Related to the notion of the ϵ-approximate nearest neighbor is the notion of neighborhood or query instability (Beyer et al., 1999): a query is said to be unstable if the ϵ-neighborhood of the query point consists of most of the data points. Although asymptotic results, such as that reported by Beyer et al. (1999), tell what happens when dimensionality is taken to infinity, nothing is said about the dimensionality at which the nearest neighbors become unstable. Pursuant to this scenario, this paper derives a closed form for the expected size of the ϵ-neighborhood in finite high-dimensional spaces, an expression that is then exploited to determine the critical dimensionality. Also, to quantify the difficulty of (approximate) nearest neighbor search, He et al. (2012) introduced the concept of relative contrast, a measure of separability of the nearest neighbor of the query point from the rest of the data, and provided an estimate which is applicable for finite dimensions. By leveraging the results concerning distance distributions, this paper derives a more accurate estimate for the relative contrast measure.

The number N_k of reverse nearest neighbors, also called the number of k-occurrences or the reverse nearest neighbor count, is the number of data points for which a given point is among their k nearest neighbors. Reverse nearest neighbors are of interest both in the database, information retrieval, and computational geometry literatures (Korn and

Muthukrishnan, 2000; Singh et al., 2003; Tao et al., 2007; Cheong et al., 2011; Yang et al., 2015), with uses having been proposed in the data mining and machine learning fields (Williams et al., 2002; Hautamäki et al., 2004; Radovanovic et al., 2009, 2010; Tomasev et al., 2014; Radovanovic et al., 2015; Tomasev and Buza, 2015), beyond being the objects of study in applied probability and mathematical psychology (Newman et al., 1983; Maloney, 1983; Tversky et al., 1983; Newman and Rinott, 1985; Yao and Simons, 1996).

Despite the usefulness and the extensive use of this construct, the precise characterization of the form of the function N_k both in the finite and infinite dimensional cases is a longstanding problem. What is already known is that for the infinite limit of size and dimension, N_k must converge in its distribution to zero; however, this result and its interpretations seem to be insufficient to characterize its observed behavior in finite samples and dimensions. Consequently, this paper derives a closed form of the number of k-occurrences associated with a given point in finite high-dimensional spaces, together with a generalized closed form of the associated limiting probability distribution that encompasses previous results and provides interpretability of its behavior and of the related hubness phenomenon.

The results, which are first illustrated for independent and identically distributed data, are subsequently extended to independent non-identically distributed data satisfying certain conditions, and then, connections with non-independent real data are depicted. Finally, it is discussed how to potentially extend the approach to Minkowski's metrics and, more generally, to distances satisfying certain conditions of spatial centrality.

Because hubness is a phenomenon of primary importance in network science, we also investigate if the findings relative to the distribution of the reverse nearest neighbors and the emergence of hubs in intrinsically high-dimensional contexts is connected to an analogous phenomenon occurring in the context of networks. The investigation reveals that for some real-life large-scale networks, the distribution of the incoming node degrees is connected to the herein-derived distribution of the infinite-dimensional k-occurrences function, which models the number of reverse k-nearest neighbors in an arbitrarily large feature space of independent dimensions. Hence, the provided distribution also appears to be suitable for modelling node-degree distributions in complex real networks.

The current study can be leveraged in several ways and in different contexts, such as in direct and reverse nearest neighbor searches, density estimation, anomaly and novelty detection, density-based clustering, and network analysis, among others. With regard to its possible applications, we can highlight approximations of measures related to distance distributions, worst-case scenarios for data analysis and retrieval techniques, design strategies that try to mitigate the curse of dimensionality, and models of complex networks. We refer to the concluding section for a more extensive discussion.

The rest of the work is organized as follows. Section 2 discusses related work concerning the concentration of distances, intrinsic dimensionality, and the number of k-occurrences and the associated hubness phenomenon. Section 3 presents the notation used to provide results. Section 4 introduces the main results of the paper. Section 5 discusses relationships between the study of the hubness phenomena occurring in high-dimensional spaces with the analogous phenomena observed in real-life, large-scale, complex networks. Section 6 concludes the work. Finally, the Appendix contains the proofs that are not reported within the main text.

2. Related Work

As already noted, the term *curse of dimensionality* is used to refer to difficulties arising when high-dimensional data must be taken into account, and one of the main aspects of this curse is *distance concentration*. In this regard, Demartines (1994) has shown that the expectation of the Euclidean norm of independent and identically distributed (i.i.d.) random vectors increases as the square root of the dimension, whereas its variance tends toward a constant and, hence, does not depend on the dimensionality. Specifically:

Theorem 1 (Demartines, 1994, cf. Theorem 2.1) *Let $\boldsymbol{X}_d$ be an i.i.d. d-dimensional random vector with common cdf F_X. Then*

$$\mathbf{E}[\|\boldsymbol{X}_d\|_2] = \sqrt{ad-b} + O(1/d) \quad \text{and} \quad \sigma^2(\|\boldsymbol{X}_d\|_2) = b + O(1/\sqrt{d}),$$

where a and b are constants depending on the central moments of F_X up to the fourth order but do not depend on the dimensionality d.

Demartines noticed that, because the Euclidean distance corresponds to the norm of the difference of two vectors, the distance between the i.i.d. random vectors must also exhibit the same behavior. This insightful result explains why high-dimensional vectors appear to be distributed around the surface of a sphere of radius $\mathbf{E}[\|\boldsymbol{X}_d\|]$ and why, because they seem to be normalized, the distances between pairs of high-dimensional random vectors tend to be similar.

The distance concentration phenomenon is usually characterized in the literature by means of a ratio between some measure related to the spread and some measure related to the magnitude of the norm, sometimes presented as the distance from a point located in the origin of the space. In particular, the conclusion is that there is a concentration of distances when the above ratio converges to 0 as the dimensionality tends to infinity.

Some authors have studied the concentration phenomenon by representing a data set as a set of n d-dimensional i.i.d. random vectors $\boldsymbol{X}_d^{(j)}$ $(1 \leq j \leq n)$ with not-necessarily common pdfs $f_{X^{(j)}}$. Specifically, the *contrast* is defined as the difference between the largest and the smallest observed norm, or rather the distance from a query point located at the origin, whereas the *relative contrast* is defined as

$$RC_d = \frac{\max_j \|\boldsymbol{X}_d^{(j)}\|_p - \min_j \|\boldsymbol{X}_d^{(j)}\|_p}{\min_j \|\boldsymbol{X}_d^{(j)}\|_p},$$

where $\|\cdot\|_p$ denotes the p-norm $\|\boldsymbol{x}_d\|_p = \left(\sum_{i=1}^d |x_i|^p\right)^{1/p}$, is the contrast normalized with respect to the smallest norm/distance.

Theorem 2 (Adapted from Beyer et al., 1999, cf. Theorem 1) *Let $\boldsymbol{X}_d^{(j)}$ $(1 \leq j \leq n)$ be n d-dimensional random vectors with common cdfs. If*

$$\lim_{d\to\infty} \sigma^2\left(\frac{\|\boldsymbol{X}_d^{(j)}\|_p}{\mathbf{E}[\|\boldsymbol{X}_d^{(j)}\|_p]}\right) = 0, \text{ then, for any } \epsilon > 0, \lim_{d\to\infty} Pr\left[RC_d \leq \epsilon\right] = 1.$$

If the hypothesis is verified, that is, if the variance of the ratio between the norm of the vectors and their expected value vanishes as the dimensionality goes to infinity, then the relative contrast also becomes smaller and smaller, and all the vectors seem to be located at approximatively the same distance from the reference vector. That is, given a query point $\boldsymbol{Q}_d$, the distance from the nearest and the furthest neighbor become negligible:

$$\lim_{d\to\infty} Pr\left[\max_j \|\boldsymbol{Q}_d - \boldsymbol{X}_d^{(j)}\|_p \leq (1+\epsilon)\min_j \|\boldsymbol{Q}_d - \boldsymbol{X}_d^{(j)}\|_p\right] = 1.$$

In (Beyer et al., 1999), it is shown that i.i.d. random vectors satisfy the above condition.

Other authors have provided characterizations of the concentration phenomenon by providing upper and lower bounds to the relative contrast in the cases of Minkowski and fractional norms (Hinneburg et al., 2000; Aggarwal et al., 2001).

Subsequently, (François et al., 2007) posed the following problem: is the concentration phenomenon a side effect of the *Empty Space Phenomenon* (Bellmann, 1961), just because we consider a finite number of points in a bounded portion of a high-dimensional space? To explore this problem, they studied the concentration phenomenon by taking the same perspective as Demartines, i.e., to refer to a distribution rather than to a finite set of points. The *relative variance*

$$RV_d = \frac{\sigma(\|\boldsymbol{X}_d\|_p)}{\mathbf{E}[\|\boldsymbol{X}_d\|_p]}$$

is a measure of concentration for distributions, corresponding to the ratio between the standard deviation and the expected value of the norm.

Theorem 3 (Adapted from François et al., 2007, cf. Theorem 5) *Let $\boldsymbol{X}_d$ be an i.i.d. d-dimensional random vector. Then*

$$\lim_{d\to\infty} RV_d = 0.$$

From the above result, they conclude that the concentration of the norms in high-dimensional spaces is an intrinsic property of the norms and not a side effect of the finite sample size or of the Empty Space Phenomenon. Because it does not depend on the sample size, this can be regarded as an extension of Demartines' results to all p-norms.

As a consequence of the distance concentration, the separation between the nearest neighbor and the farthest neighbor of a given point tend to become increasingly indistinct as the dimensionality increases.

Related to the analysis of i.i.d. data is the concept of intrinsic dimensionality. Although variables used to identify each datum could not be statistically independent, ultimately, the intrinsic dimensionality of the data is identified as the minimum number of variables needed to represent the data itself (van der Maaten et al., 2009). This corresponds in linear spaces to the number of linearly independent vectors needed to describe each point. As a matter of fact, an extensively used notion of intrinsic dimensionality, the *correlation dimension* (Grassberger and Procaccia, 1983), is based on identifying the dimensionality D at which the Euclidean space is homeomorphic to the manifold containing the support of the data:

$$D = \lim_{\delta\to 0} \frac{\ln F_{\text{dst}}(\delta)}{\ln \delta},$$

where F_{dst} denotes the cumulative distribution function of pairwise distances, which formalizes the notion that in the limit of small length-scales ($\delta \to 0$) upon which the manifold the data lie, the manifold is homeomorphic to the Euclidean space of dimension D.

And, indeed, (Demartines, 1994) mentions that if random vector components are not independent, the concentration phenomenon is still present provided that the actual number D of "degrees of freedom" is sufficiently large. Thus, results derived for i.i.d. data continue to be valid provided that the dimensionality d is replaced with D. Moreover, (Beyer et al., 1999) provided different examples of data presenting concentration, all of which share with the i.i.d. case a sparse correlation structure. (Durrant and Kabán, 2009) noted that it is difficult to identify meaningful workloads that do not exhibit concentration, and showed that for the family of linear latent variable models, a class of data distributions having non-i.i.d. dimensions, the Euclidean distance will not become concentrated as long as the number of relevant dimensions grows no more slowly than the overall data dimensions do. This also confirms that weakly dependent data lead to concentration; however, they also noted that the condition to avoid concentration is not often met in practice.

Another aspect of the curse of dimensionality problem, closely related to the distance concentration and the nearest neighbor relationship, is the so called *hubness* phenomenon. This phenomenon has been previously observed in several applications (Doddington et al., 1998; Singh et al., 2003; Aucouturier and Pachet, 2007), has recently undergone to direct investigation (Radovanovic et al., 2009, 2010; Low et al., 2013), and has been subjected to several different proposed techniques for overcoming the phenomenon (Radovanovic et al., 2015; Tomasev, 2015).

Specifically, consider the number $\mathrm{N}_k(\boldsymbol{x}_d)$ of observed points that have $\boldsymbol{x}_d$ among their k nearest neighbors. N_k is also called *k-occurrences* or the *reverse k-nearest neighbor count*.

It is known that in low dimensional spaces, the distribution of N_k complies with the binomial one and, in particular, for uniformly distributed data in low dimensions, it can be modeled as node in-degrees in the k-nearest neighbor graph, which follows the Erdős-Rényi random graph model, with a binomial degree distribution (Erdős and Rényi, 1959). However, it has been observed that as dimensionality increases, the distribution of N_k becomes skewed to the right, resulting in the emergence of *hubs*, which are points whose reverse k-nearest neighbor counts tend to be meaningfully larger than that associated with any other point.

The distribution of N_k has been explicitly studied in the applied probability and mathematical psychology communities (Newman et al., 1983; Maloney, 1983; Newman and Rinott, 1985; Tversky and Hutchinson, 1986; Yao and Simons, 1996). Almost all the results provided concern a Poisson process that spreads the vectors uniformly over $\mathbb{R}^d$, leading to the conclusion that the limiting distribution of N_k converges to the Poisson distribution with mean k. The case of continuous distributions with i.i.d. components has been considered in (Newman et al., 1983; Newman and Rinott, 1985), where the expression for the infinite-dimensional distribution of N_1 is characterized as follows.

Theorem 4 (Newman et al., 1983, cf. Theorem 7) *Let $\{\boldsymbol{X}_d^{(0)}, \boldsymbol{X}_d^{(1)}, \ldots, \boldsymbol{X}_d^{(n)}\}$ be i.i.d. random vectors with a common continuous cdf having a finite fourth moment. Let $N_1^{n,d}$ denote the number of elements from $\{\boldsymbol{X}_d^{(1)}, \ldots, \boldsymbol{X}_d^{(n)}\}$ whose nearest neighbor with*

respect to the Euclidean distance is $\boldsymbol{X}_d^{(0)}$. *Then*

$$\lim_{n\to\infty}\lim_{d\to\infty} \mathrm{N}_1^{n,d} \xrightarrow{D} 0 \qquad \textit{and} \qquad \lim_{n\to\infty}\lim_{d\to\infty} \sigma^2(\mathrm{N}_1^{n,d}) = \infty.$$

The interpretation of the above result due to (Tversky et al., 1983) is that if the number of dimensions is large relative to the number of points, a large portion of points will have reverse nearest neighbor count equaling zero, whereas a small fraction (i.e., the hubs) will score large counts.

In order to provide an explanation for hubness, (Radovanovic et al., 2010) noticed that it is expected for points that are closer to the mean of the data distribution to be closer, on average, to all other points. However, empirical evidence indicates that this tendency is amplified by high-dimensionality, making points that reside in the proximity of the datas mean become closer to all other points than their low-dimensional analogues are. This tendency causes high-dimensional points that are closer to the mean to have increased probability of being selected as k-nearest neighbors by other points, even for small values of k.

In order to formalize the above evidence in finite-dimensional spaces, the authors considered the simplified setting of normally distributed i.i.d. d-dimensional random vectors, for which the distribution of Euclidean distances, which are calculated as the square root of the sum of squares of i.i.d. normal variables, corresponds to a chi distribution with d degrees of freedom (Johnson et al., 1994) and the random variable $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|$, representing the distance from a fixed point $\boldsymbol{x}_d$ to the rest of the data, follows the noncentral chi distribution with d degrees of freedom and noncentrality parameter $\lambda = \|\boldsymbol{x}_d\|$ (Oberto and Pennecchi, 2006).

Theorem 5 (Radovanovic et al., 2010, cf. Theorem 1) *Let* $\lambda_{d,1} = \mu_{\chi(d)} + c_1\sigma_{\chi(d)}$ *and* $\lambda_{d,2} = \mu_{\chi(d)} + c_2\sigma_{\chi(d)}$, *where* $d \in \mathbb{N}^+$, $c_1 < c_2 \leq 0$, *and* $\mu_{\chi(d)}$ *and* $\sigma_{\chi(d)}$ *are the mean and standard deviation of the chi distribution with d degrees of freedom, respectively. Define* $\Delta\mu_d(\boldsymbol{x}_{d,1}, \boldsymbol{x}_{d,2}) = \mu_{\chi(d,\lambda_{d,2})} - \mu_{\chi(d,\lambda_{d,1})}$, *where* $\mu_{\chi(d,\lambda)}$ *is the mean of the noncentral chi distribution with d degrees of freedom and noncentrality parameter* λ. *Then, there exists* $d_0 \in \mathbb{N}$ *such that for every* $d > d_0$, $\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) > 0$, *and* $\Delta\mu_{d+2}(\lambda_{d+2,1}, \lambda_{d+2,2}) > \Delta\mu_d(\lambda_{d,1}, \lambda_{d,2})$.

Intuitively, $\lambda_{d,1}$ and $\lambda_{d,2}$ represent two d-dimensional points whose norms are located at c_1 and c_2, resp., standard deviations from the expected value of the norm in the dimensionality d, and for which $\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2})$ is the distance between the expected value of the associated distribution of distances.

As stated by authors, the implication of the above theorem is that hubness is an inherent property of data distributions in high-dimensional space, rather than an artifact of other factors, such as finite sample size. However, Theorem 5 only formalizes the tendency of the difference between the means of the two distance distributions to increase with the dimensionality, and the proof is specific for Gaussian data. No model to predict the number of k-occurrences or to infer the form of the underlying distribution is provided, and the characterization of the distribution probability of N_k remains an open problem.

3. Notation

In the rest of this section, upper case letters, such as X, Y, Z, ..., denote random variables (r.v.) taking values in $\mathbb{R}$. f_X (F_X, resp.) denotes the probability density function (pdf) (probability distribution function (cdf), resp.) associated with X.

Boldface uppercase letters with d as a subscript, such as $\boldsymbol{X}_d$, $\boldsymbol{Y}_d$, $\boldsymbol{Z}_d$, ..., denote d-dimensional random vectors taking values in $\mathbb{R}^d$. The components X_i ($1 \leq i \leq d$) of a random vector $\boldsymbol{X}_d = (X_1, X_2, \ldots, X_d)$ are random variables having pdfs $f_{X_i} = f_i$ (cdf $F_{X_i} = F_i$). A d-dimensional random vector is said to be independent and identically distributed (i.i.d. for short) if its random variables are independent and have common pdf $f_X = f_{X_i}$ (cdf $F_X = F_{X_i}$).

Boldface lowercase letters with d as a subscript, such as $\boldsymbol{x}_d$, $\boldsymbol{y}_d$, $\boldsymbol{z}_d$, ..., denote a specific d-dimensional vector taking value in $\mathbb{R}^d$. The components of a vector $\boldsymbol{x}_d = (x_1, x_2, \ldots, x_d)$, denoted as x_i ($1 \leq i \leq d$), are real scalar values.

Given a random variable X, w.l.o.g. and for simplicity of treatment, sometimes it is assumed that the expected value μ (or μ_X) of f_X is $\mu = 0$. If that is not the case, to satisfy the assumption, it suffices to replace during the analysis the original random variable X with the novel random variable $\hat{X} = X - \mu_X$. Thus, $\hat{\boldsymbol{X}}_d$ denotes the random vector $\boldsymbol{X}_d - \mu_X$.

σ_X or $\sigma(X)$ (or σ alone, whenever X is clear from the context) is the standard deviation of the random variable X. By μ_k ($\hat{\mu}_k$, resp.), or $\mu_{X,k}$ ($\hat{\mu}_{X,k}$, resp.) whenever X is not clear from the context, it is denoted the *k-th moment* (*k-th central moment*, resp.) ($k > 0$) $\mu_k = \mathbf{E}[X^k]$ ($\hat{\mu}_k = \mathbf{E}[(X - \mu_X)^k]$, resp.) of the random variable X, where $\mathbf{E}[X]$ is the expectation of X. Clearly, when $\mu = \mu_1 = 0$, μ_k coincides with $\hat{\mu}_k$ and $\mu_2 = \sigma^2$.

Moments of a pdf f (cdf F, resp.) are those associated with a random variable X having pdf $f_X = f$ (cdf $F_X = f$, resp.). The moments of an i.i.d. random vector $\boldsymbol{X}_d$ are those associated with its cdf F_X.

It is said that a distribution function has *finite* (*central*) *moment* μ_k, if there exists $0 \leq \mu_{top} < \infty$ such that $|\mu_k| \leq \mu_{top}$.

Whenever moments are employed during the proofs, we always assume that they exist and are finite. Moreover, if the random variable associated with a moment employed in a proof is not explicitly stated, we assume that the moment is relative to the common cdf of the random vector(s) occurring in the distribution reported in the statement of the theorem.

Moreover, it is sometimes considered the case that $\mu_3 = 0$, a condition that is referred to as null *skewness*. It is known that odd central moments, provided they exist, are null if the pdf of X is symmetric with respect to the mean (with examples of distributions having null μ_3 value being the Uniform and Normal distributions).

The notation $\mathcal{N}(\mu, \sigma^2)$ represents the Normal distribution function with mean μ and variance σ^2. By Φ (ϕ, resp.) one denotes the cdf (pdf, resp.) of the standard normal distribution, whereas by Φ_X (ϕ_X, resp.) one denotes the cdf (pdf, resp.) of the normal distribution with mean μ_X and variance σ_X^2.

Let X represent a univariate random variable that is defined in terms of a real-valued function of one or more d-dimensional random vectors. For example, X could be defined as $\|\boldsymbol{X}_d\|^2$. The notation $X \simeq \mathcal{N}(\mu_X, \sigma_X^2)$ is shorthand to denote the fact that, as $d \to \infty$, the distribution $\widehat{F}_X$ of the standard score $\frac{X - \mu_X}{\sigma_X}$ of X converges to the normal distribution

$\mathcal{N}(0,1)$. Thus, for large values of d, $\mathcal{N}(\mu_X, \sigma_X^2)$ approximates the distribution probability F_X of X, and $Pr[X \leq \delta] \approx \Phi\left(\frac{\delta - \mu_X}{\sigma_X}\right)$.

In the following, $\|\cdot\|$ denotes the L_2 norm, i.e., $\|\boldsymbol{x}_d\| = \sqrt{\sum_{i=1}^{d} x_i^2}$. Moreover, $\text{dist}(P,Q)$ denotes the Euclidean distance $\|P - Q\|$ between (random) vector P and (random) vector Q.

Let $x \in \mathbb{R}$, and let X be a random variable. Then

$$z_{x,X} = \frac{x - \mu_X}{\sigma_X}$$

represents the value x standardized with respect to the mean and the standard deviation of X. For a d-dimensional vector $\boldsymbol{x}_d$, which is the realization of a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$, the notation $z_{\boldsymbol{x}_d}$ is used as shorthand for $z_{\|\boldsymbol{x}_d\|^2, \|\boldsymbol{Y}_d\|^2}$, i.e.,

$$z_{\boldsymbol{x}_d} = z_{\|\boldsymbol{x}_d\|^2, \|\boldsymbol{Y}_d\|^2} = \frac{\|\boldsymbol{x}_d\|^2 - \mu_{\|\boldsymbol{Y}_d\|^2}}{\sigma_{\|\boldsymbol{Y}_d\|^2}}.$$

Results in the following are derived by considering distributions. However, these results can be applied to a finite set of points by taking into account large samples. In order to deal with a finite set of points, $\{\boldsymbol{Y}_d\}_n$ denotes a set of n random vectors $\{\boldsymbol{Y}_d^{(1)}, \ldots, \boldsymbol{Y}_d^{(n)}\}$, each one distributed as $\boldsymbol{Y}_d$.

Now we recall the Lyapunov Central Limit Theorem (CLT) condition. Consider the sequence $W_1, W_2, W_3, \ldots$ of independent, but not identically distributed, random variables, and let $V_d = \sum_{i=1}^{d} W_i$. By the Lyapunov CLT condition (Ash and Doléans-Dade, 1999), if for some $\delta > 0$ it holds that

$$\lim_{d \to \infty} \frac{1}{s_d^{2+\delta}} \sum_{i=1}^{d} \mathbf{E}\left[|W_i - \mathbf{E}[W_i]|^{2+\delta}\right] = 0, \text{ where } s_d^2 = \sum_{i=1}^{d} \sigma_{W_i}^2, \tag{1}$$

then, as d goes to infinity,

$$\frac{U_d - \mathbf{E}[U_d]}{\sigma(U_d)} = \frac{\sum_{i=1}^{d} W_i - \sum_{i=1}^{d} \mathbf{E}[W_i]}{\sqrt{\sum_{i=1}^{d} \sigma_{W_i}^2}} \to \mathcal{N}(0,1),$$

i.e., the standard score $(V_d - \mathbf{E}[V_d])/\sigma(V_d)$ converges in distribution to a standard normal random variable.

In the following, when a statement involves a d-dimensional vector $\boldsymbol{x}_d$, we will usually assume that $\boldsymbol{x}_d$ is the realization of a specific d-dimensional random vector $\boldsymbol{X}_d$. Moreover, we will say that a result involving the realization $\boldsymbol{x}_d$ of a random vector $\boldsymbol{X}_d$ holds *with high probability* if the statement is true for all the realizations of $\boldsymbol{X}_d$ except for a subset which becomes increasingly less probable as the dimensionality d increases.

Technically, the assumption that $\boldsymbol{x}_d$ is a realization of a random vector $\boldsymbol{X}_d$ is leveraged to attain a proof of convergence in probability. This also means that when we simultaneously account for all the realizations of a random vector $\boldsymbol{X}_d$ (by integrating on all vectors $\boldsymbol{x}_d$ such that $f_X(\boldsymbol{x}_d) > 0$), the existence of such a negligible set does not affect the final result.

4. Results

This section presents the results of the work concerning distribution of distances, nearest neighbors, and reverse nearest neighbors.

Specifically, Section 4.1, concerning the distribution of distances between intrinsically high-dimensional data, derives the expressions for the distance distribution between pairs of random vectors and between a realization of a random vector and a random vector, and analyzes the error associated with expressions.

Section 4.2 takes into account the distribution of distances from nearest neighbors, derives the expected size of the ϵ-neighborhood in high-dimensional spaces, and leverages it to characterize neighborhood instability. The section also derives a novel estimate of the relative contrast measure.

Section 4.3 addresses the problem of determining the number of k-occurrences and determines the closed form of its limiting distribution, showing that it encompasses previous results and provides interpretability of the associated hubness phenomenon.

Section 4.4 generalizes the results derived for the i.i.d. case to independent non-identically distributed data, depicting connections with the behavior in real data.

Section 4.5 discusses relationship to other distances, including Minkowski's metrics and, in general, distances satisfying certain conditions of spatial centrality.

The first three sections deal with i.i.d. random vectors. In these sections, the synthetic data sets considered consist of data generated from a uniform distribution in $[-0.5, +0.5]$, a standard normal distribution, and an exponential distribution with mean 1.

For the proofs that are not reported within the main text, the reader is referred to the Appendix.

4.1 On the Distribution of Distances for i.i.d. Data

First of all, the probability that two d-dimensional i.i.d. random vectors lie at a distance not greater than δ from one another is considered. The expression of Theorem 6 results from the fact that the distribution of the random variable $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2$ converges towards the normal distribution for large dimensionalities.

Theorem 6 *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two d-dimensional i.i.d. random vectors with common cdf F. Then, for large values of d,*

$$Pr\left[\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d) \leq \delta\right] \approx \Phi\left(\frac{\delta^2 - 2d(\mu_2 - \mu^2)}{\sqrt{2d\Big(\mu_4 + \mu_2^2 + 2\mu\big(\mu(2\mu_2 - \mu^2) - 2\mu_3\big)\Big)}}\right).$$

Proof of Theorem 6. The statement follows from the property shown in Lemma 7.

Lemma 7 $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(2d(\mu_2 - \mu^2),\ 2d\left(\mu_4 + \mu_2^2 + 2\mu\big(\mu(2\mu_2 - \mu^2) - 2\mu_3\big)\right)\right)$.

Proof of Lemma 7. The squared norm $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2$ can be written as $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 = \|\boldsymbol{X}_d\|^2 + \|\boldsymbol{Y}_d\|^2 - 2\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$, where $\|\boldsymbol{X}_d\|^2 \equiv \|\boldsymbol{Y}_d\|^2$, and $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are the following random

variables

$$\|\boldsymbol{Y}_d\|^2 = \sum_{i=1}^{d} Y_i^2 \quad \text{and} \quad \langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle = \sum_{i=1}^{d} X_i Y_i.$$

The proof proceeds by showing that, as $d \to \infty$, $\|\boldsymbol{X}_d\|^2$, $\|\boldsymbol{Y}_d\|^2$, and $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are both normally distributed and jointly normally distributed and by determining their covariance, which is accounted for in Propositions 8, 9, 10, and 11, as reported in the following.

Proposition 8 $\|\boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(d\mu_2, d(\mu_4 - \mu_2^2)\right)$.

Proof of Proposition 8. Consider the random variable

$$\|\boldsymbol{Y}_d\|^2 = \sum_{i=1}^{d} Y_i^2 = \sum_{i=1}^{d} W_i,$$

where $W_i = Y_i^2$ is a novel random variable. Then, $\mu_W = \mathbf{E}[W_i] = \mathbf{E}[Y_i^2] = \mu_2$, and $\sigma_W^2 = \mathbf{E}[W_i^2] - \mathbf{E}[W_i]^2 = \mathbf{E}[Y_i^4] - \mu_2^2 = \mu_4 - \mu_2^2$.

Consider the sequence $W_1, W_2, W_3, \ldots$ of i.i.d. random variables. By the Central Limit Theorem (CLT for short) (Ash and Doléans-Dade, 1999), the standard score of W_i is such that, as $d \to \infty$,

$$\frac{\sum_{i=1}^{d} W_i - d\mu_W}{\sqrt{d\sigma_W}} = \frac{\sum_{i=1}^{d} Y_i^2 - d\mu_2}{\sqrt{d(\mu_4 - \mu_2^2)}} \to \mathcal{N}(0,1),$$

from which the result follows. ■

Proposition 9 $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle \simeq \mathcal{N}\big(d\mu^2, d(\mu_2^2 - \mu^4)\big)$.

Proof of Proposition 9. Because $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle = \sum_{i=1}^{d} X_i Y_i = \sum_{i=1}^{d} W_i$ is the sum of a sequence $W_1, W_2, W_3, \ldots$ of i.i.d. random variables with mean $\mathbf{E}[W_i] = \mathbf{E}[X_i Y_i] = \mathbf{E}[X_i]\mathbf{E}[Y_i] = \mu^2$ and variance $\sigma^2[W_i] = \mathbf{E}[W_i^2] - \mathbf{E}[W_i]^2 = \mathbf{E}[X_i^2 Y_i^2] - (\mu^2)^2 = \mathbf{E}[X_i^2]\mathbf{E}[Y_i^2] - \mu^4 = \mu_2^2 - \mu^4$, from the CLT the result follows. ■

Proposition 10 *As $d \to \infty$, $\|\boldsymbol{X}_d\|^2$, $\|\boldsymbol{Y}_d\|^2$ and $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are jointly normally distributed.*

Proof of Proposition 10. The statement holds provided that all linear combinations $W = a\|\boldsymbol{X}_d\|^2 + b\|\boldsymbol{Y}_d\|^2 + c\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are normal. Notice that

$$W = a\left(\sum_{i=1}^{d} X_i^2\right) + b\left(\sum_{i=1}^{d} Y_i^2\right) + c\left(\sum_{i=1}^{d} X_i Y_i\right) = \sum_{i=1}^{d} \left(aX_i^2 + bY_i^2 + cX_i Y_i\right) = \sum_{i=1}^{d} W_i,$$

where $W_i = aX_i^2 + bY_i^2 + cX_i Y_i$ is a novel random variable. Because $W_1, W_2, W_3, \ldots$ is a sequence of i.i.d. random variables, the result follows from the CLT. ■

Proposition 11

$$cov\big(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle\big) = d\mu(\mu_3 - \mu_2\mu)$$
$$\big(\textit{and } cov\big(\|\boldsymbol{X}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle\big) = d\mu(\mu_3 - \mu_2\mu), \textit{ for symmetry}\big).$$

Proof of Proposition 11. See the appendix. ■

Proof of Lemma 7 (continued). Because the random variables $\|\boldsymbol{X}_d\|^2$, $\|\boldsymbol{Y}_d\|^2$, and $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are jointly normally distributed (see Proposition 10), their linear combination $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 = \|\boldsymbol{X}_d\|^2 + \|\boldsymbol{Y}_d\|^2 - 2\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ is normally distributed with mean $\mu_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2} = \mu_{\|\boldsymbol{X}_d\|^2} + \mu_{\|\boldsymbol{Y}_d\|^2} - 2\mu_{\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle} = 2d(\mu_2 - \mu^2)$, and variance

$$\begin{aligned}
\sigma^2_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2} &= 2\sigma^2_{\|\boldsymbol{Y}_d\|^2} + (-2)^2\sigma^2_{\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle} + 4(-2)cov(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle) = \\
&= 2d(\mu_4 - \mu_2^2) + 4d(\mu_2^2 - \mu^4) - 8d\mu(\mu_3 - \mu_2\mu) = \\
&= 2d\Big(\mu_4 + \mu_2^2 + 2\mu\big(\mu(2\mu_2 - \mu^2) - 2\mu_3\big)\Big).
\end{aligned}$$

■

Proof of Theorem 6 (continued). To conclude the proof: $Pr\left[\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d) \leq \delta\right] = Pr\left[\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d)^2 \leq \delta^2\right] = Pr\left[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 \leq \delta^2\right] \approx \Phi_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2}(\delta^2)$. ■

Note that, if $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ have a common pdf with null mean ($\mu = 0$), $\|\boldsymbol{Y}_d\|^2$ ($\|\boldsymbol{X}_d\|^2$ equivalently) and $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle$ are uncorrelated, and being jointly normal distributed, they are also independent. In such a case, the parameters of the distribution can be expressed in the following simplified form.

Corollary 12 *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two d-dimensional i.i.d. random vectors with common cdf F_X having mean μ. Then*

$$\|\hat{\boldsymbol{X}}_d - \hat{\boldsymbol{Y}}_d\|^2 \simeq \mathcal{N}\left(2d\hat{\mu}_2,\ 2d(\hat{\mu}_4 + \hat{\mu}_2^2)\right),$$

where $\hat{\boldsymbol{X}}_d = \boldsymbol{X}_d - \mu$ ($\hat{\boldsymbol{Y}}_d = \boldsymbol{Y}_d - \mu$, resp.) and $\hat{\mu}_k = \mathbf{E}[(X - \mu)^k]$ ($k > 0$) are the central moments of f_X (the moments of $f_{\hat{X}}$, resp.).

Proof of Corollary 12. Immediate from Theorem 7. ■

The notability of the above expression also stems from the following fact.

Proposition 13 $Pr[\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d) \leq \delta] = Pr[\text{dist}(\hat{\boldsymbol{X}}_d, \hat{\boldsymbol{Y}}_d) \leq \delta]$.

Proof of Proposition 13. Distances are not affected by translation. ■

Until now, it has been assumed that $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ have a common cdf. The following expression takes into account the case of different cdfs.

Corollary 14 *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two d-dimensional i.i.d. random vectors with cdfs F_X and F_Y, respectively. Then $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}(\mu_{X,Y},\ \sigma^2_{X,Y})$, where*

$$\begin{aligned}\mu_{X,Y} &= d(\mu_{X,2} + \mu_{Y,2} - 2\mu_X\mu_Y), \text{ and}\\ \sigma^2_{X,Y} &= d\big((\mu_{X,4} - \mu^2_{X,2}) + (\mu_{Y,4} - \mu^2_{Y,2}) + 4\mu_{X,2}\mu_{Y,2} + 4\mu_X\mu_Y\big(\mu_{X,2} + \mu_{Y,2} - \mu_X\mu_Y\big) + \\ &\quad -4\mu_X\mu_{Y,3} - 4\mu_Y\mu_{X,3}\big).\end{aligned}$$

Proof of Corollary 14. The expression can be obtained by following the same line of reasoning of Theorem 7. ■

To characterize more precisely distance distributions, it is of interest to consider the case in which one of the two vectors is held fixed. With this aim, the following Theorem 15 concerns the probability that a given d-dimensional vector $\boldsymbol{x}_d$ and the realization of a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$ lie at a distance not greater than δ from one another. The result holds under the condition that $\boldsymbol{x}_d$ itself is the realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$, with the cdf F_X of $\boldsymbol{X}_d$ not necessarily being identical to the cdf F_Y of $\boldsymbol{Y}_d$.

Formally, Theorem 15 holds with high probability because it relies on a proof of convergence in probability exploited in Proposition 17. Although not all the realizations may comply with the condition of Proposition 17 (e.g., consider the case $x_i = c^i$ with $c \neq 1$), it holds anyway for almost all the realizations, except for a set of vanishing measure.

Theorem 15 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$, and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector. Then, for large values of d, with high probability*

$$Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \delta\right] \approx \Phi\left(\frac{\delta^2 - \|\boldsymbol{x}_d\|^2 - d\mu_2 + 2\mu\sum_{i=1}^d x_i}{\sqrt{d(\mu_4 - \mu_2^2) + 4(\mu_2 - \mu^2)\|\boldsymbol{x}_d\|^2 - 4(\mu_3 - \mu\mu_2)\sum_{i=1}^d x_i}}\right),$$

where moments are relative to the random vector $\boldsymbol{Y}_d$.

Proof of Theorem 15. The proof relies on the result of Lemma 16 considering the distribution of $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2$.

Lemma 16 *With high probability*

$$\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(\|\boldsymbol{x}_d\|^2 + d\mu_2 - 2\mu\sum_{i=1}^d x_i,\ d(\mu_4 - \mu_2^2) + 4(\mu_2 - \mu^2)\|\boldsymbol{x}_d\|^2 - 4(\mu_3 - \mu\mu_2)\sum_{i=1}^d x_i\right).$$

Proof of Lemma 16. Consider the equality $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 = \|\boldsymbol{x}_d\|^2 + \|\boldsymbol{Y}_d\|^2 - 2\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$. The proof proceeds by studying the distribution of $\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$ (see Proposition 18), by showing that $\|\boldsymbol{Y}_d\|^2$ and $\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$ are jointly normally distributed (see Proposition 19), and by determining their covariance (see Proposition 20). However, a technical result that is leveraged in the sequel of the proof is first needed; this is presented in Proposition 17.

Proposition 17 *Let $\boldsymbol{X}_d$ be a d-dimensional i.i.d. random vector having cdf F_X. Moreover, let p and q be positive integers, and $\beta_0, \beta_1, \ldots, \beta_p$, $\alpha_0, \alpha_1, \ldots, \alpha_q$ be real coefficients such that $\beta_p \neq 0$ and $\alpha_q \neq 0$. Then, for any $\epsilon > 0$,*

$$\lim_{d\to\infty} Pr\left[\left|\frac{\sum_{i=1}^d\left(\sum_{j=0}^p \beta_j X_i^j\right)}{\left(\sum_{i=1}^d\left(\sum_{j=0}^q \alpha_j X_i^j\right)\right)^2}\right| \geq \epsilon\right] = 0.$$

Proof of Proposition 17. See the appendix. ■

Proposition 18 *With high probability $\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle \simeq \mathcal{N}\big(\mu\sum_{i=1}^d x_i,\ (\mu_2 - \mu^2)\|\boldsymbol{x}_d\|^2\big)$.*

Proof of Proposition 18. Consider the random variable $\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$:

$$\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle = \sum_{i=1}^d x_i Y_i = \sum_{i=1}^d W_i,$$

where $W_i = x_i Y_i$ is a novel random variable. Then, $\mu_{W_i} = \mathbf{E}[W_i] = \mathbf{E}[x_i Y_i] = x_i\mathbf{E}[Y_i] = x_i\mu$, and $\sigma^2_{W_i} = \mathbf{E}[W_i^2] - \mathbf{E}[W_i]^2 = \mathbf{E}[x_i^2 Y_i^2] - x_i^2\mu^2 = x_i^2\mu_2 - x_i^2\mu^2 = (\mu_2 - \mu^2)x_i^2$.

Consider the sequence $W_1, W_2, W_3, \ldots$ of independent, but not identically distributed, random variables. If the Lyapunov CLT condition reported in Equation (1) holds, the standard score $(\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle - \mu_{\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle})/\sigma_{\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle}$ converges in distribution to a standard normal random variable as d goes to infinity, i.e.,

$$\frac{\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle - \mu_{\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle}}{\sigma_{\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle}} = \frac{\sum_{i=1}^d W_i - \sum_{i=1}^d \mathbf{E}[W_i]}{\sum_{i=1}^d \sigma^2_{W_i}} = \frac{\sum_{i=1}^d x_i Y_i - \mu\sum_{i=1}^d x_i}{\sqrt{\mu_2 - \mu^2}\|\boldsymbol{x}_d\|} \to \mathcal{N}(0,1).$$

Thus, consider the Lyapunov condition for $\delta = 2$:

$$\lim_{d\to\infty} \frac{\sum_{i=1}^d \mathbf{E}\left[|W_i - \mathbf{E}[W_i]|^{2+\delta}\right]}{s_d^{2+\delta}}\bigg|_{\delta=2} = \lim_{d\to\infty} \frac{\sum_{i=1}^d \mathbf{E}\left[|x_i(Y_i - \mu)|^4\right]}{(\mu_2 - \mu^2)^2\|\boldsymbol{x}_d\|^4} =$$
$$= \frac{\mu_4 + \mu(6\mu\mu_2 - 4\mu_3 - 3\mu^3)}{(\mu_2 - \mu^2)^2} \cdot \lim_{d\to\infty} \frac{\sum_{i=1}^d x_i^4}{\left(\sum_{i=1}^d x_i^2\right)^2} = 0.$$

The above limit converges in probability for the r.v. $\boldsymbol{X}_d$ by Proposition 17. ■

Proposition 19 *As $d \to \infty$, with high probability $\|\boldsymbol{Y}_d\|^2$ and $\langle\boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$ are jointly normally distributed.*

Proof of Proposition 19. See the appendix. ■

Proposition 20 *cov* $\left(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle\right) = (\mu_3 - \mu\mu_2) \sum_{i=1}^{d} x_i$.

Proof of Proposition 20. See the appendix. ■

Proof of Lemma 16 (continued). To conclude the proof of Lemma 16, because the random variables $\|\boldsymbol{Y}_d\|^2$, and $\langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle$ are jointly normally distributed, then the random variable $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2$ is normally distributed with mean

$$\mu_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2} = \mu_{\|\boldsymbol{x}_d\|^2} + \mu_{\|\boldsymbol{Y}_d\|^2} - 2\mu_{\langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle} = \|\boldsymbol{x}_d\|^2 + d\mu_2 - 2\mu \sum_{i=1}^{d} x_i,$$

and variance

$$\begin{aligned} \sigma^2_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2} &= \sigma^2_{\|\boldsymbol{Y}_d\|^2} + (-2)^2 \sigma^2_{\langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle} + 2(-2)\ cov(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle). = \\ &= d(\mu_4 - \mu_2^2) + 4(\mu_2 - \mu^2)\|\boldsymbol{x}_d\|^2 - 4(\mu_3 - \mu\mu_2)\left(\sum_{i=1}^{d} x_i\right). \end{aligned}$$

■

Proof of Theorem 15 (continued). To conclude the proof: $Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \delta\right] = Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d)^2 \leq \delta^2\right] = Pr\left[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \leq \delta^2\right] = \Phi_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2}(\delta^2)$. ■

For distributions having null means, the above expressions can be simplified.

Corollary 21 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$, and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y having null mean $\mu_Y = 0$. Then, with high probability*

$$\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(\|\boldsymbol{x}_d\|^2 + d\mu_2,\ d(\mu_4 - \mu_2^2) + 4\mu_2\|\boldsymbol{x}_d\|^2 - 4\mu_3 \sum_{i=1}^{d} x_i\right),$$

where the moments are relative to the random vector $\boldsymbol{Y}_d$.

Proof of Corollary 21. The result follows by substituting $\mu = \mu_Y = 0$ in the right-hand side of the statement of Lemma 16. ■

In order to quantify the error associated with the approximations of Theorem 6 and Theorem 15, the Kolmogorov-Smirnov statistic D_n is employed here as an error measure. This statistic is usually used for comparing a theoretical cumulative distribution function F to a given empirical distribution function G_n for n observations, and it is defined as

$$D_n(G_n, F) = \sup_{\delta \in \mathbb{R}} |G_n(\delta) - F(\delta)|.$$

In our case, given an empirical distribution function $G_{d,n}$ for n observations and a theoretical distribution function F_d, both related to the dimensionality parameter d, we define the error $err_d(G_{d,n}, F_d)$ as $D_n(G_{d,n}, F_d)$.

As for the approximation of Theorem 6, $F_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2}(\delta) = \Phi\left(\frac{\delta - \mathbf{E}[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2]}{\sigma(\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2)}\right)$ is employed as theoretical cdf F_d, whereas $F^{emp}_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2,n}(\delta)$, denoting the empirical distribution of the squared distances, is employed as the empirical cdf $G_{d,n}$, and the error measured is $e_d = err_d\left(F^{emp}_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2,n}, F_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2}\right)$.

As the approximation of Theorem 15, given the realization $\boldsymbol{x}_d$ of $\boldsymbol{X}_d$, $F_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2}(\delta) = \Phi\left(\frac{\delta - \mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2]}{\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)}\right)$ is employed as a theoretical cdf, whereas $F^{emp}_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2,n}(\delta)$ denotes the empirical cdf. Specifically, we considered three points $\boldsymbol{p}_d^{(i)}$ $(1 \leq i \leq 3)$ as instances of $\boldsymbol{x}_d$. Each point $\boldsymbol{p}_d^{(i)}$ lies k_i (with $k_1 = 0$, $k_2 = 1$, and $k_3 = 5$) standard deviations $\sigma_{\|\boldsymbol{X}_d\|^2}$ away from the mean $\mu_{\|\boldsymbol{X}_d\|^2}$ of the squared norm of $\boldsymbol{X}_d$, i.e., each point $\boldsymbol{p}_d^{(i)}$ is such that $z_{\|\boldsymbol{p}_d^{(i)}\|^2, \|\boldsymbol{X}_d\|^2} = k_i$ (in particular, the generic coordinate of $\boldsymbol{p}_d^{(i)}$ has value $\left((\mu_{\|\boldsymbol{X}_d\|^2} + k_i \cdot \sigma_{\|\boldsymbol{X}_d\|^2})/d\right)^{1/2}$). The error measured for each point is $e_d^{(i)} = err_d\left(F^{emp}_{\|\boldsymbol{p}_d^{(i)} - \boldsymbol{Y}_d\|^2,n}, F_{\|\boldsymbol{p}_d^{(i)} - \boldsymbol{Y}_d\|^2}\right)$.

The empirical cdf $F^{emp}_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2,n}$ has been obtained by generating n pairs $(\boldsymbol{x}_d^{(j)}, \boldsymbol{y}_d^{(j)})$ $(1 \leq j \leq n)$ of realizations of the random vectors $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$, respectively, and then by computing $F^{emp}_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2,n}(\delta) = \frac{1}{n}\sum_{j=1}^{n} I_{[0,\delta]}\left(\text{dist}(\boldsymbol{x}_d^{(j)}, \boldsymbol{y}_d^{(j)})\right)$, where I_S denotes the indicator function (with S representing a generic set), such that $I_S(v) = 1$, if $v \in S$, and $I_S(v) = 0$, otherwise. The empirical cdf $F^{emp}_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2,n}$, is obtained by generating n realizations $\boldsymbol{y}_d^{(j)}$ $(1 \leq j \leq n)$ of the random vector $\boldsymbol{Y}_d$, and then by computing $F^{emp}_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2,n}(\delta) = \frac{1}{n}\sum_{j=1}^{n} I_{[0,\delta]}\left(\text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d^{(j)})\right)$.

We note that, for any distance threshold $\delta \geq 0$, the value err_d represents an upper bound to the error committed when the theoretical cdf of Theorem 6 (Theorem 15, resp.) is used to estimate the probability $Pr[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\| \leq \delta]$ ($Pr[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\| \leq \delta]$, resp.).

Figure 1 shows the above defined errors e_d, $e_d^{(1)}$, $e_d^{(2)}$, and $e_d^{(3)}$ (red curves), for distributions $F_X = F_Y$, uniform in $[-0.5, +0.5]$ (Fig. 1a), standard normal (Fig. 1b), and exponential with $\lambda = 1$ (Fig. 1c), respectively.

Before commenting on the results, it must be pointed out that the error err_d depends on the size n of the sample employed to build the empirical distribution. Thus, first we discuss the behavior for unbounded sample sizes n, and then take into account the effect of finite sample sizes. In order to simulate an unbounded sample size, the curves in the figures have been obtained for a very large sample size $n > 1.5 \cdot 10^8$.

From Figures 1a, 1b, and 1c it can be seen that the error err_d decreases with the dimensionality. The trend of the error curves is more regular for the uniform and normal distribution than for the exponential distribution, probably due to the skewness of the exponential distribution. The error e_d associated with the cdf $F_{\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2}$ is greater than the errors $e_d^{(i)}$ associated with the cdf $F_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2}$. Intuitively, this can be explained since the degree of uncertainty is reduced if one of the two random vectors is replaced by a fixed point. In general, it holds that $e_d^{(1)} > e_d^{(2)} > e_d^{(3)}$, thus indicating that uncertainty

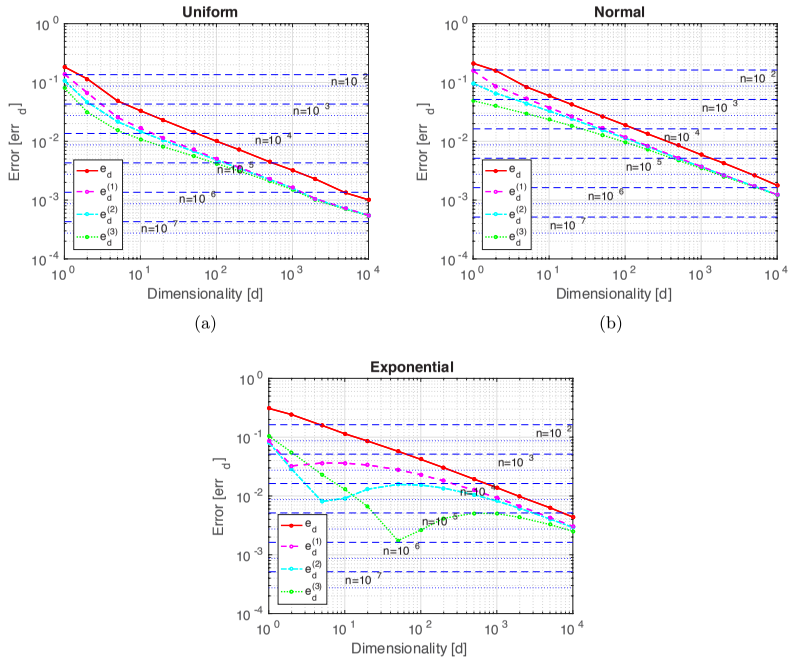

Figure 1: [Best viewed in color.] Empirical evaluation of the approximation errors of Th. 6 and Th. 15, for dimensionalities $d \in [10^0, 10^4]$ and sample sizes $n \in [10^2, 10^7]$. Error e_d (red solid line) is associated with the expression of Th. 6, whereas errors $e_d^{(1)}$ (magenta dashed line), $e_d^{(2)}$ (cyan dash-dotted line), and $e_d^{(3)}$ (green dotted line) are associated with the expression of Th. 15, for three different points whose squared norm standard scores are 0, 1, and 5, respectively. Horizontal blue lines take into account the sample size n: the dotted line is the expected error for different n values under the hypothesis that the distance distribution is indeed normal; the dashed line is the value under which the hypothesis that the sample is generated according the theoretical distribution can be accepted at the 95% confidence level.

increases towards the most largely populated regions of the space. Moreover, the larger the dimensionality d, the closer the errors $e_d^{(j)}$ to $e_d^{(1)}$.

As anticipated above, the error err_d depends on the size n of the sample employed to build the empirical distribution. Specifically, differently from the case of unbounded n values, for which the error decreases with the dimensionality, for any fixed sample size n, there exists a dimensionality d such that the error converges around a value $\overline{e}_n$. Such a value $\overline{e}_n$ corresponds to the error $D_n(\Phi_n^{emp}, \Phi)$ between the empirical cdf Φ_n^{emp} associated with a random sample of n elements of a (standard) normal distribution and the theoretical cdf Φ of a (standard) normal distribution.

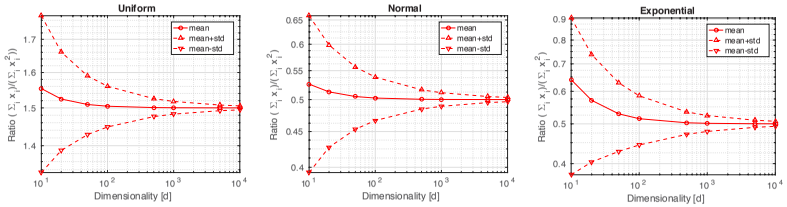
Let K be a random variable having a Kolmogorov distribution. According to the Kolmogorov-Smirnov test, the null hypothesis that the sample of n observations having empirical distribution G_n comes from the hypothesized distribution F is rejected at level $\alpha \in (0,1)$ if the statistic $\sqrt{n} \cdot D_n(G_n, F)$ is greater than the value K_α, where K_α is such that $Pr[K \leq K_\alpha] = 1 - \alpha$. It follows from the above that if, for a certain α and sample size n, it holds that err_d is smaller than $e_n^\alpha = K_\alpha \cdot n^{-1/2}$, then the hypothesis that the sample complies with the theoretical distribution can be accepted at the $1-\alpha$ confidence level, e.g., for $\alpha = 0.05$, the value $K_{0.05}$ is 1.3581. Moreover, the expected value $\overline{e}_n$ of $D_n(\Phi_n^{emp}, \Phi)$ approximately corresponds to $K_{\overline{\alpha}} \cdot n^{-1/2}$ with $\overline{\alpha} = 0.44$, i.e., to $\overline{e}_n \approx 0.8673 \cdot n^{-1/2}$.

Horizontal (blue) lines in Figures 1a, 1b, and 1c take into account the effect of the sample size n. Each pair of dashed and dotted lines is associated with a different value of $n \in \{10^2, 10^3, \ldots, 10^7\}$. Dashed lines are associated with the errors $e_n^{0.05}$, whereas dotted lines are associated with the errors $\overline{e}_n$. Let n be the actual sample size, and let d^* be the dimensionality such that the value e_{d^*} of the particular curve e_d is equal to $\overline{e}_n$ (dotted horizontal curve). Then, for $d \geq d^*$, the expected value of e_d tends to $\overline{e}_n$. Thus, for $d < d^*$, the curve of e_d is similar to the one reported in the figure, whereas for $d > d^*$, the curve of e_d tends to be horizontal, with a value close to $\overline{e}_n$. Moreover, if $e_d \leq e_n^{0.05}$ (dashed horizontal curve), then the hypothesis that the sample complies with the hypothesized distribution can be accepted at the 95% confidence level. Informally speaking, this means that in the latter case, the distribution hypothesized in Theorems 6 and 15 is indiscernible from the underlying distribution generating the observed inter-point distances.

In summary, as previously pointed out, because err_d depends on the worst-case threshold value δ, it is an upper bound to the error committed when estimating probabilities by leveraging the results previously presented. The analysis with unbounded sample size highlights that the worst-case error always decreases with the dimensionality. Moreover, let the effective error be defined as the difference between the observed error and the error expected when the data are generated according to the hypothesized distribution. The analysis of finite sample sizes highlights that, in practice, the effective error can become null.

For the distributions F_Y having both a null mean and null skewness ($\mu_3 = 0$), it follows from Propositions 19 and 20 that the random variables $\|\boldsymbol{Y}_d\|^2$ and $\langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle$ are independent.

Moreover, the distribution defined in Corollary 21, in Theorem 15 and in Lemma 16, depend only on the squared norm $\|\boldsymbol{x}_d\|^2$, whereas the actual value of $\boldsymbol{x}_d$ does not matter. However, it can be shown that the same property holds also for skewed distributions, since the term $(\sum_i x_i)$ is related to $\|\boldsymbol{x}_d\|^2$, as accounted for in the subsequent result.



(a) (b) (c)

Figure 2: Empirical validation of Proposition 22 on different distributions: (a) uniform ($\mu_1/\mu_2 = 1.5$), (b) normal ($\mu_1/\mu_2 = 0.5$), and (c) exponential ($\mu_1/\mu_2 = 0.5$). The red solid curve represents the expected value μ_W of the ratio $W = (\sum_{i=1}^{d} X_i)/\|\boldsymbol{X}_d\|^2$, whereas the red dashed curves represent the values $\mu_W + \sigma_W$ and $\mu_W - \sigma_W$, measured for $n = 20{,}000$ points and $d \in [10^1, 10^4]$.

Proposition 22 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ with cdf F_X. Then, for large values of d, with high probability*

$$\frac{\sum_{i=1}^{d} x_i}{\|\boldsymbol{x}_d\|^2} \to \frac{\mu_X}{\mu_{X,2}}.$$

Proof of Proposition 22. See the appendix. ■

Thus, the term $(\sum_i x_i)$ can be approximated by $\frac{\mu_X}{\mu_{X,2}}\|\boldsymbol{x}_d\|^2$.

Notice that the above result also states that for random vectors $\boldsymbol{X}_d$ having null mean, the term $(\sum_i x_i)$ becomes negligible with respect to $\|\boldsymbol{x}_d\|^2$ and, hence, that it can be ignored in the expression reported in Corollary 21, thus removing the dependence from the skewness of the distribution F_Y.

To empirically validate Proposition 22, the mean and the standard deviation of the ratio $W = (\sum_{i=1}^{d} X_i)/\|\boldsymbol{X}_d\|^2$ have been measured on distributions having non-null mean $\mu \neq 0$. Figure 2 reports the result of the experiment for $d \in [10, 10^4]$ and $n = 20{,}000$. Specifically, a uniform distribution with mean $\mu_1 = 0.5$ ($\mu_2 = 0.333$, $\mu_3 = 0.25$, and $\mu_4 = 0.2$) and ratio $\mu_1/\mu_2 = 1.5$ (Fig. 2a), a normal distribution with mean $\mu_1 = 1$ ($\mu_2 = 2$, $\mu_3 = 4$, and $\mu_4 = 10$) and ratio $\mu_1/\mu_2 = 0.5$ (Fig. 2b), and an exponential distribution with mean $\mu_1 = 1$ ($\mu_2 = 2$, $\mu_3 = 6$, and $\mu_4 = 24$) and ratio $\mu_1/\mu_2 = 0.5$ (Fig. 2c), were considered. It can be seen that the expected value $\mathbf{E}[W]$ of the ratio W rapidly converges to the limiting value μ_1/μ_2 and also that the standard deviation $\sigma(W)$ of the ratio W decreases with the dimensionality. Moreover, in all cases, the trend agrees with the prediction of Proposition 22, according to which it holds that $|\mathbf{E}[W] - \mu_1/\mu_2| = O(d^{-1})$ and $\sigma(W) = O(d^{-1/2})$.

4.2 On the Distribution of Nearest Neighbors for i.i.d. Data

Given a real number $\varrho \in [0, 1]$, a d-dimensional vector $\boldsymbol{x}_d$ and a d-dimensional random vector $\boldsymbol{Y}_d$, $\text{distnn}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ denotes the radius of the smallest neighborhood centered in $\boldsymbol{x}_d$ containing at least the ϱ fraction of the realizations of $\boldsymbol{Y}_d$. Moreover, $nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, or $nn_\varrho(\boldsymbol{x}_d)$ whenever $\boldsymbol{Y}_d$ is clear from the context, also called *ϱ-th nearest neighbor* of $\boldsymbol{x}_d$ w.r.t. $\boldsymbol{Y}_d$, denotes an element of the set $\{\boldsymbol{y}_d \in \mathbb{R}^d \mid f_Y(\boldsymbol{y}_d) > 0 \text{ and } \text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) = \text{distnn}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)\}$.[1] $\text{NN}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, or $\text{NN}_\varrho(\boldsymbol{x}_d)$ whenever $\boldsymbol{Y}_d$ is clear from the context, denotes the set of points $\{\boldsymbol{y}_d \in \mathbb{R}^d \mid f_Y(\boldsymbol{y}_d) > 0 \text{ and } \text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) \leq \text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))\}$.

In order to deal with finite sets of n points $\{\boldsymbol{Y}_d\}_n$, the integer parameter $k = \varrho n$ ($k \in \{1, \ldots, n\}$) has to be employed in place of ϱ. Thus, given a positive integer k, $\text{distnn}_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)$ represents the radius of the smallest neighborhood centered in $\boldsymbol{x}_d$ containing at least k points of $\{\boldsymbol{Y}_d\}_n$. Moreover, $nn_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)$ or $nn_k(\boldsymbol{x}_d)$, also called *k-th nearest neighbor* of $\boldsymbol{x}_d$ in $\{\boldsymbol{Y}_d\}_n$, denotes an element of the set $\{\boldsymbol{y}_d \in \{\boldsymbol{Y}_d\}_n \mid \text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) = \text{distnn}_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)\}$.[2] $\text{NN}_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)$, or $\text{NN}_k(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, denotes the set of points $\{\boldsymbol{y}_d \in \{\boldsymbol{Y}_d\}_n \mid \text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) \leq \text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n))\}$.

In the rest of the work, given a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ with cdf F_X, representing the distribution of the query points, and a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$ with cdf F_Y, representing the distribution of the data points, we assume w.l.o.g. that F_Y has null mean μ_Y. Indeed, if it is not the case, it is sufficient to replace them with the random vectors $\boldsymbol{X}'_d = \boldsymbol{X}_d - \mu_Y$ and $\boldsymbol{Y}'_d = \hat{\boldsymbol{Y}}_d = \boldsymbol{Y}_d - \mu_Y$ such that $\mu_{Y'} = 0$. Moreover, a realization $\boldsymbol{x}_d$ of $\boldsymbol{X}_d$ can be replaced with $\boldsymbol{x}'_d = \boldsymbol{x}_d - \mu_Y$.

The following result considers the distance separating a vector from its ϱ-th nearest neighbor w.r.t. a d-dimensional i.i.d. random vector.

Lemma 23 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ having cdf F_X. Consider the ϱ-nearest neighbor $nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ of $\boldsymbol{x}_d$ w.r.t. a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$ with cdf F_Y. Assume, w.l.o.g., that F_Y has null mean $\mu_Y = 0$. Then, for large values of d, with high probability*

$$\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)) \approx \sqrt{\|\boldsymbol{x}_d\|^2 + d\mu_2 + \Phi^{-1}(\varrho)\sqrt{d(\mu_4 - \mu_2^2) + 4\mu_2\|\boldsymbol{x}_d\|^2 - 4\mu_3 \sum_{i=1}^{d} x_i}}.$$

Proof of Lemma 23. By definition, $nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ is such that

$$Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))\right] = \varrho.$$

By Corollary 21,

$$Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))\right] \approx \Phi\left(\frac{\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))^2 - \mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2]}{\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)}\right).$$

1. Because our interest is only in the fact that $nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ satisfies the property $\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)) = \text{distnn}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, it can be assumed that $nn_\varrho(\boldsymbol{x}_d)$ is randomly selected from the above set.
2. Because our interest is only in the fact that $nn_k(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ satisfies the property $\text{dist}(\boldsymbol{x}_d, nn_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)) = \text{distnn}_k(\boldsymbol{x}_d, \{\boldsymbol{Y}_d\}_n)$, it can be assumed that $nn_k(\boldsymbol{x}_d)$ is randomly selected from the above set.

Hence, $\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))^2 \approx \mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2] + \Phi^{-1}(\varrho)\,\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)$. ■

It has been already pointed out that if F_Y has null skewness ($\mu_3 = 0$), if $F_X = F_Y$, or if F_X has null mean $\mu_X = 0$, the term $4\mu_3(\sum_i x_i)$ can be disregarded.

Due to the difficulty of answering nearest neighbor queries in high-dimensional spaces, different authors have proposed to consider approximate nearest neighbor queries (Indyk and Motwani, 1998; Arya et al., 1998), returning an ϵ-approximate nearest neighbor instead of the exact nearest neighbor: given point $\boldsymbol{x}_d$ and $\epsilon \geq 0$, a point $\boldsymbol{y}_d$ is an ϵ-approximate nearest neighbor of $\boldsymbol{x}_d$ if it holds that $\text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) \leq (1+\epsilon)\text{dist}(\boldsymbol{x}_d, nn_1(\boldsymbol{x}_d))$.

Beyer et al. (1999) called a nearest neighbor query *unstable* for a given $\epsilon \geq 0$, if the distance from the query point to most data points is less than $(1+\epsilon)$ times the distance from the query point to its nearest neighbor. Moreover, Beyer et al. (1999) have shown that in many situations, for any fixed $\epsilon > 0$, as dimensionality rises, the probability that a query is unstable converges to 1 (see Theorem 2).

Instability is undesirable because the points that fall in the enlarged query region, also called ϵ-neighborhood, are valid answers to the approximate nearest neighbor problem. Thus, the larger the expected number of data points falling within the ϵ-neighborhoods of the query points, the smaller the meaningfulness of the approximate query scenario.

Definition 24 *Let $\text{NN}^\epsilon_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$ denote the set of the ϵ-approximate ϱ-nearest neighbors of $\boldsymbol{x}_d$, also called ϵ-neighborhood, that are the realizations $\boldsymbol{y}_d$ of $\boldsymbol{Y}_d$ whose distance from $\boldsymbol{x}_d$ is within $(1+\epsilon)$ times the distance separating $\boldsymbol{x}_d$ from its ϱ-th nearest neighbor $nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, i.e.,*

$$\text{NN}^\epsilon_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d) = \{\boldsymbol{y}_d \in \mathbb{R}^d \mid f_Y(\boldsymbol{y}_d) > 0 \text{ and } \text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) \leq (1+\epsilon)\,\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d))\}.$$

In order to quantify the meaningfulness of ϵ-approximate queries, it is sensible to compute the expected size of the ϵ-neighborhoods associated with query points with respect to the data population, which is the task pursued in the following.

Theorem 25 *Let $\epsilon \geq 0$, let $\boldsymbol{X}_d$ be a d-dimensional i.i.d. random vector with cdf F_X, representing the distribution of the query points, and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y (not necessarily identical to F_X), representing the distribution of the data points. Assume, w.l.o.g., that F_Y has null mean $\mu_Y = 0$. Then, for large values of d,*

$$\mathbf{E}[|\text{NN}^\epsilon_k(\boldsymbol{X}_d, \{\boldsymbol{Y}_d\}_n)|] \approx$$
$$n\Phi\left(\frac{(\epsilon^2+2\epsilon)\,d(\mu_{X,2}+\mu_{Y,2}) + (1+\epsilon)^2\,\Phi^{-1}(\frac{k}{n})\sqrt{d\left(\mu_{Y,4} - \mu^2_{Y,2} + 4\mu_{Y,2}\mu_{X,2} - 4\mu_{Y,3}\mu_X\right)}}{\sqrt{d\left(\mu_{Y,4} - \mu^2_{Y,2} + 4\mu_{Y,2}\mu_{X,2} - 4\mu_{Y,3}\mu_X\right) + (\epsilon^2+2\epsilon)^2\,d(\mu_{X,4} - \mu^2_{X,2})}}\right).$$

Proof of Theorem 25. Consider the probability (exploiting Corollary 21, Proposition 22 and Lemmas 16 and 23)

$$\begin{aligned}
& Pr[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq (1+\epsilon)\,\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))] = \\
= \;& Pr[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d)^2 \leq (1+\epsilon)^2\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))^2] \approx \\
\approx \;& \Phi\left(\frac{(1+\epsilon)^2\left(\mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2] + \Phi^{-1}(\varrho)\,\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)\right) - \mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2]}{\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)}\right) = \\
= \;& \Phi\left(\frac{(\epsilon^2+2\epsilon)\,\mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2] + (1+\epsilon)^2\,\Phi^{-1}(\varrho)\,\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)}{\sigma(\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2)}\right) = \\
= \;& \Phi\left(\frac{(\epsilon^2+2\epsilon)(\|\boldsymbol{x}_d\|^2 + d\mu_{Y,2}) + (1+\epsilon)^2\,\Phi^{-1}(\varrho)\sqrt{d(\mu_{Y,4} - \mu^2_{Y,2}) + 4\mu_{Y,2}\|\boldsymbol{x}_d\|^2 - 4\mu_{Y,3}\frac{\mu_X}{\mu_{X,2}}\|\boldsymbol{x}_d\|^2}}{\sqrt{d(\mu_{Y,4} - \mu^2_{Y,2}) + 4\mu_{Y,2}\|\boldsymbol{x}_d\|^2 - 4\mu_{Y,3}\frac{\mu_X}{\mu_{X,2}}\|\boldsymbol{x}_d\|^2}}\right).
\end{aligned}$$

By taking into account the standard score of $\boldsymbol{x}_d$

$$\|\boldsymbol{x}_d\|^2 = z_{\boldsymbol{x}_d}\sigma_{\|\boldsymbol{X}_d\|^2} + \mu_{\|\boldsymbol{X}_d\|^2} = z_{\boldsymbol{x}_d}\sqrt{d(\mu_{X,4} - \mu^2_{X,2})} + d\mu_{X,2},$$

and by considering that for α, β, and z finite (note that $\phi(z)$ is practically negligible for $|z| \geq 5$) and d growing, $\sqrt{\alpha d + z\sqrt{\beta d}} \approx \sqrt{\alpha d}$, then the above probability can be approximated with $\Phi(a^{d,\epsilon,\varrho}_{X,Y} + b^{d,\epsilon,\varrho}_{X,Y} z_{\boldsymbol{x}_d})$, where

$$\begin{aligned}
a^{d,\epsilon,\varrho}_{X,Y} &= \frac{(\epsilon^2+2\epsilon)\,(d\mu_{X,2} + d\mu_{Y,2}) + (1+\epsilon)^2\,\Phi^{-1}(\varrho)\sqrt{d(\mu_{Y,4} - \mu^2_{Y,2}) + 4d\mu_{Y,2}\mu_{X,2} - 4d\mu_{Y,3}\mu_X}}{\sqrt{d(\mu_{Y,4} - \mu^2_{Y,2}) + 4d\mu_{Y,2}\mu_{X,2} - 4d\mu_{Y,3}\mu_X}}, \\
b^{d,\epsilon}_{X,Y} &= \frac{(\epsilon^2+2\epsilon)\sqrt{d(\mu_{X,4} - \mu^2_{X,2})}}{\sqrt{d(\mu_{Y,4} - \mu^2_{Y,2}) + 4d\mu_{Y,2}\mu_{X,2} - 4d\mu_{Y,3}\mu_X}}.
\end{aligned}$$

Consider now the expected value

$$\begin{aligned}
\mathbf{E}[|\text{NN}^\epsilon_\varrho(\boldsymbol{X}_d)|] &= \int_{\mathbb{R}^d} Pr[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq (1+\epsilon)\,\text{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))] \cdot \Pr[\boldsymbol{X}_d = \boldsymbol{x}_d]\;\mathrm{d}\boldsymbol{x}_d = \\
&= \int_{z_{d,min}}^{z_{d,max}} \Phi\left(a^{d,\epsilon,\varrho}_{X,Y} + b^{d,\epsilon}_{X,Y}\,z_{\boldsymbol{x}_d}\right)\,\phi(z_{\boldsymbol{x}_d})\;\mathrm{d}z_{\boldsymbol{x}_d}.
\end{aligned}$$

The statement then follows by leveraging the following equation (Owen, 1980)

$$\int_{-\infty}^{+\infty} \Phi(a+bz)\,\phi(z)\;\mathrm{d}x = \Phi\left(\frac{a}{\sqrt{1+b^2}}\right), \tag{2}$$

taking the limits of integration to infinity. Note that the extra domain of integration considered is associated with a negligible probability because $z_{d,min} = (\mu_{\|\boldsymbol{X}_d\|^2} - \inf\|\boldsymbol{X}_d\|^2)/\sigma_{\|\boldsymbol{X}_d\|^2}$ and $z_{d,max} = (\sup\|\boldsymbol{X}_d\|^2 - \mu_{\|\boldsymbol{X}_d\|^2})/\sigma_{\|\boldsymbol{X}_d\|^2}$, are such that both $\phi(z_{d,\min})$ and $\phi(z_{d,\max})$ rapidly approach zero. ■

In order to validate the above result, the expected value $\mathbf{E}[|\text{NN}^\epsilon_k(\boldsymbol{X}_d, \{\boldsymbol{Y}_d\}_n)|]$ is empirically estimated for different values of k, d and $\epsilon \in [0, 0.5]$, by exploiting sets of $n = 10{,}000$

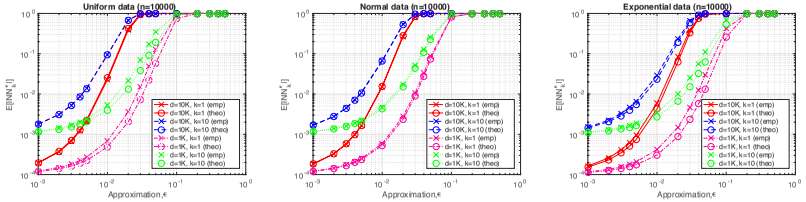


Figure 3: [Best viewed in color.] Comparison between the empirically estimated (x-marked curves) and the predicted by means of Th. 25 (o-marked curves) expected sizes of the ϵ-neighborhood, for $n = 10{,}000$, $d = 1{,}000$ and $k = 1$ (magenta dash-dotted line), $d = 1{,}000$ and $k = 10$ (green dotted line), $d = 10{,}000$ and $k = 1$ (red solid line), and $d = 10{,}000$ and $k = 10$ (blue dashed line).

realizations of the random vector $\boldsymbol{Y}_d$. Results are averaged by considering ten different sets. In the experiment, it is assumed that $F_X = F_Y$ and that each point of the set is used in turn as a query point; thus, the size of the ϵ-neighborhood may vary between k and $n-1$.

Figure 3 reports the results of this experiment for uniform, normal, and exponential i.i.d. data. The value $\mathbf{E}[|\mathrm{NN}_k^\epsilon(\boldsymbol{X}_d, \{\boldsymbol{Y}_d\}_n)|]$ empirically estimated as described above is compared with the value predicted by means of Theorem 25. The curves for the number of neighbors $k \in \{1, 10\}$ and the dimensionalities $d \in \{1{,}000, 10{,}000\}$ are reported. The curves confirm that the prediction follows the trend of the empirical evidence with the error vanishing as the dimensionality increases.

As already stated by Beyer et al. (1999), Theorem 2 only tells us what happens when we take the dimensionality to infinity, but nothing is said about the dimensionality at which do we anticipate nearest neighbors to become unstable, and the issue must be addressed through empirical studies.

The above dimensionality, called the *critical dimensionality*, can, however, be obtained as follows. Let $\theta \in [0, 1]$ represent a fraction of the data elements; the critical dimensionality $d^*_{\varrho,\epsilon,\theta}$ for the parameters ϱ and ϵ at the threshold level θ, also called selectivity, is such that

$$d^*_{\varrho,\epsilon,\theta} = \min\{d \in \mathbb{N}^+ : \mathbf{E}[|\mathrm{NN}^\epsilon_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)|] \geq \theta\},$$

i.e., the dimensionality at which the expected size of the ϵ-neighborhood contains at least the θ fraction of the data points.

Figure 4 reports the critical dimensionality for ϵ varying in $[0.001, 1]$, thresholds $\theta \in \{0.01, 0.1, 0.5\}$, $n = 10{,}000$ and $k = 1$ (i.e. $\varrho = k/(n-1) \approx 0.0001$), obtained by exploiting the expression reported in Theorem 25. For example, for $\theta = 0.1$, the plot says that for dimensionalities below the bottom curve, ϵ-neighborhoods contain on the average 10% of the points (one hundred points for $n = 10{,}000$). Note that analogous predictions can be obtained in a very similar way for any other combination of the parameters ϱ, θ, and ϵ, and distribution function F.

Figure 4 also report the values of the critical dimensionality estimated empirically (dashed lines). The plots highlight that the predicted critical dimensionality tends to the

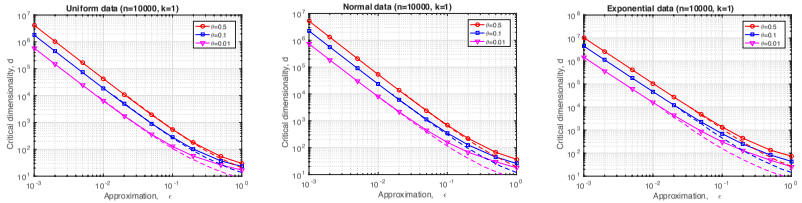

Figure 4: [Best viewed in color.] Critical dimensionality for $\epsilon \in [10^3, 10^0]$, $n = 10{,}000$, $k = 1$, and $\theta = 0.01$ (red solid line), $\theta = 0.1$ (blue solid line), and $\theta = 0.5$ (magenta solid line), predicted by exploiting Th. 25. The dashed curves represent the values of the critical dimensionality estimated empirically.

empirical one for decreasing ϵ and that the rate of convergence is directly proportional to θ. Interestingly, it can be seen that in different cases, the reported critical dimensionality is quite high (e.g., consider $\epsilon = 0.01$). Because approximate nearest neighbors must be associated with small values of θ (e.g., consider $\theta = 0.01$) to be considered meaningful, it can be concluded that the notion of approximate nearest neighbor can be considered meaningful even in high-dimensional spaces provided that the approximation factor ϵ is sufficiently small.

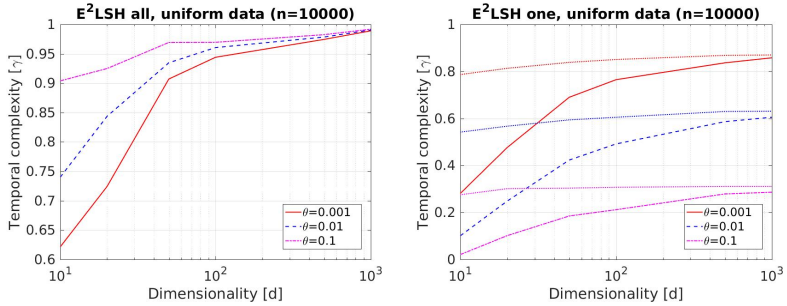
Unfortunately, this does not imply that algorithms perform efficiently in these cases. To illustrate, the researchers have proposed different algorithms for (approximate) nearest neighbor search problems. Most of these algorithms are randomized; that is, they are associated with a failure probability δ. Specifically, the *approximate near(est) neighbor search problem with failure probability* δ is defined as the problem to construct a data structure over a set of points $S \subseteq \mathbb{R}^d$ such that, given any query point $x \in \mathbb{R}^d$, with probability $1 - \delta$ reports:

P1. some $y \in S$ with $\mathrm{dist}(x, y) \leq (1 + \epsilon)r$ (*ϵ-approximate r-near neighbor*);

P2. some $y \in S$ with $\mathrm{dist}(x, y) \leq (1+\epsilon)\cdot\mathrm{dist}(x, nn(x, S))$ (*ϵ-approximate nearest neighbor*);

P3. each point $y \in S$ with $\mathrm{dist}(x, y) \leq r$ (*r-near neighbor reporting*).

The proposed algorithms offer trade-offs between the approximation factor, the space and the query time (Andoni, 2009). From the practical perspective, the space used by an algorithm should be as close to linear as possible. In this case, the best-existing solutions are based on locality-sensitive hashing (LSH) (Indyk and Motwani, 1998; Har-Peled et al., 2012). The idea of the LSH approach is to hash the points in a way that the probability of collision is much higher for points that are close (with the distance r) to each other than for those that are far apart (with distance at least $(1 + \epsilon)r$). Under different assumptions involving the parameters employed (Har-Peled et al., 2012), the LSH algorithm solves the ϵ-approximate r-near neighbor problem using $O(n^{1+\rho_\epsilon})$ extra space, $O(dn^{\rho_\epsilon})$ query time,



(a) (b)

Figure 5: Temporal complexity of the E^{2}LSH algorithm on uniform data for different selectivity values, namely $\theta = 0.1$ (red solid line), $\theta = 0.01$ (blue dashed line), and $\theta = 0.001$ (magenta dash-dotted line), and dimensions $d \in [10, 10^3]$, estimated by using $n = 10{,}000$ data points and $m = n$ query points. The plot on the left concerns the cost of reporting all the neighbors. The plot on the right concerns the cost of reporting just one neighbor. In the latter plot, dotted curves represent the complexity of sampling until a neighbor is retrieved.

and failure probability $\delta = 1/e+1/3$.[3] As for the value of the exponent ρ_ϵ, for the Euclidean distance, it is possible to achieve $\rho_\epsilon = 1/(1+\epsilon)^2 + o_\epsilon(1)$ (Andoni and Indyk, 2006), and it is known this bound is tight.

For example, consider that if $\epsilon = 0.01$, then $\rho_\epsilon = 0.980$. Because meaningfulness in intrinsically high-dimensional spaces requires smaller and smaller ϵ values, this means that, if we wish to maintain a pre-defined level of selectivity θ, we expect that the efficiency of LSH-based schemes will diminish with the intrinsic dimensionality of the space.

To empirically illustrate the relationship among selectivity θ, the intrinsic dimensionality d, and the temporal complexity γ of the search algorithm,[4] we analyzed the performances of the E^{2}LSH method as a function of the expected size θ of the r-neighborhood. The E^{2}LSH package solves the randomized r-near neighbor reporting problem exploiting the basic LSH scheme.[5] After preprocessing the data set, E^{2}LSH answers queries, typically in

3. The failure probability δ can be made arbitrarily small, say $\delta < 1/n$, by running $O(\log(n+m))$ copies of the basic LSH algorithm for *P1*, where n and m denote an upper bound on the number of points in the data structure and on the number of queries performed at any time. Moreover, *P2* can be solved by using as building blocks $O(\log n)$ copies of an algorithm for *P1*, achieving failure probability $O(\delta \log n)$ (Har-Peled et al., 2012). A similar strategy allows solving the nearest neighbor reporting problem (*P3*) by building on different data structures for *P1* associated with increasing values of r (Andoni and Indyk, 2008).
4. The *temporal complexity* is defined as the exponent $\gamma \geq 0$ such that the total number of distances D computed by the algorithm in order to report its answer is such that $D = n^\gamma$.
5. The E^{2}LSH package is available for download at `http://www.mit.edu/~andoni/LSH/`.

sub-linear time, with each near neighbor being reported with a certain probability $1 - \delta$ ($= 0.9$ by default). As for the values of the other parameters employed, we used the values determined automatically by the algorithm.

Figure 5 reports the results of the experiments on a family of uniformly distributed data sets composed of $n = 10{,}000$ points with $d \in [10, 10^3]$. We used $m = n$ different query points generated from the same distribution. We also varied the selectivity θ in $\{0.001, 0.01, 0.1\}$ by determining the radius r such that the expected fraction of r-near neighbors of the query points is θ. In Figure 5a, it can be seen that the complexity of the procedure increases with θ, and this can be explained by noting that the total number of points to be reported is directly proportional to θ. However, even if θ is held fixed, in all cases, the complexity of the algorithm for large d values tends to a linear scan of the data or to the cost γ_s of a random sampling procedure.[6] In Figure 5b, the algorithm has been enforced to report at most one near neighbor; hence, it stops the search as soon as it retrieves a near neighbor. It can now be seen that the complexity of the procedure decreases with θ, and this can be explained by noting that the probability of retrieving a neighbor is directly proportional to θ. The dotted curves represent the complexity γ_s of the procedure consisting in randomly selecting points until a r-near neighbor is retrieved. Additionally, in this case, it can be observed that the complexity degrades towards that of the random sampling procedure irrespectively of the selectivity value θ.[7]

The above analysis provides a picture of how much better an approximate search algorithm can perform than the pure random search, as a function of the selectivity and of the intrinsic dimensionality. Although the target neighborhood can be guaranteed to contain not too many points even in very large dimensional spaces, the best search algorithms may fail to perform better than random sampling. This can be explained by the poor separation of distances with the objects that are outside the approximate neighborhood.

In this regard, although the critical dimensionality is a construct with which to attempt to quantify the meaningless of a certain query, the relative contrast C_r (He et al., 2012) is a way to attempt to quantify its difficulty. Given a query point $\boldsymbol{x}_d$, the relative contrast is a measure of separability of the nearest neighbor of $\boldsymbol{x}_d$ from the rest of the data set points.

Definition 26 (Adapted from He et al., 2012) *Let DS be a data set consisting of n realizations of a random vector $\boldsymbol{Y}_d$. The relative contrast for the data set DS for a query $\boldsymbol{x}_d$, being the realization of a random vector $\boldsymbol{X}_d$, is defined as $C_r^k(\boldsymbol{x}_d) = \frac{\mathbf{E}[\mathrm{dist}(\boldsymbol{x}_d, DS)]}{\mathbf{E}[\mathrm{distnn}_k(\boldsymbol{x}_d, DS)]}$. Taking expectations with respect to queries, the relative contrast for the data set DS is*

$$C_r^k = \frac{\mathbf{E}[\mathrm{dist}(\boldsymbol{X}_d, DS)]}{\mathbf{E}[\mathrm{distnn}_k(\boldsymbol{X}_d, DS)]}.$$

He et al. (2012) provided an estimate of the relative contrast for a data set valid for independent dimensions and, moreover, provided bounds on the cost of LSH-based nearest neighbor search algorithms taking into account the relative contrast. They also noted that

6. Indeed, the expected number n^{γ_s} of points to be randomly picked in order to retrieve the $1-\delta$ fraction of the $n\theta$ data points that are r-near neighbors of the query point is $n^{\gamma_s} = n(1-\delta)$ and $\gamma_s = 1 + \log(1-\delta)/\log(n)$. E.g., for $1 - \delta = 0.9$, $\gamma_s = 0.9886$.
7. Note that, for a query having selectivity θ, the expected number of points to be randomly picked in order to retrieve exactly one r-near neighbor is $n^{\gamma_s} = 1/\theta$ and, hence, $\gamma_s = -\log(\theta)/\log(n)$.

the analysis of Beyer et al. (1999) and François et al. (2007) agree with the asymptotic behavior of the relative contrast. We refer to (He et al., 2012) for the details.

Here, we show that by exploiting the previous results, we can derive an approximation for the relative contrast C_r^k of a data set that results to be more accurate than the estimate provided by He et al. (2012). In addition, we can derive a closed form for the relative contrast $C_r^k(\boldsymbol{x}_d)$ of an individual query point.

Theorem 27 *Let $\boldsymbol{X}_d$ be a d-dimensional i.i.d. random vector with cdf F_X and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y. Assume, w.l.o.g., that F_Y has null mean $\mu_Y = 0$. Then, for large values of d,*

$$C_r^k \approx \sqrt{\frac{\sqrt{d}(\mu_{Y,2} + \mu_{X,2})}{\sqrt{d}(\mu_{Y,2} + \mu_{X,2}) + \Phi^{-1}\left(\frac{k}{n}\right)\sqrt{\mu_{Y,4} - \mu_{Y,2}^2 + 4\mu_{Y,2}\mu_{X,2} - 4\mu_{Y,3}\mu_X}}}.$$

Proof of Theorem 27. Consider the expected value of the squared distance separating a query point $\boldsymbol{X}_d$ from $nn_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)$ (leveraging Proposition 8 and Lemma 23):

$$\begin{aligned}
&\mathbf{E}[\|\boldsymbol{X}_d - nn_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)\|^2] = \mathbf{E}[\mathrm{distnn}_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)^2] = \mathbf{E}[\mathrm{dist}(\boldsymbol{X}_d, nn_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d))^2] = \\
&\qquad = \int_{\mathbb{R}^d} Pr[\boldsymbol{X}_d = \boldsymbol{x}_d] \cdot \mathrm{dist}(\boldsymbol{x}_d, nn_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d))^2 \, \mathrm{d}\boldsymbol{x}_d = \\
&\qquad = \int_0^{+\infty} \phi_{\|\boldsymbol{X}_d\|^2}(R) \cdot \left(\mu_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2} + \Phi^{-1}(\varrho)\, \sigma_{\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2}\right)\Big|_{\|\boldsymbol{x}_d\|^2 = R} \mathrm{d}R = \\
&= \int_0^{+\infty} \phi_{\|\boldsymbol{X}_d\|^2}(R) \cdot \left(R + d\mu_{Y,2} + \Phi^{-1}(\varrho)\sqrt{d(\mu_{Y,4} - \mu_{Y,2}^2) + 4\mu_{Y,2}R - 4\mu_{Y,3}\frac{\mu_X}{\mu_{X,2}}R}\right) \mathrm{d}R.
\end{aligned}$$

After approximating the R under the square root with the expected value $\mu_{\|\boldsymbol{X}_d\|^2} = d\mu_{X,2}$ of $\boldsymbol{X}_d$:

$$\begin{aligned}
&\mathbf{E}[\mathrm{dist}(\boldsymbol{X}_d, nn_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d))^2] = \int_0^{+\infty} R \cdot \phi_{\|\boldsymbol{X}_d\|^2}(R)\, \mathrm{d}R + \\
&+ \left(d\mu_{Y,2} + \Phi^{-1}(\varrho)\sqrt{d(\mu_{Y,4} - \mu_{Y,2}^2) + 4d\mu_{Y,2}\mu_{X,2} - 4d\mu_{Y,3}\mu_X}\right) \cdot \int_0^{+\infty} \phi_{\|\boldsymbol{X}_d\|^2}(R)\, \mathrm{d}R = \\
&\qquad = d(\mu_{X,2} + \mu_{Y,2}) + \Phi^{-1}(\varrho)\sqrt{d(\mu_{Y,4} - \mu_{Y,2}^2 + 4\mu_{X,2}\mu_{Y,2} - 4\mu_{Y,3}\mu_X)}.
\end{aligned}$$

Indeed, the left hand integral above corresponds to the expected value $\mu_{\|\boldsymbol{X}_d\|^2} = d\mu_{X,2}$ of of the random variable $\|\boldsymbol{X}_d\|^2$, whereas the right hand integral evaluates to one.

According to the Jensen inequality (Johnson et al., 1994), if g is a concave function, then $\mathbf{E}[g(X)] \leq g(\mathbf{E}[X])$; moreover, the larger the relative variance σ_X/μ_X of X, the closer the two above values, i.e., $\mathbf{E}[g(X)] \approx g(\mathbf{E}[X])$. Specifically, $\mathbf{E}[\|\boldsymbol{X}_d\|] = \mathbf{E}[\sqrt{\sum_i X_i^2}] \leq \sqrt{\mathbf{E}[\sum_i X_i^2]} = \sqrt{\mathbf{E}[\|\boldsymbol{X}_d\|^2]}$ and, because $\sigma_{\|\boldsymbol{X}_d\|^2}/\mu_{\|\boldsymbol{X}_d\|^2} = O(d^{-1/2})$, for large values of d, $\mathbf{E}[\mathrm{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d)] \approx \sqrt{\mathbf{E}[\mathrm{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d)^2]}$, and $\mathbf{E}[\mathrm{distnn}_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)] \approx \sqrt{\mathbf{E}[\mathrm{distnn}_\varrho(\boldsymbol{X}_d, \boldsymbol{Y}_d)^2]}$. ■

We can also provide the relative contrast $C_r^k(\boldsymbol{x}_d)$ of an individual query point $\boldsymbol{x}_d$.

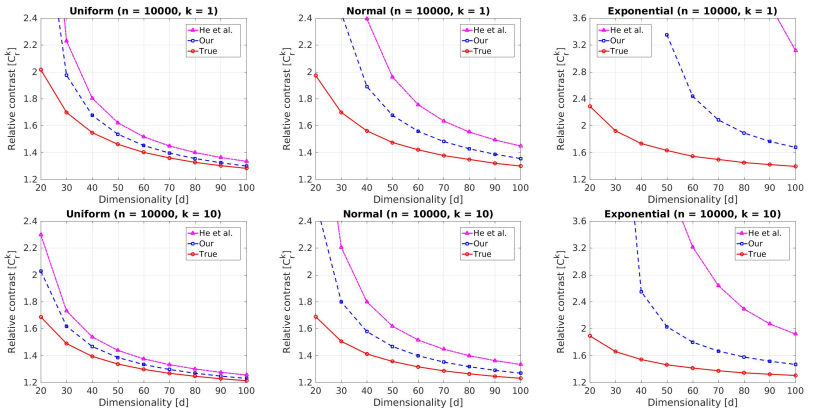


Figure 6: [Best viewed in color.] Comparison between the estimate of the relative contrast C_r provided in Theorem 27 (blue dashed line) and the estimate provided by He et al. (2012) (magenta dash-dotted line). The red solid line represents the value of the relative contrast estimated empirically.

Corollary 28 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector, and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y. Then, for large values of d, with high probability*

$$C_r^k(\boldsymbol{x}_d) \approx \sqrt{\frac{\|\boldsymbol{x}_d\|^2 + d\mu_2 - 2\mu\sum_{i=1}^d x_i}{\|\boldsymbol{x}_d\|^2 + d\mu_2 - 2\mu\sum_{i=1}^d x_i + \Phi^{-1}\left(\frac{k}{n}\right)\sqrt{d(\mu_4 - \mu_2^2) + 4\mu_2\|\boldsymbol{x}_d\|^2 - 4(\mu_3 - \mu\mu_2)\sum_{i=1}^d x_i}}}.$$

Proof of Corollary 28. Following the same line of reasoning of Theorem 27, $C_r^k(\boldsymbol{x}_d) \approx \sqrt{\frac{\mathbf{E}[\mathrm{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d)^2]}{\mathbf{E}[\mathrm{distnn}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)^2]}}$, and the statement follows by leveraging Theorem 15 and Lemma 23. ■

Figure 6 compares the approximation of the relative contrast provided in Theorem 27 to the approximation provided by He et al. (2012). In all the cases, the approximation of Theorem 27 is the more accurate. This can be understood by noting that He et al. (2012) estimated the relative contrast by considering the differences $X_i - Y_i$ between the components of a query point $\boldsymbol{X}_d$ and of a data point $\boldsymbol{Y}_d$ as novel random variables, and then by determining their expectations and standard deviations. This corresponds to ignoring the form of the distribution of distances from each individual query point and all the data points, a relationship that is conversely taken into account in Theorem 27, due to the leveraging of Theorem 16, Proposition 8, and Lemma 23.

4.3 On the Distribution of Reverse Nearest Neighbors for i.i.d. Data

Given a real number $\varrho \in [0,1]$, a d-dimensional random vector $\boldsymbol{Y}_d$, and a realization $\boldsymbol{x}_d$ of $\boldsymbol{Y}_d$, it is said that a realization $\boldsymbol{y}_d$ of $\boldsymbol{Y}_d$ is a *ϱ reverse nearest neighbor* of $\boldsymbol{x}_d$ w.r.t. $\boldsymbol{Y}_d$ if $\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{y}_d, \boldsymbol{Y}_d)$.

The size $\mathrm{N}_\varrho(\boldsymbol{x}_d, \boldsymbol{Y}_d)$, or $\mathrm{N}_\varrho(\boldsymbol{x}_d)$ whenever $\boldsymbol{Y}_d$ is clear from the context, of the *ϱ reverse nearest neighborhood* of $\boldsymbol{x}_d$ w.r.t. $\boldsymbol{Y}_d$, also called *reverse ϱ nearest neighbor count* or *ϱ-occurrences*, is the fraction of realizations $\boldsymbol{y}_d$ of $\boldsymbol{Y}_d$ such that $\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{y}_d, \boldsymbol{Y}_d)$.

As in the previous sections, in order to deal with finite sets of n points $\{\boldsymbol{Y}_d\}_n$, the integer parameter $k = \varrho n$ ($k \in \{1, \ldots, n\}$) must be employed in place of ϱ. In such a case, we speak of *k reverse nearest neighborhood*, *reverse k nearest neighbor count*, or *k-occurrences*.

Before going into the main results, the following expression provides the probability that a realization, having norm value R, of a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$ lies at distance not greater than δ from a given d-dimensional vector $\boldsymbol{x}_d$.

Lemma 29 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ with cdf F_X, and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y. Assume, w.l.o.g., that F_Y has null mean $\mu_Y = 0$. Then, for large values of d, with high probability*

$$Pr\left[\mathrm{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \delta \mid \|\boldsymbol{Y}_d\| = R\right] \approx \Phi\left(\frac{\delta^2 - R^2 - \|\boldsymbol{x}_d\|^2}{2\|\boldsymbol{x}_d\|\sqrt{\mu_2}}\right),$$

where moments are relative to the constrained random vector $\boldsymbol{Y}_d$.

Proof of Lemma 29. See the appendix. ∎

The noteworthiness of the above expression lies in the fact that, by combining it with Proposition 8, it is possible in some cases to replace multi-dimensional integrations involving the full event space $\mathbb{R}^d$ with one-dimensional integrations over the domain $\mathbb{R}_0^+$ of the squared-norm values. Specifically, it is essential to the proof of the following result.

Theorem 30 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{Y}_d$, with cdf F_Y having, w.l.o.g., null mean $\mu = 0$. Consider the reverse k nearest neighbor count $N_\varrho(\boldsymbol{x}_d)$ of $\boldsymbol{x}_d$ w.r.t. $\boldsymbol{Y}_d$. Then, for large values of d, with high probability*

$$\mathrm{N}_\varrho(\boldsymbol{x}_d) \approx \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2} - z_{\boldsymbol{x}_d}\sqrt{\mu_4 - \mu_2^2}}{2\mu_2}\right).$$

Proof of Theorem 30. First of all, note that $\mathrm{N}_\varrho(\boldsymbol{x}_d) = Pr[\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{Y}_d)]$. Consider the probability

$$\begin{aligned}
Pr[\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{Y}_d)] &= \int_{\mathbb{R}^d} Pr\left[\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{y}_d)\right] \cdot Pr[\boldsymbol{Y}_d = \boldsymbol{y}_d] \,\mathrm{d}\boldsymbol{y}_d = \\
&= \int_{\mathbb{R}^d} Pr\left[\mathrm{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) \leq \mathrm{dist}(\boldsymbol{y}_d, nn_\varrho(\boldsymbol{y}_d))\right] \cdot Pr[\boldsymbol{Y}_d = \boldsymbol{y}_d] \,\mathrm{d}\boldsymbol{y}_d = \\
&= \int_0^{+\infty} Pr\left[\mathrm{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \mathrm{dist}(\boldsymbol{Y}_d, nn_\varrho(\boldsymbol{Y}_d)) \mid \|\boldsymbol{Y}_d\|^2 = R\right] \cdot Pr\left[\|\boldsymbol{Y}_d\|^2 = R\right] \mathrm{d}R.
\end{aligned}$$

By Lemma 23 and Proposition 22, for $\|\boldsymbol{Y}_d\|^2 = R$,

$$\mathrm{dist}(\boldsymbol{Y}_d, nn_\varrho(\boldsymbol{Y}_d))^2 = R + d\mu_2 + \Phi^{-1}(\varrho)\sqrt{d(\mu_4 - \mu_2^2) + 4\mu_2 R},$$

while by Lemma 29,

$$\begin{aligned}
Pr\left[\mathrm{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \mathrm{dist}(\boldsymbol{Y}_d, nn_\varrho(\boldsymbol{Y}_d)) \mid \|\boldsymbol{Y}_d\|^2 = R\right] &\approx \\
&\approx \Phi\left(\frac{\mathrm{dist}(\boldsymbol{Y}_d, nn_\varrho(\boldsymbol{Y}_d))^2 - R - \|\boldsymbol{x}_d\|^2}{2\|\boldsymbol{x}_d\|\sqrt{\mu_2}}\right) = \\
&= \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{d(\mu_4 - \mu_2^2) + 4\mu_2 R} + d\mu_2 - \|\boldsymbol{x}_d\|^2}{2\|\boldsymbol{x}_d\|\sqrt{\mu_2}}\right),
\end{aligned}$$

from which it follows that

$$Pr[\boldsymbol{x}_d \in nn_\varrho(\boldsymbol{Y}_d)] \approx \int_0^{+\infty} \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{d(\mu_4 - \mu_2^2) + 4\mu_2 R} + d\mu_2 - \|\boldsymbol{x}_d\|^2}{2\|\boldsymbol{x}_d\|\sqrt{\mu_2}}\right) \phi_{\|\boldsymbol{Y}_d\|^2}(R) \,\mathrm{d}R,$$

where moments are relative to the constrained random vector $\boldsymbol{Y}_d$.

The proof proceeds by expressing $\|\boldsymbol{x}_d\|^2$ and R in terms of their standard scores with respect to the random variable $\|\boldsymbol{Y}_d\|^2$, i.e.,

$$\|\boldsymbol{x}_d\|^2 = \mu_{\|\boldsymbol{Y}_d\|^2} + z_{\boldsymbol{x}_d} \cdot \sigma_{\|\boldsymbol{Y}_d\|^2} \quad \text{and} \quad R = \mu_{\|\boldsymbol{Y}_d\|^2} + z_{R,\|\boldsymbol{Y}_d\|^2} \cdot \sigma_{\|\boldsymbol{Y}_d\|^2}.$$

By substituting in the left-hand side above, and by considering that for α and β being finite and d growing, $\sqrt{\alpha d} \approx \sqrt{\alpha d + \sqrt{\beta d}}$,

$$\begin{aligned}
&\Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{d(\mu_4 - \mu_2^2) + 4d\mu_2^2 + z_{R,\|\boldsymbol{Y}_d\|^2} 4\mu_2\sqrt{d(\mu_4 - \mu_2^2)}} + d\mu_2 - d\mu_2 - z_{\boldsymbol{x}_d}\sqrt{d(\mu_4 - \mu_2^2)}}{2\sqrt{\mu_2}\sqrt{d\mu_2 + z_{\boldsymbol{x}_d}\sqrt{d(\mu_4 - \mu_2^2)}}}\right) \approx \\
&\quad \approx \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{d(\mu_4 + 3\mu_2^2)} - z_{\boldsymbol{x}_d}\sqrt{d(\mu_4 - \mu_2^2)}}{2\mu_2\sqrt{d}}\right) = \\
&\quad = \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2} - z_{\boldsymbol{x}_d}\sqrt{\mu_4 - \mu_2^2}}{2\mu_2}\right) = C(z_{\boldsymbol{x}_d}, \varrho).
\end{aligned}$$

Since, for large values of d, moments tend to their unconstrained values (see proof of Lemma 29), the last expression depends on $z_{\boldsymbol{x}_d}$ and on ϱ, but not on R. Thus

$$Pr[\boldsymbol{x}_d \in \mathrm{NN}_\varrho(\boldsymbol{Y}_d)] \;\approx\; C(z_{\boldsymbol{x}_d}, \varrho) \int_0^{+\infty} \phi_{\|\boldsymbol{Y}_d\|^2}(R) \,\mathrm{d}R = C(z_{\boldsymbol{x}_d}, \varrho).$$

∎

As for the expression reported in the statement of Theorem 30, it does not explicitly depend on the dimensionality and on the exact position of the point $\boldsymbol{x}_d$ but only on the relative position of the squared norm of the point with respect to the expected value. Thus, the following definition naturally arises.

Definition 31 *Let z denote the standard score of the squared norm. Then, the infinite dimensional k-occurrences function $\mathrm{N}_\varrho^\infty : \mathbb{R} \mapsto [0,1]$, defined as*

$$\mathrm{N}_\varrho^\infty(z) \quad = \quad \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2} - z\sqrt{\mu_4 - \mu_2^2}}{2\mu_2}\right), \tag{3}$$

represents the fraction of points having a point with squared norm standard score z among their ϱ nearest neighbors.

An alternative expression can be provided by leveraging the *kurtosis* $\kappa = \frac{\mu_4}{\mu_2^2}$, a well known measure of tailedness of a probability distribution that is

$$\mathrm{N}_\varrho^\infty(z) \quad = \quad \Phi\left(\Phi^{-1}(\varrho)\frac{\sqrt{\kappa+3}}{2} - z\frac{\sqrt{\kappa-1}}{2}\right). \tag{4}$$

In particular, it holds from the development of Theorem 30 that

$$\lim_{d\to\infty} Pr[\mathrm{N}_\varrho(\boldsymbol{X}_d) = \mathrm{N}_\varrho^\infty(z)] = \phi(z), \tag{5}$$

from which it can be seen that the point $z_0 \to -\infty$ is such that $\mathrm{N}_\varrho^\infty(z_0) \to 1$ and $\phi(z_0) \to 0$. This point precisely corresponds with the expected value of $\boldsymbol{X}_d$ (the origin of the space for variables with null mean) and is the point most likely to be selected as nearest neighbor by any other point. At the same time, it is the point least likely to be observed as a realization of $\boldsymbol{X}_d$ among those having norms smaller than the expected value.

As for the point $z_\infty \to \infty$, it is such that $\mathrm{N}_\varrho^\infty(z_\infty) \to 0$ and $\phi(z_\infty) \to 0$. Hence, it is the less likely to be observed as a realization of $\boldsymbol{X}_d$, but it is also the less likely to be selected as a nearest neighbor. This point is the furthest from the mean, and it is located on the boundary of a bounded region or ad infinitum.

Figure 7 shows the curves of $\mathrm{N}_\varrho^\infty$ (red lines) for i.i.d. data coming from different distributions, together with the empirical N_k/n values (black dots), with $k = \varrho n$, in a random sample of $n = 10{,}000$ points. Theoretical $\mathrm{N}_\varrho^\infty$ curves represent the picture of what happens ad infinitum, because they provide the values to which the k-occurrences counts converge for large dimensions. We observed that in most cases, the convergence arises very soon, often a few tens of dimensions suffice. Indeed, empirical values tend to distribute along the associated curves. While the first two distributions have null skewness, the same behavior is exhibited by the third one, which instead has non-null skewness, even if, in this case, convergence appears to be slower. In any case, it appears that the value of k-occurrences predicted by means of the function $\mathrm{N}_\varrho^\infty$ usually is in good agreement with the empirical evidence, even for the smallest dimension considered in the figure. For similar plots on real data sets, we refer to Figures 10, 11, and 12, reported in the following.

It is now of interest to obtain the cdf and pdf of $\mathrm{N}_\varrho(\boldsymbol{X}_d)$ for large values, together with the associated variance and expected value.

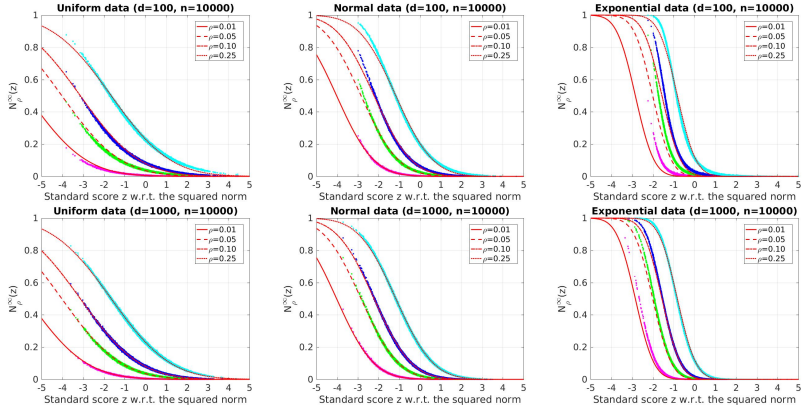

Figure 7: [Best viewed in color.] Comparison between the empirical values of the relative number of k-occurrences (N_k/n), estimated in a random sample of $n = 10{,}000$ points with $d \in \{100, 1{,}000\}$, and the values predicted by means of the function $\mathrm{N}_\varrho^\infty$ (red curves), for $\varrho = 0.01$ (magenta dots and solid red line), $\varrho = 0.01$ (green dots and dashed red line), $\varrho = 0.01$ (blue dots and dash-dotted red line), and $\varrho = 0.01$ (cyan dots and dotted red line).

Theorem 32

$$(i) \quad \lim_{d\to\infty} Pr[\mathrm{N}_\varrho(\boldsymbol{X}_d) \le \theta] = \Phi\left(\frac{\Phi^{-1}(\theta)2\mu_2 - \Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}}\right),$$

$$(ii) \quad \lim_{d\to\infty} Pr[\mathrm{N}_\varrho(\boldsymbol{X}_d) = \theta] = \frac{2\mu_2}{\sqrt{\mu_4 - \mu_2^2}} \cdot \frac{1}{\phi(\Phi^{-1}(\theta))} \cdot \phi\left(\frac{\Phi^{-1}(\theta)2\mu_2 - \Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}}\right),$$

$$(iii) \quad \lim_{d\to\infty} \sigma^2(\mathrm{N}_\varrho(\boldsymbol{X}_d)) = \varrho(1-\varrho) - 2T\left(\Phi^{-1}(\varrho), \frac{2\mu_2}{\sqrt{2(\mu_4 + \mu_2^2)}}\right), \text{ and}$$

$$(iv) \quad \lim_{d\to\infty} \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)] = \varrho,$$

where $T(h,a) = \phi(h)\int_0^a \frac{\phi(hx)}{1+x^2}\,\mathrm{d}x$ *is the Owen's T function.*

Proof of Theorem 32. See the appendix. ■

Figure 8 shows the cdfs and the pdfs of the limiting distributions of the k-occurrences for uniform, normal, and exponential distributions. As expected, the probability of observing large values of N_ϱ increases with ϱ. Moreover, it can be observed from the pdf functions that for the exponential distribution, the probability of observing $\mathrm{N}_\varrho \approx 1$ is not negligible

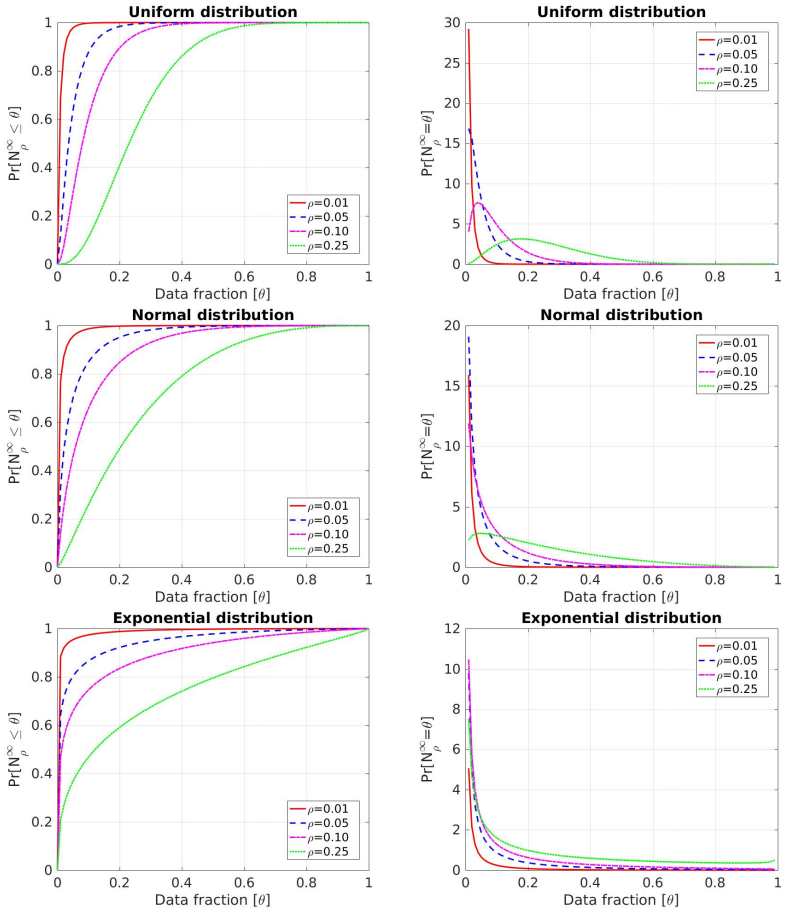

Figure 8: [Best viewed in color.] Cumulative distribution function (left column) and probability density function (right column) of the limiting distribution of the number of k-occurrences for i.i.d. random vectors (see Th. 32) according to different families of distributions, for $\varrho = 0.01$ (red solid line), $\varrho = 0.05$ (blue dashed line), $\varrho = 0.10$ (magenta dash-dotted line), and $\varrho = 0.25$ (green dotted line).

even for moderately large values of ϱ. This behavior can be better understood by looking at Figure 7, where theoretical curves of the exponential are approaching 1 earlier.

Corollary 33 *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two d-dimensional i.i.d. random vectors with common cdf F_Y having, w.l.o.g., null mean $\mu_Y = 0$. Then, for large values of d,*

$$Pr[\mathrm{N}_k(\boldsymbol{X}_d, \{\boldsymbol{Y}_d\}_n) \leq h] \approx \Phi\left(\frac{\Phi^{-1}(\frac{h}{n})2\mu_2 - \Phi^{-1}(\frac{k}{n})\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}}\right).$$

Proof of Corollary 33. The statement follows immediately from Theorem 32. ■

In order to compare the solution here derived to the large dimensional limits of the function $\mathrm{N}_k^{n,d}$ provided by Newman et al. (1983), the same limits are derived next.

Corollary 34 *Let k be a fixed positive integer. Then*

$$(i)\ \lim_{n\to\infty}\lim_{d\to\infty} \mathrm{N}_k^{n,d} \xrightarrow{D} 0,\quad (ii)\ \lim_{n\to\infty}\lim_{d\to\infty} \sigma^2(\mathrm{N}_k^{n,d}) = \infty,\ \textit{and}\ (iii)\ \lim_{n\to\infty}\lim_{d\to\infty} \mathbf{E}[\mathrm{N}_k^{n,d}] = k.$$

Proof of Corollary 34. See the appendix. ■

Results provided by Newman et al. (1983), correspond to points (i) and (ii) above for the case $k = 1$. The point (iii) is reported only as a check, because k is expected by definition of the k-occurrences.

The interpretation of the above result provided by Tversky et al. (1983), which is typically how it is reported in the related literature, is that if the number of dimensions is large relative to the number of points, one may expect to have a large proportion of points with reverse nearest neighbor counts equaling 0, and a small proportion of points with high count values. However, according to the previous findings, the convergence in distribution to zero does not have to be motivated by the excess of the dimensions with respect to the sample size, but rather by the use of a fixed-size neighborhood parameter k in the presence of large samples. As a matter of fact, the curves reported in Figure 8 tend to the zero distribution only for $\varrho = k/n \to 0$. Moreover, large counts can also be achieved in the case of small samples and large dimensionalities, as shown in Figures 7 and 8. E.g., from Equation (5), the expected number of points such that $z \leq -1$ ($z \leq -2$, resp.) is about the 15.9% (2.3%, resp.) for any sample size n. All of this suggests that hubness is definitely not an artifact of a finite sample.

4.4 The Distribution of Independent Non-Identically Distributed Data

Previous results can be extended to independent non-identically distributed random vectors. With this aim, we consider the following proposition.

Given a sequence $W_1, W_2, \ldots, W_d$ of independent non-identically distributed random variables having non-null variances [8] and finite central moments $\hat{\mu}_{i,k}$ up to the eighth mo-

8. Clearly, variables having constant domain, hence null variance, can be disregarded because they do not alter distances.

ment, we say that the sequence has *comparable* central moments if there exist positive constants $\hat{\mu}_{\max} \geq \max_{i,k}\{|\hat{\mu}_{i,k}|\}$ and $\hat{\mu}_{\min} \leq \min_i\{|\hat{\mu}_{i,k}| : \hat{\mu}_{i,k} \neq 0\}$. Intuitively, this guarantees that the ratio between the greatest and the smallest non-null moment remains limited.[9]

Proposition 35 *Let $U_d = \sum_{i=1}^{d} W_i$ be a random variable defined as the summation of a sequence of independent, but not identically distributed, random variables W_i having comparable central moments. Then*

$$U_d \simeq \mathcal{N}\left(\sum_{i=1}^{d}\mu_{W_i},\ \sum_{i=1}^{d}\sigma^2_{W_i}\right) = \mathcal{N}\left(d\cdot\overline{\mu}_W,\ d\cdot\overline{\sigma^2}_W\right),$$

where $\overline{\mu}_W = (1/d)\sum_{i=1}^{d}\mu_{W_i}$ and $\overline{\sigma^2}_W = (1/d)\sum_{i=1}^{d}\sigma^2_{W_i}$.

Proof of Proposition 35. See the appendix. ■

François et al. (2007, cf. Proposition 2) affirmed that Theorem 3 holds for independent non-identically distributed variables provided that they are normalized. Authors justify this result by noting that norms will concentrate because normalization prevents variables from having too little effect on the distance values. According to this interpretation, normalization is essential for having comparable variances. (Recall that the variance is the second order central moment.)

Definition 36 *Let $\boldsymbol{Y}_d = (Y_1, Y_2, \ldots, Y_d)$ be an independent non-identically distributed d-dimensional random vector with cdfs $\boldsymbol{F}_Y = (F_{Y_1}, F_{Y_2}, \ldots, F_{Y_d})$ having k-th moments $\boldsymbol{\mu_k} = (\mu_{Y_{1,k}}, \mu_{Y_{2,k}}, \ldots, \mu_{Y_{d,k}}) = (\mu_{1,k}, \mu_{2,k}, \ldots, \mu_{d,k})$. Moreover, given a positive integer $h, k \geq 1$, let $\tilde{\boldsymbol{\mu}}^{\boldsymbol{h}}_{\boldsymbol{k}}$ denote the average h-th degree of the k-th central moments of $\boldsymbol{Y}_d$, also referred to as average central moment for simplicity, defined as*

$$\tilde{\boldsymbol{\mu}}^{\boldsymbol{h}}_{\boldsymbol{k}} = \frac{1}{d}\sum_{i=1}^{d}\hat{\mu}^h_{i,k} = \frac{1}{d}\sum_{i=1}^{d}\mathbf{E}[(Y_i - \mu_{Y_i})^k]^h,$$

where $\hat{\mu}_{i,k}$ denotes the k-th central moment of Y_i.

Because considering random variables having null means simplifies expressions, for the sake of simplicity, we next consider the case of independent non-identically distributed random vectors having common cdfs, but we note that a similar result also holds in the more general case $\boldsymbol{F_X} \neq \boldsymbol{F_Y}$.

Theorem 37 *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two independent non-identically distributed d-dimensional random vectors with common cdfs $\boldsymbol{F}$ having means $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_d)$, non null variances, and comparable central moments, and let $\boldsymbol{x}_d$ denote a realization of $\boldsymbol{X}_d$. The results of Sections 4.1, 4.2 and 4.3 can be applied to $\boldsymbol{X}_d$, $\boldsymbol{Y}_d$, and $\boldsymbol{x}_d$ by taking into account the average central moments of $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ and the realization $\boldsymbol{x}_d - \boldsymbol{\mu}$.*

Proof of Theorem 37. See the appendix for details. ■

To illustrate the above results, real data sets having dimensionality varying at some order of magnitude are considered. The data sets are briefly described next. The *Statlog* (Landsat Satellite) data set[10] consists of multi-spectral values of pixels in 3×3 neighborhoods in a satellite image ($d = 36$, $n = 6{,}435$). The SIFT data set[11] consists of the base vectors of the `ANN_SIFT10` evaluation set used to evaluate the quality of approximate nearest neighbors search algorithms and consists of SIFT image descriptors ($d = 128$, $n = 10{,}000$). The MNIST data set[12] consists of handwritten digits which have been size-normalized and centered in a 28×28 image. The test examples have been employed ($d = 784$, $n = 10{,}000$). The *Sports* data set[13] consists of time series representing sensor measurements associated with activities performed by eight subjects for 5 minutes ($d = 5{,}625$, $n = 9{,}120$). The *NIPS* textual data set[14] consists of counts associated with words appearing in 5,812 NIPS conference papers published between 1987 and 2015 ($d = 11{,}463$, $n = 5{,}812$). The *RNA-Seq* data set[15] consists of gene expressions levels, measured by a illumina HiSeq sequencing platform, of patients having different types of tumors ($d = 20{,}531$, $n = 801$).

In the following, we also consider the *shuffled* version of the original data set. Specifically, the shuffled version of a given data set is obtained by randomly permuting the elements within every attribute. As already noted by François et al. (2007), the shuffled data set is marginally distributed as the original one, but because all the relationships between variables are destroyed, its components are independent, and its intrinsic dimension is equal to its embedding dimension.

Figure 9 reports the empirical cdf of the squared distance (solid line) associated with each data set, together with the theoretical cdf (dashed line) associated with independent but not identically data having the same average central moments of the original data, as reported in Theorem 37. The latter curve has been obtained by using the average central moments of the data according to Theorem 37. The empirical cdf of the shuffled data is also reported (dotted line).

From the linearity of the expected value, for any pair of d-dimensional random vectors, it follows that

$$\mathbf{E}[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2] = d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{X},\boldsymbol{2}} + \tilde{\boldsymbol{\mu}}_{\boldsymbol{Y},\boldsymbol{2}}) \quad \text{and} \quad \mathbf{E}[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2] = \|\boldsymbol{x}_d - \boldsymbol{\mu}_{\boldsymbol{Y}}\|^2 + d\tilde{\boldsymbol{\mu}}_{\boldsymbol{Y},\boldsymbol{2}},$$

where the equality holds also for dependent and non-identically distributed random vectors. Hence, the expected value of the pairwise distances between data set points is identical to

9. This definition fits the Lyapunov condition. In general, given a sequence $W_1, W_2, \ldots, W_d$ of independent non-identically distributed random variables having non-null finite variances, then their standardized sum converges in distribution to a standard normal random variable if and only if the Feller-Lindeberg condition holds (Feller, 1971). According to this condition, the variance $\sigma(W_i)$ of any individual term never dominates their sum s_d; hence, $\lim_{d\to\infty}\max_{i=1}^{d}\sigma^2_i(W_i)/s^2_d = 0$. Because this both necessary and sufficient for the CLT to hold, the Feller-Lindeberg condition implies the Lyapunov condition.

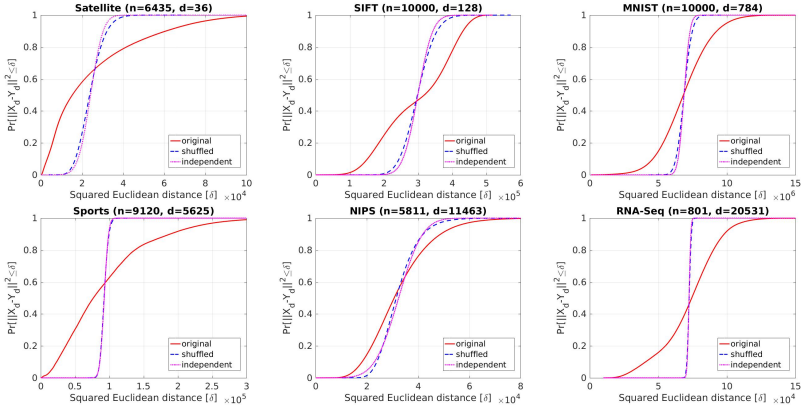

Figure 9: [Best viewed in color.] Pairwise distance distributions for real data sets, including the original data (red solid line), the shuffled data (blue dashed line), and the equivalent independent data (magenta dotted line). The last curve corresponds to the theoretical cdf associated with independent but not identically data having the same average central moments of the original data, as reported in Theorem 37.

the expected value of the theoretical distribution derived under the i.i.d. hypothesis, and also to that of the shuffled data.

The difference between the curves of the original and of the independent data suggests that the intrinsic dimensionality of the data at hand is smaller than that of the embedding space, because dependencies evidently exist between the attributes. Moreover, it can be seen that the empirical cdf of the shuffled data is very similar to that of the theoretical cdf.

These result confirm the correctness of Theorem 37, whose prediction agrees with the empirical observation on real independent data. Moreover, its approximation is accurate even in moderately large spaces, because the correspondence is good even for the smallest data set considered ($d = 36$). Moreover, these experiments testify to the meaningfulness of the analysis here accomplished as a worst-case analysis scenario, corresponding to the case in which relationships between variables are absent.

In order to verify if the data sets satisfy the requirements for the CLT to be applied, the value of the finite Lyapunov CLT condition (see Equation 1, for $\delta = 2$) has been determined on the data at hand (with the variable W_i taking value over all the terms $(x_{j,i} - x_{k,i})^2$ that can be formed with distinct pairs of data set points x_j and x_k, $1 \leq j < k \leq n$). Table 1 reports the value of the above condition (indicated as LC) together with the Relative Variance (RV) of the norm of data set points, for both the original data set (note that the shuffled data presents the same LC value as the original one) and its normalized version (obtained by substituting each attribute X_i with $(X_i - \mu_i)/\sigma_i$):

Data set	Original		Normalized	
	LC	RV	LC	RV
Satellite	0.012675	0.463934	0.014629	0.427250
SIFT	0.003382	0.063242	0.049320	0.090368
MNIST	0.000403	0.133234	25.163236	0.502937
Sports	0.072869	0.432149	0.546147	0.361839
NIPS	0.745970	0.257738	0.307322	0.241819
RNA-Seq	0.000412	0.131759	0.096444	0.175561

Table 1: Comparison between the values of the Lyapunov CLT Condition (LC) and the Relative Variance (RV) against those of the real data sets.

A small LC value (say, less than 1) indicates that the normal approximation is correct. This condition is met for all the configurations except for the normalized *MNIST* data set. Indeed, normalizing this data set is not meaningful, because attributes (corresponding to pixels) are already homogeneous (their domain consists of 256 gray levels encoded as byte values) and because the normalization has only the negative effect of exaggerating the range of variation of pixels whose domain is formed almost entirely of zeros. As a result, a few attributes dominate the distance, and this deteriorates convergence to normality. The relative variance has been reported for comparison, because it is a measure of the concentration of the data. (Note that the relative variance of the shuffled data is not coincident with that of the original one.)

Figure 10 reports the relative number of k-occurrences associated with data set points represented in terms of their squared norm standard score z. Different values for the parameter ϱ have been employed, Specifically, $\varrho \in \{0.01, 0.05, 0.10, 0.25\}$ (the color of points in the figure is magenta for $\varrho = 0.01$, green for $\varrho = 0.05$, blue for $\varrho = 0.10$ and cyan for $\varrho = 0.25$). The theoretical curves of $\mathrm{N}_\varrho^\infty(z)$, based on average central moments of the data, are also reported for comparison.

Interestingly, the real distributions of k-occurrences follow the trends of the theoretical curves; however, in contrast to the independent case, counts have much larger variability. The interpretation is that variability is associated with a lower intrinsic dimensionality and dependencies among variables, because independent data are much more widely distributed along the theoretical trend, as can be seen in Figure 7. Indeed, such behavior is also observed when considering the shuffled data set (see Figure 11). Moreover, in this case, the empirical evidence matches the behavior predicted by Theorem 37 for the independent case. In some cases, the trend appears to be different albeit generally analogous. It appears that the degree of agreement between the empirical evidence and the the theoretical prediction is directly proportional to the value of the LC condition reported in Table 1.

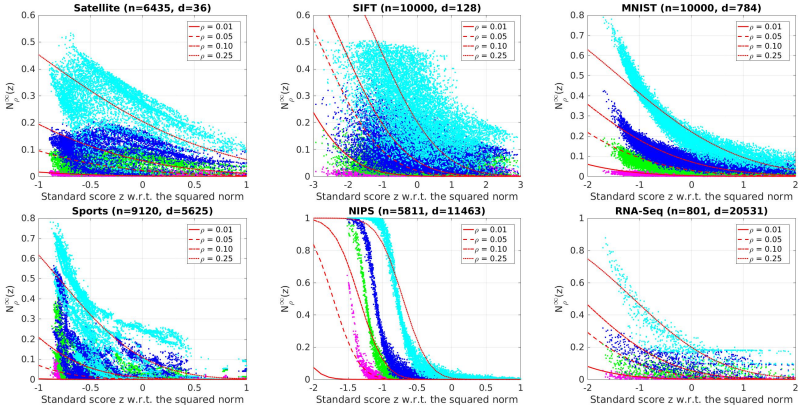

Figure 10: [Best viewed in color.] Relative number of k-occurrences associated with data set points, represented in terms of their squared norm standard score z (different colors), and the theoretical prediction according to the infinite dimensional k-occurrences function reported in Equation (4.3) (red lines), for the following values of $\varrho = k/n$: $\varrho_1 = 0.01$ (magenta-colored points and solid red line), $\varrho_2 = 0.05$ (green-colored points and dashed red line), $\varrho_3 = 0.10$ (blue-colored points and dash-dotted red line), and $\varrho_4 = 0.25$ (cyan-colored points and dotted red line).

4.5 Extension to Other Distances

In general, one may attempt to extend some of the properties discussed above to distances having the general form

$$\text{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) = h\left(\sum_{i=1}^{d} g(x_i, y_i)\right), \tag{6}$$

with $g : \mathbb{R}^2 \mapsto \mathbb{R}$ being commutative and not identically constant, and $h : \mathbb{R} \mapsto \mathbb{R}$ strictly monotonic and, hence, invertible. Indeed, let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be d-dimensional i.i.d. random vectors, and consider the random variable

$$h^{-1}\left(\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d)\right) = \sum_{i=1}^{d} g(X_i, Y_i) = \sum_{i=1}^{d} W_i.$$

Because $W_1, W_2, W_3, \ldots$ is a sequence of i.i.d. random variables, by the CLT, it can be said that $h^{-1}\left(\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d)\right) \simeq \Phi\big(d \cdot \mathbf{E}[g(X_i, Y_i)],\ d \cdot \sigma^2(g(X_i, Y_i))\big)$ and, for large values of d,

$$Pr\left[\text{dist}(\boldsymbol{X}_d, \boldsymbol{Y}_d) \leq \delta\right] \approx \Phi\left(\frac{h(\delta) - d \cdot \mathbf{E}[g(X_i, Y_i)]}{\sqrt{d} \cdot \sigma(g(X_i, Y_i))}\right).$$

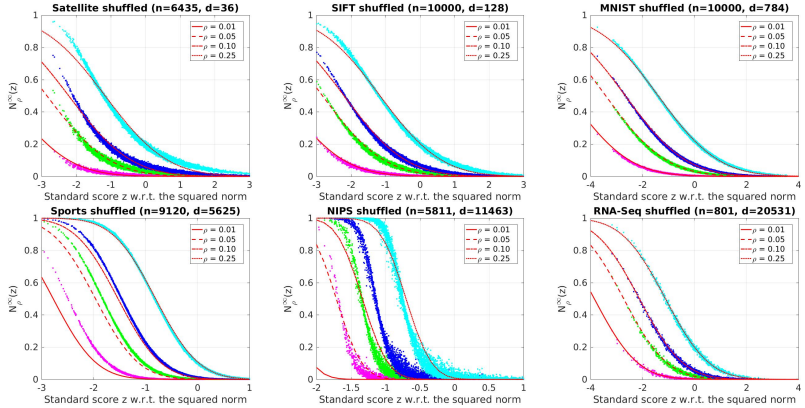

Figure 11: [Best viewed in color.] Relative number of k-occurrences associated with data set points (the shuffled version of each data set here being considered, which is obtained by randomly permuting the elements within every attribute), represented in terms of their squared norm standard score z (different colors), and theoretical prediction according to the infinite dimensional k-occurrences function reported in Equation (4.3), for the following values of $\varrho = k/n$: $\varrho_1 = 0.01$ (magenta-colored points and solid red line), $\varrho_2 = 0.05$ (green-colored points and dashed red line), $\varrho_3 = 0.10$ (blue-colored points and dash-dotted red line), and $\varrho_4 = 0.25$ (cyan-colored points and dotted red line).

As an example, consider the Minkowski norm L_p, $\|\boldsymbol{x}_d\|_p = \left(\sum_{i=1}^{d} |x_i|^p\right)^{1/p}$, with p a positive integer. Let, for the sake of simplicity, p be even, then

$$\begin{aligned}
\mathbf{E}[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p] &= d\sum_{j=0}^{p}(-1)^j \binom{p}{j} \mu_{X,p-j}\mu_{Y,j}, \text{ and} \\
\sigma^2(\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p) &= d\sum_{j=0}^{p} \binom{p}{j}^2 \sigma^2(X_i^{p-j}Y_i^j) + \\
&\quad + d\sum_{j=0}^{p}\sum_{j\neq k=0}^{p} (-1)^{j+k}\binom{p}{j}\binom{p}{k} cov(X_i^{p-j}Y_i^j, X_i^{p-k}Y_i^k).
\end{aligned}$$

Newman and Rinott (1985) reported a generalized version of Theorem 4, in which distances of the form used in Equation (6) are considered.

Theorem 38 (Adapted from Newman and Rinott, 1985, cf. Theorem 3) *Consider the generalized distance function reported in Equation* (6)*. Let* $\beta_g = corr\big(g(X,Y), g(X,Z)\big)$ *be the correlation between* $g(X,Y)$ *and* $g(X,Z)$*, where* X*,* Y*,* Z *are i.i.d. random variables*

with common distribution F, and let $0 < \sigma^2(g(X,Y)) < \infty$. If $\beta_g > 0$, then Theorem 4 holds even if the generalized distance is employed instead of the Euclidean distance.

Both the Euclidean distance and all Minkowski's metrics with $p \neq 0$ respect the condition $\beta_g > 0$. This condition implies that the location of vector components plays a role when computing pairwise distances, because when it holds, the closer the coordinate value x_i of $\boldsymbol{x}_d$ to the the expected position of X_i, the more likely it is that the vector $\boldsymbol{x}_d$ will be close to the other realizations of the same random vector.

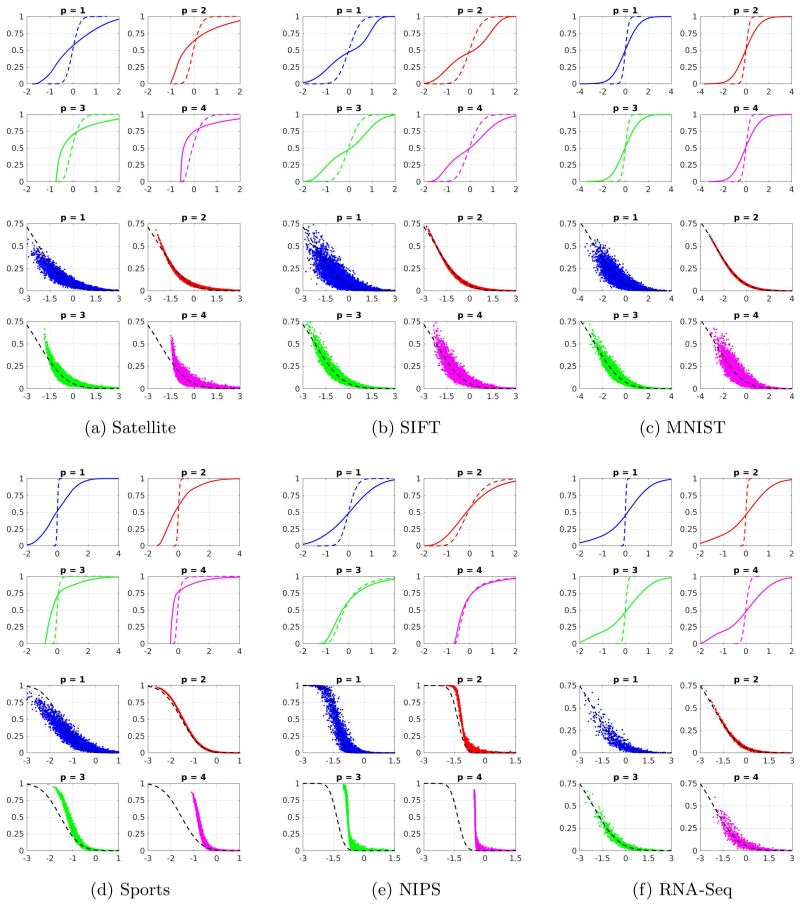
In contrast, the case $\beta_g = 0$ means that no vector occupies a special position. This condition is valid, for example, for Poisson process, which spread the vectors uniformly over $\mathbb{R}^d$. In this case, all positions within the space become equivalent and, hence, no concentration of distances is exhibited. As already noted by Radovanovic et al. (2010), the absence of spatial centrality can be intuitively used to explain the absence of hubness for cosine distance, since in this setting, no vector is more spatially central than any other, and the observation of the emergence of hubness for distance measures such as the L_p norm, Bray-Curtis, normalized Euclidean, and Canberra.

Because Theorems 16, 25 and 30, as well as related ones, are based on spatial centrality in that (the standard score of) the squared norm plays a special role in their formulation, it is conceivable that by following the same line here presented, similarly behaving closed forms can be obtained for any other distance presenting spatial centrality (namely, such that $\beta_g > 0$), expressed in terms of the standard score (or other degree) of some measure $\ell(\boldsymbol{x}_d)$ of centrality of $\boldsymbol{x}_d$. For example, for L_p norms, the natural measure of centrality is $\|\boldsymbol{x}_d\|_p^p$.

Figure 12 reports the distribution of pairwise distances and the relative number of k-occurrences for different Minkowski's metrics p. Namely, $p \in \{1,2,3,4\}$ (colors employed are blue for $p=1$, red for $p=2$, green for $p=3$, and magenta for $p=4$), on the real data sets considered in the previous section.

To facilitate the comparison of results involving different metrics, both distance values and norm values have been normalized. Specifically, let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two independent and not identically distributed random vectors whose components X_i and Y_i have the same central moments of the i-th attribute of the data set, and let $\boldsymbol{x}_d$ and $\boldsymbol{y}_d$ be two data set points. As for pairwise distance distributions, on the x-axis, the value $z_{dist}(\boldsymbol{x}_d, \boldsymbol{y}_d) = \frac{\|\boldsymbol{x}_d - \boldsymbol{y}_d\|_p^p - \mathbf{E}[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p]}{\sigma(\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p)}$ is reported, whereas for the relative number of k-occurrences, the value $z_{norm}(\boldsymbol{x}_d) = \frac{\|\boldsymbol{x}_d\|_p^p - \mathbf{E}[\|\boldsymbol{X}_d\|_p^p]}{\sigma(\|\boldsymbol{X}_d\|_p^p)}$ is reported on the x-axis.

In Figure 12, plots concerning the pairwise distance distribution (that are, for each data set, the four plots on the top), report the cdf associated with the original data set (solid line) and the cdf associated with the shuffled data (dashed line). The curve of the cdf associated with the equivalent independent data—that is, the cdf of the normal distribution having mean $\mathbf{E}[\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p]$ and standard deviation $\sigma(\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|_p^p)$—is not reported for clarity, because its curve overlaps with that of the shuffled data. In Figure 12, plots concerning k-occurrences (which are, for each data set, the four plots on the bottom) report the relative number of k-occurrences (for $k = \varrho n$ and $\varrho = 0.1$) associated with the points of the shuffled data set (color varying with p) together with the value $\mathrm{N}_k^\infty(z_{norm})$ of the infinite dimensional k-occurrences function reported in Equation (4.3) evaluated in $z_{norm}(\boldsymbol{x}_d)$ (black dashed



(a) Satellite (b) SIFT (c) MNIST

(d) Sports (e) NIPS (f) RNA-Seq

Figure 12: [Best viewed in color.] Experimental results on real data for different Minkowski's metrics p (blue for $p=1$, red for $p=2$, green for $p=3$, and magenta for $p=4$). For each data set, the 4 plots on the top show the cdfs of pairwise distances for the original (solid line) and shuffled data (dashed line). Moreover, for each data set, the 4 plots on the bottom show the relative number of k-occurrences ($k = \varrho n$ with $\varrho = 0.1$) for the points of the shuffled data set (colored dots) and the value of the function $\mathrm{N}_\varrho^\infty$ (black dashed line) reported in Equation (4.3). The values on the x-axis are standard scores using $\|\cdot\|_p^p$ as measure of centrality.

line). Interestingly, as previously hypothesized, by representing the data in terms of the standard score of the measure of centrality $\|\cdot\|_p^p$, a similar behavior can also be observed for different Minkowski's metrics p. In general, the results for $p = 1$ are very similar to those for $p = 2$, whereas for $p > 2$, it seems that the degree of agreement is related to the value of the LC condition reported in the first column of Table 1.

5. Relationship with Hubness in Network Science

Because hubness is a phenomenon of primary importance in network science, we wondered if the findings relative to the distribution of the reverse nearest neighbors and the emergence of hubs in intrinsically high-dimensions have connections with the analogous phenomenon occurring in the context of networks.

It is well understood that complex networks (Barabási and Pósfai, 2016) arise from different natural and human-made systems, e.g., the Internet, the world-wide web, citation networks and some social networks. These networks exhibit as a major property a few nodes, called *hubs*, with unusually high degree as compared to the other nodes of the network.

In most cases, it has been observed that networks are approximatively scale-free that is, they have approximate power-law degree distributions. Specifically, in most cases, the approximation is true only for the tails of the node degree distribution. Tails are associated with the larger node degrees, which are also the less probable observations, whereas most of the probability mass is associated with the smallest degree values.

Early well-known random graph models, such as the Erdős and Rényi (1959) model, do not exhibit power laws. Thus, other models for generating scale-free networks have been proposed. The Bianconi and Barabási (2001) model generates scale-free networks based on three important concepts that have been observed in real networks: growth, preferential attachment, and fitness. Preferential attachment means that the more connected a node is, the more likely it is to receive new links. Fitness is an intrinsic value associated with each node, defined as the ability to attract new links.

At least two analogies between the study herein conducted and what was depicted above can be identified by regarding nodes as point in a high-dimensional space.

First, in some cases, the behavior of the theoretical pdf of the function N_k^∞ exhibits a transition (on the basis of the value $\varrho = k/n$) between the two aforementioned families of networks (see Theorem 32 (*ii*) and the bottom left plot in Figure 8 for uniform data); namely, the behavior is binomial-like for high ϱ values and skewed to the right with the emergence of hubs for small ϱ values.

Second, the squared norm standard score z for points can be conceptualized as a value of fitness that is assigned to nodes/points according to a certain probability ($\phi(z)$, that is the standard Normal pdf, in the case of points); consequently, $\mathrm{N}_k^\infty(z)$ represents the relative expected number of times that a certain node/point with fitness z will be referred by any other node of the network/data set. The more central the node (the closer the point to the mean), the higher its fitness and the higher is its probability of being selected as a neighbor by the rest of the points.

To ascertain whether the above analogies adhere to empirical evidence, we examined the node (in-)degree distribution of real networks. Given a directed network, consisting of

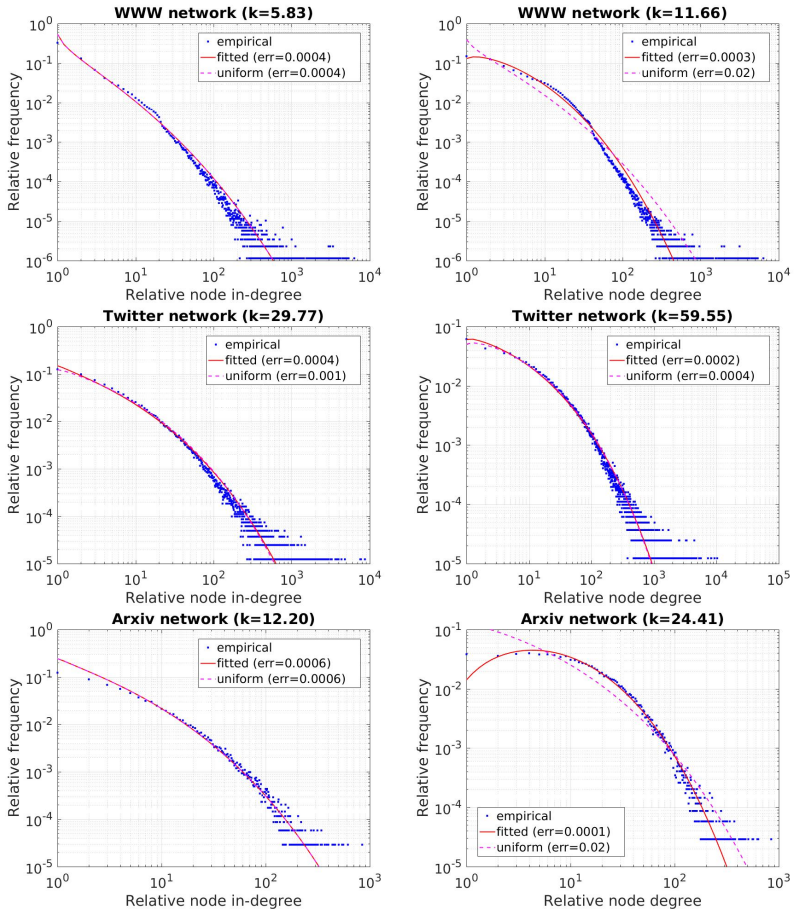


Figure 13: [Best viewed in color.] Relative node (in-)degrees (horizontal axis) and associated relative frequency (vertical axis) in log-log scale for different real-life complex networks (blue dots). Lines are associated with the probability of observing a point which has a certain number of reverse k-nearest neighbors in a set of n other points. Here, the average (in-)degree number is used as value for k. The magenta dashed line is associated with a uniform distribution in $[-0.5, +0.5]$. The red solid line is obtained using the moments minimizing the Cramér-von Mises distance between the theoretical and empirical cdfs.

n nodes and m arcs, let e_i (e_i^{in}, resp.) denote the number of arcs connected to (coming into, resp.) node n_i ($1 \leq i \leq n$).

Let $F_k(h)$ denote the discrete version of the cdf associated with the infinite dimensional k-occurrences function N_k^∞ (see Corollary 33). Then, $p_k(h) = F_k(h) - F_k(h-1)$ denotes the probability of observing a point which has exactly h reverse k-nearest neighbors in a set of n other points. As for the value of k, we used the average number of (incoming) arcs, that is $\overline{k} = \frac{1}{n}\sum_{i=1} e_i$ and $\overline{k}^{in} = \frac{1}{n}\sum_{i=1} e_i^{in}$, which is in general a rational number. This is consistent at least for incoming edges with Theorem 32 (*iv*), for which the expected value of N_k is indeed k.

We considered directed networks from the *Stanford Large Network Dataset Collection* of the Stanford Network Analysis Project (SNAP) (Leskovec and Krevl, 2014). We obtained similar results in different cases. Figure 13 reports the results concerning the following three directed networks: *WWW* (n = 875,713 nodes and m = 5,105,039 arcs), the `web-Google` web graph from Google; *Twitter* (n = 81,306 and m = 1,768,149), the `ego-Twitter` social circles from Twitter; and *Arxiv* (n = 34,546 and m = 421,578), the `cit-HepPh` arXiv high energy physics paper citation network.

Plots in Figure 13 are in a log-log scale and report on the horizontal axis the node degree and on the vertical axis the associated relative frequency. Blue dots represent the empirical values associated with each network. The magenta dashed line represents the function $p_k^u = p_k$ associated with a random variable uniformly distributed in $[-0.5, +0.5]$ ($\mu_2 = 0.08\overline{3}$, $\mu_4 = 0.0125$, and $\kappa = 1.8$). The red solid line represents the function $p_k^* = p_k$ using the values $\mu_2 = \mu_2^*$ and $\mu_4 = \mu_4^*$ (or $\kappa^* = \mu_4^*/(\mu_2^*)^2$) that minimize the Cramér-von Mises distance, also called *err* in the plots, between the cdf F_k and the empirical cdf of the node (in-)degree distribution. The Cramér-von Mises criterion corresponds to the integral of the squared difference between the empirical and the estimated distribution functions and is used to judge the goodness of fit of a cdf compared with an empirical cdf. This criterion depends on the entire cdf and gives more importance to the most probable observations. Alternative curves can be obtained by using other criteria.

Interestingly, we observed in different cases a good agreement between the empirical distribution of the number of incoming edges and the expected number of k-occurrences associated with the function p^u. In particular, the distance *err* for uniform data is in most cases similar to the distance for p^* associated with the best values for the parameters according to the Cramér-von mises statistics, and this is true especially for node in-degrees.

This suggests that for some real networks, the distribution of the incoming node degrees has connections with the herein-derived infinite-dimensional k-occurrences function N_k^∞, which models the number of reverse k-nearest neighbors in an arbitrarily large feature space of independent dimensions. Moreover, the function N_k^∞ appears to be suitable to be leveraged as a model for node-degrees distributions in complex real networks. We are currently investigating to what extent the above observations can be generalized and the use of these findings for the generation of realistic synthetic networks.

6. Concluding Discussion

This work investigated the distribution of distances in intrinsically high-dimensional spaces and leveraged this analysis to gain knowledge of phenomena related to the so-called dimensionality curse.

The study has been focused on independent data, because it is usually assumed that the number of independent dimensions dictates the intrinsic dimensionality of the data. By applying the central limit theorem to the Euclidean distance random variable, we obtained an approximation of the distance probability distribution between a given realization of a random vector and a random vector. The analysis of the error associated with the approximation highlights that, whereas the worst-case error always decreases with the dimensionality, there are configurations of n and d for which the hypothesized distance distribution can be considered equivalent, in terms of the expected empirical error, to the underlying distribution generating the observed inter-point distances.

With reference to the distribution of the nearest neighbors, we derived the expected distance of a point from its k-th nearest neighbor and the expected size of the ϵ-neighborhood in finite high-dimensional spaces, that is, the average number of points which emerge as ϵ-approximate neighbors of any other point, and then exploited it to determine the intrinsic dimensionality at which the neighborhood is expected to become unstable, called critical dimensionality. Also, a better estimate for the relative contrast for quantifying query difficulty has been obtained.

Moreover, the function N_k, or number of k-occurrences, representing the number of points which have a given point as one of their k nearest neighbors, has been investigated. Despite the extensive use of this function in many fields, including, among others, applied statistics and mathematical psychology, data mining and machine learning, information retrieval and computational geometry, the precise characterization of its form has been a longstanding problem. The limiting probability distribution of the function N_k has been derived, thereby providing full interpretability of the associated hubness problem.

It is well understood that complex networks arising from different natural conditions exhibit a few nodes, called *hubs*, of unusually high degree as compared to the other nodes of the network. Thus, we investigated if the findings relative to the distribution of the reverse nearest neighbors and the emergence of hubs in intrinsically high-dimensions is associated with the analogous phenomenon occurring in the context of networks. We concluded that for some real-life large-scale networks the distribution of the incoming node degrees is closely related to the herein-derived infinite-dimensional k-occurrences function N_k^∞ associated with uniform data and that this function is suitable to be leveraged as a model for node-degrees distribution in complex real networks.

We believe that the current study can be leveraged in several ways and in different contexts, such as direct and reverse nearest neighbor search, density estimation, anomaly and novelty detection, density-based clustering, and network analysis, as well as others, because almost all of them are based on the concepts of direct and reverse nearest neighbors. As for the study's possible applications, one is to obtain approximations of measures that are related to distance distributions. Another is to exploit the distributions for independent data as a worst-case scenario for data analysis and retrieval techniques in order to understand their behavior and limitations, in terms of meaningfulness or computational cost, as

dimensionality increases. Moreover, a deeper understanding of the behavior of intrinsically high dimensional spaces is fundamental to the design strategies that seek to mitigate the curse of dimensionality. For example, a line of research seeks to alleviate the problem by designing dissimilarity functions that suffer less on i.i.d. uniformly distributed features (François et al., 2007; Hsu and Chen, 2009). Moreover, from the discussion of Section 5, different applications within geometric models of complex networks can be devised.

To illustrate, the approximation of relative contrasts described in Section 4.2 results in estimates more accurate than those already provided, because the approach leverages a refined characterization of the distance distribution herein provided, which takes into account the relationship between the norm of the query point and its expected distance to the data points.

Additionally, the *Concentration Free Outlier Factor* (CFOF) recently introduced by Angiulli (2017) is a measure that aims to overcome the concentration problem in density estimation and outlier detection, whose behavior emerges from that of the k-occurrences function. Specifically, for a given parameter $\varrho \in [0,1]$ representing a fraction of the data population, the CFOF score of point $\boldsymbol{x}_d$ is $\mathrm{CFOF}(\boldsymbol{x}_d) = \min\{k/n : \mathrm{N}_k(\boldsymbol{x}_d) \geq n\varrho\}$, which is the smallest value for neighborhood parameter k (normalized on n) for which $\boldsymbol{x}_d$ presents a reverse neighborhood with a size of at least $n\varrho$. The intuition is that isolated points will require larger values of k than inliers in order to be selected as neighbors by an equal-sized fraction of the data population. In contrast to almost all known outlier detection measures, CFOF scores do not exhibit concentration. By leveraging the closed form of the function N_k it is possible to formally see that CFOF outliers are few in number and separated from inliers even in intrinsically high-dimensional spaces, whereas the direct use of the number of k-occurrences for outlier detection is prone to false positives. For further details, we refer to (Angiulli, 2017).

The understanding of properties characterizing high-dimensional spaces is also fundamental for enhancing intrinsic dimensionality estimation techniques. For example, Granata and Carnevale (2016), due to the difficulty of correctly working with the distance probability density function at small-length scales, propose to reconstruct that pdf at intermediate scales and then to compare it with a known pdf of a uniform distribution on a d-dimensional support.

Appendix A. Proofs

Proposition 11

$$cov\big(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d\rangle\big) = d\mu(\mu_3 - \mu_2\mu) \\ \big(and\ cov\big(\|\boldsymbol{X}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d\rangle\big) = d\mu(\mu_3 - \mu_2\mu),\ for\ symmetry\big).$$

Proof of Proposition 11. Consider the covariance

$$\begin{aligned} cov\left(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d\rangle\right) &= \mathbf{E}\big[\|\boldsymbol{Y}_d\|^2 \cdot \langle \boldsymbol{X}_d, \boldsymbol{Y}_d\rangle\big] - \mathbf{E}\big[\|\boldsymbol{Y}_d\|^2\big] \cdot \mathbf{E}\big[\langle \boldsymbol{X}_d, \boldsymbol{Y}_d\rangle\big] = \\ &= \mathbf{E}\left[\left(\sum_{i=1}^{d} Y_i^2\right) \cdot \left(\sum_{j=1}^{d} X_j Y_j\right)\right] - d\mu_2 \cdot d\mu^2 = \\ &= \mathbf{E}\left[\sum_{i=1}^{d} Y_i^3 X_i + \sum_{i=1}^{d}\sum_{i\neq j=1}^{d} X_j Y_j Y_i^2\right] - d^2\mu_2\mu^2 = \\ &= d\mu_3\mu + d(d-1)\mu_2\mu^2 - d^2\mu_2\mu^2 = d\mu(\mu_3 - \mu_2\mu). \end{aligned}$$

■

Proposition 17 *Let $\boldsymbol{X}_d$ be a d-dimensional i.i.d. random vector having cdf F_X. Moreover, let p and q be positive integers, and $\beta_0, \beta_1, \ldots, \beta_p$, $\alpha_0, \alpha_1, \ldots, \alpha_q$ be real coefficients such that $\beta_p \neq 0$ and $\alpha_q \neq 0$. Then, for any $\epsilon > 0$,*

$$\lim_{d\to\infty} Pr\left[\left|\frac{\sum_{i=1}^{d}\left(\sum_{j=0}^{p}\beta_j X_i^j\right)}{\left(\sum_{i=1}^{d}\left(\sum_{j=0}^{q}\alpha_j X_i^j\right)\right)^2}\right| \geq \epsilon\right] = 0.$$

Proof of Proposition 17. Let $U_i = \left(\sum_{j=0}^{p}\beta_j X_i^j\right)$ and $V_i = \left(\sum_{j=0}^{q}\alpha_j X_i^j\right)$ $(1 \leq i \leq d)$. Moreover, let U be $\sum_{i=1}^{d} U_i$ and let V be $\sum_{i=1}^{d} V_i$. Now it is shown that, for all $\epsilon > 0$,

$$\lim_{d\to\infty} Pr\left[\left|\frac{U}{V^2}\right| \geq \epsilon\right] = 0.$$

The mean and variance of V_i are as follows (mean and variance of U_i are similar):

$$\begin{aligned} \mathbf{E}[V_i] &= \mathbf{E}\left[\sum_{j=1}^{q}\alpha_j X_i^j\right] = \sum_{j=1}^{q}\alpha_j\mu_j, \\ \sigma^2(V_i) &= \mathbf{E}[V_i^2] - \mathbf{E}[V_i]^2 = \mathbf{E}\left[\left(\sum_{j=1}^{q}\alpha_j X_i^j\right)^2\right] - \left(\sum_{j=1}^{q}\alpha_j\mu_j\right)^2 = \\ &= \mathbf{E}\left[\sum_{j=1}^{q}\alpha_j^2 X_i^{2j} + \sum_{j=1}^{q}\sum_{k\neq j}^{q}\alpha_j\alpha_k X_i^j X_i^k\right] - \left(\sum_{j=1}^{q}\alpha_j^2\mu_j^2 + \sum_{j=1}^{q}\sum_{k\neq j}^{q}\alpha_j\alpha_k\mu_j\mu_k\right) = \\ &= \sum_{j=1}^{q}\alpha_j^2\mu_{2j} + \sum_{j=1}^{q}\sum_{k\neq j}^{q}\alpha_j\alpha_k\mu_j\mu_k - \sum_{j=1}^{q}\alpha_j^2\mu_j^2 - \sum_{j=1}^{q}\sum_{k\neq j}^{q}\alpha_j\alpha_k\mu_j\mu_k = \\ &= \sum_{j=1}^{q}\alpha_j^2\left(\mu_{2j} - \mu_j^2\right). \end{aligned}$$

We assume that moments up to $2\max\{p,q\}$ exist finite. Since both U and V are the sum of d independent identically distributed random variables, by the CLT, as $d \to \infty$,

$$U \approx \mathcal{N}\left(d\sum_{j=1}^{p}\alpha_j\mu_j,\ d\sum_{j=1}^{p}\alpha_j^2\left(\mu_{2j}-\mu_j^2\right)\right) \text{ and } V \approx \mathcal{N}\left(d\sum_{j=1}^{p}\beta_j\mu_j,\ d\sum_{j=1}^{p}\beta_j^2\left(\mu_{2j}-\mu_j^2\right)\right).$$

Consider now the random variable V^2, having mean

$$\mathbf{E}[V^2] \quad = \quad \mathbf{E}[V]^2+\sigma^2(V) = d^2\mu_{V_i}^2+d\sigma_{V_i}^2 = O(d^2).$$

Now it is essential to show that $\sigma^2(V^2)=O(d^3)$ and $cov(U,V^2)=O(d^2)$.

As for the variance $\sigma^2(V^2)=\mathbf{E}[V^4]-\mathbf{E}[V^2]^2$ of V^2, notice that the term of higher order in $\mathbf{E}[V^4]$ derives from the summation

$$\mathbf{E}\left[\sum_{i\neq j\neq k\neq h}V_iV_jV_kV_h\right] = d(d-1)(d-2)(d-3)\mu_{V_i}^4 = (d^4-6d^3+11d^2-6d)\mu_{V_i}^4,$$

and that all the other terms in $\mathbf{E}[V^4]$ are $O(d^3)$. As for $\mathbf{E}[V^2]^2 = (d^2\mu_{V_i}^2+d\sigma_{V_i}^2)^2 = d^4\mu_{V_i}^4+2d^3\mu_{V_i}^2\sigma_{V_i}^2+d^2\sigma_{V_i}^4$. Since both $\mathbf{E}[V^4]$ and $\mathbf{E}[V^2]^2$ contain as term of higher order $d^4\mu_{V_i}^4$, it then follows that $\sigma^2(V^2)=O(d^3)$.

As for the covariance $cov(U,V^2)=\mathbf{E}[U\cdot V^2]-\mathbf{E}[U]\mathbf{E}[V^2]$, similar considerations hold. Indeed, notice that the term of higher order in $\mathbf{E}[U\cdot V^2]$ derives from the summation:

$$\mathbf{E}\left[\sum_{i\neq j\neq k}U_iV_jV_k\right] = d(d-1)(d-2)\mu_{U_i}\mu_{V_i}^2$$

and that all the other terms in $\mathbf{E}[U\cdot V^2]$ are $O(d^2)$. As for $\mathbf{E}[U]\mathbf{E}[V^2] = d\mu_{U_i}(d^2\mu_{V_i}^2+d\sigma_{V_i}^2) = d^3\mu_{U_i}\mu_{V_i}^2+d^2\mu_{U_i}\sigma_{V_i}^2$. Since both $\mathbf{E}[U\cdot V^2]$ and $\mathbf{E}[U]\mathbf{E}[V^2]$ contain as term of higher order $d^3\mu_{U_i}\mu_{V_i}^2$, it then follows that $cov(U,V^2)=O(d^2)$.

By exploiting Taylor series, it can be written:

$$\begin{aligned}\mathbf{E}\left[\frac{U}{V^2}\right] &\approx \frac{\mathbf{E}[U]}{\mathbf{E}[V^2]}-\frac{cov(U,V^2)}{\mathbf{E}[V^2]^2}+\frac{\mathbf{E}[U]}{\mathbf{E}[V^2]^3}\sigma^2(V^2), \text{ and}\\ \sigma^2\left(\frac{U}{V^2}\right) &\approx \left(\frac{\mathbf{E}[U]}{\mathbf{E}[V^2]}\right)^2\left(\frac{\sigma^2[U]}{\mathbf{E}[U]^2}+\frac{\sigma^2(V^2)}{\mathbf{E}[V^2]^2}-\frac{2cov(U,V^2)}{\mathbf{E}[U]\mathbf{E}[V^2]}\right).\end{aligned}$$

Then

$$\begin{aligned}\lim_{d\to\infty}\mathbf{E}\left[\frac{U}{V^2}\right] &= \lim_{d\to\infty}\left(\frac{O(d)}{O(d^2)}-\frac{O(d^2)}{O(d^4)}+\frac{O(d)}{O(d^6)}O(d^3)\right) = \lim_{d\to\infty}O(d^{-1}) = 0, \text{ and}\\ \lim_{d\to\infty}\sigma^2\left(\frac{U}{V^2}\right) &= \lim_{d\to\infty}\left(\frac{O(d)}{O(d^2)}\right)^2\left(\frac{O(d)}{O(d^2)}+\frac{O(d^3)}{O(d^4)}-\frac{O(d^2)}{O(d^3)}\right) = \lim_{d\to\infty}O(d^{-3}) = 0.\end{aligned}$$

Since both $\mathbf{E}[U/V^2]$ and $\sigma^2(U/V^2)$ are vanishing as $d\to\infty$, by exploiting the Chebicheff theorem it can be proved that U/V^2 converges in probability to 0. Let $W_d = U/V^2$ then,

$\{W_d\}$ converges in probability towards the value zero, if for all $\epsilon>0$ the following limit evaluates to 0:

$$\lim_{d\to\infty}Pr\left[|W_d|\geq\epsilon\right] = \lim_{d\to\infty}Pr\left[|W_d-\mathbf{E}[W_d]|\geq\epsilon\right] \leq \lim_{d\to\infty}\frac{\sigma^2(W_d)}{\epsilon^2} = \lim_{d\to\infty}\frac{1}{\epsilon^2O(d^3)} = 0.$$

■

Proposition 19 *As $d\to\infty$, with high probability $\|\boldsymbol{Y}_d\|^2$ and $\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle$ are jointly normally distributed.*

Proof of Proposition 19. The proof follows a line similar to that exploited in Propositions 10 and 18. It must be shown that all linear combinations

$$Z = a\|\boldsymbol{Y}_d\|^2+b\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle = a\left(\sum_{i=1}^{d}Y_i^2\right)+b\left(\sum_{i=1}^{d}x_iY_i\right) = \sum_{i=1}^{d}(aY_i^2+bx_iY_i) = \sum_{i=1}^{d}W_i$$

are normally distributed, where $W_1,W_2,W_3,\ldots$ form a sequence of independent, but not identically distributed, random variables. The proof is completed by noticing that

$$\begin{aligned}\mathbf{E}\left[|W_i-\mathbf{E}[W_i]|^4\right] &= \mathbf{E}\left[W_i^4-4W_i^3\mathbf{E}[W_i]+6W_i^2\mathbf{E}[W_i]^2-4W_i\mathbf{E}[W_i]^3+\mathbf{E}[W_i]^4\right] =\\ &= \mathbf{E}[W_i^4]-4\mathbf{E}[W_i^3]\mathbf{E}[W_i]+6\mathbf{E}[W_i^2]\mathbf{E}[W_i]^2-3\mathbf{E}[W_i]^4 = \sum_{j=0}^{4}\alpha_jx^j,\end{aligned}$$

and

$$\sigma_{W_i}^2 \quad = \quad (b^2\mu_2)x_i^2+(2ab\mu_3)x_i+(a^2\mu_4-a\mu_2^2) = \beta_2x_i^2+\beta_1x_i+\beta_0,$$

from which the Lyapunov CLT condition (see Equation 1) for $\delta=2$:

$$\lim_{d\to\infty}\left.\frac{\mathbf{E}\left[|W_i-\mathbf{E}[W_i]|^{2+\delta}\right]}{s_d^{2+\delta}}\right|_{\delta=2} = \lim_{d\to\infty}\frac{\sum_{i=1}^{d}\left(\sum_{j=0}^{4}\alpha_jx_i^j\right)}{\left(\sum_{i=1}^{d}\left(\sum_{j=0}^{2}\beta_jx_i^j\right)\right)^2} = 0.$$

The above limit converges in probability to zero for the r.v. $\boldsymbol{X}_d$ by Proposition 17. ■

Proposition 20 $cov\left(\|\boldsymbol{Y}_d\|^2,\langle\boldsymbol{x}_d,\boldsymbol{Y}_d\rangle\right) = (\mu_3-\mu\mu_2)\sum_{i=1}^{d}x_i.$

Proof of Proposition 20. Consider the covariance

$$\begin{aligned} cov\left(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle\right) &= \mathbf{E}\left[\|\boldsymbol{Y}_d\|^2 \cdot \langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle\right] - \mathbf{E}\left[\|\boldsymbol{Y}_d\|^2\right] \cdot \mathbf{E}\left[\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle\right] = \\ &= \mathbf{E}\left[\left(\sum_{i=1}^{d} Y_i^2\right) \cdot \left(\sum_{j=1}^{d} x_j Y_j\right)\right] - d\mu_2 \cdot \mu \sum_{i=1}^{d} x_i = \\ &= \mathbf{E}\left[\sum_{i=1}^{d}\sum_{j=1}^{d} x_j Y_j Y_i^2\right] - d\mu\mu_2 \sum_{i=1}^{d} x_i = \\ &= \sum_{i=1}^{d} x_i \mathbf{E}[Y_i^3] + \sum_{i=1}^{d-1}\sum_{i\neq j=1}^{d} x_j \mathbf{E}[Y_j]\mathbf{E}[Y_i^2] - d\mu\mu_2 \sum_{i=1}^{d} x_i = \\ &= \mu_3 \sum_{i=1}^{d} x_i + (d-1)\mu\mu_2 \sum_{i=1}^{d} x_i - d\mu\mu_2 \sum_{i=1}^{d} x_i = (\mu_3 - \mu\mu_2)\sum_{i=1}^{d} x_i. \end{aligned}$$

■

Proposition 22 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ with cdf F_X. Then, for large values of d, with high probability*

$$\frac{\sum_{i=1}^{d} x_i}{\|\boldsymbol{x}_d\|^2} \to \frac{\mu_X}{\mu_{X,2}}.$$

Proof of Proposition 22. Assume that in general $\mu \in \mathbb{R}$. By the CLT, following the same line of reasoning of Proposition 8, it can be seen that the random variable

$$U = \sum_{i=1}^{d} X_i \approx \mathcal{N}\left(d\mu, d(\mu_2 - \mu^2)\right).$$

Let $V = \|\boldsymbol{X}_d\|^2 = \sum_{i=1}^{d} X_i^2$. By Proposition 8, $V \approx \mathcal{N}\big(d\mu_2, d(\mu_4 - \mu_2^2)\big)$. As for the covariance $cov(U, V)$, it is $d(\mu_3 - \mu\mu_2)$. Consider the ratio U/V. Now it is shown that

$$\lim_{d\to\infty} Pr\left[\left|\frac{U}{V} - \frac{\mu}{\mu_2}\right| \geq \epsilon\right] = 0.$$

By exploiting Taylor series, the mean of U/V is:

$$\begin{aligned} \mathbf{E}\left[\frac{U}{V}\right] &\approx \frac{\mathbf{E}[U]}{\mathbf{E}[V]} - \frac{cov(U,V)}{\mathbf{E}[V]^2} + \frac{\mathbf{E}[U]}{\mathbf{E}[V]^3}\sigma^2(V) = \frac{d\mu}{d\mu_2} - \frac{d(\mu_3 - \mu\mu_2)}{d^2\mu_2^2} + \frac{d\mu}{d^3\mu_2^3} d(\mu_4 - \mu_2^2) = \\ &= \frac{\mu}{\mu_2} - \frac{\mu_3 - \mu\mu_2}{d\mu_2^2} + \frac{\mu}{d\mu_2^3}(\mu_4 - \mu_2^2) = \frac{\mu}{\mu_2} + \frac{1}{d} \cdot \frac{\mu(\mu_4 - \mu_2^2) - \mu_2(\mu_3 - \mu\mu_2)}{\mu_2^3}, \end{aligned}$$

while the variance of U/V is:

$$\begin{aligned} \sigma^2\left(\frac{U}{V}\right) &\approx \left(\frac{\mathbf{E}[U]}{\mathbf{E}[V]}\right)^2 \left(\frac{\sigma^2[U]}{\mathbf{E}[U]^2} + \frac{\sigma^2(V)}{\mathbf{E}[V]^2} - \frac{2cov(U,V)}{\mathbf{E}[U]\mathbf{E}[V]}\right) = \\ &= \left(\frac{d\mu}{d\mu_2}\right)^2 \left(\frac{d(\mu_2 - \mu^2)}{d^2\mu^2} + \frac{d(\mu_4 - \mu_2^2)}{d^2\mu_2^2} - \frac{2d(\mu_3 - \mu\mu_2)}{d^2\mu\mu_2}\right) = \\ &= \frac{1}{d} \cdot \frac{\mu_2^2(\mu_2 - \mu^2) + \mu(\mu_4 - \mu_2^2) - 2\mu\mu_2(\mu_3 - \mu\mu_2)}{\mu_2^4}. \end{aligned}$$

The statement then follows by applying the Chebicheff theorem to show that U/V converges in probability to μ/μ_2.

$$\lim_{d\to\infty} Pr\left[\left|\frac{U}{V} - \frac{\mu}{\mu_2}\right| \geq \epsilon\right] = \lim_{d\to\infty} Pr\left[\left|\frac{U}{V} - \mathbf{E}\left[\frac{U}{V}\right]\right| \geq \epsilon\right] \leq \lim_{d\to\infty} \frac{\sigma^2\left(\frac{U}{V}\right)}{\epsilon^2} = \lim_{d\to\infty} \frac{1}{\epsilon^2 O(d)} = 0.$$

■

Lemma 29 *Let $\boldsymbol{x}_d$ denote a realization of a d-dimensional i.i.d. random vector $\boldsymbol{X}_d$ with cdf F_X and let $\boldsymbol{Y}_d$ be a d-dimensional i.i.d. random vector with cdf F_Y. Assume, w.l.o.g., that F_Y has null mean $\mu_Y = 0$. Then, for large values of d, with high probability*

$$Pr\left[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \delta \mid \|\boldsymbol{Y}_d\| = R\right] \approx \Phi\left(\frac{\delta^2 - R^2 - \|\boldsymbol{x}_d\|^2}{2\|\boldsymbol{x}_d\|\sqrt{\mu_2}}\right),$$

where moments are relative to the random vector $\boldsymbol{Y}_d$.

Proof of Lemma 29. By Proposition 19, $\|\boldsymbol{Y}_d\|^2$ and $\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$ are jointly normally distributed. Then,

$$\begin{aligned} Pr[\text{dist}(\boldsymbol{x}_d, \boldsymbol{Y}_d) \leq \delta \mid \|\boldsymbol{Y}_d\| = R] &= Pr[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\| \leq \delta \mid \|\boldsymbol{Y}_d\| = R] = \\ &= Pr[\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \leq \delta^2 \mid \|\boldsymbol{Y}_d\|^2 = R^2] = \\ &= Pr[\|\boldsymbol{x}_d\|^2 + \|\boldsymbol{Y}_d\|^2 - 2\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle \leq \delta^2 \mid \|\boldsymbol{Y}_d\|^2 = R^2]. \end{aligned}$$

Notice that, for distributions F_Y having null skewness ($\mu_{Y,3} = 0$), by Proposition 20, $\|\boldsymbol{Y}_d\|^2$ and $\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle$ are both uncorrelated and independent, and it can be written that

$$Pr[\|\boldsymbol{x}_d\|^2 + \|\boldsymbol{Y}_d\|^2 - 2\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle \leq \delta^2 \mid \|\boldsymbol{Y}_d\|^2 = R^2] = Pr[\|\boldsymbol{x}_d\|^2 + R^2 - 2\langle \boldsymbol{x}_d, \boldsymbol{Y}_d\rangle \leq \delta^2],$$

from which the statement follows by exploiting Proposition 18.

More in general ($\mu_{Y,3} \neq 0$) by leveraging properties within Theorem 15 and by Proposition 22 the distribution of the squared norm $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2$ subject to the constraint that $\|\boldsymbol{Y}_d\|^2 = R^2$, tends to the normal distribution with mean

$$\mu = \|\boldsymbol{x}_d\|^2 + R^2$$

and variance (by the assumption that F_X has null mean $\mu_X = 0$)

$$\sigma^2 = 4\mu_{Y,2}\|\boldsymbol{x}_d\|^2 - 4\mu_{Y,3}\frac{\mu_X}{\mu_{X,2}}\|\boldsymbol{x}_d\|^2 = 4\mu_{Y,2}\|\boldsymbol{x}_d\|^2,$$

from which the above expression again follows.

The above holds under the assumption that R itself is selected with high probability, that is $R^2 \approx \mathbf{E}[\|\boldsymbol{Y}_d\|^2]$, as also assumed in Theorem 30. For a generic R, the moments μ_2 and μ conditioned on $\|\boldsymbol{Y}_d\| = R$ must be used. As for $\mu_2 = \mathbf{E}[Y^2 \mid \|\boldsymbol{Y}_d\|^2 = R^2] = \mathbf{E}[Y^2 \mid d\mathbf{E}[Y^2] = R^2] = R^2/d$. As for μ conditioned on $\|\boldsymbol{Y}_d\|^2 = R^2$, it is $\mu = \mu_Y = 0$ for symmetric distributions, since for each $\boldsymbol{y}_d$ such that $\|\boldsymbol{y}_d\|^2 = R^2$, it holds that $\|-\boldsymbol{y}_d\|^2 = R^2$ and $f_Y(\boldsymbol{y}_d) = f_Y(-\boldsymbol{y}_d)$.

Moreover, the closer R^2 to $\mathbf{E}[\|\boldsymbol{Y}_d\|^2] = \mu_{\|\boldsymbol{Y}_d\|^2} = d\mu_{Y,2}$, the closer the moments to their unconditioned values. Indeed, for $k \geq 1$

$$\mathbf{E}[Y^k \mid \|\boldsymbol{Y}_d\|^2 = R^2] = \tfrac{1}{Pr[\|\boldsymbol{Y}_d\|^2 = R^2]} \left(\int_{\mathbb{R}} y^k \, f_Y(y) \, Pr\left[\left(\sum_{j>1}^{d} Y_j^2 \right) = R^2 - y^2 \right] \, \mathrm{d}y \right) \approx$$
$$\approx \tfrac{1}{\phi_{\|\boldsymbol{Y}_d\|^2}(R^2)} \left(\int_{\mathbb{R}} y^k \, f_Y(y) \, \phi_{\|\boldsymbol{Y}_d\|^2}\left(R^2 - y^2\right) \, \mathrm{d}y \right).$$

Hence, since μ_Y exists finite, as $d \to \infty$

$$\mathbf{E}\left[Y^k \mid \|\boldsymbol{Y}_d\|^2 = \mu_{\|\boldsymbol{Y}_d\|^2}\right] \approx \tfrac{1}{\phi_{\|\boldsymbol{Y}_d\|^2}\left(\mu_{\|\boldsymbol{Y}_d\|^2}\right)} \left(\int_{\mathbb{R}} y^k \, f_Y(y) \, \phi_{\|\boldsymbol{Y}_d\|^2}\left(\mu_{\|\boldsymbol{Y}_d\|^2} - y^2\right) \, \mathrm{d}y \right) =$$
$$= \tfrac{1}{\phi(0)} \left(\int_{\mathbb{R}} y^k \, f_Y(y) \, \phi\left(-y^2/\sigma_{\|\boldsymbol{Y}_d\|^2}\right) \, \mathrm{d}y \right) \approx \tfrac{\phi(0)}{\phi(0)} \int_{\mathbb{R}} y^k \, f_Y(y) \, \mathrm{d}y = \mu_{Y,k}.$$

■

Theorem 32

$$(i) \quad \lim_{d\to\infty} Pr[\mathrm{N}_\varrho(\boldsymbol{X}_d) \leq \theta] = \Phi\left(\frac{\Phi^{-1}(\theta) 2\mu_2 - \Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}} \right),$$

$$(ii) \quad \lim_{d\to\infty} Pr[\mathrm{N}_\varrho(\boldsymbol{X}_d) = \theta] = \frac{2\mu_2}{\sqrt{\mu_4 - \mu_2^2}} \cdot \frac{1}{\phi(\Phi^{-1}(\theta))} \cdot \phi\left(\frac{\Phi^{-1}(\theta) 2\mu_2 - \Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}} \right),$$

$$(iii) \quad \lim_{d\to\infty} \sigma^2(\mathrm{N}_\varrho(\boldsymbol{X}_d)) = \varrho(1-\varrho) - 2T\left(\Phi^{-1}(\varrho), \frac{2\mu_2}{\sqrt{2(\mu_4 + \mu_2^2)}} \right), \text{ and}$$

$$(iv) \quad \lim_{d\to\infty} \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)] = \varrho,$$

where $T(h,a) = \phi(h) \int_0^a \frac{\phi(hx)}{1+x^2} \, \mathrm{d}x$ *is the Owen's T function.*

Proof of Theorem 32. Since

$$\mathrm{N}_\varrho^\infty(Z_\theta) \leq \theta \implies Z_\theta \leq \frac{\Phi^{-1}(\theta) 2\mu_2 - \Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}},$$

point (i) corresponds to $\Phi(Z_\theta)$ and point (ii) to $\frac{\mathrm{d}}{\mathrm{d}\theta}\Phi(Z_\theta)$.

As for points (iii) and (iv), consider the Owen's Gaussian-type integrals reported in Equation (2) and in the following equation due to Owen (1980):

$$\int_{-\infty}^{+\infty} \Phi(a+bx)^2 \phi(x) \, \mathrm{d}x = \Phi\left(\frac{a}{\sqrt{1+b^2}} \right) - 2T\left(\frac{a}{\sqrt{1+b^2}}, \frac{1}{\sqrt{1+2b^2}} \right). \tag{7}$$

Let us consider first point (iv). Since

$$\lim_{d\to\infty} \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)] = \int_{-\infty}^{+\infty} \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2} - z\sqrt{\mu_4 - \mu_2^2}}{2\mu_2} \right) \phi(z) \, \mathrm{d}z,$$

by substituting $a = \frac{\Phi^{-1}(\varrho)\sqrt{\mu_4+3\mu_2^2}}{2\mu_2}$ and $b = -\frac{\sqrt{\mu_4-\mu_2^2}}{2\mu_2}$ in Equation (2):

$$\lim_{d\to\infty} \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)] = \Phi\left(\frac{a}{\sqrt{1+b^2}} \right) = \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 + 3\mu_2^2}} \right) = \Phi(\Phi^{-1}(\varrho)) = \varrho.$$

As for point (iii),

$$\lim_{d\to\infty} \sigma^2(\mathrm{N}_\varrho(\boldsymbol{X}_d)) = \lim_{d\to\infty} \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)^2] - \mathbf{E}[\mathrm{N}_\varrho(\boldsymbol{X}_d)]^2,$$

and by substituting a and b as above in the first (see Equation 2) and second (see Equation 7) Owen's formula the result is obtained. ■

Corollary 34 *Let k be a fixed positive integer. Then*

$$(i) \lim_{n\to\infty} \lim_{d\to\infty} \mathrm{N}_k^{n,d} \xrightarrow{D} 0, \quad (ii) \lim_{n\to\infty} \lim_{d\to\infty} \sigma^2(\mathrm{N}_k^{n,d}) = \infty, \text{ and } (iii) \lim_{n\to\infty} \lim_{d\to\infty} \mathbf{E}[\mathrm{N}_k^{n,d}] = k.$$

Proof of Corollary 34. All the points derive from Theorem 32. As for point (1) it suffices to show that $F_{N_k^{\infty,\infty}}(h) = Pr[N_k^{\infty,\infty} \leq h] = 1$ for $h > 0$, since $h = 0$ is not a continuity point for the cdf:

$$\begin{aligned}
\lim_{n\to\infty} \lim_{d\to\infty} Pr[\mathrm{N}_k^{n,d} > 0] &= 1 - \lim_{n\to\infty} \lim_{d\to\infty} Pr[\mathrm{N}_k^{n,d} \leq 0] = 1 - \lim_{n\to\infty} Pr[\mathrm{N}_k^{n,\infty} \leq 0] = \\
&= 1 - \lim_{n\to\infty} \Phi\left(\frac{\Phi^{-1}(0) 2\mu_2 - \Phi^{-1}(\frac{k}{n})\sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}} \right) = \\
&= 1 - \Phi\left(\Phi^{-1}(0) \frac{2\mu_2 - \sqrt{\mu_4 + 3\mu_2^2}}{\sqrt{\mu_4 - \mu_2^2}} \right) = 1 - \Phi(-\infty) = 1.
\end{aligned}$$

As for point (2),

$$\begin{aligned}
\lim_{n\to\infty} \lim_{d\to\infty} \sigma^2(\mathrm{N}_k^{n,d}) &= \lim_{n\to\infty} n^2 \left(\frac{k}{n} - \frac{k}{n^2} - 2T\left(\Phi^{-1}\left(\frac{k}{n}\right), \frac{2\mu_2}{\sqrt{2(\mu_4 + \mu_2^2)}} \right) \right) = \\
&= \lim_{n\to\infty} nk - k - 0 = \infty.
\end{aligned}$$

As for point (3),

$$\lim_{n\to\infty} \lim_{d\to\infty} \mathbf{E}[\mathrm{N}_k^{n,d}] = \lim_{d\to\infty} n\left(\frac{k}{n}\right) = k.$$

■

Proposition 35 *Let $U_d = \sum_{i=1}^{d} W_i$ be a random variable defined as the summation of a sequence of independent, but not identically distributed, random variables W_i having comparable central moments. Then*

$$U_d \simeq \mathcal{N}\left(\sum_{i=1}^{d} \mu_{W_i},\ \sum_{i=1}^{d} \sigma^2_{W_i}\right) = \mathcal{N}\left(d \cdot \overline{\mu}_W,\ d \cdot \overline{\sigma^2}_W\right),$$

where $\overline{\mu}_W = (1/d)\sum_{i=1}^{d} \mu_{W_i}$ and $\overline{\sigma^2}_W = (1/d)\sum_{i=1}^{d} \sigma^2_{W_i}$.

Proof of Proposition 35. For variables W_i having comparable central moments the Lyapunov CLT condition holds:

$$\lim_{d\to\infty} \frac{\sum_{i=1}^{d} \mathbf{E}\left[(W_i - \mathbf{E}[W_i])^4\right]}{\left(\sum_{i=1}^{d} \sigma^2(W_i)\right)^2} = \lim_{d\to\infty} \frac{\sum_{i=1}^{d} \hat{\mu}_{i,4}}{\left(\sum_{i=1}^{d} \hat{\mu}_{i,2}\right)^2} \leq \lim_{d\to\infty} \frac{d\hat{\mu}_{max}}{(d\hat{\mu}_{min})^2} = \lim_{d\to\infty} \frac{\hat{\mu}_{max}}{d\hat{\mu}^2_{min}} = 0.$$

■

Theorem 37. *Let $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ be two independent non-identically distributed d-dimensional random vectors with common cdfs $\boldsymbol{F}$ having means $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_d)$, non null variances, and comparable central moments, and let $\boldsymbol{x}_d$ denote a realization of $\boldsymbol{X}_d$. The results of Sections 4.1, 4.2 and 4.3 can be applied to $\boldsymbol{X}_d$, $\boldsymbol{Y}_d$, and $\boldsymbol{x}_d$ by taking into account the average central moments of $\boldsymbol{X}_d$ and $\boldsymbol{Y}_d$ and the realization $\boldsymbol{x}_d - \boldsymbol{\mu}$.*

Proof of Theorem 37. W.l.o.g. assume that $\boldsymbol{\mu} = (0, \ldots, 0)$, for otherwise it is sufficient to replace vector $\boldsymbol{X}_d$ with $\hat{\boldsymbol{X}}_d = \boldsymbol{X}_d - \boldsymbol{\mu}$ and vector $\boldsymbol{Y}_d$ with $\hat{\boldsymbol{Y}}_d = \boldsymbol{Y}_d - \boldsymbol{\mu}$. Thus, from now $\mu_i = \mathbf{E}[X_i] = \mathbf{E}[Y_i] = 0$.

Let $\boldsymbol{\mu_k} = (\mu_{k,1}, \ldots, \mu_{k,d})$ denote the k-th moments of $\boldsymbol{X}_d$ ($\boldsymbol{Y}_d$, resp.). The result follows by taking into account that the variables X_i and Y_i ($1 \leq i \leq d$) are independent but not identically distributed and, hence, by exploiting the average moments to formulate expressions.

Let $\boldsymbol{p} = (p_1, \ldots, p_d)$ and $\boldsymbol{q}_d = (q_1, \ldots, q_d)$ two d-dimensional vectors, and let h be a positive integer. In the following we denote by $\boldsymbol{p^k}$ the vector $\boldsymbol{p^k} = (p_1^k, \ldots, p_d^h)$ and by $\boldsymbol{p} \cdot \boldsymbol{q}$ the scalar product $\langle \boldsymbol{p}, \boldsymbol{q} \rangle = \sum_{i=1}^{d} p_i q_i$ of $\boldsymbol{p}$ and $\boldsymbol{q}$.

Thus, as for the results of Section 4.1, we obtain the following expressions:

(**P37.1**) $\|\boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(d\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}},\ d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} - \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}})\right)$;

(**P37.2**) $\langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle \simeq \mathcal{N}\left(0,\ \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}\right)$;

(**P37.3**) $cov(\|\boldsymbol{Y}_d\|^2, \langle \boldsymbol{X}_d, \boldsymbol{Y}_d \rangle) = 0$;

(**P37.4**) $\|\boldsymbol{X}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(2d\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}},\ 2d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} - \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}})\right)$;

(**P37.5**) $\langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle \simeq \mathcal{N}\left(0,\ \boldsymbol{\mu_2} \cdot \boldsymbol{x^2}\right)$;

(**P37.6**) $cov(\boldsymbol{Y}_d, \langle \boldsymbol{x}_d, \boldsymbol{Y}_d \rangle) = \boldsymbol{\mu_3} \cdot \boldsymbol{x_d}$;

(**P37.7**) $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(\|\boldsymbol{x}_d\|^2 + d\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}},\ d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} - \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}) + 4\boldsymbol{\mu_2} \cdot \boldsymbol{x^2_d} - 4\boldsymbol{\mu_3} \cdot \boldsymbol{x_d}\right)$.

Expression (**P37.1**) can be derived by exploiting $\mathbf{E}[\|\boldsymbol{Y}_d\|^2]$ and $\sigma(\|\boldsymbol{Y}_d\|^2)$ in terms of the average central moments of the random vectors, as illustrated next:

$$\begin{aligned}
\mathbf{E}[\|\boldsymbol{Y}_d\|^2] &= \mathbf{E}\left[\textstyle\sum_i Y_i^2\right] = \sum_i \mathbf{E}[Y_i^2] = \sum_i \mu_{i,2} = d\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}},\\
\mathbf{E}[\|\boldsymbol{Y}_d\|^4] &= \mathbf{E}\left[\left(\textstyle\sum_i Y_i^2\right)^2\right] = \mathbf{E}\left[\textstyle\sum_i Y_i^4 + \sum_{i\neq j} Y_i^2 Y_j^2\right] = \textstyle\sum_{i=1}^{d} \mu_{i,4} + \sum_{i\neq j} \mu_{i,2}\mu_{j,2}, \text{ and}\\
\sigma^2\left(\|\boldsymbol{Y}_d\|^2\right) &= \mathbf{E}[\|\boldsymbol{Y}_d\|^4] - \mathbf{E}[\|\boldsymbol{Y}_d\|^2]^2 = \mathbf{E}[\|\boldsymbol{Y}_d\|^4] - \left(\textstyle\sum_i \mu_{i,2}\right)^2 =\\
&= \mathbf{E}[\|\boldsymbol{Y}_d\|^4] - \left(\textstyle\sum_i \mu_{i,2}^2 + \sum_{i\neq j} \mu_{i,2}\mu_{j,2}\right) = \textstyle\sum_i \mu_{i,4} + \sum_i \mu_{i,2}^2 = d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} + \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}).
\end{aligned}$$

The other expressions can be obtained in an analogous manner.

Moreover, by using the same line of reasoning of Proposition 22 it can be shown that:

(**P37.8**) $\frac{\boldsymbol{\mu_3} \cdot \boldsymbol{x_d}}{\|\boldsymbol{x}_d\|^2} \to \frac{\boldsymbol{\mu_3} \cdot \boldsymbol{\mu}}{\boldsymbol{\mu_2}} = 0$, and (**P37.9**) $\frac{\boldsymbol{\mu_2} \cdot \boldsymbol{x^2_d}}{\|\boldsymbol{x}_d\|^2} \to \frac{\tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}}{\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}}}$,

and, hence, (**P37.7'**) can be reformulated only in terms of the squared norm of $\boldsymbol{x}_d$:

(**P37.7'**) $\|\boldsymbol{x}_d - \boldsymbol{Y}_d\|^2 \simeq \mathcal{N}\left(\|\boldsymbol{x}_d\|^2 + d\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}},\ d(\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} - \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}) + 4\frac{\tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}}{\tilde{\boldsymbol{\mu}}_{\boldsymbol{2}}}\|\boldsymbol{x}_d\|^2\right)$.

Expressions of Sections 4.2 and 4.3 can be obtained by exploiting the above ones and by following the same line of reasoning. For completeness, we report the final expression of the number of k-occurrences:

(**P37.10**) $N_{\varrho}^{\infty}(z) = \Phi\left(\frac{\Phi^{-1}(\varrho)\sqrt{\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} + 3\tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}} - z\sqrt{\tilde{\boldsymbol{\mu}}_{\boldsymbol{4}} - \tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}}}{2\sqrt{\tilde{\boldsymbol{\mu}}^{\boldsymbol{2}}_{\boldsymbol{2}}}}\right)$.

Abstract

In this paper we study the convergence of online gradient descent algorithms in reproducing kernel Hilbert spaces (RKHSs) without regularization. We establish a sufficient condition and a necessary condition for the convergence of excess generalization errors in expectation. A sufficient condition for the almost sure convergence is also given. With high probability, we provide explicit convergence rates of the excess generalization errors for both averaged iterates and the last iterate, which in turn also imply convergence rates with probability one. To our best knowledge, this is the first high-probability convergence rate for the last iterate of online gradient descent algorithms in the general convex setting. Without any boundedness assumptions on iterates, our results are derived by a novel use of two measures of the algorithm's one-step progress, respectively by generalization errors and by distances in RKHSs, where the variances of the involved martingales are cancelled out by the descent property of the algorithm.

Keywords: Learning theory, Online learning, Convergence analysis, Reproducing kernel Hilbert space

1. Introduction

Online gradient descent is a scalable method able to tackle large-scale data arriving in a sequential manner (Zhang, 2004; Kivinen et al., 2004; Duchi and Singer, 2009; Dieuleveut and Bach, 2016), which is becoming ubiquitous within the big data era. As a first-order method, it iteratively builds an unbiased estimate of the true gradient upon the arrival of a new example and uses this information to guide the learning process (Zinkevich, 2003; Zhang, 2004). As verified by theoretical and empirical analysis, online gradient descent enjoys comparable performance as compared to its batch counterpart such as gradient descent (Zhang, 2004; Yao, 2010; Shalev-Shwartz et al., 2011), while attaining a great computational speed-up since its gradient calculation involves only a single example. As a comparison, the gradient calculation in gradient descent requires to traverse all training examples. Recently, online gradient descent has received renewed attention due to the wide applications of its stochastic analogue, i.e., stochastic gradient descent, in training deep neural networks (Bottou, 1991; Ngiam et al., 2011; Sutskever et al., 2013).

In this paper, we are interested in the setting that training examples $\{z_t = (x_t, y_t)\}_{t\in\mathbb{N}}$ are sequentially and identically drawn from a probability measure ρ defined in the sample space $\mathcal{Z} = \mathcal{X}\times\mathcal{Y}$, where $\mathcal{X} \subset \mathbb{R}^d$ is the input space and $\mathcal{Y} \subset \mathbb{R}$ is the output space. We focus on the nonparametric setting, where the learning process is implemented in a reproducing kernel Hilbert space (RKHS) H_K associated with a Mercer kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ which is assumed to be continuous, symmetric and positive semi-definite. The space H_K is defined as the completion of the linear span of the set of functions $\{K_x(\cdot) := K(x, \cdot) : x \in \mathcal{X}\}$ with the inner producing satisfying the reproducing property $f(x) = \langle f, K_x\rangle$ for any $x \in \mathcal{X}$ and $f \in H_K$. In this setting, the use of Mercer kernels provides a unifying way to measure similarities between pairs of objects (Cortes and Vapnik, 1995; Müller et al., 2001; Steinwart, 2001; Schölkopf and Smola, 2001), which turns out to be a key to the great success of kernel methods in many practical learning problems. We wish to build a prediction rule $f \in H_K$ after seeing a sequence of training examples, the performance of which at an example (x, y) can be quantitatively measured by a loss function $\phi : \mathcal{Y} \times \mathbb{R} \to \mathbb{R}_+$ as $\phi(y, f(x))$. With a sequence $\{\eta_t\}_{t\in\mathbb{N}}$ of positive step sizes and $f_1 = 0$, online gradient descent is a realization of learning schemes by keeping a sequence of iterates as follows

$$f_{t+1} = f_t - \eta_t\phi'(y_t, f_t(x_t))K_{x_t}, \quad \forall t \in \mathbb{N}, \tag{1.1}$$

where ϕ' denotes the derivative of ϕ with respect to the second argument. Although our focus is on the nonparametric setting, it should be mentioned that the above algorithm also recovers the parametric case in which the kernel is taken to be the linear kernel with $K_x(x') = \langle x, x'\rangle, \forall x, x' \in \mathcal{X}$, to which our results also apply.

Despite its widespread applications, the theoretical understanding of the online gradient descent algorithms is still not satisfactory in the following three aspects. Firstly, boundedness assumptions on the iterates are often imposed in the literature, which may be violated in practical implementations if the underlying domain is not bounded. Although a projection of iterates onto a bounded domain guarantees the boundedness assumption, the projection operator may be time-consuming and this introduces an additional challenging problem of tuning the size of the domain. Secondly, most of the theoretical results are stated in expectation, while we are sometimes more interested in either almost sure convergence or convergence rates with high probability. Indeed, an algorithm may suffer from a high variability and should be used with caution if neither almost sure convergence nor high-probability bounds hold (Shamir and Zhang, 2013). In particular, an almost sure convergence is still lacking for online gradient descent algorithms applied to general convex problems (Ying and Zhou, 2017). Lastly, most existing convergence rates are stated for some average of iterates. Though taking average of iterates can improve the robustness

of the solution (Nemirovski et al., 2009), it can either destroy the sparsity of the solution which is crucial for a proper interpretation of models in many applications, or slow down the training speed in practical implementations (Rakhlin et al., 2012).

In this paper, we aim to take a further step to tackle the above mentioned problems. We establish a general sufficient condition and a necessary condition on the step sizes for the convergence of online gradient descent algorithms in expectation. With Doob's martingale convergence theorem and the Borel-Cantelli lemma, a sufficient condition for the almost sure convergence and explicit convergence rates with probability one are also established. Furthermore, we present high-probability bounds for both averaged iterates and the last iterate of online gradient descent algorithms. To our best knowledge, this is the first high-probability convergence rate for the last iterate of online gradient descent algorithms in the general convex setting. Our analysis does not impose any boundedness assumptions on the iterates. Indeed, we show that, although implemented in an unbounded domain, the iterates produced by (1.1) fall into a bounded domain with high probability (up to logarithmic factors). Our analysis is performed by viewing the one-step progress of online gradient descent algorithms from different yet unified perspectives: one in terms of generalization errors and one in terms of RKHS distances. For both viewpoints, we relate the one-step progress to a martingale difference sequence and a negative term due to the descent nature of the algorithm. Our novelty is to show that the dominant variance term appearing in the application of a Bernstein-type inequality to these martingales can be cancelled out by the negative terms in the one-step progress inequalities. Both viewpoints of the one-step progress are indispensable in our analysis.

The remaining parts of this paper are organized as follows. We present main results in Section 2. Discussions and comparisons with related work are given in Section 3. The proofs of main results are given in Section 4.

2. Main Results

Our convergence rates are stated for generalization errors, which, for a prediction rule $f : \mathcal{X} \to \mathbb{R}$, are defined as the expected error $\mathcal{E}(f) = \int_{\mathcal{Z}} \phi(y, f(x))d\rho$ incurred from using f to perform prediction. Our analysis requires to impose mild assumptions on the loss functions.

Assumption 1 *We assume the loss function $\phi : \mathcal{Y} \times \mathbb{R} \to \mathbb{R}_+$ is convex and differentiable with respect to the second argument. Let $\alpha \in (0, 1]$ and $L > 0$ be two constants. We assume that the gradients of ϕ are (α, L)-Hölder continuous in the sense*

$$|\phi'(y, s) - \phi'(y, \tilde{s})| \le L|s - \tilde{s}|^\alpha, \quad \forall s, \tilde{s} \in \mathbb{R}, \forall y \in \mathcal{Y}. \tag{2.1}$$

We say ϕ is smooth if it satisfies (2.1) with $\alpha = 1$. Loss functions satisfying Assumption 1 are wildly used in machine learning. Smooth loss functions include the least squares loss $\phi(y, a) = \frac{1}{2}(y-a)^2$ and the Huber loss $\phi(y, a) = \frac{1}{2}(y-a)^2$ if $|y-a| \le 1$ and $|y-a|-\frac{1}{2}$ otherwise for regression, as well as the logistic loss $\phi(y, a) = \log(1 + \exp(-ya))$ and the quadratically smoothed hinge loss $\phi(y, a) = \max\{0, 1 - ya\}^2$ for classification (Zhang, 2004). If $p \in (1, 2]$, both the p-norm hinge loss $\phi(y, a) = \max\{0, 1 - ya\}^p$ for classification and the p-th power absolute distance $\phi(y, a) = |y - a|^p$ for regression satisfy (2.1) with $\alpha = p - 1$ (Chen et al., 2004; Steinwart and Christmann, 2008).

Throughout this paper, we assume that a minimizer $f_H = \arg\min_{f \in H_K} \mathcal{E}(f)$ exists in H_K. We also assume

$$\max\big\{\sup_{y \in \mathcal{Y}} \phi(y, 0), \sup_{z \in \mathcal{Z}} \phi(y, f_H(x))\big\} < \infty \text{ and } \kappa := \sup_{x \in \mathcal{X}} \sqrt{K(x, x)} < \infty,$$

which is satisfied if the sample space $\mathcal{Z}$ is bounded. Denote $\|\cdot\|$ as the norm in H_K. We always use the notation $A_t = \mathbb{E}[\mathcal{E}(f_t)] - \mathcal{E}(f_H)$ and $\hat{A}_t = \mathcal{E}(f_t) - \mathcal{E}(f_H), \forall t \in \mathbb{N}$ for brevity, which are referred to as the expected excess generalization errors and excess generalization errors, respectively.

In the following, we present the main results of this paper. We consider three types of convergence: convergence in expectation, almost sure convergence and convergence rates with high probability.

2.1 Convergence in Expectation

The first part of our main results to be proved in Section 4.1 establishes a general sufficient condition (Theorem 1) and a necessary condition (Theorem 2) on the step size sequence $\{\eta_t\}_{t \in \mathbb{N}}$ for the convergence of A_t to zero.

Theorem 1 *Let $\{f_t\}_{t \in \mathbb{N}}$ be the sequence produced by (1.1) and suppose Assumption 1 holds with $\alpha \in (0, 1]$. If*

$$\sum_{t=1}^{\infty} \eta_t = \infty \quad \text{and} \quad \lim_{t \to \infty} \eta_t^\alpha \sum_{k=1}^{t} \eta_k^2 = 0, \tag{2.2}$$

then $\lim_{t \to \infty} \mathbb{E}[\mathcal{E}(f_t)] - \mathcal{E}(f_H) = 0$.

Theorem 2 *Let $\{f_t\}_{t \in \mathbb{N}}$ be the sequence produced by (1.1). Suppose that for any $y \in \mathcal{Y}$, the function $\phi(y, \cdot) : \mathbb{R} \to \mathbb{R}_+$ is convex and its derivative $\phi'(y, \cdot)$ is $(1, L)$-Hölder continuous. Assume that the step size sequence satisfies $\eta_t \le 1/(6L\kappa^2), \forall t \in \mathbb{N}$ and $\mathcal{E}(f_1) \ne \mathcal{E}(f_H)$. If $\lim_{t \to \infty} \mathbb{E}[\mathcal{E}(f_t)] = \mathcal{E}(f_H)$, then $\sum_{t=1}^{\infty} \eta_t = \infty$.*

Remark 3 *We now illustrate the above theorems by considering the polynomially decaying step sizes $\eta_t = \eta_1 t^{-\theta}, t \in \mathbb{N}, \theta \ge 0$. The condition $\sum_{t=1}^{\infty} \eta_t = \infty$ requires $\theta \le 1$, while the condition $\lim_{t \to \infty} \eta_t^\alpha \sum_{k=1}^{t} \eta_k^2 = 0$ requires $\theta > \frac{1}{2+\alpha}$. Therefore, Theorem 1 shows that the iteration scheme (1.1) with $\eta_t = \eta_1 t^{-\theta}$ and $\theta \in \big(\frac{1}{2+\alpha}, 1\big]$ guarantees the convergence of $\{A_t\}_{t \in \mathbb{N}}$. Theorem 2 shows that the condition $\theta \le 1$ is also necessary for the convergence.*

2.2 Almost Sure Convergence

The second part of our main results focuses on a sufficient condition (Theorem 4) for the almost sure convergence of $\{\hat{A}_t\}_{t \in \mathbb{N}}$ to zero and convergence rates with probability 1 (Theorem 6). The proofs of results in this section can be found in Section 4.2.

Theorem 4 *Let $\{f_t\}_{t \in \mathbb{N}}$ be the sequence given by (1.1). If Assumption 1 holds with $\alpha \in (0, 1]$ and the step size sequence satisfies*

$$\sum_{t=1}^{\infty} \eta_t = \infty \quad \text{and} \quad \sum_{t=1}^{\infty} \eta_t^{1+\alpha} < \infty, \tag{2.3}$$

then $\lim_{t\to\infty}\mathcal{E}(f_t)=\mathcal{E}(f_H)$ *almost surely.*

Remark 5 *According to Theorem 4, we know that* $\{\hat{A}_t\}_{t\in\mathbb{N}}$ *would converge almost surely to* 0 *if we consider either the step sizes* $\eta_t=\eta_1 t^{-\theta}$ *with* $\theta\in(\frac{1}{1+\alpha},1]$ *or the step sizes* $\eta_t=\eta_1(t\log^\beta t)^{-\frac{1}{1+\alpha}}$ *with* $\beta>1$*. Specifically, if the loss function is smooth, then we can choose either* $\eta_t=\eta_1 t^{-\theta}$ *with* $\theta\in(\frac{1}{2},1]$ *or* $\eta_t=\eta_1\big(t\log^\beta t\big)^{-\frac{1}{2}}$ *with* $\beta>1$ *to guarantee the convergence of the algorithm* (1.1) *almost surely in the sense of generalization errors.*

Theorem 6 *Suppose that Assumption 1 holds with* $\alpha\in(0,1]$*. Let* $\{f_t\}_{t\in\mathbb{N}}$ *be the sequence given by* (1.1) *with* $\eta_t=\eta_1 t^{-\theta},\theta\in(\frac{1}{\alpha+1},1)$ *and* $\eta_1\le\frac{1}{A\kappa^2}$ *(*A *is defined in* (4.27)*). Then for any* $\epsilon>0$*,*

$$\lim_{t\to\infty} t^{\min\{(1-\theta),(\alpha+1)\theta-1\}-\epsilon}\hat{A}_t=0 \text{ almost surely.} \tag{2.4}$$

Specifically, if we choose $\theta=\frac{2}{2+\alpha}$*, then* $\lim_{t\to\infty}t^{\frac{\alpha}{2+\alpha}-\epsilon}\hat{A}_t=0$ *almost surely.*

2.3 Convergence Rates with High Probability

The last part of our main results is on high-probability bounds for the excess generalization errors, the proof of which is given in Section 4.3. With high probability, Theorem 7 establishes the boundedness (up to logarithmic factors) of the weighted summation $\sum_{t=1}^T\eta_t\hat{A}_t$, from which the decay rate of the excess generalization error $\mathcal{E}(\bar{f}_T^\eta)-\mathcal{E}(f_H)$ associated to a weighted average of the iterates $\bar{f}_T^\eta:=\frac{\sum_{t=1}^T\eta_t f_t}{\sum_{t=1}^T\eta_t}$ follows directly.

Theorem 7 *Let* $\{f_t\}_{t\in\mathbb{N}}$ *be the sequence given by* (1.1)*. Suppose that Assumption 1 holds with* $\alpha\in(0,1]$*. Assume the step size sequence satisfies* $\eta_t\le\frac{1}{A\kappa^2},\eta_{t+1}\le\eta_t$ *for all* $t\in\mathbb{N}$ *and* $\sum_{t=1}^\infty\eta_t^2<\infty$*. Then, there exists a constant* $\widetilde{C}$ *independent of* T *(explicitly given in the proof) such that for any* $\delta\in(0,1)$ *the following inequality holds with probability at least* $1-\delta$

$$\sum_{t=1}^T\eta_t\big[\mathcal{E}(f_t)-\mathcal{E}(f_H)\big]\le\widetilde{C}\log^{\frac{3}{2}}\frac{2T}{\delta}\quad\text{and}\quad\mathcal{E}(\bar{f}_T^\eta)-\mathcal{E}(f_H)\le\frac{\widetilde{C}\log^{\frac{3}{2}}\frac{2T}{\delta}}{\sum_{t=1}^T\eta_t}. \tag{2.5}$$

Remark 8 *For the step size sequence* $\eta_t=\eta_1 t^{-\theta},\theta>\frac{1}{2}$*, Theorem 7 implies that* $\mathcal{E}(\bar{f}_T^\eta)-\mathcal{E}(f_H)=O\big(T^{\theta-1}\log^{\frac{3}{2}}\frac{T}{\delta}\big)$ *with probability at least* $1-\delta$*. If we consider* $\eta_t=\eta_1\big(t\log^\beta(et)\big)^{-\frac{1}{2}}$ *with* $\beta>1$*, then with probability* $1-\delta$ *we have* $\mathcal{E}(\bar{f}_T^\eta)-\mathcal{E}(f_H)=O\big(T^{-\frac{1}{2}}\log^{\frac{3+\beta}{2}}\frac{T}{\delta}\big)$*.*

A key feature of Theorem 7 distinguishing it from the existing results is that it avoids boundedness assumptions on the iterates, which are always imposed in the literature (Nemirovski et al., 2009; Duchi et al., 2010). Indeed, an essential ingredient in proving Theorem 7 is to show that $\{f_t\}_{t\in\mathbb{N}}$ produced by (1.1) would fall into a bounded ball of H_K (up to logarithmic factors) with high probability, as shown in the following proposition.

Proposition 9 *Suppose assumptions in Theorem 7 hold. Then, there exists a constant* $\bar{C}\ge1$ *independent of* T *(explicitly given in the proof) such that for any* $\delta\in(0,1)$ *the following inequality holds with probability at least* $1-\delta$

$$\max_{1\le t\le T}\|f_t-f_H\|^2\le\bar{C}\log\frac{T}{\delta}.$$

A key ingredient to prove Proposition 9 is to establish the following one-step progress inequality in terms of the RKHS distances (see (4.37))

$$\|f_{t+1}-f_H\|^2\le\|f_t-f_H\|^2+C\eta_t^2+2\eta_t\big(\mathcal{E}(f_H)-\mathcal{E}(f_t)\big)+\xi_t,$$

where C is a constant and $\{\xi_t\}_{t\in\mathbb{N}}$ is a Martingale difference sequence. Our novelty in applying a Bernstein-type inequality to control the martingale $\sum_{t=1}^T\xi_t$ is to show that the associated variances can be cancelled out by the negative term $2\sum_{t=1}^T\eta_t\big(\mathcal{E}(f_H)-\mathcal{E}(f_t)\big)$ (see (4.38) and the last inequality of Proposition 23). Although Theorem 7 only considers the behavior of the weighted average $\bar{f}_T^\eta$ of iterates, it is possible to establish similar convergence rates for the uniform average of iterates $\bar{f}_T:=\frac{1}{T}\sum_{t=1}^T f_t$ (Proposition 24).

Theorem 10 establishes a general high-probability bound for the excess generalization error of the last iterate in terms of the step size sequence.

Theorem 10 *Suppose that the assumptions in Theorem 7 hold. Then, there exists a constant* $\widetilde{C}'$ *independent of* T *(explicitly given in the proof) such that for any* $\delta\in(0,1)$ *the following inequality holds with probability at least* $1-\delta$

$$\mathcal{E}(f_{T+1})-\mathcal{E}(f_H)\le\widetilde{C}'\max\Big\{\Big[\sum_{t=\lfloor\frac{T}{2}\rfloor}^T\eta_t\Big]^{-1},\eta_{\lfloor\frac{T}{2}\rfloor},\sum_{t=\lfloor\frac{T}{2}\rfloor}^T\eta_t^{1+\alpha}\Big\}\log^2\frac{3T}{\delta}, \tag{2.6}$$

where $\lfloor\frac{T}{2}\rfloor$ *denotes the largest integer not greater than* $\frac{T}{2}$*.*

To establish high-probability error bounds for the last iterate of online gradient descent algorithm is an interesting problem which is not well studied, to our best knowledge, in the general convex setting. The key ingredient in our analysis is the following one-step progress inequality in terms of generalization errors (see (4.47))

$$\hat{A}_{t+1}\le\hat{A}_t-\eta_t\|\nabla\mathcal{E}(f_t)\|^2+\bar{\xi}_t+C\eta_t^{1+\alpha},$$

where C is a constant and $\{\bar{\xi}_t\}$ is a martingale difference sequence. A key observation of our analysis is that the variance of the martingale $\sum_{t=1}^T\bar{\xi}_t$ can be cancelled out by the negative term $-\sum_{t=1}^T\eta_t\|\nabla\mathcal{E}(f_t)\|^2$ in the above one-step progress inequality (see (4.48) and (4.52)), paving the way for the application of a Bernstein-type inequality for martingales.

We can derive explicit convergence rates in Corollary 11 by considering polynomially decaying step sizes in Theorem 10.

Corollary 11 *Let* $\{f_t\}_{t\in\mathbb{N}}$ *be the sequence given by* (1.1) *with* $\eta_t=\eta_1 t^{-\theta},\theta\in(\frac{1}{2},1)$ *and* $\eta_1\le\frac{1}{A\kappa^2}$ *If Assumption 1 holds and* $\delta\in(0,1)$*, then the following inequality holds with probability* $1-\delta$

$$\mathcal{E}(f_{T+1})-\mathcal{E}(f_H)=O\Big(T^{\max\{\theta-1,1-(1+\alpha)\theta\}}\log^2\frac{T}{\delta}\Big).$$

If we choose $\theta=\frac{2}{2+\alpha}$*, then with probability at least* $1-\delta$ *we derive* $\mathcal{E}(f_{T+1})-\mathcal{E}(f_H)=O\Big(T^{-\frac{\alpha}{2+\alpha}}\log^2\frac{T}{\delta}\Big)$*.*

Remark 12 *It should be mentioned that, unlike Theorem 7, the convergence rates in Corollary 11 depend on the smoothness parameter α and are not able to attain the minimax optimal convergence rate $O(T^{-\frac{1}{2}})$ (Agarwal et al., 2009). Indeed, for smooth loss functions, Corollary 11 establishes the convergence rate $O\big(T^{-\frac{1}{3}}\log^2\frac{T}{\delta}\big)$ with high probability, which matches the bounds in-expectation $A_T = O(T^{-\frac{1}{3}})$ up to logarithmic factors established in Moulines and Bach (2011); Ying and Zhou (2017). It remains a challenging problem to further improve the high-probability bounds for $\hat{A}_T$.*

3. Discussions

In this section, we discuss related work on convergence of online/stochastic gradient descent algorithms from three viewpoints: convergence in expectation, almost sure convergence and convergence rates with high probability.

3.1 Related Work on Convergence in Expectation

Most studies of online gradient descent algorithms focus on convergence in expectation (Zhang, 2004; Ying and Zhou, 2006; Duchi and Singer, 2009; Shamir and Zhang, 2013; Lin et al., 2016; Hardt et al., 2016; Ying and Zhou, 2017). Convergence rates $O(T^{-\frac{1}{2}})$ were established for some averaged iterates produced by (1.1) in a parametric setting with the linear kernel $K_x = x$ (Zhang, 2004). These results were extended to online gradient descent algorithms in RKHSs with the specific least squares loss function (Ying and Pontil, 2008; Dieuleveut and Bach, 2016; Guo and Shi, 2017), and online mirror descent algorithms performing updates in Banach spaces (Duchi et al., 2010). Under boundedness assumptions on the iterates and (sub)gradients, the convergence rate $O(T^{-\frac{1}{2}}\log T)$ was established for the expected excess generalization error of the last iterate (Shamir and Zhang, 2013). Recently, a general condition on the step sizes as (2.3) was established for the convergence of the algorithm (1.1), in the sense $\lim_{t\to\infty} A_t = 0$, with loss functions satisfying Assumption 1 (Ying and Zhou, 2017). This sufficient condition is stricter than our condition (2.2). To see this clearly, we consider the polynomially decaying step sizes $\eta_t = \eta_1 t^{-\theta}$, for which the condition (2.3) requires $\theta \in (\frac{1}{1+\alpha}, 1]$ while our condition (2.2) requires $\theta \in (\frac{1}{2+\alpha}, 1]$. Furthermore, our discussion also implies a necessary condition for the convergence in expectation.

Implemented in either a parametric or a nonparametric setting, regularized online learning algorithms have also received considerable attention (Kivinen et al., 2004; Smale and Yao, 2006; Ying and Zhou, 2006; Smale and Zhou, 2009), which differ from (1.1) by introducing a regularization term to avoid overfitting. This algorithm updates iterates as follows

$$f_{t+1} = (1-\lambda\eta_t)f_t - \eta_t\phi'(y_t, f_t(x_t))K_{x_t}, \tag{3.1}$$

where $\lambda > 0$ is a regularization parameter and the term $\lambda f_t + \phi'(y_t, f_t(x_t))K_{x_t}$ is used as an unbiased estimator of the gradient for the regularized generalization error $\mathcal{E}^\lambda(f) := \mathcal{E}(f) + \frac{\lambda}{2}\|f\|^2$ at $f = f_t$. Convergence rates in expectation can be stated for either the excess regularized generalization error $\mathcal{E}^\lambda(f_T) - \mathcal{E}^\lambda(f_\lambda)$ (Shamir and Zhang, 2013) or the RKHS distance $\|f_T - f_\lambda\|$ (Smale and Yao, 2006; Ying and Zhou, 2006; Yao, 2010), where $f_\lambda = \arg\min_{f\in H_K}\mathcal{E}^\lambda(f)$ is the minimizer of the regularized generalization error. When the loss function is smooth, a sufficient and necessary condition as

$$\lim_{t\to\infty}\eta_t = 0 \quad \text{and} \quad \sum_{t=1}^{\infty}\eta_t = \infty \tag{3.2}$$

was recently established for the convergence of $\{\mathbb{E}[\|f_t - f_\lambda\|^2]\}_{t\in\mathbb{N}}$ to zero in the parametric case (Lei and Zhou, 2017). A disadvantage of the regularization scheme (3.1) is that it requires to tune two sequences of hyper-parameters: a regularization parameter and the step sizes. As a comparison, an implicit regularization can be attained in the unregularized scheme (1.1) by tuning only the step sizes.

3.2 Related Work on Almost Sure Convergence

Existing almost sure convergence of online learning algorithm is mainly stated for the RKHS distances, which requires to impose some type of strong convexity assumption on the objective function $\mathcal{E}(f)$. In the parametric setting with the learning scheme (1.1), a sufficient condition as

$$\sum_{t=1}^{\infty}\eta_t = \infty \quad \text{and} \quad \sum_{t=1}^{\infty}\eta_t^2 < \infty$$

was established for the almost sure convergence of $\|f_t - f_H\|^2$ if the objective function attains a unique minimizer and satisfies (Bottou, 1998)

$$\inf_{\|f-f_H\|^2>\epsilon}\langle f - f_H, \nabla\mathcal{E}(f)\rangle > 0, \quad \forall\epsilon > 0,$$
$$\mathbb{E}_Z\big[\|\phi'(Y, f(X))K_X\|^2\big] \le \widetilde{A} + \widetilde{B}\|f - f_H\|^2, \quad \forall f \in H_K,$$

where $\widetilde{A}$ and $\widetilde{B}$ are two constants. This result was extended to the online mirror descent setting under some convexity assumption on the objective function measured by Bregman distances induced by the associated mirror map (Lei and Zhou, 2017). For polynomially decaying step sizes $\eta_t = \eta_1 t^{-\theta}$ with $\theta \in (0,1)$, almost sure convergence of $\|f_t - f_\lambda\|$ was shown for regularized online learning algorithms (3.1) specified to the least squares loss function (Yao, 2010). The analysis in Yao (2010) roots its foundation on the martingale decompositions of the reminders $f_t - f_\lambda$, which only holds in the least squares regularization setting. Almost sure convergence was recently studied for the randomized Kaczmarz algorithm (Lin and Zhou, 2015), which is an instantiation of (1.1) with $\phi(y,a) = \frac{1}{2}(y-a)^2$ and $K_x = x$. The analysis there heavily depends on a restricted strong convexity of the objective function in a linear subspace where the learning takes place, which can not apply to general loss functions. As compared to the above mentioned results, our almost sure convergence is stated for the excess generalization errors with general loss functions and requires no assumptions on the strong convexity of the objective function $\mathcal{E}(f)$.

3.3 Related Work on Convergence Rates with High Probability

In this section, we survey related work on convergence rates with high probability. We divide our discussions into two parts according to the convexity of the objective function.

As far as we know, all existing high-probability convergence rates of online gradient descent algorithms with general convex functions focus on some average of iterates (here we

are not interested in probabilistic bounds with a polynomial dependence on $1/\delta$). The following online projected gradient descent algorithm with $K_x = x$ was studied in Nemirovski et al. (2009); Duchi et al. (2010)

$$f_{t+1} = \mathrm{Proj}_{\widetilde{H}}\Big[f_t - \eta_t \phi'(y_t, f_t(x_t))K_{x_t}\Big], \tag{3.3}$$

where $\widetilde{H}$ is a compact subset of H_K and $\mathrm{Proj}_{\widetilde{H}}(f) = \arg\min_{\tilde{f}\in\widetilde{H}} \|f - \tilde{f}\|$ is the projection of f onto $\widetilde{H}$. Under the boundedness assumption

$$\mathbb{E}\Big[\exp\big[\|\phi'(y, f(x))K_x\|^2/G^2\big]\Big] \le \exp(1) \quad \forall f \in \widetilde{H},$$

it was shown that the weighted average $\bar{f}_T^{\eta} = \frac{\sum_{t=1}^T \eta_t f_t}{\sum_{t=1}^T \eta_t}$ of iterates produced by (3.3) with a constant step size satisfies the following inequality with probability $1-\delta$

$$\mathcal{E}(\bar{f}_T^{\eta}) - \mathcal{E}(f_H) = O\big(GDT^{-\frac{1}{2}}\log\delta^{-1}\big),$$

where $D = \sup_{f,\tilde{f}\in\widetilde{H}} \|f - \tilde{f}\|$ is the diameter of the subspace $\widetilde{H}$. Under a stronger assumption $\|\phi'(y, f(x))K_x\| \le G$ for all $(x, y) \in \mathcal{Z}, f \in \widetilde{H}$, the uniform average $\bar{f}_T = \frac{1}{T}\sum_{t=1}^T f_t$ of iterates produced by (3.3) with step sizes $\eta_t = \eta_1 t^{-\frac{1}{2}}$ was shown to enjoy the bound $\mathcal{E}(\bar{f}_T) - \mathcal{E}(f_H) = O(DGT^{-\frac{1}{2}}\log^{\frac{1}{2}}\frac{1}{\delta})$ with probability at least $1-\delta$. In comparison with these results, the convergence rates in Theorem 7 are derived without the projection step and any boundedness assumption on the gradients. Indeed, most of the efforts in proving Theorem 7 is to show $\|f_t - f_H\|^2 = O(\log\frac{T}{\delta})$ with probability at least $1-\delta$. It is implied that the possibly computationally expensive projection step can be removed without harming the behavior of the online gradient descent algorithms. Furthermore, Theorem 10 gives, to our best knowledge, the first high-probability bounds for the last iterate of online gradient descent algorithms in the general convex setting. A framework to transfer regret bounds of online learning algorithms to high-probability bounds for the uniform average of iterates was established by Cesa-Bianchi et al. (2004).

Now we review some high-probability studies for online gradient descent algorithms in the strongly convex setting, for which some results for the last iterate can be found in the literature. For the online regularized algorithm (3.1) with the least squares loss function and $\eta_t = \eta_1 t^{-\theta}, \theta \in [0, 1)$, the following inequality was derived with probability at least $1-\delta$ (Yao, 2010)

$$\|f_T - f_\lambda\|^2 = O\Big(\lambda^{-2+\frac{1}{1-\theta}}T^{-\theta}\log\frac{1}{\delta}\Big).$$

The analysis in Yao (2010) is based on an integral operator approach, which can not be extended to general loss functions. Under almost sure boundedness assumption $\|(\phi'(y_t, f_t(x_t)) + \lambda)K_{x_t}\| \le G$ for all $t \in \mathbb{N}$, the following improved bound for the last iterate of (3.1) with general loss functions and step sizes $\eta_t = \eta_1(t\lambda)^{-1}$ was established with probability at least $1-\delta$ (Rakhlin et al., 2012)

$$\|f_T - f_\lambda\|^2 = O\Big(G^2\lambda^{-2}T^{-1}\log\frac{\log T}{\delta}\Big). \tag{3.4}$$

Although this bound enjoys a tight dependence on T, its dependence on the regularization parameter λ is suboptimal. To make a clear comparison between this result and ours, we consider here the specific least squares loss function and assume that the regression function $f_\rho(x) := \mathbb{E}[Y|X = x]$ belongs to H_K. In this case, Lemma 13 translates (3.4) to the following high-probability bounds on excess generalization errors

$$\mathcal{E}(f_T) + \frac{\lambda}{2}\|f_T\|^2 = \mathcal{E}(f_\lambda) + \frac{\lambda}{2}\|f_\lambda\|^2 + O\Big(G^2\lambda^{-2}T^{-1}\log\frac{\log T}{\delta}\Big). \tag{3.5}$$

The assumption $f_\rho \in H_K$ implies $D(\lambda) := \mathcal{E}(f_\lambda) - \mathcal{E}(f_\rho) + \frac{\lambda}{2}\|f_\lambda\|^2 = O(\lambda)$ (Cucker and Zhou, 2007) and therefore (3.5) reads as

$$\begin{aligned}\mathcal{E}(f_T) - \mathcal{E}(f_\rho) &= \Big(\mathcal{E}(f_T) - \mathcal{E}(f_\lambda) - \frac{\lambda}{2}\|f_\lambda\|^2\Big) + \Big(\mathcal{E}(f_\lambda) - \mathcal{E}(f_\rho) + \frac{\lambda}{2}\|f_\lambda\|^2\Big)\\ &= O\Big(G^2\lambda^{-2}T^{-1}\log\frac{\log T}{\delta}\Big) + O(\lambda).\end{aligned}$$

If we choose $\lambda = c\big(G^2T^{-1}\log\frac{\log T}{\delta}\big)^{\frac{1}{3}}$ for a constant $c > 0$, then the above inequality translates to $\mathcal{E}(f_T) - \mathcal{E}(f_\rho) = O\Big(\big(G^2T^{-1}\log\frac{\log T}{\delta}\big)^{\frac{1}{3}}\Big)$, which matches our convergence rates up to logarithmic factors. Note that the regularization parameter λ needs to be tuned according to T to balance the bias and variance in (3.5), which may not be accessible in practical implementations. To deal with this issue, a class of fully online regularized algorithms was proposed and investigated by allowing the regularization parameters to vary along the learning process (Ye and Zhou, 2007; Tarres and Yao, 2014). As a comparison, without a regularization parameter to tune, the unregularized online learning algorithm (1.1) achieves a bias-variance balance by tuning only the step sizes. Furthermore, the convergence rates (3.4) require to impose the non-intuitive boundedness assumptions on the gradients encountered during the iterations, which may be violated in practical implementations. This boundedness assumption is removed in our analysis.

4. Proofs

In this section, we present the proofs for the results given in Section 2. Our discussions require to use a property established in the following lemma on functions with (α, L)-Hölder continuous gradients. This lemma is motivated by similar results in the literature (see, e.g., Ying and Zhou, 2017) and we present the proof in Section A for completeness.

Lemma 13 *Let H be a Hilbert space associated with the inner product $\langle\cdot,\cdot\rangle$. Let $\mathcal{G} : H \to \mathbb{R}$ be a convex and differentiable functional satisfying*

$$\|\nabla\mathcal{G}(f) - \nabla\mathcal{G}(\tilde{f})\| \le L\|f - \tilde{f}\|^\alpha, \quad \forall f, \tilde{f} \in H,$$

where $L > 0, \alpha \in (0, 1], \nabla$ is the gradient operator and $\|\cdot\|$ is the norm induced by the inner product. Then, the following inequality holds for any $f, \tilde{f} \in H$

$$\frac{\alpha\|\nabla\mathcal{G}(f) - \nabla\mathcal{G}(\tilde{f})\|^{\frac{1+\alpha}{\alpha}}}{(1+\alpha)L^{\frac{1}{\alpha}}} \le \mathcal{G}(f) - \big[\mathcal{G}(\tilde{f}) + \langle f - \tilde{f}, \nabla\mathcal{G}(\tilde{f})\rangle\big] \le \frac{L\|f - \tilde{f}\|^{1+\alpha}}{1+\alpha}. \tag{4.1}$$

With Lemma 13, we can derive the following lemma on gradients of loss functions at iterates of the algorithm (1.1). Its power consists in bounding the gradients for the possibly unbounded iterates $\{f_t\}_{t\in\mathbb{N}}$ by the gradients for f_H and the excess generalization errors, the first of which can be considered as a constant while the second of which are exactly the terms we are interested in. For a random variable z, we use $\mathbb{E}_z[\cdot]$ to denote the conditional expectation with respect to z.

Lemma 14 *Suppose Assumption 1 holds and $\beta \in (0,1]$. Then,*

$$\mathbb{E}_{z_t}\big[|\phi'(y_t, f_t(x_t))|^{1+\beta}\big] \le 2^\beta L^{\frac{1}{\alpha}}(1+\beta)\big[\mathcal{E}(f_t)-\mathcal{E}(f_H)\big]+ \frac{2^\beta(1-\alpha\beta)}{1+\alpha} + 2^\beta \mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^{1+\beta}\big], \quad \forall t\in\mathbb{N}. \tag{4.2}$$

Proof With the elementary inequality $|u+v|^{1+\beta} \le 2^\beta[|u|^{1+\beta}+|v|^{1+\beta}]$ and the Young's inequality

$$uv \le p^{-1}|u|^p + q^{-1}|v|^q, \quad \forall u,v\in\mathbb{R}, p^{-1}+q^{-1}=1, p\ge 0, \tag{4.3}$$

the term $|\phi'(y_t, f_t(x_t))|^{1+\beta}$ can be controlled by

$$\begin{aligned}
&|\phi'(y_t, f_t(x_t))|^{1+\beta} \le \Big[|\phi'(y_t, f_t(x_t))-\phi'(y_t, f_H(x_t))| + |\phi'(y_t, f_H(x_t))|\Big]^{1+\beta}\\
&\le 2^\beta |\phi'(y_t, f_t(x_t))-\phi'(y_t, f_H(x_t))|^{1+\beta} + 2^\beta|\phi'(y_t, f_H(x_t))|^{1+\beta}\\
&\le \frac{2^\beta\alpha(1+\beta)}{1+\alpha}|\phi'(y_t, f_t(x_t))-\phi'(y_t, f_H(x_t))|^{\frac{1+\alpha}{\alpha}} + \frac{2^\beta(1-\alpha\beta)}{1+\alpha} + 2^\beta|\phi'(y_t, f_H(x_t))|^{1+\beta}.
\end{aligned} \tag{4.4}$$

It follows from the first inequality of (4.1) that

$$\frac{\alpha}{1+\alpha}|\phi'(y_t, f_t(x_t))-\phi'(y_t, f_H(x_t))|^{\frac{1+\alpha}{\alpha}} \le L^{\frac{1}{\alpha}}\Big[\phi(y_t, f_t(x_t))-\phi(y_t, f_H(x_t))-\phi'(y_t, f_H(x_t))(f_t(x_t)-f_H(x_t))\Big].$$

Plugging the above inequality into (4.4) and taking expectations with respect to z_t (note f_t is independent of z_t), we get

$$\begin{aligned}
\mathbb{E}_{z_t}\big[|\phi'(y_t, f_t(x_t))|^{1+\beta}\big] &\le 2^\beta L^{\frac{1}{\alpha}}(1+\beta)\Big[\mathcal{E}(f_t)-\mathcal{E}(f_H)-\big\langle f_t-f_H, \mathbb{E}_{z_t}\big[\phi'(y_t, f_H(x_t))K_{x_t}\big]\big\rangle\Big]\\
&\quad + \frac{2^\beta(1-\alpha\beta)}{1+\alpha} + 2^\beta\mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^{1+\beta}\big]\\
&= 2^\beta L^{\frac{1}{\alpha}}(1+\beta)\big[\mathcal{E}(f_t)-\mathcal{E}(f_H)\big] + \frac{2^\beta(1-\alpha\beta)}{1+\alpha} + 2^\beta\mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^{1+\beta}\big].
\end{aligned}$$

Here the last identity holds since

$$\nabla\mathcal{E}(f_H) = \mathbb{E}_z\big[\phi'(y, f_H(x))K_x\big] = 0.$$

The proof is complete. ■

4.1 Proofs for Convergence in Expectation

Before proving Theorem 1 and Theorem 2 on convergence in expectation, we first present some preparatory results. Our first preliminary result is a weak result on convergence in expectation under a weak condition on the step size sequence (4.5). Eq. (4.6) implies the existence of a sub-index sequence $\{i_t\}_{t\in\mathbb{N}}$ satisfying $\lim_{t\to\infty} A_{i_t}=0$, while (4.7) shows the convergence of a weighted average of the expected excess generalization errors. This result is derived based on a one-step progress inequality in terms of distances in RKHSs (see (4.10)).

