspond to models that recover a majority of weapons (that are known in the data set). Top: Fraction of weapons recovered as a function of the fraction of stops where the individual was frisked and/or searched. In the legend, entries for CORELS (red markers) indicate the regularization parameter (λ) and whether or not extra location features were used ("location"); entries for the heuristic model (blue markers) indicate the threshold value (T). The results we report for the heuristic model are our reproduction of the results reported in Figure 9 by Goel et al. (2016) (first four open circles in that figure, from left to right; we exclude the trivial open circle showing 100% of weapons recovered at 100% of stops, obtained by setting the threshold at 0). Bottom: Comparison of TPR (open markers) and FPR (solid markers) for various CORELS and heuristic models. Models are sorted left-to-right by TPR. Markers and abbreviated horizontal tick labels correspond to the legend in the top figure. Numbers in the plot label model size; there was no variation in model size across folds, except for a single fold for CORELS ($\lambda = 0.005$, Feature Set C), which found a model of size 6.

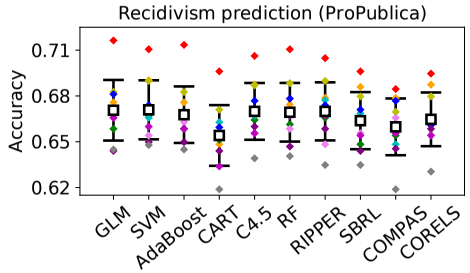

Figure 9: Two-year recidivism prediction for the ProPublica COMPAS data set. Comparison of CORELS and a panel of nine other algorithms: logistic regression (GLM), support vector machines (SVM), AdaBoost, CART, C4.5, random forests (RF), RIPPER, scalable Bayesian rule lists (SBRL), and COMPAS. For CORELS, we use regularization parameter $\lambda = 0.005$.

est (RF), RIPPER, and scalable Bayesian rule lists (SBRL).[7] We use standard R packages, with default parameter settings, for the first seven algorithms.[8] We use the same antecedent sets as input to the two rule list learning algorithms, CORELS and SBRL; for the other algorithms, the inputs are binary feature sets corresponding to the single clause antecedents in the aforementioned antecedent sets (see Appendix E).

Figure 9 shows that for the ProPublica data set, there were no statistically significant differences in test accuracies across algorithms, the difference between folds was far larger than the difference between algorithms. These algorithms also all perform similarly to the black box COMPAS algorithm. Figure 10 shows that for the NYCLU data set, logistic regression, SVM, and AdaBoost have the highest TPR's and also the highest FPR's; we show TPR and FPR due to class imbalance. For this problem, CORELS obtains an intermediate TPR, compared to other algorithms, while achieving a relatively low FPR. We conclude that CORELS produces models whose predictive performance is comparable to or better than those found via other algorithms.

Figures 11 and 12 summarize differences in predictive performance and model size for CORELS and other tree (CART, C4.5) and rule list (RIPPER, SBRL) learning algorithms. Here, we vary different algorithm parameters, and increase the number of iterations for SBRL to 10,000. For two-year recidivism prediction with the ProPublica data set (Figure 11), we plot both training and test accuracy, as a function of the number of leaves in the learned model. Due to class imbalance for the weapon prediction problem with the NYCLU stop-and-frisk data set (Figure 12), we plot both true positive rate (TPR) and false positive rate (FPR), again as a function of the number of leaves. For both problems, CORELS can learn short rule lists without sacrificing predictive performance. For listings of example optimal rule lists that correspond to the results for CORELS summarized here,

7. For SBRL, we use the C implementation at `https://github.com/Hongyuy/sbrlmod`. By default, SBRL sets $\eta = 3$, $\lambda = 9$, the number of chains to 11 and iterations to 1,000.
8. For CART, C4.5 (J48), and RIPPER, we use the R packages rpart, RWeka, and caret, respectively. By default, CART uses complexity parameter $cp = 0.01$ and C4.5 uses complexity parameter $C = 0.25$.

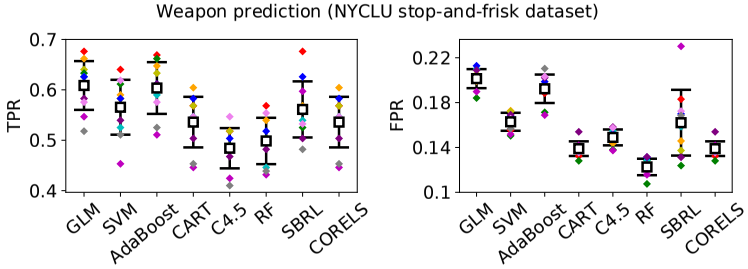

Figure 10: TPR (left) and FPR (right) for the test set, for CORELS and a panel of seven other algorithms, for the weapon prediction problem with the NYCLU stop-and-frisk data set. Means (white squares), standard deviations (error bars), and values (colors correspond to folds), for 10-fold cross-validation experiments. For CORELS, we use $\lambda = 0.01$. Note that we were unable to execute RIPPER for the NYCLU problem.

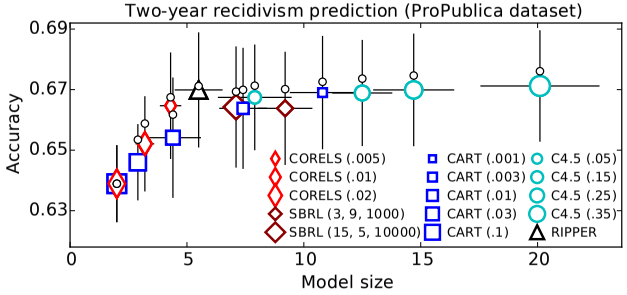

Figure 11: Training and test accuracy as a function of model size, across different methods, for two-year recidivism prediction with the ProPublica COMPAS data set. In the legend, numbers in parentheses are algorithm parameters that we vary for CORELS (λ), CART (cp), C4.5 (C), and SBRL (η, λ, i), where i is the number of iterations. Legend markers and error bars indicate means and standard deviations, respectively, across cross-validation folds. Small circles mark training accuracy means. None of the models exhibit significant overfitting; mean training accuracy never exceeds mean test accuracy by more than about 0.01.

see Appendix F. Also see Figure 25 in Appendix G; it uses the larger NYPD data set and is similar to Figure 12.

In Figure 4, we used CORELS to identify short rule lists, depending on only three features—age, prior convictions, and sex—that achieve test accuracy comparable to COMPAS (Figure 9, also see Angelino et al., 2017). If we restrict CORELS to search the space of rule lists formed from only age and prior convictions ($\lambda = 0.005$), the optimal rule lists it

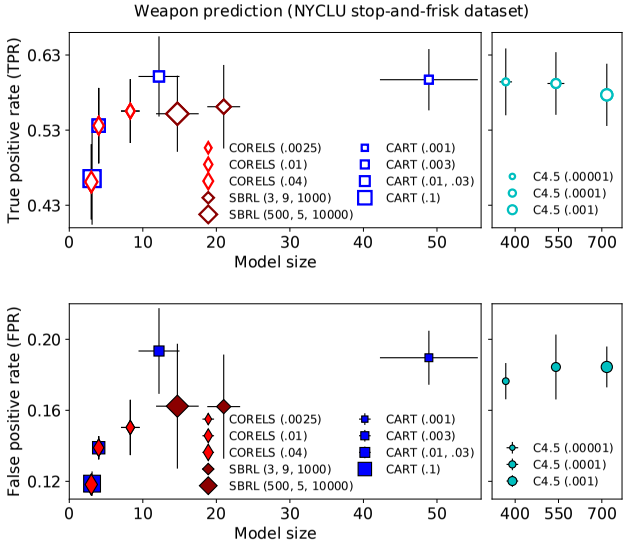

Figure 12: TPR (top) and FPR (bottom) for the test set, as a function of model size, across different methods, for weapon prediction with the NYCLU stop-and-frisk data set. In the legend, numbers in parentheses are algorithm parameters, as in Figure 11. Legend markers and error bars indicate means and standard deviations, respectively, across cross-validation folds. C4.5 finds large models for all tested parameters.

if $(priors > 3)$ **then predict** *yes*
else if $(age < 25)$ **and** $(priors = 2-3)$ **then predict** *yes*
else predict *no*

Figure 13: When restricted to two features (age, priors), CORELS ($\lambda = 0.005$) finds the same rule list across 10 cross-validation folds.

finds achieve test accuracy that is again comparable to COMPAS. CORELS identifies the same rule list across all 10 folds of 10-fold cross-validation experiments (Figure 13). In work subsequent to ours (Angelino et al., 2017), Dressel and Farid (2018) confirmed this result, in the sense that they used logistic regression to construct a linear classifier with age and prior convictions, and also achieved similar accuracy to COMPAS. However, computing a logistic regression model requires multiplication and addition, and their model cannot easily be computed, in the sense that it requires a calculator (and thus is potentially error-prone). Our rule lists require no such computation.

CORELS with different regularization parameters (NYCLU stop-and-frisk data set)

λ	Total time (s)	Time to optimum (s)	Max evaluated prefix length	Optimal prefix length
.04	.61 (.03)	.002 (.001)	6	2
.01	70 (6)	.008 (.002)	11	3
.0025	1600 (100)	56 (74)	16-17	6-10

λ	Lower bound evaluations ($\times 10^6$)	Total queue insertions ($\times 10^3$)	Max queue size ($\times 10^3$)
.04	.070 (.004)	2.2 (.1)	.9 (.1)
.01	7.5 (.6)	210 (20)	130 (10)
.0025	150 (10)	4400 (300)	2500 (170)

Table 3: Summary of CORELS executions, for the NYCLU stop-and-frisk data set ($M = 46$), for same three regularization parameter (λ) values as in Figure 12. The columns report the total execution time, time to optimum, maximum evaluated prefix length, optimal prefix length, number of times we completely evaluate a prefix d_p's lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, total number of queue insertions (this number is equal to the number of cache insertions), and the maximum queue size. For prefix lengths, we report single values or ranges corresponding to the minimum and maximum observed values; in the other columns, we report means (and standard deviations) over 10 cross-validation folds. See also Figures 14 and 15.