Proposition 15 *Let $\{f_t\}_{t\in\mathbb{N}}$ be the sequence given by (1.1) and suppose Assumption 1 holds. If*

$$\lim_{t\to\infty}\eta_t = 0 \quad \textit{and} \quad \sum_{t=1}^\infty \eta_t = \infty, \tag{4.5}$$

then

$$\liminf_{t\to\infty}\mathbb{E}[\mathcal{E}(f_t)-\mathcal{E}(f_H)] = 0 \tag{4.6}$$

and

$$\lim_{T\to\infty}\Big[\sum_{t=1}^T\eta_t\Big]^{-1}\sum_{t=1}^T\eta_t\mathbb{E}[\mathcal{E}(f_t)-\mathcal{E}(f_H)] = 0. \tag{4.7}$$

Lemma 16 *Let $\{\eta_t\}_{t\in\mathbb{N}}$ be a sequence of positive numbers. If $\lim_{t\to\infty}\eta_t=0$ and $\sum_{t=1}^\infty\eta_t=\infty$, then $\lim_{t\to\infty}\big[\sum_{k=1}^t\eta_k\big]^{-1}\sum_{k=1}^t\eta_k^2=0$.*

Proof of Proposition 15 According to the iteration strategy (1.1), we derive

$$\begin{aligned}
\|f_{t+1}-f_H\|^2 &= \|f_t-\eta_t\phi'(y_t, f_t(x_t))K_{x_t}-f_H\|^2\\
&\le \|f_t-f_H\|^2 + \eta_t^2|\phi'(y_t, f_t(x_t))|^2\kappa^2 - 2\eta_t\langle f_t-f_H, \phi'(y_t, f_t(x_t))K_{x_t}\rangle \qquad (4.8)\\
&\le \|f_t-f_H\|^2 + \eta_t^2|\phi'(y_t, f_t(x_t))|^2\kappa^2 + 2\eta_t\big[\phi(y_t, f_H(x_t))-\phi(y_t, f_t(x_t))\big]. \qquad (4.9)
\end{aligned}$$

Note that f_t is independent of z_t. Taking expectations with respect to z_t on both sides and using (4.2) with $\beta=1$, we derive

$$\begin{aligned}
&\mathbb{E}_{z_t}\big[\|f_{t+1}-f_H\|^2\big] \le \|f_t-f_H\|^2 + \eta_t^2\kappa^2\mathbb{E}_{z_t}\big[|\phi'(y_t, f_t(x_t))|^2\big] + 2\eta_t[\mathcal{E}(f_H)-\mathcal{E}(f_t)]\\
&\le \|f_t-f_H\|^2 + 4\eta_t^2\kappa^2L^{\frac{1}{\alpha}}[\mathcal{E}(f_t)-\mathcal{E}(f_H)] + \frac{2(1-\alpha)\eta_t^2\kappa^2}{1+\alpha}\\
&\qquad + 2\eta_t^2\kappa^2\mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^2\big] + 2\eta_t[\mathcal{E}(f_H)-\mathcal{E}(f_t)]\\
&= \|f_t-f_H\|^2 + 2\eta_t\big(1-2\eta_t\kappa^2L^{\frac{1}{\alpha}}\big)[\mathcal{E}(f_H)-\mathcal{E}(f_t)] + 2\eta_t^2\kappa^2\Big(\mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^2\big] + \frac{1-\alpha}{1+\alpha}\Big).
\end{aligned}$$

Since $\lim_{t\to\infty}\eta_t=0$, we can find an integer $t_1\in\mathbb{N}$ such that $\eta_t\le\frac{1}{4\kappa^2L^{\frac{1}{\alpha}}}, \forall t\ge t_1$. This together with $\mathcal{E}(f_H)\le\mathcal{E}(f_t)$ implies

$$\eta_t[\mathcal{E}(f_t)-\mathcal{E}(f_H)] \le \|f_t-f_H\|^2 - \mathbb{E}_{z_t}\big[\|f_{t+1}-f_H\|^2\big] + \gamma\eta_t^2, \quad \forall t\ge t_1, \tag{4.10}$$

where we introduce $\gamma = 2\kappa^2\Big(\mathbb{E}_{z_t}\big[|\phi'(y_t, f_H(x_t))|^2\big] + \frac{1-\alpha}{1+\alpha}\Big)$. Taking expectations followed with a summation from $t = t_1$ to $t = T$ gives

$$\sum_{t=t_1}^{T} \eta_t A_t \leq \mathbb{E}[\|f_{t_1} - f_H\|^2] + \gamma \sum_{t=t_1}^{T} \eta_t^2.$$

It then follows that

$$\begin{aligned}\lim_{T\to\infty} \big[\sum_{t=1}^{T} \eta_t\big]^{-1} \sum_{t=1}^{T} \eta_t A_t &= \lim_{T\to\infty} \big[\sum_{t=1}^{T} \eta_t\big]^{-1} \sum_{t=1}^{t_1-1} \eta_t A_t + \lim_{T\to\infty} \big[\sum_{t=1}^{T} \eta_t\big]^{-1} \sum_{t=t_1}^{T} \eta_t A_t \\ &\leq \lim_{T\to\infty} \big[\sum_{t=1}^{T} \eta_t\big]^{-1} \Big[\mathbb{E}[\|f_{t_1} - f_H\|^2] + \gamma \sum_{t=t_1}^{T} \eta_t^2\Big] = 0,\end{aligned}$$

where we have used $\lim_{t\to\infty} \big[\sum_{k=1}^{t} \eta_k\big]^{-1} \sum_{k=1}^{t} \eta_k^2 = 0$ established in Lemma 16. This establishes (4.7).

We now prove (4.6) by contradiction strategy. Suppose to the contrary that $\liminf_{t\to\infty} A_t = \tilde{a} > 0$. Then, there exists $\tilde{t} \in \mathbb{N}$ such that $A_t \geq 2^{-1}\tilde{a}, \forall t \geq \tilde{t}$, from which we derive from (4.7) that

$$0 = \lim_{T\to\infty} \frac{\sum_{t=1}^{T} \eta_t A_t}{\sum_{t=1}^{T} \eta_t} \geq \frac{\tilde{a}}{2} \lim_{T\to\infty} \frac{\sum_{t=\tilde{t}+1}^{T} \eta_t}{\sum_{t=1}^{T} \eta_t} = \frac{\tilde{a}}{2} - \frac{\tilde{a}}{2} \lim_{T\to\infty} \frac{\sum_{t=1}^{\tilde{t}} \eta_t}{\sum_{t=1}^{T} \eta_t} = \frac{\tilde{a}}{2}.$$

This leads to a contradiction. Therefore, $\liminf_{t\to\infty} A_t = 0$ and the proof is complete. ■

As our second preliminary result, Lemma 17 establishes an upper bound on $\mathbb{E}[\|f_t - f_H\|_2^2]$ in terms of the step size sequence, as well as a lower bound on $\mathbb{E}[\|\nabla\mathcal{E}(f_t)\|^2]$ in terms of the step size sequence and the expected excess generalization errors.

Lemma 17 *Let $\{f_t\}_{t\in\mathbb{N}}$ be the sequence given by (1.1). If Assumption 1 holds and $\lim_{t\to\infty} \eta_t = 0$, then there exist constants $\widehat{C}, \gamma > 0$ independent of t such that the following inequalities hold for any $t \in \mathbb{N}$*

$$\mathbb{E}[\|f_t - f_H\|^2] \leq \widehat{C} + \gamma \sum_{k=1}^{t} \eta_k^2 \tag{4.11}$$

and

$$\mathbb{E}[\|\nabla\mathcal{E}(f_t)\|^2] \geq \frac{\big(\mathbb{E}[\mathcal{E}(f_t) - \mathcal{E}(f_H)]\big)^2}{\widehat{C} + \gamma \sum_{k=1}^{t} \eta_k^2}. \tag{4.12}$$

Proof Since $\mathcal{E}(f_t) \geq \mathcal{E}(f_H)$ for all $t \in \mathbb{N}$, (4.10) implies

$$\mathbb{E}[\|f_{t+1} - f_H\|^2] \leq \mathbb{E}[\|f_t - f_H\|^2] + \eta_t^2\gamma, \quad \forall t \geq t_1,$$

where γ and t_1 are defined in the proof of Proposition 15. Taking a summation of the above inequality from $t = t_1$ to $t = T$ shows

$$\mathbb{E}[\|f_{T+1} - f_H\|^2] \leq \mathbb{E}[\|f_{t_1} - f_H\|^2] + \gamma \sum_{t=t_1}^{T} \eta_t^2 \leq \widehat{C} + \gamma \sum_{t=1}^{T} \eta_t^2,$$

where we introduce $\widehat{C} = \mathbb{E}[\|f_{t_1} - f_H\|^2]$. This establishes (4.11).

We now turn to (4.12). According to the convexity of $\mathcal{E}$ and Schwartz inequality, we get

$$\begin{aligned}\mathbb{E}[\mathcal{E}(f_t)] - \mathcal{E}(f_H) &\leq \mathbb{E}\big[\langle\nabla\mathcal{E}(f_t), f_t - f_H\rangle\big] \leq \mathbb{E}[\|\nabla\mathcal{E}(f_t)\|\|f_t - f_H\|] \\ &\leq \big(\mathbb{E}\big[\|\nabla\mathcal{E}(f_t)\|^2\big]\big)^{\frac{1}{2}} \big(\mathbb{E}\big[\|f_t - f_H\|^2\big]\big)^{\frac{1}{2}}.\end{aligned}$$

The above inequality together with (4.11) gives

$$\mathbb{E}[\big\|\nabla\mathcal{E}(f_t)\big\|^2] \geq \frac{\big(\mathbb{E}\big[\mathcal{E}(f_t) - \mathcal{E}(f_H)\big]\big)^2}{\mathbb{E}[\|f_t - f_H\|^2]} \geq \frac{\big(\mathbb{E}\big[\mathcal{E}(f_t) - \mathcal{E}(f_H)\big]\big)^2}{\widehat{C} + \gamma \sum_{k=1}^{t} \eta_k^2}.$$

This establishes (4.12) and completes the proof. ■

Remark 18 *Eq. (4.11) was derived in Ying and Zhou (2017) under an additional assumption $\sum_{k=1}^{\infty} \eta_k^{1+\alpha} < \infty$, which is removed in Lemma 17. For step sizes of the form $\eta_t = \eta_1 t^{-\theta}$ with $\frac{1}{2} < \theta \leq 1$, it was shown $\mathbb{E}[\|f_t - f_H\|^2] = O\big(t^{1-\theta}\big(\mathcal{E}(f_H) - \inf_f \mathcal{E}(f)\big)\big)$ (Lin and Zhou, 2018). As compared with the results in Ying and Zhou (2017); Lin and Zhou (2018), our discussion implies boundedness of $\mathbb{E}[\|f_t\|^2]$ under a milder condition $\sum_{k=1}^{\infty} \eta_k^2 < \infty$.*

We are now in a position to prove Theorem 1 for the convergence in expectation. Let $\epsilon > 0$ be an arbitrary small number. Our idea is to use Proposition 15, based on one-step progress in terms of the distances in RKHSs, to show that $\{A_t\}_{t\in\mathbb{N}}$ can be smaller than ϵ infinitely often. Once $A_{\tilde{t}} \leq \epsilon$ for a sufficiently large $\tilde{t}$, we can use the assumption $\lim_{t\to\infty} \eta_t^\alpha \sum_{k=1}^{t} \eta_k^2 = 0$ and the one-step progress inequality (4.15) in terms of generalization errors to show $A_t \leq \epsilon$ for any $t \geq \tilde{t}$.

Proof of Theorem 1 Since $\phi'(y, \cdot)$ is (α, L)-Hölder continuous, we can apply the second inequality of (4.1) to show that

$$\phi(y, f_{t+1}(x)) \leq \phi(y, f_t(x)) + (f_{t+1}(x) - f_t(x))\phi'(y, f_t(x)) + \frac{L}{1+\alpha}|f_{t+1}(x) - f_t(x)|^{1+\alpha}.$$

According to the reproducing property $f(x) = \langle f, K_x\rangle, \forall f \in H$ and the iteration scheme (1.1), we know

$$\begin{aligned}\phi(y, f_{t+1}(x)) &\leq \phi(y, f_t(x)) + \langle f_{t+1} - f_t, \phi'(y, f_t(x))K_x\rangle + \frac{L}{1+\alpha}|\langle f_{t+1} - f_t, K_x\rangle|^{1+\alpha} \\ &\leq \phi(y, f_t(x)) - \eta_t\langle\phi'(y_t, f_t(x_t))K_{x_t}, \phi'(y, f_t(x))K_x\rangle + \frac{L\kappa^{1+\alpha}}{1+\alpha}\|f_{t+1} - f_t\|^{1+\alpha} \\ &\leq \phi(y, f_t(x)) - \eta_t\langle\phi'(y_t, f_t(x_t))K_{x_t}, \phi'(y, f_t(x))K_x\rangle + \frac{L\kappa^{2(1+\alpha)}\eta_t^{1+\alpha}}{1+\alpha}|\phi'(y_t, f_t(x_t))|^{1+\alpha}.\end{aligned} \tag{4.13}$$

Putting (4.2) with $\beta = \alpha$ back into (4.13) followed with a conditional expectation with respect to z_t and z yields

$$\mathbb{E}_{z_t}[\mathcal{E}(f_{t+1})] = \mathbb{E}_{z_t,z}[\phi(y, f_{t+1}(x))] \le \mathbb{E}_z[\phi(y, f_t(x))] - \eta_t\big\langle \mathbb{E}_{z_t}[\phi'(y_t, f_t(x_t))K_{x_t}], \mathbb{E}_z[\phi'(y, f_t(x))K_x]\big\rangle$$
$$+ \frac{L\kappa^{2(1+\alpha)}\eta_t^{1+\alpha}}{1+\alpha}\Big[2^\alpha L^{\frac{1}{\alpha}}(1+\alpha)(\mathcal{E}(f_t) - \mathcal{E}(f_H)) + 2^\alpha(1-\alpha) + 2^\alpha \mathbb{E}_z[|\phi'(y, f_H(x))|^{1+\alpha}]\Big]$$
$$\le \mathcal{E}(f_t) - \eta_t\|\nabla\mathcal{E}(f_t)\|^2 + \frac{L\kappa^{2(1+\alpha)}2^\alpha\eta_t^{1+\alpha}\Big[L^{\frac{1}{\alpha}}(1+\alpha)(\mathcal{E}(f_t)-\mathcal{E}(f_H)) + (1-\alpha) + \mathbb{E}_z[|\phi'(y, f_H(x))|^{1+\alpha}]\Big]}{1+\alpha}.$$

Subtracting $\mathcal{E}(f_H)$ from both sides of the above inequality gives

$$\mathbb{E}_{z_t}[\mathcal{E}(f_{t+1})] - \mathcal{E}(f_H) \le \Big[1 + L^{1+\frac{1}{\alpha}}\kappa^{2(1+\alpha)}2^\alpha\eta_t^{1+\alpha}\Big](\mathcal{E}(f_t) - \mathcal{E}(f_H)) - \eta_t\|\nabla\mathcal{E}(f_t)\|^2$$
$$+ \frac{L\kappa^{2(1+\alpha)}2^\alpha\eta_t^{1+\alpha}}{1+\alpha}\Big[(1-\alpha) + \mathbb{E}_z[|\phi'(y, f_H(x))|^{1+\alpha}]\Big]. \quad (4.14)$$

Taking expectations over both sides, the above inequality can be written as

$$A_{t+1} \le (1 + a\eta_t^{1+\alpha})A_t + b\eta_t^{1+\alpha} - \eta_t\mathbb{E}[\|\nabla\mathcal{E}(f_t)\|^2], \quad (4.15)$$

where we introduce the notations

$$a = L^{1+\frac{1}{\alpha}}\kappa^{2(1+\alpha)}2^\alpha \quad \text{and} \quad b = \frac{L\kappa^{2(1+\alpha)}2^\alpha}{1+\alpha}\Big[(1-\alpha) + \mathbb{E}_z[|\phi'(y, f_H(x))|^{1+\alpha}]\Big]. \quad (4.16)$$

Plugging (4.12) into the above inequality gives

$$A_{t+1} \le (1 + a\eta_t^{1+\alpha})A_t + b\eta_t^{1+\alpha} - \frac{\eta_t A_t^2}{\widehat{C} + \gamma\sum_{k=1}^t \eta_k^2}, \quad (4.17)$$

where $\widehat{C}$ and γ are defined in the proof of Lemma 17. The assumption $\lim_{t\to\infty}\eta_t^\alpha\sum_{k=1}^t\eta_k^2 = 0$ implies $\lim_{t\to\infty}\eta_t = 0$ and therefore the assumptions of Proposition 15 hold. Let $\epsilon \in (0,1)$ be an arbitrary number. According to $\liminf_{t\to\infty} A_t = 0$ established in Proposition 15, we can find a $\tilde{t} \in \mathbb{N}$ ($\tilde{t}$ can be sufficiently large) such that $A_{\tilde{t}} \le \epsilon$ and

$$\eta_t^\alpha\big(\widehat{C} + \gamma\sum_{k=1}^t\eta_k^2\big) \le \frac{\epsilon^2}{4(a+b)}, \quad \eta_t^{1+\alpha} \le \frac{\epsilon}{2(a+b)} \quad \forall t \ge \tilde{t}. \quad (4.18)$$

We now prove by induction that $A_t \le \epsilon$ for all $t \ge \tilde{t}$. It suffices to show that $A_{t+1} \le \epsilon$ under the assumption $A_t \le \epsilon$ and $t \ge \tilde{t}$. Since $A_t \le 1$, we derive from (4.17) that

$$A_{t+1} \le A_t + (a+b)\eta_t^{1+\alpha} - \frac{\eta_t A_t^2}{\widehat{C} + \gamma\sum_{k=1}^t\eta_k^2}.$$

We now consider two cases. If $A_t^2 \ge (a+b)\eta_t^\alpha\big(\widehat{C} + \gamma\sum_{k=1}^t\eta_k^2\big)$, then we know $A_{t+1} \le A_t \le \epsilon$. Otherwise, we derive from (4.18) that

$$A_{t+1} \le A_t + (a+b)\eta_t^{1+\alpha} \le \sqrt{(a+b)\eta_t^\alpha\big(\widehat{C} + \gamma\sum_{k=1}^t\eta_k^2\big)} + (a+b)\eta_t^{1+\alpha} \le \epsilon.$$

Putting the above two cases together we derive $A_{t+1} \le \epsilon$. That is, $A_t \le \epsilon$ for all $t \ge \tilde{t}$. Since $\epsilon \in (0,1)$ is arbitrarily chosen, we get $\lim_{t\to\infty} A_t = 0$. ■

The necessary condition in Theorem 2 is established by applying the co-coercivity given in Lemma 13 to bound $\mathcal{E}(f_{t+1})$ in terms of $\mathcal{E}(f_t)$ from below.

Proof of Theorem 2 Since $\phi'(y,\cdot)$ is $(1,L)$-Hölder continuous for any $y \in \mathcal{Y}$, we have

$$\|\nabla\mathcal{E}(f) - \nabla\mathcal{E}(\tilde{f})\| = \big\|\mathbb{E}[\phi'(y, f(x))K_x - \phi'(y, \tilde{f}(x))K_x]\big\| \le \mathbb{E}\big[|\phi'(y, f(x)) - \phi'(y, \tilde{f}(x))|\|K_x\|\big]$$
$$\le L\mathbb{E}\big[|\langle f - \tilde{f}, K_x\rangle|\|K_x\|\big] \le L\kappa^2\|f - \tilde{f}\|. \quad (4.19)$$

That is, $\nabla\mathcal{E}$ is $(1, L\kappa^2)$-Hölder continuous. Lemma 13 with $\alpha = 1$ and $\nabla\mathcal{E}(f_H) = 0$ then yield the following inequality

$$\mathcal{E}(f_t) \ge \mathcal{E}(f_H) + \langle f_t - f_H, \nabla\mathcal{E}(f_H)\rangle + \frac{\|\nabla\mathcal{E}(f_t) - \nabla\mathcal{E}(f_H)\|^2}{2L\kappa^2} = \mathcal{E}(f_H) + \frac{\|\nabla\mathcal{E}(f_t)\|^2}{2L\kappa^2}. \quad (4.20)$$

It follows from the convexity of $\mathcal{E}$ and (1.1) that

$$\mathcal{E}(f_{t+1}) \ge \mathcal{E}(f_t) + \langle\nabla\mathcal{E}(f_t), f_{t+1} - f_t\rangle = \mathcal{E}(f_t) - \eta_t\big\langle\nabla\mathcal{E}(f_t), \phi'(y_t, f_t(x_t))K_{x_t}\big\rangle.$$

Taking expectations over both sides and using (4.20), we derive the following inequality for all $t \in \mathbb{N}$

$$\mathbb{E}[\mathcal{E}(f_{t+1})] \ge \mathbb{E}[\mathcal{E}(f_t)] - \eta_t\mathbb{E}[\|\nabla\mathcal{E}(f_t)\|^2] \ge \mathbb{E}[\mathcal{E}(f_t)] - 2L\kappa^2\eta_t\mathbb{E}[\mathcal{E}(f_t) - \mathcal{E}(f_H)].$$

Hence,

$$A_{t+1} \ge \big(1 - 2L\kappa^2\eta_t\big)A_t, \quad \forall t \in \mathbb{N}.$$

The assumption $\eta_t \le 1/(6L\kappa^2)$ and the elementary inequality $1 - \eta \ge \exp(-2\eta), \forall\eta \in (0, 1/3)$ (Lin and Zhou, 2015) then show

$$A_{t+1} \ge \exp\big(-4L\kappa^2\eta_t\big)A_t \ge \prod_{k=1}^t\exp\big(-4L\kappa^2\eta_k\big)A_1 = \exp\Big(-4L\kappa^2\sum_{k=1}^t\eta_k\Big)A_1,$$

which, together with the condition $\lim_{t\to\infty}A_t = 0$ and $A_1 \ne 0$, then establishes the necessary condition $\sum_{t=1}^\infty\eta_t = \infty$. ■

4.2 Proofs for Almost Sure Convergence

We use the following Doob's martingale convergence theorem (see, e.g., Doob, 1994, page 195) to prove Theorem 4 on almost sure convergence. Specifically, we will use the one-step progress inequality in terms of generalization errors to construct a supermartingale, whose almost sure convergence would imply the almost sure convergence of $\{\hat{A}_t\}_{t\in\mathbb{N}}$.

Lemma 19 *Let $\{\tilde{X}_t\}_{t\in\mathbb{N}}$ be a sequence of non-negative random variables with $\mathbb{E}[\tilde{X}_1] < \infty$ and let $\{\mathcal{F}_t\}_{t\in\mathbb{N}}$ be a nested sequence of sets of random variables with $\mathcal{F}_t \subset \mathcal{F}_{t+1}$ for all $t \in \mathbb{N}$. If $\mathbb{E}[\tilde{X}_{t+1}|\mathcal{F}_t] \le \tilde{X}_t$ for every $t \in \mathbb{N}$, then $\tilde{X}_t$ converges to a nonnegative random variable $\tilde{X}$ almost surely. Furthermore, $\tilde{X} < \infty$ almost surely.*

Proof of Theorem 4 Eq. (4.14) gives

$$\mathbb{E}_{z_t}[\hat{A}_{t+1}] \leq (1+a\eta_t^{1+\alpha})\hat{A}_t + b\eta_t^{1+\alpha}, \quad \forall t \in \mathbb{N}, \tag{4.21}$$

with a and b are defined in the proof of Theorem 1. Denote $c = \prod_{k=1}^{\infty}(1+a\eta_k^{1+\alpha})$, which, according to the elementary inequality $1+\tau \leq \exp(\tau), \tau \geq 0$ and (2.3), satisfies

$$c \leq \prod_{k=1}^{\infty} \exp(a\eta_k^{1+\alpha}) = \exp\big(a\sum_{k=1}^{\infty}\eta_k^{1+\alpha}\big) < \infty.$$

Multiplying both sides of (4.21) by $\prod_{k=t+1}^{\infty}(1+a\eta_k^{1+\alpha})$, we derive

$$\begin{aligned}\prod_{k=t+1}^{\infty}(1+a\eta_k^{1+\alpha})\mathbb{E}_{z_t}\big[\hat{A}_{t+1}\big] &\leq \prod_{k=t}^{\infty}(1+a\eta_k^{1+\alpha})\hat{A}_t + b\eta_t^{1+\alpha}\prod_{k=t+1}^{\infty}(1+a\eta_k^{1+\alpha}) \\ &\leq \prod_{k=t}^{\infty}(1+a\eta_k^{1+\alpha})\hat{A}_t + bc\eta_t^{1+\alpha}. \end{aligned} \tag{4.22}$$

Introduce the stochastic process

$$\hat{X}_t = \prod_{k=t}^{\infty}(1+a\eta_k^{1+\alpha})\hat{A}_t + bc\sum_{k=t}^{\infty}\eta_k^{1+\alpha}, \quad t \in \mathbb{N} \tag{4.23}$$

According to (2.3), we know $\mathbb{E}[\hat{X}_1] < \infty$. Eq. (4.22) implies $\mathbb{E}_{z_t}[\hat{X}_{t+1}] \leq \hat{X}_t$ for all $t \in \mathbb{N}$, that is, $\{\hat{X}_t\}_{t\in\mathbb{N}}$ is a supermartingale taking non-negative values. Lemma 19 then implies that $\lim_{t\to\infty}\hat{X}_t = \hat{X}$ for a non-negative random variable $\hat{X}$ almost surely. Let $\Omega = \{\omega = \{z_t\}_{t\in\mathbb{N}}\}$ be the set for which $\{\hat{X}_t(\omega)\}_t$ converges to $\hat{X}(\omega)$ as $t \to \infty$ and $\hat{X}(\omega) < \infty$. Then, $\Pr\{\Omega\} = 1$, where $\Pr\{\Omega\}$ denotes the probability with which the event Ω happens. Let $\omega \in \Omega$ and $\epsilon > 0$. Since $\sum_{t=1}^{\infty}\eta_t^{1+\alpha} < \infty$, we can find $\tilde{t} \in \mathbb{N}$ such that

$$\sum_{t=\tilde{t}}^{\infty}\eta_t^{1+\alpha} < \frac{\epsilon}{3bc}, \quad \prod_{k=\tilde{t}}^{\infty}(1+a\eta_k^{1+\alpha}) < 1 + \frac{\epsilon}{3\hat{X}(\omega)+\epsilon} \text{ and } |\hat{X}_t(\omega) - \hat{X}(\omega)| < \frac{\epsilon}{3}, \quad \forall t \geq \tilde{t}.$$

It then follows from (4.23) that

$$\begin{aligned}\hat{A}_t(\omega) \leq \hat{X}_t(\omega) &\leq \Big(1 + \frac{\epsilon}{3\hat{X}(\omega)+\epsilon}\Big)\hat{A}_t(\omega) + \frac{\epsilon}{3} \leq \hat{A}_t(\omega) + \frac{\epsilon\hat{X}_t(\epsilon)}{3\hat{X}(\omega)+\epsilon} + \frac{\epsilon}{3} \\ &\leq \hat{A}_t(\omega) + \frac{\epsilon\big(\hat{X}(\omega)+\frac{\epsilon}{3}\big)}{3\hat{X}(\epsilon)+\epsilon} + \frac{\epsilon}{3} \leq \hat{A}_t(\omega) + \frac{2\epsilon}{3}, \quad \forall t \geq \tilde{t},\end{aligned}$$

from which we derive

$$\hat{X}(\omega) - \epsilon \leq \hat{X}_t(\omega) - \frac{2\epsilon}{3} \leq \hat{A}_t(\omega) \leq \hat{X}(\omega) + \epsilon, \quad \forall t \geq \tilde{t}.$$

That is, $\lim_{t\to\infty}\hat{A}_t(\omega) = \hat{X}(\omega)$ for any $\omega \in \Omega$, i.e., $\lim_{t\to\infty}\hat{A}_t = \hat{X}$ almost surely. Since $\sum_{t=1}^{\infty}\eta_t^{1+\alpha} < \infty$, we know $\sum_{t=1}^{\infty}\eta_t^2 < \infty$ and $\lim_{t\to\infty}\eta_t = 0$. This further implies

$$\lim_{t\to\infty}\eta_t^{\alpha}\sum_{k=1}^{t}\eta_k^2 = 0$$

and therefore the assumptions in Theorem 1 hold. Theorem 1 shows that $\lim_{t\to\infty}\mathbb{E}[\hat{A}_t] = 0$. By Fatou's lemma, we get

$$0 \leq \mathbb{E}[\hat{X}] = \mathbb{E}\big[\lim_{t\to\infty}\hat{A}_t\big] \leq \liminf_{t\to\infty}\mathbb{E}[\hat{A}_t] = 0,$$

which implies that $\mathbb{E}[\hat{X}] = 0$ and therefore $\hat{X} = 0$ almost surely since $\hat{X}$ is non-negative. Combining the above deductions together, we know that $\lim_{t\to\infty}\hat{A}_t = 0$ almost surely. ■

Our proof of Theorem 6 is based on the following lemma which can be found in Lin and Zhou (2015) as an easy consequence of the Borel-Cantelli Lemma.

Lemma 20 *Let $\{\xi_t\}_{t\in\mathbb{N}}$ be a sequence of non-negative random variables and $\{\epsilon_t\}_{t\in\mathbb{N}}$ be a sequence of positive numbers satisfying $\lim_{t\to\infty}\epsilon_t = 0$. If $\sum_{t=1}^{\infty}\Pr\{\xi_t > \epsilon_t\} < \infty$, then ξ_t converges to 0 almost surely.*

Proof of Theorem 6 Introduce $\delta_t = t^{-2}$ for all $t \in \mathbb{N}$. According to Corollary 11, there exists a constant $\widetilde{C}_1$ such that

$$\Pr\Big\{t^{\min\{1-\theta,(\alpha+1)\theta-1\}-\epsilon}\hat{A}_t \geq \widetilde{C}_1 t^{-\epsilon}\log^2\frac{t}{\delta_t}\Big\} \leq \delta_t.$$

Since $\sum_{t=1}^{\infty}\delta_t < \infty$ and $\lim_{t\to\infty}t^{-\epsilon}\log^2\frac{t}{\delta_t} = 0$, we can apply Lemma 20 here to show (2.4). The proof is complete. ■

4.3 Proofs for Convergence Rates with High Probability

Our discussion on high-probability convergence rates roots its foundation on the following concentration inequalities of martingales. Part (a) is the Azuma-Hoeffding inequality for martingales with bounded differences (Hoeffding, 1963), while Part (b) is a Bernstein-type inequality which exploits information on variances to derive improved concentration inequalities for martingales (Zhang, 2005). A remarkable property of this Bernstein-type inequality is that it involves a conditional variance which itself is a random variable.

Lemma 21 *Let $z_1, \ldots, z_n$ be a sequence of random variables such that z_k may depend on the previous random variables $z_1, \ldots, z_{k-1}$ for all $k = 1, \ldots, n$. Consider a sequence of functionals $\xi_k(z_1, \ldots, z_k), k = 1, \ldots, n$.*

(a) Assume that $|\xi_k - \mathbb{E}_{z_k}[\xi_k]| \leq b_k$ for each k. Let $\delta \in (0,1)$. With probability at least $1-\delta$ we have

$$\sum_{k=1}^{n}\xi_k - \sum_{k=1}^{n}\mathbb{E}_{z_k}[\xi_k] \leq \Big(2\sum_{k=1}^{n}b_k^2\log\frac{1}{\delta}\Big)^{\frac{1}{2}}. \tag{4.24}$$

(b) Assume that $\xi_k - \mathbb{E}_{z_k}[\xi_k] \leq b$ for each k. Let $\rho > 0$ and $\delta \in (0,1)$. With probability at least $1-\delta$ we have

$$\sum_{k=1}^{n}\xi_k - \sum_{k=1}^{n}\mathbb{E}_{z_k}[\xi_k] \leq \frac{(e^{\rho}-\rho-1)\sigma_n^2}{\rho b} + \frac{b\log\frac{1}{\delta}}{\rho}, \tag{4.25}$$

where $\sigma_n^2 = \sum_{k=1}^{n}\mathbb{E}_{z_k}(\xi_k - \mathbb{E}_{z_k}\xi_k)^2$ is the conditional variance.

Since $\phi'(y,\cdot)$ is (α, L)-Hölder continuous, convex and non-negative, Proposition 1 in Ying and Zhou (2017) shows that $\phi(y,\cdot)$ satisfies the following self-bounding property

$$|\phi'(y,s)|^{\frac{1+\alpha}{\alpha}} \leq \frac{(1+\alpha)^{1+\frac{1}{\alpha}}}{\alpha} L^{\frac{1}{\alpha}} \phi(y,s), \quad \forall y \in \mathcal{Y}, s \in \mathbb{R}.$$

The Young's inequality (4.3) then implies

$$\begin{aligned} |\phi'(y,s)|^2 &\leq \alpha^{-\frac{2\alpha}{1+\alpha}} (1+\alpha)^2 L^{\frac{2}{1+\alpha}} \phi(y,s)^{\frac{2\alpha}{1+\alpha}} \\ &\leq \alpha^{-\frac{2\alpha}{1+\alpha}} L^{\frac{2}{1+\alpha}} (1+\alpha) \Big(2\alpha \phi(y,s) + 1 - \alpha \Big) = A\phi(y,s) + B, \end{aligned} \tag{4.26}$$

where

$$A = 2\alpha^{\frac{1-\alpha}{1+\alpha}} L^{\frac{2}{1+\alpha}} (1+\alpha) \quad \text{and} \quad B = \alpha^{-\frac{2\alpha}{1+\alpha}} L^{\frac{2}{1+\alpha}} (1-\alpha^2). \tag{4.27}$$

Below we will use Part (b) of Lemma 21 to show almost boundedness of $\{f_t\}_{t\in\mathbb{N}}$ with high probability (Proposition 9). To this aim, we first establish a crude bound on the iterates $\{f_t\}_{t\in\mathbb{N}}$ in terms of the step size sequence.

Lemma 22 *Let $\{f_t\}_{t\in\mathbb{N}}$ be the sequence given by (1.1). Assume $\eta_t \leq \frac{1}{A\kappa^2}$ for all $t \in \mathbb{N}$. Then, the following inequalities hold for all $t \in \mathbb{N}$*

$$\|f_{t+1} - f_H\|^2 \leq C_1 \sum_{k=0}^{t} \eta_k \quad \text{and} \quad \|f_{t+1}\|^2 \leq C_1 \sum_{k=1}^{t} \eta_k, \tag{4.28}$$

where we introduce for brevity $\eta_0 = 1$ and

$$C_1 = \|f_H\|_2^2 + A^{-1}B + 2\max\Big\{ \sup_{y\in\mathcal{Y}} \phi(y,0), \sup_{z\in\mathcal{Z}} \phi(y, f_H(x)) \Big\}. \tag{4.29}$$

Furthermore, if $\eta_t \leq \frac{1}{A\kappa^2}$ and $\eta_{t+1} \leq \eta_t$ for all $t \in \mathbb{N}$, we have

$$\sum_{k=1}^{t} \eta_k^2 \phi(y_k, f_k(x_k)) \leq \eta_1 \|f_H\|^2 + C_2 \sum_{k=1}^{t} \eta_k^2, \tag{4.30}$$

where we introduce

$$C_2 = 2\sup_{z\in\mathcal{Z}} \phi(y, f_H(x)) + \eta_1 \kappa^2 B. \tag{4.31}$$

Proof Plugging (4.26) into (4.9) gives

$$\begin{aligned} \|f_{t+1} - f_H\|^2 &\leq \|f_t - f_H\|^2 + \eta_t^2 \kappa^2 [A\phi(y_t, f_t(x_t)) + B] + 2\eta_t [\phi(y_t, f_H(x_t)) - \phi(y_t, f_t(x_t))] \\ &= \|f_t - f_H\|^2 + 2\eta_t \phi(y_t, f_H(x_t)) + \eta_t^2 \kappa^2 B + \eta_t (A\eta_t \kappa^2 - 2)\phi(y_t, f_t(x_t)) \\ &\leq \|f_t - f_H\|^2 + 2\eta_t \phi(y_t, f_H(x_t)) + \eta_t^2 \kappa^2 B \leq \|f_t - f_H\|^2 + \eta_t \big(2\phi(y_t, f_H(x_t)) + A^{-1} B \big), \end{aligned} \tag{4.32}$$

where the last two inequalities follow from the assumption $\eta_t \leq \frac{1}{A\kappa^2}$. According to the definitions of C_1 in (4.29) and η_0, it then follows that

$$\|f_{t+1} - f_H\|^2 = \|f_H\|^2 + \sum_{k=1}^{t} \big[\|f_{k+1} - f_H\|^2 - \|f_k - f_H\|^2 \big] \leq C_1 \sum_{k=0}^{t} \eta_k.$$

This establishes the first inequality in (4.28). We now prove the second inequality in (4.28). Notice that (4.9) also holds if we replace f_H with 0. This, together with (4.26) and $\eta_t \leq \frac{1}{A\kappa^2}$, gives

$$\begin{aligned} \|f_{t+1}\|^2 &\leq \|f_t\|^2 + \eta_t^2 \kappa^2 [A\phi(y_t, f_t(x_t)) + B] + 2\eta_t [\phi(y_t, 0) - \phi(y_t, f_t(x_t))] \\ &= \|f_t\|^2 + 2\eta_t \phi(y_t, 0) + \eta_t^2 \kappa^2 B + \eta_t (A\eta_t \kappa^2 - 2)\phi(y_t, f_t(x_t)) \\ &\leq \|f_t\|^2 + 2\eta_t \phi(y_t, 0) + \eta_t A^{-1} B. \end{aligned}$$

It is now clear

$$\|f_{t+1}\|^2 = \sum_{k=1}^{t} \big[\|f_{k+1}\|^2 - \|f_k\|^2 \big] \leq C_1 \sum_{k=1}^{t} \eta_k.$$

We now show (4.30). Applying $\eta_t \leq \frac{1}{A\kappa^2}$ in (4.32) gives

$$\eta_t \phi(y_t, f_t(x_t)) \leq \|f_t - f_H\|^2 - \|f_{t+1} - f_H\|^2 + 2\eta_t \phi(y_t, f_H(x_t)) + \eta_t^2 \kappa^2 B. \tag{4.33}$$

Multiplying both sides of the above inequality by η_t and using $\eta_{t+1} \leq \eta_t$, we derive

$$\begin{aligned} \eta_t^2 \phi(y_t, f_t(x_t)) &\leq \eta_t \big[\|f_t - f_H\|^2 - \|f_{t+1} - f_H\|^2 \big] + 2\eta_t^2 \phi(y_t, f_H(x_t)) + \eta_t^3 \kappa^2 B \\ &\leq \eta_t \|f_t - f_H\|^2 - \eta_{t+1} \|f_{t+1} - f_H\|^2 + 2\eta_t^2 \phi(y_t, f_H(x_t)) + \eta_t^3 \kappa^2 B. \end{aligned}$$

Taking a summation of the above inequality gives (4.30). The proof is complete. ■

Based on the above lemma, Proposition 23 gives a high-probability bound on $\|f_{t+1} - f_H\|^2$ in terms of $\sum_{k=1}^{t} \eta_k^2 \|f_k - f_H\|^2$. Proposition 23 is proved based on a one-step progress inequality (4.37) in terms of the RKHS distances, where the involved martingale is controlled by a Bernstein-type inequality with the dominant variance term cancelled out by the negative term $-2\sum_{k=1}^{t} \eta_k A_k$ existing in the one-step progress inequality.

Proposition 23 *Suppose assumptions in Theorem 7 hold. Let $\delta \in (0,1)$ and C_η, C_3, C_4 be constants defined by*

$$C_\eta = \sup_{k\in\mathbb{N}} \eta_k \sum_{j=0}^{k} \eta_j < \infty, \tag{4.34}$$

$$C_3 = \sup_{z_k \in \mathcal{Z}} \big\| \phi'(y_k, f_H(x_k)) K_{x_k} - \mathbb{E}_z[\phi'(y, f_H(x)) K_x] \big\|, \; C_4 = \frac{2(1-\alpha)\kappa^2}{1+\alpha} + 2\kappa^2 \mathbb{E}_z\big[|\phi'(y, f_H(x))|^2 \big]. \tag{4.35}$$

Then, there exists a constant ρ_1 (explicitly given in the proof and independent of t as well as the step size sequence) such that the following inequality holds with probability at least $1-\delta$

$$\begin{aligned} \|f_{t+1} - f_H\|^2 \leq (\eta_1 \kappa^2 A + 1)\|f_H\|^2 + (AC_2 + B)\kappa^2 \sum_{k=1}^{t} \eta_k^2 + \frac{C_4 \sum_{k=1}^{t} \big[\eta_k^2 \|f_H - f_k\|^2 \big]}{2C_1 C_\eta \kappa^2 L^{\frac{1}{\alpha}}} \\ + \frac{\big(2C_3 C_1^{\frac{1}{2}} C_\eta + 4L(C_1^{\frac{1}{2}}\kappa)^{\alpha+1} C_\eta \big) \log \frac{1}{\delta}}{\rho_1}. \end{aligned} \tag{4.36}$$

Proof The assumption $\sum_{t=1}^{\infty}\eta_t^2<\infty$ implies that C_η in (4.34) is well defined since $\eta_k\sum_{j=1}^k\eta_j\le\sum_{j=1}^k\eta_j^2<\infty$. According to (4.8) and (4.26), we derive

$$\begin{aligned}\|f_{k+1}-f_H\|^2\le\|f_k-f_H\|^2+\eta_k^2\kappa^2\big(A\phi(y_k,f_k(x_k))+B\big)+2\eta_k\langle f_H-f_k,\mathbb{E}_{z_k}[\phi'(y_k,f_k(x_k))K_{x_k}]\rangle\\+2\eta_k\big\langle f_H-f_k,\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}[\phi'(y_k,f_k(x_k))K_{x_k}]\big\rangle.\quad(4.37)\end{aligned}$$

Using the convexity of ϕ followed with a summation from $k=1$ to t gives

$$\begin{aligned}\|f_{t+1}-f_H\|^2&\le\|f_H\|^2+\kappa^2\sum_{k=1}^t\eta_k^2\big(A\phi(y_k,f_k(x_k))+B\big)+2\sum_{k=1}^t\eta_k\big[\mathcal{E}(f_H)-\mathcal{E}(f_k)\big]\\&\quad+2\sum_{k=1}^t\eta_k\big\langle f_H-f_k,\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}\big[\phi'(y_k,f_k(x_k))K_{x_k}\big]\big\rangle\\&\le(\eta_1A\kappa^2+1)\|f_H\|^2+(AC_2+B)\kappa^2\sum_{k=1}^t\eta_k^2+2\sum_{k=1}^t\eta_k\big[\mathcal{E}(f_H)-\mathcal{E}(f_k)\big]\\&\quad+2\sum_{k=1}^t\eta_k\big\langle f_H-f_k,\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}\big[\phi'(y_k,f_k(x_k))K_{x_k}\big]\big\rangle,\quad(4.38)\end{aligned}$$

where the last inequality is due to (4.30). We now estimate the last term of the above inequality with Lemma 21. To this aim, we need to control both the magnitudes and variances for the martingale difference sequences.

Introduce a sequence of functionals $\xi_k,k\in\mathbb{N}$ as follows

$$\xi_k=\eta_k\big\langle f_H-f_k,\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}\big[\phi'(y_k,f_k(x_k))K_{x_k}\big]\big\rangle.$$

It is clear

$$\begin{aligned}&\big\|\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}[\phi'(y_k,f_k(x_k))K_{x_k}]\big\|\le\big\|\phi'(y_k,f_k(x_k))K_{x_k}-\phi'(y_k,f_H(x_k))K_{x_k}\big\|\\&\quad+\big\|\phi'(y_k,f_H(x_k))K_{x_k}-\mathbb{E}_z[\phi'(y,f_H(x))K_x]\big\|+\mathbb{E}_z[\|(\phi'(y,f_H(x))-\phi'(y,f_k(x)))K_x\|]\\&\le\sup_{z_k\in\mathcal{Z}}\big\|\phi'(y_k,f_H(x_k))K_{x_k}-\mathbb{E}_z[\phi'(y,f_H(x))K_x]\big\|+2L\kappa\sup_{x\in\mathcal{X}}|f_k(x)-f_H(x)|^\alpha,\end{aligned}$$

where we have used the Jensen's inequality in the first step. But

$$|f_k(x)-f_H(x)|=|\langle f_k-f_H,K_x\rangle|\le\|f_k-f_H\|\kappa.$$

Combining the above two inequalities and using the definition of C_3 in (4.35) give

$$\big\|\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}[\phi'(y_k,f_k(x_k))K_{x_k}]\big\|\le C_3+2L\|f_k-f_H\|^\alpha\kappa^{\alpha+1}.\quad(4.39)$$

It then follows from (4.28) and $\mathbb{E}_{z_k}[\xi_k]=0$ that (note $\eta_0=1$)

$$\begin{aligned}\xi_k-\mathbb{E}_{z_k}[\xi_k]=\xi_k&\le\eta_k\|f_H-f_k\|\big\|\phi'(y_k,f_k(x_k))K_{x_k}-\mathbb{E}_{z_k}\big[\phi'(y_k,f_k(x_k))K_{x_k}\big]\big\|\\&\le\eta_kC_3\|f_H-f_k\|+2L\eta_k\kappa^{\alpha+1}\|f_H-f_k\|^{1+\alpha}\quad(4.40)\\&\le\eta_kC_3C_1^{\frac12}\big(\sum_{j=0}^{k-1}\eta_j\big)^{\frac12}+2L(C_1^{\frac12}\kappa)^{\alpha+1}\eta_k\big(\sum_{j=0}^{k-1}\eta_j\big)^{\frac{1+\alpha}{2}}\\&\le C_3C_1^{\frac12}C_\eta+2L(C_1^{\frac12}\kappa)^{\alpha+1}C_\eta.\end{aligned}$$

Here we have used the definition of C_η given in (4.34). Furthermore, according to Lemma 14 with $\beta=1$ and the definition of C_4 in (4.35), the conditional variances can be controlled by (note $\mathbb{E}[(\xi-\mathbb{E}[\xi])^2]<\mathbb{E}[\xi^2]$ for a real-valued random variable ξ)

$$\begin{aligned}\sum_{k=1}^t\mathbb{E}_{z_k}(\xi_k-\mathbb{E}_{z_k}[\xi_k])^2&\le\sum_{k=1}^t\eta_k^2\mathbb{E}_{z_k}\big[\big\langle f_H-f_k,\phi'(y_k,f_k(x_k))K_{x_k}\big\rangle^2\big]\\&\le\sum_{k=1}^t\eta_k^2\|f_H-f_k\|^2\kappa^2\mathbb{E}_{z_k}[|\phi'(y_k,f_k(x_k))|^2]\\&\le\sum_{k=1}^t\eta_k^2\|f_H-f_k\|^2\Big(4\kappa^2L^{\frac1\alpha}[\mathcal{E}(f_k)-\mathcal{E}(f_H)]+C_4\Big).\end{aligned}$$

According to (4.28) and the definition of C_η in (4.34), we can further get

$$\begin{aligned}\sum_{k=1}^t\mathbb{E}_{z_k}(\xi_k-\mathbb{E}_{z_k}[\xi_k])^2&\le4L^{\frac1\alpha}C_1\kappa^2\sum_{k=1}^t\Big[\eta_k^2\big(\sum_{j=0}^{k-1}\eta_j\big)\big(\mathcal{E}(f_k)-\mathcal{E}(f_H)\big)\Big]+C_4\sum_{k=1}^t\eta_k^2\|f_H-f_k\|^2\\&\le4L^{\frac1\alpha}C_1C_\eta\kappa^2\sum_{k=1}^t\eta_k\big(\mathcal{E}(f_k)-\mathcal{E}(f_H)\big)+C_4\sum_{k=1}^t\eta_k^2\|f_H-f_k\|^2.\end{aligned}$$

Let ρ_1 be the largest positive constant such that (such ρ_1 exists since $\lim_{\rho\to0}\frac{e^\rho-\rho-1}{\rho}=0$)

$$\frac{(e^{\rho_1}-\rho_1-1)L^{\frac1\alpha}C_1^{\frac12}\kappa^2}{C_3+2LC_1^{\frac\alpha2}\kappa^{\alpha+1}}\le\frac{\rho_1}{4}.$$

Since C_1 and C_3 do not depend on the step size sequence, ρ_1 is also a constant independent of the step size sequence. Plugging the above estimates on the magnitudes and variances of ξ_k into Part (b) of Lemma 21, we derive the following inequality with probability at least $1-\delta$

$$\begin{aligned}\sum_{k=1}^t\xi_k&\le\frac{(e^{\rho_1}-\rho_1-1)}{\rho_1\big(C_3C_1^{\frac12}C_\eta+2L(C_1^{\frac12}\kappa)^{\alpha+1}C_\eta\big)}\Big[4L^{\frac1\alpha}C_1C_\eta\kappa^2\sum_{k=1}^t\eta_k\big(\mathcal{E}(f_k)-\mathcal{E}(f_H)\big)\\&\qquad+C_4\sum_{k=1}^t\eta_k^2\|f_H-f_k\|^2\Big]+\frac{\big(C_3C_1^{\frac12}C_\eta+2L(C_1^{\frac12}\kappa)^{\alpha+1}C_\eta\big)\log\frac1\delta}{\rho_1}\\&\le\sum_{k=1}^t\eta_k\big(\mathcal{E}(f_k)-\mathcal{E}(f_H)\big)+\frac{C_4\sum_{k=1}^t\big[\eta_k^2\|f_H-f_k\|^2\big]}{4C_1C_\eta\kappa^2L^{\frac1\alpha}}+\frac{\big(C_3C_1^{\frac12}C_\eta+2L(C_1^{\frac12}\kappa)^{\alpha+1}C_\eta\big)\log\frac1\delta}{\rho_1}.\end{aligned}$$

Plugging this inequality into (4.38) gives the stated inequality with probability at least $1-\delta$. ■

According to Proposition 9 and the assumption $\sum_{k=1}^\infty\eta_k^2<\infty$, one can show essentially that $\max_{1\le t\le T}\|f_t-f_H\|^2\le\frac12\max_{1\le t\le T}\|f_t-f_H\|^2+c\log T$ for a constant $c>0$, from which one can establish the boundedness of the iterates with high probability (up to logarithmic factors).

Proof of Proposition 9 We define the subset $\Omega \subset \mathcal{Z}^T$ by

$$\Omega = \Big\{(z_1,\ldots,z_T) : \|f_{t+1}-f_H\|^2 \le C_5 + \frac{C_4\sum_{k=1}^t \big[\eta_k^2\|f_H-f_k\|^2\big]}{2C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}} + C_6\log\frac{T}{\delta} \text{ for all } t=1,\ldots,T\Big\},$$

where we introduce

$$C_5 = (\eta_1\kappa^2A+1)\|f_H\|^2 + (AC_2+B)\kappa^2\sum_{k=1}^\infty \eta_k^2, \quad C_6 = \frac{2C_3C_1^{\frac{1}{2}}C_\eta + 4L(C_1^{\frac{1}{2}}\kappa)^{\alpha+1}C_\eta}{\rho_1}. \tag{4.41}$$

Applying Proposition 23 together with union bounds on probabilities of events, we have $\Pr\{\Omega\} \ge 1-\delta$. Since $\sum_{t=1}^\infty \eta_t^2 < \infty$, there exists a $t_2 \in \mathbb{N}$ such that

$$C_4\sum_{k=t_2}^\infty \eta_k^2 \le C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}.$$

Under the event Ω, we know

$$\begin{aligned}\|f_{t+1}-f_H\|^2 &\le C_5 + \frac{C_4\sum_{k=1}^{t_2}\big[\eta_k^2\|f_H-f_k\|^2\big]}{2C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}} + \frac{C_4\sum_{k=t_2+1}^{t}\big[\eta_k^2\|f_H-f_k\|^2\big]}{2C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}} + C_6\log\frac{T}{\delta}\\ &\le C_5 + C_7 + \frac{1}{2}\max_{t_2<k\le t}\|f_k-f_H\|^2 + C_6\log\frac{T}{\delta}\\ &\le C_5 + C_7 + \frac{1}{2}\max_{1\le k\le T}\|f_k-f_H\|^2 + C_6\log\frac{T}{\delta}, \qquad \forall t=1,\ldots,T.\end{aligned}$$

where we have used the inequality

$$\frac{C_4\sum_{k=1}^{t_2}\big[\eta_k^2\|f_H-f_k\|^2\big]}{2C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}} \le \frac{C_4C_1\sum_{k=1}^{t_2}\big[\eta_k^2\sum_{j=0}^{k-1}\eta_j\big]}{2C_1C_\eta\kappa^2L^{\frac{1}{\alpha}}} := C_7.$$

Under the event Ω, it is now clear that

$$\max_{1\le t\le T}\|f_t-f_H\|^2 \le C_5 + C_7 + \frac{1}{2}\max_{1\le k\le T}\|f_k-f_H\|^2 + C_6\log\frac{T}{\delta}.$$

Solving the above linear inequality yields the stated inequality with $\bar{C} = \max\{2(C_5+C_6+C_7),1\}$ with probability at least $1-\delta$. ■

We are now in a position to prove Theorem 7 on general high-probability convergence rates for a weighted average of iterates. The underlying idea is to construct a modified martingale difference sequence by imposing a constraint on the iterates, which is then estimated by applying the Azuma-Hoeffding inequality on martingales. Furthermore, according to Proposition 9, this modified martingale difference sequence would be identical to the original martingale difference sequence with high probability. Let $\mathbb{I}_{\mathcal{A}}$ denote the indicator function of an event $\mathcal{A}$.

Proof of Theorem 7 We now introduce the following sequence of functionals $\xi_k', k = 1,\ldots,T$ by

$$\xi_k' = \eta_k\big\langle f_H - f_k, \phi'(y_k,f_k(x_k))K_{x_k} - \mathbb{E}_{z_k}\big[\phi'(y_k,f_k(x_k))K_{x_k}\big]\big\rangle\mathbb{I}_{\{\|f_k-f_H\|^2\le\bar{C}\log\frac{2T}{\delta}\}},$$

where $\bar{C}$ is defined in Proposition 9. Analogous to (4.40), we have

$$\begin{aligned}|\xi_k'| &\le \Big[\eta_kC_3\|f_H-f_k\| + 2L\eta_k\kappa^{\alpha+1}\|f_H-f_k\|^{1+\alpha}\Big]\mathbb{I}_{\{\|f_k-f_H\|^2\le\bar{C}\log\frac{2T}{\delta}\}}\\ &\le \big(C_3+2L\kappa^{\alpha+1}\big)\eta_k\max\Big(\|f_H-f_k\|^2,1\Big)\mathbb{I}_{\{\|f_k-f_H\|^2\le\bar{C}\log\frac{2T}{\delta}\}}\\ &\le \big(C_3+2L\kappa^{\alpha+1}\big)\eta_k\bar{C}\log\frac{2T}{\delta} := b_k.\end{aligned} \tag{4.42}$$

It is clear that $\mathbb{E}_{z_k}[\xi_k'] = 0$ and ξ_k' only depends on $z_1,\ldots,z_k$. According to Part (a) of Lemma 21, there exists a subset $\Omega' = \{(z_1,\ldots,z_T) : z_1,\ldots,z_T \in \mathcal{Z}\} \subset \mathcal{Z}^T$ with probability measure $\Pr\{\Omega'\} \ge 1-\frac{\delta}{2}$ such that for any $(z_1,\ldots,z_T) \in \Omega'$ the following inequality holds

$$\sum_{k=1}^T \xi_k' \le \Big(2\sum_{k=1}^T b_k^2\log\frac{2}{\delta}\Big)^{\frac{1}{2}} \le \big(C_3+2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}\Big(2\log\frac{2}{\delta}\sum_{k=1}^T\eta_k^2\Big)^{\frac{1}{2}}.$$

According to Proposition 9, there exists a subset $\Omega = \{(z_1,\ldots,z_T) : z_1,\ldots,z_T \in \mathcal{Z}\} \subset \mathcal{Z}^T$ with probability measure $\Pr\{\Omega\} \ge 1-\frac{\delta}{2}$ such that for any $(z_1,\ldots,z_T) \in \Omega$ the following inequality holds

$$\max_{1\le k\le T}\|f_k-f_H\|^2 \le \bar{C}\log\frac{2T}{\delta}.$$

Let $\{\xi_k\}_k$ be the martingale difference sequence defined in the proof of Proposition 23. For any $(z_1,\ldots,z_T) \in \Omega\cap\Omega'$, we then have

$$\sum_{k=1}^T\xi_k = \sum_{k=1}^T\xi_k' \le \big(C_3+2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}\Big(2\log\frac{2}{\delta}\sum_{k=1}^T\eta_k^2\Big)^{\frac{1}{2}}.$$

Under this intersection of these two events, it follows from (4.38) and the definition of C_5 given in (4.41) that

$$\begin{aligned}2\sum_{k=1}^T\eta_k\big[\mathcal{E}(f_k)-\mathcal{E}(f_H)\big] &\le (\eta_1A\kappa^2+1)\|f_H\|^2 + (AC_2+B)\kappa^2\sum_{k=1}^T\eta_k^2 + 2\sum_{k=1}^T\xi_k\\ &\le C_5 + 2\big(C_3+2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}\Big(2\log\frac{2}{\delta}\sum_{k=1}^T\eta_k^2\Big)^{\frac{1}{2}}.\end{aligned}$$

But $\Pr\{\Omega\cap\Omega'\} \ge 1-\delta$. Therefore, the first inequality of (2.5) holds with probability at least $1-\delta$ and

$$\widetilde{C} = \frac{C_5}{2} + \big(C_3+2L\kappa^{\alpha+1}\big)\bar{C}\Big(2\sum_{k=1}^\infty\eta_k^2\Big)^{\frac{1}{2}}.$$

The second inequality of (2.5) follows from the convexity of $\mathcal{E}(\cdot)$. The proof is complete. ■

Other than the high-probability bounds for the weighted average of iterates $\bar{f}_T^{\eta}$, we can also derive similar results for the uniform average of iterates $\bar{f}_T$. If we choose the step sizes $\eta_t = \eta_1(t\log^\beta t)^{-\frac{1}{2}}$ with $\beta > 1$, then Proposition 24 implies $\mathcal{E}(\bar{f}_T) - \mathcal{E}(f_H) = O(T^{-\frac{1}{2}}\log^{\frac{3}{2}}\frac{T}{\delta})$ with probability at least $1-\delta$. We present the proof in the appendix due to its similarity to the proof of Theorem 7.

Proposition 24 *Suppose assumptions in Theorem 7 hold. Then, for any $\delta \in (0,1)$, with probability at least $1-\frac{\delta}{2}$ we have*

$$\sum_{t=1}^T[\mathcal{E}(f_t)-\mathcal{E}(f_H)] = O\big(\big(T^{\frac{1}{2}}+\sum_{t=1}^T\eta_t\big)\log^{\frac{3}{2}}\frac{2T}{\delta}\big) \quad \text{and} \quad \mathcal{E}(\bar{f}_T)-\mathcal{E}(f_H) = O\big(\big(T^{-\frac{1}{2}}+T^{-1}\sum_{t=1}^T\eta_t\big)\log^{\frac{3}{2}}\frac{2T}{\delta}\big).$$

Theorem 10 is a specific case of Proposition 25 with $\widetilde{T} = \lfloor\frac{T}{2}\rfloor$. The step-stone in proving this proposition is the inequality (4.48) following from the one-step progress (4.47) in terms of generalization errors. The first term on the right hand side of (4.48) can be tackled by Theorem 7 on a weighted summation of $\hat{A}_t$ deduced from the one-step analysis in terms of RKHS distances. The variance of the martingales $\sum_{t=\tilde{t}}^T\bar{\xi}_t$ can be controlled by $\sum_{t=\tilde{t}}^T\eta_t\|\nabla\mathcal{E}(f_t)\|^2$, which is then cancelled out by the third term $-\sum_{t=\tilde{t}}^T\eta_t\|\nabla\mathcal{E}(f_t)\|^2$. A notable fact is that the martingale difference $\bar{\xi}_t - \mathbb{E}_{z_t}[\bar{\xi}_t]$ is bounded by $O(\eta_{\widetilde{T}})$ for all $t \geq \widetilde{T}$ with high probability, which would be small if $\widetilde{T}$ is large. We can balance the three terms on the right hand side of (4.43) by choosing an appropriate $\widetilde{T}$.

Proposition 25 *Suppose that the assumptions in Theorem 7 hold. Let $\widetilde{T} \in \mathbb{N}$ satisfy $1 \leq \widetilde{T} \leq T$. Then, there exists a constant $\widetilde{C}'$ independent of T and $\widetilde{T}$ (explicitly given in the proof) such that for any $\delta \in (0,1)$ the following inequality holds with probability at least $1-\delta$*

$$\mathcal{E}(f_{T+1}) - \mathcal{E}(f_H) \leq \widetilde{C}'\max\Big\{\big[\sum_{t=\widetilde{T}}^T\eta_t\big]^{-1}, \eta_{\widetilde{T}}, \sum_{t=\widetilde{T}}^T\eta_t^{1+\alpha}\Big\}\log^2\frac{3T}{\delta}. \tag{4.43}$$

Proof Recall that $\hat{A}_t = \mathcal{E}(f_t) - \mathcal{E}(f_H)$. According to the proof of Theorem 7, there exists a subset $\Omega = \{(z_1,\ldots,z_T) : z_1,\ldots,z_T \in \mathcal{Z}\} \subset \mathcal{Z}^T$ with $\Pr\{\Omega\} \geq 1 - \frac{2\delta}{3}$ such that for any $(z_1,\ldots,z_T) \in \Omega$, we have

$$\sum_{t=1}^T\eta_t\hat{A}_t \leq \widetilde{C}\log^{\frac{3}{2}}\frac{3T}{\delta} \quad \text{and} \quad \max_{1\leq t\leq T}\|f_t - f_H\|^2 \leq \bar{C}\log\frac{3T}{\delta}, \tag{4.44}$$

where $\widetilde{C}$ and $\bar{C}$ are constants independent of T and δ. Under the event of Ω, we have $\sum_{t=\widetilde{T}}^T\eta_t\hat{A}_t \leq \widetilde{C}\log^{\frac{3}{2}}\frac{3T}{\delta}$. Therefore, there exists a $\tilde{t} \in \mathbb{N}$ satisfying $\widetilde{T} \leq \tilde{t} \leq T$ and

$$\hat{A}_{\tilde{t}} \leq \big[\sum_{t=\widetilde{T}}^T\eta_t\big]^{-1}\widetilde{C}\log^{\frac{3}{2}}\frac{3T}{\delta}. \tag{4.45}$$

Taking expectations only with respect to z over both sides of (4.13) gives

$$\hat{A}_{t+1} \leq \hat{A}_t - \eta_t\big\langle\phi'(y_t,f_t(x_t))K_{x_t},\nabla\mathcal{E}(f_t)\big\rangle + \frac{L\kappa^{2(1+\alpha)}\eta_t^{1+\alpha}}{1+\alpha}|\phi'(y_t,f_t(x_t))|^{1+\alpha}. \tag{4.46}$$

According to (4.4), the term $|\phi'(y_t,f_t(x_t))|^{1+\alpha}$ can be controlled by

$$\begin{aligned}|\phi'(y_t,f_t(x_t))|^{1+\alpha} &\leq 2^\alpha|\phi'(y_t,f_t(x_t)) - \phi'(y_t,f_H(x_t))|^{1+\alpha} + 2^\alpha|\phi'(y_t,f_H(x_t))|^{1+\alpha}\\ &\leq 2^\alpha L^{1+\alpha}|\langle f_t - f_H, K_{x_t}\rangle|^{\alpha(1+\alpha)} + 2^\alpha|\phi'(y_t,f_H(x_t))|^{1+\alpha}\\ &\leq 2^\alpha L^{1+\alpha}\kappa^{\alpha(1+\alpha)}\|f_t - f_H\|^{\alpha(1+\alpha)} + 2^\alpha|\phi'(y_t,f_H(x_t))|^{1+\alpha}.\end{aligned}$$

Plugging the above bound into (4.46) gives

$$\begin{aligned}\hat{A}_{t+1} \leq \hat{A}_t - \eta_t\|\nabla\mathcal{E}(f_t)\|^2 + \eta_t\big\langle\nabla\mathcal{E}(f_t) - \phi'(y_t,f_t(x_t))K_{x_t},\nabla\mathcal{E}(f_t)\big\rangle\\ + \Big(\tilde{a}\|f_t - f_H\|^{\alpha(1+\alpha)} + \tilde{b}\Big)\eta_t^{1+\alpha},\end{aligned} \tag{4.47}$$

where we introduce

$$\tilde{a} = 2^\alpha L^{2+\alpha}\kappa^{(2+\alpha)(1+\alpha)}(1+\alpha)^{-1} \quad \text{and} \quad \tilde{b} = 2^\alpha L\kappa^{2(1+\alpha)}(1+\alpha)^{-1}\sup_{z\in\mathcal{Z}}|\phi'(y,f_H(x))|^{1+\alpha}.$$

Taking a summation from $t=\tilde{t}$ to T yields

$$\hat{A}_{T+1} \leq \hat{A}_{\tilde{t}} + \sum_{t=\tilde{t}}^T\Big(\tilde{a}\|f_t - f_H\|^{\alpha(1+\alpha)} + \tilde{b}\Big)\eta_t^{1+\alpha} - \sum_{t=\tilde{t}}^T\eta_t\|\nabla\mathcal{E}(f_t)\|^2 + \sum_{t=\tilde{t}}^T\bar{\xi}_t, \tag{4.48}$$

where we introduce the following two sequences of functionals

$$\begin{aligned}\bar{\xi}_t &= \eta_t\big\langle\nabla\mathcal{E}(f_t) - \phi'(y_t,f_t(x_t))K_{x_t},\nabla\mathcal{E}(f_t)\big\rangle,\\ \bar{\xi}_t' &= \eta_t\big\langle\nabla\mathcal{E}(f_t) - \phi'(y_t,f_t(x_t))K_{x_t},\nabla\mathcal{E}(f_t)\big\rangle\mathbb{I}_{\{\|f_t-f_H\|^2\leq\bar{C}\log\frac{3T}{\delta}\}}.\end{aligned}$$

Under the event Ω, it is clear $\bar{\xi}_t = \bar{\xi}_t'$. In the following, we will use Part (b) of Lemma 21 to estimate $\sum_{t=\tilde{t}}^T\bar{\xi}_t'$. It is clear that $\mathbb{E}_{z_t}[\bar{\xi}_t'] = 0$ for all $t \in \mathbb{N}$. Let $\bar{t}$ be any integer in $[\widetilde{T}, T]$. It follows from Lemma 14 with $\beta = 1$ and the definition of C_4 given in (4.35) that (note $\mathbb{E}[(\xi - \mathbb{E}[\xi])^2] < \mathbb{E}[\xi^2]$ for a real-valued random variable ξ)

$$\begin{aligned}\sum_{t=\bar{t}}^T\mathbb{E}_{z_t}\big(\bar{\xi}_t' - \mathbb{E}_{z_t}[\bar{\xi}_t']\big)^2 &\leq \sum_{t=\bar{t}}^T\eta_t^2\mathbb{E}_{z_t}\big[\big\langle\phi'(y_t,f_t(x_t))K_{x_t},\nabla\mathcal{E}(f_t)\big\rangle^2\big]\mathbb{I}_{\{\|f_t-f_H\|^2\leq\bar{C}\log\frac{3T}{\delta}\}}\\ &\leq \sum_{t=\bar{t}}^T\eta_t^2\kappa^2\|\nabla\mathcal{E}(f_t)\|^2\mathbb{E}_{z_t}\big[|\phi'(y_t,f_t(x_t))|^2\big]\mathbb{I}_{\{\|f_t-f_H\|^2\leq\bar{C}\log\frac{3T}{\delta}\}}\\ &\leq \sum_{t=\bar{t}}^T\eta_t^2\|\nabla\mathcal{E}(f_t)\|^2\big(4\kappa^2L^{\frac{1}{\alpha}}\big[\mathcal{E}(f_t) - \mathcal{E}(f_H)\big] + C_4\big)\mathbb{I}_{\{\|f_t-f_H\|^2\leq\bar{C}\log\frac{3T}{\delta}\}}.\end{aligned} \tag{4.49}$$

Analyzing analogously to (4.19), one can show that $\nabla\mathcal{E}$ is $(\alpha, L\kappa^{1+\alpha})$-Hölder continuous. Then, Lemma 13 together with $\nabla\mathcal{E}(f_H)=0$ shows that

$$\hat{A}_t = \mathcal{E}(f_t)-\mathcal{E}(f_H) \le \frac{L\kappa^{1+\alpha}\|f_t-f_H\|^{1+\alpha}}{1+\alpha}. \tag{4.50}$$

Plugging the above inequality into (4.49) shows

$$\sum_{t=\bar{t}}^{T}\mathbb{E}_{z_t}\big(\bar{\xi}'_t-\mathbb{E}_{z_t}[\bar{\xi}'_t]\big)^2 \le C_8\log\frac{3T}{\delta}\sum_{t=\bar{t}}^{T}\eta_t^2\|\nabla\mathcal{E}(f_t)\|^2 \le \eta_{\widetilde{T}}C_8\log\frac{3T}{\delta}\sum_{t=\bar{t}}^{T}\eta_t\|\nabla\mathcal{E}(f_t)\|^2, \tag{4.51}$$

where we have used $\bar{t}\ge\widetilde{T}$ and introduced

$$C_8 = \frac{4\kappa^{3+\alpha}L^{1+\frac{1}{\alpha}}\bar{C}}{1+\alpha}+C_4.$$

According to (4.39), there holds

$$\begin{aligned}\bar{\xi}'_t-\mathbb{E}_{z_t}[\bar{\xi}'_t] &\le \eta_t\big|\langle\phi'(y_t,f_t(x_t))K_{x_t}-\nabla\mathcal{E}(f_t),\nabla\mathcal{E}(f_t)\rangle\big|\mathbb{I}_{\{\|f_t-f_H\|^2\le\bar{C}\log\frac{3T}{\delta}\}}\\ &\le \eta_t\|\nabla\mathcal{E}(f_t)\|\big\|\phi'(y_t,f_t(x_t))K_{x_t}-\mathbb{E}_{z_t}[\phi'(y_t,f_t(x_t))K_{x_t}]\big\|\mathbb{I}_{\{\|f_t-f_H\|^2\le\bar{C}\log\frac{3T}{\delta}\}}\\ &\le \big(C_3+2L\|f_t-f_H\|^{\alpha}\kappa^{\alpha+1}\big)\eta_t\|\nabla\mathcal{E}(f_t)\|\mathbb{I}_{\{\|f_t-f_H\|^2\le\bar{C}\log\frac{3T}{\delta}\}},\quad \forall t\ge\bar{t}.\end{aligned}$$

Due to the $(\alpha, L\kappa^{1+\alpha})$-Hölder continuity of $\nabla\mathcal{E}$

$$\|\nabla\mathcal{E}(f_t)\| = \|\nabla\mathcal{E}(f_t)-\nabla\mathcal{E}(f_H)\| \le L\kappa^{1+\alpha}\|f_t-f_H\|^{\alpha},$$

we further get

$$\begin{aligned}\bar{\xi}'_t-\mathbb{E}_{z_t}[\bar{\xi}'_t] &\le \eta_t\big(C_3+2L\kappa^{\alpha+1}\big)\max\big(\|f_t-f_H\|^{\alpha},1\big)L\kappa^{1+\alpha}\|f_t-f_H\|^{\alpha}\mathbb{I}_{\{\|f_t-f_H\|^2\le\bar{C}\log\frac{3T}{\delta}\}}\\ &\le \eta_{\widetilde{T}}\big(C_3+2L\kappa^{\alpha+1}\big)L\kappa^{1+\alpha}\bar{C}\log\frac{3T}{\delta} := \eta_{\widetilde{T}}C_9\log\frac{3T}{\delta},\quad \forall t\ge\bar{t}.\end{aligned}$$

We can find a $\rho_2>0$ independent of T such that $(e^{\rho_2}-\rho_2-1)C_8\le\rho_2C_9$. Applying Part (b) of Lemma 21 with the above bounds on variances and magnitudes of $\bar{\xi}'_k$ followed with union bounds on probabilities, we can find a subset $\Omega'=\{(z_1,\ldots,z_T): z_1,\ldots,z_T\in\mathcal{Z}\}\subset\mathcal{Z}^T$ with $\Pr\{\Omega'\}\ge 1-\frac{\delta}{3}$ such that for any $(z_1,\ldots,z_T)\in\Omega'$ there holds (note $\mathbb{E}_{z_t}[\bar{\xi}'_t]=0$)

$$\begin{aligned}\sum_{t=\bar{t}}^{T}\bar{\xi}'_t &\le \frac{\eta_{\widetilde{T}}(e^{\rho_2}-\rho_2-1)C_8\log\frac{3T}{\delta}\sum_{t=\bar{t}}^{T}\eta_t\|\nabla\mathcal{E}(f_t)\|^2}{\eta_{\widetilde{T}}\rho_2C_9\log\frac{3T}{\delta}}+\frac{\eta_{\widetilde{T}}C_9\log^2\frac{3T}{\delta}}{\rho_2}\\ &\le \sum_{t=\bar{t}}^{T}\eta_t\|\nabla\mathcal{E}(f_t)\|^2+\frac{\eta_{\widetilde{T}}C_9\log^2\frac{3T}{\delta}}{\rho_2},\quad \forall\bar{t}\in[\widetilde{T},T].\end{aligned} \tag{4.52}$$

Under the event $\Omega\cap\Omega'$, we can plug the above inequality with $\bar{t}=\tilde{t},\bar{\xi}'_t=\bar{\xi}_t$ and $\|f_t-f_H\|^2\le\bar{C}\log\frac{3T}{\delta},\forall t=1,\ldots,T$ into (4.48) to derive

$$\begin{aligned}\hat{A}_{T+1} &\le \hat{A}_{\tilde{t}}+\Big(\tilde{a}\bar{C}\log\frac{3T}{\delta}+\tilde{b}\Big)\sum_{t=\tilde{t}}^{T}\eta_t^{1+\alpha}+\frac{\eta_{\widetilde{T}}C_9\log^2\frac{3T}{\delta}}{\rho_2}\\ &\le \big[\sum_{t=\widetilde{T}}^{T}\eta_t\big]^{-1}\widetilde{C}\log^{\frac{3}{2}}\frac{3T}{\delta}+\Big(\tilde{a}\bar{C}+\tilde{b}\Big)\log\frac{3T}{\delta}\sum_{t=\tilde{t}}^{T}\eta_t^{1+\alpha}+\frac{\eta_{\widetilde{T}}C_9\log^2\frac{3T}{\delta}}{\rho_2},\end{aligned}$$

where the last inequality is due to (4.45). This establishes the stated inequality with probability $1-\delta$ and

$$\widetilde{C}' = \widetilde{C}+\tilde{a}\bar{C}+\tilde{b}+C_9\rho_2^{-1}.$$

It is clear that $\widetilde{C}'$ is independent of T and $\widetilde{T}$. The proof is complete. ■

Proof of Corollary 11 The polynomially decaying step sizes $\eta_t=\eta_1t^{-\theta}(\theta>\frac{1}{2})$ satisfies the monotonicity and $\sum_{t=1}^{\infty}\eta_t^2<\infty$ Furthermore, we have

$$\big[\sum_{t=\lfloor\frac{T}{2}\rfloor}^{T}\eta_t\big]^{-1}\le\frac{2}{T\eta_T}=O(T^{\theta-1})\quad\text{and}\quad\sum_{t=\lfloor\frac{T}{2}\rfloor}^{T}\eta_t^{1+\alpha}\le\frac{(T+1)\eta_{\lfloor\frac{T}{2}\rfloor}^{1+\alpha}}{2}=O(T^{1-(1+\alpha)\theta}).$$

The proof is complete if we plug the above estimates into Theorem 10. ■

Appendix A. Some Additional Proofs

Proof of Lemma 16 Let $\epsilon>0$ be an arbitrary number. Since $\lim_{t\to\infty}\eta_t=0$ we can find a $t_3\in\mathbb{N}$ such that $\eta_t\le\frac{\epsilon}{2}$ for all $t\ge t_3$. Since $\sum_{t=1}^{\infty}\eta_t=\infty$, we can also find a $t_4>t_3$ such that $\sum_{k=1}^{t_3}\eta_k^2\le\frac{\epsilon}{2}\sum_{k=1}^{t_4}\eta_k$. Then, for any $t\ge t_4$, it holds

$$\begin{aligned}\big[\sum_{k=1}^{t}\eta_k\big]^{-1}\sum_{k=1}^{t}\eta_k^2 &= \big[\sum_{k=1}^{t}\eta_k\big]^{-1}\sum_{k=1}^{t_3}\eta_k^2+\big[\sum_{k=1}^{t}\eta_k\big]^{-1}\sum_{k=t_3+1}^{t}\eta_k^2\\ &\le \frac{\epsilon}{2}+\frac{\epsilon}{2}\big[\sum_{k=1}^{t}\eta_k\big]^{-1}\sum_{k=t_3+1}^{t}\eta_k\le\epsilon.\end{aligned}$$

Since $\epsilon>0$ is arbitrarily chosen, the proof is complete. ■

Proof of Lemma 13 Fix $f, \tilde{f} \in H$. Define a function $g : \mathbb{R} \to \mathbb{R}$ by $g(t) = \mathcal{G}(\tilde{f}+t(f-\tilde{f}))$. It is clear that $g'(t) = \langle f-\tilde{f}, \nabla\mathcal{G}(\tilde{f}+t(f-\tilde{f}))\rangle$ and

$$\begin{aligned}|g'(t)-g'(\tilde{t})| &= \Big\langle f-\tilde{f}, \nabla\mathcal{G}(\tilde{f}+t(f-\tilde{f})) - \nabla\mathcal{G}(\tilde{f}+\tilde{t}(f-\tilde{f}))\Big\rangle \\ &\le \|f-\tilde{f}\|\big\|\nabla\mathcal{G}\big(\tilde{f}+t(f-\tilde{f})\big) - \nabla\mathcal{G}\big(\tilde{f}+\tilde{t}(f-\tilde{f})\big)\big\| \\ &\le L\|f-\tilde{f}\|^{1+\alpha}|t-\tilde{t}|^{\alpha}.\end{aligned}$$

It then follows that

$$\begin{aligned}g(1)-g(0)-g'(0) &= \int_0^1 [g'(t)-g'(0)]dt \le \int_0^1 |g'(t)-g'(0)|dt \\ &\le L\|f-\tilde{f}\|^{1+\alpha}\int_0^1 t^{\alpha}dt = \frac{L\|f-\tilde{f}\|^{1+\alpha}}{1+\alpha},\end{aligned}$$

which amounts to the second inequality in (4.1)

$$\mathcal{G}(f) \le \mathcal{G}(\tilde{f}) + \langle f-\tilde{f}, \nabla\mathcal{G}(\tilde{f})\rangle + \frac{L\|f-\tilde{f}\|^{1+\alpha}}{1+\alpha}. \tag{A.1}$$

We now turn to the first inequality in (4.1). Fix f and $\tilde{f} \in H$. Define a functional $\mathcal{L} : H \to \mathbb{R}$ by $\mathcal{L}(\bar{f}) = \mathcal{G}(\bar{f}) - \langle \bar{f}, \nabla\mathcal{G}(f)\rangle$. It is clear that $\mathcal{L}$ is a convex function and $\nabla\mathcal{L}(f) = \nabla\mathcal{G}(f) - \nabla\mathcal{G}(f) = 0$. According to the first-order optimality condition, we know $\mathcal{L}$ attains its minimum at f and

$$\begin{aligned}\mathcal{L}(f) &= \min_{\bar{f}\in H}\mathcal{L}(\bar{f}) = \min_{\bar{f}\in H}\big[\mathcal{G}(\bar{f}) - \langle \bar{f}, \nabla\mathcal{G}(f)\rangle\big] \\ &\le \min_{\bar{f}\in H}\Big[\mathcal{G}(\tilde{f}) + \langle \bar{f}-\tilde{f}, \nabla\mathcal{G}(\tilde{f})\rangle + \frac{L\|\tilde{f}-\bar{f}\|^{1+\alpha}}{1+\alpha} - \langle \bar{f}, \nabla\mathcal{G}(f)\rangle\Big] \\ &= \mathcal{L}(\tilde{f}) + \min_{\bar{f}\in H}\Big[\langle \tilde{f}-\bar{f}, \nabla\mathcal{G}(f) - \nabla\mathcal{G}(\tilde{f})\rangle + \frac{L\|\tilde{f}-\bar{f}\|^{1+\alpha}}{1+\alpha}\Big] \\ &= \mathcal{L}(\tilde{f}) + \min_{\bar{f}\in H}\Big[\langle \bar{f}, \nabla\mathcal{G}(f) - \nabla\mathcal{G}(\tilde{f})\rangle + \frac{L\|\bar{f}\|^{1+\alpha}}{1+\alpha}\Big],\end{aligned}$$

where the inequality follows from (A.1). Taking $\bar{f} = L^{-\frac{1}{\alpha}}\|\nabla\mathcal{G}(\tilde{f}) - \nabla\mathcal{G}(f)\|^{\frac{1-\alpha}{\alpha}}\big(\nabla\mathcal{G}(\tilde{f}) - \nabla\mathcal{G}(f)\big)$ in the above inequality, we derive

$$\begin{aligned}\mathcal{L}(f) &\le \mathcal{L}(\tilde{f}) - L^{-\frac{1}{\alpha}}\|\nabla\mathcal{G}(\tilde{f}) - \nabla\mathcal{G}(f)\|^{\frac{1+\alpha}{\alpha}} + \frac{L^{-\frac{1}{\alpha}}\|\nabla\mathcal{G}(\tilde{f}) - \nabla\mathcal{G}(f)\|^{\frac{1+\alpha}{\alpha}}}{1+\alpha} \\ &= \mathcal{L}(\tilde{f}) - \frac{\alpha L^{-\frac{1}{\alpha}}}{1+\alpha}\|\nabla\mathcal{G}(f) - \nabla\mathcal{G}(\tilde{f})\|^{\frac{1+\alpha}{\alpha}}.\end{aligned}$$

This establishes the first inequality in (4.1). The proof is complete. ■

Proof of Proposition 24 Consider the following sequence of functionals $\tilde{\xi}_k, k = 1, \ldots, T$ by

$$\tilde{\xi}_k = \big\langle f_H - f_k, \phi'(y_k, f_k(x_k))K_{x_k} - \mathbb{E}_{z_k}\big[\phi'(y_k, f_k(x_k))K_{x_k}\big]\big\rangle,$$

where $\bar{C}$ is defined in Proposition 9. Eq. (4.42) implies that

$$|\tilde{\xi}_k|\mathbb{I}_{\{\|f_k-f_H\|^2\le\bar{C}\log\frac{2T}{\delta}\}} \le \big(C_3 + 2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}.$$

By Part (a) of Lemma 21, there exists a subset $\Omega' = \{(z_1, \ldots, z_T) : z_1, \ldots, z_T \in \mathcal{Z}\} \subset \mathcal{Z}^T$ with probability measure $\Pr\{\Omega'\} \ge 1 - \frac{\delta}{2}$ such that for any $(z_1, \ldots, z_T) \in \Omega'$ the following inequality holds

$$\sum_{k=1}^T \tilde{\xi}_k\mathbb{I}_{\{\|f_k-f_H\|^2\le\bar{C}\log\frac{2T}{\delta}\}} \le \big(C_3 + 2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}\Big(2T\log\frac{2}{\delta}\Big)^{\frac{1}{2}}.$$

According to Proposition 9, there exists a subset $\Omega = \{(z_1, \ldots, z_T) : z_1, \ldots, z_T \in \mathcal{Z}\} \subset \mathcal{Z}^T$ with probability measure $\Pr\{\Omega\} \ge 1 - \frac{\delta}{2}$ such that for any $(z_1, \ldots, z_T) \in \Omega$ there holds the inequality $\max_{1\le k\le T}\|f_k - f_H\|^2 \le \bar{C}\log\frac{2T}{\delta}$. Under the event $\Omega \cap \Omega'$, we then have

$$\sum_{k=1}^T \tilde{\xi}_k \le \big(C_3 + 2L\kappa^{\alpha+1}\big)\bar{C}\log\frac{2T}{\delta}\Big(2T\log\frac{2}{\delta}\Big)^{\frac{1}{2}}. \tag{A.2}$$

Furthermore, it follows from (4.37) that

$$2[\mathcal{E}(f_k) - \mathcal{E}(f_H)] \le \eta_k^{-1}\big[\|f_k - f_H\|^2 - \|f_{k+1} - f_H\|^2\big] + \eta_k\kappa^2\big(A\phi(y_k, f_k(x_k)) + B\big) + 2\tilde{\xi}_k.$$

Taking a summation of the above inequality from $k = 1$ to T yields the following inequality under the event $\Omega \cap \Omega'$

$$\begin{aligned}2\sum_{k=1}^T[\mathcal{E}(f_k) - \mathcal{E}(f_H)] \le \sum_{k=1}^{T-1}\big(\eta_{k+1}^{-1} - \eta_k^{-1}\big)\|f_{k+1} - f_H\|^2 + \eta_1^{-1}\|f_1 - f_H\|^2 \\ + \kappa^2\sum_{k=1}^T \eta_k\big(A\phi(y_k, f_k(x_k)) + B\big) + 2\sum_{k=1}^T\tilde{\xi}_k.\end{aligned} \tag{A.3}$$

It follows from (4.33) that

$$\sum_{k=1}^T \eta_k\phi(y_k, f_k(x_k)) \le \|f_H\|^2 + 2\sum_{k=1}^T \eta_k\phi(y_k, f_H(x_k)) + \kappa^2 B\sum_{k=1}^T \eta_k^2.$$

Plugging the above bound into (A.3) and using the monotonicity of η_k together with (A.2), we derive the following inequality with probability at least $1 - \delta$

$$\begin{aligned}2\sum_{k=1}^T[\mathcal{E}(f_k) - \mathcal{E}(f_H)] \le (A\kappa^2 + \eta_1^{-1})\|f_H\|^2 + \kappa^2\sum_{k=1}^T\Big(2A\eta_k\sup_z\phi(y, f_H(x)) + B\eta_k + AB\kappa^2\eta_k^2\Big) \\ + \big(C_3 + 2L\kappa^{\alpha+1}\big)\bar{C}(8T)^{\frac{1}{2}}\log^{\frac{3}{2}}\frac{2T}{\delta}.\end{aligned}$$

The proof is complete. ■

Abstract

This paper considers inference over distributed linear Gaussian models using factor graphs and Gaussian belief propagation (BP). The distributed inference algorithm involves only local computation of the information matrix and of the mean vector, and message passing between neighbors. Under broad conditions, it is shown that the message information matrix converges to a unique positive definite limit matrix for arbitrary positive semidefinite initialization, and it approaches an arbitrarily small neighborhood of this limit matrix at an exponential rate. A necessary and sufficient convergence condition for the belief mean vector to converge to the optimal centralized estimator is provided under the assumption that the message information matrix is initialized as a positive semidefinite matrix. Further, it is shown that Gaussian BP always converges when the underlying factor graph is given by the union of a forest and a single loop. The proposed convergence condition in the setup of distributed linear Gaussian models is shown to be strictly weaker than other existing convergence conditions and requirements, including the Gaussian Markov random field based walk-summability condition, and applicable to a large class of scenarios.

Keywords: Graphical Model, Large-Scale Networks, Linear Gaussian Model, Markov Random Field, Walk-summability.

1. Introduction

Inference based on a set of measurements from multiple agents on a distributed network is a central issue in many problems. While centralized algorithms can be used in small-scale networks, they face difficulties in large-scale networks, imposing a heavy communication burden when all the data is to be transported to and processed at a central processing unit. Dealing with highly distributed data has been recognized by the U.S. National Research Council as one of the big challenges for processing big data (National Research Council, 2013). Therefore, distributed inference techniques that only involve local communication and computation are important for problems arising in distributed networks.

In large-scale linear parameter learning with Gaussian measurements, Gaussian Belief Propagation (BP) (Weiss and Freeman, 2001a) provides an efficient distributed algorithm for computing the marginal means of the unknown parameters, and it has been adopted in a variety of topics including image interpolation (Xiong et al., 2010), distributed power system state inference (Hu et al., 2011), distributed beamforming (Ng et al., 2008), distributed synchronization (Du and Wu, 2013b), fast solver for system of linear equations (Shental et al., 2008a), distributed rate control in ad-hoc networks (Zhang et al., 2010), factor analyzer network (Frey, 1999), sparse Bayesian learning (Tan and Li, 2010), inter-cell interference mitigation (Lehmann, 2012), and peer-to-peer rating in social networks (Bickson and Malkhi, 2008).

Although with great empirical success (Murphy et al., 1999), it is known that a major challenge that hinders BP is the lack of theoretical guarantees of convergence in loopy networks (Chertkov and Chernyak, 2006; Gómez et al., 2007). Convergence of other forms of loopy BP are analyzed by Ihler et al. (2005), Mooij and Kappen (2005, 2007), Noorshams and Wainwright (2013), and Ravanbakhsh and Greiner (2015), but their analyses are not directly applicable to Gaussian BP. Sufficient convergence conditions for Gaussian BP have been developed in Weiss and Freeman (2001a); Malioutov et al. (2006); Moallemi and Roy (2009a); Su and Wu (2015) when the underlying Gaussian distribution is expressed in terms of pairwise connections between *scalar* variables, i.e., it is a Markov random field (MRF). However, depending on how the underlying joint Gaussian distribution is factorized, Gaussian BP may exhibit different convergence properties as different factorizations (different Gaussian models) lead to fundamentally different recursive update structures. In this paper, we study the convergence of Gaussian BP derived from the distributed linear Gaussian model. The motivation is twofold. From the factorization viewpoint, by specifically employing a factorization based on the linear Gaussian model, we are able to bypass difficulties in existing convergence analyses ((Malioutov et al., 2006) and references therein) based on Gaussian Markov random field factorization. From the distributed inference viewpoint, the linear Gaussian model and associated message passing requirements for implementing the Gaussian BP readily conform to the physical network topology arising in large-scale networks such as in (Hu et al., 2011; Ng et al., 2008; Du and Wu, 2013b; Shental et al., 2008a; Zhang et al., 2010; Frey, 1999; Tan and Li, 2010; Lehmann, 2012; Bickson and Malkhi, 2008), thus it is practically important.

Recently, Giscard et al. (2012, 2013, 2016) present a path-sum method to compute the information matrix inverse of a joint Gaussian distribution. Then, the marginal mean is obtained using the information matrix inverse. The path-sum method converges for an

arbitrary valid Gaussian model, however, it is not clear how to adapt it to the distributed and parallel inference setup. In contrast, Gaussian BP is a parallel and fully distributed method that computes the marginal means by computing only the block diagonal elements of the information matrix inverse. Though the block diagonal elements computed by Gaussian BP may not be correct, it is shown that the belief mean still converges to the correct value once Gaussian BP converges. This explains the popularity of Gaussian BP in distributed inference applications, even though its convergence properties are not fully understood.

To fill this gap, this paper studies the convergence of Gaussian BP for linear Gaussian models. Specifically, for the first time, by establishing certain contractive properties of the distributed information matrix (inverse covariance matrix) updates with respect to the Birkhoff metric, we show that, with arbitrary positive semidefinite (p.s.d.) initial message information matrix, the belief covariance for each local variable converges to a unique positive definite limit, and it approaches an arbitrarily small neighborhood of this limit matrix at an exponential rate. Consequently, the recursive equation for the message mean, which depends on the information matrix, can be reduced to a linear recursive equation. Further, we derive a necessary and sufficient convergence condition for this linear recursive equation under the assumption that the initial message information matrix is p.s.d. Furthermore, we show that, when the structure of the factor graph is the union of a single loop and a forest, Gaussian BP always converges. Finally, it is demonstrated that the proposed convergence condition for the linear Gaussian model encompasses the walk-summable convergence condition for Gaussian MRFs (Malioutov et al., 2006).

Note that there exist other distributed estimation frameworks, e.g., consensus+innovations (Kar and Moura, 2013; Kar et al., 2013) and diffusion algorithms (Cattivelli and Sayed, 2010) that enable distributed estimation of parameters and processes in multi-agent networked environments. The consensus+innovation algorithms converge in mean square sense to the centralized optimal solution under the assumption of global observability of the (aggregate) sensing model and connectivity (on the average) of the inter-agent communication network. In particular, these algorithms allow the communication or message exchange network to be different from the physical coupling network of the field being estimated where either networks can be arbitrarily connected with cycles. The results in Kar and Moura (2013); Kar et al. (2013) imply that the unknown field or parameter can be reconstructed completely at each agent in the network. For large-scale networks with high dimensional unknown variable, it may be impractical though to estimate all the unknowns at every agent. Reference (Kar, 2010, section 3.4) develops approaches to address this problem, where under appropriate conditions, each agent can estimate only a subset of the unknown parameter variables. This paper studies a different distributed inference problem where each agent learns only its own unknown random variables; this leads to lower dimensional data exchanges between neighbors.

The rest of this paper is organized as follows. Section 2 presents the system model for distributed inference. Section 3 derives the vector-valued distributed inference algorithm based on Gaussian BP. Section 4 establishes convergence conditions, and Section 5 discloses the relationship between the derived results and existing convergence conditions of Gaussian BP. Finally, Section 6 presents our conclusions.

Notation: Boldface uppercase and lowercase letters represent matrices and vectors, respectively. For a matrix $\mathbf{A}$, $\mathbf{A}^{-1}$ and $\mathbf{A}^T$ denote its inverse (if it exists) and transpose,

respectively. The symbol $\mathbf{I}_N$ denotes the $N \times N$ identity matrix, and $\mathcal{N}(\mathbf{x}|\boldsymbol{\mu}, \mathbf{R})$ stands for the probability density function (PDF) of a Gaussian random vector $\mathbf{x}$ with mean $\boldsymbol{\mu}$ and covariance matrix $\mathbf{R}$. The notation $\|\mathbf{x}-\mathbf{y}\|^2_{\mathbf{W}}$ stands for $(\mathbf{x}-\mathbf{y})^T \mathbf{W} (\mathbf{x}-\mathbf{y})$. The symbol $\propto$ represents the linear scalar relationship between two real valued functions. For Hermitian matrices $\mathbf{X}$ and $\mathbf{Y}$, $\mathbf{X} \succeq \mathbf{Y}$ ($\mathbf{X} \succ \mathbf{Y}$) means that $\mathbf{X}-\mathbf{Y}$ is positive semidefinite (definite). The sets $[\mathbf{A}, \mathbf{B}]$ are defined by $[\mathbf{A}, \mathbf{B}] = \{\mathbf{X} : \mathbf{B} \succeq \mathbf{X} \succeq \mathbf{A}\}$. The symbol $\texttt{Bdiag}\{\cdot\}$ stands for block diagonal matrix with elements listed inside the bracket; $\otimes$ denotes the Kronecker product; and $\mathbf{X}_{i,j}$ denotes the component of matrix $\mathbf{X}$ on the i-th row and j-th column.

2. Problem Statement and Markov Random Field

Consider a general connected network[1] of M agents, with $\mathcal{V} = \{1, \ldots, M\}$ denoting the set of agents, and $\mathcal{E}_{\text{Net}} \subset \mathcal{V} \times \mathcal{V}$ the set of all undirected communication links in the network, i.e., if i and j can communicate or exchange information directly, $(i,j) \in \mathcal{E}_{\text{Net}}$. At every agent $n \in \mathcal{V}$, the local observations are given by a linear Gaussian model:

$$\mathbf{y}_n = \sum_{i \in n \cup \mathcal{I}(n)} \mathbf{A}_{n,i} \mathbf{x}_i + \mathbf{z}_n, \tag{1}$$

where $\mathcal{I}(n)$ denotes the set of neighbors of agent n (i.e., all agents i with $(n,i) \in \mathcal{E}_{\text{Net}}$), $\mathbf{A}_{n,i}$ is a known coefficient matrix with full column rank, $\mathbf{x}_i$ is the local unknown parameter at agent i with dimension $N_i \times 1$ and with prior distribution $\mathbf{x}_i \sim \mathcal{N}(\mathbf{x}_i|\mathbf{0}, \mathbf{W}_i)$ ($\mathbf{W}_i \succ \mathbf{0}$), and $\mathbf{z}_n$ is the additive noise with distribution $\mathbf{z}_n \sim \mathcal{N}(\mathbf{z}_n|\mathbf{0}, \mathbf{R}_n)$, where $\mathbf{R}_n \succ 0$. It is assumed that $p(\mathbf{x}_i, \mathbf{x}_j) = p(\mathbf{x}_i)\, p(\mathbf{x}_j)$ and $p(\mathbf{z}_i, \mathbf{z}_j) = p(\mathbf{z}_i)\, p(\mathbf{z}_j)$ for $i \neq j$, and the x_i's and z_j's are independent for all i and j. The goal is to learn $\mathbf{x}_i$, based on $\mathbf{y}_n$, $p(\mathbf{x}_i)$, and $p(\mathbf{z}_n)$.[2]

In centralized estimation, all the observations $\mathbf{y}_n$'s at different agents are forwarded to a central processing unit. Define vectors $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$ as the stacking of $\mathbf{x}_n$, $\mathbf{y}_n$, and $\mathbf{z}_n$ in ascending order with respect to n, respectively; then, we obtain

$$\mathbf{y} = \mathbf{A}\mathbf{x} + \mathbf{z}, \tag{2}$$

where $\mathbf{A}$ is constructed from $\mathbf{A}_{n,i}$, with specific arrangement dependent on the network topology. Assuming $\mathbf{A}$ is of full column rank, and since (2) is a standard linear model, the optimal minimum mean squared error estimate $\widehat{\mathbf{x}} \triangleq \left[\widehat{\mathbf{x}}_1^T, \ldots, \widehat{\mathbf{x}}_M^T\right]^T$ of $\mathbf{x}$ is given by (Murphy, 2012)

$$\widehat{\mathbf{x}} = \int \mathbf{x} \frac{p(\mathbf{x})\, p(\mathbf{y}|\mathbf{x})}{\int p(\mathbf{x})\, p(\mathbf{y}|\mathbf{x})\, \mathrm{d}\mathbf{x}} \mathrm{d}\mathbf{x} = \left(\mathbf{W}^{-1} + \mathbf{A}^T \mathbf{R}^{-1} \mathbf{A}\right)^{-1} \mathbf{A}^T \mathbf{R}^{-1} \mathbf{y}, \tag{3}$$

where $\mathbf{W}$ and $\mathbf{R}$ are block diagonal matrices containing $\mathbf{W}_i$ and $\mathbf{R}_i$ as their diagonal blocks, respectively. Although well-established, centralized estimation in large-scale networks has

1. A connected network is one where any two distinct agents can communicate with each other through a finite number of hops.
2. By slightly modifying (1), the local model would allow two neighboring agents to share a common observation and the analyses in the following sections still apply. Please refer to Du et al. (2017b) for details, and Du et al. (2017a) for the corresponding models and associated (distributed) convergence conditions.

several drawbacks including: 1) the transmission of $\mathbf{y}_n$, $\mathbf{A}_{n,i}$ and $\mathbf{R}_n$ from peripheral agents to the computation center imposes large communication overhead; 2) knowledge of global network topology is needed in order to construct $\mathbf{A}$; 3) the computation burden at the computation center scales up due to the matrix inversion required in (3) with complexity order $\mathcal{O}\left(\left(\sum_{i=1}^{|\mathcal{V}|} N_i\right)^3\right)$, i.e., cubic in the dimension in general.

On the other hand, Gaussian BP running over graphical models representing the joint posterior distribution of all $\mathbf{x}_i$'s provides a distributed way to learn $\mathbf{x}_i$ locally, thereby mitigating the disadvantages of the centralized approach. In particular, with Gaussian MRF, the joint distribution $p(\mathbf{x})\,p(\mathbf{y}|\mathbf{x})$ is expressed in a pairwise form (Malioutov et al., 2006):

$$p(\mathbf{x})\,p(\mathbf{y}|\mathbf{x}) = \prod_{n\in\mathcal{V}} \psi_n\left(\mathbf{x}_n, \{\mathbf{y}_i\}_{i\in\{n\cup\mathcal{I}(n)\}}\right) \prod_{(n,i)\in\mathcal{E}_{\text{MRF}}} \psi_{n,i}(\mathbf{x}_n, \mathbf{x}_i), \tag{4}$$

where

$$\mathcal{E}_{\text{MRF}} \triangleq \mathcal{E}_{\text{Net}} \cup \{(n,i)\,|\exists k, k\neq n, k\neq i, \text{such that } (n,k)\in\mathcal{E}_{\text{Net}}, \text{and } (i,k)\in\mathcal{E}_{\text{Net}}\}; \tag{5}$$

$$\psi_n\left(\mathbf{x}_n, \{\mathbf{y}_i\}_{i\in n\cup\mathcal{I}(n)}\right) = \exp\left\{\frac{1}{2}\left(\mathbf{x}_n^T\mathbf{W}_n^{-1}\mathbf{x}_n + \sum_{i\in n\cup\mathcal{I}(n)} \mathbf{y}_i^T\mathbf{R}_i^{-1}\mathbf{x}_n\right)\right\} \tag{6}$$

is the potential function at agent n, and

$$\begin{aligned}\psi_{n,i}(\mathbf{x}_n,\mathbf{x}_i) = \exp -\Big\{\frac{1}{2}\big[&(\mathbf{A}_{n,n}\mathbf{x}_n)^T\mathbf{R}_n^{-1}(\mathbf{A}_{n,i}\mathbf{x}_i) + (\mathbf{A}_{i,n}\mathbf{x}_n)^T\mathbf{R}_i^{-1}(\mathbf{A}_{i,i}\mathbf{x}_i)\\ &+ \sum_{\substack{k\in\{\widetilde{k}\,|(\widetilde{k},i)\in\mathcal{E}_{\text{Net}},\\ (\widetilde{k},n)\in\mathcal{E}_{\text{Net}}\}}} (\mathbf{A}_{k,n}\mathbf{x}_n)^T\mathbf{R}_k^{-1}(\mathbf{A}_{k,i}\mathbf{x}_i)\big]\Big\}\end{aligned} \tag{7}$$

is the edge potential between $\mathbf{x}_n$ and $\mathbf{x}_i$. After setting up the graphical model representing the joint distribution in (4), messages are exchanged between pairs of agents n and i with $(n,i)\in\mathcal{E}_{\text{MRF}}$. More specifically, according to the standard derivation of Gaussian BP, at the ℓ-th iteration, the message passed from agent n to agent i is

$$w_{n\to i}^{(\ell)}(\mathbf{x}_i) = \int \psi_n\left(\mathbf{x}_n, \{\mathbf{y}_k\}_{k\in n\cup\mathcal{I}(n)}\right)\psi_{n,i}(\mathbf{x}_n,\mathbf{x}_i) \prod_{k\in\mathcal{I}(n)\setminus i} w_{k\to n}^{(\ell-1)}(\mathbf{x}_n)\,\mathrm{d}\mathbf{x}_n. \tag{8}$$

As shown by (8), Gaussian BP is iterative with each agent alternatively receiving messages from its neighbors and forwarding out updated messages. At each iteration, agent i computes its belief on variable $\mathbf{x}_i$ as

$$b_{\text{MRF}}^{(\ell)}(\mathbf{x}_i) \propto \psi_i\left(\mathbf{x}_i, \{\mathbf{y}_n\}_{n\in i\cup\mathcal{I}(i)}\right) \prod_{k\in\mathcal{I}(n)} w_{k\to i}^{(\ell)}(\mathbf{x}_i). \tag{9}$$

It is known that, as the messages (8) converge, the mean of the belief (9) is the exact mean of the marginal distribution of $\mathbf{x}_i$ (Weiss and Freeman, 2001a).

It might seem that our distributed inference problem is now solved, as a solution is readily available. However, there are two serious limitations for the Gaussian MRF approach.

First, messages are passed between pairs of agents in $\mathcal{E}_{\text{MRF}}$, which according to the definition (5) includes not only those direct neighbors, but also pairs that are two hops away but share a common neighbor. This is illustrated in Fig. 1, where Fig. 1(a) shows a network of 4 agents with a line between two neighboring agents indicating the availability of a physical communication link, and Fig. 1(b) shows the equivalent pairwise graph. For this example, in the physical network, there is no direct connection between agents 1 and 4, nor between agents 1 and 3. But in the pairwise representation, those connections are present. We summarize the above observations in the following remark.

Remark 1 *For a network with communication edge set $\mathcal{E}_{Net}$ and local observations following (1), the corresponding MRF graph edge set satisfies $\mathcal{E}_{MRF}\supseteq\mathcal{E}_{Net}$. Thus, Gaussian BP for Gaussian MRFs cannot be applied to the distributed inference problem with the local observation model (1).*[3]

The consequence of the above findings is that, not only does information need to be shared among agents two hops away from each other to construct the edge potential function in (7), but also the messages (8) may be required to be exchanged among non-direct neighbors, where a physical communication link is not available. This complicates significantly the message exchange scheduling.

Secondly, even if the message scheduling between non-neighboring agents can be realized, the convergence of (8) is not guaranteed in loopy networks. For Gaussian MRF with scalar variables, sufficient convergence conditions have been proposed in (Weiss and Freeman, 2001a; Malioutov et al., 2006; Su and Wu, 2015). However, depending on how the factorization of the underlying joint Gaussian distribution is performed, Gaussian BP may exhibit different convergence properties as different factorizations (different Gaussian models) lead to fundamentally different recursive update structures. Furthermore, these results apply only to scalar Gaussian BP, and extension to vector-valued Gaussian BP is nontrivial as we show in this paper.

The next section derives distributed vector inference based on Gaussian BP with high order interactions (beyond pairwise connections), where information sharing and message exchange requirement conform to the physical network topology. Furthermore, convergence conditions will be studied in Section 4, and we show in Section 5 that the convergence condition obtained is strictly weaker than, i.e., subsumes the convergence conditions in (Weiss and Freeman, 2001a; Malioutov et al., 2006; Su and Wu, 2015).

3. In Section 5, we further show that the convergence condition of Gaussian BP obtained in this paper for model (1) encompasses all existing convergence conditions of Gaussian BP for the corresponding Gaussian MRF.

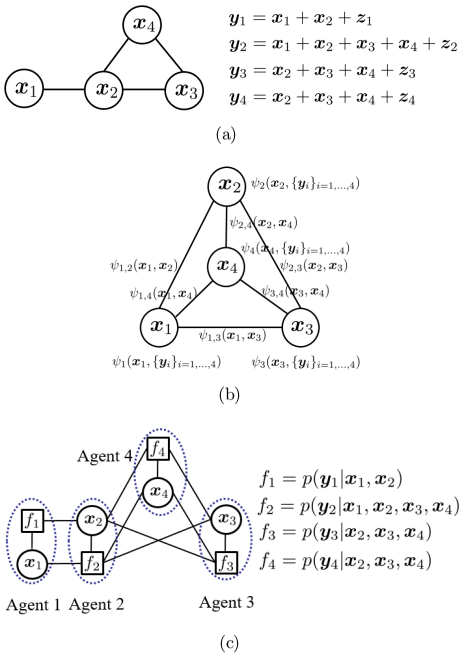

Figure 1: (a) A physical network with 4 agents, where $\{1,2\}$ and $\{2,3,4\}$ are two groups of agents that are within the communication range of each other, respectively. $\mathbf{x}_i$ is the local unknown vector, and $\mathbf{y}_i$ is the local observation at agent i that follows (1); (b) The corresponding MRF of Fig. 1 (a) with $\psi_n\left(\mathbf{x}_n, \{\mathbf{y}_i\}_{i\in n\cup\mathcal{I}(n)}\right)$ and $\psi_{n,i}\left(\mathbf{x}_n, \mathbf{x}_i\right)$ defined in (6) and (7), respectively. (c) The corresponding factor graph of Fig. 1 (a) with f_i defined in (10). Since $p(\mathbf{x}_i)$ does not involve message passing, the $p(\mathbf{x}_i)$ associated to each variable node is not drawn to keep the figure simple.

3. Distributed Inference with Vector-Valued Gaussian BP and Non-Pairwise Interaction

The joint distribution $p\left(\mathbf{x}\right)p\left(\mathbf{y}|\mathbf{x}\right)$ is first written as the product of the prior distribution and the likelihood function of each local linear Gaussian model in (1) as

$$p\left(\mathbf{x}\right)p\left(\mathbf{y}|\mathbf{x}\right) = \prod_{n\in\mathcal{V}} p\left(\mathbf{x}_n\right) \prod_{n\in\mathcal{V}} \underbrace{p\left(\mathbf{y}_n|\left\{\mathbf{x}_i\right\}_{i\in n\cup\mathcal{I}(n)}\right)}_{\triangleq f_n}. \tag{10}$$

To facilitate the derivation of the distributed inference algorithm, the factorization in (10) is expressed in terms of a factor graph (Kschischang et al., 2001), where every vector variable $\mathbf{x}_i$ is represented by a circle (called variable node) and the probability distribution of a vector variable or a group of vector variables is represented by a square (called factor node). A variable node is connected to a factor node if the variable is involved in that particular factor. For example, Fig. 1(c) shows the factor graph representation for the network in Fig. 1(a).

We derive the Gaussian BP algorithm over the corresponding factor graph to learn $\mathbf{x}_n$ for all $n \in \mathcal{V}$ (Kschischang et al., 2001). It involves two types of messages: one is the message from a variable node $\mathbf{x}_j$ to its neighboring factor node f_n, defined as

$$m^{(\ell)}_{j\to f_n}\left(\mathbf{x}_j\right) = p\left(\mathbf{x}_j\right) \prod_{f_k\in\mathcal{B}(j)\setminus f_n} m^{(\ell-1)}_{f_k\to j}\left(\mathbf{x}_j\right), \tag{11}$$

where $\mathcal{B}\left(j\right)$ denotes the set of neighbouring factor nodes of $\mathbf{x}_j$, and $m^{(\ell-1)}_{f_k\to j}\left(\mathbf{x}_j\right)$ is the message from f_k to $\mathbf{x}_j$ at time $\ell-1$. The second type of message is from a factor node f_n to a neighboring variable node $\mathbf{x}_i$, defined as

$$m^{(\ell)}_{f_n\to i}\left(\mathbf{x}_i\right) = \int\cdots\int f_n \times \prod_{j\in\mathcal{B}(f_n)\setminus i} m^{(\ell)}_{j\to f_n}\left(\mathbf{x}_j\right) \mathrm{d}\left\{\mathbf{x}_j\right\}_{j\in\mathcal{B}(f_n)\setminus i}, \tag{12}$$

where $\mathcal{B}\left(f_n\right)$ denotes the set of neighboring variable nodes of f_n. The process iterates between equations (11) and (12). At each iteration ℓ, the approximate marginal distribution, also referred to as belief, on $\mathbf{x}_i$ is computed locally at $\mathbf{x}_i$ as

$$b^{(\ell)}_{\mathrm{BP}}\left(\mathbf{x}_i\right) = p\left(\mathbf{x}_i\right) \prod_{f_n\in\mathcal{B}(i)} m^{(\ell)}_{f_n\to i}\left(\mathbf{x}_i\right). \tag{13}$$

In the sequel, we derive the exact expressions for the messages $m^{(\ell)}_{j\to f_n}\left(\mathbf{x}_j\right)$, $m^{(\ell)}_{f_n\to i}\left(\mathbf{x}_i\right)$, and belief $b^{(\ell)}_{\mathrm{BP}}\left(\mathbf{x}_i\right)$. First, let the initial messages at each variable node and factor node be in Gaussian function forms as

$$m^{(0)}_{f_n\to i}\left(\mathbf{x}_i\right) \propto \exp\left\{-\frac{1}{2}||\mathbf{x}_i - \mathbf{v}^{(0)}_{f_n\to i}||^2_{\mathbf{J}^{(0)}_{f_n\to i}}\right\}. \tag{14}$$

In Appendix A, it is shown that the general expression for the message from variable node j to factor node f_n is

$$m^{(\ell)}_{j\to f_n}\left(\mathbf{x}_j\right) \propto \exp\left\{-\frac{1}{2}||\mathbf{x}_j - \mathbf{v}^{(\ell)}_{j\to f_n}||^2_{\mathbf{J}^{(\ell)}_{j\to f_n}}\right\}, \tag{15}$$

with

$$\mathbf{J}_{j\to f_n}^{(\ell)} = \mathbf{W}_j^{-1} + \sum_{f_k\in\mathcal{B}(j)\setminus f_n} \mathbf{J}_{f_k\to j}^{(\ell-1)}, \tag{16}$$

$$\mathbf{v}_{j\to f_n}^{(\ell)} = \left[\mathbf{J}_{j\to f_n}^{(\ell)}\right]^{-1}\left[\sum_{f_k\in\mathcal{B}(j)\setminus f_n} \mathbf{J}_{f_k\to j}^{(\ell-1)}\mathbf{v}_{f_k\to j}^{(\ell-1)}\right], \tag{17}$$

where $\mathbf{J}_{f_k\to j}^{(\ell-1)}$ and $\mathbf{v}_{f_k\to j}^{(\ell-1)}$ are the message information matrix (inverse of covariance matrix) and mean vector received at variable node j at the $(\ell-1)$-th iteration, respectively. Furthermore, the message from factor node f_n to variable node i is given by

$$m_{f_n\to i}^{(\ell)}(\mathbf{x}_i) \propto \alpha_{f_n\to i}^{(\ell)} \exp\left\{-\frac{1}{2}||\mathbf{x}_i - \mathbf{v}_{f_n\to i}^{(\ell)}||^2_{\mathbf{J}_{f_n\to i}^{(\ell)}}\right\}, \tag{18}$$

with

$$\mathbf{J}_{f_n\to i}^{(\ell)} = \mathbf{A}_{n,i}^T\left[\mathbf{R}_n + \sum_{j\in\mathcal{B}(f_n)\setminus i}\mathbf{A}_{n,j}\left[\mathbf{J}_{j\to f_n}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}\mathbf{A}_{n,i}, \tag{19}$$

$$\mathbf{v}_{f_n\to i}^{(\ell)} = \left[\mathbf{J}_{f_n\to i}^{(\ell)}\right]^{-1}\mathbf{A}_{n,i}^T\left[\mathbf{R}_n + \sum_{j\in\mathcal{B}(f_n)\setminus i}\mathbf{A}_{n,j}\left[\mathbf{J}_{j\to f_n}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}\left(\mathbf{y}_n - \sum_{j\in\mathcal{B}(f_n)\setminus i}\mathbf{A}_{n,j}\mathbf{v}_{j\to f_n}^{(\ell)}\right), \tag{20}$$

and

$$\alpha_{f_n\to i}^{(\ell)} \propto \int\cdots\int \exp\left\{-\frac{1}{2}\mathbf{z}^T\mathbf{\Lambda}_{f_n\to i}^{(\ell)}\mathbf{z}\right\}\mathrm{d}\mathbf{z}. \tag{21}$$

In (21), $\mathbf{\Lambda}_{f_n\to i}^{(\ell)}$ is a diagonal matrix containing the eigenvalues of $\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}^T\mathbf{R}_n^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}} + \mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)}$, with $\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}$ denoting a row block matrix containing $\mathbf{A}_{n,j}$ as row elements for all $j\in\mathcal{B}(f_n)\setminus i$ arranged in ascending order, and $\mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)}$ denoting a block diagonal matrix with $\mathbf{J}_{j\to f_n}^{(\ell)}$ as its block diagonal elements for all $j\in\mathcal{B}(f_n)\setminus i$ arranged in ascending order.

Obviously, the validity of (18) depends on the existence of $\alpha_{f_n\to i}^{(\ell)}$. It is evident that (21) is the integral of a Gaussian distribution and equals to a constant when $\mathbf{\Lambda}_{f_n\to i}^{(\ell)} \succ \mathbf{0}$ or equivalently $\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}^T\mathbf{R}_n^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}} + \mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)} \succ \mathbf{0}$. Otherwise, $\alpha_{f_n\to i}^{(\ell)}$ does not exist. Therefore, the necessary and sufficient condition for the existence of $m_{f_n\to i}^{(\ell)}(\mathbf{x}_i)$ is

$$\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}^T\mathbf{R}_n^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}} + \mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)} \succ \mathbf{0}. \tag{22}$$

In general, the necessary and sufficient condition is difficult to be verified, as $\mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)}$ changes in each iteration. However, as $\mathbf{R}_n^{-1} \succ \mathbf{0}$, it can be decomposed as $\mathbf{R}_n^{-1} = \widetilde{\mathbf{R}}_n^T\widetilde{\mathbf{R}}_n$. Then

$$\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}^T\mathbf{R}_n^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}} = \left(\widetilde{\mathbf{R}}_n\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}\right)^T\left(\widetilde{\mathbf{R}}_n\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}\right) \succeq \mathbf{0}.$$

Hence, one simple sufficient condition to guarantee (22) is $\mathbf{J}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}^{(\ell)} \succ \mathbf{0}$ or equivalently its diagonal block matrix $\mathbf{J}_{j\to f_n}^{(\ell)} \succ \mathbf{0}$ for all $j\in\mathcal{B}(f_n)\setminus i$. The following lemma shows that setting the initial message covariances $\mathbf{J}_{f_n\to i}^{(0)} \succeq \mathbf{0}$ for all $(n,i)\in\mathcal{E}_{\mathrm{Net}}$ guarantees $\mathbf{J}_{j\to f_n}^{(\ell)} \succ \mathbf{0}$ for $\ell\geq 1$ and all $(n,j)\in\mathcal{E}_{\mathrm{Net}}$.

Lemma 2 *Let the initial messages at factor node f_k be in Gaussian forms with the initial message information matrix $\boldsymbol{J}_{f_k\to j}^{(0)} \succeq \boldsymbol{0}$ for all $k\in\mathcal{V}$ and $j\in\mathcal{B}(f_k)$. Then $\boldsymbol{J}_{j\to f_n}^{(\ell)} \succ \boldsymbol{0}$ and $\boldsymbol{J}_{f_k\to j}^{(\ell)} \succ \boldsymbol{0}$ for all $\ell\geq 1$ with $j\in\mathcal{V}$ and $f_n, f_k\in\mathcal{B}(j)$. Furthermore, in this case, all messages $m_{j\to f_n}^{(\ell)}(\boldsymbol{x}_j)$ and $m_{f_k\to j}^{(\ell)}(\boldsymbol{x}_i)$ are well defined.*

Proof See Appendix B. ■

For this factor graph based approach, according to the message updating procedure (15) and (18), message exchange is only needed between neighboring agents (an agent refers to a variable-factor pair as shown in Fig. 1 (c)). For example, the messages transmitted from agent n to its neighboring agent i are $m_{f_n\to i}^{(\ell)}(\mathbf{x}_i)$ and $m_{n\to f_i}^{(\ell)}(\mathbf{x}_n)$. Thus, the factor graph does impose a clear messaging schedule, and the message passing scheme given in (11) and (12) conforms with the network topology. Furthermore, if the messages $m_{j\to f_n}^{(\ell)}(\mathbf{x}_j)$ and $m_{f_n\to i}^{(\ell)}(\mathbf{x}_i)$ exist for all ℓ (which can be achieved using Lemma 2), the messages are Gaussian, therefore only the corresponding mean vectors and information matrices (inverse of covariance matrices) are needed to be exchanged.

Finally, if the Gaussian BP messages exist, according to the definition of belief in (13), $b_{\mathrm{BP}}^{(\ell)}(\mathbf{x}_i)$ at iteration ℓ is computed as

$$\begin{aligned}\mathbf{b}_{\mathrm{BP}}^{(\ell)}(\mathbf{x}_i) &= p(\mathbf{x}_i)\prod_{f_n\in\mathcal{B}(i)} m_{f_n\to i}^{(\ell)}(\mathbf{x}_i),\\ &\propto \mathcal{N}\left(\mathbf{x}_i|\boldsymbol{\mu}_i^{(\ell)}, \mathbf{P}_i^{(\ell)}\right),\end{aligned}$$

where the belief covariance matrix

$$\mathbf{P}_i^{(\ell)} = \left[\mathbf{W}_i^{-1} + \sum_{f_n\in\mathcal{B}(i)}\mathbf{J}_{f_n\to i}^{(\ell)}\right]^{-1}, \tag{23}$$

and mean vector

$$\boldsymbol{\mu}_i^{(\ell)} = \mathbf{P}_i^{(\ell)}\left[\sum_{f_n\in\mathcal{B}(i)}\mathbf{J}_{f_n\to i}^{(\ell)}\mathbf{v}_{f_n\to i}^{(\ell)}\right]. \tag{24}$$

The iterative algorithm based on Gaussian BP is summarized as follows. The algorithm is started by setting the messages from factor nodes to variable nodes as in (14). At each round of message exchange, every variable node computes the output messages to its neighboring factor nodes according to (16) and (17). After receiving the messages from its neighboring variable nodes, each factor node computes its output messages according to (19) and (20). The iterative computation terminates when the iterates in (15) or (18) tend to approach a fixed value or the maximum number of iterations is reached.

Remark 3 *We assume that $\boldsymbol{R}_n \succ \boldsymbol{0}$ in this paper. If, however, some of the observations are noiseless, for example, $\boldsymbol{R}_n = \boldsymbol{0}$, the local observation is $\boldsymbol{y}_n = \sum_{i\in n\cup\mathcal{I}(n)} \boldsymbol{A}_{n,i}\boldsymbol{x}_i$. Then the corresponding local likelihood function is represented by the Dirac measure $\delta(\boldsymbol{y}_n - \sum_{i\in n\cup\mathcal{I}(n)} \boldsymbol{A}_{n,i}\boldsymbol{x}_i)$. Suppose, for example, there is only one agent with $\boldsymbol{R}_n = \boldsymbol{0}$, and all others are $\boldsymbol{R}_i \succ \boldsymbol{0}$. The the joint distribution is written as*

$$p(\boldsymbol{x})\, p(\boldsymbol{y}|\boldsymbol{x}) = \delta(\boldsymbol{y}_n - \sum_{i\in n\cup\mathcal{I}(n)} \boldsymbol{A}_{n,i}\boldsymbol{x}_i) \prod_{j\in\mathcal{V}} p(\boldsymbol{x}_j) \prod_{k\in\mathcal{V}} p\left(\boldsymbol{y}_k | \{\boldsymbol{x}_i\}_{i\in k\cup\mathcal{I}(k)}\right).$$

In this case, if $\boldsymbol{A}_{n,n}$ is invertible, then, by the definition of the Dirac measure, we have $\boldsymbol{x}_n = \boldsymbol{A}_{n,n}^{-1}\left(\boldsymbol{y}_n - \sum_{i\in\mathcal{I}(n)} \boldsymbol{A}_{n,i}\boldsymbol{x}_i\right)$. By substituting this equation into all of the likelihood functions involving $\boldsymbol{x}_n$, we have the equivalent joint distribution as in (10) with all the likelihood functions having a positive definite noise covariance. We thereafter can apply Gaussian BP to this new factorization and the convergence analysis in this paper still applies. Therefore, without loss of generality, we assume all $\boldsymbol{R}_n \succ \boldsymbol{0}$. Note that when $\boldsymbol{R}_n = \boldsymbol{0}$ for all n, this problem is equivalent to solving algebraic equations, which has been studied in (Shental et al., 2008b) using Gaussian BP.

4. Convergence Analysis

The challenge of deploying the Gaussian BP algorithm for large-scale networks is in determining whether it will converge or not. In particular, it is generally known that if the factor graph contains cycles, the Gaussian BP algorithm may diverge. Thus, determining convergence conditions for the Gaussian BP algorithm is very important. Sufficient conditions for the convergence of Gaussian BP with scalar variables in loopy graphs are available in (Weiss and Freeman, 2001a; Malioutov et al., 2006; Su and Wu, 2015). However, these conditions are derived based on pairwise graphs with local functions in the form of (6) and (7). This contrasts with the model considered in this paper, where the f_n in (10) involves high-order interactions between vector variables, and thus the convergence results in (Weiss and Freeman, 2001a; Malioutov et al., 2006; Su and Wu, 2015) cannot be applied to the factor graph based vector-form Gaussian BP.

Due to the recursive updating property of $m^{(\ell)}_{j\to f_n}(\mathbf{x}_j)$ and $m^{(\ell)}_{f_n\to i}(\mathbf{x}_i)$ in (15) and (18), the message evolution can be simplified by combining these two kinds of messages into one. By substituting $\mathbf{J}^{(\ell)}_{j\to f_n}$ in (16) into (19), the updating of the message covariance matrix inverse, referred to as message information matrix in the following, can be denoted as

$$\begin{aligned}\mathbf{J}^{(\ell)}_{f_n\to i} &= \mathbf{A}^T_{n,i}\Big[\mathbf{R}_n + \sum_{j\in\mathcal{B}(f_n)\setminus i} \mathbf{A}_{n,j}\Big[\mathbf{W}_j^{-1} + \sum_{f_k\in\mathcal{B}(j)\setminus f_n} \mathbf{J}^{(\ell-1)}_{f_k\to j}\Big]^{-1}\mathbf{A}^T_{n,j}\Big]^{-1}\mathbf{A}_{n,i}\\ &\triangleq \mathcal{F}_{n\to i}\left(\left\{\mathbf{J}^{(\ell-1)}_{f_k\to j}\right\}_{(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)}\right),\end{aligned} \tag{25}$$

where $\widetilde{\mathcal{B}}(f_n,i) = \{(f_k,j)\,|j\in\mathcal{B}(f_n)\setminus i, f_k\in\mathcal{B}(j)\setminus f_n\}$. Observing that $\mathbf{J}^{(\ell)}_{f_n\to i}$ in (25) is independent of $\mathbf{v}^{(\ell)}_{j\to f_n}$ and $\mathbf{v}^{(\ell)}_{f_n\to i}$ in (17) and (18), so we can first focus on the convergence property of $\mathbf{J}^{(\ell)}_{f_n\to i}$ alone and then later on that of $\mathbf{v}^{(\ell)}_{f_n\to i}$. With the convergence characterization of $\mathbf{J}^{(\ell)}_{f_n\to i}$ and $\mathbf{v}^{(\ell)}_{f_n\to i}$, we will further investigate the convergence of belief covariances and means in (23) and (24), respectively.

Note that computing $\mathbf{P}^{(\ell)}_j$ requires all the incoming messages from neighboring nodes including $\mathbf{J}^{(\ell)}_{f_n\to j}$ as shown in (23) by replacing the subscript i with j in (23). However, according to (25), when computing $\mathbf{J}^{(\ell)}_{f_n\to i}$ the quantity $\mathbf{J}^{(\ell-1)}_{f_n\to j}$ is excluded, i.e., the quantity inside the inner square brackets equals $[\mathbf{P}^{(\ell-1)}_j]^{-1} - \mathbf{J}^{(\ell-1)}_{f_n\to j}$. Therefore, one cannot compute $\mathbf{J}^{(\ell)}_{f_n\to i}$ from $\mathbf{P}^{(\ell)}_j$ alone.

4.1 Convergence of Message Information Matrices

To efficiently represent the updates of all message information matrices, we introduce the following definitions. Let

$$\mathbf{J}^{(\ell-1)} \triangleq \mathtt{Bdiag}\left(\left\{\mathbf{J}^{(\ell-1)}_{f_n\to i}\right\}_{n\in\mathcal{V}, i\in\mathcal{B}(f_n)}\right)$$

be a block diagonal matrix with diagonal blocks being the message information matrices in the network at time $\ell-1$ with index arranged in ascending order first on n and then on i. Using the definition of $\mathbf{J}^{(\ell-1)}$, the term $\sum_{f_k\in\mathcal{B}(j)\setminus f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}$ in (25) can be written as $\boldsymbol{\Xi}_{n,j}\mathbf{J}^{(\ell-1)}\boldsymbol{\Xi}^T_{n,j}$, where $\boldsymbol{\Xi}_{n,j}$ is for selecting appropriate components from $\mathbf{J}^{(\ell-1)}$ to form the summation. Further, define $\mathbf{H}_{n,i} = \left[\{\mathbf{A}_{n,j}\}_{j\in B(f_n)\setminus i}\right]$, $\boldsymbol{\Psi}_{n,i} = \mathtt{Bdiag}\left(\left\{\mathbf{W}_j^{-1}\right\}_{j\in B(f_n)\setminus i}\right)$ and $\mathbf{K}_{n,i} = \mathtt{Bdiag}\left(\{\boldsymbol{\Xi}_{n,j}\}_{j\in B(f_n)\setminus i}\right)$, all with component blocks arranged with ascending order on j. Then (25) can be written as

$$\mathbf{J}^{(\ell)}_{f_n\to i} = \mathbf{A}^T_{n,i}\left\{\mathbf{R}_n + \mathbf{H}_{n,i}\left[\boldsymbol{\Psi}_{n,i} + \mathbf{K}_{n,i}\left(\mathbf{I}_{|\mathcal{B}(f_n)|-1}\otimes\mathbf{J}^{(\ell-1)}\right)\mathbf{K}^T_{n,i}\right]^{-1}\mathbf{H}^T_{n,i}\right\}^{-1}\mathbf{A}_{n,i}. \tag{26}$$

Now, we define the function $\mathcal{F} \triangleq \{\mathcal{F}_{1\to k},\ldots,\mathcal{F}_{n\to i},\ldots,\mathcal{F}_{n\to M}\}$ that satisfies $\mathbf{J}^{(\ell)} = \mathcal{F}\left(\mathbf{J}^{(\ell-1)}\right)$. Then, by stacking $\mathbf{J}^{(\ell)}_{f_n\to i}$ on the left side of (26) for all n and i as the block diagonal matrix $\mathbf{J}^{(\ell)}$, we obtain

$$\begin{aligned}\mathbf{J}^{(\ell)} &= \mathbf{A}^T\{\boldsymbol{\Omega} + \mathbf{H}\left[\boldsymbol{\Psi} + \mathbf{K}\left(\mathbf{I}_\varphi\otimes\mathbf{J}^{(\ell-1)}\right)\mathbf{K}^T\right]^{-1}\mathbf{H}^T\}^{-1}\mathbf{A},\\ &\triangleq \mathcal{F}\left(\mathbf{J}^{(\ell-1)}\right),\end{aligned} \tag{27}$$

where $\mathbf{A}$, $\mathbf{H}$, $\boldsymbol{\Psi}$, and $\mathbf{K}$ are block diagonal matrices with block elements $\mathbf{A}_{n,i}$, $\mathbf{H}_{n,i}$, $\boldsymbol{\Psi}_{n,i}$, and $\mathbf{K}_{n,i}$, respectively, arranged in ascending order, first on n and then on i (i.e., the same order as $\mathbf{J}^{(\ell)}_{f_n\to i}$ in $\mathbf{J}^{(\ell)}$). Furthermore, $\varphi = \sum_{n=1}^M |\mathcal{B}(f_n)|\,(|\mathcal{B}(f_n)|-1)$ and $\boldsymbol{\Omega}$ is a block diagonal matrix with diagonal blocks $\mathbf{I}_{|\mathcal{B}(f_n)|}\otimes\mathbf{R}_n$ with ascending order on n. We first present some properties of the updating operator $\mathcal{F}(\cdot)$, the proofs being provided in Appendix C.

Proposition 4 *The updating operator $\mathcal{F}(\cdot)$ satisfies the following properties:*

P 4.1: $\mathcal{F}\left(\mathbf{J}^{(\ell)}\right) \succeq \mathcal{F}\left(\mathbf{J}^{(\ell-1)}\right)$, if $\mathbf{J}^{(\ell)} \succeq \mathbf{J}^{(\ell-1)} \succeq \mathbf{0}$.

P 4.2: $\alpha\mathcal{F}\left(\mathbf{J}^{(\ell)}\right) \succ \mathcal{F}\left(\alpha\mathbf{J}^{(\ell)}\right)$ and $\mathcal{F}\left(\alpha^{-1}\mathbf{J}^{(\ell)}\right) \succ \alpha^{-1}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right)$, if $\mathbf{J}^{(\ell)} \succ \mathbf{0}$ and $\alpha > 1$.

P 4.3: Define $\mathbf{U} \triangleq \mathbf{A}^T\mathbf{\Omega}^{-1}\mathbf{A}$ and $\mathbf{L} \triangleq \mathbf{A}^T\left[\mathbf{\Omega} + \mathbf{H}\mathbf{\Psi}^{-1}\mathbf{H}^T\right]^{-1}\mathbf{A}$. With arbitrary $\mathbf{J}^{(0)} \succeq \mathbf{0}$, $\mathcal{F}\left(\mathbf{J}^{(\ell)}\right)$ is bounded by $\mathbf{U} \succeq \mathcal{F}\left(\mathbf{J}^{(\ell)}\right) \succeq \mathbf{L} \succ \mathbf{0}$ for $\ell \geq 1$.

Based on the above properties of $\mathcal{F}(\cdot)$, we can establish the convergence of the information matrices.

Theorem 5 *There exists a unique positive definite fixed point $\boldsymbol{J}^*$ for the mapping $\mathcal{F}(\cdot)$.*

Proof The set $[\mathbf{L}, \mathbf{U}]$ is a compact set. Further, according to Proposition 4, P 4.3, for arbitrary $\mathbf{J}^{(0)} \succeq \mathbf{0}$, $\mathcal{F}$ maps $[\mathbf{L}, \mathbf{U}]$ into itself starting from $\ell \geq 1$. Next, we show that $[\mathbf{L}, \mathbf{U}]$ is a convex set. Suppose that $\mathbf{X}$, $\mathbf{Y} \in [\mathbf{L}, \mathbf{U}]$, and $0 \leq t \leq 1$, then $t\mathbf{X} - t\mathbf{L}$ and $(1-t)\mathbf{Y} - (1-t)\mathbf{L}$ are positive semidefinite (p.s.d.) matrices. Since the sum of two p.s.d. matrices is a p.s.d. matrix, $t\mathbf{X} + (1-t)\mathbf{Y} \succeq \mathbf{L}$. Likewise, it can be shown that $t\mathbf{X} + (1-t)\mathbf{Y} \preceq \mathbf{U}$. Thus, the continuous function $\mathcal{F}$ maps a compact convex subset of the Banach space of positive definite matrices into itself. Therefore, the mapping $\mathcal{F}$ has a fixed point in $[\mathbf{L}, \mathbf{U}]$ according to Brouwer's Fixed-Point Theorem (Zeidler, 1985), and the fixed point is positive definite (p.d.).

Next, we prove the uniqueness of the fixed point. Suppose that there exist two fixed points $\mathbf{J}^* \succ \mathbf{0}$ and $\widetilde{\mathbf{J}}^* \succ \mathbf{0}$. Since $\mathbf{J}^*$ and $\widetilde{\mathbf{J}}^*$ are p.d., their components $\mathbf{J}^*_{f_n \to i}$ and $\widetilde{\mathbf{J}}^*_{f_n \to i}$ are also p.d. matrices. For the component blocks of $\mathbf{J}^*$ and $\widetilde{\mathbf{J}}^*$, there are two possibilities: 1) $\widetilde{\mathbf{J}}^*_{f_n \to i} - \mathbf{J}^*_{f_n \to i} \succ \mathbf{0}$ or $\widetilde{\mathbf{J}}^*_{f_n \to i} - \mathbf{J}^*_{f_n \to i}$ is indefinite for some $n, i \in \mathcal{V}$, and 2) $\widetilde{\mathbf{J}}^*_{f_n \to i} - \mathbf{J}^*_{f_n \to i} \preceq 0$ for all $n, i \in \mathcal{V}$.

For the first case, there must exist $\xi_{f_n,i} > 1$ such that $\xi_{f_n,i}\mathbf{J}^*_{f_n \to i} - \widetilde{\mathbf{J}}^*_{f_n \to i}$ has one or more zero eigenvalues, while all other eigenvalues are positive. Pick the component matrix with the maximum $\xi_{f_n,i}$ among those falling into this case, say $\xi_{f_\varrho,\tau}$, then, we can write

$$\xi_{f_\varrho,\tau}\mathbf{J}^*_{f_\varrho \to \tau} - \widetilde{\mathbf{J}}^*_{f_\varrho \to \tau} \succeq \mathbf{0}, \tag{28}$$

or in terms of the information matrices for the whole network

$$\xi_{f_\varrho,\tau}\mathbf{J}^* \succeq \widetilde{\mathbf{J}}^* \succ \mathbf{0}, \quad \xi_{f_\varrho,\tau} > 1. \tag{29}$$

Applying $\mathcal{F}$ on both sides of (29), according to the monotonic property of $\mathcal{F}(\cdot)$ as shown in Proposition 4, P 4.1, we have

$$\mathcal{F}\left(\xi_{f_\varrho,\tau}\mathbf{J}^*\right) \succeq \mathcal{F}\left(\widetilde{\mathbf{J}}^*\right) = \widetilde{\mathbf{J}}^*, \tag{30}$$

where the equality is due to $\widetilde{\mathbf{J}}^*$ being a fixed point. According to Proposition 4, P 4.2, $\xi_{f_\varrho,\tau}\mathcal{F}(\mathbf{J}^*) \succ \mathcal{F}\left(\xi_{f_\varrho,\tau}\mathbf{J}^*\right)$. Therefore, from (30), we obtain $\xi_{f_\varrho,\tau}\mathbf{J}^* \succ \widetilde{\mathbf{J}}^*$. Consequently,

$$\xi_{f_\varrho,\tau}\mathbf{J}^*_{f_\varrho,\tau} \succ \widetilde{\mathbf{J}}^*_{f_\varrho,\tau}.$$

But this contradicts with $\xi_{f_\varrho,\tau}\mathbf{J}^*_{f_\varrho,\tau} - \widetilde{\mathbf{J}}^*_{f_\varrho,\tau}$ having one or more zero eigenvalues as discussed before (28). Therefore, we must have $\mathbf{J}^* = \widetilde{\mathbf{J}}^*$.

On the other hand, if we have case two, which is $\widetilde{\mathbf{J}}^*_{f_n \to i} - \mathbf{J}^*_{f_n \to i} \preceq 0$ for all $n, i \in \mathcal{V}$, we can repeat the above derivation with the roles of $\widetilde{\mathbf{J}}^*$ and $\mathbf{J}^*$ reversed, and we would again obtain $\mathbf{J}^* = \widetilde{\mathbf{J}}^*$. Consequently, $\mathbf{J}^*$ is unique. ■

Lemma 2 states that with arbitrary p.s.d. initial message information matrices, the message information matrices will be kept as p.d. at every iteration. On the other hand, Theorem 5 indicates that there exists a unique fixed point for the mapping $\mathcal{F}$. Next, we will show that, with arbitrary initial value $\mathbf{J}^{(0)} \succeq 0$, $\mathbf{J}^{(\ell)}$ converges to a unique p.d. matrix.

Theorem 6 *The matrix sequence $\left\{\boldsymbol{J}^{(\ell)}\right\}_{l=0,1,\ldots}$ defined by (27) converges to a unique positive definite matrix $\boldsymbol{J}^*$ for any initial covariance matrix $\boldsymbol{J}^{(0)} \succeq \mathbf{0}$.*

Proof With arbitrary initial value $\mathbf{J}^{(0)} \succeq \mathbf{0}$, following Proposition 4, P 4.3, we have $\mathbf{U} \succeq \mathbf{J}^{(1)} \succeq \mathbf{L} \succ \mathbf{0}$. On the other hand, according to Theorem 5, (27) has a unique fixed point $\mathbf{J}^* \succ \mathbf{0}$. Notice that we can always choose a scalar $\alpha > 1$ such that

$$\alpha\mathbf{J}^* \succeq \mathbf{J}^{(1)} \succeq \mathbf{L}. \tag{31}$$

Applying $\mathcal{F}(\cdot)$ to (31) ℓ times, and using Proposition 4, P 4.1, we have

$$\mathcal{F}^\ell(\alpha\mathbf{J}^*) \succeq \mathcal{F}^{\ell+1}\left(\mathbf{J}^{(0)}\right) \succeq \mathcal{F}^\ell(\mathbf{L}), \tag{32}$$

where $\mathcal{F}^\ell(\mathbf{X})$ denotes applying $\mathcal{F}$ on $\mathbf{X}$ ℓ times.

We start from the left inequality in (32). According to Proposition 4, P 4.2, $\alpha\mathbf{J}^* \succ \mathcal{F}(\alpha\mathbf{J}^*)$. Applying $\mathcal{F}$ again gives $\mathcal{F}(\alpha\mathbf{J}^*) \succ \mathcal{F}^2(\alpha\mathbf{J}^*)$. Applying $\mathcal{F}(\cdot)$ repeatedly, we can obtain $\mathcal{F}^2(\alpha\mathbf{J}^*) \succ \mathcal{F}^3(\alpha\mathbf{J}^*) \succ \mathcal{F}^4(\alpha\mathbf{J}^*)$, etc. Thus $\mathcal{F}^\ell(\alpha\mathbf{J}^*)$ is a non-increasing sequence with respect to the partial order induced by the cone of p.s.d. matrices as ℓ increases. Furthermore, since $\mathcal{F}(\cdot)$ is bounded below by $\mathbf{L}$, $\mathcal{F}^\ell(\alpha\mathbf{J}^*)$ converges. Finally, since there exists only one fixed point for $\mathcal{F}(\cdot)$, $\lim_{l\to\infty}\mathcal{F}^\ell(\alpha\mathbf{J}^*) = \mathbf{J}^*$. On the other hand, for the right hand side of (32), as $\mathcal{F}(\cdot) \succeq \mathbf{L}$, we have $\mathcal{F}(\mathbf{L}) \succeq \mathbf{L}$. Applying $\mathcal{F}$ repeatedly gives successively $\mathcal{F}^2(\mathbf{L}) \succeq \mathcal{F}(\mathbf{L})$, $\mathcal{F}^3(\mathbf{L}) \succeq \mathcal{F}^2(\mathbf{L})$, etc. So, $\mathcal{F}^\ell(\mathbf{L})$ is an non-decreasing sequence (with respect to the partial order induced by the cone of p.s.d. matrices). Since $\mathcal{F}(\cdot)$ is upper bounded by $\mathbf{U}$, $\mathcal{F}^\ell(\mathbf{L})$ is a convergent sequence. Again, due to the uniqueness of the fixed point, we have $\lim_{l\to\infty}\mathcal{F}^\ell(\mathbf{L}) = \mathbf{J}^*$. Finally, taking the limit with respect to ℓ on (32), we have $\lim_{l\to\infty}\mathcal{F}^\ell\left(\mathbf{J}^{(0)}\right) = \mathbf{J}^*$, for arbitrary initial $\mathbf{J}^{(0)} \succeq \mathbf{0}$. ■

Remark 7 *According to Theorem 6, the information matrix $\boldsymbol{J}^{(\ell)}_{f_n \to i}$ converges if all initial information matrices are p.s.d., i.e., $\boldsymbol{J}^{(0)}_{f_n \to i} \succeq \boldsymbol{0}$ for all $i \in \mathcal{V}$ and $f_n \in \mathcal{B}(i)$. However, for the pairwise model, the messages are derived based on the classical Gaussian MRF based factorization (in the form of equations (6) and (7)) of the joint distribution. This differs from the model considered in this paper, where the factor f_n follows equation (10), which leads to intrinsically different recursive equations. More specifically, for BP on the*

Gaussian MRF based factorization, the information matrix does not necessarily converge for all initial nonnegative values (for the scalar variable case) as shown in (Malioutov et al., 2006; Moallemi and Roy, 2009a).

Remark 8 *Due to the computation of $\boldsymbol{J}_{f_n\to i}^{(\ell)}$ being independent of the local observations $\boldsymbol{y}_n$, as long as the network topology does not change, the converged value $\boldsymbol{J}_{f_n\to i}^{*}$ can be precomputed offline and stored at each agent, and there is no need to re-compute $\boldsymbol{J}_{f_n\to i}^{*}$ even if $\boldsymbol{y}_n$ varies.*

Another fundamental question is how fast the convergence is, and this is the focus of the discussion below. Since the convergence of a dynamic system is often studied with respect to the part metric (Chueshov, 2002), in the following, we start by introducing the part metric.

Definition 9 *Part (Birkhoff) Metric (Chueshov, 2002): For arbitrary symmetric matrices $\boldsymbol{X}$ and $\boldsymbol{Y}$ with the same dimension, if there exists $\alpha \geq 1$ such that $\alpha\boldsymbol{X} \succeq \boldsymbol{Y} \succeq \alpha^{-1}\boldsymbol{X}$, $\boldsymbol{X}$ and $\boldsymbol{Y}$ are called the parts, and $\mathrm{d}(\boldsymbol{X}, \boldsymbol{Y}) \triangleq \inf\left\{\log\alpha : \alpha\boldsymbol{X} \succeq \boldsymbol{Y} \succeq \alpha^{-1}\boldsymbol{X}, \alpha \geq 1\right\}$ defines a metric called the part metric.*

As it is useful to have an estimate of the convergence rate of $\mathbf{J}^{(\ell)}$ in terms of the more standard induced matrix norms, we further introduce the notion of monotone norms. The norms $||\cdot||_2$ and $||\cdot||_F$ (Frobenus norm) are monotone norms.

Definition 10 *Monotone Norm (Ciarlet, 1989, 2.2-10): A matrix norm $\|\cdot\|$ is monotone if*

$$\boldsymbol{X} \succeq \boldsymbol{0}, \boldsymbol{Y} \succeq \boldsymbol{X} \Rightarrow \|\boldsymbol{Y}\| \geq \|\boldsymbol{X}\|.$$

Next, for arbitrary $\epsilon > 0$, we will show that $\left\{\mathbf{J}^{(\ell)}\right\}_{l=1,..}$ approaches the ϵ-neighborhood of the fixed point $\mathbf{J}^{\star}$ exponentially fast with respect to the monotone norm. To this end, for a fixed $\epsilon > 0$, define the set

$$\mathcal{C} = \left\{\mathbf{J}^{(\ell)} | \mathbf{U} \succeq \mathbf{J}^{(\ell)} \succeq \mathbf{J}^{*} + \epsilon\mathbf{I}\right\} \cup \left\{\mathbf{J}^{(\ell)} | \mathbf{J}^{*} - \epsilon\mathbf{I} \succeq \mathbf{J}^{(\ell)} \succeq \mathbf{L}\right\}. \tag{33}$$

Theorem 11 *With the initial message information matrix set to be an arbitrary p.s.d. matrix, i.e., $\boldsymbol{J}_{f_n\to i}^{(0)} \succeq \boldsymbol{0}$, the sequence $\left\{\boldsymbol{J}^{(\ell)}\right\}_{l=0,1,...}$ approaches an arbitrarily small neighborhood of the fixed positive definite matrix $\boldsymbol{J}^{*}$ at an exponential rate with respect to any matrix norm.*

Proof Fix $\epsilon > 0$ and consider the set $\mathcal{C}$ defined in (33). It suffices to show that the quantity $\|\mathbf{J}^{(\ell)} - \mathbf{J}^{*}\|$, where $\|\cdot\|$ is a monotone norm as defined in Definition 10, decays exponentially as long as $\mathbf{J}^{(s)} \in \mathcal{C}$ for all $s \in \{0, 1, \cdots \ell\}$. To this end, for $\mathbf{J}^{(\ell)} \in \mathcal{C}$, and $\mathbf{J}^{*} \notin \mathcal{C}$ (necessarily), according to Definition 9, we have $\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right) \triangleq \inf\left\{\log\alpha : \alpha\mathbf{J}^{(\ell)} \succeq \mathbf{J}^{*} \succeq \alpha^{-1}\mathbf{J}^{(\ell)}\right\}$. Since $\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)$ is the smallest number satisfying $\alpha\mathbf{J}^{(\ell)} \succeq \mathbf{J}^{*} \succeq \alpha^{-1}\mathbf{J}^{(\ell)}$, this is equivalent to

$$\exp\left\{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathbf{J}^{(\ell)} \succeq \mathbf{J}^{*} \succeq \exp\left\{-\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathbf{J}^{(\ell)}. \tag{34}$$

Applying Proposition 4, P 4.1 to (34), we have

$$\mathcal{F}\left(\exp\left\{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathbf{J}^{(\ell)}\right) \succ \mathcal{F}(\mathbf{J}^{*}) \succ \mathcal{F}\left(\exp\left\{-\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathbf{J}^{(\ell)}\right).$$

Then applying Proposition 4, P 4.2 and considering that $\exp\left\{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\} > 1$ and $\exp\left\{-\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\} < 1$, we obtain

$$\exp\left\{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right) \succeq \mathcal{F}(\mathbf{J}^{*}) \succeq \exp\left\{-\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right).$$

Notice that, for arbitrary p.d. matrices $\mathbf{X}$ and $\mathbf{Y}$, if $\mathbf{X} - k\mathbf{Y} \succ \mathbf{0}$, then, by definition, we have $\mathbf{x}^T\mathbf{X}\mathbf{x} - k\mathbf{x}^T\mathbf{Y}\mathbf{x} > 0$ for arbitrary $\mathbf{x} \neq \mathbf{0}$. Then, there must exist $o > 0$ that is small enough such that $\mathbf{x}^T\mathbf{X}\mathbf{x} - (k+o)\,\mathbf{x}^T\mathbf{Y}\mathbf{x} > 0$ or equivalently $\mathbf{X} \succ (k+o)\,\mathbf{Y}$. Thus, as $\exp(\cdot)$ is a continuous function, there must exist some $\triangle\mathrm{d} > 0$ such that

$$\exp\left\{-\triangle\mathrm{d} + \mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right) \succ \mathcal{F}(\mathbf{J}^{*}) \succ \exp\left\{\triangle\mathrm{d} - \mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right). \tag{35}$$

Now, using the definition of the part metric, (35) is equivalent to

$$-\triangle\mathrm{d} + \mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right) \geq \mathrm{d}\left(\mathcal{F}\left(\mathbf{J}^{(\ell)}\right), \mathcal{F}(\mathbf{J}^{*})\right).$$

Hence, we obtain $\mathrm{d}\left(\mathcal{F}\left(\mathbf{J}^{(\ell)}\right), \mathcal{F}(\mathbf{J}^{*})\right) < \mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)$. Since this result holds for any $\mathbf{J}^{(\ell)} \in \mathcal{C}$, we also have $\mathrm{d}\left(\mathcal{F}\left(\mathbf{J}^{(\ell)}\right), \mathcal{F}(\mathbf{J}^{*})\right) < c\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)$, where $c = \sup_{\mathbf{J}^{(\ell)}\in\mathcal{C}} \frac{\mathrm{d}\left(\mathcal{F}\left(\mathbf{J}^{(\ell)}\right), \mathcal{F}(\mathbf{J}^{*})\right)}{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)} < 1$. Since $\mathbf{J}^{(\ell+1)} = \mathcal{F}\left(\mathbf{J}^{(\ell)}\right)$ and $\mathbf{J}^{*} = \mathcal{F}(\mathbf{J}^{*})$, we have

$$\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right) < c^{\ell}\mathrm{d}\left(\mathbf{J}^{(0)}, \mathbf{J}^{*}\right). \tag{36}$$

According to (Krause and Nussbaum, 1993, Lemma 2.3), the convergence rate of $||\mathbf{J}^{(\ell)} - \mathbf{J}^{*}||$ can be determined by that of $\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)$. More specifically,

$$||\mathbf{J}^{(\ell)} - \mathbf{J}^{*}|| \leq \left(2\exp\left\{\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\} - \exp\left\{-\mathrm{d}\left(\mathbf{J}^{(\ell)}, \mathbf{J}^{*}\right)\right\} - 1\right)\min\left\{||\mathbf{J}^{(\ell)}||, ||\mathbf{J}^{*}||\right\}, \tag{37}$$

where $||\cdot||$ is a monotone norm defined on the p.s.d. cone:

As we show in Proposition 4, P 4.3 that $\mathbf{J}^{(\ell)}$ is bounded, then $||\mathbf{J}^{(\ell)}||$ and $||\mathbf{J}^{*}||$ must be finite. Let ζ be the largest value of $\min\left\{||\mathbf{J}^{(\ell)}||, ||\mathbf{J}^{*}||\right\}$ for all $\{\mathbf{J}^{(\ell)}\}$ with $\ell \geq 0$, then $\zeta > 0$. According to (36) and (37), we have that

$$||\mathbf{J}^{(\ell)} - \mathbf{J}^{*}|| < \zeta\left(2\exp\left\{c^{\ell}d_0\right\} - \exp\left\{-c^{\ell}d_0\right\} - 1\right), \tag{38}$$

with $0 < c < 1$ and $d_0 = \mathrm{d}\left(\mathbf{J}^{(0)}, \mathbf{J}^{*}\right)$, which is a constant. The above inequality is equivalent to

$$||\mathbf{J}^{(\ell)} - \mathbf{J}^{*}|| < \zeta\left(3\exp\left\{c^{\ell}d_0\right\} - \exp\left\{c^{\ell}d_0\right\} - \exp\left\{-c^{\ell}d_0\right\} - 1\right). \tag{39}$$

Since both $\exp\left\{c^\ell d_0\right\}$ and $\exp\left\{-c^\ell d_0\right\}$ are positive and $\exp\left\{c^\ell d_0\right\}\exp\left\{-c^\ell d_0\right\} = 1$, according to the arithmetic-geometric mean inequality, we have $\exp\left\{c^\ell d_0\right\} + \exp\left\{-c^\ell d_0\right\} \geq 2\left(\exp\left\{c^\ell d_0\right\}\exp\left\{-c^\ell d_0\right\}\right)^{1/2} = 2$. Then, the right-hand side of (39) is further amplified, and we obtain

$$||\mathbf{J}^{(\ell)} - \mathbf{J}^*|| < \zeta\left(3\exp\left\{c^\ell d_0\right\} - 3\right) = 3\zeta\left(\exp\left\{c^\ell d_0\right\} - 1\right).$$

Therefore, the sequence $\left\{\mathbf{J}^{(\ell)}\right\}_{l=0,1,\ldots}$ approaches the ϵ-neighborhood (and hence any arbitrarily small neighborhood) of the fixed positive definite matrix $\mathbf{J}^*$ at an exponential rate with respect to any matrix norm. ■

The physical meaning of Theorem 11 is that the distance between $\mathbf{J}^{(\ell)}$ and $\mathbf{J}^*$ decreases exponentially fast before $\mathbf{J}^{(\ell)}$ enters $\mathbf{J}^*$'s neighborhood, which can be chosen to be arbitrarily small. Next, we study how to choose the initial value $\mathbf{J}^{(0)}$ so that $\mathbf{J}^{(\ell)}$ converges faster.

Theorem 12 *With $\mathbf{0} \preceq \boldsymbol{J}^{(0)} \preceq \boldsymbol{L}$, $\boldsymbol{J}^{(\ell)}$ is a monotonic increasing sequence, and $\boldsymbol{J}^{(\ell)}$ converges most rapidly with $\boldsymbol{J}^{(0)} = \boldsymbol{L}$. Moreover, with $\boldsymbol{J}^{(0)} \succeq \boldsymbol{U}$, $\boldsymbol{J}^{(\ell)}$ is a monotonic decreasing sequence, and $\boldsymbol{J}^{(\ell)}$ converges most rapidly with $\boldsymbol{J}^{(0)} = \boldsymbol{U}$.*

Proof Following Proposition 4, P 4.3, it can be verified that for $\mathbf{0} \preceq \mathbf{J}^{(0)} \preceq \mathbf{L}$, we have $\mathbf{J}^{(1)} \succeq \mathbf{J}^{(0)}$. Then, according to Proposition 4, P 4.1, and by induction, this relationship can be extended to $\mathbf{J}^{(\ell)} \succeq \ldots \mathbf{J}^{(1)} \succeq \mathbf{J}^{(0)}$, which states that $\mathbf{J}^{(\ell)}$ is a monotonic increasing sequence. Now, suppose that there are two sequences $\mathbf{J}^{(\ell)}$ and $\widetilde{\mathbf{J}}^{(\ell)}$ that are started with different initial values $\mathbf{0} \preceq \mathbf{J}^{(0)} \prec \mathbf{L}$ and $\mathbf{0} \preceq \widetilde{\mathbf{J}}^{(0)} \prec \mathbf{L}$, respectively. Then these two sequences are monotonically increasing and bounded by $\mathbf{J}^*$. To prove that $\mathbf{J}^{(0)} = \mathbf{L}$ leads to the fastest convergence, it is sufficient to prove that $\mathbf{J}^{(\ell)} \succ \widetilde{\mathbf{J}}^{(\ell)}$ for $\ell = 0, 1\ldots$. First, note that $\mathbf{J}^{(0)} \succ \widetilde{\mathbf{J}}^{(0)}$. Assume $\mathbf{J}^{(n)} \succ \widetilde{\mathbf{J}}^{(n)}$ for some $n \geq 0$. According to Proposition 4, P 4.1, we have $\mathcal{F}\left(\mathbf{J}^{(n)}\right) \succeq \mathcal{F}\left(\widetilde{\mathbf{J}}^{(n)}\right)$, or equivalently $\mathbf{J}^{(n+1)} \succeq \widetilde{\mathbf{J}}^{(n+1)}$. Therefore, by induction, we have proven that, with $\mathbf{J}^{(0)} = \mathbf{L}$, $\mathbf{J}^{(\ell)}$ converges more rapidly than with any other initial value $\mathbf{0} \preceq \mathbf{J}^{(0)} \prec \mathbf{L}$.

With similar logic, we can show that, with $\mathbf{J}^{(0)} \succeq \mathbf{U}$, $\mathbf{J}^{(\ell)}$ is a monotonic decreasing sequence; and, with $\mathbf{J}^{(0)} = \mathbf{U}$, $\mathbf{J}^{(\ell)}$ converges more rapidly than that with any other initial value $\mathbf{J}^{(0)} \succ \mathbf{U}$. ■

Notice that it is a common practice in the Gaussian BP literature that the initial information matrix (or inverse variance for the scalar case) is set to be $\mathbf{0}$, i.e., $\mathbf{J}^{(0)}_{f_n \to i} = \mathbf{0}$ (Weiss and Freeman, 2001a; Malioutov et al., 2006). Theorem 12 reveals that there is a better choice to guarantee faster convergence.

4.2 Convergence of Message Mean Vector

According to Theorems 6 and 11, as long as we choose $\mathbf{J}^{(0)}_{f_k \to j} \succeq \mathbf{0}$ for all $j \in \mathcal{V}$ and $f_k \in \mathcal{B}(j)$, the distance between $\mathbf{J}^{(\ell)}_{f_k \to j}$ and $\mathbf{J}^*_{f_k \to j}$ decreases exponentially fast before $\mathbf{J}^{(\ell)}_{f_k \to j}$ enters $\mathbf{J}^*_{f_k \to j}$'s neighborhood, which can be chosen to be arbitrarily small. Furthermore,

according to (16), $\left[\mathbf{J}^{(\ell)}_{j \to f_n}\right]^{-1}$ also converges to a p.d. matrix once $\mathbf{J}^{(\ell)}_{f_k \to j}$ converges, and the converged value for $\left[\mathbf{J}^{(\ell)}_{j \to f_n}\right]^{-1}$ is denoted by $\left[\mathbf{J}^*_{j \to f_n}\right]^{-1}$. Then for arbitrary initial value $\mathbf{v}^{(0)}_{f_k \to j}$, the evolution of $\mathbf{v}^{(\ell)}_{j \to f_n}$ in (17) can be written in terms of the converged message information matrices, which is

$$\mathbf{v}^{(\ell)}_{j \to f_n} = \left[\mathbf{J}^*_{j \to f_n}\right]^{-1} \sum_{f_k \in \mathcal{B}(j) \setminus f_n} \mathbf{J}^*_{f_k \to j} \mathbf{v}^{(\ell-1)}_{f_k \to j}. \tag{40}$$

Using (20), and replacing indices j, i, n with z, j, k respectively, $\mathbf{v}^{(\ell-1)}_{f_k \to j}$ is given by

$$\mathbf{v}^{(\ell-1)}_{f_k \to j} = \left[\mathbf{J}^*_{f_k \to j}\right]^{-1} \mathbf{A}^T_{k,j} \underbrace{\left[\mathbf{R}_k + \sum_{z \in \mathcal{B}(f_k) \setminus j} \mathbf{A}_{k,z} \left[\mathbf{J}^*_{z \to f_k}\right]^{-1} \mathbf{A}^T_{k,z}\right]}_{\triangleq \mathbf{M}_{k,j}}{}^{-1} \left(\mathbf{y}_k - \sum_{z \in \mathcal{B}(f_k) \setminus j} \mathbf{A}_{k,z} \mathbf{v}^{(\ell-1)}_{z \to f_k}\right). \tag{41}$$

Putting (41) into (40), we have

$$\mathbf{v}^{(\ell)}_{j \to f_n} = \mathbf{b}_{j \to f_n} - \sum_{f_k \in \mathcal{B}(j) \setminus f_n} \sum_{z \in \mathcal{B}(f_k) \setminus j} \left[\mathbf{J}^*_{j \to f_n}\right]^{-1} \mathbf{A}^T_{k,j} \mathbf{M}^{-1}_{k,j} \mathbf{A}_{k,z} \mathbf{v}^{(\ell-1)}_{z \to f_k}, \tag{42}$$

where $\mathbf{b}_{j \to f_n} = \left[\mathbf{J}^*_{j \to f_n}\right]^{-1} \sum_{f_k \in \mathcal{B}(j) \setminus f_n} \mathbf{A}^T_{k,j} \mathbf{M}^{-1}_{k,j} \mathbf{y}_k$. The above equation can be further written in compact form as

$$\mathbf{v}^{(\ell)}_{j \to f_n} = \mathbf{b}_{j \to f_n} - \mathbf{Q}_{j \to f_n} \mathbf{v}^{(\ell-1)},$$

with the column vector $\mathbf{v}^{(\ell-1)}$ containing $\mathbf{v}^{(\ell-1)}_{z \to f_k}$ for all $z \in \mathcal{V}$ and $f_k \in \mathcal{B}(z)$ as subvector with ascending index first on z and then on k. The matrix $\mathbf{Q}_{j \to f_n}$ is a row block matrix with component block $\left[\mathbf{J}^*_{j \to f_n}\right]^{-1} \mathbf{A}^T_{k,j} \mathbf{M}^{-1}_{k,j} \mathbf{A}_{k,z}$ if $f_k \in \mathcal{B}(j) \setminus f_n$ and $z \in \mathcal{B}(f_k) \setminus j$, and $\mathbf{0}$ otherwise. Let $\mathbf{Q}$ be the block matrix that stacks $\mathbf{Q}_{j \to f_n}$ with the order first on j and then on n, and $\mathbf{b}$ be the vector containing $\mathbf{b}_{j \to f_n}$ with the same stacking order as $\mathbf{Q}_{j \to f_n}$. We have

$$\mathbf{v}^{(\ell)} = -\mathbf{Q}\mathbf{v}^{(\ell-1)} + \mathbf{b}, \quad \ell \geq 1, 2, \ldots. \tag{43}$$

It is known that for arbitrary initial value $\mathbf{v}^{(0)}$, $\mathbf{v}^{(\ell)}$ converges if and only if the spectral radius $\rho(\mathbf{Q}) < 1$ (Demmel, 1997, pp. 280). Since the elements of $\mathbf{v}^{(0)}$, i.e., $\mathbf{v}^{(0)}_{j \to f_n}$, depends on $\mathbf{v}^{(0)}_{f_k \to j}$, we can choose arbitrary $\mathbf{v}^{(0)}_{f_k \to j}$. Furthermore, as $\mathbf{v}^{(\ell)}$ depends on the convergence of $\mathbf{J}^{(\ell)}$, we have the following result.

Theorem 13 *The vector sequence $\left\{\boldsymbol{v}^{(\ell)}\right\}_{l=1,2,\ldots}$ defined by (43) converges to a unique value under any initial value $\left\{\boldsymbol{v}^{(0)}_{f_k \to j}\right\}_{k \in \mathcal{V}, j \in \mathcal{B}(f_k)}$ and initial message information matrix $\boldsymbol{J}^{(0)} \succeq \mathbf{0}$ if and only if $\rho(\mathbf{Q}) < 1$.*

The row block matrix $\mathbf{Q}_j$, a row block of $\mathbf{Q}$, contains only block entries $\mathbf{0}$ and $\mathbf{Q}_{j\to f_n}$. When the observation model (1) reduces to the pairwise model, where only two unknown variables are involved in each local observation, it can be shown that $\mathbf{Q}_j$ and $\mathbf{Q}_i$ are orthogonal if $i \neq j$. A distributed convergence condition is obtained utilizing this orthogonal property in Du et al. (2017a). However, for the more general case studied in this paper, properties of $\mathbf{Q}_j$ and $\mathbf{Q}$ need to be further exploited to show when $\rho(\mathbf{Q}) < 1$ is satisfied.

In the sequel, we will show that $\rho(\mathbf{Q}) < 1$ is satisfied for a single loop factor graph with multiple chains/trees (an example is shown in Fig. 2), thus Gaussian BP converges in such a topology. Although Weiss (2000) shows the convergence of Gaussian BP on the MRF with a single loop, the analysis cannot be applied here since the local observations model (1) is different from the pairwise model in (Weiss, 2000).

Theorem 14 *For any factor graph that is the union of a single loop and a forest, with arbitrary positive semi-definite initial information matrix, i.e., $\boldsymbol{J}^{(0)}_{f_n\to i} \succeq \boldsymbol{0}$ for all $i \in \mathcal{V}$ and $f_n \in \mathcal{B}(i)$, the message information matrix $\boldsymbol{J}^{(\ell)}_{f_n\to i}$ and mean vector $\boldsymbol{v}^{(\ell)}_{i\to f_n}$ is guaranteed to converge to their corresponding unique points.*

Proof In this proof, Fig. 2 is being used as a reference throughout. For a single loop factor graph with chains/trees as shown in Fig. 2 (a), there are two kinds of nodes. One is the factors/variables in the loop, and they are denoted by $f_n/\mathbf{x}_j$. The other is the factors/variables on the chains/trees but outside the loop, denoted as $\widetilde{f}_k/\widetilde{\mathbf{z}}_i$. Then message from a variable node to a neighboring factor node on the graph can be categorized into three groups:

1) message on a tree/chain passing towards the loop, e.g., $m^{*}_{\widetilde{z}\to f_k}(\widetilde{\mathbf{x}}_z)$ and $m^{*}_{\widetilde{s}\to \widetilde{f}_k}(\widetilde{\mathbf{x}}_s)$;

2) message on a tree/chain passing away from the loop, e.g., $m^{(\ell)}_{j\to \widetilde{f}_k}(\mathbf{x}_j)$, $m^{(\ell)}_{\widetilde{s}\to \widetilde{f}_s}(\mathbf{x}_s)$ and $m^{(\ell)}_{\widetilde{z}\to \widetilde{f}_z}(\mathbf{x}_z)$;

3) message in the loop, e.g., $m^{(\ell)}_{j\to f_n}(\mathbf{x}_j)$, $m^{(\ell)}_{z\to f_k}(\mathbf{x}_z)$ and $m^{(\ell)}_{i\to f_n}(\mathbf{x}_i)$.

According to (11), computation of the messages in the first group does not depend on messages in the loop and is thus convergence guaranteed. Therefore, the message iteration number is replaced with a $*$ to denote the converged message. Also, from the definition of message computation in (11), if messages in the third group converge, the second group messages should also converge. Therefore, we next focus on showing the convergence of messages in the third group.

For a factor node f_k in the loop with $\mathbf{x}_z$ and $\mathbf{x}_j$ being its two neighboring variable nodes in the loop and $\widetilde{\mathbf{x}}_z$ being its neighboring variable node outside the loop, according to the definition of message computation in (12), we have

$$\begin{aligned} m^{(\ell)}_{f_k\to j}(\mathbf{x}_j) &= \int\int f_k \times m^{(\ell)}_{z\to f_k}(\mathbf{x}_z) \prod_{\widetilde{z}\in\mathcal{B}(f_k)\setminus j} m^{*}_{\widetilde{z}\to f_k}(\widetilde{\mathbf{x}}_z)\ \mathrm{d}\{\widetilde{\mathbf{x}}_z\}_{\widetilde{z}\in\mathcal{B}(f_k)\setminus j}\ \mathrm{d}\mathbf{x}_z, \\ &= \int m^{(\ell)}_{z\to f_k}(\mathbf{x}_z) \left[\int f_k \times \prod_{\widetilde{z}\in\mathcal{B}(f_k)\setminus j} m^{*}_{\widetilde{z}\to f_k}(\widetilde{\mathbf{x}}_z)\ \mathrm{d}\{\widetilde{\mathbf{x}}_z\}_{\widetilde{z}\in\mathcal{B}(f_k)\setminus j}\right] \mathrm{d}\mathbf{x}_z. \end{aligned} \tag{44}$$

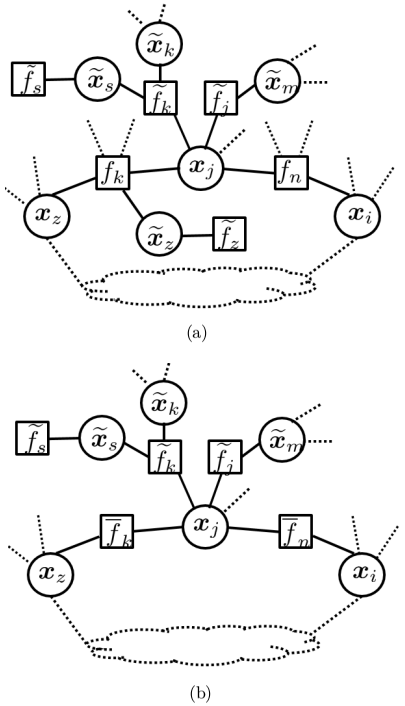

Figure 2: (a) An example of factor graph with a single loop and chains/trees topology, where the dashed line indicates possible chains/trees; (b) The equivalent factor graph of Fig 2 (a) with new factor functions that do not have neighboring variable nodes except those in the loop.

As shown in Lemma 2, $m^*_{\widetilde{z}\to f_k}(\widetilde{\mathbf{x}}_z)$ must be in Gaussian function form, which is denoted by $m^*_{\widetilde{z}\to f_k}(\widetilde{\mathbf{x}}_z) \propto \mathcal{N}\left(\widetilde{\mathbf{x}}_z|\mathbf{v}^*_{\widetilde{z}\to f_k}, \left[\mathbf{J}^*_{\widetilde{z}\to f_k}\right]^{-1}\right)$. Besides, from (1) we obtain

$$f_k = \mathcal{N}\left(\mathbf{y}_k|\mathbf{A}_{k,z}\mathbf{x}_z + \mathbf{A}_{k,j}\mathbf{x}_j + \sum_{\widetilde{z}\in\mathcal{B}(f_k)}\mathbf{A}_{k,\widetilde{z}}\widetilde{\mathbf{x}}_z, \mathbf{R}_k\right).$$

It can be shown that the inner integration in the second line of (44) is given by

$$\mathcal{N}\left(\overline{\mathbf{y}}_k|\overline{\mathbf{A}}_{k,z}\mathbf{x}_z + \overline{\mathbf{A}}_{k,j}\mathbf{x}_j, \overline{\mathbf{R}}_k\right) \triangleq \overline{f}_k,$$

where the overbar is used to denote the new constant matrix or vector. Then (44) can be written as

$$m^{(\ell)}_{f_k\to j}(\mathbf{x}_j) = \int \overline{f}_k \times m^{(\ell)}_{z\to f_k}(\mathbf{x}_z)\,\mathrm{d}\mathbf{x}_z. \tag{45}$$

Comparing (45) with (12), we obtain $m^{(\ell)}_{f_k\to j}(\mathbf{x}_j)$ as if $m^{(\ell)}_{\overline{f}_k\to j}(\mathbf{x}_j)$ is being passed to a factor node $\overline{f}_k$. Therefore, a factor graph with a single loop and multiple trees/chains is equivalent to a single loop factor graph in which each factor node has no neighboring variable node outside the loop. As a result, the example of Fig. 2 (a) is equivalent to Fig. 2 (b). In the following, we focus on this equivalent topology for the convergence analysis.

Note that, for arbitrary variable node j in the loop, there are two neighboring factor nodes in the loop. Further, using the notation for the equivalent topology, (42) is reduced to

$$\begin{aligned}\mathbf{v}^{(\ell)}_{j\to\overline{f}_n} =& -\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,z}\mathbf{v}^{(\ell-1)}_{z\to\overline{f}_k}\\ &+\underbrace{\overline{\mathbf{b}}_{j\to\overline{f}_n} - \sum_{\widetilde{f}_k\in\mathcal{B}(j)\setminus f_n}\sum_{\widetilde{s}\in\mathcal{B}(\widetilde{f}_k)\setminus j}\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1}\overline{\mathbf{A}}^T_{k,j}\overline{\mathbf{M}}^{-1}_{k,j}\overline{\mathbf{A}}_{k,\widetilde{s}}\mathbf{v}^*_{\widetilde{s}\to\widetilde{f}_k}}_{\triangleq\mathbf{c}_{j\to\overline{f}_n}},\end{aligned} \tag{46}$$

where $\mathbf{v}^*_{\widetilde{s}\to\widetilde{f}_k}$ is the converged mean vector on the chain/tree;

$$\overline{\mathbf{b}}_{j\to\overline{f}_n} = \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1}\sum_{\overline{f}_k\in\mathcal{B}(j)\setminus\overline{f}_n}\overline{\mathbf{A}}^T_{k,j}\overline{\mathbf{M}}^{-1}_{k,j}\overline{\mathbf{y}}_k$$

with $\overline{\mathbf{M}}_{k,j} = \overline{\mathbf{R}}_k + \sum_{\widetilde{s}\in\mathcal{B}(\widetilde{f}_k)\setminus j}\overline{\mathbf{A}}_{k,\widetilde{s}}\left[\mathbf{J}^*_{\widetilde{s}\to\widetilde{f}_k}\right]^{-1}\overline{\mathbf{A}}^T_{k,\widetilde{s}}$, and

$$\mathbf{T}_{k,j} = \overline{\mathbf{R}}_k + \overline{\mathbf{A}}_{k,z}\left[\mathbf{J}^*_{z\to\overline{f}_k}\right]^{-1}\overline{\mathbf{A}}^T_{k,z}, \tag{47}$$

with $\mathbf{x}_z$ and $\overline{f}_k$ in the loop where $\overline{f}_k \in \mathcal{B}(j)\setminus\overline{f}_n$ and $\mathbf{x}_z \in \mathcal{B}\left(\overline{f}_k\right)\setminus j$. By multiplying $\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{1/2}$ on both sides of (46), and defining $\boldsymbol{\beta}^{(\ell)}_{j\to\overline{f}_n} = \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{1/2}\mathbf{v}^{(\ell)}_{j\to\overline{f}_n}$, we have

$$\boldsymbol{\beta}^{(\ell)}_{j\to\overline{f}_n} = -\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,z}\left[\mathbf{J}^*_{z\to\overline{f}_k}\right]^{-1/2}\boldsymbol{\beta}^{(\ell-1)}_{z\to\overline{f}_k} + \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{1/2}\mathbf{c}_{j\to\overline{f}_n}, \tag{48}$$

Let $\boldsymbol{\beta}^{(\ell-1)}$ contain $\boldsymbol{\beta}^{(\ell-1)}_{z\to\overline{f}_k}$ for all $\mathbf{x}_z$ with $z\in\mathcal{B}\left(\overline{f}_k\right)$ and $\overline{f}_k$ being in the loop, and the index is arranged first on k and then on z. Then, the above equation is written in a compact form as

$$\boldsymbol{\beta}^{(\ell)}_{j\to\overline{f}_n} = -\mathbf{Q}_{j\to\overline{f}_n}\boldsymbol{\beta}^{(\ell-1)} + \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{1/2}\mathbf{c}_{j\to\overline{f}_n}, \tag{49}$$

where $\mathbf{Q}_{j\to\overline{f}_n}$ is a row block matrix with the only nonzero block

$$\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,z}\left[\mathbf{J}^*_{z\to\overline{f}_k}\right]^{-1/2}$$

located at the position corresponding to the position $\boldsymbol{\beta}^{(\ell)}_{z\to\overline{f}_k}$ in $\boldsymbol{\beta}^{(\ell)}$. Then let $\mathbf{Q}$ be a matrix that stacks $\mathbf{Q}_{j\to\overline{f}_n}$ as its row, where j and $\overline{f}_n$ are in the loop with $j\in\mathcal{B}\left(\overline{f}_n\right)$. Besides, let $\mathbf{c}$ be the vector containing the subvector $\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{1/2}\mathbf{c}_{j\to\overline{f}_n}$ with the same order as $\mathbf{Q}_{j\to\overline{f}_n}$ in $\mathbf{Q}$. We have

$$\boldsymbol{\beta}^{(\ell)} = -\mathbf{Q}\boldsymbol{\beta}^{(\ell-1)} + \mathbf{c}. \tag{50}$$

Since $\mathbf{Q}$ is a square matrix, $\rho(\mathbf{Q}) \le \sqrt{\rho\left(\mathbf{Q}\mathbf{Q}^T\right)}$ and therefore $\rho\left(\mathbf{Q}\mathbf{Q}^T\right) < 1$ is the sufficient condition for the convergence of $\boldsymbol{\beta}^{(\ell)}$. We next investigate the elements in $\mathbf{Q}\mathbf{Q}^T$.

Due to the single loop structure of the graph, every $\boldsymbol{\beta}^{(\ell)}_{j\to\overline{f}_n}$ in (48) would be dependent on a unique $\boldsymbol{\beta}^{(\ell)}_{z\to\overline{f}_k}$, where $\overline{f}_k\in\mathcal{B}(j)\setminus\overline{f}_n$ and $z\in\mathcal{B}\left(\overline{f}_k\right)\setminus j$ (i.e., the message two hops backward along the loop in the factor graph). Thus, the position of the non-zero block in $\mathbf{Q}_{j\to\overline{f}_n}$ will be different and non-overlapping for different combinations of $(j,\overline{f}_n)$. As a result, there exists a column permutation matrix $\boldsymbol{\Xi}$ such that $\mathbf{Q}\boldsymbol{\Xi}$ is a block diagonal matrix. Therefore, $(\mathbf{Q}\boldsymbol{\Xi})(\mathbf{Q}\boldsymbol{\Xi})^T = \mathbf{Q}\mathbf{Q}^T$ is also a diagonal matrix, and we can write

$$\mathbf{Q}\mathbf{Q}^T = \mathtt{Bdiag}\left\{\mathbf{Q}_{j\to\overline{f}_n}\mathbf{Q}^T_{j\to\overline{f}_n}\right\}_{j\,\in\,\mathcal{B}\left(\overline{f}_n\right)}.$$

As a consequence, $\rho\left(\mathbf{Q}\mathbf{Q}^T\right) < 1$ is equivalent to $\rho\left(\mathbf{Q}_{j\to\overline{f}_n}\mathbf{Q}^T_{j\to\overline{f}_n}\right) < 1$ for all j and $\overline{f}_n$ in the loop with $j\in\mathcal{B}\left(\overline{f}_n\right)$. Following the definition of $\mathbf{Q}_{j\to\overline{f}_n}$ below (49), we obtain

$$\begin{aligned}\mathbf{Q}_{j\to\overline{f}_n}\mathbf{Q}^T_{j\to\overline{f}_n} &= \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,z}\left[\mathbf{J}^*_{z\to\overline{f}_k}\right]^{-1}\overline{\mathbf{A}}^T_{k,z}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,j}\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\\ &= \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\left(\mathbf{T}_{k,j} - \overline{\mathbf{R}}_k\right)\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,j}\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2},\end{aligned} \tag{51}$$

where the second equation follows from the definition of $\mathbf{T}_{k,j}$ in (47). Besides, since $\overline{\mathbf{R}}_k \succ \mathbf{0}$, we have $\mathbf{T}_{k,j} - \overline{\mathbf{R}}_k \prec \mathbf{T}_{k,j}$. Following P B.2 in Appendix B, and due to $\mathbf{T}_{k,j} = \mathbf{T}^T_{k,j}$, we have

$$\mathbf{T}^{-1/2}_{k,j}\left(\mathbf{T}_{k,j} - \overline{\mathbf{R}}_k\right)\mathbf{T}^{-1/2}_{k,j} \prec \mathbf{I}. \tag{52}$$

Applying P B.2 in Appendix B again to (52), and making use of (51), we obtain

$$\mathbf{Q}_{j\to\overline{f}_n}\mathbf{Q}^T_{j\to\overline{f}_n} \prec \left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}\overline{\mathbf{A}}^T_{k,j}\mathbf{T}^{-1}_{k,j}\overline{\mathbf{A}}_{k,j}\left[\mathbf{J}^*_{j\to\overline{f}_n}\right]^{-1/2}. \tag{53}$$

According to (47), we have

$$\overline{\mathbf{A}}_{k,j}^T \mathbf{T}_{k,j}^{-1} \overline{\mathbf{A}}_{k,j} = \overline{\mathbf{A}}_{k,j}^T \left[\overline{\mathbf{R}}_k + \overline{\mathbf{A}}_{k,z} \left[\mathbf{J}^*_{z \to \overline{f}_k} \right]^{-1} \overline{\mathbf{A}}_{k,z}^T \right]^{-1} \overline{\mathbf{A}}_{k,j}. \tag{54}$$

On the other hand, using (19), due to $\mathcal{B}\left(\overline{f}_k\right) \setminus j = \mathbf{x}_z$ in the considered topology, the right hand side of (54) is $\mathbf{J}^*_{\overline{f}_k \to j}$. Therefore, (53) is further written as

$$\mathbf{Q}_{j \to \overline{f}_n} \mathbf{Q}_{j \to \overline{f}_n}^T \prec \left[\mathbf{J}^*_{j \to \overline{f}_n} \right]^{-1/2} \mathbf{J}^*_{\overline{f}_k \to j} \left[\mathbf{J}^*_{j \to \overline{f}_n} \right]^{-1/2}. \tag{55}$$

From (16), $\mathbf{J}^*_{j \to \overline{f}_n} = \mathbf{W}_j^{-1} + \mathbf{J}^*_{\overline{f}_k \to j} + \sum_{\widetilde{f}_k \in \mathcal{B}(j) \setminus \overline{f}_n} \mathbf{J}^*_{\widetilde{f}_k \to j}$, thus $\mathbf{J}^*_{\overline{f}_k \to j} \preceq \mathbf{J}^*_{j \to \overline{f}_n}$. Therefore, $\left[\mathbf{J}^*_{j \to \overline{f}_n} \right]^{-1/2} \mathbf{J}^*_{\overline{f}_k \to j} \left[\mathbf{J}^*_{j \to \overline{f}_n} \right]^{-1/2} \preceq \mathbf{I}$, and, together with (55), we have

$$\mathbf{Q}_{j \to \overline{f}_n} \mathbf{Q}_{j \to \overline{f}_n}^T \prec \mathbf{I}.$$

Hence $\rho\left(\mathbf{Q}_{j \to \overline{f}_n} \mathbf{Q}_{j \to \overline{f}_n}^T \right) < 1$ for all j and $\overline{f}_n$ in the loop and $j \in \mathcal{B}\left(\overline{f}_n\right)$, and equivalently $\rho(\mathbf{Q}) < 1$. This completes the proof. ■

4.3 Convergence of Belief Covariance and Mean Vector

As the computation of the belief covariance $\mathbf{P}_i^{(\ell)}$ depends on the message information matrix $\mathbf{J}^{(\ell)}_{f_n \to i}$, using Theorems 6 and 11, we can derive the convergence and uniqueness properties of $\mathbf{P}_i^{(\ell)}$.

Before we present the main result, we first present some properties of the part metric $\mathrm{d}(\mathbf{X}, \mathbf{Y})$, with positive definite arguments $\mathbf{X}$, $\mathbf{Y}$, and $\triangle\mathbf{X}$. The proofs are provided in Appendix D.

Proposition 15 *The part metric* $\mathrm{d}(\boldsymbol{X}, \boldsymbol{Y})$ *satisfies the following properties*

P 15.1: $\mathrm{d}(\mathbf{X}_1 + \mathbf{X}_2, \mathbf{Y}_1 + \mathbf{Y}_2) \leq \mathrm{d}(\mathbf{X}_1, \mathbf{Y}_1) + \mathrm{d}(\mathbf{X}_2, \mathbf{Y}_2)$;
P 15.2: $\mathrm{d}(\mathbf{X}, \mathbf{Y}) = \mathrm{d}\left(\mathbf{X}^{-1}, \mathbf{Y}^{-1}\right)$.

We now have the following result.

Corollary 16 *With arbitrary initial message information matrix* $\boldsymbol{J}^{(0)}_{f_n \to i} \succeq \boldsymbol{0}$ *for all* $i \in \mathcal{V}$ *and* $f_n \in \mathcal{B}(i)$*, the belief covariance matrix* $\boldsymbol{P}_i^{(\ell)}$ *converges to a unique p.d. matrix at an exponential rate with respect to any matrix norm before* $\boldsymbol{P}_i^{(\ell)}$ *enters* $\boldsymbol{P}_i^*$*'s neighborhood, which can be chosen to be arbitrarily small.*

Proof Since $\mathbf{J}^{(\ell)}_{f_n \to i}$ converges to a p.d. matrix, and according to (23), $\mathbf{P}_i^{(\ell)}$ also converges. Below, we study the convergence rate of $\mathbf{P}_i^{(\ell)}$. According to the definition of $\mathbf{P}_i^{(\ell)}$ in (23)

and part metric in Definition 9, we have

$$\mathrm{d}\left([\mathbf{P}_i^{(\ell)}]^{-1}, [\mathbf{P}_i^*]^{-1} \right) = \mathrm{d}\left(\mathbf{W}_i^{-1} + \sum_{f_n \in \mathcal{B}(i)} \mathbf{J}^{(\ell)}_{f_n \to i}, \mathbf{W}_i^{-1} + \sum_{f_n \in \mathcal{B}(i)} \mathbf{J}^*_{f_n \to i} \right).$$

By applying P 15.1 to the above equation, we obtain

$$\mathrm{d}\left([\mathbf{P}_i^{(\ell)}]^{-1}, [\mathbf{P}_i^*]^{-1} \right) \leq \mathrm{d}\left(\mathbf{W}_i^{-1}, \mathbf{W}_i^{-1} \right) + \sum_{f_n \in \mathcal{B}(i)} \mathrm{d}\left(\mathbf{J}^{(\ell)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right) = \sum_{f_n \in \mathcal{B}(i)} \mathrm{d}\left(\mathbf{J}^{(\ell)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right).$$

According to (36), for all $i \in \mathcal{V}$ and $f_n \in \mathcal{B}(i)$, there exist a $c < 1$ such that

$$\mathrm{d}\left(\mathbf{J}^{(\ell)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right) < c^\ell \mathrm{d}\left(\mathbf{J}^{(0)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right).$$

Applying the above inequality to compute $\left[\mathbf{P}_i^{(\ell)} \right]^{-1}$ in (24), we obtain

$$\mathrm{d}\left([\mathbf{P}_i^{(\ell)}]^{-1}, [\mathbf{P}_i^*]^{-1} \right) < c^\ell \sum_{f_n \in \mathcal{B}(i)} \mathrm{d}\left(\mathbf{J}^{(0)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right).$$

Following P 15.2, the above inequality is equivalent to

$$\mathrm{d}\left(\mathbf{P}_i^{(\ell)}, \mathbf{P}_i^* \right) < c^\ell \sum_{f_n \in \mathcal{B}(i)} \mathrm{d}\left(\mathbf{J}^{(0)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right),$$

where $\sum_{f_n \in \mathcal{B}(i)} \mathrm{d}\left(\mathbf{J}^{(0)}_{f_n \to i}, \mathbf{J}^*_{f_n \to i} \right)$ is a constant. Following the same procedure as that from (36) to (38), we can prove that $\mathbf{P}_i^{(\ell)}$ converges at an exponential rate with respect to the monotone norm before $\mathbf{P}_i^{(\ell)}$ enters $\mathbf{P}_i^*$'s neighborhood, which can be chosen to be arbitrarily small. ■

On the other hand, as shown in (24), the computation of the belief mean $\boldsymbol{\mu}_i^{(\ell)}$ depends on the belief covariance $\mathbf{P}_i^{(\ell)}$ and the message mean $\mathbf{v}^{(\ell)}_{f_n \to i}$. Thus, under the same condition as in Theorem 13, $\boldsymbol{\mu}_i^{(\ell)}$ is convergence guaranteed. Moreover, it is shown in (Weiss and Freeman, 2001b, Appendix) that, for Gaussian BP over a factor graph, the converged value of belief mean equals the optimal estimate in (3). Together with the convergence guaranteed topology revealed in Theorem 14, we have the following Corollary.

Corollary 17 *With arbitrary* $\boldsymbol{J}^{(0)}_{f_n \to i} \succeq \boldsymbol{0}$ *and arbitrary* $\boldsymbol{v}^{(0)}_{f_n \to i}$ *for all* $i \in \mathcal{V}$ *and* $f_n \in \mathcal{B}(i)$*, the mean vector* $\boldsymbol{\mu}_i^{(\ell)}$ *in (24) converges to the optimal estimate* $\widehat{\boldsymbol{x}}_i$ *in (3) if and only if* $\rho(\boldsymbol{Q}) < 1$*, where* $\boldsymbol{Q}$ *is defined in (43). Furthermore, a sufficient condition to guarantee* $\rho(\boldsymbol{Q}) < 1$ *is when the factor graph contains only one single loop connected to multiple chains/trees.*

5. Relationships with Existing Convergence Conditions

In this section, we show the relationship between our convergence condition for Gaussian BP and the recent proposed path-sum method (Giscard et al., 2016). We also show that our convergence condition is more general than the walk-summable condition (Malioutov et al., 2006) for the scalar case.

5.1 Relationship with the Path-sum Method

The path-sum method is proposed in (Giscard et al., 2012, 2013, 2016) to compute $\left(\mathbf{W}^{-1}+\mathbf{A}^T\mathbf{R}^{-1}\mathbf{A}\right)^{-1}$ in (3), in which the matrix inverse $\left(\mathbf{W}^{-1}+\mathbf{A}^T\mathbf{R}^{-1}\mathbf{A}\right)^{-1}$ is interpreted as the sum of simple paths and simple cycles on a weighted graph. The resulting formulation is guaranteed to converge to the correct value for any valid multivariate Gaussian distribution.

The BP message update equations (16), (17), (19), and (20) can be seen as a cut-off of path-sum by retaining only self-loops and backtracks (simple cycles of lengths one and two). In the presence of a graph with one or more loops, equations (16), (17), (19), and (20) do not include the terms related to simple cycles with length larger than 2. This may be a potential cause for the possible divergence of the Gaussian BP algorithm. From this perspective, the divergence can be averted if none of the walks going around the loop(s) have weight greater than one, or equivalently, that the spectral radius of the block matrix representing the loop(s) is strictly less than one. This is an intuitive explanation of the condition $\rho(\mathbf{Q})<1$ obtained in Theorem 13. It also immediately follows from these considerations that the convergence rate is at least geometric, with a cut-off of order ℓ yielding an $\mathcal{O}(\rho(\mathbf{Q})^{\ell})$ error[4].

While the path-sum framework provides an insightful interpretation of the results obtained in this paper, the path-sum algorithm may not be efficiently implementable in distributed and parallel settings, as it requires the summation over all the paths of any length. In contrast, Gaussian BP, while paying the price of non-convergence in general loopy models, makes it possible to realize parallel and fully distributed inference. In summary, though the path-sum method converges for arbitrary valid Gaussian models, it is difficult to be adapted to a distributed and parallel inference setup as the Gaussian BP method.

5.2 Relationship with the Walk-Summable Condition

We show next that, in the setup of linear Gaussian models, the condition $\rho(\mathbf{Q})<1$ as in Corollary 17 encompasses the Gaussian MRF based walk-summable (Malioutov et al. (2006)) in terms of convergence. As all existing results on Gaussian BP convergence (Malioutov et al., 2006; Moallemi and Roy, 2009b) only apply to scalar variables, we restrict the following discussion to only the scalar case. In (Malioutov et al., 2006), the starting point for the convergence analysis for Gaussian MRF is a joint multivariate Gaussian distribution

$$q(\mathbf{x})\propto\exp\Big\{-\frac{1}{2}\mathbf{x}^T\mathbf{J}\mathbf{x}+\mathbf{h}^T\mathbf{x}\Big\},\tag{56}$$

4. We thank an anonymous reviewer for this interpretation.

expressed in the normalized information form such that $\mathbf{J}_{i,i}=1$ for all i. The underlying Gaussian distribution is factorized as (Malioutov et al. (2006))

$$q(\mathbf{x})\propto\prod_{i\in\mathcal{V}}\psi_i(\mathbf{x}_i)\prod_{J_{i,j}\neq 0;i\leq j}\psi_{i,j}(\mathbf{x}_i,\mathbf{x}_j),\tag{57}$$

where

$$\psi_i(\mathbf{x}_i)=\exp\left\{-\frac{1}{2}\mathbf{J}_{i,i}\mathbf{x}_i^2+\mathbf{h}_i\right\}\quad\text{and}\quad\psi_{i,j}(\mathbf{x}_i,\mathbf{x}_j)=\exp\left\{-\mathbf{x}_i\mathbf{J}_{i,j}\mathbf{x}_j\right\}.$$

In Malioutov et al. (2006, Proposition 1), based on the interpretation that $\left[\mathbf{J}^{-1}\right]_{i,j}$ is the sum of the weights of all the walks from variable j to variable i on the corresponding Gaussian MRF, a sufficient Gaussian BP convergence condition known as walk-summability is provided, which is equivalent to

$$\mathbf{I}-|\mathbf{R}|\succ\mathbf{0},\tag{58}$$

together with the initial message variance inverse being set to 0, where $\mathbf{R}=\mathbf{I}-\mathbf{J}$ and $|\mathbf{R}|$ is matrix of entrywise absolute values of $\mathbf{R}$. In the following, we establish the relationship between walk-summable Gaussian MRF and linear Gaussian model by utilizing properties of H-matrices (Boman et al., 2005). We show that, with Gaussian MRF satisfying the walk-summable condition, the joint distribution $q(\mathbf{x})$ in (57) can be reformulated as a special case of the linear Gaussian model based factorization in (10). Moreover, Gaussian BP on this particular linear Gaussian model always converges.

Definition 18 *H-Matrices (Boman et al., 2005): A matrix $\boldsymbol{X}$ is an H-matrix if all eigenvalues of the matrix $\mathcal{H}(\boldsymbol{X})$, where $[\mathcal{H}(\boldsymbol{X})]_{i,i}=|\boldsymbol{X}_{i,i}|$, and $[\mathcal{H}(\boldsymbol{X})]_{i,j}=-|\boldsymbol{X}_{i,j}|$ have positive real parts.*

Proposition 19 *Factor width at most 2 factorization (Boman et al., 2005, Theorem 9): A symmetric H-matrix $\boldsymbol{X}$ that has non-negative diagonals can always be factorized as $\boldsymbol{X}=\boldsymbol{V}\boldsymbol{V}^T$, where $\boldsymbol{V}$ is a real matrix with each column of $\boldsymbol{V}$ containing at most 2 non-zeros.*

Let ω be an arbitrary positive value that is smaller than the minimum eigenvalue of $\mathbf{I}-|\mathbf{R}|$ and also satisfies $0<\omega<1$. According to (58), we have $(1-\omega)\mathbf{I}-|\mathbf{R}|\succ\mathbf{0}$. Furthermore, by applying $\mathcal{H}(\cdot)$ to $(1-\omega)\mathbf{I}-\mathbf{R}$, we have $[\mathcal{H}((1-\omega)\mathbf{I}-\mathbf{R})]_{i,i}=|(1-\omega)\mathbf{I}-\mathbf{R}|_{i,i}=1-\omega$ and $[\mathcal{H}((1-\omega)\mathbf{I}-\mathbf{R})]_{i,j}=-|[(1-\omega)\mathbf{I}-\mathbf{R})]_{i,j}|=-|\mathbf{R}_{i,j}|$. Thus, $\mathcal{H}((1-\omega)\mathbf{I}-\mathbf{R})=(1-\omega)\mathbf{I}-|\mathbf{R}|\succ\mathbf{0}$, and we conclude that $(1-\omega)\mathbf{I}-\mathbf{R}$ is an H-matrix. According to Proposition 19, $(1-\omega)\mathbf{I}-\mathbf{R}=\mathbf{J}-\omega\mathbf{I}=\mathbf{V}\mathbf{V}^T$, where each column of $\mathbf{V}$ contains at most 2 non-zeros. Now, we can rewrite the joint distribution in (57) as

$$\begin{aligned}q(\mathbf{x})&\propto\exp\left\{-\frac{1}{2}\mathbf{x}^T\left(\mathbf{J}-\omega\mathbf{I}\right)\mathbf{x}-\frac{1}{2}\omega\mathbf{x}^T\mathbf{x}+\mathbf{h}^T\mathbf{x}\right\}\\&=\exp\left\{-\frac{1}{2}\left(\mathbf{V}^T\mathbf{x}\right)^T\left(\mathbf{V}^T\mathbf{x}\right)-\frac{1}{2}\left(\omega\mathbf{x}^T\mathbf{x}-2\mathbf{h}^T\mathbf{x}\right)\right\}\\&\propto\exp\left\{-\frac{1}{2}\sum_{n=1}^{M}\left(V_{n,n_i}x_{n_i}+V_{n,n_j}x_{n_j}\right)^2-\frac{1}{2}\sum_{n=1}^{M}\omega(x_n-\frac{h_n}{\omega})^2\right\},\end{aligned}\tag{59}$$

where V_{n,n_i} and V_{n,n_j} denote the two possible non-zero elements on the n-th column and n_i-th and n_j-th rows, and M is the dimension of $\mathbf{x}$. Thus, a walk-summable Gaussian MRF in (56) (or equivalently (57)) can always be written as

$$q(\mathbf{x}) \propto \prod_{n=1}^{M} \underbrace{\mathcal{N}(x_n|\frac{1}{\omega}h_n, \frac{1}{\omega})}_{p(x_n)} \prod_{n=1}^{M} \underbrace{\mathcal{N}(0|V_{n,n_i}x_{n_i} + V_{n,n_j}x_{n_j}, 1)}_{f_n}. \tag{60}$$

Note that, in the above equation, $p(x_n)$ serves as the prior distribution for x_n as that in (10) and f_n is the local likelihood function with local observation being $y_n = 0$ and noise distribution $z_n \sim \mathcal{N}(z_n|0, 1)$[5]. Thus the above equation is a special case of the linear Gaussian model based factorization in (10) with the local likelihood function f_n containing only a pair of variables. For this pairwise linear Gaussian model with scalar variables, it is shown in (Moallemi and Roy, 2009b) that $\rho(\mathbf{Q}) < 1$ is fulfilled. Thus by Corollary 17, Gaussian BP always converges. In summary, for the factorization based on Gaussian MRF, if the walk-summable convergence condition is fulfilled, there is an equivalent joint distribution factorization based on linear Gaussian model; and Gaussian BP is convergence guaranteed for this linear Gaussian model.

In the following, we further demonstrate through an example that there exist Gaussian MRFs, in which the information matrix $\mathbf{J}$ fails to satisfy the walk-summable condition, but a convergence guaranteed Gaussian BP update based on the distributed linear Gaussian model representation can still be obtained. More specifically, consider the following information matrix $\mathbf{J}$ in a Gaussian MRF:

$$\mathbf{J} = \begin{bmatrix} 1 & \frac{1}{3\sqrt{2}} & \frac{1}{\sqrt{3}} & \frac{\sqrt{2}}{3} \\ \frac{1}{3\sqrt{2}} & 1 & 0 & \frac{1}{3} \\ \frac{1}{\sqrt{3}} & 0 & 1 & \frac{1}{\sqrt{6}} \\ \frac{\sqrt{2}}{3} & \frac{1}{3} & \frac{1}{\sqrt{6}} & 1 \end{bmatrix}. \tag{61}$$

The eigenvalues of $\mathbf{I} - |\mathbf{R}|$ to 4 decimal places are -0.0754, 0.9712, 1.4780, and 1.6262. According to the walk-summable definition in (58), it is non walk-summable and the convergence condition in (Malioutov et al., 2006) is inconclusive as to whether Gaussian BP converges. On the other hand, we can study the Gaussian BP convergence of this example by employing a linear Gaussian model representation, and rewriting $\mathbf{J}$ as $\mathbf{J} = \mathbf{A}^T\mathbf{R}^{-1}\mathbf{A} + \mathbf{W}^{-1}$, where

$$\mathbf{A} = \begin{bmatrix} \frac{2}{\sqrt{6}} & 0 & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{3}} & 0 & 0 \\ 0 & \frac{1}{\sqrt{3}} & 0 & \frac{1}{\sqrt{3}} \end{bmatrix}, \quad \mathbf{W} = \begin{bmatrix} 6 & 0 & 0 & 0 \\ 0 & 3 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 3 \end{bmatrix},$$

and $\mathbf{R} = \mathbf{I}$. In Fig. 3, the joint distribution of this example with Gaussian MRF and the corresponding linear Gaussian model are represented by factor graphs. As it is shown in Corollary 17, for a factor graph that is the union of a forest and a single loop, as in Fig. 3(b), Gaussian BP always converges to the exact value. This is in sharp contrast to

5. For a particular f_n, if there is only one non-zero coefficient, $f_n \times \mathcal{N}(x_n|\frac{1}{\omega}h_n, \frac{1}{\omega})$ is also proportional to a Gaussian distribution, which can be seen as a prior distribution in (10).

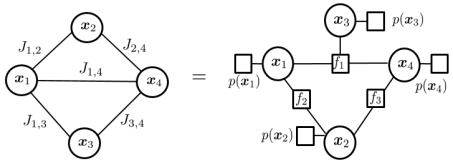

Figure 3: The Gaussian MRF corresponding to $\mathbf{J}$ in (61) with the factorization following (4); (b) The factor graph corresponding to $\mathbf{J}$ in (61) with the factorization following (10).

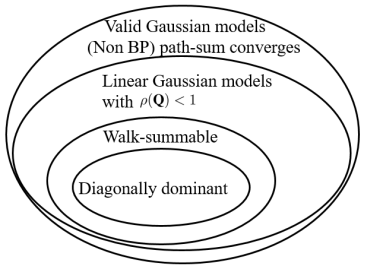

Figure 4: Venn diagram summarizing various subclasses of Gaussian models: the three inner most conditions are all for the BP algorithm while the path-sum in general does not constitute a BP algorithm.

the inconclusive convergence property when the same joint distribution is expressed using the classical Gaussian MRF in (4).

In summary, we have shown that the linear Gaussian model with $\rho(\mathbf{Q}) < 1$ encompasses walk-summable Gaussian MRF. Further, it is shown in (Malioutov et al., 2006) that the diagonally dominant convergence condition in (Weiss and Freeman, 2001a) for Gaussian BP is a special case of the walk-summable condition. Also, the convergence condition in (Su and Wu, 2015) is encompassed by walk-summable condition. Therefore, we have the Venn diagram in Fig. 4 summarizing the relations (in terms of convergence guarantees) between the convergence condition proposed in this paper and existing conditions.

6. Conclusions

This paper shows that, depending on how the factorization of the underlying joint Gaussian distribution is performed, Gaussian belief propagation (BP) may exhibit different convergence properties as different factorizations lead to fundamentally different recursive update structures. The paper studies the convergence of Gaussian BP derived from the factorization

based on the distributed linear Gaussian model. We show that the condition we present for convergence of the marginal mean based on factorizations using the linear Gaussian model is more general than the walk-summable condition (Malioutov et al., 2006) (and references therein) that is based on the Gaussian Markov random field factorization. Further, the linear Gaussian model that is studied in this paper readily conforms to the physical network topology arising in large-scale networks.

Further, the paper analyzes the convergence of the Gaussian BP based distributed inference algorithm. In particular, we show analytically that, with arbitrary positive semidefinite matrix initialization, the message information matrix exchanged among agents converges to a unique positive definite matrix, and it approaches an arbitrarily small neighborhood of this unique positive definite matrix at an exponential rate (with respect to any matrix norm). Regarding the initial information matrix, there exist positive definite initializations that guarantee faster convergence than the commonly used all-zero matrix. Moreover, under the positive semidefinite initial message information matrix condition, we present a necessary and sufficient condition of the belief mean vector to converge to the optimal centralized estimate. We also prove that Gaussian BP always converges if the corresponding factor graph is a union of a single loop and a forest. In particular, we show that the proposed convergence condition for Gaussian BP based on the linear Gaussian model leads to a strictly larger class of models in which Gaussian BP converges than those postulated by the Gaussian Markov random field based walk-summable condition. Finally, we discuss connections of Gaussian BP with the general path-sum algorithm. In the future, it will be interesting to explore if these path-sum interpretations can lead to modifications of the standard Gaussian BP algorithm that guarantee the convergence of Gaussian BP for larger classes of topologies while being also parallel and fully distributed.

Appendix A.

We first compute the first round updating message from variable node to factor node. Substituting $m^{(0)}_{f_n\to i}(\mathbf{x}_i) \propto \exp\left\{-\frac{1}{2}||\mathbf{x}_j - \mathbf{v}^{(0)}_{f_n\to i}||^2_{\mathbf{J}^{(0)}_{f_n\to i}}\right\}$ into (11) and, after algebraic manipulations, we obtain

$$m^{(1)}_{j\to f_n}(\mathbf{x}_j) \propto \exp\left\{-\frac{1}{2}||\mathbf{x}_j - \mathbf{v}^{(1)}_{j\to f_n}||^2_{\mathbf{J}^{(1)}_{j\to f_n}}\right\}, \tag{62}$$

with

$$\mathbf{J}^{(1)}_{j\to f_n} = \mathbf{W}_j^{-1} + \sum_{f_k\in\mathcal{B}(j)\setminus f_n} \mathbf{J}^{(0)}_{f_k\to j},$$

and

$$\mathbf{v}^{(1)}_{j\to f_n} = \left[\mathbf{J}^{(1)}_{j\to f_n}\right]^{-1}\left[\sum_{f_k\in\mathcal{B}(j)\setminus f_n} \mathbf{J}^{(0)}_{f_k\to j}\mathbf{v}^{(0)}_{f_k\to j}\right].$$

Next, we evaluate $m^{(1)}_{f_n\to i}(\mathbf{x}_i)$. By substituting $m^{(1)}_{j\to f_n}(\mathbf{x}_j)$ in (62) into (12), we obtain

$$\begin{aligned} m^{(1)}_{f_n\to i}(\mathbf{x}_i) \propto \int\ldots\int \exp\Big\{-\frac{1}{2}\big(\mathbf{y}_n - \sum_{j\in\mathcal{B}(f_n)}\mathbf{A}_{n,j}\mathbf{x}_j\big)^T\mathbf{R}^{-1}\big(\mathbf{y}_n - \sum_{j\in\mathcal{B}(f_n)}\mathbf{A}_{n,j}\mathbf{x}_j\big)\Big\}\times \\ \prod_{j\in\mathcal{B}(f_n)\setminus i}\exp\Big\{-\frac{1}{2}||\mathbf{x}_j - \mathbf{v}^{(1)}_{j\to f_n}||^2_{\mathbf{J}^{(1)}_{j\to f_n}}\Big\}\,\mathrm{d}\{\mathbf{x}_j\}_{j\in\mathcal{B}(f_n)\setminus i}. \end{aligned} \tag{63}$$

Let $\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}}$ and $\mathbf{v}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}$ be stacked vectors containing $\mathbf{x}_j$ and $\mathbf{v}^{(1)}_{j\to f_n}$ as vector elements for all $j\in\mathcal{B}(f_n)\setminus i$ arranged in ascending order on j, respectively; $\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}$ denotes a row block matrix containing $\mathbf{A}_{n,j}$ as row elements for all $j\in\mathcal{B}(f_n)\setminus i$ arranged in ascending order; and $\mathbf{J}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}$ is a block diagonal matrix with $\mathbf{J}^{(1)}_{j\to f_n}$ as its block diagonal elements for all $j\in\mathcal{B}(f_n)\setminus i$ arranged in ascending order. Then, (63) can be reformulated as

$$\begin{aligned} m^{(1)}_{f_n\to i}(\mathbf{x}_i) \propto & \int\ldots\int \exp\left\{-\frac{1}{2}||\mathbf{y}_n - \mathbf{A}_{n,i}\mathbf{x}_i - \mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}}\mathbf{x}^T_{\{\mathcal{B}(f_n)\setminus i\}}||^2_{\mathbf{R}^{-1}}\right\} \\ & \times\exp\left\{-\frac{1}{2}||\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}} - \mathbf{v}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n})||^2_{\mathbf{J}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}}\right\}\mathrm{d}\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}} \\ \propto & \exp\left\{-\frac{1}{2}||\mathbf{y}_n - \mathbf{A}_{n,i}\mathbf{x}_i||^2_{\mathbf{R}^{-1}}\right\} \\ & \times\int\ldots\int\exp\left\{\frac{1}{2}(\mathbf{x}^T_{\{\mathcal{B}(f_n)\setminus i\}}\mathbf{K}^{(1)}_{f_n\to i}\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}} - 2[\mathbf{h}^{(1)}_{f_n\to i}]^T\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}})\right\}\mathrm{d}\mathbf{x}_{\{\mathcal{B}(f_n)\setminus i\}}, \end{aligned} \tag{64}$$

where

$$\mathbf{K}^{(1)}_{f_n\to i} = \mathbf{A}^T_{n,\{\mathcal{B}(f_n)\setminus i\}}\mathbf{R}^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\setminus i\}} + \mathbf{J}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}$$

and

$$\mathbf{h}^{(1)}_{f_n\to i} = \mathbf{A}^T_{n,\{\mathcal{B}(f_n)\setminus i\}}\mathbf{R}^{-1}(\mathbf{y}_n - \mathbf{A}_{n,i}\mathbf{x}_i) + \mathbf{J}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}\mathbf{v}^{(1)}_{\{\mathcal{B}(f_n)\setminus i\}\to f_n}.$$

By completing the square for the integrand of (64), we obtain

$$m^{(1)}_{f_n\to i}(\mathbf{x}_i) \propto \alpha^{(1)}_{f_n\to i}\exp\left\{-\frac{1}{2}||\mathbf{y}_n-\mathbf{A}_{n,i}\mathbf{x}_i||^2_{\mathbf{R}_n^{-1}}+\frac{1}{2}\left[\mathbf{h}^{(1)}_{f_n\to i}\right]^T\left[\mathbf{K}^{(1)}_{f_n\to i}\right]^{-1}\mathbf{h}^{(\ell)}_{f_n\to i}\right\},(65)$$

with

$$\alpha^{(1)}_{f_n\to i}=\int\cdots\int\exp\left\{-\frac{1}{2}||\mathbf{x}_{\{\mathcal{B}(f_n)\backslash i\}}-\left[\mathbf{K}^{(1)}_{f_n\to i}\right]^{-1}\mathbf{h}^{(1)}_{f_n\to i}||^2_{\mathbf{K}^{(1)}_{f_n\to i}}\right\}\mathrm{d}\mathbf{x}_{\{\mathcal{B}(f_n)\backslash i\}}.$$

Next, by applying the spectral theorem to $\mathbf{K}^{(1)}_{f_n\to i}$ and after some algebraic manipulations, we simplify (65) as

$$m^{(1)}_{f_n\to i}(\mathbf{x}_i)\propto\alpha^{(1)}_{f_n\to i}\exp\left\{-\frac{1}{2}||\mathbf{x}_i-\mathbf{v}^{(1)}_{f_n\to i}||_{\mathbf{J}^{(1)}_{f_n\to i}}\right\},$$

with the inverse of the covariance, the information matrix

$$\mathbf{J}^{(1)}_{f_n\to i}=\mathbf{A}^T_{n,i}\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{J}^{(1)}_{j\to f_n}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\mathbf{A}_{n,i},$$

and the mean vector

$$\mathbf{v}^{(1)}_{f_n\to i}=\left[\mathbf{J}^{(1)}_{f_n\to i}\right]^{-1}\mathbf{A}^H_{n,i}\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{J}^{(1)}_{j\to f_n}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\left(\mathbf{y}_n-\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\mathbf{v}^{(1)}_{j\to f_n}\right),$$

and

$$\alpha^{(1)}_{f_n\to i}\propto\int\cdots\int\exp\left\{-\frac{1}{2}\mathbf{z}^T\mathbf{\Lambda}^{(1)}_{f_n\to i}\mathbf{z}\right\}\mathrm{d}\mathbf{z},\quad(66)$$

where $\mathbf{\Lambda}^{(1)}_{f_n\to i}$ is a diagonal matrix containing the eigenvalues of $\mathbf{A}^T_{n,\{\mathcal{B}(f_n)\backslash i\}}\mathbf{R}_n^{-1}\mathbf{A}_{n,\{\mathcal{B}(f_n)\backslash i\}}+\mathbf{J}^{(1)}_{\{\mathcal{B}(f_n)\backslash i\}\to f_n}$.

By induction, and following similar derivations as in (62) to (66), we obtain the general updating expressions as in (15) to (21).

Appendix B.

Before going into the proof of Lemma 2, we note the following properties of positive definite (p.d.) matrices. If $\mathbf{X}\succ\mathbf{0}$, $\mathbf{Y}\succ\mathbf{0}$, $\mathbf{Z}\succeq\mathbf{0}$ are of the same dimension, then we have (Du and Wu, 2013a):

P B.1: $\mathbf{X}+\mathbf{Y}\succ\mathbf{0}$ and $\mathbf{X}+\mathbf{Z}\succ\mathbf{0}$.

P B.2: $\mathbf{A}^T\mathbf{X}\mathbf{A}\succ\mathbf{0}$, $\mathbf{A}^T\mathbf{Z}\mathbf{A}\succeq\mathbf{0}$, $\mathbf{A}\mathbf{X}\mathbf{A}^T\succeq\mathbf{0}$ and $\mathbf{A}\mathbf{Z}\mathbf{A}^T\succeq\mathbf{0}$ for any full column rank matrix $\mathbf{A}$ with compatible dimension.

Now, we prove Lemma 2. If $\mathbf{J}^{(\ell-1)}_{f_k\to j}\succeq\mathbf{0}$ for all $f_k\in\mathcal{B}(j)\setminus f_n$, according to P B.1, $\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\succeq\mathbf{0}$. As $\mathbf{W}_j^{-1}\succ\mathbf{0}$, we have $\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\succ\mathbf{0}$, which, according to (16), is equivalent to $\mathbf{J}^{(\ell)}_{j\to f_n}\succ\mathbf{0}$. Besides, as $\mathbf{A}_{n,j}$ is full column rank, if $\left[\mathbf{J}^{(\ell)}_{j\to f_n}\right]^{-1}\succ\mathbf{0}$

for all $j\in\mathcal{B}(f_n)\backslash i$, according to P B.2, $\mathbf{A}_{n,j}\left[\mathbf{J}^{(\ell)}_{j\to f_n}\right]^{-1}\mathbf{A}^T_{n,j}\succeq\mathbf{0}$. With $\mathbf{R}_n\succ\mathbf{0}$, following P B.1, we have $\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{J}^{(\ell)}_{j\to f_n}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\succ\mathbf{0}$. As $\mathbf{A}_{n,i}$ is of full column rank, by applying P B.2 again, we have $\mathbf{A}^T_{n,i}\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{J}^{(\ell)}_{j\to f_n}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\mathbf{A}_{n,i}\succ\mathbf{0}$, which according to (19) is equivalent to $\mathbf{J}^{(\ell)}_{f_n\to i}\succ\mathbf{0}$.

In summary, we have proved that 1) if $\mathbf{J}^{(\ell-1)}_{f_k\to j}\succeq\mathbf{0}$ for all $f_k\in\mathcal{B}(j)\setminus f_n$, then $\mathbf{J}^{(\ell)}_{j\to f_n}\succ\mathbf{0}$; 2) if $\left[\mathbf{J}^{(\ell)}_{j\to f_n}\right]^{-1}\succ\mathbf{0}$ for all $j\in\mathcal{B}(f_n)\setminus i$, then $\mathbf{J}^{(\ell)}_{f_n\to i}\succ\mathbf{0}$. Therefore, by setting $\mathbf{J}^{(0)}_{f_k\to j}\succeq\mathbf{0}$ for all $k\in\mathcal{V}$ and $j\in\mathcal{B}(f_k)$, according to the results of the first case, we have $\mathbf{J}^{(1)}_{j\to f_n}\succ\mathbf{0}$ for all $j\in\mathcal{V}$ and $f_n\in\mathcal{B}(j)$. Then, applying the second case, we further have $\mathbf{J}^{(1)}_{f_n\to i}\succ\mathbf{0}$ for all $n\in\mathcal{V}$ and $i\in\mathcal{B}(f_n)$. By repeatedly using the above arguments, it follows readily that $\mathbf{J}^{(\ell)}_{f_k\to j}\succ\mathbf{0}$ and $\mathbf{J}^{(\ell)}_{j\to f_n}\succ\mathbf{0}$ for $\ell\geq1$ and with $j\in\mathcal{V}$, $f_n,f_k\in\mathcal{B}(j)$. Furthermore, according to the discussion before Lemma 2, all messages $m^{(\ell)}_{j\to f_n}(\mathbf{x}_j)$ and $m^{(\ell)}_{f_n\to i}(\mathbf{x}_i)$ exist, and are in Gaussian form as in (15) and (18).

Appendix C.

First, Proposition 4, P 4.1 is proved. Suppose that $\mathbf{J}^{(\ell)}\succeq\mathbf{J}^{(\ell-1)}\succeq\mathbf{0}$, i.e., $\mathbf{J}^{(\ell)}_{f_k\to j}\succeq\mathbf{J}^{(\ell-1)}_{f_k\to j}\succeq\mathbf{0}$ for all $(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)$, we have

$$\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell)}_{f_k\to j}\succeq\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\succ\mathbf{0}.$$

Then, according to the fact that if $\mathbf{X}\succeq\mathbf{Y}\succ\mathbf{0}$, $\mathbf{Y}^{-1}\succeq\mathbf{X}^{-1}\succ\mathbf{0}$, we have

$$\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\right]^{-1}\succeq\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell)}_{f_k\to j}\right]^{-1}\succ\mathbf{0}.$$

Since $\mathbf{A}_{n,j}$ is of full column rank and following P B.2 in Appendix B, we have

$$\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\right]^{-1}\mathbf{A}^T_{n,j}\succeq\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell)}_{f_k\to j}\right]^{-1}\mathbf{A}^T_{n,j}\succ\mathbf{0}.$$

Following the same procedure of the proof above and due to $\mathbf{R}\succ\mathbf{0}$, we can further prove that

$$\begin{aligned}&\mathbf{A}^T_{n,i}\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell)}_{f_k\to j}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\mathbf{A}_{n,i}\\ \succeq&\mathbf{A}^T_{n,i}\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}^{(\ell-1)}_{f_k\to j}\right]^{-1}\mathbf{A}^T_{n,j}\right]^{-1}\mathbf{A}_{n,i},\end{aligned}$$

which is equivalent to

$$\mathcal{F}_{n\to i}\left(\left\{\mathbf{J}_{f_k\to j}^{(\ell)}\right\}_{(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)}\right)\succeq\mathcal{F}_{n\to i}\left(\left\{\mathbf{J}_{f_k\to j}^{(\ell-1)}\right\}_{(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)}\right).$$

Since $\mathcal{F}$ contains $\mathcal{F}_{n\to i}(\cdot)$ as its component, Proposition 4, P 4.1 is proved.

Next, Proposition 4, P 4.2 is proved. Suppose that $\mathbf{J}_{f_k\to j}^{(\ell)}\succ\mathbf{0}$ for all $(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)$. As $\alpha>1$, we have

$$\alpha\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\succeq\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\succ\mathbf{0},$$

where the equality holds when $\mathbf{W}_j^{-1}=\mathbf{0}$, which corresponds to non-informative prior for $\mathbf{x}_j$. Applying the fact that if $\mathbf{X}\succeq\mathbf{Y}\succ\mathbf{0}$, $\mathbf{Y}^{-1}\succeq\mathbf{X}^{-1}\succ\mathbf{0}$, and, according to P B.2 in Appendix B, we obtain

$$\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\succeq\mathbf{A}_{n,j}\left[\alpha\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\succeq\mathbf{0}.$$

Since $\mathbf{R}_n\succ\frac{1}{\alpha}\mathbf{R}_n\succ\mathbf{0}$, we have

$$\begin{aligned}&\left[\frac{1}{\alpha}\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\alpha\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}\\&\succ\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}.\end{aligned}$$

Finally, applying P B.2 in Appendix B to the above equation and taking out the common factor α, we obtain

$$\begin{aligned}&\alpha\mathbf{A}_{n,i}^T\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}\mathbf{A}_{n,i}\\&\succ\mathbf{A}_{n,i}^T\left[\mathbf{R}_n+\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right]^{-1}\mathbf{A}_{n,j}^T\right]^{-1}\mathbf{A}_{n,i}.\end{aligned}$$

Therefore, $\alpha\mathcal{F}_{n\to i}\left(\left\{\mathbf{J}_{f_k\to j}^{(\ell)}\right\}_{(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)}\right)\succ\mathcal{F}_{n\to i}\left(\left\{\alpha\mathbf{J}_{f_k\to j}^{(\ell)}\right\}_{(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)}\right)$ if $\mathbf{J}_{f_k\to j}^{(\ell)}\succ\mathbf{0}$ for all $(f_k,j)\in\widetilde{\mathcal{B}}(f_n,i)$ and $\alpha>1$. As $\mathcal{F}$ contains $\mathcal{F}_{n\to i}(\cdot)$ as its component, Proposition 4, P 4.2 is proved. In the same way, we can prove $\mathcal{F}\left(\alpha^{-1}\mathbf{J}^{(\ell)}\right)\succ\alpha^{-1}\mathcal{F}\left(\mathbf{J}^{(\ell)}\right)$ if $\mathbf{J}^{(\ell)}\succ\mathbf{0}$ and $\alpha>1$.

At last, Proposition 4, P 4.3 is proved. From Lemma 2, if we have initial message information matrix $\mathbf{J}_{f_k\to j}^{(0)}\succeq\mathbf{0}$ for all $j\in\mathcal{V}$ and $f_k\in\mathcal{B}(j)$, then we have $\mathbf{J}_{f_k\to j}^{(\ell)}\succ\mathbf{0}$ for all

$j\in\mathcal{V}$ and $f_k\in\mathcal{B}(j)$. In such case, obviously, $\mathbf{J}^{(\ell)}\succeq\mathbf{0}$. Applying $\mathcal{F}$ to both sides of this equation, and using Proposition 4, P 4.1, we have $\mathcal{F}\left(\mathbf{J}^{(\ell)}\right)\succeq\mathcal{F}(\mathbf{0})$. On the other hand, using (27), it can be easily checked that $\mathcal{F}(\mathbf{0})=\mathbf{A}^T\left[\mathbf{\Omega}+\mathbf{H}\mathbf{\Psi}^{-1}\mathbf{H}^T\right]^{-1}\mathbf{A}\succ\mathbf{0}$, where the inequality is from Lemma 2. For proving the upper bound, we start from the fact that

$$\sum_{j\in\mathcal{B}(f_n)\backslash i}\mathbf{A}_{n,j}\left[\mathbf{W}_j^{-1}+\sum_{f_k\in\mathcal{B}(j)\backslash f_n}\mathbf{J}_{f_k\to j}^{(\ell-1)}\right]^{-1}\mathbf{A}_{n,j}^T$$

in (25), and equivalently the corresponding term

$$\mathbf{H}_{n,i}\left[\mathbf{W}_{n,i}+\mathbf{K}_{n,i}\left(\mathbf{I}_{|\mathcal{B}(f_n)|-1}\otimes\mathbf{J}^{(\ell-1)}\right)\mathbf{K}_{n,i}^T\right]^{-1}\mathbf{H}_{n,i}^T$$

in (26), are p.s.d. matrices. In (27), since

$$\mathbf{H}\left[\mathbf{\Psi}+\mathbf{K}\left(\mathbf{I}_{\sum_{n=1}^M|B(f_n)|(|B(f_n)|-1)}\otimes\mathbf{J}^{(\ell-1)}\right)\mathbf{K}^T\right]^{-1}\mathbf{H}^T$$

contains $\mathbf{H}_{n,i}\left[\mathbf{W}_{n,i}+\mathbf{K}_{n,i}\left(\mathbf{I}_{|\mathcal{B}(f_n)|-1}\otimes\mathbf{J}^{(\ell-1)}\right)\mathbf{K}_{n,i}^T\right]^{-1}\mathbf{H}_{n,i}^T$ as its block diagonal elements, it is also a p.s.d. matrix. With $\mathbf{\Omega}\succ\mathbf{0}$, adding to the above result gives

$$\mathbf{\Omega}+\mathbf{H}\left[\mathbf{\Psi}+\mathbf{K}\left(\mathbf{I}_\varphi\otimes\mathbf{J}^{(\ell)}\right)\mathbf{K}^T\right]^{-1}\mathbf{H}^T\succeq\mathbf{\Omega}\succ\mathbf{0}.$$

Inverting both sides, we obtain $\mathbf{\Omega}^{-1}\succeq\left[\mathbf{\Omega}+\mathbf{H}\left[\mathbf{\Psi}+\mathbf{K}\left(\mathbf{I}_\varphi\otimes\mathbf{J}^{(\ell)}\right)\mathbf{K}^T\right]^{-1}\mathbf{H}^T\right]^{-1}$. Finally, applying P B.2 again gives

$$\mathbf{A}^T\mathbf{\Omega}^{-1}\mathbf{A}\succeq\mathbf{A}^T\left[\mathbf{\Omega}+\mathbf{H}\left[\mathbf{\Psi}+\mathbf{K}\left(\mathbf{I}_\varphi\otimes\mathbf{J}^{(\ell)}\right)\mathbf{K}^T\right]^{-1}\mathbf{H}^T\right]^{-1}\mathbf{A}^T=\mathcal{F}\left(\mathbf{J}^{(\ell)}\right).$$

Therefore, we have $\mathbf{A}^T\mathbf{\Omega}^{-1}\mathbf{A}\succeq\mathcal{F}\left(\mathbf{J}^{(\ell)}\right)\succeq\mathbf{A}^T\left[\mathbf{\Omega}+\mathbf{H}\mathbf{\Psi}^{-1}\mathbf{H}^T\right]^{-1}\mathbf{A}\succ\mathbf{0}$.

Appendix D.

Let $\mathrm{d}(\mathbf{X}_1,\mathbf{Y}_1)=\exp\{a_1\}$ and $\mathrm{d}(\mathbf{X}_2,\mathbf{Y}_2)=\exp\{a_2\}$, and $\mathrm{d}(\mathbf{X}_1+\mathbf{X}_2,\mathbf{Y}_1+\mathbf{Y}_2)=\exp\{a_3\}$. First, P 15.1 is proved. According to the definition of part metric in Definition 9, for arbitrary symmetric p.d matrix $\mathbf{X}_1$, $\mathbf{X}_2$, $\mathbf{Y}_1$, and $\mathbf{Y}_2$, we have $\mathrm{d}(\mathbf{X}_1,\mathbf{Y}_1)$, $\mathrm{d}(\mathbf{X}_2,\mathbf{Y}_2)$, and $\mathrm{d}(\mathbf{X}_1+\mathbf{X}_2,\mathbf{Y}_1+\mathbf{Y}_2)$ correspond to

$$a_1\mathbf{X}_1\succeq\mathbf{Y}_1\succeq\frac{1}{a_1}\mathbf{X}_1,\quad a_2\mathbf{X}_2\succeq\mathbf{Y}_2\succeq\frac{1}{a_2}\mathbf{X}_2,\tag{67}$$

$$a_3(\mathbf{X}_1+\mathbf{X}_2)\succeq\mathbf{Y}_1+\mathbf{Y}_2\succeq\frac{1}{a_3}(\mathbf{X}_1+\mathbf{X}_2).\tag{68}$$

Since $\mathrm{d}(\mathbf{X}_1, \mathbf{Y}_1) > 0$ and $\mathrm{d}(\mathbf{X}_2, \mathbf{Y}_2) > 0$, we have $a_1, a_2 \geq 1$. And therefore $a_1 + a_2 > a_1$ and $a_1 + a_2 > a_2$. Then, according to (67), we have

$$(a_1 + a_2)(\mathbf{X}_1 + \mathbf{X}_2) \succeq \mathbf{Y}_1 + \mathbf{Y}_2 \succeq \frac{1}{a_1 + a_2}(\mathbf{X}_1 + \mathbf{X}_2). \tag{69}$$

Following the definition of part matric, a_3 is the smallest value satisfy the inequality in (68). Thus, by comparing (69) with (68), we obtain $a_1 + a_2 \geq a_3$ Hence, $\mathrm{d}(\mathbf{X}_1 + \mathbf{X}_2, \mathbf{Y}_1 + \mathbf{Y}_2) \leq \mathrm{d}(\mathbf{X}_1, \mathbf{Y}_1) + \mathrm{d}(\mathbf{X}_2, \mathbf{Y}_2)$.

Next, P 15.2 is proved. Following the part metric definition of $\mathrm{d}(\mathbf{X}_1, \mathbf{Y}_1)$, $a_1\mathbf{X}_1 \succeq \mathbf{Y}_1 \succeq \frac{1}{a_1}\mathbf{X}_1$, which is equivalent to $\mathbf{Y}_1^{-1} \succeq \frac{1}{a_1}\mathbf{X}_1^{-1}$ and $a_1\mathbf{X}_1^{-1} \succeq \mathbf{Y}_1^{-1}$. Thus, $\mathrm{d}(\mathbf{X}, \mathbf{Y}) = \mathrm{d}(\mathbf{X}^{-1}, \mathbf{Y}^{-1})$.

Editor: Geoff Holmes

Abstract

auDeep is a Python toolkit for deep unsupervised representation learning from acoustic data. It is based on a recurrent sequence to sequence autoencoder approach which can learn representations of time series data by taking into account their temporal dynamics. We provide an extensive command line interface in addition to a Python API for users and developers, both of which are comprehensively documented and publicly available at `https://github.com/auDeep/auDeep`. Experimental results indicate that auDeep features are competitive with state-of-the art audio classification.

Keywords: deep feature learning, sequence to sequence learning, recurrent neural networks, autoencoders, audio processing

1. Introduction

Machine learning approaches for audio processing commonly operate on a variety of hand-crafted features computed from raw audio signals. Considerable effort has been put into developing high-performing feature sets for specific tasks. Recently, representation learning, in particular deep representation learning, has received significant attention as a highly effective alternative to using such conventional feature sets (Bengio et al., 2013; Schmitt and Schuller, 2017). These techniques have been shown to be superior to feature engineering for a plethora of tasks, including speech recognition and music transcription (Bengio et al., 2013; Amiriparian et al., 2016). Sequential data such as audio, however, poses challenges for deep neural networks, as they typically require inputs of fixed dimensionality. In this regard, sequence to sequence learning with *recurrent neural networks* (RNNs) has been proposed in machine translation, for learning fixed-length representations of variable-length sequences (Sutskever et al., 2014).

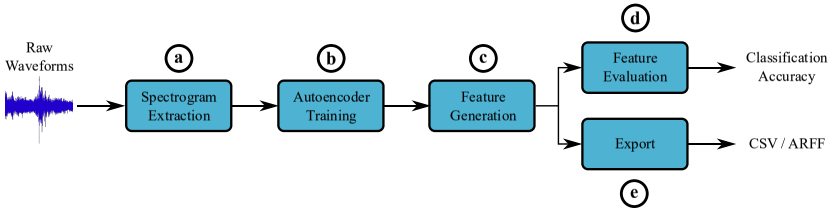

Figure 1: Illustration of the feature learning procedure with auDeep. A detailed description of the procedure is given in Section 3.1.

In this paper, we present auDeep, a first of its kind TensorFlow based Python toolkit for deep unsupervised representation learning from acoustic data. This is achieved using a recurrent sequence to sequence autoencoder approach. auDeep can be used both through its Python API as well as through an extensive command line interface.

2. Recurrent Sequence to Sequence Autoencoders

Our implementation of sequence to sequence autoencoders extends the RNN encoder-decoder model proposed by Sutskever et al. (2014). The input sequence is fed to a multi-layered *encoder* RNN which collects key information about the input sequence in its hidden state. The final hidden state of the encoder RNN is then passed through a fully connected layer, the output of which is used to initialise the hidden state of the multilayered *decoder* RNN. The function of the decoder RNN is to reconstruct the input sequence based on the information contained in the initial hidden state. The network is trained to minimise the root mean squared error between the input sequence and the reconstruction. In order to accelerate model convergence, the expected decoder output from the previous step is fed back as the input into the decoder RNN (Sutskever et al., 2014). Once training is complete, the activations of the fully connected layer are used as the representation of an input sequence.