6.7 CORELS Execution Traces, for Different Regularization Parameters

In this section, we illustrate several views of CORELS execution traces, for the NYCLU stop-and-frisk data set with $M = 46$ antecedents, for the same three regularization parameters ($\lambda = .04, .01, .025$) as in Figure 12.

Table 3 summarizes execution traces across all 10 cross-validation folds. For each value of λ, CORELS achieves the optimum in a small fraction of the total execution time. As λ decreases, these times increase because the search problems become more difficult, as is summarized by the observation that CORELS must evaluate longer prefixes; consequently, our data structures grow in size. We report the total number of elements inserted into the queue and the maximum queue size; recall from §5 that the queue elements correspond to the trie's leaves, and that the symmetry-aware map elements correspond to the trie's nodes.

The upper panels in Figure 14 plot example execution traces, from a single cross-validation fold, of both the current best objective value R^c and the lower bound $b(d_p, \mathbf{x}, \mathbf{y})$ of the prefix d_p being evaluated. These plots illustrate that CORELS certifies optimality when the lower bound matches the objective value. The lower panels in Figure 14 plot corresponding traces of an upper bound on the size of the remaining search space (Theorem 7), and illustrate that as λ decreases, it becomes more difficult to eliminate regions of the search space. For Figure 14, we dynamically and incrementally calculate $\lfloor \log_{10} \Gamma(R^c, Q) \rfloor$, which adds some computational overhead; we do not calculate this elsewhere unless noted.

Figure 15 visualizes the elements in CORELS' logical queue, for each of the executions in Figure 14. Recall from §5.5 that the logical queue corresponds to elements in the (physical)

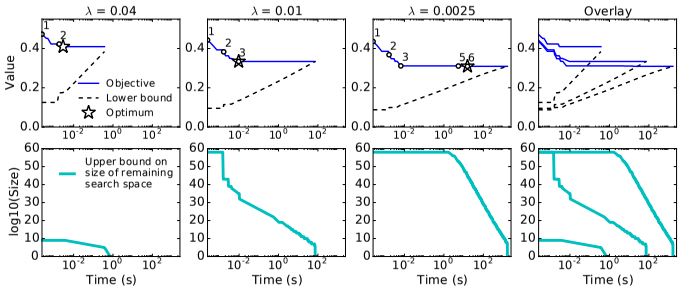

Figure 14: Example executions of CORELS, for the NYCLU stop-and-frisk data set ($M = 46$). See also Table 3 and Figure 15. Top: Objective value (solid line) and lower bound (dashed line) for CORELS, as a function of wall clock time (log scale). Numbered points along the trace of the objective value indicate when the length of the best known rule list changes and are labeled by the new length. For each value of λ, a star marks the optimum objective value and time at which it was achieved. Bottom: $\lfloor \log_{10} \Gamma(R^c, Q) \rfloor$, as a function of wall clock time (log scale), where $\Gamma(R^c, Q)$ is the upper bound on remaining search space size (Theorem 7). Rightmost panels: For visual comparison, we overlay the execution traces from the panels to the left, for the three different values of λ.

queue that have not been garbage collected from the trie; these are prefixes that CORELS has already evaluated and whose children the algorithm plans to evaluate next. As an execution progresses, longer prefixes are placed in the queue; as λ decreases, the algorithm must spend more time evaluating longer and longer prefixes.

6.8 Efficacy of CORELS Algorithm Optimizations

This section examines the efficacy of each of our bounds and data structure optimizations. We remove a single bound or data structure optimization from our final implementation and measure how the performance of our algorithm changes. We examine these performance traces on both the NYCLU and the ProPublica data sets, and highlight the result that on different problems, the relative performance improvements of our optimizations can vary.

Table 4 provides summary statistics for experiments using the full CORELS implementation (first row) and five variants (subsequent rows) that each remove a specific optimization: (1) Instead of a priority queue (§5.2) ordered by the objective lower bound, we use a queue that implements breadth-first search (BFS). (2) We remove checks that would trigger pruning via our lower bounds on antecedent support (Theorem 10) and accurate antecedent support (Theorem 11). (3) We remove the effect of our lookahead bound (Lemma 2), which otherwise tightens the objective lower bound by an amount equal to the regularization parameter λ. (4) We disable the symmetry-aware map (§5.3), our data structure that enables pruning triggered by the permutation bound (Corollary 16). (5) We do not identify sets of equivalent points, which we otherwise use to tighten the objective lower bound via the equivalent points bound (Theorem 20).

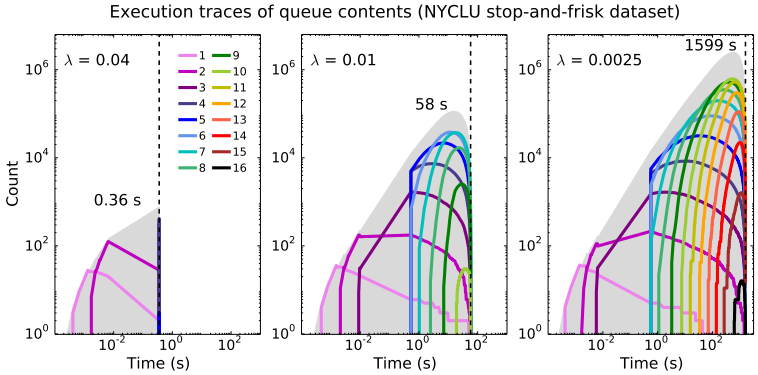

Figure 15: Summary of CORELS' logical queue, for the NYCLU stop-and-frisk data set ($M = 46$), for same three regularization parameters as in Figure 12 and Table 3. Solid lines plot the numbers of prefixes in the logical queue (log scale), colored by length (legend), as a function of wall clock time (log scale). All plots are generated using a single, representative cross-validation training set. For each execution, the gray shading fills in the area beneath the total number of queue elements, *i.e.*, the sum over all lengths; we also annotate the total time in seconds, marked with a dashed vertical line.

Removing any single optimization increases total execution time, by varying amounts across these optimizations. Similar to our experiments in §6.7, we always encounter the optimal rule list in far less time than it takes to certify optimality. As in Table 3, we report metrics that are all proxies for how much computational work our algorithm must perform; these metrics thus scale with the overall slowdown with respect to CORELS execution time (Table 4, first column).

Figure 16 visualizes execution traces of the elements in CORELS' logical queue, similar to Figure 15, for a single, representative cross-validation fold. Panels correspond to different removed optimizations, as in Table 4. These plots demonstrate that our optimizations reduce the number of evaluated prefixes and are especially effective at limiting the number of longer evaluated prefixes. For the ProPublica data set, the most important optimization is the equivalent points bound—without it, we place prefixes of at least length 10 in our queue, and must terminate these executions before they are complete. In contrast, CORELS and most other variants evaluate only prefixes up to at most length 5, except for the variant without the lookahead bound, which evaluates prefixes up to length 6.

Table 5 and Figure 17 summarize an analogous set of experiments for the NYCLU data set. Note that while the equivalent points bound proved to be the most important optimization for the ProPublica data set, the symmetry-aware map is the crucial optimization for the NYCLU data set.

Finally, Figure 18 highlights the most significant algorithm optimizations for our prediction problems: the equivalent points bound for the ProPublica data set (left) and the

Per-component performance improvement (ProPublica data set)

Algorithm variant	Total time (min)	Slow-down	Time to optimum (s)	Max evaluated prefix length
CORELS	.98 (.6)	—	1 (1)	5
No priority queue (BFS)	1.03 (.6)	1.1×	2 (4)	5
No support bounds	1.5 (.9)	1.5×	1 (2)	5
No lookahead bound	12.3 (6.2)	13.3×	1 (1)	6
No symmetry-aware map	9.1 (6.4)	8.4×	2 (3)	5
No equivalent points bound*	>130 (2.6)	>180×	>1400 (2000)	≥11

Algorithm variant	Lower bound evaluations ($\times 10^6$)	Total queue insertions ($\times 10^6$)	Max queue size ($\times 10^6$)
CORELS	26 (15)	.29 (.2)	.24 (.1)
No priority queue (BFS)	27 (16)	.33 (.2)	.20 (.1)
No support bounds	42 (25)	.40 (.2)	.33 (.2)
No lookahead bound	320 (160)	3.6 (1.8)	3.0 (1.5)
No symmetry-aware map	250 (180)	2.5 (1.7)	2.4 (1.7)
No equivalent points bound*	>940 (5)	>510 (1.1)	>500 (1.2)

Table 4: Per-component performance improvement, for the ProPublica data set ($\lambda = 0.005$, $M = 122$). The columns report the total execution time, time to optimum, maximum evaluated prefix length, number of times we completely evaluate a prefix d_p's lower bound $b(d_p, \mathbf{x}, \mathbf{y})$, total number of queue insertions (which is equal to the number of cache insertions), and maximum logical queue size. The first row shows CORELS; subsequent rows show variants that each remove a specific implementation optimization or bound. (We are not measuring the cumulative effects of removing a sequence of components.) All rows represent complete executions that certify optimality, except those labeled 'No equivalent points bound,' for which each execution was terminated due to memory constraints, once the size of the cache reached 5×10^8 elements, after consuming ∼250GB RAM. In all but the final row and column, we report means (and standard deviations) over 10 cross-validation folds. We also report the mean slowdown in total execution time, with respect to CORELS. In the final row, we report the mean (and standard deviation) of the incomplete execution time and corresponding slowdown, and a lower bound on the mean time to optimum; in the remaining fields, we report minimum values across folds. See also Figure 16.
* Only 7 out of 10 folds achieve the optimum before being terminated.

symmetry-aware map for the NYCLU data set (right). For CORELS (thin lines) with the ProPublica recidivism data set (left), the objective drops quickly, achieving the optimal value within a second. CORELS certifies optimality in about a minute—the objective lower bound steadily converges to the optimal objective (top) as the search space shrinks (bottom). As in Figure 14, we dynamically and incrementally calculate $\lfloor \log_{10} \Gamma(R^c, Q) \rfloor$, where $\Gamma(R^c, Q)$ is the upper bound (13) on remaining search space size (Theorem 7); this adds some computational overhead. In the same plots (left), we additionally highlight a

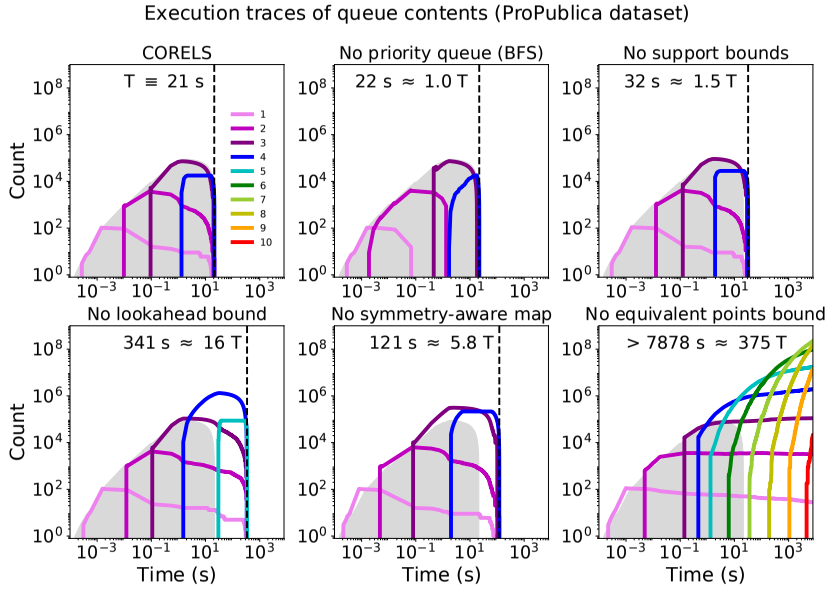

Figure 16: Summary of the logical queue's contents, for full CORELS (top left) and five variants that each remove a specific implementation optimization or bound, for the ProPublica data set ($\lambda = 0.005$, $M = 122$). See also Table 4. Solid lines plot the numbers of prefixes in the logical queue (log scale), colored by length (legend), as a function of wall clock time (log scale). All plots are generated using a single, representative cross-validation training set. The gray shading fills in the area beneath the total number of queue elements for CORELS, *i.e.*, the sum over all lengths in the top left figure. For comparison, we replicate the same gray region in the other five subfigures. For each execution, we indicate the total time in seconds, relative to the full CORELS implementation (T = 21 s), and with a dashed vertical line. The execution without the equivalent points bound (bottom right) is incomplete.

separate execution of CORELS without the equivalent points bound (Theorem 20) (thick lines). After more than 2 hours, the execution is still far from complete; in particular, the lower bound is far from the optimum objective value (top) and much of the search space remains unexplored (bottom). For the NYCLU stop-and-frisk data set (right), CORELS achieves the optimum objective in well under a second, and certifies optimality in a little over a minute. CORELS without the permutation bound (Corollary 16), and thus the symmetry-aware map, requires more than an hour, *i.e.*, orders of magnitude more time, to complete (thick lines).

Per-component performance improvement (NYCLU stop-and-frisk data set)

Algorithm variant	Total time (min)	Slow-down	Time to optimum (μs)	Max evaluated prefix length
CORELS	1.1 (.1)	—	8.9 (.1)	11
No priority queue (BFS)	2.2 (.2)	2.0×	110 (10)	11
No support bounds	1.2 (.1)	1.1×	8.8 (.8)	11
No lookahead bound	1.7 (.2)	1.6×	7.3 (1.8)	11-12
No symmetry-aware map	$>$ 73 (5)	$>$ 68×	$>$ 7.6 (.4)	$>$ 10
No equivalent points bound	4 (.3)	3.8×	6.4 (.9)	14

Algorithm variant	Lower bound evaluations ($\times 10^6$)	Total queue insertions ($\times 10^5$)	Max queue size ($\times 10^5$)
CORELS	7 (1)	2.0 (.2)	1.3 (.1)
No priority queue (BFS)	14 (1)	4.1 (.4)	1.4 (.1)
No support bounds	8 (1)	2.1 (.2)	1.3 (.1)
No lookahead bound	11 (1)	3.2 (.3)	2.1 (.2)
No symmetry-aware map	$>$ 390 (40)	$>$ 1000 (0)	$>$ 900 (10)
No equivalent points bound	33 (2)	9.4 (.7)	6.0 (.4)

Table 5: Per-component performance improvement, as in Table 4, for the NYCLU stop-and-frisk data set ($\lambda = 0.01$, $M = 46$). All rows except those labeled 'No symmetry-aware map' represent complete executions. A single fold running without a symmetry-aware map required over 2 days to complete, so in order to run all 10 folds above, we terminated execution after the prefix tree (§5.1) reached 10^8 nodes. See Table 4 for a detailed caption, and also Figure 17.

Algorithmic approach	Max evaluated prefix length	Lower bound evaluations	Predicted runtime	
CORELS	5	2.8×10^7	36 seconds	
Brute force	5	2.5×10^{10}	9.0 hours	$\approx 3.3 \times 10^4$ s
Brute force	10	5.0×10^{20}	21×10^6 years	$\approx 6.5 \times 10^{14}$ s
CORELS (1984)	5	2.8×10^7	13.5 days	$\approx 1.2 \times 10^6$ s

Table 6: Algorithmic speedup for the ProPublica data set ($\lambda = 0.005$, $M = 122$). Solving this problem using brute force is impractical due to the inability to explore rule lists of reasonable lengths. Removing only the equivalent points bound requires exploring prefixes of up to length 10 (see Table 4), a clearly intractable problem. Even with all of our improvements, however, it is only recently that processors have been fast enough for this type of discrete optimization algorithm to succeed.

6.9 Algorithmic Speedup

Table 6 shows the overall speedup of CORELS compared to a naïve implementation and demonstrates the infeasibility of running our algorithm 30 years ago. Consider an execution of CORELS for the ProPublica data set, with $M = 122$ antecedents, that evaluates prefixes

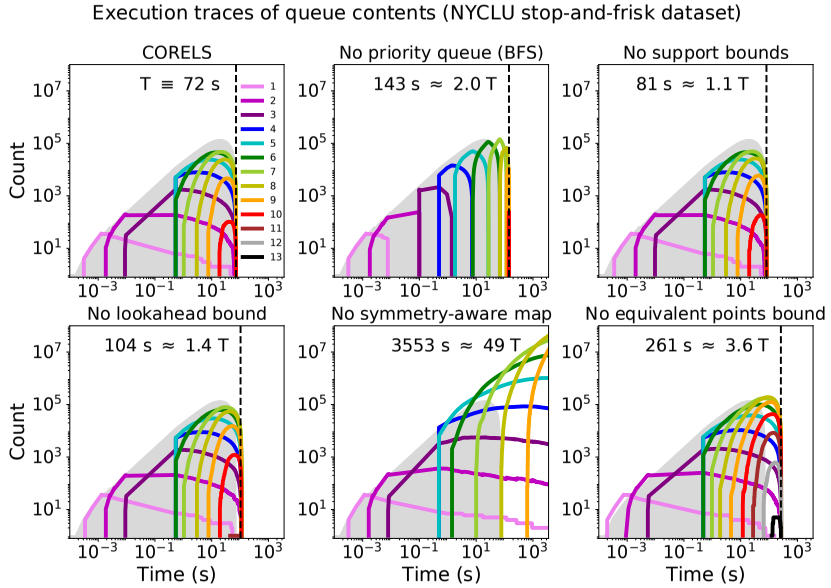

Figure 17: Summary of the logical queue's contents, for full CORELS (top left) and five variants that each remove a specific implementation optimization or bound, for the NYCLU stop-and-frisk data set ($\lambda = 0.01$, $M = 46$), as in Table 5. The execution without the symmetry-aware map (bottom center) is incomplete. See Figure 16 for a detailed caption.

up to length 5 in order to certify optimality (Table 4). A brute force implementation that naïvely considers all prefixes of up to length 5 would evaluate 2.5×10^{10} prefixes. As shown in Figure 4, the optimal rule list has prefix length 3, thus the brute force algorithm would identify the optimal rule list. However, for this approach to certify optimality, it would have to consider far longer prefixes. Without our equivalent points bound, but with all of our other optimizations, we evaluate prefixes up to at least length 10 (see Table 4 and Figure 16)—thus a brute force algorithm would have to evaluate prefixes of length 10 or longer. Naïvely evaluating all prefixes up to length 10 would require looking at 5.0×10^{20} different prefixes.