For the purposes of representation learning from acoustic data, we train sequence to sequence autoencoders built of *long short-term memory* cells or *gated recurrent units* on spectrograms, which are viewed as time dependent sequences of frequency vectors. Two of the key strengths of this approach are (i) fully unsupervised training, and (ii) the ability to account for the temporal dynamics of sequences.

3. System Overview

auDeep contains at its core a high-performing implementation of sequence to sequence autoencoders which is not specifically constrained to acoustic data. Based on this domain-independent implementation, we provide extensive additional functionality for representation learning from audio.

3.1 Practical Usage

An illustration of the feature learning procedure with auDeep is shown in Figure 1. First, spectrograms are extracted from raw audio files (cf. Figure 1a). Then, a sequence to sequence autoencoder, as previously described, is trained on the extracted spectrograms (cf. Figure 1b), and the learned representation of each instance is extracted as its feature vector (cf. Figure 1c). If instance labels are available, a classifier can then be trained and evaluated on the extracted features (cf. Figure 1d). Finally, the extracted features, and any associated metadata, can be exported to CSV or ARFF for further processing, such as classification with alternate algorithms (cf. Figure 1e).

While our system is capable of learning representations of the extracted spectrograms entirely without additional metadata, we provide the possibility to parse instance labels, data set partitions, or a cross-validation setup from a variety of common formats. If available, metadata is stored alongside the extracted spectrograms, and can be used, e. g. for evaluation of a classifier on the learned representations. To demonstrate the strength of the learned representations two conventional classifiers are built into the toolkit: a *Multilayer Perceptron* (MLP) with softmax output, and an interface to LibLINEAR (Fan et al., 2008).

3.2 Design

auDeep provides a highly modularised Python library for deep unsupervised representation learning from audio. The core sequence to sequence autoencoder models are implemented using TensorFlow. This implementation substantially extends the built-in sequence to sequence learning capabilities of TensorFlow; for example, the RNNs allow probabilistic feedback and are also reusable, self-contained modules. Furthermore, diversely structured data sets are handled by the system in a unified way without requiring time-consuming manual adjustments. The topology and parameters of autoencoders are stored as TensorFlow checkpoints which can be reused in other applications. This enables users, e. g. to pretrain the encoder RNN with auDeep and subsequently apply custom retraining. Data sets are represented in binary format using the platform-independent NetCDF standard, but we provide tools for converting data between NetCDF and CSV/ARFF.

Users are given fine-grained control over the representation learning process through the Python API and the command line interface. The system is platform-independent, and has been tested on Windows and various Linux distributions on desktop PCs and in a cluster environment. auDeep is capable of running on CPU only, and GPU-acceleration is leveraged automatically when available.

4. Experiments

We demonstrate the capabilities of auDeep on three audio classification tasks. First, we perform acoustic scene classification on the development partition of the TUT Acoustic Scenes 2017 (TUT AS 2017) data set (Mesaros et al., 2017). Furthermore, we conduct environmental sound classification (ESC) on the ESC-10 and ESC-50 data sets (Piczak, 2015b), and, finally, we perform music genre classification on the GTZAN data set (Tzanetakis and Cook, 2002).

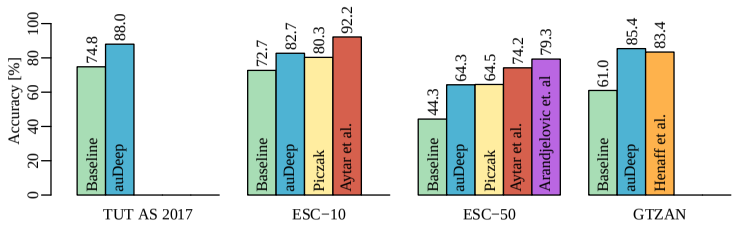

Figure 2: Comparison of auDeep to baselines and state-of-the-art on four data sets.

We train multiple autoencoder configurations using auDeep, and perform feature-level fusion of the learned representations. The fused representations are evaluated using the built-in MLP with the same cross-validation setup as used for the baseline systems on the TUT AS 2017, ESC-10, and ESC-50 data sets. For GTZAN, no predefined cross-validation setup is available, therefore we randomly generate five stratified cross-validation folds (cf. Figure 2, auDeep). Due to space limitations, we refrain from detailing our full experimental setup. However, to ensure reproducibility, we distribute the codes and parameter choices used for these experiments with auDeep.

Finally, we compare the performance of auDeep with baseline and state-of-the-art approaches for the different datasets (cf. Figure 2, identified by authors' names). We observe that auDeep either matches or outperforms a *convolutional neural network* approach (Piczak, 2015a) and a representation learning approach for ESC-10 and ESC-50, and a sparse coding approach for GTZAN (Henaff et al., 2011). The SoundNet (Aytar et al., 2016) and L3 (Arandjelovic and Zisserman, 2017) systems did achieve stronger performances on ESC-10 and ESC-50. However, this is not a straightforward comparison, as auDeep was trained using ESC-10 and ESC-50 data only whilst L3 and SoundNet were pre-trained on external corpora of 500 000 and 2+ million videos, respectively. For further details and comparisons with state-of-the-art for the TUT Acoustic Scenes 2017 corpus, the reader is referred to Amiriparian et al. (2017).

5. Conclusions

auDeep is an easy-to-use, open-source toolkit for deep unsupervised representation learning from audio with competitive performance on various audio classification tasks. Our long-term goal is to grow auDeep into a general-purpose deep audio toolkit, by integrating other deep representation learning algorithms such as conditional variational sequence to sequence autoencoders or *deep convolutional generative adversarial networks*, and by extending the feature learning functionality to regression tasks on continuously labelled data.

Abstract

Feature Selection is central to modern data science, from exploratory data analysis to predictive model-building. The "stability" of a feature selection algorithm refers to the *robustness* of its feature preferences, with respect to data sampling and to its stochastic nature. An algorithm is 'unstable' if a *small* change in data leads to *large* changes in the chosen feature subset. Whilst the idea is simple, *quantifying* this has proven more challenging—we note numerous proposals in the literature, each with different motivation and justification. We present a rigorous statistical treatment for this issue. In particular, with this work we consolidate the literature and provide (1) a deeper understanding of existing work based on a small set of properties, and (2) a clearly justified statistical approach with several novel benefits. This approach serves to identify a stability measure obeying all desirable properties, and (for the first time in the literature) allowing confidence intervals and hypothesis tests on the stability, enabling rigorous experimental comparison of feature selection algorithms.

Keywords: stability, feature selection

1. Introduction

High-dimensional data sets are the norm in data-intensive scientific domains. In application areas from bioinformatics to business analytics, it is common to collect many more measurements ("features" or "variables") than a study is able to easily cope with. This is a natural consequence of exploratory data analysis, but brings challenges of computational overhead, model interpretability and overfitting. Modern statistical regularisation methods can often control the model fit, but if the task is to identify *meaningful* subsets of features, there is a jungle of heuristics and domain-specific feature selection methods from which to pick, surveyed in several previous works, e.g. Guyon and Elisseeff (2003); Brown et al. (2012). Many authors have addressed the question of how sensitive each feature selection method is, with respect to small changes in the training data. If, with a different sample from the same training data, the chosen subset of features changes radically, then it is regarded as being an *unstable* procedure. Conversely, if the feature subset is almost static with respect to data changes, it is a *stable* procedure. Whilst the intuition here is clear, there is to date no single agreed measure to *quantify* stability, and numerous proposals in the literature.

The first published work to consider the *stability of feature selection procedures* was Kalousis et al. (2005), with extended experimental results published later as Kalousis et al. (2007). A slightly earlier technical report (Dunne et al., 2002) examined the idea in the limited scope of wrapper-based feature selection, but Kalousis et al. (2005) were the first to discuss stability in depth, independent of the particular feature selection algorithm. They defined stability as follows:

> *"We define the stability of a feature selection algorithm as the robustness of the feature preferences it produces to differences in training sets drawn from the same generating distribution P(X,C). Stability quantifies how different training sets affect the feature preferences."* (Kalousis et al., 2005, pg 2)

Kalousis et al. (2005) provided an excellent review of the issues, which we will not repeat here. One important point is how the feature preferences are represented—as a ranking, a weighting or a subset. Since any ranking or weighting can be thresholded to obtain a subset (which is often the case), the scope of this particular article is the stability of feature *subset* selection, with the other representations left for future work. The seminal work of Kalousis was followed by a flurry of publications in application areas where stability turns out to be critical, such as microarray classification (Davis et al., 2006), molecular profiling (Jurman et al., 2008) and linguistics (Wichmann and Kamholz, 2008). But, perhaps more interesting for this paper, there was also a flurry of *methodological* papers, addressing how best to quantify stability.

1.1 The Problem: How to Quantify and Estimate Stability

The *measurement* of stability is important, as it addresses a fundamental question in data science—*how much can we trust an algorithm?* If tiny changes to initial conditions result in significantly different conclusions, perhaps we should not trust the output as reflective of the true underlying mechanism. This is important, not just for pure interest's sake in machine learning, but a true interdisciplinary challenge. In biomedical fields, this is a proxy for *reproducible research* (Lee et al., 2012) indicating that whatever biological features the algorithm has found are likely to be a data artefact, not a real clinical signal worth pursuing with further resources. Jurman et al. (2008) argue that having a *stable* selected gene set is equally important as their predictive power, while Goh and Wong (2016, pg 1) state:

> *"Identifying reproducible yet relevant features is a major challenge in biological research.*[...] *We recommend augmenting statistical feature selection methods with concurrent analysis on stability and reproducibility to improve the quality of the selected features prior to experimental validation."*

This is the intuitive concept and motivation to study stability. However intuitive, precisely *quantifying* it has proven somewhat challenging. In a literature search, conducted in early 2018, we identified at least 15 different measures used to quantify the stability of feature selection algorithms (Dunne et al., 2002; Shi et al., 2006; Davis et al., 2006; Kalousis et al., 2007; Krízek et al., 2007; Kuncheva, 2007; Yu et al., 2008; Zucknick et al., 2008; Zhang et al., 2009; Lustgarten et al., 2009; Somol and Novovičová, 2010; Guzmán-Martínez and Alaiz-Rodríguez, 2011; Wald et al., 2013; Lausser et al., 2013; Goh and Wong, 2016). Most of these

were justified and evaluated, though there has been little cross-comparison. The question arises: which should we trust, in which situation? If we do not understand the properties of these measures, it leads to a questionable interpretation of the stability values obtained, and questionable research in general. As acknowledged by Boulesteix and Slawski (2009), a multiplicity[1] of methods for stability assessment may lead to publication bias—in that researchers may (hopefully unintentionally) be drawn toward the metric that reports their feature selection algorithm as more stable. Furthermore, rarely do authors acknowledge that the stability value obtained is *an estimate of a true stability*, based on the number of feature sets sampled. Any measure is an *estimator of an underlying random variable*—therefore we should be able to discuss statistical concepts such as the population parameter being estimated and the convergence properties of the estimator. In this paper, we provide such an estimator and a theoretical analysis of its properties.

1.2 Our Approach to the Problem

Our approach to this problem is to propose a small set of properties, describing desirable behaviours from a stability measure. We will argue that the properties are generic enough to be desirable in all reasonable feature selection scenarios, and that they are critical for useful comparison and interpretation of stability values. We proceed to prove whether the 5 properties hold for each of 15 measures already proposed in the literature, and find no measure satisfying all. We then propose a novel measure for which all properties provably hold, in Section 4. The proposed measure has several desirable characteristics which distinguish it from previous proposals:

1. It is based on 5 well-defined properties (Section 3) which we will argue are essential requirements for a stability measure in most (if not all) feature selection scenarios.

2. It has a clean statistical interpretation in terms of the sample variance of a set of Bernoulli variables. The clean interpretation allows us to derive a set of tools for practitioners including

   - confidence intervals for the true stability;
   - a hypothesis test to check if the true stability is above a user-defined threshold;
   - a hypothesis test to compare the stability of two algorithms on a given data set.

3. It is a proper generalization of several existing measures (and therefore the statistical tools we develop are also applicable to those measures).

4. It is computable in linear time as opposed to quadratic, as is the case for most measures in the literature.

5. Given the theoretical and computational properties above, it can reliably be used to select hyperparameters for feature selection algorithms, such as LASSO or Stability Selection (Meinshausen and Bühlmann, 2010).

1. The R package `OmicsMarkeR` provides 7 different options for measuring stability, with no guidance for which to use, in which situation (c.f. `www.rdocumentation.org/packages/OmicsMarkeR`).

In the following sections we explain our framework, first embarking on a brief review of existing literature. For a more thorough review and an extended version of this work, refer to Nogueira (2018). We also provide:

- The code in R and Matlab at `github.com/nogueirs/JMLR2018` for the proposed measure and associated statistical tools. The code for all experiments is also available, enabling reproducible research.

- A Python package and a demonstration notebook using the package at `github.com/nogueirs/JMLR2018/tree/master/python/`

- A demonstration web page at `www.cs.man.ac.uk/~gbrown/stability`

2. Background

We assume a data set of n examples $\{\mathbf{x}_i, y_i\}_{i=1}^n$ where each $\mathbf{x}_i$ is a d-dimensional feature vector and y_i is the associated label. The task of feature subset selection is to identify a subset of the dimensions, of size $k < d$, that conveys the maximum information about the label y. The challenge of feature selection can be tackled in various ways, commonly grouped in three families: filters, wrappers, and embedded methods (Guyon and Elisseeff, 2003). Filters assign a score to a feature subset (or a feature) based on statistics of the data, *independently* of any particular classifier—for example mutual information-based methods. Wrappers, on the other hand, evaluate a subset based on an error criterion (and therefore are classifier-specific). Because there are $2^d - 1$ possible feature subsets, filters and wrappers often use a search procedure such as a forward or backward search to only evaluate some of the subsets. Finally, embedded methods sit in between these two, choosing a subset as an integral part of learning a prediction model—for example LASSO and other penalized likelihood methods. The output of a feature selection algorithm is therefore either a weighting (or scoring) on the features, a ranking on the features or a subset of the features. Sorting the weights naturally gives a ranking on the features, and selecting the top-k ranked features gives a subset of the features. This way, the output of any weighting or ranking feature selection technique can be treated as a subset selection one (while the reverse is not true). The input to any given procedure is the data set, which itself is assumed to be a finite sample from a generating distribution. If the sample varies, logically the selected feature subset may vary—this variation is the *stability*.

It is important to note *why* instability may occur, and what is commonly done about it—the sources of, and solutions to instability. Several authors study how stability is influenced by data characteristics, such as noise (Shanab et al., 2011), data dimensionality, sample size (Alelyani, 2013), imbalance of the data set (Dittman et al., 2012) or feature redundancy (Gulgezen et al., 2009; Wald et al., 2013). Additionally, several works have been proposed to *increase* stability. These include variance reduction frameworks (Han and Yu, 2012), sample weighting (Yu et al., 2012), ensemble feature selection (Ditzler et al., 2015; Saeys et al., 2008) and multi-objective optimization (Baldassarre et al., 2017; Gulgezen et al., 2009; Kalousis et al., 2007).

It can be noted that each of these works, by definition, mandates the authors to *measure* stability—to know whether they have increased it, or decreased it. A typical approach to

measure stability is to first take M bootstrap samples of the provided data set, to apply feature selection to each one of them, and then to measure the variability in the M feature sets obtained. Approaches other than taking bootstraps have been considered, such as noise injection (Wald et al., 2012b; Altidor et al., 2011) or random subsampling (Wald et al., 2012a). However, in this article, we aim at measuring the variation with respect to data sampling. For this reason, we adopt the bootstrap approach due to its well understood properties and familiarity to the community.

Let $\mathcal{Z} = \{s_1, ..., s_M\}$ be a collection of feature sets, where each s_i is a subset of the d features and let a stability measure $\hat{\Phi}$ be a function taking as input $\mathcal{Z}$ and returning a stability value[2]. How can we define $\hat{\Phi}$ so that it measures the variability of the feature sets in $\mathcal{Z}$? In the literature, we find two approaches to this problem—the *similarity-based* approach and the *frequency-based* approach that we introduce in the next two sections.

2.1 Similarity-based Measures

First introduced by Dunne et al. (2002), the similarity-based approach consists in defining $\hat{\Phi}$ as the average pairwise *similarity* between the $M(M-1)$ possible pairs of feature sets in $\mathcal{Z}$, that is

$$\underbrace{\hat{\Phi}(\mathcal{Z})}_{\text{Stability measure}} = \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} \underbrace{\phi(s_i, s_j)}_{\textit{Similarity} \text{ measure}} ,$$

where ϕ is a function taking two feature sets as input and returning a similarity value. The more the feature sets in $\mathcal{Z}$ are *similar* to each other on average, the larger the value of $\hat{\Phi}(\mathcal{Z})$ will be. Therefore, the definition of $\hat{\Phi}$ and its properties critically depend on the choice of a similarity measure ϕ. Dunne et al. (2002) proposed to use the relative Hamming distance between two feature sets as a measure of their similarity. Since it was introduced, this approach gained popularity in the literature and we found to date 8 other proposals of similarity measures to be used in this context (c.f. Appendix 2.1 for more details). Kalousis et al. (2007) proposed to use the Jaccard index, Yu et al. (2008) the Dice-Sørenson index, Zucknick et al. (2008) the Ochiai index and Shi et al. (2006) the *POG* index (*Percentage of Overlapping Genes*). Kuncheva (2007) analysed some of the existing stability measures and demonstrated that they were behaving in undesirable ways. It pioneered the property-based approach, proposing a new similarity measure based on a set of 3 properties, proven to be essential to the correct comparison and interpretation of stability values. Because of its well-known properties, the proposed measure was used in many works that followed. Nevertheless, Kuncheva's measure was only defined for feature selection algorithms that guarantee to return a constant number of features. Other authors proposed to extend this measure to more general scenarios where the number of features selected is not pre-determined by the user (Lustgarten et al., 2009; Wald et al., 2012b). Nevertheless, we will see in Section 3 that the proposed extensions somehow lose some of the desirable properties.

2. We include the 'hat' notation $\hat{\Phi}$ to acknowledge that the value is an *estimate* of an underlying quantity, dependent on the sample size M.

2.2 Frequency-based Measures

An alternative representation for a feature set is to regard the feature choices as a binary string of length d, where a 1 at the f^{th} position means feature X_f has been selected in the set and a 0 means it has not been selected. This representation has driven the frequency-based approach, where one can measure stability by (for example) looking at the frequencies of selection of each feature over the M feature sets. The collection of the M feature sets can therefore be modelled as a binary matrix $\mathcal{Z}$ of size $M \times d$, where a row represents a feature set and a column represents the selection of a given feature over the M repeats as follows

$$\mathcal{Z} = \begin{pmatrix} z_{1,1} & z_{1,2} & \cdots & z_{1,d} \\ z_{2,1} & z_{2,2} & \cdots & z_{2,d} \\ \vdots & \vdots & \ddots & \vdots \\ z_{M,1} & z_{M,2} & \cdots & z_{M,d} \end{pmatrix}.$$

In the remainder of this paper, we will denote the observed frequency of selection of feature X_f by $\hat{p}_f = \frac{1}{M} \sum_{i=1}^{M} z_{i,f}$, the mean of the f^{th} column of $\mathcal{Z}$. We also model the selection of the f^{th} feature by a Bernoulli variable Z_f with unknown mean p_f. Since these two alternative representations are equivalent, with a slight abuse of notation, we will interchangeably denote by $\mathcal{Z}$ a collection of M feature sets or the matrix of M binary vectors. Intuitively, frequencies closer to 0 or 1 will indicate higher stability as it will mean that a feature is either selected on almost all M feature sets or on almost none of them; but as we will later see, defining a measure in this category can also prove to be challenging. In total, we identified 6 stability measures in this category (c.f. Appendix A.2 for more details), which are all either a function the observed frequencies of selection of each feature (Davis et al., 2006; Goh and Wong, 2016; Guzmán-Martínez and Alaiz-Rodríguez, 2011) or of the observed frequencies of selection of each feature set (Krízek et al., 2007).

3. A New Set of Properties for Stability Measures

Given the variety of stability measures published, it is sensible to ask whether any one is more valid than the others. This seems somewhat of a philosophical question—what does it mean for one stability measure to be more "correct" than another? To answer this, we adopt the perspective that a measure should (1) provably obey certain *properties* that are desirable in the domain of application and (2) provide capabilities that other measures do not. In this section, we aggregate and generalize the requirements of the literature into a set of 5 properties[3], given in Table 1, that we will show to be critical to the interpretation and comparison of stability values. For each property, we also study which one of the existing measures satisfy the property and we summarize our findings in Table 2. Our results show that none of the existing measures possess all 5 properties, which leads us to Section 4.1 where we propose a new stability measure.

3. As opposed to what has been done in some previous works (Kuncheva, 2007), these properties are functions of the *stability* measure rather than the *set similarity* measure—this will allow to compare the properties of both pairwise and non-pairwise stability measures in a single framework.

1. *Fully defined.* The stability estimator $\hat{\Phi}$ should be defined for any collection $\mathcal{Z}$ of feature sets, thus allowing for the total number of features selected to vary.
2. *Strict Monotonicity.* The stability estimator $\hat{\Phi}$ should be a strictly decreasing function of the sample variances s_f^2 of the variables Z_f.
3. *Bounds.* The stability $\hat{\Phi}$ should be upper/lower bounded by constants not dependent on the overall number of features or the number of features selected.
4. *Maximum Stability* $\leftrightarrow$ *Deterministic Selection.* A measure should achieve its maximum if-and-only-if all feature sets in $\mathcal{Z}$ are identical.
5. *Correction for Chance.* Under the Null Model of Feature Selection H_0, the expected value of $\hat{\Phi}$ should be constant.

Table 1: Proposed Properties for a Stability Measure.

3.1 Fully Defined

The first property, *Fully Defined*, is that a stability measure $\hat{\Phi}$ should be able to cope with any collection $\mathcal{Z}$ of feature sets. We observed that some of the stability measures do not obey this property. More specifically, the measures proposed by Kuncheva (2007), Krízek et al. (2007), Guzmán-Martínez and Alaiz-Rodríguez (2011) and Lausser et al. (2013) are only defined for a feature selection algorithm that would always return a constant number of features (c.f. definitions in Appendix A). Stability measures not having this property will not be defined for a wide class of feature selection algorithms, such as $L1$-regularization, and therefore such stability measures cannot be used to compare the stability of feature selection algorithms of different types.

3.2 Strict Monotonicity

By definition, all 9 similarity measures proposed to quantify stability are a strictly increasing function of the size of the intersection $|s_i \cap s_j|$ between the two sets s_i and s_j given as input (c.f. Appendix A.1). Kuncheva (2007) explicitly states this as a required property for a similarity measure. This property is implicitly defining what similarity (and therefore stability) is. Since the stability is defined as the average pairwise similarities, in the more general case, this property would naturally translate to: *For a given collection of feature sets $\mathcal{Z}$, the stability $\hat{\Phi}$ should be an increasing function of the average pairwise intersection size* $\frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} |s_i \cap s_j|$. Even though this property can be applicable to any stability measure (as it is not phrased in terms of a similarity measure any more), it is not straightforward to comprehend the meaning of this property, neither to verify if a stability measure possesses this property, especially for frequency-based measures. We can therefore wonder what this does translate to in the frequency-based representation and how can

we verify that non-pairwise measures possess this property? Theorem 1 bridges the two approaches and justifies our second property, *Strict Monotonicity*[4].

Theorem 1 *The average pairwise intersection between the M feature sets is as a linear function of the sample variances of the selection of each feature. More precisely,*

$$\frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} |s_i \cap s_j| = \bar{k} - \sum_{f=1}^{d} s_f^2, \tag{1}$$

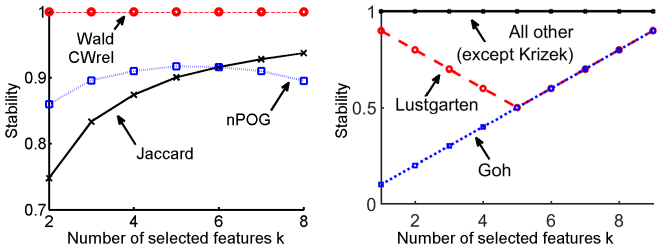
where $s_f^2 = \frac{M}{M-1} \hat{p}_f (1 - \hat{p}_f)$ is the unbiased sample variance of the selection of the f^{th} feature[5] *and where $\bar{k} = \frac{1}{M} \sum_{i=1}^{M} \sum_{f=1}^{d} z_{i,f}$ is the average number of features selected over the M feature sets.*

As we can see from Theorem 1, phrasing Monotonicity in terms of the average pairwise intersections is equivalent to phrasing it in terms of the average variance of the selection of each feature, which led to the definition of this property as stated in Table 1. This property defines *what* a stability measure should measure, rather than stating a necessary condition for a stability measure; therefore other proposals could be made for this purpose. For this reason, we will not discard the measures not having this property. However, it is interesting to note that, as we can see in Table 2, most stability measures have this property, showing some agreement upon the definition of stability across the literature, even if never stated as such. In some way, we can say that most existing measures of the literature implicitly aim at measuring the same quantity. In summary, we showed that: (1) interestingly, most stability measures of the literature possess this property, even though they were not explicitly built to that end, (2) the variance of the selection of each feature is an intuitive and simple way of measuring the variability in the choice features and (3) such a definition will allow us to derive a statistical framework for stability estimates, as we will later see in Section 4.2.

3.3 Bounds

This property was stated as necessary in several works. Somol and Novovičová (2010); Zucknick et al. (2008); Guzmán-Martínez and Alaiz-Rodríguez (2011) require a stability measure to be bounded by constants, while Kuncheva (2007) express the same requirement but for a similarity measure. Some of the measures such as Krízek et al. (2007) do not possess this property, since its maximum value depends on the number of features selected k and on the total number of features d (c.f. Appendix A.2). Unbounded measures do not allow for meaningful interpretation of stability values across problems or for different number of features selected, which can be restrictive in many applications.

4. To clarify: strict monotonicity is such that for a function g defined on a set D_g, g is a strictly monotonically (decreasing) function if $\forall x_1, x_2 \in D_g, x_1 < x_2 \Rightarrow g(x_1) > g(x_2)$. A counter-example showing the need for *strict* monotonicity (as opposed to monotonicity only) is to take any constant function: it will be monotonic as it will be an non-decreasing function of $|s_i \cap s_j|$ but cannot be interpreted as the similarity between two feature sets.
5. This expression of the sample variance is derived from a Bernoulli distribution.



(a) Forward implication (b) Backward implication

Figure 1: Illustration of the Maximum property. On the left, demonstration that Wald's measure and CW_{rel} (Somol and Novovičová, 2010) violate the forward implication. On the right, demonstration that Lustgarten's (Lustgarten et al., 2009) and Goh's (Goh and Wong, 2016) measures violate the backward implication[7].

3.4 Maximum Stability ↔ Deterministic Selection

For meaningful *interpretation* of a stability measure and comparison across problems, the range of values of a stability measure should be known and finite. Kuncheva (2007) states that IF two feature sets s_i and s_j are identical THEN their *similarity* is maximal, a desirable behaviour. Similarly, Guzmán-Martínez and Alaiz-Rodríguez (2011) also require that $\hat{\Phi}(\mathcal{Z})$ reaches its maximum whenever all the feature sets in $\mathcal{Z}$ are identical. We make this requirement a bi-implication, which translates in the general case to: $\hat{\Phi}(\mathcal{Z})$ reaches its maximum, *if-and-only-if* all feature sets in $\mathcal{Z}$ are identical, as stated in Table 1. We illustrate the need for the bi-implication below.

We used two scenarios, distinguishing the forward implication from the backward implication. First, we generated a collection of feature sets $\mathcal{Z}$ in which half of the feature sets are $\{X_1, ..., X_k\}$ and the other half are $\{X_1, ..., X_{k-1}\}$. Since there is clearly some variation in the features selected, the selection is not deterministic and we would want stability values not to be equal to their maximum. We plotted stability values against k for $d = 10$ and $M = 100$ in Figure 1a for some stability measures. We can see that Wald's measure (Wald et al., 2013) and CW_{rel} measure (Somol and Novovičová, 2010) still return their maximum value of 1. Therefore, these two measures violate the forward implication of this property. Second, we generated a collection of feature sets $\mathcal{Z}$ in which the same k features are selected on every repeat (for $d = 10$). Since the feature selection is now deterministic, we would want all stability values to be equal to their maximum. We plotted the stability values against the number of features selected k in Figure 1b. Even though the selection is completely deterministic, we can see that Lustgarten's and Goh's measure takes variable stability values depending on the number of selected features k. This shows that the two measures violate the backward implication of this property.

7. We ignored Krizek's measure in the right sub-figure as it is the only measure for which lower values correspond to higher stability and therefore, it should reach its minimum here instead of its maximum.

3.5 Correction for Chance

The fifth property, *Correction for chance*, was a novel concept introduced in the field by Kuncheva (2007) (but already existing in the statistical literature, c.f. Berry et al., 2016). This states that whenever we have *independently drawn subsets* at random, the stability value should be constant in expectation. This property was also later required by Lustgarten et al. (2009); Zhang et al. (2009); Guzmán-Martínez and Alaiz-Rodríguez (2011). When the number of features selected is constant, the notion of purely *random* feature selection is intuitive: it means that on each sample, given the number of selected features k, each one of the $\binom{d}{k}$ feature sets is equally likely to be chosen by the procedure. Now, let us take the case when the procedure does *not guarantee* to return a constant number of features, and thus produces a collection $\mathcal{Z}$ of feature sets, of varying size. We can still define the concept of *randomness* in that case: given the cardinality k_i of the i^{th} set, each one of the $\binom{d}{k_i}$ possible feature sets has an equal probability of being selected. We note that this is the assumption (sometimes implicitly) made by different authors using the concept of correction for chance, e.g. Kuncheva (2007); Lustgarten et al. (2009); Zhang et al. (2009); Guzmán-Martínez and Alaiz-Rodríguez (2011). Since we will use this concept multiple times in the remainder of the paper, we formalize this in Definition 2 and will refer to this assumption as the *Null Model of Feature Selection*.

Definition 2 (The Null Model of Feature Selection H_0) *We define the Null Model of Feature Selection as the situation where all possible permutations of the observed bits in a row of $\mathcal{Z}$ are equally likely. In other words, for all rows i in $\mathcal{Z}$, all subsets of size k_i have an equal probability of being drawn.*

Our final property, *Correction for chance* is that: under the Null Model of Feature Selection H_0, the expected value of $\hat{\Phi}$ should be constant, which for convenience we set to 0 (as done by other authors). The motivation behind such a property is that we would not want a stability measure to reflect the similarity between feature sets that might occur by chance, but only that due to the systematic decision-making of the feature selection algorithm. For illustrative purposes, we reproduced the experiment of Kuncheva (2007) in Figure 2. Let us assume that a feature selection procedure **randomly** selects k features out of $d = 10$ features and that we estimate the stability based on the $M = 100$ feature sets obtained for different values of k. As we can see, even though the feature selection procedure is random and therefore corresponds to a fully unstable situation (i.e. we are under the Null Model of Feature Selection H_0), some stability measures are strongly biased by the feature set size. For instance, we can see that using the Dice similarity measure, the stability systematically increases with the number of features selected, thus being in favour of larger feature sets. On the other hand, Kuncheva's measure that is corrected for chance gives a stability close to 0, no matter what the feature set size is as it is corrected for chance. Non-corrected measures make stability values neither comparable nor interpretable in different settings. To prove whether a measure has this property or not, we derived the value of $\mathbb{E}\left[\hat{\Phi}|H_0\right]$ for each of the existing measures in Appendix C.5 and reported the results in Table 2.

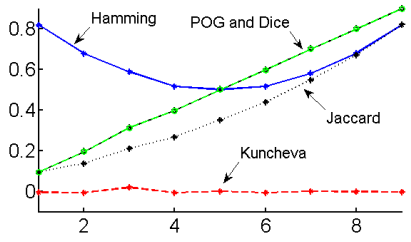


Figure 2: Illustration of the Correction-for-chance property. Stability values using Hamming, *POG*, Jaccard, Dice and Kuncheva similarity measures against the number k of features selected for $M = 100$ repeats.

Table 2: Properties of Stability Measures proposed in the literature 2002–2018. For each of the 15 measures, and for each of the 5 properties, we prove which measure satisfies which property — full proofs available in Appendix C.

3.6 Summary

In the literature, many authors advocated for the need of stability measures with well-known properties. In this section, we aggregated and generalised the properties stated as desirable in the literature into a set of desirable 5 properties[8]—applicable to any stability measure (whether similarity-based or not) and to any any feature selection algorithm (whether it selects a constant number of features or not)—in Table 1. Then, Table 2 summarizes the properties of each one of the stability measures. The first 5 measures are similarity-based measures and as we can see, they all possess all properties except Correction for chance. This weakness, noticed by Kuncheva (2007), gave rise to corrected-by-chance similarity-based measures, which are the 4 following measures of Table 2. As we can see, even though these 4 proposals all possess the Correction-for-chance property, they somehow lost some of the other desirable properties. Finally, the 6 following measures in the table are the frequency-based measures, which are more diverse in terms of the set of properties they satisfy. We note that even though CW_{rel} (Somol and Novovičová, 2010) does not possess the Correction-for-chance property, when the number of features selected is constant, we show in Appendix C.5 that it is asymptotically (as M approaches infinity) corrected for chance. We can therefore conclude that none of the stability measures in the literature possess all desired properties (even when discarding the Monotonicity property). Based on these results, we derive a novel stability measure in the next section, that not only has all desired properties, but also will allow us to develop a statistical framework for the quantification of stability.

4. A Novel Stability Measure

In this section, we propose a measure of stability which provably attains all desirable properties as discussed in the previous section. We recognise the stability measure $\hat{\Phi}$ as an estimator of a random variable, and aim to make explicit the corresponding population parameter Φ. By identifying the sampling distribution, we are able to provide tools for practitioners such as confidence intervals and hypothesis tests. This provides confidence in what the true value may be, and allows us to reliably compare stability across feature selection procedures. In the remainder of the paper, we refer to the stability measure as the *stability estimator* and to the parameter being estimated as the *population stability* or the *true stability*.

4.1 Proposed Stability Estimator

As required by the Monotonicity property, the stability should be a strictly decreasing function of the variances of the selection of each feature—for simplicity, we just negate the mean of the sample variances. As required by Correction for Chance, we rescale it by its expected value under the Null Model of Feature Selection. Finally for convenience of

8. Another property sometimes stated as desirable in the literature concerns the symmetry of the similarity measure ϕ (i.e. $\phi(s_i, s_j) = \phi(s_j, s_i)$) (Alelyani, 2013; P. and Perumal, 2016; Zucknick et al., 2008). We note that for any non-symmetric similarity measure ϕ, taking the arithmetic mean of $\phi(s_i, s_j)$ and $\phi(s_j, s_i)$ gives a symmetric similarity measure holding the same average pairwise value. Thus, the symmetry of a similarity measure ϕ is of little importance when comparing the properties of the corresponding stability measure $\hat{\Phi}$.

interpretation, we ensure that (asymptotically) the value is in the range $[0, 1]$ by taking one minus the resulting expression. Making use of Theorem 3 and by linearity of the expectation, this gives us our stability estimator as given in Definition 4.

Theorem 3 *Under the Null Model of Feature Selection H_0, for all f, the expected value of the sample variance of Z_f is $\mathbb{E}\left[s_f^2|H_0\right] = \frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)$.*

Definition 4 (Novel Measure) *We define the stability estimator as*

$$\hat{\Phi}(\mathcal{Z}) = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} s_f^2}{\mathbb{E}\left[\frac{1}{d}\sum_{f=1}^{d} s_f^2|H_0\right]} = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} s_f^2}{\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)}, \tag{2}$$

where $s_f^2 = \frac{M}{M-1}\hat{p}_f(1-\hat{p}_f)$ is the unbiased sample variance of the selection of the f^{th} feature.

We now verify that the proposed measure possesses all 5 properties. First, by construction, we can see that the measure is defined for all collections $\mathcal{Z}$, unless the denominator $\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)$ is equal to zero. This happens whenever $\bar{k} = 0$ or $\bar{k} = d$, which are the two limit cases in which the algorithm does not select any features over the M feature sets in $\mathcal{Z}$ or selects all of the features on every feature set of $\mathcal{Z}$. Since by definition, a feature selection procedure will always select a non-empty proper subset of the set of all available features, the first property *Fully defined* holds for the proposed definition of $\hat{\Phi}$. Second, by construction, $\hat{\Phi}$ is a linear function of the sample variances s_f^2 with a strictly negative slope. Therefore, the Monotonicity property holds for $\hat{\Phi}$. Third, to conform to the Bounds property—by inspection, one can see the numerator and denominator in the measure are positive quantities, therefore the upper bound is 1. For the lower bound, Appendix D shows that the minimum of $\hat{\Phi}$ is equal to $-\frac{1}{M-1}$. This shows that $\hat{\Phi}$ is bounded by -1, but is asymptotically bounded by 0 (as M approaches infinity). Fourth, let us assume for some $\mathcal{Z}$, the measure achieves its maximum, $\hat{\Phi}(\mathcal{Z}) = 1$. This state is equivalent to $\sum_{f=1}^{d} s_f^2 = 0$. Since the variance is a positive quantity, this is in turn equivalent to $s_f^2 = 0$ for all f. This case corresponds to the situation where each column of $\mathcal{Z}$ contains either all 1s or all 0s. Thus $\hat{\Phi}$ is equal to its maximum if-and-only-if all feature sets in $\mathcal{Z}$ are identical. Fifth, under the Null Model of Feature Selection H_0, by linearity of the expectation and using Theorem 3, $\mathbb{E}\left[\hat{\Phi}|H_0\right] = 0$. Therefore, the proposed measure is corrected for chance.

Theorem 5 shows that the proposed measure of stability $\hat{\Phi}$ is a generalization of some other widely used measures to feature sets of varying cardinality, hence being consistent with previous literature. As a result, all statistical tools of Section 4.2 are also valid for Kuncheva's measure and for the other equivalent measures, hence unifying some of the theory on the measurement of stability. The reformulation of Kuncheva's measure using our definition also provides a computational advantage, being $O(Md)$ instead of $O(M^2d)$ (which is the computational complexity of all pairwise measures).

Theorem 5 *When the number of features selected is constant:*

- *The stability estimator $\hat{\Phi}$ is equal to the stability measures proposed by Kuncheva (2007), Wald et al. (2013) and to nPOG (Zhang et al., 2009).*

- *The stability estimator $\hat{\Phi}$ and CW_{rel} (Somol and Novovičová, 2010) are asymptotically equivalent.*

In the next section, we provide the population parameter Φ estimated by $\hat{\Phi}$, that is the *true* stability of the feature selection procedure considered.

4.2 Statistical Tools

In the previous section, we proposed a new stability measure that possesses all desirable properties and is a generalization of some of the existing measures of the literature. We can also ask how it relates to other parts of the literature and which other fields deal with similar problems. This section demonstrates and exploits a relationship between stability and inter-rater agreement (Fleiss, 1971).

4.2.1 Viewing Stability as Inter-rater Agreement

Imagine a medical scenario—we have M doctors (more formally called *raters*) assigning a nominal category $\{1, 2, ..., q\}$ to each member of a set of d patients (called *subjects*). A useful indication of the agreement of the M raters is given by *inter-rater agreement coefficients*. We can view stability in this light—when the number of categories q is equal to 2, and each row of $\mathcal{Z}$ represents a rater, placing the d subjects into category 0 or 1. Interestingly[9], in this special case, we prove with Theorem 6 that a popular measure of inter-rater agreement, Fleiss' Kappa (Fleiss, 1971) reduces to our estimator, Definition 4. As a result, any statistical result previously derived for Fleiss' Kappa also holds for $\hat{\Phi}$. Using this relationship, we can use the work of Gwet (2008) which shows the asymptotic normality of Fleiss' Kappa, hence guaranteeing the validity of confidence intervals and hypothesis tests for large samples.

Theorem 6 *When there are only two categories (0/1), Fleiss' Kappa is equal to $\hat{\Phi}(\mathcal{Z})$.*

4.2.2 The Sampling Distribution of Stability

Let us assume each row of the matrix $\mathcal{Z}$ is an independent sample from the joint distribution $(Z_1, ..., Z_d)$, where Z_f is a Bernoulli variable with unknown population parameter p_f, where we make no assumption of independence between d covariates. In the original paper, Fleiss (1971) derives the variance of Fleiss' Kappa, but only when Φ is equal to 0, which is of little use in our case. Later on, Gwet (2008) provides a variance estimate and the asymptotic distribution of Fleiss' Kappa in the general case. In his work, Gwet (2008) assumes that the raters (samples) and subjects (features) are sampled from a larger population and then derives the variance due to the sampling of raters and the variance due to the sampling of subjects. Using the multivariate Central Limit Theorem and a linear approximation of $\hat{\Phi}$, Gwet (2008) shows that $\hat{\Phi}$ is asymptotically normal. Gwet (2008) also verifies the validity of this result for the construction of confidence intervals with Monte Carlo simulations. In our case, we assume that there is no sampling of the subjects and that the number of categories

9. Another interesting relationship that could be used in future work is that Fleiss' Kappa has also been linked to the Intra-Class Correlation Coefficient (ICC) in the binary case (Fleiss et al., 2004), so any result that applies to the ICC can also be applied to the proposed stability estimator.

$q = 2$. Under these assumptions, the variance due to the sampling of subjects derived by Gwet (2008) becomes zero and the asymptotic distribution of the stability estimator $\hat{\Phi}$ becomes the one given by Theorem 7.

Theorem 7 (Asymptotic Distribution) *As $M \to \infty$, the statistic $\hat{\Phi}$ weakly converges to a normal distribution, that is*

$$\frac{\hat{\Phi} - \Phi}{\sqrt{v(\hat{\Phi})}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1),$$

where:

- $\Phi = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} p_f(1-p_f)}{\bar{p}(1-\bar{p})}$ *is the mean of the estimator $\hat{\Phi}$ in which $\bar{p} = \frac{1}{d}\sum_{f=1}^{d} p_f$ is the average mean parameter of the d Bernoulli variables;*
- $v(\hat{\Phi}) = \frac{4}{M^2}\sum_{i=1}^{M}(\hat{\Phi}_{(i)} - \bar{\hat{\Phi}}_{(.)})^2$ *is an estimate of the variance of $\hat{\Phi}$ in which:*
  - $\hat{\Phi}_{(i)} = \frac{1}{\frac{k_i}{d}\left(1-\frac{k_i}{d}\right)}\left[\frac{1}{d}\sum_{f=1}^{d} z_{i,f}\hat{p}_f - \frac{k_i\bar{k}}{d^2} + \frac{\hat{\Phi}}{2}\left(\frac{2\bar{k}k_i}{d^2} - \frac{k_i}{d} - \frac{\bar{k}}{d} + 1\right)\right]$;
  - *and $\bar{\hat{\Phi}}_{(.)}$ is the average value of $\hat{\Phi}_{(i)}$, that is $\frac{1}{M}\sum_{i=1}^{M}\hat{\Phi}_{(i)}$.*

This asymptotic distribution allows us to identify $\hat{\Phi}$ as being an estimator of an unknown population quantity Φ. In the remainder of the paper, we refer to $\hat{\Phi}$ as being the sample stability and to Φ as being the population (or *true*) stability. The asymptotic convergence shows that $\hat{\Phi}$ is a consistent estimator of the population stability Φ. This means that as M approaches infinity, we are assured that the stability estimator $\hat{\Phi}$ will converge in probability to the population stability Φ.

4.2.3 Confidence Intervals

The asymptotic convergence to a normal distribution allows us to derive approximate confidence intervals for the population stability Φ, given below in Corollary 8. Though the provided confidence intervals are only approximate, we will see in Section 5.2 that even for relatively small values of M, the given intervals still have a good coverage probability.

Corollary 8 (Confidence Intervals) *A $(1-\alpha)$%-approximate confidence interval for Φ is*

$$\left[\hat{\Phi} - z^*_{\left(1-\frac{\alpha}{2}\right)}\sqrt{v(\hat{\Phi})}, \hat{\Phi} + z^*_{\left(1-\frac{\alpha}{2}\right)}\sqrt{v(\hat{\Phi})}\right],$$

where $z^*_{\left(1-\frac{\alpha}{2}\right)}$ is the inverse cumulative of a standard normal distribution at $1-\frac{\alpha}{2}$.

4.2.4 Hypothesis Testing

In a first scenario, let us assume a practitioner applies a feature selection procedure to M bootstrap samples, generating a matrix $\mathcal{Z}$ of size $M \times d$, and computes the stability estimate $\hat{\Phi}(\mathcal{Z})$. How can we know whether the true stability Φ is significantly greater than

a fixed value Φ_0? This can be defined formally in terms of a null hypothesis significance test.

Is the Population Stability Φ Greater than a Given Value Φ_0? In this case the hypothesis tested is

$$\begin{cases} H_0 : \Phi = \Phi_0 \\ H_1 : \Phi > \Phi_0 \end{cases}$$

Under H_0, $\Phi = \Phi_0$ and therefore the statistic $V_M = \frac{\hat{\Phi}-\Phi_0}{\sqrt{v(\hat{\Phi})}}$ is asymptotically standard normal (c.f. Theorem 7). Therefore we can apply a one-tail test as follows:

1. Compute the statistic V_M.
2. Reject H_0 if $V_M \geq z^*_{(1-\alpha)}$, where the critical value $z^*_{(1-\alpha)}$ is the $(1-\alpha)$th percentile of the standard normal distribution.

In addition, it is very common to compare stability values between algorithms. For example, Saeys et al. (2008) conclude that *"RELIEF is one of the less stable algorithms"* and *"Random Forests clearly outperform other feature selection methods regarding robustness"*. So given two stability estimates $\hat{\Phi}(\mathcal{Z}_1)$ and $\hat{\Phi}(\mathcal{Z}_2)$, can we conclude that the true stability of the first is significantly different than the second?

Do Two Feature Selection Algorithms Have Identical Stabilities? Let $\mathcal{Z}_1$ and $\mathcal{Z}_2$ be the output of two feature selection procedures. In this case, we wish to test the following hypothesis

$$\begin{cases} H_0 : \Phi_1 = \Phi_2 \\ H_1 : \Phi_1 \neq \Phi_2 \end{cases}$$

Using the asymptotic distribution of $\hat{\Phi}(\mathcal{Z}_1)$ and of $\hat{\Phi}(\mathcal{Z}_2)$ given by Theorem 7, we can derive Theorem 9. Using the given test statistic T_M, we reject H_0 if $|T_M| \geq \theta$, where θ is the $\left(1-\frac{\alpha}{2}\right)^{th}$ percentile of the standard normal distribution.

Theorem 9 *The test statistic for comparing stabilities is*

$$T_M = \frac{\hat{\Phi}(\mathcal{Z}_2) - \hat{\Phi}(\mathcal{Z}_1)}{\sqrt{v(\hat{\Phi}(\mathcal{Z}_1)) + v(\hat{\Phi}(\mathcal{Z}_2))}}.$$

Under H_0, the statistic T_M asymptotically (as M approaches infinity) follows a standard normal distribution.

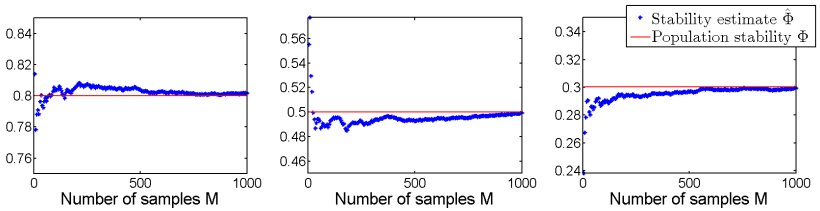
5. Empirical Validation of the Statistical Tools

Fleiss et al. (2004) propose a benchmark scale for interpretation of the value of Fleiss' Kappa. We will use the same scale for $\hat{\Phi}(\mathcal{Z})$, provided in Table 3. Stability values above 0.75 represent an excellent agreement of the feature sets beyond chance, while values below 0.4 represent a poor agreement between sampled feature sets.

In the remainder of this section, we verify the tools of the previous section, using toy data for a population stability Φ in each one of the categories. To be able to generate

Φ	**Strength of Agreement**
< 0.40	Poor
0.40 to 0.75	Intermediate to good
> 0.75	Excellent

Table 3: Benchmark scale for stability.



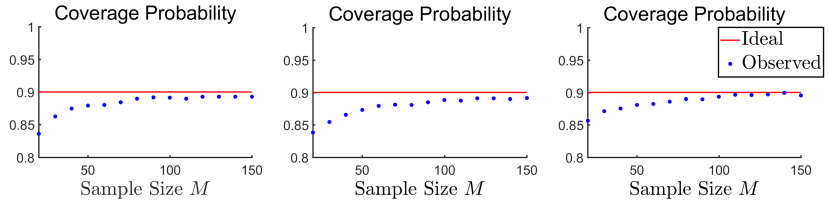
(a) Case 1: $\Phi = 0.8$ (b) Case 2: $\Phi = 0.5$ (c) Case 3: $\Phi = 0.3$

Figure 3: Consistency of the stability estimate $\hat{\Phi}(\mathcal{Z})$ for the 3 toy cases. As M increases, the value of $\hat{\Phi}(\mathcal{Z})$ gets closer to the population parameter Φ.

Bernoulli variables with a specified population stability Φ_0, we first need to chose d Bernoulli parameters $p_1, ..., p_d$ such that $\Phi = \Phi_0$. We picked 3 test cases for the values of Φ equal 0.8, 0.5 and 0.3 and for $d = 100$.

5.1 Validation of Consistency of the Estimator

In this section, we empirically show the consistency of the stability estimator $\hat{\Phi}$ in the 3 test cases described. In each case, we take M samples from the $d = 100$ Bernoulli variables with mean parameters $(p_1, ..., p_d)$. This gives us a binary matrix $\mathcal{Z}$ of size $M \times d$. We then plot the value of the stability estimate $\hat{\Phi}(\mathcal{Z})$ as we increase the number of samples M in Figure 3. As we can see, as the number of samples M increases, the value of $\hat{\Phi}(\mathcal{Z})$ approaches the true stability Φ. We chose similar scales for the 3 test cases. We observe that for relatively small values of M, (generally for $M \leq 10$), the absolute value of the difference $|\hat{\Phi}(\mathcal{Z}) - \Phi|$ is within 5% and for $M \leq 100$, within 1%. Of course, these cannot be used as a general rule of thumb for other chosen parameters p_f and d but it gives an idea of the rate of convergence of the stability estimates. In real applications, the population stability is unknown and we need tools to be able to determine which interval of values the population stability takes. This is the topic of the next section where we study the confidence intervals.



(a) Case 1: $\Phi = 0.8$ (b) Case 2: $\Phi = 0.5$ (c) Case 3: $\Phi = 0.3$

Figure 4: Coverage probabilities for the 3 test cases. We set the nominal level to be 0.90 (90%-confidence interval). The x-axis represents the sample size M and the y-axis the estimated coverage probability with 10000 repeats.

5.2 Validation of Confidence Intervals

The coverage probability of a confidence interval for Φ is the proportion of time the interval built from the data will actually contain the population stability Φ. To verify the results of Theorem 8 providing the confidence intervals, we adopted the following procedure:

1. Compute the population stability Φ using the true Bernoulli parameters $(p_1, ..., p_d)$.
2. Repeat 10,000 times:
   - Take M samples from the d variables $Z_1, ..., Z_d$ with mean $p_1, ..., p_d$.
   - Compute the $(1 - \alpha)$-approximate confidence interval using Corollary 8.
3. The estimated coverage probability is the fraction of times (from 10,000) that the true stability Φ was within the confidence intervals.

If we had exact confidence intervals, we should have an exact coverage probability of $(1-\alpha)$. However, the confidence intervals derived are only approximate. Figure 4 gives the estimated coverage probabilities in the 3 test cases for $\alpha = 10\%$, i.e. a 90%-confidence interval.

As we can see, the estimated probability quickly approaches $(1-\alpha) = 0.9$ as expected. In Table 4, we further show the observed coverage probabilities in the 3 test cases for $M = 100$ and for different values of α. The same behaviour can be seen in this table: the values get very close to the expected coverage probability of $(1-\alpha)$. We observed the same behaviour for a larger number of features ($d = 10000$) and a same number of feature sets M.

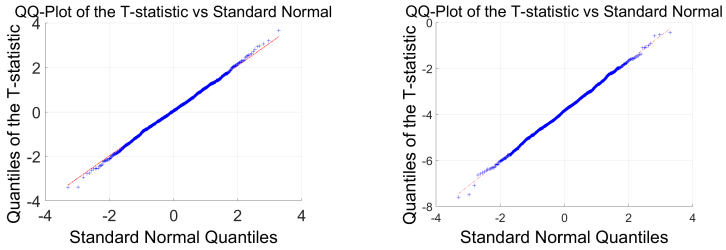
5.3 Validation of the Second Hypothesis Test

In this section, we verify the asymptotic distribution of the test statistic T_M as given by Theorem 9. To verify this result we proceed as follows:

1. Pick two set of parameters $p_1, ..., p_d$ with the desired values of Φ_1 and Φ_2.
2. Repeat 1000 times:

Case 1	$\Phi = 0.8$	98.5%	94.3%	89.0%
Case 2	$\Phi = 0.5$	98.6%	93.8%	89.0%
Case 3	$\Phi = 0.3$	98.6%	94.0%	89.3%
Ideal		99%	95%	90%

Table 4: Coverage probabilities for the 3 test cases with $M = 100$, $d = 100$, estimated via 10,000 repeats for different nominal confidence intervals.



(a) $\Phi_1 = \Phi_2 = 0.8$ (b) $\Phi_1 = 0.8$ and $\Phi_2 = 0.75$

Figure 5: QQ-plots illustrating the convergence of the statistic T_M to a standard normal distribution when $\Phi_1 = \Phi_2 = 0.8$ [LEFT] and the convergence to a non-standard Gaussian when $\Phi_1 \neq \Phi_2$ [RIGHT]. We took $d = 100$, $M = 1000$ and 1000 repeats. We note that the range of values on the y-axis of the right plot is not the same as the one of the left plot.

- Take M samples from the d variables, for each of $\mathcal{Z}_1$ and $\mathcal{Z}_2$
- Compute the corresponding statistic T_M.

We then order the 1000 estimates of T_M and plot the quantiles against that of a standard normal distribution in a Quantile-Quantile plot (QQ-plot). Figure 5 provides the result for two test cases. In the left sub-figure, the population stabilities are taken to be identical (i.e. $\Phi_1 = \Phi_2$). In that situation, the QQ-plot shows that the quantiles of the test statistic T_M are identical to the ones of a standard normal distribution, which is the result we expected. On the right sub-figure, we chose different population stabilities (i.e. $\Phi_1 \neq \Phi_2$). In this case, the QQ-plot shows that the quantiles are still the ones of a normal distribution but with a mean different from 0. Indeed, if we have a closer look at the right sub-figure, we can see that the range of values taken on the y-axis are all negative. The observed median of the statistic T_M in that case is of -3.8 and the statistic takes values in the interval $[-7.6, -0.4]$. Therefore the statistic T_M is not standard normal in that situation.

6. Experiments

The experiments of this section illustrate how the tools presented in this paper can be used by practitioners to select hyperparameters with higher stability or to compare the stability of different feature selection algorithms. This section contains two sets of experiments[10]:

- Section 6.1 focuses on the LASSO and the Elastic Net, which are both regularized regression models that select features as part of the training process. The Elastic Net is known to yield more stable coefficients than the LASSO in the presence of redundant features (Zhou, 2013). This section shows that the proposed stability measure captures this and that choosing a good trade-off between stability and accuracy can reduce the number of irrelevant features in the model with negligible loss in accuracy.
- Section 6.2 focuses on a popular technique, *Stability Selection* (Meinshausen and Bühlmann, 2010) which we apply to LASSO. The proposed framework defines the stable set as the set of features being selected with high frequency across a set of regularizing parameters. We propose to look at the stability of the *stable set* for different hyperparameters and compare it to the stability of LASSO.

6.1 The Stability of $L1/L2$ Regularized Logistic Regression

In this section, we observe how the degree of redundancy in data can affect the stability of LASSO and Elastic Net, and how we can optimize hyperparameters so that both log-likelihood and stability are taken into account. We show that stability can help recover the *true* set of relevant features. To be able to control the set of relevant features and the redundancy between them, we use a synthetic data set as described in the next section.

6.1.1 Description of the Data Set

We use a synthetic data set (Kamkar et al., 2015)—a binary classification problem, with 2000 instances and $d = 100$ features, where only the first 50 features are relevant to the target class. Instances of the positive class are identically and independently drawn from a normal distribution with mean $\mu_+ = (\underbrace{1, ..., 1}_{50}, \underbrace{0, ..., 0}_{50})$ and covariance matrix

$$\Sigma = \begin{bmatrix} \Sigma^*_{50\times 50} & \mathbf{0}_{50\times 50} \\ \mathbf{0}_{50\times 50} & \mathbf{I}_{50\times 50} \end{bmatrix},$$

where $\Sigma^*_{50\times 50}$ is the matrix with ones on the diagonal and ρ (a parameter in $[0, 1]$) controlling the degree of redundancy everywhere else. The mean for the negative class is taken equal to $\mu_- = (\underbrace{-1, ..., -1}_{50}, \underbrace{0, ..., 0}_{50})$. The larger the value of ρ, the more the 50 relevant features will be correlated to each other.

10. You can reproduce all these experiments (in Matlab or R) with the code given at `github.com/nogueirs/JMLR2018`

6.1.2 Stability of LASSO

We use a $L1$-regularized logistic regression where λ is the regularizing parameter, influencing the amount of features selected—as λ increases, more and more coefficients are equal to zero and therefore less and less features are selected. We take 2000 samples and divide them into 1000 for model selection (i.e. to select the regularizing parameter λ) and 1000 for selection of the final set of features. The model selection set can be used simply to optimize error, or to optimize error/stability simultaneously—the experiments will demonstrate that the latter provides a lower false positive rate in the final selection of features. We study 4 degrees of redundancy: $\rho = 0$ (no redundancy, the features are independent from each other), $\rho = 0.3$ (low redundancy), $\rho = 0.5$ (medium) and $\rho = 0.8$ (high). We apply $L1$-logistic regression to $M = 100$ bootstrap samples of the data set. We then compute the average out-of-bag (OOB) log-likelihood[11] and the stability of the feature selection.

Figure 6 shows the average log-likelihood (left column) and the stability (right column) versus the regularization parameter λ for the 4 degrees of redundancy chosen. For each degree of redundancy, the pink dashed-line represents the parameter λ maximizing the likelihood and the black one represents the parameter maximizing the stability. In the case of no redundancy, we can see that these two parameters produce similar values of likelihood and stability. But, as we change the degree of redundancy, this is not the case. The result can most strongly be seen in Figure 6b, where $\lambda = 0.0051$ optimizes likelihood, but if we increase to $\lambda = 0.0187$, we sacrifice a negligible amount of likelihood for a quite significant increase in stability to $\hat{\Phi} = 0.63$.

Figure 7 shows an alternative view of these results, plotting stability against likelihood. When there is no redundancy in the data (sub-figure (a)), stability seems to be an increasing function of the likelihood. For higher levels of redundancy, this results in at least *two* values of λ which achieve the *same likelihood*, but clearly one results in higher stability. In practice, to choose a hyperparameter λ, we have to pick a trade-off between likelihood of the model and stability. For this purpose, we can identify the pareto front of likelihood and stability, which is the set of points such that there is no other point with higher likelihood and higher stability. Hence, each point in the pareto front represents a different trade-off between likelihood and stability. Figure 8 summarizes the pareto fronts for the 4 degrees of redundancy. In a classic scenario, we would pick the value of λ that maximizes the likelihood only, which corresponds to the rightmost point in the figure. However, we can see that sacrificing a small amount of likelihood allows us to considerably increase stability. As we increase the degrees of redundancy, we see the best case for stability is lower. Nevertheless, all the points in a given pareto front have a similar likelihood and a similar misclassification rate. All these observations show that *stability can potentially be increased without loss of predictive power.*

We also observe that pursuing stability may help identifying the *relevant* set of features. Figure 9 gives the observed frequencies of selection $\hat{p}_f$ of each feature over the $M = 100$ bootstraps—where features $1-50$ are relevant, and $51-100$ are irrelevant in the case of high redundancy. We picked the value of λ that maximized the likelihood for the left sub-figure and a value of λ in the pareto front of stability and likelihood for the right sub-figure. On the right figure, all 50 irrelevant features have a frequency of selection equal to 0 (i.e. the

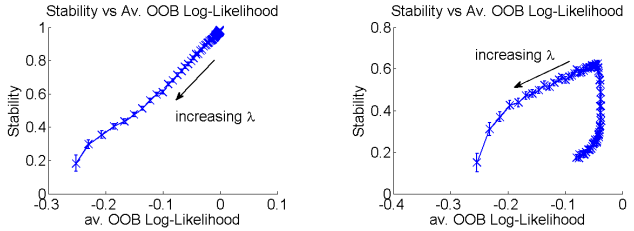
(b) Low redundancy

(c) Medium redundancy

(d) High redundancy

Figure 6: Average OOB log-likelihood [left column] and stability [right column] against the regularizing parameter λ for 4 degrees of redundancy. For each degree of redundancy, the pink dashed-line corresponds to the λ value that maximizes the likelihood and the black one corresponds to the value of λ that maximizes stability. As we can see, by choosing latter parameter λ, we gain in stability with only a small loss in likelihood.



(a) No redundancy (b) Low redundancy

(c) Medium redundancy (d) High redundancy

Figure 7: Stability (with 95%-confidence intervals) against average OOB log-likelihood for 4 degrees of redundancy.

(a) $\lambda = 1.3 \times 10^{-2}$ (b) $\lambda = 6.8 \times 10^{-2}$

Figure 9: The observed frequencies of selection $\hat{p}_f$ of each feature optimizing only the likelihood [LEFT] and choosing a trade-off between stability and likelihood [RIGHT] for high redundancy ($\rho = 0.8$). The features on the left of the red vertical line correspond to the 50 relevant features and the ones on the right to the 50 irrelevant ones.

false positive rate 0), which means they have not been selected on any of the $M = 100$ samples. This is not the case when only maximizing the likelihood: we cannot discriminate the set of relevant features from the set of irrelevant ones by looking at the frequencies of selection $\hat{p}_f$. Using the 1000 holdout set, we applied $L1$-regularised logistic regression using these two values of λ. Table 5 provides the false positives and false negatives for the 4 degrees of redundancy. The results show a decrease in the false positives when optimizing both stability and likelihood while having a limited effect on the false negatives.

Redundancy	Optimizing likelihood	Optimizing both
none	$FP = 0$, $FN = 0$	IDEM
low	$FP = 14$, $FN = 19$	$FP = 0$, $FN = 20$
medium	$FP = 0$, $FN = 26$	$FP = 0$, $FN = 26$
high	$FP = 12$, $FN = 38$	$FP = 0$, $FN = 39$

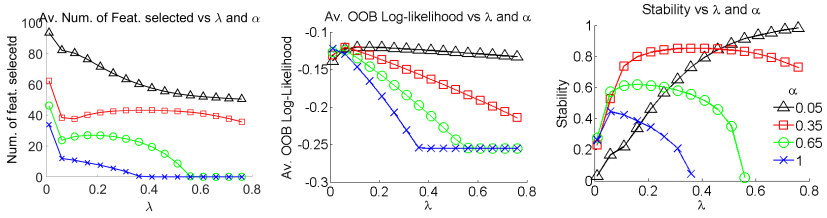
Table 5: False positives and false negatives of the final feature set for different degrees of redundancy ρ when optimizing only the likelihood against when optimizing both likelihood and stability.

6.1.3 Stability of the Elastic Net

$L1$-regularization has the effect of forcing regression coefficients to zero, hence selecting a subset of the available features. $L2$-regularization (*ridge regression*), is known to have a grouping effect: correlated features will have similar coefficients (Zhou, 2013). The Elastic Net is a convex combination of a $L1$ and a $L2$-regularization. It has two parameters, α and

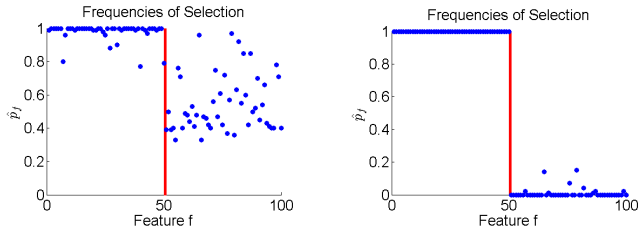
λ, where λ controls the overall weight of regularization and where α controls the balance between the two regularizing terms. When $\alpha = 1$, it becomes $L1$ (LASSO), and when $\alpha = 0$ it is $L2$ (ridge regression). As α varies, the Elastic net blends between the two and offers the advantages of both techniques—it forces some of the coefficients to be zero like LASSO while having the grouping effect of the ridge regression. Correlated features are a source of instability (Gulgezen et al., 2009; Wald et al., 2013), as feature selection procedures will tend to select a different feature from a same group of correlated features on different samples. Therefore, we expect the Elastic net to mitigate this, hence increasing stability.

In this section, we reproduce some of the experiments of the last section for the Elastic Net, optimizing the two regularizing parameters α and λ. We proceed as before, taking $M = 100$ bootstraps, and focus on the most challenging case of high redundancy ($\rho = 0.8$). We confirm in Figure 10a that as λ increases, the overall regularization increases and less features are selected. Figures 10b and 10c respectively give the average OOB log-likelihood and the stability against the values of λ for different values of α. We can see that no matter what is the value of λ chosen, $\alpha = 0.05$ has a higher likelihood than the other values of α in most cases and reaches high stability (greater than 0.90) for values of λ greater than 0.56. Interestingly, for these values of α and λ, we can see in Figure 10a that the number of features selected is around 50, which is the total number of relevant features. Let us have a closer look at $\alpha = 0.05$. If we were only optimizing the likelihood, we would pick $\lambda = 0.05$, which yields a stability of 0.34. The corresponding average misclassification error is 14%. If we wanted to also optimize stability, we could sacrifice a small amount of likelihood by picking $\lambda = 0.76$ which yields a stability of 0.98. The corresponding average OOB misclassification error is also 14%. Figure 11 gives the observed frequencies of selection $\hat{p}_f$ for $\lambda = 0.16$ on the left sub-figure (which is the value of λ that maximizes the likelihood) and for $\lambda = 0.76$ on the right sub-figure (which is a value of λ optimizing both the likelihood and the stability). We can see on the right sub-figure that when also optimizing stability, the whole set of relevant features is selected on each one of the $M = 100$ samples and irrelevant features are only rarely selected. On the left sub-figure, even though the likelihood for the given hyperparameters and the misclassification error are similar, we can see that non-relevant features are a lot more often selected in the model.



(a) Av. num. of feat. selected $\bar{k}$ (b) Likelihood (c) Stability

Figure 10: Plots against λ where each line corresponds to a different value of α in the high redundancy case ($\rho = 0.8$). We pick the $\alpha = 0.05$ as it reaches a higher likelihood for most values of λ and it can also achieve high stability.



(a) $\alpha = 0.05$ and $\lambda = 0.16$ (b) $\alpha = 0.05$ and $\lambda = 0.76$

Figure 11: The observed frequencies of selection $\hat{p}_f$ of each feature optimizing only the likelihood [LEFT] and choosing a trade-off between stability and likelihood [RIGHT] for high redundancy ($\rho = 0.8$). The features on the left of the red vertical line correspond to the 50 relevant features and the ones on the right to the 50 irrelevant ones. We can see that optimizing both stability and likelihood [RIGHT] helps recovering the set of relevant features.

6.1.4 Conclusions

In this section, we proposed a methodology to select hyperparameters using stability along with the error. On the data set used, we showed that it is possible to select a hyperparameter yielding much higher stability values without loss of predictive power. When the stability is optimized along with the likelihood of the model, the false positive rate was lower. Using the Elastic Net, we were able to achieve high stability for a similar loss than using LASSO. Enforcing high stability had the effect of discriminating the set of relevant features, helping to *recover* the true set of relevant features.

6.2 How Stable is Stability Selection?

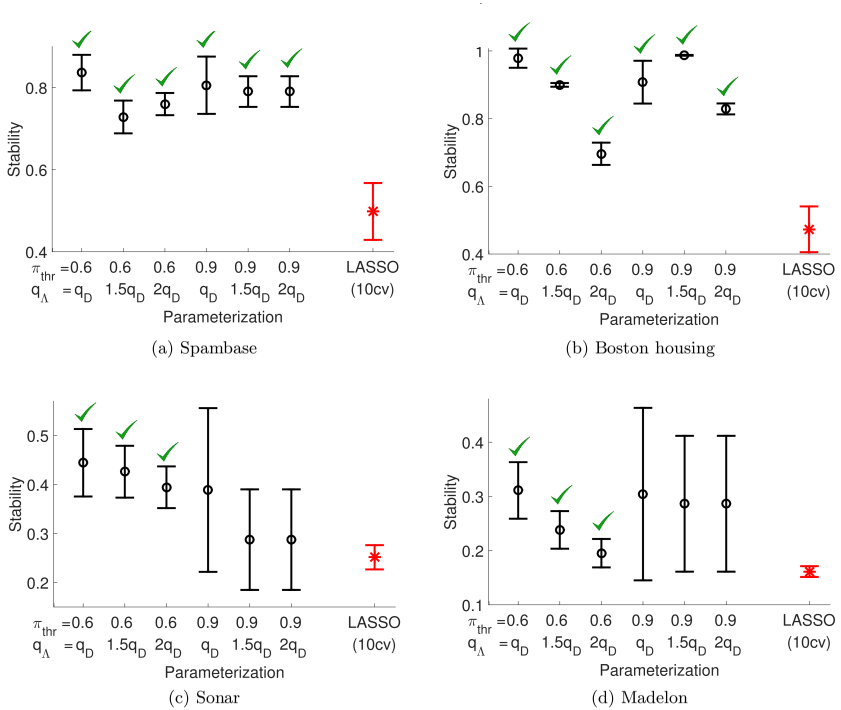
In high dimensional data sets, picking a regularizing parameter λ that recovers the *true* set of relevant features has proven to be challenging. For this reason, Meinshausen and Bühlmann (2010) introduced a technique called "*Stability Selection*", a popular and generic approach that can also be used for solving other problems of structure estimation such as graphical modelling. In this section, we focus on the use of Stability Selection in the context of feature selection with LASSO. It proposes to apply LASSO to M random sub-samples of size $\lfloor \frac{n}{2} \rfloor$ of the original data set (where n is the sample size) for a set of regularizing parameters $\lambda \in \Lambda$, where Λ is a subset of $\mathbb{R}^+$. This method considers the frequencies of selection of each feature $\hat{p}_f$ for each value of $\lambda \in \Lambda$ and defines the **set of stable variables** as *the set of all variables having a frequency of selection $\hat{p}_f \geq \pi_{thr}$ for at least one of the regularizing parameters $\lambda \in \Lambda$* (where π_{th} is a user-defined threshold). Then they propose to use the identified stable set as an approximation of the true relevant set.

The proposed technique is effectively an ensemble feature selection technique where the final set is made of all features having a high frequency of selection $\hat{p}_f$ for at least

one the chosen regularizing parameter. The main contribution of Stability Selection is that it provides a control over false discovery error rates (i.e. the number of irrelevant features identified as relevant), and as a result, a principled way to choose the amount of regularization for variable selection. In relation to our work, we can point out the following interesting facts about this work: (1) it uses the concept of frequency of selection $\hat{p}_f$ to detect relevant features; (2) it uses the underlying idea that the *stable set* does not only help recovering the true feature set but also will be more robust to the choice of regularizing parameters; (3) It provides an upper bound and an exact control of the number of false positives (i.e. the number of irrelevant features falsely selected). Therefore, this work implicitly uses the idea that selecting stable features in the final set will help recover the *true* set of relevant features, which is intimately linked to the results of the previous section where we have shown that enforcing stability could potentially reduce the number of false positives. Intuitively, the final set of variables picked by Stability Selection should be more stable in the sense of our definition $\hat{\Phi}(\mathcal{Z})$, as they select the variables showing a consensus across multiple repeats of the data with perturbations and for different regularizing parameters.

In this section, we use our proposed measure to *quantify* just how stable their *stable set* can be. To that end, we look at how much the final set picked by Stability Selection varies in the context of LASSO and we will show on 4 data sets that it will indeed yield more stable results (in the sense of $\hat{\Phi}(\mathcal{Z})$) than its non-ensemble version (LASSO). Nevertheless, we remind the reader that these experiments are purely illustrative of the concepts discussed in the paper and do not claim to be an exhaustive empirical study. Stability selection possesses 3 hyperparameters[12]: (1) the cut-off value π_{thr}, (2) the average number of features selected q_Λ over the all values of $\lambda \in \Lambda$ and (3) the set of regularizing parameters Λ (where the two last hyperparameters are dependent). We used the values suggested by the original authors: that is $\pi_{thr} \in (0.6 - 0.9)$ and q_Λ around $\sqrt{0.8d}$. Figure 12 compares the two approaches for variable selection in 4 data sets, three binary classification problems (Spambase/Sonar/Madelon) and one regression (Boston housing). To derive the 95%-interval estimate of stability, we ran the algorithms on $M = 100$ bootstraps, and used the tools presented in Section 4.2.3. The first observation is that, no matter the parametrisation, the average stability of stability selection is always higher than the stability of LASSO. Furthermore, we performed hypothesis tests at a level of significance of 5% to check for which hyperparameters Stability Selection achieved higher stability than LASSO. A green tick indicates where the null hypothesis (equal stability) was rejected. On the Sonar and Madelon data sets, the stability of Stability Selection is consistently higher than LASSO, but can present high variability for some hyperparameters (as shown by the large confidence intervals). In those cases, it failed to reject the null hypothesis. These experiments highlight the importance of statistical significance when quantifying stability and the need for such statistical tools.

12. We note that the first two hyperparameters listed hereafter effectively control the upper bound on the amount of false positives.



(a) Spambase (b) Boston housing

(c) Sonar (d) Madelon

Figure 12: Comparing the stability of LASSO and different parametrisations of Stability Selection in four classification/regression data sets. For LASSO (red star), we optimised the regularisation parameter using 10-fold cross validation and the *one-standard-error* rule—picking up the most parsimonious model within one standard error of the minimum (Hastie et al., 2009). For stability selection (black circle), we explored different parameters: for the cut-off threshold $\pi_{\text{thr}} \in \{0.60, 0.90\}$, while for the average number of selected variable $q_\Lambda \in \{q_D, 1.5q_D, 2q_D\}$, where $q_D = \sqrt{0.8d}$ is the default value. We performed hypothesis tests to check whether the stability of Stability Selection is significantly different from LASSO. The green tick means that the null hypothesis (i.e. the population stabilities are equal) has been rejected at level of significance 5%.

7. Conclusions and Future Work

In this section, we present the conclusions and then consider possible areas of future work.

7.1 Conclusions

We have provided a rigorous statistical treatment for the concept of stability in feature selection. Following a property-based approach suggested in previous works, we identified a set of 5 properties—and argued for them as desirable in most (if not all) scenarios. Then, we compared all existing stability measures in terms of properties. It emerged that no existing measure satisfied all desirable properties—to counter this, we constructed a novel measure, Definition 4. This turns out to be a generalization of several existing measures, and possesses all 5 properties. In addition, it provides new capabilities, not previously possible in the literature. We provided confidence intervals and hypothesis testing of *true* stability, and finally, we showed how these tools could be used to choose hyperparameters. An important conclusion is that optimizing stability can be potentially achieved without significant loss of accuracy, and can help identifying the *true* underlying set of features.

7.2 Future Work

In some data scenarios, the user might not want to measure the instability due to the redundancy of the features. In that scenario, the user is more interested in knowing whether features belonging to a same group of correlated features have been consistently selected, rather than looking at the selection of each feature independently. For this purpose, stability measures taking into account feature redundancy have been proposed in the literature. The relative POG (also called $POGR$) and the relative $nPOG$ (also called $nPOGR$) are both extensions of the POG measure and of the $nPOG$ measure respectively (Zhang et al., 2009) as they both reduce to their original version in the case of no redundancy. This case study is not in the scope of this paper. Nevertheless, we note that since they reduce to POG and $nPOG$, these two measures will also not possess the 5 properties. Future work might consider extending the measure we propose to take redundancy into account.

Another avenue of investigation could be the extension of the present work to other types of feature selection outputs—such as feature rankings or feature weights. A popular measure to quantify the stability of feature rankings is the pairwise Spearman's Rho. In the case of untied ranks, Nogueira et al. (2017) show that this measure can be re-written as

$$1 - \frac{\frac{1}{d}\sum_{f=1}^{d} s_f^2}{V_{rank}},$$

where s_f^2 is the sample variance of the rank of feature X_f and where V_{rank} is the expected variance under the assumption that each ranking was generated at random (i.e. each ranking is equally likely). The above equation has a similar form to the measure proposed in this paper and provides a promising direction for unifying stability of ranking and subset selection.

GB was supported by the EPSRC LAMBDA project [EP/N035127/1]. We would like to thank Dr. Adam Pocock for his valuable feedback on our work.

Appendix A. Existing Stability Measures

In the remainder of the appendices, we will add a subscript to the stability $\hat{\Phi}$ giving the author or the name of the measure for disambiguation. Whenever the subscript is omitted, we refer to our proposed stability measure as given by Definition 4.

In this section, we first review the existing similarity-based stability measures and then we focus on the frequency-based ones.

A.1 Similarity-based Measures

We remind the reader that given a similarity measure ϕ between two feature sets s_i and s_j, the resulting stability $\hat{\Phi}(\mathcal{Z})$ is taken as the average pairwise similarities between the feature sets in $\mathcal{Z}$, that is

$$\hat{\Phi}(\mathcal{Z}) = \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} \phi(s_i, s_j).$$

For simplicity, we introduce notations that will be used in the remainder of the appendices. Let $r_{i,j}$ be the short notation for $|s_i \cap s_j|$, the size of the intersection between feature sets s_i and s_j. Let k_i denote the size of feature set s_i (when the size of the feature set is assumed constant, we will simply denote it k). Table 6 provides all 9 similarity measures used in the literature in the context of stability along with their minimum and maximum value. These definitions will be later used in the proof of properties in Appendix C.

A.2 Frequency-based Measures

In this section, we give the definitions of the frequency-based measures. As these require to introduce a lot of new notations, we do not summarize them in a table like we did for similarity-based measures.

A.2.1 Goh's Measure

Goh and Wong (2016) propose to use the frequency of selection, averaged over all features, that is $\hat{\Phi}_{Goh}(\mathcal{Z}) = \frac{1}{d}\sum_{f=1}^{d} \hat{p}_f$. This measure take values in $[0, 1]$.

First used in	**Name**	**Measure**	[min, max]
Dunne et al. (2002)	Hamming	$1 - \frac{\lvert s_i \setminus s_j \rvert + \lvert s_i \setminus s_j \rvert}{d}$	$[0, 1]$
Kalousis et al. (2005)	Jaccard	$\frac{r_{i,j}}{\lvert s_i \cup s_j \rvert}$	$[0, 1]$
Yu et al. (2008)	Dice-Sørenson	$\frac{2r_{i,j}}{k_i + k_j}$	$[0, 1]$
Zucknick et al. (2008)	Ochiai	$\frac{r_{i,j}}{\sqrt{k_i k_j}}$	$[0, 1]$
Shi et al. (2006)	POG	$\frac{r_{i,j}}{k_i}$	$[0, 1]$
Kuncheva (2007)	Consistency	$\frac{r_{i,j} - \frac{k^2}{d}}{k - \frac{k^2}{d}}$	$[-1, 1]$
Lustgarten et al. (2009)	Lustgarten	$\frac{r_{i,j} - \frac{k_i k_j}{d}}{min(k_i, k_j) - max(0, k_i + k_j - d)}$	$[-1, 1]$
Wald et al. (2013)	Wald	$\frac{r_{i,j} - \frac{k_i k_j}{d}}{min(k_i, k_j) - \frac{k_i k_j}{d}}$	$[1 - d, 1]$
Zhang et al. (2009)	nPOG	$\frac{r_{i,j} - \frac{k_i k_j}{d}}{k_i - \frac{k_i k_j}{d}}$	$[1 - d, 1]$

Table 6: Similarity measures proposed in the literature 2002–2018, using the pairwise formulation. In some cases the measure is extremely simple, (e.g. percentage overlap of features) and authors are chosen simply as the first known usage of the measures in the context of stability. We note that as opposed as what can be found in some literature (Alelyani, 2013; P. and Perumal, 2016), the minimum for Wald's and $nPOG$ similarity measures is equal to $1 - d$ and not 0 (and is reached for $k_i = 1$, $k_j = d - 1$ and $r_{i,j} = 0$).

A.2.2 Davis' Measure

Davis et al. (2006, pg2) penalize the frequency to *"account for the artificial increase in stability that occurs with increasingly long gene signatures"*, as follows

$$\hat{\Phi}_{Davis}(\mathcal{Z}) = \max\left(0,\ \frac{1}{F}\sum_{f=1}^{d}\hat{p}_f - \alpha\frac{median(k_1, ..., k_M)}{d}\right), \tag{3}$$

where F is the number of features selected at least in one of the M feature sets (in other words, $F = |\cup_{i\in\{1,...,M\}} s_i|$) and where α is a hyperparameter chosen by the user. This measure also takes values in the interval $[0, 1]$.

A.2.3 Krizek's Measure

Krízek et al. (2007) treat each possible of the $\binom{d}{k}$ feature sets of k features as a random variable and estimate its Shannon entropy as

$$\hat{\Phi}_{Krizek}(\mathcal{Z}) = -\sum_{s_i\in\mathcal{Z}}\hat{p}(s_i)\log_2\hat{p}(s_i),$$

where $\hat{p}(s_i)$ is the frequency of occurrence of subset s_i in $\mathcal{Z}$ over all the $\binom{d}{k}$ possible combinations of k features taken amongst d features. It takes values in $\left[0, \log(\min(M, \binom{d}{k}))\right]$.

A.2.4 Guzmán's Measure

A measure is proposed by Guzmán-Martínez and Alaiz-Rodríguez (2011), using frequencies to compute Jensen-Shannon divergences. Originally created for feature rankings, they extend it to feature sets of k features (top-k lists of genes in the literature), using the JS-divergence, as follows

$$\hat{\Phi}(\mathcal{Z}) = 1 - \frac{D_{JS}(\mathbf{q}_1, ..., \mathbf{q}_M)}{D^*_{JS}(\mathbf{q}_1, ..., \mathbf{q}_M)}.$$

Here, each $\mathbf{q}_i$ is a distribution over features, formed by taking the bitstring on the i^{th} row of the matrix $\mathcal{Z}$, and dividing through by k, the number of bits set. D^*_{JS} is a normalizing term—according to the authors *"the divergence value for a [feature set] that is completely random"*. This ensures the value is in $[0, 1]$, but most interestingly, this is yet another work correcting the measure for chance, as introduced by Kuncheva.

A.2.5 Relative Weighted Consistency CW_{rel}

With a property-based analysis, Somol and Novovičová (2010) constructed a new stability measure called the relative weighted consistency (CW_{rel}) as

$$\hat{\Phi}(\mathcal{Z}) = \frac{d\left(M\bar{k} - D + \sum_{f=1}^{d} M\hat{p}_f(M\hat{p}_f - 1)\right) - (M\bar{k})^2 + D^2}{d\left(H^2 + M(M\bar{k} - H) - D\right) - (M\bar{k})^2 + D^2}, \tag{4}$$

where $D = (M\bar{k})\ mod\ d$ and $H = (M\bar{k})\ mod\ M$.

A.2.6 Lausser's Measure

Finally, Lausser et al. (2013) proposed a measure for feature sets of fixed size k as follows:

$$\hat{\Phi}(\mathcal{Z}) = \frac{1}{M^2 k}\sum_{i=1}^{M} i^2 a^{(i)},$$

where $a^{(i)} = \sum_{f=1}^{d}\mathbb{1}\{\sum_{j=1}^{M} z_{j,f} = i\}$ is the number of features selected exactly i times.

Appendix B. Proof of Theorems

In this section, we provide the proofs or proof sketches for the theorems and corollaries in the paper. Before we proceed to the proofs, we give the following equation, that will be repeatedly used in the proofs

$$\sum_{f=1}^{d} \hat{p}_f = \frac{1}{M} \sum_{i=1}^{M} \sum_{f=1}^{d} z_{i,f} = \frac{1}{M} \sum_{i=1}^{M} k_i = \bar{k}. \tag{5}$$

B.1 Proof of Theorem 1

In this appendix we prove the following theorem from Section 3.

Theorem 1 *The average pairwise intersection between the M feature sets is as a linear function of the sample variances of the selection of each feature, as follows*

$$\frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} r_{i,j} = \bar{k} - \sum_{f=1}^{d} s_f^2, \tag{6}$$

where $s_f^2 = \frac{M}{M-1} \hat{p}_f (1 - \hat{p}_f)$ is the sample variance of the selection of the f^{th} feature.

Proof. To prove Theorem 1, we start by calculating the average pairwise size of the intersection and show that we get the results presented.

$$\begin{aligned}
\frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} r_{i,j} &= \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{j=1}^{M} r_{i,j} - \frac{1}{M(M-1)} \sum_{i=1}^{M} r_{i,i} \\
&= \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{j=1}^{M} r_{i,j} - \frac{1}{M(M-1)} \sum_{i=1}^{M} k_i \\
&= \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{j=1}^{M} r_{i,j} - \frac{1}{M-1} \bar{k}
\end{aligned}$$

Since the i^{th} feature set $\mathcal{Z}_{(i,:)}$ and the j^{th} feature set $\mathcal{Z}_{(j,:)}$ are binary vectors, the size of their intersection $r_{i,j}$ is the number of 1s occurring at the same position in both vectors. In other words, $r_{i,j}$ is the dot product of the two feature sets, that is $\mathcal{Z}_{(i,:)} \cdot \mathcal{Z}_{(j,:)} = \sum_{f=1}^{d} z_{i,f} z_{j,f}$. By substituting in the previous equation, we get

$$\begin{aligned}
\frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} r_{i,j} &= \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{j=1}^{M} \sum_{f=1}^{d} z_{i,f} z_{j,f} - \frac{1}{M-1} \bar{k} \\
&= \frac{1}{M(M-1)} \sum_{f=1}^{d} \left(\sum_{i=1}^{M} z_{i,f} \right) \left(\sum_{j=1}^{M} z_{j,f} \right) - \frac{1}{M-1} \bar{k} \\
&= \frac{1}{M(M-1)} \sum_{f=1}^{d} \left(\sum_{i=1}^{M} z_{i,f} \right)^2 - \frac{1}{M-1} \bar{k}
\end{aligned}$$

$$\begin{aligned}
&= \frac{1}{M(M-1)} \sum_{f=1}^{d} (M \hat{p}_f)^2 - \frac{1}{M-1} \bar{k} \\
&= \frac{M}{M-1} \sum_{f=1}^{d} \left(\hat{p}_f^2 - \hat{p}_f + \hat{p}_f \right) - \frac{1}{M-1} \bar{k} \\
&= \frac{M}{M-1} \sum_{f=1}^{d} -\hat{p}_f (1 - \hat{p}_f) + \frac{M}{M-1} \sum_{f=1}^{d} \hat{p}_f - \frac{1}{M-1} \bar{k} \\
&= -\frac{M}{M-1} \sum_{f=1}^{d} \hat{p}_f (1 - \hat{p}_f) + \frac{M}{M-1} \bar{k} - \frac{1}{M-1} \bar{k} \\
&= \bar{k} - \sum_{f=1}^{d} s_f^2.
\end{aligned}$$

■

B.2 Proof of Theorem 3

In this appendix we prove the following theorem from Section 4.1.

Theorem 3 *Under the Null Model of Feature Selection H_0, for all f, the expected value of the sample variance of Z_f is $\mathbb{E}\left[s_f^2 | H_0\right] = \frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)$.*

Proof. Since s_f^2 is the unbiased sample variance of the Bernoulli variable Z_f, we have $\mathbb{E}\left[s_f^2 | H_0\right] = Var[Z_f | H_0]$, which is the value of $p_f(1 - p_f)$ under the Null Model of Feature Selection H_0.

To calculate p_f under H_0, we will start by carrying out the calculations on a simple example to clarify what is the sample space we are looking at under H_0. Let us assume we observe the matrix

$$\mathcal{Z} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \end{pmatrix}.$$

By definition, under H_0, for each row i, all permutations of the bit-string on row i are equally likely. For the first row, we have 3 possible permutations that are 100, 010, 001 and for the second row, we also have 3 possible permutations that are 110, 101, 011. Therefore, under H_0, all the $N = 3 \times 3 = 9$ following matrices are equally likely to be observed:

$$\begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix},$$
$$\begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 1 \end{pmatrix},$$
$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}.$$

Since all these matrices are equally likely to be observed under H_0, to calculate p_f, we can simply count the proportion of times feature Z_f equals 1 over the $MN = 2 \times 9 = 18$ rows. Here we would get $p_f = \frac{9}{18} = \frac{1}{2}$ for any f.

Let N be the total number of possible matrices under H_0. In the more general case, to compute p_f under H_0, we can count the proportion of times $Z_f = 1$ over the MN rows. We can decompose this into a sum over the row numbers as follows:

$$p_f = \Pr[Z_f = 1|H_0] = \frac{\sum_{i=1}^{M} N \times \Pr[Z_f = 1|\text{on row i }, H_0]}{MN}$$

$$p_f = \frac{1}{M}\sum_{i=1}^{M} \Pr[Z_f = 1|\text{on row i }, H_0], \tag{7}$$

where $\Pr[Z_f = 1|\text{on row i }, H_0]$ is the proportion of times Z_f is equal to 1 on all the permutations of the i^{th} row of $\mathcal{Z}$. Since the i^{th} row of $\mathcal{Z}$ has k_i bits set to 1, this is equal to

$$\frac{\#\{\text{bit-strings with } k_i \text{ 1s where } Z_f = 1\}}{\#\{\text{bit-strings with } k_i \text{ 1s}\}}.$$

The denominator is equal to $\binom{d}{k_i}$. For the numerator, we know X_f is set equal to 1, which means we have now $k_i - 1$ bits left to set to 1 from the remaining $d-1$ bits. Therefore the numerator is equal to $\binom{d-1}{k_i-1}$. Replacing these in the previous equation, we get that on the i^{th} row, all features have an equal probability of being selected equal to $\frac{\binom{d-1}{k_i-1}}{\binom{d}{k_i}} = \frac{k_i}{d}$. Now, replacing this in Equation (7), we get that under H_0,

$$p_f = \frac{1}{M}\sum_{i=1}^{M}\frac{k_i}{d} = \frac{\bar{k}}{d}.$$

We can verify this in our previous example, where we had $k_1 = 2$, $k_2 = 1$, $d = 3$, which gives $p_f = \frac{\bar{k}}{d} = \frac{1}{2}$ as computed previously.

Using this, we can now compute $\mathbb{E}\left[s_f^2|H_0\right] = Var[Z_f|H_0] = p_f(1-p_f) = \frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)$. ■

B.3 Proof of Theorem 5

In this appendix we prove the following theorem from Section 4.1.

Theorem 5 *When the number of features selected is constant:*

- *The stability estimator $\hat{\Phi}$ is equal to the stability measures derived by Kuncheva (2007), Wald et al. (2013) and to nPOG (Zhang et al., 2009).*
- *The stability estimator $\hat{\Phi}$ and CW_{rel} (Somol and Novovičová, 2010) are asymptotically equivalent.*

Proof. First, we show that when the number of features selected is constant equal to k, then Kuncheva's measure is equal to the proposed stability measure. The stability measure

defined by Kuncheva (2007) is

$$\hat{\Phi}_{Kuncheva}(\mathcal{Z}) = \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{r_{i,j}-\frac{k^2}{d}}{k-\frac{k^2}{d}} = \frac{1}{M(M-1)}\left(\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{r_{i,j}}{k-\frac{k^2}{d}}\right) - \frac{\frac{k^2}{d}}{k-\frac{k^2}{d}}$$

$$= \frac{1}{k-\frac{k^2}{d}}\left(\frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M} r_{i,j}\right) - \frac{\frac{k^2}{d}}{k-\frac{k^2}{d}}.$$

Using Theorem 1, we can replace the term between parenthesis in the latter equation by $k - \sum_{f=1}^{d} s_f^2$ (since the number of features selected is constant, $\bar{k} = k$). We get that

$$\hat{\Phi}_{Kuncheva}(\mathcal{Z}) = \frac{1}{k-\frac{k^2}{d}}\left(k - \sum_{f=1}^{d} s_f^2\right) - \frac{\frac{k^2}{d}}{k-\frac{k^2}{d}} = \frac{k-\frac{k^2}{d}}{k-\frac{k^2}{d}} - \frac{\sum_{f=1}^{d} s_f^2}{k-\frac{k^2}{d}} = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} s_f^2}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)},$$

which is our proposed stability measure for $\bar{k} = k$. Then, using the definitions of Wald and $nPOG$ measures given in Table 6, by replacing the cardinalities of the sets by k in the equations, they reduce to Kuncheva's measure, which proves the first part of the theorem.

We now prove the equivalence of our measure with CW_{rel}. Using Equation (4), we can rewrite CW_{rel} as

$$\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) = \frac{-\frac{1}{d}\frac{M-1}{M}\sum_{f=1}^{d} s_f^2 + \frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right) - \frac{D}{M^2 d}\left(1-\frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right) - \frac{D}{M^2 d}\left(1-\frac{D}{d}\right) + \frac{H^2}{dM^2} - \frac{H}{Md}}. \tag{8}$$

Assuming that the number of features selected is constant equal to k, we then have that $\bar{k} = k$ and hence that $H = (Mk)\ mod\ M = 0$. Therefore the above equation becomes

$$\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) = 1 - \frac{\frac{M-1}{M}\sum_{f=1}^{d} s_f^2}{k\left(1-\frac{k}{d}\right) - \frac{D}{M^2}\left(1-\frac{D}{d}\right)}.$$

We have that $D = (Mk)\ mod\ d$ which implies that D is a constant number between 0 and $d-1$. Therefore the limit of the term $\frac{D}{M^2}\left(1-\frac{D}{d}\right)$ as M approaches infinity is 0. Therefore, taking the limit of the above equation, we get

$$\lim_{M\to\infty}\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) = \lim_{M\to\infty}\left[1 - \frac{\frac{M-1}{M}\sum_{f=1}^{d} s_f^2}{k\left(1-\frac{k}{d}\right)}\right] = \lim_{M\to\infty}\hat{\Phi}(\mathcal{Z}).$$

This shows that $\lim_{M\to+\infty}\frac{\hat{\Phi}_{CW_{rel}}(\mathcal{Z})}{\hat{\Phi}(\mathcal{Z})} = 1$ and therefore we obtain that $\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) \underset{M\to+\infty}{\sim} \hat{\Phi}(\mathcal{Z})$, which is what we wanted to prove. ■

B.4 Proof of Theorem 6

In this appendix we prove the following theorem from Section 4.2.1.

Theorem 6 *When there are only two categories (0/1), Fleiss' Kappa is equal to $\hat{\Phi}(\mathcal{Z})$.*

Proof. To prove this, we start from the definition of Fleiss' Kappa as given in the original paper (Fleiss, 1971) and show that when the number of categories is equal to 2, it reduces to the proposed definition of stability (c.f. Definition 4). Fleiss (1971) defines Kappa as

$$\kappa = \frac{\bar{P} - \bar{P}_e}{1 - \bar{P}_e}, \tag{9}$$

where:

- $\bar{P}_e = \sum_{j=1}^{q} p_j^2$ in which
  - $q = 2$ is the number of categories;
  - $p_j = \frac{1}{Md} \sum_{f=1}^{d} n_{fj}$;
  - n_{fj} is the number of samples that assign f to the j^{th} category. Therefore, in our case, we have $n_{f1} = M\hat{p}_f$ and $n_{f0} = M - M\hat{p}_f$.
- $\bar{P} = \frac{1}{dM(M-1)} \sum_{f=1}^{d} \sum_{j=1}^{q} n_{fj}(n_{fj} - 1)$.

Now we can re-write this using our notation. First, we have that

- $p_1 = \frac{1}{Md} \sum_{f=1}^{d} n_{f1} = \frac{1}{Md} \sum_{f=1}^{d} M\hat{p}_f = \frac{1}{d} \sum_{f=1}^{d} \hat{p}_f = \frac{\bar{k}}{d}$;
- $p_0 = \frac{1}{Md} \sum_{f=1}^{d} n_{f0} = \frac{1}{Md} \sum_{f=1}^{d} (M - M\hat{p}_f) = 1 - \frac{1}{d} \sum_{f=1}^{d} \hat{p}_f = 1 - \frac{\bar{k}}{d}$.

Therefore,

$$\bar{P}_e = p_0^2 + p_1^2 = \frac{\bar{k}^2}{d^2} + \left(1 - \frac{\bar{k}}{d}\right)^2 = \frac{\bar{k}^2}{d^2} + 1 - 2\frac{\bar{k}}{d} + \frac{\bar{k}^2}{d^2} = 1 - 2\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right).$$

Let us now calculate $\bar{P}$.

$$\bar{P} = \frac{1}{dM(M-1)} \sum_{f=1}^{d} \sum_{j=1}^{q} n_{fj}(n_{fj} - 1)$$

$$\bar{P} = \frac{1}{dM(M-1)} \sum_{f=1}^{d} (n_{f0}(n_{f0} - 1) + n_{f1}(n_{f1} - 1))$$

$$\bar{P} = \frac{1}{dM(M-1)} \sum_{f=1}^{d} ((M - M\hat{p}_f)(M - M\hat{p}_f - 1) + M\hat{p}_f(M\hat{p}_f - 1))$$

$$\bar{P} = 1 - \frac{2}{d} \sum_{f=1}^{d} \frac{M}{M-1} \hat{p}_f(1 - \hat{p}_f) = 1 - \frac{2}{d} \sum_{f=1}^{d} s_f^2.$$

Now, substituting the two last equations back into Equation (9), we finally get that

$$\kappa = \frac{1 - \frac{2}{d}\sum_{f=1}^{d} s_f^2 - 1 + 2\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)}{1 - 1 + 2\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)} = \frac{-\frac{1}{d}\sum_{f=1}^{d} s_f^2 + \frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)}{\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)}$$

$$\kappa = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} s_f^2}{\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right)} = \hat{\Phi}(\mathcal{Z}),$$

which is what we wanted to prove. ■

B.5 Proof of Theorem 7

Theorem 7 (Asymptotic Distribution) *As $M \to \infty$, the statistic $\hat{\Phi}$ weakly converges to a normal distribution:*

$$V_M = \frac{\hat{\Phi} - \Phi}{\sqrt{v(\hat{\Phi})}} \xrightarrow{\mathcal{L}} \mathcal{N}(0, 1),$$

where:

- $\Phi = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d} p_f(1-p_f)}{\bar{p}(1-\bar{p})}$ *is the mean of the estimator $\hat{\Phi}$ in which $\bar{p} = \frac{1}{d}\sum_{f=1}^{d} p_f$ is the average mean parameter of the d Bernoulli variables;*
- $v(\hat{\Phi}) = \frac{4}{M^2}\sum_{i=1}^{M}(\hat{\Phi}_{(i)} - \hat{\bar{\Phi}}_{(.)})^2$ *is an estimate of the variance of $\hat{\Phi}$ in which:*
  - $\hat{\Phi}_{(i)} = \frac{1}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)}\left[\frac{1}{d}\sum_{f=1}^{d} z_{i,f}\hat{p}_f - \frac{k_i\bar{k}}{d^2} + \frac{\hat{\Phi}}{2}\left(\frac{2\bar{k}k_i}{d^2} - \frac{k_i}{d} - \frac{\bar{k}}{d} + 1\right)\right]$;
  - *and $\hat{\bar{\Phi}}_{(.)}$ is the average value of $\hat{\Phi}_{(i)}$, that is: $\frac{1}{M}\sum_{i=1}^{M}\hat{\Phi}_{(i)}$.*

Proof. We prove this using Theorem 6 showing the equality between our proposed measure and Fleiss' Kappa and the work of Gwet (2008) that derives the asymptotic distribution of Fleiss' Kappa, as explained in the first paragraph of Section 4.2.2. ■

B.6 Proof of Theorem 9

In this appendix we prove the following theorem from Section 4.2.4.

Theorem 9 *The test statistic for comparing stabilities is*

$$T_M = \frac{\hat{\Phi}(\mathcal{Z}_2) - \hat{\Phi}(\mathcal{Z}_1)}{\sqrt{v(\hat{\Phi}(\mathcal{Z}_1)) + v(\hat{\Phi}(\mathcal{Z}_2))}}.$$

Under H_0, the statistic T_M asymptotically (as M approaches infinity) follows a standard normal distribution.

Proof. We know from Theorem 7 that $\hat{\Phi}(\mathcal{Z}_1)$ is asymptotically normal with unknown mean Φ_1 and variance σ_1^2 and that $\hat{\Phi}(\mathcal{Z}_2)$ is asymptotically normal with unknown mean Φ_2 and variance σ_2^2. Therefore, the difference $\hat{\Phi}(\mathcal{Z}_2) - \hat{\Phi}(\mathcal{Z}_1)$ is normal with unknown mean $\Phi_2 - \Phi_1$ and with variance $\sigma_1^2 + \sigma_2^2$. Under H_0, $\Phi_2 - \Phi_1 = 0$ and we estimate this variance by $v(\hat{\Phi}(\mathcal{Z}_1)) + v(\hat{\Phi}(\mathcal{Z}_2))$ using the result of Theorem 7. This gives us the asymptotic distribution of the statistic T_M. ■

Appendix C. Proof of Properties

In this section, for each one of the 5 properties given in Section 3, we determine which measures possess the property.

C.1 First property: Fully defined

This property directly follows from the definitions of the stability measures given Appendix A. Kuncheva's, Krízek's, Guzmán's and Lausser's measures are only defined when the number of features selected is fixed, and therefore do not possess this property.

C.2 Second property: Monotonicity

Since the proofs will all be similar for similarity-based measures, we first provide the proofs for the similarity based measures and then we look at frequency-based ones.

C.2.1 Similarity-based Measures

We start by calculating the derivative for each one of the 9 the similarity measures and provide the results in Table 7. As we can see, for all 9 similarity measures, assuming that the cardinalities of the feature sets are always in $\{1,..,d-1\}$, we have that $\frac{d\phi(s_i,s_j)}{dr_{i,j}} > 0$ (some derivatives are undefined otherwise, which correspond to the limit cases where no features are selected or all the features are selected). Therefore the derivative of the stability measure $\hat{\Phi}(\mathcal{Z})$ will be positive since

$$\frac{d\hat{\Phi}(\mathcal{Z})}{d\left(\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M} r_{i,j}\right)} = \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{\partial\phi(s_i,s_j)}{\partial r_{i,j}}$$

and since a sum of strictly positive quantities is strictly positive. Therefore, all similarity-based stability measures have the Monotonicity property.

	Hamming	Jaccard	Dice	Ochiai	*POG*
$\frac{d\phi(s_i,s_j)}{dr_{i,j}}$	$\frac{2}{d}$	$\frac{k_i+k_j}{(k_i+k_j-r_{i,j})^2}$	$\frac{2}{k_i+k_j}$	$\frac{1}{\sqrt{k_i k_j}}$	$\frac{1}{k_i}$

	Kuncheva	Lustgarten	Wald	*nPOG*
$\frac{d\phi(s_i,s_j)}{dr_{i,j}}$	$\frac{1}{k-\frac{k^2}{d}}$	$\frac{1}{\min(k_i,k_j)-\max(0,k_i+k_j-d)}$	$\frac{1}{\min(k_i,k_j)-\frac{k_i k_j}{d}}$	$\frac{1}{k_i-\frac{k_i k_j}{d}}$

Table 7: Derivatives for each one of the similarity measures.

C.2.2 Goh's Measure

Using the definition of Goh's measure (c.f. Appendix A.2) and Equation (5), we have that

$$\hat{\Phi}_{Goh}(\mathcal{Z}) = \frac{1}{d}\sum_{f=1}^{d}\hat{p}_f = \frac{\bar{k}}{d}. \tag{10}$$

This is not a function of the variances of selection of each feature s_f^2, therefore the measure does not have the Monotonicity property.

C.2.3 Davis' Measure

When $\alpha = 0$, this measure reduces to Goh's measure, which does not possess the property. Therefore this measure does not possess the Monotonicity property either.

C.2.4 Krízek's Measure

To prove that this measure does not possess the Monotonicity property, we give a counter-example. Let us assume we have a procedure that selects $k = 2$ features out of $d = 4$ features in total. The two binary matrices $\mathcal{Z}_1$ and $\mathcal{Z}_2$ illustrate two different scenarios with $M = 4$ as follows

$$\mathcal{Z}_1 = \begin{bmatrix}1&1&0&0\\1&1&0&0\\0&0&1&1\\0&0&1&1\end{bmatrix} \quad \text{and} \quad \mathcal{Z}_2 = \begin{bmatrix}1&0&1&0\\1&0&1&0\\0&0&1&1\\0&0&1&1\end{bmatrix}.$$

Using Krízek's measure, we get a stability of 1 for both $\mathcal{Z}_1$ and $\mathcal{Z}_2$ (using log base 2). Now by computing the sum of variances of selection of the 4 features for the two test cases, we get $\sum_{f=1}^{4} s_f^2 = \frac{4}{3}$ for $\mathcal{Z}_1$ and $\sum_{f=1}^{4} s_f^2 = \frac{2}{3}$ for $\mathcal{Z}_2$. Therefore $\mathcal{Z}_1$ and $\mathcal{Z}_2$ have the same stability value but different sums of variance, which is a counter-example of the property.

C.2.5 Guzmán's Measure

Before proving this, we re-write Guzmán's measure using our notation (this re-writing will also be useful for later proofs). For feature sets of fixed cardinality k, the stability is defined by Guzmán-Martínez and Alaiz-Rodríguez (2011) as

$$\hat{\Phi}_{Guzman}(\mathcal{Z}) = 1 - \frac{D_{JS}(\mathbf{q}_1,...,\mathbf{q}_M)}{D^*_{JS}(\mathbf{q}_1,...,\mathbf{q}_M)},$$

where:

- $D^*_{JS}(\mathbf{q}_1,...,\mathbf{q}_M) = \log\frac{d}{k}$;
- $D_{JS}(\mathbf{q}_1,...,\mathbf{q}_M) = \frac{1}{M}\sum_{i=1}^{M}\sum_{f=1}^{d} q_{f,i}\log\frac{q_{f,i}}{\bar{q_f}}$;
- $q_{f,i} = \frac{1}{k}$ if the f^{th} feature is selected on the i^{th} run and 0 otherwise;
- $\bar{q_f} = \frac{1}{M}\sum_{i=1}^{M} q_{f,i}$.

Therefore, using our notation, we get that $q_{f,i} = z_{i,f}\frac{1}{k}$ and that $\bar{q_f} = \frac{1}{M}\frac{1}{k}\sum_{i=1}^{M} z_{i,f} = \frac{\hat{p}_f}{k}$. Therefore,

$$\begin{aligned}
\hat{\Phi}_{Guzman}(\mathcal{Z}) =& 1 - \frac{\frac{1}{kM}\sum_{i=1}^{M}\sum_{f=1}^{d} z_{i,f}\log\frac{z_{i,f}}{\hat{p}_f}}{\log\frac{d}{k}}\\
\hat{\Phi}_{Guzman}(\mathcal{Z}) =& 1 - \frac{\frac{1}{kM}\sum_{i=1}^{M}\sum_{f=1}^{d} z_{i,f}\log z_{i,f}}{\log\frac{d}{k}} + \frac{\frac{1}{kM}\sum_{i=1}^{M}\sum_{f=1}^{d} z_{i,f}\log\hat{p}_f}{\log\frac{d}{k}}\\
\hat{\Phi}_{Guzman}(\mathcal{Z}) =& 1 - \frac{\frac{1}{kM}\sum_{i=1}^{M}\sum_{f=1}^{d} z_{i,f}\log z_{i,f}}{\log\frac{d}{k}} + \frac{\frac{1}{k}\sum_{f=1}^{d}\hat{p}_f\log\hat{p}_f}{\log\frac{d}{k}}.
\end{aligned}$$

Since $z_{i,f}$ is binary, $z_{i,f}\log z_{i,f} = 0$. Therefore, the previous equation becomes

$$\hat{\Phi}_{Guzman}(\mathcal{Z}) = 1 + \frac{\frac{1}{k}\sum_{f=1}^{d}\hat{p}_f\log\hat{p}_f}{\log\frac{d}{k}} = 1 - \frac{\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f\log\hat{p}_f}{\frac{k}{d}\log\frac{k}{d}}. \tag{11}$$

Now, to prove that this measure does not have the Monotonicity property, we will give a counter-example. Let $\mathcal{Z}_1$ and $\mathcal{Z}_2$ be the two following binary matrices

$$\mathcal{Z}_1 = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 \end{pmatrix} \qquad \text{and} \qquad \mathcal{Z}_2 = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 \end{pmatrix}.$$

We show that using Guzmán's measure, $\mathcal{Z}_1$ has a lower stability than $\mathcal{Z}_2$ but also a lower average variance, thus violating the Monotonicity property. Indeed, we have $\hat{\Phi}_{Guzman}(\mathcal{Z}_1) \simeq 0.24$ and $\hat{\Phi}_{Guzman}(\mathcal{Z}_2) \simeq 0.31$ while we have a sum of variances $\simeq 0.15$ for $\mathcal{Z}_1$ and $\simeq 0.17$ for $\mathcal{Z}_2$.

C.2.6 Relative Weighted Consistency CW_{rel}

Since H, D and $\bar{k}$ only depend on the feature set cardinalities $k_1, ..., k_M$, on M and on d, we can see from Equation (8) that $\hat{\Phi}_{CW_{rel}}(\mathcal{Z})$ is a linear and strictly decreasing function of s_f^2. Therefore, CW_{rel} possesses the Monotonicity property.

C.2.7 Lausser's measure

Similarly to what has been done for Guzmán's measure, we will re-write this measure as a function of the frequencies of selection $\hat{p}_f$. This will help us understand the measure and also will be useful for other proofs involving this measure. We remind the reader that Lausser's measure is defined as

$$\hat{\Phi}_{Lausser}(\mathcal{Z}) = \frac{1}{M^2 k} \sum_{f=1}^{d} \sum_{i=1}^{M} i^2 \mathbb{1}\{\sum_{j=1}^{M} z_{j,f} = i\} = \frac{1}{M^2 k} \sum_{f=1}^{d} \left[\sum_{i=1}^{M} i^2 \mathbb{1}\{M\hat{p}_f = i\} \right].$$

Let us look at the term in between brackets that depends on the row index i. We note that the indicator term $\mathbb{1}\{M\hat{p}_f = i\}$ is equal to 1 only when i is equal to $M\hat{p}_f$ and is equal to 0 for any other value of i in $\{1, ..., M\}$. Therefore we can make the sum over i disappear since it is always equal to $(M\hat{p}_f)^2$. Hence, Lausser's Measure can be re-written as

$$\hat{\Phi}_{Lausser}(\mathcal{Z}) = \frac{1}{M^2 k} \sum_{f=1}^{d} (M\hat{p}_f)^2 = \frac{1}{k} \sum_{f=1}^{d} \hat{p}_f^2. \tag{12}$$

This simple expression helps us understand what is this measure actually measuring. Let us now show that this is a strictly decreasing function of the sum of variances $\sum_{f=1}^{d} \hat{p}_f(1-\hat{p}_f)$. We can re-write the sum of variances as follows

$$\frac{M-1}{M} \sum_{f=1}^{d} s_f^2 = \sum_{f=1}^{d} \hat{p}_f(1-\hat{p}_f) = \sum_{f=1}^{d} \hat{p}_f - \sum_{f=1}^{d} \hat{p}_f^2 = k - \sum_{f=1}^{d} \hat{p}_f^2 = k(1 - \hat{\Phi}_{Lausser}(\mathcal{Z})).$$

Therefore, Lausser's measure has the Monotonicity property.

C.3 Third property: Bounds

In this section, we verify which measures have the Bounds property as given by Table 1.

C.3.1 Similarity-based measures

If a similarity measure ϕ is bounded, i.e. if $\exists (a, b) \in \mathbb{R}^2, a \leq \phi \leq b$, then it follows that the corresponding stability measure will also be bounded. Indeed:

$$a \leq \phi \leq b \quad \Rightarrow \quad a \leq \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} \phi(s_i, s_j) \leq b \quad \Rightarrow \quad a \leq \hat{\Phi}(\mathcal{Z}) \leq b.$$

As given in Table 6, we can see that all similarity measures except Wald's measure (Wald et al., 2013) and $nPOG$ measure (Zhang et al., 2009) are bounded. Therefore, we know that their corresponding stability measures will also be bounded.

The contrary is not necessarily true. If a similarity measure is not bounded, this does not imply that the corresponding stability measure is not bounded. Nevertheless, we prove that the stability measures using Wald's and $nPOG$ similarity measures are not bounded using a counter-example. Let us assume we have the following scenario

$$\mathcal{Z} = \begin{bmatrix} 1 & 1 & 1 & 1 & ... & 1 & 0 \\ & & \vdots & & & & \\ 1 & 1 & 1 & 1 & ... & 1 & 0 \\ 0 & 0 & 0 & 0 & ... & 0 & 1 \\ & & \vdots & & & & \\ 0 & 0 & 0 & 0 & ... & 0 & 1 \end{bmatrix},$$

where the first $\frac{M}{2}$ feature sets are all identical and select the first $d-1$ features and the $\frac{M}{2}$ following ones are also identical but only select the first feature. In this situation, using Wald's similarity, the first block will give $\frac{M}{2}\left(\frac{M}{2}-1\right)$ similarities of 1 (as all feature sets in the first block are identical), the second block of feature sets will also give $\frac{M}{2}\left(\frac{M}{2}-1\right)$ similarities of 1 as all feature sets in the second block are also identical. Then the $\frac{M^2}{2}$ remaining pairs of feature sets (coming from the inter block pairs) have an intersection $r_{i,j} = 0$ and therefore a similarity equal to

$$\frac{0 - \frac{d-1}{d}}{1 - \frac{d-1}{d}} = \frac{1-d}{d-d+1} = 1 - d.$$

So overall, the stability using Wald's similarity measure is equal to

$$\hat{\Phi}_{Wald}(\mathcal{Z}) = \frac{1}{M(M-1)} \left[2\frac{M}{2}\left(\frac{M}{2}-1\right) + \frac{M^2}{2}(1-d) \right] = \frac{\frac{M}{2}-1}{M-1} + \frac{M}{2(M-1)}(1-d).$$

We can see that that the value of the stability decreases with d. Therefore, we can conclude that Wald's stability measure is not bounded by constants. Using the same scenario, we can similarly show that the $nPOG$ measure is not bounded.

C.3.2 Frequency-based measures

The range of values of all the frequency-based measures are given in the literature and recapitulated in Appendix A.2. Krízek's measure has a maximum depending on M, d and k and therefore is not bounded. All five other frequency measures (CW_{rel}, Davis' and Goh's measures) take values in $[0, 1]$ and therefore are bounded.

C.4 Fourth Property: Maximum

In this section, we show which one of the stability measures possess the Maximum property, as given in Table 1.

C.4.1 Similarity-based Measures

For the backward implication (Deterministic Selection $\rightarrow$ Maximum Stability), let us assume that all the feature sets in $\mathcal{Z}$ are identical with cardinality k, therefore $|s_i \cap s_j| = r_{i,j} = k$. By definition, for all similarity measures given in Table 1 except Lustgarten's measure, for all $i, j \in \{1, ..., M\}$, $\phi(s_i, s_j) = 1$ which means that the average pairwise similarity is also 1. Therefore all similarity-based measures have this property except Lustgarten's measure (as it is shown with a counter-example in Figure 1b).

For the forward implication (Maximum Stability $\rightarrow$ Deterministic Selection), showing that Wald's stability measure does not have this property can easily be done with a counter-example as done in the paper (c.f. Figure 1a). All other similarity-based stability measures have a maximum equal to 1. Let us assume that $\hat{\Phi}(\mathcal{Z}) = max(\hat{\Phi}) = 1$. We want to show that this implies that all feature sets in $\mathcal{Z}$ are identical.

$$\begin{aligned}
\hat{\Phi}(\mathcal{Z}) = 1 \Rightarrow & \quad \frac{1}{M(M-1)} \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} \phi(s_i, s_j) = 1 \\
\Rightarrow & \quad \sum_{i=1}^{M} \sum_{\substack{j=1 \\ j \neq i}}^{M} \phi(s_i, s_j) = M(M-1) \\
\Rightarrow & \quad \forall i \in \{0,1\}^d, \forall j \in \{0,1\}^d, j \neq i, \phi(s_i, s_j) = 1.
\end{aligned}$$

Then using the constraint that $r_{i,j}$ is a natural number less or equal than $\min(k_i, k_j)$ (since that is the maximal possible size of intersection between two sets of size k_i and k_j), it can be shown for Jaccard, Dice, *POG*, *nPOG* and Kuncheva, that this implies that $k_i = k_j = r_{i,j}$ which means that $s_i = s_j$.

C.4.2 Goh's Measure

Using Equation (10), we have that $\hat{\Phi}_{Goh}(\mathcal{Z}) = \frac{\bar{k}}{d}$. Therefore, when all feature sets in $\mathcal{Z}$ are identical, $\hat{\Phi}_{Goh}(\mathcal{Z})$ only reaches its maximal value of 1 if all features are selected (i.e., $\hat{p}_f = 1$ for all $f \in \{1, ..., d\}$). Therefore, this measure does not have the Maximum property.

C.4.3 Davis' Measure

Taking $\alpha = 0$, this measure is equal to Goh's measure (seen in the previous section). Therefore this stability measure does not have the Maximum property either.

C.4.4 Krízek's Measure

Let us show that the property is true for Krízek's stability measure. We note this measure is the only one for which lower values correspond to a higher stability and the maximum

stability is reached for a stability of 0.

$$\begin{aligned}
\hat{\Phi}_{Krizek}(\mathcal{Z}) = 0 \Leftrightarrow & \quad -\sum_{s_i \in \mathcal{Z}} \hat{p}(s_i) \log_2 \hat{p}(s_i) = 0 \\
\Leftrightarrow & \quad \forall j \in \{1, ..., \binom{d}{k}\}, \hat{p}(s_i) \log_2 \hat{p}(s_i) = 0 \\
\Leftrightarrow & \quad \forall j \in \{1, ..., \binom{d}{k}\}, \hat{p}(s_i) = 0 \text{ or } \hat{p}(s_i) = 1 \\
\Leftrightarrow & \quad \text{All feature sets in } \mathcal{Z} \text{ are identical.}
\end{aligned}$$

Therefore, Krízek's measure has the Maximum property.

C.4.5 Relative Weighted Consistency CW_{rel}

Using Equation (8), we have

$$\begin{aligned}
\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) = 1 \quad \Leftrightarrow & \quad \frac{-\frac{1}{d}\frac{M-1}{M}\sum_{f=1}^{d} s_f^2 + \frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right) - \frac{D}{M^2 d}\left(1 - \frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1 - \frac{\bar{k}}{d}\right) - \frac{D}{M^2 d}\left(1 - \frac{D}{d}\right) + \frac{H^2}{M^2 d} - \frac{H}{Md}} = 1 \\
\Leftrightarrow & \quad \sum_{f=1}^{d} s_f^2 = \frac{H}{M-1} - \frac{H^2}{M(M-1)}.
\end{aligned}$$

When all feature sets in $\mathcal{Z}$ are identical, we have $\bar{k} = k$ and therefore $H = (M\bar{k}) \mod M = 0$. Therefore the right-hand side of the above equation is 0 and the left-hand side is also 0. This proves that CW_{rel} possesses the backward implication of the Maximum property.

The forward implication is not true. We give the following counter-example

$$\mathcal{Z} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 \end{bmatrix},$$

It can easily be shown that $\hat{\Phi}_{CW_{rel}}(\mathcal{Z}) = 1$, even though all rows in $\mathcal{Z}$ are not identical. Therefore CW_{rel} does not have the Maximum property.

C.4.6 Lausser's Measure

To prove that Lausser's measure has this property, we will use the expression given in Equation (12), that is

$$\hat{\Phi}_{Lausser}(\mathcal{Z}) = \frac{1}{k} \sum_{f=1}^{d} \hat{p}_f^2.$$

Let us first assume that all feature sets in $\mathcal{Z}$ are identical. This implies that we will have exactly k features for which the value of $\hat{p}_f$ will be 1 and $d - k$ features for which it will be 0. Hence in that case, $\hat{\Phi}_{Lausser}(\mathcal{Z}) = 1$. Now let us assume that the stability is equal to 1. This means that we have $\sum_{f=1}^{d} \hat{p}_f^2 = k$. The only solution to that is when we have exactly k features with a frequency of selection equal to 1 and the other features have a frequency of selection equal to 0. Therefore Lausser's measure possesses the Maximum property.

C.5 Fifth Property: Correction for Chance

In order to prove the property of Correction for chance, we calculate the expected value of $\hat{\Phi}(\mathcal{Z})$ under the Null Model of Feature Selection H_0 for each one of the existing stability measures. If $\mathbb{E}\left[\hat{\Phi}(\mathcal{Z})|H_0\right]$ is not constant (i.e. if it depends on parameters of the problem like k or d), then it does not have this property.

C.5.1 Similarity-based Measures

It has been shown in the literature that under H_0, the intersection follows a hypergeometric distribution with known expected value equal to $\mathbb{E}\left[r_{i,j}|H_0\right] = \frac{k_i k_j}{d}$ (Lustgarten et al., 2009). Using the linearity of the expectation, we will have that $\mathbb{E}\left[\hat{\Phi}(\mathcal{Z})|H_0\right]$ of the Normalized Hamming distance, the Jaccard index, the Dice-Sørensen index, Ochiai index and the *POG* measures will depend on k_i, k_j and d. Therefore, all these stability measures will not have the property of Correction for chance. All other similarity measures will verify $\mathbb{E}\left[\hat{\Phi}(\mathcal{Z})|H_0\right] = 0$ and will have the property of Correction for chance. We detail all calculations below.

For the Hamming similarity measure, we have

$$\begin{aligned}
\mathbb{E}\left[\hat{\Phi}_{Hamming}(\mathcal{Z})|H_0\right] &= 1 - \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{k_i + k_j - \mathbb{E}\left[r_{i,j}|H_0\right]}{d} \\
&= 1 - \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{k_i + k_j - \frac{k_i k_j}{d}}{d} \\
&= 1 - \frac{1}{M(M-1)d}\left[\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}k_i + \sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}k_j - \sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{k_i k_j}{d}\right] \\
&= 1 - \frac{1}{M(M-1)d}\left[M(M-1)\bar{k} + M(M-1)\bar{k} - \frac{1}{d}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}k_i k_j\right] \\
&= 1 - 2\frac{\bar{k}}{d} + \frac{1}{M(M-1)d^2}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}k_i k_j \\
&= 1 - 2\frac{\bar{k}}{d} + \frac{1}{M(M-1)d^2}\left(M^2\bar{k}^2 - \sum_{i=1}^{M}k_i^2\right) \\
&= 1 - 2\frac{\bar{k}}{d} + \frac{M}{M-1}\frac{\bar{k}^2}{d^2} - \frac{1}{M(M-1)}\sum_{i=1}^{M}\frac{k_i^2}{d^2}.
\end{aligned}$$

In particular, when the number of features selected is constant equal to k, the above equation becomes $1 - 2\frac{k}{d}\left(1 - \frac{k}{d}\right)$, which depends on k and d. Therefore, this measure measure does not have the Correction-for-chance property.

For the Jaccard similarity measure, we have

$$\begin{aligned}
\mathbb{E}\left[\hat{\Phi}_{Jaccard}(\mathcal{Z})|H_0\right] &= \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\mathbb{E}\left[\frac{r_{i,j}}{k_i + k_j - r_{i,j}}|H_0\right] \\
&= \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\sum_{n=1}^{d}\frac{n}{k_i + k_j - n}\mathbb{P}(r_{i,j} = n|H_0).
\end{aligned}$$

Since we know that under H_0, the intersection $r_{i,j}$ follows a central hypergeometric distribution, we have that

$$\mathbb{P}(r_{i,j} = n|H_0) = \frac{\binom{k_i}{n}\binom{d-k_i}{k_j-n}}{\binom{d}{k_j}}.$$

Therefore, the expected value of the average pairwise Jaccard index under the Null Model of Feature Selection H_0 is

$$\mathbb{E}\left[\hat{\Phi}_{Jaccard}(\mathcal{Z})|H_0\right] = \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\sum_{n=1}^{d}\frac{n}{k_i + k_j - n}\frac{\binom{k_i}{n}\binom{d-k_i}{k_j-n}}{\binom{d}{k_j}}.$$

In particular, when the number of features selected is constant equal to k, the above equation becomes $\sum_{n=1}^{d}\frac{n}{2k-n}\frac{\binom{k}{n}\binom{d-k}{k-n}}{\binom{d}{k}}$, which depends on k and d. Therefore this measure does not have the Correction-for-chance property.

For the Dice coefficient, we have

$$\mathbb{E}\left[\hat{\Phi}_{Dice}(\mathcal{Z})|H_0\right] = \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{2\mathbb{E}\left[r_{i,j}|H_0\right]}{k_i + k_j} = \frac{2}{M(M-1)d}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{k_i k_j}{k_i + k_j}.$$

In particular, when the number of features selected is constant equal to k, the above equation becomes $\frac{k}{d}$, which depends on k and d. Therefore this measure does not have the Correction-for-chance property.

For Ochiai's index, we have

$$\begin{aligned}
\mathbb{E}\left[\hat{\Phi}_{Ochiai}(\mathcal{Z})|H_0\right] &= \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{\mathbb{E}\left[r_{i,j}|H_0\right]}{\sqrt{k_i k_j}} = \frac{1}{M(M-1)d}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\frac{k_i k_j}{\sqrt{k_i k_j}} \\
&= \frac{1}{M(M-1)d}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\sqrt{k_i k_j} = -\frac{1}{M-1}\frac{\bar{k}}{d} + \frac{1}{M(M-1)}\left(\sum_{i=1}^{M}\sqrt{\frac{k_i}{d}}\right)^2.
\end{aligned}$$

In particular, when the number of features selected is constant equal to k, the above equation becomes $\frac{k}{d}$, which depends on k and d. Therefore this measure does not have the Correction-for-chance property.

For *POG* measure, we use its symmetrical version equal to $\frac{r_{i,j}}{2k_i} + \frac{r_{i,j}}{2k_j}$ to carry out calculations. This results in the same stability value.

$$\begin{aligned}\mathbb{E}\left[\hat{\Phi}_{POG}(\mathcal{Z})|H_0\right] &= \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\left(\frac{\mathbb{E}\left[r_{i,j}|H_0\right]}{2k_i} + \frac{\mathbb{E}\left[r_{i,j}|H_0\right]}{2k_j}\right)\\ &= \frac{1}{M(M-1)}\sum_{i=1}^{M}\sum_{\substack{j=1\\j\neq i}}^{M}\left(\frac{k_ik_j}{2dk_i} + \frac{k_ik_j}{2dk_j}\right) = \frac{\bar{k}}{d},\end{aligned}$$

which depends on the number of feature selected and d. Therefore this measure does not have the Correction-for-chance property.

C.5.2 Frequency-based Measures

We showed in the proof of Theorem 3 (c.f. Appendix B.2), that under the Null Model of Feature Selection H_0, that p_f was equal to $\frac{\bar{k}}{d}$. Therefore, $\mathbb{E}\left[\hat{p}_f|H_0\right] = p_f = \frac{\bar{k}}{d}$. This will be used repeatedly in the proofs below.

For Goh's measure, since we have $\hat{\Phi}_{Goh}(\mathcal{Z}) = \frac{\bar{k}}{d}$ (c.f. Equation 10), this gives $\mathbb{E}\left[\hat{\Phi}_{Goh}(\mathcal{Z})|H_0\right] = \hat{\Phi}_{Goh}(\mathcal{Z}) = \frac{\bar{k}}{d}$, which is not constant. Therefore this measure does not have the property.

For Davis' Measure, we have $\mathbb{E}\left[\hat{\Phi}_{Davis}(\mathcal{Z})|H_0\right] = \hat{\Phi}_{Davis}(\mathcal{Z})$ as well. Therefore this measure does not have the Correction-for-chance property.

For Krízek's Measure, when the feature selection procedure is randomly selecting feature sets of cardinality k, the expected value of the frequency of occurrence of a feature set is equal to $\frac{1}{\binom{d}{k}}$. Therefore

$$\mathbb{E}\left[\hat{\Phi}_{Krizek}(\mathcal{Z})|H_0\right] = -\sum_{j=1}^{\binom{d}{k}}\frac{1}{\binom{d}{k}}\log\frac{1}{\binom{d}{k}} = -\log\frac{1}{\binom{d}{k}} = \log\binom{d}{k}.$$

Therefore Krízek's measure is not corrected for chance.

For Guzmán-Martinez's Measure, the stability measure is said to *"take the value zero for completely random rankings"* (Guzmán-Martínez and Alaiz-Rodríguez, 2011, pg 602), so we expect this measure to possess the Correction-for-chance property. We show this below.

$$\begin{aligned}\mathbb{E}\left[\hat{\Phi}_{Guzman}(\mathcal{Z})|H_0\right] &= 1 - \frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}\mathbb{E}\left[\hat{p}_f\log\hat{p}_f|H_0\right]\\ &= 1 - \frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}\mathbb{E}\left[\frac{\sum_{i=1}^{M}z_{i,f}}{M}\log\frac{\sum_{i=1}^{M}z_{i,f}}{M}|H_0\right].\end{aligned} \tag{13}$$

Under the Null Model of Feature Selection H_0, we have that $z_{i,f}$ follows a Bernoulli distribution with parameter $\frac{k}{d}$. Since we assumed that the samples $z_{1,f},...,z_{M,f}$ are independent and identically distributed (i.i.d.), we have that $\sum_{i=1}^{M}z_{i,f}$ follows a Binomial distribution with parameters M and $\frac{k}{d}$. Let $Y_f = \sum_{i=1}^{M}z_{i,f}$. Using this latter equation, we can calculate the expected value term of Equation (13),

$$\mathbb{E}\left[\frac{\sum_{i=1}^{M}z_{i,f}}{M}\log\frac{\sum_{i=1}^{M}z_{i,f}}{M}|H_0\right] = \mathbb{E}\left[\frac{Y_f}{M}\log\frac{Y_f}{M}|H_0\right].$$

Let $g: y \longmapsto \frac{y}{M}\log\frac{y}{M}$, we have

$$\mathbb{E}\left[\frac{\sum_{i=1}^{M}z_{i,f}}{M}\log\frac{\sum_{i=1}^{M}z_{i,f}}{M}|H_0\right] = \mathbb{E}\left[\frac{Y_f}{M}\log\frac{Y_f}{M}|H_0\right] = \mathbb{E}\left[g(Y_f)|H_0\right]. \tag{14}$$

Since g is a convex function[13] of y on the interval $(0,1]$, we can use Jensen's inequality, which gives

$$\begin{aligned}&\mathbb{E}\left[g(Y_f)|H_0\right] \geq g\left(\mathbb{E}\left[Y_f|H_0\right]\right) \Rightarrow \mathbb{E}\left[g(Y_f)|H_0\right] \geq g\left(M\frac{k}{d}\right) \Rightarrow \mathbb{E}\left[g(Y_f)|H_0\right] \geq \frac{k}{d}\log\frac{k}{d}\\ \Rightarrow\quad &\frac{1}{d}\sum_{f=1}^{d}\mathbb{E}\left[g(Y_f)|H_0\right] \geq \frac{k}{d}\log\frac{k}{d} \Rightarrow \frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}\mathbb{E}\left[g(Y_f)|H_0\right] \geq 1\\ \Rightarrow\quad &\frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}\mathbb{E}\left[g(Y_f)|H_0\right] \leq -1 \Rightarrow 1 - \frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}\mathbb{E}\left[g(Y_f)|H_0\right] \leq 0\\ \Rightarrow\quad &1 - \mathbb{E}\left[\frac{\frac{1}{d}}{\frac{k}{d}\log(\frac{k}{d})}\sum_{f=1}^{d}g(Y_f)|H_0\right] \leq 0.\end{aligned}$$

As shown by Equations (13) and (14), the left-hand-side term is equal to $\mathbb{E}\left[\hat{\Phi}_{Guzman}(\mathcal{Z})|H_0\right]$, therefore we get $\mathbb{E}\left[\hat{\Phi}_{Guzman}(\mathcal{Z})|H_0\right] \leq 0$. Since we know that $\hat{\Phi}_{Guzman}(\mathcal{Z})$ is a positive quantity, this gives us that $\mathbb{E}\left[\hat{\Phi}_{Guzman}(\mathcal{Z})|H_0\right] = 0$.

For the Relative Weighted Consistency CW_{rel}, using Equation (8), the result of Theorem 3 and by linearity of the expectation, we get

$$\mathbb{E}\left[\hat{\Phi}_{CW_{rel}}(\mathcal{Z})|H_0\right] = \frac{-\frac{1}{d}\frac{M-1}{M}\sum_{f=1}^{d}\mathbb{E}\left[s_f^2|H_0\right] + \frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right) - \frac{D}{M^2d}\left(1-\frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right) - \frac{D}{M^2d}\left(1-\frac{D}{d}\right) + \frac{H^2}{M^2d} - \frac{H}{Md}}$$

13. Indeed, its second derivative $g''(y) = \frac{1}{y\ln a}$ where a is the logarithm base used is non-negative for $y \in (0,1]$. Therefore g is convex on that interval.

$$= \frac{-\frac{1}{d}\frac{M-1}{M}\sum_{f=1}^{d}\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)+\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)+\frac{H^2}{M^2d}-\frac{H}{Md}}$$
$$= \frac{\frac{1}{M}\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)+\frac{H^2}{M^2d}-\frac{H}{Md}}.$$

Since $H = (M\bar{k}) \mod M$, H is such that $M\bar{k} = \lfloor\bar{k}\rfloor M + H$. Therefore $H = M(\bar{k} - \lfloor\bar{k}\rfloor)$. Replacing in the previous equation, we get

$$\mathbb{E}\left[\hat{\Phi}_{CW_{rel}}(\mathcal{Z})|H_0\right] = \frac{\frac{1}{M}\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)-\frac{D}{M^2d}\left(1-\frac{D}{d}\right)+\frac{(\bar{k}-\lfloor\bar{k}\rfloor)^2}{d}-\frac{\bar{k}-\lfloor\bar{k}\rfloor}{d}},$$

which is not constant. Nevertheless, when $\lfloor\bar{k}\rfloor = \bar{k}$, we have $\mathbb{E}\left[\hat{\Phi}_{CW_{rel}}(\mathcal{Z})|H_0\right] \xrightarrow[M\to\infty]{} 0$ and therefore the relative weighted consistency CW_{rel} is asymptotically corrected for chance. This is a result we expect since when the number of selected features is constant, this measure is asymptotically equivalent to our proposed measure (c.f. Theorem 5).

For Lausser's Measure, using Equation (12), we have

$$\begin{aligned}
\mathbb{E}\left[\hat{\Phi}_{Lausser}(\mathcal{Z})|H_0\right] &= \mathbb{E}\left[\frac{1}{k}\sum_{f=1}^{d}\hat{p}_f^2|H_0\right] = -\frac{1}{k}\sum_{f=1}^{d}\mathbb{E}\left[\hat{p}_f-\hat{p}_f^2-\hat{p}_f|H_0\right] \\
&= -\frac{1}{k}\sum_{f=1}^{d}\mathbb{E}\left[\hat{p}_f(1-\hat{p}_f)|H_0\right]+\frac{1}{k}\sum_{f=1}^{d}\mathbb{E}\left[\hat{p}_f|H_0\right] \\
&= -\frac{1}{k}\frac{M-1}{M}\sum_{f=1}^{d}\mathbb{E}\left[\frac{M}{M-1}\hat{p}_f(1-\hat{p}_f)|H_0\right]+\frac{1}{k}\sum_{f=1}^{d}p_f \\
&= -\frac{1}{k}\frac{M-1}{M}\sum_{f=1}^{d}p_f(1-p_f)+\frac{1}{k}\sum_{f=1}^{d}p_f.
\end{aligned}$$

As shown earlier, $\mathbb{E}\left[\hat{p}_f|H_0\right] = \frac{k}{d}$, therefore

$$\mathbb{E}\left[\hat{\Phi}_{Lausser}(\mathcal{Z})|H_0\right] = -\frac{M-1}{M}\left(1-\frac{k}{d}\right)+1 = \frac{1}{M}+\frac{M-1}{M}\frac{k}{d},$$

which is not constant. Therefore, Lausser's measure does not have this property.

Appendix D. Proof of the Lower Bound of the Proposed Measure

In this section, we prove the lower bound of the proposed stability measure given in Definition 4. To do so, we first prove the lemma below that will be used later on.

Lemma 10 $\frac{1}{d^2}\sum_{f<f'}(\hat{p}_f-\hat{p}_{f'})^2 = \frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2 - \left(\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f\right)^2$.

Proof.
Starting from the right-hand term, we get

$$\begin{aligned}
&\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2-\left(\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f\right)^2 = \left(\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2\right)-\frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=1}^{d}\hat{p}_f\hat{p}_{f'} = \frac{1}{d^2}\sum_{f=1}^{d}\left(d\hat{p}_f^2-\hat{p}_f\sum_{f'=1}^{d}\hat{p}_{f'}\right) \\
&= \frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=1}^{d}\hat{p}_f\left(\hat{p}_f-\hat{p}_{f'}\right).
\end{aligned}$$

Since the term $(\hat{p}_f - \hat{p}_{f'})$ is equal to zero when $f = f'$, by splitting the sum in two terms, this is equal to

$$\frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=1}^{f-1}\hat{p}_f\left(\hat{p}_f-\hat{p}_{f'}\right)+\frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=f+1}^{d}\hat{p}_f\left(\hat{p}_f-\hat{p}_{f'}\right) \quad .$$

The left term $\sum_{f=1}^{d}\sum_{f'=1}^{f-1}\hat{p}_f(\hat{p}_f-\hat{p}_{f'})$ is equal to $\sum_{f=1}^{d}\sum_{f'=f+1}^{d}-\hat{p}_{f'}(\hat{p}_f-\hat{p}_{f'})$. Therefore the previous equation becomes

$$\begin{aligned}
&\frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=f+1}^{d}-\hat{p}_{f'}\left(\hat{p}_f-\hat{p}_{f'}\right)+\frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=f+1}^{d}\hat{p}_f\left(\hat{p}_f-\hat{p}_{f'}\right) \\
&= \frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=f+1}^{d}\left(-\hat{p}_{f'}\left(\hat{p}_f-\hat{p}_{f'}\right)+\hat{p}_f\left(\hat{p}_f-\hat{p}_{f'}\right)\right) \\
&= \frac{1}{d^2}\sum_{f=1}^{d}\sum_{f'=f+1}^{d}\left(\hat{p}_f-\hat{p}_{f'}\right)^2 = \frac{1}{d^2}\sum_{f<f'}\left(\hat{p}_f-\hat{p}_{f'}\right)^2.
\end{aligned}$$

■

Since a sum of squares is always positive, using this lemma we have that

$$\begin{aligned}
&\frac{1}{d^2}\sum_{f<f'}(\hat{p}_f-\hat{p}_{f'})^2 \geq 0 \\
\Rightarrow\quad &\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2-\left(\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f\right)^2 \geq 0 \\
\Rightarrow\quad &\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2-\left(\frac{\bar{k}}{d}\right)^2 \geq 0 \\
\Rightarrow\quad &\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2 \geq \left(\frac{\bar{k}}{d}\right)^2 \\
\Rightarrow\quad &\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f^2-\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f \geq \left(\frac{\bar{k}}{d}\right)^2-\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f
\end{aligned}$$

$$
\begin{aligned}
\Rightarrow \quad & -\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f(1-\hat{p}_f) \geq \left(\frac{\bar{k}}{d}\right)^2 - \frac{\bar{k}}{d} \\
\Rightarrow \quad & -\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f(1-\hat{p}_f) \geq -\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right) \\
\Rightarrow \quad & \frac{\frac{1}{d}\sum_{f=1}^{d}\hat{p}_f(1-\hat{p}_f)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)} \leq 1 \\
\Rightarrow \quad & 1 - \frac{\frac{1}{d}\frac{M}{M-1}\sum_{f=1}^{d}\hat{p}_f(1-\hat{p}_f)}{\frac{\bar{k}}{d}\left(1-\frac{\bar{k}}{d}\right)} \geq 1 - \frac{M}{M-1} \\
\Rightarrow \quad & \hat{\Phi}(\mathcal{Z}) \geq -\frac{1}{M-1}.
\end{aligned}
$$

Hence, $\hat{\Phi}(\mathcal{Z})$ is lower bounded by -1 (as $M \geq 2$), but asymptotically bounded by 0. ■

Editor: Mikhail Belkin

Abstract

This paper presents NP-hardness and hardness of approximation results for maximum likelihood estimation of mixtures of spherical Gaussians.

Keywords: Mixtures of Gaussians, maximum likelihood, NP-completeness

1. Introduction

A *spherical Gaussian* in $\mathbb{R}^d$ is a distribution specified by its mean $\mu \in \mathbb{R}^d$ and variance $\sigma^2 > 0$, with density

$$N(x; \mu, \sigma^2) = \left(\frac{1}{2\pi\sigma^2}\right)^{d/2} \exp\left(-\frac{\|x-\mu\|^2}{2\sigma^2}\right).$$

(The standard notation for this Gaussian is $N(\mu, \sigma^2 I_d)$, but we will drop the identity matrix as a shorthand.)

When data arise from several sources, or form several clusters, it is common to model each source or cluster by a spherical Gaussian. If there are k sources, the resulting overall distribution is a mixture of k Gaussians,

$$\pi_1 N(\mu_1, \sigma_1^2) + \pi_2 N(\mu_2, \sigma_2^2) + \cdots + \pi_k N(\mu_k, \sigma_k^2),$$

where $\mu_i \in \mathbb{R}^d$ and σ_i^2 are the mean and variance of the ith component, and π_i is the fraction of the distribution that arises from this component. In what follows, we will often package the parameters together as $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_k)$, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_k)$, $\boldsymbol{\sigma} = (\sigma_1, \ldots, \sigma_k)$.

A standard statistical task is to fit a mixture of k Gaussians to a given data set. This is typically formulated as an optimization problem (Dempster et al., 1977), where given data points $x_1, \ldots, x_n \in \mathbb{R}^d$, the goal is to find the parameters $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ that maximize the *log-likelihood*

$$LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) = \sum_{i=1}^{n} \ln\left(\sum_{j=1}^{k} \pi_j N(x_i; \mu_j, \sigma_j^2)\right). \tag{1}$$

In this brief note, we establish the computational hardness of this estimation problem. This is in contrast with various positive results showing that, when data is in fact generated from a Gaussian mixture, it is possible to efficiently recover the mixture from a sample of polynomial size, under certain conditions; relevant work includes, for instance, Belkin and Sinha (2010), Moitra and Valiant (2010), Hsu and Kakade (2013), and Hardt and Price (2015), among others.

1.1 Gaussians with the same variance

We start with the simplest subcase, where the variances of the components are constrained to be the same.

> mixtures of spherical Gaussians with same variance: mog-sv
> *Input*: Points $x_1, \ldots, x_n \in \mathbb{R}^d$; positive integer k; unary parameter b.
> *Output*: A mixture of k spherical Gaussians with the same variance, $(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)$, whose log-likelihood
>
> $$LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) = \sum_{i=1}^{n} \ln\left(\sum_{j=1}^{k} \pi_j N(x_i; \mu_j, \sigma^2)\right)$$
>
> is within an additive factor $1/b$ of optimal.

Since the parameters of the optimal mixture are real-valued, they can only be provided to within some precision. The role of the input parameter b is to specify the desired level of accuracy. It is worth pointing out, however, that in our reductions, the coordinates of data points take values in $\{-1, 0, 1\}$ and the hardness does not stem from precision issues but rather from underlying combinatorial structure.

mog-sv is similar to the k-means clustering problem, which is NP-hard (Aloise et al., 2009).

> k-means
> *Input*: Points $x_1, \ldots, x_n \in \mathbb{R}^d$; positive integer k.
> *Output*: A collection of k "centers" $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_k)$ in $\mathbb{R}^d$ that minimize the cost function
>
> $$\Phi(\boldsymbol{\mu}) = \sum_{i=1}^{n} \min_{1 \le j \le k} \|x_i - \mu_j\|^2.$$

The biggest difference between the two problems is that k-means assigns each data point x_i to a single center μ_j (a "hard" clustering), while the mixture of Gaussians effectively spreads it out over all the centers (a "soft" clustering). Earlier work (Arora and Kannan, 2001) has established that a "hard clustering" version of the mixture of Gaussians problem is NP-hard. Here we consider the more standard formulation, and show that it is hard even when $k = 2$.

Theorem 1 mog-sv *is NP-hard on instances with* $k = 2$.

The proof follows from the observation that an additive approximation to the best mog-sv solution yields a multiplicative approximation to the best k-means solution:

Lemma 2 *Fix any data set $x_1, \ldots, x_n \in \mathbb{R}^d$ and any positive integer k. Let LL_{OPT} denote the log-likelihood of the optimal solution to* MOG-SV*, and Φ_{OPT} the lowest achievable k-means cost. For any parameters $(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)$, we have*

$$\ln \frac{\Phi(\boldsymbol{\mu})}{\Phi_{OPT}} \;\leq\; \frac{4 \ln k}{d} + \frac{2}{nd}\left(LL_{OPT} - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)\right).$$

The first term on the right-hand side comes from the discrepancy between hard and soft clustering. It can be made negligible by increasing the dimension, for instance by padding each point with extra zero-valued coordinates.

Lemma 2 can also be combined with a recent hardness of approximation result for k-means (Awasthi et al., 2015) to show that, if k is allowed to be large, MOG-SV cannot be approximated within an additive factor of $o(nd)$.

Theorem 3 *There is a family of* MOG-SV *instances with the following properties:*

- *An instance with n points has dimension $O(n)$.*
- *Each point is $\{0,1\}$-valued and has $O(1)$ nonzero coordinates.*
- *$k = \Theta(n)$.*

For some absolute constant c_o, it is NP-hard to approximate MOG-SV *on such instances within an additive factor of $c_o dn$.*

The specific form of this result (additive versus multiplicative approximation, interpoint distances that are small constants) is motivated by the unusual properties of the log-likelihood objective. To begin with, consider the problem of fitting a single Gaussian to a data set $\mathcal{X} \subset \mathbb{R}^d$ of size n. A quick calculation shows that the log-likelihood (of the maximum likelihood estimate) is

$$\frac{dn}{2} \ln \frac{d}{2\pi e} - \frac{dn}{2} \ln \text{radius}(\mathcal{X}), \quad \textit{where} \quad \text{radius}(\mathcal{X}) = \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \|x - \text{mean}(\mathcal{X})\|^2.$$

Depending on the scale of the data, this log-likelihood could be positive, negative, or zero. When fitting a mixture of k Gaussians, the log-likelihood has a term of this sort for each cluster, plus an additional term of size $\pm n \ln k$ due to the mixing weights. For the kind of instance described in the theorem, any cluster with at least two points has radius $\Theta(1)$ and thus the log-likelihoods of all reasonable mixture models lie in an interval of size $O(dn)$.

The proofs of these results appear in Section 2.

1.2 Gaussians with differing variances

When the different Gaussian components are allowed to have different variances, and $k > 1$, the maximum-likelihood solution is always degenerate. This is because it is possible to make the log-likelihood go to infinity by centering one of the Gaussians at a single data point and letting its variance go to zero. Thus, in order for the problem to be well-defined, an additional constraint must be introduced. One option is to force all variances to be non-negligible.

mixtures of spherical Gaussians with constrained variances: MOG
Input: Points $x_1, \ldots, x_n \in \mathbb{R}^d$; positive integer k; value $\sigma_o > 0$; unary integer b.
Output: A mixture of k spherical Gaussians $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ whose log-likelihood is within an additive factor $1/b$ of optimal, subject to the constraint $\sigma_1, \ldots, \sigma_k \geq \sigma_o$.

This problem is slightly further from k-means, but remains intractable.

Theorem 4 MOG *is NP-hard on instances with $k = 2$.*

The proof appears in Section 3.

2. Mixtures of spherical Gaussians with the same variance

2.1 Induced partitions

We start with a basic relation between hard and soft clustering that applies to arbitrary mixture models, not just those with Gaussian components of the same variance.

Although a mixture model represents a soft clustering, it also induces a natural hard partition. For data set $\mathcal{X}$ and mixture of Gaussians $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$, this hard partition has clusters

$$\mathcal{X}_j \;=\; \left\{ x \in \mathcal{X} \,:\, j = \operatorname*{argmax}_{\ell} \; \pi_\ell N(x; \mu_\ell, \sigma_\ell^2) \right\} \tag{2}$$

(breaking ties arbitrarily). The log-likelihood of a mixture is easily bounded in terms of the likelihood of the corresponding hard partition.

Lemma 5 *Pick any mixture $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ and data set $\mathcal{X} = \{x_1, \ldots, x_n\}$.*

(a) For any partition $(\mathcal{X}'_1, \ldots, \mathcal{X}'_k)$ of $\mathcal{X}$, we have

$$LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) \;\geq\; \sum_{j=1}^{k} \sum_{x \in \mathcal{X}'_j} \ln(\pi_j N(x; \mu_j, \sigma_j^2)).$$

(b) For the partition $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$ induced by $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$, as in Eq (2), we have

$$LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) \;\leq\; n \ln k + \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j} \ln(\pi_j N(x; \mu_j, \sigma_j^2)).$$

Proof Recall from (1) that the contribution of each data point x_i to $LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ is

$$\ln \left(\sum_{j=1}^{k} \pi_j N(x_i; \mu_j, \sigma_j^2) \right).$$

For $x_i \in \mathcal{X}'_j$, we can lower-bound this contribution by $\ln(\pi_j N(x_i; \mu_j, \sigma_j^2))$. Similarly, if $x_i \in \mathcal{X}_j$, then we can upper-bound the contribution by $\ln(k\pi_j N(x_i; \mu_j, \sigma_j^2))$, by the manner in which the hard partition $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$ is defined. ■

2.2 Proof of Lemma 2

As in the statement of Lemma 2, fix data $x_1, \ldots, x_n \in \mathbb{R}^d$, and define LL_{OPT} to be the log-likelihood of the optimal solution of MOG-SV. Let Φ_{OPT} be the optimal k-means cost.

Pick any parameters $(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)$, and let $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$ be the induced hard partition of the data set, as per Eq (2). From Lemma 5,

$$\begin{aligned} LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) &\leq n \ln k + \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j} \left(\ln \pi_j + \frac{d}{2} \ln \left(\frac{1}{2\pi\sigma^2} \right) - \frac{\|x - \mu_j\|^2}{2\sigma^2} \right) \\ &\leq n \ln k + \frac{nd}{2} \ln \left(\frac{1}{2\pi\sigma^2} \right) - \frac{1}{2\sigma^2} \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j} \|x - \mu_j\|^2 \\ &\leq n \ln k + \frac{nd}{2} \ln \left(\frac{1}{2\pi\sigma^2} \right) - \frac{\Phi(\boldsymbol{\mu})}{2\sigma^2} \\ &\leq n \ln k + \frac{nd}{2} \ln \left(\frac{nd}{2\pi\Phi(\boldsymbol{\mu})} \right) - \frac{nd}{2}, \end{aligned}$$

where the last inequality comes from solving for the optimal value of σ^2 (namely, $\Phi(\boldsymbol{\mu})/nd$) in the preceding line.

Suppose the optimal k-means solution is realized by centers $\boldsymbol{\mu}^* = (\mu_1^*, \ldots, \mu_k^*)$. Let $\pi_1^* = \cdots = \pi_k^* = 1/k$ and $\sigma^{*2} = \Phi(\boldsymbol{\mu}^*)/nd$. To bound the log-likelihood of the mixture model $(\boldsymbol{\pi}^*, \boldsymbol{\mu}^*, \sigma^*)$, we look at the hard partition that it induces, $(\mathcal{X}_1^*, \ldots, \mathcal{X}_k^*)$, and notice that $\mathcal{X}_j^*$ consists of points whose closest center is μ_j^*. We then apply Lemma 5 to get

$$\begin{aligned} LL(\boldsymbol{\pi}^*, \boldsymbol{\mu}^*, \sigma^*) &\geq \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j^*} \left(\ln \pi_j^* + \frac{d}{2} \ln \left(\frac{1}{2\pi\sigma^{*2}} \right) - \frac{\|x - \mu_j^*\|^2}{2\sigma^{*2}} \right) \\ &= -n \ln k + \frac{nd}{2} \ln \left(\frac{1}{2\pi\sigma^{*2}} \right) - \frac{1}{2\sigma^{*2}} \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j^*} \|x - \mu_j^*\|^2 \\ &= -n \ln k + \frac{nd}{2} \ln \left(\frac{1}{2\pi\sigma^{*2}} \right) - \frac{1}{2\sigma^{*2}} \Phi(\boldsymbol{\mu}^*) \\ &= -n \ln k + \frac{nd}{2} \ln \left(\frac{nd}{2\pi\Phi(\boldsymbol{\mu}^*)} \right) - \frac{nd}{2}, \end{aligned}$$

where the last equality comes from substituting in the value of σ^{*2}. Combining our bounds for the two mixtures, we get

$$\begin{aligned} LL_{OPT} - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) &\geq LL(\boldsymbol{\pi}^*, \boldsymbol{\mu}^*, \sigma^*) - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) \\ &\geq \frac{nd}{2} \ln \left(\frac{\Phi(\boldsymbol{\mu})}{\Phi(\boldsymbol{\mu}^*)} \right) - 2n \ln k. \end{aligned}$$

Rearranging terms yields the lemma statement.

2.3 Proof of Theorem 1

With Lemma 2 in place, a reduction from k-means to MOG-SV is almost immediate. There are various hardness results available for k-means (Aloise et al., 2009; Dasgupta and Freund, 2009; Mahajan et al., 2009; Awasthi et al., 2015); of these, we use Aloise et al. (2009) as a starting point.

Theorem 6 (Aloise et al. (2009)) *There exists a family of k-means instances with the following properties, for some low-order polynomials $\alpha(\cdot)$ and $\beta(\cdot)$:*

- *For an instance containing n points, each point has dimension at most $\alpha(n)$, with individual coordinates taking values in $\{-1, 0, 1\}$.*
- *It is NP-hard to approximate the best k-means solution, with $k = 2$, within a factor of $1 + 1/\beta(n)$.*

To prove Theorem 1, we reduce the problem of finding a $(1 + 1/\beta(n))$-approximate k-means solution to MOG-SV. Given an instance $x_1, \ldots, x_n$ of k-means:

- Pad each point with additional zero-valued coordinates until the dimension d exceeds $16\beta(n) \ln k$. This has no effect on interpoint distances or on the optimal k-means cost.
- Solve MOG-SV for these modified points, with precision parameter $b = 1$. This yields $(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)$ such that $LL_{OPT} - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) \leq 1$, where LL_{OPT} is the optimal log-likelihood. It follows from Lemma 2 that

  $$\ln \frac{\Phi(\boldsymbol{\mu})}{\Phi_{OPT}} \leq \frac{4 \ln k}{d} + \frac{2}{nd} \leq \frac{1}{2\beta(n)},$$

  whereupon $\Phi(\boldsymbol{\mu}) \leq \Phi_{OPT}(1 + 1/\beta(n))$.

2.4 Proof of Theorem 3

A recent hardness of approximation result for k-means shows the following.

Theorem 7 (Awasthi et al. (2015)) *There is a family of k-means instances with the following properties:*

- *An instance with n points has dimension at most n, points that are $\{0, 1\}$-valued (and have at most two non-zero coordinates), and a target number of clusters $k = \Omega(n)$.*
- *It is NP-hard to approximate the optimal k-means solution within a factor c, for some absolute constant $c > 1$.*

Pick any $c_o < (1/2) \ln c$. To see that it is hard to approximate MOG-SV within an additive factor $c_o nd$, we reduce from k-means as follows. Start with an instance $x_1, \ldots, x_n \in \mathbb{R}^d$ of the type described in Theorem 7. Then:

- If necessary, pad points with zero-valued coordinates to bring the dimension up to

  $$d \geq \frac{4 \ln k}{(\ln c) - 2c_o}.$$

- Obtain an approximate solution $(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma)$ to MOG-SV on these points such that $LL_{OPT} - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \sigma) \leq c_o nd$.

- Return the centers $\boldsymbol{\mu}$.

By Lemma 2, we have

$$\ln \frac{\Phi(\boldsymbol{\mu})}{\Phi_{OPT}} \;\leq\; \frac{4 \ln k}{d} + \frac{2}{nd} c_o nd \;\leq\; \ln c,$$

so that $\boldsymbol{\mu}$ is a c-approximate solution to the k-means instance.

3. The general case

We now consider the case where the variances are allowed to differ but are uniformly lower bounded. Specifically, a mixture model $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ is *admissible* if all $\sigma_j \geq \sigma_o$, where σ_o is supplied as part of the input.

The basic reduction still applies, with an additional device to force all variances to be close to the lower bound—and therefore approximately equal.

3.1 Controlling the variances

Lemma 8 *Fix any data set $\mathcal{X} = \{x_1, \ldots x_n\}$ in $\mathbb{R}^d$, and let $D = \max_{i \neq i'} \|x_i - x_{i'}\|$ denote its diameter. Pick any $\Delta, \delta > 0$. If the dimension d satisfies*

$$d \geq \frac{4}{\delta} \left(\frac{nD^2}{2\sigma_o^2} + n \ln k + \Delta \right), \tag{3}$$

then any admissible mixture $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ within an additive factor Δ of optimal (that is, $LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) \geq LL_{OPT} - \Delta$) has the following property: in the associated hard partition $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$, any nonempty cluster $\mathcal{X}_j$ has $\sigma_j^2 \leq \sigma_o^2(1+\delta)$.

Proof Pick any admissible mixture $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ that is within Δ of optimal, and let $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$ be the associated hard partition. Let $\widetilde{\mu}_j$ denote the cluster means:

$$\widetilde{\mu}_j \;=\; \frac{1}{|\mathcal{X}_j|} \sum_{x \in \mathcal{X}_j} x.$$

Using Lemma 5, we can compare the log-likelihood of $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ to that of the adjusted parameters $(\boldsymbol{\pi}, \widetilde{\boldsymbol{\mu}}, \widetilde{\boldsymbol{\sigma}})$, where each $\widetilde{\sigma}_j = \sigma_o$.

$$\begin{aligned}
&LL(\boldsymbol{\pi}, \widetilde{\boldsymbol{\mu}}, \widetilde{\boldsymbol{\sigma}}) - LL(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma}) \\
&\geq \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j} \left(\ln(\pi_j N(x; \widetilde{\mu}_j, \sigma_o^2)) - \ln(\pi_j N(x; \mu_j, \sigma_j^2)) \right) - n \ln k \\
&= \sum_{j=1}^{k} \sum_{x \in \mathcal{X}_j} \left(\frac{d}{2} \ln \frac{1}{2\pi\sigma_o^2} - \frac{\|x - \widetilde{\mu}_j\|^2}{2\sigma_o^2} - \frac{d}{2} \ln \frac{1}{2\pi\sigma_j^2} + \frac{\|x - \mu_j\|^2}{2\sigma_j^2} \right) - n \ln k \\
&= \sum_{j=1}^{k} \left(\frac{d|\mathcal{X}_j|}{2} \ln \frac{\sigma_j^2}{\sigma_o^2} + \sum_{x \in \mathcal{X}_j} \left(\frac{\|x - \mu_j\|^2}{2\sigma_j^2} - \frac{\|x - \widetilde{\mu}_j\|^2}{2\sigma_o^2} \right) \right) - n \ln k \\
&\geq \sum_{j=1}^{k} \left(\frac{d|\mathcal{X}_j|}{2} \ln \frac{\sigma_j^2}{\sigma_o^2} + \left(\frac{1}{2\sigma_j^2} - \frac{1}{2\sigma_o^2} \right) \sum_{x \in \mathcal{X}_j} \|x - \widetilde{\mu}_j\|^2 \right) - n \ln k \\
&\geq \sum_{j=1}^{k} |\mathcal{X}_j| \left(d \ln \frac{\sigma_j}{\sigma_o} - \frac{D^2}{2\sigma_o^2} \right) - n \ln k \;\;\geq\;\; d \ln \frac{\max_{j: \mathcal{X}_j \neq \emptyset} \sigma_j}{\sigma_o} - \frac{nD^2}{2\sigma_o^2} - n \ln k.
\end{aligned}$$

In the second-last line, we have exploited the fact that $\widetilde{\mu}_j$ is the mean of cluster $\mathcal{X}_j$, so that $\sum_{x \in \mathcal{X}_j} \|x - \widetilde{\mu}_j\|^2 \leq \sum_{x \in \mathcal{X}_j} \|x - \mu_j\|^2$, and for the last line we have used $\|x - \widetilde{\mu}_j\| \leq D$.

The difference above is at most Δ, and thus for each nonempty cluster $\mathcal{X}_j$,

$$d \ln \frac{\sigma_j}{\sigma_o} - \frac{nD^2}{2\sigma_o^2} - n \ln k \leq \Delta,$$

whereupon $\sigma_j^2 \leq \sigma_o^2(1+\delta)$ given the bound (3) on the dimension d. ■

This observation allows us to prove following analog of Lemma 2.

Lemma 9 *Following the terminology of Lemma 8, pick $\delta, \Delta > 0$ and suppose that the dimension satisfies (3). Pick any admissible mixture $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$ whose log-likelihood is within an additive factor Δ of the optimal. Then*

$$\Phi(\boldsymbol{\mu}) \;\leq\; (1+\delta) \left(2\sigma_o^2 (\Delta + 2n \ln k) + \Phi_{OPT} \right).$$

Proof Let $(\mathcal{X}_1, \ldots, \mathcal{X}_k)$ be the hard partition of the data set induced by $(\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\sigma})$. By Lemma 8, we know that for any nonempty cluster $\mathcal{X}_j$, the variance σ_j^2 is at most $(1+\delta)\sigma_o^2$.

Thus, using Lemma 5, we have

$$\begin{aligned} LL(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\sigma}) &\leq n\ln k + \sum_{j=1}^{k}\sum_{x\in\mathcal{X}_j}\left(\ln\pi_j + \frac{d}{2}\ln\frac{1}{2\pi\sigma_j^2} - \frac{\|x-\mu_j\|^2}{2\sigma_j^2}\right) \\ &\leq n\ln k + \sum_{j=1}^{k}\left(\frac{|\mathcal{X}_j|d}{2}\ln\frac{1}{2\pi\sigma_j^2} - \frac{1}{2\sigma_j^2}\sum_{x\in\mathcal{X}_j}\|x-\mu_j\|^2\right) \\ &\leq n\ln k + \frac{nd}{2}\ln\frac{1}{2\pi\sigma_o^2} - \frac{1}{2(1+\delta)\sigma_o^2}\sum_{j=1}^{k}\sum_{x\in\mathcal{X}_j}\|x-\mu_j\|^2 \\ &\leq n\ln k + \frac{nd}{2}\ln\left(\frac{1}{2\pi\sigma_o^2}\right) - \frac{\Phi(\boldsymbol{\mu})}{2(1+\delta)\sigma_o^2} \end{aligned}$$

Let $\mu_1^*,\ldots,\mu_k^*$ be an optimal k-means solution and let $(\mathcal{X}_1^*,\ldots,\mathcal{X}_k^*)$ be the hard partition of the data set induced by the mixture model $(\boldsymbol{\pi}^*,\boldsymbol{\mu}^*,\boldsymbol{\sigma}^*)$ where $\pi_j^* = 1/k$ and $\sigma_j^* = \sigma_o$ for all j. Again using Lemma 5,

$$\begin{aligned} LL(\boldsymbol{\pi}^*,\boldsymbol{\mu}^*,\boldsymbol{\sigma}^*) &\geq \sum_{j=1}^{k}\sum_{x\in\mathcal{X}_j^*}\left(\ln\pi_j^* + \frac{d}{2}\ln\frac{1}{2\pi\sigma_j^{*2}} - \frac{\|x-\mu_j^*\|^2}{2\sigma_j^{*2}}\right) \\ &= -n\ln k + \frac{nd}{2}\ln\left(\frac{1}{2\pi\sigma_o^2}\right) - \frac{\Phi(\boldsymbol{\mu}^*)}{2\sigma_o^2} \end{aligned}$$

Then by the near-optimality of $(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\sigma})$, we have

$$\begin{aligned} \Delta &\geq LL_{OPT} - LL(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\sigma}) \\ &\geq LL(\boldsymbol{\pi}^*,\boldsymbol{\mu}^*,\boldsymbol{\sigma}^*) - LL(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\sigma}) \\ &\geq \left(-n\ln k + \frac{nd}{2}\ln\frac{1}{2\pi\sigma_o^2} - \frac{\Phi(\boldsymbol{\mu}^*)}{2\sigma_o^2}\right) - \left(n\ln k + \frac{nd}{2}\ln\left(\frac{1}{2\pi\sigma_o^2}\right) - \frac{\Phi(\boldsymbol{\mu})}{2(1+\delta)\sigma_o^2}\right) \\ &= \frac{\Phi(\boldsymbol{\mu})}{2(1+\delta)\sigma_o^2} - \frac{\Phi_{OPT}}{2\sigma_o^2} - 2n\ln k \end{aligned}$$

Rearranging gives the theorem statement. ■

3.2 Proof of Theorem 4

Once again we reduce from k-means, using the hardness result of Aloise et al. (2009), summarized in Theorem 6. Recall that the family of instances for which k-means was shown to be hard has $k = 2$, $d = \text{poly}(n)$, and points with $\{-1, 0, 1\}$-valued coordinates.

Starting with such an instance $x_1,\ldots,x_n \in \mathbb{R}^d$, we show how MOG can be used to find a $(1 + 1/\beta(n))$-approximate solution to k-means.

- Let D denote the diameter of the points; it is polynomial in n.
- Set $\delta = 1/(5\beta(n))$ and
$$\sigma_o^2 = \frac{\delta}{2(1+2n\ln k)}.$$

- Pad the points with zero-valued coordinates to bring the dimension up to at least
$$d = \frac{4}{\delta}\left(\frac{nD^2}{2\sigma_o^2} + n\ln k + 1\right).$$
- Invoke MOG on these modified points, with target precision $b = 1$ and variance lower bound σ_o^2. This returns a mixture $(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\sigma})$ whose log-likelihood is at least $LL_{OPT} - 1$, subject to the variance constraint.
- Return centers $\boldsymbol{\mu}$.

Lemma 9, with $\Delta = 1$, asserts that

$$\Phi(\boldsymbol{\mu}) \;\leq\; (1+\delta)(2\sigma_o^2(1+2n\ln k) + \Phi_{OPT}) \;\leq\; (1+\delta)(\delta + \Phi_{OPT}) \;\leq\; (1+5\delta)\Phi_{OPT},$$

which is at most $(1 + 1/\beta(n))\Phi_{OPT}$. For the last inequality, we have used the fact that $\Phi_{OPT} \geq 1/2$ since all interpoint distances are ≥ 1.

Abstract

The fused lasso, also known as (anisotropic) total variation denoising, is widely used for piecewise constant signal estimation with respect to a given undirected graph. The fused lasso estimate is highly nontrivial to compute when the underlying graph is large and has an arbitrary structure. But for a special graph structure, namely, the chain graph, the fused lasso—or simply, 1d fused lasso—can be computed in linear time. In this paper, we revisit a result recently established in the online classification literature (Herbster et al., 2009; Cesa-Bianchi et al., 2013) and show that it has important implications for signal denoising on graphs. The result can be translated to our setting as follows. Given a general graph, if we run the standard depth-first search (DFS) traversal algorithm, then the total variation of any signal over the chain graph induced by DFS is no more than twice its total variation over the original graph.

This result leads to several interesting theoretical and computational conclusions. Letting m and n denote the number of edges and nodes, respectively, of the graph in consideration, it implies that for an underlying signal with total variation t over the graph, the fused lasso (properly tuned) achieves a mean squared error rate of $t^{2/3}n^{-2/3}$. Moreover, precisely the same mean squared error rate is achieved by running the 1d fused lasso on the DFS-induced chain graph. Importantly, the latter estimator is simple and computationally cheap, requiring $O(m)$ operations to construct the DFS-induced chain and $O(n)$ operations to compute the 1d fused lasso solution over this chain. Further, for trees that have bounded maximum degree, the error rate of $t^{2/3}n^{-2/3}$ cannot be improved, in the sense that it is the minimax rate for signals that have total variation t over the tree. Finally, several related results also hold—for example, the analogous result holds for a roughness measure defined by the ℓ_0 norm of differences across edges in place of the total variation metric.

Keywords: fused lasso, total variation denoising, graph denoising, depth-first search

1. Introduction

We study the graph denoising problem, i.e., estimation of a signal $\theta_0 \in \mathbb{R}^n$ from noisy data

$$y_i = \theta_{0,i} + \epsilon_i, \quad i = 1, \ldots, n, \tag{1}$$

when the components of θ_0 are associated with the vertices of an undirected, connected graph $G = (V, E)$. Without a loss of generality, we denote $V = \{1, \ldots, n\}$. Versions of this problem arise in diverse areas of science and engineering, such as gene expression analysis, protein mass spectrometry, and image denoising. The problem is also archetypal of numerous internet-scale machine learning tasks that involve propagating labels or information across edges in a network (e.g., a network of users, web pages, or YouTube videos).

Methods for graph denoising have been studied extensively in machine learning and signal processing. In machine learning, graph kernels have been proposed for classification and regression, in both supervised and semi-supervised data settings (e.g., Belkin and Niyogi (2002); Smola and Kondor (2003); Zhu et al. (2003); Zhou et al. (2005)). In signal processing, a considerable focus has been placed on the construction of wavelets over graphs (e.g., Crovella and Kolaczyk (2003); Coifman and Maggioni (2006); Gavish et al. (2010); Hammond et al. (2011); Sharpnack et al. (2013); Shuman et al. (2013)). We will focus our study on the *fused lasso* over graphs, also known as (anisotropic) *total variation* denoising over graphs. Proposed by Rudin et al. (1992) in the signal processing literature, and Tibshirani et al. (2005) in the statistics literature, the fused lasso estimate is defined by the solution of a convex optimization problem,

$$\hat{\theta}_G = \underset{\theta \in \mathbb{R}^n}{\operatorname{argmin}} \ \frac{1}{2}\|y - \theta\|_2^2 + \lambda \|\nabla_G \theta\|_1, \tag{2}$$

where $y = (y_1, \ldots, y_n) \in \mathbb{R}^n$ the vector of observed data, $\lambda \geq 0$ is a tuning parameter, and $\nabla_G \in \mathbb{R}^{m \times n}$ is the edge incidence matrix of the graph G. Note that the subscript on the incidence matrix ∇_G and the fused lasso solution $\hat{\theta}_G$ in (2) emphasize that these quantities are defined with respect to the graph G. The edge incidence matrix ∇_G can be defined as follows, using some notation and terminology from algebraic graph theory (e.g., Godsil and Royle (2001)). First, we assign an arbitrary orientation to edges in the graph, i.e., for each edge $e \in E$, we arbitrarily select one of the two joined vertices to be the head, denoted e^+, and the other to be the tail, denoted e^-. Then, we define a row $(\nabla_G)_e$ of ∇_G, corresponding to the edge e, by

$$(\nabla_G)_{e,e^+} = 1, \ \ (\nabla_G)_{e,e^-} = -1, \ \ (\nabla_G)_{e,v} = 0 \ \text{ for all } v \neq e^+, e^-,$$

for each $e \in E$. Hence, for an arbitrary $\theta \in \mathbb{R}^n$, we have

$$\|\nabla_G \theta\|_1 = \sum_{e \in E} |\theta_{e^+} - \theta_{e^-}|.$$

We can see that the particular choice of orientation does not affect the value $\|\nabla_G \theta\|_1$, which we refer to as the *total variation* of θ over the graph G.

1.1 Summary of results

We will wait until Section 1.3 to give a detailed review of literature, both computational and theoretical, on the fused lasso. Here we simply highlight a key computational aspect of the fused lasso to motivate the main results in our paper. The fused lasso solution in (2), for a graph G of arbitrary structure, is highly nontrivial to compute. For a chain graph, however, the fused lasso solution can be computed in linear time (e.g., using dynamic programming or specialized taut-string methods).

The question we address is: how can we use this fact to our advantage, when seeking to solve (2) over an arbitrary graph? Given a generic graph structure G that has m edges and n nodes, it is obvious that we can define a chain graph based on the ordering of nodes produced by depth-first search (DFS). Far less obvious is that for any signal, its total variation along the DFS-induced chain graph never exceeds twice its total variation over the original graph. This fact follows closely from a similar result found in the online graph-structured classification literature (Herbster et al., 2009; Cesa-Bianchi et al., 2013), and for our purposes, it has three notable consequences, described below.

1. No matter the structure of G, we can denoise any signal defined over this graph in $O(m+n)$ operations: $O(m)$ operations for DFS and $O(n)$ operations for the 1d fused lasso on the induced chain. We call the corresponding estimator—the 1d fused lasso run on the DFS-induced chain—the *DFS fused lasso*.

2. For an underlying signal θ_0 that generates the data, as in (1), such that $\theta_0 \in \mathrm{BV}_G(t)$, where $\mathrm{BV}_G(t)$ is the class of signals with total variation at most t, defined in (4), the DFS fused lasso estimator has mean squared error (MSE) on the order of $t^{2/3}n^{-2/3}$.

3. For an underlying signal $\theta_0 \in \mathrm{BV}_G(t)$, the fused lasso estimator over the original graph, in (2), also has MSE on the order of $t^{2/3}n^{-2/3}$.

The fact that such a fast rate, $t^{2/3}n^{-2/3}$, applies for the fused lasso estimator over *any* connected graph structure is somewhat surprising. It implies that the chain graph represents the hardest graph structure for denoising signals of bounded variation—at least, hardest for the fused lasso, since as we have shown, error rates on general connected graphs can be no worse than the chain rate of $t^{2/3}n^{-2/3}$.

We also complement these MSE upper bounds with the following minimax lower bound over trees.

4. When G is a tree of bounded max degree, the minimax MSE over the class $\mathrm{BV}_G(t)$ scales at the rate $t^{2/3}n^{-2/3}$. Hence, in this setting, the DFS fused lasso estimator attains the optimal rate, as does the fused lasso estimator over G.

Lastly, we prove the following for signals with a bounded number of nonzero edge differences.

5. For an underlying signal $\theta_0 \in \mathrm{BD}_G(s)$, where $\mathrm{BD}_G(s)$ is the class of signals with at most s nonzero edge differences, defined in (5), the DFS fused lasso (under a condition on the spacing of nonzero differences over the DFS-induced chain) has MSE on the order of $s(\log s + \log\log n)\log n/n + s^{3/2}/n$. When G is a tree, the minimax MSE over the class $\mathrm{BD}_G(s)$ scales as $s\log(n/s)/n$. Thus, in this setting, the DFS fused lasso estimator is only off by a $\log\log n$ factor provided that s is small.

Thus DFS fused lasso gives us an $O(n)$ time algorithm for nearly minimax rate-optimal denoising over trees. On paper, this only saves a factor of $O(\log n)$ operations, as recent work (to be described in Section 1.3) has produced an $O(n\log n)$ time algorithm for the fused lasso over trees, by extending earlier dynamic programming ideas over chains. However, dynamic programming on a tree is (a) much more complex than dynamic programming on a chain (since it relies on sophisticated data structures), and (b) noticeably slower in practice than dynamic programming over a chain, especially for large problem sizes. Hence there is still a meaningful difference—both in terms of simplicity and practical computational efficiency—between the DFS fused lasso estimator and the fused lasso over a generic tree.

For a general graph structure, we cannot claim that the statistical rates attained by the DFS fused lasso estimator are optimal, nor can we claim that they match those of fused lasso over the original graph. As an example, recent work (to be discussed in Section 1.3) studying the fused lasso over grid graphs shows that estimation error rates for this problem can be much faster than those attained by the DFS fused lasso (and thus the minimax rates over trees). What should be emphasized, however, is that the DFS fused lasso can still be a practically useful method for any graph, running in linear time (in the number of edges) no matter the graph structure, a scaling that is beneficial for truly large problem sizes.

1.2 Assumptions and notation

Our theory will be primarily phrased in terms of the mean squared error (MSE) for an estimator $\hat{\theta}$ of the mean parameter θ_0 in (1), assuming that $\epsilon = (\epsilon_1, \ldots, \epsilon_n)$ has i.i.d. mean zero sub-Gaussian components, i.e.,

$$\mathbb{E}(\epsilon_i) = 0, \quad \text{and} \quad \mathbb{P}(|\epsilon_i| > t) \leq M\exp\big(-t^2/(2\sigma^2)\big), \text{ all } t \geq 0, \quad \text{for } i = 1, \ldots, n, \tag{3}$$

for constants $M, \sigma > 0$. The MSE of $\hat{\theta}$ will be denoted, with a slight abuse of notation, by

$$\|\hat{\theta} - \theta_0\|_n^2 = \frac{1}{n}\|\hat{\theta} - \theta_0\|_2^2.$$

(In general, for a vector $x \in \mathbb{R}^n$, we denote its scaled ℓ_2 norm by $\|x\|_n = \|x\|_2/\sqrt{n}$.) Of course, the MSE will depend not only on the estimator $\hat{\theta}$ in question but also on the assumptions that we make about θ_0. We will focus our study on two classes of signals. The first is the *bounded variation class*, defined with respect to the graph G, and a radius parameter $t > 0$, as

$$\mathrm{BV}_G(t) = \{\theta \in \mathbb{R}^n : \|\nabla_G\theta\|_1 \leq t\}. \tag{4}$$

The second is the *bounded differences class*, defined again with respect to the graph G, and a now a sparsity parameter $s > 0$, as

$$\mathrm{BD}_G(s) = \{\theta \in \mathbb{R}^n : \|\nabla_G\theta\|_0 \leq s\}. \tag{5}$$

We call measure of roughness used in the bounded differences class the *cut metric*, given by replacing the ℓ_1 norm used to define the total variation metric by the ℓ_0 norm, i.e.,

$$\|\nabla_G \theta\|_0 = \sum_{e \in E} 1\{\theta_{e^+} \neq \theta_{e^-}\},$$

which counts the number of nonzero edge differences that appear in θ. Hence, we may think of the former class in (4) as representing a type of weak sparsity across these edge differences, and the latter class in (5) as representing a type of strong sparsity in edge differences.

When dealing with the chain graph, on n vertices, we will use the following modifications to our notation. We write $\nabla_{1\mathrm{d}} \in \mathbb{R}^{(n-1)\times n}$ for the edge incidence matrix of the chain, i.e.,

$$\nabla_{1\mathrm{d}} = \begin{bmatrix} -1 & 1 & 0 & \ldots & 0 \\ 0 & -1 & 1 & \ldots & 0 \\ \vdots & & \ddots & \ddots & \\ 0 & 0 & \ldots & -1 & 1 \end{bmatrix}. \tag{6}$$

We also write $\hat{\theta}_{1\mathrm{d}}$ for the solution of the fused lasso problem in (2) over the chain, also called the *1d fused lasso* solution, i.e., to be explicit,

$$\hat{\theta}_{1\mathrm{d}} = \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y - \theta\|_2^2 + \lambda \sum_{i=1}^{n-1} |\theta_{i+1} - \theta_i|. \tag{7}$$

We write $\mathrm{BV}_{1\mathrm{d}}(t)$ and $\mathrm{BD}_{1\mathrm{d}}(s)$ for the bounded variation and bounded differences classes with respect to the chain, i.e., to be explicit,

$$\mathrm{BV}_{1\mathrm{d}}(t) = \{\theta \in \mathbb{R}^n : \|\nabla_{1\mathrm{d}}\theta\|_1 \leq t\},$$
$$\mathrm{BD}_{1\mathrm{d}}(s) = \{\theta \in \mathbb{R}^n : \|\nabla_{1\mathrm{d}}\theta\|_0 \leq s\}.$$

Lastly, in addition to the standard notation $a_n = O(b_n)$, for sequences a_n, b_n such that a_n/b_n is upper bounded for n large enough, we use $a_n \asymp b_n$ to denote that both $a_n = O(b_n)$ and $a_n^{-1} = O(b_n^{-1})$. Also, for random sequences A_n, B_n, we use $A_n = O_{\mathbb{P}}(B_n)$ to denote that A_n/B_n is bounded in probability.

1.3 Related work

Since its inception in the signal processing and statistics communities in Rudin et al. (1992) and Tibshirani et al. (2005), respectively, there has been an impressive amount of work on total variation penalization and the fused lasso. We do not attempt to give a complete coverage, but point out some relevant computational and theoretical advances, covering the two categories separately.

Computational. On the computational side, it is first worth pointing out that there are multiple efficient algorithms for solving the fused lasso problem over a chain graph, i.e., the 1d fused lasso problem. Davies and Kovac (2001) derived an algorithm based on a "taut string" perspective that solves the 1d fused lasso problem in $O(n)$ time (but, the fact

that their taut string method solves the 1d fused lasso problem was not explicitly stated in the work). This was later extended by Condat (2012); Barbero and Sra (2014) to allow for arbitrary weights in both of the individual penalty and loss terms. Johnson (2013) proposed an entirely different $O(n)$ time algorithm for the fused lasso based on dynamic programming. The taut string and dynamic programming algorithms are extremely fast in practice (e.g., they can solve a 1d fused lasso problem with n in the tens of millions in just a few seconds on a standard laptop).

Kolmogorov et al. (2016) extended the dynamic programming approach of Johnson (2013) to solve the fused lasso problem on a tree. Their algorithm is theoretically very efficient, with $O(n \log n)$ running time, but the implementation that achieves this running time (we have found) can be practically slow for large problem sizes, compared to dynamic programming on a chain graph. Alternative implementations are possible, and may well improve practical efficiency, but as far as we see it, they will all involve somewhat sophisticated data structures in the "merge" steps in the forward pass of dynamic programming.

Barbero and Sra (2014) extended (though not in the same direct manner) fast 1d fused lasso optimizers to work over grid graphs, using operator splitting techniques like Douglas-Rachford splitting. Their techniques appear to be quite efficient in practice, and the authors provide thorough comparisons and a thorough literature review of related methods. Over general graphs structures, many algorithms have been proposed, e.g., to highlight a few: Chambolle and Darbon (2009) described a direct algorithm based on a reduction to parametric max flow programming; Hoefling (2010); Tibshirani and Taylor (2011) gave solution path algorithms (tracing out the solution in (2) over all $\lambda \in [0, \infty]$); Chambolle and Pock (2011) described what can be seen as a kind of preconditioned ADMM-style algorithm; Kovac and Smith (2011) described an active set approach; Tansey and Scott (2015) leveraged fast 1d fused lasso solvers in an ADMM decomposition over trails of the graph; most recently, Landrieu and Obozinski (2015) derived a new method based on graph cuts. We emphasize that, even with the advent of these numerous clever computational techniques for the fused lasso over general graphs, it is still far slower to solve the fused lasso over an arbitrary graph than it is to solve the fused lasso over a chain.

Theoretical. On the theoretical side, it seems that the majority of statistical theory on the fused lasso can be placed into two categories: analysis of changepoint recovery, and analysis of MSE. Some examples of works focusing on changepoint recovery are Rinaldo (2009); Harchaoui and Levy-Leduc (2010); Qian and Jia (2012); Rojas and Wahlberg (2014). The statistical theory will concern MSE rates, and hence we give a more detailed review of related literature for this topic.

We begin with results for chain graphs. Mammen and van de Geer (1997) proved, when $\theta_0 \in \mathrm{BV}_{1\mathrm{d}}(t)$, that the 1d fused lasso estimator estimator $\hat{\theta}_{1\mathrm{d}}$ with $\lambda \asymp t^{-1/3} n^{1/3}$ satisfies

$$\|\hat{\theta}_{1\mathrm{d}} - \theta_0\|_n^2 = O_{\mathbb{P}}(t^{2/3} n^{-2/3}). \tag{8}$$

This is indeed the minimax MSE rate for the class $\mathrm{BV}_{1\mathrm{d}}(t)$, as implied by the minimax results in Donoho and Johnstone (1998). (For descriptions of the above upper bound and this minimax rate in a language more in line with that of the current paper, see Tibshirani (2014).) Recently, Lin et al. (2016) improved on earlier results for the bounded differences class in Dalalyan et al. (2014), and proved that when $\theta_0 \in \mathrm{BD}_{1\mathrm{d}}(s)$, the 1d fused lasso

estimator $\hat{\theta}_{1\mathrm{d}}$ with $\lambda \asymp (nW_n)^{1/4}$ satisfies

$$\|\hat{\theta}_{1\mathrm{d}} - \theta_0\|_n^2 = O_{\mathbb{P}}\bigg(\frac{s}{n}\Big((\log s + \log\log n)\log n + \sqrt{n/W_n}\Big)\bigg), \tag{9}$$

where W_n denotes the minimum distance between positions at which nonzero differences occur in θ_0, more precisely, $W_n = \min\{|i-j| : (\nabla_{1\mathrm{d}}\theta_0)_i \neq 0, (\nabla_{1\mathrm{d}}\theta_0)_j \neq 0\}$. When these nonzero differences or "jumps" in θ_0 are evenly spaced apart, we have $W_n \asymp n/s$, and the above becomes, for $\lambda \asymp \sqrt{n}s^{-1/4}$,

$$\|\hat{\theta}_{1\mathrm{d}} - \theta_0\|_n^2 = O_{\mathbb{P}}\bigg(\frac{s(\log s + \log\log n)\log n}{n} + \frac{s^{3/2}}{n}\bigg). \tag{10}$$

This is quite close to the minimax lower bound, whose rate is $s\log(n/s)/n$, that we establish for the class $\mathrm{BD}_{1\mathrm{d}}(s)$, in Theorem 8. (The minimax lower bound that we prove in this theorem actually holds beyond the chain graph, and applies to tree graphs). We can see that the 1d fused lasso rate in (10) is only off by a factor of $\log\log n$, provided that s does not grow too fast (specifically, $s = O((\log n \log\log n)^2)$).

Beyond chain graphs, the story is in general much less clear, however, interesting results are known in special cases. For a d-dimensional grid graph, with $d \geq 2$, Hutter and Rigollet (2016) recently improved on results of Wang et al. (2016), showing that for $\theta_0 \in \mathrm{BV}_G(t) \cap \mathrm{BD}_G(s)$, the fused lasso estimator $\hat{\theta}_G$ over G satisfies

$$\|\hat{\theta}_G - \theta_0\|_n^2 = O_{\mathbb{P}}\bigg(\min\{t, s\}\frac{\log^a n}{n}\bigg). \tag{11}$$

when $\lambda \asymp \log^{a/2} n$, where $a = 2$ if $d = 2$, and $a = 1$ if $d \geq 3$. A minimax lower bound on the MSE rate for the $\mathrm{BV}_G(t)$ class over a grid G of dimension $d \geq 2$ was established to be $t\sqrt{\log(n/t)/n}$, by Sadhanala et al. (2016). This makes the rate achieved by the fused lasso in (11) nearly optimal for bounded variation signals, off by at most a $\log^{3/2} n$ factor when $d = 2$, and a $\log n$ factor when $d \geq 3$.

Wang et al. (2016); Hutter and Rigollet (2016) also derived MSE rates for the fused lasso over several other graph structures, such as Erdos-Renyi random graphs, Ramanujan d-regular graphs, star graphs, and complete graphs. As it is perhaps the most relevant to our goals in this paper, we highlight the MSE bound from Wang et al. (2016) that applies to arbitrary connected graphs. Their Theorem 3 implies, for a generic connected graph G, $\theta_0 \in \mathrm{BV}_G(t)$, that the fused lasso estimator $\hat{\theta}_G$ over G with $\lambda \asymp \sqrt{n\log n}$ satisfies

$$\|\hat{\theta}_G - \theta_0\|_n^2 = O_{\mathbb{P}}\bigg(t\sqrt{\frac{\log n}{n}}\bigg). \tag{12}$$

(See Appendix A.1 for details.) In Theorem 4, we show that the universal $tn^{-1/2}$ rate (ignoring log terms) in (12) for the fused lasso over an arbitrary connected graph can be improved to $t^{2/3}n^{-2/3}$. In Theorem 3, we show that the same rate can indeed be achieved by a simple, linear-time algorithm: the DFS fused lasso.

1.4 Outline

In Section 2, we review a simple but key lemma relating the ℓ_1 norm (and ℓ_0) norm of differences on a tree and a chain induced by running DFS. (This follows closely from an analogous result on binary signals, in Herbster et al. (2009).) We then define the DFS fused lasso estimator. In Section 3, we derive MSE rates for the DFS fused lasso, and the fused lasso over the original graph G under consideration, for signals of bounded variation. We also derive lower bounds for the minimax MSE over trees. In Section 4, we proceed similarly but for signals in the bounded differences class. In Section 5, we present numerical experiments. In Section 6, we summarize our work and also describe some potential extensions.

2. The DFS fused lasso

In this section, we define the DFS-induced chain graph and the DFS fused lasso.

2.1 Tree and chain embeddings

We start by studying some of the fundamental properties associated with total variation on general graphs, and embedded trees and chains. Given a graph $G = (V, E)$, let $T = (V, E_T)$ be an arbitrary spanning tree of G. It is clear that for any signal, its total variation over T is no larger than its total variation over G,

$$\|\nabla_T\theta\|_1 = \sum_{e\in E_T} |\theta_{e^+} - \theta_{e^-}| \leq \sum_{e\in E} |\theta_{e^+} - \theta_{e^-}| = \|\nabla_G\theta\|_1, \quad \text{for all } \theta \in \mathbb{R}^n. \tag{13}$$

The above inequality, albeit very simple, reveals to us the following important fact: if the underlying mean θ_0 in (1) is assumed to be smooth with respect to the graph G, inasmuch as $\|\nabla_G\theta_0\|_1 \leq t$, then it must also be smooth with respect to any spanning tree T of G, since $\|\nabla_T\theta_0\|_1 \leq t$. Roughly speaking, computing the fused lasso solution in (2) over a spanning tree T, instead of G, would therefore still be reasonable for the denoising purposes, as the mean θ_0 would still be smooth over T according to the total variation metric.

The same property as in (14) also holds if we replace total variation by the cut metric:

$$\|\nabla_T\theta\|_0 = \sum_{e\in E_T} 1\{\theta_{e^+} \neq \theta_{e^-}\} \leq \sum_{e\in E} 1\{\theta_{e^+} \neq \theta_{e^-}\} = \|\nabla_G\theta\|_0, \quad \text{for all } \theta \in \mathbb{R}^n. \tag{14}$$

Thus for the mean θ_0, the property $\|\nabla_G\theta_0\|_0 \leq s$ again implies $\|\nabla_T\theta_0\|_0 \leq s$ for any spanning tree T of G, and this would again justify solving the fused lasso over T, in place of G, assuming smoothness of θ_0 with respect to the cut metric in the first place.

Here we go one step further than (13), (14), and assert that analogous properties actually hold for specially embedded chain graphs. The next lemma gives the key result.

Lemma 1 *Let $G = (V, E)$ be a connected graph, where recall we write $V = \{1, \ldots, n\}$. Consider depth-first search (DFS) run on G, and denote by $v_1, \ldots, v_n$ the nodes in the order in which they are reached by DFS. Hence, DFS first visits v_1, then v_2, then v_3, etc. This induces a bijection $\tau : \{1, \ldots, n\} \to \{1, \ldots, n\}$, such that*

$$\tau(i) = v_i, \quad \textit{for all } i = 1, \ldots, n.$$

Let $P \in \mathbb{R}^{n \times n}$ denote the permutation associated with τ. Then it holds that

$$\|\nabla_{1\mathrm{d}} P\theta\|_1 \leq 2\|\nabla_G \theta\|_1, \quad \textit{for all } \theta \in \mathbb{R}^n, \tag{15}$$

as well as

$$\|\nabla_{1\mathrm{d}} P\theta\|_0 \leq 2\|\nabla_G \theta\|_0, \quad \textit{for all } \theta \in \mathbb{R}^n. \tag{16}$$

Proof The proof is simple. Observe that

$$\|\nabla_{1\mathrm{d}} P\theta\|_1 = \sum_{i=1,\ldots,n-1} |\theta_{\tau(i+1)} - \theta_{\tau(i)}|, \tag{17}$$

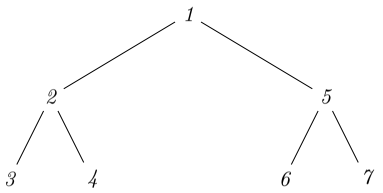
and consider an arbitrary summand $|\theta_{\tau(i+1)} - \theta_{\tau(i)}|$. There are now two cases to examine. First, suppose $\tau(i)$ is not a leaf in the spanning tree constructed by DFS; then there is an edge $e \in E$ such that $\{e^-, e^+\} = \{\tau(i), \tau(i+1)\}$, and $|\theta_{\tau(i+1)} - \theta_{\tau(i)}| = |\theta_{e^+} - \theta_{e^-}|$. Second, suppose that $\tau(i)$ is a leaf node in the DFS tree; then there is a path $p = \{p_1, \ldots, p_r\}$ in the graph such that $p_1 = \tau(i)$, $p_r = \tau(i+1)$, and each $\{p_j, p_{j+1}\} \in E$, $j = 1, \ldots, r-1$, so that by the triangle inequality

$$|\theta_{\tau(i+1)} - \theta_{\tau(i)}| \leq \sum_{j=1}^{r-1} |\theta_{p_{j+1}} - \theta_{p_j}|.$$

Applying this logic over all terms in the sum in (17), and invoking the fundamental property that DFS visits each edge exactly twice (e.g., Chapter 22 of Cormen et al. (2001)), we have established (15). The proof for (16) follows from precisely the same arguments. ■

Remark 2 *Lemma 1 has essentially already appeared in the literature, in a form for binary signals and a roughness metric given by the quadratic form in the graph Laplacian (in place the total variation metric or cut metric), see Herbster et al. (2009). The key idea behind this result and ours is the same, and the proof of Lemma 1 only requires minor modifications. For completeness, we have presented Lemma 1 and its proof anyway. More generally, we should note that graph embeddings—in particular, using chains and trees—are well-known in the online graph-based classification setting. See, e.g., Herbster et al. (2009); Cesa-Bianchi et al. (2013), and references therein.*

Example 1 *The idea behind Lemma 1 can also be clearly demonstrated through an example. We consider G to be a binary tree graph with $n = 7$ nodes, shown below, where we have labeled the nodes according to the order in which they are visited by DFS (i.e., so that here P is the identity).*



In this case,

$$\begin{aligned}
\|\Delta_{1\mathrm{d}}\theta\|_1 &= \sum_{i=1}^{6} |\theta_{i+1} - \theta_i| \\
&\leq |\theta_2 - \theta_1| + |\theta_3 - \theta_2| + \big(|\theta_3 - \theta_2| + |\theta_4 - \theta_2|\big) + \big(|\theta_4 - \theta_2| + |\theta_2 - \theta_1| + |\theta_5 - \theta_1|\big) \\
&\quad + |\theta_6 - \theta_5| + \big(|\theta_6 - \theta_5| + |\theta_7 - \theta_5|\big) \\
&\leq 2 \sum_{e \in G} |\theta_{e^+} - \theta_{e^-}| = 2\|\nabla_G \theta\|_1,
\end{aligned}$$

where in the inequality above, we have used triangle inequality for each term in parentheses individually.

2.2 The DFS fused lasso

We define the DFS fused lasso estimator, $\hat{\theta}_{\mathrm{DFS}}$, to be the fused lasso estimator over the chain graph induced by running DFS on G. Formally, if τ denotes the bijection associated with the DFS ordering (as described in Lemma 1), then the DFS-induced chain graph can be expressed as $C = (V, E_C)$ where $V = \{1, \ldots, n\}$ and $E_C = \{\{\tau(1), \tau(2)\}, \ldots, \{\tau(n-1), \tau(n)\}\}$. Denoting by P the permutation matrix associated with τ, the edge incidence matrix of C is simply $\nabla_C = \nabla_{1\mathrm{d}} P$, and the DFS fused lasso estimator is given by

$$\begin{aligned}
\hat{\theta}_{\mathrm{DFS}} &= \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y - \theta\|_2^2 + \lambda \|\nabla_{1\mathrm{d}} P\theta\|_1 \\
&= P^\top \left(\operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|Py - \theta\|_2^2 + \lambda \sum_{i=1}^{n-1} |\theta_{i+1} - \theta_i| \right).
\end{aligned} \tag{18}$$

Therefore, we only need to compute the 1d fused lasso estimator on a permuted data vector Py, and apply the inverse permutation operator $P^\top$, in order to compute $\hat{\theta}_{\mathrm{DFS}}$.

Given the permutation matrix P, the computational cost of (18) is $O(n)$, since, to recall the discussion in Section 1.3, the 1d fused lasso problem (7) can be solved in $O(n)$ operations with dynamic programming or taut string algorithms. The permutation P is obtained by running DFS, which requires $O(m)$ operations, and makes the total computation cost of the DFS fused lasso estimator $O(m+n)$.

It should be noted that, when multiple estimates are desired over the same graph G, we must only run DFS once, and all subsequent estimates on the induced chain require just $O(n)$ operations.

The bounds in (15), (16) for the DFS chain are like those in (13), (14) for spanning trees, and carry the same motivation as that discussed above for spanning trees, beneath (13), (14): if the mean θ_0 is assumed to be smooth with respect to t, insofar as its total variation satisfies $\|\nabla_G \theta_0\|_1 \leq t$, then denoising with respect to C would also be reasonable, in that $\|\nabla_{1\mathrm{d}} P\theta_0\|_1 \leq 2t$; the same can be said for the cut metric. However, it is the rapid $O(m+n)$ computational cost of the DFS fused lasso, and also the simplicity of the dynamic programming and taut string algorithms for the 1d fused lasso problem (7), that make (15), (16) particularly appealing compared to (13), (14). To recall the discussion in Section 1.3, the fused lasso can in principle be computed efficiently over a tree, in $O(n \log n)$ operations

using dynamic programming, but this requires a much more cumbersome implementation and in practice we have found it to be noticeably slower.

2.3 Running DFS on a spanning tree

We can think of the induced chain graph, as described in the last section, as being computed in two steps:

(i) run DFS to compute a spanning tree T of G;

(ii) run DFS on the spanning tree T to define the chain C.

Clearly, this is the same as running DFS on G to define the induced chain C, so decomposing this process into two steps as we have done above may seem odd. But this decomposition provides a useful perspective because it leads to the idea that we could compute the spanning tree T in Step (i) in any fashion, and then proceed with DFS on T in Step (ii) in order to define the chain C. Indeed, any spanning tree in Step (i) will lead to a chain C that has the properties (15), (16) as guaranteed by Lemma 1. This may be of interest if we could compute a spanning tree T that better represents the topology of the original graph G, so that the differences over the eventual chain C better mimicks those over G.

An example of a spanning tree whose topology is designed to reflect that of the original graph is a low-stretch spanning tree. Current interest on low-stretch spanning trees began with the breakthrough results in Elkin et al. (2008); most recently, Abraham and Neiman (2012) showed that a spanning tree with average stretch $O(\log n \log\log n)$ can be computed in $O(m \log n \log\log n)$ operations.

In Section 6.4, we discuss a setting in which the fused lasso problem (2) has arbitrary penalty weights, which gives rise to a weighted graph G. In this setting, an example of a spanning tree that can be crafted so that its edges represent important differences in the original graph is a maximum spanning tree. Prim's and Kruskal's minimum spanning tree algorithms, each of which take $O(m \log n)$ time (Cormen et al., 2001), can be used to compute a maximum spanning tree after we negate all edge weights.

2.4 Averaging multiple DFS estimators

Notice that several DFS-induced chains can be formed from a single seed graph G, by running DFS itself on G with different random starts (or random decisions about which edge to follow at each step in DFS), or by computing different spanning trees T of G (possibly themselves randomized) on which we run DFS, or by some combination, etc. Denoting by $\hat{\theta}^{(1)}_{\mathrm{DFS}}, \hat{\theta}^{(2)}_{\mathrm{DFS}}, \ldots, \hat{\theta}^{(K)}_{\mathrm{DFS}}$ the DFS fused lasso estimators fit to K different induced chains, we might believe that the average estimator, $(1/K)\sum_{k=1}^K \hat{\theta}^{(k)}_{\mathrm{DFS}}$, will have good denoising performance, as it incorporates fusion at each node in multiple directions. In Section 5, we demonstrate that this intuition holds true (at least, across the set of experiments we consider).

3. Analysis for signals of bounded variation

Throughout this section, we assume that the underlying mean θ_0 in (1) satisfies $\theta_0 \in \mathrm{BV}_G(t)$ for a generic connected graph G. We derive upper bounds on the MSE rates of the DFS fused lasso and the fused lasso over G. We also derive a tight lower bound on the minimax MSE when G is a tree that has bounded degree.

3.1 The DFS fused lasso

The analysis for the DFS fused lasso estimator is rather straightforward. By assumption, $\|\nabla_G \theta_0\|_1 \leq t$, and thus $\|\nabla_{1\mathrm{d}} P\theta_0\|_1 \leq 2t$ by (15) in Lemma 1. Hence, we may think of our model (1) as giving us i.i.d. data Py around $P\theta_0 \in \mathrm{BV}_{1\mathrm{d}}(2t)$, and we may apply existing results from Mammen and van de Geer (1997) on the 1d fused lasso for bounded variation signals, as described in (8) in Section 1.3. This establishes the following.

Theorem 3 *Consider a data model* (1)*, with i.i.d. sub-Gaussian errors as in* (3)*, and* $\theta_0 \in \mathrm{BV}_G(t)$*, where* G *is a generic connected graph. Then for any DFS ordering of* G *yielding a permutation matrix* P*, the DFS fused lasso estimator* $\hat{\theta}_{\mathrm{DFS}}$ *in* (18)*, with a choice of tuning parameter* $\lambda \asymp t^{-1/3} n^{1/3}$*, has MSE converging in probability at the rate*

$$\|\hat{\theta}_{\mathrm{DFS}} - \theta_0\|_n^2 = O_{\mathbb{P}}(t^{2/3} n^{-2/3}). \tag{19}$$

We note that, if multiple DFS fused lasso estimators $\hat{\theta}^{(1)}_{\mathrm{DFS}}, \hat{\theta}^{(2)}_{\mathrm{DFS}}, \ldots, \hat{\theta}^{(K)}_{\mathrm{DFS}}$ are computed across multiple different DFS-induced chains on G, then the average estimator clearly satisfies the same bound as in (19),

$$\left\| \frac{1}{K} \sum_{k=1}^K \hat{\theta}^{(k)}_{\mathrm{DFS}} - \theta_0 \right\|_n^2 = O_{\mathbb{P}}(t^{2/3} n^{-2/3}),$$

provided that K is held constant, by the triangle inequality.

3.2 The graph fused lasso

Interestingly, the chain embedding result (15) in Lemma 1 is not only helpful for establishing the MSE rate for the DFS fused lasso estimator in Theorem 3, but it can also be used to improve the best known rate for the original fused lasso estimator over the graph G. In Section 1.3, we described a result (12) that follows from Wang et al. (2016), establishing an MSE rate of $tn^{-1/2}$ rate (ignoring log terms) for the fused lasso estimator over a connected graph G, when $\|\nabla_G \theta_0\|_1 \leq t$. In fact, as we will now show, this can be improved to a rate of $t^{2/3} n^{-2/3}$, just as in (19) for the DFS fused lasso.

Wang et al. (2016) present a framework for deriving fast MSE rates for fused lasso estimators based on entropy. They show in their Lemma 9 that a bound in probability on the sub-Gaussian complexity

$$\max_{x \in \mathcal{S}_G(1)} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}}, \tag{20}$$

for some $0 < w < 2$, where $\mathcal{S}_G(1) = \{x \in \mathrm{row}(\nabla_G) : \|\nabla_G x\|_1 \leq 1\}$, leads to a bound in probability on the MSE of the fused lasso estimator $\hat{\theta}_G$ over G. (Wang et al. (2016) actually assume Gaussian errors, but their Lemma 9, Theorem 10, Lemma 11, and Corollary 12 still hold for sub-Gaussian errors as in (3)). The sub-Gaussian complexity in (20) is typically controlled via an entropy bound on the class $\mathcal{S}_G(1)$. Typically, one thinks of controlling

entropy by focusing on specific classes of graph structures G. Perhaps surprisingly, Lemma 1 shows we can uniformly control the sub-Gaussian complexity (20) over all connected graphs.

For any DFS-induced chain C constructed from G, note first that

$$\mathrm{row}(\nabla_G) = \mathrm{span}\{\mathbb{1}\}^\perp = \mathrm{row}(\nabla_C),$$

where $\mathbb{1} = (1, \ldots, 1) \in \mathbb{R}^n$ is the vector of all 1s. This, and (15) in Lemma 1, imply that

$$\max_{x \in \mathcal{S}_G(1)} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}} \leq \max_{x \in \mathcal{S}_C(2)} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}}.$$

Now, taking $w = 1$,

$$\max_{x \in \mathcal{S}_C(2)} \frac{\epsilon^\top x}{\|x\|_2^{1/2}} = \max_{\substack{x \,:\, \mathbb{1}^\top x = 0, \\ \|\nabla_{1\mathrm{d}} P x\|_1 \leq 2}} \frac{\epsilon^\top x}{\|x\|_2^{1/2}} = \max_{\substack{x \,:\, \mathbb{1}^\top x = 0, \\ \|\nabla_{1\mathrm{d}} x\|_1 \leq 1}} \frac{2^{-1/2}(P\epsilon)^\top x}{\|x\|_2^{1/2}} = O_{\mathbb{P}}(n^{1/4}).$$

The last step (asserting that the penultimate term is $O_{\mathbb{P}}(n^{1/4})$) holds by first noting that $P\epsilon$ is equal in law to ϵ (as we have assumed i.i.d. components of the error vector), and then applying results on the chain graph in Theorem 10, Lemma 11, and Corollary 12 of Wang et al. (2016). Applying Lemma 9 of Wang et al. (2016), we have now established the following result.

Theorem 4 *Consider a data model* (1)*, with i.i.d. sub-Gaussian errors as in* (3)*, and* $\theta_0 \in \mathrm{BV}_G(t)$*, where* G *is a generic connected graph. Then the fused lasso estimator* $\hat{\theta}_G$ *over* G*, in* (2)*, under a choice of tuning parameter* $\lambda \asymp t^{-1/3} n^{1/3}$*, has MSE converging in probability at the rate*

$$\|\hat{\theta}_G - \theta_0\|_n^2 = O_{\mathbb{P}}(t^{2/3} n^{-2/3}). \tag{21}$$

In a sense, the above theorem suggests that the chain graph is among the hardest graphs for denoising bounded variation signals, since the fused lasso estimator on any connected graph G will achieve an MSE rate in that is at least as good as in the chain rate, if not better. In this vein, it is worth emphasizing that the MSE bound in (21) is not tight for certain graph structures; a good example is the 2d grid, where we must compare (21) from the theorem to the known MSE bound in (11) from Hutter and Rigollet (2016), the latter being only log factors from optimal, as shown in Sadhanala et al. (2016). It is natural for the 2d grid graph to consider the scaling $t \asymp \sqrt{n}$ (as argued in Sadhanala et al. (2016)), in which case the rates for the fused lasso estimator are $n^{-1/3}$ from Theorem 4 versus $(\log^2 n) n^{-1/2}$ from Hutter and Rigollet (2016).

3.3 Minimax lower bound over trees

We derive a lower bound for the MSE over the class $\mathrm{BV}_G(t)$ when G is a tree graph. The proof applies Assouad's Lemma (Yu, 1997), over a discrete set of probability measures constructed by a careful partitioning of the vertices of G, that balances both the sizes of each partition element and the number of edges crossing in between partition elements. It is deferred until Appendix A.2.

Theorem 5 *Consider a data model* (1)*, with i.i.d. Gaussian errors* $\epsilon_i \sim N(0, \sigma^2)$*,* $i = 1, \ldots, n$*, and with* $\theta_0 \in \mathrm{BV}_G(t)$*, where* G *is a tree graph, having maximum degree* $d_{\max}$*. Then there exists absolute constants* $N, C > 0$*, such that for* $n/(td_{\max}) > N$*,*

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BV}_G(t)} \mathbb{E}\|\hat{\theta} - \theta_0\|_n^2 \geq C\left(\frac{t}{\sigma d_{\max}^2 n}\right)^{2/3}. \tag{22}$$

The theorem demonstrates that, for trees of bounded degree, such as the chain and balanced d-ary trees, the fused lasso estimator over the tree achieves achieves the minimax rate, as does the DFS fused lasso.

4. Analysis for signals with bounded differences

We assume that the underlying mean θ_0 in (1) satisfies $\theta_0 \in \mathrm{BD}_G(s)$ for a generic connected graph G. We analyze the MSE of the DFS fused lasso, as well as (a particular formulation of) wavelet denoising over G. We again establish a lower bound on the minimax MSE when G is a tree.

4.1 The DFS fused lasso

As it was for the bounded variation case, the analysis for the DFS fused lasso estimator is straightforward. By assumption, $\|\nabla_G \theta_0\|_0 \leq s$, thus $\|\nabla_{1\mathrm{d}} P\theta_0\|_0 \leq 2s$ by (16) in Lemma 1, and we may think of our model (1) as having i.i.d. data Py around $P\theta_0 \in \mathrm{BD}_{1\mathrm{d}}(2s)$. Applying an existing result on the 1d fused lasso for bounded differences signals, as described in (9), from Lin et al. (2016), gives the following result.

Theorem 6 *Consider a data model* (1)*, with i.i.d. sub-Gaussian errors as in* (3)*, and* $\theta_0 \in \mathrm{BD}_G(s)$*, for a connected graph* G*. Consider an arbitrary DFS ordering of* G*, that defines a permutation matrix* P *and the DFS fused lasso estimator* $\hat{\theta}_{\mathrm{DFS}}$ *in* (18)*. Denote by* $W_n = \min\{|i - j| : (\nabla_{1\mathrm{d}} P\theta_0)_i \neq 0, (\nabla_{1\mathrm{d}} P\theta_0)_j \neq 0\}$ *the minimum distance between positions, measured along the DFS-induced chain, at which nonzero differences or jumps occur in* θ_0*. Then, under a choice of tuning parameter* $\lambda \asymp (nW_n)^{1/4}$*, the DFS fused lasso estimator has MSE converging in probability at the rate*

$$\|\hat{\theta}_{\mathrm{DFS}} - \theta_0\|_n^2 = O_{\mathbb{P}}\left(\frac{s}{n}\left((\log s + \log\log n)\log n + \sqrt{n/W_n}\right)\right). \tag{23}$$

Hence, if the s *jumps along the DFS chain are evenly spaced apart, i.e.,* $W_n \asymp n/s$*, then for* $\lambda \asymp \sqrt{n} s^{-1/4}$*,*

$$\|\hat{\theta}_{\mathrm{DFS}} - \theta_0\|_n^2 = O_{\mathbb{P}}\left(\frac{s(\log s + \log\log n)\log n}{n} + \frac{s^{3/2}}{n}\right). \tag{24}$$

An undesirable feature of applying existing 1d fused lasso results for signals with bounded differences, in the above result, is the dependence on W_n in the DFS fused lasso error bound (23) (we applied the result (9) from Lin et al. (2016), but the bounds from Dalalyan et al. (2014) also depend on W_n, and as far as we can tell, so should any analysis of the 1d fused

lasso for signals with bounded differences). In the 1d setting, assuming that $W_n \asymp n/s$, which says that jumps in θ_0 occur at roughly equally spaced positions, is fairly reasonable; but to assume the same when the jumps are measured with respect to the DFS-induced chain, as we must in order to establish (24), is perhaps not. Even if the differences apparent in θ_0 over edges in G are somehow (loosely speaking) spaced far apart, running DFS could well produce an ordering such that jumps in $P\theta_0$ occur at positions very close together. We reiterate that the MSE bounds for the DFS fused lasso for bounded variation signals, in Theorem 3, do not suffer from any such complications.

4.2 Graph wavelet denoising

We compare the performances of the DFS fused lasso and wavelet denoising using spanning tree wavelets, for signals with bounded differences. For spanning tree wavelets, the construction starts with a spanning tree and carefully defines a hierarchical decomposition by recursively finding and splitting around a balancing vertex, which is a vertex whose adjacent subtrees are of size at most half of the original tree; this decomposition is used to construct an unbalanced Haar wavelet basis, as in Singh et al. (2010). In Sharpnack et al. (2013), it was shown that for any connected graph G, the constructed wavelet basis $W \in \mathbb{R}^{n \times n}$ satisfies

$$\|W\theta\|_0 \leq \lceil \log d_{\max} \rceil \lceil \log n \rceil \|\nabla_G \theta\|_0, \quad \text{for all } \theta \in \mathbb{R}^n, \tag{25}$$

where $d_{\max}$ is the maximum degree of G, and the above holds regardless of choice of spanning tree in the wavelet construction. Now consider the wavelet denoising estimator

$$\hat{\theta}_W = \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y - \theta\|_2^2 + \lambda \|W\theta\|_1. \tag{26}$$

The following is an immediate consequence of (25), the fact that the wavelet basis W is orthonormal, and standard results about soft-thresholding (e.g., Lemma 2.8 in (Johnstone, 2011)).

Theorem 7 *Consider a data model (1), with i.i.d. Gaussian errors $\epsilon_i \sim N(0, \sigma^2)$, $i = 1, \ldots, n$, and with $\theta_0 \in \mathrm{BV}_G(t)$, where G is a connected graph, having maximum degree $d_{\max}$. Then the spanning tree wavelet estimator $\hat{\theta}_W$ in (26), with a choice $\lambda \asymp \sqrt{\log n}$, has MSE converging in expectation at the rate*

$$\mathbb{E}\|\hat{\theta}_W - \theta_0\|_n^2 = O\left(\frac{s \log d_{\max} \log^2 n}{n}\right). \tag{27}$$

The result in (27) has the advantage over the DFS fused lasso result in (23) that it does not depend on a hard-to-interpret quantity like W_n, the minimum spacing between jumps along the DFS-induced chain. But when (say) $d_{\max} \asymp 1$, $s \asymp 1$, and we are willing to assume that $W_n \asymp n$ (meaning the jumps of θ_0 occur at positions evenly spaced apart on the DFS chain), we can see that the spanning tree wavelet rate in (27) is just slightly slower than the DFS fused lasso rate in (24), by a factor of $\log n / \log\log n$.

While the comparison between the DFS fused lasso and wavelet rates, (23) and (27), show an advantage to spanning tree wavelet denoising, as it does not require assumptions about the spacings between nonzero differences in θ_0, we have found nonetheless that the

DFS fused lasso to performs well in practice compared to spanning tree wavelets, and indeed often outperforms the latter in terms of MSE. Experiments comparing the two methods are presented Section 5.

4.3 Minimax lower bound for trees

We now derive a lower bound for the MSE over the class $\mathrm{BD}_G(s)$ when G is a tree graph. The proof relates the current denoising problem to one of estimating sparse normal means, with a careful construction of the sparsity set using degree properties of trees. It is deferred until Appendix A.3.

Theorem 8 *Consider a data model (1), with i.i.d. Gaussian errors $\epsilon_i \sim N(0, \sigma^2)$, $i = 1, \ldots, n$, and with $\theta_0 \in \mathrm{BD}_G(s)$, where G is a tree. Then there are absolute constants $N, C > 0$, such that for $n/s > N$,*

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BD}_G(s)} \mathbb{E}\|\hat{\theta} - \theta_0\|_n^2 \geq C\sigma^2 \frac{s}{n} \log\left(\frac{n}{s}\right). \tag{28}$$

The MSE lower bound in (28) shows that, when we are willing to assume that $W_n \asymp n/s$ in the DFS-induced chain, the DFS fused lasso estimator is a $\log\log n$ factor away from the optimal rate, provided that s is not too large, namely $s = O((\log n \log\log n)^2)$. The spanning tree wavelet estimator, on the other hand, is a $\log n$ factor from optimal, without any real restrictions on s, i.e., it suffices to have $s = O(n^a)$ for some $a > 0$. It is worth remarking that, for large enough s, the lower bound in (28) is perhaps not very interesting, as in such a case, we may as well consider the bounded variation lower bound in (22), which will likely be tighter (faster).

5. Experiments

In this section we compare experimentally the speed and accuracy of two approaches for denoising signals on graphs: the graph fused lasso, and the fused lasso along the chain graph induced by a DFS ordering. In our experiments, we see that the DFS-based denoiser sacrifices a modest amount in terms of mean squared error, while providing gains (sometimes considerable) in computational speed. This shows that our main theorem, in addition to providing new insights on MSE rates for the graph fused lasso, also has important practice consequences. For truly massive problems, where the full graph denoising problem is impractical to solve, we may use the linear-time DFS fused lasso denoiser, and obtain a favorable tradeoff of accuracy for speed.

5.1 Generic graphs

We begin by considering three examples of large graphs of (more or less) generic structure, derived from road networks in three states: California, Pennsylvania, and Texas. Data on these road networks are freely available at `https://snap.stanford.edu`. In these networks, intersections and endpoints are represented by nodes, and roads connecting these intersections or endpoints are represented by undirected edges; see Leskovec et al. (2009) for more details. For each network, we use the biggest connected component as our graph structure to run comparisons. The graph corresponding to California has $n = 1957027$ nodes

and $m = 2760388$ edges, the one for Pennsylvania has $n = 1088092$ nodes and $m = 1541898$ edges, and the graph for Texas has $n = 1351137$ nodes and $m = 1879201$ edges. We compare Laplacian smoothing versus the fused lasso over a DFS-induced chain, on the graphs from the three states. We do not compare with the fused lasso over the original graphs, due to its prohibitive computational cost at such large scales.

We used the following procedure to construct a synthetic signal $\theta_0 \in \mathbb{R}^n$ on each of the road network graphs, of piecewise constant nature:

- an initial seed node v_1 is selected uniformly at random from the nodes $V = \{1, \dots, n\}$ in the graph;
- a component C_1 is formed based on the $\lfloor n/10 \rfloor$ nodes closest to v_1 (where the distance between two nodes in the graph is given by the length of the shortest path between them);
- a second seed node v_2 is selected uniformly at random from $G \setminus C_1$;
- a component C_2 is formed based on the $\lfloor n/10 \rfloor$ nodes closest to v_2 (again in shortest path distance);
- this process is repeated[1] until we have a partition $C_1, \dots, C_{10}$ of the node set V into components of (roughly) equal size, and $\theta_0 \in \mathbb{R}^n$ is defined to take constant values on each of these components.

In our experiments, we considered 20 values of the total variation for the underlying signal. For each, the signal θ_0 was scaled appropriately to achieve the given total variation value, and data $y \in \mathbb{R}^n$ was generated by adding i.i.d. $N(0, 0.2^2)$ noise to the components of θ_0. For each data instance y, the DFS fused lasso and Laplacian smoothing estimators, the former defined by (18) and the latter by

$$\hat{\theta}_{\text{Lap}} = \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y - \theta\|_2^2 + \lambda \theta^\top L_G \theta, \tag{29}$$

where $L_G = \nabla_G^\top \nabla_G$ is the Laplacian matrix of the given graph G, and each estimator is computed over 20 values of its own tuning parameter. Then, the value of the tuning parameter minimizing the average MSE, over 50 draws of data y around θ_0, was selected for each method. Finally, this optimized MSE, averaged over the 50 draws of data y, and further, over 10 repetitions of the procedure for constructing the signal θ_0 explained above, was recorded. Figure 1 displays the optimized MSE for the DFS fused lasso and Laplacian smoothing, as the total variation of the underlying signal varies, for the three road network graphs.

As we can see from the figure, for low values of the underlying total variation, i.e., low signal-to-noise ratio (SNR) levels, Laplacian smoothing and the DFS fused lasso, each tuned to optimality, perform about the same. This is because at low enough SNR levels, each will be approximating θ_0 by something like $\bar{y}\mathbb{1}$, with $\bar{y}$ being the sample average of the data vector y. But as the SNR increases, we see that the DFS fused lasso outpeforms

1. Here, whenever isolated small components are unintentionally created, we add them to the big components

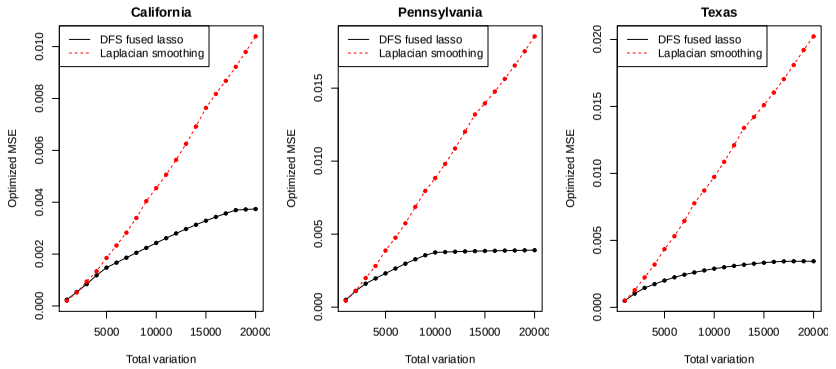


Figure 1: *The optimized MSE for the DFS fused lasso and Laplacian smoothing (i.e., MSE achieved by these methods under optimal tuning) is plotted as a function of the total variation of the underlying signal, for each of the three road network graphs. This has been averaged over 50 draws of data y for each construction of the underlying signal θ_0, and 10 repetitions in constructing θ_0 itself. For low values of the underlying total variation, i.e., low SNR levels, the two methods perform about the same, but as the SNR increases, the DFS fused lasso outperforms Laplacian smoothing by a considerable margin.*

Laplacian smoothing by a considerable amount. This might seem surprising, as Laplacian smoothing uses information from the entire graph, whereas the DFS fused lasso reduces the rich structure of the road network graph in each case to that of an embedded chain. However, Laplacian smoothing is a linear smoother (meaning that $\hat{\theta}_{\text{Lap}}$ in (29) is a linear function of the data y), and therefore it comes with certain limitations when estimating signals of bounded variation (e.g., see the seminal work of Donoho and Johnstone (1998), and the more recent graph-based work of Sadhanala et al. (2016)). In contrast, the DFS fused lasso is a nonlinear estimator, and while it discards some information in the original graph structure, it retains enough of the strong adaptivity properties of the fused lasso over the original graph to statistically dominate a linear estimator like Laplacian smoothing.

Lastly, in terms of computational time, it took an average of 82.67 seconds, 44.02 seconds, and 54.49 seconds to compute the 20 DFS fused lasso solutions (i.e., over the 20 tuning parameter values) for the road network graphs from California, Pennsylvania, and Texas, respectively (the averages are taken over the 50 draws of data y around each signal θ_0, and the 10 repetitions in constructing θ_0). By comparison, it took an average of 2748.26 seconds, 1891.97 seconds, and 1487.36 seconds to compute the 20 Laplacian smoothing solutions for the same graphs. The computations and timings were performed on a standard laptop computer (with a 2.80GHz Intel Core i7-2640M processor). For the DFS fused lasso, in each problem instance, we first computed a DFS ordering using the `dfs` function from the R package `igraph`, which is an R wrapper for a C++ implementation of DFS, and initialized the algorithm at a random node for the root. We then computed the appropriate 1d fused lasso solutions using the `trendfilter` function from the R package `glmgen`, which

is an R wrapper for a C++ implementation of the fast (linear-time) dynamic programming algorithm in Johnson (2013). For Laplacian smoothing, we used the `solve` function from the R package `Matrix`, which is an R wrapper for a C++ implementation of the sparse Cholesky-based solver in Davis and Hager (2009). For such large graphs, alternative algorithms, such as (preconditioned) conjugate gradient methods, could certainly be more efficient in computing Laplacian smoothing solutions; our reported timings are only meant to indicate that the DFS fused lasso is efficiently computable at problem sizes that are large enough that even a simple linear method like Laplacian smoothing becomes nontrivial.

5.2 2d grid graphs

Next we consider a denoising example on a 2d grid graph of dimension 1000×1000, so that the number of nodes is $n = 1000000$ and the number of edges is $m = 1998000$. We generated a synthetic piecewise constant signal $\theta_0 \in \mathbb{R}^{1000 \times 1000}$ over the 2d grid, shown in the top left corner of Figure 2, where a color scale (displayed in the accompanying color legend) is used, with red denoting the smallest possible value and yellow the largest possible value. Data $y \in \mathbb{R}^{1000 \times 1000}$ was generated by adding i.i.d. $N(0, 1)$ noise to the components of θ_0, displayed in the top middle panel of Figure 2. We then computed the 2d fused lasso solution, i.e., the fused lasso solution over the full 2d grid[2] graph, as well as three DFS-based variations: the DFS fused lasso solution using a random DFS ordering (given by running DFS beginning at a random node), labeled as "1 random DFS" in the figure; the average of DFS fused lasso solutions over 5 random DFS orderings, labeled "5 random DFS" in the figure; and the average of DFS fused lasso solutions over 2 "snake" DFS orderings (one given by collecting and joining all horizontal edges and the other all vertical edges) labeled "2 snake DFS" in the figure. The tuning parameter for each method displayed in the figure was chosen to minimize the average MSE over 100 draws of the data y from the specified model. Visually, we can see that the full 2d fused lasso solution is the most accurate, however, the 1 random DFS, 5 random DFS, and 2 snake DFS solutions all still clearly capture the structure inherent in the underlying signal. Of the three DFS variations, the 5 random DFS estimator is visually most accurate; the 1 random DFS estimator is comparably "blotchy", and the 2 snake DFS estimator is comparably "stripey".

The left panel of 3 shows the optimized MSE for each method, i.e., the minimum of the average MSE over 100 draws of the data y, when we consider 20 choices for the tuning parameter. This optimized MSE is plotted as a function of the sample size, which runs from $n = 2500$ (a 50×50 grid) to $n = 1000000$ (a 1000×1000 grid), and in each case the underlying signal is formed by taking an appropriate (sub)resolution of the image in the top left panel of Figure 2. The 2d fused lasso provides the fastest decrease in MSE as n grows, followed by the 5 random DFS estimator, then the 1 random DFS estimator, and the 2 snake DFS estimator. This is not a surprise, since the 2d fused lasso uses the information from the full 2d grid. Indeed, comparing (11) and (19), we recall that the 2d fused lasso enjoys an MSE rate of $t \log^2 n/n$ when θ_0 has 2d total variation t, whereas the

2. In the previous subsection, we remarked that the fused lasso was prohibitive to compute over the road network graphs, which each have in between 1 or 2 million nodes and 1.5 and 3 million edges. Here, we are able to compute the fused lasso over a graph with 1 million nodes and nearly 2 million edges. The difference is the specialized 2d grid structure in the present example, which is leveraged by the proximal stacking technique in Barbero and Sra (2011) that we use to compute the 2d fused lasso solutions

DFS fused lasso has an MSE rate of only $(t/n)^{2/3}$ in this setting. When $t \asymp \sqrt{n}$, which is a natural scaling for the underlying total variation in 2d and also the scaling considered in the experimental setup for the figure, these rates are $(\log^2 n)n^{-1/2}$ for the 2d fused lasso, and $n^{-1/3}$ for the DFS fused lasso. The figure uses a log-log plot, so the MSE curves all appear to have linear trends, and the fitted slopes roughly match these theoretical MSE rates (-0.58 for the 2d fused lasso, and -0.39, -0.40, and -0.36 for the three DFS variations).

The right panel of Figure 3 shows the runtimes for each method (averaged over 100 draws of the data y), as a function of the sample size n. The runtime for each method counts the total time taken to compute solutions across 20 tuning parameter values. The computations and timings were carried out on a standard desktop computer (with a 3.40GHz Intel Core i7-4770 processor). To compute 2d fused lasso solutions, we used the `TVgen` function in the Matlab package `proxTV`, which is a Matlab wrapper for a C++ implementation of the proximal stacking technique described in Barbero and Sra (2014). For the DFS fused lasso, we computed initial DFS orderings using the `dfs` function from the Matlab package `MathBGL`, and then, as before, used the C++ implementation available through `glmgen` to compute the appropriate 1d fused lasso solutions. The figure uses a log-log plot, and hence we can see that all DFS-based estimators are quite a bit more efficient than the 2d fused lasso estimator.

5.3 Tree graphs

We finish with denoising comparisons on tree graphs, for sample sizes varying from $n = 100$ to $n = 5300$. For each sample size n, a random tree is constructed via a sequential process in which each node is assigned a number of children between 2 and 10 (uniformly at random). Given a tree, an underlying signal $\theta_0 \in \mathbb{R}^n$ is constructed to be piecewise constant with total variation $5\sqrt{n}$ (the piecewise constant construction here is made easy because the oriented incidence matrix of a tree is invertible). Data $y \in \mathbb{R}^n$ was generated by adding i.i.d. $N(0, 1)$ noise to θ_0. We compared the fused lasso estimator over the full tree, 1 random DFS and 5 random DFS estimators (using the terminology from the last subsection), and the wavelet smoothing estimator defined in (26). For each estimator, we computed the entire solution path using the path algorithm of Tibshirani and Taylor (2011) implemented in the R package `genlasso`, and selected the step along the path to minimize the average MSE over 50 draws of data y around θ_0, and 10 repetitions in constructing θ_0. (The full solution path can be computed here because each estimator can be cast as a generalized lasso problem, and because the problem sizes considered here are not enormous.)

The left panel of Figure 4 plots this optimized MSE as a function of the sample size n. We see that the fused lasso estimator over the full tree and the 5 random DFS estimator perform more or less equivalently over all sample sizes. The 1 random DFS estimator is slightly worse, and the wavelet smoothing estimator is considerably worse. The right panel shows the the MSE as a function of the effective degrees of freedom of each estimator, for a particular data instance with $n = 5300$. We see that both the tree fused lasso and 1 random DFS estimators achieve their optimum MSEs at solutions of low complexity (degrees of freedom), whereas wavelet smoothing does not come close to achieving this MSE across its entire path of solutions.