However, CORELS examines only 28 million prefixes in total—a reduction of 893× compared to examining all prefixes up to length 5 and a reduction of 1.8×10^{13} for the case of length 10. On a laptop, we require about 1.3 μs to evaluate a single prefix (given by dividing the number of lower bound evaluations by the total time in Table 4). Our runtime is only about 36 seconds, but the naïve solutions of examining all prefixes up to lengths 5

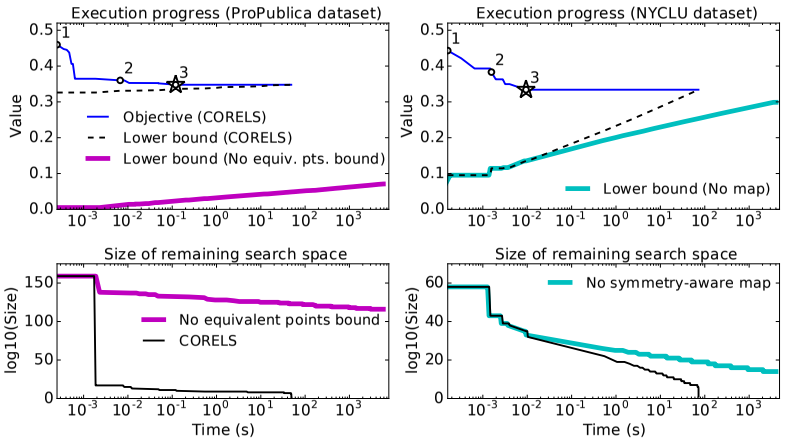

Figure 18: Execution progress of CORELS and selected variants, for the ProPublica ($\lambda = 0.005$, $M = 122$) (left) and NYCLU ($\lambda = 0.01$, $M = 46$) (right) data sets. Top: Objective value (thin solid lines) and lower bound (dashed lines) for CORELS, as a function of wall clock time (log scale). Numbered points along the trace of the objective value indicate when the length of the best known rule list changes, and are labeled by the new length. CORELS quickly achieves the optimal value (star markers), and certifies optimality when the lower bound matches the objective value. On the left, a separate and significantly longer execution of CORELS without the equivalent points (Theorem 20) bound remains far from complete, and its lower bound (thick solid line) far from the optimum. On the right, a separate execution of CORELS without the permutation bound (Corollary 16), and thus the symmetry-aware map, requires orders of magnitude more time to complete. Bottom: $\lfloor \log_{10} \Gamma(R^c, Q) \rfloor$, as a function of wall clock time (log scale), where $\Gamma(R^c, Q)$ is the upper bound (13) on remaining search space size (Theorem 7). For these problems, the equivalent points (left) and permutation (right) bounds are responsible for the ability of CORELS to quickly eliminate most of the search space (thin solid lines); the remaining search space decays much more slowly without these bounds (thick solid lines).

and 10 would take 9 hours and 21 million years, respectively. It is clear that brute force would not scale to larger problems.

We compare our current computing circumstances to those of 1984, the year when CART was published. Moore's law holds that computing power doubled every 18 months from 1984 to 2006. This is a period of 264 months, which means computing power has gone up by at least a factor of 32,000 since 1984. Thus, even with our algorithmic and data structural improvements, CORELS would have required about 13.5 days in 1984—an unreasonable amount of time. Our advances are meaningful only because we can run them on a modern

system. Combining our algorithmic improvements with the increase in modern processor speeds, our algorithm runs more than 10^{13} times faster than a naïve implementation would have in 1984. This helps explain why neither our algorithm, nor other branch-and-bound variants, had been developed before now.

7. Summary and Future Work on Bounds

Here, we highlight our most significant bounds, as well as directions for future work based on bounds that we have yet to leverage in practice.

In empirical studies, we found our equivalent support (§3.10, Theorem 15) and equivalent points (§3.14, Theorem 20) bounds to yield the most significant improvements in algorithm performance. In fact, they sometimes proved critical for finding solutions and proving optimality, even on small problems.

Accordingly, we would hope that our similar support bound (§3.13, Theorem 18) could be useful; understanding how to efficiently exploit this result in practice represents an important direction for future work. In particular, this type of bound may lead to principled approximate variants of our approach.

We presented several sets of bounds in which at least one bound was strictly tighter than the other(s). For example, the lower bound on accurate antecedent support (Theorem 11) is strictly tighter than the lower bound on accurate support (Theorem 10). It might seem that we should only use this tighter bound, but in practice, we can use both—the looser bound can be checked before completing the calculation required to check the tighter bound. Similarly, the equivalent support bound (Theorem 15) is more general than the special case of the permutation bound (Corollary 16). We have implemented data structures, which we call symmetry-aware maps, to support both of these bounds, but have not yet identified an efficient approach for supporting the more general equivalent points bound. A good solution may be related to the challenge of designing an efficient data structure to support the similar support bound.

We also presented results on antecedent rejection that unify our understanding of our lower (§3.7) and upper bounds (§3.8) on antecedent support. In a preliminary implementation (not described here), we experimented with special data structures to support the direct use of our observation that antecedent rejection propagates (§3.9, Theorem 12). We leave the design of efficient data structures for this task as future work.

During execution, we find it useful to calculate an upper bound on the size of the remaining search space—*e.g.*, via Theorem 7, or the looser Proposition 9, which incurs less computational overhead—since these provide meaningful information about algorithm progress and allow us to estimate the remaining execution time. As we illustrated in Section 6.8, these calculations also help us qualify the impact of different algorithmic bounds, *e.g.*, by comparing executions that keep or remove bounds.

When our algorithm terminates, it outputs an optimal solution of the training optimization problem, with a certificate of optimality. On a practical note, our approach can also provide useful results even for incomplete executions. As shown earlier, we have empirically observed that our algorithm often identifies the optimal rule list very quickly, compared to the total time required to prove optimality, *e.g.*, in seconds, versus minutes, respectively. Furthermore, our objective's lower bounds allow us to place an upper bound on the size of

the remaining search space, and provides guarantees on the quality of a solution output by an incomplete execution.

The order in which we evaluate prefixes can impact the rate at which we prune the search space, and thus the total runtime. We think that it is possible to design search policies that significantly improve performance.

8. Conclusion and More Possible Directions for Future Work

Finally, we would like to clarify some limitations of CORELS. As far as we can tell, CORELS is the current best algorithm for solving a specialized optimal decision tree problem. While our approach scales well to large numbers of observations, it could have difficulty proving optimality for problems with many possibly relevant features that are highly correlated, when large regions of the search space might be challenging to exclude.

CORELS is not designed for raw image processing or other problems where the features themselves are not interpretable. It could instead be used as a final classifier for image processing problems where the features were created beforehand; for instance, one could create classifiers for each part of an image, and use CORELS to create a final combined classifier. The notions of interpretability used in image classification tend to be completely different from those for structured data where each feature is separately meaningful (e.g., see Li et al., 2018). For structured data, decision trees, along with scoring systems, tend to be popular forms of transparent models. Scoring systems are sparse linear models with integer coefficients, and they can also be created from data (Ustun and Rudin, 2017, 2016).

In some of our experiments, CORELS produces a DNF formula by coincidence, but it might be possible to create a much simpler version of CORELS that only produces DNF formulae. This could build off previous algorithms for creating an optimal DNF formula (Rijnbeek and Kors, 2010; Wang et al., 2016, 2017).

CORELS does not automatically rank the subgroups in order of the likelihood of a positive outcome; doing so would require an algorithm such as Falling Rule Lists (Wang and Rudin, 2015a; Chen and Rudin, 2018), which forces the estimated probabilities to decrease along the list. Furthermore, while CORELS does not technically produce estimates of $\mathbb{P}(Y = 1 \,|\, x)$, one could form such an estimate by computing the empirical proportion $\hat{\mathbb{P}}(Y = 1 \,|\, x \text{ obeys } p_k)$ for each antecedent p_k. CORELS is also not designed to assist with causal inference applications, since it does not estimate the effect of a treatment via the conditional difference $\mathbb{P}(Y = 1 \,|\, \text{treatment} = \text{True}, x) - \mathbb{P}(Y = 1 \,|\, \text{treatment} = \text{False}, x)$. Alternative algorithms that estimate conditional differences with interpretable rule lists include Causal Falling Rule Lists (Wang and Rudin, 2015b), Cost-Effective Interpretable Treatment Regimes (CITR) (Lakkaraju and Rudin, 2017), and an approach by Zhang et al. (2015) for constructing interpretable and parsimonious treatment regimes. Alternatively, one could use a complex machine learning model to predict outcomes for the treatment group and a separate complex model for the control group that would allow counterfactuals to be estimated for each observation; from there, CORELS could be applied to produce a transparent model for personalized treatment effects. A similar approach to this was taken by Goh and Rudin (2018), who use CORELS to understand a black box causal model.

CORELS could be adapted to handle cost-sensitive learning or weighted regularization. This would require creating more general versions of our theorems, which would be an extension of this work.

While CORELS does not directly handle continuous variables, we have found that it is not difficult in practice to construct a rule set that is sufficient for creating a useful model. It may be possible to use techniques such as Fast Boxes (Goh and Rudin, 2014) to discover useful and interpretable rules for continuous data that can be used within CORELS.

An interesting direction for future research would be to create a hybrid interpretable/ black box model in the style of Wang (2018), where the rule list would eliminate large parts of the space away from the decision boundary, and the observations that remain are evaluated by a black box model rather than a default rule.

Lastly, CORELS does not create generic single-variable-split decision trees. CORELS optimizes over rule lists, which are one-sided decision trees; in our setting, the leaves of these 'trees' are conjunctions. It may be possible to generalize ideas from our approach to handle generic decision trees, which could be an interesting project for future work. There are more symmetries to handle in that case, since there would be many equivalent decision trees, leading to challenges in developing symmetry-aware data structures.

Acknowledgments

E.A. conducted most of this work while supported by the Miller Institute for Basic Research in Science, University of California, Berkeley, and hosted by Prof. M.I. Jordan at RISELab. C.D.R. is supported in part by MIT-Lincoln Labs and the National Science Foundation under IIS-1053407. E.A. would like to thank E. Jonas, E. Kohler, and S. Tu for early implementation guidance, A. D'Amour for pointing out the work by Goel et al. (2016), V. Kanade, S. McCurdy, J. Schleier-Smith and E. Thewalt for helpful conversations, and members of RISELab, SAIL, and the UC Berkeley Database Group for their support and feedback. We thank H. Yang and B. Letham for sharing advice and code for processing data and mining rules, B. Coker for his critical advice on using the ProPublica COMPAS data set, as well as V. Kaxiras and A. Saligrama for their recent contributions to our implementation and for creating the CORELS website. We are very grateful to our editor and anonymous reviewers.

Appendix A. Excessive Antecedent Support

Theorem 21 (Upper bound on antecedent support) *Let $d^* = (d_p, \delta_p, q_0, K)$ be any optimal rule list with objective R^*, i.e., $d^* \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$, and let $d_p = (p_1, \ldots, p_{k-1}, p_k, \ldots, p_K)$ be its prefix. For each $k \leq K$, antecedent p_k in d_p has support less than or equal to the fraction of all data not captured by preceding antecedents, by an amount greater than the regularization parameter λ:*

$$\operatorname{supp}(p_k, \mathbf{x} \,|\, d_p) \leq 1 - \operatorname{supp}(d_p^{k-1}, \mathbf{x}) - \lambda, \tag{37}$$

where $d_p^{k-1} = (p_1, \ldots, p_{k-1})$. For the last antecedent, i.e., when $p_k = p_K$, equality implies that there also exists a shorter optimal rule list $d' = (d_p^{K-1}, \delta_p', q_0', K-1) \in \operatorname{argmin}_d R(d, \mathbf{x}, \mathbf{y})$.

Proof First, we focus on the last antecedent p_{K+1} in a rule list d'. Let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1, \ldots, p_K)$ and objective $R(d, \mathbf{x}, \mathbf{y}) \geq R^*$, where $R^* \equiv \min_D R(D, \mathbf{x}, \mathbf{y})$ is the optimal objective. Let $d' = (d'_p, \delta'_p, q'_0, K+1)$ be a rule list whose prefix $d'_p = (p_1, \ldots, p_K, p_{K+1})$ starts with d_p and ends with a new antecedent p_{K+1}. Suppose p_{K+1} in the context of d'_p captures nearly all data not captured by d_p, except for a fraction ϵ upper bounded by the regularization parameter λ:

$$1 - \text{supp}(d_p, \mathbf{x}) - \text{supp}(p_{K+1}, \mathbf{x} \,|\, d'_p) \equiv \epsilon \leq \lambda.$$

Since d'_p starts with d_p, its prefix misclassification error is at least as great; the only discrepancy between the misclassification errors of d and d' can come from the difference between the support of the set of data not captured by d_p and the support of p_{K+1}:

$$|\ell(d', \mathbf{x}, \mathbf{y}) - \ell(d, \mathbf{x}, \mathbf{y})| \leq 1 - \text{supp}(d_p, \mathbf{x}) - \text{supp}(p_{K+1}, \mathbf{x} \,|\, d'_p) = \epsilon.$$

The best outcome for d' would occur if its misclassification error were smaller than that of d by ϵ, therefore

$$\begin{aligned} R(d', \mathbf{x}, \mathbf{y}) &= \ell(d', \mathbf{x}, \mathbf{y}) + \lambda(K+1) \\ &\geq \ell(d, \mathbf{x}, \mathbf{y}) - \epsilon + \lambda(K+1) = R(d, \mathbf{x}, \mathbf{y}) - \epsilon + \lambda \geq R(d, \mathbf{x}, \mathbf{y}) \geq R^*. \end{aligned}$$

d' is an optimal rule list, *i.e.*, $d' \in \text{argmin}_D R(D, \mathbf{x}, y)$, if and only if $R(d', \mathbf{x}, \mathbf{y}) = R(d, \mathbf{x}, \mathbf{y}) = R^*$, which requires $\epsilon = \lambda$. Otherwise, $\epsilon < \lambda$, in which case

$$R(d', \mathbf{x}, \mathbf{y}) \geq R(d, \mathbf{x}, \mathbf{y}) - \epsilon + \lambda > R(d, \mathbf{x}, \mathbf{y}) \geq R^*,$$

therefore d' is not optimal, *i.e.*, $d' \notin \text{argmin}_D R(D, \mathbf{x}, \mathbf{y})$. This demonstrates the desired result for $k = K$.

In the remainder, we prove the bound in (37) by contradiction, in the context of a rule list d''. Let d and d' retain their definitions from above, thus as before, that the data not captured by d'_p has normalized support $\epsilon \leq \lambda$, *i.e.*,

$$1 - \text{supp}(d'_p, \mathbf{x}) = 1 - \text{supp}(d_p, \mathbf{x}) - \text{supp}(p_{K+1}, \mathbf{x} \,|\, d'_p) = \epsilon \leq \lambda.$$

Thus for any rule list d'' whose prefix $d''_p = (p_1, \ldots, p_{K+1}, \ldots, p_{K'})$ starts with d'_p and ends with one or more additional rules, each additional rule p_k has support $\text{supp}(p_k, \mathbf{x} \,|\, d''_p) \leq \epsilon \leq \lambda$, for all $k > K+1$. By Theorem 10, all of the additional rules have insufficient support, therefore d''_p cannot be optimal, *i.e.*, $d'' \notin \text{argmin}_D R(D, \mathbf{x}, \mathbf{y})$. ■

Similar to Theorem 10, our lower bound on antecedent support, we can apply Theorem 21 in the contexts of both constructing rule lists and rule mining (§3.1). Theorem 21 implies that if we only seek a single optimal rule list, then during branch-and-bound execution, we can prune a prefix if we ever add an antecedent with support too similar to the support of the set of data not captured by the preceding antecedents. One way to view this result is that if $d = (d_p, \delta_p, q_0, K)$ and $d' = (d'_p, \delta'_p, q'_0, K+1)$ are rule lists such that d'_p starts with d_p and ends with an antecedent that captures all or nearly all data not captured by d_p, then the new rule in d' behaves similar to the default rule of d. As a result, the misclassification error of d' must be similar to that of d, and any reduction may not be sufficient to offset the penalty for longer prefixes.

Proposition 22 (Excessive antecedent support propagates) *Define $\phi(d_p)$ as in (19), and let $d_p = (p_1, \ldots, p_K)$ be a prefix, such that its last antecedent p_K has excessive support, i.e., the opposite of the bound in (37):*

$$\text{supp}(p_K, \mathbf{x} \,|\, d_p) > 1 - \text{supp}(d_p^{K-1}, \mathbf{x}) - \lambda,$$

where $d_p^{K-1} = (p_1, \ldots, p_{K-1})$. Let $D = (D_p, \Delta_p, Q_0, \kappa)$ be any rule list with prefix $D_p = (P_1, \ldots, P_\kappa)$ such that D_p starts with $D_p^{K'-1} = (P_1, \ldots, P_{K'-1}) \in \phi(d_p^{K-1})$ and $P_{K'} = p_K$. It follows that $P_{K'}$ has excessive support in prefix D_p, and furthermore, $D \notin \text{argmin}_d R(d, \mathbf{x}, \mathbf{y})$.

Proof Since $D_p^{K'} = (P_1, \ldots, P_{K'})$ contains all the antecedents in d_p, we have that

$$\text{supp}(D_p^{K'}, \mathbf{x}) \geq \text{supp}(d_p, \mathbf{x}).$$

Expanding these two terms gives

$$\begin{aligned} \text{supp}(D_p^{K'}, \mathbf{x}) &= \text{supp}(D_p^{K'-1}, \mathbf{x}) + \text{supp}(P_{K'}, \mathbf{x} \,|\, D_p) \\ &\geq \text{supp}(d_p, \mathbf{x}) = \text{supp}(d_p^{K-1}, \mathbf{x}) + \text{supp}(p_K, \mathbf{x} \,|\, d_p) > 1 - \lambda. \end{aligned}$$

Rearranging gives

$$\text{supp}(P_{K'}, \mathbf{x} \,|\, D_p) > 1 - \text{supp}(D_p^{K'-1}, \mathbf{x}) - \lambda,$$

thus $P_{K'}$ has excessive support in D_p. By Theorem 21, $D \notin \text{argmin}_d R(d, \mathbf{x}, \mathbf{y})$. ■

Appendix B. Proof of Theorem 15 (Equivalent Support Bound)

We begin by defining four related rule lists. First, let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1, \ldots, p_K)$ and labels $\delta_p = (q_1, \ldots, q_K)$. Second, let $D = (D_p, \Delta_p, Q_0, \kappa)$ be a rule list with prefix $D_p = (P_1, \ldots, P_\kappa)$ that captures the same data as d_p, and labels $\Delta_p = (Q_1, \ldots, Q_\kappa)$. Third, let $d' = (d'_p, \delta'_p, q'_0, K') \in \sigma(d_p)$ be any rule list whose prefix starts with d_p, such that $K' \geq K$. Denote the prefix and labels of d' by $d'_p = (p_1, \ldots, p_K, p_{K+1}, \ldots, p_{K'})$ and $\delta_p = (q_1, \ldots, q_{K'})$, respectively. Finally, define $D' = (D'_p, \Delta'_p, Q'_0, \kappa') \in \sigma(D_p)$ to be the 'analogous' rule list, *i.e.*, whose prefix $D'_p = (P_1, \ldots, P_\kappa, P_{\kappa+1}, \ldots, P_{\kappa'}) = (P_1, \ldots, P_\kappa, p_{K+1}, \ldots, p_{K'})$ starts with D_p and ends with the same $K' - K$ antecedents as d'_p. Let $\Delta'_p = (Q_1, \ldots, Q_{\kappa'})$ denote the labels of D'.