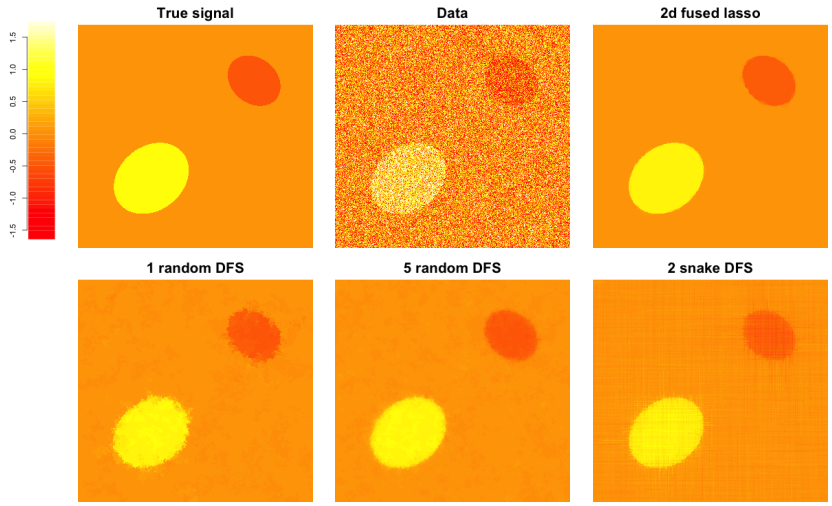

Figure 2: *Underlying signal, data, and solutions from the 2d fused lasso and different variations on the DFS fused lasso fit over a* 1000×1000 *grid.*

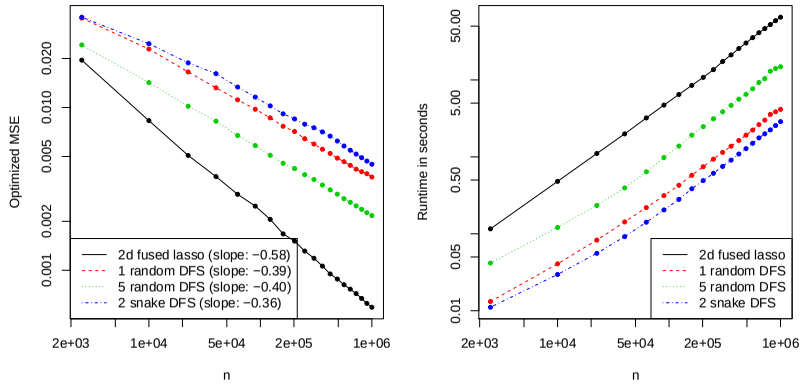

Figure 3: *Optimized MSE and runtime for the 2d fused lasso and DFS fused lasso estimators over a 2d grid, as the grid size n (total number of nodes) varies.*

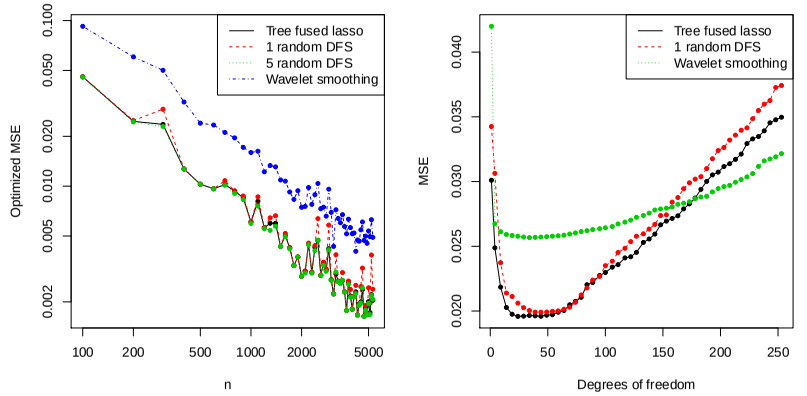

Figure 4: *The left panel shows the optimized MSE as a function of the sample size n for the fused lasso over a tree graph, as well as the 1 random DFS and 5 random DFS estimators, and wavelet smoothing. The right panel shows the MSE as a function of the degrees of freedom of each estimator, for a particular data example with* $n = 5300$.

6. Discussion

Recently, there has been a significant amount on interest on graph-structured denoising. Much of this work has focused on the construction of graph kernels or wavelet bases. We have proposed and studied a simple method, defined by computing the 1d fused lasso over a particular DFS-induced ordering of the nodes of a general graph. This linear-time algorithm comes with strong theoretical guarantees for signals of bounded variation (achieving optimal MSE rates for trees of bounded degree), as well as guarantees for signals with a bounded number of nonzero differences (achieving nearly optimal rates under a condition on the spacings of jumps along the DFS-induced chain). We summarize our theoretical results in Table 1.

Practically, we have seen that the DFS fused lasso can often represent a useful trade-off between computational efficiency and statistical accuracy, versus competing methods that offer better statistical denoising power but are more computationally expensive, especially for large problems. A simple trick like averaging multiple DFS fused lasso fits, over multiple random DFS-induced chains, often improves statistical accuracy at little increased computational cost. Several extensions along these lines, and other lines, are possible. To study any of them in detail is beyond the scope of this paper. We discuss them briefly below, leaving detailed follow-up to future work.

6.1 Beyond simple averaging

Given multiple DFS fused lasso estimators, $\hat{\theta}^{(1)}_{\mathrm{DFS}}, \ldots, \hat{\theta}^{(K)}_{\mathrm{DFS}}$, obtained using multiple DFS-induced chains computed on the same graph G, there are several possibilities for intelligently combining these estimators beyond the simple average, denoted (say) $\bar{\theta}^{(K)}_{\mathrm{DFS}} = (1/K) \sum_{k=1}^{K} \hat{\theta}^{(k)}_{\mathrm{DFS}}$.

	$\mathrm{BV}_G(t)$, $t \asymp 1$	$\mathrm{BD}_G(s)$, $s \asymp 1$
Fused lasso, $\hat{\theta}_G$	$n^{-2/3}$	unknown
Spanning tree wavelets, $\hat{\theta}_W$	unknown	$(\log^2 n \log d_{\max})/n$
DFS fused lasso, $\hat{\theta}_{\mathrm{DFS}}$	$n^{-2/3}$	$(\log n \log\log n)/n^*$
Tree lower bound	$n^{-2/3} d_{\max}^{-4/3}$	$\log n/n$

Table 1: *A summary of the theoretical results derived in this paper. All rates are on the mean squared error (MSE) scale ($\mathbb{E}\|\hat{\theta} - \theta_0\|_n^2$ for an estimator $\hat{\theta}$), and for simplicity, are presented under a constant scaling for t, s, the radii in the $\mathrm{BV}_G(t), \mathrm{BD}_G(s)$ classes, respectively. The superscript "$*$" in the $\mathrm{BD}_G(s)$ rate for the DFS fused lasso is used to emphasize that this rate only holds under the assumption that $W_n \asymp n$. Also, we write $d_{\max}$ to denote the max degree of the graph in question.*

To better preserve edges in the combined estimator, we could run a simple nonlinear filter—for example, a median filter, over $\hat{\theta}^{(1)}_{\mathrm{DFS}}, \ldots, \hat{\theta}^{(K)}_{\mathrm{DFS}}$ (meaning that the combined estimator is defined by taking medians over local neighborhoods of all of the individual estimators). A more sophisticated approach would be to compute the DFS fused lasso estimators sequentially, using the $(k-1)$st estimator to modify the response in some way in the 1d fused lasso problem that defines the kth DFS fused lasso estimator. We are intentionally vague here with the specifics, because such a modification could be implemented in various ways; for example, it could be useful to borrow ideas from the boosting literature, which would have us treat each DFS fused lasso estimator as a weak learner.

6.2 Distributed algorithm

For large graphs, we should be able to both compute a DFS ordering over G, and solve the DFS fused lasso problem in (18), in a distributed fashion. There are many algorithms for distributed DFS, offering a variety of communication and time complexities; see, e.g., Tsin (2002) for a survey. Distributed algorithms for the 1d fused lasso are not as common, though we can appeal to the now well-studied framework for distributed optimization via the alternating direction method of multipliers (ADMM) from Boyd et al. (2011). Different formulations for the auxiliary variables present us with different options for communication costs. We have found that, for a formulation that requires $O(1)$-length messages to be communicated between processors, the algorithm typically converges in a reasonably small number of iterations.

6.3 Theory for piecewise constant signals

The bounded differences class $\mathrm{BD}_G(s)$ in (5) is defined in terms of the cut metric $\|\nabla_G \theta\|_0$ of a parameter θ, which recall, counts the number of nonzero differences occurring in θ over edges in the graph G. The cut metric measures a notion of strong sparsity (compared to the weaker notion measured by the total variation metric) in a signal θ, over edge differences; but, it may not be measuring sparsity on the "right" scale for certain graphs G. Specifically,

the cut metric $\|\nabla_G \theta\|_0$ can actually be quite large for a parameter θ that is piecewise constant over G, with a small number of pieces—these are groups of connected nodes that are assigned the same constant value in θ. Over the 2d grid graph, e.g., one can easily define a parameter θ that has only (say) two constant pieces but on the order of $\sqrt{n}$ nonzero edge differences. Therefore, for such a "simple" configuration of the parameter θ, the cut metric $\|\nabla_G \theta\|_0$ is deceivingly large.

To formally define a metric that measures the number of constant pieces in a parameter θ, with respect to a graph $G = (V, E)$, we introduce a bit of notation. Denote by $Z(\theta) \subseteq E$ the subset of edges over which θ exhibits differences of zero, i.e., $Z(\theta) = \{e \in E : \theta_{e^+} = \theta_{e^-}\}$. Also write $(\nabla_G)_{Z(\theta)}$ for the submatrix of the edge incidence matrix ∇_G with rows indexed by $Z(\theta)$. We consider a metric defined by

$$\rho_G(\theta) = \mathrm{nullity}\big((\nabla_G)_{Z(\theta)}\big),$$

where $\mathrm{nullity}(\cdot)$ denotes the dimension of the null space of its argument. An equivalent definition is

$$\rho_G(\theta) = \text{the number of connected components in } (V, E \setminus Z(\theta)).$$

We may now define the *piecewise constant class*, with respect to G, and a parameter $s > 0$,

$$\mathrm{PC}_G(s) = \{\theta \in \mathbb{R}^n : \rho_G(\theta) \leq s\}.$$

It is not hard to to see that $\mathrm{BV}_G(s) \subseteq \mathrm{PC}_G(s)$ (assuming only that G is connected), but for certain graph topologies, the latter class $\mathrm{PC}_G(s)$ will be much larger. Indeed, to repeat what we conveyed above, for the 2d grid one can naturally define a parameter θ such that $\theta \in \mathrm{BD}_G(\sqrt{n})$ and $\theta \in \mathrm{PC}_G(2)$.

We conjecture that the fused lasso estimator over G can achieve a fast MSE rate when the mean θ_0 in (1) exhibits a small number of constant pieces, i.e., $\theta_0 \in \mathrm{PC}_G(s)$, provided that these pieces are of roughly equal size.

6.4 Weighted graphs

The key result in Lemma 1 can be extended to the setting of a weighted graph $G = (V, E, w)$, with $w_e \geq 0$ denoting the edge weight associated to an edge $e \in E$.

Lemma 9 *Let $G = (V, E, w)$ be a connected weighted graph, where recall we write $V = \{1, \ldots, n\}$, and we assume all edge weights are nonnegative. Consider running DFS on G, and denote by $\tau : \{1, \ldots, n\} \to \{1, \ldots, n\}$ the induced permutation, so that if $v_1, \ldots, v_n$ are the nodes in the order that they are traversed by DFS, then*

$$\tau(i) = v_i, \quad \text{for all } i = 1, \ldots, n.$$

Denote $w_{\min} = \min_{e \in E} w_e$, the minimum edge weight present in the graph, and define

$$\tilde{w}_{\tau(i),\tau(i+1)} = \begin{cases} w_e & \text{if } e = \{\tau(i), \tau(i+1)\} \in E, \\ w_{\min} & \text{otherwise,} \end{cases} \quad \text{for all } i = 1, \ldots, n-1. \tag{30}$$

It holds that

$$\sum_{i=1}^{n-1} \tilde{w}_{\tau(i),\tau(i+1)} \big|\theta_{\tau(i+1)} - \theta_{\tau(i)}\big| \leq 2 \sum_{e \in E} w_e |\theta_{e^+} - \theta_{e^-}|, \quad \textit{for all } \theta \in \mathbb{R}^n, \tag{31}$$

as well as

$$\sum_{i=1}^{n-1} \tilde{w}_{\tau(i),\tau(i+1)} 1\big\{\theta_{\tau(i+1)} \neq \theta_{\tau(i)}\big\} \leq 2 \sum_{e \in E} w_e 1\{\theta_{e^+} \neq \theta_{e^-}\}, \quad \textit{for all } \theta \in \mathbb{R}^n. \tag{32}$$

Remark 10 *As with Lemma 1, Lemma 9 has also essentially appeared in the literature, in a form for binary signals and the roughness metric being the quadratic form in the graph Laplacian, see Cesa-Bianchi et al. (2013). The main idea behind this result and Lemma 9 is the same, and the latter follows from the former with only minor modifications.*

For simplicity, when edges in the DFS chain do not appear in the original graph, we have defined their corresponding weights to be the minimum of the weights in the original graph. Instead, we could have taken the approach in Cesa-Bianchi et al. (2013), and defined the weight for such an edge in the DFS chain to be the minimum of weights from original edges in its backtracking path.

The bounds in (31), (32) are the analogies of (15), (16) but for a weighted graph G; indeed we see that we can still embed a DFS chain into G, but this chain itself comes with edge weights, as in (30). These new edge weights in the chain do not cause any computational issues; the 1d fused lasso problem with arbitrary penalty weights can still be solved in $O(n)$ time using the taut string algorithm in Barbero and Sra (2014). Thus, in principle, all of the results in this paper should carry over in some form to weighted graphs.

6.5 Robustness to signal perturbation

Here we briefly explore some robustness properties of the DFS fused lasso estimator, under perbutations of the mean parameter θ_0 in (1) with respect to a small number of nodes. This is based on the approach taken by Cesa-Bianchi et al. (2013) to study robustness in their online graph-structured classification setting. Let $G = (V, E, w)$ a weighted graph, and write $\|\nabla_G \theta\|_1$ for the weighted total variation of a signal θ, i.e.,

$$\|\nabla_G \theta\|_1 = \sum_{e \in E} w_e |\theta_{e^+} - \theta_{e^-}|.$$

Denote by θ^δ a perturbed version of θ, where any number of entries are given by adding an amount $\delta > 0$ to the corresponding entries of θ. (More general forms of perturbations can also be investigated but slightly complicate the discussion that follows, so for simplicity, we will limit ourselves to considering this simple model for perturbations.) Denote by

$$I(\theta, \theta^\delta) = \Big\{ i \in \{1, \ldots, n\} \,:\, \theta_i \neq \theta_i^\delta \Big\}$$

the subset of nodes at which the components of θ and θ^δ differ. Observe

$$\begin{aligned}
\big|\|\nabla_G \theta\|_1 - \|\nabla_G \theta^\delta\|_1\big| &= \bigg| \sum_{\{e^+, e^-\} \cap I(\theta,\theta^\delta) \neq \emptyset} w_e \left(|\theta_{e^+} - \theta_{e^-}| - |\theta^\delta_{e^+} - \theta^\delta_{e^-}|\right) \bigg| \\
&= \bigg| \sum_{|\{e^+, e^-\} \cap I(\theta,\theta^\delta)| = 1} w_e \left(|\theta_{e^+} - \theta_{e^-}| - |\theta^\delta_{e^+} - \theta^\delta_{e^-}|\right) \bigg| \\
&\leq \sum_{|\{e^+, e^-\} \cap I(\theta,\theta^\delta)| = 1} w_e \left(|\theta_{e^+} - \theta^\delta_{e^+}| + |\theta_{e^-} - \theta^\delta_{e^-}|\right) \\
&= \delta \, \mathrm{cut}_G(I(\theta, \theta^\delta)),
\end{aligned}$$

where, for a subset $S \subset V$, we use $\mathrm{cut}_G(S)$ to denote the cost of the cut in between S and S^c in the graph G, i.e., the sum of edge weights among edges with one endpoint in S and the other in S^c.

Thus we have shown that the (weighted) total variation metric associated with G has modulus of continuity $\delta \, \mathrm{cut}_G(I(\theta, \theta^\delta))$ with respect to perturbations θ^δ of θ. This scales linearly in δ, but how does it scale in $|I(\theta, \theta^\delta)|$ (the number of discrepancies)? The answer to this depends on the geometry of G, in particular, it depends on whether perturbations occur at nodes having high (weighted) degree. Even when $|I(\theta, \theta^\delta)|$ is small, $\mathrm{cut}_G(I(\theta, \theta^\delta))$ can be very large—an example is given below with G being a star graph. Further, the modulus of continuity $\delta \, \mathrm{cut}_G(I(\theta, \theta^\delta))$ is tight, i.e., it can always be achieved[3], and thus for graphs G with nodes of high (weighted) degrees, in a worst-case sense, small perturbations of θ can lead to big differences in $\|\nabla_G \theta\|_1$.

For the DFS-induced chain graph derived from G, the worst-case is not nearly as bad. Letting C denote this chain and P the corresponding permutation matrix, by the same argument as above,

$$\Big|\|\nabla_C P\theta\|_1 - \|\nabla_C P\theta^\delta\|_1\Big| \leq \delta \, \mathrm{cut}_C(I(\theta, \theta^\delta)).$$

But the key difference now is that $\mathrm{cut}_C(I(\theta, \theta^\delta))$ sums the edge weights of at most $2\,|I(\theta, \theta^\delta)|$ edges in C, due to the special structure of the chain. Denoting by

$$v_G(k) = \max_{F \subset E, |F| = k} \sum_{e \in F} w_e$$

the sum of the k largest edge weights in G, and similarly for C, we can proceed to upper bound the right-hand side above,

$$\Big|\|\nabla_C P\theta\|_1 - \|\nabla_C P\theta^\delta\|_1\Big| \leq \delta \, v_C(2\,|I(\theta, \theta^\delta)|) \leq \delta \, v_C(2\,|I(\theta, \theta^\delta)|),$$

the second inequality following from the definition of the weights in the chain graph, as in (30). When all weights in the original graph G are unity, e.g., this says that perturbing k

3. By this we mean that, for any graph G, any subset $S \subset V$ of nodes at which perturbations are to occur, there exist θ, θ^δ such that $I(\theta, \theta^\delta) = S$ and $\big|\|\nabla_G \theta\|_1 - \|\nabla_G \theta^\delta\|_1\big| = \delta \, \mathrm{cut}_G(I(\theta, \theta^\delta))$.

of the entries of any input signal by an amount δ results in a total variation difference over the DFS-induced chain of at most $2\delta k$.

Consider the following instructive example, borrowed from Cesa-Bianchi et al. (2013). Let G be a star graph, having one center node that is connected to each of the remaining $n-1$ nodes, and no other edges in the graph. Assume that all weights of G are unity, and define θ to take a value 0 on the center node, and 1 on all others. Then by flipping the value of the center node from 0 to 1, the total variation over G changes from $n-1$ to 0. However, for any DFS-induced chain, we see from the above analysis that the total variation can change by at most 2, making it more robust to such a perturbation. We can rephrase this robustness property in an interesting way. Suppose that the mean θ_0 in (1) is defined over the star graph G to take a value 0 on the center node, and 1 on all others. Then θ_0 is "close" to a signal of bounded variation, since changing only its value at the center node makes it have zero total variation, and yet in its current configuration it has total variation $n-1$. Hence, we would not expect the fused lasso estimator over G to be consistent, when fit to data drawn around θ_0. But the total variation of θ_0 as measured over the DFS-induced chain C is at most 2 (as the total variation over C is zero once we perturb the value of center node from 0 to 1). With respect to C then, the parameter θ_0 is certainly of bounded variation and using the DFS fused lasso estimator, we will achieve an MSE rate of $n^{-2/3}$. The DFS fused lasso thus exhibits a robustness property, in that it allows us to accurately estimate signals that are "close to" the set of bounded variation signals over G.

6.6 Potts and energy minimization

Replacing the total variation metric by the cut metric in the fused lasso problem (2) gives us

$$\tilde{\theta}_G = \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y-\theta\|_2^2 + \lambda \|\nabla_G \theta\|_0, \tag{33}$$

often called the *Potts minimization* problem. Because the 1d Potts minimization problem

$$\tilde{\theta}_{1\mathrm{d}} = \operatorname*{argmin}_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y-\theta\|_2^2 + \lambda \|\nabla_{1\mathrm{d}} \theta\|_0 \tag{34}$$

can be solved efficiently, e.g., in worst-case $O(n^2)$ time with dynamic programming Bellman (1961); Johnson (2013), the same strategy that we have proposed in this paper can be applied to reduce the graph Potts problem (33) to a 1d Potts problem (34), via a DFS ordering of the nodes. This may be especially interesting as the original Potts problem (33) is non–convex and generally intractable (i.e., intractable to solve to global optimality) for an arbitrary graph structure, so a reduction to a worst-case quadratic-time denoiser is perhaps very valuable.

When the optimization domain in (33) is a discrete set, the problem is often called an *energy minimization* problem, as in Boykov et al. (2001). It has not escaped our notice that our technique of denoising over DFS-induced chains could be useful for this setting, as well.

Acknowledgments

The authors thank the Associate Editor and Referees for their helpful comments, especially for pointing out the connections to the previous papers of Herbster et al. (2009); Cesa-Bianchi et al. (2013), and the signal perturbation angle covered in Section 6.5. The last author thanks Veeranjaneyulu Sadhanala and Yu-Xiang Wang for early stimulating discussions. Ryan J. Tibshirani was supported by NSF grant DMS-1554123.

Appendix A. Proofs

A.1 Derivation of (12) from Theorem 3 in Wang et al. (2016)

We first establish a result on the exact form for the inverse of (an augmented version of) the edge incidence matrix of a generic tree $T = (V, E_T)$, where, recall $V = \{1, \dots, n\}$. Without a loss of generality, we may assume that the root of T is at node 1. For $m \leq n$, we define a path in T, of length m, to be a sequence $p_1, \dots, p_m$ such that $\{p_r, p_{r+1}\} \in E_T$ for each $r = 1, \dots, m-1$. We allow for the possibility that $m = 1$, in which case the path has just one node. For any $j, k, \ell = 1, \dots, n$, we say that j is on the path from k to ℓ if there exists a path $p_1, \dots, p_m$ such that $p_1 = k$, $p_m = \ell$ and $p_r = j$ for some $r = 1, \dots, m$. For each node $i = 2, \dots, n$ (each node other than the root), we define its parent $p(i)$ to be the node connected to i which is on the path from the root to i.

We can also assume without a loss of generality that for each $i = 2, \dots, n$, the $(i-1)$st row of ∇_T corresponds to the edge $\{p(i), i\}$, and thus we can write

$$(\nabla_T)_{i-1,j} = \begin{cases} -1 & \text{if } j = p(i), \\ 1 & \text{if } j = i, \\ 0 & \text{if } j \in \{1, \dots, n\} \setminus \{i, p(i)\}. \end{cases}$$

for each $j = 1, \dots, n$. The next lemma describes the inverse of ∇_T, in the appropriate sense.

Lemma 11 *Let $e_1 = (1, 0, \dots, 0) \in \mathbb{R}^n$, and define the matrix $A_T \in \mathbb{R}^{n \times n}$ by*

$$(A_T)_{i,j} = \begin{cases} 1 & \textit{if } j \textit{ is on the path from the root to } i, \\ 0 & \textit{otherwise}, \end{cases} \tag{35}$$

for each $i, j = 1, \dots, n$. Then

$$A_T = \begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix}^{-1}.$$

Proof We will prove that the product

$$B = \begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix} A_T$$

is the identity. As the root of T corresponds to node 1, we have that by definition of A_T that its first column is

$$(A_T)_{\cdot,1} = (1, \dots, 1),$$

which implies that the first column of B is

$$B_{\cdot,1} = e_1.$$

Moreover, by definition of A_T, its first row is

$$(A_T)_{1,\cdot} = e_1^\top,$$

which implies that the first row of B is

$$B_{1,\cdot} = e_1^\top.$$

Let us now assume that i, j are each not the root. We proceed to consider three cases.

Case 1. Let $j \neq i$, and j be on the path from the root to i. Then j is also on the path from the root to $p(i)$. This implies that

$$B_{ij} = \begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix}_{i,\cdot} (A_T)_{\cdot,j} = (\nabla_T)_{i-1,\cdot}(A_T)_{\cdot,j} = 1 - 1 = 0.$$

Case 2. Let $j \neq i$, and j not be on the path from the root to i. Then j is not on the path from the root to $p(i)$, which implies that

$$B_{ij} = \begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix}_{i,\cdot} (A_T)_{\cdot,j} = (\nabla_T)_{i-1,\cdot}(A_T)_{\cdot,j} = 0 - 0 = 0.$$

Case 3. Let $j = i$. Then j is on the path from the root to i, and j is not on the path from the root to $p(i)$. Hence,

$$B_{ij} = \begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix}_{i,\cdot} (A_T)_{\cdot,j} = (\nabla_T)_{i-1,\cdot}(A_T)_{\cdot,j} = -1 \cdot 0 + 1 \cdot 1 = 1.$$

Assembling these three cases, we have shown that $B = I$, completing the proof. ■

We now establish (12).

Proof [Proof of (12)] The proof of Theorem 3 in Wang et al. (2016) proceeds as in standard basic inequality arguments for the lasso, and arrives at the step

$$\|\Pi^\perp(\hat{\theta}_G - \theta_0)\|_2^2 \leq 2\epsilon^\top \Pi^\perp(\hat{\theta}_G - \theta_0) + 2\lambda\|\nabla_G\theta_0\|_1 - 2\lambda\|\nabla_G\hat{\theta}_G\|_1,$$

where $\Pi^\perp$ is the projection matrix onto the space $\mathrm{span}\{\mathbb{1}\}^\perp$, i.e., the linear space of all vectors orthogonal to the vector $\mathbb{1} = (1, \ldots, 1) \in \mathbb{R}^n$ of all 1s. The proof in Wang et al. (2016) uses the identity $\Pi^\perp = \nabla_G^\dagger \nabla_G$, where $\nabla_G^\dagger$ denotes the pseudoinverse of ∇_G. However, notice that we may also write $\Pi^\perp = \nabla_T^\dagger \nabla_T$ for any spanning tree T of G. Then, exactly the same arguments as in Wang et al. (2016) produce the MSE bound

$$\|\hat{\theta}_G - \theta_0\|_n^2 = O_{\mathbb{P}}\bigg(\frac{M(\nabla_T)\sqrt{\log n}}{n}\|\nabla_G\theta_0\|_1\bigg),$$

where $M(\nabla_T)$ is the maximum ℓ_2 norm among the columns of $\nabla_T^\dagger$. We show below, using Lemma 11, that $M(\nabla_T) \leq \sqrt{n}$, and this gives the desired MSE rate.

For any $b \in \mathbb{R}^{n-1}$, we may characterize $\nabla_T^\dagger b$ as the unique solution $x \in \mathbb{R}^n$ to the linear system

$$\nabla_T x = b,$$

such that $\mathbb{1}^\top x = 0$, i.e., the unique solution to the linear system

$$\begin{pmatrix} e_1^\top \\ \nabla_T \end{pmatrix} x = \begin{pmatrix} a \\ b \end{pmatrix},$$

for a value of $a \in \mathbb{R}$ such that $\mathbb{1}^\top x = 0$. By Lemma 11, we may write

$$x = A_T \begin{pmatrix} a \\ b \end{pmatrix},$$

so that the constraint $0 = \mathbb{1}^\top x = na + \mathbb{1}^\top (A_T)_{\cdot,2:n} b$ gives $a = -(\mathbb{1}/n)^\top (A_T)_{\cdot,2:n} b$, and

$$x = (I - \mathbb{1}\mathbb{1}^\top/n)(A_T)_{\cdot,2:n} b.$$

Evaluating this across $b = e_1, \ldots, e_n$, we find that the maximum ℓ_2 norm of columns of $\nabla_T^\dagger$ is bounded by the maximum ℓ_2 norm of columns of $(A_T)_{\cdot,2:n}$, which, from the definition in (35), is at most $\sqrt{n}$. ■

A.2 Proof of Theorem 5

We first present two preliminary lemmas.

Lemma 12 *Let $S_1, \ldots, S_m$ be a partition of the nodes of G such that the total number of edges with ends in distinct elements of the partition is at most s. Let $k \leq \min_{i=1,\ldots,m} |S_i|$. Then*

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BV}_G(t)} \mathbb{E}\|\hat{\theta} - \theta_0\|_2^2 \geq \frac{kmt^2}{4\sigma^2 s^2} \exp\bigg(-\frac{kt^2}{\sigma^2 s^2}\bigg).$$

Proof For each $\eta \in \{-1, 1\}^m$, define

$$\theta_\eta = \frac{\delta}{2} \sum_{i=1}^m \eta_i \frac{1_{S_i}}{\sqrt{|S_i|}},$$

where $\delta > 0$ will be specified shortly. Also define the class $\mathcal{P} = \{N(\theta_\eta, \sigma^2 I) : \eta \in \{-1, 1\}^m\}$. Note that $\|\nabla_G \theta_\eta\|_1 \leq \delta s/\sqrt{k}$, so to embed $\mathcal{P}$ into the class $\{N(\theta, \sigma^2 I) : \theta \in \mathrm{BV}_G(t)\}$, we set $\delta = t\sqrt{k}/s$.

Let $\eta, \eta' \in \{-1, 1\}^m$ differ in only one coordinate. Then the KL divergence between the corresponding induced measures in $\mathcal{P}$ is $\|\theta_\eta - \theta_{\eta'}\|_2^2/\sigma^2 \leq \delta^2/\sigma^2$. Hence by Assouad's Lemma (Yu, 1997), and a well-known lower bound on the affinity between probability measures in terms of KL divergence,

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BV}_G(t)} \mathbb{E}\|\hat{\theta} - \theta_0\|_2^2 \geq \frac{\delta^2 m}{4\sigma^2} \exp\bigg(-\frac{\delta^2}{\sigma^2}\bigg).$$

The result follows by plugging in the specified value for δ. ■

Lemma 13 *Let G be a tree with maximum degree $d_{\max}$, and $k \in \{1, \dots, n\}$ be arbitrary. Then there exists a partition as in Lemma 12, $s = m - 1$, and*

$$k \leq \min_{i=1,\dots,m} |S_i| \leq k(d_{\max} + 1).$$

Proof Our proof proceeds inductively. We begin by constructing S'_1, the smallest subtree among all those having size at least k, and generated by a cut of size 1 (i.e., separated from the graph by the removal of 1 edge). Note that $|S'_1| \leq kd_{\max}$, because if not then S'_1 has at least k internal nodes, and we can remove its root to produce another subtree whose size is smaller but still at least k.

For the inductive step, assume $S'_1, \dots, S'_\ell$ have been constructed. We consider two cases. (For a subgraph G' of G, we denote by $G - G'$ the complement subgraph, given by removing all nodes in G', and all edges incident to a node in G'.)

Case 1. If $|G - \cup_{i=1}^{\ell} S'_i| > k$, then we construct $S'_{\ell+1}$, the smallest subtree of $G - \cup_{i=1}^{l} S'_i$ among all those having size at least k, and generated by a cut of size 1. As before, we obtain that $|S'_{\ell+1}| \leq kd_{\max}$.

Case 2. If $|G - \cup_{i=1}^{\ell} S'_i| \leq k$, then the process is stopped. We define $S_i = S'_i$, $i = 1, \dots, \ell - 1$, as well as $S_\ell = S'_\ell \cup (G - \cup_{i=1}^{\ell} S'_i)$. With $m = \ell$, the result follows. ■

We now demonstrate a more precise characterization of the lower bound in Theorem 5, from which the result in the theorem can be derived.

Theorem 14 *Let G be a tree with maximum degree $d_{\max}$. Then*

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BV}_G(t)} \mathbb{E}\|\hat{\theta} - \theta_0\|_2^2 \geq \frac{t^2}{4e\sigma^2 n} \left(\left(\frac{\sigma n}{2t(d_{\max} + 1)} \right)^{2/3} - 1 \right)^2.$$

Proof Set $s = m - 1$ and

$$k = \left\lfloor \left(\frac{\sigma n}{2t(d_{\max} + 1)} \right)^{2/3} \right\rfloor.$$

By Lemmas 12 and 13,

$$\begin{aligned}
\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BV}_G(t)} \mathbb{E}\|\hat{\theta} - \theta_0\|_2^2 &\geq \frac{kmt^2}{4\sigma^2 s^2} \exp\left(- \frac{kt^2}{\sigma^2 s^2} \right) \\
&\geq \frac{kt^2}{4\sigma^2 m} \exp\left(- \frac{kt^2}{\sigma^2 (m-1)^2} \right) \\
&\geq \frac{kt^2}{4\sigma^2 m} \exp\left(- \frac{t^2 k^3 (d_{\max} + 1)^2}{\sigma^2 n^2} \frac{m^2}{(m-1)^2} \right) \\
&\geq \frac{kt^2}{4\sigma^2 n} \exp\left(- \frac{4t^2 k^3 (d_{\max} + 1)^2}{\sigma^2 n^2} \right) \\
&\geq \frac{k^2 t^2}{4\sigma^2 n} \exp(-1).
\end{aligned}$$

In the above, the third line uses $n/m \leq kd_{\max}$ as given by Lemma 13, the fourth line simply uses $m \leq n$ and $m^2/(m-1)^2 \leq 4$ (as $m \geq 2$), and the last line uses the definition of k. Thus, because

$$k \geq \left(\frac{\sigma n}{2t(d_{\max} + 1)} \right)^{2/3} - 1,$$

we have established the desired result. ■

A.3 Proof of Theorem 8

First we establish that, as G is a tree, the number of nodes of degree at most 2 is at least $n/2$. Denote by d_i be the degree of the node i, for each $i = 1, \dots, n$. Then

$$2(n-1) = \sum_{i=1}^{n} d_i = \sum_{i:\, d_i \leq 2} d_i + \sum_{i:\, d_i \geq 3} d_i \geq |\{i : d_i \leq 2\}| + 3|\{i : d_i \geq 3\}| = 3n - 2|\{i : d_i \leq 2\}|.$$

Hence, rearranging, we find that $|\{i : d_i \leq 2\}| \geq n/2 + 1$.

Let $\mathcal{I} = \{i : d_i \leq 2\}$ so that $|\mathcal{I}| \geq \lceil n/2 \rceil$ and stipulate that $|\mathcal{I}|$ is even without loss of generality. Let k be the largest even number such that $k \leq s/2$. Define

$$\mathcal{B} = \{z \in \mathbb{R}^n : z_{\mathcal{I}} \in \{-1, 0, +1\}^{|\mathcal{I}|},\ z_{\mathcal{I}^c} = 0,\ \|z\|_0 = k\}.$$

Note that by construction $\mathcal{B} \subseteq \mathrm{BD}_G(s)$.

Assume $s \leq n/6$. Then this implies $k/2 \leq n/6 \leq |\mathcal{I}|/3$. By Lemma 4 in Raskutti et al. (2011), there exists $\tilde{\mathcal{B}} \subseteq \mathcal{B}$ such that

$$\log |\tilde{\mathcal{B}}| \geq \frac{k}{2} \log \left(\frac{|\mathcal{I}| - k}{k/2} \right),$$

and $\|z - z'\|_2^2 \geq k/2$ for all $z, z' \in \tilde{\mathcal{B}}$. Defining $\mathcal{B}_0 = 2\delta\tilde{\mathcal{B}}$, for $\delta > 0$ to be specified shortly, we now have $\|z - z'\|_2^2 \geq 2\delta^2 k$ for all $z, z' \in \mathcal{B}_0$.

For $\theta \in \mathcal{B}_0$, let us consider comparing the measure $P_\theta = N(\theta, \sigma^2 I)$ against $P_0 = N(0, \sigma^2 I)$: the KL divergence between these two satisfies $K(P_\theta || P_0) = \|\theta\|_2^2 / \sigma^2 = 2\delta^2 k / \sigma^2$. Let $\delta = \sqrt{\alpha\sigma^2/(2k) \log |\mathcal{B}_0|}$, for a parameter $\alpha < 1/8$ that we will specify later. We have

$$\frac{1}{|\mathcal{B}_0|} \sum_{\theta \in \mathcal{B}_0} K(P_\theta || P_0) \leq \alpha \log |\mathcal{B}_0|.$$

Hence by Theorem 2.5 in Tsybakov (2009),

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BD}_G(s)} \mathbb{P}(\|\hat{\theta} - \theta_0\|_2^2 \geq \delta^2 k) \geq \frac{\sqrt{|\mathcal{B}_0|}}{1 + \sqrt{|\mathcal{B}_0|}} \left(1 - 2\alpha - \sqrt{\frac{2\alpha}{\log |\mathcal{B}_0|}} \right). \tag{36}$$

It holds that

$$\delta^2 k = \frac{\alpha\sigma^2}{2} \log |\mathcal{B}_0| \geq \frac{\alpha\sigma^2 k}{4} \log \frac{|\mathcal{I}| - k}{k/2} \geq C\sigma^2 s \log \left(\frac{n}{s} \right),$$

for some constant $C > 0$ depending on α alone. Moreover, the right-hand side in (36) can be lower bounded by (say) 1/4 by taking α to be small enough and assuming n/s is large enough. Thus we have established

$$\inf_{\hat{\theta}} \sup_{\theta_0 \in \mathrm{BD}_G(s)} \mathbb{P}\left(\|\hat{\theta} - \theta_0\|_2^2 \geq C\sigma^2 s \log\left(\frac{n}{s}\right) \right) \geq \frac{1}{4},$$

and the result follows by Markov's inequality.

Editor: Edoardo M. Airoldi

Abstract

The stochastic block model (SBM) is a random graph model with planted clusters. It is widely employed as a canonical model to study clustering and community detection, and provides generally a fertile ground to study the statistical and computational tradeoffs that arise in network and data sciences.

This note surveys the recent developments that establish the fundamental limits for community detection in the SBM, both with respect to information-theoretic and computational thresholds, and for various recovery requirements such as exact, partial and weak recovery (a.k.a., detection). The main results discussed are the phase transitions for exact recovery at the Chernoff-Hellinger threshold, the phase transition for weak recovery at the Kesten-Stigum threshold, the optimal distortion-SNR tradeoff for partial recovery, the learning of the SBM parameters and the gap between information-theoretic and computational thresholds.

The note also covers some of the algorithms developed in the quest of achieving the limits, in particular two-round algorithms via graph-splitting, semi-definite programming, linearized belief propagation, classical and nonbacktracking spectral methods. A few open problems are also discussed.

Keywords: Community detection, clustering, stochastic block models, random graphs, unsupervised learning, spectral algorithms, computational gaps, network data analysis.

Contents

1. Introduction

1.1 Community detection

The[1] most basic task of *community detection*, or *graph clustering*, consists in partitioning the vertices of a graph into clusters that are more densely connected. From a more general point of view, community structures may also refer to groups of vertices that connect similarly to the rest of the graphs without having necessarily a higher inner density, such as disassortative communities that have higher external connectivity. Note that the terminology of 'community' is sometimes used only for assortative clusters in the literature, but we adopt here the more general definition. Community detection may also be performed on graphs where edges have labels or intensities, and if these labels represent similarities among data points, the problem may be called *data clustering*. In this monograph, we will use the terms communities and clusters exchangeably. Further one may also have access to interactions that go beyond pairs of vertices, such as in hypergraphs, and communities may not always be well separated due to overlaps. In the most general context, community detection refers to the problem of inferring similarity classes of vertices in a network by having access to measurements of local interactions.

Community detection and clustering are central problems in machine learning and data mining. A vast amount of data sets can be represented as a network of interacting items, and one of the first features of interest in such networks is to understand which items are "alike," as an end or as preliminary step towards other learning tasks. Community detection is used in particular to understand sociological behavior Goldenberg et al. (2010); Fortunato (2010); Newman et al., protein to protein interactions Chen and Yuan (2006); Marcotte et al. (1999), gene expressions Cline et al. (2007); Jiang et al. (2004), recommendation systems Linden et al. (2003); Sahebi and Cohen (2011); Wu et al. (2015), medical prognosis Sorlie et al. (2001), DNA 3D folding Cabreros et al. (2015), image segmentation Shi and Malik (1997), natural language processing Ball et al. (2011a), product-customer segmentation Clauset et al. (2004), webpage sorting Kumar et al. (1999) and more.

The field of community detection has been expanding greatly since the 80's, with a remarkable diversity of models and algorithms developed in different communities such as machine learning, network science, social science and statistical physics. These rely on various benchmarks for finding clusters, in particular cost functions based on cuts or Girvan-Newman modularity Girvan and Newman (2002). We refer to Newman (2010); Fortunato (2010); Goldenberg et al. (2010); Newman et al. for an overview of these developments.

Various fundamental questions remain nonetheless unsettled such as:

- Are there really communities? Algorithms may output community structures, but are these meaningful or artefacts?
- Can we always extract the communities when they are present; fully, partially?

1. This manuscript is the evolution of notes written for our tutorial at ISIT 2015 with M. Wainwright on Machine Learning and Information Theory, a review article for the Information Theory Newsletter, and now an extended version for a Special Issue of the Journal of Machine Learning Research. The initial goal was to explain without all the technical details and in a more general context some of the recent papers that had been written with several collaborators, but it ended up as a broader overview paper on the recent developments for the stochastic block model (with a few new additions). It mainly covers results up to 2016.

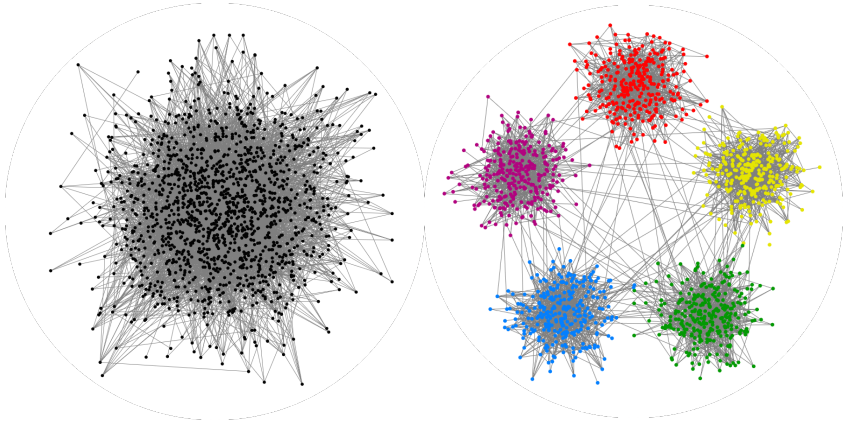

Figure 1: The above two graphs are the same graph re-organized and drawn from the SBM model with 1000 vertices, 5 balanced communities, within-cluster probability of 1/50 and across-cluster probability of 1/1000. The goal of community detection in this case is to obtain the right graph (with the true communities) from the left graph (scrambled) up to some level of accuracy. In such a context, community detection may be called graph clustering. In general, communities may not only refer to denser clusters but more generally to groups of vertices that behave similarly.

- What is a good benchmark to measure the performance of algorithms, and how good are the current algorithms?

The goal of this survey is to describe recent developments aiming at answering these questions in the context of the stochastic block model. The stochastic block model (SBM) has been used widely as a canonical model for community detection. It is arguably the simplest model of a graph with communities (see definitions in the next section). Since the SBM is a generative model for the data, it benefits from a ground truth for the communities, which allows to consider the previous questions in a formal context. On the flip side, one has to hope that the model represents a good fit for real data, which does not mean necessarily a realistic model but at least an insightful one. We believe that, similarly to the role of the discrete memoryless channel in communication theory, the SBM provides such a level of insightful abstraction. The basic model captures some of the key bottleneck phenomena, and it can be extended to more advanced and realistic refinements (such edge labels or overlapping communities). Our focus will be here on the fundamental understanding of the core SBM, without diving too much into the refined extensions.

The core SBM is defined as follows. For positive integers n, k, a probability vector p of dimension k, and a symmetric matrix W of dimension $k \times k$ with entries in $[0, 1]$, the model $\mathrm{SBM}(n, p, W)$ defines an n-vertex random graph with labelled vertices, where each vertex is assigned a community label in $\{1, \ldots, k\}$ independently under the community prior p, and

pairs of vertices with labels i and j connect independently with probability $W_{i,j}$. Further generalizations allow for labelled edges and continuous vertex labels, connecting to low-rank approximation models and 'graphons.'

A first hint on the centrality of the SBM comes from the fact that the model appeared independently in numerous scientific communities. It appeared under the SBM terminology in the context of social networks, in the machine learning and statistics literature Holland et al. (1983), while the model is typically called the planted partition model in theoretical computer science Bui et al. (1987); Dyer and Frieze (1989); Boppana (1987), and the inhomogeneous random graph in the mathematics literature Bollobás et al. (2007). The model takes also different interpretations, such as a planted spin-glass model Decelle et al. (2011), a sparse-graph code Abbe and Sandon (2015a,b) or a low-rank (spiked) random matrix model McSherry (2001); Vu (2014); Deshpande et al. (2015) among others.

In addition, the SBM has recently turned into more than a model for community detection. It provides a fertile ground for studying various central questions in machine learning, computer science and statistics: It is rich in phase transitions Decelle et al. (2011); Massoulié (2014); Mossel et al. (2014a); Abbe et al. (2016); Abbe and Sandon (2015b), allowing to study the interplay between statistical and computational barriers Y. Chen (2014); Abbe and Sandon (2015c); Banks et al. (2016); Abbe and Sandon (2017), as well as the discrepancies between probabilstic and adversarial models Moitra et al. (2016), and it serves as a test bed for algorithms, such as SDPs Abbe et al. (2016); B. Hajek (2014); Hajek et al. (2015c); Guédon and Vershynin (2016); Amini and Levina (2014); Montanari and Sen (2016); Perry and Wein (2015), spectral methods Vu (2014); Massoulié (2014); Krzakala et al. (2013); Bordenave et al. (2015); Yun and Proutiere (2014), and belief propagation Decelle et al. (2011); Abbe and Sandon (2015).

1.2 Inference on graphs

Variants of block models where edges can have labels, or where communities can overlap, allow to cover at broad set of problems in machine learning. For example, a spiked Wigner model with observation $Y = XX^T + Z$, where X is an unknown vector and Z is Wigner, can be viewed as a labeled graph where edge-(i, j)'s label is given by $Y_{ij} = X_i X_j + Z_{ij}$. If the X_i's take discrete values, e.g., $\{1, -1\}$, this is closely related to the stochastic block model—see Deshpande et al. (2015) for a precise connection. The classical data clustering problem Shalev-Shwartz and Ben-David (2014), with a matrix of similarities or dissimilarities between n points, can also be viewed as a graph with labeled edges, and generalized block models provide probabilistic models to generate such graphs, when requiring continuous labels to model Euclidean connectivity kernels. In general, models where a collection of variables $\{X_i\}$ have to be recovered from noisy observations $\{Y_{ij}\}$ that are stochastic functions of X_i, X_j, or more generally that depend on local interactions of some of the X_i's, can be viewed as inverse problems on graphs or hypergraphs that bear similarities with the basic community detection problems discussed here. This concerns in particular topic modelling, ranking, synchronization problems and other unsupervised learning problems. The specificity of the core stochastic block model is that the input variables are usually discrete.

A general abstraction of these problems can also be obtained from an information theoretic point of view, with graphical channels Abbe and Montanari (2015), themselves a special case of conditional random fields Lafferty (2001), which model conditional distributions between a collection of vertex variables X^V and a collection of edge variables Y^E on a hyper-graph $G = (V, E)$, where the conditional probability distributions factors over each edge with a local kernel Q:

$$P(y^E|x^V) = \prod_{I \in E} Q_I(y_I|x[I]),$$

where y_I is the realization of Y on the hyperedge I and $x[I]$ is the realization of X^V over the vertices incident to the hyperedge I. Our goal in this note is to discuss tools and methods for the SBM that are likely to extend to the analysis of such general models.

1.3 Fundamental limits, phase transitions and algorithms

This note focus on the *fundamental limits* of community detection, with respect to various recovery requirements. The term 'fundamental limit' here is used to emphasize the fact that we seek conditions for recovery that are *necessary and sufficient*. In the information-theoretic sense, this means finding conditions under which a given task can or cannot be solved irrespective of complexity or algorithmic considerations, whereas in the computational sense, this further constraints the algorithms to run in polynomial time in the number of vertices. As we shall see in this note, such fundamental limits are often expressed through *phase transition* phenomena, which provide sharp transitions in the relevant regimes between phases where the given task can or cannot be resolved. In particular, identifying the bottleneck regime and location of the phase transition will typically characterize the behavior of the problem in almost any other regime.

Phase transitions have proved to be often instrumental in the developments of algorithms. A prominent example is Shannon's coding theorem Shannon (1948), that gives a sharp threshold for coding algorithms at the channel capacity, and which has led the development of coding algorithms for more than 60 years (e.g., LDPC, turbo or polar codes) at both the theoretical and practical level Richardson and Urbanke (2001). Similarly, the SAT threshold Achlioptas et al. (2005) has driven the developments of a variety of satisfiability algorithms such as survey propagation Mézard et al. (2003).

In the area of clustering and community detection, where establishing rigorous benchmarks is a long standing challenge, the quest of fundamental limits and phase transition is likely to impact the development of algorithms. In fact, this has already taken place as discussed in this note, such as with two-rounds algorithms or nonbacktracking spectral methods discussed in Section 3 and 4.

1.4 Network data analysis

This note focus on the fundamentals of community detection, but we want to illustrate here how the developed theory can impact real data applications. We use the blogosphere data set from the 2004 US political elections Adamic and Glance (2005) as an archetype example.

Consider the problem where one is interested in extracting features about a collection of items, in our case $n = 1,222$ individuals writing about US politics, observing only some form of their interactions. In our example, we have access to which blogs refers to which (via hyperlinks), but nothing else about the content of the blogs. The hope is to still extract knowledge about the individual features from these simple interactions.

To proceed, build a *graph of interaction* among the n individuals, connecting two individuals if one refers to the other, ignoring the direction of the hyperlink for simplicity. Assume next that the data set is generated from a stochastic block model; assuming two communities is an educated guess here, but one can also estimate the number of communities using the methods discussed in Section 7. The type of algorithms developed in Sections 4 and 3 can then be run on this data set, and two assortative communities are obtained. In the paper Adamic and Glance (2005), Adamic and Glance recorded which blogs are right or left leaning, so that we can check how much agreement these algorithm give with this partition of the blogs. The state-of-the-art algorithms give an agreement of roughly 95% with the groundtruth Newman (2011); Jin (2015); Gao et al. (2015). Therefore, by only observing simple pairwise interactions among these blogs, without any further information on the content of the blogs, we can infer about 95% of the blogs' political inclinations.

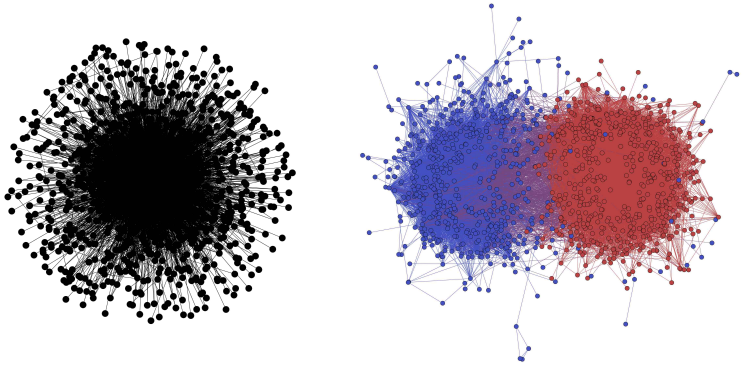

Figure 2: The above graphs represent the real data set of the political blogs from Adamic and Glance (2005). Each vertex represents a blog and each edge represents the fact that one of the blogs refers to the other. The left graph is plotted with a random arrangement of the vertices, and the right graph is the output of the ABP algorithm described in Section 4, which gives 95% accuracy on the reconstruction of the political inclination of the blogs (blue and red colors correspond to left and right leaning blogs).

Despite the fact that the blog data set is particularly 'well behaved'—there are two dominant clusters (potentially more with moderate blogs) that are balanced and well separated—the above approach can be applied to a broad collection of data sets to extract knowledge about the data from graphs of similarities. In some applications, the graph of similarity is obvious (such as in social networks with friendships), while in others, it is engineered from the data set based on metrics of similarity that need to be chosen properly. In any

case, the goal is to apply such an approach to problems for which the ground truth is unknown, such as to understand biological functionality of protein complexes; to find genetically related sub-populations; to make accurate recommendations; medical diagnosis; image classification; segmentation; page sorting; and more.

In such cases where the ground truth is not available, a key question is to understand how reliable the algorithms' outputs may be. On this matter, the theory discussed in this note gives a new perspective as follows. Following the definitions from Sections 4 and 3, the parameters estimated by fitting an SBM on this data set in the constant degree regime are

$$p_1 = 0.48,\ \ p_2 = 0.52, \quad Q = \begin{pmatrix} 52.06 & 5.16 \\ 5.16 & 47.43 \end{pmatrix}. \tag{1}$$

and in the logarithmic degree regime

$$p_1 = 0.48,\ \ p_2 = 0.52, \quad Q = \begin{pmatrix} 7.31 & 0.73 \\ 0.73 & 6.66 \end{pmatrix}. \tag{2}$$

Following the definitions of Theorem 42 from Section 4, we can now compute the SNR for these parameters in the constant-degree regime, obtaining $\lambda_2^2/\lambda_1 \approx 18$ which is much greater than 1. Thus, under an SBM model, the data is largely in a regime where communities can be detected, i.e., above the weak recovery threshold. Following the definitions of Theorem 14 from Section 3, we can also compute the CH-divergence for these parameters in the logarithmic-degree regime, obtaining $J(p, Q) \approx 2$ which is also greater than 1. Thus, under an SBM model, the data is a regime where the graph clusters could in fact be recovered entirely, i.e, above the exact recovery threshold. This does not answer whether the SBM is a good or bad model, but it gives that under this model, the data appears in a very good 'clustering regime.' This is of course counting on the fact that $n = 1,222$ is large enough to trust the asymptotic analysis. Had the SNR been too small, the model would have given us less confidence about the cluster outputs. This is the type of confidence insight that the study of fundamental limits can provide.

1.5 Brief historical overview of recent developments

This section provides a brief historical overview of the recent developments discussed in this monograph. The resurged interest in the SBM and its 'modern study' has been initiated in big part due to the paper of Decelle, Krzakala, Moore, Zdeborová Decelle et al. (2011), which conjectured[2] phase transition phenomena for the weak recovery (a.k.a. detection) problem at the Kesten-Stigum threshold and the information-computation gap at 4 symmetric communities in the symmetric case. These conjectures are backed in Decelle et al. (2011) with strong insights from statistical physics, based on the cavity method (belief propagation), and provide a detailed picture of the weak recovery problem, both for the

2. The conjecture of the Kesten-Stigum threshold in Decelle et al. (2011) was formulated with what we call in this note the max-detection criteria, asking for an algorithm to output a reconstruction of the communities that strictly improves on the trivial performance achieved by putting all the vertices in the largest community. This conjecture is formally incorrect for general SBMs, see Abbe and Sandon (2017) for a counter-example, as the notion of max-detection is too strong in some cases. The conjecture is always true for symmetric SBMs, as re-stated in Mossel et al. (2015), but it requires a different notion of detection to hold for general SBMs Abbe and Sandon (2017)—see Section 4.

algorithmic and information-theoretic behavior. Paper Decelle et al. (2011) opened a new research avenue driven by establishing such phase transitions.

One of the first paper that obtains a non-trivial algorithmic result for the weak recovery problem is Coja-Oghlan (2010) from 2010, which appeared before the conjecture (and does not achieve the threshold by a logarithmic degree factor). The first paper to make progress on the conjecture is Mossel et al. (2015) from 2012, which proves the impossibility part of the conjecture for two symmetric communities, introducing various key concepts in the analysis of block models. In 2013, Mossel et al. (2013) also obtains a result on the partial recovery of the communities, expressing the optimal fraction of mislabelled vertices when the signal-to-noise ratio is large enough in terms of the broadcasting problem on trees Kesten and Stigum (1966); Evans et al. (2000).

The positive part of the conjecture for efficient algorithm and two communities was first proved in 2014 with Massoulié (2014) and Mossel et al. (2014a), using respectively a spectral method from the matrix of self-avoiding walks and weighted non-backtracking walks between vertices.

In 2014, Abbe et al. (2014); Abbe et al. (2016) and Mossel et al. (2014b) found that the exact recovery problem for two symmetric communities has also a phase transition, in the logarithmic rather than constant degree regime, further shown to be efficiently achievable. This relates to a large body of work from the first decades of research on the SBM Bui et al. (1987); Dyer and Frieze (1989); Boppana (1987); Snijders and Nowicki (1997); Condon and Karp (1999); McSherry (2001); Bickel and Chen (2009); Choi et al. (2012); Vu (2014); Y. Chen (2014), driven by the exact or almost exact recovery problems without sharp thresholds.

In 2015, the phase transition for exact recovery is obtained for the general SBM Abbe and Sandon (2015b,c), and shown to be efficiently achievable irrespective of the number of communities. For the weak recovery problem, Bordenave et al. (2015) shows that the Kesten-Stigum threshold can be achieved with a spectral method based on the nonbacktracking (edge) operator in a fairly general setting (covering SBMs that are not necessarily symmetric), but falling short to settle the conjecture for more than two communities in the symmetric case due to technical reasons. The approach of Bordenave et al. (2015) is based on the 'spectral redemption' conjecture made in 2013 in Krzakala et al. (2013), which introduces the use of the nonbacktracking operator as a linearization of belief propagation. This is arguably the most elegant approach to the weak recovery problem, besides for the fact that the matrix is not symmetrical (to work with a symmetric matrix, the first proof of Massoulié (2014) provides also a clean description via self-avoiding walks). The general conjecture for arbitrary many symmetric or asymmetric communities is settled later in 2015 with Abbe and Sandon (2015); Abbe and Sandon (2016b), relying on a higher-order nonbacktracking matrix and a message passing implementation. It is further shown in Abbe and Sandon (2015); Abbe and Sandon (2017) that it is possible to cross information-theoretically the Kesten-Stigum threshold in the symmetric case at 4 communities, settling both positive parts of the conjectures from Decelle et al. (2011). Crossing at 5 communities is also obtained in Banks and Moore (2016); Banks et al. (2016), which further obtains the scaling of the information-theoretic threshold for a growing number of communities.

In 2016, a tight expression is obtained for partial recovery with two communities in the regime of finite SNR with diverging degrees in Deshpande et al. (2015) and Mossel and Xu

(2015) for different distortion measures. This also gives the threshold for weak recovery in the regime where the SNR in the regime of finite SNR with diverging degrees.

Other major lines of work on the SBM have been concerned with the performance of SDPs, with a precise picture obtained in Guédon and Vershynin (2016); Montanari and Sen (2016); Javanmard et al. (2016) for the weak recovery problem and in Abbe et al. (2016); B. Hajek (2014); Amini and Levina (2014); Bandeira (2015); Agarwal et al. (2015); Perry and Wein (2015) for the (almost) exact recovery problem, as well as spectral methods on classical operators McSherry (2001); Coja-Oghlan (2010); Chin et al. (2015); Xu et al. (2014); Vu (2014); Yun and Proutiere (2014); Yun and Proutiere (2015). A detailed picture has also been developed for the problem of a single planted community in Montanari (2015); Hajek et al. (2015b,a); Caltagirone et al. (2016). There is a much broader list of works on the SBMs that is not covered in this paper, specially before the 'recent developments' discussed above but also after. It is particularly challenging to track the vast literature on this subject as it is split between different communities of statistics, machine learning, mathematics, computer science, information theory, social sciences and statistical physics. This monograph covers developments mainly until 2016. There a few additional surveys available. Community detection and more generally statistical network models are discussed in Newman (2010); Fortunato (2010); Goldenberg et al. (2010), and C. Moore has a recent overview paper Moore (2017) that focuses on the weak recovery problem with emphasis on the cavity method.

The main thresholds proved for weak and exact recovery are summarized in the table below:

	Exact recovery (logarithmic degrees)
2-SSBM	$\lvert\sqrt{a}-\sqrt{b}\rvert>\sqrt{2}$ Abbe et al. (2014); Mossel et al. (2014b)
General SBM	$\min_{i<j} D_+((PQ)_i,(PQ)_j)>1$ Abbe and Sandon (2015b)

	Weak recovery (detection) (constant degrees)
2-SSBM	$(a-b)^2>2(a+b)$ Massoulié (2014); Mossel et al. (2014a)
General SBM	$\lambda_2^2(PQ)>\lambda_1(PQ)$ Bordenave et al. (2015); Abbe and Sandon (2015)

1.6 Outline

In the next section, we formally define the SBM and various recovery requirements for community detection, namely weak, partial and exact recovery. We then describe in Sections 3, 4, 5, 6 recent results that establish the fundamental limits for these recovery requirements. We further discuss in Section 7 the problem of learning the SBM parameters, and give a list of open problems in Section 8.

2. The Stochastic Block Model

The history of the SBM is long, and we omit a comprehensive treatment here. As mentioned earlier, the model appeared independently in multiple scientific communities: the terminology SBM, which seems to have dominated in the recent years, comes from the machine learning and statistics literature Holland et al. (1983), while the model is typically

called the planted partition model in theoretical computer science Bui et al. (1987); Dyer and Frieze (1989); Boppana (1987), and the inhomogeneous random graphs model in the mathematics literature Bollobás et al. (2007).

2.1 The general SBM

Definition 1 *Let n be a positive integer (the number of vertices), k be a positive integer (the number of communities), $p=(p_1,\dots,p_k)$ be a probability vector on $[k]:=\{1,\dots,k\}$ (the prior on the k communities) and W be a $k\times k$ symmetric matrix with entries in $[0,1]$ (the connectivity probabilities). The pair (X,G) is drawn under $\mathrm{SBM}(n,p,W)$ if X is an n-dimensional random vector with i.i.d. components distributed under p, and G is an n-vertex simple graph where vertices i and j are connected with probability W_{X_i,X_j}, independently of other pairs of vertices. We also define the community sets by $\Omega_i=\Omega_i(X):=\{v\in[n]: X_v=i\}, i\in[k]$.*

Thus the distribution of (X,G) where $G=([n],E(G))$ is defined as follows, for $x\in[k]^n$ and $y\in\{0,1\}^{\binom{n}{2}}$,

$$\mathbb{P}\{X=x\}:=\prod_{u=1}^n p_{x_u}=\prod_{i=1}^k p_i^{|\Omega_i(x)|} \tag{3}$$

$$\mathbb{P}\{E(G)=y|X=x\}:=\prod_{1\le u<v\le n} W_{x_u,x_v}^{y_{uv}}(1-W_{x_u,x_v})^{1-y_{uv}} \tag{4}$$

$$=\prod_{1\le i\le j\le k} W_{i,j}^{N_{ij}(x,y)}(1-W_{i,j})^{N_{ij}^c(x,y)} \tag{5}$$

where,

$$N_{ij}(x,y):=\sum_{u<v,x_u=i,x_v=j}\mathbb{1}(y_{uv}()=1), \tag{6}$$

$$N_{ij}^c(x,y):=\sum_{u<v,x_u=i,x_v=j}\mathbb{1}(y_{uv}=0)=|\Omega_i(x)||\Omega_j(x)|-N_{ij}(x,y),\quad i\neq j \tag{7}$$

$$N_{ii}^c(x,y):=\sum_{u<v,x_u=i,x_v=i}\mathbb{1}(y_{uv}=0)=|\Omega_i(x)|(|\Omega_i(x)|-1)/2-N_{ii}(x,y), \tag{8}$$

which are the number of edges and non-edges between any pair of communities. We may also talk about G drawn under $\mathrm{SBM}(n,p,W)$ without specifying the underlying community labels X.

Remark 2 *Besides for Section 8, we assume that p does not scale with n, whereas W typically does. As a consequence, the number of communities does not scale with n and the communities have linear size. Nonetheless, various results discussed in this note should extend (by inspection) to cases where k is growing slowly enough.*

Remark 3 *Note that by the law of large numbers, almost surely,*

$$\frac{1}{n}|\Omega_i|\to p_i.$$

Alternative definitions of the SBM require X to be drawn uniformly at random with the constraint that $\frac{1}{n}|\{v \in [n] : X_v = i\}| = p_i + o(1)$, or $\frac{1}{n}|\{v \in [n] : X_v = i\}| = p_i$ for consistent values of n and p (e.g., $n/2$ being an integer for two symmetric communities). For the purpose of this paper, these definitions are essentially equivalent.

2.2 The symmetric SBM

The SBM is called symmetric if p is uniform and if W takes the same value on the diagonal and the same value outside the diagonal.

Definition 4 *(X, G) is drawn under $\mathrm{SSBM}(n, k, A, B)$, if $p = \{1/k\}^k$ and W takes value A on the diagonal and B off the diagonal.*

Note also that if all entries of W are the same, then the SBM collapses to the Erdős-Rényi random graph, and no meaningful reconstruction of the communities is possible.

2.3 Recovery requirements

The goal of community detection is to recover the labels X by observing G, up to some level of accuracy. We next define the agreement, also called sometimes overlap.

Definition 5 (Agreement) *The agreement between two community vectors $x, y \in [k]^n$ is obtained by maximizing the common components between x and any relabelling of y, i.e.,*

$$A(x, y) = \max_{\pi \in S_k} \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(x_i = \pi(y_i)), \tag{9}$$

where S_k is the group of permutations on $[k]$.

Note that the relabelling permutation is used to handle symmetric communities such as in SSBM, as it is impossible to recover the actual labels in this case, but we may still hope to recover the *partition*. In fact, one can alternatively work with the community partition $\Omega = \Omega(X)$, defined earlier as the unordered collection of the k disjoint unordered subsets $\Omega_1, \ldots, \Omega_k$ covering $[n]$ with $\Omega_i = \{u \in [n] : X_u = i\}$. It is however often convenient to work with vertex labels. Further, upon solving the problem of finding the partition, the problem of assigning the labels is often a much simpler task. It cannot be resolved if symmetry makes the community label non identifiable, such as for SSBM, and it is trivial otherwise by using the community sizes and clusters/cuts densities.

For $(X, G) \sim \mathrm{SBM}(n, p, W)$ one can always attempt to reconstruct X without even taking into account G, simply drawing each component of $\hat{X}$ i.i.d. under p. Then the agreement satisfies almost surely

$$A(X, \hat{X}) \to \|p\|_2^2, \tag{10}$$

and $\|p\|_2^2 = 1/k$ in the case of p uniform. Thus an agreement becomes interesting only when it is above this value.

One can alternatively define a notion of component-wise agreement. Define the overlap between two random variables X, Y on $[k]$ as

$$O(X, Y) = \sum_{z \in [k]} (\mathbb{P}\{X = z, Y = z\} - \mathbb{P}\{X = z\}\mathbb{P}\{Y = z\}) \tag{11}$$

and $O^*(X, Y) = \max_{\pi \in S_k} O(X, \pi(Y))$. In this case, for $X, \hat{X}$ i.i.d. under p, we have $O^*(X, \hat{X}) = 0$.

All recovery requirement in this note are going to be asymptotic, taking place with high probability as n tends to infinity. We also assume in the following sections—except for Section 7—that the parameters of the SBM are known when designing the algorithms.

Definition 6 *Let $(X, G) \sim \mathrm{SBM}(n, p, W)$. The following recovery requirements are solved if there exists an algorithm that takes G as an input and outputs $\hat{X} = \hat{X}(G)$ such that*

- **Exact recovery:** $\mathbb{P}\{A(X, \hat{X}) = 1\} = 1 - o(1)$,
- **Almost exact recovery:** $\mathbb{P}\{A(X, \hat{X}) = 1 - o(1)\} = 1 - o(1)$,
- **Partial recovery:** $\mathbb{P}\{A(X, \hat{X}) \geq \alpha\} = 1 - o(1)$, $\alpha \in (0, 1)$.

In other words, exact recovery requires the entire partition to be correctly recovered, almost exact recovery allows for a vanishing fraction of misclassified vertices and partial recovery allows for a constant fraction of misclassified vertices. We call α the agreement or accuracy of the algorithm.

Different terminologies are sometimes used in the literature, with following equivalences:

- exact recovery $\iff$ strong consistency
- almost exact recovery $\iff$ weak consistency

Sometimes 'exact recovery' is also called just 'recovery' and 'almost exact recovery' is called 'strong recovery.'

As mentioned above, that values of α that are too small may not be interesting or possible. In the symmetric SBM with k communities, an algorithm that that ignores the graph and simply draws $\hat{X}$ i.i.d. under p achieves an accuracy of $1/k$. Thus the problem becomes interesting when $\alpha > 1/k$, leading to the following definition.

Definition 7 *Weak recovery or detection is solved in $\mathrm{SSBM}(n, k, A, B)$ if for $(X, G) \sim \mathrm{SSBM}(n, k, A, B)$, there exists $\varepsilon > 0$ and an algorithm that takes G as an input and outputs $\hat{X}$ such that $\mathbb{P}\{A(X, \hat{X}) \geq 1/k + \varepsilon\} = 1 - o(1)$.*

Equivalently, $\mathbb{P}\{O^*(X_V, \hat{X}_V) \geq \varepsilon\} = 1 - o(1)$ where V is uniformly drawn in $[n]$. Determining the counterpart of weak recovery in the general SBM requires some discussion. Consider an SBM with two communities of relative sizes $(0.8, 0.2)$. A random guess under this prior gives an agreement of $0.8^2 + 0.2^2 = 0.68$, however an algorithm that simply puts every vertex in the first community achieves an agreement of 0.8. In Decelle et al. (2011), the latter agreement is considered as the one to improve upon in order to detect communities, leading to the following definition:

Definition 8 *Max-detection is solved in $\mathrm{SBM}(n, p, W)$ if for $(X, G) \sim \mathrm{SBM}(n, p, W)$, there exists $\varepsilon > 0$ and an algorithm that takes G as an input and outputs $\hat{X}$ such that $\mathbb{P}\{A(X, \hat{X}) \geq \max_{i \in [k]} p_i + \varepsilon\} = 1 - o(1)$.*

As shown in Abbe and Sandon (2017), previous definition is however not the right definition to capture the Kesten-Stigum threshold in the general case. In other words, the conjecture that max-detection is always possible above the Kesten-Stigum threshold is not accurate in general SBMs. Back to our example with communities of relative sizes $(0.8, 0.2)$, an algorithm that could find a set containing $2/3$ of the vertices from the large community and $1/3$ of the vertices from the small community would not satisfy the above above detection criteria, while the algorithm produces nontrivial amounts of evidence on what communities the vertices are in. To be more specific, consider a two community SBM where each vertex is in community 1 with probability 0.99, each pair of vertices in community 1 have an edge between them with probability $2/n$, while vertices in community 2 never have edges. Regardless of what edges a vertex has it is more likely to be in community 1 than community 2, so detection according to the above definition is not impossible, but one can still divide the vertices into those with degree 0 and those with positive degree to obtain a non-trivial detection—see Abbe and Sandon (2017) for a formal counter-example.

A fix fo this issue is to consider a weighted notion of agreement, i.e.,

$$\tilde{A}(x,y) = \max_{\pi \in S_k} \frac{1}{k} \sum_{i=1}^{k} \frac{\sum_{u \in [n]} \mathbb{1}(x_u = \pi(y_u), x_u = i)}{\sum_{u \in [n]} \mathbb{1}(x_u = i)}, \tag{12}$$

which counts the number of agreeing components (up to relabellings) normalized by the size of the communities. Weak recovery (or detection) can then be defined as obtaining with high probability a weighted agreement of

$$\tilde{A}(X, \hat{X}(G)) = 1/k + \Omega_n(1),$$

and this applies to the general SBM. Another definition of detection that seems easier to manipulate and that implies the previous one is as follows; note that this definition requires a single partition even for the general SBM.

Definition 9 Weak recovery or detection *is solved in* $\mathrm{SBM}(n,p,W)$ *if for* $(X,G) \sim \mathrm{SBM}(n,p,W)$*, there exists* $\varepsilon > 0$*,* $i,j \in [k]$ *and an algorithm that takes* G *as an input and outputs a partition of* $[n]$ *into two sets* (S, S^c) *such that*

$$\mathbb{P}\{|\Omega_i \cap S|/|\Omega_i| - |\Omega_j \cap S|/|\Omega_j| \geq \epsilon\} = 1 - o(1),$$

where we recall that $\Omega_i = \{u \in [n] : X_u = i\}$.

In other words, an algorithm solves detection if it divides the graph's vertices into two sets such that vertices from two different communities have different probabilities of being assigned to one of the sets. With this definition, putting all vertices in one community does not detect, since $|\Omega_i \cap S|/|\Omega_i| = 1$ for all $i \in [k]$. Further, in the symmetric SBM, this definition implies Definition 7 provided that we fix the output:

Lemma 10 *If an algorithm solves detection in the sense of Definition 11 for a symmetric SBM, then it solves max-detection (or detection according to Decelle et al.'s definition), provided that we consider it as returning* $k-2$ *empty sets in addition to its actual output.*

See Abbe and Sandon (2016b) for the proof. The above is likely to extend to other weakly symmetric SBMs, i.e., that have constant expected degree, but not all.

Finally, note that our notion of detection requires to separate at least two communities $i,j \in [k]$. One may ask for a definition where two specific communities need to be separated:

Definition 11 *Separation of communities* i *and* j*, with* $i,j \in [k]$*, is solved in* $\mathrm{SBM}(n,p,W)$ *if for* $(X,G) \sim \mathrm{SBM}(n,p,W)$*, there exists* $\varepsilon > 0$ *and an algorithm that takes* G *as an input and outputs a partition of* $[n]$ *into two sets* (S, S^c) *such that*

$$\mathbb{P}\{|\Omega_i \cap S|/|\Omega_i| - |\Omega_j \cap S|/|\Omega_j| \geq \epsilon\} = 1 - o(1).$$

There are at least two additional questions that are natural to ask about SBMs, both can be asked for efficient or information-theoretic algorithms:

- **Distinguishability or testing:** Consider an hypothesis test where a random graph G is drawn with probability $1/2$ from an SBM model (with same expected degree in each community) and with probability $1/2$ from an Erdős-Rényi model with matching expected degree. Is is possible to decide with asymptotic probability $1/2+\varepsilon$ for some $\varepsilon > 0$ from which ensemble the graph is drawn? This requires the total variation between the two ensembles to be non-vanishing. This is also sometimes called 'detection', although we use here detection as an alternative terminology to weak recovery. Distinguishability is further discussed in Section 4.6.1.

- **Learnability:** Assume that G is drawn from an SBM ensemble, is it possible to obtain a consistent estimator for the parameters? E.g., can we learn k,p,Q from a graph drawn from $\mathrm{SBM}(n,p,Q/n)$? This is further discussed in Section 7.

The obvious implications are: exact recovery $\Rightarrow$ almost exact recovery $\Rightarrow$ partial recovery $\Rightarrow$ weak detection $\Rightarrow$ distinguishability. Moreover, for symmetric SBMs with two symmetric communities: learnability $\Leftrightarrow$ weak recovery $\Leftrightarrow$ distinguishability, but these are broken for general SBMs; see Section 7.

2.4 Model variants

There are various extensions of the basic SBM discussed in previous section, in particular:

- **Labelled SBMs:** allowing for edges to carry a label, which can model intensities of similarity functions between vertices (see for example Heimlicher et al. (2012); Xu et al. (2014); Jog and Loh (2015); Yun and Proutiere (2015) and further details in Section 3.5);

- **Degree-corrected SBMs:** allowing for a degree parameter for each vertex that scales the edge probabilities in order to makes expected degrees match the observed degrees (see for example Karrer and Newman (2011); **?**); **?**);

- **Overlapping SBMs:** allowing for the communities to overlap, such as in the mixed-membership SBM Airoldi et al. (2008), where each vertex has a profile of community memberships or a continuous label—see also Fortunato (2010); Newman and Peixoto (2015); Ball et al. (2011b); Peixoto (2015); Palla et al. (2005); Gopalan and Blei (2013); Abbe and Sandon (2015b) and further discussion in Section 3.5).

Another variant that circumvents the discussions about non-edges is to consider a **censored block model** (CBM), defined as follows (see Abbe et al. (2014a)).

Definition 12 (Binary symmetric CBM) *Let $G = ([n], E)$ be a graph and $\varepsilon \in [0,1]$. Let $X^n = (X_1, \ldots, X_n)$ with i.i.d. Bernoulli(1/2) components. Let Y be a random vector of dimension $\binom{n}{2}$ taking values in $\{0, 1, \star\}$ such that*

$$\mathbb{P}\{Y_{ij} = 1 | X_i = X_j, E_{ij} = 1\} = \mathbb{P}\{Y_{ij} = 0 | X_i \neq X_j, E_{ij} = 1\} = \varepsilon \tag{13}$$
$$\mathbb{P}\{Y_{ij} = \star | E_{ij} = 0\} = 1. \tag{14}$$

The case of an Erdos-Renyi graph is discussed in Heimlicher et al. (2012); Abbe et al. (2014a,b); Chin et al. (2015); Saade et al. (2015); Chen et al. (2014); Chen and Goldsmith (2014). Inserting the $\star$ symbol simplifies a few aspects compared to SBMs with respect to non-edges. In that sense, the CBM is a more convenient model than the SBM from a mathematical viewpoint, while behaving similarly to the SBM (when G is an Erdos-Renyi graph of degree $(a+b)/2$ and $\varepsilon = b/(a+b)$ for the two community symmetric case). The CBM can also be viewed as a synchronization model over the binary field, and more general synchronization models have been studied in **??**, with a complete description both at the fundamental and algorithmic level (generalizing in particular the results from Section 6.2).

Further, one can consider more general models of **inhomogenous random graphs** Bollobás et al. (2007), which attach to each vertex a label in a set that is not necessarily finite, and where edges are drawn independently from a given kernel conditionally on these labels. This gives in fact a way to model mixed-membership, and is also related to **graphons**, which corresponds to the case where each vertex has a continuous label.

It may be worth saying a few words about the theory of graphons and its implications for us. Lovász and co-authors introduced graphons Lovász and Szegedy (2006); Borgs et al. (2008); Lovász (2012) in the study of large graphs (also related to Szemerédi's Regularity Lemma Szemerédi (1976)), showing that[3] a convergent sequence of graphs admits a limit object, the graphon, that preserves many local and global properties of the sequence. Graphons can be represented by a measurable function $w : [0,1]^2 \to [0,1]$, which can be viewed as a continuous extensions of the connectivity matrix W used throughout this paper. Most relevant to us is that any network model that is invariant under node labelings, such as most models of practical interests, can be described by an edge distribution that is *conditionally independent* on hidden node labels, via such a measurable map w. This gives a de Finetti's theorem for label-invariant models Hoover (1979); Aldous (1981); Diaconis and Janson (2007), but does not require the topological theory behind it. Thus the theory of graphons may give a broader meaning to the study of block models, which are precisely building blocks to graphons, but for the sole purpose of studying exchangeable network models, inhomogeneous random graphs give enough degrees of freedom.

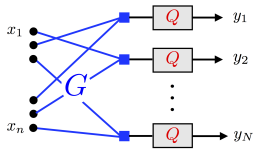
Further, many problems in machine learning and networks are also concerned with interactions of items that go beyond the pairwise setting. For example, citation or metabolic networks rely on interactions among k-tuples of vertices. In a broad context, one may thus cast the SBM and its variants into a a comprehensive class of conditional random field or

3. Initially in dense regimes and more recently for sparse regimes Borgs et al. (2014).

channel model, where edges labels depend on vertex labels,[4] such as developed in Abbe and Montanari (2015) with **graphical channels** as follows.

Let $V = [n]$ and $G = (V, E(G))$ be a hypergraph with $N = |E(G)|$. Let $\mathcal{X}$ and $\mathcal{Y}$ be two finite sets called respectively the input and output alphabets, and $Q(\cdot|\cdot)$ be a channel from $\mathcal{X}^k$ to $\mathcal{Y}$ called the kernel. To each vertex in V, assign a vertex-variable in $\mathcal{X}$, and to each edge in $E(G)$, assign an edge-variable in $\mathcal{Y}$. Let y_I denote the edge-variable attached to edge I, and $x[I]$ denote the k node-variables adjacent to I. We define a graphical channel with graph G and kernel Q as the channel $P(\cdot|\cdot)$ given by

$$P(y|x) \equiv \prod_{I \in E(G)} Q(y_I | x[I])$$
$$x \in \mathcal{X}^V, y \in \mathcal{Y}^{E(G)}$$



As we shall see for the SBM, two quantities are key to understand how much information can be carried in graphical channels: a measure on how "rich" the observation graph G is, and a measure on how "noisy" the connectivity kernel Q is. This survey quantifies the tradeoffs between these two quantities in the SBM (which corresponds to a discrete $\mathcal{X}$, a complete graph G and a specific kernel Q), in order to recover the input from the output. Similar tradeoffs are expected to take place in other graphical channels, such as in ranking, synchronization, topic modelling or other related models.

2.5 SBM regimes and topology

Before discussing when the various recovery requirements can be solved or not in SBMs, it is important to recall a few topological properties of the SBM graph.

When all the entries of W are the same and equal to w, the SBM collapses to the Erdős-Rényi model $G(n, w)$ where each edge is drawn independently with probability w. Let us recall a few basic results for this model derived mainly from Erdös and Rényi (1960):

- $G(n, c\ln(n)/n)$ is connected with high probability if and only if $c > 1$,
- $G(n, c/n)$ has a giant component (i.e., a component of size linear in n) if and only if $c > 1$,
- For $\delta < 1/2$, the neighborhood at depth $r = \delta \log_c n$ of a vertex v in $G(n, c/n)$, i.e., $B(v, r) = \{u \in [n] : d(u, v) \leq r\}$ where $d(u, v)$ is the length of the shortest path connecting u and v, tends in total variation to a Galton-Watson branching process of offspring distribution Poisson(c).

For SSBM(n, k, A, B), these results hold by essentially replacing c with the average degree.

- For $a, b > 0$, SSBM$(n, k, a\log n/n, b\log n/n)$ is connected with high probability if and only if $\frac{a+(k-1)b}{k} > 1$ (if a or b is equal to 0, the graph is of course not connected).

4. A recent paper Berthet et al. (2016) has also considered an Ising model with block structure, studying exact recovery and SDPs in this context.

- SSBM$(n, k, a/n, b/n)$ has a giant component (i.e., a component of size linear in n) if and only if $d := \frac{a+(k-1)b}{k} > 1$,
- For $\delta < 1/2$, the neighborhood at depth $r = \delta \log_d n$ of a vertex v in SSBM$(n, k, a/n, b/n)$ tends in total variation to a Galton-Watson branching process of offspring distribution Poisson(d) where d is as above.

Similar results hold for the general SBM, at least for the case of a constant excepted degrees. For connectivity, one has that SBM$(n, p, Q \log n/n)$ is connected with high probability if

$$\min_{i\in[k]} \|(\mathrm{diag}(p)Q)_i\|_1 > 1 \tag{15}$$

and is not connected with high probability if $\min_{i\in[k]} \|(\mathrm{diag}(p)Q)_i\|_1 < 1$, where $(\mathrm{diag}(p)Q)_i$ is the i-th column of $\mathrm{diag}(p)Q$.

These results are important to us as they already point regimes where exact or weak recovery is not possible. Namely, if the SBM graph is not connected, exact recovery is not possible (since there is no hope to label disconnected components with higher chance than $1/2$), hence exact recovery can take place only if the SBM parameters are in the logarithmic degree regime. In other words, exact recovery in SSBM$(n, k, a \log n/n, b \log n/n)$ is not solvable if $\frac{a+(k-1)b}{k} < 1$. This is however unlikely to provide a tight condition, i.e., exact recovery is not equivalent to connectivity, and next section will precisely investigate how much more than $\frac{a+(k-1)b}{k} > 1$ is needed to obtain exact recovery. Similarly, it is not hard to see that weak recovery is not solvable if the graph does not have a giant component, i.e., weak recovery is not solvable in SSBM$(n, k, a/n, b/n)$ if $\frac{a+(k-1)b}{k} < 1$, and we will see in Section 4 how much more is needed to go from the giant to weak recovery.

2.6 Challenges: spectral, SDP and message passing approaches

Consider the symmetric SBM with two communities, where the inner-cluster probability is a/n and the across-cluster probability is b/n, i.e., SSBM$(n, 2, a/n, b/n)$, and assume $a \geq b$. We next discuss basic approaches and the challenges that they face.

The spectral approach. Assume for simplicity that the two clusters have exactly size $n/2$, and index the first cluster with the first $n/2$ vertices. The expected adjacency matrix $\mathbb{E}A$ of this graph has four blocks given by

$$\mathbb{E}A = \begin{pmatrix} a/n \cdot 1^{n/2\times n/2} & b/n \cdot 1^{n/2\times n/2} \\ b/n \cdot 1^{n/2\times n/2} & a/n \cdot 1^{n/2\times n/2} \end{pmatrix}. \tag{16}$$

This matrix has three eigenvalues, namely $(a+b)/n$, $(a-b)/n$ and 0, where 0 has multiplicity $n-2$, and eigenvectors attached to the first two eigenvalues are

$$\left\{ \frac{a+b}{n}, \begin{pmatrix} 1^{n/2} \\ 1^{n/2} \end{pmatrix} \right\}, \left\{ \frac{a-b}{n}, \begin{pmatrix} 1^{n/2} \\ -1^{n/2} \end{pmatrix} \right\}. \tag{17}$$

Since permutations do not affect eigenvalues and permute eigenvectors, if one were to work with the expected adjacency matrix, communities could simply be recovered by taking an

eigenvector corresponding to the second largest eigenvalue, and assigning each vertex to a community depending on the sign of this eigenvector's components. Of course, we do not have access to the expected adjacency matrix, nor a tight estimate since we are observing a single shot of the SBM graph, but we can view the adjacency matrix A as a perturbation of $\mathbb{E}A$, i.e.,

$$A = \mathbb{E}A + Z$$

where $Z = (A - \mathbb{E}A)$ is the perturbation. One may hope that this perturbation is moderate, i.e., that carrying the same program as for the expected adjacency—taking the second eigenvector of A—still gives a meaningful reconstruction of the communities.

The Courant-Fisher theorem can be used to obtain a simple control on the perturbation of the eigenvalues of A from $\mathbb{E}A$. Denoting by $\lambda_1 \geq \cdots \geq \lambda_n$ and $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \cdots \geq \hat{\lambda}_n$ the ordered eigenvalues of $\mathbb{E}A$ and A respectively, we have for all $i \in [n]$,

$$|\lambda_i - \hat{\lambda}_i| \leq \|Z\|, \tag{18}$$

where $\|\cdot\|$ denotes the operator norm. Thus, if $\|Z\|$ is less than half of the least gap between the three eigenvalues $\frac{a+b}{n}$, $\frac{a-b}{n}$ and 0, the eigenvalues of A would have a preserved ordering. This would only give us hope that the eigenvectors would be correlated, but gives no guarantees so far. The Davis-Kahan Theorem can be used to that end, giving that the angle θ_i between the eigenvectors corresponding to the i-th eigenvalues has a sinus bounded as $\sin\theta_i \leq \frac{\|Z\|}{\min_{i\neq j}|\lambda_i - \lambda_j|/2}$ (this is in fact a slightly weaker statement than Davis-Kahan). Thus estimating the operator norm is crucial with this approach, and tools from random matrix theory can be used here Nadakuditi and Newman (2012); Vu (2007).

The problem with this naive approach is that it fails when a and b are too small, such as in the sparse regime (constant a, b) or even slowly growing degrees. One of the main reasons for this is that the eigenvalues are far from being properly ordered in such cases, in particular due to high degree nodes. In the sparse regime, there will be nodes of almost logarithmic degree, and these induce eigenvalues of order roughly root-logarithmic. To see this, note that an isolated star graph, i.e., a single vertex connected to k neighbors, has an eigenvalue of $\sqrt{k}$ with eigenvector having weight 1 on the center-vertex and $\sqrt{k}$ on the neighbors (recall that applying a vector to the adjacency matrix corresponds to diffusing each vector component to its neighbors).

Thus the spectrum of the adjacency matrix or standard Laplacians is blurred by 'outlier' eigenvalues in such regimes Kawamoto and Kabashima (2015), and we will need to rely on different operators that are not as sensitive. This is a real difficulty that is recurrent in practical applications of clustering algorithms. A possible approach is to try to regularize the spectrum by relying on regularized Laplacians such as in Joseph and Yu (2013); Le et al. (2015); Coja-Oghlan (2010); Vu (2014); Guédon and Vershynin (2016); Chin et al. (2015), by either trimming or shifting the matrix entries, but does not suffice in the most challenging regimes. The SBM will gives us rigorous benchmarks to understand how to design such operators. In particular, the nonbacktracking operator discussed in Section 4 will allow to run the above program (i.e., taking the second eigenvector) successfully, as it affords a 'clean' spectrum that is not contaminated by localized eigenvectors even in the weakest possible signal-to-noise regimes. As discussed next, this operator can in fact be derived as a linearization of belief propagation.

The message passing approach. Before describing the approach, let us remind ourselves of what our goals are. We defined different recovery requirements for the SBM, in particular weak and exact recovery. As discussed in Section 3, exact recovery yields a clear target for the SSBM, the optimal algorithm (minimizing the probability of failing) is the Maximum A Posteriori (MAP) algorithm that looks for the min-bisection:

$$\hat{x}_{\text{map}}(g) = \arg \max_{\substack{x \in \{+1,-1\}^n \\ x^t 1^n = 0}} x^t A x, \tag{19}$$

which is equivalent to finding a balanced ± 1 assignment to each vertex such that the number of edges with different end points is minimized. This is NP-hard in the worst-case (due to the integral constraint), but we will show that the min-bisection can be found efficiently 'with high probability' for the SBM whenever it is unique with high probability (i.e., no gap occurs!). Further, both the spectral approach described above (with some modifications) and the SDP approach described in Section 3.4 allow to achieve the threshold, and each can be viewed as a relaxation of the min-bisection problem (see Section 3.4).

For weak recovery instead, minimizing the error probability (i.e., the MAP estimator) is no longer optimal, and thus targeting the min-bisection is not necessarily the right approach. As discussed above, the spectral approach on the adjacency matrix can fail dramatically, as it will catch localized eigenvectors (e.g., high-degree nodes) rather than communities. The SDP approach seems more robust. While it does not detect communities in the most challenging regimes, it approaches the threshold fairly closely for two communities—see Javanmard et al. (2016). Nonetheless, it does not target the right figure of merit for weak recovery.

What is then the right figure of merit for weak recovery? Consider the agreement metric, i.e., minimizing the fraction of mislabelled vertices. Consider also a perturbation of the SBM parameters to a slightly asymmetric version, such that the labels can now be identified from the partition, to avoid the relabelling maximization over the communities. The agreement between the true clusters X and a reconstruction $\hat{X}$ is then given by $\sum_{v \in [n]} \mathbb{1}(X_v = \hat{X}_v(G))$, and upon observing $G = g$, the expected agreement is maximized by finding for each $v \in [n]$

$$\max_{\hat{x}_v} \mathbb{P}\{X_v = \hat{x}_v | G = g\}. \tag{20}$$

The reasons for considering an asymmetric SBM here is that the above expression is exactly equal to half in the symmetric case, which carries no information. To remediate to that, one should break the symmetry in the symmetric case by revealing some vertex labels (or use noisy labels as done in Deshpande et al. (2015), or parity of pairs of vertices). One may also relate the random agreement to its expectation with concentration arguments. These are overlooked here, but we get a hint on what the Bayes optimal algorithm should do: it should approximately maximize the posterior distribution of a single vertex given the graph. This is different than MAP which attempts to recover all vertices in one shot. In the latter context, the maximizer may not be 'typical' (e.g., the all-one vector is the most likely outcome of n i.i.d. Bernoulli(3/4) random variables, but it does not have a typical fraction of 1's).

Computing (20) is hard, as it requires computing the graph marginal which requires computing an exponential sum. This is where belief propagation comes into play, to provide a tight approximation. When the graph is a tree, the approximation is exact, and physicists have good reasons to believe that this remains true even in our context of a loopy graph Decelle et al. (2011). However, establishing such a claim rigorously is a long-standing challenge for message passing algorithms. Without a good guess on how to initialize BP, which we do not possess for the detection problem, one may simply take a random initial guess. In the symmetric case, this would still give a bias of roughly $\sqrt{n}$ vertices (from the Central Limit Theorem) towards the true partition, i.e., a initial belief of $1/2 + \Theta(1/\sqrt{n})$ towards the truth. Recall that in BP, each vertex will send its belief of being 0 or 1 to its neighbors, computing this belief using Bayes rule from the received beliefs at previous iteration, and factoring out the backtracking beliefs (i.e., do not take into account the belief of a specific vertex to update it in the next iteration). As the initial belief of $1/2$ is a trivial fix point in BP, one may attempt to approximate the update Bayes rule around the uniform beliefs, working out the linear approximation of the BP update. This gives raise to a linear operator, which is the nonbacktracking (NB) operator discussed in Section 4.5.1, and running linerazied BP corresponds to taking a power-iteration method with this operator on the original random guesses—see Section 4.5.1. Thus, we are back to a spectral method, but with an operator that is a linearization of the Bayes optimal approximation (this gave raise to the terminology 'spectral redemption' in Krzakala et al. (2013).)

The advantage of this linearized approach is that it is easier to analyze than the full BP, and one can prove statements about it, such as that it detects down to the optimal threshold Bordenave et al. (2015); Abbe and Sandon (2015). On the other hand, linerarized BP will loose some accuracy in contrast to full BP, but this can be improved by using a two-round algorithm: start with linearized BP to provably detect communities, and then enhance this reconstruction by feeding it to full BP—see for example Mossel et al. (2013); Abbe and Sandon (2016b). The latter approach gives raise to a new approach to analyzing belief propagation: can such two rounds approaches with linearization plus amplification be applied to other problems?

3. Exact Recovery

3.1 Fundamental limit and the CH threshold

Exact recovery for linear size communities has been one of the most studied problem for block models in its first decades. A partial list of papers is given by Bui et al. (1987); Dyer and Frieze (1989); Boppana (1987); Snijders and Nowicki (1997); Condon and Karp (1999); McSherry (2001); Bickel and Chen (2009); Choi et al. (2012); Vu (2014); Y. Chen (2014). In this line of work, the approach is mainly driven by the choice of the algorithms, and in particular for the model with two symmetric communities. The results look as follows[5]:

5. Some of the conditions have been borrowed from attended talks and papers and have not been checked

Bui, Chaudhuri, Leighton, Sipser '84	maxflow-mincut	$A = \Omega(1/n), B = o(n^{-1-4/((A+B)n)})$
Boppana '87	spectral meth.	$(A-B)/\sqrt{A+B} = \Omega(\sqrt{\log(n)/n})$
Dyer, Frieze '89	min-cut via degrees	$A - B = \Omega(1)$
Snijders, Nowicki '97	EM algo.	$A - B = \Omega(1)$
Jerrum, Sorkin '98	Metropolis aglo.	$A - B = \Omega(n^{-1/6+\epsilon})$
Condon, Karp '99	augmentation algo.	$A - B = \Omega(n^{-1/2+\epsilon})$
Carson, Impagliazzo '01	hill-climbing algo.	$A - B = \Omega(n^{-1/2}\log^4(n))$
McSherry '01	spectral meth.	$(A-B)/\sqrt{A} \geq \Omega(\sqrt{\log(n)/n})$
Bickel, Chen '09	N-G modularity	$(A-B)/\sqrt{A+B} = \Omega(\log(n)/\sqrt{n})$
Rohe, Chatterjee, Yu '11	spectral meth.	$A - B = \Omega(1)$

More recently, Vu Vu (2014) obtained a spectral algorithm that works in the regime where the expected degrees are logarithmic, rather than poly-logarithmic as in McSherry (2001); Choi et al. (2012). Note that exact recovery requires the node degrees to be at least logarithmic, as discussed in Section 2.5. Thus the results of Vu are tight in the scaling, and the first to apply in such great generality, but as for the other results in Table 1, they do not reveal the phase transition. The fundamental limit for exact recovery was derived first for the case of symmetric SBMs with two communities:

Theorem 13 *Abbe et al. (2014); Mossel et al. (2014b) Exact recovery in* $\mathrm{SSBM}(n, 2, a\ln(n)/n, b\ln(n)/n)$ *is solvable and efficiently so if* $|\sqrt{a}-\sqrt{b}| > \sqrt{2}$ *and unsolvable if* $|\sqrt{a}-\sqrt{b}| < \sqrt{2}$.

A few remarks regarding this result:

- At the threshold, one has to distinguish two cases: if $a, b > 0$, then exact recovery is solvable (and efficiently so) if $|\sqrt{a}-\sqrt{b}| = \sqrt{2}$ as first shown in Mossel et al. (2014b). If a or b are equal to 0, exact recovery is solvable (and efficiently so) if $\sqrt{a} > \sqrt{2}$ or $\sqrt{b} > \sqrt{2}$ respectively, and this corresponds to connectivity.
- Theorem 13 provides a necessary and sufficient condition for exact recovery, and covers all cases for exact recovery in $\mathrm{SSBM}(n, 2, A, B)$ were A and B may depend on n as long as not asymptotically equivalent (i.e., $A/B \nrightarrow 1$). For example, if $A = 1/\sqrt{n}$ and $B = \ln^3(n)/n$, which can be written as $A = \frac{\sqrt{n}}{\ln n}\frac{\ln n}{n}$ and $B = \ln^2 n \frac{\ln n}{n}$, then exact recovery is trivially solvable as $|\sqrt{a}-\sqrt{b}|$ goes to infinity. If instead $A/B \to 1$, then one needs to look at the second order terms. This is covered by Mossel et al. (2014b) for the 2 symmetric community case, which shows that for $a_n, b_n = \Theta(1)$, exact recovery is solvable if and only if $((\sqrt{a_n}-\sqrt{b_n})^2 - 1)\log n + \log\log n/2 = \omega(1)$.
- Note that $|\sqrt{a}-\sqrt{b}| > \sqrt{2}$ can be rewritten as $\frac{a+b}{2} > 1 + \sqrt{ab}$ and recall that $\frac{a+b}{2} > 2$ is the connectivity requirement in SSBM. As expected, exact recovery requires connectivity, but connectivity is not sufficient. The extra term $\sqrt{ab}$ is the 'over-sampling' factor needed to go from connectivity to exact recovery, and the connectivity threshold can be recovered by considering the case where $b = 0$. An information-theoretic interpretation of Theorem 13 is also discussed below.

We next provide the fundamental limit for exact recovery in the general SBM, in the regime of the phase transition where W scales like $\ln(n)Q/n$ for a matrix Q with positive entries.

Theorem 14 *Abbe and Sandon (2015b) Exact recovery in* $\mathrm{SBM}(n, p, \ln(n)Q/n)$ *is solvable and efficiently so if*

$$I_+(p, Q) := \min_{1\leq i<j\leq k} D_+((\mathrm{diag}(p)Q)_i \| (\mathrm{diag}(p)Q)_j) > 1$$

and is not solvable if $I_+(p, Q) < 1$, *where* D_+ *is defined by*

$$D_+(\mu\|\nu) := \max_{t\in[0,1]} \sum_x \nu(x) f_t(\mu(x)/\nu(x)), \quad f_t(y) := 1 - t + ty - y^t. \tag{21}$$

Remark 15 *Regarding the behavior at the threshold: If all the entries of* Q *are non-zero, then exact recovery is solvable (and efficiently so) if and only if* $I_+(p, Q) \geq 1$. *In general, exact recovery is solvable at the threshold, i.e., when* $I_+(p, Q) = 1$, *if and only if any two columns of* $\mathrm{diag}(p)Q$ *have a component that is non-zero and different in both columns.*

Remark 16 *In the symmetric case* $\mathrm{SSBM}(n, k, a\ln(n)/n, b\ln(n)/n)$, *the CH-divergence is maximized at the value of* $t = 1/2$, *and it reduces in this case to the Hellinger divergence between any two columns of* Q; *the theorem's inequality becomes*

$$\frac{1}{k}(\sqrt{a}-\sqrt{b})^2 > 1,$$

matching the expression obtained in Theorem 13 for 2 symmetric communities.

We discuss now some properties of the functional D_+ governing the fundamental limit for exact recovery in Theorem 14. For $t \in [0, 1]$, let

$$D_t(\mu\|\nu) := \sum_x \nu(x) f_t(\mu(x)/\nu(x)), \quad f_t(y) = 1 - t + ty - y^t, \tag{22}$$

and note that $D_+ = \max_{t\in[0,1]} D_t$. Since the function f_t satisfies

- $f_t(1) = 0$
- f_t is convex on $\mathbb{R}_+$,

the functional D_t is what is called an f-divergence Csiszár (1963), like the KL-divergence ($f(y) = y\log y$), the Hellinger divergence, or the Chernoff divergence. Such functionals have a list of common properties described in Csiszár (1963). For example, if two distributions are perturbed by additive noise (i.e., convolving with a distribution), then the divergence always increases, or if some of the elements of the distributions' support are merged, then the divergence always decreases. Each of these properties can interpreted in terms of community detection (e.g., it is easier to recovery merged communities, etc.). Since D_t collapses to the Hellinger divergence when $t = 1/2$ and since it matches the Chernoff divergence for probability measures, we call D_t the Chernoff-Hellinger (CH) divergence in Abbe and Sandon (2015b), and so for D_+ as well by a slight abuse of terminology.

Theorem 14 gives hence an operational meaning to a new f-divergence, showing that the fundamental limit for data clustering in SBMs is governed by the CH-divergence, similarly to the fundamental limit for data transmission in DMCs governed by the KL-divergence. If the columns of $\mathrm{diag}(p)Q$ are "different" enough, where difference is measured in CH-divergence, then one can separate the communities. This is analog to the channel coding theorem that says that when the output's distributions are different enough, where difference is measured in KL-divergence, then one can separate the codewords.

3.2 Proof techniques

Let $(X,G) \sim \mathrm{SBM}(n,p,W)$. Recall that to solve exact recovery, we need to find the partition of the vertices, but not necessarily the actual labels. Equivalently, the goal is to find the community partition $\Omega = \Omega(X)$ as defined in Section 2. Upon observing $G = g$, reconstructing Ω with $\hat{\Omega}(g)$ gives a probability of error given by

$$P_e := \mathbb{P}\{\Omega \neq \hat{\Omega}(G)\} = \sum_g \mathbb{P}\{\hat{\Omega}(g) \neq \Omega | G = g\}\mathbb{P}\{G = g\} \tag{23}$$

and thus an estimator $\hat{\Omega}_{\mathrm{map}}(\cdot)$ minimizing the above must minimize $\mathbb{P}\{\hat{\Omega}(g) \neq \Omega | G = g\}$ for every g. To minimize $\mathbb{P}\{\hat{\Omega}(g) \neq \Omega | G = g\}$, we must declare a reconstruction of s that maximizes the posterior distribution

$$\mathbb{P}\{\Omega = s | G = g\}, \tag{24}$$

or equivalently

$$\sum_{x \in [k]^n : \Omega(x) = s} \mathbb{P}\{G = g | X = x\} \prod_{i=1}^k p_i^{|\Omega_i(x)|}, \tag{25}$$

and any such maximizer can be chosen arbitrarily.

This defines the MAP estimator $\hat{\Omega}_{\mathrm{map}}(\cdot)$, which minimizes the probability of making an error for exact recovery. If MAP fails in solving exact recovery, no other algorithm can succeed. Note that to succeed for exact recovery, the partition shall be typical in order to make the last factor in (25) non-vanishing (i.e., communities of relative size $p_i + o(1)$ for all $i \in [k]$). Of course, resolving exactly the maximization in (24) requires comparing exponentially many terms, so the MAP estimator may not always reveal the computational threshold for exact recovery.

3.2.1 Converse: the genie-aided approach

We now describe how to obtain the impossibility part of Theorem 14. Imagine that in addition to observing G, a genie provides the observation of $X_{\sim u} = \{X_v : v \in [n] \setminus \{u\}\}$. Define now $\hat{X}_v = X_v$ for $v \in [n] \setminus \{u\}$ and

$$\hat{X}_{u,\mathrm{map}}(g, x_{\sim u}) = \arg\max_{i \in [k]} \mathbb{P}\{X_u = i | G = g, X_{\sim u} = x_{\sim u}\}, \tag{26}$$

where ties can be broken arbitrarily if they occur (we assume that an error is declared in case of ties to simplify the analysis). If we fail at recovering a single component when all others are revealed, we must fail at solving exact recovery all at once, thus

$$\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} \geq \mathbb{P}\{\exists u \in [n] : \hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u\}. \tag{27}$$

This lower bound may appear to be loose at first, as recovering the entire communities from the graph G seems much more difficult than classifying each vertex by having all others revealed (we call the latter component-MAP). We however show that is tight in the regime

considered. In any case, studying when this lower bound is not vanishing always provides a necessary condition for exact recovery.

Let $E_u := \{\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u\}$. If the events E_u were independent, we could write $\mathbb{P}\{\cup_u E_u\} = 1 - \mathbb{P}\{\cap_u E_u^c\} = 1 - (1 - \mathbb{P}\{E_1\})^n \geq 1 - e^{-n\mathbb{P}\{E_1\}}$ and if $\mathbb{P}\{E_1\} = \omega(1/n)$, this would drive $\mathbb{P}\{\cup_u E_u\}$, and thus P_e, to 1. The events E_u are not independent, but their dependencies are weak enough such that previous reasoning still applies, and P_e is driven to 1 when $\mathbb{P}\{E_1\} = \omega(1/n)$.

Formally, one can handle the dependencies with different approaches. We describe here an approach via the second moment method. Recall the following basic inequality.

Lemma 17 *If Z is a random variable taking values in $\mathbb{Z}_+ = \{0, 1, 2, \dots\}$, then*

$$\mathbb{P}\{Z = 0\} \leq \frac{\mathbb{V}\mathrm{ar} Z}{(\mathbb{E}Z)^2}.$$

We apply this inequality to

$$Z = \sum_{u \in [n]} \mathbb{1}(\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u),$$

which counts the number of components where component-MAP fails. Note that the right hand side of (27) corresponds to $\mathbb{P}\{Z \geq 1\}$ as desired. Our goal is to show that $\frac{\mathbb{V}\mathrm{ar} Z}{(\mathbb{E}Z)^2}$ stays strictly below 1 in the limit, or equivalently, $\frac{\mathbb{E}Z^2}{(\mathbb{E}Z)^2}$ stays strictly below 2 in the limit. In fact, the latter tends to 1 in the converse of Theorem 14.

Note that $Z = \sum_{u \in [n]} Z_u$ where $Z_u := \mathbb{1}(\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u)$ are binary random variables with $\mathbb{E}Z_u = \mathbb{E}Z_v$ for all u, v. Hence,[6]

$$\mathbb{E}Z = n\mathbb{P}\{Z_1 = 1\} \tag{28}$$

$$\mathbb{E}Z^2 = \sum_{u,v \in [n]} \mathbb{E}(Z_u Z_v) = \sum_{u,v \in [n]} \mathbb{P}\{Z_u = Z_v = 1\} \tag{29}$$

$$= n\mathbb{P}\{Z_1 = 1\} + n(n-1)\mathbb{P}\{Z_1 = 1\}\mathbb{P}\{Z_2 = 1 | Z_1 = 1\} \tag{30}$$

and $\frac{\mathbb{E}Z^2}{(\mathbb{E}Z)^2}$ tends to 1 if

$$\frac{n\mathbb{P}\{Z_1 = 1\} + n(n-1)\mathbb{P}\{Z_1 = 1\}\mathbb{P}\{Z_2 = 1 | Z_1 = 1\}}{n^2\mathbb{P}\{Z_1 = 1\}^2} = 1 + o(1) \tag{31}$$

or

$$\frac{1}{n\mathbb{P}\{Z_1 = 1\}} + \frac{\mathbb{P}\{Z_2 = 1 | Z_1 = 1\}}{\mathbb{P}\{Z_1 = 1\}} = 1 + o(1). \tag{32}$$

This takes place if $n\mathbb{P}\{Z_1 = 1\}$ diverges and

$$\frac{\mathbb{P}\{Z_2 = 1 | Z_1 = 1\}}{\mathbb{P}\{Z_2 = 1\}} = 1 + o(1), \tag{33}$$

6. One should normally distinguish whether vertices 1 and 2 are in the same community or not, but this has no effect on the final result.

i.e., if E_1, E_2 are asymptotically independent.

The asymptotic independence takes place due to the regime that we consider for the block model in the theorem. To given a related example, in the context of the Erdős-Rényi model $ER(n,p)$, if W_1 is 1 when vertex u is isolated and 0 otherwise, then $\mathbb{P}\{W_1 = 1|W_2 = 1\} = (1-p)^{n-2}$ and $\mathbb{P}\{W_1 = 1\} = (1-p)^{n-1}$, and thus $\frac{\mathbb{P}\{W_1=1|W_2=1\}}{\mathbb{P}\{W_1=1\}} = (1-p)^{-1}$ tends to 1 as long as p tends to 0. That is, the property of a vetex being isolated is asymptotically independent as long as the edge probability is vanishing. A similar outcomes takes place for the property of MAP-component failing when edge probabilities are vanishing in the block model.

The location of the threshold is then dictated by requirement that $n\mathbb{P}\{Z_1 = 1\}$ diverges, and this where the CH-divergence threshold emerges from a moderate deviation analysis. We next summarize what we obtained with the above reasoning, and then specialized to the regime of Theorem 14.

Theorem 18 *Let $(X,G) \sim \mathrm{SBM}(n,p,W)$ and $Z_u := \mathbb{1}(\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u)$, $u \in [n]$. If p, W are such that E_1 and E_2 are asymptotically independent, then exact recovery is not solvable if*

$$\mathbb{P}\{\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u\} = \omega(1/n). \tag{34}$$

The next lemma gives the behavior of $\mathbb{P}\{Z_1 = 1\}$ in the logarithmic degree regime.

Lemma 19 *Abbe and Sandon (2015b) Consider the hypothesis test where $H = i$ has prior probability p_i for $i \in [k]$, and where observable Y is distributed $\mathrm{Bin}(np, W_i)$ under hypothesis $H = i$. Then the probability of error $P_e(p,W)$ of MAP decoding for this test satisfies $\frac{1}{k-1}\mathrm{Over}(n,p,W) \leq P_e(p,W) \leq \mathrm{Over}(n,p,W)$ where*

$$\mathrm{Over}(n,p,W) = \sum_{i<j} \sum_{z \in \mathbb{Z}_+^k} \min(\mathbb{P}\{\mathrm{Bin}(np,W_i) = z\}p_i, \mathbb{P}\{\mathrm{Bin}(np,W_j) = z\}p_j),$$

and for a symmetric $Q \in \mathbb{R}_+^{k\times k}$,

$$\mathrm{Over}(n,p,\log(n)Q/n) = n^{-I_+(p,Q)-O(\log\log(n)/\log n)}, \tag{35}$$

where $I_+(p,Q) = \min_{i<j} D_+((\mathrm{diag}(p)Q)_i, (\mathrm{diag}(p)Q)_j)$.

Corollary 20 *Let $(X,G) \sim \mathrm{SBM}(n,p,W)$ where p is constant and $W = Q\frac{\ln n}{n}$. Then*

$$\mathbb{P}\{\hat{X}_{u,\mathrm{map}}(G, X_{\sim u}) \neq X_u\} = n^{-I_+(p,Q)+o(1)}. \tag{36}$$

A robust extension of this Lemma is proved in Abbe and Sandon (2015b) that allows for a slight perturbation of the binomial distributions. We next explain why E_1 and E_2 are asymptotically independent.

Recall that $Z_1 = \mathbb{1}(\hat{X}_{1,\mathrm{map}}(G, X_{\sim 1}) \neq X_1)$, and E_1 is the event that $Z_1 = 1$, i.e., that G and X take values g and x such that[7]

$$\mathrm{argmax}_{i\in[k]} \mathbb{P}\{X_1 = i | G = g, X_{\sim 1} = x_{\sim 1}\} \neq x_1. \tag{37}$$

7. Formally, argmax is a set, and we are asking that this set is not the singleton $\{x_1\}$. It could be that this set is not that singleton but contains x_1, in which case breaking ties may still make component-MAP succeed by luck; however this gives a probability of error of at least 1/2, and thus already fails exact recovery. This is why we declare an error in case of ties.

Let $x_{\sim 1} \in [k]^{n-1}$ and $\omega(x_{\sim 1}) :_i = |\Omega_i(x_{\sim 1})|$. We have

$$\begin{aligned}
&\mathbb{P}\{X_1 = x_1 | G = g, X_{\sim 1} = x_{\sim 1}\} && (38)\\
&\propto \mathbb{P}\{G = g | X_{\sim 1} = x_{\sim 1}, X_1 = x_1\} \cdot \mathbb{P}\{X_{\sim 1} = x_{\sim 1}, X_1 = x_1\} && (39)\\
&\propto \mathbb{P}\{G = g | X_{\sim 1} = x_{\sim 1}, X_1 = x_1\}\mathbb{P}\{X_1 = x_1\} && (40)\\
&= p(x_1) \prod_{1\leq i<j\leq k} W_{i,j}^{N_{ij}(x_{\sim 1},g)}(1-W_{i,j})^{N_{ij}^c(x_{\sim 1},g)} && (41)\\
&\quad \cdot \prod_{1\leq i\leq k} W_{i,x_1}^{N_i^{(1)}(x_{\sim 1},g)}(1-W_{i,x_1})^{\omega_i(x_{\sim 1})-N_i^{(1)}(x_{\sim 1},g)} && (42)\\
&\propto p(x_1) \prod_{1\leq i\leq k} W_{i,x_1}^{N_i^{(1)}(x_{\sim 1},g)}(1-W_{i,x_1})^{\omega_i(x_{\sim 1})-N_i^{(1)}(x_{\sim 1},g)} && (43)
\end{aligned}$$

where $N_i^{(1)}(x_{\sim 1}, g)$ is the number of neighbors that vertex 1 has in community i. We denote by $N^{(1)}$ the random vector valued in $\mathbb{Z}_+^k$ whose i-th component is $N_i^{(1)}(X_{\sim 1}, G)$, and call $N^{(1)}$ the *degree profile* of vertex 1. As just shown, $(N^{(1)}, |\Omega(X_{\sim 1})|)$ is a sufficient statistics for component-MAP. We thus have to resolve an hypothesis test with k hypotheses, where $|\Omega(X_{\sim 1})|$ contains the sizes of the k communities with $(n-1)$ vertices (irrespective of the hypothesis), and under hypothesis $X_1 = x_1$ which has prior p_{x_1}, the observable $N^{(1)}$ has distribution proportional to (43), i.e., i.i.d. components that are Binomial$(\omega_i(x_{\sim 1}), W_{i,x_1})$.

Consider now the case of two symmetric (assortative) communities to simplify the discussion. By symmetry, it is sufficient to show that

$$\frac{\mathbb{P}\{E_1 | E_2, X_1 = 1\}}{\mathbb{P}\{E_1 | X_1 = 1\}} = 1 + o(1). \tag{44}$$

Further, $|\Omega_1(X_{\sim 1})| \sim \mathrm{Bin}(n-1, 1/2)$ is a sufficient statistics for the number of vertices in each community. By standard concentration, $|\Omega_1(X_{\sim 1})| \in [n/2 - \sqrt{n}\log n, n/2 + \sqrt{n}\log n]$ with probability $1 - O(n^{-\frac{1}{2}\log n})$. Instead, from Lemma 19, we have that $\mathbb{P}\{Z_1 = 1 | |\Omega(X_{\sim 1})| \in [n/2 - \sqrt{n}\log n, n/2 + \sqrt{n}\log n]\}$ decays only polynomially to 0, thus it is sufficient to show that

$$\frac{\mathbb{P}\{E_1 | E_2, X_1 = 1, |\Omega(X_{\sim 1})| \in [n/2 - \sqrt{n}\log n, n/2 + \sqrt{n}\log n]\}}{\mathbb{P}\{E_1 | X_1 = 1, |\Omega(X_{\sim 1})| \in [n/2 - \sqrt{n}\log n, n/2 + \sqrt{n}\log n]\}} = 1 - o(1). \tag{45}$$

Recall that the error event E_1 depends only on $(N^{(1)}, |\Omega(X_{\sim 1})|)$, and $N^{(1)}$ contains two components, $N_1^{(1)}, N_2^{(1)}$, which are the number of edges that vertex 1 has in each of the two communities. It remains to show that the effect of knowing E_2 does not affect the numerator by much. This intuitively follows from the fact that for communities of constrained size, this conditioning gives only information about edge $(1,2)$ in the graph (by Markovian property of the model), which creates negligible dependencies. Showing this with a formal argument requires further technical expansions.

3.2.2 Achievability: graph-splitting and two-round algorithms

Two-rounds algorithms have proved to be powerful in the context of exact recovery. The general idea consists in using a first algorithm to obtain a good but not necessarily exact

clustering, solving a joint assignment of all vertices, and then to switch to a local algorithm that "cleans up" the good clustering into an exact one by reclassifying each vertex. This approach has a few advantages:

- If the clustering of the first round is accurate enough, the second round becomes approximately the genie-aided hypothesis test discussed in previous section, and the approach is built in to achieve the threshold;
- if the clustering of the first round is efficient, then the overall method is efficient since the second round only performs computations for each single node separately and has thus linear complexity.

Some difficulties need to be overome for this program to be carried out:

- One needs to obtain a good clustering in the first round, which is typically non-trivial;
- One needs to be able to analyze the probability of success of the second round, as the graph is no longer independent of the obtained clusters.

To resolve the latter point, we rely in Abbe et al. (2016) a technique which we call "graph-splitting" and which takes again advantage of the sparsity of the graph.

Definition 21 (Graph-splitting) *Let g be an n-vertex graph and $\gamma \in [0,1]$. The graph-splitting of g with split-probability γ produces two random graphs G_1, G_2 on the same vertex set as G. The graph G_1 is obtained by sampling each edge of g independently with probability γ, and $G_2 = g \setminus G_1$ (i.e., G_2 contains the edges from g that have not been subsampled in G_1).*

Graph splitting is convenient in part due to the following fact.

Lemma 22 *Let $(X,G) \sim \mathrm{SBM}(n,p,\log nQ/n)$, (G_1,G_2) be a graph splitting of G with parameters γ and $(X,\tilde{G}_2) \sim \mathrm{SBM}(n,p,(1-\gamma)\log nQ/n)$ with $\tilde{G}_2$ independent of G_1. Let $\hat{X} = \hat{X}(G_1)$ be valued in $[k]^n$ such that $\mathbb{P}\{A(X,\hat{X}) \geq 1-o(n)\} = 1-o(1)$. For any $v \in [n]$, $d \in \mathbb{Z}_+^k$,*

$$\mathbb{P}\{D_v(\hat{X},G_2) = d\} \leq (1+o(1))\mathbb{P}\{D_v(\hat{X},\tilde{G}_2) = d\} + n^{-\omega(1)}, \tag{46}$$

where $D_v(\hat{X},G_2)$ is the degree profile of vertex v, i.e., the k-dimensional vector counting the number of neighbors of vertex v in each community using the clustered graph $(\hat{X},G_2)$.

The meaning of this lemma is as follows. We can consider G_1 and G_2 to be approximately independent, and export the output of an algorithm run on G_1 to the graph G_2 without worrying about dependencies to proceed with component-MAP. Further, if γ is to chosen as $\gamma = \tau(n)/\log(n)$ where $\tau(n) = o(\log(n))$, then G_1 is distributed as $\mathrm{SBM}(n,p,\tau(n)Q/n)$ and G_2 remains approximately as $\mathrm{SBM}(n,p,\log nQ/n)$. This means that from our original SBM graph, we produce essentially 'for free' a preliminary graph G_1 with $\tau(n)$ expected degrees that can be used to get a preliminary clustering, and we can then improve that clustering on the graph G_2 which has still logarithmic expected degree.

Our goal is to obtain on G_1 a clustering that is almost exact, i.e., with only a vanishing fraction of misclassified vertices. If this can be achieved for some $\tau(n) = o(\log(n))$, then a

robust version of the genie-aided hypothesis test described in Section 3.2.1 can be run to re-classify each node successfully when $I_+(p,Q) > 1$. Luckily, as we shall see in Section 5, almost exact recovery can be solved with the mere requirement that $\tau(n) = \omega(1)$ (i.e., $\tau(n)$ diverges). In particular, setting $\tau(n) = \log\log(n)$ does the job. We next describe more formally the previous reasoning.

Theorem 23 *Assume that almost exact recovery is solvable in $\mathrm{SBM}(n,p,\omega(1)Q/n)$. Then exact recovery is solvable in $\mathrm{SBM}(n,p,\log nQ/n)$ if*

$$I_+(p,Q) > 1. \tag{47}$$

To see this, let $(X,G) \sim \mathrm{SBM}(n,p,\tau(n)Q/n)$, and (G_1,G_2) be a graph splitting of G with parameters $\gamma = \log\log n/\log n$. Let $(X,\tilde{G}_2) \sim \mathrm{SBM}(n,p,(1-\gamma)\tau(n)Q/n)$ with $\tilde{G}_2$ independent of G_1 (note that the same X appears twice). Let $\hat{X} = \hat{X}(G_1)$ be valued in $[k]^n$ such that $\mathbb{P}\{A(X,\hat{X}) \geq 1-o(1)\} = 1-o(1)$; note that such an $\hat{X}$ exists from the Theorem's hypothesis. Since $A(X,\hat{X}) = 1-o(1)$ with high probability, $(G_2,\hat{X})$ are functions of G and using a union bound, we have

$$\begin{aligned}
\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} &\leq \mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega | A(X,\hat{X}) = 1-o(1)\} + o(1) &(48)\\
&\leq \mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G_2,\hat{X}) \neq \Omega | A(X,\hat{X}) = 1-o(1)\} + o(1) &(49)\\
&\leq n\mathbb{P}\{X_{1,\mathrm{map}}(G_2,\hat{X}_{\sim 1}) \neq X_1 | A(X,\hat{X}) = 1-o(1)\} + o(1). &(50)
\end{aligned}$$

We next replace G_2 by $\tilde{G}_2$. Note that $\tilde{G}_2$ has already the same marginal as G_2, the only issue is that G_2 is not independent from G_1 since the two graphs are disjoint, and since $\hat{X}$ is derived from G_2, some dependencies are carried along with G_1. However, $\tilde{G}_2$ and G_2 are 'essentially independent' as stated in Lemma 22, because the probability that $\tilde{G}_2$ samples an edge that is already present in G_1 is $O(\log^2 n/n^2)$, and the expected degrees in each graph is $O(\log n)$. This takes us to

$$\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} \leq n\mathbb{P}\{X_{1,\mathrm{map}}(\tilde{G}_2,\hat{X}_{\sim 1}) \neq X_1 | A(X,\hat{X}) = 1-o(1)\}(1+o(1)) + o(1). \tag{51}$$

We can now replace $\hat{X}_{\sim 1}$ with $X_{\sim 1}$ to the expense that we may blow up this the probability by a factor $n^{o(1)}$ since $A(X,\hat{X}) = 1-o(1)$, using again the fact that expected degrees are logarithmic. Thus we have

$$\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} \leq n^{1+o(1)}\mathbb{P}\{X_{1,\mathrm{map}}(\tilde{G}_2,X_{\sim 1}) \neq X_1 | A(X,\hat{X}) = 1-o(1)\} + o(1) \tag{52}$$

and the conditioning on $A(X,\hat{X}) = 1-o(1)$ can now be removed due to independence, so that

$$\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} \leq n^{1+o(1)}\mathbb{P}\{X_{1,\mathrm{map}}(\tilde{G}_2,X_{\sim 1}) \neq X_1\} + o(1). \tag{53}$$

The last step consists in closing the loop and replacing $\tilde{G}_2$ by G, since $1-\gamma = 1-o(1)$, which uses the same type of argument as for the replacement of G_2 by $\tilde{G}_2$, with a blow up that is at most $n^{o(1)}$. As a result,

$$\mathbb{P}\{\hat{\Omega}_{\mathrm{map}}(G) \neq \Omega\} \leq n^{1+o(1)}\mathbb{P}\{X_{1,\mathrm{map}}(G,X_{\sim 1}) \neq X_1\} + o(1), \tag{54}$$

and if

$$\mathbb{P}\{X_{1,\text{map}}(G, X_{\sim 1}) \neq X_1\} = n^{-1-\varepsilon} \tag{55}$$

for $\varepsilon > 0$, then $\mathbb{P}\{\hat{\Omega}_{\text{map}}(G) \neq \Omega\}$ is vanishing as stated in the theorem.

Therefore, in view of Theorem 23, the achievability part of Theorem 14 reduces to the following result.

Theorem 24 *Abbe and Sandon (2015b) Almost exact recovery is solvable in* $\text{SBM}(n, p, \omega(1)Q/n)$, *and efficiently so.*

This follows from Theorem 50 from Abbe and Sandon (2015b) using the Sphere-comparison algorithm discussed in Section 5. Note that to prove that almost exact recovery is solvable in this regime without worrying about efficiency, the Typicality Sampling Algorithm discussed in Section 4.6.1 is already sufficient.

In conclusion, in the regime of Theorem 14, exact recovery follows from solving almost exact recovery on an SBM with degrees that grow sub-logarithmically, using graph-splitting and a clean-up round. The behavior of the component-MAP error (i.e., the probability of misclassifying a single node when others have been revealed) pings down the behavior of the threshold: if this probability is $\omega(1/n)$, exact recovery is not possible, and if it is $o(1/n)$, exact recovery is possible. Decoding for the latter is then resolved by obtaining the exponent of the component-MAP error, which brings the CH-divergence in.

3.3 Local to global amplification

Previous two sections give a lower bound and an upper bound on the probability that MAP fails at recovering the entire clusters, in terms of the probability that MAP fails at recovering a single vertex when others are revealed. Denoting by P_{global} and P_{local} these two probability of errors, we essentially[8] have

$$1 - \frac{1}{nP_{\text{local}}} + o(1) \leq P_{\text{global}} \leq nP_{\text{local}} + o(1). \tag{56}$$

This implies that P_{global} has a threshold phenomena as P_{local} varies:

$$P_{\text{global}} \to \begin{cases} 0 & \text{if } P_{\text{local}} \ll 1/n, \\ 1 & \text{if } P_{\text{local}} \gg 1/n. \end{cases} \tag{57}$$

Moreover, deriving this relies mainly on the regime of the model, rather than the specific structure of the SBM. In particular, it mainly relies on the exchangeability of the model (i.e., vertex labels have no relevance) and the fact that the vertex degrees do not grow rapidly. This suggests that this 'local to global' phenomenon takes place in a more general class of models. The expression of the threshold for exact recovery in $\text{SBM}(n, p, \log nQ/n)$ as a function of the parameters p, Q is instead specific to the model, and relies on the CH-divergence in the case of the SBM, but the moderate deviation analysis of P_{local} for other models may reveal a different functional or f-divergence.

8. The upper bound discussed in Section 3.2.2 gives $n^{1+o(1)}P_{\text{local}} + o(1)$, but the analysis can be tighten to yield a factor n instead of $n^{1+o(1)}$.

The local to global approach has also an important implication at the computational level. The achievability proof described in previous section gives directly an algorithm: use graph-splitting to produce two graphs; solve almost exact recovery on the first graph and improve locally the latter with the second graph. Since the second round is by construction efficient (it corresponds to n parallel local computations), it is sufficient to solve almost exact recovery efficiently (in the regime of diverging degrees) to obtain for free an efficient algorithm for exact recovery down to the threshold. This thus gives a computational reduction. In fact, the process can be iterated to further reduce almost exact recovery to a weaker recovery requirements, until a 'bottle-neck' problem is attained.

3.4 Semidefinite programming and spectral methods

The two-round procedure discussed in Section 3.2.2 has the advantage to only require almost exact recovery to be efficiently solved. As it can only be easier to solve almost exact rather than exact recovery, this approach may be beneficial compared to solving efficiently exact recovery in 'one shot.' The approach can also be handy in real applications, improving the communities with a clean-up phase. Nonetheless, it is also possible to achieve exact recovery in 'one shot' without relying on two-rounds. We provide here some examples of methods.

Semi-definite programming (SDP). We present here the SDP developed in Abbe et al. (2016) for the symmetric SBM with two communities and balanced clusters. SDPs were also used in various works on the SBM such as B. Hajek (2014); Guédon and Vershynin (2016); Amini and Levina (2014); Bandeira (2015); Montanari and Sen (2016); Javanmard et al. (2016). The idea is to approximate MAP decoding. Assume for the purpose of this section that we work with the symmetric SBM with two balanced clusters that are drawn uniformly at random. In this case, MAP decoding looks for a balanced partition of the vertices into two clusters such that the number of crossing edges is minimized (when the connection probability inside clusters A is less than the connection probability across clusters B, otherwise maximized). This is seen by writing the a posteriori distribution as

$$\mathbb{P}\{X = x | G = g\} \propto \mathbb{P}\{G = g | X = x\} \cdot \mathbb{1}(x \text{ is balanced}), \tag{58}$$

$$\propto A^{N_{in}}(1-A)^{\frac{n^2}{4}-N_{in}} B^{N_{out}}(1-B)^{\frac{n^2}{4}-N_{out}} \cdot \mathbb{1}(x \text{ is balanced}) \tag{59}$$

$$\propto \left(\frac{B(1-A)}{A(1-B)}\right)^{N_{out}} \cdot \mathbb{1}(x \text{ is balanced}) \tag{60}$$

where N_{in} is the number of edges that G has inside the clusters defined by x, and N_{out} is the number of crossing edges. If $A > B$, then $\frac{B(1-A)}{A(1-B)} < 1$ and MAP looks for a balanced partition that has the least number of crossing edges, i.e., a min-bisection. In the worst-case model, min-bisection is NP-hard, and approximations leave a polylogarithmic integrality gap Krauthgamer and Feige (2006). However, Theorem 14 tells us that it is still be possible to recover the min-bisection efficiently for the typical instances of the SBM, without any gap to the information-theoretic threshold.

We express now the min-bisection as a quadratic optimization problem, using $\{+1, -1\}$ variables to label the two communities. More precisely, define

$$\hat{x}_{\text{map}}(g) = \text{argmax}_{\substack{x \in \{+1,-1\}^n \\ x^t 1^n = 0}} x^t A(g) x \tag{61}$$

where $A(g)$ is the adjacency matrix of the graph g, i.e., $A(g)_{ij} = 1$ if there is an edge between vertices i and j, and $A(g)_{ij} = 0$ otherwise. The above maximizes the number of edges inside the clusters, minus the number of edges across the clusters; since the total number of edges is invariant from the clustering, this is equivalent to min-bisection.

Solving (61) is hard because of the integer constraint $x \in \{+1, -1\}^n$. A first possible relaxation is to replace this constraint with an Euclidean constraint on real vectors, turning (61) into an eigenvector problem, which is the idea behind spectral methods discussed next. The idea of SDPs is instead to lift the variables to change the quadratic optimization into a linear optimization (as for max-cut Goemans and Williamson (1995)), albeit with additional constraints. Namely, since $\mathrm{tr}(AB) = \mathrm{tr}(BA)$ for any matrices of matching dimensions, we have

$$x^t A(g) x = \mathrm{tr}(x^t A(g) x) = \mathrm{tr}(A(g) x x^t), \tag{62}$$

hence defining $X := xx^t$, we can write (61) as

$$\hat{X}_{\mathrm{map}}(g) = \mathrm{argmax}_{\substack{X \succeq 0 \\ X_{ii}=1, \forall i \in [n] \\ \mathrm{rank} X = 1 \\ X 1^n = 0}} \mathrm{tr}(A(g) X). \tag{63}$$

Note that the first three constraints on X force X to take the form xx^t for a vector $x \in \{+1, -1\}^n$, as desired, and the last constraint gives the balance requirement. The advantage of (63) is that the objective function is now linear in the lifted variable X. The constraint $\mathrm{rank} X = 1$ is responsible now for keeping the optimization hard. We hence simply remove that constraint to obtain our SDP relaxation:

$$\hat{X}_{sdp}(g) = \mathrm{argmax}_{\substack{X \succeq 0 \\ X_{ii}=1, \forall i \in [n] \\ X 1^n = 0}} \mathrm{tr}(A(g) X). \tag{64}$$

A possible approach to handle the constraint $X1^n = 0$ is to replace the adjacency matrix $A(g)$ by the matrix $B(g)$ such that $B(g)_{ij} = 1$ if there is an edge between vertices i and j, and $B(g)_{ij} = -1$ otherwise. Using $-T$ for a large T instead of -1 for non-edges would force the clusters to be balanced, and it turns out that -1 is already sufficient for our purpose. This gives another SDP:

$$\hat{X}_{SDP}(g) = \mathrm{argmax}_{\substack{X \succeq 0 \\ X_{ii}=1, \forall i \in [n]}} \mathrm{tr}(B(g) X). \tag{65}$$

The dual of this SDP is given by

$$\min_{\substack{Y_{ij}=0 \forall 1 \le i \ne j \le n \\ Y \succeq B(g)}} \mathrm{tr}(Y). \tag{66}$$

Since the dual minimization gives an upper-bound on the primal maximization, a solution is optimal if it makes the dual minima match the primal maxima. The Ansatz here consists in taking $Y = 2(D_{in} - D_{out}) + I_n$ as a candidate for the diagonal matrix Y, which gives the primal maxima. It we thus have $Y \succeq B(g)$, this is a feasible solution for the dual, and we obtain a dual certificate. The following is shown in Abbe et al. (2016) based on this reasoning.

Definition 25 *Define the SBM Laplacian for G drawn under the symmetric SBM with two communities by*

$$L_{\mathrm{SBM}} = D(G_{in}) - D(G_{out}) - A(G), \tag{67}$$

where $D(G_{in})$ ($D(G_{out})$) are the degree matrices of the subgraphs of G containing only the edges inside (respectively across) the clusters, and $A(G)$ is the adjacency matrix of G.

Theorem 26 *The SDP solves exact recovery in the symmetric SBM with 2 communities if $2L_{\mathrm{SBM}} + 11^t + I_n \succeq 0$.*

This condition is satisfies with high probability all the way down to the exact recovery threshold. In Abbe et al. (2016), it is showsn that this condition holds in a regime that does not exactly match the threshold, off roughly by a factor of 2 for large degrees. This gap is closed in B. Hajek (2014); Bandeira (2015), which show that SDPs achieve the exact recovery threshold in the symmetric case. Some results for unbalanced communities were also obtained in Perry and Wein (2015), although it is still open to achieve the general CH threshold with SDPs. Many other works have studied SDPs for the stochastic block model, we refer to Amini and Levina (2014); Abbe et al. (2016); Bandeira (2015); B. Hajek (2014); Montanari and Sen (2016); Perry and Wein (2015) for further references. In particular, Montanari and Sen (2016) shows that SDPs allow to approach the threshold for weak recovery in the two-community SSBM arbitrarily close when the expected degrees diverge.

Spectral methods. Consider again the symmetric SBM with 2 balanced communities. Recall that MAP maximizes

$$\max_{\substack{x \in \{+1,-1\}^n \\ x^t 1^n = 0}} x^t A(g) x. \tag{68}$$

The general idea behind spectral methods is to relax the integral constraint to an Euclidean constraint on real valued vectors. This lead to looking for a maximizer of

$$\max_{\substack{x \in \mathbb{R}^n : \|x\|_2^2 = n \\ x^t 1^n = 0}} x^t A(g) x. \tag{69}$$

Without the constraint $x^t 1^n = 0$, the above maximization gives precisely the eigenvector corresponding to the largest eigenvalue of $A(g)$. Note that $A(g)1^n$ is the vector containing the degrees of each node in g, and when g is an instance of the symmetric SBM, this concentrates to the same value for each vertex, and 1^n is close to an eigenvector of $A(g)$. Since $A(g)$ is real and symmetric, this suggests that the constraint $x^t 1^n = 0$ leads the maximization (69) to focus on the eigenspace orthogonal to the first eigenvector, and thus to the eigenvector corresponding to the second largest eigenvalue. Thus one can take the second largest eigenvector and round it (assigning positive and negative components to different communities) to obtain an efficient algorithm.

Equivalently, one can write the MAP estimator as a maximizer of

$$\max_{\substack{x \in \{+1,-1\}^n \\ x^t 1^n = 0}} \sum_{1 \le i < j \le n} A_{ij}(g)(x_i - x_j)^2 \tag{70}$$

since the above minimizes the size of the cut between two balanced clusters. From simple algebraic manipulations, this is equivalent to looking for maximizers of

$$\max_{\substack{x\in\{+1,-1\}^n \\ x^t 1^n=0}} x^t L(g) x, \tag{71}$$

where $L(g)$ is the classical Laplacian of the graph, i.e.,

$$L(g) = D(g) - A(g), \tag{72}$$

and $D(g)$ is the degree matrix of the graph. With this approach 1^n is precisely an eigenvector of $L(g)$ with eigenvalue 0, and the relaxation to a real valued vector leads directly to the second eigenvector of $L(g)$, which can be rounded (positive or negative) to determine the communities.

The challenge with such 'basic' spectral methods is that, as the graph becomes sparser, the fluctuations in the node degrees become more important, and this can disrupt the second largest eigenvector from concentrating on the communities (it may concentrate instead on large degree nodes). To analyze this, one may express the adjacency matrix as a perturbation of its expected value, i.e.,

$$A(G) = \mathbb{E}A(G) + (A(G) - \mathbb{E}A(G)). \tag{73}$$

When indexing the first $n/2$ rows and columns to be in the same community, the expected adjacency matrix takes the following block structure

$$\mathbb{E}A(G) = \begin{pmatrix} A^{n/2\times n/2} & B^{n/2\times n/2} \\ B^{n/2\times n/2} & A^{n/2\times n/2} \end{pmatrix}, \tag{74}$$

where $A^{n/2\times n/2}$ is the $n/2\times n/2$ matrix with all entries equal to A. As expected, $\mathbb{E}A(G)$ has two eigenvalues, the expected degree $(A+B)/2$ with the constant eigenvector, and $(A-B)/2$ with the eigenvector taking the same constant with opposite signs on each community. The spectral methods described above succeeds in recovering the true communities if the noise $Z = A(G) - \mathbb{E}A(G)$ does not disrupt the first two eigenvectors from keeping their rank. See also Section 2.6. Theorems of random matrix theory allow to analyze this type of perturbations (see Vu (2014); Bordenave et al. (2015)), most commonly when the noise is independent rather than for the specific noise occurring here, but a direct application does typically not suffice to achieve the exact recovery threshold.

For exact recovery, one can use preprocessing steps to still succeed down to the threshold using the adjacency or Laplacian matrices, in particular by trimming the high degree nodes to regularize the graph spectra Feige and Ofek (2005). We refer to the papers of Vu Vu (2014) and in particular Proutiere et al. Yun and Proutiere (2014) for spectral methods achieving the exact recovery threshold. For the weak recovery problem discussed in next section, such tricks do not suffice to achieve the threshold, and one has to rely on other types of spectral operators as discussed in Section 4 with nonbacktracking operators.[9]

9. Similarly for SDPs which likely do not achieve the weak recovery threshold Moitra et al. (2016); Montanari and Sen (2016).

Note also that for k clusters, the expected adjacency matrix has rank k, and one typically has to take the k largest eigenvectors (corresponding the k largest eigenvalues), form n vectors of dimensional k by stacking each component of the k largest vectors into a vector (typically rescaled by $\sqrt{n}$), and run k-means clustering to generalize the 'rounding' step and produce k clusters.

We refer to Ng et al. (2001); Spielman and Teng (2007); Kannan et al. (2000); von Luxburg (2007) for further details on Laplacian spectral methods and k-means, and Vu (2014); Yun and Proutiere (2014); Yun and Proutiere (2015) for applications to exact recovery in the SBM.

3.5 Extensions

In this section, we demonstrate how the tools developed in previous section allow for fairly straightforward generalizations to other type of models.

3.5.1 Edge-labels, overlaps, bi-clustering

Labelled edges. Consider the labelled stochastic block model, where edges have labels attached to them, such as to model intensities of similarity. We assume that the labels belong to $\mathcal{Y} = \mathcal{Y}_+ \cup \{0\}$, where $\mathcal{Y}_+$ is a measurable set of labels (e.g., $(0,1]$), and 0 represents the special symbol corresponding to no edge. As for $\mathrm{SBM}(n,p,W)$, we define $\mathrm{LSBM}(n,p,\mu)$ where each vertex label X_u is drawn i.i.d. under p on $[k]$, $\mu(\cdot|x,x')$ is a probability measure on $\mathcal{Y}$ for all $x,x' \in [k]$, such that for $u<v$ in $[n]$, S a measurable set of $\mathcal{Y}$,

$$\mathbb{P}\{E_{uv}(G) \in S | X_u = x_u, X_v = x_v\} = \mu(S|x_u,x_v). \tag{75}$$

As for the unlabelled case, the symbol 0 will typically have probability $1-o(1)$ for any community pair, i.e., $\mu(\cdot|x,x')$ has an atom at 0 for all $x,x' \in [k]$, while μ_+, the measure restricted to $\mathcal{Y}_+$, may be arbitrary but of measure $o(1)$.

We now explain how the genie-aided converse and the graph-splitting techniques allow to obtain the fundamental limit for exact recovery in this model, without much additional effort. Consider first the case where $\mathcal{Y}_+$ is finite, and let L be the cardinality of $\mathcal{Y}_+$, and $\mu(0|x,x') = 1 - c_{x,x'}\log n/n$ for some constant $c_{x,x'}$ for all $x,x' \in [k]$. Hence $\mu(\mathcal{Y}_+|x,x') = c_{x,x'}\log n/n$.

For the achievability part, use a graph-splitting technique of, say, $\gamma = \log\log n/\log n$. On the first graph, merge the non-zero labels to a special symbol 1, i.e., collapse the model to $\mathrm{SBM}(n,p,W^\star)$ where $W^\star_{x,x'} = \sum_{y\in\mathcal{Y}_+}\mu(y|x,x')$ by assigning all non-zero labels to 1. Using our result on almost exact recovery (see Theorem 50), we can still solve almost exact recovery for this model as the expect degrees are diverging. Now, use the obtained clustering on the second graph to locally improve it. We have a seemingly different genie-aided hypothesis test than for the classical SBM, as we have k communities but also L labels on the edges. However, since the genie-aided test reveals all other community labels than the current vertex being classified, we can simply view the different labels on the edges as sub-communities, with a total of kL virtual communities. The distribution for each hypothesis is still essentially a multivariate Binomial, where hypothesis $i \in [k]$ has $\mathrm{Bin}(np_j, W(\ell|i,j))$ neighbors in augmented community $(j,\ell) \in [k]\times[L]$. Denoting by W_ℓ the matrix whose (i,j)-entry is $W(\ell|i,j)$, we thus have from the local to global results of

Section 3.3 that the threshold is given by

$$\min_{\substack{i,i'\in[k],l,l'\in[L]\\ i\neq i',l\neq l'}} D((PW_l)_i,(PW_{l'})_{i'}). \tag{76}$$

Further, this is efficiently achievable since almost exact recovery can be solved with the algorithm discussed in the classical setting, and since the new hypothesis test remains linear in n for finite k and L.

For non finite labels, the achievability part can be treated similarly using a quantization of the labels. This gives a continuous extension of the CH-divergence, and shows that strictly above this threshold, exact recovery is efficiently solvable (although the complexity may increase with the gap to capacity shrinking). The converse and the behavior at the threshold require a few more technical steps.

Several papers have investigated the labelled SBM with labels, we refer in particular to Heimlicher et al. (2012); Xu et al. (2014); Jog and Loh (2015); Yun and Proutiere (2015). A special case of labelled block model with further applications to synchronization, correlation clustering and objet alignment problems has been defied as the censored block model in Abbe et al. (2014a,b), and was further studied in Chin et al. (2015); Saade et al. (2015); Chen et al. (2014); Chen and Goldsmith (2014). This model captures a setting in which the edges carry information about the similarity of the nodes, whereas non-edges carry zero information (as opposed to the SBM where non-edges carry a little bit of information).

Overlapping communities. Consider the following model that accounts for overlapping communities, which we call the overlapping stochastic block model (OSBM).

Definition 27 *Let $n,t\in\mathbb{Z}_+$, $f:\{0,1\}^t\times\{0,1\}^t\to[0,1]$ symmetric, and p a probability distribution on $\{0,1\}^t$. A random graph with distribution OSBM(n,p,f) is generated on the vertex set $[n]$ by drawing independently for each $v\in[n]$ the vector-labels (or user profiles) $X(v)$ under p, and by drawing independently for each $u,v\in[n]$, $u<v$, an edge between u and v with probability $f(X(u),X(v))$.*

Example 1 *One may consider $f(x,y)=\theta_g(x,y)$, where x_i encodes whether a node is in community i or not, and*

$$\theta_g(x,y)=g(\langle x,y\rangle), \tag{77}$$

where $\langle x,y\rangle=\sum_{i=1}^t x_iy_i$ counts the number of common communities between the labels x and y, and $g:\{0,1,\dots,t\}\to[0,1]$ is a function that maps the overlap score into probabilities (g is typically increasing).

We can represent the OSBM as a SBM with $k=2^t$ communities, where each community represents a possible profile in $\{0,1\}^t$. For example, two overlapping communities can be modelled by assigning nodes with a single attribute $(1,0)$ and $(0,1)$ to each of the disjoint communities and nodes with both attributes $(1,1)$ to the overlap community, while nodes having none of the attributes, i.e., $(0,0)$, may be assigned to the null community.

Assume now that we identify community $i\in[k]$ with the profile corresponding to the binary expansion of $i-1$. The prior and connectivity matrix of the corresponding SBM are then given by

$$p_i=p(b(i)) \tag{78}$$
$$W_{i,j}=f(b(i),b(j)), \tag{79}$$

where $b(i)$ is the binary expansion of $i-1$, and

$$\text{OSBM}(n,p,f)\overset{(d)}{=}\text{SBM}(n,p,W). \tag{80}$$

We can then use the results of previous sections to obtain exact recovery in the OSBM.

Corollary 28 *Exact recovery is solvable for the OSBM if the conditions of Theorem 14 apply to the SBM(n,p,W) with p and W as defined in* (78), (79).

This approach treats intersections of communities as sub-communities, and proceeds in extracting these in the case where all overlaps are of linear size. When the parameters are such that the original communities can be identified from the sub-communities, this allows to reconstruct the original communities. If the patching is not identifiable, nothing can be done to improve on what the above corollary provides. However, this approach does not seem very practical for large number of communities or for small overlaps, where one would like to have an approach that provides a soft membership of each vertex to different communities (such as a probability distribution). This connects also to the mixed-membership model Airoldi et al. (2008), and to the case of SBMs with continuous vertex labels, for which exact recovery is typically not the right metric. The problems are fairly open in such contexts, as further discussed in Section 8, with partial progress in Kaufmann et al. (2015).

Previous result can also applied to understand what level of granularity can be obtained in extracting hierarchical communities. A simple example is the case of two communities, where one of the two communities is further divided into two sub-communities, leading to connectivity matrices that encode such a nested structure. A particular case concerns the model with a single planted community, for which detailed results have been obtained in Montanari (2015); Hajek et al. (2015b,a) both for weak and exact recovery.

Bipartite communities. Another important application concerns bipartite graphs, where communities can take place on both sides of the graph. This is also called bi-clustering, and happens for example in recommendation systems, where the two sides separate users and items (such as movies), internet with users and webpages, topic modelling with documents and words, and many other examples.

From a block model point of view, such bipartite models are simply SBMs where some of the Q_{ij}'s are equal to 0. Consider for example the problem of finding botnets, where the left nodes represent the users separated in two communities, A and B, corresponding to human and robots, and where the right nodes represent the webpages separated in two communities, 1 and 2, corresponding to normal and infected pages. We can use an SBM with 4 communities such that $W_{1,1}=W_{1,2}=W_{2,2}=W_{A,A}=W_{A,B}=W_{B,B}=0$.

On can then use Theorem 14 to obtain the fundamental limit for extracting communities, or the extension of Section 3.5.2 to extract a specific community (e.g., the robots in previous example). Note that the establishment of the fundamental limit allows to quantify the fact that treating the data in the bipartite model strictly improves on collapsing the data into a single clustering problem. The collapsing part refers to building a simple graph out of the bipartite graph Zhou et al. (2007), keeping only the right or left nodes (but not both), and connecting them based on how much common neighbors the vertices have on the other side.

Hypergraphs. Another extension is concerned with hypergraphs, where the observations are not pairwise interactions but triplets or k-tuples. This takes place for example in collaboration networks, such as citation networks, where a publication represents an hyperedge on multiple authors. One can easily extend the SBM in such settings, giving a different probability for each type of hyperedges (i.e., hyperedges that are fully in one community, or that have different proportions of vertices in different communities). The fundamental limit for exact recovery in this model does not follow directly from Theorem 14, but the techniques described in Sections 3.2.1 and 3.2.2 apply, and in particular, the approach described for labeled edges above. We also refer to Angelini et al. (2015) for spectral algorithms in this context.

3.5.2 Subset of communities

Before delving into the partial recovery of the communities, one may ask whether it possible to exactly recover *subsets* of the communities, or only a specific community, while not necessarily being able to recover all others. This question is answered in Abbe and Sandon (2015b) as follows.

To determine which communities can be recovered, partition the community profiles into the largest collection of disjoint subsets such that the CH-divergence among these subsets is at least 1 (where the CH-divergence between two subsets is the minimum of the CH-divergence between any two elements in these subsets). We refer to this as the *finest partition* of the communities. Note that this gives the set of connected components in the graph where each community is a vertex, and two communities are adjacent if and only if they have a CH-divergence less than 1. Figure 3 illustrates this partition. The theorem below shows that this is indeed the most granular partition that can be recovered about the communities, in particular, it characterizes the information-theoretic and computational threshold for exact recovery in this setting.

Theorem 29 *Abbe and Sandon (2015b) Let Q be a $k \times k$ matrix with nonzero entries, $p \in (0,1)^k$ with $\sum p = 1$. Exact recovery is information-theoretically solvable in* $\mathrm{SBM}(n,p,\log(n)Q/n)$ *for a partition $[k] = \sqcup_{s=1}^{t} A_s$ if and only if for all i and j in different subsets of the partition,*

$$D_+((PQ)_i,(PQ)_j) \geq 1, \tag{81}$$

Moreover, exact recovery for a partition is efficiently solvable whenever it is information-theoretically solvable.

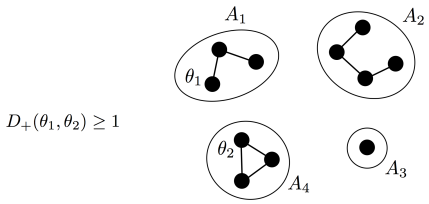


Figure 3: Finest partition: To determine which communities can be recovered in $\mathrm{SBM}(n,p,\log(n)Q/n)$, embed each community with its community profile $\theta_i = (\mathrm{diag}\, pQ)_i$ in $\mathbb{R}_+^k$ and find the partition of $\theta_1,\ldots,\theta_k$ into the largest number of subsets that are at CH-divergence at least 1 from each other.

4. Weak Recovery (a.k.a. Detection)

The focus on weak recovery, also called detection, initiated[10] with Coja-Oghlan (2010); Decelle et al. (2011). Note that weak recovery is typically investigated in SBMs where vertices have constant expected degree, as otherwise the problem can trivially be resolved by exploiting the degree variations.

4.1 Fundamental limit and KS threshold

The following conjecture was stated in Decelle et al. (2011) based on deep but non-rigorous statistical physics arguments, and is responsible in part for the resurged interest on the SBM:

Conjecture 30 *Decelle et al. (2011); Mossel et al. (2015) Let (X,G) be drawn from* $\mathrm{SSBM}(n,k,a/n,b/n)$*, i.e., the symmetric SBM with k communities, probability a/n inside the communities and b/n across. Define* $\mathrm{SNR} = \frac{(a-b)^2}{k(a+(k-1)b)}$*. Then,*

(i) For any $k \geq 2$, it is possible to solve weak recovery efficiently if and only if $\mathrm{SNR} > 1$ *(the Kesten-Stigum (KS) threshold);*

(ii) If[11] *$k \geq 4$, it is possible to solve weak recovery information-theoretically (i.e., not necessarily in polynomial time in n) for some* SNR *strictly below 1.*[12]

It was proved in Massoulié (2014); Mossel et al. (2014a) that the KS threshold can be achieved efficiently for $k = 2$, with an alternative proof later given in Bordenave et al. (2015), and Mossel et al. (2015) shows that it is impossible to detect below the KS threshold for $k = 2$. Further, Deshpande et al. (2015) extends the results for $k = 2$ to the case

10. The earlier work Reichardt and Leone (2008) also considers detection in the SBM.
11. The conjecture states that $k = 5$ is necessary when imposing the constraint that $a > b$, but $k = 4$ is enough in general.
12. Decelle et al. (2011) made in fact a more precise conjecture, stating that there is a second transition below the KS threshold for information-theoretic methods when $k \geq 4$, whereas there is a single threshold when $k = 3$.

where a and b diverge while maintaining the SNR finite. So weak recovery is closed for $k = 2$ in SSBM. It was also shown in Bordenave et al. (2015) that for SBMs with multiple communities satisfying a certain asymmetry condition (i.e., the requirement that μ_k is a simple eigenvalue in Theorem 5 of Bordenave et al. (2015)), the KS threshold can be achieved efficiently. The asymmetry requirement of Bordenave et al. (2015) does not allow to resolve Conjecture 30 for $k \geq 3$.

Concerning crossing the KS threshold with information theory, a few papers have studied bounds and information-computation tradeoffs for SBMs with a growing number of communities Y. Chen (2014), two unbalanced[13] communities Neeman and Netrapalli (2014), and a single community Montanari (2015). These do not apply to Conjecture 1 part (ii). Both positive parts of Conjecture 1 have been proved in Abbe and Sandon (2015) (with a simplified algorithm presented in Abbe and Sandon (2016b), a simplified bound in Abbe and Sandon (2016a), and a full version in Abbe and Sandon (2017)). Papers Banks and Moore (2016); Banks et al. (2016) also provide an upper-bound on the information-theoretic threshold, which crosses the KS threshold for $k = 5$ rather than $k = 4$ in the symmetric case, but with in addition a lower-bound that matches the scaling of the upper-bound for large k.

Note that the terminology 'KS threshold' comes from the reconstruction problem on trees Kesten and Stigum (1966); Evans et al. (2000); Mossel and Peres (2003); Mézard and Montanari (2006). In the binary case, a transmitter broadcasts a uniform bit to some relays, which themselves forward the received bits to other relays, etc. The goal is to reconstruct the root bit from the leaf bits as the depth of the tree diverges. In particular, for two communities, Mossel et al. (2015) makes a reduction between failing in the reconstruction problem in the tree setting and failing in detection in the SBM. This is discussed in more details in next section. The fact that the reconstruction problem on tree also gives the positive behavior for efficient algorithm requires a more involved argument discussed in Section 4.5.1.

Achieving the KS threshold raises an interesting challenge for community detection algorithms, as standard clustering methods fail to achieve the threshold Krzakala et al. (2013). This includes spectral methods based on the adjacency matrix or standard Laplacians, as well as SDPs. For standard spectral methods, a first issue is that the fluctuations in the node degrees produce high-degree nodes that disrupt the eigenvectors from concentrating on the clusters Krzakala et al. (2013).[14] A classical trick is to trim such high-degree nodes Coja-Oghlan (2010); Vu (2014); Guédon and Vershynin (2016); Chin et al. (2015), throwing away some information, but this does not suffice to achieve the KS threshold. SDPs are a natural alternative, but they also stumble[15] before the KS threshold Guédon and Vershynin (2016); Montanari and Sen (2016), focusing on the most likely rather than typical clusterings. As shown in Bordenave et al. (2015); Abbe and Sandon (2015), a linearized BP algorithm which corresponds to a spectral algorithm on a generalized non-backtracking operator provide instead a solution to the positive part to Conjecture 1 part (i).

13. Detailed results were recently obtained in Caltagirone et al. (2016) for unbalanced communities with diverging degrees.
14. This issue is further enhanced on real networks where degree variations are large.
15. The recent results of Moitra et al. (2016) on robustness to monotone adversaries suggest that SDPs can in fact not achieve the KS threshold.

4.2 Impossibility below KS for $k = 2$ and reconstruction on trees

Theorem 31 *Mossel et al. (2015) For $k = 2$, weak recovery is not solvable if* SNR ≤ 1 *(i.e., $(a-b)^2 \leq 2(a+b)$).*

This result is obtained by a reduction to the problem of reconstruction on trees, which is next discussed; we refer to Mossel and Peres (2003) for a survey on this problem. An addition result is also obtained in Mossel et al. (2015), showing that when SNR ≤ 1, the symmetric SBM with two communities is in fact contiguous to the Erdős-Rénti model with edge probability $(a+b)/(2n)$, i.e, distinguishability is not solvable in this case. Contiguity is further discussed in Section 4.6.1.

Reconstruction on trees. The problem consists in broadcasting a bit from the root of a tree down to its leaves, and trying to guess back this bit from the leaves at large depth. Consider first the case of a deterministic tree with fixed degree $c+1$, i.e., each vertex has exactly c descendants (note that the root has degree c). Assume that on each branch of the tree the incoming bit is flipped with probability $\varepsilon \in [0,1]$, and that each branch acts independently. Let $X^{(t)}$ be the bits received at depth t in this tree, with $X^{(0)}$ being the root bit, assumed to be drawn uniformly at random in $\{0,1\}$.

We now define successful detection in this context. Note that $\mathbb{E}(X^{(0)}|X^{(t)})$ is a random variable that gives the probability that $X^{(0)} = 1$ given the leaf-bits, as a function of the leaf-bits $X^{(t)}$. If this probability is equal to $1/2$, then the leaf-bits provide no useful information about the root, and we are interested in understanding whether this takes place or not in the limit of large t.

Definition 32 *Detection (usually called reconstruction) in the tree model is solvable if* $\lim_{t\to\infty} \mathbb{E}|\mathbb{E}(X^{(0)}|X^{(t)}) - 1/2| > 0$. *Equivalently, detection is solvable if* $\lim_{t\to\infty} I(X^{(0)}; X^{(t)}) > 0$, *where I is the mutual information.*

Note that the above limits exist due to monotonicity arguments. The results for detection this model are as follows.

Theorem 33 *In the tree model with constant degree c and flip probability ε,*

- *Kesten and Stigum (1966) detection is solvable if $c(1-2\varepsilon)^2 > 1$,*
- *Bleher et al. (1995); Evans et al. (2000) detection is not solvable*[16] *if $c(1-2\varepsilon)^2 \leq 1$.*

Thus detection in the tree model is solvable if and only if $c(1-2\varepsilon)^2 > 1$, which gives rise to the so-called Kesten-Stigum (KS) threshold in this tree context. Note that Mossel and Peres (2003) further shows that the KS threshold is sharp for "census reconstruction," i.e., deciding about the root-bit by taking majority on the leaf-bits, which is shown to still hold in models such as the multicolor Potts model where the KS threshold is no longer sharp for reconstruction.

To see the two parts of Theorem 33, note that the number 0-bits minus 1-bits at generation t, i.e, $\sum_{i\in[c^t]}(-1)^{X_i^{(t)}}$ is a random variable with expectation of order $c^t(1-2\varepsilon)^t$

16. The proof from Evans et al. (2000) appeared first in 1996.

with a sign depending on the value of the root-bit, and with variance of order c^t. Thus the signal-to-noise ratio (i.e., the ratio between the expectation and the standard deviation of this statistic) is $(\sqrt{c}(1-2\varepsilon))^t$, and $\sqrt{c}(1-2\varepsilon) > 1$ allows to make reliable inference about the root-bit as t diverges. In the binary case and with the flip model considered for the noise, it turns out that the mutual information is sub-additive among leaves Evans et al. (2000), i.e., $I(X^{(0)}; X^{(t)}) \leq \sum_{i=1}^{c^t} I(X^{(0)}; X_i^{(t)}) = c^t I(X^{(0)}; X_1^{(t)})$ (this is however not true in general for binary non-symmetric noise or for non-binary labels). The channel between $X^{(0)}$ and a single leaf-bit $X_1^{(t)}$ corresponds to the addition of t Bernoulli(ε) random variables, and it is easy to check that its mutual information scales as $(1-2\varepsilon)^{2t}$, which shows that $I(X^{(0)}; X^{(t)})$ is upper bounded by $c^t(1-2\varepsilon)^{2t}$. Hence, if $c(1-2\varepsilon)^2$ is less than 1, the information of the root-bit is lost.

We will soon turn to the connection between the reconstruction on tree problem and weak recovery in the SBM. It is easy to guess that the tree for us will not be a fixed degree tree, but the local neighborhood of an SBM vertex, which is a Gaton-Watson tree with Poisson offspring. We first state the above results for Galton-Walton trees.

Definition 34 *A Galton-Walton tree with offspring distribution μ on $\mathbb{Z}_+$ is a rooted tree where the number of descendants from each vertex is independently drawn under the distribution μ. We denote by $T^{(t)} \sim GW(\mu)$ a Galton-Walton tree with offspring μ and t generations of descendants.*

Note that detection in the context of a random tree is defined by requiring that

$$\lim_{t\to\infty} \mathbb{E}|\mathbb{E}(X^{(0)}|X^{(t)}, T^{(t)}) - 1/2| > 0,$$

where $X^{(t)}$ are the variables at generation t obtained from broadcasting the root-bit as in the previous case. In Evans et al. (2000), it is shown that the threshold $c(1-2\varepsilon)^2 > 0$ is necessary and sufficient for detection for a large class of offspring distributions, where c is the expectation of μ, such as the Poisson(c) distribution that is of interest to us. Another important extension is the 'robust reconstruction' problem Janson and Mossel (2004), where the leaves are not revealed exactly but in a noisy fashion. It was shown in Janson and Mossel (2004) that for very noisy leaves, the KS threshold is also tight.

The connection with the SBM comes from the fact that if one picks a vertex v in the SBM graph, its neighborhood at small enough depth behaves likes a Galton-Watson tree of offspring Poisson($(a+b)/2$), and the labelling on the vertices behaves like the broadcasting process discussed above with a flip probability of $b/(a+b)$. Note that the latter parameter is precisely the probability that two vertices have different labels given that there is an edge between them. More formally, if the depth is $t \leq (1/2-\delta)\log(n)/\log(a+b)/2)$ for some $\delta > 0$, then the true distribution and the above one have a vanishing total variation when n diverges. This depth requirement can be understood from the fact the expected number of leaves in that case is in expectation $n^{1/2-\delta}$, and by the birthday paradox, no collision will likely occur between two vertices neighborhoods if $\delta > 0$.

To establish Theorem 31, it is sufficient to argue that, if it impossible to detect a single vertex when a genie reveals all the leaves at such a depth, it must be impossible to detect. In fact, consider $\mathbb{P}\{X_u = x_u | G = g, X_v = x_v\}$, the posterior distribution given the graph

and an arbitrary vertex revealed (here u and v are arbitrary and chosen before the graph is drawn). With high probability, these vertices will not be at small graph-distance of each other, and one can open a small neighborhood around u of dept, say, $\log\log(n)$. Now reveal not only the value of X_v but in fact all the values at the boundary of this neighborhood. This is an easier problem since the neighborhood is a tree with high probability and since there is approximately a Markov relationship between these boundary vertices and the original X_v (note that 'approximate' is used here since there is a negligible effect of non-edges to handle). We are now back to the broadcasting problem on tree discussed above, and the requirement $c(1-2\varepsilon)^2 \leq 0$ gives a sufficient condition for detection to fail. Since $c = (a+b)/2$ and $\varepsilon = b/(a+b)$, this gives $(a-b)^2 \leq 2(a+b)$.

The reduction extends to more than two communities (i.e., non-binary labels broadcasted on trees) and to asymmetrical communities, but the tightness of the KS bound is no longer present in these cases. For two asymmetrical communities, the result still extends if the communities are roughly symmetrical, using Borgs et al. (2006) and Mossel et al. (2013); pri. For more than three symmetric communities, new gap phenomena take place as discussed in Section 4.6.

4.3 Achieving KS for $k = 2$

Theorem 35 *Massoulié (2014); Mossel et al. (2014a) For $k = 2$, weak recovery is efficiently solvable if* SNR > 1 *(i.e., $(a-b)^2 > 2(a+b)$).*

The first paper Massoulié (2014) is based[17] on a spectral method from the matrix of self-avoiding walks (entry (i,j) counts the number of self-avoiding walks of moderate size between vertices i and j) Massoulié (2014), the second on counting weighted non-backtracking walks between vertices Mossel et al. (2014a). The first method has a complexity of $O(n^{1+\varepsilon})$, $\varepsilon > 0$, while the second method affords a lesser complexity of $O(n\log^2 n)$ but with a large constant (see discussion in Mossel et al. (2014a)). These papers appeared in 2014 and were the first to achieve the KS threshold for two communities.

Later in 2015, Bordenave et al. (2015) obtains an alternative proof on a spectral method with the matrix of non-backtracking walks between directed edges. The paper gives a detailed analysis of the spectrum of the nonbacktracking operator and allows going beyond the SBM with 2 communities, requiring a certain condition in the SBM parameters to obtain a result for detection (the precise conditions are the uniformity of p and the requirement that μ_k is a simple eigenvalue of M in Theorem 5 of Bordenave et al. (2015)), falling short of proving the positive part of Conjecture 1.(i) for $k \geq 3$ due to technical reasons (the second eigenvalue in this case has multiplicity at least 2). In Abbe and Sandon (2015), another variant based on higher order nonbacktracking power iterations is shown to achieve the KS threshold in the general SBM.

The nonbacktracking operator was first proposed for the SBM in Krzakala et al. (2013), also described as a linearization of BP, with formal results obtained in Bordenave et al. (2015). This gives a new approach to community detection, and a strong case for nonbacktracking operators. Linearizations of BP of similar nature were already used in Janson and Mossel (2004) in the context of robust reconstruction on trees. As the nonbacktracking

17. Related ideas relying on shortest paths were also considered in Bhattacharyya and Bickel (2014).

matrix is not normal, Saade et al. (2014) also introduced an alternative approach based on the Bethe Hessian operator.

We next discuss the algorithm of Bordenave et al. (2015) for 2 symmetric communities. We define first the nonbacktracking matrix of a graph.

Definition 36 *[The nonbacktracking (NB) matrix.] Hashimoto (1989) Let $G = (V, E)$ be a simple graph and let $\vec{E}$ be the set of oriented edges obtained by doubling each edge of E into two directed edge. The non-backtracking matrix B is a $|\vec{E}| \times |\vec{E}|$ matrix indexed by the elements of $\vec{E}$ such that, for $e = (e_1, e_2), f = (f_1, f_2) \in \vec{E}$,*

$$B_{e,f} = \mathbb{1}(e_2 = f_1)\mathbb{1}(e_1 \neq f_2), \tag{82}$$

i.e., entry (e, f) of B is 1 if e and f follow each other without creating a loop, and 0 otherwise.

The non-backtracking matrix can be used to count efficiently non-backtracking walks in a graph. Recall that a walk in a graph is a sequence of adjacent vertices whereas a non-backtracking walk is a walk that does not repeat a vertex within 2 steps. Counting walks of a given length can simply be done by taking powers of the adjacency matrix. The non-backtracking matrix allows for a similar approach to count nonbacktracking walks between edges. To obtain the number of non-backtracking walks of length $k \geq 2$ starting at a directed edge e and ending in a directed edge f, one simply needs to take entry (e, f) of the power matrix B^{k-1}. Note also that to count paths, i.e., walks that do not repeat any vertex, no such efficient method is known and the count is #P-complete.

The nonbacktracking matrix B of a graph was introduced by Hashimoto Hashimoto (1989) to study the Ihara zeta function, with the identity $\det(I - zB) = \frac{1}{\zeta(z)}$, where ζ is the Ihara zeta function of the graph. In particular, the poles of the Ihara zeta function are the reciprocals of the eigenvalues of B. Studying the spectrum of a graph thus implies properties on the location of the Ihara zeta function. The matrix is further used to define the graph Riemann hypothesis Horton et al. (2006), and studying its spectrum for random graphs such as the block model allows for generalizations of notions of Ramanujan graphs and Friedman's Theorem Friedman (2003) to non-regular cases, see also Bordenave et al. (2015). The operator that we study is a natural extension of the classical nonbacktracking operator of Hashimoto, where we prohibit not only standard backtracks but also finite cycles.

We now describe the spectral algorithm based on the nonbacktracking matrix to detect communities in the symmetric SBM with two communities.

Nonbacktracking eigenvector extraction algorithm Krzakala et al. (2013); Bordenave et al. (2015).
Input: An n-vertex graph g and a parameter $\tau \in \mathbb{R}$.
(1) Construct the nonbacktracking matrix B of the graph g.
(2) Extract the eigenvector ξ_2 corresponding to the second largest eigenvalue of B.
(3) Assign vertex v to the first community if $\sum_{e:e_2=v} \xi_2(e) > \tau/\sqrt{n}$ and to the second community otherwise.

It is shown in Bordenave et al. (2015) that the exists a $\tau \in \mathbb{R}$ such that above algorithm solves detection if $(a-b)^2 > 2(a+b)$, i.e., down to the KS threshold. For more than two communities, the above algorithm needs to be modified and its proof of detection currently applies to some cases of SBMs as previously discussed (balanced communities and no multiplicity of eigenvalues).

A quick intuition on why the nonbacktracking matrix is more amenable for community detection than the adjacency matrix is obtained by taking powers of these matrices. In the case of the adjacency matrix, powers are counting walks from a vertex to another, and these get multiplied around high-degree vertices since the walk can come in and out of such vertices in multiple ways. Instead, by construction of the nonbacktracking matrix, taking powers forces a directed edge to leave to another directed edge that does not backtrack, preventing such amplifications around high-degree vertices. So the nonbacktracking gives a way to mitigate the degree-variations and to avoid localized eigenvector (recall discussion in Section 2.6), arguably more efficiently than trimming which removes information from the graph. This property is reflected in the spectrum of the nonbacktracking matrix, which has for largest eigenvalue (in magnitude) λ_1 (which is real positive). Then the question if the second largest eigenvalue λ_2 appears before $\sqrt{\lambda_1}$, i.e.,

$$\sqrt{\lambda_1} < |\lambda_2| \leq \lambda_1, \tag{83}$$

weak recovery can be solved by using the eigenvector corresponding to λ_2 to obtain the non-trivial separation Bordenave et al. (2015).

Extracting the second eigenvector of the nonbacktracking matrix directly may not be the most efficient way to proceed, specially as the graph gets denser. A power iteration method is a natural implementation, likely to be used by softwares, but this requires additional proofs as discussed next. The approach of Mossel et al. (2014a) based on the count of weighted nonbacktracking walks between vertices provides another practical alternative.

4.4 Achieving KS for general k

The next result proves the positive parts of Conjecture 1.

Theorem 37 *Abbe and Sandon (2015) (part 1 presented in Abbe and Sandon (2016b) and part 2 presented in Abbe and Sandon (2016a).)*

1. *For any $k \geq 2$, weak recovery is solvable in $O(n \log n)$ if* SNR > 1 *with the approximate acyclic belief propagation (ABP) algorithm;*

2. *For any $k \geq 4$, weak recovery is information-theoretically solvable for some* SNR *strictly below* 1 *with the typicality sampling (TS) algorithm.*

We describe next the two algorithms used in previous theorem. In brief, ABP is a belief propagation algorithm where the update rules are linearized around the uniform prior and where the feedback on short cycles is mitigated; TS is a non-efficient algorithm that samples uniformly at random a clustering having typical clusters' volumes and cuts. The fact that BP with a random initialization can achieve the KS threshold for arbitrary k was conjectured in the original paper Decelle et al. (2011), but handling random initialization and cycles with

BP is a classical challenge. A linearized version is more manageable to analyze, although the effect of cycles remains a difficulty to overcome.

The simplest linearized version of BP is to repeatedly update beliefs about a vertex's community based on its neighbor's suspected communities while avoiding backtrack. However, this only works ideally if the graph is a tree. The correct response to a cycle would be to discount information reaching the vertex along either branch of the cycle to compensate for the redundancy of the two branches. Due to computational issues we simply prevent information from cycling around constant size cycles. We also add steps where a multiple of the beliefs in the previous step are subtracted from the beliefs in the current step to prevent the beliefs from settling into an equilibrium where vertices' communities are sytematically misrepresented in ways that add credibility to each other.

Approximate message passing algorithms have also been developed in other contexts, such as in Donoho et al. (2009) for compressed sensing with approximate message passing (AMP) and state evolution. This approach applies to dense graphs whereas the approximation of ABP applies to the sparse regime. We refer to Section 6.4 for discussions on how the output of ABP can be fed into standard BP in order to achieve optimal accuracy for partial recovery.

The approach of ABP is also related to Mossel et al. (2014a); Bordenave et al. (2015), while diverging in several parts. Some technical expansions are similar to those carried in Mossel et al. (2014a), such as the weighted sums over nonbacktracking walks and the SAW decomposition in Mossel et al. (2014a), which are similar to the compensated nonbacktracking walk counts and Shard decomposition of Abbe and Sandon (2015). The approach of Abbe and Sandon (2015) is however developed to cope with the general SBM model, in particular the compensation of dominant eigenvalues due to the linearization, which is particularly delicate. The algorithm complexity of Abbe and Sandon (2015) is also slightly reduced by a logarithmic factor compared to Mossel et al. (2014a).

As seen below, ABP can also be interpreted as a power iteration method on a generalized nonbacktracking operator, where the random initialization of the beliefs in ABP corresponds to the random vector to which the power iteration is applied. This formalizes the connection described in Krzakala et al. (2013) and makes ABP closely related to Bordenave et al. (2015) that proceeds with eigenvector extraction rather than power iteration. This distinction requires particular care at the proof level. The approach of ABP also differs from Bordenave et al. (2015) in that it relies on a generalization of the nonbacktracking matrix Hashimoto (1989) with higher order nonbacktracks (see Definition 38 below), and relies on different proof techniques to cope with the setting of Conjecture 1. The current proof requires the backtrack order r to be a constant but not necessarily 2. While we believe that $r = 2$ may suffice for the sole purpose of achieving the KS threshold, we also suspect that larger backtracks may be necessary for networks with more small cycles, such as many of those that occur in practice.

We next describe the message passing implementation of ABP with a simplified version ABP* that applies to the general SBM (with constant expected degree but not necessarily symmetric; see Section 4.5 for its performance in the general SBM). We then define the generalized nonbacktracking matrix and the spectral counter-part of ABP*.

ABP*. Abbe and Sandon (2016b)
Input: a graph G and parameters $m, r \in \mathbb{Z}_+$.

1. For each adjacent v and v' in G, randomly draw $y^{(1)}_{v,v'}$ from a Normal distribution. Assign $y^{(t)}_{v,v'}$ to 0 for $t < 1$.

2. For each $1 < t \le m$, set

$$z^{(t-1)}_{v,v'} = y^{(t-1)}_{v,v'} - \frac{1}{2|E(G)|} \sum_{(v'',v''')\in E(G)} y^{(t-1)}_{v'',v'''}$$

for all adjacent v and v'. For each adjacent v, v' in G that are not part of a cycle of length r or less, set

$$y^{(t)}_{v,v'} = \sum_{v'':(v',v'')\in E(G), v''\neq v} z^{(t-1)}_{v',v''},$$

and for the other adjacent v, v' in G, let v''' be the other vertex in the cycle that is adjacent to v, the length of the cycle be r', and set

$$y^{(t)}_{v,v'} = \sum_{v'':(v',v'')\in E(G), v''\neq v} z^{(t-1)}_{v',v''} - \sum_{v'':(v,v'')\in E(G), v''\neq v', v''\neq v'''} z^{(t-r')}_{v,v''}$$

unless $t = r'$, in which case set $y^{(t)}_{v,v'} = \sum_{v'':(v',v'')\in E(G), v''\neq v} z^{(t-1)}_{v',v''} - z^{(1)}_{v''',v}$.

3. Set $y'_v = \sum_{v':(v',v)\in E(G)} y^{(m)}_{v,v'}$ for all $v \in G$. Return $(\{v : y'_v > 0\}, \{v : y'_v \le 0\})$.

Remarks:

1. In the $r = 2$ case, one does not need to find cycles and one can exit step 2 after the second line. As mentioned above, we rely on a less compact version of the algorithm to prove the theorem, but expect that the above also succeeds at detection as long as $m > 2\ln(n)/\ln(\mathrm{SNR}) + \omega(1)$.

2. What the algorithm does if (v, v') is in multiple cycles of length r or less is unspecified above, as there is no such edge with probability $1 - o(1)$ in the sparse SBM. This can be modified for more general settings. The simplest such modification is to apply this adjustment independently for each such cycle, setting

$$y^{(t)}_{v,v'} = \sum_{\substack{v'':(v',v'')\in E(G)\\ v''\neq v}} z^{(t-1)}_{v',v''} - \sum_{r'=1}^{r} \sum_{v''':(v,v''')\in E(G)} C^{(r')}_{v''',v,v'} \sum_{\substack{v'':(v,v'')\in E(G)\\ v''\neq v', v''\neq v'''}} z^{(t-r')}_{v,v''},$$

where $C^{(r')}_{v''',v,v'}$ denotes the number of length r' cycles that contain v''', v, v' as consecutive vertices, substituting $z^{(1)}_{v''',v}$ for $\sum_{v'':(v,v'')\in E(G), v''\neq v', v''\neq v'''} z^{(t-r')}_{v,v''}$ when $r' = t$. This does not exactly count r-nonbacktracking walks, but it gives a good enough approximation.

3. The purpose of setting $z^{(t-1)}_{v,v'} = y^{(t-1)}_{v,v'} - \frac{1}{2|E(G)|}\sum_{(v'',v''')\in E(G)} y^{(t-1)}_{v'',v'''}$ is to ensure that the average value of the $y^{(t)}$ is approximately 0, and thus that the eventual division of the vertices into two sets is roughly even. There is an alternate way of doing this in which we simply let $z^{(t-1)}_{v,v'} = y^{(t-1)}_{v,v'}$ and then compensate for any bias of $y^{(t)}$ towards positive or negative values at the end. More specifically, we define Y to be the $n \times m$ matrix such that for all t and v, $Y_{v,t} = \sum_{v':(v',v)\in E(G)} y^{(t)}_{v,v'}$, and M to be the $m \times m$ matrix such that $M_{i,i} = 1$ and $M_{i,i+1} = -\lambda_1$ for all i, and all other entries of M are equal to 0. Then we set $y' = YM^{m'}e_m$, where $e_m \in \mathbb{R}^m$ denotes the unit vector with 1 in the m-th entry, and m' is a suitable integer.

4. This algorithm is intended to classify vertices with an accuracy nontrivially better than that attained by guessing randomly. However, it is relatively easy to convert this to an algorithm that classifies vertices with optimal accuracy. Once one has reasonable initial guesses of which communities the vertices are in, one can then use full belief propagation to improve this to an optimal classification. See further details in Section 6.4.

In order to prove that ABP solves detection, a few modifications are made relative to the vanilla version described above. The main differences are as follows. First, at the end we assign vertices to sets with probabilities that scale linearly with their entries in y' instead of simply assigning them based on the signs of their entries. This allows us to use the fact that the average values of y'_v for v in different communities differ to prove that vertices from different communities have different probabilities of being assigned to the first set. Second, we remove a small fraction of the edges from the graph at random at the beginning of the algorithm. Then we define y''_v to be the sum of $y'_{v'}$ over all v' connected to v by paths of a suitable length with removed edges at their ends in order to eliminate some dependency issues. Also, instead of just compensating for PQ's dominant eigenvalue, we also compensate for some of its smaller eigenvalues. We refer to Abbe and Sandon (2015) for the full description of the official ABP algorithm. Note that while it is easier to prove that the ABP algorithm works, the ABP* algorithm should work at least as well in practice.

We now define the generalized nonbacktracking matrix and the spectral implementation of ABP.

Definition 38 *[The r-nonbacktracking (r-NB) matrix.] Let $G = (V, E)$ be a simple graph and let $\vec{E}_r$ be the set of directed paths of length $r-1$ obtained on E. The r-nonbacktracking matrix $B^{(r)}$ is a $|\vec{E}_r| \times |\vec{E}_r|$ matrix indexed by the elements of $\vec{E}_r$ such that, for $e = (e_1, \dots, e_{r-1}), f = (f_1, \dots, f_{r-1}) \in \vec{E}_r$,*

$$B^{(r)}_{e,f} = \prod_{i=1}^{r-1} \mathbb{1}((e_{i+1})_2 = (f_i)_1)\mathbb{1}((e_1)_1 \neq (f_{r-1})_2), \tag{84}$$

i.e., entry (e, f) of $B^{(r)}$ is 1 if f extends e by one edge (i.e., the last $r-1$ edges of e agree with the first $r-1$ edges of f) without creating a loop, and 0 otherwise.

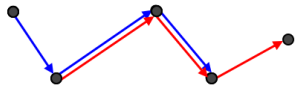

Figure 4: Two paths of length 3 that contribute to an entry of 1 in $B^{(4)}$.

Remark 39 *Note that $B^{(2)} = B$ is the classical nonbacktracking matrix from Definition 36. As for $r = 2$, we have that $((B^{(r)})^{k-1})_{e,f}$ counts the number of r-nonbacktracking walks of length k from e to f.*

r-nonbacktracking power iteration algorithm. Abbe and Sandon (2015)
Input: a graph G and parameters $m, m' \in \mathbb{Z}_+$; denote by d the average degree of the graph.
(1) Draw $y^{(1)}$ of dimension $|\vec{E}_r|$ with i.i.d. Normal components.
(2) For each $1 < t \leq m$, let $y^{(t)} = B^{(r)}y^{(t-1)}$.
(3) Change $y^{(m)}$ to $(B^{(r)} - dI)^{m'}y^{(m-m')}$.
(4) For each v, set $y'_v = \sum_{v':(v',v)\in E(G)} y^{(m)}_{v,v'}$ and return $(\{v : y'_v > 0\}, \{v : y'_v \leq 0\})$.

Parameters should be chosen as discussed for ABP*.

4.5 Weak recovery in the general SBM

Given parameters p and Q in the general model SBM$(n, p, Q/n)$, let P be the diagonal matrix such that $P_{i,i} = p_i$ for each $i \in [k]$. Also, let $\lambda_1, ..., \lambda_h$ be the distinct eigenvalues of PQ in order of nonincreasing magnitude.

Definition 40 *Define the signal-to-noise ratio of* SBM$(n, p, Q/n)$ *by*

$$\text{SNR} = \lambda_2^2/\lambda_1.$$

In the k community symmetric case where vertices in the same community are connected with probability a/n and vertices in different communities are connected with probability b/n, we have $\text{SNR} = (\frac{a-b}{k})^2/(\frac{a+(k-1)b}{k}) = (a-b)^2/(k(a+(k-1)b))$, which is the quantity in Conjecture 1.

Theorem 41 *Bordenave et al. (2015) Let $G \sim$ SBM$(n, p, Q/n)$ such that $p = (1/k, \dots, 1/k)$ and such that PQ has an eigenvector with corresponding eigenvalue in $(\sqrt{\lambda_1}, \lambda_1)$ of single multiplicity. If* SNR > 1*, then weak recovery is efficiently solvable.*

Theorem 42 *Abbe and Sandon (2015); Abbe and Sandon (2017) Let $G \sim$ SBM$(n, p, Q/n)$ for p, Q arbitrary. If* SNR > 1*, then weak recovery is efficiently solvable.*

For the symmetric SBM, the above reduces to part (1) of Theorem 37, which proves the first positive part of Conjecture 1. Note that Decelle et al. (2011) extends Conjecture 1 to the general setting, where max-detection is claimed to be efficiently solvable if and only if $\lambda_2^2 > \lambda_1$. This statement is however not true, as discussed in Section 2.3. An

example is obtained for example by taking an SSBM with two symmetric communities of intra-connectivity $3/n$, small enough extra-connectivity, and breaking one community into 4 identical sub-communities. Then max-detection is not solvable if $\lambda_2^2 > \lambda_1$, but it is solvable for our notion of definition (weak recovery). If one uses that definition, then we also conjecture that such a statement holds, i.e., detection is efficiently solvable if and only if $\lambda_2^2 > \lambda_1$ (besides for the case where λ_1 has multiplicity more than one, for which it is sufficient to have $\lambda_1 > 1$, and always focusing on the case of constant expected degrees).

The full version of ABP is described in Abbe and Sandon (2015), but as for the symmetric case, the version ABP* described in previous section applies to the general setting, replacing d with the largest eigenvalue of PQ. Theorem 42 provides general condition for solving efficiently detection in the SBM with linear size communities. We also conjecture that this is a tight condition, i.e., if SNR < 1, then efficient detection is not solvable. However, establishing formally such a converse argument seems out of reach at the moment: as we shall see in next section, except for a few possible cases with low values of k (e.g., symmetric SBMs with $k = 2, 3$), it is possible to detect information-theoretically when SNR < 1, and thus one cannot get a converse for efficient algorithms by considering all algorithms (requiring significant headways in complexity theory that are likely go beyond the scope of SBMs). On the other hand, Decelle et al. (2011) provides non-formal arguments based on statistical physics arguments that such a converse hold. It would be interesting to further connect the computational barriers occurring here with those from other problems such as planted clique Alon et al. (1998), or as in Berthet and Rigollet (2013).

Finally, the extension to models discussed in Section 3.5 can also be understood in the lens of weak recovery. The case of edge labels or hyperedges need a separate treatment, since the reductions described in Section 3.5 are specific to exact recovery. The converse for weak recovery in the labelled SBM is covered in Heimlicher et al. (2012). The bipartite case can instead be treated as a special case of the threshold $\lambda_2^2/\lambda_1 > 1$ when the matrix Q has 0 entries.

Concerning the separation of specific communities, the results from Abbe and Sandon (2015) imply that communities i and j can be separated if there exists an eigenvector w of PQ such that $w_i \neq w_j$ and the eigenvalue of PQ corresponding to w has a magnitude of at least $\sqrt{\lambda_1}$.

4.5.1 Proof technique: approximate acyclic belief propagation (ABP)

For simplicity, consider first the two community symmetric case where vertices in the same community are adjacent with probability a/n and vertices in different communities are adjacent with probability b/n. We describe the ABP algorithm that implies Theorem 42; more specifically, if SNR > 1, then there exist $r \in \mathbb{Z}^+$, $c > 0$, and $m : \mathbb{Z}^+ \to \mathbb{Z}^+$ such that ABP$(G, m(n), r, c, (\lambda_1, ..., \lambda_h))$ solves detection and runs in $O(n \log n)$ time.

Consider determining the community of v using belief propagation, assuming some preliminary guesses about the vertices t edges away from it, and assuming that the subgraph of G induced by the vertices within t edges of v is a tree. For any vertex v' such that $d(v, v') < t$, let $C_{v'}$ be the set of the children of v'. If we believe based on either our prior knowledge or propagation of beliefs up to these vertices that v'' is in community 1 with probability $\frac{1}{2} + \frac{1}{2}\epsilon_{v''}$ for each $v'' \in C_{v'}$, then the algorithm will conclude that v' is in

community 1 with a probability of

$$\frac{\prod_{v'' \in C_{v'}} (\frac{a+b}{2} + \frac{a-b}{2}\epsilon_{v''})}{\prod_{v'' \in C_{v'}} (\frac{a+b}{2} + \frac{a-b}{2}\epsilon_{v''}) + \prod_{v'' \in C_{v'}} (\frac{a+b}{2} - \frac{a-b}{2}\epsilon_{v''})}.$$

If all of the $\epsilon_{v''}$ are close to 0, then this is approximately equal to

$$\frac{1 + \sum_{v'' \in C_{v'}} \frac{a-b}{a+b}\epsilon_{v''}}{2 + \sum_{v'' \in C_{v'}} \frac{a-b}{a+b}\epsilon_{v''} + \sum_{v'' \in C_{v'}} -\frac{a-b}{a+b}\epsilon_{v''}} = \frac{1}{2} + \frac{a-b}{a+b} \sum_{v'' \in C_{v'}} \frac{1}{2}\epsilon_{v''}.$$

That means that the belief propagation algorithm will ultimately assign an average probability of approximately $\frac{1}{2} + \frac{1}{2}(\frac{a-b}{a+b})^t \sum_{v'': d(v,v'')=t} \epsilon_{v''}$ to the possibility that v is in community 1. If there exists ϵ such that $E_{v'' \in \Omega_1}[\epsilon_{v''}] = \epsilon$ and $E_{v'' \in \Omega_2}[\epsilon_{v''}] = -\epsilon$ (recall that $\Omega_i = \{v : \sigma_v = i\}$), then on average we would expect to assign a probability of approximately $\frac{1}{2} + \frac{1}{2}\left(\frac{(a-b)^2}{2(a+b)}\right)^t \epsilon$ to v being in its actual community, which is enhanced as t increases when SNR > 1. Note that since the variance in the probability assigned to the possibility that v is in its actual community will also grow as $\left(\frac{(a-b)^2}{2(a+b)}\right)^t$, the chance that this will assign a probability of greater than $1/2$ to v being in its actual community will be $\frac{1}{2} + \Theta\left(\left(\frac{(a-b)^2}{2(a+b)}\right)^{t/2}\right)$.

Equivalently, given a vertex v and a small t, the expected number of vertices that are t edges away from v is approximately $(\frac{a+b}{2})^t$, and the expected number of these vertices in the same community as v is approximately $(\frac{a-b}{2})^t$ greater than the expected number of these vertices in the other community. So, if we had some way to independently determine which community a vertex is in with an accuracy of $\frac{1}{2} + \epsilon$ for small ϵ, we could guess that each vertex is in the community that we think that the majority of the vertices t steps away from it are in to determine its community with an accuracy of roughly $\frac{1}{2} + \left(\frac{(a-b)^2}{2(a+b)}\right)^{t/2} \epsilon$.

One idea for the initial estimate is to simply guess the vertices' communities at random, in the expectation that the fractions of the vertices from the two communities assigned to a community will differ by $\theta(1/\sqrt{n})$ by the central limit theorem. Unfortunately, for any t large enough that $\left(\frac{(a-b)^2}{2(a+b)}\right)^{t/2} > \sqrt{n}$, we have that $\left(\frac{(a+b)}{2}\right)^t > n$ which means that our approximation breaks down before t gets large enough to detect communities. In fact, t would have to be so large that not only would neighborhoods not be tree like, but vertices would have to be exhausted.

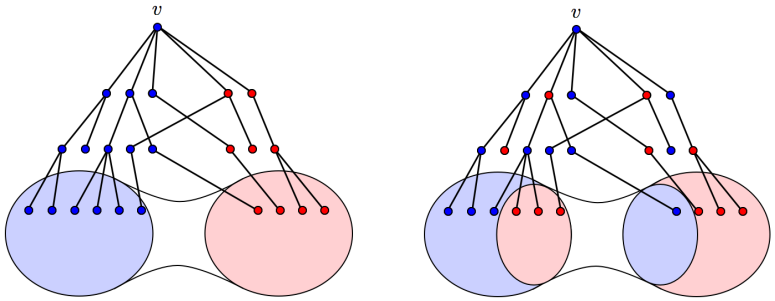

Figure 5: The left figure shows the neighborhood of vertex v pulled from the SBM graph at depth $c \log_{\lambda_1} n$, $c < 1/2$, which is a tree with high probability. If one had an educated guess about each vertex's label, of good enough accuracy, then it would be possible to amplify that guess by considering only such small neighborhoods (deciding with the majority at the leaves). However, we do not have such an educated guess and thus initialize our labels at random, obtaining a small advantage of roughly $\sqrt{n}$ vertices by luck (i.e., the central limit theorem), in either an agreement or disagreement form. This is illustrated in agreement form in the right figure. We next attempt to amplify that lucky guess by exploiting the information of the SBM graph. Unfortunately, the graph is too sparse to let us amplify that guess by considering tree like or even loopy neighborhoods; the vertices would have to be exhausted. This takes us to considering nonbacktracking walks.

One way to handle this would be to stop counting vertices that are t edges away from v, and instead count each vertex a number of times equal to the number of length t paths from v to it.[18] Unfortunately, finding all length t paths starting at v can be done efficiently only for values of t that are smaller than what is needed to amplify a random guess to the extent needed here. We could instead calculate the number of length t walks from v to each vertex more quickly, but this count would probably be dominated by walks that go to a high degree vertex and then leave and return to it repeatedly, which would throw the calculations off. On the other hand, most reasonably short nonbacktracking walks are likely to be paths, so counting each vertex a number of times equal to the number of nonbacktracking walks of length t from v to it seems like a reasonable modification. That said, it is still possible that there is a vertex that is in cycles such that most nonbacktracking walks simply leave and return to it many times. In order to mitigate this, we use r-nonbacktracking walks, walks in which no vertex reoccurs within r steps of a previous occurrence, such that walks cannot return to any vertex more than t/r times.

Unfortunately, this algorithm would not work because the original guesses will inevitably be biased towards one community or the other. So, most of the vertices will have more r-nonbacktracking walks of length t from them to vertices that were suspected of being in that community than the other. One way to deal with this bias would be to subtract the

18. This type of approach is considered in Bhattacharyya and Bickel (2014).

average number of r-nonbacktracking walks to vertices in each set from each vertex's counts. Unfortunately, that will tend to undercompensate for the bias when applied to high degree vertices and overcompensate for it when applied to low degree vertices. So, we modify the algorithm that counts the difference between the number of r-nonbacktracking walks leading to vertices in the two sets to subtract off the average at every step in order to prevent a bias from building up.

One of the features of our approach is that it extends fairly naturally to the general SBM. Despite the potential presence of more than 2 communities, we still only assign one value to each vertex, and output a partition of the graph's vertices into two sets in the expectation that different communities will have different fractions of their vertices in the second set. One complication is that the method of preventing the results from being biased towards one comunity does not work as well in the general case. The problem is, by only assigning one value to each vertex, we compress our beliefs onto one dimension. That means that the algorithm cannot detect biases orthogonal to that dimension, and thus cannot subtract them off. We then cancel out the bias by subtracting multiples of the counts of the numbers of r-nonbacktracking walks of some shorter length that will also have been affected by it.

4.6 Crossing KS and the information-computation gap

4.6.1 Information-theoretic threshold

We discuss in this section SBM regimes where detection can be solved information-theoretically. As stated in Conjecture 1 and proved in Theorem 42, the information-computation gap—defined as the gap between the KS and IT thresholds—takes place when the number of communities k is larger than 4. We provide an information-theoretic (IT) bound for SSBM$(n, k, a/n, b/n)$ that confirms this, showing further that the gap grows fast with the number of communities in some regimes.

The information-theoretic bound described below is obtained by using a non-efficient algorithm that samples uniformly at random a clustering that is typical, i.e., that has the right proportions of edges inside and across the clusters. Note that to capture the exact information-theoretic threshold, one would have to rely on tighter estimates on the posterior distribution of the clsuters given the graph. A possibility is to estimate the limit of the normalized mutual information between the clusters and the graph, i.e., $\frac{1}{n} I(X; G)$, as done in Deshpande et al. (2015) for the regime of finite SNR with diverging degrees[19]—see Section 6.2. Recent results also made significant headways for the finite degree regime in the disassortative case Coja-Oghlan et al. (2016). Another possibility is to estimate the limiting total variation or KL-divergence between the graph distribution in the SBM vs. Erdős-Rényi model of matching expected degree. The limiting total variation is positive if and only if an hypothesis test can distinguish between the two models with a chance better than half. The easy implication of this is that if the total variation is vanishing, the weak recovery is not solvable (otherwise we would detect virtual clusters in the Erdős-Rényi model). This used in Banks and Moore (2016) to obtain a lower-bound on the information-theoretic threshold, using a contiguity argument, see further details at the end of this section.

19. Similar results were also obtained recently in a more general context in Caltagirone et al. (2016); Lelarge and Miolane (2016).

To obtain our information-theoretic upper-bound, we rely on the following sampling algorithm:

Typicality Sampling Algorithm. Given an n-vertex graph G and $\delta > 0$, the algorithm draws $\hat{\sigma}_{\rm typ}(G)$ uniformly at random in

$$\begin{aligned} T_\delta(G) =& \{x \in \text{Balanced}(n,k) : \\ & \sum_{i=1}^{k} |\{G_{u,v} : (u,v) \in \binom{[n]}{2} \text{ s.t. } x_u = i, x_v = i\}| \geq \frac{an}{2k}(1-\delta), \\ & \sum_{i,j\in[k], i<j} |\{G_{u,v} : (u,v) \in \binom{[n]}{2} \text{ s.t. } x_u = i, x_v = j\}| \leq \frac{bn(k-1)}{2k}(1+\delta)\}, \end{aligned}$$

where the above assumes that $a > b$; flip the above two inequalities in the case $a < b$.

The bound that is obtained below is claimed to be tight at the extremal regimes of a and b. For $b = 0$, $\text{SSBM}(n, k, a/n, 0)$ is simply a patching of disjoint Erdős-Rényi random graph, and thus the information-theoretic threshold corresponds to the giant component threshold, i.e., $a > k$, achieved by separating the giants. This breaks down for b positive, however small, but we expect that the bound derived below remains tight in the scaling of small b. For $a = 0$, the problem corresponds to planted coloring, which is already challenging Alon and Kahale (1997). The bound obtained below gives in this case that detection is information-theoretically solvable if $b > ck \ln k + o_k(1)$, $c \in [1, 2]$. This scaling is further shown to be tight in Banks and Moore (2016), which also provides a simple upper-bound that scales as $k \ln k$ for $a = 0$. Overall, the bound below shows that the KS threshold gives a much more restrictive regime than what is possible information-theoretically, as the latter reads $b > k(k-1)$ for $a = 0$.

Theorem 43 *Let $d := \frac{a+(k-1)b}{k}$, assume $d > 1$, and let $\tau = \tau_d$ be the unique solution in $(0,1)$ of $\tau e^{-\tau} = de^{-d}$, i.e., $\tau = \sum_{j=1}^{+\infty} \frac{j^{j-1}}{j!}(de^{-d})^j$. The Typicality Sampling Algorithm detects*[20] *communities in $\text{SSBM}(n, k, a/n, b/n)$ if*

$$\frac{a\ln a + (k-1)b\ln b}{k} - \frac{a+(k-1)b}{k}\ln\frac{a+(k-1)b}{k} \tag{85}$$

$$> \min\left(\frac{1-\tau}{1-\tau k/(a+(k-1)b)}2\ln(k), 2\ln(k) - 2\ln(2)e^{-a/k}(1-(1-e^{-b/k})^{k-1})\right). \tag{86}$$

This bound strictly improves on the KS threshold for $k \geq 4$:

Corollary 44 *Conjecture 1 part (ii) holds.*

See Abbe and Sandon (2017) for a numerical example. Note that (86) simplifies to

$$\frac{1}{2\ln k}\left(\frac{a\ln a + (k-1)b\ln b}{k} - d\ln d\right) > \frac{1-\tau}{1-\tau/d} =: f(\tau, d), \tag{87}$$

20. Setting $\delta > 0$ small enough gives the existence of $\varepsilon > 0$ for detection.

and since $f(\tau, d) < 1$ when $d > 1$ (which is needed for the presence of the giant), detection is already solvable in $\text{SBM}(n, k, a, b)$ if

$$\frac{1}{2\ln k}\left(\frac{a\ln a + (k-1)b\ln b}{k} - d\ln d\right) > 1. \tag{88}$$

The above bound[21] corresponds to the regime where there is no bad clustering that is typical with high probability. However, the above bound is not tight in the extreme regime of $b = 0$, since it reads $a > 2k$ as opposed to $a > k$, and it only crosses the KS threshold at $k = 5$. Before explaining how to obtain tight interpolations, we provide further insight on the bound of Theorem 43.

Defining $a_k(b)$ as the unique solution of

$$\frac{1}{2\ln k}\left(\frac{a\ln a + (k-1)b\ln b}{k} - d\ln d\right) \tag{89}$$

$$= \min\left(f(\tau, d), 1 - \frac{e^{-a/k}(1-(1-e^{-b/k})^{k-1})\ln(2)}{\ln(k)}\right) \tag{90}$$

and simplifying the bound in Theorem 43 gives the following.

Corollary 45 *Detection is solvable*

$$\text{in} \quad \text{SBM}(n,k,0,b) \quad \text{if} \quad b > \frac{2k\ln k}{(k-1)\ln\frac{k}{k-1}} f(\tau, b(k-1)/k), \tag{91}$$

$$\text{in} \quad \text{SBM}(n,k,a,b) \quad \text{if} \quad a > a_k(b), \quad \text{where } a_k(0) = k. \tag{92}$$

Remark 46 *Note that (92) approaches the optimal bound given by the presence of the giant at $b = 0$, and we further conjecture that $a_k(b)$ gives the correct first order approximation of the information-theoretic bound for small b.*

Remark 47 *Note that the k-colorability threshold for Erdős-Rényi graphs grows as $2k\ln k$ Achlioptas and Naor (2005). This may be used to obtain an information-theoretic bound, which would however be looser than the one obtained above.*

It is possible to see that this gives also the correct scaling in k for $a = 0$, i.e., that for $b < (1-\varepsilon)k\ln(k) + o_k(1)$, $\varepsilon > 0$, detection is information-theoretically impossible. To see this, consider $v \in G$, $b = (1-\epsilon)k\ln(k)$, and assume that we know the communities of all vertices more than $r = \ln(\ln(n))$ edges away from v. For each vertex r edges away from v, there will be approximately k^ϵ communities that it has no neighbors in. Then vertices $r-1$ edges away from v have approximately $k^\epsilon \ln(k)$ neighbors that are potentially in each community, with approximately $\ln(k)$ fewer neighbors suspected of being in its community than in the average other community. At that point, the noise has mostly drowned out the signal and our confidence that we know anything about the vertices' communities continues to degrade with each successive step towards v.

21. The analog of this bound in the unbalanced case already provides examples to crossing KS for two communities, such as with $p = (1/10, 9/10)$ and $Q = (0, 81; 81, 72)$.

A different approach is developed in Banks and Moore (2016) to prove that the scaling in k is in fact optimal, obtaining both upper and lower bounds on the information-theoretic threshold that match in the regime of large k when $(a-b)/d = O(1)$. In terms of the expected degree, the threshold reads as follows.

Theorem 48 *Banks and Moore (2016); Banks et al. (2016) When $(a-b)/d = O(1)$, the critical value of d satisfies $d = \Theta\left(\frac{d^2 k \log k}{(a-b)^2}\right)$, i.e., $\mathrm{SNR} = \Theta(\log(k)/k)$.*

The upper-bound in Banks and Moore (2016) corresponds essentially to (88), the regime in which the first moment bound is vanishing. The lower-bound is based on a contiguity argument and second moment estimates from Achlioptas and Naor (2005). The idea is to compare the distribution of graphs drawn from the SBM, i.e.,

$$\mu_{\mathrm{SBM}}(g) := \sum_{x \in [k]^n} \mathbb{P}\{G = g | X = x\} \mathbb{P}\{X = x\} \tag{93}$$

with the distribution of graphs drawn from the Erdős-Rényi model with matching expected degree, call it μ_{ER}. If one can show that

$$\|\mu_{\mathrm{SBM}} - \mu_{\mathrm{ER}}\|_1 \to 0, \tag{94}$$

then upon observing a graph drawn from either of the two models, say with probability half for each, it is impossible to decide from which ensemble the graph is drawn with probability asymptotically greater than half. Thus it is not possible to solve weak recovery (otherwise one would detect clusters in the Erdős-Rényi model). A sufficient condition to imply (94) is to show that $\mu_{\mathrm{SBM}} \trianglelefteq \mu_{\mathrm{ER}}$, i.e., if for any sequence of event E_n such that $\mu_{\mathrm{ER}}(E_n) \to 0$, it must be that $\mu_{\mathrm{SBM}} \to 0$. In particular, μ_{SBM} and μ_{ER} are called contiguous if $\mu_{\mathrm{SBM}} \trianglelefteq \mu_{\mathrm{ER}}$ and $\mu_{\mathrm{ER}} \trianglelefteq \mu_{\mathrm{SBM}}$, but only the first of these conditions is needed here. Further, this is implied from Cauchy-Schwarz if the ratio function

$$\rho(G) := \mu_{\mathrm{SBM}}(G)/\mu_{\mathrm{ER}}(G)$$

has a bounded second moment, i.e., $\mathbb{E}_{G \sim \mathrm{ER}} \rho^2(G) = O(1)$, which is shown in Banks and Moore (2016) (see also Moore (2017) for more details).

4.7 Nature of the gap

The nature of such gap phenomena can be understood from different perspectives. One interpretation comes from the behavior of belief propagation (or the cavity method).

Above the Kesten-Stigum threshold, the uniform fixed point is unstable and BP does not get attracted to it and reaches on most initialization a non-trivial solution. In particular, the ABP algorithm discussed in Section 4.5.1, which starts with a random initialization giving a mere bias of order $\sqrt{n}$ vertices towards the true partition (due to the Central Limit Theorem), is enough to make linearized BP reach a non-trivial fixed point. Below the information-theoretic threshold, the non-trivial fixed points are no longer present, and BP settles in a solution that represents a noisy-clustering, i.e., one that would also take place in the Erős-Rényi model due to the model fluctuations. In the gap region, non-trivial

fixed points are still present, but the trivial fixed points are locally stable and attracts most initializations. One could try multiple initializations until a non-trivial fixed point is reached, using for example the graph-splitting technique discussed in Section 3 to test such solutions. However, it is believed that an exponential number of initializations is needed to reach such a good solution. See Moore (2017) for further discussions.

This connects to the energy landscape of the possible clusterings: in this gap region, the non-trivial fixed-points have a very small basin of attraction, and they can only attract an exponentially small fraction of initializations. To connect to the results from Section 3 and the two-rounds procedure, there too the picture is related the energy landscape. Above the CH threshold, an almost exact solution having $n - o(n)$ correctly labeled vertices can be converted to an exact solution by degree-profiling. This is essentially saying that BP at depth 1, i.e., computing the likelihood of a vertex based on its direct neighbors, allows to reach the global maxima of the likelihood function with such a strong initialization. In other words, the BP view, or more precisely understanding how accurate our initial beliefs need to be in order to amplify these to non-trivial levels based on neighbords at a given depth, is related to the landscape of the objective functions.

The gap phenomenon also admits a local manifestation in the context of ABP, having to do with the approximation discussed in Section 4.5.1, where the non-linear terms behave differently from $k = 3$ to $k = 4$ due to the loss of a diminishing return property. Understanding better such gap phenomena is an active research area.

4.7.1 Proof technique for crossing KS

We explain in this section how to obtain the bound in Theorem 43. A first question is to estimate the likelihood that a bad clustering, i.e., one that has an overlap close to $1/k$ with the true clustering, belongs to the typical set. As clusters sampled from the TS algorithm are balanced, a bad clustering must split each cluster roughly into k balanced subgroups that belong to each community, see Figure 6. It is thus unlikely to keep the right proportions of edges inside and across the clusters, but depending on the exponent of this rare event, and since there are exponentially many bad clusterings, there may exist one bad clustering that looks typical.

As illustrated in Figure 6, the number of edges that are contained in the clusters of a bad clustering is roughly distributed as the sum of two Binomial random variables,

$$E_{\mathrm{in}} \dot{\sim} \mathrm{Bin}\left(\frac{n^2}{2k^2}, \frac{a}{n}\right) + \mathrm{Bin}\left(\frac{(k-1)n^2}{2k^2}, \frac{b}{n}\right),$$

where we use $\dot{\sim}$ to emphasize that this is an approximation that ignores the fact that the clustering is not exactly bad and exactly balanced. Note that the expectation of the above distribution is $\frac{n}{2k}\frac{a+(k-1)b}{k}$. In contrast, the true clustering would have a distribution given by $\mathrm{Bin}(\frac{n^2}{2k}, \frac{a}{n})$, which would give an expectation of $\frac{an}{2k}$. In turn, the number of edges that are crossing the clusters of a bad clustering is roughly distributed as

$$E_{\mathrm{out}} \dot{\sim} \mathrm{Bin}\left(\frac{n^2(k-1)}{2k^2}, \frac{a}{n}\right) + \mathrm{Bin}\left(\frac{n^2(k-1)^2}{2k^2}, \frac{b}{n}\right),$$

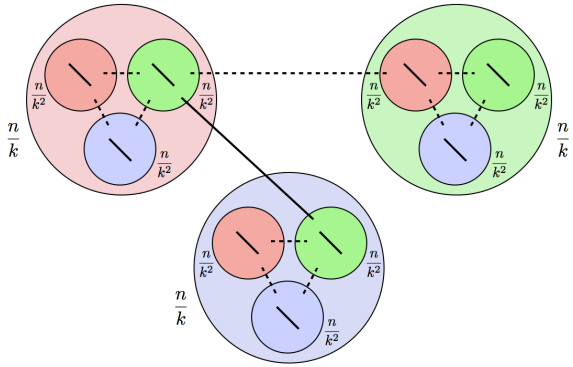

Figure 6: A bad clustering roughly splits each community equally among the k communities. Each pair of nodes connects with probability a/n among vertices of same communities (i.e., same color groups, plain line connections), and b/n across communities (i.e., different color groups, dashed line connections). Only some connections are displayed in the Figure to ease the visualization.

which has an expectation of $\frac{n(k-1)}{2k}\frac{a+(k-1)b}{k}$. In contrast, the true clustering would have the above replaced by $\mathrm{Bin}(\frac{n^2(k-1)}{2k}, \frac{b}{n})$, and an expectation of $\frac{bn(k-1)}{2k}$.

Thus, we need to estimate the rare event that the Binomial sum deviates from its expectations. While there is a large list of bounds on Binomial tail events, the number of trials here is quadratic in n and the success bias decays linearly in n, which require particular care to ensure tight bounds. We derive these in Abbe and Sandon (2015), obtaining that $\mathbb{P}\{x_{\mathrm{bad}} \in T_\delta(G) | x_{\mathrm{bad}} \in B_\epsilon\}$ behaves when ε, δ are arbitrarily small as

$$\exp\left(-\frac{n}{k}A\right)$$

where $A := \frac{a+b(k-1)}{2}\ln\frac{k}{a+(k-1)b} + \frac{a}{2}\ln a + \frac{b(k-1)}{2}\ln b$. One can then use the fact that $|T_\delta(G)| \geq 1$ with high probability, since the planted clustering is typical with high probability, and using a union bound and the fact that there are at most k^n bad clusterings:

$$\begin{aligned} P\{\hat{X}(G) \in B_\epsilon\} &= E_G \frac{|T_\delta(G) \cap B_\epsilon|}{|T_\delta(G)|} && (95)\\ &\leq E_G |T_\delta(G) \cap B_\epsilon| + o(1) && (96)\\ &\leq k^n \cdot \mathbb{P}\{x_{\mathrm{bad}} \in T_\delta(G) | x_{\mathrm{bad}} \in B_\epsilon\} + o(1). \end{aligned}$$

Checking when the above upper-bound vanishes already gives a regime that crosses the KS threshold when $k \geq 5$, and scales properly in k when $a = 0$. However, it does not interpolate the correct behavior of the information-theoretic bound in the extreme regime of $b = 0$ and does not cross at $k = 4$. In fact, for $b = 0$, the union bound requires $a > 2k$ to imply no bad typical clustering with high probability, whereas as soon as $a > k$, an algorithm that simply separates the two giants in $\mathrm{SBM}(n, k, a, 0)$ and assigns communities uniformly at random for the other vertices solves detection. Thus when $a \in (k, 2k]$, the union bound is loose. To remediate to this, we next take into account the topology of the SBM graph to tighten our bound on $|T_\delta(G)|$.

Since the algorithm samples a typical clustering, we only need the number of bad and typical clusterings to be small compared to the total number of typical clusterings, in expectation. Namely, we can get a tighter bound on the probability of error of the TS algorithm by obtaining a tighter bound on the typical set size than simply 1, i.e., estimating (95) without relying on the loose bound from (96). We proceed here with three level of refinements to bound the typical set size. In each level, we construct a random labelling of the vertices that maintain the planted labelling a typical one, and then use entropic estimates to count the number of such typical labellings.

First we exploit the large fraction of nodes that are in tree-like components outside of the giant. Conditioned on being on a tree, the SBM labels are distributed as in a broadcasting problem on a Galton-Watson tree—see Section 4.2. Specifically, for a uniformly drawn root node X, each edge in the tree acts as a k-ary symmetric channel. Thus, labelling the nodes in the trees according to the above distribution and freezing the giant to the correct labels leads to a typical clustering with high probability. The resulting bound matches the giant component bound at $b = 0$, but is unlikely to scale properly for small b. To improve on this, we next take into account the vertices in the giant that belong to planted trees, and follow the same program as above, except that the root node (in the giant) is now frozen to the correct label rather than being uniformly drawn. This gives a bound that we claim is tight at the first order approximation when b is small. Finally, we also take into account vertices that are not saturated, i.e., whose neighbors do not cover all communities and who can thus be swapped without affecting typicality. The final bound allows to cross at $k = 4$.

5. Almost Exact Recovery

5.1 Regimes

Almost exact recovery, also called weak consistency in the statistics literature, or strong recovery, has been investigated in various papers such as Yun and Proutiere (2014); Amini and Levina (2014); Gao et al. (2015); Mossel et al. (2014b); Yun and Proutiere (2014); Abbe and Sandon (2015b).

In the symmetric case, necessary and sufficient conditions have been identified.

Theorem 49 *Almost exact recovery is solvable in* $\mathrm{SSBM}(n, k, a_n/n, b_n/n)$ *if and only if*

$$\frac{(a_n - b_n)^2}{k(a_n + (k-1)b_n)} = \omega(1). \qquad (97)$$

This result appeared in several papers. A first appearance is from Yun and Proutiere (2014) where it results from the case of non-adaptive random samples, also from Mossel et al. (2014b) for $k = 2$, and from Abbe and Sandon (2015b) for $k \geq 2$. For the general

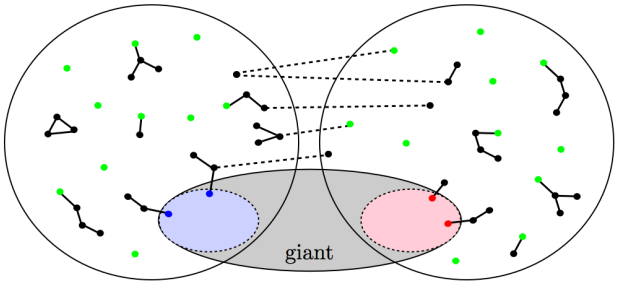

Figure 7: Illustration of the topology of SBM(n,k,a,b) for $k=2$. A giant component covering the two communities takes place when $d=\frac{a+(k-1)b}{k}>1$; a linear fraction of vertices belong to isolated trees (including isolated vertices), and a linear fraction of vertices in the giant are on planted trees. The following is used to estimate the size of the typical set in Abbe and Sandon (2017). For isolated trees, sample a bit uniformly at random for a vertex (green vertices) and propagate the bit according to the symmetric channel with flip probability $b/(a+(k-1)b)$ (plain edges do not flip whereas dashed edges flip). For planted trees, do the same but freeze the root bit to its true value.

SBM(n,p,W), a natural extension of the above statement would be to require

$$\frac{n\lambda_2(\mathrm{diag}(p)W)^2}{\lambda_1(\mathrm{diag}(p)W)}=\omega(1). \tag{98}$$

This is shown to imply almost exact recovery with additional requirements on the SBM in Abbe and Sandon (2015b), but it is unlikely to give a necessary and sufficient condition in the general case. It remains thus open to characterize in great generality when almost exact recovery is solvable or not.

5.2 Algorithms and proof techniques

The following result gives an achievability result that applies to the general SBM in the regime where $W=\omega(1)Q$, which is particularly important for the results on exact recovery discussed in Section 3.

Theorem 50 *Abbe and Sandon (2015b) For any $k\in\mathbb{Z}$, $p\in(0,1)^k$ with $|p|=1$, and symmetric matrix Q with no two rows equal, there exist $\epsilon(c)=O(1/\ln(c))$ such that for all sufficiently large c, it is possible to detect communities in SBM$(n,p,cQ/n)$ with accuracy $1-e^{-\Omega(c)}$ and complexity $O_n(n^{1+\epsilon(c)})$. In particular, almost exact recovery is solvable efficiently in SBM$(n,p,\omega(1)Q/n)$.*

Note that the exponential scaling in c above is optimal. The optimal constant in the exponent is obtained in Gao et al. (2015) for symmetric SBMs, and the optimal expression beyond the exponent is obtained in Deshpande et al. (2015); Mossel and Xu (2015) for a specific regime. We do not cover in details the algorithms for almost exact recovery, as these can be seen as a byproduct of the algorithms discussed for weak recovery in previous section, which all achieve almost exact recovery when the signal-to-noise ratio diverges. On the other hand, weak recovery requires additional sophistication that are not necessary for almost exact recovery.

A simpler yet efficient and general algorithm that allows for almost exact recovery, and used in Theorem 50 above, is the Sphere-comparison Algorithm described next. The idea is to compare neighborhoods of vertices at a given depth in the graph, to decide whether two vertices are in the same community or not. This algorithm has desirable features for real data implementations, as it seems to handle well certain types of degree variations and cliques. To ease the presentation of the algorithm's idea, we consider the symmetric case SSBM$(n,k,a/n,b/n)$ and let $d:=(a+(k-1)b)/k$ be the average degree.

Definition 51 *For any vertex v, let $N_{r[G]}(v)$ be the set of all vertices with shortest path in G to v of length r. We often drop the subscript G if the graph in question is the original SBM.*

For an arbitrary vertex v and reasonably small r, there will be typically about d^r vertices in $N_r(v)$, and about $(\frac{a-b}{k})^r$ more of them will be in v's community than in each other community. Of course, this only holds when $r<\log n/\log d$ because there are not enough vertices in the graph otherwise. The obvious way to try to determine whether or not two vertices v and v' are in the same community is to guess that they are in the same community if $|N_r(v)\cap N_r(v')|>d^{2r}/n$ and different communities otherwise. Unfortunately, whether or not a vertex is in $N_r(v)$ is not independent of whether or not it is in $N_r(v')$, which compromises this plan. Instead, we propose to rely again on a *graph-splitting* step: Randomly assign every edge in G to some set E with a fixed probability c and then count the number of edges in E that connect $N_{r[G\backslash E]}$ and $N_{r'[G\backslash E]}$. Formally:

Definition 52 *For any $v,v'\in G$, $r,r'\in\mathbb{Z}$, and subset of G's edges E, let $N_{r,r'[E]}(v\cdot v')$ be the number of pairs (v_1,v_2) such that $v_1\in N_{r[G\backslash E]}(v)$, $v_2\in N_{r'[G\backslash E]}(v')$, and $(v_1,v_2)\in E$.*

Note that E and $G\backslash E$ are disjoint. However, G is sparse enough that the two graphs can be treated as independent for the reasons discussed in Section 3.2.2. Thus, given v,r, and denoting by $\lambda_1=(a+(k-1)b)/k$ and $\lambda_2=(a-b)/k$ the two eigenvalues of PQ in the symmetric case, the expected number of intra-community neighbors at depth r from v is approximately $\frac{1}{k}(\lambda_1^r+(k-1)\lambda_2^r)$, whereas the expected number of extra-community neighbors at depth r from v is approximately $\frac{1}{k}(\lambda_1^r-\lambda_2^r)$ for each of the other $(k-1)$ communities. All of these are scaled by $1-c$ if we do the computations in $G\backslash E$. Using now the emulated independence between E and $G\backslash E$, and assuming v and v' to be in the same community, the expected number of edges in E connecting $N_{r[G\backslash E]}(v)$ to $N_{r'[G\backslash E]}(v')$ is approximately given by the inner product

$$u^t(cPQ)u,$$

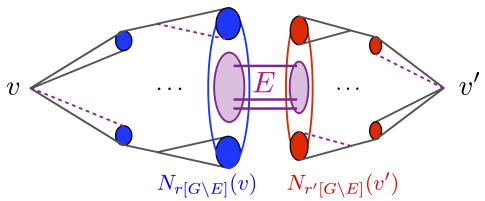

Figure 8: Sphere comparison: The algorithm takes a graph-splitting of the graph with a constant probability, and decides whether two vertices are in the same community or not based on the number of crossing edges (in the first graph of the graph-split) between the two neighborhoods' spheres at a given depth of each vertices (in the second graph of the graph-split). A careful choice of r, r' allows to reduce the complexity of the algorithm, but in general, $r = r' = \frac{3}{4}\log n/\log d$ suffices for the algorithm to succeed (where d is the average degree).

where

$$u = \frac{1}{k}(\lambda_1^r + (k-1)\lambda_2^r, \lambda_1^r - \lambda_2^r, \ldots, \lambda_1^r - \lambda_2^r)$$

and (PQ) is the matrix with $a/2$ on the diagonal and $b/2$ elsewhere. When v and v' are in different communities, the inner product is instead between u and a permutation of u that moves the first component. After simplifications, this gives

$$N_{r,r'[E]}(v \cdot v') \approx \frac{c(1-c)^{r+r'}}{n}\left[d^{r+r'+1} + \left(\frac{a-b}{k}\right)^{r+r'+1}(k\delta_{\sigma_v,\sigma_{v'}} - 1)\right] \tag{99}$$

where $\delta_{\sigma_v,\sigma_{v'}}$ is 1 if v and v' are in the same community and 0 otherwise, and where $\approx$ means that the right hand side is with high probability the dominant term of the left hand side. In order for $N_{r,r'[E]}(v \cdot v')$ to depend on the relative communities of v and v', it must be that $c(1-c)^{r+r'}|\frac{a-b}{k}|^{r+r'+1}k$ is large enough, i.e., more than n, so $r + r'$ needs to be at least $\log n/\log|\frac{a-b}{k}|$. This can then be used as a basis of the algorithm to decide whether pairs of vertices are in the same community or not, and thus to recover communities. As we shall see in Section 7.1, this approach can also be adapted to work without knowledge of the model parameters.

We conclude this section by noting that one can also study more specific almost exact recovery requirements, allowing for a specified number of misclassified vertices $s(n)$. This is investigated in Yun and Proutiere (2015) when $s(n)$ is moderately small (at most logarithmic), with an extension of Theorem 50 that applies to this more general setting. The case where $s(n)$ is linear, i.e., a constant fraction of errors, is more challenging and discussed in the next section.

6. Partial Recovery

Recall that partial recovery refers to the a fraction of misclassified vertices that is constant, whereas previous section investigates a fraction of misclassified vertices that is vanishing.

6.1 Regimes

In the symmetric SSBM$(n, k, a/n, b/n)$, the regime for partial recovery takes place when the following notion of SNR is finite:

$$\text{SNR} := \frac{(a-b)^2}{k(a+(k-1)b)} = O(1). \tag{100}$$

This regime takes place under two circumstances:

A. If a, b are constant, i.e., the constant degree regime,

B. If a, b are functions of n that diverge such that the numerator and denominator in SNR scale proportionally.

Our main goal is to identify the optimal tradeoff between SNR and the fraction of misclassified vertices, or between SNR and the MMSE or entropy of the clusters. The latter has in particular application to the compression of graphs Abbe (2016). We first mention some bounds.

Upper bounds on the fraction of incorrectly recovered vertices were demonstrated, among others, in Abbe and Sandon (2015b); Yun and Proutiere (2014); Chin et al. (2015). As detailed in Theorem 50, Abbe and Sandon (2015b) provides a bound of the type $C\exp(-c\text{SNR})$ for the general SBM. A refined bound that applies to the general SBM with arbitrary connectivity matrix $W = Q/n$ is also provided in Abbe and Sandon (2015b). In Yun and Proutiere (2014), a spectral algorithm is shown to reach an upper bounded of $C\exp\{-\text{SNR}/2\}$ for the two symmetric case, and in a suitable asymptotic sense. An upper bound of the form $C\exp(-\text{SNR}/4.1)$—again for a spectral algorithm—was obtained earlier in Chin et al. (2015). Further, Gao et al. (2015) also establishes minimax optimal rate of $C\exp\{-\text{SNR}/2\}$ in the case of large SNR and for certain types of SBMs, further handling a growing number of communities (to the expense of looser bounds).

It was shown in Mossel et al. (2013) that for the $k = 2$ symmetric case, when the SNR is sufficiently large, the optimal fraction of nodes that can be recovered is determined by the broadcasting problem on tree Evans et al. (2000) and achieved by a variant of belief propagation. That is, the probability of recovering the bit correctly from the leaves at large depth allows to determine the fraction of nodes that can be correctly labeled in the SBM in this regime. It remains open to establish such a result at arbitrary finite SNR.

We next describe a result that gives for the two-symmetric SBM the exact expression of the optimal tradeoffs between SNR and the MMSE (or the mutual information) of the clusters in the B regime at all finite SNR, and a tight approximation in the A regime for large degrees.

6.2 Distortion-SNR tradeoff

For $(X,G) \sim \mathrm{SSBM}(n,2,p_n,q_n)$, the mutual information of the SBM is $I(X;G)$, where

$$I(X;G) = H(G) - H(G|X) = H(X) - H(X|G),$$

and H denotes the entropy. We next introduce the normalized MMSE of the SBM:

$$\mathsf{MMSE}_n(\mathrm{SNR}) \equiv \frac{1}{n(n-1)}\mathbb{E}\Big\{\big\|XX^{\mathsf{T}} - \mathbb{E}\{XX^{\mathsf{T}}|G\}\big\|_F^2\Big\}. \tag{101}$$

$$= \min_{\widehat{x}_{12}:\mathcal{G}_n\to\mathbb{R}} \mathbb{E}\big\{\big[X_1X_2 - \widehat{x}_{12}(G)\big]^2\big\}. \tag{102}$$

To state our result that provides a single-letter characterization of the per-vertex MMSE (or mutual information), we need to introduce the *effective Gaussian scalar channel*. Namely, define the Gaussian channel

$$Y_0 = Y_0(\gamma) = \sqrt{\gamma}\, X_0 + Z_0, \tag{103}$$

where $X_0 \sim \mathsf{Unif}(\{+1,-1\})$ independent[22] of $Z_0 \sim \mathsf{N}(0,1)$. We denote by $\mathsf{mmse}(\gamma)$ and $\mathsf{I}(\gamma)$ the corresponding minimum mean square error and mutual information:

$$\mathsf{I}(\gamma) = \mathbb{E}\,\log\Big\{\frac{\mathrm{d}p_{Y|X}(Y_0(\gamma)|X_0)}{\mathrm{d}p_Y(Y_0(\gamma))}\Big\}, \tag{104}$$

$$\mathsf{mmse}(\gamma) = \mathbb{E}\big\{(X_0 - \mathbb{E}\{X_0|Y_0(\gamma)\})^2\big\}. \tag{105}$$

Note that these quantities can be written explicitly as Gaussian integrals of elementary functions:

$$\mathsf{I}(\gamma) = \gamma - \mathbb{E}\log\cosh\big(\gamma + \sqrt{\gamma}\,Z_0\big), \tag{106}$$

$$\mathsf{mmse}(\gamma) = 1 - \mathbb{E}\big\{\tanh(\gamma + \sqrt{\gamma}\,Z_0)^2\big\}. \tag{107}$$

We are now in position to state the result.

Theorem 53 *Deshpande et al. (2015) For any $\lambda > 0$, let $\gamma_* = \gamma_*(\lambda)$ be the largest non-negative solution of the equation*

$$\gamma = \lambda\big(1 - \mathsf{mmse}(\gamma)\big) \tag{108}$$

and

$$\Psi(\gamma,\lambda) = \frac{\lambda}{4} + \frac{\gamma^2}{4\lambda} - \frac{\gamma}{2} + \mathsf{I}(\gamma). \tag{109}$$

Let $(X,G) \sim \mathrm{SSBM}(n,2,p_n,q_n)$ and define[23] *$\mathrm{SNR} := n\,(p_n-q_n)^2/(2(p_n+q_n)(1-(p_n+q_n)/2))$. Assume that, as $n\to\infty$, (i) $\mathrm{SNR}\to\lambda$ and (ii) $n(p_n+q_n)/2(1-(p_n+q_n)/2)\to\infty$.*

22. Throughout the paper, we will generally denote scalar equivalents of vector/matrix quantities with the 0 subscript

23. Note that this is asymptotically the same notion of SNR as defined earlier when p_n, q_n vanish.

Then,

$$\lim_{n\to\infty} \mathsf{MMSE}_n(\mathrm{SNR}) = 1 - \frac{\gamma_*(\lambda)^2}{\lambda^2} \tag{110}$$

$$\lim_{n\to\infty} \frac{1}{n} I(X;G) = \Psi(\gamma_*(\lambda),\lambda). \tag{111}$$

Further, this implies $\lim_{n\to\infty}\mathsf{MMSE}_n(\mathrm{SNR}) = 1$ for $\lambda \le 1$ (i.e., no meaningful detection) and $\lim_{n\to\infty}\mathsf{MMSE}_n(\mathrm{SNR}) < 1$ for $\lambda > 1$ (detection achieved).

Corollary 54 *Deshpande et al. (2015) When $p_n = a/n, q_n = b/n$, where a,b are bounded as n diverges, there exists an absolute constant C such that*

$$\limsup_{n\to\infty}\Big|\frac{1}{n}I(X;G) - \Psi(\gamma_*(\lambda),\lambda)\Big| \le \frac{C\lambda^{3/2}}{\sqrt{a+b}}. \tag{112}$$

Here λ, $\psi(\gamma,\lambda)$ and $\gamma_*(\lambda)$ are as in Theorem 53.

A few remarks about previous theorem and corollary:

- Theorem 53 shows that the normalized MMSE (or mutual information) is non-trivial if and only if $\lambda > 1$. This extends the results on weak recovery Massoulié (2014); Mossel et al. (2015) discussed in Section 4 from the A to the B regime for finite SNR, closing weak recovery in the SSBM with two communities;

- The result also gives upper and lower bound for the optimal agreement. Let

  $$\mathsf{Overlap}_n(\mathrm{SNR}) = \frac{1}{n}\sup_{\widehat{\boldsymbol{s}}:\mathcal{G}_n\to\{+1,-1\}^n}\mathbb{E}\big\{|\langle X,\widehat{\boldsymbol{s}}(G)\rangle|\big\}.$$

  Then,

  $$1 - \mathsf{MMSE}_n(\mathrm{SNR}) + O(n^{-1}) \le \mathsf{Overlap}_n(\mathrm{SNR}) \tag{113}$$

  $$\le \sqrt{1 - \mathsf{MMSE}_n(\mathrm{SNR})} + O(n^{-1/2}). \tag{114}$$

- In Mossel and Xu (2015), tight expressions similar to those obtained in Theorem 53 for the MMSE are obtained for the optimal expected agreement with additional scaling requirements. Namely, it is shown that for $\mathrm{SSBM}(n,2,a/n,b/n)$ with $a = b + \mu\sqrt{b}$ and $b = o(\log n)$, the least fraction of misclassified vertices is in expectation given by $Q(\sqrt{v^*})$ where v^* is the unique fixed point of the equation $v = \frac{\mu^2}{4}\mathbb{E}\tanh(v + v\sqrt{Z})$, Z is normal distributed, and Q is the Q-function for the normal distribution. Similar results were also reported in Zhang et al. (2016) for the overlap metric, and Lesieur et al. (2015) for the MMSE.

- Note that Theorem 53 requires merely diverging degrees (arbitrarily slowly), in contrast to results from random matrix theory such as Baik et al. (2005) that would require poly-logarithmic degrees to extract communities from the spiked Wigner model.

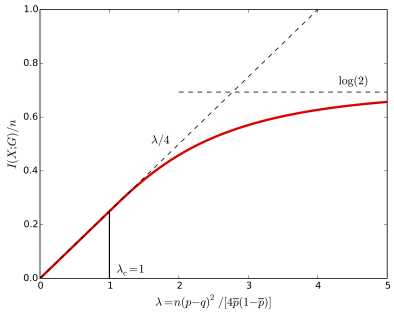

Figure 9: Asymptotic mutual information per vertex of the symmetric stochastic block model with two communities, as a function of the signal-to-noise ratio λ. The dashed lines are simple upper bounds: $\lim_{n\to\infty} I(X;G)/n \le \lambda/4$ and $I(X;G)/n \le \log 2$.

6.3 Proof technique and spiked Wigner model

Theorem 53 gives an exact expression for the normalized MMSE and mutual information in terms of an effective Gaussian noise channel. The reason for the Gaussian distribution to emerge is that the proof of the result shows as a side result that in the regime of the theorem, the SBM model is equivalent to a spiked Wigner model given by

$$Y = \sqrt{\lambda/n} X X^t + Z$$

where Z is a Wigner random matrix (i.e., symmetric with i.i.d. Normal entries), and where we recall that λ corresponds to the limit of SNR.