Next, we claim that the difference in the objectives of rule lists d' and d is the same as the difference in the objectives of rule lists D' and D. Let us expand the first difference as

$$\begin{aligned} &R(d', \mathbf{x}, \mathbf{y}) - R(d, \mathbf{x}, \mathbf{y}) = \ell(d', \mathbf{x}, \mathbf{y}) + \lambda K' - \ell(d, \mathbf{x}, \mathbf{y}) - \lambda K \\ &= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) + \ell_0(d'_p, q'_0, \mathbf{x}, \mathbf{y}) - \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) - \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) + \lambda(K' - K). \end{aligned}$$

Similarly, let us expand the second difference as

$$\begin{aligned} &R(D', \mathbf{x}, \mathbf{y}) - R(D, \mathbf{x}, \mathbf{y}) = \ell(D', \mathbf{x}, \mathbf{y}) + \lambda\kappa' - \ell(D, \mathbf{x}, \mathbf{y}) - \lambda\kappa \\ &= \ell_p(D'_p, \Delta'_p, \mathbf{x}, \mathbf{y}) + \ell_0(D'_p, Q'_0, \mathbf{x}, \mathbf{y}) - \ell_p(D_p, \Delta_p, \mathbf{x}, \mathbf{y}) - \ell_0(D_p, Q_0, \mathbf{x}, \mathbf{y}) + \lambda(K' - K), \end{aligned}$$

where we have used the fact that $\kappa' - \kappa = K' - K$.

The prefixes d_p and D_p capture the same data. Equivalently, the set of data that is not captured by d_p is the same as the set of data that is not captured by D_p, *i.e.*,

$$\{x_n : \neg \operatorname{cap}(x_n, d_p)\} = \{x_n : \neg \operatorname{cap}(x_n, D_p)\}.$$

Thus, the corresponding rule lists d and D share the same default rule, *i.e.*, $q_0 = Q_0$, yielding the same default rule misclassification error:

$$\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) = \ell_0(D_p, Q_0, \mathbf{x}, \mathbf{y}).$$

Similarly, prefixes d'_p and D'_p capture the same data, and thus rule lists d' and D' have the same default rule misclassification error:

$$\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) = \ell_0(D_p, Q_0, \mathbf{x}, \mathbf{y}).$$

At this point, to demonstrate our claim relating the objectives of d, d', D, and D', what remains is to show that the difference in the misclassification errors of prefixes d'_p and d_p is the same as that between D'_p and D_p. We can expand the first difference as

$$\ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) - \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{n=1}^{N} \sum_{k=K+1}^{K'} \operatorname{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n],$$

where we have used the fact that since d'_p starts with d_p, the first K rules in d'_p make the same mistakes as those in d_p. Similarly, we can expand the second difference as

$$\begin{aligned}
\ell_p(D'_p, \Delta'_p, \mathbf{x}, \mathbf{y}) - \ell_p(D_p, \Delta_p, \mathbf{x}, \mathbf{y}) &= \frac{1}{N} \sum_{n=1}^{N} \sum_{k=\kappa+1}^{\kappa'} \operatorname{cap}(x_n, P_k \,|\, D'_p) \wedge \mathbb{1}[Q_k \neq y_n] \\
&= \frac{1}{N} \sum_{n=1}^{N} \sum_{k=K+1}^{K'} \operatorname{cap}(x_n, p_k \,|\, D'_p) \wedge \mathbb{1}[Q_k \neq y_n] \\
&= \frac{1}{N} \sum_{n=1}^{N} \sum_{k=K+1}^{K'} \operatorname{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] \qquad (38) \\
&= \ell_p(d'_p, \delta'_p, \mathbf{x}, \mathbf{y}) - \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}).
\end{aligned}$$

To justify the equality in (38), we observe first that prefixes D'_p and d'_p start with κ and K antecedents, respectively, that capture the same data. Second, prefixes D'_p and d'_p end with exactly the same ordered list of $K' - K$ antecedents, therefore for any $k = 1, \ldots, K' - K$, antecedent $P_{\kappa+k} = p_{K+k}$ in D'_p captures the same data as p_{K+k} captures in d'_p. It follows that the corresponding labels are all equivalent, *i.e.*, $Q_{\kappa+k} = q_{K+k}$, for all $k = 1, \ldots, K' - K$, and consequently, the prefix misclassification error associated with the last $K' - K$ antecedents of d'_p is the same as that of D'_p. We have therefore shown that the difference between the objectives of d' and d is the same as that between D' and D, *i.e.*,

$$R(d', \mathbf{x}, \mathbf{y}) - R(d, \mathbf{x}, \mathbf{y}) = R(D', \mathbf{x}, \mathbf{y}) - R(D, \mathbf{x}, \mathbf{y}). \qquad (39)$$

Next, suppose that the objective lower bounds of d and D obey $b(d_p, \mathbf{x}, \mathbf{y}) \leq b(D_p, \mathbf{x}, \mathbf{y})$, therefore

$$\begin{aligned}
R(d, \mathbf{x}, \mathbf{y}) &= \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) + \lambda K \\
&= b(d_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) \\
&\leq b(D_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) = b(D_p, \mathbf{x}, \mathbf{y}) + \ell_0(D_p, Q_0, \mathbf{x}, \mathbf{y}) = R(D, \mathbf{x}, \mathbf{y}).
\end{aligned} \qquad (40)$$

Now let d^* be an optimal rule list with prefix constrained to start with d_p,

$$d^* \in \operatorname*{argmin}_{d^\dagger \in \sigma(d_p)} R(d^\dagger, \mathbf{x}, \mathbf{y}),$$

and let K^* be the length of d^*. Let D^* be the analogous κ^*-rule list whose prefix starts with D_p and ends with the same $K^* - K$ antecedents as d^*, where $\kappa^* = \kappa + K^* - K$. By (39),

$$R(d^*, \mathbf{x}, \mathbf{y}) - R(d, \mathbf{x}, \mathbf{y}) = R(D^*, \mathbf{x}, \mathbf{y}) - R(D, \mathbf{x}, \mathbf{y}). \qquad (41)$$

Furthermore, we claim that D^* is an optimal rule list with prefix constrained to start with D_p,

$$D^* \in \operatorname*{argmin}_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y}). \qquad (42)$$

To demonstrate (42), we consider two separate scenarios. In the first scenario, prefixes d_p and D_p are composed of the same antecedents, *i.e.*, the two prefixes are equivalent up to a permutation of their antecedents, and as a consequence, $\kappa = K$ and $\kappa^* = K^*$. Here, every rule list $d'' \in \sigma(d_p)$ that starts with d_p has an analogue $D'' \in \sigma(D_p)$ that starts with D_p, such that d'' and D'' obey (39), and vice versa, and thus (42) is a direct consequence of (41).

In the second scenario, prefixes d_p and D_p are not composed of the same antecedents. Define $\phi = \{p_k : (p_k \in d_p) \wedge (p_k \notin D_p)\}$ to be the set of antecedents in d_p that are not in D_p, and define $\Phi = \{P_k : (P_k \in D_p) \wedge (P_k \notin d_p)\}$ to be the set of antecedents in D_p that are not in d_p; either $\phi \neq \emptyset$, or $\Phi \neq \emptyset$, or both.

Suppose $\phi \neq \emptyset$, and let $p \in \phi$ be an antecedent in ϕ. It follows that there exists a subset of rule lists in $\sigma(D_p)$ that do not have analogues in $\sigma(d_p)$. Let $D'' \in \sigma(D_p)$ be such a rule list, such that its prefix $D''_p = (P_1, \ldots, P_\kappa, \ldots, p, \ldots)$ starts with D_p and contains p among its remaining antecedents. Since p captures a subset of the data that d_p captures, and D_p captures the same data as d_p, it follows that p does not capture any data in D''_p, *i.e.*,

$$\frac{1}{N} \sum_{n=1}^{N} \operatorname{cap}(x_n, p \,|\, D''_p) = 0 \leq \lambda.$$

By Theorem 10, antecedent p has insufficient support in D'', and thus D'' cannot be optimal, *i.e.*, $D'' \notin \operatorname{argmin}_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y})$. By a similar argument, if $\Phi \neq \emptyset$ and $P \in \Phi$, and $d'' \in \sigma(d_p)$ is any rule list whose prefix starts with d_p and contains antecedent P, then d'' cannot be optimal, *i.e.*, $d'' \notin \operatorname{argmin}_{d^\dagger \in \sigma(d_p)} R(d^\dagger, \mathbf{x}, \mathbf{y})$.