In other words, the per-dimension mutual information turns out to be *universal* across multiple noise models and does not depend on the microscopic details of the noise distribution, but only on the first two moments, i.e., the SNR in our case. The formal statement of the equivalence is as follows:

Theorem 55 (Equivalence of SBM and Gaussian models) *Let $I(X;G)$ be the mutual information of* SSBM$(n,2,p_n,q_n)$ *with* SNR $\to \lambda$ *and $n(p_n+q_n)/2(1-(p_n+q_n)/2) \to \infty$, and $I(X;Y)$ be the mutual information for spiked Wigner model $Y = \sqrt{\lambda/n} X X^t + Z$. Then, there is a constant C independent of n such that*

$$\frac{1}{n}\big|I(X;G) - I(X;Y)\big| \le C\left(\frac{\lambda^{3/2}}{\sqrt{n(p_n+q_n)/2(1-(p_n+q_n)/2)}} + |\mathrm{SNR}-\lambda|\right). \qquad (115)$$

To obtain the limiting expression for the normalized mutual information in Theorem 53, notice first that for $Y(\lambda) = \sqrt{\lambda/n} X X^t + Z$,

$$\frac{1}{n} I(X;Y(0)) = 0 \qquad \frac{1}{n} I(X;Y(\infty)) = \log(2).$$

Next, (i) use the fundamental theorem of calculus to express these boundary conditions as an integral of the derivative of the mutual information, (ii) the I-MMSE identity Guo et al. (2005) to express this derivative in terms of the MMSE, (iii) upper-bound the MMSE with error with the specific estimate obtained from the AMP algorithm Donoho et al. (2009), (iv) evaluate the asymptotic performance of the AMP estimate using the density evolution technique Bayati and Montanari (2011); Deshpande and Montanari (2014), and (v) notice that this matches the original value of $\log(2)$ in the limit of n tending to infinty:

$$\log(2) \overset{(i)}{=} \frac{1}{n}\int_0^\infty \frac{\partial}{\partial\lambda} I(XX^t; Y(\lambda))\, d\lambda \qquad (116)$$

$$\overset{(ii)}{=} \frac{1}{4n^2}\int_0^\infty \mathrm{MMSE}(XX^t|Y(\lambda))\, d\lambda \qquad (117)$$

$$\overset{(iii)}{\le} \frac{1}{4n^2}\int_0^\infty \mathbb{E}(XX^t - \hat{x}_{\mathrm{AMP},\lambda}(\infty)\hat{x}^t_{\mathrm{AMP},\lambda}(\infty))^2\, d\lambda \qquad (118)$$

$$\overset{(iv)}{=} \Psi(\gamma_*(\infty),\infty) - \Psi(\gamma_*(0),0) + o_n(1) \qquad (119)$$

$$\overset{(v)}{=} \log(2) + o_n(1). \qquad (120)$$

This implies that (iii) is in fact an equality asymptotically, and using monotonicity and continuity properties of the integrant, the identify must hold for all SNR as stated in the theorem. The only caveat not discussed here is the fact that AMP needs an initialization that is not fully symmetric to converge to the right solution, which causes the insertion in the proof of a noisy observation on the true labels X at the channel output to break the symmetry for AMP (removing then this information by taking a limit).

6.4 Optimal detection for constant degrees

Obtaining the expression for the optimal agreement at finite SNR when the degrees are constant remains an open problem (see also Sections 5 and 8). The problem is settled for high enough SNR in Mossel et al. (2013), with the following expression relying on reconstruction error for the broadcasting on tree problem.

Define the optimal agreement fraction as

$$P_{G_n}(a,b) := \frac{1}{2} + \sup_f \mathbb{E}\Big|\frac{1}{n}\sum_v \mathbb{1}(f(v,G_n) = X_v) - \frac{1}{2}\Big|. \qquad (121)$$

Note that the above expression takes into account the symmetry of the problem and can also been interpreted as a normalized agreement or probability. Let $P_G(a,b) := \limsup_g P_{G_n}(a,b)$. Define now the counter-part for the broadcasting problem on tree: Back to the notation of Section 4.2, define $T^{(t)}$ as the Galton-Watson tree with Poisson$((a+b)/2)$ offspring, flip probability $b/(a+b)$ and depth t, and define the optimal inference probability of the root as

$$P_T(a,b) := \frac{1}{2} + \lim_{t\to\infty} \mathbb{E}\big|\mathbb{E}(X^{(0)}|X^{(t)}) - 1/2\big|. \qquad (122)$$

The reduction from Mossel et al. (2015) discussed in Section 4.2 allows to deduce that $P_G(a,b) \le P_T(a,b)$, and this is conjectured to be an equality, as shown for large enough SNR:

Theorem 56 *Mossel et al. (2013) There exists C large enough such that if* $\mathrm{SNR} > C$ *then* $P_G(a,b) = P_T(a,b)$*, and this normalized agreement is efficiently achievable.*

The theorem in Mossel et al. (2013) has a weak requirement of $\mathrm{SNR} > C\log(a+b)$, but later developments allow for the improved version stated above. Note that $P_T(a,b)$ gives only an implicit expression for the optimal fraction, though it admits a variational representation due to Mézard and Montanari (2006).

In Decelle et al. (2011), it is conjectured that BP gives the optimal agreement at all SNR. However, the problem with BP is the classical one, it is hard to analyze it in the context of loopy graphs with a random initialization. Another strategy here is to proceed with a two-round procedure, which is used to establish the above results in Mossel et al. (2013) for two communities, with a variant discussed in Abbe and Sandon (2016b) for multiple communities. The idea is to use a simpler algorithm to obtain a non-trivial reconstruction when $\mathrm{SNR} > 1$, see Section 4, and to then improve the accuracy using full BP at shorter depth. To show that the accuracy achieved is optimal, one has to also show that a noisy version of the reconstruction on tree problem Janson and Mossel (2004), where leaves do not have exact labels but noisy labels, leads to the same probability of error at the root. This is expected to take place for two communities at all SNR above the KS threshold, and it was shown in Mossel et al. (2013) for the case of large enough SNR. This type of claim is not expected to hold for general k. For more than two communities, one needs to convert first the output of the algorithm discussed in Section 4.5.1, which gives two sets that correlated with their communities, into a nontrivial assignment of a belief to each vertex; this is discussed in Abbe and Sandon (2017). Then one uses these beliefs as starting probabilities for a belief propagation algorithm of depth $\ln(n)/3\ln(\lambda_1)$, which runs now on a tree-like graph.

7. Learning the SBM

In this section we investigate the problem of estimating the SBM parameters by observing a one shot realization of the graph. We consider first the case where degrees are diverging, where estimation can be obtained as a side result of universal almost exact recovery, and the case of constant degrees, where estimation can be performed without being able to recover the clusters but only above the weak recovery threshold.

7.1 Diverging degree regime

For diverging degrees, one can estimate the parameters by solving first universal almost exact recovery, and proceeding then to basic estimates on the clusters' cuts and volumes. This requires solving an harder problem potentially, but turns out to be solvable as shown next:

Theorem 57 *Abbe and Sandon (2015c) Given $\delta > 0$ and for any $k \in \mathbb{Z}$, $p \in (0,1)^k$ with $\sum p_i = 1$ and $0 < \delta \leq \min p_i$, and any symmetric matrix Q with no two rows equal such that every entry in Q^k is strictly positive (in other words, Q such that there is a nonzero probability of a path between vertices in any two communities in a graph drawn from SBM$(n,p,Q/n)$), there exist $\epsilon(c) = O(1/\ln(c))$ such that for all sufficiently large α, the Agnostic-sphere-comparison algorithm detects communities in graphs drawn from SBM$(n,p,\alpha Q/n)$ with accuracy at least $1-e^{-\Omega(\alpha)}$ in $O_n(n^{1+\epsilon(\alpha)})$ time.*

Note that the knowledge on δ in this theorem can be removed if $\alpha = \omega(1)$. We then obtain:

Corollary 58 *Abbe and Sandon (2015c) The number of communities k, the community prior p and the connectivity matrix Q can be consistently estimated in quasi-linear time in SBM$(n,p,\omega(1)Q/n)$.*

Recall that in Section 5 we discussed the Sphere-comparison algorithm, where the neighborhoods at depth r and r' from two vertices are compared in order to decide whether the vertices are in the same community or not. The key statistics was the number of crossing edges (in the background graph of the graph-split) between these two neighborhoods:

$$N_{r,r'[E]}(v\cdot v') \approx \frac{c(1-c)^{r+r'}}{n}\left[d^{r+r'+1} + \left(\frac{a-b}{k}\right)^{r+r'+1}(k\delta_{\sigma_v,\sigma_{v'}}-1)\right] \tag{123}$$

where $\delta_{\sigma_v,\sigma_{v'}}$ is 1 if v and v' are in the same community and 0 otherwise. A difficulty is that for a specific pair of vertices, the $d^{r+r'+1}$ term will be multiplied by a random factor dependent on the degrees of v, v', and the nearby vertices. So, in order to stop the variation in the $d^{r+r'+1}$ term from drowning out the $\left(\frac{a-b}{k}\right)^{r+r'+1}(k\delta_{\sigma_v,\sigma_{v'}}-1)$ term, it is necessary to cancel out the dominant term. This motivates the introduction in Abbe and Sandon (2015c) of the following **sign-invariant statistics**:

$$\begin{aligned} &I_{r,r'[E]}(v\cdot v') := N_{r+2,r'[E]}(v\cdot v')\cdot N_{r,r'[E]}(v\cdot v') - N^2_{r+1,r'[E]}(v\cdot v') \\ &\approx \frac{c^2(1-c)^{2r+2r'+2}}{n^2}\cdot\left(d-\frac{a-b}{k}\right)^2\cdot d^{r+r'+1}\left(\frac{a-b}{k}\right)^{r+r'+1}(k\delta_{\sigma_v,\sigma_{v'}}-1) \end{aligned}$$

In particular, for $r+r'$ odd, $I_{r,r'[E]}(v\cdot v')$ will tend to be positive if v and v' are in the same community and negative otherwise, irrespective of the specific values of a,b,k. That suggests the following agnostic algorithm for partial recovery, which requires knowledge of $\delta < 1/k$ in the constant degree regime (i.e., an upper bound on the number communities), but not in the regime where a,b scale with n.

Note that for symmetric SBMs, SDPs Abbe et al. (2016); B. Hajek (2014); Hajek et al. (2015c); Bandeira (2015) can be used to recover the communities without knowledge of the parameters, and thus to learn the parameters in the symmetric case. A different line of work has also studied the problem of estimating 'graphons' Choi et al. (2012); Airoldi et al. (2013); Olhede and Wolfe (2014) via block models, assuming regularity conditions on the graphon, such as piecewise Lipschitz, to obtain estimation guarantees. In addition, Borgs et al. (2015) considers private graphon estimation in the logarithmic degree regime, and obtains a non-efficient procedure to estimate 'graphons' in an appropriate version of the L_2 norm. More recently, Borgs et al. (2015) extends the type of results from Wolfe and Olhede (2013) to a much more general family of 'graphons' and to sparser regimes (though still with diverging degrees) with efficient methods (based on degrees) and non-efficient methods (based on least square and least cut norm).

Agnostic-sphere-comparison. Assume knowledge of $\delta > 0$ such that $\min_{i\in[k]} p_i \geq \delta$ and let d be the average degree of the graph:

1. Set $r = r' = \frac{3}{4}\log n/\log d$ and put each of the graph's edges in E with probability $1/10$.
2. Set $k_{\max} = 1/\delta$ and select $k_{\max}\ln(4k_{\max})$ random vertices, $v_1, ..., v_{k_{\max}\ln(4k_{\max})}$.
3. Compute $I_{r,r'[E]}(v_i \cdot v_j)$ for each i and j. If there is a possible assignment of these vertices to communities such that $I_{r,r'[E]}(v_i \cdot v_j) > 0$ if and only if v_i and v_j are in the same community, then randomly select one vertex from each apparent community, $v[1], v[2], ...v[k']$. Otherwise, fail.
4. For every v' in the graph, guess that v' is in the same community as the $v[i]$ that maximizes the value of $I_{r,r'[E]}(v[i] \cdot v')$.

7.2 Constant degree regime

In the case of the constant degree regime, it is not possible to recover the clusters (let alone without knowing the parameters), and thus estimation has to be done differently. The first paper that shows how to estimate the parameter in this regime tightly is Mossel et al. (2015), which is based on approximating cycle counts by nonbacktracking walks. An alternative method based on expectation-maximization using the Bethe free energy is also proposed in Decelle et al. (2011) (without a rigorous analysis).

Theorem 59 *Mossel et al. (2015) Let $G \sim \mathrm{SSBM}(n, 2, a/n, b/n)$ such that $(a-b)^2 > 2(a+b)$, and let C_m be the number of m-cycles in G, $\hat{d}_n = 2|E(G)|/n$ be the average degree in G and $\hat{f}_n = (2m_n C_{m_n} - \hat{d}_n^{m_n})^{1/m_n}$ where $m_n = \lfloor \log^{1/4}(n) \rfloor$. Then $\hat{d}_n + \hat{f}_n$ and $\hat{d}_n - \hat{f}_n$ are consistent estimators for a and b respectively. Further, there is a polynomial time estimator to calculate $\hat{d}_n$ and $\hat{f}_n$.*

This theorem is extended in Abbe and Sandon (2015) for the symmetric SBM with k clusters, where k is also estimated. The first step needed is the following estimate.

Lemma 60 *Let C_m be the number of m-cycles in $\mathrm{SBM}(n, p, Q/n)$. If $m = o(\log\log(n))$, then*

$$\mathbb{E}C_m \sim \mathbb{V}\mathrm{ar}C_m \sim \frac{1}{2m}\mathrm{tr}(\mathrm{diag}(p)Q)^m. \tag{124}$$

To see this lemma, note that there is a cycle on a given selection of m vertices with probability

$$\sum_{x_1,...,x_m\in[k]} \frac{Q_{x_1,x_2}}{n} \cdot \frac{Q_{x_2,x_3}}{n} \cdot \ldots \cdot \frac{Q_{x_m,x_1}}{n} \cdot p_{x_1} \cdot \ldots \cdot p_{x_m} = \mathrm{tr}(\mathrm{diag}(p)Q/n)^m. \tag{125}$$

Since there are $\sim n^m/2m$ such selections, the first moment follows. The second moment follows from the fact that overlapping cycles do not contribute to the second moment. See

Mossel et al. (2015) for proof details for the 2-SSBM and Abbe and Sandon (2015) for the general SBM.

Hence, one can estimate $\frac{1}{2m}\mathrm{tr}(\mathrm{diag}(p)Q)^m$ for slowly growing m. In the symmetric SBM, this gives enough degrees of freedom to estimate the three parameters a, b, k. Theorem 59 uses for example the average degree ($m = 1$) and slowly growing cycles to obtain a system of equation that allows to solve for a, b. This extends easily to all symmetric SBMs, and the efficient part follows from the fact that for slowly growing m, the cycle counts coincides with the nonbacktracking walk counts with high probability Mossel et al. (2015). Note that Theorem 59 provides a tight condition for the estimation problem, i.e., Mossel et al. (2015) also shows that when $(a-b)^2 \leq 2(a+b)$ (which we recall is equivalent to the requirement for impossibility of weak recovery) the SBM is contiguous to the Erdős-Rényi model with edge probability $(a+b)/(2n)$.

However, for the general SBM, the problem is more delicate and one has to first stabilize the cycle count statistics to extract the eigenvalues of PQ, and use detection methods to further peal down the parameters p and Q. Deciding which parameters can or cannot be learned in the general SBM seems to be a non-trivial problem. This is also expected to come into play in the estimation of graphons Choi et al. (2012); Airoldi et al. (2013); Borgs et al. (2015).

8. Open Problems

The establishment of fundamental limits for community detection in the SBM have appeared in the recent years. There is therefore a long list of open problems and directions to pursue, both related to the SBM and to its extensions. We provide here a partial list:

- *Exact recovery for sub-linear communities.* Theorems 14 and 29 give a fairly comprehensive result for exact recovery in the case of linear-size communities, i.e., when the entries of p and its dimension k do not scale with n. If $k = o(\log(n))$, and the communities remain reasonably balanced, most of the developed techniques extend. However new phenomena seem to take place beyond this regime, with again gaps between information and computational thresholds. In Y. Chen (2014), some of this is captured by looking at coarse regimes of the parameters. It would be interesting to pursue sub-linear communities in the lens of phase transitions and information-computation gaps.
- *Partial recovery.* What is the fundamental tradeoff between the SNR and the distortion (MMSE or agreement) for partial recovery in the constant degree regime? As a preliminary result, one may attempt to show that $I(X;G)/n$ admits a limit in the constant degree regime. This is proved in Abbe and Montanari (2015) for two symmetric disassortative communities,[24] but the assortative case remains open. Establishing the expression for the optimal tradeoff in partial recovery is unknown for $k \geq 3$ (and only known for large enough SNR for $k = 2$ Mossel et al. (2013)).
- *The information-computation gap:*

24. Limiting expressions have recently been obtained for disassortative communities in Coja-Oghlan et al. (2016).

- Can we locate the exact information-theoretic threshold for weak recovery when $k \geq 3$? Recent results and precise conjectures were recently obtained in Caltagirone et al. (2016), for the regime of finite SNR with diverging degrees discussed in Section 6.2.
- Can we strengthen the evidences that the KS threshold is the computational threshold? In the general sparse SBM, this corresponds to the following conjecture:

  Conjecture 61 *Let $k \in \mathbb{Z}_+$, $p \in (0,1)^k$ be a probability distribution, Q be a $k \times k$ symmetric matrix with nonnegative entries. If $\lambda_2^2 < \lambda_1$, then there is no polynomial time algorithm that can solve weak recovery in G drawn from* $\mathrm{SBM}(n, p, Q/n)$.

- *Learning the general sparse SBM.* Under what condition can we learn the parameters in $\mathrm{SBM}(n, p, Q/n)$ efficiently or information-theoretically?
- *Scaling laws:* What is the optimal scaling/exponents of the probability of error for the various recovery requirements? How large need the graph be, i.e., what is the scaling in n, so that the probability of error in the discussed results[25] is below a given threshold?
- *Beyond the SBM:*
  - How do previous results and open problems generalize to the extensions of SBMs with labels, degree-corrections, overlaps, etc. beyond cases discussed in Section 3.5? In the related line of work for graphons Choi et al. (2012); Airoldi et al. (2013); Borgs et al. (2015), are there fundamental limits in learning the model or recovering the vertex parameters up to a given distortion? It was shown in Moitra et al. (2016); Makarychev et al. (2015) that monotone adversaries can interestingly shift the threshold for weak recovery; what is the threshold for such adversarial models and variants for adding loops?
  - Can we establish fundamental limits and algorithms achieving the limits for other unsupervised machine learning problems, such as topic modelling, ranking, Gaussian mixture clustering, low-rank matrix recovery (see Deshpande and Montanari (2014) for sparse PCA) or the graphical channels discussed in Section 1.2?
- *Semi-supervised extensions:* How do the fundamental limits change in a semi-supervised setting,[26] i.e., when some of the vertex labels are revealed, exactly or probabilistically?
- *Dynamical extensions:* In some cases, the network may be dynamical and one may observe different time instances of the network. How does one integrate such dynamics to understand community detection?[27]

25. Recent work Young et al. (2016) has investigated finite size information-theoretic analysis for detection.
26. Partial results and experiments were obtained for a semi-supervised model Zhang et al. (2014). Another setting with side-information is considered in Clauset et al. (2004) with metadata available at the network vertices.
27. Partial results were recently obtained in Ghasemian et al. (2016).

Acknowledgements

I would like to thank my collaborators from the main papers discussed in the manuscript, in particular, A. Bandeira, Y. Deshpande, G. Hall, A. Montanari, C. Sandon, the many colleagues with whom I had conservations on the topic, in particular, E. Airoldi, C. Bordenave, F. Krzakala, M. Lelarge, L. Massoulié, C. Moore, E. Mossel, A. Sly, V. Vu, L. Zdeborová, as well as the various colleagues, students and anonymous reviewers who gave useful comments on the earlier drafts.

Abstract

Large-scale regression problems where both the number of variables, p, and the number of observations, n, may be large and in the order of millions or more, are becoming increasingly more common. Typically the data are sparse: only a fraction of a percent of the entries in the design matrix are non-zero. Nevertheless, often the only computationally feasible approach is to perform dimension reduction to obtain a new design matrix with far fewer columns and then work with this compressed data.

b-bit min-wise hashing (Li and König, 2011; Li et al., 2011) is a promising dimension reduction scheme for sparse matrices which produces a set of random features such that regression on the resulting design matrix approximates a kernel regression with the resemblance kernel. In this work, we derive bounds on the prediction error of such regressions. For both linear and logistic models, we show that the average prediction error vanishes asymptotically as long as $q\|\boldsymbol{\beta}^*\|_2^2/n \to 0$, where q is the average number of non-zero entries in each row of the design matrix and $\boldsymbol{\beta}^*$ is the coefficient of the linear predictor.

We also show that ordinary least squares or ridge regression applied to the reduced data can in fact allow us fit more flexible models. We obtain non-asymptotic prediction error bounds for interaction models and for models where an unknown row normalisation must be applied in order for the signal to be linear in the predictors.

Keywords: large-scale data, min-wise hashing, resemblance kernel, ridge regression, sparse data.

1. Introduction

The modern field of high-dimensional statistics has now developed a powerful range of methods to deal with data sets where the number of variables p may greatly exceed the number of variables n (see Bühlmann and van de Geer (2011) for an overview of recent advances). The prototypical example of microarray data, where p may be in the tens of thousands but n is typically not more than a few hundred, has motivated much of this development. Yet not all modern data sets come in this sort of shape and size. The emerging area of 'large-scale data' or the more vaguely defined 'Big Data' is a response to the increasing prevalence of computationally challenging data sets as arise in text analysis or web-scale prediction tasks, to give two examples. Here both n and p can run into the millions or more, particularly if interactions are considered. In these 'large p, large n' regression scenarios, one can imagine situations where ordinary least squares (OLS) has a competitive performance for prediction, but the sheer size of the data renders it infeasible for computational rather than statistical reasons.

An important feature of many large-scale data sets is that they are sparse: the overwhelming majority of entries in the design matrices are exactly zero. This is not to be confused with signal sparsity, a common assumption in the high-dimensional context. Indeed, when the design matrix is sparse, having only a few variables that contribute to the response would make the expected response values of all observations with no non-zero entries for the important variables exactly the same; one expects that such a property would not be possessed by many data sets. However, similarly to the way in which many high-dimensional techniques exploit sparsity to improve statistical efficiency, one might hope that sparsity in the data could be leveraged to yield both computational and statistical improvements, and indeed we demonstrate in this work that this can be achieved.

Kernel machines are an important class of machine learning methods for which such large-scale data poses particularly serious computational challenges. For example, standard implementations of kernel ridge regression would have computational complexity $O(n^3)$ and a storage cost of $O(n^2)$ when p is considered fixed; a large p will increase these computational costs depending on the kernel to be used. There has therefore been a great deal of work on approximating kernel machines by first randomly mapping the $n \times p$ design matrix $\mathbf{X}$ to a $n \times d$ matrix $\mathbf{S}$ with $d \ll p$ such that dot products between rows of $\mathbf{S}$ approximate the kernel evaluated on the corresponding rows of $\mathbf{X}$. Then a regular ridge regression on $\mathbf{S}$ will resemble a kernel ridge regression on $\mathbf{X}$, for example.

A remarkably effective way of forming $\mathbf{S}$ that is applicable when the design matrix is sparse and binary, is b-bit min-wise hashing (Li and König, 2011; Li et al., 2011) which is based on an earlier technique called min-wise hashing (Broder et al., 1998; Cohen et al., 2001; Datar and Muthukrishnan, 2002). Here $\mathbf{S}$ is constructed such that the dot product between any two rows of $\mathbf{S}$, $\mathbf{s}_i^T\mathbf{s}_j$, can approximate the *resemblance* or *Jaccard similarity* or between the corresponding rows of $\mathbf{X}$, defined as $|\mathbf{z}_i \cap \mathbf{z}_j|/|\mathbf{z}_i \cup \mathbf{z}_j|$ where $\mathbf{z}_i = \{k : X_{ik} \neq 0\}$.

The empirical performance of regression and classification procedures following b-bit min-wise hashing (Li et al., 2011, 2013) is particularly impressive. Existing theory on b-bit min-wise hashing (Li and König, 2011) has focused on the variance and bias in the approximation of the kernel. However, there remain significant gaps in our theoretical understanding of this important procedure when used to approximate a kernel machine:

(a) What sorts of regression models is the resemblance kernel well-suited for and how does sparsity of the design matrix play a role?

(b) What is the loss in prediction accuracy due to the approximation provided by b-bit min-wise hashing for different sorts of regression procedures?

(c) What is the overall prediction error incurred by different regression methods following b-bit min-wise hashing in different regression models?

An answer to (c) would be the ultimate goal here, and it would appear that in order to tackle this one must first solve (a) and (b). In this paper, we take a very different approach and aim to answer (c) directly: rather than considering what sorts of functions lie in the reproducing kernel Hilbert space (RKHS) associated with the resemblance kernel and have low RKHS norms, we look at the sorts of signals that can be approximated well by linear combinations of columns of the matrix $\mathbf{S}$ constructed by b-bit min-wise hashing. In this way, we use the random feature expansions provided by b-bit min-wise hashing to understand the predictive properties of the resemblance kernel.

1.1 Our contributions and organisation of the paper

In this paper we derive finite-sample bounds on the expected risk of linear and logistic regression following dimension reduction through b-bit min-wise hashing under various different models. Our results show that the method, and hence also the resemblance kernel, are particularly suited to sparse data.

We describe the b-bit min-wise hashing algorithm in Section 2 and also discuss in greater details the connection to the resemblance kernel. We also introduce a generalisation of b-bit min-wise hashing applicable to sparse data with real-valued entries motivated by our theory. Perhaps the simplest sorts of signals that we could hope to be able to fit well are linear signals of the form $\mathbf{X}\boldsymbol{\beta}^*$. In Section 3 we first consider how well a linear combination of columns of $\mathbf{S}$ can approximate such a signal. We then study a much larger class of signals defined by first scaling the rows of $\mathbf{X}$ in different ways depending on their sparsity and then forming a linear signal from a scaled version of $\mathbf{X}$. Some form of row normalisation is often performed on the original data as a pre-processing step, but the optimal normalisation to use is seldom known; our theory shows how b-bit min-wise hashing, and hence also the resemblance kernel, is able to automatically discover an appropriate scaling in several settings.

In Section 4.1 we study the performance of ordinary least squares, ridge regression and ℓ_2-penalised logistic regression using the reduced design matrix it creates. Our results are applicable to both linear signals and nonlinear signals of the sort described above. In the former setting, we show that the expected mean-squared prediction error is bounded by a small constant times $\sqrt{q/n}\,\|\boldsymbol{\beta}^*\|_2$, where q is the average number nonzero entries in the rows of $\mathbf{X}$ and $\boldsymbol{\beta}^*$ is the coefficient vector. We present similar results for logistic regression.

In Section 5 we study another form of nonlinear signal that can be approximated by the b-bit minwise hashing and the resemblance kernel: we show that interaction models in the original data can also be captured by main effects regression on the compressed data. Variable importance measures are discussed in Section 6. We conclude with a discussion in Section 7. The appendix contains all proofs, an additional result concerning the implications of our approximation error bound for properties of the RKHS of the resemblance kernel, and an empirical study validating our bounds.

1.2 Related work

There has been very little work in understanding properties of the resemblance kernel. One of the few pieces of work in this direction is Bouchard et al. (2013), who show that the kernel matrix with entries given by the Jaccard similarity between different elements of the

power set of $\{1,\ldots,p\}$ minus the empty set is positive definite. It follows that the RKHS of the resemblance kernel contains every real-valued function on p-dimensional binary vectors (see Section B). However, this result is not informative for understanding which sorts of regression models a kernel ridge regression will perform well for, a question which we provide some answers to through our study of b-bit min-wise hashing.

Approximating kernel methods using random feature expansions was pioneered by Rahimi and Recht (2007) who used random Fourier features to approximate translation invariant kernels such as the Gaussian kernel. Sutherland and Schneider (2015) provides bounds on the approximation of the corresponding kernel as well as bounds on the distance between the predictions from regression on the random features and kernel ridge regression in terms of distances between the true kernel and its approximation. Le et al. (2013) introduce a scheme related to random Fourier features that further improves the computational efficiency. Rahimi and Recht (2008) consider more general random feature expansions and study how well they can approximate functions in a family determined by the distribution of feature expansions in terms of a certain form of function norm defined on the family. Rahimi and Recht (2009) provides prediction error bounds for a method that minimises the empirical risk of a weighted sum of random feature expansions where weights are constrained in ℓ_∞-norm. Bach (2017) studies how well random feature expansions can approximate elements of their corresponding RKHS in terms of the eigenvalues of the associated kernel integral operator. The Nyström method (Williams and Seeger, 2001) is related and aiming at a computationally efficient low-rank approximation to the full kernel matrix; see (Bach, 2013) and (Rudi et al., 2015) for approximation guarantees.

A distinguishing feature of our work is that bounds are obtained not in terms of the norm of the RKHS of the resemblance kernel, which would be difficult to interpret, but in terms of quantities derived directly from the different models considered (we look at linear models with unknown row scaling and at nonlinear interaction models). We could divide the analysis into two parts: (i) first we could try to understand the predictive accuracy when using exact kernel regression with the resemblance kernel for such true regression functions and then (ii) in a second step understand how much predictive accuracy we lose by using b-bit minwise hashing as an approximation to using exact kernel regression with the resemblance kernel. Instead of making these two separate steps, we study here directly how well b-bit minwise hashing performs for these model classes.

Properties of b-bit min-wise hashing related to similarity search are studied in Li and König (2011). Theory concerning its use for large-scale learning is presented in Li et al. (2011) which quantifies the mean and variance of entries in the Gram matrix $\mathbf{S}\mathbf{S}^T$ and its relationship to the resemblance kernel as well as providing comparisons with random projections and *Vowpal Wabbit*. Random feature expansions for other types of kernels are developed in Shi et al. (2009); Weinberger et al. (2009); Vedaldi and Zisserman (2012); Kar and Karnick (2012); Li (2014); Pennington et al. (2015).

More generally, there is a huge variety of dimension reduction schemes across the statistics and computer science literature. Performing principal component analysis (Jolliffe, 1986) (PCA) and retaining only the first d components is one of the most popular methods. One drawback however in the large-scale data setting is that computing the principal components can be computationally demanding. The method of random projections, motivated by the celebrated Johnson–Lindenstrauss lemma (Johnson and Lindenstrauss, 1984), offers

dimension reduction at a low computational cost. In this scheme, $\mathbf{X}$ is mapped to $\mathbf{XA}$, where $\mathbf{A}$ is a $p \times d$ matrix typically with i.i.d. random entries. Efficient implementations are discussed in Achlioptas (2001); Li et al. (2006) and some numerical results on random projections and a wider literature review are in Fradkin and Madigan (2003); Vempala (2005). The software package *Vowpal Wabbit* (Langford et al., 2007) is a popular learning system for large-scale data sets that uses sparse random projections.

A separate line of work has considered pre-multiplying $\mathbf{X}$ with a random matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$ to produce a reduced matrix $\mathbf{AX} \in \mathbb{R}^{m \times p}$, known as a *sketch*. Though the dimension p is not reduced, when n is large, performing OLS on the sketched matrix may be possible despite the computational infeasibility of applying least squares directly to $\mathbf{X}$. A number of works have studied properties sketched least squares (see Boutsidis and Drineas (2009); Drineas et al. (2011); Mahoney (2011); Pilanci and Wainwright (2015) and references therein) whilst Pilanci and Wainwright (2014) propose an iterative variant of this scheme. Yang et al. (2017) considers sketching ideas in the context of kernel ridge regression.

2. b-bit min-wise hashing

Given a sparse design matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$, the aim of dimension reduction is to map this to a compressed matrix $\mathbf{S} \in \mathbb{R}^{n \times d}$, in a way that is computationally efficient and such that the relevant information in $\mathbf{X}$ is preserved in $\mathbf{S}$. Section 2.2 describes the mapping to $\mathbf{S}$ under b-bit min-wise hashing for binary data, as proposed in Li and König (2011) and Li et al. (2011). The construction may seem unintuitive at first sight, but we will try to shed light on why the scheme works for linear and interaction models throughout the manuscript.

2.1 Notation

Given a matrix $\mathbf{U}$, we will write $\mathbf{u}_i$ and $\mathbf{U}_j$ for the ith row and jth column respectively, where both are to be regarded as column vectors. The ijth entry will be denoted U_{ij}. A vector of 1's will be denoted $\mathbf{1}$.

When the parentheses following probability and expectation signs, $\mathbb{P}$ and $\mathbb{E}$, enclose multiple potential sources of randomness, we will sometimes add subscripts to indicate what is being considered as random. For example, if U and V are random variables, we may write $\mathbb{E}_U(U|V)$ for the conditional expectation of U given V, and $\mathbb{E}_{U,V}(U+V)$ for the expected value of $U+V$.

2.2 Construction of S with b-bit min-wise hashing and binary variables

The compressed matrix $\mathbf{S}$ generated by b-bit min-wise hashing consists of blocks of size 2^b, where we may choose the number of blocks L. Each block is created using a random permutation and the blocks of columns form a collection of L i.i.d. random matrices.

There are three steps to the construction.

Step 1: Generate a random permutation of the set $\{1, \ldots, p\}$, π_l, and permute the columns of $\mathbf{X}$ according to this permutation.

Step 2: Search along each row of the permuted design matrix (in order of increasing column index) and record in the vector $\mathbf{H}_l \in \mathbb{N}^n$ the indices of the variables (indexed as in the original order) with the first non-zero value or the vector $\mathbf{M}_l \in \mathbb{N}^n$ the indices of the variables (indexed as in the permuted order) with the first non-zero value.

Step 3: Form $\mathbf{S}_l \in \{0,1\}^{n \times 2^b}$ with ith row given by the last b bits of the binary representation of the ith entry of $\mathbf{M}_l$. For example, when $b = 1$, all odd numbers in $\mathbf{M}_l$ map to the vector $(0,1)$, whereas all even numbers map to $(1,0)$.

This construction is illustrated for a toy example in Table 1.

$\mathbf{X} = \begin{array}{c} \begin{matrix} 1 & 2 & 3 & 4 \end{matrix} \\ \begin{pmatrix} \cdot & 1 & \cdot & 1 \\ \cdot & \cdot & 1 & 1 \\ 1 & \cdot & 1 & \cdot \\ \cdot & 1 & 1 & \cdot \\ 1 & 1 & \cdot & \cdot \end{pmatrix} \end{array} \overset{\pi_l = 2314}{\mapsto} \begin{array}{c} \begin{matrix} 3 & 1 & 2 & 4 \end{matrix} \\ \begin{pmatrix} \cdot & \cdot & \mathbf{1} & 1 \\ \mathbf{1} & \cdot & \cdot & 1 \\ \mathbf{1} & 1 & \cdot & \cdot \\ \mathbf{1} & \cdot & 1 & \cdot \\ \cdot & \mathbf{1} & 1 & \cdot \end{pmatrix} \end{array}$	$\mathbf{H}_l = \begin{pmatrix} 2 \\ 3 \\ 3 \\ 3 \\ 1 \end{pmatrix}, \mathbf{M}_l = \begin{pmatrix} 3 \\ 1 \\ 1 \\ 1 \\ 2 \end{pmatrix}$	$\mathbf{S}_l = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$
Step 1: non-zero indices whose variable indices will appear in $\mathbf{H}_l$ in Step 2 are in bold.	*Step 2.*	*Step 3.*

Table 1: Steps 1–3 applied to a toy example with $b = 2$. Dots represent zeroes.

We can think of each column of $\mathbf{S}_l$ as representing different categories for the observations. The matrix $\mathbf{S}_l$ itself codes for the assignment of the different rows of $\mathbf{X}$ to the different categories. Different blocks $\mathbf{S}_l$ then represent different random categorisations. Identical rows will always be assigned the same categories and the more different the rows are, the less likely they are to be assigned the same category. The notion of difference here is that of *resemblance*; see Section 2.4

Note that one would not necessarily follow the above steps when implementing b-bit min-wise hashing. In practice, one would not store the entire matrix of signs nor all the random permutations. In an implementation, hash functions (Carter and Wegman, 1979) would be used to create the matrix $\mathbf{S}$ deterministically, though it is beyond the scope of this paper to go into the details; see Li et al. (2013) for more information and further computational improvements. With this approach, $\mathbf{S}$ would be created row-by-row, and only a single observation from $\mathbf{X}$ would need to be kept in memory at any one time. Furthermore, many rows could be created in parallel. Other ideas such as one-permutation hashing (Li et al., 2012) can also be used to speed up the pre-processing step.

2.3 Continuous data and additional randomisation

For continuous data, we introduce a modification where we replace the map extracting the last b bits by L random maps in the following way. Fix b and let $\mathbf{\Psi} \in \{1, \ldots, 2^b\}^{p \times L}$ be a random matrix with independent entries each having the uniform distribution on the set $\{1, \ldots, 2^b\}$. We then create $\mathbf{S}$ by modifying the previous Step 3 to the following.

Step 3: Form $\mathbf{S}_l \in \{0,1\}^{n \times 2^b}$ with ith row all zero except component $\Psi_{H_{il}l}$ takes the value 1.

Step 4: If $\mathbf{X}$ is not binary, multiply the ith row of $\mathbf{S}_l$ by $X_{iH_{il}}$.

This generalisation is motivated by our theoretical results on how well the column space of $\mathbf{S}$ can capture different sorts of signals (see Section 3.1).

Let $\mathbf{z}_i = \{k : X_{ik} \neq 0\}$ be the set of variable indices whose entries have non-zero values for the ith observation. Performing the steps above for all $l = 1, \ldots, L$, we get $n \times L$ matrices $\mathbf{H}$, and $\mathbf{M}$ given by

$$H_{il} = \arg\min_{k \in \mathbf{z}_i} \pi_l(k), \tag{1}$$

$$M_{il} = \min_{k \in \mathbf{z}_i} \pi_l(k) = \pi_l(H_{il}), \tag{2}$$

The matrix $\mathbf{S}$ is a binary $n \times 2^b L$ matrix. With a slight abuse of notation, we will denote by $\mathbf{S}_{ilc}$ the cth entry in the lth block of $\mathbf{S}$:

$$S_{ilc} := S_{i(c+(l-1)2^b)} = X_{iH_{il}} \mathbb{1}_{\{\Psi_{H_{il}l} = c\}}, \qquad \text{for } c = 1, \ldots, 2^b. \tag{3}$$

If not stated otherwise, we will work with this second randomised variation of b-bit min-wise hashing from now on. We emphasise that we do not make the claim this version is to be preferred over the original proposal of Li and König (2011) and Li et al. (2011) when data is binary. We simply introduce the additional randomisation here to simplify the analysis. We note that the two versions are essentially identical for all practical purposes when b is not too large.

2.4 The resemblance kernel

We now briefly describe the connection between b-bit min-wise hashing and the resemblance kernel alluded to earlier. This is not needed for the rest of the paper, though it provides some intuition for the scheme. A more detailed analysis from this perspective is carried out by Li et al. (2011) and we refer the reader to Hofmann et al. (2008) for a review of kernel methods and the kernel trick.

Suppose $\mathbf{X}$ is binary. Consider the normalised Gram matrix of the compressed design $\mathbf{S}$ from (randomised) b-bit min-wise hashing, $\mathbf{S}\mathbf{S}^T/L$. The expected value of the ijth component may be calculated as follows.

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T \mathbf{s}_j / L) &= \frac{1}{L} \sum_{l=1}^{L} \sum_{c=1}^{2^b} \mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbb{1}_{\{\Psi_{H_{il}l} = c\}} \mathbb{1}_{\{\Psi_{H_{jl}l} = c\}}) \\
&= \mathbb{P}(\Psi_{H_{il}l} = \Psi_{H_{jl}l}) \\
&= \mathbb{P}(\Psi_{H_{il}l} = \Psi_{H_{jl}l} | H_{il} = H_{jl}) \mathbb{P}(H_{il} = H_{jl}) \\
&\quad + \mathbb{P}(\Psi_{H_{il}l} = \Psi_{H_{jl}l} | H_{il} \neq H_{jl}) \{1 - \mathbb{P}(H_{il} = H_{jl})\} \\
&= \frac{|\mathbf{z}_i \cap \mathbf{z}_j|}{|\mathbf{z}_i \cup \mathbf{z}_j|} (1 - 2^{-b}) + 2^{-b}.
\end{aligned}$$

Thus the ijth entry is an average of L i.i.d. random variables with expectation a constant plus a constant times the resemblance between the ith and jth rows of $\mathbf{X}$. If an intercept term is included when regressing on $\mathbf{S}$, the additive constant plays no part, and the scaling would be absorbed into the scaling of the regression coefficients. We also note that when $\mathbf{X}$ is continuous, the resulting kernel is similar to the the CoRE kernels of Li (2014).

Now as the resemblance kernel is positive definite, the theory surrounding the kernel trick tells us that any ℓ_2-regularised regression on $\mathbf{S}$ is effectively approximating a regularised regression on transformed data $\phi(\mathbf{x}_i)$ where $\phi : \{0,1\}^p \to \mathcal{H}$ and $\mathcal{H}$ is a high-dimensional inner product space (the feature space). This space may be taken to be a reproducing kernel Hilbert space (RKHS), and then ϕ and $\mathcal{H}$ are uniquely defined.

Although this is encouraging, the kernel trick does not guarantee that regression on $\mathbf{S}$ will necessarily have good predictive properties for models of interest. To gain a better understanding, we must study the regularisation properties of the resemblance kernel itself: what characterises those elements of the associated RKHS $\mathcal{H}$ that have low norm and thus will be penalised less?

A direct analysis of the RKHS corresponding to the resemblance kernel in those terms seems challenging. We take a different approach and explicitly construct regression coefficients for $\mathbf{S}$ that approximate signals of interest. By showing that particular signals can be approximated well, we are indirectly discovering elements of $\mathcal{H}$ with low RKHS norm (see also Section B for more details).

3. Approximation error

In this section, we present results that bound the expected prediction error when performing regression on the reduced design matrix $\mathbf{S}$ in the contexts of the linear and logistic regression models. Note that throughout the rest of the manuscript, by b-bit min-wise hashing we are referring to the randomised variant described in Section 2.3. Let q_i be the number of non-zero entries in the ith row of $\mathbf{X}$, and let $\delta_i = q_i/p$ be the row sparsity. We will assume that the signal we wish to approximate for the ith observation takes the form

$$\kappa(\delta_i) \mathbf{x}_i^T \boldsymbol{\beta}^*. \tag{4}$$

Here $\boldsymbol{\beta}^* \in \mathbb{R}^p$ is an unknown vector of coefficients and the function κ allows the ith linear predictor to be scaled in a way which depends on the number of non-zero entries in the ith row of $\mathbf{X}$. Some normalisations of special interest include:

(a) $\kappa(\delta)$ constant. This yields standard linear or logistic regression models.

(b) $\kappa(\delta) \propto \delta^{-1/2}$. In text analysis with a bag of words representation of documents, rows of $\mathbf{X}$ are often scaled to have the same ℓ_2-norm to help balance situations when documents vary greatly in length (Banerjee et al., 2005). When $\mathbf{X}$ is binary, this is exactly achieved by taking $\kappa(\delta) = p^{-1/2}\delta^{-1/2}$, so $\kappa(\delta_i) = q_i^{-1/2}$.

(c) $\kappa(\delta) \propto \delta^{-1}$. This leads to a ℓ_1-norm scaling as opposed to the ℓ_2-norm scaling mentioned above.

Throughout we will assume that $\mathbf{X} \in [-1,1]^{n \times p}$, so the entries in $\mathbf{X}$ are bounded. This covers the important case of binary design but also allows for real-valued entries.

The first step in obtaining our prediction error results is to construct a vector $\mathbf{b}^*$ such that $\mathbf{s}_i^T \mathbf{b}^*$ is close to $\kappa(\delta_i) \mathbf{x}_i^T \boldsymbol{\beta}^*$ on average.

3.1 Un-scaled signals

We will first consider un-scaled signals where $\kappa(\delta)$ in (4) is a constant. Non-constant row-scaling is treated in more detail in the Section 3.2. To begin with we will assume that $q_i = q \geq 1$ for all $i = 1, \ldots, n$, a restriction which simplifies the results but highlights some interesting properties of b-bit min-wise hashing. Unequal row sparsity is treated in detail in the appendix in Section A.4 but a sketch of the results are given just below Theorem 1.

To simplify notation, we first introduce the following norm for $\boldsymbol{\beta} \in \mathbb{R}^p$,

$$\|\boldsymbol{\beta}\|_b^2 := \|\boldsymbol{\beta}\|_2^2 + (2^b - 2)\sum_{k=1}^{p} \frac{\|\mathbf{X}_k\|_2^2}{n}\beta_k^2. \tag{5}$$

For $b = 1$, we have of course that $\|\boldsymbol{\beta}\|_b^2 = 2\|\boldsymbol{\beta}\|_2^2$. For larger values of b, the norm is influenced more heavily by the second term which can be seen to be the weighted version of the ℓ_2-norm, where the weight of each variable is proportional to its squared ℓ_2-norm. We will first discuss how well the original signal can be approximated with the column space of the matrix $\mathbf{S}$ generated by the b-bit min-wise hashing operation.

Theorem 1 *Let $\mathbf{S}$ be the matrix generated by b-bit min-wise hashing. Then there exists a vector $\mathbf{b}^* \in \mathbb{R}^{2^b L}$ with the following properties.*

(i) The approximation is unbiased: $\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{S}\mathbf{b}^*) = \mathbf{X}\boldsymbol{\beta}^*$.

(ii) The norm is bounded by

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^*\|_2^2) \leq \frac{(2-\delta)q}{L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_2^2.$$

(iii) The approximation error is bounded by

$$\frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{S}\mathbf{b}^* - \mathbf{X}\boldsymbol{\beta}^*\|_2^2) \leq \frac{(2-\delta)q}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2.$$

Specifically, for $b = 1$, $\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{S}\mathbf{b}^* - \mathbf{X}\boldsymbol{\beta}^*\|_2^2)/n \leq (2-\delta)q\|\boldsymbol{\beta}^*\|_2^2/L$.

A form of the approximation error (iii) and the norm bound (ii) continue to be valid in the non-equal sparsity case under a mild restriction on the size of L, where we get instead of (iii) the bound

$$\frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{S}\mathbf{b}^* - \mathbf{X}\boldsymbol{\beta}^*\|_2^2) \leq \frac{6\bar{q}}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2,$$

where $\bar{q}$ is the the average of the q_i; see Theorem 12 in the appendix for details.

The results above show that the signal $\mathbf{X}\boldsymbol{\beta}^*$ can be well approximated by a linear combination of the columns in the matrix $\mathbf{S}$ if we generate a sufficiently large number of permutations L, especially for sparse data matrices. Another useful property of $\mathbf{b}^*$ here, aside from the approximation accuracy it delivers, is given in (ii): on average, $\|\mathbf{b}^*\|_2^2$ is small when L is large. This proves to be useful when studying the application of ridge regression.

This result has interesting implications for the resemblance kernel and its RKHS $\mathcal{H}$. In particular, it shows that if we constrain the input space to contain those vectors with

sparsity q, linear functions $f_{\boldsymbol{\beta}}$ defined by coefficients $\boldsymbol{\beta} \in \mathbb{R}^p$ with $\sum_j \beta_j = 0$ have RKHS norm satisfying $\|f_{\boldsymbol{\beta}}\|_{\mathcal{H}}^2 \leq (2-\delta)q\|\boldsymbol{\beta}\|_2^2$. As these properties of the RKHS are not directly used in any subsequent results, we defer formal presentation of these facts to Section B in the appendix.

Whilst the bound on the expectation of $\|\mathbf{b}^*\|_2^2$ is almost constant as b changes, the approximation error bound (iii) does vary with b. Consider the case where $\mathbf{X}$ is binary and let $\gamma_k = \|\mathbf{X}_k\|_2^2/n$ be the column sparsity. Typically one would expect $\|\boldsymbol{\beta}^*\|_2^2$ to be significantly larger than $\sum_{k=1}^p \gamma_k \beta_k^{*2}$ and thus increasing b by 1 almost halves the approximation error when b is small.

A proof of Theorem 1 is given in Section A of the appendix; here we briefly sketch some of the main ideas. Note that

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{S}\mathbf{b}^*) = \sum_{l=1}^{L} \mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}\Big(\sum_{c=1}^{2^b} \mathbf{S}_{lc} b_{lc}^*\Big). \tag{6}$$

We construct $\mathbf{b}^*$ with the following two properties: each of the L blocks of $\mathbf{b}^*$ are i.i.d. with the lth block only depending on π_l and $\boldsymbol{\Psi}_l$; and each of the L summands in (6) equals $\mathbf{X}\boldsymbol{\beta}^*/L$. With each of the L summands being unbiased in this way, we see that the approximation error is controlled by the variance of the sum; this variance scales as $1/L$ since the summands are i.i.d.

At first sight it may seem surprising that it is possible to exhibit a $\mathbf{b}^*$ with each block having the unbiasedness property discussed above. However, the following construction gives an indication of the possibilities. Using our convention that the cth component of the lth block of $\mathbf{b}^*$ is indexed as $b_{lc}^* := b_{c+(l-1)2^b}^*$, consider taking

$$b_{lc}^* = \frac{q}{L}\sum_{k=1}^{p} \beta_k^* \frac{\mathbb{1}_{\{\Psi_{lk}=c\}} - 2^{-b}}{1-2^{-b}}. \tag{7}$$

Then writing $\boldsymbol{\psi} = \boldsymbol{\Psi}_1$, $\pi = \pi_1$, $H_i = H_{i1}$ we have

$$\begin{aligned}\frac{L}{q}\mathbb{E}_{\pi,\boldsymbol{\psi}}\Big(\sum_{c=1}^{2^b} S_{lc} b_{1c}^*\Big) &= \mathbb{E}_{\pi,\boldsymbol{\psi}}\Big(\sum_{c=1}^{2^b}\sum_{j=1}^{p} X_{ij}\mathbb{1}_{\{H_i=j,\psi_j=c\}}\sum_{k=1}^{p}\beta_k^*\frac{\mathbb{1}_{\{\psi_k=c\}}-2^{-b}}{1-2^{-b}}\Big)\\ &= \mathbb{E}_{\pi,\boldsymbol{\psi}}\Big(\sum_{j=1}^{p} X_{ij}\mathbb{1}_{\{H_i=j\}}\sum_{k=1}^{p}\beta_k^*\frac{\mathbb{1}_{\{\psi_k=\psi_j\}}-2^{-b}}{1-2^{-b}}\Big).\end{aligned} \tag{8}$$

Now since $\mathbb{E}_{\boldsymbol{\psi}}\{(\mathbb{1}_{\{\psi_k=\psi_j\}} - 2^{-b})/(1-2^{-b})\} = \mathbb{1}_{\{k=j\}}$ we see the above display equals

$$q\sum_{k=1}^{p} X_{ik}\beta_k^* \mathbb{P}_\pi(H_i = k) = \mathbf{X}\boldsymbol{\beta}^*.$$

The final line uses the fact that for k with $X_{ik} \neq 0$, $\mathbb{P}_\pi(H_i = k)$ is the reciprocal of the number of non-zero entries in the ith row of $\mathbf{X}$; with our simplifying assumption of equal row sparsity, this is precisely $1/q$. Note one could scale the rows of $\mathbf{S}$ according to the number of non-zeroes in each row to achieve unbiasedness in the case of unequal row

sparsity. However as shown in Section A.4, it turns out that by incurring some bias one can still keep the approximation error low even in this situation without having to perform any sort of scaling.

The form of $\mathbf{b}^*$ used in the proof of Theorem 1 differs slightly from that in (7) by introducing a random weight multiplying each coefficient that decays as $\pi_l(k)$ increases. This reduces the variance and yields the approximation error in (iii) that has a factor q rather than the factor of p which would be obtained from (7).

3.2 Row-scaled signals

We now turn to the more general setting with unequal row sparsity and signal given by (4). We consider the family of scaling functions $\delta \mapsto (\delta_{\min}/\delta)^a$ where $\delta_{\min} = \min_i \delta_i$, for $1/2 \le a \le 1$. Including $\delta_{\min}$ in the scaling functions means that were the row sparsity to be equal, the approximation error here would be of the same form as that considered in Theorems 1. We could alternatively replace $\delta_{\min}$ with the average of the δ_i for the same effect, but using $\delta_{\min}$ helps to simplify the results. Writing $q_{\min} = \min_i q_i$, we have the following results.

Theorem 2 *Let $L \ge 5$ and assume $\delta_{\min} \le 1/2$ if $a = 1/2$, and $L > 2/(2a-1)$ if $a > 1/2$. Then there exists $\mathbf{b}^* \in \mathbb{R}^L$ depending on a such that the approximation error satisfies*

$$\frac{1}{n}\sum_{i=1}^n \mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}[\{(\delta_{\min}/\delta_i)^a \mathbf{x}_i^T\boldsymbol{\beta}^* - \mathbf{s}_i^T\mathbf{b}^*\}^2] \le \begin{cases} \dfrac{q_{\min}}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2 \log\{4\log(L)/\delta_{\min}\} & \text{if } a = 1/2, \\ \dfrac{q_{\min}}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2 \dfrac{1}{2a-1}[\log\{2(2a-1)L\}]^{2a-1} & \text{if } 1/2 < a \le 1, \end{cases}$$

and the norm of $\mathbf{b}^*$ is bounded in expectation by

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^*\|_2^2) \le \begin{cases} \dfrac{q_{\min}\log\{4\log(L)/\delta_{\min}\}}{L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_2^2 & \text{if } a = 1/2, \\ \dfrac{1}{2a-1}\dfrac{q_{\min}[\log\{2(2a-1)L\}]^{2a-1}}{L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_2^2 & \text{if } 1/2 < a \le 1. \end{cases}$$

The min-wise hashing based dimension reduction scheme appears to be well-suited to approximating signals scaled by a power of the sparsity, with the approximation error only incurring a further multiplicative term involving $\log(L)$ compared to the results of Theorem 1.

We now briefly outline how we construct coefficient vectors $\mathbf{b}^*$ achieving the bounds above. Consider the following refinement of (7):

$$b_{lc}^* = \frac{1}{L}\sum_{k=1}^p \beta_k^* \frac{\mathbb{1}_{\{\Psi_{lk}=c\}} - 2^{-b}}{1-2^{-b}} w_{\pi_l(k)},$$

where $\mathbf{w} \in \mathbb{R}^p$ is a vector of non-negative weights. Arguing as in (8) but replacing $q\beta_k^*$ with $\beta_k^* w_{\pi(k)}$ we arrive at

$$L\mathbb{E}_{\pi,\psi}\Big(\sum_{c=1}^{2^b} S_{lc} b_{1c}^*\Big) = \sum_{k=1}^p X_{ik}\beta_k^* \mathbb{E}_\pi(\mathbb{1}_{\{H_i=k\}} w_{\pi(k)}).$$

Recall that writing $M_i = M_{i1}$, $M_i = \pi(H_i)$, the position of the first non-zero entry in row i under permutation π. Note that H_i and M_i are independent. Now for large p, M_i behaves roughly like a geometric random variable with parameter δ_i. Thus for k with $X_{ik} \ne 0$,

$$\mathbb{E}_\pi(\mathbb{1}_{\{H_i=k\}} w_{\pi(k)}) = \mathbb{E}_\pi(\mathbb{1}_{\{H_i=k\}} w_{M_i}) \approx \frac{1}{p\delta_i}\sum_{\ell=1}^p w_\ell \delta_i(1-\delta_i)^{\ell-1} = \frac{1}{p}\sum_{\ell=1}^p w_\ell(1-\delta_i)^{\ell-1}.$$

If $w_{\ell+1} = p(-1)^\ell \kappa^{(\ell)}(1)/\ell!$ we see that the RHS resembles a Taylor series of $\kappa(\delta_i)$ about 1. In this way we can approximate a large family of row-scaled signals.

4. Prediction error

The approximation error results in the three previous sections allow us to derive bounds on the prediction errors for linear and logistic regression models with potentially row-scaled data. Here we will present results under the assumption of q non-zero entries per row and also where the scaling function κ is proportional to the square-root function

$$\kappa_0(\delta) = \sqrt{\delta_{\min}/\delta}. \tag{9}$$

However, all of the approximation error results can be extended to results on prediction error via general theorems on prediction error we present in Section D. In particular, Theorem 12 can be used to show that versions of the equal row sparsity results hold more generally with q replaced by the average number of non-zeroes per row $\bar{q}$ provided L is not excessively large.

4.1 Linear regression models

Assume we have the following approximately linear model:

$$Y_i = \alpha^* + \kappa(\delta_i)\mathbf{x}_i^T\boldsymbol{\beta}^* + \varepsilon_i, \qquad 1 = 1, \ldots, n. \tag{10}$$

Here α^* is the intercept and $\mathbf{x}_i \in [-1,1]^p$. We assume that the random noise $\boldsymbol{\varepsilon} \in \mathbb{R}^n$ satisfies $\mathbb{E}(\varepsilon_i) = 0$, $\mathbb{E}(\varepsilon_i^2) = \sigma^2$ and $\mathrm{Cov}(\varepsilon_i, \varepsilon_j) = 0$.

Our results here give bounds on a mean-squared prediction error (MSPE) of the form

$$\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) := \frac{1}{n}\sum_{i=1}^n \mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}\{(\alpha^* + \kappa(\delta_i)\mathbf{x}_i^T\boldsymbol{\beta}^* - \hat{\alpha} - \mathbf{S}\hat{\mathbf{b}})^2\} \tag{11}$$

where $\hat{\alpha}$ and $\hat{\mathbf{b}}$ are the estimated intercept and regression coefficients arising from regression on $\mathbf{S}$. Note we consider a denoising-type error: the error on the data used to fit the regression coefficients. Bounds on the prediction error at new observations would require conditions on the distribution of observations and we have avoided making any such assumptions for the results here.

4.1.1 Ordinary least squares

Perhaps the simplest way to estimate the linear model is to apply a least squares estimator,

$$(\hat{\alpha}, \hat{\mathbf{b}}) := \underset{(\alpha,\mathbf{b})\in\mathbb{R}\times\mathbb{R}^{2^b L}}{\arg\min} \|\mathbf{Y} - \alpha\mathbf{1} - \mathbf{S}\mathbf{b}\|_2^2, \tag{12}$$

to the matrix $\mathbf{S}$. We have the following theorem.

Theorem 3 *Let $(\hat{\alpha}, \hat{\mathbf{b}})$ be the least squares estimator (12). We have the bound*

$$\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) \;\le\; \frac{C}{2^b L(1-2^{-b})}\,\|\boldsymbol{\beta}^*\|_b^2 + 2^b L\frac{\sigma^2}{n}.$$

For equal row sparsity δ we have $C = (2-\delta)q$. For unequal row sparsity, when $\kappa = \kappa_0$ as in (9), the result holds for $C = q_{\min}\log\{4\log(L)/\delta_{\min}\}$.

An optimal choice L_b^* of L will balance the approximation error and variance contributions (first and second term on the right hand side respectively). In the equal row sparsity we arrive at

$$L_b^* = \frac{\sqrt{(2-\delta)qn}}{2^b\sqrt{1-2^{-b}}}\|\boldsymbol{\beta}^*\|_b$$

which yields an optimal MSPE of the order $\sigma\sqrt{q/n}\|\boldsymbol{\beta}^*\|_b$. If we ignore log terms the rate is analogous in the case of uneven row-sparsity. The slow rate in n seems unavoidable if we do not make stronger conditions on the design. Indeed, a similar error rate is obtained in Theorem 21 of Maillard and Munos (2012) and in Kaban (2014) for OLS following dimension reduction by random projections. More precisely: projecting K times with a random projection, followed by an OLS estimation is shown in Kaban (2014) to lead to a bound on MSPE of

$$\frac{1}{K}\,\|\boldsymbol{\beta}^*\|_\kappa^2 + K\frac{\sigma^2}{n}, \tag{13}$$

where the norm $\|\cdot\|_\kappa$ depends on the eigenvalue structure of the design matrix. In contrast the bound we have above for min-wise hashing depends in contrast on the sparsity q through the constant C. The bound (13) is otherwise structurally identical to the bound for b-bit min-wise hashing above, and the role of the number L of projections is now taken by the number K of random projections. The optimal values of K and L are both of order $\sqrt{n}$, leading to the same convergence rate of the risk as $n\to\infty$.

To better understand the implications of Theorem 3, it is helpful to fix the size of the signal so that $\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2/n = 1$, and look at whether we can show consistency of the method as both $p, n\to\infty$. If the signal is spread out and all variables have the same sparsity, $\|\boldsymbol{\beta}^*\|_b$ will be of order $\sqrt{p/q}$ and the MSPE will vanish when $p/n\to 0$, which excludes the high-dimensional setting.

However, now assume that the signal is concentrated on a fixed set of variables. The norm $\|\boldsymbol{\beta}^*\|_b$ is then constant as p increases and all that is required for consistency is $q/n\to 0$ (or $q_{\min}/n\to 0$ for the more general case of uneven row-sparsity).

An interesting scenario is one of increasing variable sparseness. In many applications, the more predictor variables are added the sparser they tend to become. In text analysis,

the first block of predictor variables might encode the presence of individual words. The next block might code for bigrams and the following, higher order N-grams. With this design, predictor variables in each successive block become sparser than the previous. It is then interesting to consider how much the MSPE can increase if we add a block with many sparse variables which contain no additional signal contribution. The result above indicates that the MSPE only increases as $\sqrt{q}$. Adding a block of several million (sparse) bigrams might thus have the same statistical effect as adding several thousand (denser) unigrams (individual words).

We now comment the optimal choice of L and computational complexity. If we assume fixed $\|\boldsymbol{\beta}^*\|_2$ and $n = O(q)$, which is all that would be required to keep the prediction error bounded asymptotically, then the optimal dimension of the min-wise projection scales as $L_b^* = O(q)$, considering b fixed here. This dimension will in general be a substantial reduction over the original dimension of the data, p, and would result in a correspondingly large reduction in the computational cost of regression. Indeed, ridge regression or the LAR algorithm (Efron et al., 2004) applied to $\mathbf{X}$ would have complexity $O(q^2 p)$, and one would expect that the Lasso (Tibshirani, 1996) would have similar computational cost. In contrast, OLS applied to $\mathbf{S}$ would only require $O(q^3)$ operations, an improvement of q/p. The discussion above considered an optimal choice of $L \approx L_b^*$. Even if we cannot afford to work with the optimal dimension L_b^* for computational reasons, the bound will still be useful for smaller values of L. The guarantee on prediction accuracy could not be obtained if, for example, simply a random subset of L predictors were chosen and the remaining ones discarded.

The dependence of the bound on b is also interesting: a minimum value occurs for $b = 1$. However, this would imply a larger value of L_b^*. Note the memory requirement for storing $\mathbf{S}$ would be $O(nL_b^* b)$ as b bits would be required to store the locations of each of the nL_b^* nonzeroes. We see that with a constraint on nbL or on the number of permutations L, larger values of b are more favourable, particularly with high sparsity, as this would tend to make $\|\boldsymbol{\beta}^*\|_b$ not much larger than $\|\boldsymbol{\beta}^*\|_2$. A different perspective on the optimal choice of b based on the variance of inner products of rows of $\mathbf{S}$ is taken in Li and König (2011), with similar conclusions.

4.1.2 Ridge regression

Instead of using a least-squares estimator on the transformed data matrix $\mathbf{S}$ we can also apply ridge regression (Hoerl and Kennard, 1970). For a given $\lambda > 0$, the regression coefficients are found by

$$(\hat{\alpha}_\lambda, \hat{\mathbf{b}}_\lambda) := \underset{(\alpha,\mathbf{b})\in\mathbb{R}\times\mathbb{R}^L}{\arg\min} \|\mathbf{Y} - \hat{\alpha}\mathbf{1} - \mathbf{S}\mathbf{b}\|_2^2 \;\text{ such that }\; \|\mathbf{b}\|_2^2 \le \lambda, \tag{14}$$

The theorem below gives a bound on the MSPE of $(\hat{\alpha}, \hat{\mathbf{b}}_\lambda)$.

Theorem 4 *There exist regularisation parameters λ depending on $\boldsymbol{\beta}^*$ and $\mathbf{S}$ such that*

$$\mathrm{MSPE}((\hat{\alpha}_\lambda, \hat{\mathbf{b}}_\lambda)) \;\le\; \sigma\sqrt{\frac{2C}{(1-2^{-b})n}}\|\boldsymbol{\beta}^*\|_2 + \frac{C}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2 + \frac{\sigma^2}{n}.$$

Here the value of C is defined as in Theorem 3 by $C = (2-\delta)q$ for equal row sparsity δ and $C = q_{\min}\log\{4\log(L)/\delta_{\min}\}$ for $\kappa = \kappa_0$ and unequal row-sparsity.

The ridge regression result for large L is similar to that for OLS with an optimal L_b^*, though there is a small difference: the leading terms are $\sigma\|\boldsymbol{\beta}^*\|_2\sqrt{q/n}$ and $\sigma\|\boldsymbol{\beta}^*\|_b\sqrt{q/n}$ respectively. Ridge regression takes advantage of the fact that not only do we have a $\mathbf{b}^*$ such that $\mathbf{S}\mathbf{b}^*$ and $\mathbf{X}\boldsymbol{\beta}^*$ are close, we also know that there is a $\mathbf{b}^*$ with this property that has low ℓ_2-norm. Our bound on the expected squared ℓ_2-norm of $\mathbf{b}^*$ ((ii) in Theorem 1) does not depend much on b. In contrast, OLS only makes use of the approximation error result, (iii) in Theorem 1.

Note that when L is large, regardless of the value of b, ridge regression on $\mathbf{S}$ approximates a kernel ridge regression using the resemblance kernel (see Section 2.4). The MSPE of a kernel ridge regression with the resemblance kernel should of course not depend on b, and this observation largely agrees with our result.

Another key difference between ridge regression and OLS here is the following: achieving a good prediction error with OLS hinges on a careful choice of L. In contrast, with ridge regression, L can (and should) be chosen very large, from a purely statistical point of view. However, the constraint on the ℓ_2-norm of $\hat{\mathbf{b}}$ needs to be chosen carefully with ridge regression, typically by cross-validation. In practice, the number L of dimensions can be chosen as large as possible according to the available computational budget.

4.2 Logistic regression

We give an analogous result to Theorem 4 for classification problems under logistic loss. Let $\mathbf{x}_i \in [-1,1]^p$ and let $\mathbf{Y} \in \{0,1\}^n$ be an associated vector of class labels. We assume the model

$$Y_i \sim \text{Bernoulli}(p_i); \qquad \log\left(\frac{p_i}{1-p_i}\right) = \kappa(\delta_i)\mathbf{x}_i^T\boldsymbol{\beta}^*, \tag{15}$$

with the Y_i independent for $i = 1,\ldots,n$. Note that we have omitted the separate intercept term for simplicity.

Here we consider a linear classifier constructed by ℓ_2-constrained logistic regression. One can obtain a similar result for unconstrained logistic regression based on Lemma 6.6 of Bühlmann and van de Geer (2011), but we do not pursue this further here. Define

$$\hat{\mathbf{b}}_\lambda = \arg\min_{\mathbf{b}} \frac{1}{n}\sum_{i=1}^n \left[-Y_i\mathbf{s}_i^T\mathbf{b} + \log\{1+\exp(\mathbf{s}_i^T\mathbf{b})\}\right] \quad \text{such that} \quad \|\mathbf{b}\|_2^2 \le \lambda. \tag{16}$$

Let $\mathcal{E}(\hat{\mathbf{b}}_\lambda)$ denote the excess risk of $\hat{\mathbf{b}}_\lambda$ under logistic loss, so

$$\mathcal{E}(\hat{\mathbf{b}}_\lambda) = \frac{1}{n}\sum_{i=1}^n \left[-p_i\mathbf{s}_i^T\hat{\mathbf{b}}_\lambda + \log\{1+\exp(\mathbf{s}_i^T\hat{\mathbf{b}}_\lambda)\}\right] - \frac{1}{n}\sum_{i=1}^n \left[-p_i\kappa(\delta_i)\mathbf{x}_i^T\boldsymbol{\beta}^* + \log\{1+\exp(\kappa(\delta_i)\mathbf{x}_i^T\boldsymbol{\beta}^*)\}\right]. \tag{17}$$

We can now state the analogous result to Theorem 4.

Theorem 5 *Define $\tilde{p} \in \mathbb{R}$ by*

$$\tilde{p} := \frac{1}{n}\sum_{i=1}^n p_i(1-p_i) \le \frac{1}{2}. \tag{18}$$

Then we have that there exists a λ depending $\boldsymbol{\beta}^*$ and $\mathbf{S}$ such that

$$\mathbb{E}_{\mathbf{Y},\boldsymbol{\pi},\boldsymbol{\Psi}}\{\mathcal{E}(\hat{\mathbf{b}}_\lambda)\} \le \sqrt{\frac{2\tilde{p}C}{(1-2^{-b})n}}\|\boldsymbol{\beta}^*\|_2 + \frac{C}{2^{b+2}L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2.$$

Here the value of C is defined as in Theorem 3 by $C = (2-\delta)q$ for equal row sparsity δ and $C = q_{\min}\log\{4\log(L)/\delta_{\min}\}$ for $\kappa = \kappa_0$ and unequal row-sparsity.

The result illustrates that the usefulness of b-bit min-wise hashing is not limited to regression problems. In fact, most applications of are classification problems (Li and König, 2011) and our analysis of b-bit min-wise hashing here gives a theoretical explanation for its performance in these cases.

5. Interaction models

One of the compelling aspects of regression and classification with b-bit min-wise hashing is the fact that a particular form of interactions between variables can be fitted. This does not require any change in the procedure other than a possible increase in L. To be clear, in order to capture interactions with b-bit min-wise hashing, just as in the main effects case, we create a reduced matrix $\mathbf{S}$ and then fit a main effects model to $\mathbf{S}$. The dimension of the compressed data, 2^bL, can still be substantially smaller than the $O(p^2)$ number of coefficients that would need to be estimated if the interactions were modelled in the conventional way, and so the resulting computational advantage can be very large.

Note that in situations where the number of original predictors, p, may be manageable, including interactions explicitly can quickly become computationally infeasible. For example, if we start with, 10^5 variables, the two-way interactions number more than a billion. For larger values of p, even methods such as Random Forest (Breiman, 2001) or Rule Ensembles (Friedman and Popescu, 2008) would suffer similar computational problems.

We now describe a type of interaction model that can be fitted with b-bit min-wise hashing. Let $\mathbf{f}^* \in \mathbb{R}^n$ be given by

$$f_i^* = \sum_{k=1}^p X_{ik}\theta_k^{*,(1)} + \sum_{k,k_1=1}^p X_{ik}\mathbb{1}_{\{X_{ik_1}=0\}}\Theta_{k,k_1}^{*,(2)}, \quad i = 1,\ldots,n, \tag{19}$$

where $\boldsymbol{\theta}^{*,(1)} \in \mathbb{R}^p$ is a vector of coefficients for the main effects terms, and $\boldsymbol{\Theta}^{*,(2)} \in \mathbb{R}^{p\times p}$ is a matrix of coefficients for interactions whose diagonal entries are zero. As elsewhere in the paper, throughout this section we will assume that $\mathbf{X} \in [-1,1]^{n\times p}$. Note that if $\mathbf{X}$ were a binary matrix, then (19) parametrises (in fact over-parametrises) all linear combinations of bivariate functions of predictors; that is all possible two-way interactions are included in the model.

In general, the interaction model includes the tensor product of the set of original variables with the columns of an $n \times p$ matrix with ikth entry $\mathbb{1}_{\{X_{ik}=0\}}$. The value zero is thus given a special status and the model seems particularly appropriate in the sparse design setting we are considering here.

5.1 Approximation error

We will assume that the number of non-zero entries in each row of $\mathbf{X}$ is $q \geq 1$. However, we believe our proof techniques can be extended to the unequal sparsity and unknown row scaling scenario dealt with in Section 3.2. Furthermore, for technical reasons, we assume here that $p \geq 3$.

Let $\mathbf{\Theta}^*$ collect together $\boldsymbol{\theta}^{*,(1)}$ and $\mathbf{\Theta}^{*,(2)}$ and define the following norms analogously to (5):

$$\|\mathbf{\Theta}^*\| := \|\boldsymbol{\theta}^{*,(1)}\|_2 + \left(2(2-\delta)q \sum_{k,k_1,k_2} \left|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\right|\right)^{1/2}, \tag{20}$$

$$\|\mathbf{\Theta}^*\|_b := \|\boldsymbol{\theta}^{*,(1)}\|_b + \left\{2(2-\delta)q\left(\sum_{k,k_1,k_2}\left|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\right| + \delta(2^b-2)\sum_{k,k_1,k_2}\frac{\|\mathbf{X}_k\|_2^2}{n}\left|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\right|\right)\right\}^{1/2}. \tag{21}$$

Theorem 6 *Suppose we have exactly q non-zero entries in each row of $\mathbf{X}$. Then there exists a vector $\mathbf{b}^* \in \mathbb{R}^{2^b L}$ with the following properties:*

(i) The approximation is unbiased, $\mathbb{E}_{\boldsymbol{\pi},\mathbf{\Psi}}(\mathbf{S}\mathbf{b}^*) = \mathbf{f}^*$.

(ii) The ℓ_2-norm is bounded by

$$\mathbb{E}_{\boldsymbol{\pi},\mathbf{\Psi}}(\|\mathbf{b}^*\|_2^2) \leq \frac{(2-\delta)q}{L(1-2^{-b})}\|\mathbf{\Theta}^*\|^2.$$

(iii) The approximation error is bounded by

$$\mathbb{E}_{\boldsymbol{\pi},\mathbf{\Psi}}(\|\mathbf{S}\mathbf{b}^* - \mathbf{f}^*\|_2^2)/n \leq \frac{(2-\delta)q}{2^b L(1-2^{-b})}\|\mathbf{\Theta}^*\|_b^2.$$

The bound on the approximation error in (iii) is most suited to situations where there are a fixed number of interaction terms, so

$$\sum_{k,k_1,k_2}\left|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\right| = O(1). \tag{22}$$

Then we see that the contribution of the interaction terms to the bound on the approximation error is of order q^2. On the other hand, if we are considering a growing number of many small interaction terms, much tighter bounds than that given by (iii) can be obtained. The bounds above show in particular that the form of function given by (19) lies in the RKHS of the resemblance kernel and its RKHS norm is upper bounded by $(2-\delta)q\|\mathbf{\Theta}^*\|^2$; further details are given in the appendix Section B.

The results for interaction models corresponding to Theorems 3, 4 and 5 now follow.

5.2 Prediction error

We now present results for linear and logistic regression models where the signal involves interactions.

5.2.1 Linear regression models

Assume the model (10) and define the MSPE by (11) but in both cases with $\mathbf{X}\boldsymbol{\beta}^*$ now replaced by $\mathbf{f}^*$ (19). As in the previous section, we will assume that $\mathbf{X}$ has q non-zero entries in each row. When OLS estimation is used, we have the following result.

Theorem 7 *Let $(\hat{\alpha}, \hat{\mathbf{b}})$ be the least squares estimator (12). Then*

$$\text{MSPE}((\hat{\alpha},\hat{\mathbf{b}})) \;\leq\; \frac{(2-\delta)q}{2^b L(1-2^{-b})}\|\mathbf{\Theta}^*\|_b^2 + 2^b L\frac{\sigma^2}{n}.$$

To interpret the result, consider a situation where there are a fixed number of interaction and main effects of fixed size, so in particular (22) holds. Then treating b as fixed, the optimal L, $L^* = O(\sqrt{q^2 n/\sigma})$. If n, q and p increase by collecting new data and adding uninformative variables, then in order for the MSPE to vanish asymptotically, we require $q^2/n \to 0$. Compare this to the corresponding requirement of OLS applied to $\mathbf{X}$, that $p^2/n \to 0$. Particularly in situations of increasing variable sparseness, as discussed in Section 4.1.1, this can amount to a large statistical advantage.

The computational gains can be equally great. If, for example, $n \approx q^2$, then $L^* = O(q^2)$. If ridge regression were applied to $\mathbf{X}$ augmented by $O(p^2)$ interaction terms, the number of operations required would be $O(p^2q^4)$; OLS using $\mathbf{S}$ has complexity $O(q^6)$. If instead $n \approx p^2$, then regression with explicitly coded interaction terms would have complexity $O(p^6)$, whilst with the compressed data this would be reduced to $O(p^4q^2)$.

As in the main effects case, the ridge regression result is similar.

Theorem 8 *Let the ridge regression estimator be given by* (14)*. There exists λ depending on $\mathbf{f}^*$ and $\mathbf{S}$ such that we have*

$$\text{MSPE}((\hat{\alpha},\hat{\mathbf{b}})) \;\leq \sigma\sqrt{\frac{(2-\delta)q}{n(1-2^{-b})}}\|\mathbf{\Theta}^*\| + \frac{(2-\delta)q}{2^b L(1-2^{-b})}\|\mathbf{\Theta}^*\|_b^2 + \frac{\sigma^2}{n}.$$

Similarly to Theorem 4 the result here suggests choosing a large L is always better from a statistical point of view. However, for computational reasons, it may not be possible to take L much larger than L^*.

5.2.2 Logistic regression

Here we assume the model (15) and define the excess risk by (17), but in both cases with $\mathbf{X}\boldsymbol{\beta}^*$ replaced by $\mathbf{f}^*$.

Theorem 9 *Define $\tilde{p} \in \mathbb{R}$ as in* (18) *and the ℓ_2-penalised logistic regression estimator as in* (16)*. Then we have that there exists λ such that*

$$\mathbb{E}_{\mathbf{Y},\boldsymbol{\pi},\mathbf{\Psi}}\{\mathcal{E}(\hat{\mathbf{b}}_\lambda)\} \leq \sigma\sqrt{\frac{\tilde{p}(2-\delta)q}{n(1-2^{-b})}}\|\mathbf{\Theta}^*\| + \frac{(2-\delta)q}{2^{b+2}L(1-2^{-b})}\|\mathbf{\Theta}^*\|_b^2.$$

One could continue to look at higher-order interaction models by adding three-way interactions in (19) and adapting (20) and (21) in suitable ways. However, being able to show that two-way interaction models can be fitted with b-bit min-wise hashing may well be sufficient for most applications.

6. Extensions

We now describe some extensions to the methodology.

6.1 Variable importance

Typically prediction, rather than model selection, is the primary goal in large-scale applications with sparse data, one reason for this being that we cannot expect a very small subset of variables to approximate the signal well when the design matrix is sparse. Nevertheless, it is often illuminating to study the influence of specific variables or look for the variables that have the largest influence on predictions. Indeed, such study is often undertaken following applications of Random Forest (Breiman, 2001), where several variable importance measures allow practitioners to better interpret the fits produced.

We now describe how importance measures can be obtained for b-bit min-wise hashing as described in Section 2.3. Let $\hat{f} : \mathbb{R}^p \to \mathbb{R}$ be the regression function created following regression on b-bit min-wise hashed data, and let $\hat{f}_i := \hat{f}(\mathbf{x}_i)$. Furthermore, for $k = 1, \ldots, p$, let $\hat{f}^{(-k)} := \hat{f}(\mathbf{x}_i^{(-k)})$, where $\mathbf{x}_i^{(-k)}$ is equal to $\mathbf{x}_i$ but with kth component set to zero.

The vector $\hat{\mathbf{f}} - \hat{\mathbf{f}}^{(-k)}$ is the difference in predictions obtained when fitting to $\mathbf{X}$, and those obtained when fitting to $\mathbf{X}$ with the kth column set to zero. When the underlying model in $\mathbf{X}$ contains only main effects (10) and no structural error is present, we might expect that

$$\hat{\mathbf{f}} - \hat{\mathbf{f}}^{(-k)} \approx \boldsymbol{\beta}_k^* \mathbf{X}_k.$$

To obtain a measure of variable importance, one could look at the ℓ_2-norm of $\hat{\mathbf{f}} - \hat{\mathbf{f}}^{(-k)}$, for example (Breiman, 2001).

The difference in predictions can be computed relatively easily by considering the $n \times 2^b L$ matrix $\tilde{\mathbf{S}}$ with entries given by $\tilde{S}_{ilc} = \tilde{S}_{i(c+(l-1)2^b} = X_{i\tilde{H}_{il}} \mathbb{1}_{\{\Psi_{\tilde{H}_{il}l} = c\}}$, where

$$\tilde{H}_{il} := \underset{k \in \mathbf{z}_i \setminus H_{il}}{\arg\min}\, \pi_l(k).$$

Thus $\tilde{H}_{il}$ is the variable index in $\mathbf{z}_i$ whose value under permutation π_l is second smallest among $\{\pi_l(k) : k \in \mathbf{z}_i\}$. If $\mathbf{z}_i \setminus H_{il} = \emptyset$, we simply set $\tilde{S}_{il} = 0$. Then

$$\hat{f}_i - \hat{f}_i^{(-k)} = \sum_{l=1}^{L} \mathbb{1}_{\{H_{il}=k\}} \sum_{c=1}^{2^b} (S_{ilc} - \tilde{S}_{ilc}) \hat{b}_{lc}. \tag{23}$$

Note that we only need to store the $n \times L$ matrix $\mathbf{H}$ and $n \times 2^b L$ matrices $\mathbf{S}$ and $\tilde{\mathbf{S}}$ to compute the variable importance for all variables; moreover the latter matrices only have at most nL non-zero entries each.

Interaction effects are not directly visible, but do manifest themselves in the form of a higher variability among $\{\hat{f}_i - \hat{f}_i^{(-k)} : \mathbf{x}_i \approx \mathbf{x}\}$, for any given value of $\mathbf{x}$, if variable k is involved in an interaction term. In principle, one could attempt to detect this increased variability, but further investigation of this is beyond the scope of the current work.

6.2 Other fitting procedures

Here we have only considered OLS, ridge regression and ℓ_2-penalised logistic regression as prediction methods after reducing the design matrix. However, it is also conceivable that other fitting procedures could be suitable. In particular, it would be interesting to look at matching pursuit, boosting and the Lasso, for which results in (Tropp, 2004; Bühlmann, 2006; Van De Geer, 2008) could be leveraged. Matching pursuit would have the computational advantage that the entire $\mathbf{S}$ matrix would not need to be held in memory. Instead, one could create the columns during the fitting process. Such an approach may be useful for problems where the dimension of the hashing-matrix, $2^b L$, needs to be very large to achieve a desired predictive accuracy.

7. Discussion

In this paper we have derived approximation error bounds for b-bit min-wise hashing. We were able to show that not only does b-bit min-wise hashing take advantage of sparsity in the design matrix computationally, it is also able to exploit this for improved statistical performance. In particular, the MSPE of regression following dimension reduction by b-bit min-wise hashing is of the form $\sqrt{q/n}\|\boldsymbol{\beta}^*\|_2$ if the data follow a linear model with coefficient vector $\boldsymbol{\beta}^*$ and q is the average number of non-zero variables for an observation. The linear model can then be well-approximated by the low-dimensional b-bit min-wise hashed data if the norm of $\|\boldsymbol{\beta}^*\|_2$ is low, as occurs, for example if the signal is approximately replicated in distinct blocks of variables.

In addition, we have shown that more complicated models such as interaction models can be fitted by a regression on the hashed data matrix that contains only main effects. Though a larger dimension L of the hashed data may be required than when approximating a main effects model, no further changes are needed to the procedure.

These bounds also reveal some of the predictive properties of the resemblance kernel, and provide an insight into the sorts of regression functions that have small norm in its associated RKHS. More generally, we believe that random feature expansions may well be useful as a theoretical tool to understand properties of otherwise intractable kernels. We expect to see more extensions and applications b-bit min-wise hashing and other random feature expansions, both as computational and theoretical tools, in the future.

Appendix A. Approximation error results

In this section we prove results on the approximation error presented in the main text (Theorems 1, 2 and 6) as well as an additional result on the approximation error of linear signals when row sparsity is not necessarily equal (Theorem 12).

A.1 Preliminary results

We will let q_i be the number of non-zeroes in the ith row of $\mathbf{X}$ and define $\delta_i = q_i/p$. We will assume that $q_i \geq 1$ for all i. For the proofs of results on approximation error in settings with just main effects, we will make use of the following lemma. This lemma formalises the ideas of the discussion at the end of Section 3.2, that the elements of $\mathbf{M}$ behave rather like geometric random variables.

Lemma 10 *There exist random functions $\{g_l(k)\}_{l=1,\ldots,L,\, k=1,\ldots,p}$ defined on the same probability space as the permutations $\boldsymbol{\pi}$ with the following properties:*

(i) The random variables $\{g_1(k)\}_{k=1,\ldots,p}, \ldots, \{g_L(k)\}_{k=1,\ldots,p}$ are i.i.d. and are independent of $\boldsymbol{\Psi}$.

(ii) The rank of $g_l(k)$ among $g_l(1), \ldots, g_l(p)$ taken in increasing order is $\pi_l(k)$.

(iii) Marginally $g_l(k) \sim Geo(p^{-1})$.

(iv) $G_{il} := \min_{k \in \mathbf{z}_i} g_l(k) = g_l(H_{il}) \sim Geo(\delta_i)$.

(v) $\mathbf{G}$ and $\mathbf{H}$ are independent.

Proof First consider generating permutations $\boldsymbol{\pi}$ in the following way. Let $m \in \mathbb{N}$ and let $\sigma_1^{(m)}, \ldots, \sigma_L^{(m)}$ be L i.i.d. random permutations of $\{1, \ldots, mp\}$. For $k = 1, \ldots, p$, let

$$g_l^{(m)}(k) = \min_{a=0,\ldots,m-1} \sigma_l^{(m)}(k + ap).$$

Note that the $g_l^{(m)}(k)$ are all distinct and any ordering of them is equally likely so they define a random permutation of $\{1, \ldots, p\}$. Furthermore, for $j = 1, \ldots, mp - m + 1$,

$$\mathbb{P}(g_l^{(m)}(k) = j) = \binom{mp - j}{m - 1} \Big/ \binom{mp}{m} = \frac{1}{p}\left(1 - \frac{1 - m^{-1}}{p - m^{-1}}\right) \cdots \left(1 - \frac{1 - m^{-1}}{p - (j-1)m^{-1}}\right).$$

Thus

$$\mathbb{P}(g_l^{(m)}(k) = j) \to \frac{1}{p}\left(1 - \frac{1}{p}\right)^{j-1}$$

as $m \to \infty$ for $j = 1, 2, \ldots$. Similarly $G_{il}^{(m)} := \min_{k \in \mathbf{z}_i} g_l^{(m)}(k)$ has $\mathbb{P}(G_{il}^{(m)} = j) \to \delta_i(1 - \delta_i)^{j-1}$ as $m \to \infty$. Note that $\mathbf{G}^{(m)}$ and $\mathbf{H}$ are independent. Thus

$$\{g_l^{(m)}(k)\}_{l=1,\ldots,L, k=1,\ldots,p} \xrightarrow{d} \{g_l(k)\}_{l=1,\ldots,L, k=1,\ldots,p}$$

as $m \to \infty$ with the random variables $g_l(k)$ having the properties given in the statement of the lemma. ■

In the proofs which follow, we will consider the permutations as having been generated as described by Lemma 10. We will let $\pi = \pi_1$, $M_i = M_{i1}$, $g = g_1$, $G_1 = G_{i1}$, $H_i = H_{i1}$ and $\boldsymbol{\psi} = \boldsymbol{\Psi}_1$. Let $C = 2^b$, $\nu = 2^{-b}$.

The next lemma introduces the general form of $\mathbf{b}^*$ that we will use for the main effects results. It also establishes results on the mean and variance of the approximation and gives a bound on $\mathbb{E}(\|\mathbf{b}^*\|_2^2)$; these will form the basis of the theorems to follow.

Lemma 11 *For a given sequence of weights $\{w_j\}_{j=1}^{\infty}$, let $\tilde{\mathbf{b}}^* \in \mathbb{R}^{LC}$ be given by*

$$\tilde{b}^*_{lc} = \frac{1}{L}\sum_{k=1}^{p} \beta^*_k \frac{\mathbb{1}_{\{\Psi_{lk} = c\}} - \nu}{1 - \nu} w_{g_l(k)}$$

and let $\mathbf{b}^* = \mathbb{E}(\tilde{\mathbf{b}}^* | \boldsymbol{\pi})$. We have the following.

(i)

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T \mathbf{b}^*) = \frac{1}{p}\mathbf{x}_i^T \boldsymbol{\beta}^* \sum_{\ell=1}^{\infty} (1 - \delta_i)^{\ell - 1} w_\ell.$$

(ii)

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^*\|_2^2) \leq \frac{1}{pL(1-\nu)} \|\boldsymbol{\beta}^*\|_2^2 \sum_{\ell=1}^{\infty} w_\ell^2. \tag{24}$$

(iii)

$$\mathrm{Var}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T \mathbf{b}^*) \leq \frac{1}{pL(1-\nu)} \left(\nu \|\boldsymbol{\beta}^*\|_2^2 + (1 - 2\nu) \sum_{k=1}^{p} X_{ik}^2 \beta_k^{*2}\right) \sum_{\ell=1}^{\infty} w_\ell^2. \tag{25}$$

Proof First note that

$$\mathbb{E}\left(\frac{\mathbb{1}_{\{\psi_k = \psi_j\}} - \nu}{1 - \nu} \middle| \psi_j\right) = \begin{cases} 1 & \text{if } k = j \\ 0 & \text{otherwise} \end{cases} \tag{26}$$

$$\mathbb{E}\left(\frac{\mathbb{1}_{\{\psi_k = \psi_j\}} - \nu}{1 - \nu} \frac{\mathbb{1}_{\{\psi_\ell = \psi_j\}} - \nu}{1 - \nu} \middle| \psi_j\right) = \begin{cases} 1 & \text{if } k = \ell = j \\ 0 & \text{if } k \neq \ell \\ \frac{\nu}{1-\nu} & \text{otherwise.} \end{cases} \tag{27}$$

For (i), we have

$$\begin{aligned} \mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T \mathbf{b}^*) &= \mathbb{E}_{g,\psi}\left(\sum_{c=1}^{C}\sum_{j=1}^{p} X_{ij} \mathbb{1}_{\{H_i = j\}} \mathbb{1}_{\{\psi_j = c\}} \sum_{k=1}^{p} \beta_k^* \frac{\mathbb{1}_{\{\psi_k = c\}} - \nu}{1 - \nu} w_{g(k)}\right) \\ &= \mathbb{E}_g\left(\sum_{k=1}^{p} X_{ik} \mathbb{1}_{\{H_i = k\}} \beta_k^* w_{g(k)}\right) \\ &= \frac{1}{q_i}\sum_{k=1}^{p} X_{ik} \beta_k^* \mathbb{E}(w_{G_i}), \end{aligned}$$

where to arrive at the second line we used (26).

Turning to (ii), note that each component of $\mathbf{b}^*$ has mean zero and so

$$\mathbb{E}(b^{*2}_{lc}) = \mathrm{Var}(b^*_{lc}) = \mathrm{Var}\{\mathbb{E}(\tilde{b}^*_{lc} | \boldsymbol{\pi})\} \leq \mathrm{Var}(\tilde{b}^*_{lc}).$$

Now we have

$$\mathbb{E}_{g_1,\ldots,g_L,\boldsymbol{\Psi}}\|\tilde{\mathbf{b}}^*\|_2^2 = \frac{1}{L}\sum_{c=1}^{C}\sum_{k,\ell}\beta_k^*\beta_\ell^*\mathbb{E}\Big(\frac{\mathbb{1}_{\{\psi_k=c\}}-\nu}{1-\nu}\frac{\mathbb{1}_{\{\psi_\ell=c\}}-\nu}{1-\nu}\Big)\mathbb{E}(w_{g(k)}w_{g(\ell)})$$

Using (27), we get

$$\mathbb{E}_{g_1,\ldots,g_L,\boldsymbol{\Psi}}\|\tilde{\mathbf{b}}^*\|_2^2 = \frac{1}{L(1-\nu)}\sum_k \beta_k^{*2}\mathbb{E}(w_{g(k)}^2) \le \frac{1}{pL(1-\nu)}\|\boldsymbol{\beta}^*\|_2^2\sum_{\ell=1}^{\infty}w_\ell^2.$$

For (iii) we argue as follows.

$$\begin{aligned}\mathrm{Var}(\mathbf{s}_i^T\mathbf{b}^*) &\le \mathrm{Var}(\mathbf{s}_i^T\tilde{\mathbf{b}}^*)\\ &\le \frac{1}{L}\mathbb{E}_{g,\psi}\Big(X_{iH_i}^2\sum_{k,\ell}\beta_k^*\beta_\ell^*\frac{\mathbb{1}_{\{\psi_k=\psi_{H_i}\}}-\nu}{1-\nu}\frac{\mathbb{1}_{\{\psi_\ell=\psi_{H_i}\}}-\nu}{1-\nu}w_{g(k)}w_{g(\ell)}\Big)\end{aligned}$$

Using (27) and the fact that $\mathbf{X}\in[-1,1]^{n\times p}$, we have

$$\begin{aligned}\mathrm{Var}(\mathbf{s}_i^T\mathbf{b}^*) &\le \frac{1}{L}\mathbb{E}\Big\{X_{iH_i}^2\Big(\frac{\nu}{1-\nu}\sum_{k=1}^{p}(\beta_k^*)^2w_{g(k)}^2+\frac{1-2\nu}{1-\nu}(\beta_{H_i}^*)^2w_{G_i}^2\Big)\Big\} \qquad (28)\\ &\le \frac{1}{L(1-\nu)}\Big\{\nu\sum_{k=1}^{p}\beta_k^{*2}\mathbb{E}(w_{g(k)}^2)+\frac{1-2\nu}{q_i}\mathbb{E}(w_{G_i}^2)\sum_{k=1}^{p}X_{ik}^2\beta_k^{*2}\Big\}.\end{aligned}$$

The result then follows as

$$\sum_{\ell=1}^{\infty}w_\ell^2 \ge \mathbb{E}(w_{g(k)}^2) = \frac{1}{p}\sum_{\ell=1}^{\infty}w_\ell^2\Big(1-\frac{1}{p}\Big)^{\ell-1} \ge \frac{\delta_i}{q_i}\sum_{\ell=1}^{\infty}w_\ell^2(1-\delta_i)^{\ell-1} = \frac{\mathbb{E}(w_{G_i}^2)}{q_i}.$$

■

A.2 Proof of Theorem 1

We use a $\mathbf{b}^*$ and $\tilde{\mathbf{b}}^*$ as in Lemma 11 but here we choose the weights w_ℓ so as to minimise $\sum_{\ell=1}^{\infty}w_\ell^2$ (a term which features in our upper bounds on the variance and $\mathbb{E}(\|\mathbf{b}^*\|_2^2)$) subject to the unbiasedness constraint (i). The unbiasedness constraint amounts to

$$\sum_{\ell=1}^{\infty}(1-\delta)^{\ell-1}w_\ell = p.$$

Performing the minimisation with this constraint yields

$$w_\ell = p\frac{(1-\delta)^{\ell-1}}{\sum_{\ell=1}^{\infty}(1-\delta)^{2\ell-2}}.$$

With this choice we have

$$\sum_{\ell=1}^{\infty}w_\ell^2 = p^2\Big(\sum_{\ell=1}^{\infty}(1-\delta)^{2\ell-2}\Big)^{-1} = p^2\{1-(1-\delta)^2\} = (2-\delta)qp.$$

Substituting into (24) and (25) then yields the result.

A.3 Proof of Theorem 2

We use a $\mathbf{b}^*$ and $\tilde{\mathbf{b}}^*$ as in Lemma 11 but here we take

$$w_{\ell+1} = p(-1)^\ell\frac{\kappa^{(\ell)}(1)}{\ell!}\{\mathbb{1}_{\{\ell\le\lfloor m\rfloor\}}+(m-\lfloor m\rfloor)\mathbb{1}_{\{\ell=\lceil m\rceil\}}\}$$

where $m>0$ is a parameter to be chosen. Thus the weights correspond to coefficients from a truncated Taylor series expansion of κ about 1. We have

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}[\{(\delta_{\min}/\delta_i)^a\mathbf{x}_i^T\boldsymbol{\beta}^*-\mathbf{s}_i^T\mathbf{b}^*\}^2] = \{(\delta_{\min}/\delta_i)^a\mathbf{x}_i^T\boldsymbol{\beta}^*-\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T\mathbf{b}^*)\}^2+\mathrm{Var}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T\mathbf{b}^*).$$

We first bound the variance term by bounding the squared sum of the sequence of weights. To this end, we note that by Lemma 20

$$\frac{\delta_{\min}^{-2a}}{p^2}\sum_{\ell=1}^{\infty}w_\ell^2 \le 1+a^2+a^2e^{2a}\Big(\sum_{\ell=2}^{\lfloor m\rfloor}\frac{1}{\ell^{2(1-a)}}+\frac{m-\lfloor m\rfloor}{\lceil m\rceil^{2(1-a)}}\Big).$$

Now

$$\begin{aligned}\sum_{\ell=2}^{\lfloor m\rfloor}\frac{1}{\ell^{2(1-a)}}+\frac{m-\lfloor m\rfloor}{\lceil m\rceil^{2(1-a)}} &\le \int_1^m\frac{1}{\ell^{2(a-1)}}d\ell\\ &= \begin{cases}\frac{m^{2a-1}-1}{2a-1} & \text{if } a\ne 1/2\\ \log(m) & \text{if } a=1/2.\end{cases}\end{aligned}$$

Let

$$\tau_a(m) = \begin{cases}e\log(me^{5/e})/4 & \text{if } a=1/2,\\ a^2e^{2a}m^{2a-1}/(2a-1) & \text{if } 1/2<a\le 1.\end{cases}$$

Then

$$\sum_{\ell=1}^{\infty}w_\ell^2 \le p^2\delta_{\min}^{2a}\tau_a(m). \qquad (29)$$

The variance is then at most

$$\delta_{\min}^{2a}\tau_a(m)\frac{p}{L(1-\nu)}\Big(\nu\|\boldsymbol{\beta}^*\|_2^2+(1-2\nu)\sum_{k=1}^{p}X_{ik}^2\beta_k^{*2}\Big).$$

Turning now to the bias term, note first that by (i) of Lemma 11, this is equal to

$$(\mathbf{x}_i^T\boldsymbol{\beta}^*)^2\Big\{(\delta_{\min}/\delta_i)^a-\frac{1}{p}\sum_{\ell=1}^{\infty}(1-\delta_i)^{\ell-1}w_\ell\Big\}^2. \qquad (30)$$

We see this is bounded above by

$$\delta_{\min}^{2a}(\mathbf{x}_i^T\boldsymbol{\beta}^*)^2\Big\{ae^a\Big(\sum_{\ell=\lceil m\rceil}^{\infty}(1-\delta_i)^\ell\frac{1}{\ell^{1-a}}\Big)\Big\}^2.$$

Now

$$\sum_{\ell=\lceil m\rceil}^{\infty}(1-\delta_i)^{\ell}\frac{1}{\ell^{1-a}} \le \frac{e^{-\delta_i m}}{m^{1-a}\delta_i}.$$

By the Cauchy–Schwarz inequality (assuming $X_{ij}\in[-1,1]$)

$$\frac{(\mathbf{x}_i^T\boldsymbol{\beta}^*)^2}{\delta_i} = \frac{1}{\delta_i}\Big(\sum_{k\in\mathbf{z}_i} X_{ik}\beta_k^*\Big)^2 \le p\sum_{k=1}^{p} X_{ik}^2\beta_k^{*2} \le p\|\boldsymbol{\beta}^*\|_2^2.$$

Thus the squared bias is at most

$$\frac{p}{1-\nu}\frac{a^2e^{2a}}{m^{1-2a}}\max_{i=1,\ldots,n}\Big(\frac{e^{-2\delta_i m}}{m\delta_i}\Big)\Big(\nu\|\boldsymbol{\beta}^*\|_2^2 + (1-2\nu)\sum_{k=1}^{p}X_{ik}^2\beta_k^{*2}\Big).$$

Therefore the MSE (now averaging over the observations) is bounded by the minimum over $m>0$ of

$$\frac{p}{L(1-2^{-b})}\delta_{\min}^{2a}\Big\{\tau_a(m) + \frac{a^2e^{2a}}{m^{1-2a}}\max_{i=1,\ldots,n}\Big(\frac{e^{-2\delta_i m}}{m\delta_i}\Big)\Big\}\|\boldsymbol{\beta}^*\|_b^2.$$

For $a=1/2$, we set $m=\log(L)/\{2\delta_{\min}\}$. This yields

$$\begin{aligned}\min_{m>0}\Big\{\tau_{1/2}(m) + \frac{Le}{4}\max_{i=1,\ldots,n}\Big(\frac{e^{-2\delta_i m}}{m\delta_i}\Big)\Big\} &\le \frac{e}{4}\Big\{\log\Big(\frac{\log(L)e^{5/e}}{2\delta_{\min}}\Big) + \frac{2}{\log(L)}\Big\}\\ &\le \log\{4\log(L)/\delta_{\min}\}\end{aligned}$$

provided $L\ge 10$ and $\delta_{\min}\le 1/2$. Finally the bound for $a>1/2$ comes from setting

$$m = \frac{1}{2}\log\{2(2a-1)L\}/\delta_{\min}$$

which gives

$$\begin{aligned}\min_{m>0}\Big\{\tau_a(m) + \frac{La^2e^{2a}}{m^{1-2a}}\max_{i=1,\ldots,n}\Big(\frac{e^{-2\delta_i m}}{m\delta_i}\Big)\Big\} &\le \frac{\delta_{\min}^{1-2a}a^2e^{2a}}{2^{2a-1}(2a-1)}[\log\{2(2a-1)L\}]^{2a-2}\log\{2(2a-1)eL\}\\ &\le \frac{4\delta_{\min}^{1-2a}}{1-2a}[\log\{2(2a-1)L\}]^{2a-1}\end{aligned}$$

for $L\ge 2/(1-2a)$. Using the bounds on τ_a with these choices of m and (29), we obtain the bounds on $\mathbb{E}(\|\mathbf{b}^*\|_2^2)$ by substituting into (24).

A.4 Unequal row sparsity and constant row-scaling

Here we prove results indicated after the presentation of Theorem 1 in Section 3.1. When the scaling function is simply the constant 1, the spread of the δ_i becomes more critical in determining how well the signal can be approximated. Define

$$\bar\delta = \frac{1}{n}\sum_{i=1}^{n}\delta_i,$$

$$\mathcal{V}(\boldsymbol{\delta}) = \frac{1}{\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2}\sum_{i=1}^{n}(\mathbf{x}_i^T\boldsymbol{\beta}^*)^2(\delta_i-\bar\delta)^2.$$

Theorem 12 *Suppose*

$$2^bL(1-2^{-b}) \le \frac{p(2\bar\delta)^3\|\boldsymbol{\beta}^*\|_b^2}{\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2\mathcal{V}(\boldsymbol{\delta})/n}. \tag{31}$$

Then there exists $\mathbf{b}^*\in\mathbb{R}^L$ *such that the approximation error satisfies*

$$\frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}\{\|\mathbf{X}\boldsymbol{\beta}^* - \mathbf{S}\mathbf{b}^*\|_2^2\} \le \frac{6p\bar\delta}{2^bL(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2, \tag{32}$$

and

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^*\|_2^2) \le \frac{2\bar q}{L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_2^2. \tag{33}$$

Provided 2^bL is not too large, we recover essentially the same approximation error bound as Theorem 1 up to a constant factor, but with the row sparsity replaced by the average row sparsity $\bar\delta$. In the simple situation where the entries of $\mathbf{X}$ are realisations of i.i.d. Bernoulli random variables with probability δ, we would have $\bar\delta\approx\delta$, $\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2/n\approx\delta\|\boldsymbol{\beta}^*\|_2^2$ and $\mathcal{V}(\boldsymbol{\delta})\approx\delta/p$. Substituting these values into the requirement on 2^bL shows that the condition reduces to $2^bL\le 8p^2\delta\{1+(2^b-2)\delta\}$. Note that typically one would choose 2^bL of the order $\bar\delta p$. More generally, provided $\mathcal{V}(\boldsymbol{\delta})$ and $\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2/\|\boldsymbol{\beta}^*\|_2^2$ are small, we can expect that the bound of Theorem 1 will hold true, up to a constant factor.

Proof of Theorem 12

We use a $\mathbf{b}^*$ and $\tilde{\mathbf{b}}^*$ as in Lemma 11 taking

$$w_\ell = p(1-\bar\delta)^{\ell-1}\mathbb{1}_{\{\ell\le m\}}\frac{\bar\delta(2-\bar\delta)}{1-(1-\bar\delta)^{2m}}.$$

where $m\in\mathbb{N}$ is a parameter to be chosen. This gives

$$\frac{1}{p^2}\sum_{\ell=1}^{\infty}w_\ell^2 = \frac{\bar\delta(2-\bar\delta)}{1-(1-\bar\delta)^{2m}},$$

which gives us a bound on the variance term.

Lemma 11 (i) gives the expression for the bias term. To bound this, first note that

$$\frac{1}{p}\sum_{\ell=1}^{m}(1-\bar\delta)^{\ell-1}w_\ell = 1.$$

Next

$$\begin{aligned}\Big[\sum_{\ell=1}^{m}(1-\bar\delta)^{\ell-1}\{(1-\bar\delta)^{\ell-1}-(1-\delta_i)^{\ell-1}\}\Big]^2 &= (\delta_i-\bar\delta)^2\Big[\sum_{\ell=1}^{m}(1-\bar\delta)^{\ell-1}\sum_{k=0}^{\ell-2}(1-\bar\delta)^k(1-\delta_i)^{\ell-2-k}\Big]^2\\ &\le (\delta_i-\bar\delta)^2\Big(\sum_{\ell=1}^{m}(1-\bar\delta)^{\ell-1}(\ell-1)\Big)^2\\ &= \min\Big\{\frac{m(m-1)}{2},\frac{1}{\bar\delta^2}\Big\}(\delta_i-\bar\delta)^2.\end{aligned}$$

Also note that as

$$(1-\bar{\delta})^{2m} \leq 1 - 2m\bar{\delta} + m(2m-1)\bar{\delta}^2$$

we have

$$\begin{aligned}\frac{\bar{\delta}(2-\bar{\delta})}{1-(1-\bar{\delta})^{2m}} &\leq \frac{2}{2m - m(2m-1)\bar{\delta}}\mathbb{1}_{\{m \leq 1/(2\bar{\delta})\}} + \frac{2}{1/\bar{\delta} - (1/\bar{\delta}-1)/2}\mathbb{1}_{\{m > 1/(2\bar{\delta})\}} \\ &\leq \max\left(\frac{2}{m+1/2}, \frac{4\bar{\delta}}{1+\bar{\delta}}\right)\end{aligned}$$

and for $m \leq 1/(2\bar{\delta}) + 1/2$,

$$\frac{m(m-1)}{2}\max\left(\frac{2}{m+1/2}, \frac{4\bar{\delta}}{1+\bar{\delta}}\right) \leq (m-1/2)\mathbb{1}_{\{1 < m \leq 1/(2\bar{\delta})+1/2\}}.$$

Thus the overall approximation error is bounded above by the minimum over $m = 1, 2, \ldots, \lfloor 1/(2\bar{\delta}) + 1/2 \rfloor$ of

$$\mathbb{1}_{\{m>1\}}(m-1/2)^2\frac{1}{n}\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2\mathcal{V}(\boldsymbol{\delta}) + \max\left(\frac{2}{m+1/2}, 4\bar{\delta}\right)\frac{p}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2,$$

which in turn is bounded by the minimum over $m \in [0, 1/(2\bar{\delta})]$ of

$$m^2\frac{1}{n}\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2\mathcal{V}(\boldsymbol{\delta}) + \frac{2}{m}\frac{p}{2^b L(1-2^{-b})}\|\boldsymbol{\beta}^*\|_b^2. \tag{34}$$

Optimising over $m > 0$ in the above then gives

$$m = \min\left\{\left(\frac{p\|\boldsymbol{\beta}^*\|_b^2}{2^b L(1-2^{-b})\|\mathbf{X}\boldsymbol{\beta}^*\|_2^2\mathcal{V}(\boldsymbol{\delta})/n}\right)^{1/3}, \frac{1}{2\bar{\delta}}\right\}.$$

The condition on L (31) ensures that the minimum is achieved at $1/(2\bar{\delta})$. Substituting this value of m into (34) then gives (32). For (33) we note that

$$\sum_{\ell=1}^{\infty} w_\ell^2 \leq 2p^2\bar{\delta};$$

the result follows using Lemma 11 (ii).

A.5 Proof of Theorem 6

We let $\mathbf{b}^* = \mathbf{b}^{*,(1)} + \mathbf{b}^{*,(2)}$ where $\mathbf{b}^{*,(1)}$ is chosen in line with Theorem 1. Explicitly, let $\mathbf{b}^{*,(1)} = \mathbb{E}(\tilde{\mathbf{b}}^*|\boldsymbol{\pi})$ where

$$\tilde{b}_{lc}^* = \frac{p}{L}\sum_{k=1}^{p}\theta_k^{*,(1)}\frac{\mathbb{1}_{\{\Psi_{lk}=c\}} - \nu}{1-\nu}\frac{(1-\delta)^{g_l(k)-1}}{\sum_{\ell=1}^{\infty}(1-\delta)^{2\ell-2}}.$$

We construct $\mathbf{b}^{*,(2)}$ to approximate the interactions as follows. Let

$$b_{lc}^{*,(2)} = \frac{pq}{L}\sum_{k=1}^{p}\frac{\mathbb{1}_{\{\Psi_{lk}=c\}} - \nu}{1-\nu}\sum_{k_1=1}^{p}\Theta_{kk_1}^{*,(2)}\mathbb{1}_{\{\pi_l(k_1)<\pi_l(k)\}}w_{\pi_l(k)},$$

where $\mathbf{w} \in \mathbb{R}^p$ is a vector of weights to be chosen such that

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T\mathbf{b}^{*,(2)}) = \sum_{k,k_1} X_{ik}\mathbb{1}_{\{X_{ik_1}=0\}}\Theta_{kk_1}^{*,(2)}. \tag{35}$$

We compute

$$\begin{aligned}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\mathbf{s}_i^T\mathbf{b}^{*,(2)}) &= \frac{pq}{L}\sum_{l=1}^{L}\sum_{c=1}^{C}\mathbb{E}_{\pi_l,\boldsymbol{\Psi}_l}\left(S_{ilc}\sum_{k=1}^{p}\frac{\mathbb{1}_{\{\Psi_{kl}=c\}}-\nu}{1-\nu}\sum_{k_1=1}^{p}\Theta_{kk_1}^{*,(2)}\mathbb{1}_{\{\pi_l(k_1)<\pi_l(k)\}}w_{\pi_l(k)}\right) \\ &= pq\mathbb{E}_{\pi,\boldsymbol{\psi}}\left(\sum_{c=1}^{C}\sum_{j=1}^{p}X_{ij}\mathbb{1}_{\{H_i=j\}}\mathbb{1}_{\{\psi_j=c\}}\sum_{k=1}^{p}\frac{\mathbb{1}_{\{\psi_k=c\}}-\nu}{1-\nu}\sum_{k_1=1}^{p}\Theta_{kk_1}^{*,(2)}\mathbb{1}_{\{\pi(k_1)<\pi(k)\}}w_{\pi(k)}\right) \\ &= pq\mathbb{E}_{\pi}\left(\sum_{k=1}^{p}X_{ik}\mathbb{1}_{\{H_i=k\}}\sum_{k_1=1}^{p}\Theta_{kk_1}^{*,(2)}\mathbb{1}_{\{\pi(k_1)<\pi(k)\}}\sum_{\ell=2}^{p}w_\ell\mathbb{1}_{\{\pi(k)=\ell\}}\right).\end{aligned}$$

where in the final line we have appealed to (26). Now observe that for $k \in \mathbf{z}_i$,

$$\mathbb{1}_{\{H_i=k\}}\mathbb{1}_{\{\pi(k_1)<\pi(k)\}}\mathbb{1}_{\{\pi(k)=\ell\}} = \mathbb{1}_{\{X_{ik_1}=0\}}\mathbb{1}_{\{H_i=k\}}\mathbb{1}_{\{M_i=\ell,\,\pi(k_1)<\ell\}},$$

and $\mathbb{1}_{\{H_i=k\}}$ and $\mathbb{1}_{\{M_i=\ell,\,\pi(k_1)<\ell\}}$ are independent. Thus we have

$$\begin{aligned}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}((\mathbf{S}\mathbf{b}^{*,(2)})_i) &= \sum_{k,k_1}X_{ik}\mathbb{1}_{\{X_{ik_1}=0\}}\Theta_{kk_1}^{*,(2)}\sum_{\ell=1}^{p}p\mathbb{P}_\pi(M_i=\ell,\pi(k_1)<\ell)w_\ell \\ &= \sum_{k,k_1}X_{ik}\mathbb{1}_{\{X_{ik_1}=0\}}\Theta_{kk_1}^{*,(2)}\sum_{\ell=2}^{p}(\ell-1)\mathbb{P}_\pi(M_i=\ell|\,\pi(k_1)<\ell)w_\ell \\ &= \sum_{k,k_1}X_{ik}\mathbb{1}_{\{X_{ik_1}=0\}}\Theta_{kk_1}^{*,(2)}\sum_{\ell=2}^{p}(\ell-1)\frac{\binom{p-\ell}{q-1}}{\binom{p-1}{q}}w_\ell.\end{aligned}$$

Thus if we choose $\mathbf{w}$ such that

$$\sum_{\ell=2}^{p}(\ell-1)\frac{\binom{p-\ell}{q-1}}{\binom{p-1}{q}}w_\ell = 1, \tag{36}$$

property (35) will be satisfied.

Next we compute

$$\begin{aligned}
\mathbb{E}(\|\mathbf{b}^{*,(2)}\|_2^2) &\leq \frac{p^2q^2}{L(1-\nu)}\sum_{k=1}^{p}\mathbb{E}\Big\{\Big(\sum_{k_1=1}^{p}\Theta^{*,(2)}_{kk_1}\mathbb{1}_{\{\pi(k_1)<\pi(k)\}}\Big)^2 w^2_{\pi(k)}\Big\} \\
&= \frac{p^2q^2}{L(1-\nu)}\sum_{k=1}^{p}\sum_{\ell=1}^{p} w_\ell^2\Big(\sum_{k_1}(\Theta^{*,(2)}_{kk_1})^2\mathbb{P}(\pi(k)=\ell,\pi(k_1)<\ell) \\
&\qquad + \sum_{k_1\neq k_2}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\mathbb{P}(\pi(k)=\ell,\pi(k_1)<\ell,\pi(k_2)<\ell)\Big) \\
&= \frac{pq^2}{L(1-\nu)}\sum_{k=1}^{p}\sum_{\ell=2}^{p} w_\ell^2\Big(\frac{\ell-1}{p-1}\sum_{k_1}(\Theta^{*,(2)}_{kk_1})^2 + \frac{(\ell-1)(\ell-2)}{(p-1)(p-2)}\sum_{k_1\neq k_2}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big) \\
&\leq \frac{pq^2}{(p-1)L(1-\nu)}\sum_{k,k_1,k_2}\Big|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big|\sum_{\ell=2}^{p}(\ell-1)w_\ell^2. \qquad (37)
\end{aligned}$$

Choosing

$$w_\ell = \frac{\binom{p-\ell}{q-1}\Big/\binom{p-1}{q}}{\sum_{\ell'=2}^{p}(\ell'-1)\left\{\binom{p-\ell'}{q-1}\Big/\binom{p-1}{q}\right\}^2} \qquad (38)$$

minimises (37) subject to (36) to give

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^{*,(2)}\|_2^2) \leq \frac{pq^2}{(p-1)L(1-\nu)}\sum_{k,k_1,k_2}\Big|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big|\left\{\sum_{\ell=1}^{p-1}\ell\left(\frac{\binom{p-1-\ell}{q-1}}{\binom{p-1}{q}}\right)^2\right\}^{-1}.$$

Finally, Lemma 19 bounds the right-most term from above to yield

$$\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{b}^{*,(2)}\|_2^2) \leq \frac{2\{(2-\delta)q\}^2}{L(1-\nu)}\sum_{k,k_1,k_2}\Big|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big|. \qquad (39)$$

Now we turn to the mean-squared error. Observe that $\mathbf{s}_i^T\mathbf{b}^*$ is a sum of L independent random variables, each having the same distribution as

$$\sum_{c=1}^{C}S_{i1c}b^*_{1c} = \sum_{c=1}^{C}S_{i1c}(b^{*,(1)}_{1c}+b^{*,(2)}_{1c}).$$

Thus

$$\begin{aligned}
\mathrm{Var}(\mathbf{s}_i^T\mathbf{b}^*) &\leq \frac{1}{L}\mathbb{E}\Big(\sum_{c=1}^{C}S_{i1c}(b^{*,(1)}_{1c}+b^{*,(2)}_{1c})\Big)^2 \\
&\leq \frac{1}{L}\left[\left\{\mathbb{E}\Big(\sum_{c=1}^{C}S_{i1c}\mathbf{b}^{*,(1)}_{1c}\Big)^2\right\}^{1/2} + \left\{\mathbb{E}\Big(\sum_{c=1}^{C}S_{i1c}\mathbf{b}^{*,(2)}_{1c}\Big)^2\right\}^{1/2}\right]^2,
\end{aligned}$$

where we have used the Cauchy–Schwarz inequality in the final line. Now using the fact that $\|\mathbf{X}\|_\infty \leq 1$, and following the argument that leads to (28), we arrive at

$$\begin{aligned}
\mathbb{E}\Big(\sum_{c=1}^{C}S_{i1c}\mathbf{b}^{*,(2)}_{1c}\Big)^2 = p^2q^2\mathbb{E}\Big\{&\frac{\nu}{1-\nu}\sum_{k=1}^{p}\Big(\sum_{k_1=1}^{p}\Theta^{*,(2)}_{kk_1}\mathbb{1}_{\{\pi(k_1)<\pi(k)\}}w_{\pi(k)}\Big)^2 \\
&+ \frac{1-2\nu}{1-\nu}X^2_{iH_i}\Big(\sum_{k_1=1}^{p}\Theta^{*,(2)}_{H_ik_1}\mathbb{1}_{\{\pi(k_1)<M_i\}}w_{M_i}\Big)^2\Big\}. \qquad (40)
\end{aligned}$$

We have

$$\begin{aligned}
&\mathbb{E}\Big\{X^2_{iH_i}\Big(\sum_{k_1=1}^{p}\Theta^{*,(2)}_{H_ik_1}\mathbb{1}_{\{\pi(k_1)<M_i\}}w_{M_i}\Big)^2\Big\} = \frac{1}{q}\sum_{k=1}^{p}\sum_{\ell=1}^{p}X^2_{ik}\mathbb{E}\Big\{\Big(\sum_{k_1}\Theta^{*,(2)}_{k,k_1}\mathbb{1}_{\{\pi(k_1)<\ell\}}w_\ell\Big)^2\mathbb{1}_{\{M_i=\ell\}}\Big\} \\
&= \sum_{k=1}^{p}X^2_{ik}\sum_{\ell=2}^{p}w_\ell^2\Big(\sum_{k_1}(\Theta^{*,(2)}_{kk_1})^2\mathbb{P}(M_i=\ell,\pi(k_1)<\ell) + \sum_{k_1\neq k_2}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\mathbb{P}(M_i=\ell,\pi(k_1)<\ell,\pi(k_2)<\ell)\Big) \\
&= \sum_{k=1}^{p}X^2_{ik}\sum_{\ell=2}^{p}w_\ell^2\Big(\frac{\ell-1}{p-1}\frac{\binom{p-\ell}{q-1}}{\binom{p-1}{q}}\sum_{k_1}(\Theta^{*,(2)}_{kk_1})^2 + \frac{(\ell-1)(\ell-2)}{(p-1)(p-2)}\frac{\binom{p-\ell}{q-1}}{\binom{p-2}{q}}\sum_{k_1\neq k_2}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big). \qquad (41)
\end{aligned}$$

Now

$$\frac{\binom{p-\ell}{q-1}}{\binom{p-1}{q}} \leq \frac{q}{p-1} \qquad \text{and} \qquad \frac{\ell-2}{p-2}\frac{\binom{p-\ell}{q-1}}{\binom{p-2}{q}} \leq \frac{q}{p-1}.$$

Thus by Lemma 19 the quantity in (41) is at most

$$\frac{2(2-\delta)^2\delta}{p^2}\sum_{k,k_1,k_2}^{p}\Big|X^2_{ik}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big|.$$

Returning to (40) and using the argument leading to (37) therefore gives us

$$\mathbb{E}\Big(\sum_{c=1}^{C}S_{i1c}\mathbf{b}^{*,(2)}_{1c}\Big)^2 \leq 2(2-\delta)^2q^2\Big(\frac{\nu}{1-\nu}\sum_{k,k_1,k_2}\Big|\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big| + \delta\frac{1-2\nu}{1-\nu}\sum_{k,k_1,k_2}\Big|X^2_{ik}\Theta^{*,(2)}_{kk_1}\Theta^{*,(2)}_{kk_2}\Big|\Big),$$

which then gives part (iii) of the result.

Appendix B. Implications for the RKHS of the resemblance kernel

We first observe the following result that is an immediate consequence of Bouchard et al. (2013).

Proposition 13 *Consider the resemblance kernel with input space $\mathcal{X} = \{0,1\}^p$ and let $\mathcal{H}$ be the corresponding RKHS. Then $\mathcal{H}$ contains every function $f : \mathcal{X} \to \mathbb{R}$.*

Proof Let $\mathbf{X} \in \mathbb{R}^{|\mathcal{X}|\times p}$ be the matrix with each row a different element of $\mathcal{X}$ and let $\mathbf{K} \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{X}|}$ be the matrix with $K_{\mathbf{x}\mathbf{x}'} = k(\mathbf{x}, \mathbf{x}')$ where k is the resemblance kernel. Bouchard et al. (2013) shows that $\mathbf{K}$ is positive definite. Given $f : \mathcal{X} \to \mathbb{R}$, let $\mathbf{f} \in \mathbb{R}^{|\mathcal{X}|}$ be the vector of function evaluations so $f_x = f(x)$. Let $\alpha = \mathbf{K}^{-1}\mathbf{f}$. Then

$$f(\cdot) = \sum_{x\in\mathcal{X}} \alpha_x k(\cdot, x)$$

so $f \in \mathcal{H}$. ■

The following corollary of Theorem 6 derives properties of the RKHS associated with the resemblance kernel from our approximation error bounds.

Corollary 14 *Let $\mathcal{H}$ be the RKHS of the resemblance kernel k when the input space $\mathcal{X} \subset \{0,1\}^p$ is constrained such that every element has q non-zeroes. Suppose $p \geq 3$. For $\boldsymbol{\theta}^{(1)} \in \mathbb{R}^p$, $\boldsymbol{\Theta}^{(2)} \in \mathbb{R}^{p\times p}$ and $\boldsymbol{\Theta} = (\boldsymbol{\theta}^{(1)}, \boldsymbol{\Theta}^{(2)})$, define $f_{\boldsymbol{\Theta}} : \mathcal{X} \to \mathbb{R}$ by*

$$f_{\boldsymbol{\Theta}}(\mathbf{x}) = \sum_{k=1}^{p} x_k \theta_k^{(1)} + \sum_{k=1}^{p}\sum_{j=1}^{p} x_k(1-x_j)\Theta_{k,j}^{(2)}.$$

Suppose $\boldsymbol{\Theta}$ is such that $f_{\boldsymbol{\Theta}}$ is centred so $\sum_{\mathbf{x}\in\mathcal{X}} f_{\boldsymbol{\Theta}}(\mathbf{x}) = 0$ Then $f_{\boldsymbol{\Theta}} \in \mathcal{H}$ and $\|f_{\boldsymbol{\Theta}}\|_{\mathcal{H}}^2 \leq (2-\delta)q\|\boldsymbol{\Theta}\|^2$. In particular if $\boldsymbol{\Theta}^{(2)} = \mathbf{0}$ then $\|f_{\boldsymbol{\theta}^{(1)}}\|_{\mathcal{H}}^2 \leq (2-\delta)q\|\boldsymbol{\theta}^{(1)}\|_2^2$.

Proof Let $\mathbf{K} \in \mathbb{R} \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{X}|}$ be the matrix with $K_{xx'} = k(x, x')$. We will make use of the fact that $\mathbf{K}$ is positive definite (Bouchard et al., 2013). Suppose $\mathbf{X} \in \{0,1\}^{|\mathcal{X}|\times p}$ has as each row a different element of $\mathcal{X}$. For $L \in \mathbb{N}$, let $\mathbf{S}_L$ be the matrix formed from 1-bit min-wise hashing applied to $\mathbf{X}$ and let $\mathbf{K}_L = 2\mathbf{S}_L\mathbf{S}_L^T/L - \mathbf{J}$ where $\mathbf{J}$ is a $|\mathcal{X}| \times |\mathcal{X}|$ matrix of 1's. Given $\boldsymbol{\Theta}$, let $\mathbf{b}_L^*$ be as in the proof of Theorem 6 (see Section A.5) constructed using the permutations and $\boldsymbol{\Psi}$ matrix corresponding to $\mathbf{S}_L$.

Let $k_L : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be the random kernel associated with $\mathbf{K}_L$, that is $k(x, x') = K_{L,xx'}$; further let $\mathcal{H}_L$ be the associated RKHS. Let $\tilde{\mathbf{b}}_L$ be a centred version of $\mathbf{b}_L^*$ so $\tilde{\mathbf{b}}_L = \mathbf{b}_L^* - \bar{\mathbf{b}}^*{}_L$. Observe that $\|\tilde{\mathbf{b}}_L\|_2^2 \leq \|\mathbf{b}_L^*\|_2^2$. Let $f_L : \mathcal{X} \to \mathbb{R}$ be given by $f_L(x) = (S_L\tilde{\mathbf{b}}_L)_x$. Then $f_L \in \mathcal{H}_L$ and $\|f_L\|_{\mathcal{H}_L}^2 = L\|\tilde{\mathbf{b}}_L\|_2^2/2$.

Note that the construction of $\mathbf{b}_L^*$ ensures that each component block is i.i.d. Thus as $L \to \infty$, we have that almost surely

$$L\|\tilde{\mathbf{b}}_L\| \leq L\|\mathbf{b}_L^*\|_2^2 \to L^2\mathbb{E}\|(b_{L,1}^*, b_{L,2}^*)^T\|_2^2 \leq 2(2-\delta)q\|\boldsymbol{\Theta}\|^2$$

(note that the expression on the right hand side of the limit does not in fact depend on L). Also $\mathbf{K}_L \to \mathbf{K}$ almost surely by the strong law of large numbers (see Section 2.4).

Now observe that as $\mathbf{f}$ is centred, $\|\mathbf{S}_L\tilde{\mathbf{b}}_L - \mathbf{f}\|_2^2 \leq \|\mathbf{S}_L\mathbf{b}_L^* - \mathbf{f}\|_2^2$. Thus from Theorem 6 (iii) we have that $\mathbf{S}_L\tilde{\mathbf{b}}_L \to \mathbf{f}$ in probability where $\mathbf{f} \in \mathbb{R}^{|\mathcal{X}|}$ has components $f_x = f_{\boldsymbol{\Theta}}(x)$. Therefore there exists a subsequence L_j along which $\mathbf{S}_{L_j}\tilde{\mathbf{b}}_{L_j} \to \mathbf{f}$ almost surely. Thus, there exists a realisation of the random elements above such that simultaneously $\mathbf{K}_{L_j} \to \mathbf{K}$, $f_{L_j}(x) \to f(x)$ as $j \to \infty$ and $\lim_{j\to\infty} \|f_{L_j}\|_{\mathcal{H}_{L_j}}^2 \leq (2-\delta)q\|\boldsymbol{\Theta}\|^2$. In particular we have that $\|f_{L_j}\|_{\mathcal{H}_{L_j}}$ is bounded for all j. Applying Lemma 21 then gives the result. ■

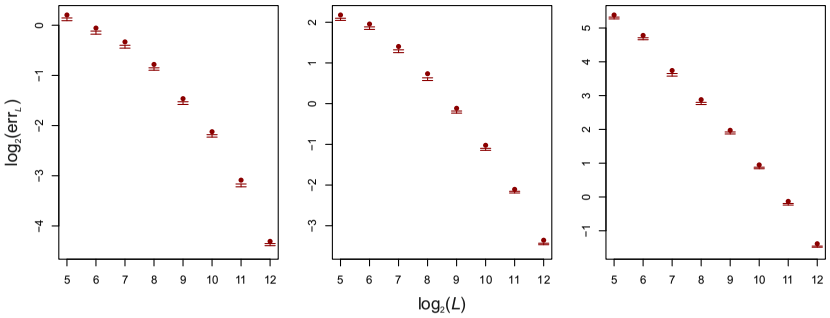

Figure 1: Plot of $\log_2(\text{err}_L)$ against $\log_2(L)$ for $q = 500, 1000, 5000$ going from left to right. The bars give the first and third quartiles of $\log_2(\text{err}_L)$ over the 100 simulations, and the circles give maximum values.

Appendix C. Empirical verification of Theorem 1

In order to assess whether the scaling in L provided by (iii) of Theorem 1 is in line with what is observed in practice, we looked at several numerical experiments. We generated design matrices $\mathbf{X} \in \{0,1\}^{n\times p}$ with different levels of sparsity $q \in \{500, 1000, 5000\}$ and $(n, p) = (10^4, 10^5)$. Different $\mathbf{S}$ matrices were constructed for each of the three $\mathbf{X}$ matrices with $\log_2 L \in \{5, 6, \ldots, 12\}$. We then generated 100 vectors of coefficients $\boldsymbol{\beta}^* \in \mathbb{R}^p$ with $\|\boldsymbol{\beta}^*\|_2 = 1$ for each setting and examined

$$\text{err}_L := \min_{\mathbf{b}\in\mathbb{R}^L} \|\mathbf{X}\boldsymbol{\beta}^* - \mathbf{S}\mathbf{b}\|_2^2/n. \tag{42}$$

Plots of $\log_2(\text{err}_L)$ against $\log_2(L)$ are given in Figure 1. Given the scaling in L suggested by Theorem 1 (iii), we would expect the points to lie on a straight line with slope -1.. We see this is indeed approximately the case for lager L and q.

Note that Theorem 1 does not make the claim that the $\mathbf{b}^*$ given is optimal in the sense of (42). Indeed it also satisfies unbiasedness and has a low ℓ_2-norm in expectation: properties not necessarily satisfied by the minimiser of (42). Moreover, the bound must encompass a worst case in terms of $\mathbf{X}$ and the direction of $\boldsymbol{\beta}^*$; tighter bounds may be used at the expense of a more complicated dependence on the precise form of $\mathbf{X}$ and $\boldsymbol{\beta}^*$. However, we see from the empirical study that the scaling in L provided by the result approximately parallels that corresponding to the minimiser of (42).

The details of the simulation study are as follows. The design $\mathbf{X}$ was generated randomly with the first $p/100$ columns containing $q/10$ 1's and the remaining columns containing $9q/10$ 1's. This mimics the setting of increasing variable sparsity described in Section 4.1. The vector of coefficients $\boldsymbol{\beta}^*$ had its first $p/100$ entries generated independently with an Exp(1) distribution and the remaining entries were set to 0; $\boldsymbol{\beta}^*$ was then scaled to have ℓ_2-norm 1.

Appendix D. Prediction error results

Here we prove results for the prediction error under linear and logistic regression models. We denote the signal to be estimated by $\mathbf{f}^*$ and assume the existence of a $\mathbf{b}^* \in \mathbb{R}^{2^b L}$ with

$$\frac{1}{n}\mathbb{E}(\|\mathbf{f}^* - \mathbf{S}\mathbf{b}^*\|_2^2) \le c_1/L$$
$$\mathbb{E}(\|\mathbf{b}^*\|_2^2) \le c_2/L.$$

Explicit constructions for such coefficient vectors are provided in the previous section. Using the results here in conjunction with the approximation error results proved in Section A yield Theorems 3–9: for example, substituting (iii) of Theorem 1 immediately gives Theorem 3.

D.1 Linear regression

We assume the model

$$\mathbf{Y} = \alpha^*\mathbf{1} + \mathbf{f}^* + \boldsymbol{\varepsilon}, \tag{43}$$

where $\mathrm{Var}(\boldsymbol{\varepsilon}) = \sigma^2\mathbf{I}$ and our goal is to estimate $\mathbf{f}^*$.

Theorem 15 *Let $(\hat{\alpha}, \hat{\mathbf{b}})$ be the least squares estimator (12). Then*

$$\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) \;\le\; \frac{c_1}{L} + \frac{\sigma^2\{(2^b-1)L+1\}}{n}.$$

Proof Let us write

$$\mathbf{Y} = \alpha^*\mathbf{1} + \mathbf{f}^* + \boldsymbol{\varepsilon} = \alpha^*\mathbf{1} + \mathbf{S}\mathbf{b}^* + \boldsymbol{\Delta} + \boldsymbol{\varepsilon},$$

so $\boldsymbol{\Delta}$ is the approximation error of $\mathbf{S}\mathbf{b}^*$. Then we have

$$\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) = \frac{1}{n}\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\alpha^*\mathbf{1} + \mathbf{f}^* - \hat{\alpha}\mathbf{1} - \mathbf{S}\hat{\mathbf{b}}\|_2^2).$$

Now let $\check{\mathbf{S}} = (\mathbf{1}\ \mathbf{S})$, and $\mathbf{P}_{\check{\mathbf{S}}}$ be the projection on to the column space of $\check{\mathbf{S}}$ (so $\mathbf{P}_{\check{\mathbf{S}}} = \check{\mathbf{S}}\check{\mathbf{S}}^+$, where $\check{\mathbf{S}}^+$ denotes the Moore–Penrose pseudoinverse of $\check{\mathbf{S}}$). We have the following decomposition.

$$\begin{aligned}\alpha^*\mathbf{1} + \mathbf{f}^* - \hat{\alpha}\mathbf{1} - \mathbf{S}\hat{\mathbf{b}} &= \alpha^*\mathbf{1} + \mathbf{f}^* - \mathbf{P}_{\check{\mathbf{S}}}\mathbf{Y} \\ &= \alpha^*\mathbf{1} + \mathbf{S}\mathbf{b}^* + \boldsymbol{\Delta} - \mathbf{P}_{\check{\mathbf{S}}}(\alpha^*\mathbf{1} + \mathbf{S}\mathbf{b}^* + \boldsymbol{\Delta} + \boldsymbol{\varepsilon}) \\ &= (\mathbf{I} - \mathbf{P}_{\check{\mathbf{S}}})\boldsymbol{\Delta} - \mathbf{P}_{\check{\mathbf{S}}}\boldsymbol{\varepsilon}.\end{aligned}$$

Hence

$$\begin{aligned}\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) &= \frac{1}{n}\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}(\|(\mathbf{I} - \mathbf{P}_{\check{\mathbf{S}}})\boldsymbol{\Delta} - \mathbf{P}_{\check{\mathbf{S}}}\boldsymbol{\varepsilon}\|_2^2) \\ &= \frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|(\mathbf{I} - \mathbf{P}_{\check{\mathbf{S}}})\boldsymbol{\Delta}\|_2^2) + \frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}\{\mathbb{E}_{\boldsymbol{\varepsilon}}(\|\mathbf{P}_{\check{\mathbf{S}}}\boldsymbol{\varepsilon}\|_2^2 \,|\, \boldsymbol{\pi}, \boldsymbol{\Psi})\} \\ &\le \frac{1}{n}\mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\boldsymbol{\Delta}\|_2^2) + \frac{\sigma^2\{(2^b-1)L+1\}}{n} \qquad (44) \\ &\le \frac{c_1}{L} + \frac{\sigma^2\{(2^b-1)L+1\}}{n},\end{aligned}$$

where in for (44) we have used the fact that $\mathrm{rank}(\check{\mathbf{S}}) \le (2^b-1)L + 1$ as each the L blocks sums to a vector of 1's ■

Theorem 16 *There exists λ depending on $\mathbf{f}^*$ and $\mathbf{S}$ such that defining*

$$(\hat{\alpha}, \hat{\mathbf{b}}) := \operatorname*{arg\,min}_{(\alpha,\mathbf{b})\in\mathbb{R}\times\mathbb{R}^L} \|\mathbf{Y} - \hat{\alpha}\mathbf{1} - \mathbf{S}\mathbf{b}\|_2^2 \;\; \textit{such that} \;\; \|\mathbf{b}\|_2^2 \le \lambda,$$

we have

$$\mathrm{MSPE}((\hat{\alpha}, \hat{\mathbf{b}})) \;\le\; \sigma\sqrt{\frac{c_2}{n}} + \frac{c_1}{L} + \frac{\sigma^2}{n}.$$

Proof We will take $\lambda = \|\mathbf{b}^*\|_2^2$. Let a bar over any vector $\mathbf{v}$ denote the average of the components of $\mathbf{v}$, so $\bar{\mathbf{v}} = \sum_j v_j$. Note that $\hat{\alpha} = \overline{\mathbf{Y} - \mathbf{S}\hat{\mathbf{b}}}$, and define $\hat{a}^* = \overline{\mathbf{Y} - \mathbf{S}\mathbf{b}^*}$. By our choice of λ, we have that

$$\|\mathbf{Y} - \hat{\alpha}\mathbf{1} - \mathbf{S}\hat{\mathbf{b}}\|_2^2 \le \|\mathbf{Y} - \hat{a}^*\mathbf{1} - \mathbf{S}\mathbf{b}^*\|_2^2.$$

Noting that for any $\mathbf{v}, \mathbf{u} \in \mathbb{R}^n$, $\mathbf{v}^T(\mathbf{u} - \bar{\mathbf{u}}\mathbf{1}) = (\mathbf{v} - \bar{\mathbf{v}}\mathbf{1})^T\mathbf{u}$, rearranging the inequality above we get

$$\|\alpha^*\mathbf{1} + \mathbf{f}^* - \hat{\alpha}\mathbf{1} - \mathbf{S}\hat{\mathbf{b}}\|_2^2 \le 2(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}(\hat{\mathbf{b}} - \mathbf{b}^*) + \|\alpha^*\mathbf{1} + \mathbf{f}^* - \hat{a}^*\mathbf{1} - \mathbf{S}\mathbf{b}^*\|_2^2. \tag{45}$$

Now observe that

$$\begin{aligned}\|\alpha^*\mathbf{1} + \mathbf{f}^* - \hat{a}^*\mathbf{1} - \mathbf{S}\mathbf{b}^*\|_2^2 &= \|\mathbf{f}^* - \overline{\mathbf{f}^*}\mathbf{1} - (\mathbf{S}\mathbf{b}^* - \overline{\mathbf{S}\mathbf{b}^*}\mathbf{1})\|_2^2 + n\bar{\boldsymbol{\varepsilon}}^2 \\ &\le \|\mathbf{f}^* - \mathbf{S}\mathbf{b}^*\|_2^2 + n\bar{\boldsymbol{\varepsilon}}^2. \qquad (46)\end{aligned}$$

As $\mathbf{b}^*$ is independent of $\boldsymbol{\varepsilon}$, taking expectations of (45) yields

$$\mathrm{MSPE}(\hat{\mathbf{b}}) = \frac{2}{n}\mathbb{E}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}\hat{\mathbf{b}}\} + \frac{1}{n}\mathbb{E}(\|\mathbf{f}^* - \mathbf{S}\mathbf{b}^*\|_2^2) + \frac{\sigma^2}{n}. \tag{47}$$

Now using the fact that $\|\hat{\mathbf{b}}\|_2 \le \|\mathbf{b}^*\|_2$ and applying the Cauchy–Schwarz inequality we have

$$\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}\hat{\mathbf{b}}\} \le \sqrt{\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}\{\|\mathbf{S}^T(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})\|_2^2\}}\sqrt{\mathbb{E}(\|\mathbf{b}^*\|_2^2)}.$$

But

$$\begin{aligned}\mathbb{E}_{\boldsymbol{\varepsilon}}(\|\mathbf{S}^T(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})\|_2^2|\boldsymbol{\pi}, \boldsymbol{\Psi}) &= \mathbb{E}_{\boldsymbol{\varepsilon}}[\mathrm{Tr}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}\mathbf{S}^T(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})\}|\boldsymbol{\pi}, \boldsymbol{\Psi}] \\ &= \mathbb{E}_{\boldsymbol{\varepsilon}}[\mathrm{Tr}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}\mathbf{S}^T\}|\boldsymbol{\pi}, \boldsymbol{\Psi}] \\ &= \mathrm{Tr}[\mathbb{E}_{\boldsymbol{\varepsilon}}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\}\mathbf{S}\mathbf{S}^T] \\ &= \sigma^2\|(\mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^T)\mathbf{S}\|_F^2 \le \sigma^2\|\mathbf{S}\|_F^2 \le \sigma^2 nL,\end{aligned}$$

whence

$$\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}\{(\boldsymbol{\varepsilon} - \bar{\boldsymbol{\varepsilon}}\mathbf{1})^T\mathbf{S}\hat{\mathbf{b}}\} \le \sigma\sqrt{c_2 n}. \tag{48}$$

Substituting in to (47) then gives the result. ■

D.2 Logistic regression

We give an analogous result to Theorem 4 for classification problems under logistic loss. Let $\mathbf{X} \in [-1,1]^{n\times p}$ be the design matrix of predictor variables and let $\mathbf{Y} \in \{0,1\}^n$ be an associated vector of class labels. We assume the model

$$Y_i \sim \text{Bernoulli}(p_i); \qquad \log\left(\frac{p_i}{1-p_i}\right) = f_i,$$

with the Y_i independent for $1 \le i \le n$. Define

$$\hat{\mathbf{b}}_\lambda = \arg\min_{\mathbf{b}} \frac{1}{n}\sum_{i=1}^n \left[-Y_i \mathbf{s}_i^T\mathbf{b} + \log\{1+\exp(\mathbf{s}_i^T\mathbf{b})\}\right] \text{ such that } \|\mathbf{b}\|_2^2 \le \lambda.$$

Let $\mathcal{E}(\hat{\mathbf{b}}_\lambda)$ denote the excess risk of $\hat{\mathbf{b}}_\lambda$ under logistic loss, so

$$\mathcal{E}(\hat{\mathbf{b}}_\lambda) = \frac{1}{n}\sum_{i=1}^n \left[-p_i \mathbf{s}_i^T\hat{\mathbf{b}}_\lambda + \log\{1+\exp(\mathbf{s}_i^T\hat{\mathbf{b}}_\lambda)\}\right] - \frac{1}{n}\sum_{i=1}^n \left[-p_i f_i + \log\{1+\exp(f_i)\}\right].$$

Theorem 17 *Let $\tilde{p} \in \mathbb{R}$ be given by (18). Then we have that there exists λ such that*

$$\mathbb{E}_{\mathbf{Y},\boldsymbol{\pi},\boldsymbol{\Psi}}\{\mathcal{E}(\hat{\mathbf{b}}_\lambda)\} \le \frac{c_1}{4L} + \sqrt{\tilde{p}c_2/n}.$$

Proof We take $\lambda = \|\mathbf{b}^*\|_2^2$. By the definition of $\hat{\mathbf{b}}$ (dropping the subscript λ), we have

$$\frac{1}{n}\sum_{i=1}^n \left[-Y_i \mathbf{s}_i^T\hat{\mathbf{b}} + \log\{1+\exp(\mathbf{s}_i^T\hat{\mathbf{b}})\}\right] \le \frac{1}{n}\sum_{i=1}^n \left[-Y_i \mathbf{s}_i^T\mathbf{b}^* + \log\{1+\exp(\mathbf{s}_i^T\mathbf{b}^*)\}\right].$$

Using this, analogously to (45) we get,

$$\mathcal{E}(\hat{\mathbf{b}}) \le \frac{1}{n}\sum_{i=1}^n (Y_i - p_i)\{\mathbf{S}(\hat{\mathbf{b}} - \mathbf{b}^*)\}_i + \mathcal{E}(\mathbf{b}^*).$$

Let $\boldsymbol{\varepsilon} := \mathbf{Y} - \mathbf{p}$ be the residual vector. Since $\mathbf{b}^*$ is independent of $\boldsymbol{\varepsilon}$, after taking expectations we arrive at

$$\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}\{\mathcal{E}(\hat{\mathbf{b}})\} \le \frac{1}{n}\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}(\boldsymbol{\varepsilon}^T\mathbf{S}\hat{\mathbf{b}}) + \mathbb{E}_{\boldsymbol{\pi},\boldsymbol{\Psi}}\{\mathcal{E}(\mathbf{b}^*)\}.$$

Write $h(a) = \log(1+e^a)$. By the mean value theorem, we have

$$\begin{aligned}|\mathcal{E}(\mathbf{b}^*)| &= \frac{1}{n}\sum_{i=1}^n |h(\mathbf{s}_i^T\mathbf{b}^*) - h(f_i) - (\mathbf{s}_i^T\mathbf{b}^* - f_i)h'(f_i)| \\ &\le \frac{1}{n}\sup_{a\in\mathbb{R}} h''(a)\|\mathbf{f}^* - \mathbf{S}\mathbf{b}^*\|_2^2 \le \frac{c_1}{4L}.\end{aligned}$$

The same argument that leads to (48) gives

$$\frac{1}{n}\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}(\boldsymbol{\varepsilon}^T\mathbf{S}\hat{\mathbf{b}}) \le \frac{1}{n}\sqrt{\mathbb{E}_{\boldsymbol{\varepsilon},\boldsymbol{\pi},\boldsymbol{\Psi}}(\|\mathbf{S}^T\boldsymbol{\varepsilon}\|_2^2)}\sqrt{c_2/L} \le \sqrt{\tilde{p}c_2/n}.$$

Collecting together the various inequalities, we get the required result. ■

Appendix E. Technical lemmas

In this section we collect all technical lemmas used by the results presented earlier.

Lemma 18 *Let $(a_i)_{i=1}^\infty$ and $(b_i)_{i=1}^\infty$ be two sequences of non-negative, non-increasing, real numbers such that that there is some $i^* \in \mathbb{N}$ for which*

$$\begin{aligned}a_i &\le b_i \quad \text{for all } i \le i^*, \\ a_i &\ge b_i \quad \text{for all } i > i^*.\end{aligned}$$

(i) If

$$\sum_{i=1}^\infty a_i = \sum_{i=1}^\infty b_i < \infty,$$

and $m \ge 1$, then

$$\sum_{i=1}^\infty a_i^m \le \sum_{i=1}^\infty b_i^m.$$

(ii) If $(c_i)_{i=1}^\infty$ is a sequence of non-negative, non-decreasing real numbers and

$$\sum_{i=1}^\infty b_i \le \sum_{i=1}^\infty a_i < \infty, \ \sum_{i=1}^\infty c_i a_i, \ \sum_{i=1}^\infty c_i b_i < \infty,$$

then

$$\sum_{i=1}^\infty c_i a_i \ge \sum_{i=1}^\infty c_i b_i.$$

Proof Note that the sequence $(b_i)_{i=1}^\infty$ majorises $(a_i)_{i=1}^\infty$ (see page 191 of Steele (2004)). Result (i) follows from applying Schur's majorisation inequality (Steele (2004); page 201) with the convex function $x \mapsto x^m$ on $[0,\infty)$.

For (ii) we argue,

$$\sum_{i=1}^{i^*} c_i(b_i - a_i) \le c_{i^*}\sum_{i=1}^{i^*}(b_i - a_i) \le c_{i^*}\sum_{i>i^*}(a_i - b_i) \le \sum_{i>i^*} c_i(a_i - b_i).$$

■

Lemma 19 *Let $q, p \in \mathbb{N}$ with $q \ge 1$, $p \ge \max\{q, 3\}$. We have*

$$\sum_{\ell=1}^{p-1} \ell\left(\frac{\binom{p-1-\ell}{q-1}}{\binom{p-1}{q}}\right)^2 \ge \frac{1}{2(2-q/p)^2}\frac{p^2}{(p-1)^2}.$$

Proof Let the sequences $(a_\ell)_{\ell=1}^\infty$ and $(b_\ell)_{\ell=1}^\infty$ be defined by

$$a_\ell = \begin{cases} \left(\frac{\binom{p-1-\ell}{q-1}}{\binom{p-1}{q}}\right)^2 & \text{if } 1 \le \ell \le p-1 \\ 0 & \text{otherwise,} \end{cases}$$

$$b_\ell = \begin{cases} \left(\frac{q}{p-1}\right)^2 & \text{if } \ell \le \left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor \\ \frac{q}{2(p-1)-q} - \left(\frac{q}{p-1}\right)^2 \left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor & \text{if } \ell = \left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor + 1 \\ 0 & \text{otherwise.} \end{cases}$$

Let the sequence $(c_\ell)_{\ell=1}^\infty$ be defined by $c_\ell = \ell$. Note the sequences $(a_\ell)_{\ell=1}^\infty$, $(b_\ell)_{\ell=1}^\infty$ and $(c_\ell)_{\ell=1}^\infty$ satisfy the hypotheses of Lemma 18. Thus

$$\sum_{\ell=1}^{p-1} \ell a_\ell \ge \sum_{\ell=1}^{p-1} \ell b_\ell,$$

and

$$\begin{aligned} \sum_{\ell=1}^{p-1} \ell b_\ell = \frac{1}{2}\left(\frac{q}{p-1}\right)^2 \left(\left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor + 1\right) \left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor \\ + \left(\frac{q}{p-1}\right)^2 \left(\frac{(p-1)^2}{\{2(p-1)-q\}q} - \left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor\right) \left(\left\lfloor \frac{(p-1)^2}{\{2(p-1)-q\}q} \right\rfloor + 1\right). \end{aligned}$$

Letting $x = (p-1)^2/[\{2(p-1)-q\}q]$, we have

$$\begin{aligned} \sum_{\ell=1}^{p-1} \ell b_\ell &= \frac{1}{2}(\lfloor x \rfloor + 1)\lfloor x \rfloor + (x - \lfloor x \rfloor)(\lfloor x \rfloor + 1) \\ &= \frac{1}{2}x(x+1) - \frac{1}{2}\{(x - \lfloor x \rfloor)\lfloor x \rfloor + (x - \lfloor x \rfloor)(x+1)\} + (x - \lfloor x \rfloor)(\lfloor x \rfloor + 1). \end{aligned}$$

Since $1 \ge 1/2 + (x - \lfloor x \rfloor)/2$, we see that

$$(x - \lfloor x \rfloor)(\lfloor x \rfloor + 1) \ge \frac{1}{2}(x - \lfloor x \rfloor)(x + 1 + \lfloor x \rfloor),$$

so

$$\begin{aligned} \sum_{\ell=1}^{p-1} \ell b_\ell &\ge \frac{1}{2}x(x+1) \\ &= \frac{1}{2}\left(\frac{(p-1)^2}{\{2(p-1)-q\}q} + 1\right)\frac{q}{2(p-1)-q} \\ &= \frac{1}{2(p-1)}\frac{p + \{2 - q/(p-1)\}q - 1}{\{2 - q/(p-1)\}^2} \\ &\ge \frac{1}{2(p-1)}\frac{p+q}{\{2 - q/(p-1)\}^2} \\ &\ge \frac{1}{2(2-q/p)^2}\frac{p^2}{(p-1)^2}. \end{aligned}$$

■

Lemma 20 *Let $\kappa(\delta) = \delta^{-a}$ where $a \in [0,1]$. For $\ell \ge 2$,*

$$\left|\frac{\kappa^{(\ell)}(1)}{\ell!}\right| \le a e^a \frac{1}{\ell^{1-a}}.$$

Proof

$$\begin{aligned} \left|\frac{\kappa^{(\ell)}(1)}{\ell!}\right| &= \frac{a(a+1)\cdots(a+\ell-1)}{1\cdot 2\cdots \ell} \\ &= \frac{a}{\ell}\frac{a+1}{1}\frac{a+2}{2}\cdots\frac{a+\ell-1}{\ell-1}. \end{aligned}$$

By Jensen's inequality

$$\begin{aligned} \frac{1}{\ell-1}\left\{\log\left(\frac{a+1}{1}\right) + \log\left(\frac{a+2}{2}\right) + \cdots + \log\left(\frac{a+\ell-1}{\ell-1}\right)\right\} \\ \le \log\left(1 + \frac{a\{1+\log(\ell-1)\}}{\ell-1}\right), \end{aligned}$$

and

$$\left(1 + \frac{a\{1+\log(\ell-1)\}}{\ell-1}\right)^{\ell-1} \le \exp[a\{1+\log(\ell-1)\}].$$

Thus

$$\left|\frac{\kappa^{(\ell)}(1)}{\ell!}\right| \le a e^a \frac{(\ell-1)^a}{\ell} \le a e^a \frac{1}{\ell^{1-a}}.$$

■

Lemma 21 *Suppose we have a sequence of positive definite kernels $\{k_L\}_{L=1}^\infty$ on a finite input space $\mathcal{X}$. For $L \in \mathbb{N}$, let $\mathbf{K}_L \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{X}|}$ be the matrix with $K_{L,xx'} = k_L(x,x')$. Suppose that $\mathbf{K}_L \to \mathbf{K}$ where $\mathbf{K}$ is positive definite and corresponds to kernel k. Let the RKHS's associated with k_L and k be $\mathcal{H}_L$ and $\mathcal{H}$ respectively. Suppose $f_L \in \mathcal{H}_L$ satisfies $|f_L(x) - f(x)| \to 0$ for some $f : \mathcal{X} \to \mathbb{R}$ and all $x \in \mathcal{X}$, and $\|f_L\|_{\mathcal{H}_L} < C$ for some $C > 0$. Then $f \in \mathcal{H}$ and $\|f_L\|_{\mathcal{H}_L} \to \|f\|_{\mathcal{H}}$ as $L \to \infty$.*

Proof Since $\mathcal{X}$ is finite, for each L there exists $\boldsymbol{\alpha}_L \in \mathbb{R}^{|\mathcal{X}|}$ with $(f_L(x))_{x\in\mathcal{X}} = \mathbf{K}_L\boldsymbol{\alpha}_L$. Writing $\mathbf{f} = (f(x))_{x\in\mathcal{X}}$, we have $\mathbf{K}_L\boldsymbol{\alpha}_L \to \mathbf{f}$. Now $\mathbf{f} = \mathbf{K}\boldsymbol{\alpha}$ where $\boldsymbol{\alpha} = \mathbf{K}^{-1}\mathbf{f}$ showing that $f \in \mathcal{H}$.

It remains to show that $\boldsymbol{\alpha}_L^T\mathbf{K}_L\boldsymbol{\alpha}_L \to \boldsymbol{\alpha}^T\mathbf{K}\boldsymbol{\alpha}$. Note that $\mathbf{K}_L$ is positive definite for L sufficiently large, so the fact that $\boldsymbol{\alpha}_L^T\mathbf{K}_L\boldsymbol{\alpha}_L < C$ ensures the $\boldsymbol{\alpha}_L$ are bounded. Now suppose, for a contradiction, that there exists $\epsilon > 0$ and a subsequence L_j with

$$|\boldsymbol{\alpha}_{L_j}^T\mathbf{K}_{L_j}\boldsymbol{\alpha}_{L_j} - \boldsymbol{\alpha}^T\mathbf{K}\boldsymbol{\alpha}| > \epsilon. \tag{49}$$

Then as the $\boldsymbol{\alpha}_{L_j}$ are bounded, there exists a further subsequence $L_{j_m} = l_m$ such that $\boldsymbol{\alpha}_{l_m} \to \boldsymbol{\alpha}_*$ as $m \to \infty$. But then since the fact that $\mathbf{K}_L \to \mathbf{K}$ implies the maximal eigenvalues of the $\mathbf{K}_L$ are bounded, $\boldsymbol{\alpha}_{l_m}^T \mathbf{K}_{l_m} \boldsymbol{\alpha}_{l_m} \to \boldsymbol{\alpha}_*^T K_{l_m} \boldsymbol{\alpha}_*$ as $m \to \infty$. But then $\boldsymbol{\alpha}_{l_m}^T \mathbf{K}_{l_m} \boldsymbol{\alpha}_{l_m} \to \boldsymbol{\alpha}_*^T \mathbf{K} \boldsymbol{\alpha}_*$, contradicting (49). ■

Abstract

The use of convex regularizers allows for easy optimization, though they often produce biased estimation and inferior prediction performance. Recently, nonconvex regularizers have attracted a lot of attention and outperformed convex ones. However, the resultant optimization problem is much harder. In this paper, a popular subclass of ℓ_1-based nonconvex sparsity-inducing and low-rank regularizers is considered. This includes nonconvex variants of lasso, sparse group lasso, tree-structured lasso, nuclear norm and total variation regularizers. We propose to move the nonconvexity from the regularizer to the loss. The nonconvex regularizer is then transformed to a familiar convex one, while the resultant loss function can still be guaranteed to be smooth. Learning with the convexified regularizer can be performed by existing efficient algorithms originally designed for convex regularizers (such as the proximal algorithm, Frank-Wolfe algorithm, alternating direction method of multipliers and stochastic gradient descent). This is further extended to consider cases where the convexified regularizer does not have a closed-form proximal step, and when the loss function is nonconvex nonsmooth. Extensive experiments on a variety of machine learning application scenarios show that optimizing the transformed problem is much faster than running the state-of-the-art on the original problem.

Keywords: Nonconvex optimization, Nonconvex regularization, Proximal algorithm, Frank-Wolfe algorithm, Matrix completion

1. Introduction

Regularized risk minimization is fundamental to machine learning. It admits a tradeoff between the empirical loss and regularization as:

$$\min_x F(x) \equiv f(x) + g(x), \tag{1}$$

where x is the model parameter, f is the loss and g is the regularizer. The choice of regularizers is important and application-specific, and is often the crux to obtain good prediction performance. Popular examples include the sparsity-inducing regularizers, which have been commonly used in image processing (Beck and Teboulle, 2009; Mairal et al., 2009; Jenatton et al., 2011) and high-dimensional feature selection (Tibshirani et al., 2005; Jacob et al., 2009; Liu and Ye, 2010); and the low-rank regularizers, which have obtained good empirical performance on various matrix and tensor learning tasks such as collaborative filtering (Candès and Recht, 2009; Mazumder et al., 2010) and visual data analysis (Liu et al., 2013; Lu et al., 2014).

Most of these regularizers are convex. Well-known examples include the ℓ_1-regularizer for sparse coding (Donoho, 2006), and the nuclear norm regularizer in low-rank matrix learning (Candès and Recht, 2009). Besides having nice theoretical guarantees, convex regularizers also allow easy optimization. Popular optimization algorithms in machine learning include the proximal algorithm (Parikh and Boyd, 2013), Frank-Wolfe (FW) algorithm (Jaggi, 2013), alternating direction method of multipliers (ADMM) (Boyd et al., 2011), stochastic gradient descent (SGD) and its variants (Bottou, 1998; Xiao and Zhang, 2014). Many of these are efficient, scalable, and have sound convergence properties.

However, convex regularizers often lead to biased estimation. For example, in sparse coding, the solution obtained by the ℓ_1-regularizer is often not as sparse and accurate (Zhang, 2010b). In low-rank matrix learning, the estimated rank obtained with the nuclear norm regularizer is often much higher (Mazumder et al., 2010). To alleviate this problem, a number of nonconvex regularizers, which are variants of the convex ℓ_1-norm, have been recently proposed. Examples include the Geman penalty (GP) (Geman and Yang, 1995), log-sum penalty (LSP) (Candès et al., 2008), minimax concave plus (MCP) penalty (Zhang, 2010a), Laplace penalty (Trzasko and Manduca, 2009), and smoothly clipped absolute deviation (SCAD) penalty (Fan and Li, 2001). As can be seen from Figure 1, they are all (i) nonsmooth at zero, which encourage a sparse solution; and (ii) concave, which place a smaller penalty than the ℓ_1-regularizer on features with large magnitudes. Empirically, these nonconvex regularizers usually outperform convex regularizers.

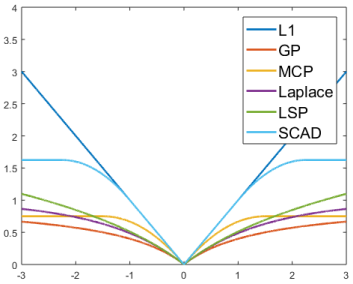

Figure 1: Plot of various nonconvex variants of the convex ℓ_1-regularizer.

In this paper, we consider a popular subclass of ℓ_1-based nonconvex sparsity-inducing and low-rank regularizers such as nonconvex variants of the lasso, sparse group lasso, tree-structured lasso, nuclear norm and total variation regularizers. Even with a convex loss, the resulting nonconvex problem (1) is much harder to optimize. One can use general-purpose nonconvex optimization solvers such as the concave-convex procedure (Yuille and Rangarajan, 2002). Unfortunately, the subproblem in each iteration can be as expensive as the original problem, and the concave-convex procedure is thus often slow in practice (Gong et al., 2013; Zhong and Kwok, 2014).

Recently, the proximal algorithm has been extended for nonconvex problems. Examples include nonconvex inexact proximal splitting (NIPS) (Sra, 2012), inertial proximal algorithm for non-convex optimization (IPiano) (Ochs et al., 2014), unified treatment of accelerated gradient (UAG) (Ghadimi and Lan, 2016), general iterative shrinkage and thresholding (GIST) (Gong et al.,

2013), inertial forward-backward (IFB) algorithm (Bot et al., 2016), and nonmonotone accelerated proximal gradient (nmAPG) (Li and Lin, 2015) algorithm. Specifically, NIPS, IPiano and UAG allow f in (1) to be Lipschitz smooth (and possibly nonconvex) but g has to be convex; while GIST, IFB and nmAPG further allow g to be nonconvex. The current state-of-the-art is nmAPG. Nevertheless, efficient computation of the underlying proximal operator is only possible for simple nonconvex regularizers. When the regularizer is complicated, such as the nonconvex versions of the fused lasso and overlapping group lasso regularizers (Zhong and Kwok, 2014), the corresponding proximal step has to be solved numerically and is again expensive. Another approach is by using the proximal average (Zhong and Kwok, 2014), which computes and averages the proximal step of each underlying regularizer. As the proximal step is only approximate, its convergence is usually slower than typical applications of the proximal algorithm (Yu, 2013; Li and Lin, 2015).

When f is smooth, there are endeavors to extend other algorithms from convex to nonconvex optimization. For the global consensus problem, standard ADMM converges only when g is convex (Hong et al., 2016). When g is nonconvex, convergence of ADMM is only established for problems of the form $\min_{x,y} f(x) + g(y) : y = Ax$, where matrix A has full row rank (Li and Pong, 2015). The convergence of ADMM in more general cases is an open issue. More recently, the stochastic variance reduced gradient (SVRG) algorithm (Xiao and Zhang, 2014), which is a SGD variant with reduced variance in the gradient estimates, has also been extended for problems with nonconvex f, but the regularizer g is still required to be convex (Reddi et al., 2016a; Zhu and Hazan, 2016).

Sometimes, it is desirable to have a nonsmooth loss f. For example, the absolute loss is more robust to outliers than the square loss, and has been popularly used in applications such as image denoising (Yan, 2013), robust dictionary learning (Zhao et al., 2011) and robust PCA (Candès et al., 2011). The resulting optimization problem becomes more challenging. When both f and g are convex, ADMM is often the main optimization tool for problem (1) (He and Yuan, 2012). However, when either f or g is nonconvex, ADMM no longer guarantees convergence. Besides, the loss f may also be nonconvex as this is more robust to outliers and can obtain better performance (e,g., ℓ_0-norm (Yan, 2013) and capped-ℓ_1 norm (Sun et al., 2013)). However, when f is nonsmooth and nonconvex, none of the above-mentioned algorithms (i.e., proximal algorithms, FW algorithms, ADMM, and SVRG) can be used. As a last resort, one can use more general nonconvex optimization approaches such as convex concave programming (CCCP) (Yuille and Rangarajan, 2002), which is slow in general.

In this paper, we first consider the case where the loss function f is smooth (possibly nonconvex) and the regularizer g is nonconvex. We propose to handle nonconvex regularizers by reusing the abundant repository of efficient convex algorithms originally designed for convex regularizers. Motivated by the fact that recent proximal algorithms (Gong et al., 2013; Li and Lin, 2015; Zhong and Kwok, 2014) all rely on the smoothness of f and a simple closed-form proximal step for g, the key is to shift nonconvexity associated with the nonconvex regularizer to the loss function. The nonconvex regularizer is then transformed to a familiar convex regularizer, while the transformed loss function is still smooth. To illustrate the practical usefulness of this convexification scheme, we show how it can be used with popular optimization algorithms in machine learning. For example, for the proximal algorithm, the resultant proximal step can be much easier after transformation. Specifically, for the nonconvex tree-structured lasso and nonconvex sparse group lasso, we show that the corresponding proximal steps have closed-form solutions on the transformed problems, but not on the original ones. For the nonconvex total variation problem, though there is no closed-form solution for the proximal step before and after the transformation, we show that the proximal step

is still cheaper and easier for optimization after the transformation. To allow further speedup, we propose a proximal algorithm variant that allows the use of inexact proximal steps with convex g when it has no closed-form proximal step solution. For the FW algorithm, we consider its application to nonconvex low-rank matrix learning problems, and propose a variant with guaranteed convergence to a critical point of the nonconvex problem. For SVRG in stochastic optimization and ADMM in consensus optimization, we show that these algorithms have convergence guarantees on the transformed problems but not on the original ones.

We further consider the case where f is both nonconvex and nonsmooth (and g is nonconvex). We demonstrate that problem (1) can be similarly transformed to an equivalent problem with a smooth loss and convex regularizer. However, as the proximal step with the transformed regularizer has to be solved numerically and exact proximal step is required, usage with the proximal algorithm may not be efficient. We show that this can be alleviated by the proposed inexact proximal algorithm. Finally, in the experiments, we demonstrate the above-mentioned advantages of optimizing the transformed problems instead of the original ones on various tasks, and show that running algorithms on the transformed problems can be much faster than running the state-of-the-art on the original problems.

The rest of the paper is organized as follows. Section 2 provides a review on the related works. The main idea for problem transformation is presented in Section 3, and its usage with various algorithms are discussed in Section 4. Experimental results are shown in Section 5, and the last section gives some concluding remarks. All the proofs are in Appendix A. Note that this paper extends a shorter version published in the International Conference of Machine Learning (Yao and Kwok, 2016).

Notation: We denote vectors and matrices by lowercase and uppercase boldface letters, respectively. For a vector $x \in \mathbb{R}^d$, $\|x\|_2 = (\sum_{i=1}^d |x_i|^2)^{1/2}$ is its ℓ_2-norm, $\mathrm{Diag}(x)$ returns a diagonal matrix $X \in \mathbb{R}^{d\times d}$ with $X_{ii} = x_i$. For a matrix $X \in \mathbb{R}^{m\times n}$ (where $m \le n$ without loss of generality), its nuclear norm is $\|X\|_* = \sum_{i=1}^m \sigma_i(X)$, where $\sigma_i(X)$'s are the singular values of X, and its Frobenius norm is $\|X\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n X_{ij}^2}$, and $\|X\|_\infty = \max_{i,j} |X_{ij}|$. For a square matrix X, $X \in \mathcal{S}_+$ indicates it is positive semidefinite. For two matrices X and Y, $\langle X, Y\rangle = \sum_{i,j} X_{ij}Y_{ij}$. For a smooth function f, $\nabla f(x)$ is its gradient at x. For a convex but nonsmooth f, $\partial f(x) = \{u : f(y) \ge f(x) + \langle u, y - x\rangle\}$ is its subdifferential at x, and $g \in \partial f(x)$ is a subgradient.

Given a function (e.g., f), a bar on top (e.g., $\bar{f}$) indicates the function is smooth but not necessarily convex, and a breve on top (e.g., $\breve{f}$) means that it is convex but not necessarily smooth.

2. Related Works

In this section, we review some popular algorithms for solving (1). Here, f is assumed to be Lipschitz smooth.

2.1 Convex-Concave Procedure (CCCP)

The convex-concave procedure (CCCP) (Yuille and Rangarajan, 2002; Lu, 2012) is a popular and general solver for (1). It assumes that F can be decomposed as a difference of convex (DC) functions (Hiriart-Urruty, 1985), i.e., $F(x) = \breve{F}(x) + \hat{F}(x)$ where $\breve{F}$ is convex and $\hat{F}$ is concave. In each

CCCP iteration, $\hat{F}$ is linearized at x_t, and x_{t+1} is generated as

$$x_{t+1} = \arg\min_x \breve{F}(x) + \hat{F}(x_t) - (x - x_t)^\top s_t, \tag{2}$$

where $s_t \in \partial(-\hat{F}(x_t))$ is a subgradient. This is a convex problem and can be easier than directly minimizing F.

However, CCCP is expensive as (2) needs to be exactly solved. Sequential convex programming (SCP) (Lu, 2012) improves its efficiency when F is of the form in (1). It assumes that f is L-Lipschitz smooth (possibly nonconvex); while g can be nonconvex, but admits a DC decomposition as $g(x) = \breve{\zeta}(x) + \hat{\zeta}(x)$ where $\breve{\zeta}$ is convex and $\hat{\zeta}$ is concave. It then generates x_{t+1} as

$$\begin{aligned} x_{t+1} &= \arg\min_x f(x_t) + (x - x_t)^\top \nabla f(x_t) + \frac{L}{2}\|x - x_t\|_2^2 + \breve{\zeta}(x) + \hat{\zeta}(x_t) - (x - x_t)^\top s_t \\ &= \arg\min_x \frac{1}{2}\|x - x_t - s_t + \frac{1}{L}\nabla f(x_t)\|_2^2 + \breve{\zeta}(x), \end{aligned} \tag{3}$$

where $s_t \in \partial\left(-\hat{\zeta}(x_t)\right)$. When $\breve{\zeta}$ is a simple function, (3) has a closed-form solution, and SCP can be faster than CCCP. For example, when $\breve{\zeta}(x) = \|x\|_1$, (3) is the proximal step of the ℓ_1-norm and has a closed-form solution (Tibshirani, 1996). However, convergence of SCP is still slow in general (Gong et al., 2013; Zhong and Kwok, 2014; Li and Lin, 2015).

2.2 Proximal Algorithm

The proximal algorithm (Parikh and Boyd, 2013) has been popularly used for optimization problems of the form in (1). Let f be convex and L-Lipschitz smooth, and g is convex. The proximal algorithm generates iterates $\{x_t\}$ as

$$\begin{aligned} x_{t+1} &= \arg\min_x f(x_t) + (x - x_t)^\top \nabla f(x_t) + \frac{L}{2}\|x - x_t\|_2^2 + g(x) \\ &= \text{prox}_{\frac{1}{L}g}\left(x_t - \frac{1}{L}\nabla f(x_t)\right), \end{aligned}$$

where $\text{prox}_g(z) \equiv \arg\min_x \frac{1}{2}\|x - z\|_2^2 + g(x)$ is the proximal step, The proximal algorithm converges at a rate of $O(1/T)$. This can be further accelerated to $O(1/T^2)$ by modifying the generation of $\{x_t\}$ as (Beck, 2009; Nesterov, 2013):

$$\begin{aligned} y_t &= x_t + \frac{\alpha_{t-1} - 1}{\alpha_t}(x_t - x_{t-1}), \\ x_{t+1} &= \text{prox}_{\frac{1}{L}g}\left(y_t - \frac{1}{L}\nabla f(y_t)\right), \end{aligned}$$

where $\alpha_0 = \alpha_1 = 1$ and $\alpha_{t+1} = \frac{1}{2}(\sqrt{4\alpha_t^2 + 1} + 1)$.

Recently, the proximal algorithm has been extended to nonconvex optimization. In particular, NIPS (Sra, 2012), IPiano (Ochs et al., 2014) and UAG (Ghadimi and Lan, 2016) allow f to be nonconvex, while g is still required to be convex. GIST (Gong et al., 2013), IFB (Bot et al., 2016) and nmAPG (Li and Lin, 2015) further remove this restriction and allow g to be nonconvex. It is desirable that the proximal step has a closed-form solution. This is true for many convex regularizers such as the lasso regularier (Tibshirani, 1996), tree-structured lasso regularizer (Liu and Ye, 2010; Jenatton et al., 2011) and sparse group lasso regularizer (Jacob et al., 2009). However, when g is nonconvex, a closed-form solution only exists when g is simple (e.g., nonconvex lasso regularizer (Gong et al., 2013)), but not for the more general cases (e.g., nonconvex tree-structured lasso regularizer (Zhong and Kwok, 2014)).

On the other hand, Zhong and Kwok (2014) used the proximal average (Bauschke et al., 2008) to handle complicated g's of the form $g(x) = \sum_{i=1}^K \mu_i g_i(x)$, where each g_i has a simple proximal step. The iterates are generated as

$$x_{t+1} = \sum_{i=1}^K \mu_i \cdot \text{prox}_{\frac{\mu_i}{L}g_i}\left(x_t - \frac{1}{L}\nabla f(x_t)\right) / \sum_{i=1}^K \mu_i.$$

Each of the constituent proximal steps $\text{prox}_{\frac{\mu_i}{L}g_i}(\cdot)$ can be computed inexpensively, and the per-iteration complexity is low. However, it only approximates $\text{prox}_g(z)$ and consequently also the original problem (1). Empirically, its convergence can be slow.

2.3 Frank-Wolfe (FW) Algorithm

The FW algorithm (Frank and Wolfe, 1956) is used for solving optimization problems of the form

$$\min_x f(x) \ : \ x \in \mathcal{C}, \tag{4}$$

where f is Lipschitz-smooth and convex, and $\mathcal{C}$ is a compact convex set. Recently, it has been popularly used in machine learning (Jaggi, 2013). In each iteration, the FW algorithm generates the next iterate x_{t+1} as

$$s_t = \arg\min_{s \in \mathcal{C}} s^\top \nabla f(x_t), \tag{5}$$

$$\gamma_t = \arg\min_{\gamma \in [0,1]} f((1-\gamma)x_t + \gamma s_t), \tag{6}$$

$$x_{t+1} = (1 - \gamma_t)x_t + \gamma_t s_t. \tag{7}$$

Here, (5) is a linear subproblem which can often be easily solved; (6) performs line search, and the next iterate x_{t+1} is generated from a convex combination of x_t and s_t in (7). The FW algorithm has a convergence rate of $O(1/T)$ (Jaggi, 2013).

In this paper, we will focus on using the FW algorithm to learn a low-rank matrix $X \in \mathbb{R}^{m \times n}$. Without loss of generality, we assume that $m \leq n$. The nuclear norm $\|X\|_*$ of X is the tightest convex envelope of rank(X), and is often used as a low-rank regularizer (Candès and Recht, 2009). The low-rank matrix learning problem can be written as

$$\min_X f(X) + \mu\|X\|_*, \tag{8}$$

where f is the loss. For example, in matrix completion (Candès and Recht, 2009),

$$f(X) = \frac{1}{2}\|\mathcal{P}_\Omega(X - O)\|_F^2, \tag{9}$$

where O is the observed incomplete matrix, $\Omega \in \{0,1\}^{m \times n}$ contains indices to the observed entries in O, and $[P_\Omega(A)]_{ij} = A_{ij}$ if $\Omega_{ij} = 1$, and 0 otherwise.

The FW algorithm for this nuclear norm regularized problem is shown in Algorithm 1 (Zhang et al., 2012). Let the iterate at the tth iteration be X_t. As in (5), the following linear subproblem has to be solved (Jaggi, 2013):

$$\min_{S:\|S\|_*\leq 1} \langle S, \nabla f(X_t)\rangle. \tag{10}$$

This can be obtained from the rank-one SVD of $\nabla f(X_t)$ (step 3). Similar to (6), line search is performed at step 4. As a rank-one matrix is added into X_t in each iteration, it is convenient to write X_t as

$$\sum_{i=1}^{t} u_i v_i^\top = U_t V_t^\top, \tag{11}$$

where $U_t = [u_1, \ldots, u_t]$ and $V_t = [v_1, \ldots, v_t]$. The FW algorithm has a convergence rate of $O(1/T)$ (Jaggi, 2013). To make it empirically faster, Algorithm 1 also performs optimization at step 6 (Laue, 2012; Zhang et al., 2012). Substituting $\|X\|_* = \min_{X=UV^\top} \frac{1}{2}\left(\|U\|_F^2 + \|V\|_F^2\right)$ (Srebro et al., 2004) into (8), we have the following local optimization problem:

$$\min_{U,V} f(UV^\top) + \frac{\mu}{2}(\|U\|_F^2 + \|V\|_F^2). \tag{12}$$

This can be solved by standard solvers such as L-BFGS (Nocedal and Wright, 2006).

Algorithm 1 Frank-Wolfe algorithm for problem (8) with f convex (Zhang et al., 2012).

1: $U_1 = [\,]$ and $V_1 = [\,]$;
2: **for** $t = 1 \ldots T$ **do**
3: $[u_t, s_t, v_t] = \text{rank1SVD}(\nabla f(X_t))$;
4: $[\alpha_t, \beta_t] = \arg\min_{\alpha\geq 0, \beta\geq 0} f(\alpha X_t + \beta u_t v_t^\top) + \mu(\alpha\|X_t\|_* + \beta)$;
5: $\bar{U}_t = \left[\sqrt{\alpha_t}U_t; \sqrt{\beta_t}u_t\right]$ and $\bar{V}_t = \left[\sqrt{\alpha_t}V_t; \sqrt{\beta_t}v_t\right]$;
6: obtain $[U_{t+1}, V_{t+1}]$ from (12), using $\bar{U}_t$ and $\bar{V}_t$ for warm-start; // $X_{t+1} = U_{t+1}V_{t+1}^\top$
7: **end for**
8: **return** U_{T+1} and V_{T+1}.

2.4 Alternating Direction Method of Multipliers (ADMM)

ADMM is a simple but powerful algorithm first introduced in the 1970s (Glowinski and Marroco, 1975). Recently, it has been popularly used in diverse fields such as machine learning, data mining and image processing (Boyd et al., 2011). It can be used to solve optimization problems of the form

$$\min_{x,y}\ f(x) + g(y)\ :\ Ax + By = c, \tag{13}$$

where f, g are convex functions, and A, B (resp. c) are constant matrices (resp. vector) of appropriate sizes. Consider the augmented Lagrangian $\mathcal{L}(x, y, u) = f(x) + g(y) + u^\top(Ax + By - c) + \frac{\tau}{2}\|Ax + By - c\|_2^2$, where u is the vector of Lagrangian multipliers, and $\tau > 0$ is a penalty parameter. At the tth iteration of ADMM, the values of x, y and u are updated as

$$x_{t+1} = \arg\min_x \mathcal{L}(x, y_t, u_t), \tag{14}$$

$$y_{t+1} = \arg\min_y \mathcal{L}(x_{t+1}, y, u_t), \tag{15}$$

$$u_{t+1} = u_t + \tau(Ax_{t+1} + By_{t+1} - c). \tag{16}$$

By minimizing $L(x, y, u_k)$ w.r.t. x and y in an alternating manner ((14) and (15)), ADMM can more easily decompose the optimization problem when f, g are separable.

In this paper, we will focus a special case of (13), namely, the consensus optimization problem:

$$\min_{y,x^1,\ldots,x^M} \sum_{i=1}^{M} f_i(x^i) + g(y)\quad :\quad x^1 = \cdots = x^M = y. \tag{17}$$

Here, each f_i is Lipschitz-smooth, x^i is the variable in the local objective f_i, and y is the global consensus variable. This type of problems is often encountered in machine learning, signal processing and wireless communication (Bertsekas and Tsitsiklis, 1989; Boyd et al., 2011). For example, in regularized risk minimization, y is the model parameter, f_i is the regularized risk functional defined on the ith data subset, and g is the regularizer. The augmented Lagrangian for (17) is

$$\mathcal{L}(y, x^1, \ldots, x^M, u^1, \ldots, u^M) = g(y) + \sum_{i=1}^{M} f_i\left(x^i\right) + (u^i)^\top(x^i - y) + \frac{\tau}{2}\|x^i - y\|_2^2,$$

where u^i is the dual variable for the constraint $x^i = y$. Substituting into (14)-(16), we have

$$x_{t+1}^i = \arg\min_{x^i} f_i(x^i) + (u_t^i)^\top(x^i - y_t) + \frac{\tau}{2}\|x^i - y_t\|_2^2,\quad i = 1, \ldots, M, \tag{18}$$

$$y_{t+1} = \arg\min_y \frac{1}{2}\left\|y - \sum_{i=1}^{M}\left(x_t^i + \frac{1}{\tau}u_t^i\right)\right\|_2^2 + \frac{1}{\tau}g(y) = \text{prox}_{\frac{1}{\tau}g}\left(\sum_{i=1}^{M} x_t^i + \frac{1}{\tau}u_t^i\right), \tag{19}$$

$$u_{t+1} = u_t + \tau\left(x_{t+1}^i + y_{t+1}\right),\quad i = 1, \ldots, M.$$

When f_i is smooth and g is convex, ADMM converges to a critical point of (17) (Hong et al., 2016). However, when g is nonconvex, its convergence is still an open issue.

3. Shifting Nonconvexity from Regularizer to Loss

In recent years, a number of nonconvex regularizers have been proposed. Examples include the Geman penalty (GP) (Geman and Yang, 1995), log-sum penalty (LSP) (Candès et al., 2008) and Laplace penalty (Trzasko and Manduca, 2009). In general, learning with nonconvex regularizers is much more difficult than learning with convex regularizers. In this section, we show how to move the nonconvex component from the nonconvex regularizers to the loss function. Existing algorithms can then be reused to learn with the convexified regularizers.

First, we make the following standard assumptions on (1).

A1. F is bounded from below and $\lim_{\|x\|_2\to\infty} F(x) = \infty$;

A2. f is L-Lipschitz smooth (i.e., $\|\nabla f(x) - \nabla f(y)\|_2 \leq L\|x - y\|_2$), but possibly nonconvex.

Let κ be a function that is concave, non-decreasing, ρ-Lipschitz smooth with κ' non-differentiable at finite points, and $\kappa(0) = 0$. All nonconvex regularizers in Table 1 satisfy the requirements on κ.

In this paper, we consider g of the following forms:

	$\kappa(\alpha)$	$\kappa'(\alpha)$	κ_0	ρ
GP (Geman and Yang, 1995)	$\frac{\beta\alpha}{\theta+\alpha}$	$\frac{\beta\theta}{(\theta+\alpha)^2}$	$\frac{\beta}{\theta}$	$\frac{2\beta}{\theta^2}$
LSP (Candès et al., 2008)	$\beta\log(1+\frac{\alpha}{\theta})$	$\frac{\beta}{\theta+\alpha}$	$\frac{\beta}{\theta}$	$\frac{\beta}{\theta^2}$
MCP (Zhang, 2010a)	$\begin{cases}\beta\alpha-\frac{\alpha^2}{2\theta} & \alpha\le\beta\theta\\ \frac{1}{2}\theta\beta^2 & \alpha>\beta\theta\end{cases}$	$\begin{cases}\beta-\frac{\alpha}{\theta} & \alpha\le\beta\theta\\ 0 & \alpha>\beta\theta\end{cases}$	β	$\frac{1}{\theta}$
Laplace (Trzasko and Manduca, 2009)	$\beta(1-\exp(-\frac{\alpha}{\theta}))$	$\frac{\beta}{\theta}\exp\left(-\frac{\alpha}{\theta}\right)$	$\frac{\beta}{\theta}$	$\frac{\beta}{\theta^2}$
SCAD (Fan and Li, 2001)	$\begin{cases}\beta\alpha & \alpha\le\beta\\ \frac{-\alpha^2+2\theta\beta\alpha-\beta^2}{2(\theta-1)} & \beta<\alpha\le\theta\beta\\ \frac{\beta^2(1+\theta)}{2} & \alpha>\theta\beta\end{cases}$	$\begin{cases}\beta & \alpha\le\beta\\ \frac{-\alpha+\theta\beta}{\theta-1} & \beta<\alpha\le\theta\beta\\ 0 & \alpha>\theta\beta\end{cases}$	β	$\frac{1}{\theta-1}$

Table 1: Example nonconvex regularizers. Here, $\kappa_0 \equiv \kappa'(0)$ and $\beta > 0$. For SCAD, $\theta > 2$, whereas for others, $\theta > 0$.

C1. $g(x) = \sum_{i=1}^K \mu_i g_i(x)$, where $\mu_i \ge 0$,

$$g_i(x) = \kappa(\|A_i x\|_2), \tag{20}$$

and A_i is a matrix. When κ is the identity function, $g(x)$ reduces to the convex regularizer $\sum_{i=1}^K \mu_i \|A_i x\|_2$. By using different A_i's, g becomes various structured sparsity regularizers such as the group lasso (Jacob et al., 2009), fused lasso (Tibshirani et al., 2005), and graphical lasso (Jacob et al., 2009).

C2. $g(X) = \mu \sum_{i=1}^m \kappa(\sigma_i(X))$, where X is a matrix and $\mu \ge 0$. When κ is the identity function, g reduces to the nuclear norm.

First, consider g in **C1**. Rewrite each nonconvex g_i in (20) as

$$g_i(x) = \bar{g}_i(x) + \kappa_0\|A_i x\|_2, \tag{21}$$

where $\kappa_0 = \kappa'(0)$, and $\bar{g}_i(x) = \kappa(\|A_i x\|_2) - \kappa_0\|A_i x\|_2$. Obviously, $\kappa_0\|A_i x\|_2$ is convex but nonsmooth. The following shows that $\bar{g}_i$, though nonconvex, is concave and Lipschitz smooth.

Proposition 1 *$\kappa(\|z\|_2) - \kappa_0\|z\|_2$, where $z \in \mathbb{R}^d$, is concave and 2ρ-Lipschitz smooth.*

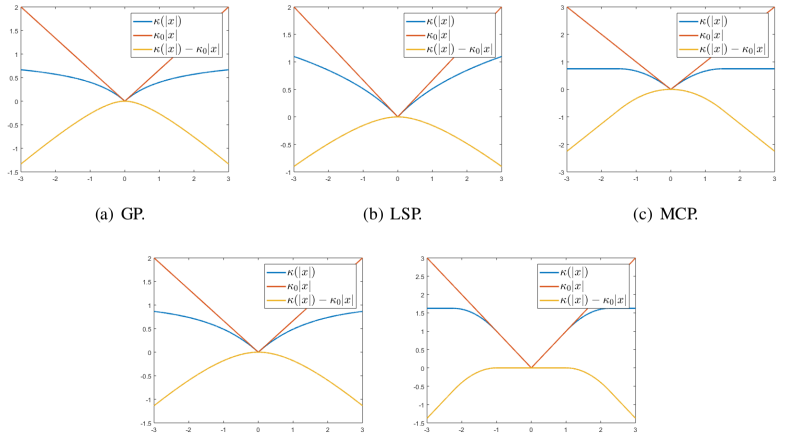
Corollary 2 *$\bar{g}_i$ is concave and Lipschitz smooth with modulus $\bar{L}_i = 2\rho\|A_i\|_F$.*

Corollary 3 *$g(x)$ can be decomposed as $\bar{g}(x) + \breve{g}(x)$, where $\bar{g}(x) \equiv \sum_{i=1}^K \mu_i \bar{g}_i(x)$ is concave and Lipschitz-smooth, while $\breve{g}(x) \equiv \kappa_0 \sum_{i=1}^K \mu_i \|A_i x\|_2$ is convex but nonsmooth.*

Remark 4 *When $A_i = Diag(e_i)$, where e_i is the unit vector for dimension i, $\|A_i x\|_2 = |x_i|$ and*

$$g(x) = \sum_{i=1}^d \mu_i \kappa(\|A_i x\|_2) = \sum_{i=1}^d \mu_i \kappa(|x_i|). \tag{22}$$

Using Corollary 3, g can be decomposed as $\bar{g}(x) + \breve{g}(x)$, where $\bar{g}(x) \equiv \sum_{i=1}^d \mu_i(\kappa(|x_i|) - \kappa_0|x_i|)$ is concave and 2ρ-Lipschitz smooth, while $\breve{g}(x) \equiv \kappa_0 \sum_{i=1}^d \mu_i|x_i|$ is convex and nonsmooth. When $d = 1$ and $\mu_1 = 1$, an illustration of $g(x) = \kappa(|x|)$, $\bar{g}(x) = \kappa(|x|) - \kappa_0|x|$ and $\breve{g}(x) = \kappa_0|x|$ for the various nonconvex regularizers is shown in Figure 2. When κ is the identity function and $\mu_1 = \cdots = \mu_m = \mu$, g in (22) reduces to the lasso regularizer $\mu\|x\|_1$.



(a) GP. (b) LSP. (c) MCP.

(d) Laplace. (e) SCAD.

Figure 2: Decompositions of the regularizers in Table 1 ($\beta = 1$ for all regularizers; $\theta = 2.25$ for SCAD and 1.5 for others).

Using Corollary 3, problem (1) can then be rewritten as

$$\min_x \bar{f}(x) + \breve{g}(x), \tag{23}$$

where $\bar{f}(x) \equiv f(x) + \bar{g}(x)$. Note that $\bar{f}$ (which can be viewed as an augmented loss) is Lipschitz smooth while $\breve{g}$ (viewed as a convexified regularizer) is convex but possibly nonsmooth. In other words, nonconvexity is shifted from the regularizer g to the loss f, while ensuring that the augmented loss is smooth.

When X is a matrix, similar to Corollary 3, the following Proposition holds for g in **C2**.

Proposition 5 *Any g in **C2** can be decomposed as $\bar{g}(X) + \breve{g}(X)$, where*

$$\bar{g}(X) \equiv \mu \sum_{i=1}^m \kappa(\sigma_i(X)) - \mu\kappa_0\|X\|_* \tag{24}$$

is concave and 2ρ-Lipschitz smooth, and $\breve{g}(X) \equiv \kappa_0\|X\|_*$ is convex and nonsmooth.

Since $\bar{g}$ is concave and $\breve{g}$ is convex, the nonconvex regularizer $g = \breve{g} - (-\bar{g})$ can be viewed as a difference of convex functions (DC) (Hiriart-Urruty, 1985). Lu (2012); Gong et al. (2013); Zhong and Kwok (2014) also relied on DC decompositions of the nonconvex regularizer. However, they do not utilize this in the computational procedures, while we use the DC decomposition to simplify the regularizers. As will be seen, though the DC decomposition of a nonconvex function is not unique in general, the particular one proposed here is crucial for efficient optimization.

4. Example Use Cases

In this section, we provide concrete examples to show how the proposed convexification scheme can be used with various optimization algorithms. An overview is summarized in Table 2.

	section	advantages
proximal algorithm	4.1, 4.6	cheaper proximal step
FW algorithm	4.2	cheaper linear subproblem
(consensus) ADMM	4.3	cheaper proximal step; provide convergence guarantee
SVRG	4.4	cheaper proximal step; provide convergence guarantee
mOWL-QN	4.5	simpler analysis; capture curvature information

Table 2: Using the proposed convexification scheme with various algorithms.

4.1 Proximal Algorithms

In this section, we provide example applications on using the proximal algorithm for nonconvex structured sparse learning. The proximal algorithm has been commonly used for learning with convex regularizers (Parikh and Boyd, 2013). With a nonconvex regularizer, the underlying proximal step becomes much more challenging. Gong et al. (2013); Li and Lin (2015) and Bot et al. (2016) extended proximal algorithm to simple nonconvex g, but cannot handle more complicated nonconvex regularizers such as the tree-structured lasso regularizer (Liu and Ye, 2010; Schmidt et al., 2011), sparse group lasso regularizer (Jacob et al., 2009) and total variation regularizer (Nikolova, 2004). Using the proximal average (Bauschke et al., 2008), Zhong and Kwok (2014) can handle nonconvex regularizers of the form $g = \sum_{i=1}^{K} \mu_i g_i$, where each g_i is simple. However, the solutions obtained are only approximate. General nonconvex optimization techniques such as the concave-convex procedure (CCCP) (Yuille and Rangarajan, 2002) or its variant sequential convex programming (SCP) (Lu, 2012) can also be used, though they are slow in general (Gong et al., 2013; Zhong and Kwok, 2014).

Using the proposed transformation, one only needs to solve the proximal step of a standard convex regularizer instead of that of a nonconvex regularizer. This allows reuse of existing solutions for the proximal step and is much less expensive. As proximal algorithms have the same convergence guarantee for convex and nonconvex f (Gong et al., 2013; Li and Lin, 2015; Yao et al., 2017), solving the transformed problem can be much faster. The following gives some specific examples.

4.1.1 NONCONVEX SPARSE GROUP LASSO

In sparse group lasso, the feature vector x is divided into groups. Let $\mathcal{G}_j$ be the set containing dimensions of x that are in group j, and $\left[x_{\mathcal{G}_j}\right]_i = x_i$ if $i \in \mathcal{G}_j$ and 0 otherwise. Given training samples $\{(a_1, y_1), \ldots, (a_N, y_N)\}$, (convex) sparse group lasso is formulated as (Jacob et al., 2009):

$$\min_x \sum_{i=1}^{N} \ell(y_i, a_i^\top x) + \lambda \|x\|_1 + \sum_{j=1}^{K} \mu_j \|x_{\mathcal{G}_j}\|_2, \tag{25}$$

where ℓ is a smooth loss, and K is the number of (non-overlapping) groups.

For the nonconvex extension, the regularizer becomes

$$g(x) = \lambda \sum_{i=1}^{d} \kappa(|x_i|) + \sum_{j=1}^{K} \mu_j \kappa(\|x_{\mathcal{G}_j}\|_2). \tag{26}$$

Using Corollary 3 and Remark 4, the convexified regularizer is $\breve{g}(x) = \kappa_0(\lambda\|x\|_1 + \sum_{j=1}^{K} \mu_j \|x_{\mathcal{G}_j}\|_2)$. Its proximal step can be easily computed by the algorithm in (Yuan et al., 2011). Specifically, the proximal operator of $\breve{g}$ can be obtained by computing $\text{prox}_{\mu_j\|\cdot\|_2}(\text{prox}_{\lambda\|\cdot\|_1}(x_{\mathcal{G}_j}))$ for each group separately. This can then be used with any proximal algorithm that can handle nonconvex objectives (as $\bar{f}$ is nonconvex). In particular, we will adopt the state-of-the-art nonmontonic APG (nmAPG) algorithm (Li and Lin, 2015) (shown in Algorithm 2). On the other hand, note that nmAPG cannot be directly used with the nonconvex regularizer g in (26), as the corresponding proximal step has no inexpensive closed-form solution.

Algorithm 2 Nonmonotonic APG (nmAPG) (Li and Lin, 2015).

Initialize $z_1 = x_1 = x_0$, $\alpha_0 = 0$, $\alpha_1 = 1$, $\eta \in [0, 1)$, $c_1 = F(x_1)$, $q_1 = 1$, and stepsize $\tau > \bar{L}$, $\delta \in (0, \tau - \bar{L})$;
for $t = 1, \ldots, T$ **do**
  $y_t = x_t + \frac{\alpha_{t-1}}{\alpha_t}(z_t - x_t) + \frac{\alpha_{t-1}-1}{\alpha_t}(x_t - x_{t-1})$;
  $z_{t+1} = \text{prox}_{\frac{1}{\tau}\breve{g}}(y_t - \frac{1}{\tau}\nabla \bar{f}(y_t))$;
  if $F(z_{t+1}) \le c_t - \frac{\delta}{2}\|z_{t+1} - y_t\|_2^2$ **then**
    $x_{t+1} = z_{t+1}$;
  else
    $v_{t+1} = \text{prox}_{\frac{1}{\tau}\breve{g}}(x_t - \frac{1}{\tau}\nabla \bar{f}(x_t))$;
    $x_{t+1} = \begin{cases} z_{t+1} & F(z_{t+1}) \le F(v_{t+1}) \\ v_{t+1} & \text{otherwise} \end{cases}$;
  end if
  $\alpha_{t+1} = \frac{1}{2}(\sqrt{4\alpha_t^2 + 1} + 1)$;
  $q_{t+1} = \eta q_t + 1$;
  $c_{t+1} = \frac{\eta q_t c_t + F(x_{t+1})}{q_{t+1}}$;
end for
return x_{T+1};

4.1.2 NONCONVEX TREE-STRUCTURED GROUP LASSO

In (convex) tree-structured group lasso (Liu and Ye, 2010; Jenatton et al., 2011), the dimensions in x are organized as nodes in a tree, and each group corresponds to a subtree. The regularizer is of the form $\sum_{j=1}^{K} \lambda_j \|x_{\mathcal{G}_j}\|_2$. Interested readers are referred to (Liu and Ye, 2010) for details.

For the nonconvex extension, $g(x)$ becomes $\sum_{j=1}^{K} \lambda_j \kappa(\|x_{\mathcal{G}_j}\|_2)$. Again, there is no closed-form solution of its proximal step. On the other hand, the convexified regularizer is $\breve{g}(x) \equiv \kappa_0 \sum_{j=1}^{K} \lambda_j \|x_{\mathcal{G}_j}\|_2$. As shown in (Liu and Ye, 2010), its proximal step can be computed efficiently by processing all the groups once in some appropriate order.

4.1.3 NONCONVEX TOTAL VARIATION (TV) REGULARIZER

In an image, nearby pixels are usually strongly correlated. The TV regularizer captures such behavior by assuming that changes between nearby pixels are small. Given an image $X \in \mathbb{R}^{m \times n}$, the TV regularizer is defined as $\text{TV}(X) = \|D_v X\|_1 + \|X D_h\|_1$ (Nikolova, 2004), $D_v = \begin{bmatrix} -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{bmatrix} \in \mathbb{R}^{(m-1)\times m}$ and $D_h = \begin{bmatrix} -1 & & \\ 1 & \ddots & \\ & \ddots & -1 \\ & & 1 \end{bmatrix} \in \mathbb{R}^{n \times (n-1)}$ are the horizontal and vertical partial derivative operators, respectively. Thus, it is popular on image processing problems, such as image denoising and deconvolution (Nikolova, 2004; Beck and Teboulle, 2009).

As in previous sections, the nonconvex extension of TV regularizer can be defined as

$$\sum_{i=1}^{m-1} \sum_{j=1}^{m} \kappa\left(\left|[D_v X]_{ij}\right|\right) + \sum_{i=1}^{n} \sum_{j=1}^{n-1} \kappa\left(\left|[X D_h]_{ij}\right|\right). \tag{27}$$

Again, it is not clear how its proximal step can be efficiently computed. Instead, with the proposed transformation, the transformed problem is

$$\min_X \bar{f}(X) + \mu\kappa_0 \text{TV}(X),$$

where μ is the regularization parameter, $\bar{f}(X) = f(X) + \mu \sum_{i=1}^{m-1} \sum_{j=1}^{m} (\kappa(|[D_v X]_{ij}|) - \kappa_0 |[D_v X]_{ij}|) + \mu \sum_{i=1}^{n} \sum_{j=1}^{n-1} (\kappa(|[X D_h]_{ij}|) - \kappa_0 |[X D_h]_{ij}|)$ is concave and Lipschitz smooth. One then only needs to compute the proximal step of the standard TV regularizer.

Unlike the proximal steps in Sections 4.1.1 and 4.1.2, the proximal step of the TV regularizer has no closed-form solution and needs to be solved iteratively. In this case, Schmidt et al. (2011) showed that using inexact proximal steps can make proximal algorithms faster, but they only considered the situation where both f and g are convex. In the following, we extend nmAPG (Algorithm 2), which can be used with nonconvex objectives, to allow for inexact proximal steps (steps 5 and 9 of Algorithm 3). However, Lemma 2 of (Li and Lin, 2015), which is key to the convergence of nmAPG, no longer holds because of the inexact proximal step. To fix this problem, in step 6 of Algorithm 3, we use $F(X_t)$ instead of c_t in Algorithm 2. We also drop the comparison of $F(Z_{t+1})$ and $F(V_{t+1})$ (originally in step 9 of Algorithm 2).

Inexactness of the proximal step can be controlled as follows. Let $P = X - \frac{1}{\tau}\nabla \bar{f}(X)$, and $h(X) \equiv \frac{1}{2}\|X - P\|_F^2 + \frac{1}{\tau}\breve{g}(X)$ be the objective in $\text{prox}_{\frac{1}{\tau}\breve{g}}(P)$. As $\breve{g}(X) = \kappa_0 \text{TV}(X)$ is convex,

Algorithm 3 Inexact nmAPG.

1: Initialize $\tilde{Z}_1 = X_1 = X_0$, $\alpha_0 = 0$, $\alpha_1 = 1$ and stepsize $\tau > \bar{L}$, $\delta \in (0, \tau - \bar{L})$;
2: **for** $t = 1, \ldots, T$ **do**
3: choose tolerance ϵ_t;
4: $Y_t = X_t + \frac{\alpha_{t-1}}{\alpha_t}(Z_t - X_t) + \frac{\alpha_{t-1}-1}{\alpha_t}(X_t - X_{t-1})$;
5: $\tilde{Z}_{t+1}$ = approximate $\text{prox}_{\frac{1}{\tau}\breve{g}}(Y_t - \frac{1}{\tau}\nabla \bar{f}(Y_t))$, with inexactness $\vartheta_{t+1} \le \epsilon_t$;
6: **if** $F(\tilde{Z}_{t+1}) \le F(X_t) - \frac{\delta}{2}\|\tilde{Z}_{t+1} - Y_t\|_F^2$ **then**
7: $X_{t+1} = \tilde{Z}_{t+1}$;
8: **else**
9: X_{t+1} = approximate $\text{prox}_{\frac{1}{\tau}\breve{g}}(X_t - \frac{1}{\tau}\nabla \bar{f}(X_t))$, with inexactness $\vartheta_{t+1} \le \epsilon_t$;
10: **end if**
11: $\alpha_{t+1} = \frac{1}{2}(\sqrt{4\alpha_t^2 + 1} + 1)$;
12: **end for**
13: **return** X_{T+1};

h is also convex. Let $\tilde{X}$ be an inexact solution of this proximal step. The inexactness $h(\tilde{X}) - h(\text{prox}_{\frac{1}{\tau}\breve{g}}(P))$ is upper-bounded by the duality gap $\vartheta \equiv h(\tilde{X}) - \mathcal{D}(\tilde{W})$, where $\mathcal{D}$ is the dual of h, and $\tilde{W}$ is the corresponding dual variable. In steps 5 and 9 of Algorithm 3, we solve the proximal step until the duality gap ϑ_{t+1} is smaller than a given threshold ϵ_t. The following Theorem shows convergence of Algorithm 3.

Theorem 6 *Let $\sum_{t=1}^{\infty} \epsilon_t < \infty$. The sequence $\{X_t\}$ generated from Algorithm 3 has at least one limit point, and every limit point is also a critical point of* (1).

If the proximal step is exact, $\|V_t - \text{prox}_{\frac{1}{\tau}\breve{g}}(V_t - \frac{1}{\tau}\nabla \bar{f}(V_t))\|_F^2$ can be used to measure how far V_t is from a critical point (Gong et al., 2013; Ghadimi and Lan, 2016). In Algorithm 3, the proximal step is inexact, and X_{t+1} is an inexact solution to $\text{prox}_{\frac{1}{\tau}\breve{g}}(V_t - \frac{1}{\tau}\nabla \bar{f}(V_t))$, where $V_t = Y_t$ if step 7 is executed, and $V_t = X_t$ if step 9 is executed. As X_{t+1} converges to a critical point of (1), we propose using $d_t \equiv \|X_{t+1} - V_t\|_F^2$ to measure how far X_{t+1} is from a critical point. The following Proposition shows a $O(1/T)$ convergence rate on $\min_{t=1,\ldots,T} d_t$.

Proposition 7 *(i) $\lim_{t\to\infty} d_t = 0$; and (ii) $\min_{t=1,\ldots,T} d_t$ converges to zero at a rate of $O(1/T)$.*

Note that the (exact) nmAPG in Algorithm 2 cannot handle the nonconvex g in (27) efficiently, as the corresponding proximal step has no closed-form solution but has to be solved exactly. Even the proposed inexact nmAPG (Algorithm 3) cannot be directly used with nonconvex g. As the dual of the nonconvex proximal step is difficult to derive and the optimal duality gap is nonzero in general, the proximal step's inexactness cannot be easily controlled.

Remark 8 *As mentioned in Section 3, the proposed decomposition of the nonconvex regularizer g can be regarded as a DC decomposition, which is not unique in general. For example, in Section 4.1.1, we might try to add a quadratic term to convexify the nonconvex sparse group lasso regularizer. Specifically, we can decompose $g(x)$ in (26) as $\breve{\varsigma}(x) + \hat{\varsigma}(x)$, where*

$$\breve{\varsigma}(x) = \lambda \sum_{i=1}^{d} \left(\kappa(|x_i|) + \frac{\rho}{2}x_i^2\right) + \sum_{j=1}^{K} \mu_j \left(\kappa(\|x_{\mathcal{G}_j}\|_2) + \frac{\rho}{2}\|x_{\mathcal{G}_j}\|_2^2\right), \tag{28}$$

and $\hat{\varsigma}(x) = -\frac{\rho}{2}\sum_{j=1}^{K}(\mu_j+\lambda)\|x_{\mathcal{G}_j}\|_2^2$. *It can be easily shown that* $\hat{\varsigma}$ *is concave, and the following Proposition 9 shows that* $\check{\varsigma}$ *is convex. Thus,* F *can be transformed as* $F(x) = \bar{f}(x) + \check{\varsigma}(x)$, *where* $\bar{f}(x) = f(x) + \hat{\varsigma}(x)$ *is Lipschitz-smooth, and* $\check{\varsigma}$ *is convex but nonsmooth. However, the proximal step associated with* $\check{\varsigma}$ *has no simple closed-form solution.*

Proposition 9 $\kappa(\|\cdot\|) + \frac{\rho}{2}\|\cdot\|^2$, *where* $\|\cdot\|$ *is a norm, is convex.*

Similarly, in Section 4.1.2, we can also add a quadratic term to convexify the nonconvex tree-structured group lasso regularizer as $\sum_{j=1}^{K}\lambda_j(\kappa(\|x_{\mathcal{G}_j}\|_2)+\frac{\rho}{2}\|x_{\mathcal{G}_j}\|_2^2)$. *The corresponding proximal step is*

$$\min_x \frac{1}{2}\|x-z\|_2^2 + \sum_{j=1}^{K}\lambda_j\left(\kappa\left(\|x_{\mathcal{G}_j}\|_2\right) + \frac{\rho}{2}\|x_{\mathcal{G}_j}\|_2^2\right). \tag{29}$$

However, inexpensive closed-form solution on the proximal step is only known for tree-structured group lasso regularizers of the form $\sum_{j=1}^{K}\lambda_j\|x_{\mathcal{G}_j}\|_2$ *(Jenatton et al., 2011; Liu and Ye, 2010). Thus, (29) has to be iteratively solved (e.g., using ADMM), and is slow.*

In Section 4.1.3, by adding quadratic terms to the nonconvex TV regularizer, it becomes $\sum_{i=1}^{m-1}\sum_{j=1}^{m}(\kappa(|[D_vX]_{ij}|)+\frac{\rho}{2}[D_vX]_{ij}^2)+\sum_{i=1}^{n}\sum_{j=1}^{n-1}(\kappa(|[XD_h]_{ij}|)+\frac{\rho}{2}[XD_h]_{ij}^2)$, *where* $\rho>0$ *is a constant. The corresponding proximal step is*

$$\min_X \frac{1}{2}\|X-Z\|_F^2+\mu\sum_{i=1}^{m-1}\sum_{j=1}^{m}\Big(\kappa\left(|[D_vX]_{ij}|\right)+\frac{\rho}{2}[D_vX]_{ij}^2\Big)+\mu\sum_{i=1}^{n}\sum_{j=1}^{n-1}\Big(\kappa\left(|[XD_h]_{ij}|\right)+\frac{\rho}{2}[XD_h]_{ij}^2\Big),$$

which is difficult to solve. Morevoer, unlike the proposed convexification scheme, the dual of the above is difficult to derive.

4.2 Frank-Wolfe Algorithm

In this section, we use the Frank-Wolfe algorithm to learn a low-rank matrix $X \in \mathbb{R}^{m\times n}$ for matrix completion (Section 2.3). The nuclear norm regularizer in (8) may over-penalize top singular values. Recently, there is growing interest to replace this with nonconvex regularizers (Lu et al., 2014, 2015; Yao et al., 2015). Hence, instead of (8), we consider

$$\min_X f(X) + \mu\sum_{i=1}^{m}\kappa(\sigma_i(X)). \tag{30}$$

When κ is the identity function, (30) reduces to (8). Note that the FW algorithm cannot be directly used on (8), as its linear subproblem in (10) then becomes $\min_{S:\sum_{i=1}^{m}\kappa(\sigma_i(S))\le 1}\langle S, \nabla f(X_t)\rangle$, which is difficult to solve.

Using Proposition 5, problem (30) is transformed into

$$\min_X \bar{f}(X) + \bar{\mu}\|X\|_*, \tag{31}$$

where

$$\bar{f}(X) = f(X) + \bar{g}(X),\ \ \bar{g}(X) = \mu\sum_{i=1}^{m}(\kappa(\sigma_i(X)) - \kappa_0\sigma_i(X)), \tag{32}$$

and $\bar{\mu} = \mu\kappa_0$. Although this only involves the standard nuclear norm regularizer, Algorithm 1 still cannot be used as $\bar{f}$ in (32) is no longer convex. A FW variant allowing nonconvex $\bar{f}$ is proposed in (Bredies et al., 2009). However, condition 1 in (Bredies et al., 2009) requires g to satisfy $\lim_{\|X\|_F\to\infty}\frac{g(X)}{\|X\|_F} = \infty$. This condition does not hold with $g(X) = \|X\|_*$ in (31), as

$$\frac{\|X\|_*}{\|X\|_F} = \sqrt{\frac{(\sum_{i=1}^{m}\sigma_i)^2}{\sum_{i=1}^{m}\sigma_i^2}} \le \sqrt{\frac{m\sum_{i=1}^{m}\sigma_i^2}{\sum_{i=1}^{m}\sigma_i^2}} = \sqrt{m} < \infty.$$

In the following, we propose a nonconvex FW variant (Algorithm 4) for the transformed problem (31). It is similar to the original FW Algorithm 1, but with three important modifications. First, $\bar{g}(X)$ in (32) depends on the singular values of X, which cannot be directly obtained from the $UV^\top$ factorization in (11). Instead, we use the low-rank factorization

$$X = UBV^\top, \tag{33}$$

where $U \in \mathbb{R}^{m\times k}$, $V \in \mathbb{R}^{n\times k}$ are orthogonal and $B \in \mathcal{S}_+^{k\times k}$ is positive semidefinite.

Algorithm 4 Frank-Wolfe algorithm for solving the nonconvex problem (31).

1: $U_1 = [\,]$, $B_1 = [\,]$ and $V_1 = [\,]$;
2: **for** $t = 1\dots T$ **do**
3: $[u_t, s_t, v_t] = \text{rank1SVD}(\nabla\bar{f}(X_t))$;
4: obtain α_t and β_t from (36);
5: $[\bar{U}_t, \bar{B}_t, \bar{V}_t] = \text{warmstart}(U_t, u_t, V_t, v_t, B_t, \alpha_t, \beta_t)$;
6: obtain $[U_{t+1}, B_{t+1}, V_{t+1}]$ from (37), using $\bar{U}_t$, $\bar{B}_t$ and $\bar{V}_t$ for warm-start;
// $X_{t+1} = U_{t+1}B_{t+1}V_{t+1}^\top$
7: **end for**
8: **return** U_{T+1}, B_{T+1} and V_{T+1}.

The second problem is that line search in Algorithm 1 is inefficient in general when operated on a nonconvex $\bar{f}$. Specifically, step 4 in Algorithm 1 then becomes

$$[\alpha_t, \beta_t] = \arg\min_{\alpha\ge 0,\beta\ge 0}\bar{f}(\alpha X_t + \beta u_t v_t^\top) + \bar{\mu}(\alpha\|X_t\|_* + \beta). \tag{34}$$

To solve (34), we have to compute $\frac{\partial\bar{f}(S)}{\partial\alpha}$ and $\frac{\partial\bar{f}(S)}{\partial\beta}$, where $S = \alpha X_t + \beta u_t v_t^\top$. As shown in Proposition 10, this requires the SVD of S and can be expensive.

Proposition 10 *Let the SVD of* S *be* $U_S\mathit{Diag}([\sigma_1(S),\dots,\sigma_m(S)])V_S^\top$. *Then*

$$\frac{\partial\bar{f}(S)}{\partial\alpha} = \alpha\langle X_t, \nabla\bar{f}(S)\rangle, \quad \textit{and} \quad \frac{\partial\bar{f}(S)}{\partial\beta} = \beta u_t^\top\nabla\bar{f}(S)v_t,$$

where $\nabla\bar{f}(S) = \nabla f(S) + \mu U_S\mathit{Diag}(w)V_S^\top$, *and* $w = [\kappa'(\sigma_i(S)) - \kappa_0] \in \mathbb{R}^m$.

Alternatively, as S is a rank-one update of X_t, one can perform incremental update on SVD, which takes $O((m+n)t^2)$ time (Golub and Van Loan, 2012). However, every time α, β are changed, this incremental SVD has to be recomputed, and is thus inefficient.

To alleviate this problem, we approximate $\bar{f}(S)$ by an upper bound as

$$\begin{aligned}\bar{f}(S) &= \bar{f}(X_t + (\alpha-1)X_t + \beta u_t v_t^\top) \\ &\leq \bar{f}(X_t) + \langle (\alpha-1)X_t + \beta u_t v_t^\top, \nabla \bar{f}(X_t)\rangle + \frac{\bar{L}}{2}\|(\alpha-1)X_t + \beta u_t v_t^\top\|_F^2. \end{aligned} \quad (35)$$

As (u_t, v_t) is obtained from the rank-1 SVD of $\nabla \bar{f}(X_t)$, we have $\|u_t v_t^\top\|_F = 1$ and $u_t^\top \nabla \bar{f}(X_t) v_t = s_t$. Moreover, $X_t = U_t B_t V_t^\top$, and so $\|X_t\|_F = \|B_t\|_F$ and $\|X_t\|_* = \mathrm{Tr}\,(B_t)$. Substituting these and the upper bound (35) into (34), we obtain a simple quadratic program:

$$\begin{aligned}\min_{\alpha\geq 0, \beta\geq 0} \quad & \frac{(\alpha-1)^2\bar{L}}{2}\|B_t\|_F^2 + (\alpha-1)\beta\bar{L}(u_t^\top U_t)B_t(V_t^\top v_t) + \frac{\beta^2\bar{L}}{2} + \beta s_t \\ & + \alpha\langle B_t, U_t^\top \nabla \bar{f}(X_t) V_t\rangle + \bar{\mu}(\alpha\|B_t\|_* + \beta). \end{aligned} \quad (36)$$

Note that the objective in (36) is convex, as the RHS in (35) is convex and the last term from (34) is affine. Using the following Corollary 11, $\langle B_t, U_t^\top \nabla \bar{f}(X_t) V_t\rangle$ in (36) can be obtained as

$$\langle B_t, U_t^\top \nabla \bar{f}(X_t) V_t\rangle = \langle B_t, U_t^\top \nabla f(X_t) V_t\rangle + \bar{\mu}\sum_{i=1}^{t}\sigma_i(B_t)(\kappa'(\sigma_i(B_t)) - \kappa_0).$$

Corollary 11 *For X in (33), let the SVD of B be $U_B Diag([\sigma_1(B), \ldots, \sigma_k(B)])V_B^\top$. Then, $\nabla \bar{f}(X) = \nabla f(X) + \bar{\mu}(UU_B)Diag(w)(VV_B)^\top$, where $w = [\kappa'(\sigma_i(B)) - \kappa_0] \in \mathbb{R}^k$.*

Instead of requiring SVD on X_t, it only requires SVD on B_t (which is of size $t \times t$ at the tth iteration of Algorithm 4). As the target matrix is supposed to be low-rank, $t \ll m$. Hence, all the coefficients in (36) can be obtained in $O((m+n)t^2 + \|\Omega\|_1 t)$ time. Besides, (36) is a quadratic program with only two variables, and thus can be very efficiently solved.

The third modification is that with $\bar{f}$ instead of f, (12) can no longer be used for local optimization, as $\bar{g}(X)$ in (32) depends on the singular values of X. On the other hand, with the decomposition of X in (33) and Proposition 12 below, (31) can be rewritten as

$$\begin{aligned}\min_{U,B,V} \quad & f(UBV^\top) + \bar{g}(B) + \bar{\mu}\,\mathrm{Tr}\,(B) && (37)\\ \text{s.t.} \quad & U^\top U = I, V^\top V = I, B \in \mathcal{S}_+. && (38)\end{aligned}$$

This can be efficiently solved using matrix optimization techniques on the Grassmann manifold (Ngo and Saad, 2012).

Proposition 12 *For orthogonal matrices U and V, $\bar{g}(UBV^\top) = \bar{g}(B)$.*

In Algorithm 4, step 5 is used to warm-start (37), and the procedure is shown in Algorithm 5. It expresses $X_t = \alpha_t U_{t-1} B_{t-1} V_{t-1}^\top + \beta_t u_t v_t^\top$ obtained in step 4 to the form $U_t B_t V_t^\top$ so that the orthogonal constraints on U_t, V_t in (38) are satisfied.

Existing analysis for the FW algorithm cannot be used on this nonconvex problem. The following Theorem shows convergence of Algorithm 4 to a critical point of (8).

Theorem 13 *If* (8) *has a rank-r critical point, then Algorithm 4 converges to a critical point of* (8) *after r iterations.*

Algorithm 5 warmstart$(U_t, u_t, V_t, v_t, B_t, \alpha_t, \beta_t)$.

1: $[\bar{U}_t, R_{\bar{U}_t}] = \mathrm{QR}([U_t, u_t])$; // QR denotes the QR factorization
2: $[\bar{V}_t, R_{\bar{V}_t}] = \mathrm{QR}([V_t, v_t])$;
3: $\bar{B}_t = R_{\bar{U}_t}\begin{bmatrix}\alpha_t B_t & 0 \\ 0 & \beta_t\end{bmatrix} R_{\bar{V}_t}^\top$;
4: **return** $\bar{U}_t$, $\bar{B}_t$ and $\bar{V}_t$;

As in Remark 8, an alternative convexification approach is to decompose the regularizer in (30) as $\breve{\varsigma}(X) + \hat{\varsigma}(X)$, where $\hat{\varsigma}(X) = -\frac{\rho}{2}\sum_{i=1}^m \sigma_i^2(X)$ and $\breve{\varsigma}(X) = \sum_{i=1}^m \kappa(\sigma_i(X)) + \frac{\rho}{2}\sigma_i^2(X)$. The corresponding linear subproblem in (5) becomes $\min_{S:\breve{\varsigma}(S)\leq 1}\langle S, \nabla f(X_t)\rangle$, which is difficult to solve. On the other hand, with the proposed procedure, the subproblem associated with the transformed problem (31) can be easily solved via rank-1 SVD (Jaggi, 2013).

4.3 Alternating Direction Method of Multipliers (ADMM)

In this section, we consider using ADMM on the consensus optimization problem (17). When all the f_i's and g are convex, ADMM has a convergence rate of $O(1/T)$ (He and Yuan, 2012). Recently, ADMM has been extended to problems where g is convex but f_i's are nonconvex (Hong et al., 2016). However, when g is nonconvex, such as when a nonconvex regularizer is used in regularized risk minimization, the convergence of ADMM is still an open reseach problem.

Using the proposed transformation, we can decompose a nonconvex g as $\bar{g} + \breve{g}$, where $\bar{g}$ is concave and Lipschitz-smooth, while $\breve{g}$ is convex but possibly nonsmooth. Problem (17) can then be rewritten as

$$\min_{y, x^1, \ldots, x^M} \sum_{i=1}^M \bar{f}_i(x^i) + \breve{g}(y) \quad : \quad x^1 = \cdots = x^M = y, \quad (39)$$

where $\bar{f}_i(x) = f_i(x) + \frac{1}{M}\bar{g}(x)$. Let p^i be the dual variable for the constraint $x^i = y$. The augmented Lagrangian for (39) is

$$\mathcal{L}\left(y, x^1, \ldots, x^M, p^1, \ldots, p^M\right) = \breve{g}(y) + \sum_{i=1}^M \bar{f}_i(x^i) + (p^i)^\top(x^i - y) + \frac{\tau}{2}\|x^i - y\|_2^2.$$

Using (14) and (15), we have the following update equations at iteration t:

$$\begin{aligned} x_{t+1}^i &= \arg\min_{x^i} \bar{f}_i(x^i) + (p_t^i)^\top(x^i - y_t) + \frac{\tau}{2}\|x^i - y_t\|_2^2, \quad i = 1, \ldots, M, \\ y_{t+1} &= \arg\min_y \frac{1}{2}\left\|y - \sum_{i=1}^M\left(x_t^i + \frac{1}{\tau}p_t^i\right)\right\|_2^2 + \frac{1}{\tau}\breve{g}(y) = \mathrm{prox}_{\frac{1}{\tau}\breve{g}}\left(\sum_{i=1}^M x_t^i + \frac{1}{\tau}p_t^i\right). \end{aligned} \quad (40)$$

As in previous sections, the proximal step in (40), which is associated with the convex $\breve{g}$, is usually easier to compute than the proximal step associated with the original nonconvex g. Moreover, since $\breve{g}$ is convex, convergence results in Theorem 2.4 of (Hong et al., 2016) can now be applied. Specifically, the sequence $\{y_t, \{x_t^i\}\}$ generated by the ADMM procedure is bounded and all its limit points are critical points of (39).

As in Remark 8, the alternative convexification approach based on adding a quadratic regularizer (Proposition 9) does not help. For example, when g is the nonconvex tree-structured lasso regularizer, after adding a quadratic regularizer $\frac{\rho}{2}\|y_{\mathcal{G}_j}\|_2^2$, the y_t update in (19) becomes

$$y_{t+1} = \arg\min_y \frac{1}{2}\left\| y - \sum_{i=1}^{M}\left(x_t^i + \frac{1}{\tau}p_t^i\right)\right\|_2^2 + \frac{1}{\tau}\sum_{j=1}^{K}\lambda_j\left(\kappa\left(\|y_{\mathcal{G}_j}\|_2\right) + \frac{\rho}{2}\|y_{\mathcal{G}_j}\|_2^2\right).$$

which is still difficult to solve.

4.4 Stochastic Variance Reduced Gradient

Variance reduction methods have been commonly used to speed up the often slow convergence of SGD. Examples include the stochastic variance reduced gradient (SVRG) and its proximal extension Prox-SVRG (Xiao and Zhang, 2014). They can be used for the following optimization problem

$$\min_x \sum_{i=1}^{N}\ell(y_i, a_i^\top x) + g(x), \tag{41}$$

where $\{(a_1, y_1), \ldots, (a_N, y_N)\}$ are the training samples, ℓ is a smooth convex loss function, and g is a convex regularizer. Recently, Prox-SVRG is also extended for nonconvex objectives. Reddi et al. (2016a) and Zhu and Hazan (2016) considered smooth nonconvex ℓ but without g. This is further extended to the case of smooth ℓ and convex nonsmooth g in (Reddi et al., 2016b). However, convergence is still unknown for the more general case where the regularizer g is also nonconvex.

Using the proposed transformation, (41) can be rewritten as

$$\min_x \sum_{i=1}^{N}\left(\ell(y_i, a_i^\top x) + \frac{1}{N}\bar{g}(x)\right) + \breve{g}(x),$$

where $\ell + \frac{1}{N}\bar{g}$ is smooth and $\breve{g}$ is convex. The convergence results of Theorem 1 of (Reddi et al., 2016b) can now be applied, which shows that SVRG generates a bounded sequence and all its limit points are critical points of (41).

As in Remark 8, adding a quadratic term to convexify the nonconvex regularizer does not make the corresponding proximal step easier, and so does not help.

4.5 With OWL-QN

In this section, we consider OWL-QN (Andrew and Gao, 2007) and its variant mOWL-QN (Gong and Ye, 2015b), which are efficient algorithms for the ℓ_1-regularization problem

$$\min_x f(x) + \mu\|x\|_1. \tag{42}$$

Recently, Gong and Ye (2015a) proposed a nonconvex generalization for (42), in which the standard ℓ_1 regularizer is replaced by the nonconvex $g(x) = \mu\sum_{i=1}^{d}\kappa(|x_i|)$:

$$\min_x f(x) + \mu\sum_{i=1}^{d}\kappa(|x_i|). \tag{43}$$

Gong and Ye (2015a) proposed a sophisticated algorithm (HONOR) which involves a combination of quasi-Newton and gradient descent steps. Though the algorithm is similar to OWL-QN and mOWL-QN, the convergence analysis in (Gong and Ye, 2015b) cannot be directly applied as the regularizer is nonconvex. Instead, a non-trivial extension was developed in (Gong and Ye, 2015a).

Here, by convexifying the nonconvex regularizer, (43) can be rewritten as

$$\min_x \bar{f}(x) + \mu\kappa_0\|x\|_1, \tag{44}$$

where $\bar{f}(x) = f(x) + \bar{g}(x)$, and $\bar{g}(x) = \mu\sum_{i=1}^{d}(\kappa(|x_i|) - \kappa_0|x_i|)$. It is easy to see that the analysis in (Gong and Ye, 2015b) can be extended to handle smooth but nonconvex $\bar{f}$. As a result, Theorem 1 in (Gong and Ye, 2015b) can still be applied. Thus, mOWL-QN is guaranteed to generate a bounded sequence and its limit points are critical points of (42).

As in previous subsections, adding a quadratic term to convexify the nonconvex regularizer does not help. The mOWL-QN can only work with the ℓ_1-regularizer, but not with the modified regularizer $\breve{\varsigma}(x) = \frac{\rho\mu}{2}\|x\|_2^2 + \mu\sum_{i=1}^{d}\kappa(|x_i|)$.

Problem (43) can be solved by either (i) directly using HONOR, or (ii) using mOWL-QN on the transformed problem (44). We believe that the latter approach is computationally more efficient. In (43), the Hessian depends on both terms in the objective, as the second-order derivative of κ is not zero in general. However, HONOR constructs the approximate Hessian using only information from f, and thus ignores the curvature information due to $\sum_{i=1}^{d}\kappa(|x_i|)$. On the other hand, the Hessian in (44) depends only on $\bar{f}$, as the Hessian due to $\|x\|_1$ is zero (Andrew and Gao, 2007), and mOWL-QN now extracts Hessian from $\bar{f}$. Hence, optimizing (44) with mOWL-QN is potentially faster, as all the second-order information is utilized. This will be verified empirically in Section 5.4.

4.6 Nonsmooth and Nonconvex Loss

In many applications, besides having nonconvex regularizers, the loss function may also be nonconvex and nonsmooth. In this section, we consider using the nonconvex functions in Figure 1 as the loss function. Thus, neither f nor g in (1) is convex, smooth. The optimization problem becomes even harder, and many existing algorithms cannot be used. In particular, the proximal algorithm requires f in (1) to be smooth (possibly nonconvex) (Gong et al., 2013; Li and Lin, 2015; Bot et al., 2016). The FW algorithm requires f in (4) to be smooth and convex (Jaggi, 2013). For the ADMM, it allows f in the consensus problem to be smooth, but g has to be convex (Hong et al., 2016). For problems of the form $\min_{x,z} f(y) + g(y) : y = Ax$, ADMM requires A to have full row-rank (Li and Pong, 2015). As will be seen, it is not satisfied for problems considered in this section. CCCP (Yuille and Rangarajan, 2002) and smoothing (Chen, 2012) are more general and can still be used, but are usually very slow.

In this section, we consider two application examples, and show how they can be efficiently solved with the proposed transformation.

4.6.1 TOTAL VARIATION IMAGE DENOISING

Using the (convex) ℓ_1 loss and (convex) TV regularizer introduced in Section 4.1.3, consider the following optimization problem:

$$\min_X \|Y - X\|_1 + \mu\mathrm{TV}(X), \tag{45}$$

where $Y \in \mathbb{R}^{m\times n}$ is a given corrupted image, and X is the target image to be recovered. The use of nonconvex loss and regularizer often produce better performance (Yan, 2013). Thus, we consider the following nonconvex extension:

$$\min_X \sum_{i=1}^{m}\sum_{j=1}^{n} \kappa\left(\left|[Y-X]_{ij}\right|\right) + \mu \sum_{i=1}^{m-1}\sum_{j=1}^{m} \kappa\left(\left|[D_vX]_{ij}\right|\right) + \mu \sum_{i=1}^{n}\sum_{j=1}^{n-1} \kappa\left(\left|[XD_h]_{ij}\right|\right), \quad (46)$$

where both the loss and regularizer are nonconvex and nonsmooth. As discussed above, this can be solved by CCCP and smoothing. However, as will be experimentally demonstrated in Section 5.5, the convergence is slow.

Using the proposed transformation on both the loss and regularizer, problem (46) can be transformed to the following problem:

$$\min_X \bar{f}(X) + \kappa_0\|X-Y\|_1 + \kappa_0\mu\text{TV}(X), \quad (47)$$

where

$$\begin{aligned}\bar{f}(X) =& \sum_{i=1}^{m}\sum_{j=1}^{n} \kappa\left(\left|[Y-X]_{ij}\right|\right) - \kappa_0\|Y-X\|_1 \\ &+ \mu\left[\sum_{i=1}^{m-1}\sum_{j=1}^{m} \kappa\left(\left|[D_vX]_{ij}\right|\right) - \kappa_0\|D_vX\|_1 + \sum_{i=1}^{n}\sum_{j=1}^{n-1} \kappa\left(\left|[XD_h]_{ij}\right|\right) - \kappa_0\|XD_h\|_1\right]\end{aligned}$$

is smooth and nonconvex. As (47) is not a consensus problem, the method in (Hong et al., 2016) cannot be used. To use the ADMM algorithm in (Li and Pong, 2015), extra variables and constraints $Z_v = D_vX$ and $Z_h = XD_h$ have to be imposed. However, the full row-rank condition in (Li and Pong, 2015) does not hold.

In this section, we consider the proximal algorithm. Given some Z, the proximal step in (47) is

$$\arg\min_X \frac{1}{2}\|X-Z\|_F^2 + \frac{1}{\tau}\left(\|X-Y\|_1 + \mu\text{TV}(X)\right), \quad (48)$$

where τ is the stepsize. Though this has no closed-form solution, $\|X-Y\|_1 + \mu\text{TV}(X)$ in (48) is convex and one can monitor inexactness of the proximal step via the duality gap. Thus, we can use the proposed inexact nmAPG algorithm in Algorithm 3 for (47). It can be shown that the dual of (48) is

$$\begin{aligned}\min_{W,P,Q}\quad & \frac{1}{2\tau}\|W + \mu D_v^\top P + \mu Q D_h^\top\|_F^2 - \langle Z, W\rangle - \mu\langle D_vZ, P\rangle - \mu\langle ZD_h, Q\rangle + \langle Y, W\rangle \\ \text{s.t.}\quad & \|W\|_\infty \le 1, \|P\|_\infty \le 1 \text{ and } \|Q\|_\infty \le 1,\end{aligned} \quad (49)$$

and the primal variable can be recovered as $X = Z - \frac{1}{\tau}(W + \mu D_v^\top P + \mu Q D_h^\top)$. By substituting the obtained X into (48) and $\{W, P, Q\}$ into (49), the duality gap can be computed in $O(mn)$ time. As (49) is a smooth and convex problem, both accelerated gradient descent (Nesterov, 2013) and L-BFGS (Nocedal and Wright, 2006) can be applied. Algorithm 3 is then guaranteed to converge to a critical point of (46) (Theorem 6 and Proposition 7).