To finish justifying claim (42) for the second scenario, first define

$$\tau(d_p, \Phi) \equiv \{d'' = (d''_p, \delta''_p, q''_0, K'') : d'' \in \sigma(d_p) \text{ and } p_k \notin \Phi, \forall p_k \in d''_p\} \subset \sigma(d_p)$$

to be the set of all rule lists whose prefixes start with d_p and do not contain any antecedents in Φ. Now, recognize that the optimal prefixes in $\tau(d_p, \Phi)$ and $\sigma(d_p)$ are the same, *i.e.*,

$$\operatorname*{argmin}_{d^\dagger \in \tau(d_p, \Phi)} R(d^\dagger, \mathbf{x}, \mathbf{y}) = \operatorname*{argmin}_{d^\dagger \in \sigma(d_p)} R(d^\dagger, \mathbf{x}, \mathbf{y}),$$

and similarly, the optimal prefixes in $\tau(D_p, \phi)$ and $\sigma(D_p)$ are the same, *i.e.*,

$$\operatorname*{argmin}_{D^\dagger \in \tau(D_p, \phi)} R(D^\dagger, \mathbf{x}, \mathbf{y}) = \operatorname*{argmin}_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y}).$$

Since we have shown that every $d'' \in \tau(d_p, \Phi)$ has a direct analogue $D'' \in \tau(D_p, \phi)$, such that d'' and D'' obey (39), and vice versa, we again have (42) as a consequence of (41).

We can now finally combine (40) and (42) to obtain the desired inequality in (21):

$$\min_{d' \in \sigma(d_p)} R(d', \mathbf{x}, \mathbf{y}) = R(d^*, \mathbf{x}, \mathbf{y}) \leq R(D^*, \mathbf{x}, \mathbf{y}) = \min_{D' \in \sigma(D_p)} R(D', \mathbf{x}, \mathbf{y}).$$

Appendix C. Proof of Theorem 18 (Similar Support Bound)

We begin by defining four related rule lists. First, let $d = (d_p, \delta_p, q_0, K)$ be a rule list with prefix $d_p = (p_1, \ldots, p_K)$ and labels $\delta_p = (q_1, \ldots, q_K)$. Second, let $D = (D_p, \Delta_p, Q_0, \kappa)$ be a rule list with prefix $D_p = (P_1, \ldots, P_\kappa)$ and labels $\Delta_p = (Q_1, \ldots, Q_\kappa)$. Define ω as in (22) and Ω as in (23), and require that $\omega, \Omega \leq \lambda$. Third, let $d' = (d'_p, \delta'_p, q'_0, K') \in \sigma(d_p)$ be any rule list whose prefix starts with d_p, such that $K' \geq K$. Denote the prefix and labels of d' by $d'_p = (p_1, \ldots, p_K, p_{K+1}, \ldots, p_{K'})$ and $\delta_p = (q_1, \ldots, q_{K'})$, respectively. Finally, define $D' = (D'_p, \Delta'_p, Q'_0, \kappa') \in \sigma(D_p)$ to be the 'analogous' rule list, *i.e.*, whose prefix $D'_p = (P_1, \ldots, P_\kappa, P_{\kappa+1}, \ldots, P_{\kappa'}) = (P_1, \ldots, P_\kappa, p_{K+1}, \ldots, p_{K'})$ starts with D_p and ends with the same $K' - K$ antecedents as d'_p. Let $\Delta'_p = (Q_1, \ldots, Q_{\kappa'})$ denote the labels of D'.

The smallest possible objective for D', in relation to the objective of d', reflects both the difference between the objective lower bounds of D and d and the largest possible discrepancy between the objectives of d' and D'. The latter would occur if d' misclassified all the data corresponding to both ω and Ω while D' correctly classified this same data, thus

$$R(D', \mathbf{x}, \mathbf{y}) \geq R(d', \mathbf{x}, \mathbf{y}) + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \omega - \Omega. \tag{43}$$

Now let D^* be an optimal rule list with prefix constrained to start with D_p,

$$D^* \in \operatorname*{argmin}_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y}),$$

and let κ^* be the length of D^*. Also let d^* be the analogous K^*-rule list whose prefix starts with d_p and ends with the same $\kappa^* - \kappa$ antecedents as D^*, where $K^* = K + \kappa^* - \kappa$. By (43),

we obtain the desired inequality in (24):

$$\begin{aligned}\min_{D^\dagger \in \sigma(D_p)} R(D^\dagger, \mathbf{x}, \mathbf{y}) &= R(D^*, \mathbf{x}, \mathbf{y}) \\ &\geq R(d^*, \mathbf{x}, \mathbf{y}) + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \omega - \Omega \\ &\geq \min_{d^\dagger \in \sigma(d_p)} R(d^\dagger, \mathbf{x}, \mathbf{y}) + b(D_p, \mathbf{x}, \mathbf{y}) - b(d_p, \mathbf{x}, \mathbf{y}) - \omega - \Omega.\end{aligned}$$

Appendix D. Proof of Theorem 20 (Equivalent Points Bound)

We derive a lower bound on the default rule misclassification error $\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y})$, analogous to the lower bound (26) on the misclassification error $\ell(d, \mathbf{x}, \mathbf{y})$ in the proof of Proposition 19. As before, we sum over all sets of equivalent points, and then for each such set, we count differences between class labels and the minority class label of the set, instead of counting mistakes made by the default rule:

$$\begin{aligned}\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) &= \frac{1}{N} \sum_{n=1}^{N} \neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[q_0 \neq y_n] \\ &= \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[q_0 \neq y_n] \, \mathbb{1}[x_n \in e_u] \\ &\geq \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \neg \operatorname{cap}(x_n, d_p) \wedge \mathbb{1}[y_n = q_u] \, \mathbb{1}[x_n \in e_u] = b_0(d_p, \mathbf{x}, \mathbf{y}),\end{aligned} \tag{44}$$

where the final equality comes from the definition of $b_0(d_p, \mathbf{x}, \mathbf{y})$ in (28). Since we can write the objective $R(d, \mathbf{x}, \mathbf{y})$ as the sum of the objective lower bound $b(d_p, \mathbf{x}, \mathbf{y})$ and default rule misclassification error $\ell_0(d_p, q_0, \mathbf{x}, \mathbf{y})$, applying (44) gives a lower bound on $R(d, \mathbf{x}, \mathbf{y})$:

$$\begin{aligned}R(d, \mathbf{x}, \mathbf{y}) = \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) + \lambda K &= b(d_p, \mathbf{x}, \mathbf{y}) + \ell_0(d_p, q_0, \mathbf{x}, \mathbf{y}) \\ &\geq b(d_p, \mathbf{x}, \mathbf{y}) + b_0(d_p, \mathbf{x}, \mathbf{y}).\end{aligned} \tag{45}$$

It follows that for any rule list $d' \in \sigma(d)$ whose prefix d'_p starts with d_p, we have

$$R(d', \mathbf{x}, \mathbf{y}) \geq b(d'_p, \mathbf{x}, \mathbf{y}) + b_0(d'_p, \mathbf{x}, \mathbf{y}). \tag{46}$$

Finally, we show that the lower bound on $R(d, \mathbf{x}, \mathbf{y})$ in (45) is not greater than the lower bound on $R(d', \mathbf{x}, \mathbf{y})$ in (46). First, let us define

$$\Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}) \equiv \frac{1}{N} \sum_{u=1}^{U} \sum_{n=1}^{N} \sum_{k=K+1}^{K'} \operatorname{cap}(x_n, p_k \mid d'_p) \wedge \mathbb{1}[x_n \in e_u] \, \mathbb{1}[y_n = q_u]. \tag{47}$$

Now, we write a lower bound on $b(d'_p, \mathbf{x}, \mathbf{y})$ with respect to $b(d_p, \mathbf{x}, \mathbf{y})$:

$$
\begin{aligned}
b(d'_p, \mathbf{x}, \mathbf{y}) &= \ell_p(d'_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K' = \frac{1}{N}\sum_{n=1}^{N}\sum_{k=1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] + \lambda K' \\
&= \ell_p(d_p, \delta_p, \mathbf{x}, \mathbf{y}) + \lambda K + \frac{1}{N}\sum_{n=1}^{N}\sum_{k=K}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] + \lambda(K' - K) \\
&= b(d_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{n=1}^{N}\sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n] + \lambda(K' - K) \\
&= b(d_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{u=1}^{U}\sum_{n=1}^{N}\sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[q_k \neq y_n]\, \mathbb{1}[x_n \in e_u] + \lambda(K' - K) \\
&\geq b(d_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{u=1}^{U}\sum_{n=1}^{N}\sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[y_n = q_u]\, \mathbb{1}[x_n \in e_u] + \lambda(K' - K) \\
&= b(d_p, \mathbf{x}, \mathbf{y}) + \Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}) + \lambda(K' - K), \qquad (48)
\end{aligned}
$$

where the last equality uses (47). Next, we write $b_0(d_p, \mathbf{x}, \mathbf{y})$ with respect to $b_0(d'_p, \mathbf{x}, \mathbf{y})$,

$$
\begin{aligned}
b_0(d_p, \mathbf{x}, \mathbf{y}) &= \frac{1}{N}\sum_{u=1}^{U}\sum_{n=1}^{N} \neg\,\mathrm{cap}(x_n, d_p) \wedge \mathbb{1}[x_n \in e_u]\, \mathbb{1}[y_n = q_u] \\
&= \frac{1}{N}\sum_{u=1}^{U}\sum_{n=1}^{N} \left(\neg\,\mathrm{cap}(x_n, d'_p) + \sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \right) \wedge \mathbb{1}[x_n \in e_u]\, \mathbb{1}[y_n = q_u] \\
&= b_0(d'_p, \mathbf{x}, \mathbf{y}) + \frac{1}{N}\sum_{u=1}^{U}\sum_{n=1}^{N}\sum_{k=K+1}^{K'} \mathrm{cap}(x_n, p_k \,|\, d'_p) \wedge \mathbb{1}[x_n \in e_u]\, \mathbb{1}[y_n = q_u]. \qquad (49)
\end{aligned}
$$

Rearranging (49) gives

$$
b_0(d'_p, \mathbf{x}, \mathbf{y}) = b_0(d_p, \mathbf{x}, y) - \Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}). \qquad (50)
$$

Combining (46) with first (50) and then (48) gives the desired inequality in (27):

$$
\begin{aligned}
R(d', \mathbf{x}, \mathbf{y}) &\geq b(d'_p, \mathbf{x}, \mathbf{y}) + b_0(d'_p, \mathbf{x}, \mathbf{y}) \\
&= b(d'_p, \mathbf{x}, \mathbf{y}) + b_0(d_p, \mathbf{x}, y) - \Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}) \\
&\geq b(d_p, \mathbf{x}, \mathbf{y}) + \Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}) + \lambda(K' - K) + b_0(d_p, \mathbf{x}, y) - \Upsilon(d'_p, K, \mathbf{x}, \mathbf{y}) \\
&= b(d_p, \mathbf{x}, \mathbf{y}) + b_0(d_p, \mathbf{x}, y) + \lambda(K' - K) \geq b(d_p, \mathbf{x}, \mathbf{y}) + b_0(d_p, \mathbf{x}, \mathbf{y}).
\end{aligned}
$$

Appendix E. Data Processing Details and Antecedent Mining

In this appendix, we provide details regarding datasets used in our experiments (Section 6).

E.1 ProPublica Recidivism Data Set

Table 7 shows the 6 attributes and corresponding 17 categorical values that we use for the ProPublica data set. From these, we construct 17 single-clause antecedents, for example, $(age = 23 - 25)$. We then combine pairs of these antecedents as conjunctions to form two-clause antecedents, *e.g.*, $(age = 23 - 25) \wedge (priors = 2 - 3)$. By virtue of our lower bound on antecedent support, (Theorem 10, §3.7), we eliminate antecedents with support less than 0.005 or greater than 0.995, since $\lambda = 0.005$ is the smallest regularization parameter value we study for this problem. With this filtering step, we generate between 121 and 123 antecedents for each fold; without it, we would instead generate about 130 antecedents as input to our algorithm.

Note that we exclude the 'current charge' attribute (which has two categorical values, 'misdemeanor' and 'felony'); for individuals in the data set booked on multiple charges, this attribute does not appear to consistently reflect the most serious charge.

Feature	Value range	Categorical values	Count
sex	—	male, female	2
age	18-96	18-20, 21-22, 23-25, 26-45, >45	5
juvenile felonies	0-20	0, >0	2
juvenile misdemeanors	0-13	0, >0	2
juvenile crimes	0-21	0, >0	2
priors	0-38	0, 1, 2-3, >3	4

Table 7: Categorical features (6 attributes, 17 values) from the ProPublica data set. We construct the feature *juvenile crimes* from the sum of *juvenile felonies*, *juvenile misdemeanors*, and the number of juvenile crimes that were neither felonies nor misdemeanors (not shown).

E.2 NYPD Stop-and-frisk Data Set

This data set is larger than, but similar to the NYCLU stop-and-frisk data set, described next.

E.3 NYCLU Stop-and-frisk Data Set

The original data set contains 45,787 records, each describing an incident involving a stopped person; the individual was frisked in 30,345 (66.3%) of records and and searched in 7,283 (15.9%). In 30,961 records, the individual was frisked and/or searched (67.6%); of those, a criminal possession of a weapon was identified 1,445 times (4.7% of these records). We remove 1,929 records with missing data, as well as a small number with extreme values for the individual's age—we eliminate those with age < 12 or > 89. This yields a set of 29,595 records in which the individual was frisked and/or searched. To address the class imbalance for this problem, we sample records from the smaller class with replacement. We generate cross-validation folds first, and then resample within each fold. In our 10-fold cross-validation experiments, each training set contains 50,743 observations. Table 8 shows the 5

categorical attributes that we use, corresponding to a total of 28 values. Our experiments use these antecedents, as well as negations of the 18 antecedents corresponding to the two features *stop reason* and *additional circumstances*, which gives a total of 46 antecedents.

Feature	Values	Count
stop reason	suspicious object, fits description, casing, acting as lookout, suspicious clothing, drug transaction, furtive movements, actions of violent crime, suspicious bulge	9
additional circumstances	proximity to crime scene, evasive response, associating with criminals, changed direction, high crime area, time of day, sights and sounds of criminal activity, witness report, ongoing investigation	9
city	Queens, Manhattan, Brooklyn, Staten Island, Bronx	5
location	housing authority, transit authority, neither housing nor transit authority	3
inside or outside	inside, outside	2

Table 8: Categorical features (5 attributes, 28 values) from the NYCLU data set.

Appendix F. Example Optimal Rule Lists, for Different Values of λ

For each of our prediction problems, we provide listings of optimal rule lists found by CORELS, across 10 cross-validation folds, for different values of the regularization parameter λ. These rule lists correspond to the results for CORELS summarized in Figures 11 and 12 (§6.6). Recall that as λ decreases, optimal rule lists tend to grow in length.

F.1 ProPublica Recidivism Data Set

We show example optimal rule lists that predict two-year recidivism. Figure 19 shows examples for regularization parameters $\lambda = 0.02$ and 0.01. Figure 20 shows examples for $\lambda = 0.005$; Figure 4 (§6.3) showed two representative examples.

For the largest regularization parameter $\lambda = 0.02$ (Figure 19), we observe that all folds identify the same length-1 rule list. For the intermediate value $\lambda = 0.01$ (Figure 19), the folds identify optimal 2-rule or 3-rule lists that contain the nearly same prefix rules, up to permutations. For the smallest value $\lambda = 0.005$ (Figure 20), the folds identify optimal 3-rule or 4-rule lists that contain the nearly same prefix rules, up to permutations. Across all three regularization parameter values and all folds, the prefix rules always predict the positive class label, and the default rule always predicts the negative class label. We note that our objective is not designed to enforce any of these properties.

Two-year recidivism prediction ($\lambda = 0.02$)

if ($priors > 3$) **then predict** *yes* ▷ **Found by all 10 folds**
else predict *no*

Two-year recidivism prediction ($\lambda = 0.01$)

Figure 22: Example optimal rule lists for the NYPD stop-and-frisk data set (Feature Set D) found by CORELS with regularization parameters $\lambda = 0.01$ (top) and 0.005 (bottom), across 10 cross-validation folds. For $\lambda = 0.005$, we show results from 7 folds; the remaining 3 folds were equivalent, up to a permutation of the prefix rules, and started with the same first prefix rule.

F.3 NYCLU Stop-and-frisk Data Set

We show example optimal rule lists that predict whether a weapon will be found on a stopped individual who is frisked or searched, learned from the NYCLU data set. Figure 23 shows regularization parameters $\lambda = 0.04$ and 0.01, and Figure 24 shows $\lambda = 0.0025$. We showed a representative solution for $\lambda = 0.01$ in Figure 5 (§6.3).

For each of the two larger regularization parameters in Figure 23, $\lambda = 0.04$ (top) and 0.01 (bottom), we observe that across the folds, all the optimal rule lists contain the same or equivalent rules, up to a permutation. With the smaller regularization parameter $\lambda = 0.0025$ (Figure 24), we observe a greater diversity of longer optimal rule lists, though they share similar structure.

Figure 24: Example optimal rule lists for the NYCLU stop-and-frisk data set $\lambda = 0.0025$.

Appendix G. Additional Results on Predictive Performance and Model Size for CORELS and Other Algorithms

In this appendix, we plot TPR, FPR, and model size for CORELS and three other algorithms, using the NYPD data set (Feature Set D).

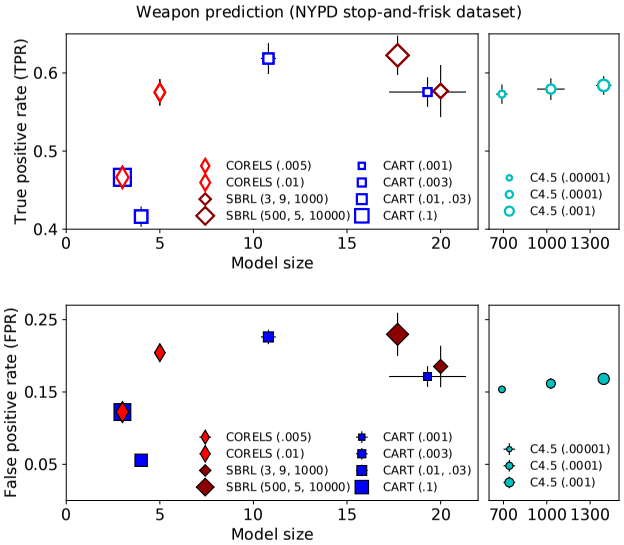

Figure 25: TPR (top) and FPR (bottom) for the test set, as a function of model size, across different methods, for weapon prediction with the NYPD stop-and-frisk data set (Feature Set D). In the legend, numbers in parentheses are algorithm parameters, as in Figure 12. Legend markers and error bars indicate means and standard deviations, respectively, across cross-validation folds. C4.5 finds large models for all tested parameters.