Note that it is more advantageous to transform both the loss and regularizer in (47). If only the regularizer in (46) is transformed, we obtain

$$\bar{f}_{\text{TV}}(X) + \sum_{i=1}^{m}\sum_{j=1}^{n} \kappa\left(\left|[Y-X]_{ij}\right|\right) + \kappa_0\mu\text{TV}(X), \quad (50)$$

where

$$\bar{f}_{\text{TV}}(X) = \mu\left[\sum_{i=1}^{m-1}\sum_{j=1}^{m} \kappa\left(\left|[D_vX]_{ij}\right|\right) - \kappa_0\|D_vX\|_1 + \sum_{i=1}^{n}\sum_{j=1}^{n-1} \kappa\left(\left|[XD_h]_{ij}\right|\right) - \kappa_0\|XD_h\|_1\right]$$

is nonconvex. The corresponding proximal step for (50) is

$$\arg\min_X \frac{1}{2}\|X-Z\|_F^2 + \frac{1}{\tau}\left(\sum_{i=1}^{m}\sum_{j=1}^{n} \kappa\left(\left|[Y-X]_{ij}\right|\right) + \kappa_0\mu\text{TV}(X)\right). \quad (51)$$

While the proximal steps in both (48) and (51) have no closed-form solution, working with (48) is more efficient. As (48) is convex, its dual can be efficiently solved with methods such as accelerated gradient descent and L-BFGS. In contrast, (51) is nonconvex, its duality gap is nonzero, and so can only be solved in the primal with slower methods like CCCP and smoothing. Besides, one can only use the more expensive nmAPG (Algorithm 2) but not the proposed inexact proximal algorithm.

One may also consider simultaneously transforming both the loss and regularizer using the decomposition discussed in Remark 8. However, it is not helpful here. By adding and subtracting a quadratic term, the objective in (46) can be decomposed as $\breve{\varsigma}(X) + \hat{\varsigma}(X)$, where

$$\begin{aligned}\hat{\varsigma}(X) =& -\sum_{i=1}^{m}\sum_{j=1}^{n}\frac{\rho}{2}[Y-X]_{ij}^2 - \frac{\rho\mu}{2}\sum_{i=1}^{m-1}\sum_{j=1}^{m}[D_vX]_{ij}^2 - \frac{\rho\mu}{2}\sum_{i=1}^{n}\sum_{j=1}^{n-1}[XD_h]_{ij}^2, \\ \breve{\varsigma}(X) =& \sum_{i=1}^{m}\sum_{j=1}^{n}\left(\kappa(|\,[Y-X]_{ij}\,|) + \frac{\rho}{2}[Y-X]_{ij}^2\right) \\ &+ \mu\sum_{i=1}^{m-1}\sum_{j=1}^{m}\left(\kappa(|[D_vX]_{ij}|) + \frac{\rho}{2}[D_vX]_{ij}^2\right) + \mu\sum_{i=1}^{n}\sum_{j=1}^{n-1}\left(\kappa(|[XD_h]_{ij}|) + \frac{\rho}{2}[XD_h]_{ij}^2\right).\end{aligned}$$

We need to solve the proximal step associated with $\breve{\varsigma}(X)$, which is difficult.

4.6.2 ROBUST SPARSE CODING

The second application is robust sparse coding, which has been popularly used in face recognition (Yang et al., 2011), image analysis (Lu et al., 2013) and background modeling (Zhao et al., 2011). Given an observed signal $y \in \mathbb{R}^m$, the goal is to seek a robust sparse representation $x \in \mathbb{R}^d$ of y based on the dictionary $D \in \mathbb{R}^{m\times d}$ (which is assumed to be fixed here). Mathematically, it is formulated as the following optimization problem:

$$\min_x \|y - Dx\|_1 + \mu\|x\|_1.$$

Its nonconvex extension is:

$$\min_x \sum_{j=1}^m \kappa(|[y-Dx]_j|) + \mu \sum_{i=1}^d \kappa(|x_i|). \tag{52}$$

Using the proposed transformation, problem (52) becomes

$$\min_x \bar{f}(x) + \kappa_0 \|y - Dx\|_1 + \mu\kappa_0 \|x\|_1, \tag{53}$$

where

$$\bar{f}(x) = \mu \sum_{j=1}^d \kappa(|x_j|) - \kappa_0 \mu \|x\|_1 + \sum_{j=1}^m \kappa(|[y-Dx]_j|) - \kappa_0 \|y - Dx\|_1$$

is smooth and nonconvex. Again, we use the inexact nmAPG algorithm in Algorithm 3. The proximal step for (53) is

$$\arg\min_x \frac{1}{2}\|x - z\|_2^2 + \frac{1}{\tau}(\|y - Dx\|_1 + \mu\|x\|_1), \tag{54}$$

where τ is the stepsize and z is given. As in Section 4.6.1, $\|y - Dx\|_1 + \mu\|x\|_1$ in (54) is convex, and one can monitor inexactness of the proximal step by the duality gap. The dual of (54) is

$$\min_{p,q} \frac{1}{2\tau}\|D^\top p + \mu q\|_2^2 - p^\top Dz - \mu q^\top z \ : \ \|p\|_\infty \le 1, \|q\|_\infty \le 1. \tag{55}$$

As in (49), this can be solved with L-BFGS or accelerated gradient descent. The primal variable can be recovered as $x = z - \frac{1}{\tau}(D^\top p + \mu q)$, and the duality gap can be checked in $O(md)$ time.

If only the regularizer is transformed, we obtain

$$\min_x \sum_{j=1}^m \kappa(|[y-Dx]_j|) + \bar{f}_{\text{RSC}}(x) + \kappa_0\mu\|x\|_1, \tag{56}$$

where $\bar{f}_{\text{RSC}}(x) = \mu\sum_{j=1}^d \kappa(|x_j|) - \kappa_0\mu\|x\|_1$. The corresponding proximal step is

$$\arg\min_x \frac{1}{2}\|x - z\|_2^2 + \sum_{j=1}^m \kappa(|[y-Dx]_j|) + \kappa_0\mu\|x\|_1, \tag{57}$$

which still involve the nonconvex function κ. As in Section 4.6.1, (55) is easier to solve than (57).

As in previous sections, adding a quadratic term to convexify the loss and regularizer is not helpful. The objective in (52) will then be decomposed as $\breve{\varsigma}(X) + \hat{\varsigma}(X)$, where

$$\hat{\varsigma}(X) = -\frac{\rho}{2}\sum_{j=1}^m [y-Dx]_j^2 - \frac{\rho\mu}{2}\sum_{i=1}^d x_i^2,$$

$$\breve{\varsigma}(X) = \sum_{j=1}^m \left(\kappa(|[y-Dx]_j|) + \frac{\rho}{2}[y-Dx]_j^2\right) + \mu\sum_{i=1}^d \left(\kappa(|x_i|) + \frac{\rho}{2}x_i^2\right),$$

and the proximal step associated with $\breve{\varsigma}(X)$ is again difficult to solve.

5. Experiments

In this section, we perform experiments on using the proposed procedure with (i) proximal algorithms (Sections 5.1 and 5.2); (ii) Frank-Wolfe algorithm (Section 5.3); (iii) comparision with HONOR (Section 5.4) and (vi) image denoising (Section 5.5). Experiments are performed on a PC with Intel i7 CPU and 32GB memory. All algorithms are implemented in Matlab.

5.1 Nonconvex Sparse Group Lasso

In this section, we perform experiments on the nonconvex sparse group lasso model in Section 4.1.1. For simplicity, assume that $\mu_1 = \cdots = \mu_K = \mu$. Using the square loss, (25) becomes

$$\min_x \frac{1}{2}\|y - A^\top x\|_2^2 + \lambda\sum_{i=1}^d \kappa\left(|x_i|\right) + \mu\sum_{j=1}^K \kappa\left(\|x_{\mathcal{G}_j}\|_2\right), \tag{58}$$

where $A = [a_1, \ldots, a_N]$. In this experiment, we use the LSP regularizer in Table 1 (with $\theta = 0.5$) as $\kappa(\cdot)$. The synthetic data set is generated as follows. We set $d = 200{,}000$. The ground-truth parameter $\bar{x} \in \mathbb{R}^d$ is divided into 200 non-overlapping groups: $\{1, \ldots, 1000\}$, $\{1001, \ldots, 2000\}$, $\ldots$, $\{199001, \ldots, 200000\}$ (Figure 3). We randomly set 87.5% of the groups to zero. In each nonzero group, we randomly set 50% of its features to zero, and generate the nonzero features from the standard normal distribution $\mathcal{N}(0, 1)$. The whole data set has $400{,}000$ samples, and entries of the input $A \in \mathbb{R}^{200{,}000\times 400{,}000}$ is a sparse matrix with 0.01% nonzero elements which are generated from $\mathcal{N}(0, 1)$. The ground-truth output is $\bar{y} = A^\top\bar{x}$. This is then corrupted by random Gaussian noise ϵ in $\mathcal{N}(0, 0.05)$ to produce $y = \bar{y} + \epsilon$.

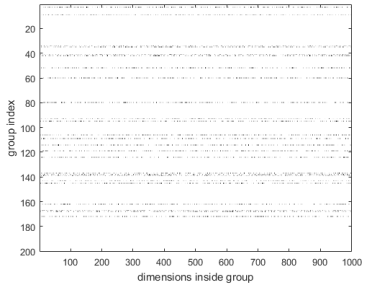


Figure 3: An example ground-truth parameter $\bar{x} \in \mathbb{R}^{200000}$. It is reshaped as a 200×1000 matrix, with each row representing a group.

The proposed algorithm will be called N2C (Nonconvex-to-Convex). The proximal step of the convexified regularizer $\breve{g}(x) = \kappa_0(\lambda\|x\|_1 + \sum_{j=1}^K \mu_j\|x_{\mathcal{G}_j}\|_2)$ is obtained using the algorithm in (Yuan et al., 2011). The nmAPG algorithm (Algorithm 2) in (Li and Lin, 2015) is used for optimization. This will be compared with the following state-of-the-art algorithms:

1. SCP: Sequential convex programming (Lu, 2012), in which the LSP regularizer is decomposed as in (28).

2. GIST (Gong et al., 2013): Since the nonconvex regularizer is not separable, the associated proximal operator has no closed-form solution. Instead, we use SCP (with warm-start) to solve it numerically.

3. GD-PAN (Zhong and Kwok, 2014): It performs gradient descent with the proximal average (Bauschke et al., 2008) of the nonconvex regularizers. Closed-form solutions for the proximal operators of each individual regularizer are obtained separately, and then averaged.

4. nmAPG with the original nonconvex regularizer: As in GIST, the proximal step is solved numerically by SCP.

5. As a baseline, we also compare with the FISTA (Beck, 2009) algorithm, which solves the convex sparse group lasso model (with κ removed from (58)).

We do not compare with the concave-convex procedure (Yuille and Rangarajan, 2002), which has been shown to be slow (Gong et al., 2013; Zhong and Kwok, 2014).

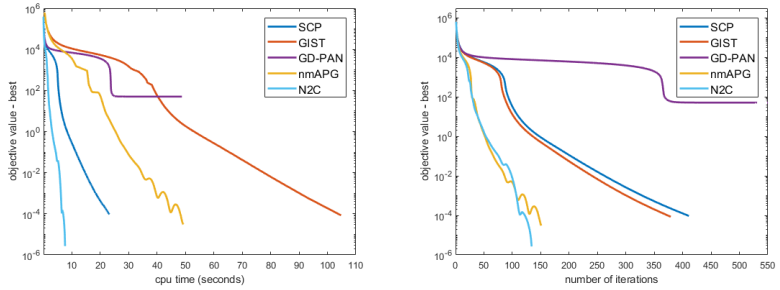
We use 50% of the data for training, another 25% as validation set to tune λ, μ in (58), and the rest for testing. The stepsize is fixed at $\tau = \sigma_1(A^\top A)$. For performance evaluation, we use the (i) testing root-mean-squared error (RMSE) on the predictions; (ii) absolute error between the obtained parameter $\hat{x}$ and the corresponding ground-truth $\bar{x}$: ABS $= \|\hat{x} - \bar{x}\|_1/d$; and (iii) CPU time. To reduce statistical variability, the experimental results are averaged over 5 repetitions.

Results are shown in Table 3. As can be seen, all the nonconvex models obtain better errors (RMSE and ABS) than the convex FISTA. As for the training speed, N2C is the fastest. SCP, GIST, nmAPG and N2C all solve the original problem (1), and have the same recovery performance. GD-PAN solves an approximate problem in each iteration, and its error is slightly worse than the other nonconvex algorithms on this data set.

	non-accelerated			accelerated		convex
	SCP	GIST	GD-PAN	nmAPG	N2C	FISTA
RMSE	**48.9±0.1**	**48.9±0.1**	49.2±0.1	**48.9±0.1**	**48.9±0.1**	64.0±0.1
ABS	**3.1±0.1**	**3.1±0.1**	5.5±0.1	**3.1±0.1**	**3.1±0.1**	13.0±0.1
CPU time(sec)	23.2±7.5	105.6±24.6	33.7±11.7	43.0±3.5	**7.9±1.2**	5.1±0.8

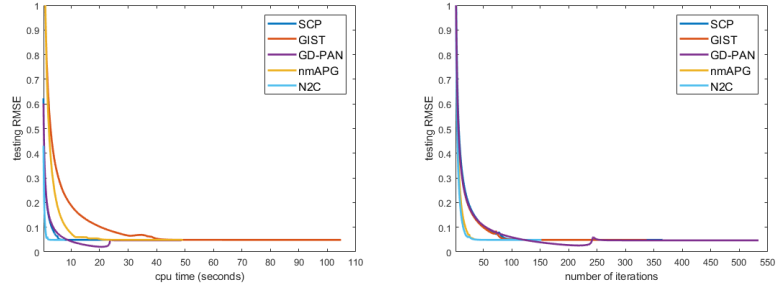
Table 3: Results on nonconvex sparse group lasso. RMSE and ABS are scaled by 10^{-3}, and the CPU time is in seconds. The best and comparable results (according to the paired t-test with 95% confidence) are highlighted.

Figure 4(a) shows convergence of the objective with time for a typical run. SCP, GIST, nmAPG and N2C all converge towards the same objective value. GD-PAN can only approximate the original problem. Thus, it converges to an objective value which is larger than the others. Figure 4(b) shows the convergence with number of iterations. As can be seen, N2C and nmAPG, which are based on the same state-of-the-art proximal algorithm (Algorithm 2), require nearly the same number of iterations for convergence. However, as N2C has an inexpensive closed-form solution for its proximal step, it is much faster when measured in terms of time (Figure 4(a)). Figure 5 shows convergence of the testing RMSE. Its behaviour is similar to those observed in Figure 4. Overall, N2C, which uses acceleration and inexpensive proximal step, is the fastest.



(a) Objective vs CPU time (seconds). (b) Objective vs number of iterations.

Figure 4: Convergence of objective on nonconvex sparse group lasso. In the ordinate, "best" refers to the smallest objective value obtained among the various methods. Note that FISTA is not shown as its (convex) objective is different from the others.



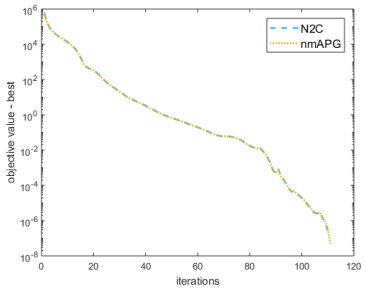
(a) Testing RMSE vs CPU time (seconds). (b) Testing RMSE vs number of iterations.

Figure 5: Convergence of the testing RMSE on nonconvex sparse group lasso.

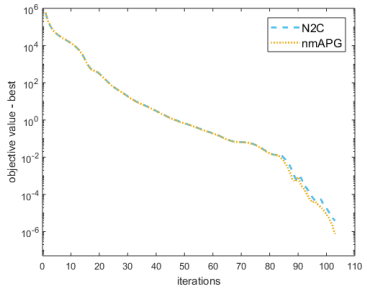
5.1.1 IMPACT OF NONCONVEXITY OF THE LOSS ON NMAPG

Recall that N2C uses nmAPG as the underlying proximal algorithm solver. Thus, in the above experiment, we have compared the performance of using nmAPG on (i) the transformed problem, which has a convex regularizer and a more nonconvex loss; and (ii) the original problem, which has a nonconvex regularizer and a less nonconvex loss). In the following, we will provide more empirical evidence that the increased nonconvexity of the transformed loss does not harm convergence of nmAPG. Instead of tuning the regularization parameter μ in (58) using the validation set, we vary μ in $\{0.01, 0.1, 1\}$. A larger μ makes the regularizer g more nonconvex, and more nonconvexity will be transferred to $\bar{f}$ by the proposed transformation. The other parts of the experimental setup are the same. Figure 6 compares the convergence behavior of N2C and nmAPG w.r.t. the number

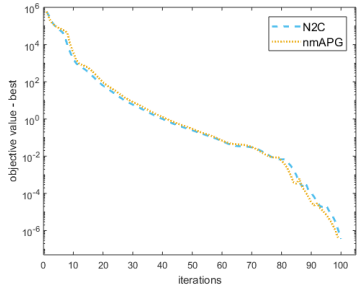
of iterations. As can be seen, they are almost identical, which agrees with Figure 4(b). Hence, nonconvexity of the loss have little effect on the empirical performance of nmAPG.



(a) $\mu = 0.01$.



(b) $\mu = 0.1$.



(c) $\mu = 1$.

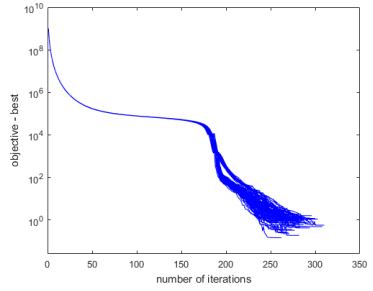
Figure 6: Convergence of N2C and nmAPG on nonconvex sparse group lasso with various μ.

5.1.2 NONCONVEX OPTIMIZATION

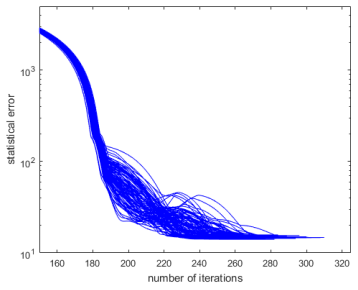
As discussed in (Ge et al., 2015), there are two main theoretical issues in optimizing nonconvex functions. The first issue is that it may be hard to find the global minimum. However, it has been shown that for composite minimization problems with nonconvex regularizer and the loss function satisfying the restricted strong convexity condition (of which nonconvex lasso is such an example), *all stationary points* can have nearly the same statistical error[1] (Loh and Wainwright, 2015). Note that with the proposed transformation, the transformed optimization problem has the same stationary points as the original problem, and so all stationary points still have nearly the same statistical error. To verify this, we experiment on the nonconvex sparse group lasso with 100 different initializations. Figure 7 shows the convergence behaviour and the obtained statistical error from the N2C algorithm. As can be seen from Figure 7(a), the differences in the final objective values obtained from different

1. Let $\bar{x}$ be the ground-truth predictor and x be an arbitrary stationary point. The statistical error is defined as $\|x - \bar{x}\|_2$.

initialization are small. From Figure 7(b), we can also see that the obtained solutions have nearly the same statistical error.



(a) objective vs number of iterations.



(b) statistical error vs number of iterations.

Figure 7: Objective / statistical error on nonconvenx sparse group lasso ($\mu = 1$). Here, N2C algorithm is used, and the "best" in Figure 7(a) is the lowest objective among the 100 random runs.

The second issue is that even finding a local minimum can be hard, as the optimizer may get trapped in saddle points. However, recent papers (Ge et al., 2015, 2017, 2016; Lee et al., 2016, 2017) have shown that batch gradient descent and noisy stochastic gradient descent almost never converge to saddle points, and can converge to a local minimizer. We expect that a similar result also holds for proximal gradient descent, but will leave this as future work.

5.2 Nonconvex Tree-Structured Group Lasso

In this section, we perform experiments on the nonconvex tree-structured group lasso model in Section 4.1.2. Following (Liu and Ye, 2010), we use the face data set *JAFFE*[2], which contains 213 256×256 images with seven facial expressions: anger, disgust, fear, happy, neutral, sadness and surprise. Their tree structure, which is based on pixel neighborhoods, is also used here. The number of groups K is 341.

Since our goal is only to demonstrate usefulness of the proposed convexification scheme, we focus on the binary classification problem "anger vs not-anger" (with 30 anger images and 183 non-anger images). The logistic loss is used, which is more appropriate for classification. Given training samples $\{(a_1, y_1), \ldots, (a_N, y_N)\}$, the optimization problem is then

$$\min_x \sum_{i=1}^{N} w_i \log\left(1 + \exp(-y_i \cdot a_i^\top x)\right) + \mu \sum_{i=1}^{K} \lambda_i \kappa\left(\|x_{\mathcal{G}_i}\|_2\right), \tag{59}$$

where $\kappa(\cdot)$ is the LSP regularizer (with $\theta = 0.5$), w_i's are weights (set to be the reciprocal of the size of sample i's class) used to alleviate class imbalance, and $\lambda_i = 1/\sqrt{\|\mathcal{G}_i\|_1}$ as in (Liu and Ye,

2. http://www.kasrl.org/jaffe.html

2010). We use 60% of the data for training, 20% as validation set to tune μ, and the rest for testing. For the proposed N2C algorithm, the proximal step of the convexified regularizer is obtained as in (Liu and Ye, 2010).

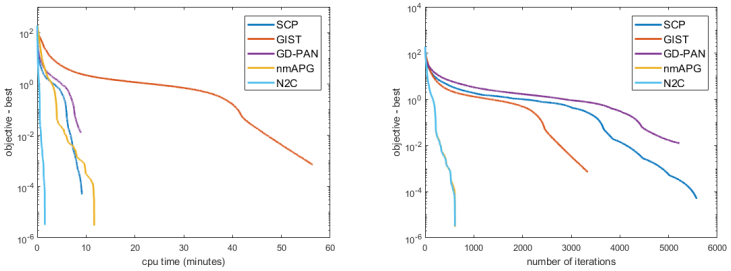
As in Section 5.1, we compare the proposed N2C with SCP, GIST, GD-PAN, nmAPG, and FISTA. The stepsize η is obtained by line search. For performance evaluation, we use (i) the testing accuracy; (ii) solution sparsity (i.e., percentage of nonzero elements); and (iii) CPU time. To reduce statistical variability, the experimental results are averaged over 5 repetitions.

Results are shown in Table 4. As can be seen, all nonconvex models have similar testing accuracies, and they again outperform the convex model. Moreover, solutions from the nonconvex models are sparser. Overall, N2C is the fastest and has the sparsest solution.

	non-accelerated			accelerated		convex
	SCP	GIST	GD-PAN	nmAPG	N2C	FISTA
testing accuracy (%)	**99.5±1.0**	**99.5±1.0**	**99.5±1.0**	**99.5±1.0**	**99.5±1.0**	96.7±1.3
sparsity (%)	**9.8±0.9**	11.6±3.6	**9.7±0.9**	**9.6±0.9**	**9.6±0.8**	24.1±0.8
CPU time (min)	10.3±1.5	68.0±17.2	12.0±2.4	11.7±1.3	**1.7±0.2**	0.5±0.1

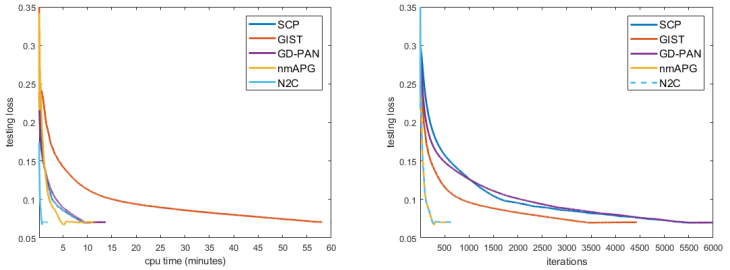
Table 4: Results on tree-structured group lasso. The best and comparable results (according to the paired t-test with 95% confidence) are highlighted.

Figure 8 shows convergence of the algorithms versus CPU time and number of iterations. The observations are similar to those in Figure 8, and N2C is the fastest. GIST is the slowest, as it does not utilize acceleration and its proximal step is solved numerically which is expensive. GD-PAN converges to a less optimal solution due to its use of approximation. Moreover, as in Section 5.1, nmAPG and N2C show similar convergence behavior w.r.t. the number of iterations (Figure 8(b)), but N2C is much faster w.r.t. time (Figure 8(a)). Convergence of the testing loss is shown in Figure 9.



(a) Objective vs CPU time (minutes). (b) Objective vs number of iterations.

Figure 8: Convergence of objective on nonconvex tree-structured group lasso. Note that the curves for nmAPG and N2C overlap in Figure 8(b).



(a) Testing loss vs CPU time (minutes). (b) Testing loss vs number of iterations.

Figure 9: Convergence of testing loss on nonconvex tree-structured group lasso.

As in Section 5.1.1, Figure 10 shows the convergence of N2C and nmAPG w.r.t. the number of iterations when μ is varied in $\{0.01, 0.1, 1\}$. Again, their behavior are almost identical. Hence, the increased nonconvexity of the transformed loss does not harm convergence of nmAPG.

5.3 Nonconvex Low-Rank Matrix Completion

In this section, we perform experiments on nonconvex low-rank matrix completion (Section 4.2), with the square loss in (30). The LSP regularizer is used, with $\theta = \sqrt{\mu}$ as in (Yao et al., 2015). We use the data sets MovieLens, Netflix and Yahoo, which have been commonly used for evaluating matrix completion (Mazumder et al., 2010; Wen et al., 2012; Hsieh and Olsen, 2014). The MovieLens and Netflix data sets contain ratings $\{1, 2, \ldots, 5\}$ assigned by various users on movies, while the Yahoo data set contains ratings $\{10, 20, \ldots, 100\}$ on music. Following (Yao et al., 2015), we normalize the ratings to zero mean and unit variance.

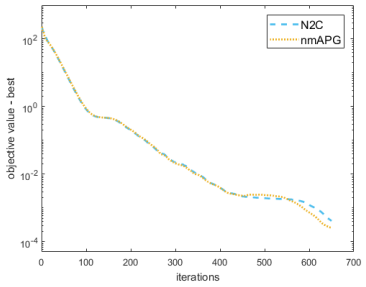
		#users	#movies	#ratings
MovieLens	100K	943	1,682	100,000
	1M	6,040	3,449	999,714
	10M	69,878	10,677	10,000,054
Netflix		480,189	17,770	100,480,507
Yahoo		249,012	296,111	62,551,438

Table 5: Recommendation data sets used in the experiments.

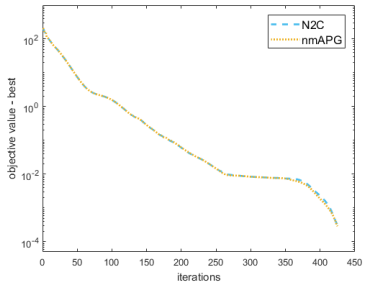
5.3.1 MOVIELENS

The proposed FW procedure (Algorithm 4), denoted N2C-FW, is compared with the following algorithms:

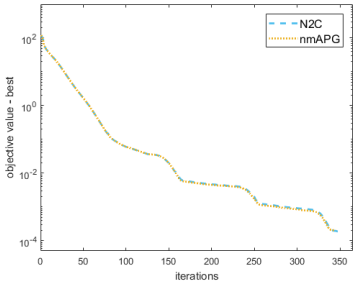
1. FaNCL (Yao et al., 2015): This is a recent nonconvex matrix regularization algorithm. It is based on the proximal algorithm using efficient approximate SVD and automatic thresholding of singular values.



(a) $\mu = 0.01$.



(b) $\mu = 0.1$.



(c) $\mu = 1$.

Figure 10: Convergence of N2C and nmAPG on tree-structured group lasso with various μ.

2. LMaFit (Wen et al., 2012): It factorizes X as a product of low-rank matrices $U \in \mathbb{R}^{m\times k}$ and $V \in \mathbb{R}^{n\times k}$. The nonconvex objective $\frac{1}{2}\|P_\Omega(UV^\top - O)\|_F^2$ is then minimized by alternating minimization on U and V using gradient descent.

3. Active subspace selection (denoted "active") (Hsieh and Olsen, 2014): This solves the (convex) nuclear norm regularized problem (with κ being the identity function in (8)) by using the active row/column subspaces to reduce the optimization problem size.

We do not compare with IRNN (Lu et al., 2014) and GPG (Lu et al., 2015), which have been shown to be much slower than FaNCL (Yao et al., 2015).

Following (Yao et al., 2015), we use 50% of the ratings for training, 25% for validation and the rest for testing. For performance evaluation, we use (i) the testing RMSE; and (ii) the recovered rank. To reduce statistical variability, the experimental results are averaged over 5 repetitions.

Results are shown in Table 6. As can be seen, the nonconvex models (N2C-FW, FaNCL and LMaFit) achieve lower RMSEs than the convex model (active subspace selection), with N2C-FW having the smallest RMSE. Moreover, the convex model needs a much higher rank than the nonconvex models, which agrees with previous observations in (Mazumder et al., 2010; Yao et al., 2015). Thus, its running time is also much longer than the others. Figure 11 compares convergence of N2C and FaNCL w.r.t. the objective in (30). The objectives of LMaFit and active subspace selection are different from N2C-FW, and thus are not shown. As can be seen, though FaNCL uses singular value thresholding to truncate the SVD, it does not control the rank as directly as N2C-FW and so is still slower. Figures 12 compares convergence of the testing RMSE on all algorithms. As the recovered matrix ranks for the nonconvex models are very low ($2-9$ in Table 6), N2C-FW is much faster than the others as it starts from a rank-one matrix and only increases its rank by one in each iteration.

		RMSE	rank	CPU time(sec)
100K	N2C-FW	**0.855±0.004**	2	**0.8±0.1**
	FaNCL	0.857±0.003	2	2.6±0.5
	LMaFit	0.867±0.004	2	1.8±0.2
	(convex) active	0.875±0.002	52	9.4±0.3
1M	N2C-FW	**0.785±0.001**	5	**19.9±0.5**
	FaNCL	0.786±0.001	5	53.6±6.5
	LMaFit	0.812±0.002	5	45.1±2.7
	(convex) active	0.811±0.001	106	124.6±1.3
10M	N2C-FW	**0.778±0.001**	9	313.0±2.2
	FaNCL	0.779±0.001	9	615.7±6.0
	LMaFit	0.797±0.001	9	**264.9±3.9**
	(convex) active	0.808±0.001	137	904.8±30.2

Table 6: Results on the MovieLens data sets. The best results (according to the paired t-test with 95% confidence) are highlighted.

5.3.2 NETFLIX AND YAHOO

Next, we perform experiments on two very large recommendation data sets, Netflix and Yahoo (Table 5). We randomly use 50% of the observed ratings for training, 25% for validation and the rest for testing. As active subspace selection has been shown to be slower and inferior to the others (Table 6), it is not compared here. Each experiment is repeated five times. Results are shown in Table 7, and a more detailed convergence comparison with CPU time is shown in Figures 13 and 14. Again, N2C is much faster than FaNCL, and has the lowest testing RMSE.

5.4 Comparison with HONOR

In this section, we experimentally compare the proposed method with HONOR (Section 4.5) on the model in (43), using the logistic loss and LSP regularizer. Following (Gong and Ye, 2015a), we fix $\mu = 1$ in (43), and θ in the LSP regularizer to 0.01μ. Experiments are performed on three large data sets,[3] kdd2010a, kdd2010b and url (Table 8). Both kdd2010a and kdd2010b are educational data sets, and the task is to predict students' successful attempts to answer concepts related to algebra.

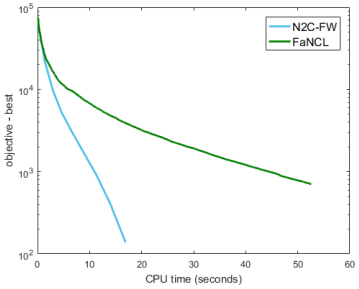
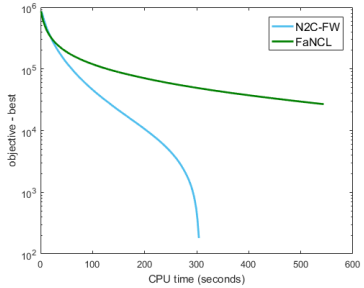
(a) MovieLens-100K.



(b) MovieLens-1M.



(c) MovieLens-10M.

Figure 11: Convergence of objective vs CPU time on the MovieLens data sets for nonconvex low-rank matrix completion.

The url data set contains a collection of websites, and the task is to predict whether a particular website is malicious. We compare

1. running HONOR directly on (43). The threshold of the hybrid step in HONOR is set to 10^{-10}, which yields the best empirical performance in (Gong and Ye, 2015a);

2. running mOWL-QN (Gong and Ye, 2015b) on the transformed problem (44).

To reduce statistical variability, the experimental results are averaged over 5 repetitions.

Figure 15 shows convergence of the objective (which is the same in (43) and (44)) with CPU time. As can be seen, mOWL-QN converges faster than HONOR. This validates our claim that the curvature information of the nonconvex regularizer helps.

(c) MovieLens-10M.

Figure 12: Convergence of testing RMSE vs CPU time on the MovieLens data sets for nonconvex low-rank matrix completion.

5.5 Image Denoising

In this section, we perform experiments on total variation image denoising with nonconvex loss and nonconvex regularizer (as introduced in Section 4.6.1). The LSP function (with $\theta = 1$) is used as κ in (46) on both the loss and regularizer. Eight popular images[4] are used (Figure 16). They are then corrupted by pepper-and-salt noise, with 10% of the pixels randomly set to 0 or 255 with equal probabilities.

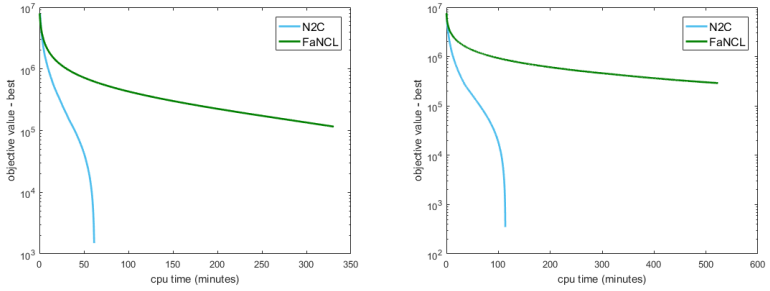
For performance evaluation, we use the RMSE $= \sqrt{\frac{1}{mn}\sum_{i=1}^{m}\sum_{j=1}^{n}(X_{ij} - \bar{X}_{ij})^2}$, where $\bar{X} \in \mathbb{R}^{m\times n}$ is the clean image, and $X \in \mathbb{R}^{m\times n}$ is the recovered image. To tune μ, we pick the value that leads to the smallest RMSE on the first four images (boat, couple, fprint, hill). Denoising performance is then reported on the remaining images (house, lena, man, peppers).

The following algorithms will be compared:

4. http://www.cs.tut.fi/~foi/GCF-BM3D/

		RMSE	rank	CPU time(min)
Netflix	N2C-FW	**0.792±0.001**	13	**64.9±1.8**
	FaNCL	0.793±0.001	13	322.1±7.3
	LMaFit	0.807±0.001	15	98.2±1.8
Yahoo	N2C-FW	**0.643±0.001**	9	**111.3±13.5**
	FaNCL	0.650±0.001	9	444.7±92.4
	LMaFit	0.666±0.001	12	179.3±37.5

Table 7: Results on the Netflix and Yahoo data sets. The best results (according to the paired t-test with 95% confidence) are highlighted.



(a) Netflix. (b) Yahoo.

Figure 13: Convergence of objective vs CPU time on the Netflix and Yahoo data sets for nonconvex low-rank matrix completion.

1. CCCP (Yuille and Rangarajan, 2002): Proposition 9 is used to construct the DC decomposition for κ (Details are in Appendix B.1);
2. Smoothing (Chen, 2012): The nonsmooth κ is smoothed, and then gradient descent is used (Details are in Appendix B.2);
3. nmAPG (Li and Lin, 2015): This optimizes (50) with Algorithm 2, and the exact proximal step is solved numerically using CCCP;
4. inexact-nmAPG: This optimizes (47) with Algorithm 3 (with $\epsilon_t = 0.95^t$), and the inexact proximal step is solved numerically using L-BFGS.
5. As a baseline, we also compare with ADMM (Boyd et al., 2011) with the convex formulation.

To reduce statistical variability, the experimental results are averaged over 5 repetitions.

The RMSE results are shown in Table 9. As can be seen, the (convex) ADMM formulation leads to the highest RMSE, while CCCP, smoothing, nmAPG and inexact-nmAPG have the same RMSE which is lower than that of ADMM. This agrees with previous observations that nonconvex formulations can yield better performance than the convex ones. Timing results are shown in

Table 8: Data sets used in the comparison with HONOR.

Table 10 and Figure 17. As can be seen, smoothing has low iteration complexity but suffers from slow convergence. CCCP and nmAPG both need to exactly solve a subproblem, and thus are also slow. The inexact-nmAPG algorithm does not guarantee the objective value to be monotonically decreasing as iteration proceeds. As the inexactness is initially large, there is an initial spike in the objective. However, inexact-nmAPG then quickly converges, and is much faster than all the baselines.

6. Conclusion

In this paper, we proposed a novel approach to learning with nonconvex regularizers that are variants of the convex ℓ_1-norm. By moving the nonconvexity associated with the nonconvex regularizer

	house	lena	man	peppers

to the loss, the nonconvex regularizer is convexified to become a familiar convex regularizer while the augmented loss is still Lipschitz smooth. This allows one to reuse efficient algorithms originally designed for convex regularizers on the transformed problem. To illustrate usages with the proposed transformation, we plug it into many popular optimization algorithms. First, we consider the proximal algorithm, and showed that while the proximal step is expensive on the

original problem, it becomes much easier on the transformed problem. We further propose an inexact proximal algorithm, which allows inexact update of proximal step when it does not have a closed-form solution. Second, we combine the proposed convexification scheme with the Frank-Wolfe algorithm on learning low-rank matrices, and showed that its crucial linear programming step becomes cheaper and more easily solvable. As no convergence results exist on this nonconvex problem, we designed a novel Frank-Wolfe algorithm based on the proposed transformation and with convergence guarantee. Third, when using with ADMM and SVRG, we showed that the existing convergence results can be applied on the transformed problem but not on the original one. We further extend the proposed transformation to handle nonconvex and nonsmooth loss functions, and illustrate its benefits on the total variation model and robust sparse coding. Finally, we demonstrate the empirical advantages of working with the transformed problems on various tasks with both synthetic and real-world data sets. Experimental results show that better performance can be obtained with nonconvex regularizers, and algorithms on the transformed problems run much faster than the state-of-the-art on the original problems.

Appendix A. Proofs

A.1 Proposition 1

Proof First, we introduce a few Lemmas.

Lemma 14 (Golub and Van Loan (2012)) *For $x \neq 0$, the gradient of the ℓ_2-norm is $\nabla_{x_i}\|x\|_2 = x_i/\|x\|_2$.*

Let $h(z) = \kappa(\|z\|_2) - \kappa_0\|z\|_2$.

Lemma 15

$$\nabla_{z_i} h(z) = \begin{cases} \frac{\kappa'(\|z\|_2)-\kappa_0}{\|z\|_2} z_i & z \neq 0 \\ 0 & \textit{otherwise} \end{cases}. \tag{60}$$

Proof For $z \neq 0$, $\|z\|_2$ is differentiable (Lemma 14), and we obtain the first part of (60). For $z = 0$, let $\bar{h}_i(z) = \frac{\kappa'(\|z\|_2)-\kappa_0}{\|z\|_2} z_i$. Consider any Δ with $\|\Delta\|_2 = 1$.

$$\begin{aligned} \lim_{\alpha\to 0^+} \bar{h}_i(0+\alpha\Delta) &= \lim_{\alpha\to 0^+} \frac{\kappa'(\|\alpha\Delta\|_2) - \kappa_0}{\|\alpha\Delta\|_2}\alpha\Delta_i \\ &= \lim_{\alpha\to 0^+} (\kappa'(\alpha) - \kappa_0)\Delta_i = 0, \end{aligned}$$

as $\lim_{\alpha\to 0^+} \kappa'(\alpha) - \kappa_0 = 0$. Thus, $h(z)$ is smooth at $z = 0$, and we obtain the second part of (60). ■

Lemma 16 (Eriksson et al. (2004)) *Let $f : \mathbb{R} \to \mathbb{R}$ be a differentiable function. If its derivative f' is bounded, then f is Lipschitz-continuous with constant c where c is equal to the maximum value of $|f'|$.*

Lemma 17 (Eriksson et al. (2004)) *If a continuous function $f : \mathbb{R} \to \mathbb{R}$ is L_1-Lipschitz continuous in $[a, b]$ and L_2-Lipschitz continuous in $[b, c]$ (where $-\infty \leq a < b < c \leq \infty$), then it is $\max(L_1, L_2)$-Lipschitz continuous in $[a, c]$.*

Lemma 18 *Let z be an arbitrary vector, and e_i be the unit vector with only its ith dimension equal to 1. Define $\hat{h}_i(\gamma) = \frac{\kappa'(\|z+e_i\gamma\|_2)-\kappa_0}{\|z+e_i\gamma\|_2}(z_i + \gamma)$. Then, $\hat{h}$ is 2ρ-Lipschitz continuous.*

Proof Let the finite non-differentiable points of κ' be $\{\hat{\alpha}_1, \ldots, \hat{\alpha}_k\}$, where $\hat{\alpha}_1 < \cdots < \hat{\alpha}_k$. We partition $(-\infty, \infty)$ into intervals $(-\infty, \hat{\alpha}_1] \cup [\hat{\alpha}_1, \hat{\alpha}_2] \cup \cdots \cup [\hat{\alpha}_k, \infty)$, such that κ'' exists in each interval. Let $w = z + e_i\gamma$. For any interval,

$$\hat{h}_i'(\gamma) = \frac{\kappa''(\|w\|_2)}{\|w\|_2}(z_i+\gamma)^2 + \left(1 - \frac{(z_i+\gamma)^2}{\|w\|_2^2}\right)\frac{\kappa'(\|w\|_2) - \kappa_0}{\|w\|_2}. \tag{61}$$

Let $\phi(\alpha) = \kappa'(\alpha) - \kappa_0$, where $\alpha \geq 0$. Note that $\phi(0) = 0$. Moreover, $\phi(\alpha)$ is ρ-Lipschitz continuous as κ is ρ-Lipschitz smooth. Thus,

$$|\phi(\alpha) - \phi(0)| = |\kappa'(\alpha) - \kappa_0| \leq \rho\alpha,$$

and so

$$\left|\kappa'(\|w\|_2) - \kappa_0\right| \leq \rho\|w\|_2. \tag{62}$$

Note that $(z_i + \gamma)^2 \leq \|w\|_2^2$, (61) can be rewritten as

$$\begin{aligned} \left|\hat{h}_i'(\gamma)\right| &\leq \left|\frac{\kappa''(\|w\|_2)}{\|w\|_2}(z_i+\gamma)^2\right| + \left|\left(1 - \frac{(z_i+\gamma)^2}{\|w\|_2^2}\right)\frac{\kappa'(\|w\|_2) - \kappa_0}{\|w\|_2}\right| \\ &\leq \left|\kappa''(\|w\|_2)\right| + \left|\frac{\kappa'(\|w\|_2) - \kappa_0}{\|w\|_2}\right| \leq 2\rho, \end{aligned}$$

where the last inequality is due to that κ is ρ-Lipschitz smooth and (62). Thus, $|\hat{h}_i'(\gamma)| \leq 2\rho$, and by Lemma 16, we have $\hat{h}_i(\gamma)$ is 2ρ-Lipschitz continuous on any interval. Obviously $\hat{h}_i$ is continuous, and we conclude that $\hat{h}_i$ is also 2ρ-Lipschitz continuous by Lemma 17. ■

From Lemma 18, $\hat{h}_i$ is 2ρ-Lipschitz continuous. Thus, ∇h is 2ρ-Lipschitz continuous in each of its dimensions. For any $x, y \in \mathbb{R}^d$,

$$\begin{aligned} \|\nabla h(x) - \nabla h(y)\|_2^2 &= \sum_{i=1}^d [\nabla_{x_i} h(x) - \nabla_{y_i} h(y)]^2 \\ &\leq 4\rho^2 \sum_{i=1}^d (x_i - y_i)^2 = 4\rho^2\|x - y\|_2^2, \end{aligned}$$

and hence h is 2ρ-Lipschitz smooth. Finally, we will show that $h(z)$ is also concave.

Lemma 19 (Boyd and Vandenberghe (2004)) *$\phi(x) = \pi(q(x))$ is concave if π is concave, non-increasing and q is convex.*

Let $\pi(\alpha) = \kappa(\alpha) - \kappa_0\alpha$, where $\alpha \geq 0$. Note that π is concave. Moreover, $\pi(0) = 0$ and $\pi'(\alpha) \leq 0$. Thus, $\pi(\alpha)$ is non-increasing on $\alpha \geq 0$. Next, let $q(z) = \|z\|_2$. Then, $h(z) \equiv \kappa(\|z\|_2) - \kappa_0\|z\|_2 = \pi(q(z))$. As q is convex, $h(z)$ is concave from Lemma 19. ■

A.2 Corollary 2

Proof From Proposition 1 and the definition of $\bar{g}_i$, we can see that $\bar{g}_i$ is concave. Then, for any x, y,

$$\|\nabla h(A_i x) - \nabla h(A_i y)\|_2^2 \leq 4\rho^2\|A_i x - A_i y\|_2^2 \leq 4\rho^2\|A_i\|_F^2\|x - y\|_2^2.$$

Thus, $\bar{g}_i$ is $2\rho\|A_i\|_F$-Lipschitz smooth. ■

A.3 Corollary 3

Proof It is easy to see that $\breve{g}(x) = \kappa_0 \sum_{i=1}^K \mu_i\|A_i x\|_2$ is convex but not smooth. Using Corollary 2, as each $\bar{g}_i$ is concave and Lipschitz-smooth, $\bar{g}$ is also concave and Lipschitz-smooth. ■

A.4 Proposition 5

Proof First, we introduce a few Lemmas.

Definition 20 (Bertsekas (1999)) *A function $f : \mathbb{R}^m \to \mathbb{R}$ is* absolute symmetric *if $f([x_1; \ldots; x_m]) = f\left([|x_{\pi(1)}|; \ldots; |x_{\pi(m)}|]\right)$ for any permutation π.*

Lemma 21 (Lewis and Sendov (2005)) *Let $\sigma(X) = [\sigma_1(X); \ldots; \sigma_m(X)]$ be the vector containing singular values of X. For an absolute symmetric function $f : \mathbb{R}^m \to \mathbb{R}$, $\phi(X) \equiv f(\sigma(X))$ is concave on X if and only if f is concave.*

From the definition of $\bar{g}$ in (24),

$$\bar{g}(X) = \bar{\mu}\sum_{i=1}^m(\kappa(\sigma_i(X)) - \kappa_0\|X\|_*) = \bar{\mu}\sum_{i=1}^m(\kappa(\sigma_i(X)) - \kappa_0\sigma_i(X)).$$

Let

$$h(x) = \bar{\mu}\sum_{i=1}^m(\kappa(|x_i|) - \kappa_0|x_i|). \tag{63}$$

Obviously, h is absolute symmetric. From Remark 4, h is concave. Thus, $\bar{g}$ is also concave by Lemma 21.

Lemma 22 (Lewis and Sendov (2005)) *Let the SVD of X be $U\text{Diag}(\sigma(X))V^\top$, where $\sigma(X) = [\sigma_1(X); \ldots; \sigma_m(X)]$, $f : \mathbb{R}^m \to \mathbb{R}$ be smooth and absolute symmetric, and $\phi(X) \equiv f(\sigma(X))$. We have*

1. *$\nabla\phi(X) = U\text{Diag}(\nabla f(\sigma(X)))V^\top$; and*
2. *If f is L-Lipschitz smooth, then ϕ is also L-Lipschitz smooth.*

From Remark 4, h in (63) is 2ρ-Lipschitz smooth. Hence, from Lemma 22, $\bar{g}(X)$ is also 2ρ-Lipschitz smooth and $\nabla\bar{g}(X) = U\text{Diag}(\nabla h(\sigma(X)))V^\top$. ■

A.5 Proposition 9

Proof First, we introduce the following Lemma.

Lemma 23 (Boyd and Vandenberghe (2004)) *$\phi(x) = \pi(q(x))$ is convex if π is convex, non-decreasing and q is convex.*

Let $\pi(\alpha) = \kappa(\alpha) + \frac{\rho}{2}\alpha^2$ where $\alpha \geq 0$. As κ is ρ-Lipschitz smooth, $\kappa'(\beta) - \kappa'(\alpha) \leq \rho(\alpha - \beta)$. Thus, $\pi'(\alpha) - \pi'(\beta) = \kappa'(\alpha) + \rho\alpha - \kappa'(\beta) - \rho\beta \geq 0$, i.e., π is convex. Besides, $\pi'(0) = \kappa'(0) \geq 0$. Thus, $\pi'(\alpha) \geq 0$ and π is also non-decreasing. Let $q(x) = \|x\|$ which is obviously convex as $\|\cdot\|$ is a norm, we can express $\phi(x) = \pi(q(x)) = \kappa(\|x\|_x) + \frac{\rho}{2}\|x\|^2$. Finally, $\phi(x)$ is also convex due to Lemma 23. ■

A.6 Theorem 6

Proof First, we introduce a few Lemmas.

Lemma 24 *Let $\tilde{X}$ be an inexact solution of the proximal step $\min_Z h(Z)$, where $h(Z) = \frac{1}{2}\|Z - (X - \frac{1}{\tau}\nabla\bar{f}(X))\|_F^2 + \frac{1}{\tau}\breve{g}(Z)$. Let $\hat{X} = \arg\min_Z h(Z)$. If $h(\tilde{X}) - h(\hat{X}) \leq \epsilon$, then*

$$F(\tilde{X}) \leq F(X) - \frac{\tau - \bar{L}}{2}\|\tilde{X} - X\|_F^2 + \tau\epsilon.$$

Proof Let $\phi(Z) = \langle Z - X, \nabla f(X)\rangle + \frac{\tau}{2}\|Z - X\|_F^2 + \breve{g}(Z)$. We have

$$\hat{X} = \arg\min_Z h(Z) = \arg\min_Z \phi(Z), \tag{64}$$

$$\phi(Z) = \tau h(Z) - \frac{1}{\tau}\|\nabla\bar{f}(X)\|_F^2. \tag{65}$$

From (64), we have

$$\phi(\hat{X}) = \langle\hat{X} - X, \nabla f(X)\rangle + \frac{\tau}{2}\|\hat{X} - X\|_F^2 + \breve{g}(\hat{X}) \leq \breve{g}(X). \tag{66}$$

As $h(\tilde{X}) - h(\hat{X}) \leq \epsilon$, from (65) (note that $\|\nabla\bar{f}(X)\|_F^2$ is a constant), we have

$$\phi(\tilde{X}) - \phi(\hat{X}) = \tau(h(\tilde{X}) - h(\hat{X})) \leq \tau\epsilon.$$

Then with (66), we have $\phi(\tilde{X}) \le \tau\epsilon + \phi(\hat{X}) \le \breve{g}(X) + \tau\epsilon$, i.e.,

$$\langle \tilde{X} - X, \nabla f(X)\rangle + \frac{\tau}{2}\|\tilde{X} - X\|_F^2 + \breve{g}(\tilde{X}) \le \breve{g}(X) + \tau\epsilon. \tag{67}$$

As $\bar{f}$ is $\bar{L}$-Lipschitz smooth,

$$\bar{f}(\tilde{X}) \le \bar{f}(X) + \langle \tilde{X} - X, \nabla f(X)\rangle + \frac{\bar{L}}{2}\|\tilde{X} - X\|_F^2.$$

Combining with (67), we obtain

$$\bar{f}(\tilde{X}) + \frac{\tau}{2}\|\tilde{X} - X\|_2^2 + \breve{g}(\tilde{X}) \le \bar{f}(X) + \frac{\bar{L}}{2}\|\tilde{X} - X\|_F^2 + \breve{g}(X) + \tau\epsilon.$$

Thus, $F(\tilde{X}) \le F(X) - \frac{\tau-\bar{L}}{2}\|\tilde{X} - X\|_F^2 + \tau\epsilon$. ■

If step 6 in Algorithm 3 is satisfied, $X_{t+1} = \tilde{Z}_{t+1}$, and

$$F(X_{t+1}) \le F(X_t) - \frac{\delta}{2}\|X_{t+1} - Y_t\|_F^2. \tag{68}$$

Otherwise, step 9 is executed, and from Lemma 24, we have

$$F(X_{t+1}) \le F(X_t) - \frac{\tau - \bar{L}}{2}\|X_{t+1} - X_t\|_F^2 + \tau\epsilon_t. \tag{69}$$

Partition $\Omega(T) = \{1, 2, \ldots, T\}$ into $\Omega_1(T)$ and $\Omega_2(T)$, such that step 7 is performed if $t \in \Omega_1(T)$; and execute step 9 otherwise. Combining (68) and (69), we have

$$\begin{aligned}
&F(X_1) - F(X_{T+1})\\
&\ge \frac{\delta}{2}\sum_{t\in\Omega_1(T)}\|X_{t+1} - Y_t\|_F^2 + \frac{\tau-\bar{L}}{2}\sum_{t\in\Omega_2(T)}\left(\|X_{t+1} - X_t\|_F^2 - \tau\epsilon_t\right),\\
&\ge \frac{\delta}{2}\sum_{t\in\Omega_1(T)}\|X_{t+1} - Y_t\|_F^2 + \frac{\tau-\bar{L}}{2}\sum_{t\in\Omega_2(T)}\|X_{t+1} - X_t\|_F^2 - \frac{(\tau-\bar{L})\tau}{2}\sum_{t\in\Omega_2(T)}\epsilon_t\\
&\ge \frac{\delta}{2}\sum_{t\in\Omega_1(T)}\|X_{t+1} - Y_t\|_F^2 + \frac{\tau-\bar{L}}{2}\sum_{t\in\Omega_2(T)}\|X_{t+1} - X_t\|_F^2 - \frac{(\tau-\bar{L})\tau}{2}\sum_{t=1}^{\infty}\epsilon_t\\
&\ge \frac{\delta}{2}\sum_{t\in\Omega_1(T)}\|X_{t+1} - Y_t\|_F^2 - c_1 + \frac{\tau-\bar{L}}{2}\sum_{t\in\Omega_2(T)}\|X_{t+1} - X_t\|_F^2,
\end{aligned} \tag{70}$$

where $c_1 = \frac{(\tau-\bar{L})\tau}{2}\sum_{t=1}^{\infty}\epsilon_t < \infty$ and $c_1 \ge 0$. From (70), we have

$$\begin{aligned}
F(X_1) - \inf_X F(X) + c_1 &\ge F(X_1) - \lim_{T\to\infty} F(X_{T+1}) + c_1\\
&\ge \lim_{T\to\infty}\frac{\delta}{2}\sum_{t\in\Omega_1(T)}\|X_{t+1} - Y_t\|_F^2 + \frac{\tau-\bar{L}}{2}\sum_{t\in\Omega_2(T)}\|X_{t+1} - X_t\|_F^2\\
&\equiv c_2.
\end{aligned} \tag{71}$$

From Assumption A1, $c_2 \le F(X_1) - \inf_X F(X) + c_1 < \infty$. Thus, $c_2 \ge 0$ is a finite constant. Let $\Omega_1^\infty = \lim_{T\to\infty}\Omega_1(T)$, and $\Omega_2^\infty = \lim_{T\to\infty}\Omega_2(T)$. Consider the three cases:

1. $|\Omega_1^\infty|$ is finite, and $|\Omega_2^\infty|$ is infinite. As $|\Omega_2^\infty| = \infty$ and $\lim_{\|X\|_F\to\infty} F(X) = \infty$ from Assumption A1 and (71), we have

$$\lim_{t\in\Omega_2^\infty, t\to\infty}\|X_{t+1} - X_t\|_F^2 = 0.$$

Thus, there exists a limit point such that $X_* = \lim_{t_j\in\Omega_2^\infty, t_j\to\infty} X_{t_j}$ for a subsequence $\{X_{t_j}\}$ of $\{X_t\}$. Since $\lim_{t_j\to\infty}\epsilon_{t_j} = 0$, then

$$\lim_{t_j\in\Omega_2^\infty, t_j\to\infty} X_{t_j+1} = \lim_{t_j\in\Omega_2^\infty, t_j\to\infty}\mathrm{prox}_{\frac{1}{\tau}\breve{g}}(X_{t_j} - \frac{1}{\tau}\nabla\bar{f}(X_{t_j})).$$

As a result,

$$0 \in \lim_{t_j\in\Omega_2^\infty, t_j\to\infty}\frac{1}{\tau}\nabla\bar{f}(X_{t_j}) + (X_{t_j+1} - X_{t_j}) + \frac{1}{\tau}\partial\breve{g}(X_{t_j+1}).$$

Since both $\lim_{t_j\in\Omega_2^\infty, t_j\to\infty} X_{t_j} = \lim_{t_j\in\Omega_2^\infty, t_j\to\infty} X_{t_j+1} = X_*$, we then have $\nabla\bar{f}(X_*) + \partial\breve{g}(X_*) \ni 0$, and X_* is a critical point of (1).

2. $|\Omega_1^\infty|$ is infinite, and $|\Omega_2^\infty|$ is finite. As Ω_1^∞ is infinite and $\lim_{\|X\|_F\to\infty} F(X) = \infty$ from Assumption A1 and (71), we have

$$\lim_{t_j\in\Omega_1^\infty, t_j\to\infty}\|X_{t_j+1} - Y_{t_j}\|_F^2 = 0$$

for a subsequence $\{X_{t_j}\}$ of $\{X_t\}$. Thus, there exist a limit point such that

$$X_* = \lim_{t_j\in\Omega_1^\infty, t_j\to\infty} X_{t_j+1} = \lim_{t_j\in\Omega_1^\infty, t_j\to\infty} Y_{t_j}. \tag{72}$$

As $\lim_{t_j\to\infty}\epsilon_{t_j} = 0$, we have

$$0 \in \lim_{t_j\in\Omega_1^\infty, t_j\to\infty}\frac{1}{\tau}\nabla\bar{f}(Y_{t_j}) + (X_{t_j+1} - Y_{t_j}) + \frac{1}{\tau}\partial\breve{g}(X_{t_j+1}).$$

From (72), we have $\nabla\bar{f}(X_*) + \partial\breve{g}(X_*) \ni 0$ and X_* is a critical point of (1).

3. Both $|\Omega_1^\infty|$ and $|\Omega_2^\infty|$ are infinite. From the above two cases, we can see that once $|\Omega_1^\infty|$ or $|\Omega_2^\infty|$ is infinite, then $\{X_t\}$ is bounded, and any limit point of $\{X_t\}$ is also a critical point. In the third case, both $|\Omega_1^\infty|$ and $|\Omega_2^\infty|$ are infinite. Thus, any limit point of $\{X_t\}$ is also a critical point of (1).

As a result, $\{X_t\}$ is bounded and its limits points are critical points of (1). ■

A.7 Proposition 7

Proof From (71), we have

$$\frac{\delta}{2}\sum_{t_1\in\Omega_1(T)}\|X_{t_1+1} - Y_{t_1}\|_F^2 + \frac{\tau-\bar{L}}{2}\sum_{t_2\in\Omega_2(T)}\|X_{t_2+1} - X_{t_2}\|_F^2 < c_2, \tag{73}$$

where $c_2 \in (0, \infty)$ is a positive constant. Let $c_3 = \min(\frac{\delta}{2}, \frac{\tau - \bar{L}}{2})$. From the definition of V_t, (73) can be rewritten as

$$c_3 \sum_{t=1}^{T} \|X_{t+1} - V_t\|_F^2 \leq \frac{\delta}{2} \sum_{t_1 \in \Omega_1(T)} \|X_{t_1+1} - Y_{t_1}\|_F^2 + \frac{\tau - \bar{L}}{2} \sum_{t_2 \in \Omega_2(T)} \|X_{t_2+1} - X_{t_2}\|_F^2 \leq c_2.$$

Since c_2 is finite, thus $\lim_{t\to\infty} d_t \equiv \|X_{t+1} - V_t\|_F^2 = 0$. Besides, we have

$$\min_{t=1,\ldots,T} \sum_{t=1}^{T} \|X_{t+1} - V_t\|_F^2 \leq \frac{1}{T} \sum_{t=1}^{T} \|X_{t+1} - V_t\|_F^2 \leq \frac{c_2}{c_3 T}.$$

■

A.8 Proposition 10

Proof Note from (32) that $\nabla \bar{f}(S) = \nabla f(S) + \nabla \bar{g}(S)$. Using the matrix chain rule, since $S = \alpha X_t + \beta u_t v_t^\top$ and $\frac{\partial S}{\partial \alpha} = X_t$, then

$$\frac{\partial \bar{f}(S)}{\partial \alpha} = \left\langle \nabla \bar{f}(S), \frac{\partial S}{\partial \alpha} \right\rangle = \alpha \langle X_t, \nabla \bar{f}(S) \rangle.$$

Similarly, since $\frac{\partial S}{\partial \beta} = u_t v_t^\top$,

$$\frac{\partial \bar{f}(S)}{\partial \beta} = \left\langle \nabla \bar{f}(S), \frac{\partial S}{\partial \beta} \right\rangle = \beta \left\langle u_t v_t^\top, \nabla \bar{f}(S) \right\rangle = \beta \left(u_t^\top \nabla \bar{f}(S) v_t \right).$$

As $\bar{g}(S) = \mu \sum_{i=1}^{m} \kappa(\sigma_i(S)) - \mu \kappa_0 \sigma_i(S)$, using Lemma 22, $\nabla \bar{f}(X) = \nabla f(S) + \mu U_S \text{Diag}(w) V_S^\top$ and $w_i = \kappa'(\sigma_i(S)) - \kappa_0$. ■

A.9 Corollary 11

Proof Note that the SVD of X is $(UU_B)\text{Diag}([\sigma_1(B), \ldots, \sigma_k(B)])(VV_B)^\top$. Using Lemma 22,

$$\nabla \bar{f}(X) = \nabla f(X) + \nabla \bar{g}(X) = \nabla f(X) + \mu (UU_B) \text{Diag}(w) (VV_B)^\top,$$

where $w \in \mathbb{R}^k$ with $w_i = \kappa'(\sigma_i(B)) - \kappa_0$. ■

A.10 Proposition 12

Proof As $\bar{g}(X)$ is defined on the singular values of the input matrix X, we only need to show that $UBV^\top$ and B have the same singular values. Let the SVD of B be $U_B \text{Diag}(\sigma(B)) V_B^\top$, where $\sigma(B) = [\sigma_1(B), \ldots, \sigma_m(B)]$. As U and V are orthogonal, it is easy to see that $(UU_B)\,\text{Diag}(\sigma(B))\,(V_B V)^\top$ is the SVD of X. Thus, the Proposition holds. ■

A.11 Theorem 13

Proof We first introduce two Propositions.

Proposition 25 (Mishra et al. (2013)) *For a square matrix X, let $sym(X) = \frac{1}{2}(X + X^\top)$. The first-order optimality conditions for* (37) *are*

$$\begin{aligned} \nabla \bar{f}(X) VB - U\, sym(U^\top \nabla \bar{f}(X) VB) &= 0, \\ (\nabla \bar{f}(X))^\top UB - V\, sym(V^\top \nabla \bar{f}(X) UB) &= 0, \\ sym(U^\top \nabla \bar{f}(X) V) + \bar{\mu} I &= 0. \end{aligned}$$

Proposition 26 *If* (31) *has a critical point with rank r, choose the sizes of matrices U, V and B be $m \times r$, $n \times r$ and $r \times r$, respectively. Then, any critical point of* (37) *is also a critical point of* (31).

Proof The subdifferential of the nuclear norm can be obtained as (Watson, 1992)

$$\partial \|X\|_* = \{UV^\top + W : U^\top W = 0, WV = 0, \|W\|_\infty \leq 1\}, \tag{74}$$

where $X = UBV^\top$. Let $\hat{X} = \hat{U}\hat{B}\hat{V}^\top$ be a critical point of (37). We have $\text{sym}(\hat{U}^\top \nabla \bar{f}(\hat{X}) \hat{V}) + \bar{\mu} I = 0$ due to Proposition 25. From the property of the matrix norm, we have

$$\lambda = \|\,\text{sym}(\hat{U}^\top \nabla \bar{f}(\hat{X}) \hat{V})\|_\infty \leq \|\hat{U}^\top \nabla \bar{f}(\hat{X}) \hat{V}\|_\infty \leq \|\nabla \bar{f}(\hat{X})\|_\infty.$$

The equality holds only when $\nabla \bar{f}(\hat{X}) = -\bar{\mu} \hat{U} \hat{V}^\top - \bar{\mu} \hat{U}_\perp \hat{\Sigma}_\perp \hat{V}_\perp^\top$, where $\hat{U}_\perp$ and $\hat{V}_\perp$ are orthogonal matrices with $\hat{U}^\top \hat{U}_\perp = 0$ and $\hat{V}^\top \hat{V}_\perp = 0$, and $\hat{\Sigma}_\perp$ is a diagonal matrix with positive elements $[\Sigma_\perp]_{ii} \leq 1$. Combining this with (74), we have

$$\nabla \bar{f}(\hat{X}) \in -\bar{\mu} \partial \|\hat{X}\|_*. \tag{75}$$

Then, for (31), if X_* is a critical point, we have

$$\nabla \bar{f}(X_*) \in -\bar{\mu} \partial \|X_*\|_*. \tag{76}$$

Comparing (75) and (76), the difference is on the ranks of $\hat{X}$ and X_*. As (31) has a critical point with rank-r, $\hat{X}$ is also a critical point of (31). ■

In Algorithm 4, the sizes of U, V and B are selected as $m \times t$, $n \times t$, and $t \times t$, respectively. If (31) has a critical point with rank r, then as iteration goes and $t = r$, from Proposition 26, Algorithm 4 will return a critical point of (31). ■

Appendix B. Details in Section 5.5

B.1 CCCP

Using Proposition 9, we can decompose $\kappa(|x|) = \hat{\varsigma}(x) + \check{\varsigma}(x)$, where $\hat{\varsigma}(x) = -\frac{\rho}{2} x^2$ is convex and $\check{\varsigma}(x) = \kappa(|x|) + \frac{\rho}{2} x^2$ is concave. Apply the above decomposition on κ in (46), and we have the

following DC decomposition:

$$\breve{F}(X) = \sum_{i=1}^{m}\sum_{j=1}^{n} \breve{\varsigma}\left([Y-X]_{ij}\right) + \mu \sum_{i=1}^{m-1}\sum_{j=1}^{m} \breve{\varsigma}\left([D_v X]_{ij}\right) + \mu \sum_{i=1}^{n}\sum_{j=1}^{n-1} \breve{\varsigma}\left([XD_h]_{ij}\right),$$

$$\hat{F}(X) = \sum_{i=1}^{m}\sum_{j=1}^{n} \hat{\varsigma}\left([Y-X]_{ij}\right) + \mu \sum_{i=1}^{m-1}\sum_{j=1}^{m} \hat{\varsigma}\left([D_v X]_{ij}\right) + \mu \sum_{i=1}^{n}\sum_{j=1}^{n-1} \hat{\varsigma}\left([XD_h]_{ij}\right).$$

The CCCP procedures at Section 2.1 can then be applied.

B.2 Smoothing

As the LSP is used as κ, a smoothed version of it can be obtained as $\tilde{\kappa}_\lambda(x) = \beta \log\left(1 + \frac{h_\lambda(x)}{\theta}\right)$, where $h_\lambda(x) = \begin{cases} |x| & \text{if } |x| \geq \lambda \\ \frac{x^2}{2\lambda} + \frac{\lambda}{2} & \text{otherwise} \end{cases}$. Thus, (46) is smoothed as

$$\breve{F}_\lambda(X) = \sum_{i=1}^{m}\sum_{j=1}^{n} \tilde{\kappa}_\lambda\left([Y-X]_{ij}\right) + \mu \sum_{i=1}^{m-1}\sum_{j=1}^{m} \tilde{\kappa}_\lambda\left([D_v X]_{ij}\right) + \mu \sum_{i=1}^{n}\sum_{j=1}^{n-1} \tilde{\kappa}_\lambda\left([XD_h]_{ij}\right).$$

Gradient descent is then used for optimization (Chen, 2012). Specifically, we need to minimize a sequence of subproblems $\{\breve{F}_{\lambda_1}(X), \breve{F}_{\lambda_2}(X), \dots\}$ with $\lambda_i = \lambda_0 \nu^i$, and using X from $\breve{F}_{\lambda_{i-1}}(X)$ to warm start $\breve{F}_{\lambda_i}(X)$. In the experiment, we set $\lambda_0 = 0.1$ and $\nu = 0.95$.

Abstract

Modes and ridges of the probability density function behind observed data are useful geometric features. Mode-seeking clustering assigns cluster labels by associating data samples with the nearest modes, and estimation of density ridges enables us to find lower-dimensional structures hidden in data. A key technical challenge both in mode-seeking clustering and density ridge estimation is accurate estimation of the ratios of the first- and second-order density derivatives to the density. A naive approach takes a three-step approach of first estimating the data density, then computing its derivatives, and finally taking their ratios. However, this three-step approach can be unreliable because a good density estimator does not necessarily mean a good density derivative estimator, and division by the estimated density could significantly magnify the estimation error. To cope with these problems, we propose a novel estimator for the *density-derivative-ratios*. The proposed estimator does not involve density estimation, but rather *directly* approximates the ratios of density derivatives of any order. Moreover, we establish a convergence rate of the proposed estimator. Based on the proposed estimator, novel methods both for mode-seeking clustering and density ridge estimation are developed, and the respective convergence rates to the mode and ridge of the underlying density are also established. Finally, we experimentally demonstrate that the developed methods significantly outperform existing methods, particularly for relatively high-dimensional data.

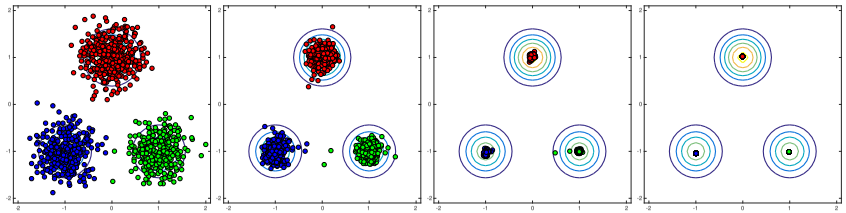
Keywords: Density Derivative, Geometric Feature, Mode-Seeking Clustering, Density Ridge Estimation

1. Introduction

Characterizing the probability density function underlying observed data is a fundamental problem in machine learning. One approach is to consider geometric properties of the density such as modes and ridges. Estimation of such geometric properties is a challenging task, yet offers a variety of applications (Wasserman, 2018).

The *modes* (i.e., local maxima) of probability density functions have received much attention over the years. A motivation of estimating the modes classically appeared in the seminal work on kernel density estimation (Parzen, 1962). More recently, the modes of density functions for random curves have been used in functional data analysis (Gasser et al., 1998). Furthermore, in supervised learning, modal regression associates input variables with the modes of the conditional density function of the output variable, and enables us to simultaneously capture multiple functional relationships between the input and output (Sager and Thisted, 1982; Carreira-Perpiñán, 2000, 2001; Einbeck and Tutz, 2006; Chen et al., 2016a; Sasaki et al., 2016). One of the most natural applications is clustering. *Mean shift clustering* (MS) makes use of the modes of the estimated density function (Fukunaga and Hostetler, 1975; Cheng, 1995; Comaniciu and Meer, 2002): MS initially regards all data samples as candidates for cluster centers, and then iteratively updates them toward the nearest modes of the estimated density by gradient ascent (Fig.1). Finally, the data samples which converge to the same mode are assigned the same cluster label. Unlike standard clustering methods such as k-means clustering (MacQueen, 1967) and mixture-model-based clustering (Melnykov and Maitra, 2010), the notable advantage is that the number of clusters is automatically determined according to the number of detected modes. MS has been applied to a wide range of tasks such as image segmentation (Comaniciu and Meer, 2002; Tao et al., 2007; Wang et al., 2004) and object tracking (Collins, 2003; Comaniciu et al., 2000). (See also a recent review article by Carreira-Perpiñán (2015))

A *ridge* of the probability density function generalizes the notion of the mode. The density ridge is a lower-dimensional hidden structure of the data (Fig.2), and the zero-dimensional ridge can be interpreted as the mode (Genovese et al., 2014). Application of density ridge estimation can be found in a variety of fields such as filamentary structure estimation in cosmology (Chen et al., 2016c), extraction of curvilinear structures (e.g., blood vessels in the eyes) in medical imaging (You et al., 2011), and shape analysis in computer vision (Su et al., 2013) (See Pulkkinen (2015) for more



(a) Iteration=0 (b) Iteration=1 (c) Iteration=3 (d) Iteration=10

Figure 1: Illustration of a mode-seeking process. The contour plot indicates the probability density function that generates the data samples.

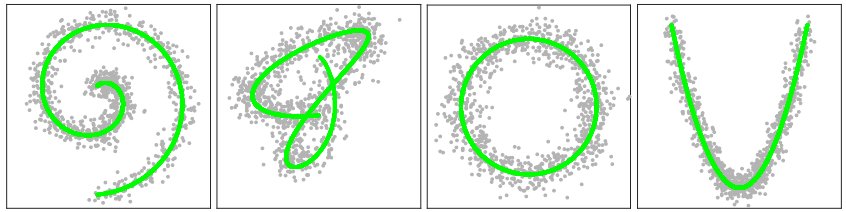


Figure 2: Examples of the density ridges hidden in data. Gray dot points and green curves indicate data samples and density ridges, respectively.

applications). Density ridge estimation is closely related to manifold estimation. When data is assumed to be generated on a lower-dimensional manifold with additive Gaussian noise, density ridge estimation offers a way to circumvent the difficulty of manifold estimation: Genovese et al. (2014) theoretically proved that the density ridges capture the essential properties of such manifolds and estimating the density ridge is substantially easier than estimating the manifold. A practical algorithm called *subspace constrained mean shift* (SCMS) by Ozertem and Erdogmus (2011). SCMS is an extension to MS, but a projected gradient ascent method is performed to find density ridges instead of the gradient ascent method in MS; the gradient vector of the estimated density is projected to the subspace which is orthogonal to the ridge. Such a subspace can be obtained by applying principal component analysis to an estimate of the Hessian matrix of the log-density, which is composed of the ratios of the first- and second-order density derivatives to the density. Along the projected gradient vector, SCMS updates data points toward the ridge of the estimated density until convergence.

For MS, the technical challenge is accurate estimation of the derivatives of the probability density function. To derive practical methods, MS takes a two-step approach, firstly estimating the probability density function and then computing its derivatives (Comaniciu and Meer, 2002, Section 2).[1] However, this approach can be unreliable because a good density estimator does not

1. As reviewed in Section 3.2, practical methods themselves do not perform initial density estimation.

necessarily imply a good density derivative estimator in many practical situations. For example, small random fluctuations in a density estimate can create fake modes and may produce large errors in density-derivative estimation, even if the density estimate is fairly good in terms of density estimation (Genovese et al., 2016, Fig.1). Therefore, testing methods have been proposed to investigate whether the estimated modes are real modes from the underlying data density or fake modes due to the random fluctuations (Godtliebsen et al., 2002; Duong et al., 2008; Genovese et al., 2016). For SCMS, it is even more challenging to estimate the ratios of density derivatives to the density, but SCMS also naively estimates the ratios by adding one more step to the two-step approach in MS: the computed density derivatives are divided by the estimated density. However, such a division could strongly magnify estimation error.

To cope with these problems, we propose a novel estimator of the ratios of density derivatives to the density. In stark contrast with the approaches in MS and SCMS, the key idea is to *directly* estimate the ratios without going through density estimation. Moreover, we theoretically analyze the proposed estimator and establish a convergence rate. The direct approach has been adopted and proved to be useful both empirically and theoretically when estimating the ratio of two probability density functions (Sugiyama et al., 2008; Nguyen et al., 2008; Kanamori et al., 2009, 2012; Sugiyama et al., 2012; Kpotufe, 2017). Here, we follow the direct approach in the context of a different problem and derive an estimator in a substantially different way. Previously, a direct estimator has been proposed for the log-density derivatives (Beran, 1976; Cox, 1985), which are the ratios of first-order density derivatives to the density. On the other hand, the proposed estimator in this paper approximates the ratio of the derivatives of any order to the density, and thus generalizes the previous estimator.

The proposed estimator is first applied to mode-seeking clustering. We derive an update rule for mode-seeking based on a fixed-point algorithm, while inheriting the advantage of MS: the proposed clustering method also does not require the number of clusters to be specified in advance. This is advantageous because clustering is an unsupervised learning problem and tuning the number of clusters is not straightforward in general. Next, based on the mode-seeking clustering, we propose a novel method for density ridge estimation. For both methods, we prove the consistency of the mode and ridge estimators, and establish the convergence rates. Finally, we experimentally demonstrate that our proposed methods outperform MS and SCMS, particularly for high(er)-dimensional data.

This paper is organized as follows: In Section 2, we propose a novel estimator for the ratio of the derivatives of any order to the density, and establish a non-parametric convergence rate. The proposed estimator is applied to develop novel methods for mode-seeking clustering and density ridge estimation in Sections 3 and 4 respectively, and both methods are theoretically analyzed. Section 5 experimentally investigates the performance of the proposed methods for mode-seeking clustering and density ridge estimation. Section 6 concludes this paper. Preliminary results of this paper were presented at ECML/PKDD 2014 (Sasaki et al., 2014) and AISTATS 2017 (Sasaki et al., 2017). However, in addition to combining the results in those conference papers, we have added new theoretical analysis of the proposed estimator, mode-seeking clustering and density ridge estimation methods. From a theoretical stand point, we further improved upon the methods appeared in the conference papers, and performed more experiments in this paper.

2. Direct Estimation of Density-Derivative-Ratios

This section proposes a novel estimator of the ratios of density derivatives to the density and performs theoretical analysis.

2.1 Problem Formulation

Suppose that n i.i.d. samples, which were drawn from a probability distribution on $\mathbb{R}^D$ with density $p(\boldsymbol{x})$, are available:

$$\mathcal{D} := \{\boldsymbol{x}_i = (x_i^{(1)}, x_i^{(2)}, \ldots, x_i^{(D)})^\top\}_{i=1}^n \overset{\text{i.i.d.}}{\sim} p(\boldsymbol{x}).$$

Here, our goal is to estimate the ratio of the $|\boldsymbol{j}|$-th order partial derivative of $p(\boldsymbol{x})$ to $p(\boldsymbol{x})$ from $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$,

$$\frac{\partial_{\boldsymbol{j}} p(\boldsymbol{x})}{p(\boldsymbol{x})}, \tag{1}$$

where $\partial_{\boldsymbol{j}} = \frac{\partial^{|\boldsymbol{j}|}}{\partial^{j_1} x^{(1)} \partial^{j_2} x^{(2)} \ldots \partial^{j_D} x^{(D)}}$, $\boldsymbol{j} = (j_1, j_2, \ldots, j_D)^\top$ and $|\boldsymbol{j}| = j_1 + j_2 + \cdots + j_D$ for non-negative integers $j_i = 0, 1, \ldots, |\boldsymbol{j}|$. For instance, when $|\boldsymbol{j}| = 1$ (or $|\boldsymbol{j}| = 2$), $\partial_{\boldsymbol{j}} p(\boldsymbol{x})/p(\boldsymbol{x})$ is a single element of $\nabla p(\boldsymbol{x})/p(\boldsymbol{x})$ (or of $\nabla\nabla p(\boldsymbol{x})/p(\boldsymbol{x})$).

2.2 Least-Squares Density-Derivative-Ratios

Our main idea is to directly fit a model $r_{\boldsymbol{j}}(\boldsymbol{x})$ to $\partial_{\boldsymbol{j}} p(\boldsymbol{x})/p(\boldsymbol{x})$ under the squared-loss:

$$\begin{aligned} J_{\boldsymbol{j}}(r_{\boldsymbol{j}}) &:= \int \left\{ r_{\boldsymbol{j}}(\boldsymbol{x}) - \frac{\partial_{\boldsymbol{j}} p(\boldsymbol{x})}{p(\boldsymbol{x})} \right\}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\ &= \int \{r_{\boldsymbol{j}}(\boldsymbol{x})\}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} - 2 \int r_{\boldsymbol{j}}(\boldsymbol{x}) \partial_{\boldsymbol{j}} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} + \int \left\{ \frac{\partial_{\boldsymbol{j}} p(\boldsymbol{x})}{p(\boldsymbol{x})} \right\}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}. \end{aligned} \tag{2}$$

The first term on the right-hand side of (2) can be naively estimated from samples and the third term is ignorable, but it seems challenging to estimate the second term because it includes the derivative of the unknown density. However, as in Sasaki et al. (2015), repeatedly applying *integration by parts* allows us to transform the second term as

$$\int r_{\boldsymbol{j}}(\boldsymbol{x}) \left\{ \partial_{\boldsymbol{j}} p(\boldsymbol{x}) \right\} \mathrm{d}\boldsymbol{x} = (-1)^{|\boldsymbol{j}|} \int \left\{ \partial_{\boldsymbol{j}} r_{\boldsymbol{j}}(\boldsymbol{x}) \right\} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}, \tag{3}$$

where we assumed that as $|x^{(j)}| \to \infty$ for all j, the product of $\partial_{\boldsymbol{j}_1} r_{\boldsymbol{j}}(\boldsymbol{x})$ and $\partial_{\boldsymbol{j}_2} p(\boldsymbol{x})$ approaches zero for any pairs of $\boldsymbol{j}_1$ and $\boldsymbol{j}_2$ satisfying $|\boldsymbol{j}_1| + |\boldsymbol{j}_2| = |\boldsymbol{j}| - 1$ for $|\boldsymbol{j}_1|, |\boldsymbol{j}_2| = 0, 1, \ldots, |\boldsymbol{j}| - 1$. As a result, the right-hand side of (3) can be easily estimated from samples. Then, an empirical version of (2) is given by

$$\widehat{J}_{\boldsymbol{j}}(r_{\boldsymbol{j}}) := \frac{1}{n} \sum_{i=1}^n \left\{ r_{\boldsymbol{j}}(\boldsymbol{x}_i)^2 - 2(-1)^{|\boldsymbol{j}|} \partial_{\boldsymbol{j}} r_{\boldsymbol{j}}(\boldsymbol{x}_i) \right\} + \text{const.} \tag{4}$$

After adding the regularizer $R(r_{\boldsymbol{j}})$, the estimator is defined as the minimizer of

$$\widehat{r}_{\boldsymbol{j}} := \operatorname*{argmin}_{r_{\boldsymbol{j}}} \left[\widehat{J}_{\boldsymbol{j}}(r_{\boldsymbol{j}}) + \lambda_{\boldsymbol{j}} R(r_{\boldsymbol{j}}) \right], \tag{5}$$

where $\lambda_{\boldsymbol{j}}$ is the regularization parameter.

We call this method the *least-squares density-derivative ratios* (LSDDR). Note that when $|\boldsymbol{j}| = 1$, $J_{\boldsymbol{j}}$ is called the Fisher divergence and has been used for parameter estimation of unnnormalized statistical models (Hyvärinen, 2005), density estimation with the computationally intractable partition function (Sriperumbudur et al., 2017), and direct estimation of log-density derivatives (Beran, 1976; Cox, 1985; Sasaki et al., 2014). Therefore, LSDDR can be regarded as a generalization of such methods to higher-order derivatives.

2.3 Theoretical Analysis of LSDDR

Next, we theoretically analyze LSDDR.

2.3.1 PRELIMINARIES AND NOTATIONS

For a D-dimensional vector $\boldsymbol{x} \in \mathbb{R}^D$, the norm is defined by $\|\boldsymbol{x}\| := \sqrt{\sum_{j=1}^D (x^{(j)})^2}$. For a domain $\mathcal{X} (\subseteq \mathbb{R}^D)$, $C(\mathcal{X})$ denotes the space of all continuous functions on $\mathcal{X}$. Furthermore, we define the L^p space of functions f on $\mathcal{X}$: For $1 \leq p \leq \infty$, $L^p(\mathcal{X}) := \{f : \|f\|_p < \infty\}$ where $\|\cdot\|_p$ is the L^p norm defined by $\|f\|_p := \left(\int |f(\boldsymbol{x})|^p \mathrm{d}\boldsymbol{x} \right)^{\frac{1}{p}}$ with the Lebesgue measure for $1 \leq p < \infty$ and $\|f\|_\infty := \operatorname{ess\,sup}_{\boldsymbol{x} \in \mathcal{X}} |f(\boldsymbol{x})|$. For $f \in L^1(\mathbb{R}^D)$, the *Fourier transform* is defined as

$$f^\wedge(\boldsymbol{\omega}) := \frac{1}{(2\pi)^{D/2}} \int f(\boldsymbol{x}) e^{-i\boldsymbol{\omega}^\top \boldsymbol{x}} \mathrm{d}\boldsymbol{x},$$

where i denotes the imaginary unit.

Let $\mathcal{H}$ be a reproducing kernel Hilbert space (RKHS) over $\mathcal{X}$ uniquely associated with the reproducing kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. The norm and inner product on $\mathcal{H}$ are denoted by $\|\cdot\|_{\mathcal{H}}$ and $\langle \cdot, \cdot \rangle_{\mathcal{H}}$, respectively. k is a real-valued, symmetric and positive definite function and has the reproducing property: For all $\boldsymbol{x} \in \mathcal{X}$ and $f \in \mathcal{H}$, $\langle f, k(\cdot, \boldsymbol{x}) \rangle_{\mathcal{H}} = f(\boldsymbol{x})$. An example of reproducing kernels is the *Gaussian kernel*, $k(\boldsymbol{x}, \boldsymbol{y}) = \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{y}\|^2}{2\sigma^2} \right)$ where $\sigma > 0$ is the width parameter. Another example is the *Matérn kernel*, $k(\boldsymbol{x}, \boldsymbol{y}) = \psi(\boldsymbol{x} - \boldsymbol{y}) = \frac{2^{1-s}}{\Gamma(s)} \|\boldsymbol{x} - \boldsymbol{y}\|^{s - D/2} \mathfrak{K}_{D/2-s}(\|\boldsymbol{x} - \boldsymbol{y}\|)$, whose corresponding RKHS $\mathcal{H}$ coincides with the Sobolev space H_2^s with the smoothness parameter $s > D/2$ (Wendland, 2004, Chapter 10):

$$\mathcal{H} = H_2^s := \left\{ f \in L^2(\mathbb{R}^D) \cap C(\mathbb{R}^D) : \int (1 + \|\boldsymbol{\omega}\|^2)^s |f^\wedge(\boldsymbol{\omega})|^2 \mathrm{d}\boldsymbol{\omega} < \infty \right\}.$$

$\Gamma(\cdot)$ denotes the Gamma function, and $\mathfrak{K}_v(\cdot)$ is the modified Bessel function of the second kind of order v.

2.3.2 THE CONVERGENCE RATE OF LSDDR

Here, we derive a rate of convergence for LSDDR under the RKHS norm. To this end, we assume that the true density-derivative-ratio is contained in $\mathcal{H}$:

$$r_{\boldsymbol{j}}^*(\boldsymbol{x}) := \frac{\partial_{\boldsymbol{j}} p(\boldsymbol{x})}{p(\boldsymbol{x})} \in \mathcal{H}.$$

Furthermore, we restrict the search space of $r_{\boldsymbol{j}}$ to $\mathcal{H}$ and express LSDDR with $R(r_{\boldsymbol{j}}) = \|r_{\boldsymbol{j}}\|_{\mathcal{H}}^2$ as

$$\widehat{r}_{\boldsymbol{j}} = \operatorname*{argmin}_{r_{\boldsymbol{j}} \in \mathcal{H}} \left[\widehat{J}_{\boldsymbol{j}}(r_{\boldsymbol{j}}) + \lambda_{\boldsymbol{j}} \|r_{\boldsymbol{j}}\|_{\mathcal{H}}^2 \right]. \tag{6}$$

To establish a convergence rate under the RKHS norm, we make the following assumptions as in Sriperumbudur et al. (2013):

(A) $\mathcal{X}$ is compact.

(B) k is $2|\boldsymbol{j}|$ continuously differentiable.

(C) The following equation holds:

$$\int_{\mathcal{X}} k(\cdot, \boldsymbol{x}) \partial_{\boldsymbol{j}} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} = (-1)^{|\boldsymbol{j}|} \int_{\mathcal{X}} \partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}.$$

(D) For all $\boldsymbol{j}$, there exists $\epsilon \geq 1$ subject to

$$\left(\int_{\mathcal{X}} \|k(\cdot, \boldsymbol{x})\|_{\mathcal{H}}^{2\epsilon} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \right)^{\frac{1}{2\epsilon}} < \infty \quad \text{and} \quad \left(\int_{\mathcal{X}} \|\partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x})\|_{\mathcal{H}}^{\epsilon} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \right)^{\frac{1}{\epsilon}} < \infty.$$

Assumption **(A)** makes $\mathcal{H}$ separable (Steinwart and Christmann, 2008, Lemma 4.33) and the separability of $\mathcal{H}$ is required to apply Proposition A.2 in Sriperumbudur et al. (2013). Assumption **(B)** ensures that arbitrary functions in $\mathcal{H}$ are $2|\boldsymbol{j}|$ continuously differentiable (Steinwart and Christmann, 2008, Corollary 4.36). Assumption **(C)** holds under mild assumptions of k and p as in (3). From Assumption **(D)**, $J_{\boldsymbol{j}}(r_{\boldsymbol{j}}) < \infty$ when $\epsilon = 1$. Then, the following theorem establishes the convergence rate under the RKHS norm:

Theorem 1 *Let*

$$C := \int_{\mathcal{X}} k(\cdot, \boldsymbol{x}) \otimes k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x},$$

where $\otimes$ denotes the tensor product, be an operator on $\mathcal{H}$. If there exists $\gamma > 0$ such that $r_{\boldsymbol{j}}^*$ is in the range of C^γ (i.e., $r_{\boldsymbol{j}}^* \in \mathcal{R}(C^\gamma)$), then

$$\|\widehat{r}_{\boldsymbol{j}} - r_{\boldsymbol{j}}^*\|_{\mathcal{H}} = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}} \right),$$

with $\epsilon = 2$ and $\lambda_{\boldsymbol{j}} = O\left(n^{-\max\left\{\frac{1}{4}, \frac{1}{2(\gamma+1)}\right\}} \right)$ as $n \to \infty$.

The proof is given in Appendix A. We followed the proof techniques in Sriperumbudur et al. (2013), but adopted them to a different problem: Sriperumbudur et al. (2013) proposed and analyzed a non-parametric estimator for log-densities with the intractable partition functions based on the Fisher divergence, which is a special case of $J_{\boldsymbol{j}}$ at $|\boldsymbol{j}| = 1$. The range space assumption $r_{\boldsymbol{j}}^* \in \mathcal{R}(C^\gamma)$ is closely related to the smoothness of $r_{\boldsymbol{j}}^*$ (Sriperumbudur et al., 2013, Section 4.2): Larger γ implies that $r_{\boldsymbol{j}}^*$ is smoother. As seen in Sections 3.3.3 and 4.3.2, Theorem 1 is particularly useful in the analysis of our mode-seeking clustering and density ridge estimation methods.

Remark 2 *By following Sriperumbudur et al. (2017, Section 4.2), Theorem 1 has some connection to the minimax theory (Tsybakov, 2009) under Sobolev spaces where for any $\alpha > s \geq 0$, the minimax rate is given by*

$$\inf_{\widehat{r}_{\boldsymbol{j},n}} \sup_{r_{\boldsymbol{j}}^* \in H_2^\alpha} \|\widehat{r}_{\boldsymbol{j},n} - r_{\boldsymbol{j}}^*\|_{H_2^s} \asymp n^{-\frac{\alpha - s}{2(\alpha - s) + D}}.$$

$\inf$ *is taken over possible estimators $\widehat{r}_{\boldsymbol{j},n}$, and $a_n \asymp b_n$ means that a_n / b_n has lower- and upper-bounds away from zero and infinity, respectively. To establish a connection to Sobolev spaces, suppose that the Matérn kernel is employed whose corresponding RKHS is a Sobolev space $\mathcal{H} = H_2^s$ with the smoothness parameter $s > D/2$. As proved in Appendix B, when the true density belongs to $L^1(\mathbb{R}^D)$ (i.e., $p \in L^1(\mathbb{R}^D)$), $r_{\boldsymbol{j}}^* \in \mathcal{R}(C^\gamma)$ for $\gamma \geq 1$ implies that $r_{\boldsymbol{j}}^* \in H_2^{\frac{3D}{2} - \frac{1}{2} + \epsilon}$ for arbitrarily small $\epsilon > 0$. Then, the convergence rate $n^{-\frac{1}{4}}$ is minimax optimal under $\mathcal{H} = H_2^{D - \frac{1}{2} + \epsilon}$. Furthermore, this result implies that the dimension effect is veiled through the relative smoothness between two Sobolev spaces ($H_2^{\frac{3D}{2} - \frac{1}{2} + \epsilon}$ and $H_2^{D - \frac{1}{2} + \epsilon}$), and therefore the rate in Theorem 1 is independent of data dimension D. Details are provided in Appendix B.*

2.4 Practical Implementation of LSDDR

Here, we describe practical implementation of LSDDR.

- *A practical version of LSDDR*: The representer theorem (Zhou, 2008, Theorem 2) states that the estimator $\widehat{r}_{\boldsymbol{j}}$ should take the following form:

$$\widehat{r}_{\boldsymbol{j}}(\boldsymbol{x}) = \sum_{i=1}^{n} \alpha_{\boldsymbol{j}}^{(i)} k(\boldsymbol{x}, \boldsymbol{x}_i) + \beta_{\boldsymbol{j}}^{(i)} \partial_{\boldsymbol{j}}' k(\boldsymbol{x}, \boldsymbol{x}') \Big|_{\boldsymbol{x}' = \boldsymbol{x}_i} = \sum_{i=1}^{2n} \theta_{\boldsymbol{j}}^{(i)} \psi_{\boldsymbol{j}}^{(i)}(\boldsymbol{x}) = \boldsymbol{\theta}_{\boldsymbol{j}}^\top \boldsymbol{\psi}_{\boldsymbol{j}}(\boldsymbol{x}), \tag{7}$$

  where $\partial_{\boldsymbol{j}}'$ denotes the partial derivative with respect to $\boldsymbol{x}'$,

$$\theta_{\boldsymbol{j}}^{(i)} := \begin{cases} \alpha_{\boldsymbol{j}}^{(i)} & i = 1, \ldots, n, \\ \beta_{\boldsymbol{j}}^{(i-n)} & i = n+1, \ldots, 2n, \end{cases} \qquad \psi_{\boldsymbol{j}}^{(i)}(\boldsymbol{x}) := \begin{cases} k(\boldsymbol{x}, \boldsymbol{x}_i) & i = 1, \ldots, n, \\ \partial_{\boldsymbol{j}}' k(\boldsymbol{x}, \boldsymbol{x}') \Big|_{\boldsymbol{x}' = \boldsymbol{x}_{i-n}} & i = n+1, \ldots, 2n. \end{cases}$$

  To estimate $\boldsymbol{\theta}_{\boldsymbol{j}}$, we substitute (7) into $\widehat{J}_{\boldsymbol{j}}$ in (4). Then, when $R(r_{\boldsymbol{j}}) = \boldsymbol{\theta}_{\boldsymbol{j}}^\top \boldsymbol{\theta}_{\boldsymbol{j}}$, the optimal solution of $\boldsymbol{\theta}_{\boldsymbol{j}}$ can be computed analytically as

$$\widehat{\boldsymbol{\theta}}_{\boldsymbol{j}} := \operatorname*{argmin}_{\boldsymbol{\theta}_{\boldsymbol{j}}} \left[\boldsymbol{\theta}_{\boldsymbol{j}}^\top \widehat{\boldsymbol{G}}_{\boldsymbol{j}} \boldsymbol{\theta}_{\boldsymbol{j}} - 2(-1)^{|\boldsymbol{j}|} \boldsymbol{\theta}_{\boldsymbol{j}}^\top \widehat{\boldsymbol{h}}_{\boldsymbol{j}} + \lambda_{\boldsymbol{j}} \boldsymbol{\theta}_{\boldsymbol{j}}^\top \boldsymbol{\theta}_{\boldsymbol{j}} \right] = (-1)^{|\boldsymbol{j}|} \left(\widehat{\boldsymbol{G}}_{\boldsymbol{j}} + \lambda_{\boldsymbol{j}} \mathbf{I}_{2n} \right)^{-1} \widehat{\boldsymbol{h}}_{\boldsymbol{j}},$$

where $\mathbf{I}_{2n}$ denotes the $2n$ by $2n$ identity matrix,

$$\widehat{\boldsymbol{G}}_{\boldsymbol{j}} := \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\psi}_{\boldsymbol{j}}(\boldsymbol{x}_i)\boldsymbol{\psi}_{\boldsymbol{j}}(\boldsymbol{x}_i)^\top \qquad \text{and} \qquad \widehat{\boldsymbol{h}}_{\boldsymbol{j}} := \frac{1}{n}\sum_{i=1}^{n} \partial_{\boldsymbol{j}}\boldsymbol{\psi}_{\boldsymbol{j}}(\boldsymbol{x}_i).$$

Finally, a practical version of LSDDR is given by

$$\widehat{r}_{\boldsymbol{j}}(\boldsymbol{x}) := \widehat{\boldsymbol{\theta}}_{\boldsymbol{j}}^\top \boldsymbol{\psi}_{\boldsymbol{j}}(\boldsymbol{x}) = \sum_{i=1}^{n} \widehat{\alpha}_{\boldsymbol{j}}^{(i)} k(\boldsymbol{x}, \boldsymbol{x}_i) + \widehat{\beta}_{\boldsymbol{j}}^{(i)} \partial'_{\boldsymbol{j}} k(\boldsymbol{x}, \boldsymbol{x}')\Big|_{\boldsymbol{x}'=\boldsymbol{x}_i}.$$

- *Model selection by cross-validation*: Model selection is a crucial problem in LSDDR. As in standard model selection methods for kernel density estimation (Bowman, 1984; Sheather, 2004), we take a least-squares approach based on (2), and optimize the model parameters (parameters in $k(\cdot,\cdot)$ and the regularization parameter $\lambda_{\boldsymbol{j}}$) by cross-validation as follows:

  1. Divide the samples $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$ into T disjoint subsets $\{\mathcal{D}_t\}_{t=1}^T$.
  2. Obtain the estimator $\widehat{r}_{\boldsymbol{j}}^{(t)}(\boldsymbol{x})$ from $\mathcal{D} \setminus \mathcal{D}_t$ (i.e., $\mathcal{D}$ without $\mathcal{D}_t$), and then compute $\widehat{J}_{\boldsymbol{j}}$ from the hold-out samples as

  $$\mathrm{CV}(t) := \frac{1}{|\mathcal{D}_t|}\sum_{\boldsymbol{x}\in\mathcal{D}_t}\left[\left\{\widehat{r}_{\boldsymbol{j}}^{(t)}(\boldsymbol{x})\right\}^2 - 2(-1)^{|\boldsymbol{j}|}\partial_{\boldsymbol{j}}\widehat{r}_{\boldsymbol{j}}^{(t)}(\boldsymbol{x})\right],$$

  where $|\mathcal{D}_t|$ denotes the number of elements in $\mathcal{D}_t$.
  3. Choose the model that minimizes $\frac{1}{T}\sum_{t=1}^T \mathrm{CV}(t)$.

2.5 Notation

In the rest of this paper, we consider LSDDR only for $|\boldsymbol{j}| = 1$ and $|\boldsymbol{j}| = 2$. Therefore, we use more specific notations as follows:

- (Sections 3 and 4) For $|\boldsymbol{j}| = 1$, a first order density-derivative-ratio corresponds to a first order derivative of the log-density, and we express the true derivative as

$$g_j(\boldsymbol{x}) := \frac{\partial_j p(\boldsymbol{x})}{p(\boldsymbol{x})} = \partial_j \log p(\boldsymbol{x}),$$

where $\partial_j := \frac{\partial}{\partial x^{(j)}}$. Then, LSDDR to $g_j(\boldsymbol{x})$ is denoted by

$$\widehat{g}_j(\boldsymbol{x}) := \sum_{i=1}^{2n} \widehat{\theta}_j^{(i)} \psi_j^{(i)}(\boldsymbol{x}) = \sum_{i=1}^{n} \widehat{\alpha}_j^{(i)} k(\boldsymbol{x}, \boldsymbol{x}_i) + \widehat{\beta}_j^{(i)} \partial'_j k(\boldsymbol{x}, \boldsymbol{x}')\Big|_{\boldsymbol{x}'=\boldsymbol{x}_i},$$

where ∂'_j denotes the partial derivative with respect to the j-th coordinate in $\boldsymbol{x}'$, and the subscript j of $\widehat{\theta}_j^{(i)}$ is simplified from $\boldsymbol{j}$ because only one element in $\boldsymbol{j}$ is one and the others are zeros when $|\boldsymbol{j}| = 1$.

- (Section 4) For $|\boldsymbol{j}| = 2$, we express a true second order density-derivative-ratio by $[\boldsymbol{H}(\boldsymbol{x})]_{ij} := \frac{\partial_i\partial_j p(\boldsymbol{x})}{p(\boldsymbol{x})}$ where $[\boldsymbol{H}(\boldsymbol{x})]_{ij}$ denotes the (i,j)-th element of the matrix $\boldsymbol{H}(\boldsymbol{x})$. LSDDR to $[\boldsymbol{H}(\boldsymbol{x})]_{ij}$ is denoted by $[\widehat{\boldsymbol{H}}(\boldsymbol{x})]_{ij}$.

3. Application to Mode-Seeking Clustering

This section applies LSDDR to mode-seeking clustering.

3.1 Problem Formulation for Clustering

Suppose that we are given a collection of data samples $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$. The goal of clustering is to assign a cluster label $c_i \in \{1, \ldots, c\}$ to each data sample $\boldsymbol{x}_i$, where c denotes the number of clusters, and is *unknown*.

3.2 Brief Review of Mean Shift Clustering

Mean shift clustering (MS) (Fukunaga and Hostetler, 1975; Cheng, 1995; Comaniciu and Meer, 2002) is a popular clustering method, and has been applied in a wide-range of fields such as image segmentation (Comaniciu and Meer, 2002; Tao et al., 2007; Wang et al., 2004) and object tracking (Collins, 2003; Comaniciu et al., 2000) (see a recent review article by Carreira-Perpiñán (2015)). MS initially regards all data samples as candidates of cluster centers, and updates them toward the nearest modes of the estimated density by gradient ascent. Finally, the same cluster label is assigned to the data samples which converge to the same mode. Unlike standard clustering methods such as *k-means clustering* (MacQueen, 1967), MS automatically determines the number of clusters according to the number of detected modes.

To update data samples, the technical challenge is to accurately estimate the gradient of $p(\boldsymbol{x})$. MS takes a two-step approach: The first step performs kernel density estimation (KDE) as

$$\widehat{p}_{\mathrm{KDE}}(\boldsymbol{x}) := \frac{1}{Z_{n,h}}\sum_{i=1}^{n} K_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h^2}\right),$$

where K_{KDE} is a kernel function for KDE, $Z_{n,h}$ is the normalizing constant, and h denotes the bandwidth parameter. Then, the second step computes the partial derivatives of $\widehat{p}_{\mathrm{KDE}}(\boldsymbol{x})$ as

$$\begin{aligned}\partial_j \widehat{p}_{\mathrm{KDE}}(\boldsymbol{x}) &= \frac{1}{h^2 Z_{n,h}}\sum_{i=1}^{n}(x_i^{(j)} - x^{(j)}) G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h^2}\right) \\ &= \frac{1}{h^2 Z_{n,h}}\left\{\sum_{i=1}^{n} G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h^2}\right)\right\}\left\{\frac{\sum_{i=1}^n x_i^{(j)} G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h^2}\right)}{\sum_{i=1}^n G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h^2}\right)} - x^{(j)}\right\},\end{aligned}$$

where $G_{\mathrm{KDE}}(t) = -\frac{\mathrm{d}}{\mathrm{d}t}K_{\mathrm{KDE}}(t)$.

By denoting the τ-th update of a data sample by $\boldsymbol{z}_k^\tau = (z_k^{(\tau,1)}, z_k^{(\tau,2)}, \ldots, z_k^{(\tau,D)})^\top$ where $\boldsymbol{z}_k^0 = \boldsymbol{x}_k$, setting $\partial_j \widehat{p}_{\mathrm{KDE}}(\boldsymbol{x}) = 0$ yields the following fixed-point iteration formula:

$$z_k^{(\tau+1,j)} = \frac{\sum_{i=1}^n x_i^{(j)} G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{z}_k^\tau-\boldsymbol{x}_i\|^2}{2h^2}\right)}{\sum_{i=1}^n G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{z}_k^\tau-\boldsymbol{x}_i\|^2}{2h^2}\right)}. \tag{8}$$

Simple calculation shows that (8) can be equivalently expressed as

$$\boldsymbol{z}_k^{\tau+1} = \boldsymbol{z}_k^{\tau} + \frac{h^2 Z_{n,h}}{\sum_{i=1}^n G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{z}_k^{\tau}-\boldsymbol{x}_i\|^2}{2h^2}\right)} \nabla \widehat{p}_{\mathrm{KDE}}(\boldsymbol{x})|_{\boldsymbol{x}=\boldsymbol{z}_k^{\tau}} = \boldsymbol{z}_k^{\tau} + \widehat{\boldsymbol{m}}_{\mathrm{KDE}}(\boldsymbol{z}_k^{\tau}), \tag{9}$$

where ∇ denotes the vector differential operator with respect to $\boldsymbol{x}$, and $\widehat{\boldsymbol{m}}_{\mathrm{KDE}}(\boldsymbol{z}) = (\widehat{m}^{(1)}_{\mathrm{KDE}}(\boldsymbol{z}), \widehat{m}^{(2)}_{\mathrm{KDE}}(\boldsymbol{z}), \ldots, \widehat{m}^{(D)}_{\mathrm{KDE}}(\boldsymbol{z}))^\top$ is called the *mean shift vector* and defined by

$$\widehat{\boldsymbol{m}}_{\mathrm{KDE}}(\boldsymbol{z}) = \frac{h^2 Z_{n,h}}{\sum_{i=1}^n G_{\mathrm{KDE}}\left(\frac{\|\boldsymbol{z}-\boldsymbol{x}_i\|^2}{2h^2}\right)} \nabla \widehat{p}_{\mathrm{KDE}}(\boldsymbol{x})|_{\boldsymbol{x}=\boldsymbol{z}}. \tag{10}$$

Eq.(9) indicates that MS performs gradient ascent. To speed up MS, acceleration strategies were also developed in Carreira-Perpiñán (2006).

Properties of MS have been theoretically well-investigated (Cheng, 1995; Fashing and Tomasi, 2005; Ghassabeh, 2013; Arias-Castro et al., 2016). For instance, a sequence $\{\boldsymbol{z}_k^{\tau}, \tau = 0, 1, 2, \ldots\}$ generated by MS converges to a mode of $\widehat{p}_{\mathrm{KDE}}(\boldsymbol{x})$ as τ goes infinity (Comaniciu and Meer, 2002; Li et al., 2007; Ghassabeh, 2013); Carreira-Perpiñán (2007) showed that the algorithm of MS is equivalent to the EM algorithm (Dempster et al., 1977) when $K_{\mathrm{KDE}}(t) = \exp(-t)$; Furthermore, Fashing and Tomasi (2005) proved that MS performs a bound optimization. Although MS has good theoretical properties, the two-step approach in gradient estimation seems practically inappropriate because a good-density estimator does not necessarily mean a good-density gradient estimator. A more appropriate way would be to directly estimate the gradient. Following this idea, we apply LSDDR to mode-seeking clustering.

3.3 Least-Squares Log-Density Gradient Clustering

Here, LSDDR is employed to develop a novel mode-seeking clustering method because LSDDR is an estimator of a single element in the log-density gradient when $|\boldsymbol{j}| = 1$. The proposed clustering method is called the *least-squares log-density gradient clustering* (LSLDGC).

3.3.1 FIXED-POINT ITERATION

First, when we estimate the j-th element in $\boldsymbol{g}(\boldsymbol{x}) = \nabla \log p(\boldsymbol{x})$, the form of the kernel function is restricted as

$$k(\boldsymbol{x}, \boldsymbol{x}_i) = \phi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right),$$

where σ_j denotes a bandwidth parameter, and ϕ is a non-negative, monotonically non-increasing, convex and differentiable function. For example, when $\phi(t) = \exp(-t)$, $k(\boldsymbol{x}, \boldsymbol{x}_i)$ is the Gaussian kernel. Under the restriction, LSDDR can be rewritten as

$$\widehat{g}_j(\boldsymbol{x}) = \sum_{i=1}^n \left[\widehat{\alpha}_j^{(i)} \phi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) + \widetilde{\beta}_j^{(i)} \frac{x_i^{(j)} - x^{(j)}}{\sigma_j^2} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right], \tag{11}$$

where $\widetilde{\beta}_j^{(i)} = -\widehat{\beta}_j^{(i)}$ and $\varphi(t) = -\frac{\mathrm{d}}{\mathrm{d}t}\phi(t)$.

For our mode-seeking clustering method, we derive a fixed-point iteration similarly to MS. When $\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) \neq 0$, (11) can be expanded as

$$\begin{aligned}\widehat{g}_j(\boldsymbol{x}) &= \sum_{i=1}^n \left[\widehat{\alpha}_j^{(i)} \phi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) + \frac{\widetilde{\beta}_j^{(i)} x_i^{(j)}}{\sigma_j^2} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right] - \frac{x^{(j)}}{\sigma_j^2} \sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{\sigma_j^2}\right) \\ &= \frac{1}{\sigma_j^2} \sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) \left[\frac{\sum_{i=1}^n \left[\sigma_j^2 \widehat{\alpha}_j^{(i)} \phi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) + \widetilde{\beta}_j^{(i)} x_i^{(j)} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right]}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)} - x^{(j)}\right].\end{aligned}$$

As in MS, setting $\widehat{g}_j(\boldsymbol{x}) = 0$ yields the following update formula:

$$z_k^{(\tau+1,j)} = \frac{\sum_{i=1}^n \left[\sigma_j^2 \widehat{\alpha}_j^{(i)} \phi\left(\frac{\|\boldsymbol{z}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) + \widetilde{\beta}_j^{(i)} x_i^{(j)} \varphi\left(\frac{\|\boldsymbol{z}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right]}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{z}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)}, \tag{12}$$

where $\boldsymbol{z}_k^{\tau}$ denotes the τ-th update of a data sample initialized by $\boldsymbol{x}_k$. Eq.(12) can be also equivalently expressed as

$$z^{(\tau+1,j)} = z^{(\tau,j)} + \frac{\sigma_j^2}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{z}^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)} \widehat{g}_j(\boldsymbol{z}^{\tau}) = z^{(\tau,j)} + \widehat{m}^{(j)}(\boldsymbol{z}^{\tau}), \tag{13}$$

where

$$\widehat{m}^{(j)}(\boldsymbol{z}) := \frac{\sigma_j^2}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{z}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)} \widehat{g}_j(\boldsymbol{z}). \tag{14}$$

When $\widehat{\alpha}_j^{(i)} = 0$ and $\widetilde{\beta}_j^{(i)} = 1/n$, (12) is reduced to the MS update formula (8). Thus, LSLDGC includes MS as a special case.

The form of (12) motivates us to develop a coordinate-wise update rule. From $j = 1$ to $j = D$, we iteratively update one coordinate at a time by simply modifying (12) as

$$z_k^{(\tau+1,j)} = \frac{\sum_{i=1}^n \left[\sigma_j^2 \widehat{\alpha}_j^{(i)} \phi\left(\frac{\|\tilde{\boldsymbol{z}}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) + \widetilde{\beta}_j^{(i)} x_i^{(j)} \varphi\left(\frac{\|\tilde{\boldsymbol{z}}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right]}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\tilde{\boldsymbol{z}}_k^{\tau}-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)}, \tag{15}$$

where

$$\tilde{\boldsymbol{z}}_k^{\tau} = (z_k^{(\tau+1,1)}, \ldots, z_k^{(\tau+1,j-1)}, z_k^{(\tau,j)}, z_k^{(\tau,j+1)}, \ldots, z_k^{(\tau,D)})^\top.$$

Note that the $(j-1)$-th and j-th elements in $\tilde{\boldsymbol{z}}_k^{\tau}$ are different in terms of τ. As shown below, this coordinate-wise update rule has a nice theoretical property.

3.3.2 SUFFICIENT CONDITIONS FOR MONOTONIC HILL-CLIMBING

LSLDGC updates data samples towards the modes like hill-climbing. Here, we show sufficient conditions for monotonic hill-climbing, i.e., LSLDGC makes data samples never climbing-down. The challenge in this analysis is that unlike MS, we cannot know the estimated density, and thus it is not straightforward to investigate this property for LSLDGC. To overcome this challenge, we employ *path integral*[2] (Strang, 1991): For the vector field $\boldsymbol{g}(\boldsymbol{x}) = \nabla \log p(\boldsymbol{x})$ and a differentiable curve $\boldsymbol{\gamma}(t)$, $t \in [0, s]$ connecting $\boldsymbol{x}$ and $\boldsymbol{y}$, i.e., $\boldsymbol{\gamma}(0) = \boldsymbol{y}$, $\boldsymbol{\gamma}(s) = \boldsymbol{x}$, the standard formula of path integral is given by

$$D_{\boldsymbol{g}}[\boldsymbol{x}|\boldsymbol{y}] := \int_0^s \mathrm{I} < \boldsymbol{g}(\boldsymbol{\gamma}(t)), \dot{\boldsymbol{\gamma}}(t) > \mathrm{d}t = \log p(\boldsymbol{x}) - \log p(\boldsymbol{y}), \tag{16}$$

where $\dot{\boldsymbol{\gamma}}(t) = \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{\gamma}(t)$ and $\mathrm{I} < \cdot, \cdot >$ denotes the inner product. The notable property of path integral is that the integral is independent of any choice of a path, and determined only by the two points, $\boldsymbol{y}$ and $\boldsymbol{x}$, as shown in the most right-hand side of (16). In this analysis, we use the following path along with one coordinate at a time repeatedly:

$$\begin{aligned}\boldsymbol{y} = (y^{(1)}, y^{(2)}, y^{(3)}, \ldots, y^{(D)}) &\to (x^{(1)}, y^{(2)}, y^{(3)}, \ldots, y^{(D)}) \to (x^{(1)}, x^{(2)}, y^{(3)}, \ldots, y^{(D)}) \\ &\to (x^{(1)}, x^{(2)}, x^{(3)}, \ldots, y^{(D)}) \to \cdots \to (x^{(1)}, x^{(2)}, x^{(3)}, \ldots, x^{(D)}) = \boldsymbol{x}. \end{aligned} \tag{17}$$

By substituting our gradient estimate $\widehat{\boldsymbol{g}}(\boldsymbol{x})$ into the middle part of (16) under the path (17),

$$\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}] := \int_0^s \mathrm{I} < \widehat{\boldsymbol{g}}(\boldsymbol{\gamma}(t)), \dot{\boldsymbol{\gamma}}(t) > \mathrm{d}t = \sum_{j=1}^{D} \int_{y^{(j)}}^{x^{(j)}} \widehat{g}_j(x^{(1)}, x^{(2)}, \ldots, z^{(j)}, \ldots, y^{(D)}) \mathrm{d}z^{(j)}. \tag{18}$$

From (16), $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}]$ can be regarded as an estimator of $\log p(\boldsymbol{x}) - \log p(\boldsymbol{y})$ when we fix the curve that connects $\boldsymbol{x}$ and $\boldsymbol{y}$. Thus, $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^{\tau}] \geq 0$ for all τ implies that the data samples updated by LSLDGC never climb down. The following theorem provides some sufficient conditions:

Theorem 3 *Suppose that ϕ is a non-negative, monotonically non-increasing, convex and differentiable function. Then, if $\widehat{\alpha}_j^{(i)} = 0$ and $\widetilde{\beta}_j^{(i)} \geq 0$, under the coordinate-wise update rule* (15) *and path* (17)*,*

$$\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^{\tau}] \geq 0.$$

The proof is deferred to Appendix C.

Remark 4 *Theorem 3 shows sufficient conditions that LSLDGC with the coordinate-wise update rule* (15) *makes data samples monotonically hill-climb towards the modes. However, without satisfying the conditions, we empirically observed that most of data samples monotonically converge to modes. Therefore, we conjecture that some milder conditions exist, and do not apply all sufficient conditions in practice. Practical implementation is described in Section 3.4.*

2. Path integral is also called *line integral*.

Remark 5 *For another update rule* (12)*, sufficient conditions for monotonic hill-climbing were not established as in Theorem 3. However, Theorem 7 implies that accurate mode-seeking is possible for both update rules as long as $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^{\tau}]$ is kept non-negative for all τ. Therefore, in practice, whenever $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^{\tau}]$ is negative, we perform standard gradient ascent. The details are given in Section 3.4.*

Remark 6 *Sufficient conditions for monotonic hill-climbing have been established in MS (Comaniciu and Meer, 2002; Li et al., 2007; Ghassabeh, 2013). The main difference is that we obtain the difference of two log-density estimates from a gradient estimate, while previous work directly begins with density estimation based on KDE. Thus, the proof is substantially different.*

Theorem 3 holds under the path (17). However, the following theorem states that as n increases, $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}]$ approaches $D_{\boldsymbol{g}}[\boldsymbol{x}|\boldsymbol{y}]$, which is independent of the choice of a path:

Theorem 7 *Suppose that both $\boldsymbol{g}$ and $\widehat{\boldsymbol{g}}$ are finite on the path* (17) *and the assumptions in Theorem 1 hold. Then, for arbitrary $\boldsymbol{x}$ and $\boldsymbol{y}$,*

$$\left| D_{\boldsymbol{g}}[\boldsymbol{x}|\boldsymbol{y}] - \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}] \right| \leq \|\boldsymbol{g} - \widehat{\boldsymbol{g}}\|_\infty \|\boldsymbol{x} - \boldsymbol{y}\|_1 \leq O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}} \right),$$

where $\|\cdot\|_1$ denotes the ℓ_1 norm.

The proof is given in Appendix D.

Remark 8 *Theorem 7 shows*

$$|D_{\boldsymbol{g}}[\boldsymbol{z}_k^{\tau}|\boldsymbol{z}_k^{\tau+1}] - \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau}|\boldsymbol{z}_k^{\tau+1}]| \leq \|\boldsymbol{g} - \widehat{\boldsymbol{g}}\|_\infty \|\boldsymbol{z}_k^{\tau} - \boldsymbol{z}_k^{\tau+1}\|_1. \tag{19}$$

From (19)*, the non-negativity of $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau}|\boldsymbol{z}_k^{\tau+1}]$ implies that $D_{\boldsymbol{g}}[\boldsymbol{z}_k^{\tau}|\boldsymbol{z}_k^{\tau+1}]$ is also non-negative when n is sufficiently large. Thus, Theorem 7 ensures that accurate mode-seeking is possible by both update rules* (12) *and* (15)*.*

3.3.3 THE CONVERGENCE RATE TO THE TRUE MODE SET

First, we define the set of the true mode points as

$$\mathcal{M} := \{\boldsymbol{\mu} \ : \ \boldsymbol{g}(\boldsymbol{\mu}) = \boldsymbol{0}, \nabla \boldsymbol{g}(\boldsymbol{\mu}) \prec \boldsymbol{O}\}, \tag{20}$$

where $\nabla \boldsymbol{g}(\boldsymbol{\mu})$ is the Hessian matrix of the log-density at a mode point $\boldsymbol{\mu}$, and $\nabla \boldsymbol{g}(\boldsymbol{\mu}) \prec \boldsymbol{O}$ means that $\nabla \boldsymbol{g}(\boldsymbol{\mu})$ is (strictly) negative definite. The set of the estimated mode points is also denoted by $\widehat{\mathcal{M}}$. Our goal is to establish the convergence rate between $\mathcal{M}$ and $\widehat{\mathcal{M}}$ under the Hausdorff distance:

$$\mathrm{Haus}(\mathcal{A}, \mathcal{B}) := \max\left(\sup_{\boldsymbol{x}\in\mathcal{A}} \inf_{\boldsymbol{y}\in\mathcal{B}} \|\boldsymbol{x} - \boldsymbol{y}\|, \sup_{\boldsymbol{y}\in\mathcal{B}} \inf_{\boldsymbol{x}\in\mathcal{A}} \|\boldsymbol{x} - \boldsymbol{y}\| \right), \tag{21}$$

where $\mathcal{A}$ and $\mathcal{B}$ denote two sets.

The following theorem establishes the convergence rate of $\mathrm{Haus}(\widehat{\mathcal{M}}, \mathcal{M})$.

Theorem 9 *Suppose that the assumptions in Theorem 1 hold. Further assume that each mode point $\boldsymbol{\mu} \in \mathcal{M}$ is approximated by a unique estimated mode point $\widehat{\boldsymbol{\mu}} \in \widehat{\mathcal{M}}$. Then, with high probability,*

$$\mathrm{Haus}(\widehat{\mathcal{M}}, \mathcal{M}) = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right). \tag{22}$$

The proof can be seen in Appendix E.

Remark 10 *Chen et al. (2016b, Theorem 1) established the following convergence rate based on KDE: With the asymptotically optimal bandwidth $h = O\left(n^{-\frac{1}{D+6}}\right)$,*

$$\mathit{Haus}(\widehat{\mathcal{M}}_{KDE}, \mathcal{M}) = O_{\mathrm{P}}\left(n^{-\frac{2}{D+6}}\right), \tag{23}$$

where $\widehat{\mathcal{M}}_{KDE}$ denotes the set of mode points based on KDE. Eq.(23) shows that the convergence rate of $\mathit{Haus}(\widehat{\mathcal{M}}_{KDE}, \mathcal{M})$ depends on data dimension D, although direct comparison to our result is not straightforward due to the different assumptions in both analyses.

3.4 Practical Implementation of LSLDGC

Here, we describe details of practical implementation of LSLDGC.

- *Sufficient conditions in Theorem 3*: The conditions, $\widehat{\alpha}_j^{(i)} = 0$ and $\widetilde{\beta}_j^{(i)} \left(= -\widehat{\beta}_j^{(i)}\right) \geq 0$, ensure that $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1} | \boldsymbol{z}_k^{\tau}] \geq 0$. Here, we set $\widehat{\alpha}_j^{(i)} = 0$ for all i and j, and the coordinate-wise update rule (15) is simplified as

$$z_k^{(\tau+1,j)} = \frac{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} x_i^{(j)} \varphi\left(\frac{\|\tilde{\boldsymbol{z}}_k^{\tau} - \boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)}{\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\tilde{\boldsymbol{z}}_k^{\tau} - \boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)}.$$

  The same simplification is applied to the update rule (12) as well. This significantly reduces the computational costs in LSDDR because $\alpha_j^{(i)}$ do not need to be estimated. On the other hand, to satisfy $\widetilde{\beta}_j^{(i)} \geq 0$, we have to solve a constrained optimization problem, which tends to be time-consuming. Therefore, the unconstrained optimization problem is solved as in Section 3.4, but as a remedy we perform gradient ascent whenever $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1} | \boldsymbol{z}_k^{\tau}] < 0$. Details of the gradient ascent are given below.

- *Stability in the mode-seeking process*: The derivation of (12) indicates that the mode-seeking (hill-climbing) process in LSLDGC can be unstable when $f_j(\boldsymbol{z}_k^{\tau}) := \sum_{i=1}^n \widetilde{\beta}_j^{(i)} \varphi\left(\frac{\|\boldsymbol{z}_k^{\tau} - \boldsymbol{x}_i\|}{2\sigma_j^2}\right)$ is close to zero. To cope with this problem, we simply perform gradient ascent when $f_j(\boldsymbol{z}_k^{\tau})$ is close to zero.

- *Gradient ascent*: Whenever $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1} | \boldsymbol{z}_k^{\tau}] < 0$ or $\exists j$, $f_j(\boldsymbol{z}_k^{\tau}) \approx 0$, we perform the following gradient ascent:

$$\boldsymbol{z}_k^{\tau+1} = \boldsymbol{z}_k^{\tau} + \eta \widehat{\boldsymbol{g}}(\boldsymbol{z}_k^{\tau}), \tag{24}$$

  where the step size parameter η is selected so that $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau} + \eta \widehat{\boldsymbol{g}}(\boldsymbol{z}_k^{\tau}) | \boldsymbol{z}_k^{\tau}]$ is maximized.

- *Choice of the kernel function*: Throughout the paper, we use the Gaussian kernel:

$$k(\boldsymbol{x}, \boldsymbol{x}_i) = \phi\left(\frac{\|\boldsymbol{x} - \boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) = \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{x}_i\|^2}{2\sigma_j^2}\right).$$

  The Gaussian kernel satisfies the conditions of ϕ in Theorem 3, and is a universal kernel associated with which RKHS covers a wide range of functions (Micchelli et al., 2006).

- *Decreasing the computation costs*: After the simplification above, LSDDR requires to compute the inverse of a $2n$ by $2n$ matrix, which is computationally costly to large n. To decrease the computation costs, we reduce the number of center points as $\phi\left(\frac{\|\boldsymbol{x} - \boldsymbol{c}_i\|^2}{2\sigma_j^2}\right)$ and $\varphi\left(\frac{\|\boldsymbol{x} - \boldsymbol{c}_i\|^2}{2\sigma_j^2}\right)$ where $\{\boldsymbol{c}_i\}_{i=1}^b$ is a randomly chosen subset of $\{\boldsymbol{x}_i\}_{i=1}^n$. As a result, the coefficients can be represented as $\widetilde{\boldsymbol{\beta}}_j = (\widetilde{\beta}_j^{(1)}, \widetilde{\beta}_j^{(2)}, \ldots, \widetilde{\beta}_j^{(b)})^{\top}$. Appendix F shows that this significantly decreases the computation cost without scarifying clustering performance. In this paper, we fix the number of centers at $b = \min(n, 100)$ as long as we do not specify it.

The mode-seeking algorithm in LSLDGC is summarized in Figs.3 and 4.[3]

4. Application to Density Ridge Estimation

This section applies LSDDR to density ridge estimation and develops a novel method.

4.1 Problem Formulation for Density Ridge Estimation

For a positive integer d such that $d < D$, the goal is to estimate from a collection of data samples $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$ the d-dimensional *density ridge*, which is defined as a collection of points satisfying

$$\mathcal{R} := \{\boldsymbol{x} \in \mathbb{R}^D \mid \|\mathbf{V}(\boldsymbol{x})\mathbf{V}(\boldsymbol{x})^{\top} \boldsymbol{g}(\boldsymbol{x})\| = 0, \eta_{d+1}(\boldsymbol{x}) < 0\}, \tag{25}$$

where $\boldsymbol{g}(\boldsymbol{x}) = \nabla \log p(\boldsymbol{x})$, $\mathbf{V}(\boldsymbol{x}) = (\boldsymbol{v}_{d+1}, \ldots, \boldsymbol{v}_D)$, and $\boldsymbol{v}_i$ is the eigenvector associated with the eigenvalue $\eta_i(\boldsymbol{x})$ of the Hessian matrix of the logarithm of the probability density function, $\nabla\nabla \log p(\boldsymbol{x})$. We assume that the eigenvalues are sorted in descending order such that $\eta_1(\boldsymbol{x}) \geq \eta_2(\boldsymbol{x}) \geq \cdots \geq \eta_D(\boldsymbol{x})$.

Here, we defined the density ridge in terms of the logarithm of the probability density function because our practical algorithm is proposed based on the logarithm. While the density ridge has been previously defined without the logarithm (Eberly, 1996; Ozertem and Erdogmus, 2011; Genovese et al., 2014; Chen et al., 2015b), both definitions offer the same density ridge.

4.2 Brief Review of Subspace Constrained Mean Shift

A practical algorithm for density ridge estimation called *subspace constrained mean shift* (SCMS) was proposed by Ozertem and Erdogmus (2011). SCMS extends MS: SCMS performs projected gradient ascent on the subspace orthogonal to the density ridge, while MS updates data points by

3. A MATLAB package of LSLDGC is available at `https://sites.google.com/site/hworksites/home/software/lsldg`.

Input: $\{\boldsymbol{x}_i\}_{i=1}^n$.

$\left\{\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b\right\} \leftarrow \text{LSDDR1}(\{\boldsymbol{x}_i\}_{i=1}^n)$;

for $k = 1$ to n **do**
  $\tau \leftarrow 0$;
  $\boldsymbol{z}_k^\tau \leftarrow \boldsymbol{x}_k$;
  repeat
    $\{\boldsymbol{z}_k^{\tau+1}, \{f_j\}_{j=1}^D\} \leftarrow \text{ModeSeeking}(\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau)$
    $\widehat{D} \leftarrow \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^\tau]$;

    if $\widehat{D} < 0$ or $\exists j,\ |f_j| \approx 0$ **then**
      $\boldsymbol{z}_k^{\tau+1} \leftarrow \boldsymbol{z}_k^\tau + \eta\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau)$;
      $\widehat{D} \leftarrow \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1}|\boldsymbol{z}_k^\tau]$;
    end if
    $\tau \leftarrow \tau + 1$;
  until
  $\boldsymbol{z}_k \leftarrow \boldsymbol{z}_k^\tau$;
end for

Outputs: $\{\boldsymbol{z}_i\}_{i=1}^n$.

Figure 3: The mode-seeking algorithm in LSLDGC. LSDDR1($\{\boldsymbol{x}_i\}_{i=1}^n$) denotes the LSDDR estimator for the first-order density-derivative-ratios from data samples $\{\boldsymbol{x}_i\}_{i=1}^n$, and $\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D$ and $\{\boldsymbol{c}_i\}_{i=1}^b$ are the coefficients and (sub-sampled) centers, respectively. ModeSeeking($\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau$) is a single step mode-seeking process whose details are given in Fig.4. The update of $\boldsymbol{z}_k^\tau$ terminates when either $\widehat{D}$ or $\|\boldsymbol{z}_k^{\tau+1} - \boldsymbol{z}_k^\tau\|$ is less than a small positive constant.

Input: $\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau$

$\boldsymbol{z}_k^{\tau+1} \leftarrow \boldsymbol{z}_k^\tau + \widehat{\boldsymbol{m}}(\boldsymbol{z}_k^\tau)$;

$\{f_j\}_{j=1}^D \leftarrow \left\{\widetilde{\boldsymbol{\beta}}_j^\top \boldsymbol{\varphi}_j(\boldsymbol{z}_k^\tau)\right\}_{j=1}^D$;

Outputs: $\boldsymbol{z}_k^{\tau+1}, \{f_j\}_{j=1}^D$.

Input: $\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau$
$\tilde{\boldsymbol{z}} \leftarrow \boldsymbol{z}_k^\tau$;
for $j \in \{1, \ldots, D\}$ **do**
  $\tilde{z}^{(j)} \leftarrow z_k^{(\tau,j)} + m^{(j)}(\tilde{\boldsymbol{z}})$;
  $f_j \leftarrow \widetilde{\boldsymbol{\beta}}_j^\top \boldsymbol{\varphi}_j(\tilde{\boldsymbol{z}})$;
end for
$\boldsymbol{z}_k^{\tau+1} \leftarrow \tilde{\boldsymbol{z}}$;
Outputs: $\boldsymbol{z}_k^{\tau+1}, \{f_j\}_{j=1}^D$.

Figure 4: Two mode-seeking algorithms in LSLDGC. The left figure uses the update rule (12), while the right one is based on the coordinate-wise update rule (15). $\boldsymbol{\varphi}_j(\boldsymbol{z}) = (\varphi_j^{(1)}(\boldsymbol{z}), \varphi_j^{(2)}(\boldsymbol{z}), \ldots, \varphi_j^{(b)}(\boldsymbol{z}))^\top$ where $\varphi_j^{(i)}(\boldsymbol{z}) = \varphi\left(\frac{\|\boldsymbol{z}-\boldsymbol{c}_i\|^2}{2\sigma_j^2}\right)$.

gradient ascent. SCMS obtains such a subspace as the span of the eigenvectors of the negative Hessian matrix of the log-density, which is called the *inverse local-covariance matrix* (Ozertem and Erdogmus, 2011):

$$\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}) := -\nabla\nabla \log p(\boldsymbol{x}) = -\frac{\nabla\nabla p(\boldsymbol{x})}{p(\boldsymbol{x})} + \frac{\nabla p(\boldsymbol{x})\nabla p(\boldsymbol{x})^\top}{p(\boldsymbol{x})^2} = -\boldsymbol{H}(\boldsymbol{x}) + \boldsymbol{g}(\boldsymbol{x})\boldsymbol{g}(\boldsymbol{x})^\top. \quad (26)$$

An advantage of employing the log-density is discussed in the context of manifold estimation in Genovese et al. (2014): Theorem 7 in Genovese et al. (2014) states that when D-dimensional data is assumed to be generated on a d-dimensional manifold with D-dimensional Gaussian noise, the density ridge is close to the lower-dimensional manifold in the sense of the Hausdorff distance, and thus can be a surrogate for the manifold. This surrogate property holds in an $O(1)$ neighborhood of the manifold for the log-density, while the theorem holds in an $O(\sigma_n)$ neighborhood of the manifold for the (non-log) density, where σ_n is the standard deviation of the Gaussian noise. Furthermore, when $p(\boldsymbol{x})$ is Gaussian, (26) reduces to the inverse of the covariance matrix. This allows us to intuitively understand that SCMS finds the subspace by PCA to the non-stationary covariance matrix at a location $\boldsymbol{x}$ around the ridge.

In practice, SCMS substitutes $\widehat{p}_{\text{KDE}}(\boldsymbol{x})$ into (26):

$$\widehat{\boldsymbol{\Sigma}}_{\text{KDE}}^{-1}(\boldsymbol{x}) := -\frac{\nabla\nabla\widehat{p}_{\text{KDE}}(\boldsymbol{x})}{\widehat{p}_{\text{KDE}}(\boldsymbol{x})} + \frac{\nabla\widehat{p}_{\text{KDE}}(\boldsymbol{x})\nabla\widehat{p}_{\text{KDE}}(\boldsymbol{x})^\top}{\widehat{p}_{\text{KDE}}(\boldsymbol{x})^2}.$$

Then, SCMS obtains the orthogonal projector to the subspace as $\widehat{\boldsymbol{L}}_{\text{KDE}}(\boldsymbol{x}) = \widehat{\mathbf{V}}_{\text{KDE}}(\boldsymbol{x})\widehat{\mathbf{V}}_{\text{KDE}}(\boldsymbol{x})^\top$, where $\widehat{\mathbf{V}}_{\text{KDE}}(\boldsymbol{x}) \in \mathbb{R}^{D\times(D-d)}$ consists of the $D-d$ eigenvectors associated with the $D-d$ largest eigenvalues of $\widehat{\boldsymbol{\Sigma}}_{\text{KDE}}^{-1}(\boldsymbol{x})$. Then, the update rule of SCMS is given by

$$\boldsymbol{z}^{\tau+1} = \boldsymbol{z}^\tau + \widehat{\boldsymbol{L}}_{\text{KDE}}(\boldsymbol{z}^\tau)\widehat{\boldsymbol{m}}_{\text{KDE}}(\boldsymbol{z}^\tau), \quad (27)$$

where $\boldsymbol{z}^\tau$ denotes the τ-th update of an arbitrarily initialized point and $\widehat{\boldsymbol{m}}_{\text{KDE}}(\boldsymbol{x})$ is the mean shift vector defined in (10). Eq.(27) is repeatedly applied until convergence. The monotonic hill-climbing property for SCMS is proved in Ghassabeh et al. (2013).

One of the key challenges in SCMS is to accurately estimate $\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})$ in (26). SCMS takes a three-step approach, i.e., estimate $p(\boldsymbol{x})$ by KDE, compute its derivatives, and plug them into $\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})$. However, this approach can perform poorly because of the same reason as MS, i.e., a good density estimator does not necessarily mean a good density derivative estimator. In addition, division by the estimated density could further magnify the estimation error for density derivatives. To cope with this problem, we employ LSDDR for direct estimation of density-derivative-ratios in $\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})$ without going through density estimation and division, and propose a novel method for density ridge estimation.

4.3 Least-Squares Density Ridge Finder

Based on LSDDR, we develop a novel density ridge finder called the *least-squares density ridge finder* (LSDRF), which extends LSLDGC for density ridge estimation.

Input: $\{\boldsymbol{x}_i\}_{i=1}^n, \{\boldsymbol{y}_k\}_{k=1}^{n'}$.

$\left\{\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b\right\} \leftarrow \mathrm{LSDDR1}(\{\boldsymbol{x}_i\}_{i=1}^n)$;
$\left\{\{\widetilde{\boldsymbol{\theta}}_j\}_{j=1}^{D(D+1)/2}, \{\boldsymbol{c}'_i\}_{i=1}^b\right\} \leftarrow \mathrm{LSDDR2}(\{\boldsymbol{x}_i\}_{i=1}^n)$;

for $k = 1$ to n' **do**
  $\tau \leftarrow 0$;
  $\boldsymbol{z}_k^\tau \leftarrow \boldsymbol{y}_k$;
  repeat
    $\{\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau), \widehat{\boldsymbol{m}}(\boldsymbol{z}_k^\tau)\} \leftarrow \mathrm{ComputeGrad}(\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau)$;
    $\widehat{\boldsymbol{L}}(\boldsymbol{z}_k^\tau) \leftarrow \mathrm{ComputeProjector}(\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau), \{\widehat{\boldsymbol{\theta}}_j\}_{j=1}^{D(D+1)/2}, \{\boldsymbol{c}'_i\}_{i=1}^b, \boldsymbol{z}_k^\tau)$;

    $\boldsymbol{z}_k^{\tau+1} \leftarrow \boldsymbol{z}_k^\tau + \widehat{\boldsymbol{L}}(\boldsymbol{z}_k^\tau)\widehat{\boldsymbol{m}}(\boldsymbol{z}_k^\tau)$;
    $\{f_j\}_{j=1}^D \leftarrow \left\{\widetilde{\boldsymbol{\beta}}_j^\top \boldsymbol{\varphi}_j(\boldsymbol{z}_k^\tau)\right\}_{j=1}^D$;

    $\widehat{D} \leftarrow \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1} | \boldsymbol{z}_k^\tau]$;

    if $\widehat{D} < 0$ or $\exists j,\ |f_j| \approx 0$ **then**
      $\boldsymbol{z}_k^{\tau+1} \leftarrow \boldsymbol{z}_k^\tau + \eta\widehat{\boldsymbol{L}}(\boldsymbol{z}_k^\tau)\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau)$;
      $\widehat{D} \leftarrow \widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}_k^{\tau+1} | \boldsymbol{z}_k^\tau]$;
    end if
    $\tau \leftarrow \tau + 1$;
  until
  $\boldsymbol{z}_k \leftarrow \boldsymbol{z}_k^\tau$;
end for

Outputs: $\{\boldsymbol{z}_k\}_{k=1}^{n'}$.

Figure 5: The algorithm of LSDRF. $\mathrm{LSDDR2}(\{\boldsymbol{x}_i\}_{i=1}^n)$ denotes the LSDDR estimator for the second-order density-derivative-ratios, and $\{\widehat{\boldsymbol{\theta}}_j\}_{j=1}^{D(D+1)/2}$ are the corresponding coefficient vectors. $\{\boldsymbol{y}_k\}_{k=1}^{n'}$ are initial points to approximate the density ridge. $\mathrm{ComputeGrad}(\{\widetilde{\boldsymbol{\beta}}_j\}_{j=1}^D, \{\boldsymbol{c}_i\}_{i=1}^b, \boldsymbol{z}_k^\tau)$ computes the estimated log-density gradient $\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau)$ and $\widehat{\boldsymbol{m}}(\boldsymbol{z}_k^\tau)$ in (14), while $\mathrm{ComputeProjector}(\widehat{\boldsymbol{g}}(\boldsymbol{z}_k^\tau), \{\widehat{\boldsymbol{\theta}}_j\}_{j=1}^{D(D+1)/2}, \{\boldsymbol{c}'_i\}_{i=1}^b, \boldsymbol{z}_k^\tau)$ computes the subspace projector $\widehat{\boldsymbol{L}}(\boldsymbol{z}_k^\tau)$. The update of $\boldsymbol{z}_k^\tau$ terminates when either $\widehat{D}$ or $\|\boldsymbol{z}_k^{\tau+1} - \boldsymbol{z}_k^\tau\|$ is less than a small positive constant. The other notations follow Figs.3 and 4.

4.3.1 ALGORITHM OF LSDRF

The algorithm of LSDRF essentially follows the same line as SCMS, which performs projected gradient ascent. By employing LSDDR, we obtain an estimate of $\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})$ as

$$\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x}) := -\widehat{\boldsymbol{H}}(\boldsymbol{x}) + \widehat{\boldsymbol{g}}(\boldsymbol{x})\widehat{\boldsymbol{g}}^\top(\boldsymbol{x}), \tag{28}$$

where we recall that $\widehat{g}_j(\boldsymbol{x})$ and $[\widehat{\boldsymbol{H}}(\boldsymbol{x})]_{ij}$ are LSDDR to $\partial_j p(\boldsymbol{x})/p(\boldsymbol{x})$ and $\partial_i\partial_j p(\boldsymbol{x})/p(\boldsymbol{x})$, respectively. Then, we obtain the orthogonal projector to the subspace as $\widehat{\boldsymbol{L}}(\boldsymbol{x}) = \widehat{\mathbf{V}}(\boldsymbol{x})\widehat{\mathbf{V}}^\top(\boldsymbol{x})$ where $\widehat{\mathbf{V}}(\boldsymbol{x})$ consists of the $D-d$ eigenvectors associated with the $D-d$ largest eigenvalues of $\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x})$. By replacing $\widehat{\boldsymbol{L}}_{\mathrm{KDE}}(\boldsymbol{x})$ and $\widehat{\boldsymbol{m}}_{\mathrm{KDE}}(\boldsymbol{x})$ in (27) with $\widehat{\boldsymbol{L}}(\boldsymbol{x})$ and $\widehat{\boldsymbol{m}}(\boldsymbol{x})$ respectively, the following update rule for LSDRF is obtained by

$$\boldsymbol{z}^{\tau+1} = \boldsymbol{z}^\tau + \widehat{\boldsymbol{L}}(\boldsymbol{z}^\tau)\widehat{\boldsymbol{m}}(\boldsymbol{z}^\tau), \tag{29}$$

where $\widehat{\boldsymbol{m}}(\boldsymbol{x}) = (\widehat{m}^{(1)}(\boldsymbol{x}), \widehat{m}^{(2)}(\boldsymbol{x}), \ldots, \widehat{m}^{(D)}(\boldsymbol{x}))$ is used in LSLDGC for mode-seeking whose definition is given in (14).

The implementation techniques of LSLDGC in Section 3.4 are inherited, but LSDRF performs projected gradient ascent instead of the gradient ascent: Whenever $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}^{\tau+1} | \boldsymbol{z}^\tau] < 0$ or $\exists j, f_j(\boldsymbol{z}^{(\tau)}) \approx 0$, we perform the projected gradient ascent as

$$\boldsymbol{z}^{\tau+1} = \boldsymbol{z}^\tau + \eta\widehat{\boldsymbol{L}}(\boldsymbol{z}^\tau)\widehat{\boldsymbol{g}}(\boldsymbol{z}^\tau). \tag{30}$$

The step size parameter η is selected so that $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{z}^\tau + \eta\widehat{\boldsymbol{L}}(\boldsymbol{z}^\tau)\widehat{\boldsymbol{g}}(\boldsymbol{z}^\tau) | \boldsymbol{z}^\tau]$ is maximized. The algorithm of LSDRF is summarized in Fig.5.[4] The algorithm is essentially the same as LSLDGC based on the update rule (12) (Figs. 3 and 4), where we only replace (13) and (24) in LSLDGC with (29) and (30) in LSDRF, respectively. Unlike clustering, for density ridge estimation, the starting points $\boldsymbol{z}^{\tau=0}$ are arbitrary, but in this paper, we set them at data samples $\boldsymbol{x}_i$ because data samples are fairly good starting points.

4.3.2 THE CONVERGENCE RATE TO THE TRUE RIDGE

Here, we establish the convergence rate to understand how the estimated ridge approaches to the true ridge as n increases. Based on LSDDR, the estimated ridge is defined as

$$\widehat{\mathcal{R}} := \{\boldsymbol{x} \in \mathbb{R}^D \mid \|\widehat{\mathbf{V}}(\boldsymbol{x})\widehat{\mathbf{V}}(\boldsymbol{x})^\top \widehat{\boldsymbol{g}}(\boldsymbol{x})\| = 0, \widehat{\eta}_{d+1}(\boldsymbol{x}) < 0\},$$

where $\widehat{\eta}_i(\boldsymbol{x})$ denotes the i-th largest eigenvalue of $-\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x})$.

In our analysis, we make the following assumptions:

(A0) Kernel boundedness: $k(\boldsymbol{x}, \boldsymbol{x}')$ and $\partial_j\partial'_j k(\boldsymbol{x}, \boldsymbol{x}')$ for all j are uniformly bounded, where ∂'_j denotes the partial derivative with respect to the j-th coordinate in $\boldsymbol{x}'$.

(A1) Differentiability and boundedness: Let $B_D(\boldsymbol{x}, \delta)$ be the D-dimensional ball of radius $\delta > 0$ centered at $\boldsymbol{x}$ and let $\mathcal{R} \oplus \delta := \cup_{\boldsymbol{x} \in \mathcal{R}} B_D(\boldsymbol{x}, \delta)$. For all $\boldsymbol{x} \in \mathcal{R} \oplus \delta$, the $|\boldsymbol{j}|$-th order derivatives of $\log p(\boldsymbol{x})$ for $|\boldsymbol{j}| = 0, 1, 2, 3$ exist and are bounded.

4. A MATLAB package of LSDRF is available at `https://sites.google.com/site/hworksites/home/software/lsdrf`.

(A2) Eigengap: Assume that there exists $\kappa > 0$ and δ such that for all $\boldsymbol{x} \in \mathcal{R} \oplus \delta$, $\eta_{d+1}(\boldsymbol{x}) < -\kappa$ and $\eta_d(\boldsymbol{x}) - \eta_{d+1}(\boldsymbol{x}) > \kappa$, where $\eta_i(\boldsymbol{x})$ denotes the i-th eigenvalue of $\nabla\nabla \log p(\boldsymbol{x})$.

(A3) Path smoothness: For each $\boldsymbol{x} \in \mathcal{R} \oplus \delta$,

$$\|\boldsymbol{L}^{\perp}(\boldsymbol{x})\boldsymbol{g}(\boldsymbol{x})\| \cdot \|\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})\|_{\max} < \frac{\kappa^2}{2D^{3/2}},$$

where $\boldsymbol{L}^{\perp}(\boldsymbol{x}) := \mathbf{I}_D - \boldsymbol{V}(\boldsymbol{x})\boldsymbol{V}(\boldsymbol{x})^{\top}$, $\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x}) := \nabla \mathrm{vec}\left(\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})\right)$, $\mathrm{vec}(\cdot)$ denotes vectorization of matrices by concatenating the columns, and $\|\boldsymbol{A}\|_{\max} := \max_{i,j} |[\boldsymbol{A}]_{ij}|$. The (i,j)-th element in $\nabla \mathrm{vec}\left(\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})\right)$ $(\in \mathbb{R}^{D^2 \times D})$ is given by $\partial_j [\mathrm{vec}\left(\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})\right)]_i$.

Assumptions (A2) and (A3) are a straightforward modification of the assumptions in Genovese et al. (2014) from the (non-log) density to the log-density. Assumption (A2) indicates that the density ridge has a sharp and curvilinear shape in the subspace orthogonal to the ridge. Assumption (A3) indicates that $\|\boldsymbol{L}^{\perp}(\boldsymbol{x})\boldsymbol{g}(\boldsymbol{x})\|$ and $\|\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})\|_{\max}$ are both bounded. Since $\boldsymbol{L}^{\perp}(\boldsymbol{x})$ is orthogonal to $\boldsymbol{V}(\boldsymbol{x})\boldsymbol{V}(\boldsymbol{x})^{\top}$ for all $\boldsymbol{x}$, the boundedness of $\|\boldsymbol{L}^{\perp}(\boldsymbol{x})\boldsymbol{g}(\boldsymbol{x})\|$ implies that the gradient $\boldsymbol{g}(\boldsymbol{x})$ is not too steep in the orthogonal subspace. The boundedness of $\|\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})\|_{\max}$ means that the third-order derivative is bounded and thus the subspace direction does not abruptly change, which implies that the (projected) gradient ascent path cannot be too wiggly (Genovese et al., 2014, Section 2.2). Note that Assumptions (A1)-(A3) are only valid in the neighborhood around the ridge.

Let

$$\epsilon' := \max_j \|g_j(\boldsymbol{x}) - \widehat{g}_j(\boldsymbol{x})\|_{\infty}, \qquad \epsilon'' := \max_{ij} \|[\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})]_{ij} - [\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x})]_{ij}\|_{\infty},$$

$$\epsilon''' := \max_{ij} \|[\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})]_{ij} - [\widehat{\boldsymbol{\Sigma}}^{-1\prime}(\boldsymbol{x})]_{ij}\|_{\infty}.$$

To establish the convergence rate, we rely on two lemmas. The first lemma is a simple modification of Theorem 4 in Genovese et al. (2014) to the log-density from the (non-log) density, and we use it without proof. The lemma states that if ϵ', ϵ'' and ϵ''' are sufficiently small, then the true and estimated ridges are close to each other:

Lemma 11 *Suppose that (A1)-(A3) hold. Let $\psi := \max\{\epsilon', \epsilon''\}$ and $\Psi := \max\{\epsilon', \epsilon'', \epsilon'''\}$. When Ψ is sufficiently small, the following statements hold:*

(i) Conditions (A2) and (A3) hold for $\widehat{\boldsymbol{g}}$, $\widehat{\boldsymbol{\Sigma}}^{-1}$ and $\widehat{\boldsymbol{\Sigma}}^{-1\prime}$.

(ii) $\mathrm{Haus}(\mathcal{R}, \widehat{\mathcal{R}})$ *is bounded as*

$$\mathrm{Haus}(\mathcal{R}, \widehat{\mathcal{R}}) = O(\psi). \tag{31}$$

The next lemma characterizes the convergence rates of ϵ', ϵ'' and ϵ''' when we employ LSDDR:

Lemma 12 *Suppose that the assumptions in Theorem 1 and (A0) hold. When LSDDR is applied for density-derivative-ratio estimation,*

$$\epsilon' = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right), \tag{32}$$

$$\epsilon'' = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right), \tag{33}$$

$$\epsilon''' = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right). \tag{34}$$

The proof is given in Appendix G.

Combining Lemma 11 with Lemma 12 yields the following theorem:

Theorem 13 *Suppose that the assumptions in Theorem 1 and (A0)-(A3) hold. Then,*

$$\mathrm{Haus}(\mathcal{R}, \widehat{\mathcal{R}}) = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right). \tag{35}$$

Proof Lemma 12 ensures that $\psi = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right)$. This completes the proof from (31). ■

Remark 14 *Genovese et al. (2014, Eq.(1)) established the following convergence rate based on KDE:*

$$\mathrm{Haus}(\mathcal{R}, \widehat{\mathcal{R}}_{KDE}) = O_{\mathrm{P}}\left(\left(\frac{\log n}{n}\right)^{\frac{2}{D+8}}\right), \tag{36}$$

where $\widehat{\mathcal{R}}_{KDE}$ denotes the estimated ridge by KDE. Comparison to our result is difficult, but the main difference is that the rate in (36) *explicitly depends on data dimension D.*

5. Numerical Illustration on Mode-Seeking Clustering and Density Ridge Estimation

This section experimentally illustrates the performance of the proposed methods for mode-seeking clustering and density ridge estimation on a variety of datasets.

5.1 Illustration on Clustering

First, we illustrate the performance of LSLDGC both on artificial and benchmark datasets.

5.1.1 ARTIFICIAL DATASETS: LSLDGC VS MS

Here, we compare the performance of LSLDGC to MS with two different bandwidth selection methods:

- **LSLDGC**: LSLDGC based on the update rule (12). The width parameter σ_j in the Gaussian kernel and regularization parameter λ_j were selected by cross-validation as in Section 2.4. We selected ten candidates of σ_j and λ_j from $c_\sigma \times \sigma_{\mathrm{med}}^{(j)}$ $(0.5 \leq c_\sigma \leq 5)$ and 10^m $(-3 \leq m \leq 0)$, respectively where $\sigma_{\mathrm{med}}^{(j)}$ is the median value of $|x_i^{(j)} - x_k^{(j)}|$ with respect to i and k.
- **LSLDGC$_{\mathbf{CW}}$**: LSLDGC based on the coordinate-wise update rule (15). The same cross-validation was performed as above.
- **MS$_{\mathbf{LS}}$**: The bandwidth parameter h was cross-validated based on the standard *integrated squared error*. We selected ten candidates of h from $10^l \times h_{\mathrm{med}}$ $(-1.5 \leq l \leq 0)$ where h_{med} is the median value of $|x_i^{(j)} - x_k^{(j)}|$ with respect to i, j and k.

- **$\mathrm{MS}_{\mathrm{NR}}$**: The bandwidth parameter h was determined by

$$\bar{S}_n \left(\frac{4}{D+4}\right)^{\frac{1}{D+6}} n^{-\frac{1}{d+6}},$$

where $\bar{S}_n = \frac{1}{nD}\sum_{j=1}^{D}\sum_{i=1}^{n}(x_i^{(j)} - \bar{x}^{(j)})^2$ and $\bar{x}^{(j)} = \frac{1}{n}\sum_{i=1}^{n} x_i^{(j)}$. This bandwidth parameter was used in Chen et al. (2016b) and a slight modification of the normal reference rule (Silverman, 1986).

First, we generated three kinds of two-dimensional data as follows:

(a) **Three Gaussian blobs** (Fig.6(a)): Each data sample was drawn from a mixture of three Gaussians with means $(0,1)^\top$, $(-1,-1)^\top$ and $(1,-1)^\top$, and covariance matrices $0.1\mathbf{I}_2$. The mixing coefficients were $0.4, 0.3, 0.3$, respectively.

(b) **Two curves** (Fig.6(d)): Two curves are generated as $(x^{(1)}, x^{(2)}) = (\cos(\pi t^{(1)}), \sin(\pi t^{(1)}))^\top$ and $(x^{(1)}, x^{(2)}) = (-\cos(\pi t^{(2)}) + 1, -\sin(\pi t^{(2)}))^\top$ where $t^{(1)}$ and $t^{(2)}$ are independently drawn from the Gaussian density with mean 0.5 and standard deviation 0.15. Then, Gaussian noise with covariance matrix $0.1\mathbf{I}_2$ was added to these curves. The numbers of data samples for both curves were approximately same.

(c) **Two curves & a Gaussian blob** (Fig.6(g)): Data samples from the Gaussian density with mean 0 and standard deviation 0.1 were added to the two curves similarly generated as in (b). The number of samples for the two curves was same, and for the Gaussian blob, we set the number at $n/3$ approximately.

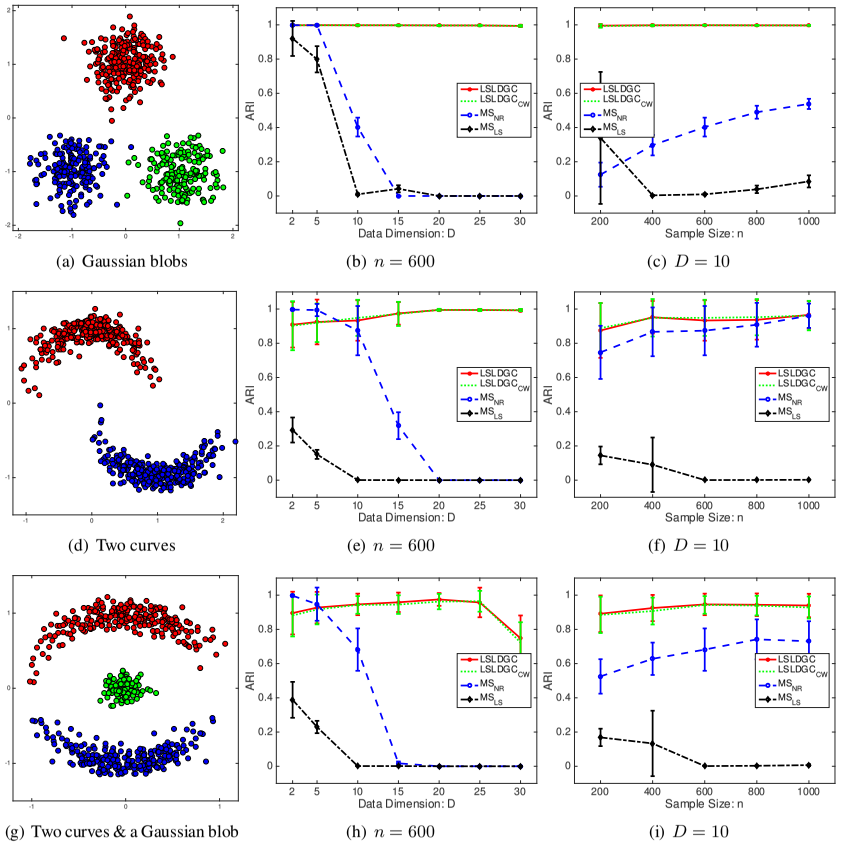
When higher-dimensional data were generated, we simply appended Gaussian variables with mean 0 and standard deviation 0.1 to the two-dimensional data. Clustering performance was measured by the adjusted Rand index (ARI) (Hubert and Arabie, 1985): ARI takes a value less than or equal to one, a larger value indicates a better clustering result, and when a clustering result is perfect, the ARI value equals to one.

Fig.6(b,e,h) clearly indicates the advantage of our clustering methods over MS: Both LSLDGC and $\mathrm{LSLDGC}_{\mathrm{CW}}$ significantly outperform $\mathrm{MS}_{\mathrm{LS}}$ and $\mathrm{MS}_{\mathrm{NR}}$ particularly for higher-dimensional data. When the dimensionality of data is low, $\mathrm{MS}_{\mathrm{NR}}$ performs well to all kinds of datasets. However, the ARI values of both $\mathrm{MS}_{\mathrm{LS}}$ and $\mathrm{MS}_{\mathrm{NR}}$ quickly approach zero as the dimensionality of data increases. These unsatisfactory results seem to be due to the fact that the bandwidth selection in KDE is more difficult for high(er)-dimensional data. Thus, our direct approach would be more suitable particularly for high(er)-dimensional data.

Both LSLDGC and $\mathrm{LSLDGC}_{\mathrm{CW}}$ keep the ARI values high on a wide range of sample sizes (Fig.6(c,f,i)). The performance of $\mathrm{MS}_{\mathrm{NR}}$ is improved as n increases. However, $\mathrm{MS}_{\mathrm{LS}}$ performs rather worse for large(r) datasets. The least-squares cross-validation often suggests small bandwidth parameters for large(r) datasets, which make the estimated density unsmooth. Thus, the estimated density can include a lot of spurious modes with small peaks even if it was good in terms of density estimation. This also supports that our direct estimation is a more appropriate approach.

5.1.2 BENCHMARK DATASETS

Next, we investigate the performance of LSLDGC over the following benchmark datasets:



(a) Gaussian blobs (b) $n = 600$ (c) $D = 10$

(d) Two curves (e) $n = 600$ (f) $D = 10$

(g) Two curves & a Gaussian blob (h) $n = 600$ (i) $D = 10$

Figure 6: Clustering performance on artificial data. Each point and error bar denote the average and standard deviation of ARI over 50 runs, respectively.

Table 1: The average and standard deviation of ARI values over 50 runs. A larger value means a better result. Numbers in the parentheses are standard deviations. The best and comparable methods judged by the unpaired t-test at the significance level 1% are described in boldface.

- *Banknote* ($D = 4, n = 100, \text{ and } c = 2$) (Bache and Lichman, 2013)[5]: This dataset consists of four-dimensional features from 400 by 400 images for genuine and forged banknote-like specimens. The features were extracted by wavelet transformation. We randomly chose 50 samples from each of the two classes.

- *Accelerometry* ($D = 5, n = 300, \text{ and } c = 3$)[6]: The ALKAN dataset contains 3-axis (i.e., x-, y-, and z-axes) accelerometric data. During the data collection, subjects were instructed to perform walking, running, and standing up. After segmenting each data stream into windows, five orientation-invariant-features were computed from each window (Sugiyama et al., 2014). We randomly chose 100 samples from each of the three classes.

5. https://archive.ics.uci.edu/ml/datasets/banknote+authentication#
6. http://alkan.mns.kyutech.ac.jp/web/data.html

- *Olive oil* ($D = 8, n = 200, \text{ and } c = 9$) (Forina et al., 1983). This dataset was obtained from the R software.[7] The dataset includes eight chemical measurements on different specimen of olive oil produced in nine regions in Italy. We randomly chose 200 samples.

- *Vowel* ($D = 10, n = 110, \text{ and } c = 11$) (Turney, 1993; Bache and Lichman, 2013)[8]: This consists utterance data for eleven vowels of British English. Each utterance is expressed by a ten-dimensional vector. We randomly chose 10 samples from each of the eleven classes.

- *Sat-image* ($D = 36, n = 120, \text{ and } c = 6$) (Bache and Lichman, 2013)[9]: The dataset contains the multi-spectral values of pixels in 3×3 neighborhoods in a satellite image with six classes. We randomly chose 20 samples from each of the six classes.

- *Speech* ($D = 50, n = 400, \text{ and } c = 2$). An in-house speech dataset (Sugiyama et al., 2014), which contains short utterance samples recorded from 2 male subjects speaking in French with sampling rate 44.1kHz. 50-dimensional line spectral frequencies vectors (Kain and Macon, 1998) were computed from each utterance sample. We randomly chose 200 samples from each of the two classes.

As preprocessing, each data sample was standardized by the sample mean and standard deviation in coordinate-wise manner. For comparison, we applied *k-means clustering* (KM) (MacQueen, 1967) and *spectral clustering* (SC) (Ng et al., 2001; Shi and Malik, 2000) to the same datasets. Since KM and SC require to input the number of clusters, we set it at the correct number.

As seen in the illustration on artificial data, when the dimensionality of data is low, the performance of LSLDGC, $\text{LSLDGC}_{\text{CW}}$ and MS_{NR} is comparable, but LSLDGC and $\text{LSLDGC}_{\text{CW}}$ significantly work better than MS_{NR} to higher-dimensional datasets (sat-image and speech datasets). KM and SC have prior information about the number of clusters. Nonetheless, the performance of LSLDGC and $\text{LSLDGC}_{\text{CW}}$ are often better than KM and SC.

From the results of both the artificial and benchmark datasets, we conclude that LSLDGC and $\text{LSLDGC}_{\text{CW}}$ are advantageous to relatively high-dimensional data.

5.2 Illustration on Density Ridge Estimation

Next, we illustrate the performance of LSDRF, and compare LSDRF with SCMS both on artificial and standard benchmark datasets.

5.2.1 ARTIFICIAL DATA: LSDRF VS SCMS

The performance of LSDRF is compared to SCMS with two different bandwidth selection methods:

- **LSDRF**: When estimating $g_j(\boldsymbol{x})$, we selected ten candidates of the width parameter in the Gaussian kernel and the regularization parameter from $10^l \times \sigma_{\text{med}}^{(j)}$ ($-0.3 \leq l \leq 1$) and 10^m ($-4 \leq m \leq 0$), respectively. When estimating $[\boldsymbol{H}(\boldsymbol{x})]_{ij}$, ten candidates of the width parameter in the Gaussian kernel were selected from $10^l \times \sqrt{\sigma_{\text{med}}^{(i)} \sigma_{\text{med}}^{(j)}}$ ($-0.3 \leq l \leq 1$). For the regularization parameter, we used the same candidates as in $g_j(\boldsymbol{x})$.

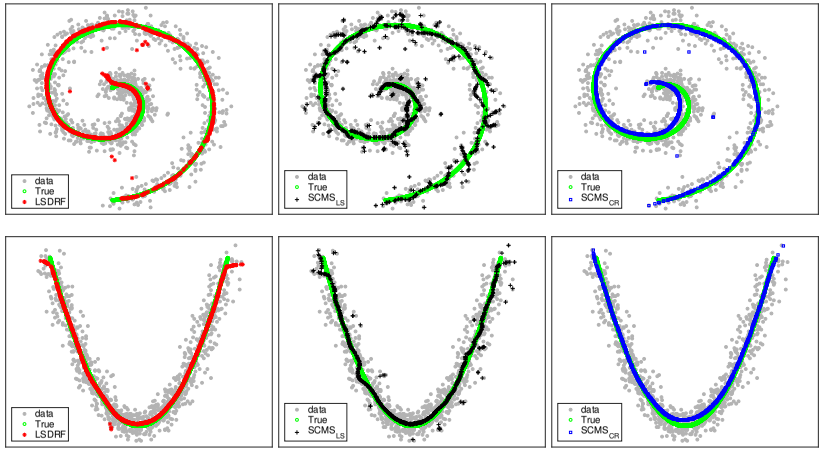
8. https://archive.ics.uci.edu/ml/datasets/Connectionist+Bench+(Vowel+Recognition+-+Deterding+Data)
9. https://archive.ics.uci.edu/ml/datasets/Statlog+(Landsat+Satellite)



(a) LSDRF (b) SCMS_{LS} (c) SCMS_{CR}

Figure 7: Comparison of the two estimated ridges by LSDRF, SCMS_{LS} and SCMS_{CR}.

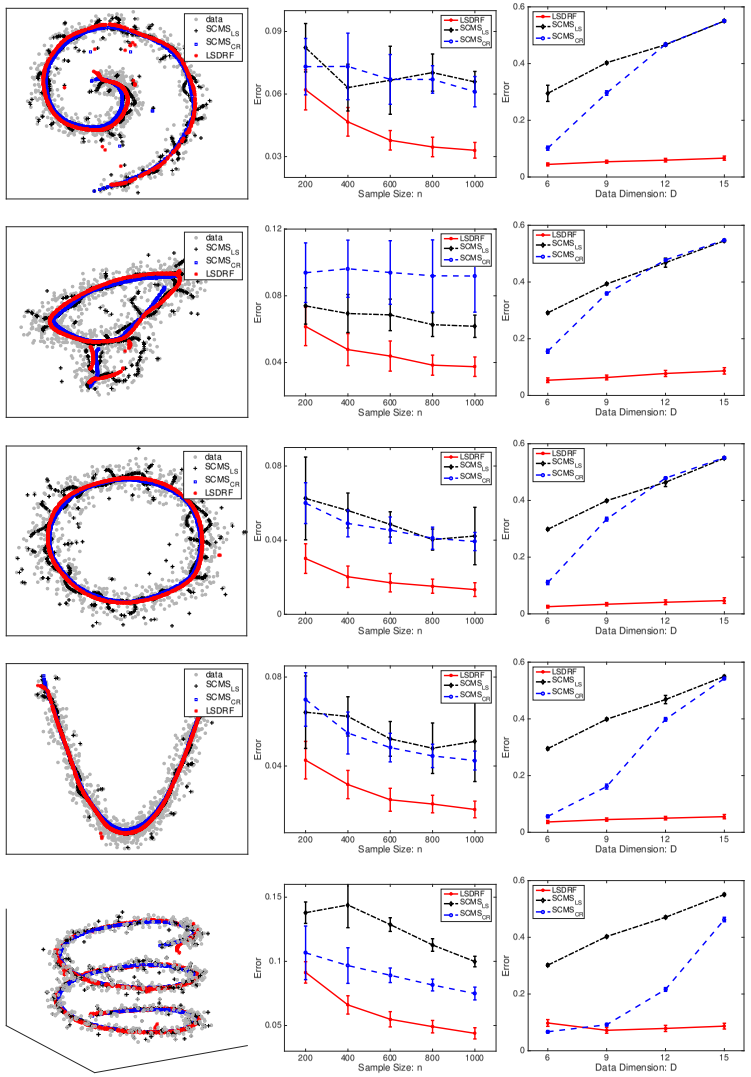
- **SCMS_{LS}**: The bandwidth parameter h was cross-validated based on the standard *integrated squared error*. We selected ten candidates of h from $10^l \times h_{\text{med}}$ $(-1.5 \leq l \leq 0)$ where h_{med} is the median value of $|x_i^{(j)} - x_k^{(j)}|$ with respect to i, j and k.
- **SCMS_{CR}**: The bandwidth parameter h was cross-validated based on the coverage risk proposed in Chen et al. (2015a). As suggested in Chen et al. (2015a), we selected ten candidates of h from $10^l \times h_{\text{NR}}$ $(-1 \leq l \leq 0)$ where h_{NR} is the bandwidth based on the normal reference rule (Silverman, 1986).

We investigate the performance of these methods on a variety of simulated datasets.[10] The i-th observation of data was generated according to $x_i^{(j)} = f^{(j)}(t_i) + n_i^{(j)}$, where t_i was taken from some range at regular intervals, $f^{(j)}(\cdot)$ denotes some fixed function, and $n_i^{(j)}$ was the Gaussian noise with mean 0 and standard deviation 0.15. Higher-dimensional data were created by appending the Gaussian variables with mean 0 and standard deviation 0.15. The estimation error was measured by

$$\text{Error} = \frac{1}{n}\sum_{i=1}^{n} \min_l \|\widehat{\boldsymbol{y}}_i - \boldsymbol{f}(t_l)\|, \tag{37}$$

where $\boldsymbol{f}(\cdot) = (f^{(1)}(\cdot), f^{(2)}(\cdot), \ldots, f^{(D)}(\cdot))^\top$ and $\widehat{\boldsymbol{y}}_i$ denotes an estimate of the density ridge point from $\boldsymbol{x}_i$.

10. Most of the datasets are generated using a MATLAB package made by Jakob Verbeek, which is available at `http://lear.inrialpes.fr/people/verbeek/code/kseg_soft.tar.gz`.



(a) Density ridge estimates (b) Error against sample size (c) Error against data dimension

Figure 8: Performance of ridge estimation on artificial data. Each point and error bar denote the average and standard deviation of ARI over 50 runs, respectively. For (c), $n = 1000$. Errors for ridge estimation are computed according to (37).

The estimated ridges are visualized in Fig.7. SCMS_{LS} provides a broken and non-smooth ridge estimate because the selected bandwidth by the least-squares cross-validation is small for density ridge estimation as in mode-seeking clustering. In contrast, the ridges estimated by LSDRF and SCMS_{CR} are smooth. However, SCMS_{CR} gives a biased estimate around highly curved region in the true ridge (e.g., the centers of the spiral and quadratic curve in Fig.7), while the bias in LSDDR seems smaller. This implies that LSDRF more accurately estimates density ridges. The accuracy of LSDRF is quantified on a variety of artificial datasets in Fig 8. LSDRF produces smaller errors particularly when the sample size is large (Fig 8(b)). In addition, as in mode-seeking clustering, the performance of LSDRF is even better when the dimensionality of data is higher (Fig. 8(c)). This implies that our direct approach is useful for high(er)-dimensional data.

5.2.2 DENSITY RIDGE ESTIMATION ON REAL-WORLD DATASETS

Next, we apply LSDRF to real-world datasets. As in Pulkkinen (2015), we employed the following two datasets:

- *New Madrid earthquake* dataset: This seismological dataset was downloaded from the Center for Earthquake Research and Information.[11] The dataset contains positional information for earthquakes around the New Madrid seismic zone from 1974 to 2016, providing $11,131$ samples. The three regions in Figs.9(a,b,c) were extracted according to (a) $(-90.2, -89.25)$, (b) $(-92.5, -92.15)$ and (c) $(-85.5, -83.5)$ degrees for the latitude range, respectively. For the longitude range, (a) $(36, 36.8)$, (b) $(35.2, 35.4)$ and (c) $(34.5, 36.5)$ degrees were selected. The total numbers of the original data samples and reduced data samples in each region were (a) $(N, n) = (5902, 500)$, (b) $(N, n) = (1548, 300)$ and (c) $(N, n) = (594, 200)$.

- *Shapley galaxy* dataset: This dataset was downloaded from the Center for Astrostatistics at Pennsylvania State University.[12] The dataset contains information about the three-dimensional sky angles and recession velocity of $4,215$ galaxies. As done in Pulkkinen (2015), we transformed the data samples into the three-dimensional Cartesian coordinates based on the fact that the recession velocity is proportional to the radial distance (Drinkwater et al., 2004). The three regions in Figs 10(a,b,c) were extracted according to a velocity range: (a) $(6000, 20000)$ km/s, (b) $(1500, 6000)$ km/s and (c) $(6000, 10500)$ km/s, respectively. The total numbers of the original data samples and reduced data samples in each region were (a) $(N, n) = (2849, 500)$, (b) $(N, n) = (595, 200)$ and (c) $(N, n) = (351, 150)$.

In each dataset, we focused on three regions containing prominent features, and standardized data samples in each region by subtracting the mean value and dividing by standard deviation in a dimension-wise manner. Here, the standardized data samples are collectively denoted by $\widetilde{\mathcal{D}} = \{\widetilde{\boldsymbol{x}}_i\}_{i=1}^N$. Before applying density ridge estimation methods, we performed preprocessing to remove clutter noises: KDE was applied to the dataset of each region, and then the data samples $\widetilde{\boldsymbol{x}}_i$ in each region were removed when $\frac{\widehat{p}_{\text{KDE}}(\widetilde{\boldsymbol{x}}_i)}{\max_j[\widehat{p}_{\text{KDE}}(\widetilde{\boldsymbol{x}}_j)]} < 10^{-3}$. After noise removal, we randomly chose n data samples from each region, and applied the three density ridge estimation methods to the sub-sampled data. The sub-sampled data are collectively expressed by $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$. For performance comparison, we computed the logarithm of $\widehat{p}_{\text{KDE}}$ on the estimated density ridges, which

(a) Madrid 1 (b) Madrid 2 (c) Madrid 3

Figure 9: Density ridge estimation to three regions in the New Madrid earthquake dataset. The three regions (a,b,c) were extracted according to a range of latitude and longitude. The first, second and third rows correspond to results from LSDRF, SCMS_{LS} and SCMS_{CR}, respectively.

is given by

$$\mathcal{L} = \frac{1}{n}\sum_{i=1}^{n} \log \widehat{p}_{\text{KDE}}(\widehat{\boldsymbol{y}}_i),$$

where the centers of the kernel function in $\widehat{p}_{\text{KDE}}$ were set at the original data samples $\widetilde{\boldsymbol{x}}_i$ in each region, and $\widehat{\boldsymbol{y}}_i$ denotes an estimated density ridge point from $\boldsymbol{x}_i$. If $\mathcal{L}$ is larger, the performance can be interpreted to be better because ridges are defined on relatively high density areas. Unlike the

Figure 10: Density ridge estimation to three regions in the Shapley galaxy dataset. The three regions were extracted according to a range of recession velocity. The first, second and third rows correspond to results from LSDRF, $\mathrm{SCMS}_{\mathrm{LS}}$ and $\mathrm{SCMS}_{\mathrm{CR}}$, respectively.

last illustration, for $\mathrm{SCMS}_{\mathrm{LS}}$, we employed the following adaptive-bandwidth Gaussian kernel:

$$\frac{1}{(2\pi h_i^2)^{D/2}} \exp\left(-\frac{\|\boldsymbol{x}-\boldsymbol{x}_i\|^2}{2h_i^2}\right),$$

where h_i denotes the bandwidth parameter. We restricted h_i at the m-nearest neighbor Euclidean distance from $\boldsymbol{x}_i$ to $\boldsymbol{x}_j$ $(i \neq j)$, and performed cross-validation with respect to m whose candidates were 128, 64, 32, 16, 8 and 4. For $\mathrm{SCMS}_{\mathrm{LS}}$, the ten candidates of the bandwidth parameter were selected from $10^l \times h_{\mathrm{NR}}$ $(-0.3 \leq l \leq 0)$. For LSDRF, we employed all data samples $\{\boldsymbol{x}_i\}_{i=1}^n$ as the centers of the Gaussian kernel, and used the median value of $\mathrm{CV}(t)$ in Section 2.4 instead of the mean value in cross-validation.

Table 2: The average and standard deviation of the performance measure $\mathcal{L}$ over 50 runs. Madrid 1, 2 and 3 (or Shapley 1, 2 and 3) correspond to the three regions in Fig.9 (or Fig.10). A larger value means a better result. Numbers in the parentheses are standard deviations. The best and comparable methods judged by the unpaired t-test at the significance level 1% are described in boldface.

New Madrid earthquake			
	LSDRF	$\mathrm{SCMS}_{\mathrm{LS}}$	$\mathrm{SCMS}_{\mathrm{CR}}$
Madrid 1	**-0.511(0.101)**	-0.610(0.072)	-0.571(0.075)
Madrid 2	**0.001(0.175)**	**0.029(0.065)**	-0.076(0.075)
Madrid 3	**-1.173(0.132)**	-1.238(0.086)	-1.238(0.098)

Shapley galaxy			
	LSDRF	$\mathrm{SCMS}_{\mathrm{LS}}$	$\mathrm{SCMS}_{\mathrm{CR}}$
Shapley 1	**0.188(0.093)**	0.094(0.073)	0.063(0.121)
Shapley 2	**-1.120(0.145)**	-1.220(0.097)	-1.462(0.223)
Shapley 3	**-1.295(0.114)**	-1.544(0.076)	-1.581(0.091)

Ridges estimated by LSDRF are smooth and seem to qualitatively well-match the ridges in the underlying data, and $\mathrm{SCMS}_{\mathrm{CR}}$ and $\mathrm{SCMS}_{\mathrm{LS}}$ also perform fairly good (Figs.9 and 10). Table 2 is quantitative comparison by $\mathcal{L}$, showing that LSDRF compares favorably with both $\mathrm{SCMS}_{\mathrm{CR}}$ and $\mathrm{SCMS}_{\mathrm{LS}}$.

6. Conclusion

In this paper, we proposed a novel estimator of the ratios of the density derivatives to the density. In stark contrast with the approaches in mean shift clustering and subspace constrained mean shift, our approach is to *directly* estimate the *density-derivative-ratios* without going through density estimation and computing the ratios. The proposed estimator was theoretically investigated, and the convergence rate was established. We applied the proposed estimator to mode-seeking clustering and density ridge estimation, and developed practical methods. Moreover, theoretical analysis were also performed to these methods , and the convergence rates to the mode and ridge of the true density were established. Our experimental illustration demonstrated that the proposed methods for mode-seeking clustering and density ridge estimation outperformed existing methods particularly for high(er)-dimensional data.

This paper focused only on mode-seeking clustering and density ridge estimation. The proposed estimator can be useful or extended for other problems. For instance, making use of the global mode (the global maximum) of a conditional density enables us to develop a regression method robust against outliers (Yao et al., 2012). Non-parametric estimation of the mode is also needed in functional data analysis (Gasser et al., 1998). In future, we explore novel applications of the proposed estimator.

Appendix A. Proof of Theorem 1

Proof We first derive the following two lemmas by modifying the proof techniques in Sriperumbudur et al. (2013):

Lemma 15 *With $\epsilon = 1$ in Assumption* **(D)***, the following statements hold:*

(i) For J_j with the regularizer,

$$J_j^\lambda(r_j) := J_j(r_j) + \lambda_j \|r_j\|_{\mathcal{H}}^2,$$

the minimizer of J_j^λ is given by

$$r_j^\lambda := \operatorname*{argmin}_{r_j \in \mathcal{H}} J_j^\lambda(r_j) = (C + \lambda_j I)^{-1} \xi_j = (C + \lambda_j I)^{-1} C r_j^*,$$

where $C = \int_{\mathcal{X}} k(\cdot, \boldsymbol{x}) \otimes k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}$, $\otimes$ is the tensor product, and

$$\xi_j := (-1)^{|j|} \int_{\mathcal{X}} \partial_j k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}.$$

(ii) $\widehat{J}_j(r_j)$ can be equivalently expressed as

$$\widehat{J}_j(r_j) = 1 < r_j - r_j^*, \widehat{C}(r_j - r_j^*) >_{\mathcal{H}},$$

where

$$\widehat{C} := \frac{1}{n} \sum_{i=1}^n k(\cdot, \boldsymbol{x}_i) \otimes k(\cdot, \boldsymbol{x}_i) \quad \textit{and} \quad \widehat{\xi}_j := \frac{(-1)^{|j|}}{n} \sum_{i=1}^n \partial_j k(\cdot, \boldsymbol{x}_i).$$

Then, $\widehat{r}_j$ is given by

$$\widehat{r}_j = \operatorname*{argmin}_{r_j \in \mathcal{H}} \left[\widehat{J}_j(r_j) + \lambda_j \|r_j\|_{\mathcal{H}}^2 \right] = (\widehat{C} + \lambda_j I)^{-1} \widehat{\xi}_j.$$

Lemma 16 *With $\epsilon = 2$ in Assumption* **(D)***,*

$$\|\widehat{\xi}_j - \widehat{C} r_j^*\|_{\mathcal{H}} = O_{\mathrm{P}}\left(n^{-1/2}\right). \tag{38}$$

The proofs of these lemmas can be seen in Appendices A.1 and A.2, respectively.

Next, we make use of the proof of Theorem 5 in Sriperumbudur et al. (2013) to prove Theorem 1. From Lemma 15,

$$\begin{aligned}
\widehat{r}_j - r_j^\lambda &= (\widehat{C} + \lambda_j I)^{-1} \widehat{\xi}_j - r_j^\lambda \\
&= (\widehat{C} + \lambda_j I)^{-1} \left\{ \widehat{\xi}_j - \widehat{C} r_j^\lambda - \lambda_j r_j^\lambda \right\} \\
&= (\widehat{C} + \lambda_j I)^{-1} (\widehat{\xi}_j - \widehat{C} r_j^*) + (\widehat{C} + \lambda_j I)^{-1} (C - \widehat{C})(r_j^\lambda - r_j^*),
\end{aligned}$$

where we used $\lambda_j r_j^\lambda = C(r_j^* - r_j^\lambda)$ from Lemma 15(i). Therefore,

$$\begin{aligned}
\|\widehat{r}_j - r_j^*\|_{\mathcal{H}} &\leq \|\widehat{r}_j - r_j^\lambda\|_{\mathcal{H}} + \|r_j^\lambda - r_j^*\|_{\mathcal{H}}. \\
&\leq \|(\widehat{C} + \lambda_j I)^{-1}\| (\|\widehat{\xi}_j - \widehat{C} r_j^*\|_{\mathcal{H}} + \|C - \widehat{C}\| \mathcal{A}_0(\lambda_j)) + \mathcal{A}_0(\lambda_j),
\end{aligned}$$

where $\mathcal{A}_0(\lambda_j) = \|r_j^\lambda - r_j^*\|_{\mathcal{H}}$. It can be shown that $\|(\widehat{C} + \lambda_j I)^{-1}\| \leq 1/\lambda_j$ for sufficiently small λ_j. Thus, Lemma 16 shows that the first term can be bounded by $O_{\mathrm{P}}\left(\frac{1}{\lambda_j \sqrt{n}}\right)$. In addition, with the proof techniques in Fukumizu et al. (2007, Lemma 5), $\|C - \widehat{C}\| \leq \|C - \widehat{C}\|_{\mathrm{HS}} = O_{\mathrm{P}}(n^{-1/2})$ with $\epsilon = 2$ where $\|\cdot\|_{\mathrm{HS}}$ denotes the Hilbert-Schmidt norm. Thus, the second term is of the order $O_{\mathrm{P}}\left(\frac{\mathcal{A}_0(\lambda_j)}{\sqrt{n}\lambda_j}\right)$. From these results,

$$\|\widehat{r}_j - r_j^*\|_{\mathcal{H}} \leq O_{\mathrm{P}}\left(\frac{1}{\lambda_j \sqrt{n}}\right) + O_{\mathrm{P}}\left(\frac{\mathcal{A}_0(\lambda_j)}{\sqrt{n}\lambda_j}\right) + \mathcal{A}_0(\lambda_j). \tag{39}$$

Propostion A.2 in Sriperumbudur et al. (2013) states that if $r_j^* \in \mathcal{R}(C^\gamma)$ and C is a bounded and self-adjoint compact operator on a separable $\mathcal{H}$, the following inequality holds:

$$\mathcal{A}_0(\lambda_j) \leq \max(1, \|C\|^{\gamma - 1}) \lambda_j^{\min(1,\gamma)} \|C^{-\gamma} r_j^*\|_{\mathcal{H}}. \tag{40}$$

It can be easily verified that C is a self-adjoint operator. Assumption (D) with $\epsilon = 2$ ensures that C is a Hilbert-Schmidt operator and therefore compact because it is bounded in terms of the Hilbert-Schmidt norm. Thus, applying (40) to (39) completes the proof when choosing $\lambda_j = O\left(n^{-\max\left\{\frac{1}{4}, \frac{1}{2(\gamma+1)}\right\}}\right)$ as $n \to \infty$. ■

A.1 Proof of Lemma 15

Proof *(i)* From the definition of J_j,

$$\begin{aligned}
J_j(r_j) &= \int_{\mathcal{X}} \left\{ r_j(\boldsymbol{x}) - r_j^*(\boldsymbol{x}) \right\}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int_{\mathcal{X}} 1 < r_j - r_j^*, k(\cdot, \boldsymbol{x}) >_{\mathcal{H}}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int_{\mathcal{X}} 1 < r_j - r_j^*, (k(\cdot, \boldsymbol{x}) \otimes k(\cdot, \boldsymbol{x}))(r_j - r_j^*) >_{\mathcal{H}} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int_{\mathcal{X}} 1 < r_j - r_j^*, C_{\mathrm{x}}(r_j - r_j^*) >_{\mathcal{H}} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= 1 < r_j - r_j^*, C(r_j - r_j^*) >_{\mathcal{H}},
\end{aligned}$$

where $C_{\mathrm{x}} := k(\cdot, \boldsymbol{x}) \otimes k(\cdot, \boldsymbol{x})$. Expanding the right-hand side above transforms $J_{\boldsymbol{j}}^{\lambda}$ as

$$\begin{aligned} J_{\boldsymbol{j}}^{\lambda}(r_{\boldsymbol{j}}) &= 1 < r_{\boldsymbol{j}}, C r_{\boldsymbol{j}} >_{\mathcal{H}} - 2 1 < r_{\boldsymbol{j}}, C r_{\boldsymbol{j}}^* >_{\mathcal{H}} + 1 < r_{\boldsymbol{j}}^*, C r_{\boldsymbol{j}}^* >_{\mathcal{H}} + \lambda_{\boldsymbol{j}} 1 < r_{\boldsymbol{j}}, r_{\boldsymbol{j}} >_{\mathcal{H}} \\ &= 1 < r_{\boldsymbol{j}}, (C + \lambda_{\boldsymbol{j}} I) r_{\boldsymbol{j}} >_{\mathcal{H}} - 2 1 < r_{\boldsymbol{j}}, C r_{\boldsymbol{j}}^* >_{\mathcal{H}} + 1 < r_{\boldsymbol{j}}^*, C r_{\boldsymbol{j}}^* >_{\mathcal{H}} . \end{aligned} \tag{41}$$

For the second term in (41), we compute

$$\begin{aligned} 1 < r_{\boldsymbol{j}}, C r_{\boldsymbol{j}}^* >_{\mathcal{H}} &= 1 < r_{\boldsymbol{j}}, \int_{\mathcal{X}} k(\cdot, \boldsymbol{x}) r_{\boldsymbol{j}}^*(\boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} >_{\mathcal{H}} \\ &= 1 < r_{\boldsymbol{j}}, \int_{\mathcal{X}} k(\cdot, \boldsymbol{x}) \partial_{\boldsymbol{j}} p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} >_{\mathcal{H}} \\ &= 1 < r_{\boldsymbol{j}}, (-1)^{|\boldsymbol{j}|} \int_{\mathcal{X}} \partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} >_{\mathcal{H}} \\ &= 1 < r_{\boldsymbol{j}}, \xi_{\boldsymbol{j}} >_{\mathcal{H}}, \end{aligned} \tag{42}$$

where we applied Assumption **(C)**, and

$$\xi_{\boldsymbol{j}} = (-1)^{|\boldsymbol{j}|} \int_{\mathcal{X}} \partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}.$$

Comparing the left-hand side with the right-hand side at the last line in (42) gives

$$C r_{\boldsymbol{j}}^* = \xi_{\boldsymbol{j}}. \tag{43}$$

Eq.(43) is valid because (42) holds for arbitrary $r_{\boldsymbol{j}} \in \mathcal{H}$.

Simple calculation after substituting (42) into (41) provides

$$J_{\boldsymbol{j}}^{\lambda}(r_{\boldsymbol{j}}) = \|(C + \lambda_{\boldsymbol{j}} I)^{1/2} r_{\boldsymbol{j}} - (C + \lambda_{\boldsymbol{j}} I)^{-1/2} \xi_{\boldsymbol{j}}\|_{\mathcal{H}}^2 - 1 < \xi_{\boldsymbol{j}}, (C + \lambda_{\boldsymbol{j}} I)^{-1} \xi_{\boldsymbol{j}} >_{\mathcal{H}} + 1 < r_{\boldsymbol{j}}^*, C r_{\boldsymbol{j}}^* >_{\mathcal{H}},$$

Since the second and third terms in the right-hand side above do not include $r_{\boldsymbol{j}}$, the minimizer of $J_{\boldsymbol{j}}^{\lambda}(r_{\boldsymbol{j}})$ is given by $r_{\boldsymbol{j}}^{\lambda} = (C + \lambda_{\boldsymbol{j}} I)^{-1} \xi_{\boldsymbol{j}} = (C + \lambda_{\boldsymbol{j}} I)^{-1} C r_{\boldsymbol{j}}^*$ where (43) was applied.

(ii) It follows from (i) by substituting C and $\xi_{\boldsymbol{j}}$ with $\widehat{C}$ and $\widehat{\xi}_{\boldsymbol{j}}$, respectively. ■

A.2 Proof of Lemma 16

Proof We first compute the expectation of $\|\widehat{\xi}_{\boldsymbol{j}} - \widehat{C} r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2$ as

$$E\|\widehat{\xi}_{\boldsymbol{j}} - \widehat{C} r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2 = \frac{n-1}{n} \|\xi_{\boldsymbol{j}} - C r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2 + \frac{1}{n} \int_{\mathcal{X}} \|(-1)^{|\boldsymbol{j}|} \partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x}) + C_{\mathrm{x}} r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2 p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x}, \tag{44}$$

where $C_{\mathrm{x}} = k(\cdot, \boldsymbol{x}) \otimes k(\cdot, \boldsymbol{x})$. Eq.(43) indicates that the first term in the right-hand side of (44) vanishes, i.e., $\|\xi_{\boldsymbol{j}} - C r_{\boldsymbol{j}}^*\|_{\mathcal{H}} = 0$. From

$$\|(-1)^{|\boldsymbol{j}|} \partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x}) + C_{\mathrm{x}} r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2 \leq 2 \|\partial_{\boldsymbol{j}} k(\cdot, \boldsymbol{x})\|_{\mathcal{H}}^2 + 2 \|C_{\mathrm{x}}\|_{\mathrm{HS}}^2 \|r_{\boldsymbol{j}}^*\|_{\mathcal{H}}^2,$$

Assumption (D) with $\epsilon = 2$ ensures that the second term in the right-hand side of (44) is finite. Thus, applying the Chebyshev's inequality proves the lemma because $E(\widehat{\xi}_{\boldsymbol{j}} - \widehat{C} r_{\boldsymbol{j}}^*) = \xi_{\boldsymbol{j}} - C r_{\boldsymbol{j}}^* = 0$ from (43). ■

Appendix B. Connection to the Minimax Theory

This appendix provides details for the connections to the minimax theory discussed in the remark after Theorem 1. First, we introduce the following results:

- By the minimax theory (Tsybakov, 2009), Eq.(10) in Sriperumbudur et al. (2017) shows the minimax rate: For any $\alpha > \delta \geq 0$,

$$\inf_{\widehat{r}_{\boldsymbol{j},n}} \sup_{r_{\boldsymbol{j}}^* \in H_2^{\alpha}} \|\widehat{r}_{\boldsymbol{j},n} - r_{\boldsymbol{j}}^*\|_{H_2^{\delta}} \asymp n^{-\frac{\alpha-\delta}{2(\alpha-\delta)+D}}. \tag{45}$$

- The following proposition provides necessary conditions for $r_{\boldsymbol{j}}^* \in R(C)$:

Proposition 17 *Suppose that $\psi, \phi \in C(\mathbb{R}^D) \cap L^1(\mathbb{R}^D)$ are real-valued, shift-invariant and positive definite kernel functions. Let $\mathcal{H}$ and $\mathcal{G}$ be RKHSs associated with $\psi(\boldsymbol{x} - \boldsymbol{y})$ and $\phi(\boldsymbol{x} - \boldsymbol{y})$, respectively. For $2 \leq r \leq \infty$, assume that the followings hold,*

$$p \in L^{\frac{r}{r-1}}(\mathbb{R}^D), \quad \left\| \frac{\phi^{\wedge}}{\psi^{\wedge}} \right\|_{\infty} < \infty \quad \textit{and} \quad \left\| \frac{\psi^{\wedge 2}}{\phi^{\wedge}} \right\|_{\frac{r}{r-2}} < \infty.$$

Then, $r_{\boldsymbol{j}}^* \in R(C)$ implies that $r_{\boldsymbol{j}}^* \in \mathcal{G} \subset \mathcal{H}$, where $k(\boldsymbol{x}, \boldsymbol{y}) = \psi(\boldsymbol{x} - \boldsymbol{y})$ in the operator C.

The proof of Proposition 17 is deferred to Section B.1. The conditions are necessary ones for $r_{\boldsymbol{j}}^* \in R(C^{\beta})$ with $\beta > 1$ as well because $R(C^{\beta_1}) \subset R(C^{\beta_2})$ for $0 < \beta_1 < \beta_2 < \infty$ (Sriperumbudur et al., 2017, Section 4.2 and Appendix B.3).

Recall that when the *Matérn kernel*, $k(\boldsymbol{x}, \boldsymbol{y}) = \psi(\boldsymbol{x} - \boldsymbol{y}) = \frac{2^{1-s}}{\Gamma(s)} \|\boldsymbol{x} - \boldsymbol{y}\|^{s - D/2} \mathfrak{K}_{D/2-s}(\|\boldsymbol{x} - \boldsymbol{y}\|)$, is employed, the corresponding RKHS $\mathcal{H}$ is the Sobolev space H_2^s with $s > D/2$ (Wendland, 2004, Chapter 10):

$$\mathcal{H} = H_2^s := \left\{ f \in L^2(\mathbb{R}^D) \cap C(\mathbb{R}^D) : \int (1 + \|\boldsymbol{\omega}\|^2)^s |f^{\wedge}(\boldsymbol{\omega})|^2 \mathrm{d}\boldsymbol{\omega} < \infty \right\}.$$

Theorem 6.13 in Wendland (2004) gives the Fourier transform of ψ as

$$\psi^{\wedge}(\boldsymbol{\omega}) = (1 + \|\boldsymbol{\omega}\|^2)^{-s}.$$

When $p \in L^1(\mathbb{R}^D)$, applying Proposition 17 ensures that $r_{\boldsymbol{j}}^* \in R(C)$ implies $r_{\boldsymbol{j}}^* \in H_2^{s'} \subset H_2^s$ with $\frac{D}{2} < s \leq s' < 2s + \frac{1}{2} - \frac{D}{2}$. Thus, $r_{\boldsymbol{j}}^* \in H_2^{2s + \frac{1}{2} - \frac{D}{2} - \epsilon}$ for arbitrarily small $\epsilon > 0$. Then, if we chose $\mathcal{H} = H_2^{D - \frac{1}{2} + \epsilon}$, the rate $n^{-\frac{1}{4}}$ in Theorem 1 is minimax optimal (Set $\alpha = 2s + \frac{1}{2} - \frac{D}{2} - \epsilon$ and $\delta = s$ in (45), equate the exponent in the right-hand side of (45) with $-\frac{1}{4}$, and solve it with respect to s). Similar discussion is possible when $p \in L^2(\mathbb{R}^D)$: The rate is minimax optimal under the choice of $\mathcal{H} = H_2^{\frac{D}{2} + \epsilon}$.

B.1 Proof of Proposition 17

Here, we modify the proof of Proposition 8 in Sriperumbudur et al. (2017).

Proof To characterize RKHSs induced by shift-invariant kernels, we employ the following lemma:

Lemma 18 (Theorem 10.12 in Wendland (2004)) *Let $\psi(\boldsymbol{x}-\boldsymbol{y})$ be a real-valued, symmetric and positive definite kernel. When $\psi \in C(\mathbb{R}^D) \cap L^1(\mathbb{R}^D)$, it induces the following Hilbert space,*

$$\mathcal{H} := \left\{ f \in C(\mathbb{R}^D) \cap L^2(\mathbb{R}^D) : \frac{f^\wedge}{\sqrt{\psi^\wedge}} \in L^2(\mathbb{R}^D) \right\},$$

with the reproducing kernel $\psi(\boldsymbol{x}-\boldsymbol{y})$ and inner product,

$$\langle f, g \rangle_{\mathcal{H}} := \frac{1}{(2\pi)^{D/2}} \int \frac{f^\wedge(\boldsymbol{\omega})\overline{g^\wedge(\boldsymbol{\omega})}}{\psi^\wedge(\boldsymbol{\omega})} \mathrm{d}\boldsymbol{\omega}.$$

$\overline{g^\wedge(\boldsymbol{\omega})}$ above denotes the complex conjugate of $g^\wedge(\boldsymbol{\omega})$. In particular, every f in $\mathcal{H}$ can be recovered from its Fourier transform $f^\wedge \in L^1(\mathbb{R}^D) \cap L^2(\mathbb{R}^D)$ as

$$f(\boldsymbol{x}) = \frac{1}{(2\pi)^{D/2}} \int f^\wedge(\boldsymbol{\omega}) e^{i\boldsymbol{x}^\top \boldsymbol{\omega}} \mathrm{d}\boldsymbol{\omega}. \tag{46}$$

Let us express an RKHS $\mathcal{G}$ induced by another real-valued, symmetric and positive definite kernel $\phi(\boldsymbol{x}-\boldsymbol{y})$. We first show that $\mathcal{G} \subset \mathcal{H}$ if $\left\| \frac{\phi^\wedge(\boldsymbol{\omega})}{\psi^\wedge(\boldsymbol{\omega})} \right\|_\infty < \infty$. From Lemma 18, for $g \in \mathcal{G}$, the norm in $\mathcal{H}$ is computed as

$$\|g\|_{\mathcal{H}}^2 = \frac{1}{(2\pi)^{D/2}} \int \frac{|g^\wedge(\boldsymbol{\omega})|^2}{\psi^\wedge(\boldsymbol{\omega})} \mathrm{d}\boldsymbol{\omega} = \frac{1}{(2\pi)^{D/2}} \int \frac{|g^\wedge(\boldsymbol{\omega})|^2 \phi^\wedge(\boldsymbol{\omega})}{\phi^\wedge(\boldsymbol{\omega})\psi^\wedge(\boldsymbol{\omega})} \mathrm{d}\boldsymbol{\omega} \leq \|g\|_{\mathcal{G}}^2 \left\| \frac{\phi^\wedge(\boldsymbol{\omega})}{\psi^\wedge(\boldsymbol{\omega})} \right\|_\infty < \infty.$$

Thus, $g \in \mathcal{H}$, which indicates that $\mathcal{G} \subset \mathcal{H}$.

Next, we show that $r_{\boldsymbol{j}}^* \in R(C)$ indicates $r_{\boldsymbol{j}}^* \in \mathcal{G}$. Since $r_{\boldsymbol{j}}^* \in R(C)$, there exists $f \in \mathcal{H}$ such that $r_{\boldsymbol{j}}^* = Cf$, i.e.,

$$\begin{aligned}
r_{\boldsymbol{j}}^*(\boldsymbol{y}) &= \int k(\boldsymbol{x}, \boldsymbol{y}) f(\boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int \psi(\boldsymbol{x}-\boldsymbol{y}) f(\boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int \left[\frac{1}{(2\pi)^{D/2}} \int \psi^\wedge(\boldsymbol{\omega}) e^{i(\boldsymbol{x}-\boldsymbol{y})^\top \boldsymbol{\omega}} \mathrm{d}\boldsymbol{\omega} \right] f(\boldsymbol{x}) p(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \\
&= \int \left[\frac{1}{(2\pi)^{D/2}} \int f(\boldsymbol{x}) p(\boldsymbol{x}) e^{i\boldsymbol{x}^\top \boldsymbol{\omega}} \mathrm{d}\boldsymbol{x} \right] \psi^\wedge(\boldsymbol{\omega}) e^{-i\boldsymbol{y}^\top \boldsymbol{\omega}} \mathrm{d}\boldsymbol{\omega} \\
&= \int (f^\wedge * p^\wedge)(-\boldsymbol{\omega}) \psi^\wedge(\boldsymbol{\omega}) e^{-i\boldsymbol{y}^\top \boldsymbol{\omega}} \mathrm{d}\boldsymbol{\omega},
\end{aligned} \tag{47}$$

where we applied (46) to $\psi(\boldsymbol{x}-\boldsymbol{y})$ on the third line and Fubini's theorem on the fourth line, and $*$ denotes the convolution such that

$$(f * p)(\boldsymbol{x}) := \int f(\boldsymbol{y}) p(\boldsymbol{x}-\boldsymbol{y}) \mathrm{d}\boldsymbol{y}.$$

Eq.(47) indicates that the Fourier transform of $r_{\boldsymbol{j}}^*$ is given by

$$r_{\boldsymbol{j}}^{*\wedge}(\boldsymbol{\omega}) = (f^\wedge * p^\wedge)(-\boldsymbol{\omega}) \psi^\wedge(\boldsymbol{\omega}).$$

Computing the norm of $r_{\boldsymbol{j}}^*$ in $\mathcal{G}$ yields

$$\|r_{\boldsymbol{j}}^*\|_{\mathcal{G}}^2 = \int |(f^\wedge * p^\wedge)(-\boldsymbol{\omega})|^2 \frac{\psi^\wedge(\boldsymbol{\omega})^2}{\phi^\wedge(\boldsymbol{\omega})} \mathrm{d}\boldsymbol{\omega} \leq \|(f^\wedge * p^\wedge)^2\|_{r/2} \left\| \frac{\psi^{\wedge 2}}{\phi^\wedge} \right\|_{\frac{r}{r-2}} = \|f^\wedge * p^\wedge\|_r^2 \left\| \frac{\psi^{\wedge 2}}{\phi^\wedge} \right\|_{\frac{r}{r-2}},$$

where Hölder inequality was applied with $2 \leq r \leq \infty$. Then, Young's convolution and Hausdorff-Young inequalities (Beckner, 1975) yield

$$\|f^\wedge * p^\wedge\|_r \leq \|f^\wedge\|_1 \cdot \|p^\wedge\|_r \leq \|f^\wedge\|_1 \cdot \|p\|_{\frac{r}{r-1}} < \infty$$

Thus, by Lemma 18, $r_{\boldsymbol{j}}^* \in R(C)$ indicates $r_{\boldsymbol{j}}^* \in \mathcal{G}$. ■

Appendix C. Proof of Theorem 3

Proof Suppose that $\widehat{\alpha}_j^{(i)} = 0$ and $\widetilde{\beta}_j^{(i)} \left(= -\widehat{\beta}_j^{(i)} \right) \geq 0$ for all i and j. Computing the integral in (18) shows that

$$\begin{aligned}
\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}] &= \sum_{j=1}^D \int_{y^{(j)}}^{x^{(j)}} \widehat{g}_j(x^{(1)}, \ldots, x^{(j-1)}, z^{(j)}, y^{(j+1)}, \ldots, y^{(D)}) \mathrm{d}z^{(j)} \\
&= \sum_{j=1}^D \sum_{i=1}^n \widetilde{\beta}_j^{(i)} \left[\phi\left(\frac{\|\boldsymbol{z}_x^j - \boldsymbol{x}_i\|^2}{2\sigma_j^2} \right) - \phi\left(\frac{\|\boldsymbol{z}_y^j - \boldsymbol{x}_i\|^2}{2\sigma_j^2} \right) \right],
\end{aligned} \tag{48}$$

where we used the relation $\partial_j' \phi\left(\|\boldsymbol{x}-\boldsymbol{x}'\|^2\right) = -\partial_j \phi\left(\|\boldsymbol{x}-\boldsymbol{x}'\|^2\right)$, and

$$\begin{aligned}
\boldsymbol{z}_y^j &= (x^{(1)}, \ldots, x^{(j-1)}, y^{(j)}, y^{(j+1)}, \ldots, y^{(D)})^\top \\
\boldsymbol{z}_x^j &= (x^{(1)}, \ldots, x^{(j-1)}, x^{(j)}, y^{(j+1)}, \ldots, y^{(D)})^\top.
\end{aligned} \tag{49}$$

Note that the j-th elements in $\boldsymbol{z}_y^j$ and $\boldsymbol{z}_x^j$ only differ. To ensure that the right-hand side in (48) is non-negative, we need to show that for all j,

$$\sum_{i=1}^n \widetilde{\beta}_j^{(i)} \left[\phi\left(\frac{\|\boldsymbol{z}_x^j - \boldsymbol{x}_i\|^2}{2\sigma_j^2} \right) - \phi\left(\frac{\|\boldsymbol{z}_y^j - \boldsymbol{x}_i\|^2}{2\sigma_j^2} \right) \right] \geq 0. \tag{50}$$

To obtain a lower bound of the left-hand side in (50), we use the following inequality, which comes from the convexity of ϕ:

$$\phi\left(\frac{\|\boldsymbol{z}_x^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)-\phi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right) \geq \frac{1}{2\sigma_j^2}\varphi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\left[(y^{(j)}-x_i^{(j)})^2-(x^{(j)}-x_i^{(j)})^2\right]. \tag{51}$$

Since all $\widetilde{\beta}_j^{(i)}$ are assumed to be non-negative, (51) provides

$$\begin{aligned}
&\sum_{i=1}^n \widetilde{\beta}_j^{(i)}\left[\phi\left(\frac{\|\boldsymbol{z}_x^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)-\phi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\right]\\
&\geq \frac{1}{2\sigma_j^2}\sum_{i=1}^n \widetilde{\beta}_j^{(i)}\varphi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\left[(y^{(j)}-x_i^{(j)})^2-(x^{(j)}-x_i^{(j)})^2\right]\\
&= \frac{1}{2\sigma_j^2}\sum_{i=1}^n \widetilde{\beta}_j^{(i)}\varphi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)\left[(y^{(j)})^2-(x^{(j)})^2\right]-\underbrace{\sum_{i=1}^n \widetilde{\beta}_j^{(i)}x_i^{(j)}\varphi\left(\frac{\|\boldsymbol{z}_y^j-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)}_{(\star)}\frac{(y^{(j)}-x^{(j)})}{\sigma_j^2}.
\end{aligned} \tag{52}$$

Finally, we set $\boldsymbol{y}=\boldsymbol{z}_k^\tau$ and $\boldsymbol{x}=\boldsymbol{z}_k^{\tau+1}$ in $\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}]$, and therefore

$$\begin{aligned}
\boldsymbol{z}_y^j &= (z_k^{(\tau+1,1)},\ldots,z_k^{(\tau+1,j-1)},z_k^{(\tau,j)},z_k^{(\tau,j+1)},\ldots,z_k^{(\tau,D)})^\top=\tilde{\boldsymbol{z}}_k^\tau\\
\boldsymbol{z}_x^j &= (z_k^{(\tau+1,1)},\ldots,z_k^{(\tau+1,j-1)},z_k^{(\tau+1,j)},z_k^{(\tau+1,j+1)},\ldots,z_k^{(\tau,D)})^\top.
\end{aligned}$$

Applying the coordinate-wise update rule (15) to $(\star)$, the right-hand side in (52) becomes

$$\frac{1}{2\sigma_j^2}\sum_{i=1}^n \widetilde{\beta}_j^{(i)}\varphi\left(\frac{\|\tilde{\boldsymbol{z}}_k^\tau-\boldsymbol{x}_i\|^2}{2\sigma_j^2}\right)(z_k^{(\tau,j)}-z_k^{(\tau+1,j)})^2\geq 0.$$

This proves (50), and thus the proof was completed. ■

Appendix D. Proof of Theorem 7

Proof Under the path (17),

$$D_{\boldsymbol{g}}[\boldsymbol{x}|\boldsymbol{y}]-\widehat{D}_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}]=\sum_{j=1}^D\int_{j-1}^j {}_1<\boldsymbol{g}(\boldsymbol{\gamma}_j(t))-\widehat{\boldsymbol{g}}(\boldsymbol{\gamma}_j(t)),\dot{\boldsymbol{\gamma}}_j(t)>\mathrm{d}t$$

where the curve $\boldsymbol{\gamma}_j(t)$, $t\in[j-1,j]$ connects $\boldsymbol{z}_y^j$ and $\boldsymbol{z}_x^j$ by the line segment whose definition is given in (49). Then, we obtain

$$\left|\int_{j-1}^j {}_1<\boldsymbol{g}(\boldsymbol{\gamma}_j(t))-\widehat{\boldsymbol{g}}(\boldsymbol{\gamma}_j(t)),\dot{\boldsymbol{\gamma}}_j(t)>\mathrm{d}t\right|\leq\|\boldsymbol{g}-\widehat{\boldsymbol{g}}\|_\infty|y^{(j)}-x^{(j)}|.$$

Therefore,

$$|D_{\boldsymbol{g}}[\boldsymbol{x}|\boldsymbol{y}]-D_{\widehat{\boldsymbol{g}}}[\boldsymbol{x}|\boldsymbol{y}]|\leq\|\boldsymbol{g}-\widehat{\boldsymbol{g}}\|_\infty\|\boldsymbol{y}-\boldsymbol{x}\|_1.$$

Finally, with Lemma 12, the theorem was proved. ■

Appendix E. Proof of Theorem 9

We modify the proof of Theorem 1 in Chen et al. (2016b), and apply Lemma 12.

Proof Suppose that a mode point $\boldsymbol{\mu}_j\in\mathcal{M}$ is uniquely approximated by an estimated mode point $\widehat{\boldsymbol{\mu}}_j\in\widehat{\mathcal{M}}$. Then, the Taylor expansion gives

$$\begin{aligned}
\widehat{\boldsymbol{g}}(\boldsymbol{\mu}_j) &= \widehat{\boldsymbol{g}}(\widehat{\boldsymbol{\mu}}_j)+\nabla\widehat{\boldsymbol{g}}(\boldsymbol{\mu}_j)(\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j)+o(\|\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j\|)\\
&= \nabla\widehat{\boldsymbol{g}}(\boldsymbol{\mu}_j)(\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j)+o(\|\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j\|),
\end{aligned} \tag{53}$$

where $\widehat{\boldsymbol{g}}(\widehat{\boldsymbol{\mu}}_j)=\boldsymbol{0}$. On the other hand, from Lemma 12,

$$\widehat{g}_j(\boldsymbol{\mu}_j)=\widehat{g}_j(\boldsymbol{\mu}_j)-g_j(\boldsymbol{\mu}_j)=O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4},\frac{\gamma}{2(\gamma+1)}\right\}}\right), \tag{54}$$

where $g_j(\boldsymbol{\mu}_j)=0$. Since all eigenvalues of $\nabla\boldsymbol{g}(\boldsymbol{\mu}_j)$ are strictly negative by the definition in (20), the following relation and Lemma 12 ensures that $\nabla\widehat{\boldsymbol{g}}(\boldsymbol{\mu}_j)$ is invertible with a high probability: By the derivative reproducing property (Zhou, 2008),

$$|\partial_i g_j(\boldsymbol{x})-\partial_i\widehat{g}_j(\boldsymbol{x})|=|\langle g_j-\widehat{g}_j,\partial_i k(\boldsymbol{x},\cdot)\rangle_{\mathcal{H}}|\leq\|g_j-\widehat{g}_j\|_{\mathcal{H}}|\partial_i'\partial_i k(\boldsymbol{x}',\boldsymbol{x})|_{\boldsymbol{x}'=\boldsymbol{x}}|=O\left(\|g_j-\widehat{g}_j\|_{\mathcal{H}}\right),$$

where the Cauchy-Schwarz inequality was applied, ∂_i' denotes the partial derivative with respect to the i-th element in $\boldsymbol{x}'$, and $\partial_i'\partial_i k$ is assumed to be uniformly bounded. Thus, combining (53) with (54) yields

$$\|\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j\|=O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4},\frac{\gamma}{2(\gamma+1)}\right\}}\right).$$

The fact,

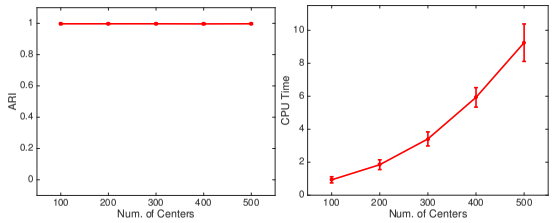
$$\mathrm{Haus}(\widehat{\mathcal{M}},\mathcal{M})=\max_j\|\boldsymbol{\mu}_j-\widehat{\boldsymbol{\mu}}_j\|,$$

proves the theorem. ■

Appendix F. Reducing the Kernel Centers

This appendix investigates clustering performance and computational costs of LSLDGC when the number of kernel centers is changed. We performed similar experiments in Section 5.1. In the experiments, datasets with the three Gaussian blobs (Fig.6(g)) were used.

Fig.11 shows that LSLDGC with a small number of kernel centers significantly reduces the computation costs without scarifying the clustering performance.



(a) ARI (b) CPU time

Figure 11: Clustering performance and CPU time against the number of kernel centers. Each point and error bar denote the average and standard deviation of (a) ARI and (b) CPU time over 50 runs, respectively. The dataset used in this figure is the three Gaussian blobs in Section 5.1 when $(D, n) = (5, 500)$

Appendix G. Proof of Lemma 12

Proof For ϵ', the Cauchy-Schwarz inequality gives

$$|\widehat{g}_j(\boldsymbol{x}) - g_j(\boldsymbol{x})| = |\langle \widehat{g}_j - g_j, k(\cdot, \boldsymbol{x})\rangle_{\mathcal{H}}| \leq \|\widehat{g}_j - g_j\|_{\mathcal{H}} |k(\boldsymbol{x}, \boldsymbol{x})|.$$

Since $k(\boldsymbol{x}, \boldsymbol{x})$ is assumed to be finite,

$$\epsilon' = \max_j \|\widehat{g}_j(\boldsymbol{x}) - g_j(\boldsymbol{x})\|_\infty \leq O\left(\|\widehat{g}_j - g_j\|_{\mathcal{H}}\right) = O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right), \tag{55}$$

where we applied Theorem 1.

For ϵ'', similar computation yields

$$\begin{aligned}
&|[\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x})]_{ij} - [\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})]_{ij}| \\
&= |-(\widehat{g}_i(\boldsymbol{x})\widehat{g}_j(\boldsymbol{x}) - g_i(\boldsymbol{x})g_j(\boldsymbol{x})) + [\widehat{\boldsymbol{H}}(\boldsymbol{x})]_{ij} - [\boldsymbol{H}(\boldsymbol{x})]_{ij}| \\
&\leq |\widehat{g}_i(\boldsymbol{x})\widehat{g}_j(\boldsymbol{x}) - g_i(\boldsymbol{x})g_j(\boldsymbol{x})| + |[\widehat{\boldsymbol{H}}(\boldsymbol{x})]_{ij} - [\boldsymbol{H}(\boldsymbol{x})]_{ij}| \\
&\leq |\widehat{g}_i(\boldsymbol{x})| \cdot |\widehat{g}_j(\boldsymbol{x}) - g_j(\boldsymbol{x})| + |g_j(\boldsymbol{x})| \cdot |\widehat{g}_i(\boldsymbol{x}) - g_i(\boldsymbol{x})| + |[\widehat{\boldsymbol{H}}(\boldsymbol{x})]_{ij} - [\boldsymbol{H}(\boldsymbol{x})]_{ij}| \\
&\leq \left\{|g_i(\boldsymbol{x})| \cdot \|\widehat{g}_j - g_j\|_{\mathcal{H}} + |\widehat{g}_j(\boldsymbol{x})| \cdot \|\widehat{g}_i - g_i\|_{\mathcal{H}} + \|[\widehat{\boldsymbol{H}}]_{ij} - [\boldsymbol{H}]_{ij}\|_{\mathcal{H}}\right\} |k(\boldsymbol{x}, \boldsymbol{x})|,
\end{aligned}$$

where we applied the following inequality on the fourth line:

$$\begin{aligned}
|\widehat{g}_i(\boldsymbol{x})\widehat{g}_j(\boldsymbol{x}) - g_i(\boldsymbol{x})g_j(\boldsymbol{x})| &= |\widehat{g}_i(\boldsymbol{x})\widehat{g}_j(\boldsymbol{x}) - \widehat{g}_i(\boldsymbol{x})g_j(\boldsymbol{x}) + \widehat{g}_i(\boldsymbol{x})g_j(\boldsymbol{x}) - g_i(\boldsymbol{x})g_j(\boldsymbol{x})| \\
&= |\widehat{g}_i(\boldsymbol{x})(\widehat{g}_j(\boldsymbol{x}) - g_j(\boldsymbol{x})) + g_j(\boldsymbol{x})(\widehat{g}_i(\boldsymbol{x}) - g_i(\boldsymbol{x}))| \\
&\leq |\widehat{g}_i(\boldsymbol{x})| \cdot |\widehat{g}_j(\boldsymbol{x}) - g_j(\boldsymbol{x})| + |g_j(\boldsymbol{x})| \cdot |\widehat{g}_i(\boldsymbol{x}) - g_i(\boldsymbol{x})|.
\end{aligned}$$

Thus, we obtain

$$\begin{aligned}
\epsilon'' &= \max_{ij} \max_{\boldsymbol{x}} |[\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x})]_{ij} - [\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})]_{ij}| \\
&\leq \max_{ij} O\left(\max(\|\widehat{g}_j - g_j\|_{\mathcal{H}}, \|\widehat{g}_i - g_i\|_{\mathcal{H}}, \|[\widehat{\boldsymbol{H}}]_{ij} - [\boldsymbol{H}]_{ij}\|_{\mathcal{H}})\right) \\
&= O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right),
\end{aligned} \tag{56}$$

where it follows from Theorem 1.

For ϵ''', we resort to the derivative reproducing property proved in Zhou (2008): For all $f \in \mathcal{H}$,

$$\partial_j f(\boldsymbol{x}) = {}_1 < f, \partial_j k(\cdot, \boldsymbol{x}) >_{\mathcal{H}}.$$

Using this relation, we obtain

$$\begin{aligned}
|[\widehat{\boldsymbol{\Sigma}}^{-1\prime}(\boldsymbol{x})]_{ij} - [\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})]_{ij}| &= |\partial_j[\mathrm{vec}(\widehat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x}))]_i - \partial_j[\mathrm{vec}(\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}))]_i| \\
&= |\langle [\mathrm{vec}(\widehat{\boldsymbol{\Sigma}}^{-1})]_i - [\mathrm{vec}(\boldsymbol{\Sigma}^{-1})]_i, \partial_j k(\cdot, \boldsymbol{x})\rangle_{\mathcal{H}}| \\
&\leq \|\mathrm{vec}(\widehat{\boldsymbol{\Sigma}}^{-1})]_i - [\mathrm{vec}(\boldsymbol{\Sigma}^{-1})]_i\|_{\mathcal{H}} |\partial'_i \partial_i k(\boldsymbol{x}', \boldsymbol{x})|_{\boldsymbol{x}'=\boldsymbol{x}}|,
\end{aligned}$$

where ∂'_j denote the derivative with respect to the j-th coordinate in $\boldsymbol{x}'$. Since $|\partial'_j \partial_j k|$ is assumed to be finite, (56) provides

$$\begin{aligned}
\epsilon''' &= \max_{ij} \max_{\boldsymbol{x}} |[\widehat{\boldsymbol{\Sigma}}^{-1\prime}(\boldsymbol{x})]_{ij} - [\boldsymbol{\Sigma}^{-1\prime}(\boldsymbol{x})]_{ij}| \\
&\leq \max_i O\left(\|[\mathrm{vec}(\widehat{\boldsymbol{\Sigma}}^{-1})]_i - [\mathrm{vec}(\boldsymbol{\Sigma}^{-1})]_i\|_{\mathcal{H}}\right) \\
&= O_{\mathrm{P}}\left(n^{-\min\left\{\frac{1}{4}, \frac{\gamma}{2(\gamma+1)}\right\}}\right),
\end{aligned}$$

where the last equation comes from (56) because $[\mathrm{vec}(\boldsymbol{\Sigma}^{-1})(\boldsymbol{x})]_i$ denotes a single element in $\boldsymbol{\Sigma}^{-1}(\boldsymbol{x})$. ■

Abstract

The number of trees T in the random forest (RF) algorithm for supervised learning has to be set by the user. It is unclear whether T should simply be set to the largest computationally manageable value or whether a smaller T may be sufficient or in some cases even better. While the principle underlying bagging is that more trees are better, in practice the classification error rate sometimes reaches a minimum before increasing again for increasing number of trees. The goal of this paper is four-fold: (i) providing theoretical results showing that the expected error rate may be a non-monotonous function of the number of trees and explaining under which circumstances this happens; (ii) providing theoretical results showing that such non-monotonous patterns cannot be observed for other performance measures such as the Brier score and the logarithmic loss (for classification) and the mean squared error (for regression); (iii) illustrating the extent of the problem through an application to a large number (n = 306) of datasets from the public database OpenML; (iv) finally arguing in favor of setting T to a computationally feasible large number as long as classical error measures based on average loss are considered.

Keywords: Random forest, number of trees, bagging, out-of-bag, error rate

1. Introduction

The random forest (RF) algorithm for classification and regression, which is based on the aggregation of a large number T of decision trees, was first described in its entirety by Breiman (2001). T is one of several important parameters which have to be carefully chosen by the user. Some of these parameters are *tuning parameters* in the sense that both too high and too low parameter values yield sub-optimal performances; see Segal (2004) for an early study on the effect of such parameters. It is unclear, however, whether the number of trees T should simply be set to the largest computationally manageable value or whether a smaller T may be sufficient or in some cases even better, in which case T should ideally be tuned carefully. This question is relevant to any user of RF and has been the topic of much informal discussion in the scientific community, but has to our knowledge never been addressed systematically from a theoretical and empirical point of view.

Breiman (2001) provides proofs of convergence for the generalization error in the case of classification random forest for growing number of trees. This means that the error rate for a given test or training dataset converges to a certain value. Moreover, Breiman (2001) proves that there exists an upper bound for the generalization error. Similarly he proves the convergence of the mean squared generalization error for regression random forests and also provides an upper bound. However, these results do not answer the question of whether the number of trees is a tuning parameter or should be set as high as computationally feasible, although convergence properties may at first view be seen as an argument in favor of a high number of trees. Breiman (1996a) and Friedman (1997) note that bagging and aggregation methods can make good predictors better but poor predictors can be transformed into worse. Hastie et al. (2001) show in a simple example that for a single observation that is incorrectly classified (in the binary case), bagging can worsen the expected missclassification rate. In Section 3.1 we will further analyse this issue and examine the outcome of aggregating performances for several observations.

Since each tree is trained individually and without knowledge of previously trained trees, however, the risk of overfitting when adding more trees discussed by Friedman (2001) in the case of boosting is not relevant here.

The number of trees is sometimes considered as a tuning parameter in current literature (Raghu et al., 2015); see also Barman et al. (2014) for a study in which different random seeds are tested to obtain better forests—a strategy implicitly assuming that a random forest with few trees may be better than a random forest with many trees. The R package `RFmarkerDetector` (Palla and Armano, 2016) even provides a function, 'tuneNTREE', to tune the number of trees. Of note, the question of whether a smaller number of trees may be better has often been discussed in online forums (see Supplementary File 1 for a non-exhaustive list of links) and seems to remain a confusing issue to date, especially for beginners.

A related but different question is whether a smaller number of trees is *sufficient* (as opposed to "better") in the sense that more trees do not improve accuracy. This question is examined, for example, in the very early study by Latinne et al. (2001) or by Hernández-Lobato et al. (2013). Another important contribution to that question is the study by Oshiro et al. (2012), which compared the performance in terms of the Area Under the ROC Curve (AUC) of random forests with different numbers of trees on 29 datasets. Their main conclusion is that the performance of the forest does not always substantially improve as the number of trees grows and after having trained a certain number of trees (in their case 128) the AUC performance gain obtained by adding more trees is minimal. The study of Oshiro et al. (2012) provides important empirical support for the existence of a "plateau", but does not directly address the question of whether a smaller number of trees may be substantially better and does not investigate this issue from a theoretical perspective, thus making the conclusions dependent on the 29 examined datasets.

In this context, the goal of our paper is four-fold: (i) providing theoretical results showing that, in the case of binary classification, the expected error rate may be a non-monotonous function of the number of trees and explaining under which circumstances this happens; (ii) providing theoretical results showing that such non-monotonous patterns cannot be observed for other performance measures such as the Brier score and the logarithmic loss (for classification) and the mean squared error (for regression); (iii) illustrating the extent of the problem through an application to a large number (n = 306) of datasets from the public database OpenML; (iv) finally arguing in favor of setting it to a computationally feasible

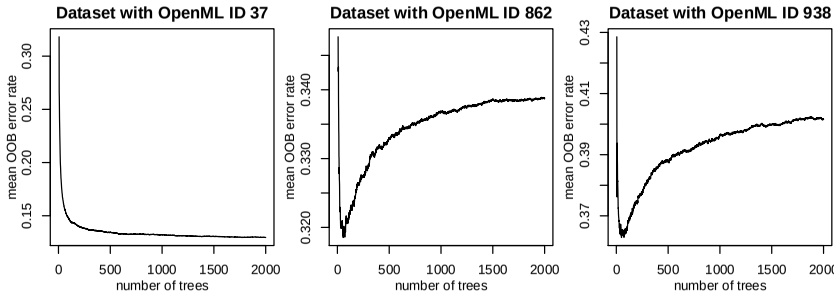

Figure 1: Mean OOB error rate curves for OpenML datasets with IDs 37, 862 and 938. The curves are averaged over 1000 independent runs of random forest.

large number as long as classical error measures based on average loss are considered. Furthermore, we introduce our new R package `OOBCurve`, which can be used to examine the convergence of various performance measures.

To set the scene, we first address this issue empirically by looking at the curve depicting the out-of-bag (OOB) error rate (see Section 2 for a definition of the OOB error) for different number of trees (also called OOB error rate curve) for various datasets from the OpenML database (Vanschoren et al., 2013). To obtain more stable results and better estimations for the expected error rate we repeat this procedure 1000 times for each dataset and average the results.

For most datasets we observe monotonously decreasing curves with growing number of trees as in the left panel of Figure 1, while others yield strange non-monotonous patterns, for example the curves of the datasets with the OpenML ID 862 and 938, which are also depicted in Figure 1. The initial error rate drops steeply before starting to increase after a certain number of trees before finally reaching a plateau.

At first view, such non-monotonous patterns are a clear argument in favor of tuning T. We claim, however, that it is important to understand why and in which circumstances such patterns happen in order to decide whether or not T should be tuned in general. In Section 3, we address this issue from a theoretical point of view, by formulating the expected error rate as a function of the probabilities ε_i of correct classification by a single tree for each observation i of the training dataset, for $i = 1, \ldots, n$ (with n denoting the size of the training dataset). This theoretical view provides a clear explanation of the non-monotonous error rate curve patterns in the case of classification. With a similar approach, we show that such non-monotonous patterns cannot be obtained with the Brier score or the logarithmic loss as performance measures, which are based on probability estimations and also not for the mean squared error in the case of regression. Only for the AUC we can see non-monotonous curves as well.

The rest of this paper is structured as follows. Section 2 gives a brief introduction into random forest and performance estimation. Theoretical results are presented in Section 3, while the results of a large empirical study based on 306 datasets from the public database OpenML are reported in Section 4. More precisely, we empirically validate our theoretical model for the error as a function of the number of trees as well as our statements regarding the properties of datasets yielding non-monotonous patterns. We finally argue in Section 5 that there is no inconvenience—except additional computational cost—in adding trees to a random forest and that T should thus not be seen as a tuning parameter as long as classical performance measures based on the average loss are considered.

2. Background: Random Forest and Measures of Performance

In this section we introduce the random forest method, the general notation and some well known performance measures.

2.1 Random Forest

The random forest (RF) is an ensemble learning technique consisting of the aggregation of a large number T of decision trees, resulting in a reduction of variance compared to the single decision trees. In this paper we consider the original version of RF first described by Breiman (2001), while acknowledging that other variants exist, for example RF based on conditional inference trees (Hothorn et al., 2006) which address the problem of variable selection bias investigated by Strobl et al. (2007). Our considerations are however generalizable to many of the available RF variants and other methods that use randomization techniques.

A prediction is obtained for a new observation by aggregating the predictions made by the T single trees. In the case of regression RF, the most straightforward and common procedure consists of averaging the prediction of the single trees, while majority voting is usually applied to aggregate classification trees. This means that the new observation is assigned to the class that was most often predicted by the T trees.

While RF can be used for various types of response variables including censored survival times or (as empirically investigated in Section 4) multicategorical variables, in this paper we mainly focus on the two most common cases, binary classification and regression.

2.2 General Notations

From now on, we consider a fixed training dataset D consisting of n observations, which is used to derive prediction rules by applying the RF algorithm with a number T of trees. Ideally, the performance of these prediction rules is estimated based on an independent test dataset, denoted as D_{test}, consisting of n_{test} test observations.

Considering the ith observation from the test dataset ($i = 1, \ldots, n_{test}$), we denote its true response as y_i, which can be either a numeric value (in the case of regression) or the binary label 0 vs. 1 (in the case of binary classification). The predicted value output by tree t (with $t = 1, \ldots, T$) is denoted as $\hat{y}_{it}$, while $\hat{y}_i$ stands for the predicted value output by the whole random forest. Note that, in the case of regression, $\hat{y}_i$ is usually obtained by

averaging as

$$\hat{y}_i = \frac{1}{T}\sum_{t=1}^{T} \hat{y}_{it}.$$

In the case of classification, $\hat{y}_i$ is usually obtained by majority voting. For binary classification, it is equivalent to computing the same average as for regression, which now takes the form

$$\hat{p}_i = \frac{1}{T}\sum_{t=1}^{T} I(\hat{y}_{it} = 1)$$

and is denoted as $\hat{p}_i$ (standing for probability), and finally deriving $\hat{y}_i$ as

$$\hat{y}_i = \begin{cases} 1 & \text{if } \hat{p}_i > 0.5, \\ 0 & \text{otherwise.} \end{cases}$$

2.3 Measures of Perfomance for Binary Classification and Regression

In regression as well as in classification, the performance of a RF for observation i is usually quantified through a so-called loss function measuring the discrepancy between the true response y_i and the predicted response $\hat{y}_i$ or, in the case of binary classification, between y_i and $\hat{p}_i$. For both regression and binary classification, the classical and most straightforward measure is defined for observation i as

$$e_i \;=\; (y_i - \hat{y}_i)^2 \;=\; L(y_i, \hat{y}_i),$$

with $L(.,.)$ standing for the loss function $L(x, y) = (x - y)^2$. In the case of regression this is simply the squared error. Another common loss function in the regression case is the absolute loss $L(x, y) = |x - y|$. For binary classification both measures simplify to $e_i = 0$ if observation i is classified correctly by the RF, $e_i = 1$ otherwise, which we will simply denote as *error* from now on. One can also consider the performance of single trees, that means the discrepancy between y_i and $\hat{y}_{it}$. We define e_{it} as

$$e_{it} = L(y_i, \hat{y}_{it}) = (y_i - \hat{y}_{it})^2$$

and the mean error—a quantity we need to derive our theoretical results on the dependence of performance measures on the number of tree T—as

$$\varepsilon_i = E(e_{it}),$$

where the expectation is taken over the possible trees conditionally on D. The term ε_i can be interpreted as the difficulty to predict y_i with single trees. In the case of binary classification, we have $(y_i - \hat{y}_{it})^2 = |y_i - \hat{y}_{it}|$ and ε_i can be simply estimated as $|y_i - \hat{p}_i|$ from a RF with a large number of trees.

In the case of binary classification, it is also common to quantify performance through the use of the Brier score, which has the form

$$b_i \;=\; (y_i - \hat{p}_i)^2 = L(y_i, \hat{p}_i)$$

or of the logarithmic loss

$$l_i \;=\; -(y_i \ln(\hat{p}_i) + (1 - y_i)\ln(1 - \hat{p}_i)).$$

Both of them are based on $\hat{p}_i$ rather than $\hat{y}_i$, and can thus be only defined for the whole RF and not for single trees.

The area under the ROC curve (AUC) cannot be expressed in terms of single observations, as it takes into account all observations at once by ranking the $\hat{p}_i$-values. It can be interpreted as the probability that the classifier ranks a randomly chosen observation with $y_i = 1$ higher than a randomly chosen observation with $y_i = 0$. The larger the AUC, the better the discrimination between the two classes. The (empirical) AUC is defined as

$$\text{AUC} = \frac{\sum_{i=1}^{n_1}\sum_{j=1}^{n_2} S(\hat{p}_i^{\star}, \hat{p}_j^{\star\star})}{n_1 n_2},$$

where $\hat{p}_1^{\star}, ..., \hat{p}_{n_1}^{\star}$ are probability estimations for the n_1 observations with $y_i = 1$, $\hat{p}_1^{\star\star}, ..., \hat{p}_{n_2}^{\star\star}$ are probability estimations for the n_2 observations with $y_i = 0$ and $S(.,.)$ is defined as $S(p, q) = 0$ if $p < q$, $S(p, q) = 0.5$ if $p = q$ and $S(p, q) = 1$ if $p > q$. The AUC can also be interpreted as the Mann-Whitney U-Statistic divided by the product of n_1 and n_2.

2.4 Measures for Multiclass Classification

The measures defined in the previous section can be extended to the multiclass classification case. Let K denote the number of classes ($K > 2$). The response y_i takes values in $\{1, ..., K\}$. The error for observation i is then defined as

$$e_i = I(y_i \neq \hat{y}_i).$$

We denote the estimated probability of class k for observation i as

$$\hat{p}_{ik} = \frac{1}{T}\sum_{t=1}^{T} I(\hat{y}_{it} = k).$$

The logarithmic loss is then defined as

$$l_i = \sum_{k=1}^{K} -I(y_i = k)\log(\hat{p}_{ik})$$

and the generalized Brier score is defined as

$$b_i = \sum_{k=1}^{K} (\hat{p}_{ik} - I(y_i = k))^2,$$

which in the binary case is twice the value of the definition that was used in the previous section. Following Hand and Till (2001), the AUC can also be generalized to the multiclass case as

$$\text{AUC} = \frac{1}{K(K-1)}\sum_{j=1}^{K}\sum_{\substack{k=1 \\ k\neq j}}^{K} \text{AUC}(j, k),$$

where $\text{AUC}(j, k)$ is the AUC between class k and j, see also Ferri et al. (2009) for more details. It is equivalent to the definition given in Section 2.3 in the binary classification case.

2.5 Test Dataset Error vs. Out-of-Bag Error

In the cases where a test dataset D_{test} is available, performance can be assessed by averaging the chosen performance measure (as described in the previous paragraphs) over the n_{test} observations. For example the classical error rate (for binary classification) and the mean squared error (for regression) are computed as

$$\frac{1}{n_{test}} \sum_{i=1}^{n_{test}} L(y_i, \hat{y}_i),$$

with $L(x, y) = (x-y)^2$, while the mean absolute error (for regression) is obtained by defining $L(.,.)$ as $L(x, y) = |x - y|$. Note that, in the context of regression, Rousseeuw (1984) proposes to consider the median $med\,(L(y_1, \hat{y}_1), ..., L(y_{n_{test}}, \hat{y}_{n_{test}}))$, instead of averaging, which results in the median squared error for the loss function $L(x, y) = (x - y)^2$ and in the median absolute error for the loss function $L(x, y) = |x - y|$. These measures are more robust against outliers and contamination (Rousseeuw, 1984).

An alternative to the use of a test dataset is the out-of-bag error which is calculated by using the out-of-bag (OOB) estimations of the training observations. OOB predictions are calculated by predicting the class, the probability (in the classification case) or the real value (in the regression case) for each training observation i (for $i = 1, \ldots, n$) by using only the trees for which this observation was not included in the bootstrap sample (i.e., it was not used to construct the tree). Note that these predictions are obtained based on a subset of trees—including on average $T \times 0.368$ trees. These predictions are ultimately compared to the true values by calculating performance measures (see Sections 2.3, 2.4 and 2.5).

3. Theoretical Results

In this section we compute the expected performance—according to the error, the Brier score and the logarithmic loss outlined in Section 2.3—of a binary classification or regression RF consisting of T trees as estimated based on the n_{test} test observations, while considering the training dataset as fixed. For the AUC we prove that it can be a non-monotonous function in T. The case of other measures (mean absolute error, median of squared error and median of absolute error for regression) and multiclass classification is much more more complex to investigate from a theoretical point of view. It will be examined empirically in Section 4.

In this section we are concerned with *expected* performances, where expectation is taken over the sets of T trees. Our goal is to study the monotonicity of the expected errors with respect to T. The number T of trees is considered a parameter of the RF and now mentioned in parentheses everytime we refer to the whole forest.

3.1 Error Rate (Binary Classification)

We first show that for single observations the expected error rate curve can be increasing and then show exemplified how this can influence the shape of the average curve of several observations. The observation that bagging can worsen the expected error rate of a single observation was already done by Hastie et al. (2001), Breiman (1996a) and Friedman (1997). In this section we provide a general formula explaining this observation, and then extend our theoretical considerations to further performance measures in the following sections.

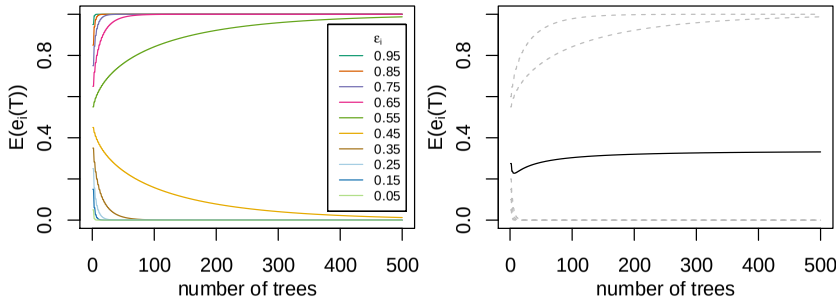

Figure 2: Left: Expected error rate curves for different ε_i values. Right: Plot of the average curve (black) of the curves with $\varepsilon_1 = 0.05$, $\varepsilon_2 = 0.1$, $\varepsilon_3 = 0.15$, $\varepsilon_4 = 0.2$, $\varepsilon_5 = 0.55$ and $\varepsilon_6 = 0.6$ (depicted in grey and dotted)

3.1.1 Theoretical Considerations

Let us first consider the classical error rate $e_i(T)$ for observation i with a RF including T trees and derive its expectation, conditionally on the training set D,

$$E(e_i(T)) \quad = \quad E\left(I\left(\frac{1}{T}\sum_{t=1}^{T} e_{it} > 0.5\right)\right) = P\left(\sum_{t=1}^{T} e_{it} > 0.5 \cdot T\right).$$

We note that e_{it} is a binary variable with $E(e_{it}) = \varepsilon_i$. Given a fixed training dataset D and observation i, the e_{it}, $t = 1, ..., T$ are mutually independent. It follows that the sum $X_i = \sum_t^T e_{it}$ follows the binomial distribution $B(T, \varepsilon_i)$. It is immediate that the contribution of observation i to the expected error rate, $P(X_i > 0.5 \cdot T)$, is an increasing function in T for $\varepsilon_i > 0.5$ and a decreasing function in T for $\varepsilon_i < 0.5$.

Note that so far we ignored the case where $\sum_{t=1}^{T} e_{it} = 0.5 \cdot T$, which may happen when T is even. In this case, the standard implementation in R (`randomForest`) assigns the observation randomly to one of the two classes. This implies that $0.5 \cdot P(\sum_{t=1}^{T} e_{it} = 0.5 \cdot T)$ has to be added to the above term, which does not affect our considerations on the ε_i's role.

3.1.2 Impact on Error Rate Curves

The error rate curve for observation i is defined as the curve described by the function $e_i : T \to \mathbb{R}$. The expectation $E(e_i(T))$ of the error rate curve for observation i with the mentioned adjustment in the case of an even number of trees can be seen in the left plot of Figure 2 for different values of ε_i. Very high and very low values of ε_i lead to rapid convergence, while for ε_i-values close to 0.5 more trees are needed to reach the plateau. The error rate curve obtained for a test dataset consists of the average of the error rate curves of the single observations. Of course, if trees are good classifiers we should have $\varepsilon_i < 0.5$ for most observations. In many cases, observations with $\varepsilon_i > 0.5$ will be compensated by

observations with $\varepsilon_i < 0.5$ in such a way that the expected error rate curve is monotonously decreasing. This is typically the case if there are many observations with $\varepsilon_i \approx 0$ and a few with $\varepsilon_i \approx 1$. However, if there are many observations with $\varepsilon_i \approx 0$ and a few observations with $\varepsilon_i \geq 0.5$ that are close to 0.5, the expected error rate curve initially falls down quickly because of the observation with $\varepsilon_i \approx 0$ and then grows again slowly as the number of trees increases because of the observations with $\varepsilon_i \geq 0.5$ close to 0.5. In the right plot of Figure 2 we can see (black solid line) the mean of the expected error rate curves for $\varepsilon_1 = 0.05$, $\varepsilon_2 = 0.1$, $\varepsilon_3 = 0.15$, $\varepsilon_4 = 0.2$, $\varepsilon_5 = 0.55$ and $\varepsilon_6 = 0.6$ (displayed as gray dashed lines) and can see exactly the non-monotonous pattern that we expected: due to the ε_i's 0.55 and 0.6 the average curve increases again after reaching a minimum. In Section 4 we will see that the two example datasets whose non-monotonous out-of-bag error rate curves are depicted in the introduction have a similar distribution of ε_i.

We see that the convergence rate of the error rate curve is only dependent on the distribution of the ε_i's of the observations. Hence, the convergence rate of the error rate curve is not directly dependent on the number of observations n or the number of features, but these characteristics could influence the empirical distribution of the ε_i's and hence possibly the convergence rate as outlined in Section 4.4.1.

3.2 Brier Score (Binary Classification) and Squared Error (Regression)

We now turn to the Brier score and compute the expected Brier score contribution of observation i for a RF including T trees, conditional on the training set D. We obtain

$$\begin{aligned} E(b_i(T)) &= E((y_i - \hat{p}_i(T))^2) = E\left(\left(y_i - \frac{1}{T}\sum_{t=1}^{T}\hat{y}_{it}\right)^2\right) \\ &= E\left(\left(\frac{1}{T}\sum_{t=1}^{T}(y_i - \hat{y}_{it})\right)^2\right) = E\left(\left(\frac{1}{T}\sum_{t=1}^{T}e_{it}\right)^2\right). \end{aligned}$$

From $E(Z^2) = E(Z)^2 + Var(Z)$ with $Z = \frac{1}{T}\sum_{t=1}^{T} e_{it}$ it follows:

$$E(b_i(T)) = E(e_{it})^2 + \frac{Var(e_{it})}{T},$$

which is obviously a strictly monotonous decreasing function of T. This also holds for the average over the observations of the test dataset. In the case of binary classification, we have $e_{it} \sim \mathcal{B}(1, \varepsilon_i)$, yielding $E(e_{it}) = \varepsilon_i$ and $Var(e_{it}) = \varepsilon_i(1-\varepsilon_i)$, thus allowing the formulation of $E(b_i(T))$ as $E(b_i(T)) = \varepsilon_i^2 + \frac{\varepsilon_i(1-\varepsilon_i)}{T}$. Note that the formula $E(b_i(T)) = E(e_{it})^2 + Var(e_{it})/T$ is also valid for the squared error in the regression case, except that in this case we would write $\hat{y}_i$ instead of $\hat{p}_i$ in the first line.

3.3 Logarithmic Loss (Binary Classification)

As outlined in Section 2.3, another usual performance measure based on the discrepancy between y_i and $\hat{p}_i$ is the logarithmic loss $l_i(T) = -(y_i \ln(\hat{p}_i(T)) + (1 - y_i)\ln(1 - \hat{p}_i(T)))$. Noticing that $\hat{p}_i(T) = 1 - \frac{1}{T}\sum_{t=1}^{T} e_{it}$ for $y_i = 1$ and $\hat{p}_i(T) = \frac{1}{T}\sum_{t=1}^{T} e_{it}$ for $y_i = 0$, it can

be in both cases $y_i = 0$ and $y_i = 1$ reformulated as

$$l_i(T) = -\ln\left(1 - \frac{1}{T}\sum_{t=1}^{T} e_{it}\right).$$

In the following we ensure that the term inside the logarithm is never zero by adding a very small value a to $1 - \frac{1}{T}\sum_{t=1}^{T} e_{it}$. The logarithmic loss $l_i(T)$ is then always defined and its expectation exists. This is similar to the solution adopted in the `mlr` package, where 10^{-15} is added in case that the inner term of the logarithm equals zero.

With $Z := 1 - \frac{1}{T}\sum_{t=1}^{T} e_{it} + a$, we can use the Taylor expansion,

$$\begin{aligned} E\left[f(Z)\right] =& E\left[f(\mu_Z + (Z - \mu_Z))\right] \\ \approx& E\left[f(\mu_Z) + f'(\mu_Z)\left(Z - \mu_Z\right) + \frac{1}{2}f''(\mu_Z)\left(Z - \mu_Z\right)^2\right] \\ =& f(\mu_Z) + \frac{f''(\mu_Z)}{2} \cdot Var(Z) = f(E(Z)) + \frac{f''(E(Z))}{2} \cdot Var(Z) \end{aligned}$$

where μ_Z stands for $E(Z)$ and $f(.)$ as $f(.) = -\ln(.)$. We have $Var(Z) = \frac{\varepsilon_i(1-\varepsilon_i)}{T}$, $E(Z) = 1 - \varepsilon_i + a$, $f(E(Z)) = -\ln(1 - \varepsilon_i + a)$ and $f''(E(Z)) = (1 - \varepsilon_i + a)^{-2}$, finally yielding

$$E(l_i(T)) \approx -\ln(1 - \varepsilon_i + a) + \frac{\varepsilon_i(1 - \varepsilon_i)}{2T(1 - \varepsilon_i + a)^2},$$

which is obviously a decreasing function of T. The Taylor approximation gets better and better for increasing T, since the variance of $l_i(T)$ decreases with increasing T and thus $l_i(T)$ tends to get closer to its expectancy.

3.4 Area Under the ROC Curve (AUC) (Classification)

For the AUC, considerations such as those we made for the error rate, the Brier score and the logarithmic loss are impossible, since the AUC is not the sum of individual contributions of the observations. It is however relatively easy to see that the expected AUC is not always an increasing function of the number T of trees. For example, think of the trivial example of a test dataset consisting of two observations with responses y_1 resp. y_2 and $E(\hat{p}_1(T)) = 0.4$ resp. $E(\hat{p}_2(T)) = 0.6$. If $y_1 = 0$ and $y_2 = 1$, the expected AUC curve increases monotonously with T, as the probability of a correct ordering according to the calculated scores $\hat{p}_1(T)$ and $\hat{p}_2(T)$ increases. However, if $y_1 = 1$ and $y_2 = 0$, we obtain a monotonously decreasing function, as the probability of a wrong ordering gets higher with increasing number of trees. It is easy to imagine that for different combinations of $E(\hat{p}_i(T))$, one can obtain increasing curves, decreasing curves or non-monotonous curves.

3.5 Adapting the Models to the OOB Error

The "OOB estimator" of the performance outlined in Section 2.5 is commonly considered as an acceptable proxy of the performance estimator obtained through the use of an independent test dataset or through resampling-techniques such as cross-validation (Breiman, 1996b) for a random forest including $T \times 0.368$ trees. Compared to these techniques, the

OOB estimator has the major advantage that it neither necessitates to fit additional random forests (which is advantageous in terms of computational resources) nor to reduce the size of the dataset through data splitting. For these reasons, we will consider OOB performance estimators in our empirical study.

However, if we consider the OOB error instead of the test error from an independent dataset, the formulas given in the previous subsections are not directly applicable. After having trained T trees, for making an OOB estimation for an observation we can only use the trees for which the observation was out-of-bag. If we take a simple bootstrap sample from the n training observation when bagging we have *on average* only $T \cdot (1 - \frac{1}{n})^n \approx T \cdot \exp(-1) \approx T \cdot 0.368$ trees for predicting the considered observation. This means that we would have to replace T by $T \cdot \exp(-1)$ in the above formulas and that the formulas are no longer exact because $T \cdot \exp(-1)$ is only an average. Nonetheless it is still a good approximation as confirmed in our benchmark experiments.

4. Empirical Results

This section shows a large-scale empirical study based on 193 classification tasks and 113 regression tasks from the public database OpenML (Vanschoren et al., 2013). The datasets are downloaded with the help of the `OpenML` R package (Casalicchio et al., 2017). The goals of this study are to (i) give an order of magnitude of the frequency of non-monotonous patterns of the error rate curve in real data settings; (ii) empirically confirm our statement that observations with ε_i greater than (but close to) 0.5 are responsible for non-monotonous patterns; (iii) analyse the results for other classification measures, the multiclass classification and several regression measures; (iv) analyse the convergence rate of the OOB curves.

4.1 Selection of Datasets

To select the datasets to be included in our study we define a set of candidate datasets—in our case the datasets available from the OpenML platform (Vanschoren et al., 2013)—and a set of inclusion criteria as recommended in Boulesteix et al. (2017). In particular, we do not select datasets with respect to the results they yield, thus warranting representativity.

Our inclusion criteria are as follows: (i) the dataset has predefined tasks in OpenML (see Vanschoren et al., 2013, for details on the OpenML nomenclature); (ii) it includes less than 1000 observations; (iii) it includes less than 1000 features. The two latter criteria aim at keeping the computation time feasible.

Cleaning procedures such as the deletion of duplicated datasets (whole datasets that appear twice in the OpenML database) are also applied to obtain a decent collection of datasets. No further modification of the tasks and datasets were done.

This procedure yields a total of 193 classification tasks and 113 regression tasks.

From the 193 classification tasks, 149 are binary classification tasks and 44 multiclass classification tasks.

The tasks contained easy, medium and difficult tasks - for binary classification tasks the mean (out-of-bag) AUC of a random forest with 2000 trees was 0.841, the minimum 0.502, the first quartile 0.732, the median 0.870, the third quartile 0.962 and the maximum 1. Similarly the regression tasks contained easy and difficult tasks with a mean R^2 of 0.559.

4.2 Study Design

For each dataset we run the RF algorithm with $T = 2000$ trees 1000 times successively with different seeds using the R package `randomForest` (Liaw and Wiener, 2002) with the default parameter settings. We choose 2000 trees because in a preliminary study on a subset of the datasets we could observe that convergence of the OOB curves was reached within these 2000 trees. Note that all reported results regarding the performance gain and convergence are made with the out-of-bag predictions. As for these predictions on average only $\exp(-1) \cdot T$ of the T trees are used, the convergence of independent test data is faster by the factor 2.7. For the classification tasks we calculate the OOB curves for the error rate, the balanced error rate, the (multiclass) Brier score, the logarithmic loss and the (multiclass) AUC using our new package `OOBCurve`, see details in the next section.

For the regression tasks we calculate the OOB curves using the mean squared error, the mean absolute error, the median squared error and the median of absolute error as performance measures. We parallelize the computations using the R package `batchtools` (version 0.9.0) (Lang et al., 2017). For each measure and each dataset, the final curve is obtained by simply averaging over the 1000 runs of RF. We plot each of them in three files separetely for binary classification, multiclass classification and regression. In the plots the x-axis starts at $T = 11$ since overall performance estimates are only defined if each observation was out-of-bag in at least one of the T trees, which is not always the case in practice for $T < 10$. We plot the curves only until $T = 500$, as no interesting patterns can be observed after this number of trees (data not shown). The graphics, the R-codes and the results of our experiment can be found on `https://github.com/PhilippPro/tuneNtree`.

4.3 The R Package `OOBCurve`

The calculation of out-of-bag estimates for different performance measures is implemented in our new R package `OOBCurve`. More precisely, it takes a random forest constructed with the R package `randomForest` (Liaw and Wiener, 2002) or `ranger` (Wright, 2016) as input and can calculate the OOB curve for any measure that is available from the `mlr` package (Bischl et al., 2016). The `OOBCurve` package is available on CRAN R package repository and also on Github (`https://github.com/PhilippPro/OOBCurve`). It is also possible to calculate OOB curves of other hyperparameters of RF such as `mtry` with this package.

4.4 Results for Binary Classification

The average gain in performance in the out-of-bag performance for 2000 trees instead of 11 trees is -0.0324 for the error rate, -0.0683 for the brier score, -2.383 for the logarithmic loss and 0.0553 for the AUC. In the following we will concentrate on the visual analysis of the graphs and are especially interested in the results of the error rate.

4.4.1 Overall Results for the OOB Error Rate Curves

We observe in the graphs of the OOB error rate curves that for most datasets the curve is quickly decreasing until it converges to a dataset-specific plateau value. In 16 cases which make approximately 10% of the datasets, however, the curve grows again after reaching its lowest value, leading to a value at 2000 trees that is by at least 0.005 bigger than the

lowest value of the OOB error rate curve for $T \in [10, 250]$. This happens mainly for smaller datasets, where a few observations can have a high impact on the error curve. Of these 16 cases 15 belong to the smaller half of the datasets—ordered by the number of observations multiplied with the number of features. The mean increase of these 16 datasets was 0.020 (median: 0.012). The difference in mean and median is mainly caused by one outlier where the increase was around 0.117.

4.4.2 Datasets with Non-Monotonous OOB Error Rate Curve

We now examine in more detail the datasets yielding non-monotonous patterns. In particular, the histograms of the estimates $\hat{\varepsilon}_i = |y_i - \hat{p}_i|$ of the observation-specific errors ε_i are of interest, since our theoretical results prove that the distribution of the ε_i determines the form of the expected error rate curve. To get these histograms we compute the estimates $\hat{\varepsilon}_i$ of the observation-specific errors ε_i (as defined in Section 2.3) from a RF with a big number $T = 100000$: the more trees, the more accurate the estimates of ε_i.

The histograms for the exemplary datasets considered in the introduction (see Figure 1) are displayed in Figure 3. A typical histogram for an OOB curve with monotonously decreasing error rate curve is displayed in the left panel. The heights of the bins of this histogram of the $\hat{\varepsilon}_i$ are monotonously decreasing from 0 to 1.

The histograms for the non-monotonous error rate curves from the introduction can be seen in the middle (OpenML ID 862) and right (OpenML ID 938) panels of Figure 3. In both cases we see that a non-negligible proportion of observations have ε_i larger than but close to 0.5. This is in agreement with our theoretical results. With growing number of trees the chance that these observations are incorrectly classified increases, while the chance for observations with $\varepsilon_i \approx 0$ is already very low—and thus almost constant. Intuitively we expect such shapes of histograms for datasets with few observations—where by chance the shape of the histogram of the $\hat{\varepsilon}_i$ could look like in our two examples. For bigger datasets we expect smoother shapes of the histogram, yielding strictly decreasing error rate curves.

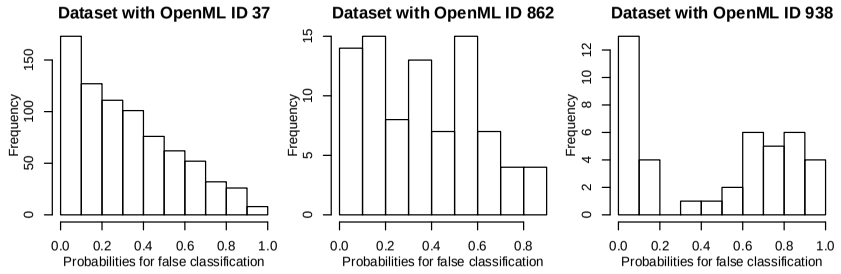

Figure 3: Histograms of the estimates of ε_i $(i = 1, \ldots, n)$ from random forests with 100000 trees for dataset with IDs 36, 862 and 938

	error rate		Brier score		logarithmic loss		AUC	
error rate	**1.00**	(1.00)	**0.28**	(0.44)	**0.27**	(0.45)	**-0.18**	(-0.43)
Brier score	**0.72**	(0.86)	**1.00**	(1.00)	**0.96**	(0.98)	**-0.63**	(-0.87)
logarithmic loss	**0.65**	(0.84)	**0.93**	(0.95)	**1.00**	(1.00)	**-0.63**	(-0.87)
AUC	**-0.64**	(-0.85)	**-0.84**	(-0.95)	**-0.81**	(-0.92)	**1.00**	(1.00)

Table 1: Linear (bottom-left) and rank (top-right) correlation results for binary classification datasets and for multiclass classification (in brackets)

4.4.3 Other Measures

For the Brier score and the logarithmic loss we observe, as expected, monotonically decreasing curves for all datasets. The expected AUC curve usually appears as a growing function in T. In a few datasets such as the third binary classification example (OpenML ID 905), however, it falls after reaching a maximum.

To assess the similarity between the different curves, we calculate the Bravais-Pearson linear correlation and Kendall's τ rank correlation between the values of the OOB curves of the different performance measures and average these correlation matrices over all datasets. Note that we do not perform any correlation tests, since the assumption of independent identically distributed observations required by these tests is not fulfilled: our correlation analyses are meant to be explorative. The results can be seen in Table 1. The Brier score and logarithmic loss have the highest correlation. They are also more correlated to the AUC than to the error rate, which has the lowest correlation to all other measures.

4.5 Results for Multiclass Classification

The average gain in out-of-bag performance for 2000 trees instead of 11 trees is -0.0753 for the error rate, -0.1282 for the brier score, -5.3486 for the logarithmic loss and 0.0723 for the AUC. These values are higher than the ones from binary classification. However, the visual observations we made for the binary classification also hold for the multiclass classification. For 5 of the 44 datasets the minimum error rate for $T \in [11; 250]$ is lower by more than 0.005 than the error rate for $T = 2000$. In contrast to the binary classification case, 3 of these 5 datasets belong to the bigger half of the datasets. The results for the correlation are quite similar, although the correlation (see Table 1) is in general slightly higher than in the binary case.

4.6 Results for Regression

The average performance gain regarding the out-of-bag performance of the R^2 for 2000 trees compared to 11 trees is 0.1249. In the OOB curves for regression we can observe the monotonously decreasing pattern expected from theory in the case of the most widely used mean squared error (mse). The mean absolute error (mae) is also strictly decreasing for all the datasets considered in our study.

For the median squared error (medse) and the median absolute error (medae), we get a performance gain by using 2000 trees instead of 10 in most but not all cases (around 80% of the datasets). In many cases (around 50%) the minimum value for $T \in [11; 250]$ is smaller

than the value for $T = 2000$ which means that growing more trees is rather disadvantagous in these cases in terms of medse and medae. This could be explained by the fact that each tree in a random forest tries to minimize the squared error in the splits and therefore adding more trees to the forest will improve the mean squared error but not necessarily measures that use the median. More specifically, one could imagine that the additional trees focus on the reduction of the error for outlying observations at the price of an increase of the median error. In a simulated dataset (linear model with 200 observations, 5 relevant features and 5 non-relevant features drawn from a multivariate normal distribution) we could observe this pattern (data not shown). Without outlier all expected curves are strictly decreasing. When adding an outlier (changing the outcome of one observation to a very big value) the expected curves of mse and mae are still strictly decreasing, while the expected curves of medse and medae show are increasing for higher T. The curves of the measures which take the mean of the losses of all observations have a high linear and rank correlation (> 0.88), as well as the curves of the measures which take the median of the losses (> 0.97). Correlation between these two groups of measures are lower, around 0.5 for the linear correlation coefficient and around 0.2 for the rank correlation coefficient.

4.7 Convergence

It is clearly visible from the out-of-bag curves (`https://github.com/PhilippPro/tuneNtree/tree/master/graphics`) that increasing the number of trees yields a substantial performance gain in most of the cases, but the biggest performance gain in the out-of-bag curves can be seen while growing the first 250 trees. Setting the number of trees from 10 to 250 in the binary classification case provides an average decrease of 0.0306 of the error rate and an increase of 0.0521 of the AUC. On the other hand, using 2000 trees instead of 250 does not yield a big performance gain, the average error rate improvement is only 0.0018 (AUC: 0.0032). The improvement in the multiclass case is bigger with an average improvement of the error rate of 0.0739 (AUC: 0.0665) from 10 trees to 250 and an average improvement of 0.0039 (AUC: 0.0057) for using 2000 trees instead of 250. For regression we have an improvement of 0.1210 of the R^2 within the first 250 trees and an improvement of 0.0039 for using 2000 trees instead of 250. These results are concordant with a comment by Breiman (1996a) (Section 6.2) who notes that fewer bootstrap replicates are necessary when the outcome is numerical and more are required for an increasing number of classes.

5. Conclusions and Extensions

In this section we draw conclusions of the given results and discuss possible extensions.

5.1 Assessment of the Convergence

For the assessment of the convergence in the classification case we generally recommend using measures other than the error rate, such as AUC, the Brier score or the logarithmic loss for which the OOB curves are much more similar as we have seen in our correlation analysis. Their convergence rate is not so dependent on observations with ε_i close to 0.5 (in the binary classification case), and they give an indication of the general stability of the probability estimations of all observations. This can be especially important if the threshold

for classification is not set a priori to 0.5. The new `OOBCurve` R package is a tool to examine the rate of convergence of the trained RF with any measure that is available in the `mlr` R package. It is important to remember that for the calculation of the OOB error curve at T only $\exp(-1) \cdot T$ trees are used. Thus, as far as future independent data is concerned, the convergence of the performances is by $\exp(1) \approx 2.7$ faster than observed from our OOB curves. Having this in mind, our observations (see Section 4.7) are in agreement with the results of Oshiro et al. (2012), who conclude that after growing 128 trees no big gain in the AUC performance could be achieved by growing more trees.

5.2 Why More Trees Are Better

Non-monotonous expected error rate curves observed in the case of binary classification might be seen as an argument in favour of tuning the number T of trees. Our results, however, suggest that tuning is not recommendable in the case of classification. Firstly, non-monotonous patterns are observed only with some performance measures such as the error rate and the AUC in case of classification. Measures such as the Brier score or the logarithmic loss, which are based on probabilities rather than on the predicted class and can thus be seen as more refined, do not yield non-monotonous patterns, as theoretically proved in Section 3 and empirically observed based on a very large number of datasets in Section 4. Secondly, non-monotonous patterns in the expected error rate curves are the result of a particular rare combination of ε_i's in the training data. Especially if the training dataset is small, the chance is high that the distribution of the ε_i will be different for independent test data, for example values of ε_i close to but larger than 0.5 may not be present. In this case, the expected error rate curve for this independent future dataset would not be non-monotonous, and a large T is better. Thirdly, even in the case of non-monotonic expected error rate curves, the minimal error rate value is usually only slightly smaller than the value at convergence (see Section 4.4.1). We argue that this very small gain - which, as outlined above, is relevant only for future observations with $\varepsilon_i > 0.5$ - probably does not compensate the advantage of using more trees in terms of other performance measures or in terms of the precision of the variable importance measures, which are very commonly used in practice.

In the case of regression, our theoretical results show that the expected out-of-bag mse curve is monotonously decreasing. For the mean absolute error the empirical results suggest the same. In terms of the less common measures *median* squared error and *median* absolute error (as opposed to *mean* losses), however, performance may get worse with increasing number of trees. More research is needed.

5.3 Extensions

Note that our theoretical results are not only valid for random forest but generalizable to any ensemble method that uses a randomization technique, since the fact that the base learners are trees and the specific randomization procedure (for example bagging) do not play any role in our proofs. Our theoretical results could possibly be extended to the multiclass case, as supported by our results obtained with 44 multiclass datasets.

Although we claim that increasing the number of trees cannot harm noticeably as far as measures based on average loss are considered, our empirical results show that for most of the examined datasets, the biggest performance gain is achieved when training the first

100 trees. However, the rate of convergence may be influenced by other hyperparameters of the RF. For example lower sample size while taking bootstrap samples for each tree, bigger constraints on the tree depth or more variables lead to less correlated trees and hence more trees are needed to reach convergence.

One could also think of an automatic break criterion which stops the training automatically according to the convergence of the OOB curves. For example, training could be stopped if the last T_{last} trees did not improve performance by more than Δ, where T_{last} and Δ are parameters that should be fixed by the user as a compromise between performance and computation time. Note that, if variable importances are computed, it may be recommended to also consider their convergence. This issue also requires more research.

Acknowledgments

We would like to thank Alexander Dürre for useful comments on the approximation of the logarithmic loss and Jenny Lee for language editing.

Abstract

1-norm support vector machine (SVM) generally has competitive performance compared to standard 2-norm support vector machine in classification problems, with the advantage of automatically selecting relevant features. We propose a divide-and-conquer approach in the large sample size and high-dimensional setting by splitting the data set across multiple machines, and then averaging the *debiased* estimators. Extension of existing theoretical studies to SVM is challenging in estimation of the inverse Hessian matrix that requires approximating the Dirac delta function via smoothing. We show that under appropriate conditions the aggregated estimator can obtain the same convergence rate as the central estimator utilizing all observations.

Keywords: classification, debiased estimator, distributed estimator, divide and conquer, sparsity

1. Introduction

The support vector machine (SVM) is a widely used tool for classification (Vapnik, 2013; Scholkopf and Smola, 2001; Cristianini and Shawe-Taylor, 2000). Although the original motivation of Cortes and Vapnik (1995) is in terms of finding a maximum-margin hyperplane, its equivalent formulation as a regularized functional optimization problem is perhaps more easily understood by statisticians and more amenable for statistical asymptotic analysis. In the standard formulation the penalized functional is a sum of the hinge loss plus an l_2-norm regularization term. Statistical properties of the SVM, especially its nonlinear version using general kernels, has been studied in a lot of works recently including but not limited to Bartlett et al. (2006); Blanchard et al. (2008); Lin (2000, 2004); Steinwart and Scovel (2007); Steinwart (2005); Zhang (2004). In this work, we focus on penalized linear SVM with large sample size and large dimension, with particular emphasis on dealing with distributed estimation in such contexts.

Data sets with thousands of features have become increasingly common recently in many real-world applications. For example, a microarray data set typically contains more than 10,000 genes. A drawback of standard SVM based on l_2-norm penalty is that it can be adversely affected if many redundant variables are included in building the decision rule. A modern approach to feature selection is based on the idea of shrinkage. This approach involves fitting a model involving all p predictors. However, the estimated coefficients are shrunk towards zero. In particular with appropriate choice of penalty some of the coefficients may be estimated to be exactly zero. Automatic variable selection using penalized estimation that can shrink some coefficients to be exactly zero was pioneered in Tibshirani (1996) using an l_1-norm penalty (or called lasso penalty). Other penalties proposed include those in Fan and Li (2001), Zou (2006) and Zhang (2010).

The idea of using l_1 norm to automatically select variables has been extended to classification problems. van de Geer (2008) analyzed lasso penalized estimator for generalized linear models which include logistic regression as a special case. Zhu et al. (2003) proposed the l_1-norm support vector machine and oracle properties of SCAD-penalized support vector machines were established in Park et al. (2012), based on the Bahadur representation of Koo et al. (2008). See also the earlier work of Bradley and Mangasarjan (1998); Song et al. (2002). When feature dimension is larger than the sample size, Peng et al. (2016); Zhang et al. (2016) obtained the convergence rate of the SCAD and lasso-penalized estimators for SVM, respectively. Our work follows the lead of these works on understanding the statistical properties of the estimated SVM coefficients, instead of on generalization error rates or empirical risk.

In this paper, we focus on distributed estimation of l_1 penalized linear SVM coefficients using multiple computing machines. The simplest and most popular approach in data parallelism is averaging: each machine uses a part of the data and obtains a local estimator using the standard estimation methods and sends it back to the master machine which combines the local estimators by simple averaging into an aggregated estimator. In the classical regime concerning fixed dimensional problems, this has been advocated in McDonald et al. (2009), and was also studied by Zinkevich et al. (2010); Zhang et al. (2013, 2015); Balcan et al. (2015); Zhao et al. (2016). In all these studies, the typical outcome of asymptotic analysis is that under suitable assumptions, in particular that the number of machines are not excessive compared to the sample size, the aggregated estimator enjoys the same or similar statistical properties as the centralized estimator obtained by a single machine using all observations (if the centralized estimator can be feasibly obtained). Such results convincingly illustrate that the divide-and-conquer strategy works in the big data world. In the high dimensional regime, for lasso penalized estimators, there is a well-known bias-variance trade-off. When the tuning parameter in the penalty is chosen optimally in each local machine, the size of bias and standard deviation are of the same order. Aggregation can decrease the variance thanks to the magic of central limit theorem or some related finite-sample bounds for averages of mean zero random variables, but it cannot decrease the bias in general. Thus debiasing becomes crucial to reduce the bias to a smaller order before aggregation. This is done for sparse linear regression in Lee et al. (2017), which shows the debiased estimator in van de Geer et al. (2014) works satisfactorily for parameter inferences. Lee et al. (2017) studied both the least squares estimator and the more general M-estimator with *smooth* loss functions using an l_1 (LASSO) penalty and applied it to distributed estimation. Our study of linear SVM coefficients differs significantly from Lee et al. (2017) due to the unsmooth nature of the hinge loss function. In particular, estimation of the

Hessian matrix which involves Dirac delta function requires a smoothing procedure, which is nontrivial to analyze.

The rest of the paper is organized as follow. After a brief introduction of some notations below, we consider debiased l_1-norm SVM in Section 2.1. Although the main focus is on distributed estimation, we need to first consider statistical properties of debiased estimator on a single machine, which requires a lengthy and detailed analysis. Once this is done, properties of the aggregated estimator are relatively easy to establish, as is done in Section 2.2. In terms of l_∞ norm, the aggregated estimator has the convergence rate $O_p(\sqrt{\log p/N})$ when the number of features is p and the total sample size is N under appropriate assumptions. However, its convergence rate in l_1 or l_2 norm is unacceptably larger, which motivated a further thresholding step in Section 2.3. Section 3 report some numerical results to demonstrate the finite sample performance of the proposed estimators. Finally, we conclude this paper with a discussion in Section 4.

Notations. For a vector $\mathbf{a} = (a_1, \ldots, a_n)^{\mathrm{T}}$, $\|\mathbf{a}\|_\infty = \max_j |a_j|$, $\|\mathbf{a}\|_1 = \sum_j |a_j|$, $\|\mathbf{a}\| = (\sum_j a_j^2)^{1/2}$ and $\|\mathbf{a}\|_0$ is the number of nonzero components of $\mathbf{a}$. For a matrix $\mathbf{A} = \{a_{ij}\}_{i,j=1}^n$, $\|\mathbf{A}\|_\infty = \max_{i,j} |a_{ij}|$, $\|\mathbf{A}\|_1 = \sum_{i,j} |a_{ij}|$ and $\|\mathbf{A}\|_{L_1} = \max_i \sum_j |a_{ij}|$. Throughout the paper, C denotes a generic constant that may assume different values even on the same line.

2. Divide-and-conquer for l_1-SVM

2.1 Debiased l_1-SVM

We begin with the basic setup of SVM for binary classification. We observe a simple random sample $(\mathbf{x}_i, y_i), i = 1, \ldots, N$, from an unknown distribution $P(\mathbf{x}, y)$. Here $y_i \in \{-1, 1\}$ is the class label and $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^{\mathrm{T}}$ is the p-dimensional features. For simplicity of presentation, we do not use any special treatment for the intercept, although the intercept term is typically not shrunk in l_1-SVM. The standard linear SVM estimates the parameters by solving

$$\min_{\boldsymbol{\beta} \in \mathbb{R}^p} N^{-1} \sum_{i=1}^N L(y_i, \mathbf{x}_i^{\mathrm{T}} \boldsymbol{\beta}) + \lambda \|\boldsymbol{\beta}\|^2,$$

where L is the hinge loss function $L(y, t) = \max\{0, 1 - yt\}$ and λ is the regularization parameter which changes with N (typically converging to zero as N goes to infinity), but we suppress its dependence on N in our notation. Throughout the paper we make the mild assumption that

$$\log N = O(\log p).$$

This does not mean $p \geq N$, but exclude the case that p is fixed. This restriction is mainly to make the notation slightly simpler. Without this restriction, Theorem 1 below still hold with $\log p$ replaced by $\log(\max\{p, N\})$, and the probability $1 - p^{-C}$ replaced by $1 - (\max\{p, N\})^{-C}$.

Variable selection is of particular interest when p is large compared to N, due to its ability to avoid overfitting as well as to enhance interpretation. The l_1-SVM (Zhu et al., 2003) estimates the parameter by solving

$$\min_{\boldsymbol{\beta} \in \mathbb{R}^p} N^{-1} \sum_{i=1}^N L(y_i, \mathbf{x}_i^{\mathrm{T}} \boldsymbol{\beta}) + \lambda \|\boldsymbol{\beta}\|_1. \tag{1}$$

The l_1 penalty here encourages sparsity of the solution (Tibshirani, 1996, 1997).

Let $\boldsymbol{\beta}_0 = (\beta_{01}, \ldots, \beta_{0p})^{\mathrm{T}}$ be the true parameter, which is defined as the minimizer of the population hinge loss,

$$\boldsymbol{\beta}_0 = \arg\min_{\boldsymbol{\beta}} E[L(y, \mathbf{x}^{\mathrm{T}} \boldsymbol{\beta})]. \tag{2}$$

We assume $\boldsymbol{\beta}_0$ exists and is unique. Koo et al. (2008) provided some regularity conditions under which $\boldsymbol{\beta}_0$ is unique and $\boldsymbol{\beta}_0 \neq \mathbf{0}$. Towards variable selection in SVM, it is natural to assume $\boldsymbol{\beta}_0$ is sparse. Let $A = \{1 \leq j \leq p : \beta_{0j} \neq 0\}$ be the support set of $\boldsymbol{\beta}_0$ with $s = |A|$ the cardinality of A.

As calculated rigorously in Koo et al. (2008), the gradient vector and the Hessian matrix of the population hinge loss in Equation 2 is given by

$$S(\boldsymbol{\beta}) \quad = \quad -E[I\{y\mathbf{x}^{\mathrm{T}} \boldsymbol{\beta} \leq 1\} \mathbf{x} y]$$

and

$$\mathbf{H}(\boldsymbol{\beta}) = E[\delta(1 - y\mathbf{x}^{\mathrm{T}} \boldsymbol{\beta}) \mathbf{x}\mathbf{x}^{\mathrm{T}}],$$

respectively, where $\delta(.)$ is the Dirac delta function. Let f and g be the conditional density of $\mathbf{x}$ given $y = 1$ and $y = -1$, respectively.

(A1) The densities f and g are bounded and continuously differentiable with bounded partial derivatives, with compact support. x_j's are bounded random variables. Without loss of generality, we assume the distribution of $\mathbf{x}$ has a support contained in $[0, 1]^p$.

Under assumption (A1), $\mathbf{H}(\boldsymbol{\beta})$ is well-defined and continuous in $\boldsymbol{\beta}$.

Due to the penalty term, the penalized estimator is generally biased (i.e. shrunk towards zero). Conceptually, λ controls the trade-off between bias and standard deviation of the estimator. While averaging will reduce the standard deviation of the estimator, it generally cannot reduce the bias. Thus it is important to apply a debiasing mechanism before we aggregate estimators from different machines. For simplicity of presentation, for now we focus on the properties of the debiased estimator using all observations and later we will argue (almost trivially) these properties hold for the local estimates, uniformly over M machines. In this subsection, with $M = 1$, we have $N = n$ where n is the sample size on a single machine.

Let $\widehat{\boldsymbol{\beta}}$ be the penalized estimator obtained from Equation 1. It is known that $\widehat{\boldsymbol{\beta}}$ satisfies the Karush-Kuhn-Tucker (KKT) conditions:

$$\frac{1}{N} \sum_{i=1}^N \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}} \widehat{\boldsymbol{\beta}}) + \lambda \kappa = 0 \tag{3}$$

where $L_t(y, t)$ is a sub-derivative of $L(y, t)$ with respect to t, and $\kappa = (\kappa_1, \ldots, \kappa_p)^{\mathrm{T}}$ with $\kappa_j = \mathrm{sign}(\widehat{\beta}_j)$ if $\widehat{\beta}_j \neq 0$ and $\kappa_j \in [-1, 1]$ if $\widehat{\beta}_j = 0$.

When the loss is twice differentiable, a simple Taylor's expansion can be used to expand $L_t(y_i, \mathbf{x}_i^{\mathrm{T}} \widehat{\boldsymbol{\beta}})$ at $\boldsymbol{\beta}_0$ as in van de Geer et al. (2014). For the nonsmooth loss function here, we

need to use empirical processes techniques. Let $G_n = \sqrt{n}(P_n - P)$ be the empirical process, where P is the population distribution of $(\mathbf{x}, y)$ and P_n is the empirical distribution of the observations. Informally, when $\widehat{\boldsymbol{\beta}}$ is close to $\boldsymbol{\beta}_0$, $G_n(\mathbf{x}\{L_t(y, \mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}}) - L_t(y, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)\})$ is small, and thus

$$\begin{aligned} & \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}) \\ \approx\ & \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0) + E\mathbf{x}L_t(y, \mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}}) - E\mathbf{x}L_t(y, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \\ \approx\ & \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0) + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0). \end{aligned} \tag{4}$$

Then

$$\begin{aligned} 0 &= \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}) + \lambda\kappa \\ &\approx \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0) + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0) + \lambda\kappa \\ &= \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0) + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0) - \frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}), \end{aligned}$$

where we used Equation 3 in both the first and the last inequality, and this leads to

$$\widehat{\boldsymbol{\beta}} \approx \boldsymbol{\beta}_0 + [\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}\frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}) - [\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}\frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0),$$

if $\mathbf{H}(\boldsymbol{\beta}_0)$ is invertible. Since the last term in the right hand side above has mean zero, we are motivated to define the debiased estimator as

$$\widetilde{\boldsymbol{\beta}} = \widehat{\boldsymbol{\beta}} - [\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}\frac{1}{N}\sum_{i=1}^{N} \mathbf{x}_i L_t(y_i, \mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}), \tag{5}$$

and we set $L_t(y,t) = -yI\{yt \le 1\}$. However, $\mathbf{H}(\boldsymbol{\beta}_0)$ is unknown in two aspects. On one hand, the true parameter $\boldsymbol{\beta}_0$ is unknown and should be replaced by its estimator, say $\widehat{\boldsymbol{\beta}}$. On the other hand, $\mathbf{H}(\boldsymbol{\beta}) = E[\delta(1 - y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta})\mathbf{x}\mathbf{x}^{\mathrm{T}}]$ is an expectation which should be approximated by samples. Although expectations are usually easily estimated by a simple moment estimator, this is not the case here, since there may not even be a single sample that satisfies exactly $y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta} = 1$ and $\delta(.)$ as a generalized function should be treated carefully. Finally, after $\mathbf{H}(\boldsymbol{\beta})$ is approximated by samples, high-dimensionality means that the usual algebraic inverse of the estimator may not be well-defined and some approximate inverse must be used.

Thus it seems one major component of the estimation is the approximation of $[\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}$ and we deal with this problem first. To motivate an estimator of $\mathbf{H}(\boldsymbol{\beta})$, we can start from

its antiderivative $S(\boldsymbol{\beta}) = E[-I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta} \le 1\}\mathbf{x}y]$. For any given $\boldsymbol{\beta}$, $S(\boldsymbol{\beta})$ can be approximated by $-N^{-1}\sum_{i=1}^{N} I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta} \le 1\}\mathbf{x}_i\mathbf{y}_i$. If this were differentiable, we could use its derivative as an estimator of $\mathbf{H}(\boldsymbol{\beta})$. This observation motivates us to smooth the indicator function using some cumulative distribution function, say Q, and approximates $S(\boldsymbol{\beta})$ by $-N^{-1}\sum_{i=1}^{N} Q((1 - y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta})/h)\mathbf{x}_i y_i$. When the bandwidth parameter h is sufficiently small, $Q(./h)$ will approximate $I\{. \ge 0\}$ well. Assuming Q is differentiable, then it is natural to approximate $\mathbf{H}(\boldsymbol{\beta})$ by

$$\widehat{\mathbf{H}}(\boldsymbol{\beta}) = N^{-1}\sum_{i=1}^{N}(1/h)q((1 - y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta})/h)\mathbf{x}_i\mathbf{x}_i^{\mathrm{T}},$$

where $q(.)$ is the density of the distribution Q (derivative of Q), and thus $\mathbf{H}(\boldsymbol{\beta}_0)$ is estimated by $\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})$ where $\widehat{\boldsymbol{\beta}}$ is the l_1-SVM estimator.

Since the rank of $\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})$ is at most N, $\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})$ is singular when p is larger than N. Even when p is smaller than N and $\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})$ is non-singular, the standard inverse $[\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})]^{-1}$ is often not a good estimator of $\mathbf{H}(\boldsymbol{\beta}_0)$ when p is diverging with N. An approximate inverse of $\mathbf{H}(\boldsymbol{\beta}_0)$ can be found via an approach similar to that used in Cai et al. (2011) as

$$\begin{aligned} &\widehat{\boldsymbol{\Theta}} = \arg\min \|\boldsymbol{\Theta}\|_1 \\ &\text{subject to } \|\boldsymbol{\Theta}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}}) - \mathbf{I}\|_\infty \le Cb_N, \end{aligned} \tag{6}$$

for some tuning parameter $b_N \to 0$. Note that Cai et al. (2011) would use a slightly different constraint on $\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})\boldsymbol{\Theta} - \mathbf{I}\|_\infty$, while our constraint is more convenient in the current context since we *pre-multiply* the gradient of the loss by $[\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}$ in Equation 5. We note that the constraint $\|\boldsymbol{\Theta}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}}) - \mathbf{I}\|_\infty \le Cb_N$ is obviously the same as $\|\boldsymbol{\Theta}_{j\cdot}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}}) - \mathbf{e}_j^{\mathrm{T}}\|_\infty \le Cb_N, \forall j$, where $\boldsymbol{\Theta}_{j\cdot}$ is the j-th row of $\boldsymbol{\Theta}$ (as a row vector) and $\mathbf{e}_j$ is the unit vector with j-th componenet 1. Thus the optimization problem can be solved row by row. This actually was noted in Cai et al. (2011) in their Lemma 1 (since their constraint is $\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})\boldsymbol{\Theta} - \mathbf{I}\|_\infty \le Cb_N$, their problem can be solved column by column).

Before proceeding, we impose some additional assumptions.

(A2) $\boldsymbol{\beta}_0 \ne \mathbf{0}$ and without loss of generality we assume $\beta_{01} = \max_{1\le j\le p}|\beta_{0j}|$.

(A3) $\|\boldsymbol{\Theta}_0\|_{L_1} \le C_N$, where $\boldsymbol{\Theta}_0 = [\mathbf{H}(\boldsymbol{\beta}_0)]^{-1}$.

(A4) $\|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_1 \le Cs\sqrt{\frac{\log p}{N}}$ with probability at least $1 - p^{-C}$, where $s = |\mathrm{supp}\{\boldsymbol{\beta}_0\}|$ is the number of nonzero entries in $\boldsymbol{\beta}_0$.

(A5) The density q is an even function, twice continuously differentiable, with $\int x^2 q(x)dx < \infty$, $\int q^2(x)dx < \infty$, $\int (q')^2(x)dx < \infty$, $\sup_x q'(x) < \infty$, $\sup_x q''(x) < \infty$, where q' and q'' are the first two derivatives of q.

(A6) $\|\widehat{\boldsymbol{\beta}}\|_0 \le K$ with probability at least $1 - p^{-C}$.

Assumption (A2) is mild. Koo et al. (2008) gives sufficient conditions that guarantee $\boldsymbol{\beta}_0 \ne \mathbf{0}$. To simplify the bounds below one can think of β_{01} as bounded away from zero so that it will disappear from the bounds. Note that β_{01} is the largest nonzero coefficient. In the

literature of sparse regression, it is often assumed that the *smallest* nonzero coefficient is large enough so that it can be distinguished from zero coefficients, which is a totally different assumption. Cai et al. (2011) assumed that their inverse Hessian matrix has a bounded L_1 norm (such an assumption is obviously related to sparsity of the matrix), which motivated our assumption (A3). We allow C_N in (A3) to be diverging for slightly greater generality. In particular, this mean we need to have a control on the l_1 norm of the rows of the inverse Hessian matrix. Due to that l_1 norm is a convex relaxation of the l_0 norm, we call such matrix as approximately sparse. Again, it is probably easier for the reader to regard C_N as a fixed constant. We further discuss (A3) in detail in Appendix B. Theorem 4 of Peng et al. (2016) showed $\|\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\| = O_p(\sqrt{s\log p/N})$ which together with their Lemma 2 implies $\|\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_1 = O_p(s\sqrt{\log p/N})$ as in (A4). It is also easy to choose a density that satisfies (A5), such as the standard normal density, which will be used in our numerical studies. In (A6), we assume the estimator is sufficiently sparse. This can be guaranteed in several different ways. First, we conjecture it could be proved that $\|\widehat{\boldsymbol{\beta}}\|_0 = O_p(s)$ for SVM coefficient using a similar strategy as for Theorem 3 of Belloni and Chernozhukov (2011), although the details looks quite lengthy. Second, one could add a thresholding step similar to what we will use in subsection 2.3 later to get a sparse estimator. Finally, we could add an constraint $\|\boldsymbol{\beta}\| \le K$ to the lasso problem. Such a constrained penalized problem was also proposed in Fan and Lv (2013); Zheng et al. (2014). In any case, one could expect that K is of the same order as s, the sparsity of $\boldsymbol{\beta}_0$.

We first state several propositions whose proof is left to Appendix A. The first proposition considers the accuracy bound of $\widehat{\boldsymbol{\Theta}}$ as an approximation of the inverse of $\mathbf{H}(\boldsymbol{\beta}_0)$. The second proposition shows that the first approximation in Equation 4 is sufficiently accurate based on the empirical processes results. Finally, the third proposition establishes a Lipschitz property of the Hessian matrix which implies that the second approximation in Equation 4 is sufficiently accurate.

Proposition 1 *Under assumptions (A1)-(A5), with probability at least* $1-p^{-C}$,

$$\|\widehat{\boldsymbol{\Theta}}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}}) - \mathbf{I}\|_\infty \le Cb_N,$$
$$\|\widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0) - \mathbf{I}\|_\infty \le Cb_N,$$
$$\textit{and}$$
$$\|\widehat{\boldsymbol{\Theta}}\|_{L_1} \le C_N,$$

when we set $b_N = C_N\left(\left(\frac{1}{\beta_{01}} + \sqrt{\frac{\log p}{Nh^3\beta_{01}}} + \frac{\log p}{Nh^2}\right)s\sqrt{\frac{\log p}{N}} + \frac{s^2\log p}{Nh^3} + \frac{h}{\beta_{01}^2} + \sqrt{\frac{\log p}{Nh\beta_{01}}}\right)$.

Proposition 2 *Under assumptions (A1)-(A6), with probability at least* $1-p^{-C}$,

$$\left\|\frac{1}{N}\sum_i y_i\mathbf{x}_i(I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}) - Ey\mathbf{x}(I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\})\right\|_\infty$$
$$\le Ca_N,$$

where $a_N = \left(\left(\frac{s}{\beta_{01}}\sqrt{\frac{\log p}{N}}\right)^{1/2}\sqrt{\frac{K\log p}{N}} + \frac{K\log p}{N}\right)$.

Proposition 3 *(Local Lipschitz property of* $\mathbf{H}(\boldsymbol{\beta})$*) Under assumptions (A1) and (A2) and in addition* $2\|\boldsymbol{\beta}-\boldsymbol{\beta}_0\|_1 \le \beta_{01} := \max_j|\beta_{0j}|$*, we have*

$$\|\mathbf{H}(\boldsymbol{\beta}) - \mathbf{H}(\boldsymbol{\beta}_0)\|_\infty \le \frac{C}{\beta_{01}^3}\|\boldsymbol{\beta}_0\|_1\|\boldsymbol{\beta}-\boldsymbol{\beta}_0\|_1.$$

Now we derive a finite-sample bound for $\|\widetilde{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_\infty$.

Theorem 1 *Under assumptions (A1)-(A6) and that* $s\sqrt{\log p/N} = o(\beta_{01})$*, we have*

$$\|\widetilde{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_\infty \le C\left(C_N\left(a_N + \sqrt{\frac{\log p}{N}} + \frac{\|\boldsymbol{\beta}_0\|_1}{\beta_{01}^3}\frac{s^2\log p}{N}\right) + b_N s\sqrt{\frac{\log p}{N}}\right)$$

with probability at least $1-p^{-C}$.

Proof of Theorem 1. We have

$$\begin{aligned}
&\widetilde{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\\
=\;& \widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0 + \widehat{\boldsymbol{\Theta}}\left\{\frac{1}{N}\sum_i y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\}\right\}\\
=\;& (\mathbf{I}-\widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0))(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0) + \widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0) + \widehat{\boldsymbol{\Theta}}\left\{\frac{1}{N}\sum_i y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\}\right\}\\
=\;& (\mathbf{I}-\widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0))(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0)\\
&+\widehat{\boldsymbol{\Theta}}\Big\{\frac{1}{N}\sum_i y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\} + E[y\mathbf{x}I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\}] - E[y\mathbf{x}I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}]\\
&\qquad +\mathbf{a}_N + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0)\Big\},
\end{aligned} \tag{7}$$

where $\mathbf{a}_N = \frac{1}{N}\sum_i y_i\mathbf{x}_i(I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}) - Ey\mathbf{x}(I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\})$ with $\|\mathbf{a}_N\|_\infty \le a_N$ with probability $1-p^{-C}$.

Using Proposition 1, the first term above is bounded by $\|\mathbf{I}-\widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty\|\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_1 \le b_N s\sqrt{\log p/N}$ with probability at least $1-p^{-C}$. We also have

$$\begin{aligned}
&\left\|E[y\mathbf{x}I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\}] - E[y\mathbf{x}I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}] + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0)\right\|_\infty\\
=\;& \|(\mathbf{H}(\boldsymbol{\beta}^*) - \mathbf{H}(\boldsymbol{\beta}_0))(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0)\|_\infty\\
\le\;& \|\mathbf{H}(\boldsymbol{\beta}^*) - \mathbf{H}(\boldsymbol{\beta}_0)\|_\infty\|\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_1\\
\le\;& \frac{C}{\beta_{01}^3}\|\boldsymbol{\beta}_0\|_1\|\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_1^2,
\end{aligned}$$

where $\boldsymbol{\beta}^*$ lies between $\boldsymbol{\beta}_0$ and $\widehat{\boldsymbol{\beta}}$. Furthermore, using Hoeffding's inequality and the union bound,

$$P\left(\left\|\frac{1}{N}\sum_i y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}\right\|_\infty > t\right) \le 2p\exp\{-CNt^2\}.$$

and thus

$$\left\| \frac{1}{N} \sum_i y_i x_i I\{y_i \mathbf{x}_i^{\mathrm{T}} \boldsymbol{\beta}_0 \le 1\} \right\|_\infty \le C\sqrt{\frac{\log p}{N}},$$

with probability at least $1 - p^{-C}$.

Finally, combining the various bounds above and using that for any vector $\mathbf{a}$, $\|\widehat{\boldsymbol{\Theta}}\mathbf{a}\|_\infty \le \|\widehat{\boldsymbol{\Theta}}\|_{L_1}\|\mathbf{a}\|_\infty$, we can get that the second term of Equation 7 is bounded by a constant multiple of $C_n\left(a_N + \sqrt{\frac{\log p}{N}} + \frac{\|\boldsymbol{\beta}_0\|_1}{\beta_{01}^3}\frac{s^2\log p}{N}\right)$ with probability at least $1 - p^{-C}$. ■

In l_∞ norm, based on Theorem 1, we can see that under reasonable assumptions (see for example corollary 1) the debiased estimator has the convergence rate $\sqrt{\log p/N}$, which is the dominating term in the bound. However, in terms of l_1 or l_2 norm, since $\widetilde{\boldsymbol{\beta}}$ is non-sparse, we generally have $\|\widetilde{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_1 = O_p(p\sqrt{\log p/N})$ and $\|\widetilde{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\| = O_p(\sqrt{p\log p/N})$, which is much larger than the bounds for the centralized estimator $\|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_1 = O_p(s\sqrt{\log p/N})$ and $\|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\| = O_p(\sqrt{s\log p/N})$ (Peng et al., 2016), where s is the number of nonzero components in $\boldsymbol{\beta}_0$. Post-processing using thresholding can be used to address this problem, which we will consider after we discuss distributed estimation next.

2.2 Distributed estimation

We now consider distributed estimation, in which the whole data set is evenly distributed to M machines, with M possibly diverging with N. The size of the data at each local machine is $n = N/M$, assumed to be an integer for simplicity. On each machine m, $1 \le m \le M$, we use the local data to obtain $\widehat{\boldsymbol{\beta}}^{(m)}$, $\widehat{\boldsymbol{\Theta}}^{(m)}$, and the debiased estimator $\widetilde{\boldsymbol{\beta}}^{(m)}$. Finally, the aggregated estimator is defined by

$$\bar{\boldsymbol{\beta}} = \frac{1}{M}\sum_{m=1}^M \widetilde{\boldsymbol{\beta}}^{(m)}.$$

Theorem 2 *Under assumptions (A1)-(A6) (with N replaced by n, and in (A4) and (A6) $\widehat{\boldsymbol{\beta}}$ replaced by $\widehat{\boldsymbol{\beta}}^{(m)}$, $m = 1, \ldots, M$), and that $s\sqrt{\log p/n} = o(\beta_{01})$, we have*

$$\|\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty \le C\left(C_n\left(a_n + \sqrt{\frac{\log p}{N}} + \frac{\|\boldsymbol{\beta}_0\|_1}{\beta_{01}^3}\frac{s^2\log p}{n}\right) + b_n s\sqrt{\frac{\log p}{n}}\right),$$

with probability at least $1 - p^{-C}$, where $a_n = \left(\left(\frac{s}{\beta_{01}}\sqrt{\frac{\log p}{n}}\right)^{1/2}\sqrt{\frac{K\log p}{n}} + \frac{K\log p}{n}\right)$ and $b_n = C_n\left(\left(\frac{1}{\beta_{01}} + \sqrt{\frac{\log p}{nh^3\beta_{01}}} + \frac{\log p}{nh^2}\right)s\sqrt{\frac{\log p}{n}} + \frac{s^2\log p}{nh^3} + \frac{h}{\beta_{01}^2} + \sqrt{\frac{\log p}{nh\beta_{01}}}\right)$

Proof of Theorem 2. Let $D_m \subset \{1, \ldots, N\}$ with cardinality $|D_m| = n$ be the indices of the sub-data-set distributed to machine m. We have

$$\begin{aligned}
&\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0 \\
= \;& \frac{1}{M}\sum_{m=1}^M (\mathbf{I} - \widehat{\boldsymbol{\Theta}}^{(m)}\mathbf{H}(\boldsymbol{\beta}_0))(\widehat{\boldsymbol{\beta}}^{(m)} - \boldsymbol{\beta}_0) \\
&+\frac{1}{M}\sum_{m=1}^M \widehat{\boldsymbol{\Theta}}^{(m)}\left\{\frac{1}{n}\sum_{i\in D_m} y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta} \le 1\}\right\} \\
&-\frac{1}{M}\sum_{m=1}^M \widehat{\boldsymbol{\Theta}}^{(m)}\left\{E\left[y\mathbf{x}\left(I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}}^{(m)} \le 1\} - I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}\right)\right] + \mathbf{H}(\boldsymbol{\beta}_0)(\widehat{\boldsymbol{\beta}}^{(m)} - \boldsymbol{\beta}_0)\right\} \\
&-\frac{1}{M}\sum_{m=1}^M \widehat{\boldsymbol{\Theta}}^{(m)}\mathbf{a}_n^{(m)},
\end{aligned}$$

where $\mathbf{a}_n^{(m)} = \frac{1}{n}\sum_{i\in D_m} y_i\mathbf{x}_i(I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}) - Ey\mathbf{x}(I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}} \le 1\} - I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\})$ with $\|\mathbf{a}_n\|_\infty \le a_n$ with probability at least $1 - p^{-C}$.

For terms other than the second one above, the proof is exactly the same as for the proof of Theorem 1. Note that for each machine m, all derived inequalities hold with probability at least $1 - p^{-C}$ (note C can be chosen to be arbitrarily large) and thus they hold with probability at least $1 - Mp^{-C}$ simultaneously for all M machines. Since we assumed $\log M \le \log N = O(\log p)$, $1 - Mp^{-C}$ can again be written as $1 - p^{-C}$ (with a different C). For the second term above, the difference from the calculations in Theorem 1 is that here $\widehat{\boldsymbol{\Theta}}^{(m)}$ is different for different m. Let $\mathbf{e}_j \in \mathbb{R}^p$ be the unit vector with a single one for the j-th entry and let $a_{ij} = y_i\mathbf{e}_j^{\mathrm{T}}\widehat{\boldsymbol{\Theta}}^{(m)}\mathbf{x}_i$ if $i \in D_m$. Note $|a_{ij}| = |\mathbf{e}_j^{\mathrm{T}}\widehat{\boldsymbol{\Theta}}^{(m)}\mathbf{x}_i| \le \|\mathbf{e}_j\|_\infty\|\widehat{\boldsymbol{\Theta}}^{(m)}\|_{L_1}\|\mathbf{x}_i\|_\infty \le CC_n$ with probability at least $1 - p^{-C}$. By Hoeffding's inequality, we have

$$\begin{aligned}
& P\left(\left|\frac{1}{M}\sum_{m=1}^M \mathbf{e}_j^{\mathrm{T}}\widehat{\boldsymbol{\Theta}}^{(m)}\left\{\frac{1}{n}\sum_{i\in D_m} y_i\mathbf{x}_i I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}\right\}\right| > t\right) \\
= \;& P\left(\left|\frac{1}{N}\sum_{m\le M, i\in D_m} a_{ij} I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}\right| > t\right) \\
\le \;& 2\exp\left\{-CC_n^{-2}Nt^2\right\}. \qquad (8)
\end{aligned}$$

Thus

$$\left\|\frac{1}{M}\sum_{m=1}^M \widehat{\boldsymbol{\Theta}}^{(m)}\left\{\frac{1}{n}\sum_{i\in D_m} y_i\mathbf{x}_i I_{\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1\}}\right\}\right\|_\infty \le CC_n\sqrt{\frac{\log p}{N}},$$

with probability at least $1 - p^{-C}$. ■

Under reasonable assumptions, the dominating term in the bounds in Theorem 2 is $\sqrt{\log p/N}$. One version of such assumptions is presented below without proof, since it is based on simple algebra.

Corollary 1 *Assume the same conditions as in Theorem 2. In addition, we assume* $s, K, \|\boldsymbol{\beta}_0\|$ *are bounded,* β_{01} *is bounded away from zero,* $h \sim n^{-1/5}$, $\log p/n^{2/5} \to 0$ *and* $M^3 = O(N/\log p)$, *then*

$$\|\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty \leq C\sqrt{\frac{\log p}{N}},$$

with probability at least $1 - p^{-C}$.

Remark 1 *In our case,* M *can scale like* $(N/\log p)^{1/3}$ *while for the smooth loss consider in Lee et al. (2017),* M *can scale as* $(N/\log p)^{1/2}$. *This is mainly due to that for the unsmooth loss function, the empirical process as in Proposition 2 has a slower rate. In particular, in Proposition 2 the derived bound in terms of* N *scales as* $N^{-3/4}$. *For smooth loss, this term would have been* N^{-1}, *which eventually leads to the constraint that* M *should scale like* $N^{1/3}$ *instead of* $N^{1/2}$. *Although we are not claiming the bound of Proposition 2 is optimal, it is common to see that for unsmooth functions the empirical process converges slower than that for smooth functions (Belloni and Chernozhukov, 2011).*

2.3 Thresholding aggregated estimator

As mentioned in subsection 2.1, the l_2 norm of $\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0$ is generally unfavorably large compared to the centralized estimator using all observations. This is also illustrated in our simulations. To improve performance, thresholding can be used as a post-processing step which produced a sparse aggregate estimator. Let c be a threshold level. We define $\bar{\boldsymbol{\beta}}^c = (\bar{\beta}_1^c, \ldots, \bar{\beta}_p^c)^{\mathrm{T}}$ where $\bar{\beta}_j^c = \bar{\beta}_j I\{|\bar{\beta}_j| > c\}$. Here for illustration we used hard thresholding and similar results hold for soft thresholding. Under appropriate choice of the threshold, the thresholded estimator has the same convergence rate as the centralized estimator in l_1 and l_2 norm, when choosing $c \asymp \sqrt{\log p/N}$.

Theorem 3 *On the event* $c > \|\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty$, *we have* $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_\infty \leq 2c$, $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_1 \leq 2sc$ *and* $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\| \leq 2\sqrt{s}c$.

Proof of Theorem 3. Using $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_\infty \leq \|\bar{\boldsymbol{\beta}}^c - \bar{\boldsymbol{\beta}}\|_\infty + \|\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty \leq 2c$ giving the first result. Since $c > \|\bar{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty$, we have $\bar{\boldsymbol{\beta}}_j^c = 0$ if $\boldsymbol{\beta}_{0j} = 0$ and thus the support of $\bar{\boldsymbol{\beta}}^c$ is contained in that of $\boldsymbol{\beta}_0$. This implies $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_1 \leq s\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_\infty \leq 2sc$ and $\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\| \leq \sqrt{s}\|\bar{\boldsymbol{\beta}}^c - \boldsymbol{\beta}_0\|_\infty \leq 2\sqrt{s}c$. ■

3. Simulations

We illustrate the performances of the distributed estimators of the linear SVM coefficients via simulations. We generate the data from the following model. First $y_i, i = 1, \ldots, N$ are generated from the binary distribution $P(y_i = 1) = P(y_i = -1) = 0.5$. Given $y_i = 1$, $\mathbf{x}_i$ is generated from a multivariate normal distribution with mean $\boldsymbol{\mu} = (0.2, -0.2, 0.3, 0.4, 0.5, 0, \ldots, 0)^{\mathrm{T}}$ and covariance matrix $\boldsymbol{\Sigma} = (\sigma_{jj'})$ with $\sigma_{jj} = 1$ for all j, $\sigma_{jj'} = 0.2$ if $j \leq 5, j' \leq 5, j \neq j'$, $\sigma_{jj'} = 0$ otherwise. Given $y_i = -1$, $\mathbf{x}_i$ is generated from a multivariate normal distribution with mean $-\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. By the calculations in Appendix B of Peng et al. (2016), the true parameter can be found to be $\boldsymbol{\beta}_0 = (0.217, -0.503, 0.397, 0.573, 0.750, 0, \ldots, 0)^{\mathrm{T}}$.

The tuning parameters λ in the penalty and the bound Cb_n used in finding the matrix inverse are selected by 5-fold cross-validation in each local machine. For the threshhold c, we choose c such that the number of nonzero components of $\bar{\boldsymbol{\beta}}$ is equal to the maximum number of nonzero components in the M local estimates. The bandwidth h is another tuning parameter. Kato (2012) has derived the optimal bandwidth for quantile regression, but it is hard to see whether similar results can be obtained in the current setting. Thus we have used Silverman's rule of thumb for kernel density estimation $h = 1.06\widehat{\sigma}n^{-1/5}$ where $\widehat{\sigma}$ is the sample standard deviation of $1 - y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}$. In our context this rule of thumb has no theoretical support, but seems to work well in practice. In our case, it seems we do not need to estimate the Hessian optimally since our purpose is not to perform inferences of $\boldsymbol{\beta}$. Finally, we use standard normal density as the smoothing kernel q.

We compute the centralized estimator (CE), the naive aggregated estimator without using bias correction (NAE), the aggregated estimator after debiasing (AE), and the final thresholded estimator (TE). The accuracy of the estimators are assessed by the l_∞ error ($\|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_\infty$), the l_2 error ($\|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|$), as well as the prediction error based on independently generated $50,000$ observations.

First, we set $N = 20,000$, $M = 1, 5, 10, 15, 20, 25, 30$ ($M = 1$ is the centralized estimator) and $p = 5000$. Figure 1 shows errors of the estimators that change with M, based on 100 data sets generated in each scenario. The performances generally deteriorate with the increase of M. In terms of l_∞ error the effect of thresholding is very small if any, and both TE and AE (almost identical) are better than NAE. In terms of l_2 error, AE is much worse than NAE. This is due to that AE is non-sparse and the summation of small errors over p variables can be very large. On the other hand, although NAE may have large errors on the nonzero coefficients due to the large bias, the error is small on many zero coefficients which are estimated exactly as zero (NAE is sparse). Thresholding is effective in reducing the l_2 error as well as prediction error.

In the second set of simulations, we still use $p = 5000$ and consider different sample sizes $N = 10000, 20000, 30000, 40000, 50000$, and fix the number of samples in each local machine to be $n = 5000$ (and thus the number of machines M increases with N from 2 to 10). For this simulation, as suggested by a reviewer, we also compute the thresholded estimator (after debiasing and aggregation) using the true Hessian (the true Hessian can be computed as explained in Appendix B). From the reported results in Figure 2, it is seen that the proposed estimator TE has errors decreasing with total sample size, while the errors of the naive aggregated estimator are much larger. For AE which is non-sparse, its performance in terms of l_2 and prediction error is the worst among different estimators. It is also seen that the thresholded estimator using the true Hessian has similar performances as TE.

The simulations are carried out on the computational cluster Katana in the University of New South Wales. For the second set of simulations for example, the central estimators require from 4 to 29 hours to compute depending on the sample size, to finish all 100 repetitions, while the distributed estimator requires about 2 hours for all sample sizes.

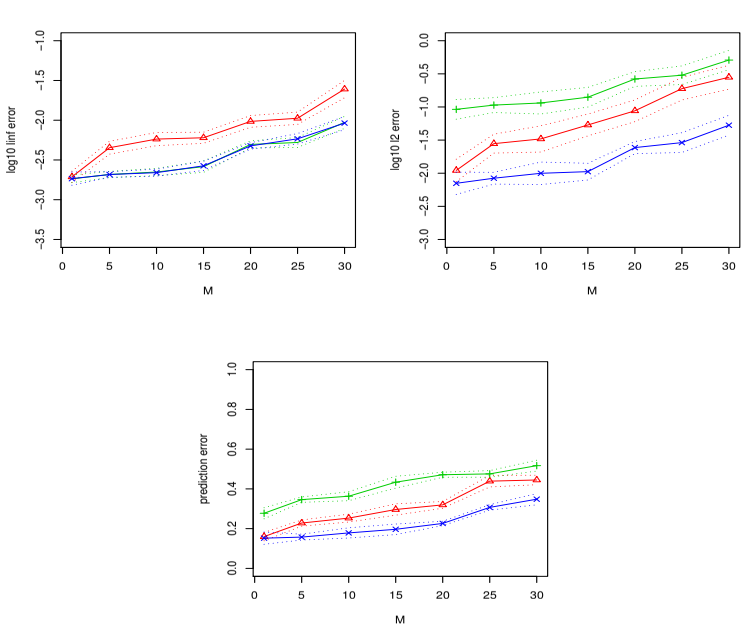

Figure 1: The l_∞, l_2 and prediction errors of estimates with $M \in \{1, 5, 10, 15, 20, 25, 30\}$ ($M = 1$ represents the centralized estimator). $\triangle$(red): naive aggregated estimator (NAE); +(green): the aggregated estimator after debiasing (AE); $\times$(blue): the thresholded estimator (TE). The l_∞ and l_2 errors are in the logarithmic scale with base 10. The dotted lines are computed based on the 100 repetitions showing 2 standard deviations of the estimated error.

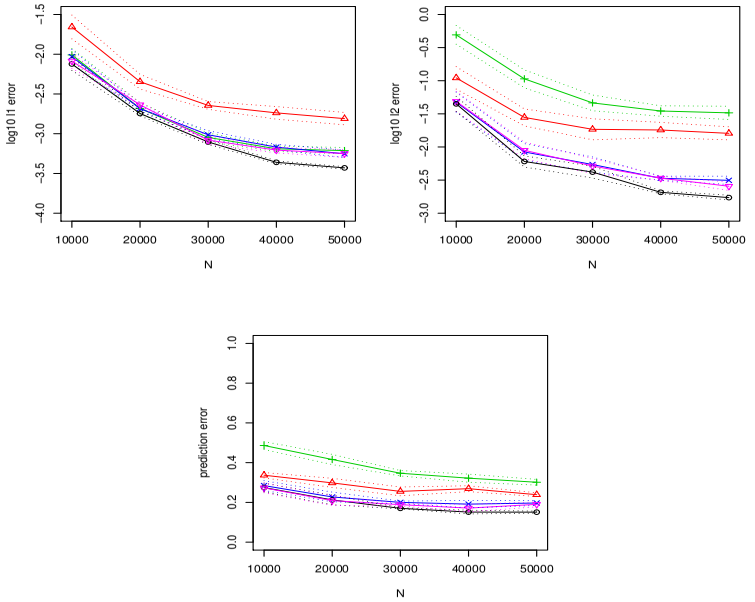

Figure 2: The l_∞ and l_2 errors of estimates with $p = 5000$ and $N \in \{10000, 20000, 30000, 40000, 50000\}$. $\circ$(black): centralized estimator (CE); $\triangle$(red): naive aggregated estimator (NAE); +(green): the aggregated estimator after debiasing (AE); $\times$(blue): the thresholded estimator (TE). $\triangledown$(purple): the thresholded estimator when the true Hessian is used in debiasing. The l_∞ and l_2 errors are in the logarithmic scale with base 10. The dotted lines are computed based on the 100 repetitions showing 2 standard deviations of the estimated error.

4. Conclusion

In this paper, we consider distributed estimation of l_1-penalized linear SVM. As long as the number of machines is not too large, the distributed estimator has the same convergence rate as the centralized estimator in l_∞, l_1 and l_2 norms, if the estimator is thresholded to retain sparsity.

We note that the optimization problem of Equation 6 can be solved row by row, and thus can also be done in a distributed way. Using local data, each local machine can obtain estimates for p/M rows of $\mathbf{\Theta}$ and then these estimates can be combined to obtain a *single* estimate of $\mathbf{\Theta}$ that satisfies $\|\widehat{\mathbf{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0)-\mathbf{I}\|_\infty \le Cb_n$ with probability at least $1-p^{-C}$, where $b_n = C_n\left(\left(\frac{1}{\beta_{01}}+\sqrt{\frac{\log p}{nh^3\beta_{01}}}+\frac{\log p}{nh^2}\right)s\sqrt{\frac{\log p}{n}}+\frac{s^2\log p}{nh^3}+\frac{h}{\beta_{01}^2}+\sqrt{\frac{\log p}{nh\beta_{01}}}\right)$ and the same bound as in Theorem 2 for $\|\bar{\boldsymbol{\beta}}-\boldsymbol{\beta}_0\|_\infty$ hold with minor modifications of the proofs. For ease of implementation, we do not investigate this alternative in our numerical studies.

Once an aggregated estimator of $\boldsymbol{\beta}$ is obtained, one can use this estimator in the evaluation of the inverse of $\mathbf{H}(\widehat{\boldsymbol{\beta}})$ in each local machine. This iterative approach requires further communications among the central machine and local machines, and we do not observe improved performances of the iterative estimator empirically.

A few problems remain open in this study, among possibly many others. First, there is a gap in theory and simulation in that (A1) assumed that the covariates are bounded while the simulations are based on a multivariate normal distribution for covariates. We used the assumption of bounded covariates for at least two reasons. One reason is that we rely on the results of Peng et al. (2016), who assumed boundedness of predictors. The second reason is that we have used boundedness in our own derivation in various places, even though such assumption may be relaxed with more efforts and much messier proof. Another open question is whether the implied constraint on M mentioned at the end of Section 2.2 is tight. This appears to be a challenging open question that we are not currently able to answer.

Acknowlegements

The authors sincerely thank the Action Editor Professor Jie Peng, and two anonymous reviewers for their insightful comments and suggestions which greatly improved the paper. The research of Lian is partially supported by City University of Hong Kong Start Up Grant 7200521.

Appendix A. Proofs of Propositions.

Proof of Proposition 1. We first show that

$$\|\widehat{\mathbf{\Theta}}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{I}\|_\infty \le Cb_N \text{ and } \|\widehat{\mathbf{\Theta}}\|_{L_1} \le C_N. \tag{9}$$

First, we note these will be implied by that

$$\|\mathbf{\Theta}_0\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{I}\|_\infty \le Cb_N. \tag{10}$$

In fact, Equation 10 means the constrained optimization problem is feasible and the feasibility of $\widehat{\mathbf{\Theta}}$ immediately implies the first equation of Equation 9. For the second equation

of Equation 9, we only need to note that by Equation 10 and the definition of the constrained optimization problem, which can be solved for each row of $\mathbf{\Theta}$ separately, we have $\|\widehat{\mathbf{\Theta}}\|_{L_1} \le \|\mathbf{\Theta}_0\|_{L_1}$.

To establish Equation 10, we bound $\|\mathbf{\Theta}_0\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{I}\|_\infty = \|\mathbf{\Theta}_0(\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0))\|_\infty \le \|\mathbf{\Theta}_0\|_{L_1}\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty$. Furthermore, we write

$$\begin{aligned} & \|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty \\ \le\ & \|E[\widehat{\mathbf{H}}(\boldsymbol{\beta}_0)]-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty + \|\widehat{\mathbf{H}}(\boldsymbol{\beta}_0)-E[\widehat{\mathbf{H}}(\boldsymbol{\beta}_0)]\|_\infty + \|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\widehat{\mathbf{H}}(\boldsymbol{\beta}_0)\|_\infty \\ =:\ & I_1+I_2+I_3. \end{aligned}$$

First we consider I_1 and show that for any bounded function $s(\mathbf{x})$ whose partial derivatives are also bounded, we have

$$\left|E\left[\frac{1}{h}q\left(\frac{1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right]-E\left[\delta(1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})\right]\right| \le Ch/\beta_{01}^2,$$

and we will then obtain $I_1 \le Ch/\beta_{01}^2$ by setting $s(\mathbf{x}) = x_j x_{j'}, 1 \le j, j' \le p$.

In fact, since, for example, $E[\delta(1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})] = P(y=1)E[\delta(1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})|y=1]+P(y=-1)E[\delta(1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})|y=-1]$, we only need to consider conditional expectation given $y=1$ (conditional expectation given $y=-1$ is similar). Write $\boldsymbol{\beta}_{0,-1} = (\beta_{02},\ldots,\beta_{0p})^{\mathrm{T}}$ and $\mathbf{x}_{-1} = (x_2,\ldots,x_p)^{\mathrm{T}}$. Then, by a change of variable $(x_1,\ldots,x_p) \to (z_1,x_2,\ldots,x_p)$ with $z_1 = \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$, we have

$$\begin{aligned} & E[\frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})|y=1] \\ = & \int \frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})f(\mathbf{x})d\mathbf{x} \\ = & \int \frac{1}{h}q\left(\frac{1-z_1}{h}\right)s\left(\frac{z_1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)f\left(\frac{z_1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dz_1d\mathbf{x}_{-1} \\ \overset{u=(1-z_1)/h}{=} & \int q(u)s\left(\frac{1-uh-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)f\left(\frac{1-uh-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dud\mathbf{x}_{-1} \\ = & \int q(u)(sf)\left(\frac{1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dud\mathbf{x}_{-1} \\ & -\int q(u)(sf)^{(1)}\left(\frac{1-*-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}^2}uhdud\mathbf{x}_{-1}, \end{aligned}$$

where $(sf)^{(1)}$ is the partial derivative of $(sf)(.)$ with respect to its first variable and $*$ represents a value between 0 and uh, and

$$\begin{aligned} & E[\delta(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})|y=1] \\ = & \int \delta(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})f(\mathbf{x})d\mathbf{x} \\ = & \int s\left(\frac{1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)f\left(\frac{1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dz_1d\mathbf{x}_{-1}. \end{aligned}$$

Using $\int q(u)du = 1$, $\int |u|q(u)du < \infty$, and that $(sf)^{(1)}$ is bounded, we get

$$\begin{aligned} & \left| E[\frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})|y=1] - E[\delta(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)s(\mathbf{x})|y=1]\right| \\ = & \left| \int q(u)(sf)^{(1)}\left(\frac{1-*-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}}, \mathbf{x}_{-1}\right)\frac{1}{\beta_{01}^2}uhdud\mathbf{x}_{-1}\right| \\ \leq & Ch/\beta_{01}^2, \end{aligned}$$

and thus

$$I_1 \leq Ch/\beta_{01}^2. \tag{11}$$

Next we deal with I_2. Again with a bounded function s, we have $\left|\frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right| \leq C/h$ and

$$\begin{aligned} & E\left[\left(\frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right)^2 |y=1]\right] \\ = & \int \frac{1}{h^2}q^2\left(\frac{1-z_1}{h}\right)s^2\left(\frac{z_1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}}, \mathbf{x}_{-1}\right)f\left(\frac{z_1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}}, \mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dz_1d\mathbf{x}_{-1} \\ = & \int \frac{1}{h}q^2(u)(s^2f)\left(\frac{1-uh-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}}, \mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dud\mathbf{x}_{-1} \\ \leq & C/(h\beta_{01}), \end{aligned} \tag{12}$$

since $\int q^2(u)du < \infty$. Thus

$$E\left[\left(\frac{1}{h}q\left(\frac{1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right)^r \Big| y=1\right] \leq (C/h)^{r-2}(1/(h\beta_{01})),\ r \geq 2.$$

By Bernstein's inequality (Lemma 2.2.11 in van der Vaart and Wellner (1996)),

$$\begin{aligned} & P\left(\left|\frac{1}{N}\sum_i I_{\{y_i=1\}}\frac{1}{h}q\left(\frac{1-y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x}_i) - E\left[I_{\{y=1\}}\frac{1}{h}q\left(\frac{1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right]\right| > t\right) \\ \leq & 2\exp\left\{-C\frac{Nht^2}{t+\beta_{01}^{-1}}\right\}, \end{aligned}$$

and the same inequality holds with $y=1$, $y_i=1$ replaced by $y=-1$, $y_i=-1$, and thus

$$\left|\frac{1}{N}\sum_i \frac{1}{h}q\left(\frac{1-y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x}_i) - E\left[\frac{1}{h}q\left(\frac{1-y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0}{h}\right)s(\mathbf{x})\right]\right| \leq C\left(\sqrt{\frac{\log p}{Nh\beta_{01}}} + \frac{\log p}{Nh}\right) \tag{13}$$

with probability at least $1-p^{-C}$ (note C here can be arbitrarily large as long as we are willing to set the constant C in the display above to be large enough). By choosing $s(\mathbf{x}) = x_jx_{j'}$, using the the union bound,

$$I_2 \leq C\left(\sqrt{\frac{\log p}{Nh\beta_{01}}} + \frac{\log p}{Nh}\right), \tag{14}$$

with probability at least $1-p^{-C}$.

Finally, we bound I_3. By Taylor's expansion, we have

$$\begin{aligned} & \left|\frac{1}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q((1-\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}})/h)/h - \frac{1}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q((1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h\right| \\ \leq & \left|\frac{C}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q'((1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2\cdot\mathbf{x}_i^{\mathrm{T}}(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0)\right| \\ & + \left|\frac{C}{2N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q''(*)/h^3\cdot(\mathbf{x}_i^{\mathrm{T}}(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}_0))^2\right| \\ =: & J_1 + J_2, \end{aligned}$$

where $*$ denotes a value between $(1-\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}})/h$ and $(1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h$. The second term above is easy to deal with. Since $q''(.)$ is bounded, we get

$$J_2 \leq \frac{Cs^2\log p}{Nh^3},$$

with probability $1-p^{-C}$. Although J_1 could be bounded similar to J_2, a more careful calculation will yield a tighter bound. For this we write

$$\begin{aligned} & \left|\frac{1}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q'(1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0/h)/h^2\right| \\ \leq & \left|\frac{1}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q'((1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2 - E[I_{\{y=1\}}x_jx_{j'}q'(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0/h)/h^2]\right| \\ & + \left|E[I_{\{y=1\}}x_jx_{j'}q'(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0/h)/h^2]\right|. \end{aligned}$$

Similar to Equation 12, we have $|q'((1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2| \leq C/h^2$ and $E[(q'((1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2)^2|y=1] \leq C/(h^3\beta_{01})$, and by the same arguments as those that lead to Equation 13, we get

$$\begin{aligned} & \max_{j,j'}\left|\frac{1}{N}\sum_i I_{\{y_i=1\}}x_{ij}x_{ij'}q'((1-\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2 - E[I_{\{y=1\}}x_jx_{j'}q'(1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0/h)/h^2]\right| \\ \leq & C\left(\sqrt{\frac{\log p}{Nh^3\beta_{01}}} + \frac{\log p}{Nh^2}\right), \end{aligned}$$

with probability at least $1-p^{-C}$. Furthermore, for any bounded $s(\mathbf{x})$ whose partial derivatives are also bounded, we have

$$\begin{aligned}
& \left|E[s(\mathbf{x})q'((1-\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0)/h)/h^2|y=1]\right| \\
= & \left|\int q'((1-z_1)/h)/h^2\cdot(sf)\left(\frac{z_1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{\beta_{01}}dz_1d\mathbf{x}_{-1}\right| \\
= & \left|\int q'(u)\cdot(sf)\left(\frac{1-uh-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)\frac{1}{h\beta_{01}}dud\mathbf{x}_{-1}\right| \\
= & \left|\int (sf)\left(\frac{1-\mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_{01}},\mathbf{x}_{-1}\right)(\int q'(u)du)\frac{1}{h\beta_{01}}d\mathbf{x}_{-1}\right|+\left|\int q'(u)u(sf)^{(1)}(*)\frac{1}{\beta_{01}^2}dud\mathbf{x}_{-1}\right| \\
\leq & C/\beta_{01}^2,
\end{aligned}$$

using that $\int q'(u)du=0$. Thus

$$J_1\leq C\left(\frac{1}{\beta_{01}^2}+\sqrt{\frac{\log p}{Nh^3\beta_{01}}}+\frac{\log p}{Nh^2}\right)\cdot s\sqrt{\frac{\log p}{N}}$$

with probability at least $1-p^{-C}$ and then

$$I_3\leq C\left(\left(\frac{1}{\beta_{01}^2}+\sqrt{\frac{\log p}{Nh^3\beta_{01}}}+\frac{\log p}{Nh^2}\right)\cdot s\sqrt{\frac{\log p}{N}}+\frac{s^2\log p}{Nh^3}\right), \tag{15}$$

with probability at least $1-p^{-C}$. Combining bounds in Equation 11, Equation 14 and Equation 15, we get

$$\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty\leq C\left(\left(\frac{1}{\beta_{01}^2}+\sqrt{\frac{\log p}{Nh^3\beta_{01}}}+\frac{\log p}{Nh^2}\right)\cdot s\sqrt{\frac{\log p}{N}}+\frac{s^2\log p}{Nh^3}+\frac{h}{\beta_{01}^2}+\sqrt{\frac{\log p}{Nh\beta_{01}}}\right),$$

and thus

$$\|\boldsymbol{\Theta}_0\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{I}\|_\infty\leq Cb_N,$$

with probability at least $1-p^{-C}$.

Finally, we also have

$$\begin{aligned}
& \|\widehat{\boldsymbol{\Theta}}\mathbf{H}(\boldsymbol{\beta}_0)-\mathbf{I}\|_\infty \\
\leq & \|\widehat{\boldsymbol{\Theta}}\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{I}\|_\infty+\|\widehat{\boldsymbol{\Theta}}(\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0))\|_\infty \\
\leq & Cb_N+\|\widehat{\boldsymbol{\Theta}}\|_{L_1}\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty \\
\leq & Cb_N,
\end{aligned}$$

using the bound for $\|\widehat{\mathbf{H}}(\widehat{\boldsymbol{\beta}})-\mathbf{H}(\boldsymbol{\beta}_0)\|_\infty$ above. ■

Proof of Proposition 2. We define $\Omega=\{\boldsymbol{\beta}\in\mathbb{R}^p:\|\boldsymbol{\beta}\|_0\leq K,\|\boldsymbol{\beta}-\boldsymbol{\beta}_0\|_1\leq Cs\sqrt{\log p/N}\}$ and we have $\widehat{\boldsymbol{\beta}}\in\Omega$ with probability at least $1-p^{-C}$. Define the class of functions

$$\mathcal{G}_j=\{yx_j(I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}\leq 1\}-I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1\}):\boldsymbol{\beta}\in\Omega\},$$

with squared integrable envelope function $F(\mathbf{x},y)=|x_j|$.

We decompose Ω as $\Omega=\cup_{T\subset\{1,\ldots,p\},|T|\leq K}\Omega(T)$ with $\Omega(T)=\{\boldsymbol{\beta}:\text{ support of }\boldsymbol{\beta}\subset T\}\cap\Omega$. We also define $\mathcal{G}_j(T)=\{yx_j(I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}\leq 1\}-I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1\}):\boldsymbol{\beta}\in\Omega(T)\}$.

By Lemma 2.6.15, Lemma 2.6.18 (vi) and (viii) (actually by the proof of Lemma 2.6.18 (viii)) in van der Vaart and Wellner (1996), for each fixed $T\subset\{1,\ldots,p\}$ with $|T|\leq K$, $\mathcal{G}_j(T)$ is a VC-subgraph with index bounded by $K+2$ and by Theorem 2.6.7 of van der Vaart and Wellner (1996), we have

$$N(\epsilon,\mathcal{G}_j(T),L_2(P_n))\leq\left(\frac{C\|F\|_{L_2(P_n)}}{\epsilon}\right)^{CK}\leq\left(\frac{C}{\epsilon}\right)^{CK}.$$

Since there are at most $\binom{p}{K}\leq(ep/K)^K$ different such T, we have

$$N(\epsilon,\mathcal{G}_j,L_2(P_n))\leq\left(\frac{C}{\epsilon}\right)^{CK}\left(\frac{ep}{K}\right)^K\leq\left(\frac{Cp}{\epsilon}\right)^{CK},$$

and thus

$$N(\epsilon,\cup_{j=1}^p\mathcal{G}_j,L_2(P_n))\leq p\left(\frac{Cp}{\epsilon}\right)^{CK}.$$

Let $\sigma^2=\sup_{f\in\cup_j\mathcal{G}_j}Pf^2$. Then by Theorem 3.12 of Koltchinskii (2011), we have

$$E\|R_n\|_{\cup_j\mathcal{G}_j}\leq C\left(\sigma\sqrt{\frac{K\log p}{N}}+\frac{K\log p}{N}\right),$$

where $\|R_n\|_{\cup_j\mathcal{G}_j}=\sup_{f\in\cup_j\mathcal{G}_j}N^{-1}\sum_{i=1}^N\varepsilon_if(\mathbf{x}_i,y_i)$ with ε_i being i.i.d. Rademacher random variables. Using the symmetrization inequality which states that $E\|P_n-P\|_{\cup_j\mathcal{G}_j}\leq 2E\|R_n\|_{\cup_j\mathcal{G}_j}$, where $\|P_n-P\|_{\cup_j\mathcal{G}_j}=\sup_{f\in\cup_j\mathcal{G}_j}N^{-1}\sum_i f(\mathbf{x}_i,y_i)-Ef(\mathbf{x},y)$, Talagrand's inequality (page 24 of Koltchinskii (2011)) gives

$$P\left(\|P_n-P\|_{\cup_j\mathcal{G}_j}\geq C\left(\sigma\sqrt{\frac{K\log p}{N}}+\frac{K\log p}{N}+\sqrt{\frac{\sigma^2t}{N}}+\frac{t}{N}\right)\right)\leq e^{-t},$$

that is, with probability at least $1-p^{-C}$,

$$\begin{aligned}
& \left\|\frac{1}{N}\sum_i y_i\mathbf{x}_i(I\{y_i\mathbf{x}_i^{\mathrm{T}}\widehat{\boldsymbol{\beta}}\leq 1\}-I\{y_i\mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1\})-Ey\mathbf{x}(I\{y\mathbf{x}^{\mathrm{T}}\widehat{\boldsymbol{\beta}}\leq 1\}-I\{y\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1\})\right\|_\infty \\
\leq & C\left(\sigma\sqrt{\frac{K\log p}{N}}+\frac{K\log p}{N}\right).
\end{aligned}$$

Finally, we need to decide the size of σ^2. For $\boldsymbol{\beta}\in\Omega$, we have that

$$\begin{aligned}
& E[(I\{\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}\leq 1\}-I\{\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1\})^2|y=1] \\
\leq & P(\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}\leq 1,\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\geq 1|y=1)+P(\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}\geq 1,\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1|y=1) \\
\leq & P(1\leq\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1+Cs\sqrt{\log p/N}|y=1)+P(1-Cs\sqrt{\log p/N}\leq\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0\leq 1|y=1) \\
\leq & Cs\sqrt{\log p/N}/\beta_{01},
\end{aligned}$$

where we used in the second inequality the fact that $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta} \le 1 \le \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$ implies $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \le 1 + |\mathbf{x}^{\mathrm{T}}(\boldsymbol{\beta} - \boldsymbol{\beta}_0)| \le 1 + C\|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_1$ and similarly that $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 \ge 1 - C\|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_1$, and in the last inequality we used that the density of $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$ conditional on $y = 1$ is bounded by $1/\beta_{01}$. This last observation follows easily from that, by change of variable $z_1 = \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$, the joint density of $(z_1, \mathbf{x}_{-1})$ conditional on $y = 1$ is given by

$$f((z_1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1})/\beta_{01}, \mathbf{x}_{-1})/\beta_{01}.$$

Thus we have $\sigma^2 \le Cs\sqrt{\log p/N}/\beta_{01}$ which proved the proposition. ■

Proof of Proposition 3. By integrating over x_1 first, we have for $s(\mathbf{x}) = x_j x_{j'}$,

$$\begin{aligned}
&\int \delta(1 - \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}) s(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} - \int \delta(1 - \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0) s(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} \\
= &\int \frac{1}{\beta_1}(sf)\left(\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_1}, \mathbf{x}_{-1}\right) d\mathbf{x}_{-1} - \int \frac{1}{\beta_{01}}(sf)\left(\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, \mathbf{x}_{-1}\right) d\mathbf{x}_{-1} \\
= &\frac{\beta_{01} - \beta_1}{\beta_1\beta_{01}} \int (sf)\left(\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_1}, \mathbf{x}_{-1}\right) d\mathbf{x}_{-1} + \frac{1}{\beta_{01}} \int (sf)^{(1)}(*, \mathbf{x}_{-1}) \mathbf{x}_{-1}^{\mathrm{T}} \left(\frac{\boldsymbol{\beta}_{0,-1}}{\beta_{01}} - \frac{\boldsymbol{\beta}_{-1}}{\beta_1}\right) d\mathbf{x}_{-1},
\end{aligned}$$

where $*$ represents a value between $\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}$ and $\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{-1}}{\beta_1}$. Using $|\beta_1 - \beta_{01}| \le \|\boldsymbol{\beta} - \boldsymbol{\beta}_0\|_1 \le \beta_{01}/2$, $\beta_1 \ge \beta_{01} - |\beta_1 - \beta_{01}| \ge (1/2)\beta_{01}$, and $\|\frac{\boldsymbol{\beta}_{0,-1}}{\beta_{01}} - \frac{\boldsymbol{\beta}_{-1}}{\beta_1}\|_1 \le \frac{\|\boldsymbol{\beta}_0\|_1 \cdot \|\boldsymbol{\beta}_1 - \boldsymbol{\beta}_{01}\|_1}{|\beta_{01}\beta_1|} \le \frac{C}{\beta_{01}^2}\|\boldsymbol{\beta}_0\|_1\|\boldsymbol{\beta}_1 - \boldsymbol{\beta}_{01}\|_1$, the lemma is proved. ■

Appendix B. Discussions of Assumption (A3).

First we show that $\mathbf{H}(\boldsymbol{\beta}_0)$ can also be expressed as

$$c_1 E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | y = 1, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] + c_2 E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | y = -1, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = -1], \tag{16}$$

for two positive constants c_1, c_2. Indeed, let $h(z, x_2, \ldots, x_p)$ be the joint density of $(z = \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0, x_2, \ldots, x_p)^{\mathrm{T}}$. We have $h(z, x_2, \ldots, x_p) = f(\frac{z - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, x_2, \ldots, x_p)\frac{1}{\beta_{01}}$. Then, for any function $s(\mathbf{x})$, we have

$$\begin{aligned}
&E[\delta(1 - \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0) s(\mathbf{x}) | y = 1] \\
= &\int \delta(1 - \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0) s(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} \\
= &\int s(\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, x_2, \ldots, x_p) f(\frac{z - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, x_2, \ldots, x_p)\frac{1}{\beta_{01}} d\mathbf{x}_{-1},
\end{aligned}$$

and

$$\begin{aligned}
&E[s(\mathbf{x}) | y = 1, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] \\
= &E[s(\frac{z - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, x_2, \ldots, x_p) | y = 1, z = 1] \\
= &\int s(\frac{1 - \mathbf{x}_{-1}^{\mathrm{T}}\boldsymbol{\beta}_{0,-1}}{\beta_{01}}, x_2, \ldots, x_p) \frac{h(1, x_2, \ldots, x_p)}{h_z(1)} d\mathbf{x}_{-1},
\end{aligned}$$

where h_z is the marginal density of $z = \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$ conditional on $y = 1$. Thus we see that

$$E[\delta(1 - \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0) s(\mathbf{x}) | y = 1] = h_z(1) E[s(\mathbf{x}) | y = 1, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1],$$

which implies Equation 16

Let's further assume that y is independent of $\mathbf{x}$ given $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0$. This is a natural sufficient dimension reduction type of assumption. This is the case for example if the class label is generated as in our simulations, or if the data follows the popular logistic regression model. Also assume $\mathbf{x}$ is multivariate normal. Then $E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | y = 1, \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] = E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1]$ by the conditional independence. Since $\mathbf{x}$ has a symmetric distribution, $E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] = E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = -1]$ and thus the Hessian is equal to a constant multiple of $E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1]$. Now we examine the inverse of $E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1]$.

Assume $E[\mathbf{x}] = \mathbf{0}$ and $Cov(\mathbf{x}) = E[\mathbf{x}\mathbf{x}^{\mathrm{T}}] = \mathbf{S}$. The literature on high-dimensional precision matrix estimation typically assume that $\mathbf{S}^{-1}$ is sparse or approximately sparse to make the estimation feasible. We first see how the inverse of $E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1]$ is related to $\mathbf{S}$ under normality. By the normality of $\mathbf{x}$, $(\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0, x_1, \ldots, x_p)$ is again (degenerate) normal with covariance matrix

$$\begin{pmatrix} \boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S}\boldsymbol{\beta}_0 & \boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S} \\ \mathbf{S}\boldsymbol{\beta}_0 & \mathbf{S} \end{pmatrix}.$$

Then by the property of multivariate normal distribution,

$$\begin{aligned}
E[\mathbf{x} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] &= \mathbf{S}\boldsymbol{\beta}_0/(\boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S}\boldsymbol{\beta}_0), \\
Cov(\mathbf{x} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1) &= \mathbf{S} - \frac{\mathbf{S}\boldsymbol{\beta}_0\boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S}}{\boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S}\boldsymbol{\beta}_0},
\end{aligned}$$

and thus

$$E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] = E[\mathbf{x} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] E^{\mathrm{T}}[\mathbf{x} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1] + Cov(\mathbf{x} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1) = \mathbf{S} + a\mathbf{S}\boldsymbol{\beta}_0\boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S},$$

where a is a scalar. By the Sherman-Morrison formula,

$$\begin{aligned}
&(E[\mathbf{x}\mathbf{x}^{\mathrm{T}} | \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1])^{-1} \\
= &\mathbf{S}^{-1} - \frac{a}{1 + a\boldsymbol{\beta}_0^{\mathrm{T}}\mathbf{S}\boldsymbol{\beta}_0}\boldsymbol{\beta}_0\boldsymbol{\beta}_0^{\mathrm{T}}.
\end{aligned}$$

Thus the Hessian matrix is sparse if both $\mathbf{S}^{-1}$ and $\boldsymbol{\beta}_0$ are sparse.

Now we consider several popular and concrete cases.

Case 1. Consider the autoregressive correlation matrix where the (i, j) entry of $\mathbf{S}$ is $s_{ij} = \rho^{|i-j|}, |\rho| < 1$. In this case, it is known that

$$\mathbf{S}^{-1} = \frac{1}{1 - \rho^2} \begin{pmatrix} 1 & -\rho & & & & \\ -\rho & 1 + \rho^2 & -\rho & & & \\ & -\rho & \ddots & \ddots & & \\ & & \ddots & \ddots & \ddots & \\ & & & \ddots & 1 + \rho^2 & -\rho \\ & & & & -\rho & 1 \end{pmatrix}.$$

In particular we can see $\|\mathbf{S}^{-1}\|_{L_1} = 1/(1-|\rho|)$ independent of the size of the matrix.

Case 2. Assume $\mathbf{S}$ is a banded matrix with a fixed bandwidth, then by Theorem 2.2 of Demko (1977), the (i,j) entry of $\mathbf{S}^{-1}$ is bounded by $C\gamma^{|i-j|}$ for some constants $C > 0$, $0 < \gamma < 1$. Thus $\mathbf{S}^{-1}$ is approximately sparse in the sense that $\|\mathbf{S}^{-1}\|_{L_1}$ is bounded.

Case 3. Consider the exchangeable correlation matrix where all the non-diagonal entries of $\mathbf{S}$ are equal to ρ. Here we are not able to give theoretical properties of $\mathbf{S}^{-1}$ but will numerically compute the L_1 norm of the inverse of $(E[\mathbf{x}\mathbf{x}^{\mathrm{T}}|\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1])^{-1}$.

For all three cases, we set $\boldsymbol{\beta}_0 = (1,1,1,1,1,0,\ldots,0)^{\mathrm{T}}$ and $\rho = 0.3$ and report the numerical value of the L_1 norm of the inverse of $(E[\mathbf{x}\mathbf{x}^{\mathrm{T}}|\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1])^{-1}$ in Table 1. We see that in case 1 and 2 the L_1 norm does not change with p. For case 1, this can be theoretically shown easily. It seems to be an extremely cumbersome exercise to show this for case 2, however, and thus we do not try to establish this theoretically. For case 3, we see that numerically the norm increases very slowly with p.

Table 1: L_1 norm of the inverse of $E[\mathbf{x}\mathbf{x}^{\mathrm{T}}|\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}_0 = 1]$.

	$p = 50$	$p = 100$	$p = 200$	$p = 500$	$p = 1000$	$p = 5000$
case 1	5.578	5.578	5.578	5.578	5.578	5.578
case 2	5.889	5.889	5.889	5.889	5.889	5.889
case 3	7.066	7.230	7.316	7.368	7.385	7.399

Abstract

Recent work on follow the perturbed leader (FTPL) algorithms for the adversarial multi-armed bandit problem has highlighted the role of the hazard rate of the distribution generating the perturbations. Assuming that the hazard rate is bounded, it is possible to provide regret analyses for a variety of FTPL algorithms for the multi-armed bandit problem. This paper pushes the inquiry into regret bounds for FTPL algorithms beyond the bounded hazard rate condition. There are good reasons to do so: natural distributions such as the uniform and Gaussian violate the condition. We give regret bounds for both bounded support and unbounded support distributions without assuming the hazard rate condition. We also disprove a conjecture that the Gaussian distribution cannot lead to a low-regret algorithm. In fact, it turns out that it leads to near optimal regret, up to logarithmic factors. A key ingredient in our approach is the introduction of a new notion called the generalized hazard rate.

Keywords: online learning, regret, multi-armed bandits, follow the perturbed leader, gradient based algorithms

1. Introduction

Starting from the seminal work of Hannan (1957) and later developments due to Kalai and Vempala (2005), perturbation based algorithms (called "Follow the Perturbed Leader (FTPL)") have occupied a central place in online learning. Another major family of online learning algorithms, called "Follow the Regularized Leader (FTRL)", is based on the idea of regularization. In special cases, such as the exponential weights algorithm for the experts problem, it has been folk knowledge that regularization and perturbation ideas are connected. That is, the exponential weights algorithm can be understood as either using negative entropy regularization or Gumbel distributed perturbations (for example, see the discussion in Abernethy et al. (2014)).

Recent work have begun to further uncover the connections between perturbation and regularization. For example, in online linear optimization, one can understand regularization and perturbation as simply two different ways to smooth a non-smooth potential function. The former corresponds to infimal convolution smoothing and the latter corresponds to stochastic (or integral convolution) smoothing (Abernethy et al., 2014). Having a generic framework for understanding perturbations allows one to study a wide variety of online linear optimization games and a number of interesting perturbations.

FTRL and FTPL algorithms have also been used beyond "full information" settings. "Full information" refers to the fact that the learner observes the entire move of the adversary. The multi-armed bandit problem is one of the most fundamental examples of "partial information" settings. Regret analysis of the multi-armed bandit problem goes back to the work of Robbins (1952) who formulated the stochastic version of the problem. The non-stochastic, or adversarial, version was formulated by Auer et al. (2002), who provided the EXP3 algorithm achieving $O(\sqrt{NT \log N})$ regret in T rounds with N arms. They also showed a lower bound of $\Omega(\sqrt{NT})$, which was later matched by the Poly-INF algorithm (Audibert and Bubeck, 2009; Audibert et al., 2011). The Poly-INF algorithm can be interpreted as an FTRL algorithm with negative Tsallis entropy regularization (Audibert et al., 2011; Abernethy et al., 2015). For a recent survey of both stochastic and non-stochastic bandit problems, see Bubeck and Cesa-Bianchi (2012).

For the non-stochastic multi-armed bandit problem, Kujala and Elomaa (2005) and Poland (2005) both showed that using the exponential (actually double exponential/Laplace) distribution in an FTPL algorithm coupled with standard unbiased estimation technique yields near-optimal $O(\sqrt{NT \log N})$ regret. Unbiased estimation needs access to arm probabilities that are not explicitly available when using an FTPL algorithm. Neu and Bartók (2013) introduced the geometric resampling scheme to approximate these probabilities while still guaranteeing low regret. Recently, Abernethy et al. (2015) analyzed FTPL for adversarial multi-armed bandits and provided regret bounds under the condition that the hazard rate of the perturbation distribution is bounded. This condition allowed them to consider a variety of perturbation distributions beyond the exponential, such as Gamma, Gumbel, Frechet, Pareto, and Weibull.

Unfortunately, the bounded hazard rate condition is violated by two of the most widely known distributions: namely the uniform[1] and the Gaussian distributions. Therefore, the results of Abernethy et al. (2015) say nothing about the regret incurred in an adversarial multi-armed bandit problem when we use these distributions (without forced exploration) to generate perturbations. Contrast this to the full information experts setting where using these distributions as perturbations yields optimal $\sqrt{T}$ regret and even yields the optimal $\sqrt{\log N}$ dependence on the dimension in the Gaussian case (Abernethy et al., 2014).

The Gaussian distribution has lighter tails than the exponential. The hazard rate of a Gaussian increases linearly on the real line (and is hence unbounded) whereas the exponential has a constant hazard rate. Does having too light a tail make a perturbation inherently bad? The uniform is even worse from a light tail point of view: it has bounded support! In fact, Kujala and Elomaa (2005) had trouble dealing with the uniform distribution and remarked, "we failed to analyze the expert setting when the perturbation distribution was uniform." Does having a bounded support make a perturbation even worse? Or is it that the hazard rate condition is just a sufficient condition without being anywhere close to nec-

1. The uniform distribution is also historically significant as it was used in the original FTPL algorithm of Hannan (1957).

essary for a good regret bound to exist. The analysis of Abernethy et al. (2015) suggests that perhaps a bounded hazard rate is critical. They even made the following conjecture.

Conjecture 1 *If a distribution $\mathcal{D}$ has a monotonically increasing hazard rate $h_{\mathcal{D}}(x)$ that does not converge as $x \to +\infty$ (e.g., Gaussian), then there is a sequence of gains that causes the corresponding FTPL algorithm to incur at least a linear regret.*

The main contribution of this paper is to provide answers to the questions raised above. First, we show that boundedness of the hazard rate is certainly not a requirement for achieving sublinear (in T) regret. Bounded support distributions, like the uniform, violate the boundedness condition on the hazard rate in the most extreme way. Their hazard rate blows up not just asymptotically at infinity, as in the Gaussian case, but as one approaches the right edge of the support. Yet, we can show (Corollary 5) that using the uniform distribution results in a regret bound of $O((NT)^{2/3})$. This bound is clearly not optimal. But optimality is not the point here. What is surprising, especially if one regards Conjecture 1 as plausible, is that a non-trivial sublinear bound holds at all. In fact, we show (Corollary 6) that using *any* continuous distribution with bounded support and bounded density results in a sublinear regret bound.

Second, moving beyond bounded support distributions to ones with unbounded support, we settle Conjecture 1 in the negative. In Theorem 12 we show that, instead of suffering linear regret as predicted by Conjecture 1, a perturbation algorithm using the Gaussian distribution enjoys a near optimal regret bound of $O(\sqrt{NT \log N} \log T)$. A key ingredient in our approach is a new quantity that we call the *generalized hazard rate* of a distribution. We show that bounded generalized hazard rate is enough to guarantee sublinear regret in T (Theorem 8).

Finally, we investigate the relationship between tail behavior of random perturbations and the regret they induce. We show that heavy tails, along with some fairly mild assumptions, guarantee a bounded hazard rate (Theorem 15) and hence previous results can yield regret bounds for these perturbations. However, light tails can fail to have a bounded hazard rate. Nevertheless, we show that under reasonable conditions, light tailed distributions do have a bounded *generalized* hazard rate (Theorem 16). This result allows us to show that reasonably behaved light-tailed distributions lead to near optimal regret (Corollary 17). In particular, the exponential power (or generalized normal) family of distributions yields near optimal regret (Theorem 19)

2. Follow the Perturbed Leader Algorithm for Bandits

Recall the setting of the adversarial multi-armed bandit problem (Auer et al., 2002). An adversary (or Nature) chooses gain vectors $g_t \in [-1, 0]^N$ for $1 \le t \le T$ ahead of the game. Such an adversary is called *oblivious*. At round $t = 1, \dots, T$ in a repeated game, the learner must choose a distribution $p_t \in \Delta_N$ over the set of N available arms (or actions). The learner plays action i_t sampled according to p_t and accumulates the gains $g_{t,i_t} \in [-1, 0]$. The learner observes only g_{t,i_t} and receives no information about the values $g_{t,j}$ for $j \neq i_t$.

The learner's goal is to minimize the *regret*. Regret is defined to be the difference in the realized gains and the gains of the best fixed action in hindsight:

$$\text{Regret}_T := \max_{i \in [N]} \sum_{t=1}^{T} (g_{t,i} - g_{t,i_t}).$$

To be precise, we consider the *expected* regret, where the expectation is taken with respect to the learner's randomization. Note that, under an oblivious adversary, the only random variables in the above expression are the actions i_t of the learner. For convenience, define the cumulative gain vectors $G_t, t = 1, 2, \dots, T$ by

$$G_t := \sum_{s=1}^{t} g_s.$$

2.1 The Gradient-Based Algorithmic Template

We will consider the algorithmic template described in Framework 1, which is the Gradient Based Prediction Algorithm (GBPA) (see, for example, Abernethy et al. (2015)). Let Δ^N be the $(N-1)$-dimensional probability simplex in $\mathbb{R}^N$. Denote the standard basis vector along the ith dimension by $\mathbf{e}_i$. At any round t, the action choice i_t is made by sampling from the distribution p_t which is obtained by applying the gradient of a convex function $\tilde{\Phi}$ to the estimate $\hat{G}_{t-1}$ of the cumulative gain vector so far. The choice of $\tilde{\Phi}$ is flexible but it must be a differentiable convex function such that its gradient is always in Δ^N.

Note that we do not require the range of $\nabla\tilde{\Phi}$ be contained in the *interior* of the probability simplex. If we required the gradient to lie in the interior, we would not be able to deal with bounded support distributions such as the uniform distribution. Even though some entries of the probability vector p_t might be 0, the estimation step is always well defined since $p_{t,i_t} > 0$. But allowing $p_{t,i}$ to be zero means that $\hat{g}_t$ is not exactly an unbiased estimator of g_t. Instead, it is an unbiased estimator on the support of p_t. That is, $\mathbb{E}[\hat{g}_{t,i} | i_{1:t-1}] = g_{t,i}$ for any i such that $p_{t,i} > 0$. Here, $i_{1:t-1}$ is shorthand for $i_1, \dots, i_{t-1}$. Therefore, irrespective of whether $p_{t,i} = 0$ or not, we always have

$$\mathbb{E}[p_{t,i} \hat{g}_{t,i} | i_{1:t-1}] = p_{t,i} g_{t,i}. \tag{1}$$

When $p_{t,i} = 0$, we have $\hat{g}_{t,i} = 0$ but $g_{t,i} \le 0$, which means that $\hat{g}_t$ overestimates g_t outside the support of p_t. Hence, we also have

$$\mathbb{E}[\hat{g}_t | i_{1:t-1}] \succeq g_t, \tag{2}$$

where $\succeq$ means element-wise greater than.

We now present a basic result bounding the expected regret of GBPA in the multi-armed bandit setting. It is basically just a simple modification of the arguments in Abernethy et al. (2015) to deal with the possibility that $p_{t,i} = 0$. We state and prove this result here for completeness without making any claim of novelty.

Framework 1: Gradient-Based Prediction Alg. (GBPA) Template for Multi-Armed Bandits.

GBPA($\tilde{\Phi}$): $\tilde{\Phi}$ is a differentiable convex function such that $\nabla\tilde{\Phi} \in \Delta^N$
Nature: Adversary chooses gain vectors $g_t \in [-1,0]^N$ for $t = 1, \ldots, T$
Learner initializes $\hat{G}_0 = 0$
for $t = 1$ to T **do**
  Sampling: Learner chooses i_t according to the distribution $p_t = \nabla\tilde{\Phi}(\hat{G}_{t-1})$
  Cost: Learner incurs (and observes) gain $g_{t,i_t} \in [-1,0]$
  Estimation: Learner creates estimate of gain vector $\hat{g}_t := \frac{g_{t,i_t}}{p_{t,i_t}}\mathbf{e}_{i_t}$
  Update: Cumulative gain estimate so far $\hat{G}_t = \hat{G}_{t-1} + \hat{g}_t$
end for

Lemma 1 (Decomposition of the Expected Regret) *Define the non-smooth potential* $\Phi(G) = \max_i G_i$. *The expected regret of GBPA*($\tilde{\Phi}$) *can be written as*

$$\mathbb{E}\text{Regret}_T = \Phi(G_T) - \mathbb{E}\left[\sum_{t=1}^{T}\langle p_t, g_t\rangle\right]. \tag{3}$$

Furthermore, the expected regret of GBPA($\tilde{\Phi}$) *can be bounded by the sum of an overestimation, an underestimation, and a divergence penalty:*

$$\mathbb{E}\text{Regret}_T \le \underbrace{\tilde{\Phi}(0)}_{\text{overestimation penalty}} + \mathbb{E}\left[\underbrace{\Phi(\hat{G}_T) - \tilde{\Phi}(\hat{G}_T)}_{\text{underestimation penalty}}\right] + \mathbb{E}\left[\sum_{t=1}^{T}\underbrace{\mathbb{E}[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}]}_{\text{divergence penalty}}\right],$$

where the expectations are over the sampling of i_t *and* $D_{\tilde{\Phi}}$ *is the Bregman divergence induced by* $\tilde{\Phi}$.

Proof First, note that the regret, by definition, is

$$\text{Regret}_T = \Phi(G_T) - \sum_{t=1}^{T}\langle \mathbf{e}_{i_t}, g_t\rangle.$$

Under an oblivious adversary, only the summation on the right hand side is random. Moreover $\mathbb{E}[\langle \mathbf{e}_{i_t}, g_t\rangle | i_{1:t-1}] = \langle p_t, g_t\rangle$. This proves the claim in (3).

From (1), we know that $\mathbb{E}[\langle p_t, \hat{g}_t\rangle | i_{1:t-1}] = \langle p_t, g_t\rangle$ even if some entries in p_t might be zero. Therefore, we have

$$\mathbb{E}\text{Regret}_T = \Phi(G_T) - \mathbb{E}\left[\sum_{t=1}^{T}\langle p_t, \hat{g}_t\rangle\right]. \tag{4}$$

From (2), we know that $G_T \le \mathbb{E}[\hat{G}_T]$. This implies

$$\Phi(G_T) \le \Phi(\mathbb{E}[\hat{G}_T]) \le \mathbb{E}[\Phi(\hat{G}_T)], \tag{5}$$

where the first inequality is because $G \succeq G' \Rightarrow \Phi(G) \ge \Phi(G')$, and the second inequality is due to the convexity of Φ. Plugging (5) into (4) yields

$$\mathbb{E}\text{Regret}_T \le \mathbb{E}\left[\Phi(\hat{G}_T) - \sum_{t=1}^{T}\langle p_t, \hat{g}_t\rangle\right]. \tag{6}$$

Now, recalling the definition of Bregman divergence

$$D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1}) = \tilde{\Phi}(\hat{G}_t) - \tilde{\Phi}(\hat{G}_{t-1}) - \left\langle \nabla\tilde{\Phi}(\hat{G}_{t-1}), \hat{G}_t - \hat{G}_{t-1}\right\rangle,$$

we can write,

$$\begin{aligned}
-\sum_{t=1}^{T}\langle p_t, \hat{g}_t\rangle &= -\sum_{t=1}^{T}\left\langle \nabla\tilde{\Phi}(\hat{G}_{t-1}), \hat{g}_t\right\rangle \\
&= -\sum_{t=1}^{T}\left\langle \nabla\tilde{\Phi}(\hat{G}_{t-1}), \hat{G}_t - \hat{G}_{t-1}\right\rangle \\
&= \sum_{t=1}^{T}\left(D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1}) + \tilde{\Phi}(\hat{G}_{t-1}) - \tilde{\Phi}(\hat{G}_t)\right) \\
&= \tilde{\Phi}(\hat{G}_0) - \tilde{\Phi}(\hat{G}_T) + \sum_{t=1}^{T} D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1}).
\end{aligned} \tag{7}$$

The proof ends by plugging (7) into (6) and noting that $\tilde{\Phi}(\hat{G}_0) = \tilde{\Phi}(0)$ is not random. ■

2.2 Stochastic Smoothing of Potential Function

Let $\mathcal{D}$ be a continuous distribution with finite expectation, probability density function f, and cumulative distribution function F. Consider GBPA with potential function of the form:

$$\tilde{\Phi}(G; \mathcal{D}) = \mathbb{E}_{Z_1,\ldots,Z_N \overset{\text{i.i.d.}}{\sim} \mathcal{D}}\Phi(G + Z), \tag{8}$$

which is a *stochastic smoothing* of the non-smooth function $\Phi(G) = \max_i G_i$. Note that $Z = (Z_1, \ldots, Z_N) \in \mathbb{R}^N$. We will often hide the dependence on the distribution $\mathcal{D}$ if the distribution is obvious from the context or when the dependence on $\mathcal{D}$ is not of importance in the argument. Since Φ is convex, $\tilde{\Phi}$ is also convex. For stochastic smoothing, we have the following result to control the underestimation and overestimation penalty.

Lemma 2 *For any* G, *we have*

$$\Phi(G) + \mathbb{E}[Z_1] \le \tilde{\Phi}(G) \le \Phi(G) + EMAX(N),$$

where $EMAX(N)$ *is any function such that*

$$\mathbb{E}_{Z_1,\ldots,Z_N}[\max_i Z_i] \le EMAX(N).$$

In particular, this implies that the overestimation penalty $\tilde{\Phi}(0)$ is upper bounded by $\Phi(0) + EMAX(N) = EMAX(N)$ and the underestimation penalty $\Phi(\hat{G}_T) - \tilde{\Phi}(\hat{G}_T)$ is upper bounded by $-\mathbb{E}[Z_1]$.

Proof We have,

$$\begin{aligned}\Phi(G) + \mathbb{E}[Z_1] &= \max_i G_i + \mathbb{E}[Z_i] = \max_i (G_i + \mathbb{E}[Z_i]) \\ &\le \mathbb{E}[\max_i (G_i + Z_i)] = \tilde{\Phi}(G) \\ &\le \mathbb{E}[\max_i G_i + \max_i Z_i] = \max_i G_i + \mathbb{E}[\max_i Z_i] = \Phi(G) + \mathbb{E}[\max_i Z_i].\end{aligned}$$

Noting that $\mathbb{E}[\max_i Z_i] \le EMAX(N)$ finishes the proof. ■

Observe that $\Phi(G+Z)$ as a function of G is differentiable with probability 1 (under the randomness of the Z_i's) due to the fact that Z_i's are random variables with a density. By Proposition 2.3 of Bertsekas (1973), we can swap the order of differentiation and expectation:

$$\nabla\tilde{\Phi}(G;\mathcal{D}) = \mathbb{E}_{Z_1,\ldots,Z_N \overset{\text{i.i.d}}{\sim} \mathcal{D}} e_{i^*}, \text{ where } i^* = \arg\max_{i=1,\ldots,N} \{G_i + Z_i\}.$$

Note that, for any G, the random index i^* is unique with probability 1. Hence, ties between arms can be resolved arbitrarily. It is clear from above that $\nabla\tilde{\Phi}$, being an expectation of vectors in the probability simplex, is in the probability simplex. Thus, it is a valid potential to be used in Framework 1. Now we derive an identity to write the gradient of the smoothed potential function in terms of the expectation of the cumulative distribution function,

$$\begin{aligned}\nabla_i\tilde{\Phi}(G) = \frac{\partial\tilde{\Phi}}{\partial G_i} &= \mathbb{E}_{Z_1,\ldots,Z_N} \mathbf{1}\{G_i + Z_i > G_j + Z_j, \forall j \ne i\} \\ &= \mathbb{E}_{\tilde{G}_{-i}}[\mathbb{P}_{Z_i}[Z_i > \tilde{G}_{-i} - G_i]] = \mathbb{E}_{\tilde{G}_{-i}}[1 - F(\tilde{G}_{-i} - G_i)]\end{aligned}$$

where $\tilde{G}_{-i} = \max_{j\ne i} G_j + Z_j$. If $\mathcal{D}$ has unbounded support then this partial derivative is non-zero for all i given any G. However, it can be zero if $\mathcal{D}$ has bounded support. Similarly, we have the following useful identity that writes the diagonal of the Hessian of the smoothed potential function in terms of the expectation of the probability density function.

$$\begin{aligned}\nabla^2_{ii}\tilde{\Phi}(G) = \frac{\partial}{\partial G_i}\nabla_i\tilde{\Phi}(G) &= \frac{\partial}{\partial G_i}\mathbb{E}_{\tilde{G}_{-i}}[1 - F(\tilde{G}_{-i} - G_i)] \\ &= \mathbb{E}_{\tilde{G}_{-i}}\left[\frac{\partial}{\partial G_i}(1 - F(\tilde{G}_{-i} - G_i))\right] = \mathbb{E}_{\tilde{G}_{-i}} f(\tilde{G}_{-i} - G_i).\end{aligned} \tag{9}$$

2.3 Connection to Follow the Perturbed Leader

The sampling step of Framework 1 with a stochastically smoothed Φ as the potential $\tilde{\Phi}$ (Equation 8) can be done efficiently. Instead of evaluating the expectation (Equation 2.2), we just take a random sample. Doing so gives us an equivalent of Follow the Perturbed Leader Algorithm (FTPL) (Kalai and Vempala, 2005) applied to the bandit setting. On the other hand, the estimation step is hard because generally there is no closed-form expression for $\nabla\tilde{\Phi}$.

To address this issue, Neu and Bartók (2013) proposed Geometric Resampling (GR), an iterative resampling process to estimate $\nabla\tilde{\Phi}$ (with bias). They showed that the extra regret after stopping at M iterations of GR introduces an estimation bias that is at most $\frac{NT}{eM}$ as an additive term. That is, all GBPA regret bounds that we prove will hold for the corresponding FTPL algorithm that does M iterations of GR at every time step, with an extra additive $\frac{NT}{eM}$ term. This extra term does not affect the regret rate as long as $M = \sqrt{NT}$, because the lower bound for any adversarial multi-armed bandit algorithm is of the order $\sqrt{NT}$.

2.4 The Role of the Hazard Rate and Its Limitation

In previous work, Abernethy et al. (2015) proved that for a continuous random variable Z with finite and nonnegative expectation and support on the whole real line $\mathbb{R}$, if the hazard rate of the random variable is bounded, i.e.,

$$\sup_z \frac{f(z)}{1 - F(z)} < \infty,$$

then the expected regret of GBPA can be upper bounded as

$$\mathbb{E}\text{Regret}_T = O\Big(\sqrt{NT \times EMAX(N)}\Big).$$

Common families of distributions whose regret can be controlled in this way include Gumbel, Frechet, Weibull, Pareto, and Gamma (see Abernethy et al. (2015) for details). However, there are many other families of distributions where the hazard rate condition fails. For example, if the random variable has a bounded support, then the hazard rate would certainly explode at the end of the support. This is, in some sense, an extreme case of violation because the random variable does not even have a tail. There are also some random variables that do have support on $\mathbb{R}$ but have unbounded hazard rate, e.g., Gaussian, where the hazard rate monotonically increases to infinity. How can we perform analyses of the expected regret of GBPA using those random variables as perturbations? To address these issues, we need to go beyond the hazard rate.

3. Perturbations with Bounded Support

In this section, we prove that GBPA with any continuous distribution that has bounded support and bounded density enjoys sublinear expected regret. From Lemma 1 we see that the expected regret can be upper bounded by the sum of three terms. The overestimation penalty can be bounded very easily via Lemma 2 for a distribution with bounded support. The underestimation penalty is non-positive as long as the distribution has non-negative expectation. The only term that needs to be controlled with some effort is the divergence penalty.

We first present a general lemma that allows us to write the divergence penalty for a stochastically smoothed potential $\tilde{\Phi}$ as a sum involving certain double integrals.

Lemma 3 *When using a stochastically smoothed potential as in (8), the divergence penalty can be written as*

$$\mathbb{E}\left[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}\right] = \sum_{i \in supp(p_t)} p_{t,i} \int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|} \mathbb{E}_{\hat{G}_{-i}}\left[\int_0^s f(\hat{G}_{-i} - \hat{G}_{t-1,i} + r)dr\right] ds \quad (10)$$

where $p_t = \nabla\tilde{\Phi}(\hat{G}_{t-1})$, $\hat{G}_{-i} = \max_{j \neq i} \hat{G}_{t-1,j} + Z_j$ *and* $supp(p_t) = \{i : p_{t,i} > 0\}$.

Proof To reduce clutter, we drop the time subscripts: we use $\hat{G}$ to denote the cumulative estimate $\hat{G}_{t-1}$, $\hat{g}$ to denote the marginal estimate $\hat{g}_t = \hat{G}_t - \hat{G}_{t-1}$, p to denote p_t, and g to denote the true gain g_t. Note that by definition of Framework 1, $\hat{g}$ is a sparse vector with one non-zero and non-positive coordinate $\hat{g}_{i_t} = g_{i_t}/p_{i_t} = -|g_{i_t}/p_{i_t}|$. Moreover, conditioned on $i_{1:t-1}$, i_t takes value i with probability p_i. For any $i \in \text{supp}(p)$, let

$$h_i(r) = D_{\tilde{\Phi}}(\hat{G} - r\mathbf{e}_i, \hat{G}),$$

so that $h_i'(r) = -\nabla_i\tilde{\Phi}\left(\hat{G} - r\mathbf{e}_i\right) + \nabla_i\tilde{\Phi}\left(\hat{G}\right)$ and $h_i''(r) = \nabla_{ii}^2\tilde{\Phi}\left(\hat{G} - r\mathbf{e}_i\right)$. Now we write:

$$\begin{aligned}
\mathbb{E}[D_{\tilde{\Phi}}(\hat{G} + \hat{g}, \hat{G})|i_{1:t-1}] &= \sum_{i \in \text{supp}(p)} p_i D_{\tilde{\Phi}}(\hat{G} + g_i/p_i\mathbf{e}_i, \hat{G}) = \sum_{i \in \text{supp}(p)} p_i D_{\tilde{\Phi}}(\hat{G} - |g_i/p_i|\,\mathbf{e}_i, \hat{G}) \\
&= \sum_{i \in \text{supp}(p)} p_i h_i(|g_i/p_i|) = \sum_{i \in \text{supp}(p)} p_i \int_0^{|g_i/p_i|} \int_0^s h_i''(r)dr\,ds \\
&= \sum_{i \in \text{supp}(p)} p_i \int_0^{|g_i/p_i|} \int_0^s \nabla_{ii}^2\tilde{\Phi}\left(\hat{G} - r\mathbf{e}_i\right) dr\,ds \\
&= \sum_{i \in \text{supp}(p)} p_i \int_0^{|g_i/p_i|} \int_0^s \mathbb{E}_{\hat{G}_{-i}} f(\hat{G}_{-i} - \hat{G}_i + r)dr\,ds \\
&= \sum_{i \in \text{supp}(p_t)} p_{t,i} \int_0^{|g_i/p_i|} \mathbb{E}_{\hat{G}_{-i}}\left[\int_0^s f(\hat{G}_{-i} - \hat{G}_i + r)dr\right] ds.
\end{aligned}$$

The second equality on the first line implicitly used the assumption that $g_i \leq 0$, i.e., the "gains" are non-positive. The second equality on the second line used that $h_i(0) = 0$, and the equality on the fourth line used Equation (9). ■

Note that each summand in the divergence penalty expression above involves an integral of the density function of the distribution $\mathcal{D}$ over an interval. The main idea to control the divergence penalty for a bounded support distribution is to truncate the interval at the end of the support. For points that are close to the end of the support, we bound the integral by the product of the bound on the density and the interval length. For points that are far from the end of the support, we bound the integral through the hazard rate as was done by Abernethy et al. (2015).

For a general continuous random variable Z with bounded density, bounded support, we first shift it (which obviously does not change the distribution of the random action choice

i_t and hence the expected regret) and scale it so that the support is a subset of $[0, 1]$ with $\sup\{z : F(z) = 0\} = 0$ and $\inf\{z : F(z) = 1\} = 1$ where F denotes the CDF of Z. A benefit of this normalization is that the expectation of the random variable becomes non-negative so the underestimation penalty is guaranteed to be non-positive. After scaling, we assume that the bound on the density is L. We consider the perturbation ηZ where $\eta > 0$ is a tuning parameter. Write $F_\eta(x)$ and $f_\eta(x)$ to denote the CDF and PDF of the scaled random variable ηZ respectively. If F is strictly increasing, we know that F^{-1} exists. If not, define $F^{-1}(y) = \inf\{z : F(z) = y\}$. Elementary calculation gives the following useful facts:

$$F_\eta(z) = F(\frac{z}{\eta}), f_\eta(z) = \frac{f(\frac{z}{\eta})}{\eta}, F_\eta^{-1}(y) = \eta F^{-1}(y).$$

Theorem 4 (Divergence Penalty Control, Bounded Support) *The divergence penalty in the GBPA regret bound using the scaled perturbation ηZ, where Z is drawn from a bounded support distribution satisfying the conditions above, can be upper bounded, for any $\epsilon > 0$, by*

$$NL\Big(\frac{1}{2\eta\epsilon} + 1 - F^{-1}(1-\epsilon)\Big).$$

Proof From Lemma 3, we have, with $\hat{G}_{-i} = \max_{j \neq i} \hat{G}_{t-1,j} + \eta Z_j$,

$$\begin{aligned}
&\mathbb{E}\left[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}\right] \\
&= \sum_{i \in \text{supp}(p_t)} p_{t,i} \int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|} \mathbb{E}_{\hat{G}_{-i}}\left[\int_0^s f_\eta(\hat{G}_{-i} - \hat{G}_{t-1,i} + r)dr\right] ds \\
&= \sum_{i \in \text{supp}(p_t)} p_{t,i} \int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|} \mathbb{E}_{\hat{G}_{-i}}\left[\int_{\hat{G}_{-i} - \hat{G}_{t-1,i}}^{\hat{G}_{-i} - \hat{G}_{t-1,i} + s} f_\eta(z)dz\right] ds \\
&\leq \sum_{i \in \text{supp}(p_t)} p_{t,i} \int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|} \Big(\mathbb{E}_{\hat{G}_{-i}}\Big[\underbrace{\int_{[\hat{G}_{-i} - \hat{G}_{t-1,i}, \hat{G}_{-i} - \hat{G}_{t-1,i} + s] \setminus [F_\eta^{-1}(1-\epsilon), \eta]} f_\eta(z)dz}_{(I)}\Big] \\
&\quad + \underbrace{\int_{[F_\eta^{-1}(1-\epsilon), \eta]} f_\eta(z)dz}_{(II)}\Big) ds. \qquad (11)
\end{aligned}$$

We bound the two integrals above differently. For the first integral, we add the restriction $f_\eta(z) > 0$ by intersecting the integral interval with the support of the function $f_\eta(z)$, denoted

as $I_{f_\eta(z)}$ so that $1 - F_\eta(z)$ is not 0 on the interval to be integrated. Thus, we get,

$$\begin{aligned}(I) &= \int_{([\hat{G}_{-i}-\hat{G}_{t-1,i},\hat{G}_{-i}-\hat{G}_{t-1,i}+s]\setminus[F_\eta^{-1}(1-\epsilon),\eta])\cap I_{f_\eta(z)}} f_\eta(z)dz \\ &= \int_{([\hat{G}_{-i}-\hat{G}_{t-1,i},\hat{G}_{-i}-\hat{G}_{t-1,i}+s]\setminus[F_\eta^{-1}(1-\epsilon),\eta])\cap I_{f_\eta(z)}} (1-F_\eta(z))\cdot\frac{f_\eta(z)}{1-F_\eta(z)}dz \\ &\le \int_{([\hat{G}_{-i}-\hat{G}_{t-1,i},\hat{G}_{-i}-\hat{G}_{t-1,i}+s]\setminus[F_\eta^{-1}(1-\epsilon),\eta])\cap I_{f_\eta(z)}} (1-F_\eta(z))\cdot\frac{L}{\eta\epsilon}dz \\ &\le (1-F_\eta(\hat{G}_{-i}-\hat{G}_{t-1,i}))\frac{sL}{\eta\epsilon}. \end{aligned} \tag{12}$$

The first inequality holds because $f_\eta(z) \le L/\eta$ and $(1-F_\eta(z)) \ge \epsilon$ on the set of z's over which we are integrating. The second inequality holds because on the set under consideration $1 - F_\eta(z) \le 1 - F_\eta(\hat{G}_{-i} - \hat{G}_{t-1,i})$ and the measure of the set is at most s.

For the second integral, we use the bound $f_\eta(z) \le L/\eta$ again to get,

$$(II) = \int_{[F_\eta^{-1}(1-\epsilon),\eta]} f_\eta(z)dz \le \frac{L}{\eta}\cdot(\eta - F_\eta^{-1}(1-\epsilon)). \tag{13}$$

Plugging (12) and (13) into (11), we can bound the divergence penalty by,

$$\begin{aligned}&\le \sum_{i\in\text{supp}(p_t)} p_{t,i}\int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|}\Big(\mathbb{E}_{\hat{G}_{-i}}[1-F_\eta(\hat{G}_{-i}-\hat{G}_{t-1,i})]\frac{sL}{\eta\epsilon}+\frac{L(\eta-F_\eta^{-1}(1-\epsilon))}{\eta}\Big)ds \\ &= \sum_{i\in\text{supp}(p_t)} p_{t,i}\int_0^{\left|\frac{g_{t,i}}{p_{t,i}}\right|}\Big(p_{t,i}\frac{sL}{\eta\epsilon}+L(1-F^{-1}(1-\epsilon))\Big)ds \\ &= \sum_{i\in\text{supp}(p_t)} p_{t,i}\Big(p_{t,i}\frac{L}{\eta\epsilon}\frac{g_{t,i}^2}{2p_{t,i}^2}+L(1-F^{-1}(1-\epsilon))\frac{|g_{t,i}|}{p_{t,i}}\Big) \\ &\le \sum_{i\in\text{supp}(p_t)} \Big(\frac{L}{2\eta\epsilon}+L(1-F^{-1}(1-\epsilon))\Big) \\ &\le NL\Big(\frac{1}{2\eta\epsilon}+1-F^{-1}(1-\epsilon)\Big).\end{aligned}$$

The second to last inequality holds because $|g_{t,i}| \le 1$ and the last inequality holds because the sum over i is at most over all N arms. ■

The regret bound for the uniform distribution is now an easy corollary.

Corollary 5 (Regret Bound for Uniform) *For GBPA run with a stochastically smoothed potential using an appropriately scaled $[0,1]$ uniform perturbation where $\eta = (NT)^{2/3}$, the expected regret can be upper bounded by $3(NT)^{2/3}$.*

Proof For $[0,1]$ uniform distribution, we have $L = 1$, $F^{-1}(1-\epsilon) = 1-\epsilon$ so the divergence penalty is upper bounded by

$$NT(\frac{1}{2\eta\epsilon}+\epsilon).$$

If we let $\epsilon = \frac{1}{\sqrt{2\eta}}$, we can see that the divergence penalty is upper bounded by $NT\sqrt{\frac{2}{\eta}}$. Together with the overestimation penalty which is trivially bounded by η and a non-positive underestimation penalty, we see that the final regret bound is

$$NT\sqrt{\frac{2}{\eta}}+\eta.$$

Setting $\eta = (NT)^{2/3}$ gives the desired result. ■

For a general perturbation with bounded support and bounded density, the rate at which $1 - F^{-1}(1-\epsilon)$ goes to 0 as $\epsilon \to 0$ can vary but we can always guarantee sublinear expected regret.

Corollary 6 (Asymptotic Regret Bound for Bounded Support) *For stochastically smoothed GBPA using general continuous random variable ηZ where Z has bounded density and bounded support contained in $[0,1]$ and $\eta = (NT)^{2/3}$, the expected regret grows sublinearly, i.e.,*

$$\lim_{T\to\infty}\frac{\mathbb{E}\text{Regret}_T}{T} = 0.$$

Proof For a general distribution, let $\epsilon = \frac{1}{\sqrt{\eta}}$. Since the overestimation penalty is trivially bounded by η and the underestimation penalty is non-positive, the expected regret can be upper bounded by

$$LNT\Big(\frac{1}{2\sqrt{\eta}}+1-F^{-1}(1-\frac{1}{\sqrt{\eta}})\Big)+\eta.$$

Setting $\eta = (NT)^{2/3}$ we see that the expected regret can be upper bounded by

$$(\frac{L}{2}+1)(NT)^{2/3}+LNT(1-F^{-1}(1-\frac{1}{\sqrt{\eta}}).$$

Since

$$\lim_{T\to\infty} 1-F^{-1}(1-\frac{1}{\sqrt{\eta}}) = \lim_{\eta\to\infty} 1-F^{-1}(1-\frac{1}{\sqrt{\eta}}) = 1-F^{-1}(1) = 0,$$

we conclude that

$$\lim_{T\to\infty}\frac{\mathbb{E}\text{Regret}_T}{T} = 0.$$

■

4. Perturbations with Unbounded Support

Unlike perturbations with bounded support, perturbations with unbounded support (on the right) do have non-zero right tail probabilities, ensuring that $p_{t,i} > 0$ always. However, the tail behavior may be such that the hazard rate is unbounded. Still, under mild assumptions, perturbations with unbounded support (on the right) can also be shown to have near optimal expected regret in T, using the notion of *generalized hazard rate* that we now introduce.

4.1 Generalized Hazard Rate

We already know how to control the underestimation and overestimation penalties via Lemma 2. So our main focus will be to control the divergence penalty. Towards this end, we define the generalized hazard rate for a continuous random variable Z with support unbounded on the right, parameterized by $\alpha \in [0, 1)$, as

$$h_\alpha(z) := \frac{f(z)|z|^\alpha}{(1 - F(z))^{1-\alpha}},$$

where $f(z)$ and $F(z)$ denotes the PDF and CDF of Z respectively. Note that by setting $\alpha = 0$ we recover the standard hazard rate.

One of the main results of this paper is the following. Note that it includes the result (Lemma 4.3) of Abernethy et al. (2015) as a special case.

Theorem 7 (Divergence Penalty Control via Generalized Hazard Rate) *Let $\alpha \in [0, 1)$. Suppose we have $\forall z \in \mathbb{R}, h_\alpha(z) \le C$. Then,*

$$\mathbb{E}[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}] \le \frac{2C}{1-\alpha} \times N.$$

Proof Because of the unbounded support of Z, $\mathrm{supp}(p_t) = \{1, \dots, N\}$. Lemma 3 gives us:

$$\begin{aligned}
\mathbb{E}[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}] =& \sum_{i=1}^N p_{t,i} \int_0^{|g_{t,i}/p_{t,i}|} \mathbb{E}_{\tilde{G}_{-i}} \int_0^s f(\tilde{G}_{-i} - \hat{G}_{t-1,i} + r) dr ds \\
=& \sum_{i=1}^N p_{t,i} \int_0^{|g_{t,i}/p_{t,i}|} \mathbb{E}_{\tilde{G}_{-i}} \int_{\tilde{G}_{-i} - \hat{G}_{t-1,i}}^{\tilde{G}_{-i} - \hat{G}_{t-1,i} + s} f(z) dz ds \\
\le& C \sum_{i=1}^N p_{t,i} \int_0^{|g_{t,i}/p_{t,i}|} \mathbb{E}_{\tilde{G}_{-i}} \int_{\tilde{G}_{-i} - \hat{G}_{t-1,i}}^{\tilde{G}_{-i} - \hat{G}_{t-1,i} + s} (1 - F(z))^{1-\alpha} |z|^{-\alpha} dz\, ds \\
\le& C \sum_{i=1}^N p_{t,i} \int_0^{|g_{t,i}/p_{t,i}|} \mathbb{E}_{\tilde{G}_{-i}} (1 - F(\tilde{G}_{-i} - \hat{G}_{t-1,i}))^{1-\alpha} \\
& \times \int_{\tilde{G}_{-i} - \hat{G}_{t-1,i}}^{\tilde{G}_{-i} - \hat{G}_{t-1,i} + s} |z|^{-\alpha} dz\, ds.
\end{aligned}$$

Since the function $|z|^{-\alpha}$ is symmetric in z, monotonically decreasing as $|z| \to \infty$, we have

$$\int_{\tilde{G}_{-i} - \hat{G}_{t-1,i}}^{\tilde{G}_{-i} - \hat{G}_{t-1,i} + s} |z|^{-\alpha} dz \le \int_{-s/2}^{s/2} |z|^{-\alpha} dz = \frac{2^\alpha}{1-\alpha} s^{1-\alpha}.$$

Also, note that $z^{1-\alpha}$ is a concave function in z. Hence, by Jensen's inequality,

$$\mathbb{E}_{\tilde{G}_{-i}}[(1 - F(\tilde{G}_{-i} - \hat{G}_{t-1,i}))^{1-\alpha}] \le (\mathbb{E}_{\tilde{G}_{-i}}[1 - F(\tilde{G}_{-i} - \hat{G}_{t-1,i}])^{1-\alpha} = p_{t,i}^{1-\alpha}.$$

Therefore,

$$\begin{aligned}
\mathbb{E}[D_{\tilde{\Phi}}(\hat{G}_t, \hat{G}_{t-1})|i_{1:t-1}] &\le \frac{2^\alpha C}{1-\alpha} \sum_{i=1}^N p_{t,i} \int_0^{|g_{t,i}/p_{t,i}|} p_{t,i}^{1-\alpha} s^{1-\alpha} ds \\
&= \frac{2^\alpha C}{1-\alpha} \sum_{i=1}^N p_{t,i}^{2-\alpha} \int_0^{|g_{t,i}/p_{t,i}|} s^{1-\alpha} ds \\
&= \frac{2^\alpha C}{(1-\alpha)(2-\alpha)} \sum_{i=1}^N p_{t,i}^{2-\alpha} |g_{t,i}/p_{t,i}|^{2-\alpha} \\
&= \frac{2^\alpha C}{(1-\alpha)(2-\alpha)} \sum_{i=1}^N |g_{t,i}|^{2-\alpha} \\
&\le \frac{2^\alpha C}{(1-\alpha)(2-\alpha)} N \le \frac{2C}{1-\alpha} N.
\end{aligned}$$

■

A regret bound now easily follows.

Theorem 8 (Regret Bound via Generalized Hazard Rate) *Suppose we use a stochastically smoothed GBPA with perturbation ηZ, with Z's generalized hazard rate being bounded: $h_\alpha(x) \le C, \forall x \in \mathbb{R}$ for some $\alpha \in [0, 1)$, and*

$$\mathbb{E}_{Z_1,\dots,Z_N}[\max_i Z_i] - \mathbb{E}[Z_1] \le Q(N),$$

where $Q(N)$ is some function of N. Then, if we set $\eta = (\frac{2CNT}{(1-\alpha)Q(N)})^{1/(2-\alpha)}$, the expected regret of GBPA is no greater than

$$2 \times (\frac{2C}{1-\alpha})^{1/(2-\alpha)} \times (NT)^{1/(2-\alpha)} \times Q(N)^{(1-\alpha)/(2-\alpha)}.$$

In particular, this implies that the algorithm has sublinear expected regret.

Proof The divergence penalty can be controlled through Theorem 7 once we have bounded generalized hazard rate. It remains to control the overestimation and underestimation penalty. By Lemma 2, they are at most $\mathbb{E}_{Z_1,\dots,Z_n}[\max_i Z_i]$ and $-\mathbb{E}[Z_1]$ respectively. Suppose we scale the perturbation Z by $\eta > 0$, i.e., we add ηZ_i to each coordinate. It is easy to see that $\mathbb{E}[\max_{i=1,\dots,n} \eta Z_i] = \eta \mathbb{E}[\max_{i=1,\dots,n} Z_i]$ and $\mathbb{E}[\eta Z_1] = \eta \mathbb{E}[Z_1]$. For the divergence penalty, observe that $F_\eta(t) = F(t/\eta)$ and thus $f_\eta(t) = \frac{1}{\eta} f(t/\eta)$. Hence, the bound on the generalized hazard rate for perturbation ηZ is $\eta^{\alpha-1} C$. Plugging new bounds for the scaled perturbations into Lemma 1 gives us

$$\mathbb{E}\mathrm{Regret}_T \le \eta^{\alpha-1} \frac{2C}{1-\alpha} \times NT + \eta Q(N).$$

Setting $\eta = (\frac{2CNT}{(1-\alpha)Q(N)})^{1/(2-\alpha)}$ finishes the proof. ■

4.2 Gaussian Perturbation

In this section we prove that GBPA with the standard Gaussian perturbation incurs a near optimal expected regret in both N and T. Let $F(z)$ and $f(z)$ denote the CDF and PDF of standard Gaussian distribution.

Lemma 9 (Baricz (2008)) *For standard Gaussian random variable, we have*

$$z < \frac{f(z)}{1-F(z)} < \frac{z}{2} + \frac{\sqrt{z^2+4}}{2}.$$

This lemma together with example 2.6 in Thomas (1971) show that the hazard rate of a standard Gaussian random variable increases monotonically to infinity. However, we can still bound the generalized hazard rate for strictly positive α.

Lemma 10 (Generalized Hazard Bound for Gaussian) *For any $\alpha \in (0,1)$, we have*

$$\frac{f(z)|z|^\alpha}{(1-F(z))^{1-\alpha}} \le \frac{2}{\alpha}.$$

The proof of this lemma is deferred to the appendix.

The bounded generalized hazard rate shown in the above lemma can be used to control the divergence penalty. Combined with other knowledge of the standard Gaussian random variable we are able to give a bound on the expected regret.

Corollary 11 *The expected regret of GBPA with an appropriately scaled standard Gaussian random variable as perturbation where $\eta = \left(\frac{4NT}{\alpha(1-\alpha)\sqrt{2\log N}}\right)^{1/(2-\alpha)}$ has an expected regret at most*

$$2(C_1C_2NT)^{1/(2-\alpha)}(\sqrt{2\log N})^{(1-\alpha)/(2-\alpha)}$$

where $C_1 = \frac{2}{\alpha}$, $C_2 = \frac{2}{1-\alpha}$, for any $\alpha \in (0,1)$.

Proof It is known that for standard Gaussian random variable, we have $\mathbb{E}[Z_1] = 0$ and

$$\mathbb{E}_{Z_1,\ldots,Z_n}[\max_i Z_i] \le \sqrt{2\log N}.$$

Plug in to Theorem 8 gives the result. ■

It remains to optimally tune α in the above bound.

Theorem 12 (Regret Bound for Gaussian) *The expected regret of GBPA with an appropriately scaled standard Gaussian random variable as perturbation where $\eta = \left(\frac{4NT}{\alpha(1-\alpha)\sqrt{2\log N}}\right)^{1/(2-\alpha)}$ and $\alpha = \frac{1}{\log T}$ has an expected regret at most*

$$96\sqrt{NT} \times N^{1/\log T}\sqrt{\log N}\log T$$

for $T > 4$. If we assume that $T > N$, the expected regret can be upper bounded by

$$278\sqrt{NT} \times \sqrt{\log N}\log T.$$

The proof of this theorem is also deferred to the appendix.

4.3 Sufficient Condition for Near Optimal Regret

In Section 4.1 we showed that if the generalized hazard rate of a distribution is bounded, the expected regret of the GBPA can be controlled. In this section, we are going to prove that under reasonable assumptions on the distribution of the perturbation, the FTPL enjoys near optimal expected regret. Note that most proofs in this section are deferred to the appendix.

Assumptions (a)-(c). Before we proceed, let us formally state our assumptions on the distributions we will consider. The distribution needs to (a) be continuous and have bounded density (b) have finite expectation (c) have support unbounded in the $+\infty$ direction.

Note that if the expectation of the random perturbation is negative, we shift it so that the expectation is zero. Hence the underestimation penalty is non-positive. In addition to the assumptions we have made above, we make another assumption on the eventual monotonicity of the hazard rate.

Assumption (d) $h_0(z) = \dfrac{f(z)}{1-F(z)}$ is eventually monotone.

"Eventually monotone" means that $\exists z_0 \ge 0$ such that if $z > z_0$, $\frac{f(z)}{1-F(z)}$ is non-decreasing or non-increasing. This assumption might appear hard to check, but numerous theorems are available to establish the monotonicity of hazard rate, which is much stronger than what we are assuming here. For example, see Theorem 2.4 in Thomas (1971), Theorem 2 and Theorem 4 in Chechile (2003), Chechile (2009). In fact, most natural distributions do satisfy this assumption (Bagnoli and Bergstrom, 2005).

Before we proceed, we mention a standard classification of random variables into two classes based on their tail property.

Definition 13 (see, for example, Foss et al. (2009)) *A function $f(z) \ge 0$ is said to be heavy-tailed if and only if*

$$\limsup_{z\to\infty} f(z)e^{\lambda z} = \infty \quad \text{for all } \lambda > 0.$$

A distribution with CDF $F(z)$ and $\overline{F}(z) = 1 - F(z)$ is said to be heavy-tailed if and only if $\overline{F}(z)$ is heavy-tailed. If the distribution is not heavy-tailed, we say that it is light-tailed.

It turns out that under assumptions (a)-(d), if the distribution is also heavy-tailed, then the hazard rate itself is bounded. If the distribution is light-tailed, we need an additional assumption on the eventual monotonicity of a function similar to the generalized hazard rate to ensure the boundedness of the generalized hazard rate. But before we state and prove the main results, we introduce some functions and prove an intermediate lemma that will be useful to prove the main results.

Define $R(z) = -\log\overline{F}(z)$ so that we have $\overline{F}(z) = e^{-R(x)}$ and $R'(z) = \frac{f(z)}{\overline{F}(z)} = h_0(z)$.

Lemma 14 *Under assumptions (a)-(d), we have*

$$\overline{F}(z)e^{\lambda z} \text{ is eventually monotone } \forall \lambda > 0.$$

Proof Let $g(z) = \overline{F}(z)e^{\lambda z}$, then $g'(z) = e^{\lambda z}\overline{F}(z)(\lambda - \frac{f(z)}{\overline{F}(z)})$. Since $\frac{f(z)}{\overline{F}(z)}$ is eventually monotone by assumption (d), $g'(z)$ is eventually positive, negative or zero. The lemma immediately follows. ■

We are finally ready to present the main results in this section.

Theorem 15 (Heavy Tail Implies Bounded Hazard) *Under assumptions (a) - (d), if the distribution is also heavy-tailed, then the hazard rate is bounded, i.e.,*

$$\sup_z \frac{f(z)}{\overline{F}(z)} < \infty.$$

Unlike heavy-tailed distributions, the hazard rate of light-tailed distributions might be unbounded. However, it turns out that if we make an additional assumption on the eventual monotonicity of a function similar to the generalized hazard rate, we can still guarantee the boundedness of the generalized hazard rate.

Assumption (e) $\exists \delta \in (0, 1]$ such that $\frac{f(z)}{(1-F(z))^{1-\delta}}$ is eventually monotone.

Theorem 16 (Light Tail Implies Bounded Generalized Hazard) *Under assumptions (a) - (e), if the distribution is also light-tailed, then for any $\alpha \in (\delta, 1)$, the generalized hazard rate $h_\alpha(z)$ is bounded, i.e.,*

$$\sup_z \frac{f(z)|z|^\alpha}{(\overline{F}(z))^{1-\alpha}} < \infty.$$

Combining the above result with control of the divergence penalty gives us the following corollary.

Corollary 17 *Under assumptions (a)-(e), if the distribution is also light-tailed, the expected regret of GBPA with appropriately scaled perturbations drawn from that distribution is, for all $\alpha \in (\delta, 1)$ and $\xi > 0$,*

$$O\Big((TN)^{1/(2-\alpha)}N^\xi\Big).$$

In particular, if assumption (e) holds for all $\delta \in (0, 1)$, then the expected regret of GBPA is $O\Big((TN)^{1/2+\epsilon}\Big)$ for all $\epsilon > 0$, i.e., it is near optimal in both N and T.

Next we consider a family of light-tailed distributions that do not have a bounded hazard rate.

Definition 18 *The exponential power (or generalized normal) family of distributions, denoted as $\mathcal{D}_\beta$ where $\beta > 1$, is defined via the cdf*

$$f_\beta(z) = C_\beta e^{-z^\beta}, \quad z \geq 0.$$

The next theorem shows that GBPA with perturbations from this family of distributions enjoys near optimal expected regret in both N and T.

Theorem 19 (Regret Bound for Exponential Power Family) *$\forall \beta > 1$, the expected regret of GBPA with appropriately scaled perturbations drawn from $\mathcal{D}_\beta$ is, for all $\epsilon > 0$, $O\Big((TN)^{1/2+\epsilon}\Big)$.*

5. Conclusion and Future Work

Previous work on providing regret guarantees for FTPL algorithms in the adversarial multi-armed bandit setting required a bounded hazard rate condition. We have shown how to go beyond the hazard rate condition but a number of questions remain open. For example, what if we use FTPL with perturbations from discrete distributions such as Bernoulli distribution? In the full information setting Devroye et al. (2013) and Van Erven et al. (2014) have considered random walk perturbation and dropout perturbation, both leading to minimax optimal regret. But to the best of our knowledge those distributions have not been analyzed in the adversarial multi-armed bandit problem.

An unsatisfactory aspect of even the tightest bounds for FTPL algorithms from existing work, including ours, is that they never reach the minimax optimal $O(\sqrt{NT})$ bound. They come very close to it: up to logarithmic factors. It is known that FTRL algorithms, using the negative Tsallis entropy as the regularizer, can achieve the optimal bound (Audibert and Bubeck, 2009; Audibert et al., 2011; Abernethy et al., 2015). Is there a perturbation that can achieve the optimal bound?

We only considered multi-armed bandits in this work. There has been some interest in using FTPL algorithms for combinatorial bandit problems (see, for example, Neu and Bartók (2013)). In future work, it will be interesting to extend our analysis to combinatorial bandit problems.

Appendix A. Proofs

A.1 Proof of Lemma 10

Proof Since the numerator of the left hand side is an even function of z, and the denominator is a decreasing function, and the inequality is trivially true when $z = 0$, it suffices to prove for $z > 0$, which we assume for the rest of the proof. From Lemma 9 we can derive that

$$\frac{f(z)}{1-F(z)} < z + 1.$$

Therefore,

$$\begin{aligned}\frac{f(z)|z|^\alpha}{(1-F(z))^{1-\alpha}} &\leq \frac{f(z)z^\alpha}{(\frac{f(z)}{z+1})^{1-\alpha}} = (f(z)z)^\alpha(z+1)^{1-\alpha} \\ &\leq f(z)^\alpha(z+1) \leq zf(z)^\alpha + 1 = \sqrt{\frac{1}{2\pi}}ze^{-\alpha z^2/2} + 1.\end{aligned}$$

Let $g(z) = ze^{-\alpha z^2/2}$, $g'(z) = (1-\alpha z^2)e^{-\alpha z^2/2}$. Therefore $g(z)$ is maximized at $z^* = \sqrt{\frac{1}{\alpha}}$. Therefore,

$$\frac{f(z)|z|^\alpha}{(1-F(z))^{1-\alpha}} \le \sqrt{\frac{1}{2\pi}} ze^{-\alpha z^2/2} + 1 \le \sqrt{\frac{1}{2\pi}} z^* + 1 \le z^* + 1 = \sqrt{\frac{1}{\alpha}} + 1 \le \frac{2}{\alpha}.$$

■

A.2 Proof of Theorem 12

Proof From Corollary 11 we see that the expected regret can be upper bounded by

$$2(C_1C_2NT)^{1/(2-\alpha)}(\sqrt{2\log N})^{(1-\alpha)/(2-\alpha)}$$

where $C_1 = \frac{2}{\alpha}$ and $C_1 = \frac{2}{1-\alpha}$. Note that

$$\begin{aligned}
&2(C_1C_2NT)^{1/(2-\alpha)}(\sqrt{2\log N})^{(1-\alpha)/(2-\alpha)} \\
\le& 4(C_1C_2)^{1/(2-\alpha)} N^{1/(2-\alpha)} \sqrt{\log N}^{(1-\alpha)/(2-\alpha)} T^{1/(2-\alpha)} \\
=& 4N^{1/(2-\alpha)} \sqrt{\log N}^{(1-\alpha)/(2-\alpha)} T^{1/2} \times (C_1C_2)^{1/(2-\alpha)} T^{\alpha/(4-2\alpha)} \\
\le& 4N^{1/2} N^{\alpha/(4-2\alpha)} \sqrt{\log N} T^{1/2} \times (\frac{4}{\alpha(1-\alpha)})^{1/(2-\alpha)} T^{\alpha/(4-2\alpha)} \\
\le& 4N^{1/2} N^{\alpha} \sqrt{\log N} T^{1/2} \times \frac{4T^\alpha}{\alpha(1-\alpha)} \\
\le& 16\sqrt{NT} N^\alpha \sqrt{\log N} \times \frac{T^\alpha}{\alpha(1-\alpha)}.
\end{aligned}$$

■

If we let $\alpha = \frac{1}{\log T}$, then $T^\alpha = T^{1/\log T} = e < 3$. Then, we have, for $T > 4$,

$$\frac{T^\alpha}{\alpha(1-\alpha)} \le \frac{3\log T}{1-\frac{1}{\log T}} = \frac{3\log^2 T}{\log T - 1} \le 6\log T.$$

Putting things together finishes the proof.

A.3 Proof of Theorem 15

Proof If the distribution is heavy-tailed, we have

$$\lim_{z\to\infty} \sup \overline{F}(z) e^{\lambda z} = \infty \quad \text{for all } \lambda > 0.$$

By Lemma 14, we can erase the supremum operator and just write

$$\lim_{z\to\infty} \overline{F}(z) e^{\lambda z} = \infty \quad \text{for all } \lambda > 0.$$

Hence,

$$\lim_{z\to\infty} \overline{F}(z) e^{\lambda z} = \lim_{x\to\infty} e^{-R(z)+\lambda z} = \infty \text{ for all } \lambda > 0 \Rightarrow \limsup_{z\to\infty} \frac{R(z)}{z} = 0.$$

Note that $R'(z) = \frac{f(z)}{\overline{F}(z)}$, which is eventually monotone by assumption. Therefore, we can conclude that

$$\limsup_{z\to\infty} R'(z) < \infty \Rightarrow \sup_z \frac{f(z)}{\overline{F}(z)} < \infty.$$

■

A.4 Proof of Theorem 16

Proof If the distribution is light-tailed, we have

$$\lim_{z\to\infty} \overline{F}(z) e^{\lambda^* z} < \infty \quad \text{for some } \lambda^* > 0.$$

This immediately implies that

$$\lim_{z\to\infty} \overline{F}(z)^a z^b = 0 \quad \forall a, b > 0. \tag{14}$$

Consider $\lim_{z\to\infty} \frac{f(z)}{\overline{F}(z)} = \lim_{z\to\infty} R'(z)$. If $\lim_{z\to\infty} R'(z) < \infty$ we can immediately conclude that $\sup_z \frac{f(z)}{1-F(z)} < \infty$. If $\lim_{z\to\infty} R'(z) = \infty$ instead, note that

$$\lim_{z\to\infty} \int_{-z}^{z} R'(t) e^{-\delta R(t)} dt = -\frac{1}{\delta} e^{-\delta R(z)} \Big|_{z=-\infty}^{z=+\infty} = \frac{1}{\delta} < \infty.$$

Moreover, since $\lim_{z\to\infty} R'(z) = \infty$, $R'(z)e^{-\delta R(z)}$ is strictly positive for all $z > z_0$ for some z_0. Furthermore, $R'(z)e^{-\delta R(z)} = \frac{f(z)}{(\overline{F}(z))^{1-\delta}}$ is eventually monotone by assumption (e),

Therefore, we can conclude that

$$\lim_{z\to\infty} R'(z) e^{-\delta R(z)} = \frac{f(z)}{(\overline{F}(z))^{1-\delta}} = 0.$$

$\forall \alpha \in (\delta, 1)$, from Equation (14) we have $\lim_{z\to+\infty} z^\alpha \overline{F}(z)^{\alpha-\delta} = 0$, so

$$\lim_{z\to+\infty} \frac{f(z) z^\alpha}{(\overline{F}(z))^{1-\alpha}} = \lim_{z\to+\infty} \frac{f(z)}{\overline{F}(z)^{1-\delta}} \times z^\alpha \overline{F}(z)^{\alpha-\delta} = 0.$$

and hence

$$\sup_z \frac{f(z) z^\alpha}{(1-F(z))^{1-\alpha}} < \infty \quad \forall \alpha \in (\delta, 1).$$

■

A.5 Proof of Corollary 17

Proof For a light-tailed distribution $\mathcal{D}$, we have

$$\lim_{z\to\infty} \overline{F}_{\mathcal{D}}(z)e^{\lambda^* z} < \infty \quad \text{for some } \lambda^* > 0.$$

This implies that

$$\overline{F}_{\mathcal{D}}(z) \le Ce^{-\lambda^* z} \text{ for some } C > 0, z > z_0.$$

Let random variable Z follows distribution $\mathcal{D}$. Since Z might take negative values, we define a new distribution $\mathcal{D}'$ that only takes non-negative value by

$$f_{D'}(z) = \begin{cases} \frac{1}{p_{\mathcal{D}+}} f_D(z) & \text{if } z \ge 0 \\ 0 & \text{otherwise} \end{cases}$$

where $p_{\mathcal{D}+} = \mathbb{P}(Z \ge 0) > 0$ by right unbounded support assumption. Clearly, with this definition of $\mathcal{D}'$ we see that $\mathbb{E}_{Z_1,\dots,Z_N\sim\mathcal{D}}[\max_i Z_i] \le \mathbb{E}_{Z_1,\dots,Z_N\sim\mathcal{D}'}[\max_i Z_i]$ and for $z > z_0$, we have $\overline{F}_{\mathcal{D}'}(z) = \frac{\overline{F}_{\mathcal{D}}(z)}{p_{\mathcal{D}+}} \le C'e^{-\lambda^* z}$ where $C' = \frac{C}{p_{\mathcal{D}+}}$. Note that

$$\begin{aligned}
\mathbb{E}_{Z_1,\dots,Z_N\sim\mathcal{D}}[\max_i Z_i] &\le \mathbb{E}_{Z_1,\dots,Z_N\sim\mathcal{D}'}[\max_i Z_i] \\
&= \int_0^\infty \mathbb{P}(\max_i Z_i > x)dx \\
&\le u + \int_u^\infty \mathbb{P}(\max_i Z_i > z)dz \\
&\le u + N\int_u^\infty \mathbb{P}(Z_i > z)dz \\
&\le u + N\int_u^\infty C'e^{-\lambda^* z}dz \quad \text{assuming } u > z_0 \\
&= u + \frac{C'N}{\lambda^*}e^{-\lambda^* u}.
\end{aligned}$$

If we let $u = \frac{\log(N)}{\lambda^*}$, obviously $u > z_0$ if N is sufficiently large. Thus, we see that

$$\mathbb{E}_{Z_1,\dots,Z_N\sim\mathcal{D}}[\max_i Z_i] \le \frac{\log(N)}{\lambda^*} + C' = O(N^\xi) \quad \forall \xi > 0. \tag{15}$$

From Theorem 16 we see that $\forall \alpha \in (\delta, 1)$,

$$\frac{f(z)z^\alpha}{(1-F(z))^{1-\alpha}} \le C_\alpha \quad \forall z \in \mathbb{R}. \tag{16}$$

Plug 15 and 16 into Theorem 8 gives the desired result. ■

A.6 Proof of Corollary 19

Proof By Corollary 17 we only need to check that assumptions (a)-(d) hold for distribution $\mathcal{D}_\beta$, exponential power family is light-tailed, and assumption (e) also holds for any $\delta \in (0, 1)$. By observing the density function f_β we can trivially see that assumptions (a)-(c) hold and that the exponential power family is light-tailed. Therefore, define

$$g_{\delta,\beta}(z) = \frac{f_\beta(z)}{(\overline{F}_\beta(z))^{1-\delta}} = \frac{f_\beta(z)}{(1-F_\beta(z))^{1-\delta}},$$

it suffices to show that $\forall \delta \in [0, 1), g_{\delta,\beta}(z)$ is eventually monotone. Note that

$$\begin{aligned}
g'_{\delta,\beta}(z) &= \frac{f'_\beta(z)(1-F_\beta(z))^{1-\delta} + (1-\delta)(1-F_\beta(z))^{-\delta}f_\beta^2(z)}{(1-F_\beta(z))^{2-2\delta}} \\
&= \frac{C_\beta^2 e^{-z^\beta}}{(1-F_\beta(z))^{2-\delta}} \times \Big((1-\delta)e^{-z^\beta} - \beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt\Big).
\end{aligned}$$

It further suffices to show that

$$m_{\delta,\beta}(z) = (1-\delta)e^{-z^\beta} - \beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt$$

is eventually non-negative or non-positive $\forall \beta > 1, \delta \in [0, 1)$. Note that since $\beta > 1$,

$$\beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt = \int_z^\infty \beta z^{\beta-1}e^{-t^\beta}dt < \int_z^\infty \beta t^{\beta-1}e^{-t^\beta}dt = e^{-z^\beta}. \tag{17}$$

Therefore, $m_{0,\beta}(z) > 0$ for all $z \ge 0$, i.e., the hazard rate is always increasing and assumption (d) is satisfied. Now, we are left to show that $m_{\delta,\beta}(z)$ is eventually non-negative or non-positive for any $\delta \in (0, 1)$. Note that

$$\begin{aligned}
\beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt &= \beta(\frac{z}{z+1})^{\beta-1}(z+1)^{\beta-1}\int_z^\infty e^{-t^\beta}dt \\
&\ge \beta(\frac{z}{z+1})^{\beta-1}(z+1)^{\beta-1}\int_z^{z+1} e^{-t^\beta}dt \\
&\ge (\frac{z}{z+1})^{\beta-1}\int_z^{z+1}\beta t^{\beta-1}e^{-t^\beta}dt \\
&= (\frac{z}{z+1})^{\beta-1}\Big(e^{-z^\beta} - e^{-(z+1)^\beta}\Big).
\end{aligned}$$

Therefore,

$$\begin{aligned}
\liminf_{z\to\infty} \frac{\beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt}{e^{-z^\beta}} &\ge \liminf_{z\to\infty} \frac{(\frac{z}{z+1})^{\beta-1}\Big(e^{-z^\beta} - e^{-(z+1)^\beta}\Big)}{e^{-z^\beta}} \\
&= \lim_{z\to\infty}(\frac{z}{z+1})^{\beta-1} - \lim_{z\to\infty}(\frac{z}{z+1})^{\beta-1}e^{z^\beta-(z+1)^\beta} \\
&= 1.
\end{aligned}$$

From Equation (17) we know that

$$\limsup_{z\to\infty} \frac{\beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt}{e^{-z^\beta}} \leq 1.$$

Hence, we conclude that

$$\lim_{z\to\infty} \frac{\beta z^{\beta-1}\int_z^\infty e^{-t^\beta}dt}{e^{-z^\beta}} = 1,$$

which implies that $m_{\delta,\beta}(z)$ is eventually non-positive for any $\delta \in (0,1)$, i.e., assumption (e) holds for any $\delta \in (0,1)$.

Abstract

The cyclic block coordinate descent-type (CBCD-type) methods, which perform iterative updates for a few coordinates (a block) simultaneously throughout the procedure, have shown remarkable computational performance for solving strongly convex minimization problems. Typical applications include many popular statistical machine learning methods such as elastic-net regression, ridge penalized logistic regression, and sparse additive regression. Existing optimization literature has shown that for strongly convex minimization, the CBCD-type methods attain iteration complexity of $\mathcal{O}(p\log(1/\epsilon))$, where ϵ is a pre-specified accuracy of the objective value, and p is the number of blocks. However, such iteration complexity explicitly depends on p, and therefore is at least p times worse than the complexity $\mathcal{O}(\log(1/\epsilon))$ of gradient descent (GD) methods. To bridge this theoretical gap, we propose an improved convergence analysis for the CBCD-type methods. In particular, we first show that for a family of quadratic minimization problems, the iteration complexity $\mathcal{O}(\log^2(p)\cdot\log(1/\epsilon))$ of the CBCD-type methods matches that of the GD methods in term of dependency on p, up to a $\log^2 p$ factor. Thus our complexity bounds are sharper than the existing bounds by at least a factor of $p/\log^2(p)$. We also provide a lower bound to confirm that our improved complexity bounds are tight (up to a $\log^2(p)$ factor), under the assumption that the largest and smallest eigenvalues of the Hessian matrix do not scale with p. Finally, we generalize our analysis to other strongly convex minimization problems beyond quadratic ones.

Keywords: cyclic block coordinate descent, gradient descent, strongly convex minimization, quadratic minimization, improved iteration complexity

*. Some preliminary results in this paper were presented at the 19th International Conference on Artificial Intelligence and Statistics (Li et al., 2016).

1. Introduction

We consider a class of composite convex minimization problems:

$$x^* = \operatorname*{argmin}_{x\in\mathbb{R}^d} \mathcal{F}(x),\ \mathcal{F}(x) = \mathcal{L}(x) + \mathcal{R}(x), \tag{1}$$

where $\mathcal{L}(\cdot)$ is a twice differentiable loss function and $\mathcal{R}(\cdot)$ is a possibly nonsmooth and strongly convex penalty function. Many popular statistical machine learning problems are of the form (1), such as elastic-net regression (Zou and Hastie, 2005), ridge penalized logistic regression (Hastie et al., 2009), support vector machine (Vapnik and Vapnik, 1998) and many others (Hastie et al., 2009). For notational simplicity, we assume that there exists a partition of d coordinates such that

$$x = [x_1^\top, \ldots, x_p^\top]^\top \in \mathbb{R}^d,$$

where $x_j \in \mathbb{R}^{d_j}$, $d = \sum_{j=1}^p d_j$, and $d_j \ll p$. The penalty function $\mathcal{R}(x)$ in these applications is block coordinate decomposable, i.e., $\mathcal{R}(x) = \sum_{j=1}^p \mathcal{R}_j(x_j)$. Then we can rewrite the objective in (1) as

$$\mathcal{F}(x) = \mathcal{L}(x_1, \ldots, x_p) + \sum_{j=1}^p \mathcal{R}_j(x_j).$$

Many algorithms such as gradient decent-type (GD-type) methods (Nesterov, 2004, 2007; Beck and Teboulle, 2009b,a; Becker et al., 2011), cyclic block coordinate descent-type (CBCD-type) methods (Luo and Tseng, 1992; Tseng, 1993, 2001; Friedman et al., 2007; Liu et al., 2009; Tseng and Yun, 2009; Saha and Tewari, 2013; Nutini et al., 2015; Zhao and Liu, 2015; Zhao et al., 2014b,a, 2012; Li et al., 2015b), and alternating direction method of multipliers (ADMM) (Gabay and Mercier, 1976; Boyd et al., 2011; He and Yuan, 2015; Hong and Luo, 2012; Zhao and Liu, 2012; Liu et al., 2014, 2015; Li et al., 2015a)) have been proposed to solve (1). Among these algorithms, the CBCD-type methods have been immensely successful (Friedman et al., 2007, 2010; Mazumder et al., 2011; Tibshirani et al., 2012; Razaviyayn et al., 2013; Zhao et al., 2014a). One popular instance of the CBCD-type methods is the cyclic block coordinate minimization (CBCM) method, which minimizes (1) with respect to a single block of variables while holding the rest fixed. Particularly, at the $(t+1)$-th iteration, given $x^{(t)}$, we choose to solve a collection of optimization problems: For $j = 1, \ldots, p$,

$$x_j^{(t+1)} = \operatorname*{argmin}_{x_j}\ \mathcal{L}\left(x_{1:(j-1)}^{(t+1)}, x_j, x_{(j+1):p}^{(t)}\right) + \mathcal{R}_j(x_j), \tag{2}$$

where $x_{1:(j-1)}^{(t+1)}$ and $x_{(j+1):p}^{(t)}$ are defined as

$$x_{1:(j-1)}^{(t+1)} = [x_1^{(t+1)\top}, \ldots, x_{j-1}^{(t+1)\top}]^\top \text{ and } x_{(j+1):p}^{(t)} = [x_{j+1}^{(t)\top}, \ldots, x_p^{(t)\top}]^\top.$$

For some applications (e.g. elastic-net penalized linear regression), we can obtain a simple closed form solution to (2), but for many other applications (e.g. ridge-penalized logistic regression), (2) does not admit a closed form solution and requires more sophisticated optimization procedures.

A popular alternative to CBCD-type methods is to solve a quadratic approximation of (2) using the cyclic block coordinate gradient descent (CBCGD) method. For notational simplicity, we denote the partial gradient $\nabla_{x_j}\mathcal{L}(x)$ by $\nabla_j\mathcal{L}(x)$. Then the CBCGD method solves a collection of optimization problems: For $j = 1, \ldots, p$,

$$x_j^{(t+1)} = \underset{x_j}{\operatorname{argmin}} \ (x_j - x_j^{(t)})^\top \nabla_j \mathcal{L}\left(x_{1:(j-1)}^{(t+1)}, x_{j:p}^{(t)}\right) + \frac{\eta_j}{2}\|x_j - x_j^{(t)}\|^2 + \mathcal{R}_j(x_j), \tag{3}$$

where $\eta_j > 0$ is a step-size parameter for the j-th block.

There have been many results on iteration complexity of block coordinate descent-type (BCD-type) methods, but most of them focus on the randomized BCD-type methods, where blocks are randomly chosen with replacement in each iteration (Shalev-Shwartz and Tewari, 2011; Richtárik and Takáč, 2012; Lu and Xiao, 2015), which demonstrate better iteration complexities than cyclic BCD-type methods in the worst case scenarios (Lee and Wright, 2016; Sun and Ye, 2016). In contrast, existing literature on cyclic BCD-type methods is rather limited. Beck and Tetruashvili (2013) focus on minimizing smooth objective functions, and has shown that given a pre-specified accuracy ϵ for the objective value, the CBCGD method attains linear iteration complexity of $\mathcal{O}(\log(1/\epsilon))$ for minimizing smooth and strongly convex problems, and sublinear iteration complexity of $\mathcal{O}(1/\epsilon)$ for smooth and nonstrongly convex problems. Hong et al. (2017); Yun (2014); Sun and Hong (2015) focus on minimizing nonsmooth composite objective functions such as (1), and has shown that the CBCM and CBCGD methods attain sublinear iteration complexity of $\mathcal{O}(1/\epsilon)$, when the objective function is nonstronlgy convex.

Here, we are interested in establishing an improved iteration complexity of the CBCM and CBCGD methods, when the nonsmooth composite objective function is strongly convex. Beck and Tetruashvili (2013) has shown that for smooth minimization, the CBCGD method attains linear iteration complexity of

$$\mathcal{O}\left(\frac{L_{\max} \cdot pL^2 \log(1/\epsilon)}{L_{\min}^2 \cdot \mu}\right), \tag{4}$$

where L is the Lipschitz constant of the gradient of the objective function, μ is the strongly convex constant of the objective function, $L_{\max} = \max_i L_i$, $L_{\min} = \min_i L_i$, and L_i is the Lipschitz constant of i-th block of the gradient of the objective function. However, such an iteration complexity depends on p (the number of blocks), and therefore is at least p times worse than the complexity $\mathcal{O}\left(\mu^{-1}L\log(1/\epsilon)\right)$ of the gradient descent (GD) methods.

To bridge this theoretical gap, we propose an improved convergence analysis for the CBCD-type methods. Specifically, we show that for a family of quadratic minimization problems, the iteration complexity of the CBCD-type methods matches that of the GD

methods in term of dependency on p up to a $\log^2(p)$ factor. More precisely, when $\mathcal{L}(x)$ is quadratic, the iteration complexity of the CBCGD method is

$$\mathcal{O}\left(\frac{\log^2(p)L^2\log(1/\epsilon)}{L_{\min}^{\mu} \cdot \mu}\right), \tag{5}$$

where $L_{\min}^{\mu} = \min_i\{L_i + \mu_i\}$ and μ_i is the strongly convex constant with respect to the i-th block of variables. Note that $L_{\min}^{\mu} \geq L_{\min}$. As can be seen easily, (5) is better than (4) by a factor of at least $\frac{L_{\max}\cdot p}{L_{\min}\cdot\log^2(p)}$. Note that We also provide a lower bound analysis that confirms that our improved iteration complexity is tight up to a $\log^2(p)$ factor if the largest and smallest eigenvalues of the Hessian matrix do not scale with p. Similar results hold for the CBCM method. We remark here that when the problem is quadratic (e.g., ridge-penalized linear regression with squared loss), (1) can be written as solving a linear system. Then the CBCM method is equivalent to the Gauss-Siedel method, which also has a linear convergence rate (Golub and Van Loan, 2012). Nevertheless, our major effort is to improve the dependence of the constant factor on the problem parameters (e.g., the block size p and Lipchitz constant L) in the iteration complexity, which is more difficult to analyze in the blockwise minimization case for the Gauss-Siedel method.[1] In addition, the Gauss-Siedel method is not applicable beyond the quadratic case in general.

Finally, we generalize our analysis to other strongly convex minimization problems beyond quadratic minimization. Specifically, for smooth minimization, the iteration complexity of the CBCGD method is

$$\mathcal{O}\left(\frac{L_{\max}^{\beta} \cdot pL^{\beta} \log(1/\epsilon)}{L_{\min}^{\beta} \cdot \mu}\right), \tag{6}$$

where $L^{\beta} = L + \beta$, $L_{\max}^{\beta} = \max_i\{L_i + \beta_i\}$, $L_{\min}^{\beta} = \min_i\{L_i + \beta_i\}$, β is the Lipchitz constant of gradient $\nabla\mathcal{R}(\cdot)$, and β_i is the Lipchitz constant of i-th block of gradient $\nabla_i\mathcal{R}(\cdot)$ for smooth $\mathcal{R}(\cdot)$. Note that L^{β}, $L_{\max}^{\beta}$, and $L_{\min}^{\beta}$ are the Lipchitz constants of the gradient (and the corresponding blocks) of the objective function, which are identical to those considered in Beck and Tetruashvili (2013) when the objective is of the composite form as in (1). This indicates that (6) is better than (4) by a factor of $L^{\beta}/L_{\min}^{\beta}$, which is at least of order $\sqrt{p}$ and can be much more significant for ill-conditioned problems. Similar results hold for nonsmooth regularized minimization and their counter parts for the CBCM method; for more details refer to Table 1. It is worth mentioning that all the above results on the CBCD-type methods can be used to establish the iteration complexity for the popular permuted BCM (PBCM) and permuted BCGD (PBCGD) methods, in which the blocks are randomly sampled without replacement in each round. Improvement in terms of the dependence on constants are provided in Sun and Hong (2015) for the nonstronlgy convex problems.

The rest of the paper is organized as follows. In Section 2, we introduce notations and preliminary assumptions. Then we provide the main results of improved convergence

1. It requires to find an upper bound of the contraction constant $\|H_L^{-1}(H - H_L)\|$ in the Gauss-Siedel method, where H is the coefficient matrix of the linear system and H_L is the lower triangular matrix of H. Note that it requires $\|H_L^{-1}(H - H_L)\| < 1$ for the convergence of the Gauss-Siedel method.

Table 1: Compared with Beck and Tetruashvili (2013), our contributions are manyfold: (1) Developing the iteration complexity bounds of the CBCM and CBCGD methods for different specifications on $\mathcal{L}(\cdot)$ and $\mathcal{R}(\cdot)$; (2) Developing the iteration complexity bound of CBCGD for quadratic $\mathcal{L}(\cdot)$ + nonsmooth $\mathcal{R}(\cdot)$; (3) Improving the iteration complexity bound of CBCGD for smooth $\mathcal{R}(\cdot)$.

[h]	CBCM	General Convex	Nonsmooth	$\mathcal{O}\left(\frac{L_{\max}\cdot pL\log(1/\epsilon)}{\mu_{\min}\cdot\mu}\right)$	N/A

Remark: See Theorem 3 for [a] and [b]; See Theorem 4 for [e] and [f]; See Theorem 7 for [c]; See Theorem 8 for [d], [g], and [h]. When $\mathcal{R}(\cdot)$ is nonsmooth, the optimization problem is actually solved by the cyclic block coordinate proximal gradient (CBCPGD) method. For notational convenience in this paper, however, we simply call it the CBCGD method.

analysis for CBCD-type approachs in Section 3. Numerical evaluations are provided in Section 4, followed by further discussions in Section 5.

2. Notations and Assumptions

We start with introducing notations used in this paper. Given a vector $\boldsymbol{v} = (v_1, \ldots, v_d)^\top \in \mathbb{R}^d$, we define vector norms: $\|\boldsymbol{v}\|_1 = \sum_j |v_j|$, $\|\boldsymbol{v}\|^2 = \sum_j v_j^2$, and $\|\boldsymbol{v}\|_\infty = \max_j |v_j|$. Let $\{\mathcal{A}_1, \ldots, \mathcal{A}_p\}$ be a partition of all d coordinates with $|\mathcal{A}_j| = d_j$ and $\sum_{j=1}^p d_j = d$. We use $\boldsymbol{v}_j$ to denote the subvector of $\boldsymbol{v}$ with all indices in $\mathcal{A}_j$. Given a matrix $A \in \mathbb{R}^{d\times d}$, we use $\lambda_{\max}(A)$ and $\lambda_{\min}(A)$ to denote the largest and smallest eigenvalues of A. We denote $\|A\|$ as the spectral norm of A (i.e., the largest singular value). We denote $\otimes$ and $\odot$ as the Kronecker product and Hadamard (entrywise) product for two matrices respectively.

Before we proceed with our analysis, we introduce some assumptions on $\mathcal{L}(\cdot)$ and $\mathcal{R}(\cdot)$.

Assumption 1 *$\mathcal{L}(\cdot)$ is convex, and its gradient mapping $\nabla\mathcal{L}(\cdot)$ is Lipschitz continuous and also blockwise Lipschitz continuous, i.e., there exist positive constants L and L_j's such that for any $x, x' \in \mathbb{R}^d$ and $j = 1, \ldots, p$, we have*

$$\|\nabla\mathcal{L}(x') - \nabla\mathcal{L}(x)\| \le L\|x - x'\| \text{ and } \|\nabla_j\mathcal{L}\left(x_{1:(j-1)}, x'_j, x_{(j+1):p}\right) - \nabla_j\mathcal{L}(x)\| \le L_j\|x_j - x'_j\|.$$

We define $L_{\max} = \max_j L_j$ and $L_{\min} = \min_j L_j$.

Assumption 2 *$\mathcal{R}(\cdot)$ is strongly convex and also blockwise strongly convex, i.e., there exist positive constants μ and μ_j's such that for any $x, x' \in \mathbb{R}^d$ and $j = 1, \ldots, p$, we have*

$$\mathcal{R}(x) \ge \mathcal{R}(x') + (x - x')^\top\xi' + \frac{\mu}{2}\|x - x'\|^2 \text{ and}$$
$$\mathcal{R}_j(x_j) \ge \mathcal{R}_j(x'_j) + (x_j - x'_j)^\top\xi'_j + \frac{\mu_j}{2}\|x_j - x'_j\|^2,$$

for all $\xi' \in \partial\mathcal{R}(x')$. We define $\mu_{\min} = \min_j \mu_j$.

For notational simplicity, we define auxiliary variables

$$L^\mu_{\min} = \min_j L_j + \mu_j \text{ and } y^{(t,j)} = [x^{(t)\top}_{1:(j-1)}, x^{(t-1)\top}_{j:p}]^\top,\ j = 1, \ldots, p. \tag{7}$$

We remark that $y^{(t,j)}$ serves as an intermediate variable in our analysis, which has the first $j-1$ blocks of variables updated and the remaining blocks unchanged at t-th iteration. Our analysis considers $L_{\min}$, $L_{\max}$, $L^\mu_{\min}$, $\mu_{\min}$, μ, and $d_{\max} = \max_j d_j$ as constants, which do not scale with the block size p as in existing literature (Beck and Tetruashvili, 2013).

3. Improved Convergence Analysis

Our analysis consists of the following three steps:

(1) Characterize the successive descent after each CBCD iteration;

(2) Characterize the gap towards the optimal objective value after each CBCD iteration;

(3) Combine (1) and (2) to establish the iteration complexity bound.

We present our analysis under different specifications on $\mathcal{L}(\cdot)$ and $\mathcal{R}(\cdot)$.

3.1 Quadratic Minimization

We first consider a scenario, where $\mathcal{L}(\cdot)$ is a quadratic function. Particularly, we solve

$$x^* = \operatorname*{argmin}_{x\in\mathbb{R}^d} \mathcal{L}(x) + \mathcal{R}(x) = \operatorname*{argmin}_{\substack{x_j\in\mathbb{R}^{d_j}\\ j=1,\ldots,p}} \frac{1}{2}\left\|\sum_{j=1}^p A_{*j}x_j - b\right\|^2 + \sum_{j=1}^p \mathcal{R}_j(x_j), \tag{8}$$

where $A_{*j} \in \mathbb{R}^{n\times d_j}$ for $j = 1, ..., p$. Typical applications of (8) in statistical machine learning include ridge regression, elastic-net penalized regression, and sparse additive regression.

We first characterize the successive descent of the CBCGD method.

Lemma 1 *Recall that $\mathcal{F}$ is the objective defined in (1). Suppose that Assumptions 1 and 2 hold. We choose $\eta_j = L_j$ for the CBCGD method. Then for all $t \ge 1$, we have*

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \ge \frac{L^\mu_{\min}}{2}\|x^{(t)} - x^{(t+1)}\|^2.$$

Proof At t-th iteration, there exists a $\xi_j^{(t+1)} \in \partial \mathcal{R}_j(x_j^{(t+1)})$ satisfying the optimality condition for each sub-problem:

$$\nabla_j \mathcal{L}(y^{(t+1,j)}) + \eta_j(x_j^{(t+1)} - x_j^{(t)}) + \xi_j^{(t+1)} = 0. \tag{9}$$

Then by definition of CBCGD given in (3), we have

$$\begin{aligned}\mathcal{F}(y^{(t+1,j+1)}) \leq \mathcal{L}(y^{(t+1,j)}) &+ (y^{(t+1,j+1)} - y^{(t+1,j)})^\top \nabla \mathcal{L}(y^{(t+1,j)}) \\ &+ \frac{L_j}{2}\|y^{(t+1,j)} - y^{(t+1,j+1)}\|^2 + \mathcal{R}(y^{(t+1,j+1)}).\end{aligned}$$

This further implies

$$\begin{aligned}&\mathcal{F}(y^{(t+1,j)}) - \mathcal{F}(y^{(t+1,j+1)}) = \mathcal{L}(y^{(t+1,j)}) + \mathcal{R}(y^{(t+1,j)}) \\ &\geq (y^{(t+1,j)} - y^{(t+1,j+1)})^\top \nabla \mathcal{L}(y^{(t+1,j)}) - \frac{L_j}{2}\|y^{(t+1,j)} - y^{(t+1,j+1)}\|^2 \\ &\qquad + \mathcal{R}(y^{(t+1,j)}) - \mathcal{R}(y^{(t+1,j+1)}) \\ &= (x_j^{(t)} - x_j^{(t+1)})^\top \nabla_j \mathcal{L}(y^{(t+1,j+1)}) - \frac{L_j}{2}\|x_j^{(t+1)} - x_j^{(t)}\|^2 + \mathcal{R}_j(x_j^{(t)}) - \mathcal{R}_j(x_j^{(t+1)}).\end{aligned} \tag{10}$$

By Assumptions 2, we have

$$\mathcal{R}_j(x_j^{(t)}) - \mathcal{R}_j(x_j^{(t+1)}) \geq (x_j^{(t)} - x_j^{(t+1)})^\top \xi_j^{(t+1)} + \frac{\mu_j}{2}\|x_j^{(t)} - x_j^{(t+1)}\|^2. \tag{11}$$

Combining (9), (10), and (11), we have

$$\mathcal{F}(y^{(t+1,j)}) - \mathcal{F}(y^{(t+1,j+1)}) \geq \frac{L_j + \mu_j}{2}\|x_j^{(t)} - x_j^{(t+1)}\|^2. \tag{12}$$

We complete the proof via summation of (12) over $j = 1, \ldots, p$ and the definition of $L_{\min}^{\mu}$. ■

Next, we characterize the gap towards the optimal objective value.

Lemma 2 *Suppose that Assumptions 1 and 2 hold with $d \geq 2$. Then for all $t \geq 1$, we have*

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq \frac{8L^2 \log^2(3pd_{\max})}{\mu}\|x^{(t+1)} - x^{(t)}\|^2.$$

Proof Since $\mathcal{L}(x)$ is quadratic, its second order Taylor expansion is tight, i.e.

$$\mathcal{L}(x^*) = \mathcal{L}(x^{(t+1)}) + \langle \nabla \mathcal{L}(x^{(t+1)}), x^* - x^{(t+1)} \rangle + \frac{1}{2}\|A(x^{(t+1)} - x^*)\|^2, \tag{13}$$

where $A = [A_{*1}, \ldots, A_{*p}] \in \mathbb{R}^{n \times d}$.

Consider matrices $\widetilde{P}$ and $\widetilde{A}$, defined as

$$\widetilde{P} = \begin{bmatrix} L_1 & 0 & 0 & \ldots & 0 & 0 \\ 0 & L_2 & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \vdots & \vdots \\ 0 & 0 & & \ldots & 0 & L_p \end{bmatrix} \in \mathbb{R}^{p \times p} \quad \text{and} \quad \widetilde{A} = \begin{bmatrix} A_{*1} & 0 & 0 & \ldots & 0 & 0 \\ 0 & A_{*2} & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \vdots & \vdots \\ 0 & 0 & & \ldots & 0 & A_{*p} \end{bmatrix} \in \mathbb{R}^{np \times d}.$$

For simplicity, we assume that $d_1 = \ldots = d_p = m = d/p$. For any $s \in \mathbb{Z}^+$, we define the lower triangular matrix $D_s \in \mathbb{R}^{s \times s}$ as

$$D_s = \begin{bmatrix} 1 & 0 & 0 & \ldots & 0 & 0 \\ 1 & 1 & 0 & \ldots & 0 & 0 \\ 1 & 1 & 1 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \vdots & \vdots \\ 1 & 1 & 1 & \ldots & 1 & 1 \end{bmatrix}$$

By the definition of L_j, we have that for all $j = 1, \ldots, p$,

$$L_j \geq \lambda_{\max}(A_j^\top A_j).$$

which gives us the following inequality

$$\widetilde{P} \otimes I_m \succeq \widetilde{A}^\top \widetilde{A}. \tag{14}$$

To characterize the gap towards the optimal objective, we have

$$\begin{aligned}&\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) + \frac{\mu}{2}\|x^{(t+1)} - x^*\|^2 \\ &\overset{\text{(i)}}{\leq} \langle \nabla \mathcal{L}(x^{(t+1)}), x^{(t+1)} - x^* \rangle + \mathcal{R}(x^{(t+1)}) - \mathcal{R}(x^*) + \frac{\mu}{2}\|x^{(t+1)} - x^*\|^2 \\ &\overset{\text{(ii)}}{\leq} \langle \nabla \mathcal{L}(x^{(t+1)}), x^{(t+1)} - x^* \rangle + \langle \xi^{(t+1)}, x^{(t+1)} - x^* \rangle \\ &\overset{\text{(iii)}}{\leq} \sum_{j=1}^{p} \langle \nabla_j \mathcal{L}(x^{(t+1)}) - \nabla_j \mathcal{L}\left(x^{(t)}\right), x_j^{(t+1)} - x_j^* \rangle - \sum_{j=1}^{p} L_j \langle x_j^{(t+1)} - x_j^{(t)}, x_j^{(t+1)} - x_j^* \rangle \\ &= \sum_{j=1}^{p} \Big\langle \sum_{k \geq j} A_k(x_k^{(t+1)} - x_k^{(t)}), A_j(x_j^{(t+1)} - x_j^*) \Big\rangle - (x^{(t+1)} - x^{(t)})^\top (\widetilde{P} \otimes I_m)(x^{(t+1)} - x^*) \\ &\leq (x^{(t+1)} - x^{(t)})^\top \widetilde{A}^\top (D_p \otimes I_n) \widetilde{A}(x^{(t+1)} - x^*) - (x^{(t+1)} - x^{(t)})^\top (\widetilde{P} \otimes I_m)(x^{(t+1)} - x^*) \\ &= (x^{(t+1)} - x^{(t)})^\top \left(\widetilde{A}^\top (D_p \otimes I_n) \widetilde{A} - \widetilde{P} \otimes I_m \right) (x^{(t+1)} - x^*) \\ &\overset{\text{(iv)}}{=} (x^{(t+1)} - x^{(t)})^\top \left(\left(A^\top A - \widetilde{A}^\top \widetilde{A} \right) \odot D_d + \widetilde{A}^\top \widetilde{A} - \widetilde{P} \otimes I_m \right) (x^{(t+1)} - x^*),\end{aligned}$$

where (i) is from (13) as $\|A(x^{(t+1)} - x^*)\|^2 \geq 0$, (ii) is from Assumption 2, (iii) is from the optimality condition to the subproblem associated with x_j,

$$\langle \nabla_j \mathcal{L}(y^{(t+1,j)}) + L_j(x_j^{(t+1)} - x_j^{(t)}) + \xi_j^{(t+1)}, x_j - x_j^{(t+1)} \rangle \geq 0 \text{ for any } x_j \in \mathbb{R}^m,$$

and (iv) comes from the fact that

$$\widetilde{A}^\top (D_p \otimes I_m) \widetilde{A} = \left(A^\top A - \widetilde{A}^\top \widetilde{A} \right) \odot D_d + \widetilde{A}^\top \widetilde{A}, \tag{15}$$

where $\odot$ denotes the Hadamard product. We rewrite (15) in this way because a tight upper bound of the spectral norm of R.H.S. is easier to be obtained than the spectral norm of L.H.S. after subtracting $\widetilde{P} \otimes I_m$.

For notational convenience, we define

$$B = \left(A^\top A - \widetilde{A}^\top \widetilde{A}\right) \odot D_d + \widetilde{A}^\top \widetilde{A} - \widetilde{P} \otimes I_m,$$

then we have

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq (x^{(t+1)} - x^{(t)})^\top B(x^{(t+1)} - x^*) - \frac{\mu}{2}\|x^{(t+1)} - x^*\|^2. \tag{16}$$

Minimizing the R.H.S. of the above inequality over x^*, we obtain

$$-\mu(x^* - x^{(t+1)}) - B^\top(x^{(t+1)} - x^{(t)}) = 0.$$

which implies

$$x^* = -\frac{B^\top(x^{(t+1)} - x^{(t)})}{\mu} + x^{(t+1)}. \tag{17}$$

In addition, we have

$$\begin{aligned}
\|B\| &\overset{\text{(i)}}{\leq} \|\left(A^\top A - \widetilde{A}^\top \widetilde{A}\right) \odot D_d\| + \|\widetilde{A}^\top \widetilde{A} - \widetilde{P} \otimes I_m\| \\
&\overset{\text{(ii)}}{\leq} \|A^\top A - \widetilde{A}^\top \widetilde{A}\| \left(1 + \frac{1}{\pi} + \frac{\log(d)}{\pi}\right) + \|\widetilde{A}^\top \widetilde{A} - \widetilde{P} \otimes I_m\| \\
&\overset{\text{(iii)}}{\leq} \left(\|A^\top A\| + \|\widetilde{A}^\top \widetilde{A}\|\right) \left(1 + \frac{1}{\pi} + \frac{\log(d)}{\pi}\right) + \|\widetilde{A}^\top \widetilde{A} - \widetilde{P} \otimes I_m\| \\
&\overset{\text{(iv)}}{\leq} 4\|A^\top A\| \left(1 + \frac{1}{\pi} + \frac{\log(d)}{\pi}\right) \overset{\text{(v)}}{\leq} 4L\log(3pd_{\max}),
\end{aligned} \tag{18}$$

where (i) and (iii) are from the triangle inequality, (iv) is from (14) and the fact that $\|\widetilde{A}^\top \widetilde{A}\| \leq \|A^\top A\|$, and (v) is from $\|A^\top A\| \leq L$, $1 + \frac{1}{\pi} + \frac{\log(d)}{\pi} \leq \log(3d)$ for all $d \geq 2$, and $d \leq pd_{\max}$. Inequality (ii) follows from the result on the spectral norm of the triangular truncation operator in Angelos et al. (1992) (Theorem 1). More specifically, let us define

$$L_d = \max\left\{\frac{\|A \odot D_d\|}{\|A\|} : A \in \mathbb{R}^{d\times d}, A \neq 0\right\},$$

which is the largest ratio between the spectral norm of the triangular truncation of A (the Hadamard product of A and D_d) and the spectral norm of A. Then for any $d \geq 2$, we have from Angelos et al. (1992) that

$$\left|\frac{L_d}{\log d} - \frac{1}{\pi}\right| \leq \frac{\left(1 + \frac{1}{\pi}\right)}{\log d}.$$

Plugging (17) into (16), we obtain

$$\begin{aligned}
\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) &\leq \frac{1}{2\mu}\|B(x^{(t+1)} - x^{(t)})\|^2 \overset{\text{(i)}}{\leq} \frac{\|B\|^2}{2\mu}\|x^{(t+1)} - x^{(t)}\|^2 \\
&\overset{\text{(ii)}}{\leq} \frac{8L^2\log^2(3pd_{\max})}{\mu}\|x^{(t+1)} - x^{(t)}\|^2,
\end{aligned}$$

where (i) comes from the Cauchy-Schwarz inequality, (ii) is from (18). ■

Using Lemmas 1 and 2, we establish the iteration complexity bound of the CBCGD method for minimizing (8) in the next theorem.

Theorem 3 *Suppose that Assumptions 1 and 2 hold with $d \geq 2$. We choose $\eta_j = L_j$ for the CBCGD method. Given a pre-specified accuracy $\epsilon > 0$ of the objective value, we need at most*

$$\left\lceil \frac{\mu L^\mu_{\min} + 16L^2\log^2(3pd_{\max})}{\mu L^\mu_{\min}} \log\left(\frac{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)}{\epsilon}\right)\right\rceil$$

iterations for the CBCGD method to ensure that $\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \epsilon$, where $L^\mu_{\min}$ is defined in (7).

Proof Combining Lemmas 1 and 2, we obtain

$$\begin{aligned}
\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) &= [\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)})] + [\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*)] \\
&\geq \frac{L^\mu_{\min}}{2}\|x^{(t)} - x^{(t+1)}\|^2 + [\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*)] \\
&\geq \left(1 + \frac{L^\mu_{\min}\mu}{16L^2\log^2(3pd_{\max})}\right)[\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*)].
\end{aligned}$$

Recursively applying the above inequality for $t \geq 1$, we obtain

$$\frac{\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*)}{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)} \leq \left(1 - \frac{\mu L^\mu_{\min}}{\mu L^\mu_{\min} + 16L^2\log^2(3pd_{\max})}\right)^t.$$

To ensure $\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \epsilon$, we only need a large enough t to ensure that

$$\left(1 - \frac{\mu L^\mu_{\min}}{\mu L^\mu_{\min} + 16L^2\log^2(3pd_{\max})}\right)^t [\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)] \leq \epsilon. \tag{19}$$

We complete the proof by combining (19) and the basic inequality $\kappa \geq \log^{-1}\left(\frac{\kappa}{\kappa-1}\right)$. ■

As can be seen in Theorem 3, the iteration complexity depends on p only in the order of $\log^2(p)$, which is generally mild in practice. The iteration complexity of the CBCM method can be established in a similar manner.

Theorem 4 *Suppose that Assumptions 1 and 2 hold with $d \geq 2$. Given a pre-specified accuracy ϵ, we need at most*

$$\left\lceil \frac{\mu\mu_{\min} + 64L^2\log^2(3pd_{\max})}{\mu\mu_{\min}} \log\left(\frac{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)}{\epsilon}\right)\right\rceil$$

iterations for the CBCM method such that $\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \epsilon$

Proof The overall proof also consists of three major steps: (i) successive descent, (ii) gap towards the optimal objective value, and (iii) iteration complexity.

Successive Descent: At t-th iteration, there exists a $\xi_j^{(t+1)} \in \partial\mathcal{R}_j(x_j^{(t+1)})$ satisfying the optimality condition:

$$\nabla_j\mathcal{L}(y^{(t+1,j+1)}) + \xi_j^{(t+1)} = 0. \tag{20}$$

Then we have

$$\begin{aligned}
&\mathcal{F}(y^{(t+1,j)}) - \mathcal{F}(y^{(t+1,j+1)}) \overset{\text{(i)}}{\geq} (x_j^{(t)} - x_j^{(t+1)})^\top \nabla_j\mathcal{L}(y^{(t+1,j+1)}) + \mathcal{R}_j(x_j^{(t)}) - \mathcal{R}_j(x_j^{(t+1)}) \\
&\overset{\text{(ii)}}{\geq} \left(\nabla_j\mathcal{L}(y^{(t+1,j+1)}) + \xi_j^{(t+1)}\right)^\top (x_j^{(t)} - x_j^{(t+1)}) + \frac{\mu_j}{2}\|x_j^{(t)} - x_j^{(t+1)}\|^2 \\
&\overset{\text{(iii)}}{=} \frac{\mu_j}{2}\|x_j^{(t)} - x_j^{(t+1)}\|^2,
\end{aligned} \tag{21}$$

where (i) is from the convexity of $\mathcal{L}(\cdot)$, (ii) is from Assumptions 2, and (iii) is from (20). By summation of (12) over $j = 1, \ldots, p$, we have

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \geq \frac{\mu_{\min}}{2}\|x^{(t)} - x^{(t+1)}\|^2.$$

Gap towards the Optimal Objective Value: The proof follows the same arguments with the proof of Lemma 2, with a few differences.

First,with the optimality condition to the subproblem associated with x_j,

$$\langle \nabla_j\mathcal{L}(x^{(t)}) + \xi_j^{(t+1)}, x_j - x_j^{(t+1)}\rangle \geq 0 \text{ for any } x_j \in \mathbb{R}^m,$$

we have

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq (x^{(t+1)} - x^{(t)})^\top B(x^{(t+1)} - x^*) - \frac{\mu}{2}\|x^{(t+1)} - x^*\|^2,$$

where $B = \left(A^\top A - \widetilde{A}^\top\widetilde{A}\right) \odot D_d + \widetilde{A}^\top\widetilde{A}$.

Then, using the same technique to bound the eigenvalues for matrices with Hadamard product, we have

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq \frac{L^2\log^2(3d) + L_{\max}^2}{\mu}\|x^{(t+1)} - x^{(t)}\|^2 \leq \frac{2L^2\log^2(3d)}{\mu}\|x^{(t+1)} - x^{(t)}\|^2.$$

Iteration Complexity: The analysis follows from the counter part of Theorem 3. ■

Theorem 4 establishes that the iteration complexity of the CBCM method matches that of the CBCGD method. To the best of our knowledge, Theorems 3 and 4 are the sharpest iteration complexity analysis of the CBCD-type methods for minimizing (8). We further provide an example to establish the tightness of the above result in Appendix A.

3.2 General Smooth Minimization

We next consider general strongly convex smooth minimization, which includes Beck and Tetruashvili (2013) as a special case with $\mathcal{R}(x) = 0$. Here we require $\mathcal{R}(x)$ to be smooth and strongly convex.

Assumption 3 *$\mathcal{R}(\cdot)$ is smooth and also blockwise smooth, i.e., there exist positive constants β and β_j's such that for $x, x' \in \mathbb{R}^d$ and $j = 1, \ldots, p$, we have*

$$\mathcal{R}(x) \leq \mathcal{R}(x') + (x - x')^\top\nabla\mathcal{R}(x') + \frac{\beta}{2}\|x - x'\|^2 \text{ and}$$

$$\mathcal{R}_j(x_j) \leq \mathcal{R}_j(x_j') + (x_j - x_j')^\top\nabla_j\mathcal{R}(x') + \frac{\beta_j}{2}\|x_j - x_j'\|^2.$$

Moreover, we define $\beta_{\max} = \max_j \beta_j$.

Moreover, we assume that the Hessian matrix H of the objective function $\mathcal{F}$ exists, which is denoted as $H_{ij}(x) = \frac{\partial\mathcal{F}(x)}{\partial x_i \partial x_j}$.

Since the objective function is globally smooth, the CBCGD method can directly take the update form: For $j = 1, \ldots, p$,

$$x_j^{(t+1)} = x_j^{(t)} - \eta_j\left(\nabla_j\mathcal{L}(y^{(t+1,j+1)}) + \nabla\mathcal{R}_j(x_j^{(t)})\right),$$

where $\eta_j > 0$ is a step-size parameter for the j-th block.

Typical applications of the general strongly convex smooth minimization in statistical machine learning includes ridge penalized logistic regression, and ridge penalized multinomial regression. It is worth mentioning that our analysis for the general case is applicable to smooth quadratic minimization, but is very different from the analysis in previous sections for quadratic minimization.

We first characterize the successive descent after each coordinate gradient descent (CGD) iteration.

Lemma 5 *Suppose that Assumptions 1 and 3 hold. We choose $\eta_j = L_j + \beta_j$ for the CBCGD method. Then for all $t \geq 1$, there exists $\boldsymbol{z}^{(t,j)}$ in the line segment of $(x^{(t)}, y^{(t,j)})$ for each $j \in \{1, \ldots, p\}$ such that*

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \geq \frac{\|\nabla\mathcal{F}(x^{(t)})\|^2}{2\left(L_{\max}^\beta + \frac{\|H\|^2}{L_{\min}^\beta}\right)},$$

where H is defined as

$$H \triangleq \begin{bmatrix} 0 & 0 & 0 & \ldots & 0 & 0 \\ H_{21} & 0 & 0 & \ldots & 0 & 0 \\ H_{31} & H_{32} & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \ddots & \vdots \\ H_{p1} & H_{p2} & H_{p3} & \ldots & H_{p,p-1} & 0 \end{bmatrix}, \tag{22}$$

with $H_{ji} \triangleq H_{ji}(\boldsymbol{z}^{(t,j)}) = \frac{\partial\mathcal{F}(\boldsymbol{z}^{(t,j)})}{\partial z_j \partial z_i}$, and $L_{\min}^\beta$ and $L_{\max}^\beta$ are defined as

$$L_{\min}^\beta = \min\{L_j^\beta = L_j + \beta_j, j = 1, \ldots, p\} \quad \text{and} \quad L_{\max}^\beta = \max\{L_j^\beta = L_j + \beta_j, j = 1, \ldots, p\}.$$

Proof We first provide a lower bound of the successive descent using the gradient of $\mathcal{F}(\cdot)$ based on the Lipschitz continuity of $\nabla\mathcal{F}(\cdot)$. We have that $y^{(t,j)}$ and $y^{(t,k+1)}$ only differ at the k-th coordinate, and $\nabla_j\mathcal{F}(y^{t,k})$ has Lipschitz gradient with Lipschitz constant F_j, which implied

$$\begin{aligned}\mathcal{F}(y^{(t,j+1)}) &\leq \mathcal{F}(y^{(t,j)}) + (y^{(t,j+1)} - y^{(t,j)})^\top \nabla_j \mathcal{F}(y^{(t,j)}) + \frac{F_j}{2}\|y^{(t,j+1)} - y^{(t,j)}\|^2 \\ &\overset{\text{(i)}}{=} \mathcal{F}(y^{(t,j)}) - \frac{2L_j^\beta - F_j}{2(L_j^\beta)^2}\|\nabla_j \mathcal{F}(y^{(t,j)})\|^2 \overset{\text{(ii)}}{\leq} \mathcal{F}(y^{(t,j)}) - \frac{1}{2L_j^\beta}\|\nabla_j \mathcal{F}(y^{(t,j)})\|^2,\end{aligned}$$

where (i) is from that $x_j^{(t+1)} = x_j^{(t)} - \frac{\nabla_j \mathcal{F}(y^{(t,j)})}{L_j^\beta}$, and (ii) is from the fact that $L_j^\beta \geq F_j$. Then the decrease of the objective is

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) = \sum_{k=1}^p \mathcal{F}(y^{(t,j)}) - \mathcal{F}(y^{(t,j+1)}) \geq \sum_{k=1}^p \frac{1}{2L_j^\beta}\|\nabla_j \mathcal{F}(y^{(t,j)})\|^2. \tag{23}$$

For simplicity, we assume that $d_1 = ... = d_p = m = d/p$. By the Mean Value Theorem, there exists $\boldsymbol{z}^{(t,j)}$ such that

$$\begin{aligned}&\nabla_j \mathcal{F}(x^{(t)}) = \nabla_j \mathcal{F}(x^{(t)}) - \nabla_j \mathcal{F}(y^{(t,j)}) + \nabla_j \mathcal{F}(y^{(t,j)}) \\ &\overset{\text{(i)}}{=} \nabla(\nabla_j \mathcal{F}(\boldsymbol{z}^{(t,j)}))^\top (x^{(t)} - y^{(t,j)}) + \nabla_j \mathcal{F}(y^{(t,j)}) \\ &= \left[\tfrac{\partial \mathcal{F}(\boldsymbol{z}^{(t,j)})}{\partial z_j \partial z_1}, \ldots, \tfrac{\partial \mathcal{F}(\boldsymbol{z}^{(t,j)})}{\partial z_j \partial z_{j-1}}, 0, \ldots, 0\right] \left[\tfrac{\left(x_1^{(t)} - x_1^{(t+1)}\right)^\top}{L_1^\beta}, \ldots, \tfrac{\left(x_{j-1}^{(t)} - x_{j-1}^{(t+1)}\right)^\top}{L_{j-1}^\beta}, 0, \ldots, 0\right]^\top + \nabla_j \mathcal{F}(y^{(t,j)}) \\ &= \left[\tfrac{H_{j1}}{\sqrt{L_1^\beta}}, \ldots, \tfrac{H_{j,j-1}}{\sqrt{L_{j-1}^\beta}}, 0, \ldots, 0\right] \left[\tfrac{\left(x_1^{(t)} - x_1^{(t+1)}\right)^\top}{\sqrt{L_1^\beta}}, \ldots, \tfrac{\left(x_{j-1}^{(t)} - x_{j-1}^{(t+1)}\right)^\top}{\sqrt{L_{j-1}^\beta}}, 0, \ldots, 0\right]^\top + \nabla_j \mathcal{F}(y^{(t,j)}) \\ &= \left[\tfrac{H_{j1}}{\sqrt{L_1^\beta}}, \ldots, \tfrac{H_{j,j-1}}{\sqrt{L_{j-1}^\beta}}, \sqrt{L_j^\beta} \cdot I_m, 0, \ldots, 0\right] \left[\tfrac{\nabla_1 \mathcal{F}(y^{(t,1)})^\top}{\sqrt{L_1^\beta}}, \ldots, \tfrac{\nabla_p \mathcal{F}(y^{(t,p)})^\top}{\sqrt{L_p^\beta}}\right]^\top = h_j^\top f\end{aligned}$$

where (i) is from the mean-value theorem, $h_j = \left[\frac{H_{j1}}{\sqrt{L_1^\beta}}, \ldots, \frac{H_{j,j-1}}{\sqrt{L_{j-1}^\beta}}, \sqrt{L_j^\beta} \cdot I_m, 0, \ldots, 0\right]^\top$ and $f = \left[\frac{\nabla_1 \mathcal{F}(y^{(t,1)})^\top}{\sqrt{L_1^\beta}}, \ldots, \frac{\nabla_p \mathcal{F}(y^{(t,p)})^\top}{\sqrt{L_p^\beta}}\right]^\top$. Let $\widetilde{H}$ be

$$\widetilde{H} = \begin{bmatrix} h_1^\top \\ \vdots \\ h_p^\top \end{bmatrix} = \begin{bmatrix} \sqrt{L_1^\beta} \cdot I_m & 0 & 0 & \ldots & 0 & 0 \\ \frac{H_{21}(\boldsymbol{z}^{(t,2)})}{\sqrt{L_1^\beta}} & \sqrt{L_2^\beta} \cdot I_m & 0 & \ldots & 0 & 0 \\ \frac{H_{31}(\boldsymbol{z}^{(t,3)})}{\sqrt{L_1^\beta}} & \frac{H_{32}(\boldsymbol{z}^{(t,3)})}{\sqrt{L_2^\beta}} & \sqrt{L_3^\beta} \cdot I_m & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \ddots & \vdots \\ \frac{H_{p1}(\boldsymbol{z}^{(t,p)})}{\sqrt{L_1^\beta}} & \frac{H_{p2}(\boldsymbol{z}^{(t,p)})}{\sqrt{L_2^\beta}} & \frac{H_{p3}(\boldsymbol{z}^{(t,p)})}{\sqrt{L_3^\beta}} & \ldots & \frac{H_{p,p-1}(\boldsymbol{z}^{(t,p)})}{\sqrt{L_{p-1}^\beta}} & \sqrt{L_p^\beta} \cdot I_m \end{bmatrix}$$

Then we have

$$\begin{aligned}\|\nabla\mathcal{F}(x^{(t)})\|^2 &= \sum_{j=1}^p \|\nabla_j \mathcal{F}(x^{(t)})\|^2 = \sum_{j=1}^p \|h_j^\top f\|^2 = \|\widetilde{H}f\|^2 \\ &\leq \|\widetilde{H}\|^2\|f\|^2 = \|\widetilde{H}\|^2 \sum_{k=1}^p \frac{1}{2L_j^\beta}\|\nabla_j \mathcal{F}(y^{(t,j)})\|^2.\end{aligned} \tag{24}$$

Let $\widetilde{P}$ be defined as in the proof of Lemma 2. Then we have

$$\|\widetilde{H}\|^2 = \|\widetilde{P}^{1/2} + H\widetilde{P}^{-1/2}\|^2 \leq 2\left(\|\widetilde{P}^{1/2}\|^2 + \|H\widetilde{P}^{-1/2}\|^2\right) \leq 2\left(L_{\max}^\beta + \frac{\|H\|^2}{L_{\min}^\beta}\right), \tag{25}$$

Combining (23), (24) and (25), we have

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \geq \sum_{k=1}^p \frac{1}{2L_j^\beta}\|\nabla_j \mathcal{F}(y^{(t,j)})\|^2 \geq \frac{\|\nabla\mathcal{F}(x^{(t)})\|^2}{\|\widetilde{H}\|^2} \geq \frac{\|\nabla\mathcal{F}(x^{(t)})\|^2}{2\left(L_{\max}^\beta + \frac{\|H\|^2}{L_{\min}^\beta}\right)}.$$

■

We now characterize the gap towards the optimal objective after each CGD iteration.

Lemma 6 *Suppose that Assumptions 1 and 2 hold. Then, for all $t \geq 1$, we have*

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \frac{\|\nabla\mathcal{F}(x^{(t)})\|^2}{2\mu}.$$

Proof From the convexity of $\mathcal{L}(\cdot)$ and strong convexity of $\mathcal{R}(\cdot)$, we have

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq (x^{(t)} - x^*)^\top \nabla\mathcal{F}(x^{(t)}) - \frac{\mu}{2}\|x^{(t)} - x^*\|^2.$$

Minimizing the right hand side over x^*, we have $x^* = x^{(t)} - \frac{\nabla\mathcal{F}(x^{(t)})}{\mu}$ and the desired result. ■

Combining the two lemmas above, we establish the iteration complexity bound of CGD.

Theorem 7 *Suppose that Assumption 1, 2 and 3 hold. We choose $\eta_j = L_j + \beta_j$. Then, given a pre-specified accuracy ϵ, we need at most*

$$\left\lceil \frac{L_{\max}^\beta + \frac{pL^\beta L_{\max}^\beta}{L_{\min}^\beta}}{\mu} \log\left(\frac{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)}{\epsilon}\right) \right\rceil$$

iterations such that $\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \epsilon$, where $L^\beta = L + \beta$.

Proof We first bound $\|H\|$. Since $\mathcal{F}$ is convex, we have that $\nabla^2\mathcal{F}$ is positive semi-definite (PSD). This implies that there exists a matrix A such that $\nabla^2\mathcal{F} = AA^\top$, where A can be written as

$$A = \left[A_{1*}^\top, \ldots, A_{p*}^\top\right]^\top$$

and A_{i*} is the i-th row submatrix of A with $\|A_{i*}\| \leq \sqrt{L_i^\beta}$ and $\|A\| \leq \sqrt{L^\beta}$. Then we have

$$\begin{aligned}\|H\|^2 = \|H^\top H\| &\overset{\text{(i)}}{\leq} \sum_{i=1}^p \|(H^\top H)_{ii}\| = \sum_{i=1}^p \|H_{*i}\|^2 \leq \sum_{i=1}^p \|\nabla^2_{*i}\mathcal{F}\|^2 = \sum_{i=1}^p \|A_{i*}A\|^2 \\ &\leq \sum_{j=1}^p \|A_{*i}\|^2\|A\|^2 \leq pL^\beta L_i^\beta \leq pL^\beta L_{\max}^\beta, \end{aligned} \tag{26}$$

where (i) is from the norm compression inequality for block partitioned PSD matrix Horn and Johnson (2012) (Section 3.5). Thus we only need to combine Lemmas 5 and 6, and complete the proof by following similar lines to the proof of Theorem 3. ■

As can be seen from Theorem 7, the established iteration complexity bound is sharper than that in Beck and Tetruashvili (2013) by a factor of $L^\beta/L_{\min}^\beta$, which is at least of order $\sqrt{p}$ in generic settings and can be $\gg \sqrt{p}$ for ill-conditioned problems.

3.3 General Nonsmooth Minimization

We provide an iteration complexity bound of the CBCM and CBCGD methods for a general $\mathcal{L}(\cdot)$ and a nonsmooth $\mathcal{R}(\cdot)$.

Theorem 8 *Suppose that Assumptions 1 and 2 hold. We choose $\eta_j = L_j$ for the CBCGD method. Then given a pre-specified accuracy ϵ of the objective value, we need at most*

$$\left\lceil \frac{\mu L_{\min}^\mu + 4pL\cdot L_{\max}}{\mu L_{\min}^\mu} \log\left(\frac{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)}{\epsilon}\right)\right\rceil$$

iterations for the CBCGD method and at most

$$\left\lceil \frac{\mu\mu_{\min} + pL\cdot L_{\max}}{\mu\mu_{\min}} \log\left(\frac{\mathcal{F}(x^{(0)}) - \mathcal{F}(x^*)}{\epsilon}\right)\right\rceil$$

iterations for the CBCM method to guarantee $\mathcal{F}(x^{(t)}) - \mathcal{F}(x^*) \leq \epsilon$.

Proof The three major steps are as follows.

Successive Descent: For CBCGD, using the same analysis of Lemma 1, we have that for all $t \geq 1$,

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \geq \frac{L_{\min}^\mu}{2}\|x^{(t)} - x^{(t+1)}\|^2.$$

For CBCM, using the same analysis of Theorem 4, we have that for all $t \geq 1$,

$$\mathcal{F}(x^{(t)}) - \mathcal{F}(x^{(t+1)}) \geq \frac{\mu_{\min}}{2}\|x^{(t)} - x^{(t+1)}\|^2.$$

Gap towards the Optimal Objective Value: By the strong convexity of $\mathcal{R}(\cdot)$, we have

$$\mathcal{F}(x) - \mathcal{F}(x^{(t+1)}) \geq \frac{\mu}{2}\|x - x^{(t+1)}\|^2 + (x - x^{(t+1)})^\top(\nabla\mathcal{L}(x^{(t+1)}) + \xi^{(t+1)}), \tag{27}$$

where $\xi_j^{(t+1)} \in \partial\mathcal{R}_j(x_j^{(t+1)})$. We then minimize both sides of (27) with respect to x and obtain

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq \frac{\|\nabla\mathcal{L}(x^{(t+1)}) + \xi^{(t+1)}\|^2}{2\mu}, \tag{28}$$

For CBCGD, we have

$$\begin{aligned}&\|\nabla\mathcal{L}(x^{(t+1)}) + \xi^{(t+1)}\|^2 \overset{\text{(i)}}{\leq} \sum_{j=1}^p \|\nabla_j\mathcal{L}(x^{(t+1)}) - \nabla_j\mathcal{L}(y^{(t+1,j+1)}) - L_j(x_j^{(t+1)} - x_j^{(t)})\|^2 \\ &\leq \sum_{j=1}^p 2\|\nabla_j\mathcal{L}(x^{(t+1)}) - \nabla_j\mathcal{L}(y^{(t+1,j+1)})\|^2 + 2L_j^2\|x_j^{(t+1)} - y_j^{(t+1,j)}\|^2 \\ &\overset{\text{(ii)}}{\leq} \sum_{j=1}^p 2\|\nabla(\nabla_j\mathcal{L}(z))\|\cdot\|(x^{(t+1)} - y^{(t+1,j+1)})\|^2 + 2L_j^2\|x_j^{(t+1)} - y_j^{(t+1,j)}\|^2 \\ &\overset{\text{(iii)}}{\leq} 4pL\cdot L_{\max}\|x^{(t+1)} - x^{(t)}\|^2, \end{aligned} \tag{29}$$

where (i) comes from the optimality condition

$$\nabla_j\mathcal{L}(y^{(t+1,j+1)}) + L_j(x_j^{(t+1)} - x_j^{(t)}) + \xi_j^{(t+1)} = 0,$$

(ii) is from the mean-value theorem and Cauchy-Schwarz inequality, and (iii) is from the same argument as in the proof of Theorem 7. Combining (28) and (29), we have

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq \frac{2pL\cdot L_{\max}\|x^{(t+1)} - x^{(t)}\|^2}{\mu}.$$

For CBCM, we have

$$\begin{aligned}\|\nabla\mathcal{L}(x^{(t+1)}) + \xi^{(t+1)}\|^2 &\overset{\text{(i)}}{\leq} \sum_{j=1}^p \|\nabla_j\mathcal{L}(x^{(t+1)}) - \nabla_j\mathcal{L}(y^{(t+1,j+1)})\|^2 \\ &\overset{\text{(ii)}}{\leq} pL\cdot L_{\max}\|x^{(t+1)} - x^{(t)}\|^2, \end{aligned} \tag{30}$$

where (i) comes from the optimality condition

$$\nabla_j\mathcal{L}(y^{(t+1,j+1)}) + \xi_j^{(t+1)} = 0$$

and (ii) is from the same argument as (29). Combining (28) and (30), we have

$$\mathcal{F}(x^{(t+1)}) - \mathcal{F}(x^*) \leq \frac{pL \cdot L_{\max}\|x^{(t+1)} - x^{(t)}\|^2}{2\mu}.$$

Iteration Complexity: The analysis follows from the counter part of Theorem 3. ■

Theorem 8 is a general result for the minimization of smooth loss function plus a non-smooth penalty function. In contrast, Beck and Tetruashvili (2013) only cover general smooth minimization. We also remark that the results of Theorem 7 and Theorem 8 are no better than their quadratic counterparts in Theorem 3 and Theorem 4 as $L \leq pL_{\max}$ in general.

3.4 Extensions to Nonstrongly Convex Minimization

For nonstrongly convex minimization, we only need to add a strongly convex perturbation to the objective function

$$\widehat{x} = \operatorname{argmin} \mathcal{F}(x) + \frac{\sigma}{2}\|x\|^2, \tag{31}$$

where $\sigma > 0$ is a perturbation parameter. Then, the results above can be used to analyze the CBCD-type methods for minimizing (31). Eventually, by setting σ as a reasonable small value, we can establish $\mathcal{O}(1/\epsilon)$-type iteration complexity bounds up to a $\log(1/\epsilon)$ factor. See Shalev-Shwartz and Zhang (2014) for more details.

4. Numerical Results

We consider two typical statistical machine learning problems as examples to illustrate our analysis.

(I) Elastic-net Penalized Linear Regression: Let $A \in \mathbb{R}^{n\times d}$ be the design matrix, and $b \in \mathbb{R}^n$ be the response vector. We solve the following optimization problem

$$\min_{x\in\mathbb{R}^d} \quad \frac{1}{2n}\|b - Ax\|^2 + \lambda_1\|x\|^2 + \lambda_2\|x\|_1,$$

where λ is the regularization parameter. We set n = 10,000 and d = 20,000. We simply treat each coordinate as a block (i.e., $d_{\max} = 1$). Each row of A is independently sampled from a 20,000-dimensional Gaussian distribution with mean 0 and covariance matrix Σ. We randomly select 2,000 entries of x, each of which is independently sampled from a uniform distribution over support $(-2, +2)$. The response vector b is generated by the linear model $b = Ax + \epsilon$, where ϵ is sampled from an n-variate Gaussian distribution $N(0, I_n)$. We set $\lambda_1 = \sqrt{\log 1/n}$ and $\lambda_2 = \sqrt{\log d/n} \approx 0.0315$. We normalize A to have $\|A_{*j}\| = \sqrt{n}$ for $j = 1, .., d$, where A_{*j} denotes the j-th column of A. For the BCGD method, we choose $\eta_j = 1$. For the gradient descent method, we either choose $\eta = \lambda_{\max}\left(\frac{1}{n}A^\top A\right)$, or adaptively select η by backtracking line search.

(II) Ridge Penalized Logistic Regression: We solve the following optimization problem

$$\min_{x\in\mathbb{R}^d} \quad \frac{1}{n}\sum_{i=1}^{n}\left[\log(1+\exp(x^\top A_{i*})) - b_i x^\top A_{i*}\right] + \lambda\|x\|^2.$$

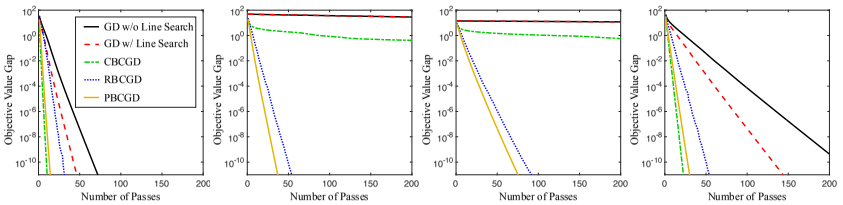
We generate the design matrix A and regression coefficient vector x using the same scheme as sparse linear regression. Again we treat each coordinate as a block (i.e., $d_{\max} = 1$). The response $b = [b_1, ..., b_n]^\top$ is generated by the logistic model $b_i = \text{Bernoulli}([1 + \exp(-x^\top A_{*i})]^{-1})$. We set $\lambda = \sqrt{1/n}$. For the BCGD method, we choose $\eta_j = \frac{1}{4}$. For gradient descent methods, we choose either the step size $\eta = \frac{1}{4}\lambda_{\max}\left(\frac{1}{n}A^\top A\right)$ or adaptively select η by backtracking line search.

We evaluate the computational performance using the number of passes over p blocks of coordinates (normalized iteration complexity). For the CBCGD method, we count one iteration as one pass (all p blocks). For the randomized BCGD (RBCGD) method, we count p iterations as one pass (since it only updates one block in each iteration). Besides the CBCGD and RBCGD methods, we also consider a variant of the CBCGD method named the permuted BCGD (PBCGD) method, which randomly permutes all indices for the p blocks in each iteration. Since the RBCGD and PBCGD methods are inherently stochastic, we report the objective values averaged over 20 different runs. Moreover, for the RBCGD method, the block of coordinates is selected uniformly at random in each iteration. We consider four different settings for both elastic-net penalized linear regression and ridge penalized logistic regression based on different choices of the covariance matrix Σ for generating the design matrix. We always choose $\Sigma_{jj} = 1$ for $j = 1, \ldots, d$, and for any $k \neq j$, we set (I) $\Sigma_{jk} = 0$; (II) $\Sigma_{jk} = 0.5$; (III) $\Sigma_{jk} = 0.75$; (IV) $\Sigma_{jk} = 0.5^{|j-k|}$. Note that the condition number of the Hessian matrix depends on Σ. Setting (I) and (IV) tend to yield well-conditioned Hessian matrices whereas Settings (II) and (III) tend to yield a badly conditioned Hessian matrix.

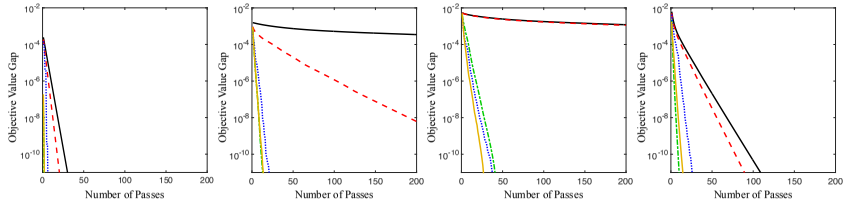
Figure 1 plots the gap between the objective value and the optimal as a function of number of passes for different methods. Our empirical findings can be summarized as follows: (1) All BCD-type methods attain better performance than the GD methods; (2) When the Hessian matrix is ill conditioned, i.e., in Setting (II) and (III), the CBCGD performs worse than the RBCGD and PBCGD methods, which suggests that there is a gap between cyclic and randomized BCGD. (3) When the Hessian matrix is well conditioned (e.g., in Settings (I) and (IV)), all three BCD-type methods attain good performance, and the CBCGD method slightly outperforms the PBCGD method; (4) The CBCGD method outperforms the RBCGD method in Setting (IV).

5. Discussions

Existing literature has established an iteration complexity of $\mathcal{O}(L\cdot\log(1/\epsilon)/\mu)$ for the gradient descent methods when solving strongly convex composite problems. However, our analysis shows that the CBCD-type methods only attains an iteration complexity of $\mathcal{O}(pLL_{\max}\cdot\log(1/\epsilon)/(L_{\min}\mu))$. Even though our analysis further shows that the iteration complexity of the CBCD-type methods can be further improved to $\mathcal{O}(\log^2(p)L^2\cdot\log(1/\epsilon)/(L_{\min}\mu))$ for a quadratic $\mathcal{L}(\cdot)$, there still exists a gap of factor $L\log^2 p/L_{\min}$. As our numerical experiments



(a) Enet (I) (b) Enet (II) (c) Enet (III) (d) Enet (IV)



(e) Logit (I) (f) Logit (II) (g) Logit (III) (h) Logit (IV)

Figure 1: Comparison among different methods under different settings. "RBCGD" and "PBCGD" denote the randomized BCD-type and permuted BCD-type methods respectively. The vertical axis corresponds to the gap towards the optimal objective value, $\log[\mathcal{F}(x) - \mathcal{F}(x^*)]$; the horizontal axis corresponds to the number of passes over p blocks of coordinates. Though all methods attain linear iteration complexity, their empirical behaviors are different from each others. Note that in plot (b) the curves for the CBCGD method and the RBCGD methods overlap.

show, however, the CBCD-type methods can actually attain a better computational performance than the gradient methods regardless of whether $\mathcal{L}(\cdot)$ is quadratic or not, thereby suggesting that perhaps there is still room for improvement in the iteration complexity analysis of the CBCD-type methods.

It is also worth mentioning that though some literature claims that the CBCD-type methods works as well as the randomized BCD-type methods in practice, there do exist some counter examples, e.g. our experiment in Setting (I), where the CBCD-type methods fail significantly. This suggests that the CBCD-type methods do have some possible disadvantages in practice. To the best of our knowledge, we are not aware of any similar experimental results reported in existing literature.

Furthermore, our numerical results show that the permuted BCD-type methods, which can be viewed as a hybrid of the cyclic and the randomized BCD-type (RBCD-type) methods, has a stable performance irrespective of the problem being well conditioned or not. But to the best of our knowledge, no iteration complexity result has been established for the permuted BCD-type (PBCD-type) methods. We leave these problems for future investigation.

Appendix A. The Tightness of the Iteration Complexity for Quadratic Problems

We next provide an example to establish the tightness of the above result. We consider the following optimization problem

$$\min_x \mathcal{H}(x) := \|Bx\|^2, \tag{32}$$

where $B \in \mathbb{R}^{p\times p}$ is a tridiagonal Toplitz matrix defined as follows:

$$B = \begin{bmatrix} 3 & 1 & 0 & 0 & \dots & 0 & 0 & 0 \\ 1 & 3 & 1 & 0 & \dots & 0 & 0 & 0 \\ 0 & 1 & 3 & 1 & \dots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & 1 & 3 & 1 \\ 0 & 0 & 0 & 0 & \dots & 0 & 1 & 3 \end{bmatrix}.$$

Note that the minimizer to (32) is $x^* = [0, 0, \dots, 0]^\top$, and the eigenvalues of B are given by $3 + 2\cos(j\pi/(j+1))$ for $j = 1, \dots, p$. Since the Hessian matrix of (32) is $2B^\top B$, we have

$$L = \lambda_{\max}(2B^\top B) \le 50, \mu = \lambda_{\min}(2B^\top B) \ge 2, \mu_{\min} = 10.$$

Clearly, for this problem the largest and smallest eigenvalues of the Hessian matrix, as well as L/γ do not scale with p. We consider each coordinate $x_j \in \mathbb{R}$ as a block. Then the problem can be rewritten as $\min \|\sum_{j=1}^p B_{*j}x_j\|$, where B_{*j} denotes the j-th column of B. Given an initial solution $x^{(0)}$, we can show that $x^{(1)}$ is generated by

$$\begin{cases} x_1^{(1)} &= -\frac{1}{4}\left(4x_2^{(0)} + x_3^{(0)}\right), \\ x_2^{(1)} &= -\frac{1}{5}\left(4x_1^{(1)} + 4x_3^{(0)} + x_4^{(0)}\right) \\ x_3^{(1)} &= -\frac{1}{5}\left(x_1^{(1)} + 4x_2^{(1)} + x_4^{(0)} + x_5^{(0)}\right), \\ x_j^{(1)} &= -\frac{1}{5}\left(x_{j-2}^{(1)} + 4x_{j-1}^{(1)} + x_{j+1}^{(0)} + x_{j+2}^{(0)}\right), \\ x_{p-1}^{(1)} &= -\frac{1}{5}\left(x_{p-3}^{(1)} + 4x_{p-2}^{(0)} + 4x_p^{(0)}\right), \\ x_p^{(1)} &= -\frac{1}{4}\left(x_{p-2}^{(1)} + 4x_{p-1}^{(1)}\right). \end{cases} \tag{33}$$

Now we choose the initial solution

$$x^{(0)} = \left[1, \frac{9}{32}, \frac{7}{8}, 1, \dots, 1, 1\right]^\top.$$

Then by (33), we obtain

$$x^{(1)} = \left[-\frac{1}{2}, -\frac{1}{2}, \ldots, -\frac{1}{2}, -\frac{3}{10}, -\frac{17}{40}\right]^\top,$$

which yields

$$\mathcal{H}(x^{(1)}) - \mathcal{H}(x^*) \geq \frac{25}{4}(p-3),$$
$$\|x^{(0)} - x^*\|^2 \leq p - 2 + \left(\frac{9}{32}\right)^2 + \left(\frac{7}{8}\right)^2 \leq p - 1.$$

Therefore, we have

$$\frac{\mathcal{H}(x^{(1)}) - \mathcal{H}(x^*)}{\|x^{(0)} - x^*\|^2} \geq \frac{25(p-3)}{4p} \geq \frac{22}{4}.$$

This implies that when the largest and smallest eigenvalues of the Hessian matrix do not scale with p (the number of blocks), the iteration complexity is independent of p, and cannot be further improved. Though the independence of p is only shown for the first iteration, we have similar claims in the subsequent iterations. We omit the detailed derivation due the heavy algebraic calculation.

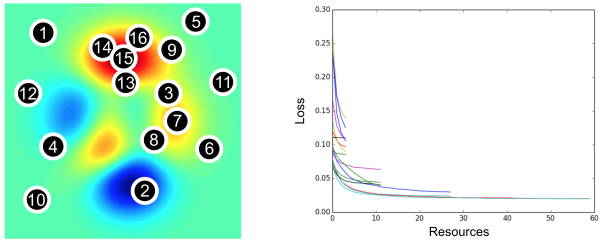
Abstract

Performance of machine learning algorithms depends critically on identifying a good set of hyperparameters. While recent approaches use Bayesian optimization to adaptively select configurations, we focus on speeding up random search through adaptive resource allocation and early-stopping. We formulate hyperparameter optimization as a pure-exploration non-stochastic infinite-armed bandit problem where a predefined resource like iterations, data samples, or features is allocated to randomly sampled configurations. We introduce a novel algorithm, HYPERBAND, for this framework and analyze its theoretical properties, providing several desirable guarantees. Furthermore, we compare HYPERBAND with popular Bayesian optimization methods on a suite of hyperparameter optimization problems. We observe that HYPERBAND can provide over an order-of-magnitude speedup over our competitor set on a variety of deep-learning and kernel-based learning problems.

Keywords: hyperparameter optimization, model selection, infinite-armed bandits, online optimization, deep learning

1. Introduction

In recent years, machine learning models have exploded in complexity and expressibility at the price of staggering computational costs. Moreover, the growing number of tuning parameters associated with these models are difficult to set by standard optimization techniques. These "hyperparameters" are inputs to a machine learning algorithm that govern how the algorithm's performance generalizes to new, unseen data; examples of hyperparameters include those that impact model architecture, amount of regularization, and learning rates. The quality of a predictive model critically depends on its hyperparameter configuration, but it is poorly understood how these hyperparameters interact with each other to affect the resulting model.



(a) Configuration Selection (b) Configuration Evaluation

Figure 1: (a) The heatmap shows the validation error over a two-dimensional search space with red corresponding to areas with lower validation error. Configuration selection methods adaptively choose new configurations to train, proceeding in a sequential manner as indicated by the numbers. (b) The plot shows the validation error as a function of the resources allocated to each configuration (i.e. each line in the plot). Configuration evaluation methods allocate more resources to promising configurations.

Consequently, practitioners often default to brute-force methods like random search and grid search (Bergstra and Bengio, 2012).

In an effort to develop more efficient search methods, the problem of hyperparameter optimization has recently been dominated by *Bayesian optimization* methods (Snoek et al., 2012; Hutter et al., 2011; Bergstra et al., 2011) that focus on optimizing hyperparameter *configuration selection*. These methods aim to identify good configurations more quickly than standard baselines like random search by selecting configurations in an adaptive manner; see Figure 1(a). Existing empirical evidence suggests that these methods outperform random search (Thornton et al., 2013; Eggensperger et al., 2013; Snoek et al., 2015b). However, these methods tackle the fundamentally challenging problem of simultaneously fitting and optimizing a high-dimensional, non-convex function with unknown smoothness, and possibly noisy evaluations.

An orthogonal approach to hyperparameter optimization focuses on speeding up *configuration evaluation*; see Figure 1(b). These approaches are adaptive in computation, allocating more resources to promising hyperparameter configurations while quickly eliminating poor ones. Resources can take various forms, including size of training set, number of features, or number of iterations for iterative algorithms. By adaptively allocating resources, these approaches aim to examine orders-of-magnitude more hyperparameter configurations than approaches that uniformly train all configurations to completion, thereby quickly identifying good hyperparameters. While there are methods that combine Bayesian optimization with adaptive resource allocation (Swersky et al., 2013, 2014; Domhan et al., 2015; Klein et al.,

2017a), we focus on speeding up random search as it offers a simple and theoretically principled launching point (Bergstra and Bengio, 2012).[1]

We develop a novel configuration evaluation approach by formulating hyperparameter optimization as a pure-exploration adaptive resource allocation problem addressing how to allocate resources among randomly sampled hyperparameter configurations.[2] Our procedure, Hyperband, relies on a principled early-stopping strategy to allocate resources, allowing it to evaluate orders-of-magnitude more configurations than black-box procedures like Bayesian optimization methods. Hyperband is a general-purpose technique that makes minimal assumptions unlike prior configuration evaluation approaches (Domhan et al., 2015; Swersky et al., 2014; György and Kocsis, 2011; Agarwal et al., 2011; Sparks et al., 2015; Jamieson and Talwalkar, 2015).

Our theoretical analysis demonstrates the ability of Hyperband to adapt to unknown convergence rates and to the behavior of validation losses as a function of the hyperparameters. In addition, Hyperband is 5× to 30× faster than popular Bayesian optimization algorithms on a variety of deep-learning and kernel-based learning problems. A theoretical contribution of this work is the introduction of the pure-exploration, infinite-armed bandit problem in the non-stochastic setting, for which Hyperband is one solution. When Hyperband is applied to the special-case stochastic setting, we show that the algorithm comes within log factors of known lower bounds in both the infinite (Carpentier and Valko, 2015) and finite K-armed bandit settings (Kaufmann et al., 2015).

The paper is organized as follows. Section 2 summarizes related work in two areas: (1) hyperparameter optimization, and (2) pure-exploration bandit problems. Section 3 describes Hyperband and provides intuition for the algorithm through a detailed example. In Section 4, we present a wide range of empirical results comparing Hyperband with state-of-the-art competitors. Section 5 frames the hyperparameter optimization problem as an infinite-armed bandit problem and summarizes the theoretical results for Hyperband. Finally, Section 6 discusses possible extensions of Hyperband.

2. Related Work

In Section 1, we briefly discussed related work in the hyperparameter optimization literature. Here, we provide a more thorough coverage of the prior work, and also summarize significant related work on bandit problems.

2.1 Hyperparameter Optimization

Bayesian optimization techniques model the conditional probability $p(y|\lambda)$ of a configuration's performance on an evaluation metric y (i.e., test accuracy), given a set of hyperparameters λ.

1. Random search will asymptotically converge to the optimal configuration, regardless of the smoothness or structure of the function being optimized, by a simple covering argument. While the rate of convergence for random search depends on the smoothness and is exponential in the number of dimensions in the search space, the same is true for Bayesian optimization methods without additional structural assumptions (Kandasamy et al., 2015).
2. A preliminary version of this work appeared in Li et al. (2017). We extend the previous paper with a thorough theoretical analysis of Hyperband; an infinite horizon version of the algorithm with application to stochastic infinite-armed bandits; additional intuition and discussion of Hyperband to facilitate its use in practice; and additional results on a collection of 117 multistage model selection tasks.

Sequential Model-based Algorithm Configuration (SMAC), Tree-structure Parzen Estimator (TPE), and Spearmint are three well-established methods (Feurer et al., 2014). SMAC uses random forests to model $p(y|\lambda)$ as a Gaussian distribution (Hutter et al., 2011). TPE is a non-standard Bayesian optimization algorithm based on tree-structured Parzen density estimators (Bergstra et al., 2011). Lastly, Spearmint uses Gaussian processes (GP) to model $p(y|\lambda)$ and performs slice sampling over the GP's hyperparameters (Snoek et al., 2012).

Previous work compared the relative performance of these Bayesian searchers (Thornton et al., 2013; Eggensperger et al., 2013; Bergstra et al., 2011; Snoek et al., 2012; Feurer et al., 2014, 2015). An extensive survey of these three methods by Eggensperger et al. (2013) introduced a benchmark library for hyperparameter optimization called HPOlib, which we use for our experiments. Bergstra et al. (2011) and Thornton et al. (2013) showed Bayesian optimization methods empirically outperform random search on a few benchmark tasks. However, for high-dimensional problems, standard Bayesian optimization methods perform similarly to random search (Wang et al., 2013). Recent methods specifically designed for high-dimensional problems assume a lower effective dimension for the problem (Wang et al., 2013) or an additive decomposition for the target function (Kandasamy et al., 2015). However, as can be expected, the performance of these methods is sensitive to required inputs; i.e. the effective dimension (Wang et al., 2013) or the number of additive components (Kandasamy et al., 2015).

Gaussian processes have also been studied in the bandit setting using confidence bound acquisition functions (GP-UCB), with associated sublinear regret bounds (Srinivas et al., 2010; Grünewälder et al., 2010). Wang et al. (2016) improved upon GP-UCB by removing the need to tune a parameter that controls exploration and exploitation. Contal et al. (2014) derived a tighter regret bound than that for GP-UCB by using a mutual information acquisition function. However, van der Vaart and van Zanten (2011) showed that the learning rate of GPs are sensitive to the definition of the prior through an example with a poor prior where the learning rate degraded from polynomial to logarithmic in the number of observations n. Additionally, without structural assumptions on the covariance matrix of the GP, fitting the posterior is $O(n^3)$ (Wilson et al., 2015). Hence, Snoek et al. (2015a) and Springenberg et al. (2016) proposed using Bayesian neural networks, which scale linearly with n, to model the posterior.

Adaptive configuration evaluation is not a new idea. Maron and Moore (1997) and Mnih and Audibert (2008) considered a setting where the training time is relatively inexpensive (e.g., k-nearest-neighbor classification) and evaluation on a large validation set is accelerated by evaluating on an increasing subset of the validation set, stopping early configurations that are performing poorly. Since subsets of the validation set provide unbiased estimates of its expected performance, this is an instance of the *stochastic* best-arm identification problem for multi-armed bandits (see the work by Jamieson and Nowak, 2014, for a brief survey).

In contrast, we address a setting where the evaluation time is relatively inexpensive and the goal is to early-stop long-running training procedures by evaluating partially trained models on the full validation set. Previous approaches in this setting either require strong assumptions or use heuristics to perform adaptive resource allocation. György and Kocsis (2011) and Agarwal et al. (2011) made parametric assumptions on the convergence behavior of training algorithms, providing theoretical performance guarantees under these assumptions. Unfortunately, these assumptions are often hard to verify, and empirical performance can

drastically suffer when they are violated. Krueger et al. (2015) proposed a heuristic based on sequential analysis to determine stopping times for training configurations on increasing subsets of the data. However, the theoretical correctness and empirical performance of this method are highly dependent on a user-defined "safety zone."

Several hybrid methods combining adaptive configuration selection and evaluation have also been introduced (Swersky et al., 2013, 2014; Domhan et al., 2015; Kandasamy et al., 2016; Klein et al., 2017a; Golovin et al., 2017). The algorithm proposed by Swersky et al. (2013) uses a GP to learn correlation between related tasks and requires the subtasks as input, but efficient subtasks with high informativeness for the target task are unknown without prior knowledge. Similar to the work by Swersky et al. (2013), Klein et al. (2017a) modeled the conditional validation error as a Gaussian process using a kernel that captures the covariance with downsampling rate to allow for adaptive evaluation. Swersky et al. (2014), Domhan et al. (2015), and Klein et al. (2017a) made parametric assumptions on the convergence of learning curves to perform early-stopping. In contrast, Golovin et al. (2017) devised an early-stopping rule based on predicted performance from a nonparametric GP model with a kernel designed to measure the similarity between performance curves. Finally, Kandasamy et al. (2016) extended GP-UCB to allow for adaptive configuration evaluation by defining subtasks that monotonically improve with more resources.

In another line of work, Sparks et al. (2015) proposed a halving style bandit algorithm that did not require explicit convergence behavior, and Jamieson and Talwalkar (2015) analyzed a similar algorithm originally proposed by Karnin et al. (2013) for a different setting, providing theoretical guarantees and encouraging empirical results. Unfortunately, these halving style algorithms suffer from the "n versus B/n" problem, which we will discuss in Section 3.1. Hyperband addresses this issue and provides a robust, theoretically principled early-stopping algorithm for hyperparameter optimization.

We note that Hyperband can be combined with any hyperparameter sampling approach and does not depend on random sampling; the theoretical results only assume the validation losses of sampled hyperparameter configurations are drawn from some stationary distribution. In fact, subsequent to our submission, Klein et al. (2017b) combined adaptive configuration selection with Hyperband by using a Bayesian neural network to model learning curves and only selecting configurations with high predicted performance to input into Hyperband.

2.2 Bandit Problems

Pure exploration bandit problems aim to minimize the simple regret, defined as the distance from the optimal solution, as quickly as possible in any given setting. The pure-exploration multi-armed bandit problem has a long history in the stochastic setting (Even-Dar et al., 2006; Bubeck et al., 2009), and was recently extended to the non-stochastic setting by Jamieson and Talwalkar (2015). Relatedly, the stochastic pure-exploration infinite-armed bandit problem was studied by Carpentier and Valko (2015), where a pull of each arm i yields an i.i.d. sample in $[0, 1]$ with expectation ν_i, where ν_i is a loss drawn from a distribution with cumulative distribution function, F. Of course, the value of ν_i is unknown to the player, so the only way to infer its value is to pull arm i many times. Carpentier and Valko (2015) proposed an anytime algorithm, and derived a tight (up to polylog factors) upper bound on its error assuming what we will refer to as the β-parameterization of F described in

Section 5.3.2. However, their algorithm was derived specifically for the β-parameterization of F, and furthermore, they must estimate β before running the algorithm, limiting the algorithm's practical applicability. Also, the algorithm assumes stochastic losses from the arms and thus the convergence behavior is known; consequently, it does not apply in our hyperparameter optimization setting.[3] Two related lines of work that both make use of an underlying metric space are Gaussian process optimization (Srinivas et al., 2010) and X-armed bandits (Bubeck et al., 2011), or bandits defined over a metric space. However, these works either assume stochastic rewards or need to know something about the underlying function (e.g. an appropriate kernel or level of smoothness).

In contrast, Hyperband is devised for the non-stochastic setting and automatically adapts to unknown F without making any parametric assumptions. Hence, we believe our work to be a generally applicable pure exploration algorithm for infinite-armed bandits. To the best of our knowledge, this is also the first work to test out such an algorithm on a real application.

3. Hyperband Algorithm

In this section, we present the Hyperband algorithm. We provide intuition for the algorithm, highlight the main ideas via a simple example that uses iterations as the adaptively allocated resource, and present a few guidelines on how to deploy Hyperband in practice.

3.1 Successive Halving

Hyperband extends the SuccessiveHalving algorithm proposed for hyperparameter optimization by Jamieson and Talwalkar (2015) and calls it as a subroutine. The idea behind the original SuccessiveHalving algorithm follows directly from its name: uniformly allocate a budget to a set of hyperparameter configurations, evaluate the performance of all configurations, throw out the worst half, and repeat until one configuration remains. The algorithm allocates exponentially more resources to more promising configurations. Unfortunately, SuccessiveHalving requires the number of configurations n as an input to the algorithm. Given some finite budget B (e.g., an hour of training time to choose a hyperparameter configuration), B/n resources are allocated on average across the configurations. However, for a fixed B, it is not clear a priori whether we should (a) consider many configurations (large n) with a small average training time; or (b) consider a small number of configurations (small n) with longer average training times.

We use a simple example to better understand this tradeoff. Figure 2 shows the validation loss as a function of total resources allocated for two configurations with terminal validation losses ν_1 and ν_2. The shaded areas bound the maximum deviation of the intermediate losses from the terminal validation loss and will be referred to as "envelope" functions.[4] It is possible to distinguish between the two configurations when the envelopes no longer overlap. Simple arithmetic shows that this happens when the width of the envelopes is less than $\nu_2 - \nu_1$, i.e., when the intermediate losses are guaranteed to be less than $\frac{\nu_2 - \nu_1}{2}$ away from the

3. See the work by Jamieson and Talwalkar (2015) for detailed discussion motivating the non-stochastic setting for hyperparameter optimization.
4. These envelope functions are guaranteed to exist; see discussion in Section 5.2 where we formally define these envelope (or γ) functions.

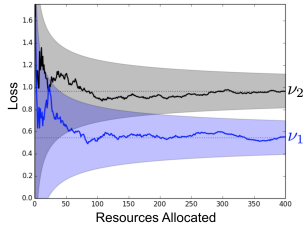


Figure 2: The validation loss as a function of total resources allocated for two configurations is shown. ν_1 and ν_2 represent the terminal validation losses at convergence. The shaded areas bound the maximum distance of the intermediate losses from the terminal validation loss and monotonically decrease with the resource.

terminal losses. There are two takeaways from this observation: more resources are needed to differentiate between the two configurations when either (1) the envelope functions are wider or (2) the terminal losses are closer together.

However, in practice, the optimal allocation strategy is unknown because we do not have knowledge of the envelope functions nor the distribution of terminal losses. Hence, if more resources are required before configurations can differentiate themselves in terms of quality (e.g., if an iterative training method converges very slowly for a given data set or if randomly selected hyperparameter configurations perform similarly well), then it would be reasonable to work with a small number of configurations. In contrast, if the quality of a configuration is typically revealed after a small number of resources (e.g., if iterative training methods converge very quickly for a given data set or if randomly selected hyperparameter configurations are of low-quality with high probability), then n is the bottleneck and we should choose n to be large.

Certainly, if meta-data or previous experience suggests that a certain tradeoff is likely to work well in practice, one should exploit that information and allocate the majority of resources to that tradeoff. However, without this supplementary information, practitioners are forced to make this tradeoff, severely hindering the applicability of existing configuration evaluation methods.

3.2 Hyperband

Hyperband, shown in Algorithm 1, addresses this "n versus B/n" problem by considering several possible values of n for a fixed B, in essence performing a grid search over feasible value of n. Associated with each value of n is a minimum resource r that is allocated to all configurations before some are discarded; a larger value of n corresponds to a smaller r and hence more aggressive early-stopping. There are two components to Hyperband; (1) the inner loop invokes SuccessiveHalving for fixed values of n and r (lines 3–9) and (2) the outer loop iterates over different values of n and r (lines 1–2). We will refer to each such run of SuccessiveHalving within Hyperband as a "bracket." Each bracket is designed to use approximately B total resources and corresponds to a different tradeoff between n

Algorithm 1: Hyperband algorithm for hyperparameter optimization.

input : R, η (default $\eta = 3$)
initialization : $s_{\max} = \lfloor \log_\eta(R) \rfloor$, $B = (s_{\max}+1)R$
1 **for** $s \in \{s_{\max}, s_{\max}-1, \ldots, 0\}$ **do**
2 $\quad n = \lceil \frac{B}{R}\frac{\eta^s}{(s+1)} \rceil$, $\quad r = R\eta^{-s}$
$\quad$ `// begin SuccessiveHalving with` (n, r) `inner loop`
3 $\quad T =$ `get_hyperparameter_configuration`(n)
4 $\quad$ **for** $i \in \{0, \ldots, s\}$ **do**
5 $\quad\quad n_i = \lfloor n\eta^{-i} \rfloor$
6 $\quad\quad r_i = r\eta^i$
7 $\quad\quad L = \{$`run_then_return_val_loss`$(t, r_i) : t \in T\}$
8 $\quad\quad T =$ `top_k`$(T, L, \lfloor n_i/\eta \rfloor)$
9 $\quad$ **end**
10 **end**
11 **return** *Configuration with the smallest intermediate loss seen so far.*

and B/n. Hence, a single execution of Hyperband takes a finite budget of $(s_{max}+1)B$; we recommend repeating it indefinitely.

Hyperband requires two inputs (1) R, the maximum amount of resource that can be allocated to a single configuration, and (2) η, an input that controls the proportion of configurations discarded in each round of SuccessiveHalving. The two inputs dictate how many different brackets are considered; specifically, $s_{\max}+1$ different values for n are considered with $s_{\max} = \lfloor \log_\eta(R) \rfloor$. Hyperband begins with the most aggressive bracket $s = s_{\max}$, which sets n to maximize exploration, subject to the constraint that at least one configuration is allocated R resources. Each subsequent bracket reduces n by a factor of approximately η until the final bracket, $s = 0$, in which every configuration is allocated R resources (this bracket simply performs classical random search). Hence, Hyperband performs a geometric search in the average budget per configuration and removes the need to select n for a fixed budget at the cost of approximately $s_{\max}+1$ times more work than running SuccessiveHalving for a single value of n. By doing so, Hyperband is able to exploit situations in which adaptive allocation works well, while protecting itself in situations where more conservative allocations are required.

Hyperband requires the following methods to be defined for any given learning problem:

- `get_hyperparameter_configuration`(n) – a function that returns a set of n i.i.d. samples from some distribution defined over the hyperparameter configuration space. In this work, we assume uniformly sampling of hyperparameters from a predefined space (i.e., hypercube with min and max bounds for each hyperparameter), which immediately yields consistency guarantees. However, the more aligned the distribution is towards high quality hyperparameters (i.e., a useful prior), the better Hyperband will perform (see Section 6 for further discussion).

	$s=4$		$s=3$		$s=2$		$s=1$		$s=0$	
i	n_i	r_i	n_i	r_i	n_i	r_i	n_i	r_i	n_i	r_i
0	81	1	27	3	9	9	6	27	5	81
1	27	3	9	9	3	27	2	81		
2	9	9	3	27	1	81				
3	3	27	1	81						
4	1	81								

Table 1: The values of n_i and r_i for the brackets of Hyperband corresponding to various values of s, when $R = 81$ and $\eta = 3$.

- `run_then_return_val_loss(t, r)` – a function that takes a hyperparameter configuration t and resource allocation r as input and returns the validation loss after training the configuration for the allocated resources.

- `top_k(configs, losses, k)` – a function that takes a set of configurations as well as their associated losses and returns the top k performing configurations.

3.3 Example Application with Iterations as a Resource: LeNet

We next present a concrete example to provide further intuition about Hyperband. We work with the MNIST data set and optimize hyperparameters for the LeNet convolutional neural network trained using mini-batch stochastic gradient descent (SGD).[5] Our search space includes learning rate, batch size, and number of kernels for the two layers of the network as hyperparameters (details are shown in Table 2 in Appendix A).

We define the resource allocated to each configuration to be number of iterations of SGD, with one unit of resource corresponding to one epoch, i.e., a full pass over the data set. We set R to 81 and use the default value of $\eta = 3$, resulting in $s_{\max} = 4$ and thus 5 brackets of SuccessiveHalving with different tradeoffs between n and B/n. The resources allocated within each bracket are displayed in Table 1.

Figure 3 shows an empirical comparison of the average test error across 70 trials of the individual brackets of Hyperband run separately as well as standard Hyperband. In practice, we do not know a priori which bracket $s \in \{0, \ldots, 4\}$ will be most effective in identifying good hyperparameters, and in this case neither the most ($s = 4$) nor least aggressive ($s = 0$) setting is optimal. However, we note that Hyperband does nearly as well as the optimal bracket ($s = 3$) and outperforms the baseline uniform allocation (i.e., random search), which is equivalent to bracket $s = 0$.

3.4 Different Types of Resources

While the previous example focused on iterations as the resource, Hyperband naturally generalizes to various types of resources:

5. Code and description of algorithm used is available at `http://deeplearning.net/tutorial/lenet.html`.

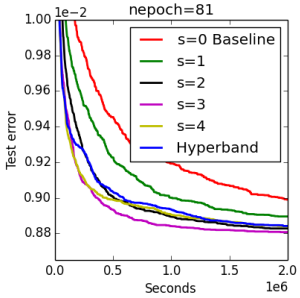

Figure 3: Performance of individual brackets s and Hyperband.

- **Time** – Early-stopping in terms of time can be preferred when various hyperparameter configurations differ in training time and the practitioner's chief goal is to find a good hyperparameter setting in a fixed wall-clock time. For instance, training time could be used as a resource to quickly terminate straggler jobs in distributed computation environments.

- **Data Set Subsampling** – Here we consider the setting of a black-box batch training algorithm that takes a data set as input and outputs a model. In this setting, we treat the resource as the size of a random subset of the data set with R corresponding to the full data set size. Subsampling data set sizes using Hyperband, especially for problems with super-linear training times like kernel methods, can provide substantial speedups.

- **Feature Subsampling** – Random features or Nyström-like methods are popular methods for approximating kernels for machine learning applications (Rahimi and Recht, 2007). In image processing, especially deep-learning applications, filters are usually sampled randomly, with the number of filters having an impact on the performance. Downsampling the number of features is a common tool used when hand-tuning hyperparameters; Hyperband can formalize this heuristic.

3.5 Setting R

The resource R and η (which we address next) are the only required inputs to Hyperband. As mentioned in Section 3.2, R represents the maximum amount of resources that can be allocated to any given configuration. In most cases, there is a natural upper bound on the maximum budget per configuration that is often dictated by the resource type (e.g., training set size for data set downsampling; limitations based on memory constraint for feature downsampling; rule of thumb regarding number of epochs when iteratively training neural networks). If there is a range of possible values for R, a smaller R will give a result faster (since the budget B for each bracket is a multiple of R), but a larger R will give a better guarantee of successfully differentiating between the configurations.

Moreover, for settings in which either R is unknown or not desired, we provide an infinite horizon version of Hyperband in Section 5. This version of the algorithm doubles

the budget over time, $B \in \{2, 4, 8, 16, \ldots\}$, and for each B, tries all possible values of $n \in \left\{2^k : k \in \{1, \ldots, \log_2(B)\}\right\}$. For each combination of B and n, the algorithm runs an instance of the (infinite horizon) SuccessiveHalving algorithm, which implicitly sets $R = \frac{B}{2\log_2(n)}$, thereby growing R as B increases. The main difference between the infinite horizon algorithm and Algorithm 1 is that the number of unique brackets grows over time instead of staying constant with each outer loop. We will analyze this version of Hyperband in more detail in Section 5 and use it as the launching point for the theoretical analysis of standard (finite horizon) Hyperband.

Note that R is also the number of configurations evaluated in the bracket that performs the most exploration, i.e $s = s_{\max}$. In practice one may want $n \leq n_{\max}$ to limit overhead associated with training many configurations on a small budget, i.e., costs associated with initialization, loading a model, and validation. In this case, set $s_{\max} = \lfloor \log_\eta(n_{\max}) \rfloor$. Alternatively, one can redefine one unit of resource so that R is artificially smaller (i.e., if the desired maximum iteration is 100k, defining one unit of resource to be 100 iterations will give $R = 1,000$, whereas defining one unit to be 1k iterations will give $R = 100$). Thus, one unit of resource can be interpreted as the minimum desired resource and R as the ratio between maximum resource and minimum resource.

3.6 Setting η

The value of η is a knob that can be tuned based on *practical* user constraints. Larger values of η correspond to more aggressive elimination schedules and thus fewer rounds of elimination; specifically, each round retains $1/\eta$ configurations for a total of $\lfloor \log_\eta(n) \rfloor + 1$ rounds of elimination with n configurations. If one wishes to receive a result faster at the cost of a sub-optimal asymptotic constant, one can increase η to reduce the budget per bracket $B = (\lfloor \log_\eta(R) \rfloor + 1)R$. We stress that results are not very sensitive to the choice of η. If our theoretical bounds are optimized (see Section 5), they suggest choosing $\eta = e \approx 2.718$, but in practice we suggest taking η to be equal to 3 or 4.

Tuning η will also change the number of brackets and consequently the number of different tradeoffs that Hyperband tries. Usually, the possible range of brackets is fairly constrained, since the number of brackets is logarithmic in R; namely, there are $(\lfloor \log_\eta(R) \rfloor + 1) = s_{\max} + 1$ brackets. For our experiments in Section 4, we chose η to provide 5 brackets for the specified R; for most problems, 5 is a reasonable number of n versus B/n tradeoffs to explore. However, for large R, using $\eta = 3$ or 4 can give more brackets than desired. The number of brackets can be controlled in a few ways. First, as mentioned in the previous section, if R is too large and overhead is an issue, then one may want to control the overhead by limiting the maximum number of configurations to $n_{\max}$, thereby also limiting $s_{\max}$. If overhead is not a concern and aggressive exploration is desired, one can (1) increase η to reduce the number of brackets while maintaining R as the maximum number of configurations in the most exploratory bracket, or (2) still use $\eta = 3$ or 4 but only try brackets that do a baseline level of exploration, i.e., set $n_{\min}$ and only try brackets from $s_{\max}$ to $s = \lfloor \log_\eta(n_{\min}) \rfloor$. For computationally intensive problems that have long training times and high-dimensional search spaces, we recommend the latter. Intuitively, if the number of configurations that can be trained to completion (i.e., trained using R resources) in a reasonable amount of time is on the order of the dimension of the search space and not exponential in the dimension, then

it will be impossible to find a good configuration without using an aggressive exploratory tradeoff between n and B/n.

3.7 Overview of Theoretical Results

The theoretical properties of Hyperband are best demonstrated through an example. Suppose there are n configurations, each with a given terminal validation error ν_i for $i = 1, \ldots, n$. Without loss of generality, index the configurations by performance so that ν_1 corresponds to the best performing configuration, ν_2 to the second best, and so on. Now consider the task of identifying the best configuration. The optimal strategy would allocate to each configuration i the minimum resource required to distinguish it from ν_1, i.e., enough so that the envelope functions (see Figure 2) bound the intermediate loss to be less than $\frac{\nu_i - \nu_1}{2}$ away from the terminal value. In contrast, the naive uniform allocation strategy, which allocates B/n to each configuration, has to allocate to every configuration the maximum resource required to distinguish any arm ν_i from ν_1. Remarkably, the budget required by SuccessiveHalving is only a small factor of the optimal because it capitalizes on configurations that are easy to distinguish from ν_1.

The relative size of the budget required for uniform allocation and SuccessiveHalving depends on the envelope functions bounding deviation from terminal losses as well as the distribution from which ν_i's are drawn. The budget required for SuccessiveHalving is smaller when the optimal n versus B/n tradeoff discussed in Section 3.1 requires fewer resources per configuration. Hence, if the envelope functions tighten quickly as a function of resource allocated, or the average distances between terminal losses is large, then SuccessiveHalving can be substantially faster than uniform allocation. These intuitions are formalized in Section 5 and associated theorems/corollaries are provided that take into account the envelope functions and the distribution from which ν_i's are drawn.

In practice, we do not have knowledge of either the envelope functions or the distribution of ν_i's, both of which are integral in characterizing SuccessiveHalving's required budget. With Hyperband we address this shortcoming by hedging our aggressiveness. We show in Section 5.3.3 that Hyperband, despite having no knowledge of the envelope functions nor the distribution of ν_i's, requires a budget that is only log factors larger than that of SuccessiveHalving.

4. Hyperparameter Optimization Experiments

In this section, we evaluate the empirical behavior of Hyperband with three different resource types: iterations, data set subsamples, and feature samples. For all experiments, we compare Hyperband with three well known Bayesian optimization algorithms—SMAC, TPE, and Spearmint—using their default settings. We exclude Spearmint from the comparison set when there are conditional hyperparameters in the search space because it does not natively support them (Eggensperger et al., 2013). We also show results for SuccessiveHalving corresponding to repeating the most exploratory bracket of Hyperband to provide a baseline for aggressive early-stopping.[6] Additionally, as standard baselines against which to measure

6. This is not done for the experiments in Section 4.2.1, since the most aggressive bracket varies from dataset to dataset with the number of training points.

all speedups, we consider random search and "random 2×," a variant of random search with twice the budget of other methods. Of the hybrid methods described in Section 2, we compare to a variant of SMAC using the early termination criterion proposed by Domhan et al. (2015) in the deep learning experiments described in Section 4.1. We think a comparison of Hyperband to more sophisticated hybrid methods introduced recently by Klein et al. (2017a) and Kandasamy et al. (2017) is a fruitful direction for future work.

In the experiments below, we followed these loose guidelines when determining how to configuration Hyperband:

1. The maximum resource R should be reasonable given the problem, but ideally large enough so that early-stopping is beneficial.

2. η should depend on R and be selected to yield ≈ 5 brackets with a minimum of 3 brackets. This is to guarantee that Hyperband will use a baseline degree of early-stopping and prevent too coarse of a grid of n vs B tradeoffs.

4.1 Early-Stopping Iterative Algorithms for Deep Learning

For this benchmark, we tuned a convolutional neural network[7] with the same architecture as that used in Snoek et al. (2012) and Domhan et al. (2015). The search spaces used in the two previous works differ, and we used a search space similar to that of Snoek et al. (2012) with 6 hyperparameters for stochastic gradient decent and 2 hyperparameters for the response normalization layers (see Appendix A for details). In line with the two previous works, we used a batch size of 100 for all experiments.

Data sets: We considered three image classification data sets: CIFAR-10 (Krizhevsky, 2009), rotated MNIST with background images (MRBI) (Larochelle et al., 2007), and Street View House Numbers (SVHN) (Netzer et al., 2011). CIFAR-10 and SVHN contain 32×32 RGB images while MRBI contains 28×28 grayscale images. Each data set was split into a training, validation, and test set: (1) CIFAR-10 has 40k, 10k, and 10k instances; (2) MRBI has 10k, 2k, and 50k instances; and (3) SVHN has close to 600k, 6k, and 26k instances for training, validation, and test respectively. For all data sets, the only preprocessing performed on the raw images was demeaning.

Hyperband Configuration: For these experiments, one unit of resource corresponds to 100 mini-batch iterations (10k examples with a batch size of 100). For CIFAR-10 and MRBI, R was set to 300 (or 30k total iterations). For SVHN, R was set to 600 (or 60k total iterations) to accommodate the larger training set. Given R for these experiments, we set $\eta = 4$ to yield five SuccessiveHalving brackets for Hyperband.

Results: Each searcher was given a total budget of $50R$ per trial to return the best possible hyperparameter configuration. For Hyperband, the budget is sufficient to run the outer loop twice (for a total of 10 SuccessiveHalving brackets). For SMAC, TPE, and random search, the budget corresponds to training 50 different configurations to completion. Ten independent trials were performed for each searcher. The experiments took the equivalent of over 1 year of GPU hours on NVIDIA GRID K520 cards available on Amazon EC2 `g2.8xlarge` instances. We set a total budget constraint in terms of

Figure 4: Average test error across 10 trials. Label "SMAC (early)" corresponds to SMAC with the early-stopping criterion proposed in Domhan et al. (2015) and label "bracket $s = 4$" corresponds to repeating the most exploratory bracket of Hyperband.

iterations instead of compute time to make comparisons hardware independent.[8] Comparing progress by iterations instead of time ignores overhead costs, e.g. the cost of configuration selection for Bayesian methods and model initialization and validation costs for Hyperband. While overhead is hardware dependent, the overhead for Hyperband is below 5% on EC2 `g2.8xlarge` machines, so comparing progress by time passed would not change results significantly.

For CIFAR-10, the results in Figure 4(a) show that Hyperband is over an order-of-magnitude faster than its competitiors. For MRBI, Hyperband is over an order-of-

8. Most trials were run on Amazon EC2 g2.8xlarge instances but a few trials were run on different machines due to the large computational demand of these experiments.

magnitude faster than standard configuration selection approaches and 5× faster than SMAC (early). For SVHN, while Hyperband finds a good configuration faster, Bayesian optimization methods are competitive and SMAC (early) outperforms Hyperband. The performance of SMAC (early) demonstrates there is merit to combining early-stopping and adaptive configuration selection.

Across the three data sets, Hyperband and SMAC (early) are the only two methods that consistently outperform random 2×. On these data sets, Hyperband is over 20× faster than random search while SMAC (early) is $\leq 7\times$ faster than random search within the evaluation window. In fact, the first result returned by Hyperband after using a budget of $5R$ is often competitive with results returned by other searchers after using $50R$. Additionally, Hyperband is less variable than other searchers across trials, which is highly desirable in practice (see Appendix A for plots with error bars).

As discussed in Section 3.6, for computationally expensive problems in high-dimensional search spaces, it may make sense to just repeat the most exploratory brackets. Similarly, if meta-data is available about a problem or it is known that the quality of a configuration is evident after allocating a small amount of resource, then one should just repeat the most exploratory bracket. Indeed, for these experiments, bracket $s = 4$ vastly outperforms all other methods on CIFAR-10 and MRBI and is nearly tied with SMAC (early) for first on SVHN.

While we set R for these experiments to facilitate comparison to Bayesian methods and random search, it is also reasonable to use infinite horizon Hyperband to grow the maximum resource until a desired level of performance is reached. We evaluate infinite horizon Hyperband on CIFAR-10 using $\eta = 4$ and a starting budget of $B = 2R$. Figure 4(a) shows that infinite horizon Hyperband is competitive with other methods but does not perform as well as finite horizon Hyperband within the $50R$ budget limit. The infinite horizon algorithm underperforms initially because it has to tune the maximum resource R as well and starts with a less aggressive early-stopping rate. This demonstrates that in scenarios where a max resource is known, it is better to use the finite horizon algorithm. Hence, we focus on the finite horizon version of Hyperband for the remainder of our empirical studies.

Finally, CIFAR-10 is a very popular data set and state-of-the-art models achieve much lower error rates than what is shown in Figure 4. The difference in performance is mainly attributable to higher model complexities and data manipulation (i.e. using reflection or random cropping to artificially increase the data set size). If we limit the comparison to published results that use the same architecture and exclude data manipulation, the best human expert result for the data set is 18% error and the best hyperparameter optimized results are 15.0% for Snoek et al. (2012)[9] and 17.2% for Domhan et al. (2015). These results exceed ours on CIFAR-10 because they train on 25% more data, by including the validation set, and also train for more epochs. When we train the best model found by Hyperband on the combined training and validation data for 300 epochs, the model achieved a test error of 17.0%.

9. We were unable to reproduce this result even after receiving the optimal hyperparameters from the authors through a personal communication.

4.2 Data Set Subsampling

We studied two different hyperparameter search optimization problems for which Hyperband uses data set subsamples as the resource. The first adopts an extensive framework presented in Feurer et al. (2015) that attempts to automate preprocessing and model selection. Due to certain limitations of the framework that fundamentally limited the impact of data set downsampling, we conducted a second experiment using a kernel classification task.

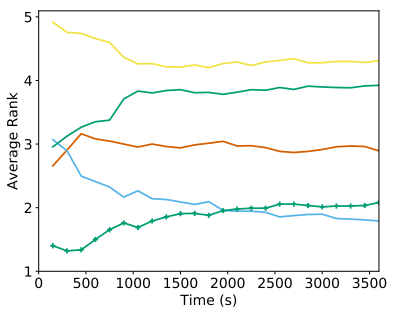
4.2.1 117 Data Sets

We used the framework introduced by Feurer et al. (2015), which explored a structured hyperparameter search space comprised of 15 classifiers, 14 feature preprocessing methods, and 4 data preprocessing methods for a total of 110 hyperparameters. We excluded the meta-learning component introduced in Feurer et al. (2015) used to warmstart Bayesian methods with promising configurations, in order to perform a fair comparison with random search and Hyperband. Similar to Feurer et al. (2015), we imposed a 3GB memory limit, a 6-minute timeout for each hyperparameter configuration and a one-hour time window to evaluate each searcher on each data set. Twenty trials of each searcher were performed per data set and all trials in aggregate took over a year of CPU time on `n1-standard-1` instances from Google Cloud Compute. Additional details about our experimental framework are available in Appendix A.

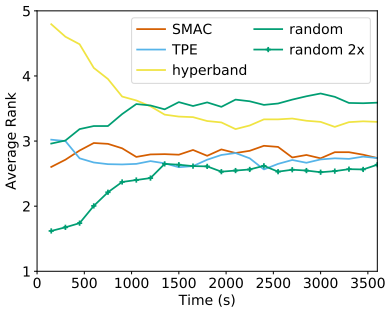
Data sets: Feurer et al. (2015) used 140 binary and multiclass classification data sets from OpenML, but 23 of them are incompatible with the latest version of the OpenML plugin (Feurer, 2015), so we worked with the remaining 117 data sets. Due to the limitations of the experimental setup (discussed in Appendix A), we also separately considered 21 of these data sets, which demonstrated at least modest (though still sublinear) training speedups due to subsampling. Specifically, each of these 21 data sets showed on average at least a 3× speedup due to 8× downsampling on 100 randomly selected hyperparameter configurations.

Hyperband Configuration: Due to the wide range of dataset sizes, with some datasets having fewer than 10k training points, we ran Hyperband with $\eta = 3$ to allow for at least 3 brackets without being overly aggressive in downsampling on small datasets. R was set to the full training set size for each data set and the maximum number of configurations for any bracket of SuccessiveHalving was limited to $n_{\max} = \max\{9, R/1000\}$. This ensured that the most exploratory bracket of Hyperband will downsample at least twice. As mentioned in Section 3.6, when $n_{\max}$ is specified, the only difference when running the algorithm is $s_{\max} = \lfloor \log_\eta(n_{\max}) \rfloor$ instead of $\lfloor \log_\eta(R) \rfloor$.

Results: The results on all 117 data sets in Figure 5(a,b) show that Hyperband outperforms random search in test error rank despite performing worse in validation error rank. Bayesian methods outperform Hyperband and random search in test error performance but also exhibit signs of overfitting to the validation set, as they outperform Hyperband by a larger margin on the validation error rank. Notably, random 2× outperforms all other methods. However, for the subset of 21 data sets, Figure 5(c) shows that Hyperband outperforms all other searchers on test error rank, including random 2× by a very small margin. While these results are more promising, the effectiveness of Hyperband was restricted in this experimental framework; for smaller data sets, the startup overhead was



(a) Validation Error on 117 Data Sets



(b) Test Error on 117 Data Sets

high relative to total training time, while for larger data sets, only a handful of configurations could be trained within the hour window.

We note that while average rank plots like those in Figure 5 are an effective way to aggregate information across many searchers and data sets, they provide no indication about the *magnitude* of the differences between the performance of the methods. Figure 6, which charts the difference between the test error for each searcher and that of random search across all 117 datasets, highlights the small difference in the magnitude of the test errors across searchers.

These results are not surprising; as mentioned in Section 2.1, vanilla Bayesian optimization methods perform similarly to random search in high-dimensional search spaces. Feurer et al. (2015) showed that using meta-learning to warmstart Bayesian optimization methods improved performance in this high-dimensional setting. Using meta-learning to identify a

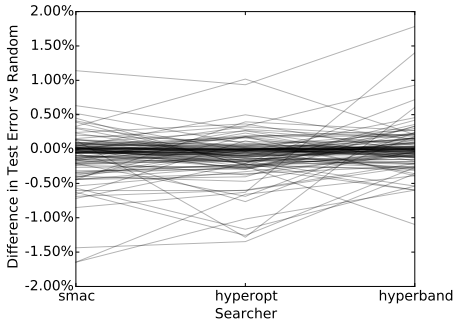

Figure 6: Each line plots, for a single data set, the difference in test error versus random search for each search, where lower is better. Nearly all the lines fall within the -0.5% and 0.5% band and, with the exception of a few outliers, the lines are mostly flat.

promising distribution from which to sample configurations as input into Hyperband is a direction for future work.

4.2.2 Kernel Regularized Least Squares Classification

For this benchmark, we tuned the hyperparameters of a kernel-based classifier on CIFAR-10. We used the multi-class regularized least squares classification model, which is known to have comparable performance to SVMs (Rifkin and Klautau, 2004; Agarwal et al., 2014) but can be trained significantly faster.[10] The hyperparameters considered in the search space include preprocessing method, regularization, kernel type, kernel length scale, and other kernel specific hyperparameters (see Appendix A for more details). For Hyperband, we set $R = 400$, with each unit of resource representing 100 datapoints, and $\eta = 4$ to yield a total of 5 brackets. Each hyperparameter optimization algorithm was run for ten trials on Amazon EC2 `m4.2xlarge` instances; for a given trial, Hyperband was allowed to run for two outer loops, bracket $s = 4$ was repeated 10 times, and all other searchers were run for 12 hours.

Figure 7 shows that Hyperband returned a good configuration after completing the first SuccessiveHalving bracket in approximately 20 minutes; other searchers failed to reach this error rate on average even after the entire 12 hours. Notably, Hyperband was able to evaluate over 250 configurations in this first bracket of SuccessiveHalving, while competitors were able to evaluate only three configurations in the same amount of time. Consequently, Hyperband is over 30× faster than Bayesian optimization methods and 70× faster than random search. Bracket $s = 4$ sightly outperforms Hyperband but the terminal

10. The default SVM method in Scikit-learn is single core and takes hours to train on CIFAR-10, whereas a block coordinate descent least squares solver takes less than 10 minutes on an 8 core machine.

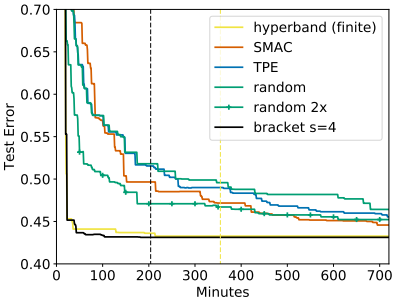

Figure 7: Average test error of the best kernel regularized least square classification model found by each searcher on CIFAR-10. The color coded dashed lines indicate when the last trial of a given searcher finished.

performance for the two algorithms are the same. Random 2× is competitive with SMAC and TPE.

4.3 Feature Subsampling to Speed Up Approximate Kernel Classification

Next, we examine the performance of Hyperband when using features as a resource on a random feature kernel approximations task. Features were randomly generated using the method described in Rahimi and Recht (2007) to approximate the RBF kernel, and these random features were then used as inputs to a ridge regression classifier. The hyperparameter search space included the preprocessing method, kernel length scale, and L_2 penalty. While it may seem natural to use infinite horizon Hyperband, since the fidelity of the approximation improves with more random features, in practice, the amount of available machine memory imposes a natural upper bound on the number of features. Thus, we used finite horizion Hyperband with a maximum resource of 100k random features, which comfortably fit into a machine with 60GB of memory. Additionally, we set one unit of resource to be 100 features, so $R = 1000$. Again, we set $\eta = 4$ to yield 5 brackets of SuccessiveHalving. We ran 10 trials of each searcher, with each trial lasting 12 hours on a `n1-standard-16` machine from Google Cloud Compute. The results in Figure 8 show that Hyperband is around 6× faster than Bayesian methods and random search. Hyperband performs similarly to bracket $s = 4$. Random 2× outperforms Bayesian optimization algorithms.

4.4 Experimental Discussion

While our experimental results show Hyperband is a promising algorithm for hyperparameter optimization, a few questions naturally arise:

1. What impacts the speedups provided by Hyperband?
2. Why does SuccessiveHalving seem to outperform Hyperband?
3. What about hyperparameters that should depend on the resource?

We next address each of these questions in turn.

4.4.1 Factors Impacting the Performance of Hyperband

For a given R, the most exploratory SuccessiveHalving round performed by Hyperband evaluates R configurations using a budget of $(\lfloor \log_\eta(R) \rfloor + 1)R$, which gives an upper bound on the potential speedup over random search. If training time scales linearly with the resource, the maximum speedup offered by Hyperband compared to random search is $\frac{R}{(\lfloor \log_\eta(R) \rfloor + 1)}$. For the values of η and R used in our experiments, the maximum speedup over random search is approximately 50× given linear training time. However, we observe a range of speedups from 6× to 70× faster than random search. The differences in realized speedup can be explained by three factors:

1. *How training time scales with the given resource.* In cases where training time is superlinear as a function of the resource, Hyperband can offer higher speedups. For instance, if training scales like a polynomial of degree $p > 1$, the maximum speedup for Hyperband over random search is approximately $\frac{\eta^p - 1}{\eta^p - 1} R$. In the kernel least square classifier experiment discussed in Section 4.2.2, the training time scaled quadratically as a function of the resource, which explains why the realized speedup of 70× is higher than the maximum expected speedup given linear scaling.

2. *Overhead costs associated with training.* Total evaluation time also depends on fixed overhead costs associated with evaluating each hyperparameter configuration, e.g., initializing a model, resuming previously trained models, and calculating validation error. For example, in the downsampling experiments on 117 data sets presented in Section 4.2.1, Hyperband did not provide significant speedup because many data sets could be trained in a matter of a few seconds and the initialization cost was high relative to training time.

3. *The difficulty of finding a good configuration.* Hyperparameter optimization problems can vary in difficulty. For instance, an 'easy' problem is one where a randomly sampled configuration is likely to result in a high-quality model, and thus we only need to evaluate a small number of configurations to find a good setting. In contrast, a 'hard' problem is one where an arbitrary configuration is likely to be bad, in which case many configurations must be considered. Hyperband leverages downsampling to boost the number of configurations that are evaluated, and thus is better suited for 'hard' problems where more evaluations are actually necessary to find a good setting. Generally, the difficulty of a problem scales with the dimensionality of the search space. For low-dimensional problems, the number of configurations evaluated by random search and Bayesian methods is exponential in the number of dimensions so good coverage can be achieved. For instance, the low-dimensional ($d = 3$) search space in our feature subsampling experiment in Section 4.3 helps explain why Hyperband is

only 6× faster than random search. In contrast, for the neural network experiments in Section 4.1, we hypothesize that faster speedups are observed for Hyperband because the dimension of the search space is higher.

4.4.2 Comparison to SuccessiveHalving

With the exception of the LeNet experiment (Section 3.3) and the 117 Datasets experiment (Section 4.2.1), the most aggressive bracket of SuccessiveHalving outperformed Hyperband in all of our experiments. In hindsight, we should have just run bracket $s = 4$, since aggressive early-stopping provides massive speedups on many of these benchmarking tasks. However, as previously mentioned, it was unknown a priori that bracket $s = 4$ would perform the best and that is why we have to cycle through all possible brackets with Hyperband. Another question is what happens when one increases s even further, i.e. instead of 4 rounds of elimination, why not 5 or even more with the same maximum resource R? In our case, $s = 4$ was the most aggressive bracket we could run given the minimum resource per configuration limits imposed for the previous experiments. However, for larger data sets, it is possible to extend the range of possible values for s, in which case, Hyperband may either provide even faster speedups if more aggressive early-stopping helps or be slower by a small factor if the most aggressive brackets are essentially throwaways.

We believe prior knowledge about a task can be particularly useful for limiting the range of brackets explored by Hyperband. In our experience, aggressive early-stopping is generally safe for neural network tasks and even more aggressive early-stopping may be reasonable for larger data sets and longer training horizons. However, when pushing the degree of early-stopping by increasing s, one has to consider the additional overhead cost associated with examining more models. Hence, one way to leverage meta-learning would be to use learning curve convergence rate, difficulty of different search spaces, and overhead costs of related tasks to determine the brackets considered by Hyperband.

4.4.3 Resource Dependent Hyperparameters

In certain cases, the setting for a given hyperparameter should depend on the allocated resource. For example, the maximum tree depth regularization hyperparameter for random forests should be higher with more data and more features. However, the optimal tradeoff between maximum tree depth and the resource is unknown and can be data set specific. In these situations, the rate of convergence to the true loss is usually slow because the performance on a smaller resource is not indicative of that on a larger resource. Hence, these problems are particularly difficult for Hyperband, since the benefit of early-stopping can be muted. Again, while Hyperband will only be a small factor slower than that of SuccessiveHalving with the optimal early-stopping rate, we recommend removing the dependence of the hyperparameter on the resource if possible. For the random forest example, an alternative regularization hyperparameter is minimum samples per leaf, which is less dependent on the training set size. Additionally, the dependence can oftentimes be removed with simple normalization. For example, the regularization term for our kernel least squares experiments were normalized by the training set size to maintain a constant tradeoff between the mean-squared error and the regularization term.

5. Theory

In this section, we introduce the pure-exploration non-stochastic infinite-armed bandit (NIAB) problem, a very general setting which encompasses our hyperparameter optimization problem of interest. As we will show, Hyperband is in fact applicable to problems far beyond just hyperparameter optimization. We begin by formalizing the hyperparameter optimization problem and then reducing it to the pure-exploration NIAB problem. We subsequently present a detailed analysis of Hyperband in both the infinite and finite horizon settings.

5.1 Hyperparameter Optimization Problem Statement

Let $\mathcal{X}$ denote the space of valid hyperparameter configurations, which could include continuous, discrete, or categorical variables that can be constrained with respect to each other in arbitrary ways (i.e. $\mathcal{X}$ need not be limited to a subset of $[0,1]^d$). For $k = 1, 2, \ldots$ let $\ell_k \colon \mathcal{X} \to [0,1]$ be a sequence of loss functions defined over $\mathcal{X}$. For any hyperparameter configuration $x \in \mathcal{X}$, $\ell_k(x)$ represents the validation error of the model trained using x with k units of resources (e.g. iterations). In addition, for some $R \in \mathbb{N} \cup \{\infty\}$, define $\ell_* = \lim_{k \to R} \ell_k$ and $\nu_* = \inf_{x \in \mathcal{X}} \ell_*(x)$. Note that $\ell_k(\cdot)$ for all $k \in \mathbb{N}$, $\ell_*(\cdot)$, and ν_* are all unknown to the algorithm a priori. In particular, it is uncertain how quickly $\ell_k(x)$ varies as a function of x for any fixed k, and how quickly $\ell_k(x) \to \ell_*(x)$ as a function of k for any fixed $x \in \mathcal{X}$.

We assume hyperparameter configurations are sampled randomly from a known probability distribution $p(x) \colon \mathcal{X} \to [0, \infty)$, with support on $\mathcal{X}$. In our experiments, $p(x)$ is simply the uniform distribution, but the algorithm can be used with any sampling method. If $X \in \mathcal{X}$ is a random sample from this probability distribution, then $\ell_*(X)$ is a random variable whose distribution is unknown since $\ell_*(\cdot)$ is unknown. Additionally, since it is unknown how $\ell_k(x)$ varies as a function of x or k, one cannot necessarily infer anything about $\ell_k(x)$ given knowledge of $\ell_j(y)$ for any $j \in \mathbb{N}$, $y \in \mathcal{X}$. As a consequence, we reduce the hyperparmeter optimization problem down to a much simpler problem that ignores all underlying structure of the hyperparameters: we only interact with some $x \in \mathcal{X}$ through its loss sequence $\ell_k(x)$ for $k = 1, 2, \ldots$. With this reduction, the particular value of $x \in \mathcal{X}$ does nothing more than index or uniquely identify the loss sequence.

Without knowledge of how fast $\ell_k(\cdot) \to \ell_*(\cdot)$ or how $\ell_*(X)$ is distributed, the goal of Hyperband is to identify a hyperparameter configuration $x \in \mathcal{X}$ that minimizes $\ell_*(x) - \nu_*$ by drawing as many random configurations as desired while using as few total resources as possible.

5.2 The Pure-Exploration Non-stochastic Infinite-Armed Bandit Problem

We now formally define the bandit problem of interest, and relate it to the problem of hyperparameter optimization. Each "arm" in the NIAB game is associated with a sequence that is drawn randomly from a distribution over sequences. If we "pull" the ith drawn arm exactly k times, we observe a loss $\ell_{i,k}$. At each time, the player can either draw a new arm (sequence) or pull a previously drawn arm an additional time. There is no limit on the number of arms that can be drawn. We assume the arms are identifiable only by their index

i (i.e. we have no side-knowledge or feature representation of an arm), and we also make the following two additional assumptions:

Assumption 1 *For each $i \in \mathbb{N}$ the limit $\lim_{k\to\infty} \ell_{i,k}$ exists and is equal to ν_i.*[11]

Assumption 2 *Each ν_i is a bounded i.i.d. random variable with cumulative distribution function F.*

The objective of the NIAB problem is to identify an arm $\hat{\imath}$ with small $\nu_{\hat{\imath}}$ using as few total pulls as possible. We are interested in characterizing $\nu_{\hat{\imath}}$ as a function of the total number of pulls from all the arms. Clearly, the hyperparameter optimization problem described above is an instance of the NIAB problem. In this case, arm i correspondes to a configuration $x_i \in \mathcal{X}$, with $\ell_{i,k} = \ell_k(x_i)$; Assumption 1 is equivalent to requiring that $\nu_i = \ell_*(x_i)$ exists; and Assumption 2 follows from the fact that the arms are drawn i.i.d. from $\mathcal{X}$ according to distribution function $p(x)$. F is simply the cumulative distribution function of $\ell_*(X)$, where X is a random variable drawn from the distribution $p(x)$ over $\mathcal{X}$. Note that since the arm draws are independent, the ν_i's are also independent. Again, this is not to say that the validation losses do not depend on the settings of the hyperparameters; the validation loss could well be correlated with certain hyperparameters, but this is not used in the algorithm and no assumptions are made regarding the correlation structure.

In order to analyze the behavior of Hyperband in the NIAB setting, we must define a few additional objects. Let $\nu_* = \inf\{m : \mathbb{P}(\nu \le m) > 0\} > -\infty$, since the domain of the distribution F is bounded. Hence, the cumulative distribution function F satisfies

$$\mathbb{P}(\nu_i - \nu_* \le \epsilon) = F(\nu_* + \epsilon) \tag{1}$$

and let $F^{-1}(y) = \inf_x\{x : F(x) \le y\}$. Define $\gamma\colon \mathbb{N} \to \mathbb{R}$ as the pointwise smallest, monotonically decreasing function satisfying

$$\sup_i |\ell_{i,j} - \ell_{i,*}| \le \gamma(j)\ , \quad \forall j \in \mathbb{N}. \tag{2}$$

The function γ is guaranteed to exist by Assumption 1 and bounds the deviation from the limit value as the sequence of iterates j increases. For hyperparameter optimization, this follows from the fact that ℓ_k uniformly converges to ℓ_* for all $x \in \mathcal{X}$. In addition, γ can be interpretted as the deviation of the validation error of a configuration trained on a subset of resources versus the maximum number of allocatable resources. Finally, define R as the first index such that $\gamma(R) = 0$ if it exists, otherwise set $R = \infty$. For $y \ge 0$ let $\gamma^{-1}(y) = \min\{j \in \mathbb{N}\colon \gamma(j) \le y\}$, using the convention that $\gamma^{-1}(0) := R$ which we recall can be infinite.

As previously discussed, there are many real-world scenarios in which R is finite and known. For instance, if increasing subsets of the full data set is used as a resource, then the maximum number of resources cannot exceed the full data set size, and thus $\gamma(k) = 0$ for all $k \ge R$ where R is the (known) full size of the data set. In other cases such as iterative training problems, one might not want to or know how to bound R. We separate these two settings into the *finite horizon* setting where R is finite and known, and the *infinite horizon*

11. We can always define $\ell_{i,k}$ so that convergence is guaranteed, i.e. taking the infimum of a sequence.

SuccessiveHalving (Infinite horizon)
Input: Budget B, n arms where $\ell_{i,k}$ denotes the kth loss from the ith arm
Initialize: $S_0 = [n]$.
For $k = 0, 1, \ldots, \lceil \log_2(n) \rceil - 1$
  Pull each arm in S_k for $r_k = \lfloor \frac{B}{|S_k|\lceil \log_2(n) \rceil} \rfloor$ times.
  Keep the best $\lfloor |S_k|/2 \rfloor$ arms in terms of the r_kth observed loss as S_{k+1}.
Output : $\hat{\imath}$, $\ell_{\hat{\imath}, \lfloor \frac{B/2}{\lceil \log_2(n) \rceil} \rfloor}$ where $\hat{\imath} = S_{\lceil \log_2(n) \rceil}$

Hyperband (Infinite horizon)
Input: None
For $k = 1, 2, \ldots$
  For $s \in \mathbb{N}$ s.t. $k - s \ge \log_2(s)$
    $B_{k,s} = 2^k$, $n_{k,s} = 2^s$
    $\hat{\imath}_{k,s}, \ell_{\hat{\imath}_{k,s}, \lfloor \frac{2^{k-1}}{s} \rfloor} \leftarrow$ SuccessiveHalving $(B_{k,s}, n_{k,s})$

Figure 9: (Top) The SuccessiveHalving algorithm proposed and analyzed in Jamieson and Talwalkar (2015) for the non-stochastic setting. Note this algorithm was originally proposed for the stochastic setting in Karnin et al. (2013). (Bottom) The Hyperband algorithm for the infinite horizon setting. Hyperband calls SuccessiveHalving as a subroutine.

setting where no bound on R is known and it is assumed to be infinite. While our empirical results suggest that the finite horizon may be more practically relevant for the problem of hyperparameter optimization, the infinite horizon case has natural connections to the literature, and we begin by analyzing this setting.

5.3 Infinite Horizon Setting ($R = \infty$)

Consider the Hyperband algorithm of Figure 9. The algorithm uses SuccessiveHalving (Figure 9) as a subroutine that takes a finite set of arms as input and outputs an estimate of the best performing arm in the set. We first analyze SuccessiveHalving (SH) for a given set of limits ν_i and then consider the performance of SH when ν_i are drawn randomly according to F. We then analyze the Hyperband algorithm. We note that the algorithm of Figure 9 was originally proposed by Karnin et al. (2013) for the stochastic setting. However, Jamieson and Talwalkar (2015) analyzed it in the non-stochastic setting and also found it to work well in practice. Extending the result of Jamieson and Talwalkar (2015) we have the following theorem:

Theorem 1 *Fix n arms. Let $\nu_i = \lim_{\tau\to\infty} \ell_{i,\tau}$ and assume $\nu_1 \leq \cdots \leq \nu_n$. For any $\epsilon > 0$ let*

$$z_{SH} = 2\lceil\log_2(n)\rceil \max_{i=2,\ldots,n} i\,(1+\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i-\nu_1}{2}\right\}\right))$$
$$\leq 2\lceil\log_2(n)\rceil\left(n+\sum_{i=1,\ldots,n}\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i-\nu_1}{2}\right\}\right)\right)$$

If the SuccessiveHalving *algorithm of Figure 9 is run with any budget $B > z_{SH}$ then an arm $\hat{\imath}$ is returned that satisfies $\nu_{\hat{\imath}} - \nu_1 \leq \epsilon/2$. Moreover, $|\ell_{\hat{\imath},\lfloor\frac{B/2}{\lceil\log_2(n)\rceil}\rfloor} - \nu_1| \leq \epsilon$.*

The next technical lemma will be used to characterize the problem dependent term $\sum_{i=1,\ldots,n}\gamma^{-1}\left(\max\left\{\frac{\epsilon}{4}, \frac{\nu_i-\nu_1}{2}\right\}\right)$ when the sequences are drawn from a probability distribution.

Lemma 2 *Fix $\delta \in (0,1)$. Let $p_n = \frac{\log(2/\delta)}{n}$. For any $\epsilon \geq 4(F^{-1}(p_n) - \nu_*)$ define*

$$\mathbf{H}(F,\gamma,n,\delta,\epsilon) := 2n\int_{\nu_*+\epsilon/4}^{\infty}\gamma^{-1}(\tfrac{t-\nu_*}{4})dF(t) + \left(\tfrac{4}{3}\log(2/\delta) + 2nF(\nu_*+\epsilon/4)\right)\gamma^{-1}\left(\tfrac{\epsilon}{16}\right)$$

and $\mathbf{H}(F,\gamma,n,\delta) := \mathbf{H}(F,\gamma,n,\delta,4(F^{-1}(p_n)-\nu_*))$ so that

$$\mathbf{H}(F,\gamma,n,\delta) = 2n\int_{p_n}^{1}\gamma^{-1}(\tfrac{F^{-1}(t)-\nu_*}{4})dt + \tfrac{10}{3}\log(2/\delta)\gamma^{-1}\left(\tfrac{F^{-1}(p_n)-\nu_*}{4}\right).$$

For n arms with limits $\nu_1 \leq \cdots \leq \nu_n$ drawn from F, then

$$\nu_1 \leq F^{-1}(p_n) \quad \text{and} \quad \sum_{i=1}^{n}\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i-\nu_1}{2}\right\}\right) \leq \mathbf{H}(F,\gamma,n,\delta,\epsilon)$$

for any $\epsilon \geq 4(F^{-1}(p_n)-\nu_*)$ with probability at least $1-\delta$.

Setting $\epsilon = 4(F^{-1}(p_n)-\nu_*)$ in Theorem 1 and using the result of Lemma 2 that $\nu_* \leq \nu_1 \leq \nu_* + (F^{-1}(p_n)-\nu_*)$, we immediately obtain the following corollary.

Corollary 3 *Fix $\delta \in (0,1)$ and $\epsilon \geq 4(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*)$. Let $B = 4\lceil\log_2(n)\rceil\mathbf{H}(F,\gamma,n,\delta,\epsilon)$ where $\mathbf{H}(F,\gamma,n,\delta,\epsilon)$ is defined in Lemma 2. If the* SuccessiveHalving *algorithm of Figure 9 is run with the specified B and n arm configurations drawn randomly according to F, then an arm $\hat{\imath} \in [n]$ is returned such that with probability at least $1-\delta$ we have $\nu_{\hat{\imath}} - \nu_* \leq \left(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*\right) + \epsilon/2$. In particular, if $B = 4\lceil\log_2(n)\rceil\mathbf{H}(F,\gamma,n,\delta)$ and $\epsilon = 4(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*)$ then $\nu_{\hat{\imath}} - \nu_* \leq 3\left(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*\right)$ with probability at least $1-\delta$.*

Note that for any fixed $n \in \mathbb{N}$ we have for any $\Delta > 0$

$$\mathbb{P}(\min_{i=1,\ldots,n}\nu_i - \nu_* \geq \Delta) = (1-F(\nu_*+\Delta))^n \approx e^{-nF(\nu_*+\Delta)}$$

which implies $\mathbb{E}[\min_{i=1,\ldots,n}\nu_i - \nu_*] \approx F^{-1}(\frac{1}{n}) - \nu_*$. That is, n needs to be sufficiently large so that it is probable that a good limit is sampled. On the other hand, for any fixed n, Corollary 3 suggests that the total resource budget B needs to be large enough in order to overcome the rates of convergence of the sequences described by γ. Next, we relate SH to a naive approach that uniformly allocates resources to a fixed set of n arms.

5.3.1 Non-Adaptive Uniform Allocation

The non-adaptive uniform allocation strategy takes as inputs a budget B and n arms, allocates B/n to each of the arms, and picks the arm with the lowest loss. The following results allow us to compare with SuccessiveHalving.

Proposition 4 *Suppose we draw n random configurations from F, train each with $j = \min\{B/n, R\}$ iterations, and let $\hat{\imath} = \arg\min_{i=1,\ldots,n}\ell_j(X_i)$. Without loss of generality assume $\nu_1 \leq \ldots \leq \nu_n$. If*

$$B \geq n\gamma^{-1}\left(\tfrac{1}{2}(F^{-1}(\tfrac{\log(1/\delta)}{n}) - \nu_*)\right) \tag{3}$$

then with probability at least $1-\delta$ we have $\nu_{\hat{\imath}} - \nu_* \leq 2\left(F^{-1}\left(\frac{\log(1/\delta)}{n}\right) - \nu_*\right)$. In contrast, there exists a sequence of functions ℓ_j that satisfy F and γ such that if

$$B \leq n\gamma^{-1}\left(2(F^{-1}(\tfrac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)\right)$$

then with probability at least δ, we have $\nu_{\hat{\imath}} - \nu_* \geq 2(F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)$, where c is a constant that depends on the regularity of F.

For any fixed n and sufficiently large B, Corollary 3 shows that SuccessiveHalving outputs an $\hat{\imath} \in [n]$ that satisfies $\nu_{\hat{\imath}} - \nu_* \lesssim F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*$ with probability at least $1-\delta$. This guarantee is similar to the result in Proposition 4. However, SuccessiveHalving achieves its guarantee as long as[12]

$$B \simeq \log_2(n)\left[\log(1/\delta)\gamma^{-1}\left(F^{-1}(\tfrac{\log(1/\delta)}{n}) - \nu_*\right) + n\int_{\frac{\log(1/\delta)}{n}}^{1}\gamma^{-1}(F^{-1}(t)-\nu_*)dt\right], \tag{4}$$

and this sample complexity may be substantially smaller than the budget required by uniform allocation shown in Eq. (3) of Proposition 4. Essentially, the first term in Eq. (4) represents the budget allocated to the constant number of arms with limits $\nu_i \approx F^{-1}(\frac{\log(1/\delta)}{n})$ while the second term describes the number of times the sub-optimal arms are sampled before discarded. The next section uses a particular parameterization for F and γ to help better illustrate the difference between the sample complexity of uniform allocation (Equation 3) versus that of SuccessiveHalving (Equation 4).

5.3.2 A Parameterization of F and γ for Interpretability

To gain some intuition and relate the results back to the existing literature, we make explicit parametric assumptions on F and γ. We stress that all of our results hold for general F and γ as previously stated, and this parameterization is simply a tool to provide intuition. First assume that there exists a constant $\alpha > 0$ such that

$$\gamma(j) \simeq \left(\frac{1}{j}\right)^{1/\alpha}. \tag{5}$$

12. We say $f \simeq g$ if there exist constants c, c' such that $cg(x) \leq f(x) \leq c'g(x)$.

Note that a large value of α implies that the convergence of $\ell_{i,k} \to \nu_i$ is very slow.

We will consider two possible parameterizations of F. First, assume there exists positive constants β such that

$$F(x) \simeq \begin{cases} (x-\nu_*)^\beta & \text{if } x \geq \nu_* \\ 0 & \text{if } x < \nu_* \end{cases}. \tag{6}$$

Here, a large value of β implies that it is very rare to draw a limit close to the optimal value ν_*. The same model was studied in Carpentier and Valko (2015). Fix some $\Delta > 0$. As discussed in the preceding section, if $n = \frac{\log(1/\delta)}{F(\nu_*+\Delta)} \simeq \Delta^{-\beta}\log(1/\delta)$ arms are drawn from F then with probability at least $1-\delta$ we have $\min_{i=1,\dots,n} \nu_i \leq \nu_* + \Delta$. Predictably, both uniform allocation and SuccessiveHalving output a $\nu_{\hat{\imath}}$ that satisfies $\nu_{\hat{\imath}} - \nu_* \lesssim \left(\frac{\log(1/\delta)}{n}\right)^{1/\beta}$ with probability at least $1-\delta$ provided their measurement budgets are large enough. Thus, if $n \simeq \Delta^{-\beta}\log(1/\delta)$ and the measurement budgets of the uniform allocation (Equation 3) and SuccessiveHalving (Equation 4) satisfy

$$\begin{aligned} \text{Uniform allocation} \quad & B \simeq \Delta^{-(\alpha+\beta)}\log(1/\delta) \\ \text{SuccessiveHalving} \quad & B \simeq \log_2(\Delta^{-\beta}\log(1/\delta))\left[\Delta^{-\alpha}\log(1/\delta) + \frac{\Delta^{-\beta}-\Delta^{-\alpha}}{1-\alpha/\beta}\log(1/\delta)\right] \\ & \simeq \log(\Delta^{-1}\log(1/\delta))\log(\Delta^{-1})\ \Delta^{-\max\{\beta,\alpha\}}\log(1/\delta) \end{aligned}$$

then both also satisfy $\nu_{\hat{\imath}} - \nu_* \lesssim \Delta$ with probability at least $1-\delta$.[13] SuccessiveHalving's budget scales like $\Delta^{-\max\{\alpha,\beta\}}$, which can be significantly smaller than the uniform allocation's budget of $\Delta^{-(\alpha+\beta)}$. However, because α and β are unknown in practice, neither method knows how to choose the optimal n or B to achieve this Δ accuracy. In Section 5.3.3, we show how Hyperband addresses this issue.

The second parameterization of F is the following discrete distribution:

$$F(x) = \frac{1}{K}\sum_{j=1}^{K} \mathbf{1}\{x \leq \mu_j\} \qquad \text{with} \qquad \Delta_j := \mu_j - \mu_1 \tag{7}$$

for some set of unique scalars $\mu_1 < \mu_2 < \cdots < \mu_K$. Note that by letting $K \to \infty$ this discrete CDF can approximate any piecewise-continuous CDF to arbitrary accuracy. In particular, this model can have multiple means take the same value so that α mass is on μ_1 and $1-\alpha$ mass is on $\mu_2 > \mu_1$, capturing the stochastic infinite-armed bandit model of Jamieson et al. (2016). In this setting, both uniform allocation and SuccessiveHalving output a $\nu_{\hat{\imath}}$ that is within the top $\frac{\log(1/\delta)}{n}$ fraction of the K arms with probability at least $1-\delta$ if their budgets are sufficiently large. Thus, let $q > 0$ be such that $n \simeq q^{-1}\log(1/\delta)$. Then, if the measurement budgets of the uniform allocation (Equation 3) and SuccessiveHalving (Equation 4) satisfy

$$\begin{aligned} \text{Uniform allocation} \quad & B \simeq \log(1/\delta)\begin{cases} K \max_{j=2,\dots,K} \Delta_j^{-\alpha} & \text{if } q = 1/K \\ q^{-1}\Delta_{\lceil qK \rceil}^{-\alpha} & \text{if } q > 1/K \end{cases} \\ \text{SuccessiveHalving} \quad & B \simeq \log(q^{-1}\log(1/\delta))\log(1/\delta)\begin{cases} \Delta_2^{-\alpha} + \sum_{j=2}^{K} \Delta_j^{-\alpha} & \text{if } q = 1/K \\ \Delta_{\lceil qK \rceil}^{-\alpha} + \frac{1}{qK}\sum_{j=\lceil qK \rceil}^{K} \Delta_j^{-\alpha} & \text{if } q > 1/K, \end{cases} \end{aligned}$$

an arm that is in the best q-fraction of arms is returned, i.e. $\hat{\imath}/K \approx q$ and $\nu_{\hat{\imath}} - \nu_* \lesssim \Delta_{\lceil \max\{2,qK\} \rceil}$, with probability at least $1-\delta$. This shows that the average resource per arm for uniform allocation is that required to distinguish the top q-fraction from the best, while that for SuccessiveHalving is a small multiple of the average resource required to distinguish an arm from the best; the difference between the max and the average can be very large in practice. We remark that the value of ϵ in Corollary 3 is carefully chosen to make the SuccessiveHalving budget and guarantee work out. Also note that one would never take $q < 1/K$ because $q = 1/K$ is sufficient to return the best arm.

5.3.3 Hyperband Guarantees

The Hyperband algorithm of Figure 9 addresses the tradeoff between the number of arms n versus the average number of times each one is pulled B/n by performing a two-dimensional version of the so-called "doubling trick." For each fixed B, we non-adaptively search a predetermined grid of values of n spaced geometrically apart so that the incurred loss of identifying the "best" setting takes a budget no more than $\log(B)$ times the budget necessary if the best setting of n were known ahead of time. Then, we successively double B so that the cumulative number of measurements needed to arrive at the necessary B is no more than $2B$. The idea is that even though we do not know the optimal setting for B, n to achieve some desired error rate, the hope is that by trying different values in a particular order, we will not waste too much effort.

Fix $\delta \in (0,1)$. For all (k,s) pairs defined in the Hyperband algorithm of Figure 9, let $\delta_{k,s} = \frac{\delta}{2k^3}$. For all (k,s) define

$$\mathcal{E}_{k,s} := \{B_{k,s} > 4\lceil \log_2(n_{k,s}) \rceil \mathbf{H}(F, \gamma, n_{k,s}, \delta_{k,s})\} = \{2^k > 4s\mathbf{H}(F, \gamma, 2^s, 2k^3/\delta)\}$$

Then by Corollary 3 we have

$$\mathbb{P}\left(\bigcup_{k=1}^{\infty}\bigcup_{s=1}^{k}\{\nu_{i_{k,s}} - \nu_* > 3\big(F^{-1}\big(\tfrac{\log(4k^3/\delta)}{2^s}\big) - \nu_*\big)\} \cap \mathcal{E}_{k,s}\right) \leq \sum_{k=1}^{\infty}\sum_{s=1}^{k}\delta_{k,s} = \sum_{k=1}^{\infty}\frac{\delta}{2k^2} \leq \delta.$$

For sufficiently large k we will have $\bigcup_{s=1}^{k}\mathcal{E}_{k,s} \neq \emptyset$, so assume $B = 2^k$ is sufficiently large. Let $\hat{\imath}_B$ be the empirically best-performing arm output from SuccessiveHalving of round $k_B = \lfloor \log_2(B) \rfloor$ of Hyperband of Figure 9 and let $s_B \leq k_B$ be the largest value such that

13. These quantities are intermediate results in the proofs of the theorems of Section 5.3.3.

$\mathcal{E}_{k_B,s_B}$ holds. Then

$$\nu_{i_B} - \nu_* \leq 3\big(F^{-1}(\frac{\log(4\lfloor \log_2(B)\rfloor^3/\delta)}{2^{s_B}}) - \nu_*\big) + \gamma(\lfloor \frac{2^{\lfloor \log_2(B)\rfloor - 1}}{\lfloor \log_2(B)\rfloor}\rfloor).$$

Also note that on stage k at most $\sum_{i=1}^{k} iB_{i,1} \leq k\sum_{i=1}^{k} B_{i,1} \leq 2kB_{k,s} = 2\log_2(B_{k,s})B_{k,s}$ total samples have been taken. While this guarantee holds for general F, γ, the value of s_B, and consequently the resulting bound, is difficult to interpret. The following corollary considers the β, α parameterizations of F and γ, respectively, of Section 5.3.2 for better interpretation.

Theorem 5 *Assume that Assumptions 1 and 2 of Section 5.2 hold and that the sampled loss sequences obey the parametric assumptions of Equations 5 and 6. Fix $\delta \in (0,1)$. For any $T \in \mathbb{N}$, let $\hat{\imath}_T$ be the empirically best-performing arm output from* SuccessiveHalving *from the last round k of* Hyperband *of Figure 9 after exhausting a total budget of T from all rounds, then*

$$\nu_{\hat{\imath}_T} - \nu_* \leq c\left(\frac{\overline{\log}(T)^3\overline{\log}(\log(T)/\delta)}{T}\right)^{1/\max\{\alpha,\beta\}}$$

for some constant $c = \exp(O(\max\{\alpha,\beta\}))$ where $\overline{\log}(x) = \log(x)\log\log(x)$.

By a straightforward modification of the proof, one can show that if uniform allocation is used in place of SuccessiveHalving in Hyperband, the uniform allocation version achieves $\nu_{\hat{\imath}_T} - \nu_* \leq c\left(\frac{\log(T)\overline{\log}(\log(T)/\delta)}{T}\right)^{1/(\alpha+\beta)}$. We apply the above theorem to the stochastic infinite-armed bandit setting in the following corollary.

Corollary 6 *[Stochastic Infinite-armed Bandits] For any step k, s in the infinite horizon* Hyperband *algorithm with $n_{k,s}$ arms drawn, consider the setting where the jth pull of the ith arm results in a stochastic loss $Y_{i,j} \in [0,1]$ such that $\mathbb{E}[Y_{i,j}] = \nu_i$ and $\mathbb{P}(\nu_i - \nu_* \leq \epsilon) = c_1^{-1}\epsilon^{\beta}$. If $\ell_j(i) = \frac{1}{j}\sum_{s=1}^{j} Y_{i,s}$ then with probability at least $1 - \delta/2$ we have $\forall k \geq 1, 0 \leq s \leq k, 1 \leq i \leq n_{k,s}, 1 \leq j \leq B_k$,*

$$|\nu_i - \ell_{i,j}| \leq \sqrt{\frac{\log(B_k n_{k,s}/\delta_{k,s})}{2j}} \leq \sqrt{\log(\tfrac{16B_k}{\delta})}\left(\tfrac{2}{j}\right)^{1/2}.$$

Consequently, if after B total pulls we define $\widehat{\nu}_B$ as the mean of the empirically best arm output from the last fully completed round k, then with probability at least $1 - \delta$

$$\widehat{\nu}_B - \nu_* \leq \mathrm{polylog}(B/\delta)\max\{B^{-1/2}, B^{-1/\beta}\}.$$

The result of this corollary matches the anytime result of Section 4.3 of Carpentier and Valko (2015) whose algorithm was built specifically for the case of stochastic arms and the β parameterization of F defined in Eq. (6). Notably, this result also matches the *lower bounds* shown in that work up to poly-logarithmic factors, revealing that Hyperband is nearly tight for this important special case. However, we note that this earlier work has a more careful analysis for the fixed budget setting.

Theorem 7 *Assume that Assumptions 1 and 2 of Section 5.2 hold and that the sampled loss sequences obey the parametric assumptions of Equations 5 and 7. For any $T \in \mathbb{N}$, let $\hat{\imath}_T$ be the empirically best-performing arm output from* SuccessiveHalving *from the last round k of* Hyperband *of Figure 9 after exhausting a total budget of T from all rounds. Fix $\delta \in (0,1)$ and $q \in (1/K, 1)$ and let $z_q = \log(q^{-1})(\Delta_{\lceil \max\{2,qK\}\rceil}^{-\alpha} + \frac{1}{qK}\sum_{i=\lceil \max\{2,qK\}\rceil}^{K} \Delta_i^{-\alpha})$. Once $T = \widetilde{\Omega}\left(z_q \log(z_q)\log(1/\delta)\right)$ total pulls have been made by* Hyperband *we have $\widehat{\nu}_T - \nu_* \leq \Delta_{\lceil \max\{2,qK\}\rceil}$ with probability at least $1 - \delta$ where $\widetilde{\Omega}(\cdot)$ hides $\log\log(\cdot)$ factors.*

Appealing to the stochastic setting of Corollary 6 so that $\alpha = 2$, we conclude that the sample complexity sufficient to identify an arm within the best q proportion with probabiltiy $1 - \delta$, up to log factors, scales like $\log(1/\delta)\log(q^{-1})(\Delta_{\lceil qK\rceil}^{-\alpha} + \frac{1}{qK}\sum_{i=\lceil qK\rceil}^{K}\Delta_i^{-\alpha})$. One may interpret this result as an extension of the distribution-dependent pure-exploration results of Bubeck et al. (2009); but in our case, our bounds hold when the number of pulls is potentially much smaller than the number of arms K. When $q = 1/K$ this implies that the best arm is identified with about $\log(1/\delta)\log(K)\{\Delta_2^{-2} + \sum_{i=2}^{K}\Delta_i^{-2}\}$ which matches known upper bounds Karnin et al. (2013); Jamieson et al. (2014) and lower bounds Kaufmann et al. (2015) up to log factors. Thus, for the stochastic K-armed bandit problem Hyperband recovers many of the known sample complexity results up to log factors.

5.4 Finite Horizon Setting ($R < \infty$)

In this section we analyze the algorithm described in Section 3, i.e. finite horizon Hyperband. We present similar theoretical guarantees as in Section 5.3 for infinite horizon Hyperband, and fortunately much of the analysis will be recycled. We state the finite horizon version of the SuccessiveHalving and Hyperband algorithms in Figure 10.

The finite horizon setting differs in two major ways. First, in each bracket at least one arm will be pulled R times, but no arm will be pulled more than R times. Second, the number of brackets, each representing SuccessiveHalving with a different tradeoff between n and B, is fixed at $\log_\eta(R) + 1$. Hence, since we are sampling sequences randomly i.i.d., increasing B over time would just multiply the number of arms in each bracket by a constant, affecting performance only by a small constant.

Theorem 8 *Fix n arms. Let $\nu_i = \ell_{i,R}$ and assume $\nu_1 \leq \cdots \leq \nu_n$. For any $\epsilon > 0$ let*

$$z_{SH} = \eta(\log_\eta(R) + 1)\Big[n + \sum_{i=1}^{n} \min\left\{R, \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_1}{2}\right\}\right)\right\}\Big]$$

If the Successive Halving algorithm of Figure 10 is run with any budget $B \geq z_{SH}$ then an arm $\hat{\imath}$ is returned that satisfies $\nu_{\hat{\imath}} - \nu_1 \leq \epsilon/2$.

Recall that $\gamma(R) = 0$ in this setting and by definition $\sup_{y \geq 0}\gamma^{-1}(y) \leq R$. Note that Lemma 2 still applies in this setting and just like above we obtain the following corollary.

Corollary 9 *Fix $\delta \in (0,1)$ and $\epsilon \geq 4(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*)$. Let $\mathbf{H}(F,\gamma,n,\delta,\epsilon)$ be as defined in Lemma 2 and $B = \eta\log_\eta(R)(n + \max\{R, \mathbf{H}(F,\gamma,n,\delta,\epsilon)\})$. If the* SuccessiveHalving *algorithm of Figure 10 is run with the specified B and n arm configurations drawn randomly*

SuccessiveHalving (Finite horizon)

input: Budget B, and n arms where $\ell_{i,k}$ denotes the kth loss from the ith arm, maximum size R, $\eta \geq 2$ ($\eta = 3$ by default).

Initialize: $S_0 = [n]$, $s = \min\{t \in \mathbb{N} : nR(t+1)\eta^{-t} \leq B, t \leq \log_\eta(\min\{R, n\})\}$.

For $k = 0, 1, \ldots, s$

Set $n_k = \lfloor n\eta^{-k} \rfloor$, $r_k = \lfloor R\eta^{k-s} \rfloor$

Pull each arm in S_k for r_k times.

Keep the best $\lfloor n\eta^{-(k+1)} \rfloor$ arms in terms of the r_kth observed loss as S_{k+1}.

Output : $\hat{\imath}, \ell_{\hat{\imath},R}$ where $\hat{\imath} = \arg\min_{i \in S_{s+1}} \ell_{i,R}$

Hyperband (Finite horizon)

Input: Budget B, maximum size R, $\eta \geq 2$ ($\eta = 3$ by default)

Initialize: $s_{\max} = \lfloor \log(R)/\log(\eta) \rfloor$

For $k = 1, 2, \ldots$

For $s = s_{\max}, s_{\max} - 1, \ldots, 0$

$B_{k,s} = 2^k$, $n_{k,s} = \lceil \frac{2^k \eta^s}{R(s+1)} \rceil$

$\hat{\imath}_s, \ell_{\hat{\imath}_s,R} \leftarrow$ SuccessiveHalving $(B_{k,s}, n_{k,s}, R, \eta)$

Figure 10: The finite horizon SuccessiveHalving and Hyperband algorithms are inspired by their infinite horizon counterparts of Figure 9 to handle practical constraints. Hyperband calls SuccessiveHalving as a subroutine.

according to F then an arm $\hat{\imath} \in [n]$ is returned such that with probability at least $1 - \delta$ we have $\nu_{\hat{\imath}} - \nu_* \leq \left(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*\right) + \epsilon/2$. In particular, if $B = 4\lceil \log_2(n) \rceil \mathbf{H}(F, \gamma, n, \delta)$ and $\epsilon = 4(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*)$ then $\nu_{\hat{\imath}} - \nu_* \leq 3\left(F^{-1}(\frac{\log(2/\delta)}{n}) - \nu_*\right)$ with probability at least $1 - \delta$.

As in Section 5.3.2 we can apply the α, β parameterization for interpretability, with the added constraint that $\sup_{y \geq 0} \gamma^{-1}(y) \leq R$ so that $\gamma(j) \simeq \mathbf{1}_{j<R} \left(\frac{1}{j}\right)^{1/\alpha}$. Note that the approximate sample complexity of SuccessiveHalving given in Eq. (4) is still valid for the finite horizon algorithm.

Fixing some $\Delta > 0$, $\delta \in (0, 1)$, and applying the parameterization of Eq. (6) we recognize that if $n \simeq \Delta^{-\beta} \log(1/\delta)$ and the sufficient sampling budgets (treating η as an absolute constant) of the uniform allocation (Equation 3) and SuccessiveHalving (Eq. (4)) satisfy

$$\text{Uniform allocation} \qquad B \simeq R\Delta^{-\beta} \log(1/\delta)$$

$$\text{SuccessiveHalving} \qquad B \simeq \log(\Delta^{-1} \log(1/\delta)) \log(1/\delta) \left[R + \Delta^{-\beta} \frac{1 - (\alpha/\beta) R^{1-\beta/\alpha}}{1 - \alpha/\beta} \right]$$

then both also satisfy $\nu_{\hat{\imath}} - \nu_* \lesssim \Delta$ with probability at least $1 - \delta$. Recalling that a larger α means slower convergence and that a larger β means a greater difficulty of sampling a good limit, note that when $\alpha/\beta < 1$ the budget of SuccessiveHalving behaves like $R + \Delta^{-\beta} \log(1/\delta)$ but as $\alpha/\beta \to \infty$ the budget asymptotes to $R\Delta^{-\beta} \log(1/\delta)$.

We can also apply the discrete-CDF parameterization of Eq. (7). For any $q \in (0, 1)$, if $n \simeq q^{-1} \log(1/\delta)$ and the measurement budgets of the uniform allocation (Equation 3) and SuccessiveHalving (Equation 4) satisfy

$$\text{Uniform allocation:} \qquad B \simeq \log(1/\delta) \begin{cases} K \min\left\{R, \max_{j=2,\ldots,K} \Delta_j^{-\alpha}\right\} & \text{if } q = 1/K \\ q^{-1} \min\{R, \Delta_{\lceil qK \rceil}^{-\alpha}\} & \text{if } q > 1/K \end{cases}$$

SuccessiveHalving:

$$B \simeq \log(q^{-1} \log(1/\delta)) \log(1/\delta) \begin{cases} \min\{R, \Delta_2^{-\alpha}\} + \sum_{j=2}^{K} \min\{R, \Delta_j^{-\alpha}\} & \text{if } q = 1/K \\ \min\{R, \Delta_{\lceil qK \rceil}^{-\alpha}\} + \frac{1}{qK} \sum_{j=\lceil qK \rceil}^{K} \min\{R, \Delta_j^{-\alpha}\} & \text{if } q > 1/K \end{cases}$$

then an arm that is in the best q-fraction of arms is returned, i.e. $\hat{\imath}/K \approx q$ and $\nu_{\hat{\imath}} - \nu_* \lesssim \Delta_{\lceil \max\{2, qK\} \rceil}$, with probability at least $1 - \delta$. Once again we observe a stark difference between uniform allocation and SuccessiveHalving, particularly when $\Delta_j^{-\alpha} \ll R$ for many values of $j \in \{1, \ldots, n\}$.

Armed with Corollary 9, all of the discussion of Section 5.3.3 preceding Theorem 5 holds for the finite case ($R < \infty$) as well. Predictably analogous theorems also hold for the finite horizon setting, but their specific forms (with the polylog factors) provide no additional insights beyond the sample complexities sufficient for SuccessiveHalving to succeed, given immediately above.

It is important to note that in the finite horizon setting, for all sufficiently large B (e.g. $B > 3R$) and all distributions F, the budget B of SuccessiveHalving should scale *linearly* with $n \simeq \Delta^{-\beta} \log(1/\delta)$ as $\Delta \to 0$. Contrast this with the infinite horizon setting in which the ratio of B to n can become unbounded based on the values of α, β as $\Delta \to 0$. One consequence of this observation is that in the finite horizon setting it suffices to set B large enough to identify an Δ-good arm with just constant probability, say 1/10, and then repeat SuccessiveHalving m times to boost this constant probability to probability $1 - (\frac{9}{10})^m$. While in this theoretical treatment of Hyperband we grow B over time, in practice we recommend fixing B as a multiple of R as we have done in Section 3. The fixed budget version of finite horizon Hyperband is more suitable for practical application due to the constant time, instead of exponential time, between configurations trained to completion in each outer loop.

6. Conclusion

We conclude by discussing three potential extensions related to parallelizing Hyperband for distributed computing, adjusting for training methods with different convergence rates, and combining Hyperband with non-random sampling methods.

Distributed implementations. Hyperband has the potential to be parallelized since arms are independent and sampled randomly. The most straightforward parallelization scheme is to distribute individual brackets of SuccessiveHalving to different machines. This can be done asynchronously and as machines free up, new brackets can be launched

with a different set of arms. One can also parallelize a single bracket so that each round of SuccessiveHalving runs faster. One drawback of this method is that if R can be computed on one machine, the number of tasks decreases exponentially as arms are whittled down so a more sophisticated job priority queue must be managed. Devising parallel generalizations of Hyperband that efficiently leverage massive distributed clusters while minimizing overhead costs is an interesting avenue for future work.

Adjusting for different convergence rates. A second open challenge involves generalizing the ideas behind Hyperband to settings where configurations have drastically differing convergence rates. Configurations can have different convergence rates if they have hyperparameters that impact convergence (e.g., learning rate decay for SGD or neural networks with differing numbers of layers or hidden units), and/or if they correspond to different model families (e.g., deep networks versus decision trees). The core issue arises when configurations with drastically slower convergence rates ultimately result in better models. To address these issues, we should be able to adjust the resources allocated to each configuration so that a fair comparison can be made at the time of elimination.

Incorporating non-random sampling. Finally, Hyperband can benefit from different sampling schemes aside from simple random search. Quasi-random methods like Sobol or latin hypercube which were studied in Bergstra and Bengio (2012) may improve the performance of Hyperband by giving better coverage of the search space. Alternatively, meta-learning can be used to define intelligent priors informed by previous experimentation (Feurer et al., 2015). Finally, as mentioned in Section 2, exploring ways to combine Hyperband with adaptive configuration selection strategies is a very promising future direction.

Appendix A. Additional Experimental Results

Additional details for experiments presented in Section 3 and 4 are provided below.

A.1 LeNet Experiment

The search space for the LeNet example discussed in Section 3.3 is shown in Table 2.

Hyperparameter	Scale	Min	Max
Learning Rate	log	1e-3	1e-1
Batch size	log	1e1	1e3
Layer-2 Num Kernels (k2)	linear	10	60
Layer-1 Num Kernels (k1)	linear	5	k2

Table 2: Hyperparameter space for the LeNet application of Section 3.3. Note that the number of kernels in Layer-1 is upper bounded by the number of kernels in Layer-2.

A.2 Experiments Using Alex Krizhevsky's CNN Architecture

For the experiments discussed in Section 4.1, the exact architecture used is the 18% model provided on cuda-convnet for CIFAR-10.[14]

Search Space: The search space used for the experiments is shown in Table 3. The learning rate reductions hyperparameter indicates how many times the learning rate was reduced by a factor of 10 over the maximum iteration window. For example, on CIFAR-10, which has a maximum iteration of 30,000, a learning rate reduction of 2 corresponds to reducing the learning every 10,000 iterations, for a total of 2 reductions over the 30,000 iteration window. All hyperparameters, with the exception of the learning rate decay reduction, overlap with those in Snoek et al. (2012). Two hyperparameters in Snoek et al. (2012) were excluded from our experiments: (1) the width of the response normalization layer was excluded due to limitations of the Caffe framework and (2) the number of epochs was excluded because it is incompatible with dynamic resource allocation.

Data Splits: For CIFAR-10, the training (40,000 instances) and validation (10,000 instances) sets were sampled from data batches 1-5 with balanced classes. The original test set (10,000 instances) was used for testing. For MRBI, the training (10,000 instances) and validation (2,000 instances) sets were sampled from the original training set with balanced classes. The original test set (50,000 instances) was used for testing. Lastly, for SVHN, the train, validation, and test splits were created using the same procedure as that in Sermanet et al. (2012).

Comparison with Early-Stopping: Domhan et al. (2015) proposed an early-stopping method for neural networks and combined it with SMAC to speed up hyperparameter optimization. Their method stops training a configuration if the probability of the configuration beating the current best is below a specified threshold. This probability is estimated by extrapolating learning curves fit to the intermediate validation error losses of a configuration.

14. The model specification is available at `http://code.google.com/p/cuda-convnet/`.

Hyperparameter	Scale	Min	Max
Learning Parameters			
Initial Learning Rate	log	$5 * 10^{-5}$	5
Conv1 L_2 Penalty	log	$5 * 10^{-5}$	5
Conv2 L_2 Penalty	log	$5 * 10^{-5}$	5
Conv3 L_2 Penalty	log	$5 * 10^{-5}$	5
FC4 L_2 Penalty	log	$5 * 10^{-3}$	500
Learning Rate Reductions	integer	0	3
Local Response Normalization			
Scale	log	$5 * 10^{-6}$	5
Power	linear	0.01	3

Table 3: Hyperparameters and associated ranges for the three-layer convolutional network.

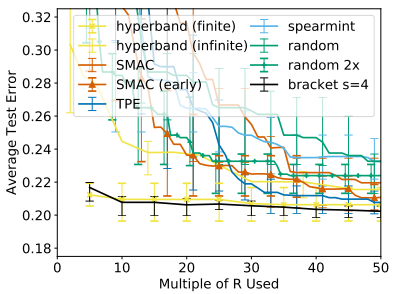
If a configuration is terminated early, the predicted terminal value from the estimated learning curves is used as the validation error passed to the hyperparameter optimization algorithm. Hence, if the learning curve fit is poor, it could impact the performance of the configuration selection algorithm. While this approach is heuristic in nature, it could work well in practice so we compare Hyperband to SMAC with early termination (labeled SMAC (early) in Figure 11). We used the conservative termination criterion with default parameters and recorded the validation loss every 400 iterations and evaluated the termination criterion 3 times within the training period (every 8k iterations for CIFAR-10 and MRBI and every 16k iterations for SVHN).[15] Comparing the performance by the number of total iterations as mulitple of R is conservative because it does not account for the time spent fitting the learning curve in order to check the termination criterion.

A.3 117 Data Sets Experiment

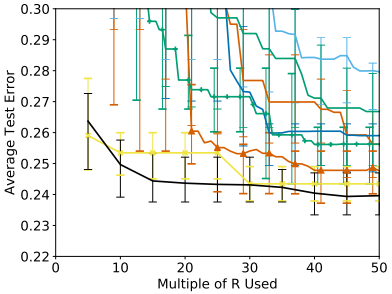
For the experiments discussed in Section 4.2.1, we followed Feurer et al. (2015) and imposed a 3GB memory limit, a 6-minute timeout for each hyperparameter configuration and a one-hour time window to evaluate each searcher on each data set. Moreover, we evaluated the performance of each searcher by aggregating results across all data sets and reporting the average rank of each method. Specifically, the hour training window is divided up into 30 second intervals and, at each time point, the model with the best validation error at that time is used in the calculation of the average error across all trials for each (data set-searcher) pair. Then, the performance of each searcher is ranked by data set and averaged across all data sets. All experiments were performed on Google Cloud Compute n1-standard-1 instances in us-central1-f region with 1 CPU and 3.75GB of memory.

Data Splits: Feurer et al. (2015) split each data set into 2/3 training and 1/3 test set, whereas we introduce a validation set to avoid overfitting to the test data. We also used 2/3 of the data for training, but split the rest of the data into two equally sized validation and test sets. We reported results on both the validation and test data. Moreover, we performed

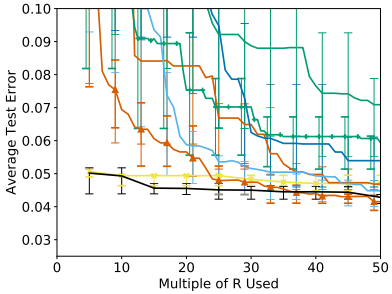
15. We used the code provided at https://github.com/automl/pylearningcurvepredictor.



(a) CIFAR-10



(b) MRBI



(c) SVHN

Figure 11: Average test error across 10 trials is shown in all plots. Error bars indicate the top and bottom quartiles of the test error corresponding to the model with the best validation error

20 trials of each (data set-searcher) pair, and as in Feurer et al. (2015) we kept the same data splits across trials, while using a different random seed for each searcher in each trial.

Shortcomings of the Experimental Setup: The benchmark contains a large variety of training set sizes and feature dimensions[16] resulting in random search being able to test 600 configurations on some data sets but just dozens on others. Hyperband was designed under the implicit assumption that computation scaled at least linearly with the data set size. For very small data sets that are trained in seconds, the initialization overheads dominate the computation and subsampling provides no computational benefit. In addition, many of the classifiers and preprocessing methods under consideration return memory errors as they require storage quadratic in the number of features (e.g., covariance matrix) or the number of observations (e.g., kernel methods). These errors usually happen immediately (thus wasting little time); however, they often occur on the full data set and not on subsampled data sets. A searcher like Hyperband that uses a subsampled data set could spend significant time training on a subsample only to error out when attempting to train it on the full data set.

A.4 Kernel Classification Experiments

Table 4 shows the hyperparameters and associated ranges considered in the kernel least squares classification experiment discussed in Section 4.2.2.

Hyperparameter	Type	Values
preprocessor	Categorical	min/max, standardize, normalize
kernel	Categorical	rbf, polynomial, sigmoid
C	Continuous	log $[10^{-3}, 10^{5}]$
gamma	Continuous	log $[10^{-5}, 10]$
degree	if kernel=poly	integer [2, 5]
coef0	if kernel=poly, sigmoid	uniform [-1.0, 1.0]

Table 4: Hyperparameter space for kernel regularized least squares classification problem discussed in Section 4.2.2.

The cost term C is divided by the number of samples so that the tradeoff between the squared error and the L_2 penalty would remain constant as the resource increased (squared error is summed across observations and not averaged). The regularization term λ is equal to the inverse of the scaled cost term C. Additionally, the average test error with the top and bottom quartiles across 10 trials are show in Figure 12.

Table 5 shows the hyperparameters and associated ranges considered in the random features kernel approximation classification experiment discussed in Section 4.3. The regularization term λ is divided by the number of features so that the tradeoff between the squared error and the L_2 penalty would remain constant as the resource increased. Additionally, the average test error with the top and bottom quartiles across 10 trials are show in Figure 13.

16. Training set size ranges from 670 to 73,962 observations, and number of features ranges from 1 to 10,935.

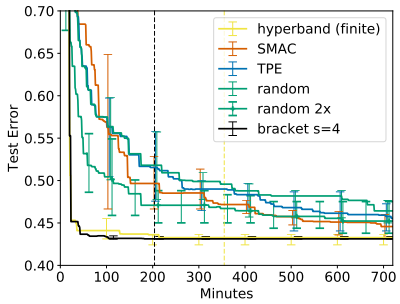


Figure 12: Average test error of the best kernel regularized least square classification model found by each searcher on CIFAR-10. The color coded dashed lines indicate when the last trial of a given searcher finished. Error bars correspond to the top and bottom quartiles of the test error across 10 trials.

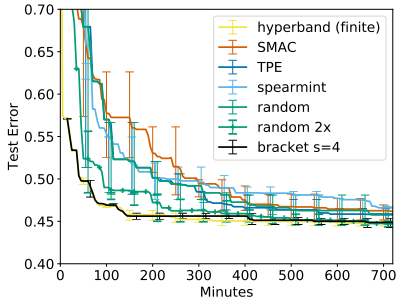

Figure 13: Average test error of the best random features model found by each searcher on CIFAR-10. The test error for Hyperband and bracket $s = 4$ are calculated in every evaluation instead of at the end of a bracket. Error bars correspond to the top and bottom quartiles of the test error across 10 trials.

Hyperparameter	Type	Values
preprocessor	Categorical	none, min/max, standardize, normalize
λ	Continuous	$\log\,[10^{-3}, 10^{5}]$
gamma	Continuous	$\log\,[10^{-5}, 10]$

Table 5: Hyperparameter space for random feature kernel approximation classification problem discussed in Section 4.3.

Appendix B. Proofs

In this section, we provide proofs for the theorems presented in Section 5.

B.1 Proof of Theorem 1

Proof First, we verify that the algorithm never takes a total number of samples that exceeds the budget B:

$$\sum_{k=0}^{\lceil \log_2(n)\rceil - 1} |S_k| \left\lfloor \frac{B}{|S_k|\lceil \log(n)\rceil} \right\rfloor \leq \sum_{k=0}^{\lceil \log_2(n)\rceil - 1} \frac{B}{\lceil \log(n)\rceil} \leq B\,.$$

For notational ease, let $\ell_{i,j} := \ell_j(X_i)$. Again, for each $i \in [n] := \{1, \ldots, n\}$ we assume the limit $\lim_{k\to\infty} \ell_{i,k}$ exists and is equal to ν_i. As a reminder, $\gamma : \mathbb{N} \to \mathbb{R}$ is defined as the pointwise smallest, monotonically decreasing function satisfying

$$\max_i |\ell_{i,j} - \nu_i| \leq \gamma(j)\ , \quad \forall j \in \mathbb{N}. \tag{8}$$

Note γ is guaranteed to exist by the existence of ν_i and bounds the deviation from the limit value as the sequence of iterates j increases.

Without loss of generality, order the terminal losses so that $\nu_1 \leq \nu_2 \leq \cdots \leq \nu_n$. Assume that $B \geq z_{SH}$. Then we have for each round k

$$\begin{aligned}
r_k &\geq \frac{B}{|S_k|\lceil \log_2(n)\rceil} - 1 \\
&\geq \frac{2}{|S_k|} \max_{i=2,\ldots,n} i\left(1 + \gamma^{-1}\big(\max\big\{\frac{\epsilon}{4}, \frac{\nu_i - \nu_1}{2}\big\}\big)\right) - 1 \\
&\geq \frac{2}{|S_k|}\left(\lfloor |S_k|/2\rfloor + 1\right)\left(1 + \gamma^{-1}\big(\max\big\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big\}\big)\right) - 1 \\
&\geq \left(1 + \gamma^{-1}\big(\max\big\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big\}\big)\right) - 1 \\
&= \gamma^{-1}\big(\max\big\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big\}\big),
\end{aligned}$$

where the fourth line follows from $\lfloor |S_k|/2\rfloor \geq |S_k|/2 - 1$.

First we show that $\ell_{i,t} - \ell_{1,t} > 0$ for all $t \geq \tau_i := \gamma^{-1}\big(\frac{\nu_i - \nu_1}{2}\big)$. Given the definition of γ, we have for all $i \in [n]$ that $|\ell_{i,t} - \nu_i| \leq \gamma(t) \leq \frac{\nu_i - \nu_1}{2}$ where the last inequality holds for $t \geq \tau_i$. Thus, for $t \geq \tau_i$ we have

$$\begin{aligned}
\ell_{i,t} - \ell_{1,t} &= \ell_{i,t} - \nu_i + \nu_i - \nu_1 + \nu_1 - \ell_{1,t} \\
&= \ell_{i,t} - \nu_i - (\ell_{1,t} - \nu_1) + \nu_i - \nu_1 \\
&\geq -2\gamma(t) + \nu_i - \nu_1 \\
&\geq -2\frac{\nu_i - \nu_1}{2} + \nu_i - \nu_1 \\
&= 0.
\end{aligned}$$

Under this scenario, we will eliminate arm i before arm 1 since on each round the arms are sorted by their empirical losses and the top half are discarded. Note that by the assumption the ν_i limits are non-decreasing in i so that the τ_i values are non-increasing in i.

Fix a round k and assume $1 \in S_k$ (note, $1 \in S_0$). The above calculation shows that

$$t \geq \tau_i \implies \ell_{i,t} \geq \ell_{1,t}. \tag{9}$$

Consequently,

$$\begin{aligned}
\{1 \in S_k,\ \ 1 \notin S_{k+1}\} &\iff \left\{\sum_{i\in S_k} \mathbf{1}\{\ell_{i,r_k} < \ell_{1,r_k}\} \geq \lfloor |S_k|/2\rfloor\right\} \\
&\implies \left\{\sum_{i\in S_k} \mathbf{1}\{r_k < \tau_i\} \geq \lfloor |S_k|/2\rfloor\right\} \\
&\implies \left\{\sum_{i=2}^{\lfloor |S_k|/2\rfloor+1} \mathbf{1}\{r_k < \tau_i\} \geq \lfloor |S_k|/2\rfloor\right\} \\
&\iff \left\{r_k < \tau_{\lfloor |S_k|/2\rfloor+1}\right\}.
\end{aligned}$$

where the first line follows by the definition of the algorithm, the second by Equation 9, and the third by τ_i being non-increasing (for all $i < j$ we have $\tau_i \geq \tau_j$ and consequently, $\mathbf{1}\{r_k < \tau_i\} \geq \mathbf{1}\{r_k < \tau_j\}$ so the *first* indicators of the sum not including 1 would be on before any other i's in $S_k \subset [n]$ sprinkled throughout $[n]$). This implies

$$\{1 \in S_k,\ \ r_k \geq \tau_{\lfloor |S_k|/2\rfloor+1}\} \implies \{1 \in S_{k+1}\}. \tag{10}$$

Recalling that $r_k \geq \gamma^{-1}\big(\max\big\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big\}\big)$ and $\tau_{\lfloor |S_k|/2\rfloor+1} = \gamma^{-1}\big(\frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big)$, we examine the following three exhaustive cases:

- **Case 1:** $\frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2} \geq \frac{\epsilon}{4}$ and $1 \in S_k$

  In this case, $r_k \geq \gamma^{-1}\big(\frac{\nu_{\lfloor |S_k|/2\rfloor+1} - \nu_1}{2}\big) = \tau_{\lfloor |S_k|/2\rfloor+1}$. By Equation 10 we have that $1 \in S_{k+1}$ since $1 \in S_k$.

- **Case 2:** $\frac{\nu_{\lfloor |S_k|/2 \rfloor + 1} - \nu_1}{2} < \frac{\epsilon}{4}$ and $1 \in S_k$

  In this case $r_k \geq \gamma^{-1}\left(\frac{\epsilon}{4}\right)$ but $\gamma^{-1}\left(\frac{\epsilon}{4}\right) < \tau_{\lfloor |S_k|/2 \rfloor + 1}$. Equation 10 suggests that it may be possible for $1 \in S_k$ but $1 \notin S_{k+1}$. On the good event that $1 \in S_{k+1}$, the algorithm continues and on the next round either case 1 or case 2 could be true. So assume $1 \notin S_{k+1}$. Here we show that $\{1 \in S_k, \quad 1 \notin S_{k+1}\} \implies \max_{i \in S_{k+1}} \nu_i \leq \nu_1 + \epsilon/2$. Because $1 \in S_0$, this guarantees that SuccessiveHalving either exits with arm $\widehat{i} = 1$ or some arm $\widehat{i}$ satisfying $\nu_{\widehat{i}} \leq \nu_1 + \epsilon/2$.

  Let $p = \min\{i \in [n] : \frac{\nu_i - \nu_1}{2} \geq \frac{\epsilon}{4}\}$. Note that $p > \lfloor |S_k|/2 \rfloor + 1$ by the criterion of the case and

  $$r_k \geq \gamma^{-1}\left(\frac{\epsilon}{4}\right) \geq \gamma^{-1}\left(\frac{\nu_i - \nu_1}{2}\right) = \tau_i, \quad \forall i \geq p.$$

  Thus, by Equation 9 ($t \geq \tau_i \implies \ell_{i,t} \geq \ell_{1,t}$) we have that arms $i \geq p$ would always have $\ell_{i,r_k} \geq \ell_{1,r_k}$ and be eliminated before or at the same time as arm 1, presuming $1 \in S_k$. In conclusion, if arm 1 is eliminated so that $1 \in S_k$ but $1 \notin S_{k+1}$ then $\max_{i \in S_{k+1}} \nu_i \leq \max_{i<p} \nu_i < \nu_1 + \epsilon/2$ by the definition of p.

- **Case 3:** $1 \notin S_k$

  Since $1 \in S_0$, there exists some $r < k$ such that $1 \in S_r$ and $1 \notin S_{r+1}$. For this r, only case 2 is possible since case 1 would proliferate $1 \in S_{r+1}$. However, under case 2, if $1 \notin S_{r+1}$ then $\max_{i \in S_{r+1}} \nu_i \leq \nu_1 + \epsilon/2$.

Because $1 \in S_0$, we either have that 1 remains in S_k (possibly alternating between cases 1 and 2) for all k until the algorithm exits with the best arm 1, or there exists some k such that case 3 is true and the algorithm exits with an arm $\widehat{i}$ such that $\nu_{\widehat{i}} \leq \nu_1 + \epsilon/2$. The proof is complete by noting that

$$|\ell_{\widehat{i}, \lfloor \frac{B/2}{\lceil \log_2(n) \rceil} \rfloor} - \nu_1| \leq |\ell_{\widehat{i}, \lfloor \frac{B/2}{\lceil \log_2(n) \rceil} \rfloor} - \nu_{\widehat{i}}| + |\nu_{\widehat{i}} - \nu_1| \leq \epsilon/4 + \epsilon/2 \leq \epsilon$$

by the triangle inequality and because $B \geq 2\lceil \log_2(n) \rceil \gamma^{-1}(\epsilon/4)$ by assumption.

The second, looser, but perhaps more interpretable form of z_{SH} follows from the fact that $\gamma^{-1}(x)$ is non-increasing in x so that

$$\max_{i=2,\ldots,n} i\,\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_1}{2}\right\}\right) \leq \sum_{i=1,\ldots,n} \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_1}{2}\right\}\right).$$

■

B.2 Proof of Lemma 2

Proof Let $p_n = \frac{\log(2/\delta)}{n}$, $M = \gamma^{-1}\left(\frac{\epsilon}{16}\right)$, and $\mu = \mathbb{E}[\min\{M, \gamma^{-1}\left(\frac{\nu_i - \nu_*}{4}\right)\}]$. Define the events

$$\xi_1 = \{\nu_1 \leq F^{-1}(p_n)\}$$
$$\xi_2 = \left\{\sum_{i=1}^{n} \min\{M, \gamma^{-1}\left(\tfrac{\nu_i - \nu_*}{4}\right)\} \leq n\mu + \sqrt{2n\mu M \log(2/\delta)} + \tfrac{2}{3} M \log(2/\delta)\right\}$$

Note that $\mathbb{P}(\xi_1^c) = \mathbb{P}(\min_{i=1,\ldots,n} \nu_i > F^{-1}(p_n)) = (1-p_n)^n \leq \exp(-np_n) \leq \frac{\delta}{2}$. Moreover, $\mathbb{P}(\xi_2^c) \leq \frac{\delta}{2}$ by Bernstein's inequality since

$$\mathbb{E}\left[\min\{M, \gamma^{-1}\left(\tfrac{\nu_i - \nu_*}{4}\right)\}^2\right] \leq \mathbb{E}\left[M \min\{M, \gamma^{-1}\left(\tfrac{\nu_i - \nu_*}{4}\right)\}\right] = M\mu.$$

Thus, $\mathbb{P}(\xi_1 \cap \xi_2) \geq 1 - \delta$ so in what follows assume these events hold.

First we show that if $\nu_* \leq \nu_1 \leq F^{-1}(p_n)$, which we will refer to as equation $(*)$, then $\max\left\{\frac{\epsilon}{4}, \frac{\nu_i - \nu_1}{2}\right\} \geq \max\left\{\frac{\epsilon}{4}, \frac{\nu_i - \nu_*}{4}\right\}$.

Case 1: $\frac{\epsilon}{4} \leq \frac{\nu_i - \nu_1}{2}$ and $\epsilon \geq 4(F^{-1}(p_n) - \nu_*)$.

$$\frac{\nu_i - \nu_1}{2} \overset{(*)}{\geq} \frac{\nu_i - \nu_* + \nu_* - F^{-1}(p_n)}{2} = \frac{\nu_i - \nu_*}{4} + \frac{\nu_i - \nu_*}{4} - \frac{F^{-1}(p_n) - \nu_*}{2} \overset{(*)}{\geq} \frac{\nu_i - \nu_*}{4} + \frac{\nu_i - \nu_1}{4} - \frac{F^{-1}(p_n) - \nu_*}{2} \overset{\text{Case 1}}{\geq} \frac{\nu_i - \nu_*}{4}.$$

Case 2: $\frac{\epsilon}{4} > \frac{\nu_i - \nu_1}{2}$ and $\epsilon \geq 4(F^{-1}(p_n) - \nu_*)$.

$$\frac{\nu_i - \nu_*}{4} = \frac{\nu_i - \nu_1}{4} + \frac{\nu_1 - \nu_*}{4} \overset{\text{Case 2}}{<} \frac{\epsilon}{8} + \frac{\nu_1 - \nu_*}{4} \overset{(*)}{\leq} \frac{\epsilon}{8} + \frac{F^{-1}(p_n) - \nu_*}{4} \overset{\text{Case 2}}{<} \frac{\epsilon}{4}$$

which shows the desired result.

Consequently, for any $\epsilon \geq 4(F^{-1}(p_n) - \nu_*)$ we have

$$\begin{aligned}
\sum_{i=1}^{n} \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_1}{2}\right\}\right) &\leq \sum_{i=1}^{n} \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_*}{4}\right\}\right) \\
&\leq \sum_{i=1}^{n} \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{16}, \tfrac{\nu_i - \nu_*}{4}\right\}\right) \\
&= \sum_{i=1}^{n} \min\{M, \gamma^{-1}\left(\tfrac{\nu_i - \nu_*}{4}\right)\} \\
&\leq n\mu + \sqrt{2n\mu M \log(1/\delta)} + \tfrac{2}{3} M \log(1/\delta) \\
&\leq \left(\sqrt{n\mu} + \sqrt{\tfrac{2}{3} M \log(2/\delta)}\right)^2 \leq 2n\mu + \tfrac{4}{3} M \log(2/\delta).
\end{aligned}$$

A direct computation yields

$$\begin{aligned}
\mu &= \mathbb{E}[\min\{M, \gamma^{-1}\left(\tfrac{\nu_i - \nu_*}{4}\right)\}] \\
&= \mathbb{E}[\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{16}, \tfrac{\nu_i - \nu_*}{4}\right\}\right)] \\
&= \gamma^{-1}\left(\tfrac{\epsilon}{16}\right) F(\nu_* + \epsilon/4) + \int_{\nu_* + \epsilon/4}^{\infty} \gamma^{-1}(\tfrac{t - \nu_*}{4}) dF(t)
\end{aligned}$$

so that

$$\begin{aligned}
&\sum_{i=1}^{n} \gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i - \nu_1}{2}\right\}\right) \leq 2n\mu + \tfrac{4}{3} M \log(2/\delta) \\
&\quad = 2n \int_{\nu_* + \epsilon/4}^{\infty} \gamma^{-1}(\tfrac{t - \nu_*}{4}) dF(t) + \left(\tfrac{4}{3} \log(2/\delta) + 2nF(\nu_* + \epsilon/4)\right) \gamma^{-1}\left(\tfrac{\epsilon}{16}\right)
\end{aligned}$$

which completes the proof. ■

B.3 Proof of Proposition 4

We break the proposition up into upper and lower bounds and prove them seperately.

B.4 Uniform Allocation

Proposition 10 *Suppose we draw n random configurations from F, train each with a budget of j,*[17] *and let $\hat{\imath} = \arg\min_{i=1,\dots,n} \ell_j(X_i)$. Let $\nu_i = \ell_*(X_i)$ and without loss of generality assume $\nu_1 \leq \ldots \leq \nu_n$. If*

$$B \geq n\gamma^{-1}\left(\tfrac{1}{2}(F^{-1}(\tfrac{\log(1/\delta)}{n}) - \nu_*)\right) \tag{11}$$

then with probability at least $1-\delta$ we have $\nu_{\hat{\imath}} - \nu_* \leq 2\left(F^{-1}\left(\frac{\log(1/\delta)}{n}\right) - \nu_*\right)$.

Proof Note that if we draw n random configurations from F and $i_* = \arg\min_{i=1,\dots,n} \ell_*(X_i)$ then

$$\begin{aligned}\mathbb{P}\left(\ell_*(X_{i_*}) - \nu_* \leq \epsilon\right) &= \mathbb{P}\Big(\bigcup_{i=1}^{n}\{\ell_*(X_i) - \nu_* \leq \epsilon\}\Big) \\ &= 1 - (1 - F(\nu_* + \epsilon))^n \geq 1 - e^{-nF(\nu_*+\epsilon)}\,,\end{aligned}$$

which is equivalent to saying that with probability at least $1-\delta$, $\ell_*(X_{i_*}) - \nu_* \leq F^{-1}(\log(1/\delta)/n) - \nu_*$. Furthermore, if each configuration is trained for j iterations then with probability at least $1-\delta$

$$\begin{aligned}&\ell_*(X_i) - \nu_* \leq \ell_j(X_i) - \nu_* + \gamma(j) \leq \ell_j(X_{i_*}) - \nu_* + \gamma(j) \\ &\leq \ell_*(X_{i_*}) - \nu_* + 2\gamma(j) \leq F^{-1}\left(\tfrac{\log(1/\delta)}{n}\right) - \nu_* + 2\gamma(j).\end{aligned}$$

If our measurement budget B is constrained so that $B = nj$ then solving for j in terms of B and n yields the result. ■

The following proposition demonstrates that the upper bound on the error of the uniform allocation strategy in Proposition 4 is in fact tight. That is, for any distribution F and function γ there exists a loss sequence that requires the budget described in Eq. (3) in order to avoid a loss of more than ϵ with high probability.

Proposition 11 *Fix any $\delta \in (0,1)$ and $n \in \mathbb{N}$. For any $c \in (0,1]$, let $\mathcal{F}_c$ denote the space of continuous cumulative distribution functions F satisfying*[18] $\inf_{x\in[\nu_*,1-\nu_*]} \inf_{\Delta\in[0,1-x]} \frac{F(x+\Delta)-F(x+\Delta/2)}{F(x+\Delta)-F(x)} \geq c$. *And let Γ denote the space of monotonically decreasing functions over $\mathbb{N}$. For any $F \in \mathcal{F}_c$ and $\gamma \in \Gamma$ there exists a probability distribution μ over $\mathcal{X}$ and a sequence of functions $\ell_j : \mathcal{X} \to \mathbb{R}$ $\forall j \in \mathbb{N}$ with $\ell_* := \lim_{j\to\infty} \ell_j$, $\nu_* = \inf_{x\in\mathcal{X}} \ell_*(x)$ such that $\sup_{x\in\mathcal{X}} |\ell_j(x) - \ell_*(x)| \leq \gamma(j)$ and $\mathbb{P}_\mu(\ell_*(X) - \nu_* \leq \epsilon) = F(\epsilon)$. Moreover, if n configurations $X_1, \dots, X_n$ are drawn from μ and $\hat{\imath} = \arg\min_{i\in1,\dots,n} \ell_{B/n}(X_i)$ then with probability at least δ*

$$\ell_*(X_{\hat{\imath}}) - \nu_* \geq 2(F^{-1}(\tfrac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)$$

whenever $B \leq n\gamma^{-1}\left(2(F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)\right)$.

Proof Let $\mathcal{X} = [0,1]$, $\ell_*(x) = F^{-1}(x)$, and μ be the uniform distribution over $[0,1]$. Define $\widehat{\nu} = F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)})$ and set

$$\ell_j(x) = \begin{cases}\widehat{\nu} + \frac{1}{2}\gamma(j) + (\widehat{\nu} + \frac{1}{2}\gamma(j) - \ell_*(x)) & \text{if } |\widehat{\nu} + \frac{1}{2}\gamma(j) - \ell_*(x)| \leq \frac{1}{2}\gamma(j) \\ \ell_*(x) & \text{otherwise.}\end{cases}$$

Essentially, if $\ell_*(x)$ is within $\frac{1}{2}\gamma(j)$ of $\widehat{\nu} + \frac{1}{2}\gamma(j)$ then we set $\ell_j(x)$ equal to $\ell_*(x)$ reflected across the value $2\widehat{\nu} + \gamma(j)$. Clearly, $|\ell_j(x) - \ell_*(x)| \leq \gamma(j)$ for all $x \in \mathcal{X}$.

Since each $\ell_*(X_i)$ is distributed according to F, we have

$$\mathbb{P}\Big(\bigcap_{i=1}^{n}\{\ell_*(X_i) - \nu_* \geq \epsilon\}\Big) = (1 - F(\nu_* + \epsilon))^n \geq e^{-nF(\nu_*+\epsilon)/(1-F(\nu_*+\epsilon))}\,.$$

Setting the right-hand-side greater than or equal to δ/c and solving for ϵ, we find $\nu_* + \epsilon \geq F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) = \widehat{\nu}$.

Define $I_0 = [\nu_*, \widehat{\nu})$, $I_1 = [\widehat{\nu}, \widehat{\nu} + \frac{1}{2}\gamma(B/n))$ and $I_2 = [\widehat{\nu} + \frac{1}{2}\gamma(B/n), \widehat{\nu} + \gamma(B/n)]$. Furthermore, for $j \in \{0,1,2\}$ define $N_j = \sum_{i=1}^{n} \mathbf{1}_{\ell_*(X_i)\in I_j}$. Given $N_0 = 0$ (which occurs with probability at least δ/c), if $N_1 = 0$ then $\ell_*(X_i) - \nu_* \geq F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) + \frac{1}{2}\gamma(B/n)$ and the claim is true.

Below we will show that if $N_2 > 0$ whenever $N_1 > 0$ then the claim is also true. We now show that this happens with at least probability c whenever $N_1 + N_2 = m$ for any $m > 0$. Observe that

$$\begin{aligned}\mathbb{P}(N_2 > 0 | N_1 + N_2 = m) &= 1 - \mathbb{P}(N_2 = 0 | N_1 + N_2 = m) \\ &= 1 - (1 - \mathbb{P}(\nu_i \in I_2 | \nu_i \in I_1 \cup I_2))^m \geq 1 - (1-c)^m \geq c\end{aligned}$$

since

$$\mathbb{P}(\nu_i \in I_2 | \nu_i \in I_1 \cup I_2) = \frac{\mathbb{P}(\nu_i \in I_2)}{\mathbb{P}(\nu_i \in I_1 \cup I_2)} = \frac{\mathbb{P}(\nu_i \in [\widehat{\nu} + \frac{1}{2}\gamma, \widehat{\nu} + \gamma])}{\mathbb{P}(\nu_i \in [\widehat{\nu}, \widehat{\nu} + \gamma])} = \frac{F(\widehat{\nu} + \gamma) - F(\widehat{\nu} + \frac{1}{2}\gamma)}{F(\widehat{\nu} + \gamma) - F(\widehat{\nu})} \geq c\,.$$

Thus, the probability of the event that $N_0 = 0$ and $N_2 > 0$ whenever $N_1 > 0$ occurs with probability at least $\delta/c \cdot c = \delta$, so assume this is the case in what follows.

Since $N_0 = 0$, for all $j \in \mathbb{N}$, each X_i must fall into one of three cases:

1. $\ell_*(X_i) > \widehat{\nu} + \gamma(j) \iff \ell_j(X_i) > \widehat{\nu} + \gamma(j)$
2. $\widehat{\nu} \leq \ell_*(X_i) < \widehat{\nu} + \frac{1}{2}\gamma(j) \iff \widehat{\nu} + \frac{1}{2}\gamma(j) < \ell_j(X_i) \leq \widehat{\nu} + \gamma(j)$

17. Here j can be bounded (finite horizon) or unbounded (infinite horizon).

18. Note that this condition is met whenever F is convex. Moreover, if $F(\nu_* + \epsilon) = c_1^{-1}\epsilon^\beta$ then it is easy to verify that $c = 1 - 2^{-\beta} \geq \frac{1}{2}\min\{1, \beta\}$.

3. $\widehat{\nu} + \frac{1}{2}\gamma(j) \le \ell_*(X_i) \le \widehat{\nu} + \gamma(j) \iff \widehat{\nu} \le \ell_j(X_i) \le \widehat{\nu} + \frac{1}{2}\gamma(j)$

The first case holds since within that regime we have $\ell_j(x) = \ell_*(x)$, while the last two cases hold since they consider the regime where $\ell_j(x) = 2\widehat{\nu} + \gamma(j) - \ell_*(x)$. Thus, for any i such that $\ell_*(X_i) \in I_2$ it must be the case that $\ell_j(X_i) \in I_1$ and vice versa. Because $N_2 \ge N_1 > 0$, we conclude that if $\hat{\imath} = \arg\min_i \ell_{B/n}(X_i)$ then $\ell_{B/n}(X_{\hat{\imath}}) \in I_1$ and $\ell_*(X_{\hat{\imath}}) \in I_2$. That is, $\nu_{\hat{\imath}} - \nu_* \ge \widehat{\nu} - \nu_* + \frac{1}{2}\gamma(j) = F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_* + \frac{1}{2}\gamma(j)$. So if we wish $\nu_{\hat{\imath}} - \nu_* \le 2(F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)$ with probability at least δ then we require $B/n = j \ge \gamma^{-1}\left(2(F^{-1}(\frac{\log(c/\delta)}{n+\log(c/\delta)}) - \nu_*)\right)$. ■

B.5 Proof of Theorem 5

Proof Step 1: Simplify $\mathbf{H}(F,\gamma,n,\delta)$. We begin by simplifying $\mathbf{H}(F,\gamma,n,\delta)$ in terms of just n,δ,α,β. In what follows, we use a constant c that may differ from one inequality to the next but remains an absolute constant that depends on α,β only. Let $p_n = \frac{\log(2/\delta)}{n}$ so that

$$\gamma^{-1}\left(\tfrac{F^{-1}(p_n)-\nu_*}{4}\right) \le c\left(F^{-1}(p_n) - \nu_*\right)^{-\alpha} \le c\, p_n^{-\alpha/\beta}$$

and

$$\int_{p_n}^1 \gamma^{-1}(\tfrac{F^{-1}(t)-\nu_*}{4})dt \le c\int_{p_n}^1 t^{-\alpha/\beta}dt \le \begin{cases} c\log(1/p_n) & \text{if } \alpha=\beta \\ c\frac{1-p_n^{1-\alpha/\beta}}{1-\alpha/\beta} & \text{if } \alpha\neq\beta. \end{cases}$$

We conclude that

$$\begin{aligned}\mathbf{H}(F,\gamma,n,\delta) &= 2n\int_{p_n}^1 \gamma^{-1}(\tfrac{F^{-1}(t)-\nu_*}{4})dt + \tfrac{10}{3}\log(2/\delta)\gamma^{-1}\left(\tfrac{F^{-1}(p_n)-\nu_*}{4}\right) \\ &\le c p_n^{-\alpha/\beta}\log(1/\delta) + cn\begin{cases}\log(1/p_n) & \text{if } \alpha=\beta \\ \frac{1-p_n^{1-\alpha/\beta}}{1-\alpha/\beta} & \text{if } \alpha\neq\beta.\end{cases}\end{aligned}$$

Step 2: Solve for $(B_{k,l}, n_{k,l})$ in terms of Δ. Fix $\Delta > 0$. Our strategy is to describe $n_{k,l}$ in terms of Δ. In particular, parameterize $n_{k,l}$ such that $p_{n_{k,l}} = c\frac{\log(4k^3/\delta)}{n_{k,l}} = \Delta^\beta$ so that $n_{k,l} = c\Delta^{-\beta}\log(4k^3/\delta)$ so

$$\begin{aligned}\mathbf{H}(F,\gamma,n_{k,l},\delta_{k,l}) &\le c p_{n_{k,l}}^{-\alpha/\beta}\log(1/\delta_{k,l}) + cn_{k,l}\begin{cases}\log(1/p_{n_{k,l}}) & \text{if } \alpha=\beta \\ \frac{1-p_{n_{k,l}}^{1-\alpha/\beta}}{1-\alpha/\beta} & \text{if } \alpha\neq\beta.\end{cases} \\ &\le c\log(k/\delta)\left[\Delta^{-\alpha} + \begin{cases}\Delta^{-\beta}\log(\Delta^{-1}) & \text{if } \alpha=\beta \\ \frac{\Delta^{-\beta}-\Delta^{-\alpha}}{1-\alpha/\beta} & \text{if } \alpha\neq\beta\end{cases}\right] \\ &\le c\log(k/\delta)\min\{\tfrac{1}{|1-\alpha/\beta|}, \log(\Delta^{-1})\}\Delta^{-\max\{\beta,\alpha\}}\end{aligned}$$

where the last line follows from

$$\begin{aligned}\Delta^{\max\{\beta,\alpha\}}\frac{\Delta^{-\beta}-\Delta^{-\alpha}}{1-\alpha/\beta} &= \beta\frac{\Delta^{\max\{0,\alpha-\beta\}}-\Delta^{\max\{0,\beta-\alpha\}}}{\beta-\alpha} \\ &= \beta\begin{cases}\frac{1-\Delta^{\beta-\alpha}}{\beta-\alpha} & \text{if } \beta>\alpha \\ \frac{1-\Delta^{\alpha-\beta}}{\alpha-\beta} & \text{if } \beta<\alpha\end{cases} \le c\min\{\tfrac{1}{|1-\alpha/\beta|}, \log(\Delta^{-1})\}.\end{aligned}$$

Using the upperbound $\lceil\log(n_{k,l})\rceil \le c\log(\log(k/\delta)\Delta^{-1}) \le c\log(\log(k/\delta))\log(\Delta^{-1})$ and letting $z_\Delta = \log(\Delta^{-1})^2\Delta^{-\max\{\beta,\alpha\}}$, we conclude that

$$\begin{aligned}B_{k,l} &< \min\{2^k : 2^k > 4\lceil\log(n_{k,l})\rceil\mathbf{H}(F,\gamma,n_{k,l},\delta_{k,l})\} \\ &< \min\{2^k : 2^k > c\log(k/\delta)\log(\log(k/\delta))z_\Delta\} \\ &\le c z_\Delta \log(\log(z_\Delta)/\delta)\log(\log(\log(z_\Delta)/\delta)) \\ &= c z_\Delta \overline{\log}(\log(z_\Delta)/\delta).\end{aligned}$$

Step 3: Count the total number of measurements. Moreover, the total number of measurements before $\hat{\imath}_{k,l}$ is output is upperbounded by

$$T = \sum_{i=1}^k\sum_{j=l}^i B_{i,j} \le k\sum_{i=1}^k B_{i,1} \le 2kB_{k,1} = 2B_{k,1}\log_2(B_{k,1})$$

where we have employed the so-called "doubling trick": $\sum_{i=1}^k B_{i,1} = \sum_{i=1}^k 2^i \le 2^{k+1} = 2B_{k,\hat{\imath}}$. Simplifying,

$$T \le c z_\Delta\overline{\log}(\log(z_\Delta)/\delta)\overline{\log}(z_\Delta\log(\log(z_\Delta)/\delta)) \le c\Delta^{-\max\{\beta,\alpha\}}\overline{\log}(\Delta^{-1})^3\overline{\log}(\log(\Delta^{-1})/\delta)$$

Solving for Δ in terms of T obtains

$$\Delta = c\left(\frac{\overline{\log}(T)^3\overline{\log}(\log(T)/\delta)}{T}\right)^{1/\max\{\alpha,\beta\}}.$$

Because the output arm is just the empirical best, there is some error associated with using the empirical estimate. The arm returned returned on round (k,l) is pulled $\lfloor\frac{2^{k-1}}{l}\rfloor \gtrsim B_{k,l}/\log(B_{k,l})$ times so the possible error is bounded by $\gamma(B_{k,l}/\log(B_{k,l})) \le c\left(\frac{\log(B_{k,l})}{B_{k,l}}\right)^{1/\alpha} \le c\left(\frac{\log(B)^2\log(\log(B))}{B}\right)^{1/\alpha}$ which is dominated by the value of Δ solved for above. ■

B.6 Proof of Theorem 7

Proof Step 1: Simplify $\mathbf{H}(F,\gamma,n,\delta,\epsilon)$. We begin by simplifying $\mathbf{H}(F,\gamma,n,\delta,\epsilon)$ in terms of just n,δ,α,β. As before, we use a constant c that may differ from one inequality to the next but remains an absolute constant. Let $p_n = \frac{\log(2/\delta)}{n}$ First we solve for ϵ by noting that we identify the best arm if $\nu_{\hat{\imath}} - \nu_* < \Delta_2$. Thus, if $\nu_{\hat{\imath}} - \nu_* \le \left(F^{-1}(p_n) - \nu_*\right) + \epsilon/2$ then we set

$$\epsilon = \max\left\{2\left(\Delta_2 - \left(F^{-1}(p_n) - \nu_*\right)\right), 4\left(F^{-1}(p_n) - \nu_*\right)\right\}$$

so that

$$\nu_i - \nu_* \leq \max\left\{3\big(F^{-1}(p_n) - \nu_*\big), \Delta_2\right\} = \Delta_{\lceil \max\{2, cKp_n\}\rceil}.$$

We treat the case when $3\big(F^{-1}(p_n) - \nu_*\big) \leq \Delta_2$ and the alternative separately.

First assume $3\big(F^{-1}(p_n) - \nu_*\big) > \Delta_2$ so that $\epsilon = 4\big(F^{-1}(p_n) - \nu_*\big)$ and $\mathbf{H}(F, \gamma, n, \delta, \epsilon) = \mathbf{H}(F, \gamma, n, \delta)$. We also have

$$\gamma^{-1}\left(\tfrac{F^{-1}(p_n)-\nu_*}{4}\right) \leq c\left(F^{-1}\left(p_n\right) - \nu_*\right)^{-\alpha} \leq c\,\Delta^{-\alpha}_{\lceil p_n K\rceil}$$

and

$$\int_{p_n}^1 \gamma^{-1}(\tfrac{F^{-1}(t)-\nu_*}{4})dt = \int_{F^{-1}(p_n)}^1 \gamma^{-1}(\tfrac{x-\nu_*}{4})dF(x) \leq \frac{c}{K}\sum_{i=\lceil p_n K\rceil}^K \Delta_i^{-\alpha}$$

so that

$$\begin{aligned}\mathbf{H}(F, \gamma, n, \delta) &= 2n\int_{p_n}^1 \gamma^{-1}(\tfrac{F^{-1}(t)-\nu_*}{4})dt + \tfrac{10}{3}\log(2/\delta)\gamma^{-1}\left(\tfrac{F^{-1}(p_n)-\nu_*}{4}\right)\\ &\leq c\Delta^{-\alpha}_{\lceil p_n K\rceil}\log(1/\delta) + \frac{cn}{K}\sum_{i=\lceil p_n K\rceil}^K \Delta_i^{-\alpha}.\end{aligned}$$

Now consider the case when $3\big(F^{-1}(p_n) - \nu_*\big) \leq \Delta_2$. In this case $F(\nu_* + \epsilon/4) = 1/K$, $\gamma^{-1}\left(\frac{\epsilon}{16}\right) \leq c\Delta_2^{-\alpha}$, and $\int_{\nu_*+\epsilon/4}^\infty \gamma^{-1}(\frac{t-\nu_*}{4})dF(t) \leq c\sum_{i=2}^K \Delta_i^{-\alpha}$ so that

$$\begin{aligned}\mathbf{H}(F, \gamma, n, \delta, \epsilon) &= 2n\int_{\nu_*+\epsilon/4}^\infty \gamma^{-1}(\tfrac{t-\nu_*}{4})dF(t) + \left(\tfrac{4}{3}\log(2/\delta) + 2nF(\nu_* + \epsilon/4)\right)\gamma^{-1}\left(\tfrac{\epsilon}{16}\right)\\ &\leq c(\log(1/\delta) + n/K)\Delta_2^{-\alpha} + \frac{cn}{K}\sum_{i=2}^K \Delta_i^{-\alpha}.\end{aligned}$$

Step 2: Solve for $(B_{k,l}, n_{k,l})$ in terms of Δ. Note there is no improvement possible once $p_{n_{k,l}} \leq 1/K$ since $3\big(F^{-1}(1/K) - \nu_*\big) \leq \Delta_2$. That is, when $p_{n_{k,l}} \leq 1/K$ the algorithm has found the best arm but will continue to take samples indefinetely. Thus, we only consider the case when $q = 1/K$ and $q > 1/K$. Fix $\Delta > 0$. Our strategy is to describe $n_{k,l}$ in terms of q. In particular, parameterize $n_{k,l}$ such that $p_{n_{k,l}} = c\frac{\log(4k^3/\delta)}{n_{k,l}} = q$ so that $n_{k,l} = cq^{-1}\log(4k^3/\delta)$ so

$$\begin{aligned}\mathbf{H}(F, \gamma, n_{k,l}, \delta_{k,l}, \epsilon_{k,l}) &\leq c\begin{cases}(\log(1/\delta_{k,l}) + \frac{n_{k,l}}{K})\Delta_2^{-\alpha} + \frac{n_{k,l}}{K}\sum_{i=2}^K \Delta_i^{-\alpha} & \text{if } 5\big(F^{-1}(p_{n_{k,l}}) - \nu_*\big) \leq \Delta_2\\ \Delta^{-\alpha}_{\lceil p_{n_{k,l}} K\rceil}\log(1/\delta_{k,l}) + \frac{n_{k,l}}{K}\sum_{i=\lceil p_{n_{k,l}} K\rceil}^K \Delta_i^{-\alpha} & \text{if otherwise}\end{cases}\\ &\leq c\log(k/\delta)\begin{cases}\Delta_2^{-\alpha} + \sum_{i=2}^K \Delta_i^{-\alpha} & \text{if } q = 1/K\\ \Delta^{-\alpha}_{\lceil qK\rceil} + \frac{1}{qK}\sum_{i=\lceil qK\rceil}^K \Delta_i^{-\alpha} & \text{if } q > 1/K.\end{cases}\\ &\leq c\log(k/\delta)\Delta^{-\alpha}_{\lceil \max\{2, qK\}\rceil} + \frac{1}{qK}\sum_{i=\lceil \max\{2, qK\}\rceil}^K \Delta_i^{-\alpha}\end{aligned}$$

Using the upperbound $\lceil\log(n_{k,l})\rceil \leq c\log(\log(k/\delta)q^{-1}) \leq c\log(\log(k/\delta))\log(q^{-1})$ and letting $z_q = \log(q^{-1})(\Delta^{-\alpha}_{\lceil \max\{2,qK\}\rceil} + \frac{1}{qK}\sum_{i=\lceil \max\{2,qK\}\rceil}^K \Delta_i^{-\alpha})$, we apply the exact sequence of steps as in the proof of Theorem 5 to obtain

$$T \leq cz_q\overline{\log}(\log(z_q)/\delta)\overline{\log}(z_q\log(\log(z_q)/\delta))$$

Because the output arm is just the empirical best, there is some error associated with using the empirical estimate. The arm returned on round (k, l) is pulled $\lceil\frac{2^{k-1}}{l}\rceil \geq cB_{k,l}/\log(B_{k,l})$ times so the possible error is bounded by $\gamma(B_{k,l}/\log(B_{k,l})) \leq c\left(\frac{\log(B_{k,l})}{B_{k,l}}\right)^{1/\alpha} \leq c\left(\frac{\log(T)^2\log(\log(T))}{T}\right)^{1/\alpha}$. This is dominated by $\Delta_{\lceil \max\{2,qK\}\rceil}$ for the value of T prescribed by the above calculation, completing the proof. ■

B.7 Proof of Theorem 8

Proof Let s denote the index of the last stage, to be determined later. If $\widetilde{r}_k = R\eta^{k-s}$ and $\widetilde{n}_k = n\eta^{-k}$ so that $r_k = \lfloor\widetilde{r}_k\rfloor$ and $n_k = \lfloor\widetilde{n}_k\rfloor$ then

$$\sum_{k=0}^s n_k r_k \leq \sum_{k=0}^s \widetilde{n}_k\widetilde{r}_k = nR(s+1)\eta^{-s} \leq B$$

since, by definition, $s = \min\{t \in \mathbb{N} : nR(t+1)\eta^{-t} \leq B, t \leq \log_\eta(\min\{R, n\})\}$. It is straightforward to verify that $B \geq z_{SH}$ ensures that $r_0 \geq 1$ and $n_s \geq 1$.

The proof for Theorem 1 holds here with a few modifications. First, we derive a lower bound on the resource per arm r_k per round if $B \geq z_{SH}$ with generalized elimination rate η:

$$\begin{aligned}r_k &\geq \frac{B}{|S_k|(\lfloor\log_\eta(n)\rfloor + 1)} - 1\\ &\geq \frac{\eta}{|S_k|}\max_{i=2,\ldots,n} i\left(1 + \min\left\{R, \gamma^{-1}\big(\max\left\{\frac{\epsilon}{4}, \frac{\nu_i - \nu_1}{2}\right\}\big)\right\}\right) - 1\\ &\geq \frac{\eta}{|S_k|}\left(\lfloor|S_k|/\eta\rfloor + 1\right)\left(1 + \min\left\{R, \gamma^{-1}\big(\max\left\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor|S_k|/2\rfloor+1} - \nu_1}{2}\right\}\big)\right\}\right) - 1\\ &\geq \left(1 + \min\left\{R, \gamma^{-1}\big(\max\left\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor|S_k|/2\rfloor+1} - \nu_1}{2}\right\}\big)\right\}\right) - 1\\ &= \min\left\{R, \gamma^{-1}\big(\max\left\{\frac{\epsilon}{4}, \frac{\nu_{\lfloor|S_k|/2\rfloor+1} - \nu_1}{2}\right\}\big)\right\}.\end{aligned}$$

Also, note that $\gamma(R) = 0$, hence if the minimum is ever active, $\ell_{i,R} = \nu_i$ and we know the true loss. The rest of the proof is same as that for Theorem 1 for η in place of 2.

In addition, we note that

$$\max_{i=n_s+1,\ldots,n} i\,\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i-\nu_1}{2}\right\}\right) \leq n_s\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_{n_s+1}-\nu_1}{2}\right\}\right) + \sum_{i>n_s}\gamma^{-1}\left(\max\left\{\tfrac{\epsilon}{4}, \tfrac{\nu_i-\nu_1}{2}\right\}\right).$$

Abstract

The principal submatrix localization problem deals with recovering a $K \times K$ principal submatrix of elevated mean μ in a large $n \times n$ symmetric matrix subject to additive standard Gaussian noise, or more generally, mean zero, variance one, subgaussian noise. This problem serves as a prototypical example for community detection, in which the community corresponds to the support of the submatrix. The main result of this paper is that in the regime $\Omega(\sqrt{n}) \le K \le o(n)$, the support of the submatrix can be weakly recovered (with $o(K)$ misclassification errors on average) by an optimized message passing algorithm if $\lambda = \mu^2 K^2/n$, the signal-to-noise ratio, exceeds $1/e$. This extends a result by Deshpande and Montanari previously obtained for $K = \Theta(\sqrt{n})$ and $\mu = \Theta(1)$. In addition, the algorithm can be combined with a voting procedure to achieve the information-theoretic limit of exact recovery with sharp constants for all $K \ge \frac{n}{\log n}(\frac{1}{8e} + o(1))$. The total running time of the algorithm is $O(n^2 \log n)$.

Another version of the submatrix localization problem, known as noisy biclustering, aims to recover a $K_1 \times K_2$ submatrix of elevated mean μ in a large $n_1 \times n_2$ Gaussian matrix. The optimized message passing algorithm and its analysis are adapted to the bicluster problem assuming $\Omega(\sqrt{n_i}) \le K_i \le o(n_i)$ and $K_1 \asymp K_2$. A sharp information-theoretic condition for the weak recovery of both clusters is also identified.

Keywords: Submatrix localization, biclustering, message passing, spectral algorithms computational complexity, high-dimensional statistics

1. Introduction

The problem of *submatrix detection* and *localization*, also known as *noisy biclustering* (Hartigan, 1972; Shabalin et al., 2009; Kolar et al., 2011; Butucea and Ingster, 2013; Butucea et al., 2015; Ma and Wu, 2015; Chen and Xu, 2014; Cai et al., 2017), deals with finding a submatrix with an elevated mean in a large noisy matrix, which arises in many applications such as social network analysis and gene expression data analysis. A widely studied statistical model is the following:

$$W = \mu \mathbf{1}_{C_1^*} \mathbf{1}_{C_2^*}^\top + Z, \tag{1}$$

where $\mu > 0$, $\mathbf{1}_{C_1^*}$ and $\mathbf{1}_{C_2^*}$ are indicator vectors of the row and column support sets $C_1^* \subset [n_1]$ and $C_2^* \subset [n_2]$ of cardinality K_1 and K_2, respectively, and Z is an $n_1 \times n_2$ matrix consisting of independent standard normal entries. The objective is to accurately locate the submatrix by estimating the row and column support based on the large matrix W.

For simplicity we start by considering the symmetric version of this problem, namely, locating a principal submatrix, and later extend our theoretic and algorithmic findings to the asymmetric case. To this end, consider

$$W = \mu \mathbf{1}_{C^*} \mathbf{1}_{C^*}^\top + Z, \tag{2}$$

where $C^* \subset [n]$ has cardinality K and Z is an $n \times n$ symmetric matrix with $\{Z_{ij}\}_{1 \le i \le j \le n}$ being mutually independent standard normal. Given the data matrix W, the problem of interest is to recover C^*. This problem has been investigated in (Deshpande and Montanari, 2015; Montanari et al., 2015; Hajek et al., 2017) as a prototypical example of the *hidden community problem*,[1] because the distribution of the entries exhibits a community structure, namely, $W_{i,j} \sim \mathcal{N}(\mu, 1)$ if both i and j belong to C^* and $W_{i,j} \sim \mathcal{N}(0, 1)$ if otherwise.

Assuming that C^* is drawn from all subsets of $[n]$ of cardinality K uniformly at random, we focus on the following two types of recovery guarantees.[2] Let $\xi = \mathbf{1}_{C^*} \in \{0,1\}^n$ denote the indicator of the community. Let $\widehat{\xi} = \widehat{\xi}(A) \in \{0,1\}^n$ be an estimator.

- We say that $\widehat{\xi}$ *exactly recovers* ξ if, as $n \to \infty$, $\mathbb{P}[\xi \ne \widehat{\xi}] \to 0$.
- We say that $\widehat{\xi}$ *weakly recovers* ξ if, as $n \to \infty$, $d(\xi, \widehat{\xi})/K \to 0$ in probability, where d denotes the Hamming distance.

The weak recovery guarantee is phrased in terms of convergence in probability, which turns out to be equivalent to convergence in mean. Indeed, the existence of an estimator satisfying $d(\xi, \widehat{\xi})/K \to 0$ is equivalent to the existence of an estimator such that $\mathbb{E}[d(\xi, \widehat{\xi})] = o(K)$ (see (Hajek et al., 2017, Appendix A) for a proof). Clearly, any estimator achieving exact recovery also achieves weak recovery; for bounded K, these two criteria are equivalent.

Intuitively, for a fixed matrix size n, as either the submatrix size K or the signal strength μ decreases, it becomes more difficult to locate the submatrix. A key role is played by the parameter

$$\lambda = \frac{\mu^2 K^2}{n},$$

which is the signal-to-noise ratio for classifying an index i according to the statistic $\sum_j W_{i,j}$, which is distributed according to $\mathcal{N}(\mu K, n)$ if $i \in C^*$ and $\mathcal{N}(0, n)$ if $i \notin C^*$. As shown in

1. A slight variation of the model in (Deshpande and Montanari, 2015; Hajek et al., 2017) is that the data matrix therein is assumed to have zero diagonal. As shown in (Hajek et al., 2017), the absence of the diagonal has no impact on the statistical limit of the problem as long as $K \to \infty$, which is the case considered in the present paper.
2. Exact and weak recovery are called strong consistency and weak consistency in (Amini et al., 2013; Mossel et al., 2015), respectively.

Appendix A, it turns out that if the submatrix size K grows linearly with n, the information-theoretic limits[3] of both weak and exact recovery are easily attainable via thresholding. To see this, note that in the case of $K \asymp n$ simply thresholding the row sums can provide weak recovery in $O(n^2)$ time provided that $\lambda \to \infty$, which coincides with the information-theoretic conditions of weak recovery as proved in (Hajek et al., 2017). Moreover, in this case, one can show that this thresholding algorithm followed by a linear-time voting procedure achieves exact recovery whenever information-theoretically possible. Thus, this paper concentrates on weak and exact recovery in the sublinear regime of

$$\Omega(\sqrt{n}) \le K \le o(n). \tag{3}$$

We show that an optimized message passing algorithm provides weak recovery in nearly linear – $O(n^2 \log n)$ – time if $\lambda > 1/e$. This extends the sufficient conditions obtained in (Deshpande and Montanari, 2015) for the regime $K = \Theta(\sqrt{n})$ and $\mu = \Theta(1)$.[4] Our algorithm is the same as the message passing algorithm proposed in (Deshpande and Montanari, 2015), except that we find the polynomial that maximizes the signal-to-noise ratio via Hermite polynomials instead of using the truncated Taylor series as in (Deshpande and Montanari, 2015). The proofs follow closely those in (Deshpande and Montanari, 2015), with the most essential differences described at the end of Section 2.

We observe that $\lambda > 1/e$ is much more stringent than $\lambda > \frac{4K}{n} \log \frac{n}{K}$, the information-theoretic weak recovery threshold established in (Hajek et al., 2017). It is an open problem whether any polynomial-time algorithm can provide weak recovery for $\lambda \le 1/e$. In addition, we show that if $\lambda > 1/e$, the message passing algorithm followed by a linear-time voting procedure can provide exact recovery whenever information-theoretically possible. This procedure achieves the optimal exact recovery threshold determined in (Hajek et al., 2017) with sharp constants if $K \ge (\frac{1}{8e} + o(1)) \frac{n}{\log n}$. See Section 3.1 for a detailed comparison with information-theoretic limits.

The message passing algorithm is simpler to formulate and analyze for the principal submatrix recovery problem; nevertheless, we show in Section 5 how to adapt the message passing algorithm and its analysis to the biclustering problem. Sharp conditions for exact recovery for the biclustering problem was obtained in (Butucea et al., 2015). We show that calculations in (Butucea et al., 2015) with minor adjustments provide information-theoretic conditions for weak recovery as well. The connection between weak and exact recovery via the voting procedure described in (Hajek et al., 2017) carries over to the biclustering problem.

The analysis of the message passing algorithm is based on the moment method adopted in (Deshpande and Montanari, 2015). When the noise matrix Z is Gaussian, an alternative technique to analyze message passing algorithms is introduced in (Bayati and Montanari, 2011) and generalized by (Javanmard and Montanari, 2013). A distinct advantage of the moment method in our context is that the Gaussian assumption can be relaxed to a sub-gaussian assumption. Accordingly, we introduce the following assumption.

3. In this paper, by information-theoretic limits, we mean the sufficient and necessary conditions for attaining weak or exact recovery by any estimator, regardless of its computational cost.
4. The main results (Theorems 1 and 3) of (Deshpande and Montanari, 2015) assume $\mu = \Theta(1)$ but not $K = \Omega(\sqrt{n})$). This is because, as pointed out at the end of the proof of (Deshpande and Montanari, 2015, Theorem 3), if $K = \omega(\sqrt{N})$, then the spectral method and its proof in (Alon et al., 1998) already work. However, the state evolution analysis of message passing algorithm still assumes $K = \Theta(\sqrt{n})$ as stated in (Deshpande and Montanari, 2015, Lemma 2.2).

Assumption 1 *Given $C^* \in [n]$ and $\mu > 0$, the following holds. W is an $n \times n$ symmetric matrix with $\{W_{ij}\}_{1 \le i \le j \le n}$ being mutually independent random variables. Let $Z_{ij} = W_{ij} - \mu \mathbf{I}_{\{i,j \in C^*\}}$. Then $\mathbb{E}[Z_{ij}] = 0$ for all i, j, and $\mathsf{var}(Z_{ij}) = 1$ for $(i,j) \notin C^* \times C^*$. Finally, there is a constant $\gamma > 0$ that does not depend on n such that $\mathbb{E}\left[e^{sZ_{ij}}\right] \le e^{\gamma s^2/2}$ for $s \in \mathbb{R}$, i.e. the W's and Z's are subgaussian with proxy variance γ.*

The variance of a subgaussian random variable is less than or equal to its proxy variance, so Assumption 1 implies $\gamma \ge 1$, and $\mathsf{var}(Z_{ij}) \le \gamma$ for all $i, j \in [n]$ and all $n \ge 1$. Of course, Assumption 1 holds in the Gaussian case such that the Z_{ij} are all $\mathcal{N}(0,1)$ random variables.

Notation For any positive integer n, let $[n] = \{1, \dots, n\}$. For any set $T \subset [n]$, let $|T|$ denote its cardinality and T^c denote its complement. For two sets S, T, let $S \Delta T = (S \setminus T) \cup (T \setminus S)$ denote the set difference. For an $m \times n$ matrix M, let $\|M\|$ and $\|M\|_{\mathrm{F}}$ denote its spectral and Frobenius norm, respectively. Let $\sigma_i(M)$ denote its singular values ordered decreasingly. For any $S \subset [m], T \subset [n]$, let $M_{ST} \in \mathbb{R}^{|S| \times |T|}$ denote $(M_{ij})_{i \in S, j \in T}$ and for $m = n$ abbreviate $M_S = M_{SS}$. For a vector x, let $\|x\|$ denote its Euclidean norm. We use standard big O notations, e.g., for any sequences $\{a_n\}$ and $\{b_n\}$, $a_n = \Theta(b_n)$ or $a_n \asymp b_n$ if there is an absolute constant $c > 0$ such that $1/c \le a_n/b_n \le c$. All logarithms are natural and we use the convention $0 \log 0 = 0$. Let Φ and Q denote the cumulative distribution function (CDF) and complementary CDF of the standard normal distribution, respectively. For $\epsilon \in [0,1]$, define the binary entropy function $h(\epsilon) \triangleq \epsilon \log \frac{1}{\epsilon} + (1-\epsilon) \log \frac{1}{1-\epsilon}$. We say a sequence of events $\mathcal{E}_n$ holds with high probability, if $\mathbb{P}\{\mathcal{E}_n\} \to 1$ as $n \to \infty$. Denote the Kolmogorov-Smirnov (KS) distance between distributions μ and ν by $d_{\mathrm{KS}}(\mu, \nu) \triangleq \sup_{x \in \mathbb{R}} |\mu((-\infty, x]) - \nu((-\infty, x])|$.

2. Algorithms and main results

To avoid a plethora of factors $\frac{1}{\sqrt{n}}$ in the notation, we describe the message-passing algorithm using the scaled version

$$A = \frac{1}{\sqrt{n}} W. \tag{4}$$

Under Assumption 1, the entries A_{ij} are subgaussian with proxy variance $\frac{\gamma}{n}$, mean 0 or $\frac{\mu}{\sqrt{n}}$, and variance $\frac{1}{n}$ for $(i,j) \notin C^* \times C^*$. This section presents algorithms and theoretical guarantees for the symmetric model (2). Extensions to the asymmetric case for the biclustering problem (1) are given in Section 5.2.

Let $f(\cdot, t) \colon \mathbb{R} \to \mathbb{R}$ be a scalar function for each iteration t. Let $\theta_{i \to j}^{t+1}$ denote the message transmitted from index i to index j at iteration $t+1$, which is given by

$$\theta_{i \to j}^{t+1} = \sum_{\ell \in [n] \setminus \{i,j\}} A_{\ell i} f(\theta_{\ell \to i}^t, t), \quad \forall j \ne i \in [n]. \tag{5}$$

with the initial conditions $\theta^0_{i\to j} \equiv 0$. Moreover, let θ^{t+1}_i denote index i's belief at iteration $t+1$, which is given by

$$\theta^{t+1}_i = \sum_{\ell \in [n]\setminus\{i\}} A_{\ell i} f(\theta^t_{\ell\to i}, t). \tag{6}$$

The form of (5) is inspired by belief propagation algorithms, which have the natural non-backtracking property: the message sent from i to j at time $t+1$ does not depend on the message sent from j to i at time t, thereby reducing the effect of echoes of messages sent by j.

To present an informal derivation of the *state evolution equations*, which track the asymptotic distributions of the messages, let us postulate the following assumptions: Suppose that for each fixed t, as $n \to \infty$: (a) the empirical distribution of $(\theta^t_i : i \in C^*)$ converges to $\mathcal{N}(\mu_t, \tau_t^2)$ and the empirical distribution of $(\theta^t_i : i \in [n]\backslash C^*)$ converges to $\mathcal{N}(0, \tau_t^2)$; (b) $\{\theta^t_{i\to j}\}$ are independent of A; (c) $\theta^t_{i\to j} \approx \theta^t_i$. Then it follows from (6) and $K = o(n)$ that for any $i \in C^*$,

$$\begin{aligned}
\mathbb{E}\left[\theta^{t+1}_i \mid \{\theta^t_{\ell\to i} : \ell \neq i\}\right] &\overset{(b)}{=} \sum_{\ell\in[n]\setminus\{i\}} \mathbb{E}\left[A_{\ell i}\right] f(\theta^t_{\ell\to i}, t) \\
&= \frac{\mu}{\sqrt{n}} \sum_{\ell \in C^*\setminus\{i\}} f(\theta^t_{\ell\to i}, t) \\
&\xrightarrow[n\to\infty]{(a),(c)} \sqrt{\lambda}\, \mathbb{E}\left[f(\mu_t + \tau_t Z, t)\right],
\end{aligned}$$

and for any $i \in [n]$,

$$\begin{aligned}
\mathsf{var}\left(\theta^{t+1}_i \mid \{\theta^t_{\ell\to i} : \ell \neq i\}\right) &\overset{(b)}{=} \sum_{\ell\in[n]\setminus\{i\}} \mathsf{var}\left(A_{\ell i}\right) f(\theta^t_{\ell\to i}, t)^2 \\
&= \frac{1}{n} \sum_{\ell\in[n]\setminus(C^*\cup\{i\})} f(\theta^t_{\ell\to i}, t)^2 + o(1) \\
&\xrightarrow[n\to\infty]{(a),(c)} \mathbb{E}\left[f(\tau_t Z, t)^2\right],
\end{aligned}$$

where Z represents a generic standard normal random variable. Since the conditional means and variances have deterministic limits, those are also the limits of the unconditional means and variances. Therefore, we get the following recursive equations for $t \geq 0$:

$$\mu_{t+1} = \sqrt{\lambda}\mathbb{E}\left[f(\mu_t + \tau_t Z, t)\right], \tag{7}$$

$$\tau_{t+1} = \mathbb{E}\left[f(\tau_t Z, t)^2\right], \tag{8}$$

where the initial conditions are $\mu_0 = \tau_0 = 0$. Following (Deshpande and Montanari, 2015), we call (7) and (8) the *state evolution equations*. The heuristic derivation of state evolution equations given above is certainly not rigorous mainly due to the dependency between $\theta^t_{i\to j}$'s and A. In Section 6, we present a rigorous justification of state evolution equations via the moment method following (Deshpande and Montanari, 2015). A crucial fact that we exploit

is the non-backtracking property of the message passing rule (5), which has the effect of reducing the dependency between $\theta^t_{i\to j}$'s and A.

Suppose, for the time being, that message distributions are Gaussian with parameters accurately tracked by the state evolution equations. Then it is reasonable to estimate C^* by selecting those indices i such that θ^{t+1}_i exceeds a given threshold. More specifically, classifying an index i based on θ^{t+1}_i boils down to testing two Gaussian hypotheses with signal-to-noise ratio $\frac{\mu_{t+1}}{\tau_{t+1}}$. This gives guidance for selecting the functions $f(\cdot, t)$ based on μ_t and τ_t to maximize $\frac{\mu_{t+1}}{\tau_{t+1}}$. For $t = 0$ any choice of f is equivalent, so long as $f(0,0) > 0$. Without loss of generality, for $t \geq 1$, we can assume that the variances are normalized, namely, $\tau_t = 1$ (e.g., we take $f(0,0) = 1$ to make $\tau_1 = 1$) and choose $f(\cdot, t)$ to be the maximizer of

$$\max_g \{\mathbb{E}[g(\mu_t + Z)] \colon \mathbb{E}[g(Z)^2] = 1\} \tag{9}$$

where $Z \sim \mathcal{N}(0,1)$. By change of measure, $\mathbb{E}[g(\mu_t + Z)] = \mathbb{E}[g(Z)\rho(Z)]$, where

$$\rho(x) = \frac{\mathrm{d}\mathcal{N}(\mu_t, 1)}{\mathrm{d}\mathcal{N}(0,1)}(x) = e^{x\mu_t - \mu_t^2/2}. \tag{10}$$

Clearly, the best g aligns with ρ and we obtain

$$f(x,t) = \frac{\rho(x)}{\sqrt{\mathbb{E}[\rho^2(Z)]}} = e^{x\mu_t - \mu_t^2}. \tag{11}$$

With this optimized f, we have $\tau_t \equiv 1$ and the state evolution (7) reduces to

$$\mu_{t+1} = \sqrt{\lambda}\mathbb{E}\left[f(\mu_t + Z, t)\right] = \sqrt{\lambda} e^{\frac{\mu_t^2}{2}},$$

or, equivalently,

$$\mu^2_{t+1} = \lambda e^{\mu_t^2}. \tag{12}$$

Therefore if $\lambda > 1/e$, then (12) has no fixed point and hence $\mu_t \to \infty$ as $t \to \infty$.

Directly carrying out the above heuristic program, however, seems challenging. To rigorously justify the state evolution equations in Section 6, we rely on the the method of moments, requiring f to be a polynomial, which prompts us to look for the best polynomial of a given degree that maximizes the signal-to-noise ratio. Denoting the corresponding state evolution by $(\widehat{\mu}_t, \widehat{\tau}_t)$, we aim to solve the following finite-degree version of (9):

$$\max\{\mathbb{E}[g(\widehat{\mu}_t + Z)] \colon \mathbb{E}[g(Z)^2] = 1, \deg(g) \leq d\}. \tag{13}$$

As shown in Lemma 7, this problem can be easily solved via Hermite polynomials, which form an orthogonal basis with respect to the Gaussian measure, and the optimal choice, denoted by $f_d(\cdot, t)$, is the best degree-d L_2-approximation of the the likelihood ratio (10), which can be obtained by normalizing the first $d+1$ terms in the orthogonal expansion of (10). Compared to (Deshpande and Montanari, 2015, Lemma 2.3) which shows the existence of a good choice of polynomial that approximates the ideal state evolution (12) based on Taylor expansions, our approach is to find the best message-passing rule of a given

degree which results in the following state evolution that is optimal among all polynomial f of degree d:

$$\widehat{\mu}_{t+1}^2 = \lambda \sum_{k=0}^{d} \frac{\widehat{\mu}_t^{2k}}{k!}. \tag{14}$$

For any $\lambda > 1/e$, there is an explicit choice of the degree d depending only on λ denoted by $d^*(\lambda)$,[5] so that $\widehat{\mu}_t \to \infty$ as $t \to \infty$ and the state evolution (14) for fixed t correctly predicts the asymptotic behavior of the messages when $n \to \infty$. Therefore, as discussed above, $\widetilde{C}$ produced by thresholding messages θ_i^t, is likely to contain a large portion of C^*, but since $K = o(n)$, it may (and most likely will) also contain a large number of indices not in C^*. Following (Deshpande and Montanari, 2015, Lemma 2.4), we show that the power iteration[6] (a standard spectral method) in Algorithm 1 can remove a large portion of the outlier vertices in $\widetilde{C}$.

Combining message passing plus spectral cleanup yields Algorithm 1 for estimating C^* based on the messages θ_i^t, with theoretical guarantees given in Theorem 1.

Algorithm 1 Message passing

1: Input: $n, K \in \mathbb{N}$, $\mu > 0$, $A \in \mathbb{R}^{n\times n}$, $d^*, t^* \in \mathbb{N}$, and $s^* > 0$.
2: Initialize: $\theta_{i\to j}^0 = 0$ for all $i, j \in [n]$ with $i \neq j$ and $\theta_i^0 = 0$. For $t \geq 0$, define the sequence of degree-d^* polynomials $f_{d^*}(\cdot, t)$ as per Lemma 7 and $\widehat{\mu}_t$ in (14).
3: Run $t^* - 1$ iterations of message passing as in (5) with $f = f_{d^*}$ and compute $\theta_i^{t^*}$ for all $i \in [n]$ as per (6).
4: Find the set $\widetilde{C} = \{i \in [n] : \theta_i^{t^*} \geq \widehat{\mu}_{t^*}/2\}$.
5: (Cleanup via power method) Recall that $A_{\widetilde{C}}$ denotes the restriction of A to the rows and columns with index in $\widetilde{C}$. Sample u^0 uniformly from the unit sphere in $\mathbb{R}^{|\widetilde{C}|}$ and compute $u^{t+1} = A_{\widetilde{C}} u^t / \|A_{\widetilde{C}} u^t\|$ for $0 \leq t \leq \lceil s^* \log n \rceil - 1$. Let $\widehat{u} = u^{\lceil s^* \log n \rceil}$. Return $\widehat{C}$, the set of K indices i in $\widetilde{C}$ with the largest values of $|\widehat{u}_i|$.

Theorem 1 *Fix $\lambda > 1/e$. Let K and μ depend on n in such a way that $\mu^2 K^2/n \to \lambda$ and $\Omega(\sqrt{n}) \leq K \leq o(n)$ as $n \to \infty$. Suppose either C^* is deterministic with $|C^*| \equiv K$, or C^* is random such that $|C^*|/K \to 1$ in probability as $n \to \infty$. Suppose Assumption 1 holds for some $\gamma > 0$. Let $d = d^*(\lambda)$ as in (28). For every $\eta \in (0, 1)$, there exist explicit positive constants t^*, s^*, c depending on λ, η and γ such that Algorithm 1 returns $\widehat{C}$ satisfying $|\widehat{C} \Delta C^*| \leq \eta K$, with probability converging to one as $n \to \infty$, and the total time complexity is bounded by $c(\eta, \lambda, \gamma) n^2 \log n$, where $c(\eta, \lambda, \gamma) \to \infty$ as either $\eta \to 0$ or $\lambda \to 1/e$.*

Remark 2 *Algorithm 1 requires the knowledge of the parameter λ to define the sequence of polynomials $f_{d^*}(\cdot, t)$ and $\widehat{\mu}_t$, and the knowledge of the parameter K in the spectral cleanup step. To avoid the need to know K, we can simply replace the last step of the spectral cleanup (involving choosing the K coordinates of the largest magnitude of $\widehat{u}$) by applying k-means with $k = 2$ on the set $\{|\widehat{u}_i| : i \in \widetilde{C}\}$. See Appendix C for details. With this modification, Theorem 1 continues to hold as long as λ (or a lower bound thereof) is known in order to set the degree d^* and the iteration number t^*.*

5. See (28) and Remark 9 for the expression.
6. As far as statistical utility is concerned, we could replace $\widehat{u}$ produced by the power iteration by the leading singular vector of $A_{\widetilde{C}}$, but that would incur a higher time complexity because singular value decomposition in general takes $O(n^3)$ time to compute.

Remark 3 *As pointed out in (Deshpande and Montanari, 2015, Remeark 2.5), the effective signal-to-noise ratio λ can be potentially improved by a suitable entrywise pre-processing of the observed matrix W. In particular, in (4) we let $A_{ij} = g(W_{ij})$ for some transformation function $g : \mathbb{R} \to \mathbb{R}$. The optimal transformation g in the Gaussian case for which $\gamma = 1$ is given by the maximizer of*

$$\max_g \left\{ \mathbb{E}\left[g(\mu + Z)\right] - \mathbb{E}\left[g(Z)\right] : \mathbb{E}\left[g(Z)^2\right] = \frac{1}{n} \right\}.$$

In view of (9) and (10), the optimal transformation is the scaled likelihood ratio:

$$A_{ij} = \frac{1}{\sqrt{n(e^{\mu^2} - 1)}} \left(\frac{\mathrm{d}\mathcal{N}(\mu, 1)}{\mathrm{d}\mathcal{N}(0, 1)}(W_{ij}) - 1 \right) = \frac{1}{\sqrt{n(e^{\mu^2} - 1)}} \left(e^{W_{ij}\mu - \mu^2/2} - 1 \right)$$

and the signal-to-noise ratio λ is increased to

$$\widetilde{\lambda} = \frac{K^2}{n} \left(e^{\mu^2} - 1 \right).$$

If the resulting A_{ij} is subgaussian with scale $O(1/n)$, then Theorem 1 still applies. However, even if the results extend, in the regime of $K \gg \sqrt{n}$ which we are mostly interested in, we have $\mu \to 0$ and $\widetilde{\lambda} = \lambda(1 + o(1))$, and thus pre-processing cannot boost the signal-to-noise ratio asymptotically.

After the message passing algorithm and spectral cleanup are applied in Algorithm 1, a final linear-time voting procedure is deployed to obtain weak or exact recovery, leading to Algorithm 2 next. As in (Deshpande and Montanari, 2015), we consider a threshold estimator for each vertex i based on a sum over $\widehat{C}$ given by $r_i = \sum_{j \in \widehat{C}} A_{ij}$. Intuitively, r_i can be viewed as the aggregated "votes" received by the index i in $\widehat{C}$, and the algorithm picks the set of K indices with the most significant "votes". To show that this voting procedure succeeds in weak recovery, a key step is to prove that r_i is close to $\sum_{j \in C^*} A_{ij}$. If $\mu = \Theta(1)$ as in (Deshpande and Montanari, 2015), given that $|\widehat{C} \triangle C^*| = o(K)$, the error incurred by summing over $\widehat{C}$ instead of over C^* could be bounded by truncating A_{ij} to a large magnitude. However, for $\mu \to 0$ that approach fails. Our approach is to introduce the clean-up procedure in Algorithm 2 based on the *successive withholding* method described in (Hajek et al., 2017) (see also (Condon and Karp, 2001; Mossel et al., 2014) for variants of this method). In particular, we randomly partition the set of vertices into $1/\delta$ subsets. One at a time, one subset, say S, is withheld to produce a reduced set of vertices S^c, on which we apply Algorithm 1. The estimate obtained from S^c is then used by the voting procedure to classify the vertices in S. The analysis of the two stages is decoupled because conditioned on C^*, the outcome of Algorithm 1 depends only on A_{S^c}, which is independent of A_{SS^c} used in the voting.

Algorithm 2 Message passing plus voting

1: Input: $n, K \in \mathbb{N}$, $\mu > 0$, $A \in \mathbb{R}^{n\times n}$, $\delta \in (0,1)$ with $1/\delta, n\delta \in \mathbb{N}$, $d^*, t^* \in \mathbb{N}$, and $s^* > 0$.
2: Partition $[n]$ into $1/\delta$ subsets S_k of size $n\delta$ randomly.
3: (Approximate recovery) For each $k = 1, \ldots, 1/\delta$, run Algorithm 1 (message passing for approximate recovery) with input $\big(n(1-\delta), \lceil K(1-\delta)\rceil, \mu, A_{S_k^c}, d^*, t^*, s^*\big)$ which outputs $\widehat{C}_k$.
4: (Clean up) For each $k = 1, \ldots, 1/\delta$ compute $r_i = \sum_{j\in\widehat{C}_k} A_{ij}$ for all $i \in S_k$ and return C', the set of K indices in $[n]$ with the largest values of r_i.

The following theorem provides a sufficient condition for the message passing plus voting cleanup procedure (Algorithm 2) to achieve weak recovery, and, if an additional sufficient condition is also satisfied, exact recovery.

Theorem 4 *Suppose K and μ depend on n in such a way that $\frac{\mu^2 K^2}{n} \to \lambda$ for some fixed $\lambda > 1/e$, and $\Omega(\sqrt{n}) \le K \le o(n)$ as $n \to \infty$. Suppose Assumption 1 holds for some $\gamma > 0$ and $|C^*| = K$. Let $\delta > 0$ be such that $\lambda e(1-\delta) > 1$. Define $d^* = d^*(\lambda(1-\delta))$ as per (28). Then there exist positive constants t^*, s^*, c determined explicitly by δ, λ and γ, such that*

1. *(Weak recovery) Algorithm 2 returns C' with $|C'\Delta C^*|/K \to 0$ in probability as $n \to \infty$.*
2. *(Exact recovery) Furthermore, assume that*

$$\liminf_{n\to\infty} \frac{\sqrt{K}\mu}{\sqrt{2\log K} + \sqrt{2\log n}} > \sqrt{\gamma}. \tag{15}$$

Let $\delta > 0$ be chosen such that for all sufficiently large n,

$$\min\left\{\lambda e(1-\delta), \frac{K\mu(1-2\delta)}{\sqrt{2K\gamma\log K} + \sqrt{2K\gamma\log(n-K)} + \delta\sqrt{K}}\right\} > 1.$$

Then Algorithm 2 returns C' with $\mathbb{P}\{C' \neq C^*\} \to 0$ as $n \to \infty$.

The total time complexity is bounded by $c(\delta,\lambda,\gamma)n^2\log n$, where $c(\delta,\lambda,\gamma) \to \infty$ as $\delta \to 0$ or $\lambda \to 1/e$.

Remark 5 *Theorem 4 ensures Algorithm 2 achieves exact recovery if both (15) and $\lambda > 1/e$ hold; it is of interest to compare these two conditions. Note that*

$$\frac{\sqrt{K}\mu}{\sqrt{2\log K} + \sqrt{2\log n}} = \sqrt{\lambda e} \times \sqrt{\frac{n}{8eK\log n}} \frac{2}{(1 + \sqrt{\log K/\log n})}.$$

Hence, if $\liminf_{n\to\infty} K\log n/n \ge 1/(8e\gamma)$, then $\liminf_{n\to\infty} \log K/\log n = 1$; thus (15) implies $\lambda > 1/e$ and hence (15) alone is sufficient for Algorithm 2 to succeed. If instead $\limsup_{n\to\infty} K\log n/n \le 1/(8e\gamma)$, then $\lambda > 1/e$ implies (15) and thus $\lambda > 1/e$ alone is sufficient for Algorithm 2 to succeed. The asymptotic regime considered in (Deshpande and Montanari, 2015) entails $K = \Theta(\sqrt{n})$, in which case the condition $\lambda > 1/e$ is sufficient for exact recovery, as shown in (Deshpande and Montanari, 2015). The idea of upgrading weak recovery to exact recovery via a local voting procedure has also appeared in (Abbe et al., 2016; Mossel et al., 2015; Abbe and Sandon, 2015; Yun and Proutiere, 2015) under the context of stochastic block models with community sizes scaling linearly in n. As shown in (Hajek et al., 2017, Corollary 4) in the Gaussian case for which $\gamma = 1$, the condition (15), with strict inequality replaced by greater than or equal, is necessary for exact recovery.

We finish this section by discussing the connections and distinctions to the previous work (Deshpande and Montanari, 2015). Versions of Theorems 1 and 4 are given in (Deshpande and Montanari, 2015) for the case $K = \Theta(\sqrt{n})$ and $\mu = \Theta(1)$. We extend the range of K to $\Omega(\sqrt{n}) \le K \le o(n)$, showing that the message passing plus a cleanup procedure achieves the optimal exact recovery threshold in the Gaussian case with sharp constants if $K \ge (\frac{1}{8e} + o(1))\frac{n}{\log n}$. The algorithms and proofs are nearly the same; we comment here on the main difficulties we encountered when allowing $K/\sqrt{n} \to \infty$ and $\mu \to 0$.

First, a key ingredient in the proof of Theorem 1 is Lemma 6. Its proof is based on the moment method and a larger K requires modification of bounds from (Deshpande and Montanari, 2015) used in calculating the moments of messages, i.e., $\mathbb{E}\left[(\theta^t_{i\to j})^m\right]$ for fixed $m \in \mathbb{N}$, by a more careful counting argument. We refer the interested readers to Remark 31 right after the proof of Lemma 6 for more details.

Secondly, after the message passing algorithm and spectral cleanup are applied in Algorithm 1, a final cleanup procedure is applied to obtain weak recovery or exact recovery (when possible). As in (Deshpande and Montanari, 2015), we consider a threshold estimator for each vertex i based on a sum over $\widehat{C}$. If $K = \Theta(\sqrt{n})$ as assumed in (Deshpande and Montanari, 2015), then λ being a constant implies that the mean μ is bounded away from zero. In this case if $|\widehat{C}\triangle C^*| = o(K)$, the error incurred by summing over $\widehat{C}$ instead of over C^* could be bounded by truncating A_{ij} to a large magnitude $\bar{\rho}$ and bounding the difference of sums by $\bar{\rho}\big|C^*\triangle\widehat{C}\big| = o(K) \ll \mu K$. However, for $K \gg \sqrt{n}$ with vanishing μ this approach fails. Instead, we rely on the cleanup procedure in Algorithm 2 which entails running Algorithm 1 for $1/\delta$ times on subsampled vertices. A related difference we encounter is that if K is large enough then the condition $\lambda > 1/e$ alone is not sufficient for exact recovery, but adding the information-theoretic condition (15) suffices.

Lastly, the method of moments requires $f(\cdot, t)$ to be a polynomial so that the exponential function (11), which results in the ideal state evolution (12), cannot be directly applied. It is shown in (Deshpande and Montanari, 2015, Lemma 2.3) that for any $\lambda > 1/e$ and any threshold M there exists $d^* = d^*(\lambda, M)$ so that taking f to be the truncated Taylor series of (11) up to degree d^* results in the state evolution $\widehat{\mu}_t$ which exceeds M after some finite time $t^*(\lambda, M)$; however, no explicit formula of d^*, which is needed to instantiate Algorithm 1, is provided. Although in principle this does not pose any algorithmic problem as d^* can be found by an exhaustive search in $O(1)$ time independent of n, it is more satisfactory to find the best polynomial message passing rule explicitly which maximizes the signal-to-noise ratio for a given degree (Lemma 7) and provides an explicit formula of d^* as a function of λ only (Remark 9).

3. Statistical optimality and computational considerations

3.1 Comparison with information-theoretic limits in the Gaussian case

As noted in the introduction, in the regime $K = \Theta(n)$, a thresholding algorithm based on row sums provides weak and, if a voting procedure is also used, exact recovery whenever it is informationally possible in the Gaussian case. In this subsection, we compare the performance of the message passing algorithms to the information-theoretic limits on the recovery problem in the regime (3). Throughout this section we restrict attention to the Gaussian case, such that $Z_{ij} \sim \mathcal{N}(0,1)$ and $\gamma = 1$. Also, for converse results, we assume the true community C^* is a subset of $[n]$ of cardinality K selected uniformly at random. Notice that the comparison here takes into account the sharp constant factors. Information-theoretic limits for the biclustering problem are discussed in Section 5.1.

Weak recovery The information-theoretic threshold for weak recovery has been determined in (Hajek et al., 2017, Theorem 2), which, in the regime of (3), boils down to the following: If

$$\liminf_{n\to\infty} \frac{K\mu^2}{4\log\frac{n}{K}} > 1, \tag{16}$$

then weak recovery is possible; conversely, if weak recovery is possible, then

$$\liminf_{n\to\infty} \frac{K\mu^2}{4\log\frac{n}{K}} \geq 1. \tag{17}$$

This implies that the minimal signal-to-noise ratio for weak recovery is

$$\lambda \geq (4+\epsilon)\frac{K}{n}\log\frac{n}{K}$$

for any $\epsilon > 0$, which vanishes in the sublinear regime of $K = o(n)$. In contrast, in the regime of (3), message passing (Algorithm 1) demands a non-vanishing signal-to-noise ratio, namely, $\lambda > 1/e$, to achieve weak recovery. No polynomial-time algorithm is known to succeed if $\lambda \leq 1/e$, suggesting that computational complexity might incur a severe penalty on the statistical optimality when $K = o(n)$.

Exact recovery When the submatrix size satisfies (3), if (15) with $\gamma = 1$ holds, then exact recovery is possible; conversely, if exact recovery is possible, then

$$\liminf_{n\to\infty} \frac{\sqrt{K}\mu}{\sqrt{2\log K} + \sqrt{2\log n}} \geq 1. \tag{18}$$

See (Hajek et al., 2017, Corollary 4). This implies that the minimal signal-to-noise ratio for exact recovery is

$$\lambda \geq (2+\epsilon)\frac{K}{n}\left(\sqrt{\log n} + \sqrt{\log K}\right)^2 \tag{19}$$

for any $\epsilon > 0$. Consequently, we find that the critical submatrix size for which message passing (plus cleanup) can achieve optimal exact recovery is $\frac{n}{\log n}$. Specifically,

- $K = \omega\left(\frac{n}{\log n}\right)$. In this regime, the right hand side of (19) goes to ∞ and hence the minimal signal-to-noise ratio for exact recovery is much higher than that of weak recovery via message passing, namely, $1/e$. Thus, exact recovery can be attainable in polynomial-time by message-passing plus voting clean-up (Algorithm 2).

- $K = \Theta(\frac{n}{\log n})$. In this regime, if we let $K = \frac{\rho n}{\log n}$, the right hand side of (19) is at least $1/e$ if $\rho \geq \frac{1}{8e}$ and strictly less than $1/e$ otherwise. In view of Theorem 4, we conclude that message passing plus voting cleanup (Algorithm 2) achieves the sharp threshold of exact recovery if

$$K \geq \left(\frac{1}{8e} + o(1)\right)\frac{n}{\log n}. \tag{20}$$

- $K = o\left(\frac{n}{\log n}\right)$. In this regime, the right hand side of (19) is $o(1)$. No polynomial-time algorithm (including semidefinite programming relaxation (Hajek et al., 2016)) is known to achieve weak, let alone exact, recovery, when $\lambda = o(1)$.

A counterpart of this conclusion for the biclustering problem is obtained in Remark 20 in terms of the submatrix sizes.

3.2 Comparison with the spectral limit

It is reasonable to conjecture that $\lambda > 1$ is the spectral limit for recoverability by spectral estimation methods. This conjecture is rather vague, because it is difficult to define what constitutes spectral methods. Nevertheless, some evidence for this conjecture is provided by (Deshpande and Montanari, 2015, Proposition 1.1), which, in turn, is based on results on the spectrum of a random matrix perturbed by adding a rank-one deterministic matrix (Knowles and Yin, 2013, Theorem 2.7).

The message passing framework used in this paper itself provides some evidence for the conjecture. Indeed, if $f(x,0) \equiv 1$ and $f(x,t) = x$ for all $t \geq 1$, the iterates θ^t are close to what is obtained by iterated multiplication by the matrix A, beginning with the all one vector, which is the power method for computation of the eigenvector corresponding to the principal eigenvalue of A.[7] To be more precise, with this linear f the message passing equation (5) can be expressed in terms of powers of the *non-backtracking matrix* $\mathbf{B} \in \mathbb{R}^{\binom{n}{2}\times\binom{n}{2}}$ associated with the matrix A, defined by $B_{ef} = A_{e_1,e_2}\mathbf{1}_{\{e_2=f_1\}}\mathbf{1}_{\{e_1\neq f_2\}}$, where $e = (e_1, e_2)$ and $f = (f_1, f_2)$ are directed pairs of indices. Let $\Theta^t \in \mathbb{R}^{n(n-1)}$ denote the messages on directed edges with $\Theta^t_e = \theta^t_{e_1\to e_2}$. Then, (5) simply becomes $\Theta^t = \mathbf{B}^t\mathbf{1}$. To evaluate the performance of this method, we turn to the state evolution equations (7) and (8), which yield $\mu_t = \lambda^{t/2}$ and $\tau_t = 1$ for all $t \geq 1$. Therefore, by a simple variation of Algorithm 1 and Theorem 1, if $\lambda > 1$, the linear message passing algorithm can provide weak recovery.

For the submatrix *detection* problem, namely, testing $\mu = 0$ (pure noise) versus $\mu > 0$, as opposed to support recovery, if λ is fixed with $\lambda > 1$, a simple thresholding test based

7. If we included i, j in the summation in (5) and (6), then we would have $\theta^t = A^t\mathbf{1}$ exactly. Since the entries of A are $O_P(1/\sqrt{n})$, we expect this only incurs a small difference to the sum for finite number of iterations.

on the largest eigenvalue of the matrix A provides detection error probability converging to zero (Féral and Péché, 2007), while if $\lambda < 1$ no test based solely on the eigenvalues of A can achieve vanishing probability of error (Montanari et al., 2015). It remains, however, to establish a solid connection between the detection and estimation problem for submatrix localization for spectral methods.

3.3 Computational barriers in the Gaussian case

A recent line of work (Kolar et al., 2011; Ma and Wu, 2015; Chen and Xu, 2014; Cai et al., 2017) has uncovered a fascinating interplay between statistical optimality and computational efficiency for the *recovery* problem and the related *detection* and *estimation* problem.[8] Assuming the hardness of the planted clique problem, rigorous computational lower bounds have been obtained in (Ma and Wu, 2015; Cai et al., 2017) through reduction arguments in the Gaussian case. In particular, it is shown in (Ma and Wu, 2015) that when $K = n^\alpha$ for $0 < \alpha < 2/3$, merely achieving the information-theoretic limits of detection within any constant factor (let alone sharp constants) is as hard as detecting the planted clique; the same hardness also carries over to exact recovery in the same regime. Furthermore, it is shown that the hardness of estimating this type of matrix, which is both low-rank and sparse, highly depends on the loss function (Ma and Wu, 2015, Section 5.2). For example, for $K = \Theta(\sqrt{n})$, entry-wise thresholding attains an $O(\log n)$ factor of the minimax mean-square error; however, if the error is gauged in squared operator norm instead of Frobenius norm, attaining an $O(\sqrt{n}/\log n)$ factor of the minimax risk is as hard as solving planted clique. Similar reductions have been shown in (Cai et al., 2017) for exact recovering of the submatrix of size $K = n^\alpha$ and the planted clique recovery problem for any $0 < \alpha < 1$.

The results in (Ma and Wu, 2015; Cai et al., 2017) revealed that the difficulty of submatrix localization crucially depends on the size and planted clique hardness kicks in if $K = n^{1-\Theta(1)}$. In search of the exact phase transition point where statistical and computational limits depart, we further zoom into the regime of $K = n^{1-o(1)}$. We showed in (Hajek et al., 2016) no computational gap exists in the regime $K = \omega(n/\log n)$, since a semidefinite programming relaxation of the maximum likelihood estimator can achieve the information limit for exact recovery with sharp constants. The current paper further pushes the boundary to $K \geq \frac{n}{\log n}(\frac{1}{8e} + o(1))$, in which case the sharp information limits can be attained in nearly linear-time via message passing plus clean-up. However, as soon as $K \leq \frac{n}{\log n}(\frac{1}{8e} - \epsilon)$ for any $\epsilon > 0$, a gap emerges between the statistical limits and the sufficient condition of message passing plus clean-up, given by $\lambda > 1/e$.

4. Proofs of algorithm correctness

We first justify the state evolution equations via the following key lemma, which establishes the asymptotic normality of the empirical distribution of messages with mean and variance given by (7) and (8). A version of this lemma is proved in (Deshpande and Montanari, 2015) by assuming $\mu = \Theta(1)$ and $K = \Theta(\sqrt{n})$. The proof is given in Section 6 using the method of moments, closely following (Deshpande and Montanari, 2015).

8. The papers (Kolar et al., 2011; Ma and Wu, 2015; Chen and Xu, 2014; Cai et al., 2017) considered the biclustering version of the submatrix localization problem (1).

Lemma 6 *Let $f(\cdot, t)$ be a finite-degree polynomial for each $t \geq 0$. Let K and μ depend on n such that $\frac{K^2\mu^2}{n} \equiv \lambda$ for some $\lambda > 0$ and $\Omega(\sqrt{n}) \leq K \leq o(n)$. Suppose Assumption 1 holds for some $\gamma > 0$, and suppose either C^* is deterministic with $|C^*| \equiv K$, or C^* is random such that $|C^*|/K \to 1$ in probability as $n \to \infty$. Let $A = W/\sqrt{n}$ and set $\theta^0_{i\to j} = 0$. Consider the message passing algorithm defined by (5) and (6). Then for each fixed t, as $n \to \infty$,*

$$d_{\mathrm{KS}}\left(\frac{1}{|C^*|}\sum_{i\in C^*}\delta_{\theta_i^t},\, \mathcal{N}(\mu_t, \tau_t^2)\right) \xrightarrow{p} 0,$$
$$d_{\mathrm{KS}}\left(\frac{1}{n-|C^*|}\sum_{i\notin C^*}\delta_{\theta_i^t},\, \mathcal{N}(0, \tau_t^2)\right) \xrightarrow{p} 0,$$

where μ_t and τ_t are defined in (7) and (8), respectively; $\frac{1}{|C^*|}\sum_{i\in C^*}\delta_{\theta_i^t}$ and $\frac{1}{n-|C^*|}\sum_{i\notin C^*}\delta_{\theta_i^t}$ are the empirical distributions of θ_i^t for $i \in C^*$ and $i \notin C^*$, respectively.

Next we prove Theorems 1-4. Lemma 6 implies that if $i \in C^*$, then $\theta_i^t \sim \mathcal{N}(\mu_t, \tau_t^2)$; if $i \notin C^*$, then $\theta_i^t \sim \mathcal{N}(0, \tau_t^2)$. Ideally, one would pick the optimal $f(x,t) = e^{\mu_t(x-\mu_t)}$ which result in the optimal state evolution $\mu_{t+1} = \sqrt{\lambda}e^{\mu_t^2/2}$ and $\tau_t = 1$ for all $t \geq 1$. Furthermore, if $\lambda > 1/e$, then $\mu_t \to \infty$ as $t \to \infty$, and thus we can hope to estimate C^* by selecting the indices i such that θ_i^t exceeds a certain threshold. The caveat is that Lemma 6 needs f to be a polynomial of finite degree. Next we proceed to find the best degree-d polynomial for iteration t, denoted by $f_d(\cdot, t)$, which maximizes the signal to noise ratio.

Recall that the Hermite polynomials $\{H_k : k \geq 0\}$ are the orthogonal polynomials with respect to the standard normal distribution (cf. (Szegö, 1975, Section 5.5)), given by

$$H_k(x) = (-1)^k\frac{\varphi^{(k)}(x)}{\varphi(x)} = \sum_{i=0}^{\lfloor k/2\rfloor}(-1)^i(2i-1)!!\binom{k}{2i}x^{k-2i}, \tag{21}$$

where φ denotes the standard normal density and $\varphi^{(k)}(x)$ is its k-th derivative; in particular, $H_0(x) = 1, H_1(x) = x, H_2(x) = x^2 - 1$. Furthermore, $\deg(H_k) = k$ and $\{H_0, \ldots, H_d\}$ span all polynomials of degree at most d. For $Z \sim \mathcal{N}(0,1)$, $\mathbb{E}[H_m(Z)H_n(Z)] = m!\delta_{m=n}$ and $\mathbb{E}[H_k(\mu + Z)] = \mu^k$ for all $\mu \in \mathbb{R}$; hence the relative density $\frac{\mathrm{d}\mathcal{N}(\mu,1)}{\mathrm{d}\mathcal{N}(0,1)}(x) = e^{\mu x - \mu^2/2}$ admits the following expansion:

$$e^{\mu x - \mu^2/2} = \sum_{k=0}^{\infty}H_k(x)\frac{\mu^k}{k!}. \tag{22}$$

Truncating and normalizing the series at the first $d+1$ terms immediately yields the solution to (13) as the best degree-d L_2-approximation to the relative density, described as follows:

Lemma 7 *Fix $d \in \mathbb{N}$ and define $\widehat{\mu}_t$ according to the iteration (14) with $\widehat{\mu}_0 = 0$, namely,*

$$\widehat{\mu}_{t+1}^2 = \lambda G_d(\widehat{\mu}_t^2), \qquad G_d(\mu) = \sum_{k=0}^{d}\frac{\mu^k}{k!}. \tag{23}$$

Define

$$f_d(x,t) = \sum_{k=0}^{d} a_k H_k(x), \tag{24}$$

where $a_k \triangleq \frac{\widehat{\mu}_t^k}{k!}(\sum_{k=0}^{d} \frac{\widehat{\mu}_t^{2k}}{k!})^{-1/2}$. *Then* $f_d(\cdot,t)$ *is the unique maximizer of (13) and the state evolution (7) and (8) with* $f = f_d$ *coincides with* $\tau_t = 1$ *and* $\mu_t = \widehat{\mu}_t$. *Furthermore, for any* $d \geq 2$ *the equation*

$$G_d(a) = aG_{d-1}(a) \tag{25}$$

has a unique positive solution, denoted by a_d^*. *Let*

$$\lambda_d^* = \frac{1}{G_{d-1}(a_d^*)} \tag{26}$$

and define $\lambda_1^* = 1$. *Then*

1. *for any* $d \in \mathbb{N}$ *and any* $\lambda > \lambda_d^*$, $\widehat{\mu}_t \to \infty$ *as* $t \to \infty$ *and hence for any* $M > 0$,

$$t^*(\lambda, M) = \inf\{t : \widehat{\mu}_t > M\} \tag{27}$$

   is finite;

2. $\lambda_d^* \downarrow 1/e$ *monotonically as* $d \to \infty$ *according to* $\lambda_d^* = 1/e + \frac{1/e^2 + o(1)}{(d+1)!}$.

Remark 8 *The best affine update gives* $\lambda_1^* = 1$; *for the best quadratic update,* $a_2^* = \sqrt{2}$ *and hence* $\lambda_2^* = \frac{1}{1+\sqrt{2}} \approx 0.414$. *More values of the threshold are given below, which converges to* $1/e \approx 0.368$ *rapidly.*

d	1	2	3	4	5
λ_d^*	1	0.414	0.376	0.369	0.368

Remark 9 *Let*

$$d^*(\lambda) = \inf\{d \in \mathbb{N} : \lambda_d^* < \lambda\}, \tag{28}$$

which is finite for any $\lambda > 1/e$. *Then for any* $d \geq d^*$, $\widehat{\mu}_t \to \infty$ *as* $t \to \infty$. *As* λ *approaches the critical value* $1/e$, *the degree* $d^*(\lambda)$ *blows up according to* $d^*(\lambda) = \Theta(\log \frac{1}{\lambda e - 1} / \log\log \frac{1}{\lambda e - 1})$, *as a consequence of the last part of Lemma 7.*

Remark 10 (Best affine message passing) *For* $d = 1$, *the best state evolution is given by*

$$\widehat{\mu}_{t+1}^2 = \lambda(1 + \widehat{\mu}_t^2)$$

and the corresponding optimal update rule is

$$f_1(x,t) = \frac{1 + \widehat{\mu}_t x}{\sqrt{1 + \widehat{\mu}_t^2}}.$$

This is strictly better than $f(x,t) = x$ *described in Section 3.2 which gives* $\widehat{\mu}_{t+1}^2 = \lambda \widehat{\mu}_t^2$; *nevertheless, in order to have* $\widehat{\mu}_t \to \infty$ *we still need to assume the spectral limit* $\lambda \geq 1$.

Proof [Proof of Lemma 7] Note that any degree-d polynomial g can be written in terms of the linear combination:

$$f_d(x,t) = \sum_{k=0}^{d} c_k H_k(x),$$

where the coefficients $\{c_k\}$ satisfy $\mathbb{E}[g^2(Z)] = \sum_{k=0}^{d} k! c_k^2 = 1$. By a change of measure, $\mathbb{E}[g(\widehat{\mu}_t + Z)] = \mathbb{E}[g(Z) e^{\widehat{\mu}_t Z - \widehat{\mu}_t^2/2}] = \sum_{k=0}^{d} c_k \widehat{\mu}_t^k$, in view of the orthogonal expansion (22). Thus, to solve the maximization problem (13), it is equivalent to solving

$$\max_{c_k} \left\{ \sum_{k=0}^{d} c_k \widehat{\mu}_t^k : \sum_{k=0}^{d} k! c_k^2 = 1 \right\}.$$

By Cauchy-Schwarz inequality, the optimal coefficients and the optimal polynomial $f_d(\cdot,t)$ are given by (24), resulting in the following state evolution

$$\widehat{\mu}_{t+1} = \sqrt{\lambda} \max\{\mathbb{E}[g(\widehat{\mu}_t + Z)] \colon \mathbb{E}[g(Z)^2] = 1, \deg(g) \leq d\} = \left(\lambda \sum_{k=0}^{d} \frac{\widehat{\mu}_t^{2k}}{k!} \right)^{1/2},$$

which is equivalent to (23).

Next we analyze the behavior of the iteration (23). The case of $d = 1$ follows from the obvious fact that $\widehat{\mu}_{t+1}^2 = \lambda(\widehat{\mu}_t^2 + 1)$ diverges if and only if $\lambda \geq 1$. For $d \geq 2$, note that G_d is a strictly convex function with $G_d(0) = 1$ and $G_d' = G_{d-1}$. Also, $(G_d(a) - aG_{d-1}(a))' = -aG_d''(a) < 0$. Thus, $G_d(a) - aG_{d-1}(a)$ is strictly decreasing on $a > 0$ with value $\frac{1}{d!}$ at $a = 1$ and limit $-\infty$ as $a \to \infty$, so (25) has a unique positive solution a_d^* and it satisfies $a_d^* > 1$. Furthermore, $(G_d(a) - aG_{d-1}(a))'\big|_{a=1} = -\sum_{k=0}^{d-2} \frac{1}{k!}$, so by Taylor's theorem,

$$G_d(a) - aG_{d-1}(a) = \frac{1}{d!} - (a-1) \sum_{k=0}^{d-2} \frac{1}{k!} + O((a-1)^2),$$

yielding

$$a_d^* = 1 + \frac{1}{d! \sum_{k=0}^{d-2} \frac{1}{k!}} + O(1/(d!)^2).$$

Consider next the values of λ such that $\widehat{\mu}_t$ diverges. For very large λ, $G_d(a)$ dominates a/λ pointwise and $\widehat{\mu}_t$ diverges. The critical value of λ is when $G_d(a)$ and a/λ meet tangentially, namely,

$$\lambda G_{d-1}(a) = 1, \quad \lambda G_d(a) = a,$$

whose solution is given by $a = a_d^*$ and $\lambda = \lambda_d^*$, where

$$\begin{aligned}
\lambda_d^* &\triangleq \frac{1}{G_{d-1}(a_d^*)} = \frac{1}{G_{d-1}(1) + G_{d-1}'(1)(a_d^* - 1) + O((a_d^* - 1)^2)} \\
&= \frac{1}{\sum_{k=0}^{d} \frac{1}{k!} + O(1/(d!)^2)} = 1/e + \frac{\sum_{k=d+1}^{\infty} 1/k! + O(1/(d!)^2)}{e \sum_{k=0}^{d} 1/k!} \\
&= 1/e + \frac{1/e^2 + o(1)}{(d+1)!}.
\end{aligned}$$

Thus, λ_d^* is the minimum value such that for all $\lambda > \lambda_d^*$, $\lambda G_d(a) > a$ for all $a > 0$, so that starting from any $\widehat{\mu}_t \geq 0$ we have $\widehat{\mu}_t \to \infty$ monotonically. The fact λ_d^* is decreasing in d follows from the fact G_d is pointwise increasing in d. ■

Lemmas 6 and 7 immediately imply the following partial recovery results.

Lemma 11 *Assume that $\lambda > 1/e$ and $\Omega(\sqrt{n}) \leq K \leq o(n)$. Fix any $\epsilon \in (0,1)$. Let $M = \sqrt{8\log(1/\epsilon)}$ and run the message passing algorithm for t iterations with $f = f_{d^*}$, $d^* = d^*(\lambda)$ as in (28), and $t = t^*(\lambda, M)$ as in (27). Let $\widetilde{C} = \{i : \theta_i^{t^*} \geq \widehat{\mu}_{t^*}/2\}$. Then with probability converging to one as $n \to \infty$,*

$$\frac{1}{K}|\widetilde{C} \cap C^*| \geq 1 - \epsilon \tag{29}$$

$$K(1-\epsilon) \leq |\widetilde{C}| \leq n\epsilon. \tag{30}$$

Proof Notice that

$$|\widetilde{C} \cap C^*| = \sum_{i \in C^*} \mathbf{1}_{\{\theta_i^{t^*} \geq \widehat{\mu}_{t^*}/2\}}.$$

By the choice of $f = f_d$ in (24), we have $\tau_t = 1$ for all $t \geq 1$. It follows from Lemma 6 that

$$\lim_{n\to\infty} \frac{1}{K}|\widetilde{C} \cap C^*| = \mathbb{P}\left\{\widehat{\mu}_{t^*} + Z \geq \widehat{\mu}_{t^*}/2\right\}, \tag{31}$$

where the convergence is in probability. Notice that we have used $d = d^*(\lambda)$ and $t = t^*(\lambda, M)$ defined by (28) and (27) in Lemma 7. Thus $\widehat{\mu}_{t^*} \geq M = \sqrt{8\log(1/\epsilon)}$ and

$$\mathbb{P}\left\{\widehat{\mu}_{t^*} + Z \leq \widehat{\mu}_{t^*}/2\right\} = Q(\widehat{\mu}_{t^*}/2) \leq e^{-\widehat{\mu}_{t^*}^2/8} \leq \epsilon,$$

which, in view of (31), implies (29) with probability converging to one as $n \to \infty$. Similarly, Lemma 6 implies that in probability

$$\lim_{n\to\infty} \frac{1}{n}|\widetilde{C} \backslash C^*| = \mathbb{P}\left\{Z \geq \widehat{\mu}_{t^*}/2\right\} = Q(\widehat{\mu}_{t^*}/2) \leq \epsilon. \tag{32}$$

Since $K = o(n)$, we have $\mathbb{P}\{K(1-\epsilon) \leq |\widetilde{C}| \leq n\epsilon\} \to 1$. ■

Although $\widetilde{C}$ contains a large portion of C^*, since $|\widetilde{C}|$ is linear in n with high probability, i.e., $|\widetilde{C}|/n \to Q(\widehat{\mu}_{t^*}/2)$ by Lemma 6, it is bound to contain a large number of outlier indices. The next lemma, closely following (Deshpande and Montanari, 2015, Lemma 2.4), shows that given the conclusion of Lemma 11, the power iteration in Algorithm 1 can remove most of the outlier indices in $\widetilde{C}$. Its proof is presented in Appendix B.

Lemma 12 *Suppose $\lambda = \frac{\mu^2 K^2}{n} \geq 1/e$, $K \to \infty$, $|C^*|/K \to 1$ in probability, and $\widetilde{C}$ is a set (possibly depending on A) such that (29) – (30) hold for some $0 < \epsilon < \epsilon_0$, where $0 < \epsilon_0 \leq 1/2$ is determined by $1 - \epsilon_0 = 8e\sqrt{4\gamma h(\epsilon_0) + 10\gamma\epsilon_0}$. Let*

$$s^* = \frac{2}{\log(\sqrt{\lambda}(1-\epsilon)/(8\sqrt{4e\gamma h(\epsilon) + 10e\gamma\epsilon}))}, \tag{33}$$

where $h(\epsilon) \triangleq \epsilon\log\frac{1}{\epsilon} + (1-\epsilon)\log\frac{1}{1-\epsilon}$ is the binary entropy function. Then $\widehat{C}$ with $|\widehat{C}| \equiv K$ produced by Algorithm 1 returns $|\widehat{C}\Delta C^*| \leq \eta(\epsilon,\lambda,\gamma)K$, with probability converging to one as $n \to \infty$, where

$$\eta(\epsilon,\lambda,\gamma) = 2\epsilon + e\gamma\frac{4608h(\epsilon) + 11520\epsilon}{\lambda(1-\epsilon)^2}. \tag{34}$$

Proof [Proof of Theorem 1] Given $\eta \in (0,1)$, choose an arbitrary $\epsilon \in (0,\epsilon_0)$ such that $\eta(\epsilon,\lambda,\gamma)$ defined in (34) is at most η. With t^* specified in Lemma 11 and s^* specified in Lemma 12, the probabilistic performance guarantee in Theorem 1 readily follows by combining Lemmas 11 and 12. The time complexity of Algorithm 1 follows from the fact that for both the BP algorithm and the power method each iteration has complexity $O(n^2)$ and Algorithm 1 entails running BP and the power method for t^* and $\lceil s^*\log n\rceil$ iterations respectively; both t^* and s^* are constants depending only on η, λ, and γ. ■

Proof [Proof of Theorem 4] (Weak recovery) Fix $k \in [1/\delta]$ and let $C_k^* = C^* \cap S_k^c$. Define the $n(1-\delta)\times n(1-\delta)$ matrix $A_k \triangleq A_{S_k^c}$, which corresponds to the submatrix localization problem for a planted community C_k^* whose size has a hypergeometric distribution, resulting from sampling without replacement, with parameters $(n, K, (1-\delta)n)$ and mean $(1-\delta)K$. By a result of (Hoeffding, 1963), the distribution of $|C_k^*|$ is convex order dominated by the distribution that would result from sampling with replacement, namely, the Binom $\left(n(1-\delta), \frac{K}{n}\right)$ distribution. In particular, Chernoff bounds for Binom$(n(1-\delta), \frac{K}{n})$ also hold for $|C_k^*|$, so $|C_k^*|/((1-\delta)K) \to 1$ in probability as $n \to \infty$. Note that $\frac{((1-\delta)K)^2\mu^2}{n(1-\delta)} \to \lambda(1-\delta)$ and $\lambda(1-\delta)e > 1$ by the choice of δ. Let $d^*(\lambda(1-\delta))$ be given in (28), i.e.,

$$d^*(\lambda(1-\delta)) = \inf\{d \in \mathbb{N} : \lambda_d^* < \lambda(1-\delta)\}.$$

Choose an arbitrary $\epsilon \in (0,\epsilon_0)$ to satisfy $\eta(\epsilon,\lambda(1-\delta),\gamma) \leq \delta$, i.e.,

$$2\epsilon + e\gamma\frac{4608h(\epsilon) + 11520\epsilon}{\lambda(1-\delta)(1-\epsilon)^2} \leq \delta.$$

Define $\widehat{\mu}_t$ recursively according to (14) with λ replaced by $\lambda(1-\delta)$ and $\widehat{\mu}_0 = 0$, i.e.,

$$\widehat{\mu}_{t+1}^2 = \lambda(1-\delta)\sum_{k=0}^{d}\frac{\widehat{\mu}_t^{2k}}{k!}.$$

Define $t^*(\delta,\lambda,\gamma)$ according to (27) with $M = 8\log(1/\epsilon)$, and $s^*(\delta,\lambda,\gamma)$ according to (33) with λ replaced by $\lambda(1-\delta)$. Then Theorem 1 with n and K replaced by $n(1-\delta)$ and $\lceil K(1-\delta)\rceil$ implies that as $n \to \infty$,

$$\mathbb{P}\left\{|\widehat{C}_k\triangle C_k^*| \leq \delta K \text{ for } 1 \leq k \leq 1/\delta\right\} \to 1.$$

Given $(C_k^*, \widehat{C}_k)$, each of the random variables $r_i\sqrt{n}$ for $i \in S_k$ is conditionally subgaussian with proxy variance at most $K\gamma$. Furthermore, on the event, $\mathcal{E}_k = \{|\widehat{C}_k\triangle C_k^*| \leq \delta K\}$,

$$|\widehat{C}_k \cap C_k^*| \geq |\widehat{C}_k| - |\widehat{C}_k\triangle C_k^*| = \lceil K(1-\delta)\rceil - |\widehat{C}_k\triangle C_k^*| \geq K(1-2\delta).$$

Therefore, on the event $\mathcal{E}_k$, for $i \in S_k \cap C^*$, $r_i\sqrt{n}$ has mean greater than or equal to $K(1-2\delta)\mu$, and for $i \in S_k \backslash C^*$, r_i has mean zero.

Define the following set by thresholding

$$C_o' = \{i \in [n] : r_i \geq (1-2\delta)\sqrt{\lambda}/2\}$$

The number of indices in S_k incorrectly classified by $C_o' \cap S_k$ satisfies (use $|S_k| = \delta n$):

$$\mathbb{E}\left[\left|(C_o' \cap S_k)\Delta(C^* \cap S_k)\right|\right] \leq \delta n e^{-\Omega(n/K)},$$

where the last inequality follows because r_i is subgaussian with proxy variance at most $\gamma K/n$. Summing over $k \in [1/\delta]$ yields $\mathbb{E}\left[|C_o'\Delta C^*|\right] \leq ne^{-\Omega(n/K)}$. By Markov's inequality,

$$\mathbb{P}\left\{|C_o'\Delta C^*| \geq K^2/n\right\} \leq \frac{n^2}{K^2} e^{-\Omega(n/K)} \overset{K=o(n)}{=} o(1).$$

Instead of C_o', Algorithm 2 outputs C' which selects the K indices in $[n]$ with the largest values of r_i. Applying the same argument as that at the end of the proof of Lemma 12, we get $|C^*\triangle C'| \leq 2|C^*\triangle C_o'| + ||C^*| - K|$, and hence $|C^*\triangle C'|/K \to 0$ in probability.

(Exact recovery) By the union bound and Chernoff's bound for subgaussian random variables, the maximum of m subgaussian random variables X_i with zero mean and proxy variance at most γ satisfies that

$$\begin{aligned}\mathbb{P}\left\{\max_{1\leq i\leq m} X_i \geq \sqrt{\gamma}\left(\sqrt{2\log m} + t\right)\right\} &\leq m\exp\left(-\left(\sqrt{2\log m}+t\right)^2/2\right) \\ &= \exp\left(-t\sqrt{2\log m} - t^2/2\right).\end{aligned}$$

It follows that $\max_{1\leq i\leq m} X_i$ is at most $\sqrt{2\gamma\log m} + o_P(1)$ as $m \to \infty$. Also, for $k \in [1/\delta]$, $|S_k \cap C^*| \leq |C^*| = K$ and $|S_k\backslash C^*| \leq |[n]\backslash C^*| = n - K$. Therefore,

$$\min_{i\in S_k\cap C^*} r_i\sqrt{n} \geq K(1-2\delta)\mu - \sqrt{2K\gamma\log K} + o_P(\sqrt{K}) \tag{35}$$

$$\max_{j\in S_k\backslash C^*} r_i\sqrt{n} \leq \sqrt{2K\gamma\log(n-K)} + o_P(\sqrt{K}). \tag{36}$$

Since k ranges over a finite number of values, namely, $[1/\delta]$, (35) and (36) continue to hold with left-hand sides replaced by $\min_{i\in C^*} r_i\sqrt{n}$ and $\max_{j\notin C^*} r_i\sqrt{n}$, respectively. Therefore, by the choice of δ, $\min_{i\in C^*} r_i\sqrt{n} > \max_{j\in[n]\backslash C^*} r_i\sqrt{n}$ with probability converging to one as $n \to \infty$ and so $C' = C^*$ with probability converging to one as well.

(Time complexity) The running time of Algorithm 2 is dominated by invoking Algorithm 1 for a constant number, $1/\delta$, of times, and the number of iterations within Algorithm 1 is $(t^* + s^*\log n)n^2$, with both t^* and $s^* \to \infty$ as either $\delta \to 0$ or $\lambda \to 1/e$. In particular, the threshold comparisons require $O(n^2)$ computations. Thus, the total complexity of Algorithm 2 is as stated in the theorem. ■

5. The Gaussian biclustering problem

We return to the biclustering problem where the goal is to locate a submatrix whose row and column support need not coincide. Consider the model (1) parameterized by $(n_1, n_2, K_1, K_2, \mu)$ indexed by a common n with $n \to \infty$. In Section 5.1 we present the information limits for weak and exact recovery for the Gaussian bicluster model. The sharp conditions given for exact recovery are from (Butucea et al., 2015), and calculations from (Butucea et al., 2015) with minor adjustment provide conditions for weak recovery as well. Section 5.2 shows how the optimized message passing algorithm and its analysis can be extended from the symmetric case to the asymmetric case for biclustering and compares its performance to the fundamental limits. As originally observed in (Hajek et al., 2017) for recovering the principal submatrix, the connection between weak and exact recovery via the voting procedure extends to the biclustering problem as well. Note that for the sake of simplicity, we focus on Gaussian biclustering where the noise matrix Z is Gaussian; the results can be readily extended to the case where Z has subguassian entries as we did in the symmetric case.

5.1 Information-theoretic limits for Gaussian biclustering

Information-theoretic conditions ensuring exact recovery of both C_1^* and C_2^* by the maximum likelihood estimator (MLE), i.e.,

$$(\widehat{C}_1^{\mathsf{MLE}}, \widehat{C}_2^{\mathsf{MLE}}) = \operatorname*{arg\,max}_{\substack{|C_1|=K_1\\|C_2|=K_2}} \sum_{\substack{i\in C_1\\ j\in C_2}} W_{ij}$$

are obtained in (Butucea et al., 2015). While (Butucea et al., 2015) does not focus on conditions for weak recovery, the calculations therein combined with the voting procedure for exact recovery described in (Hajek et al., 2017) in fact resolve the information limits for both weak and exact recovery in the bicluster Gaussian model. Throughout this section we assume that $K_i = o(n_i)$ for $i = 1, 2$. For the converse results we assume C_i^* is a subset of $[n_i]$ of cardinality K_i selected uniformly at random for $i = 1, 2$, with C_1^* independent of C_2^*. Let

$$\lambda_i = \frac{K_i^2\mu^2}{n_i}, \quad \text{for } i = 1, 2.$$

Theorem 13 (Weak recovery thresholds for Gaussian biclustering) *If*

$$\liminf_{n\to\infty} \frac{\mu\sqrt{K_1K_2}}{\sqrt{2(K_1\log(n_1/K_1) + K_2\log(n_2/K_2))}} > 1, \tag{37}$$

then both C_1^* and C_2^* can be weakly recovered by the MLE. Conversely, if both C_1^* and C_2^* can be weakly recovered by some estimator, then

$$\liminf_{n\to\infty} \frac{\mu\sqrt{K_1K_2}}{\sqrt{2(K_1\log(n_1/K_1) + K_2\log(n_2/K_2)}} \geq 1. \tag{38}$$

If C_2^* (C_1^*) can be weakly recovered, one can further obtain exact recovery of C_1^* (C_2^*) via a voting cleanup procedure similar to Algorithm 2; it uses the method of successive withholding. We give the voting procedure in Algorithm 3 for exact recovery of C_1^* based on weak recovery of C_2^*; exact recovery of C_2^* based on weak recovery of C_1^* is analogous.

Algorithm 3 Weak recovery of C_2^* plus cleanup for exact recovery of C_1^*

1: Input: $n_1, n_2, K_1, K_2 \in \mathbb{N}$, $\mu > 0$, $A \in \mathbb{R}^{n_1 \times n_2}$, $\delta \in (0,1)$ with $1/\delta, n_1\delta \in \mathbb{N}$.
2: (Partition) Partition $[n_1]$ into $1/\delta$ subsets S_k of size $n_1\delta$ randomly.
3: (Approximate recovery) For each $k = 1, \ldots, 1/\delta$, let A_k denote the restriction of A to the rows with index in S_k^c, run an estimator capable of weak recovery of C_2^* with input $(n_1(1-\delta), n_2, \lceil K_1(1-\delta)\rceil, K_2, \mu, A_k)$ which outputs $\widehat{C}_{2k}$.
4: (Clean up) For each $k = 1, \ldots, 1/\delta$ compute $r_i = \sum_{j \in \widehat{C}_{2k}} A_{ij}$ for all $i \in S_k$ and return C_1', the set of K indices in $[n_1]$ with the largest values of r_i.

Theorem 14 (Exact recovery thresholds for Gaussian biclustering)
If for some small $\delta > 0$, C_2^* can be weakly recovered even if a fraction δ of the rows of the matrix are hidden, and if

$$\liminf_{n\to\infty} \frac{\sqrt{K_2}\mu}{\sqrt{2\log K_1} + \sqrt{2\log n_1}} > 1, \tag{39}$$

then C_1^* can be exactly recovered by the voting procedure. Conversely, if C_1^* can be exactly recovered by some estimator, then

$$\liminf_{n\to\infty} \frac{\sqrt{K_2}\mu}{\sqrt{2\log K_1} + \sqrt{2\log n_1}} \geq 1. \tag{40}$$

Similarly, if for some small $\delta > 0$, C_1^* can be weakly recovered even if a fraction δ of the columns of the matrix are hidden, and if

$$\liminf_{n\to\infty} \frac{\sqrt{K_1}\mu}{\sqrt{2\log K_2} + \sqrt{2\log n_2}} > 1, \tag{41}$$

then C_2^* can be exactly recovered by the voting procedure. Conversely, if C_2^* can be exactly recovered by some estimator, then

$$\liminf_{n\to\infty} \frac{\sqrt{K_1}\mu}{\sqrt{2\log K_2} + \sqrt{2\log n_2}} \geq 1. \tag{42}$$

The proofs of Theorems 13 and 14 are given in Appendix D. The sufficient conditions involving δ in Theorem 14 require a certain robustness of the estimator for weak recovery. If the rows indexed by a set S, with $S \subset [n_1]$ and $|S| = \delta n_1$, are hidden, then the observed matrix has dimensions $n_1(1-\delta)\times n_2$ and the planted submatrix has $K_1 - |S \cap C_1^*| \approx K_1(1-\delta)$ rows and K_2 columns. It is shown in (Hajek et al., 2017, Section IV.B) that the MLE has this robustness property for weak recovery of a principal submatrix, and a similar extension can be established for weak recovery for biclustering. The estimator used is the MLE based on the assumption that the submatrix to be found has shape $K_1(1-\delta) \times K_2$. With that extension in hand, the following corollary is a consequence of the two theorems, and it recovers the main result of (Butucea et al., 2015).

Corollary 15 *If (37), (39), and (41) hold, then C_1^* and C_2^* can both be exactly recovered by the MLE. Conversely, if exact recovery is possible, then (38), (40), and (42) hold.*

We conclude this subsection with a few remarks on Theorems 13 and 14:

1. If $n_1 = n_2$ and $K_1 = K_2$, the sufficient conditions and the necessary conditions for weak and for exact recovery, respectively, are identical to those in (Hajek et al., 2017) for the recovery of a $K \times K$ principal submatrix with elevated mean, in a symmetric $n \times n$ Gaussian matrix. Basically, in the bicluster problem the data matrix provides roughly twice the information (because the matrix is not symmetric) and there is twice the information to be learned, namely C_1^* and C_2^* instead of only C^*, and the factors of two cancel to yield the same conditions. It therefore follows from (Hajek et al., 2017, Remark 7), that if $n_1 = n_2$ and $K_1 = K_2 \leq n_1^{1/9}$, then (37) implies (39) and (41); in this regime, (37) alone is the sharp condition for both weak and exact recovery.

2. If $\lambda_i = \frac{K_i^2\mu^2}{n_i}$ are two fixed positive constants and if $K_1 \asymp K_2$, then (37) holds for all sufficiently large n, so weak recovery is information theoretically possible. In contrast, our proof that the optimized message passing algorithm provides weak recovery in this regime requires $(\lambda_1, \lambda_2) \in \mathcal{G}$, where $\mathcal{G}$ is defined in (52) in the next subsection.

5.2 Message passing algorithm for the Gaussian biclustering model

Suppose $n_i \to \infty$ and $\Omega(\sqrt{n_i}) \leq K_i \leq o(n_i)$ for $i \in \{0,1\}$, as $n \to \infty$. The belief propagation algorithm and our analysis of it for recovery of a single set of indices can be naturally adapted to the biclustering model.

Let $f(\cdot, t) : \mathbb{R} \to \mathbb{R}$ be a scalar function for each iteration t. To be definite, we shall describe the algorithm such that at each iteration, the messages are passed either from the row indices to the column indices, or vice-versa, but not both. The messages are defined as follows for $t \geq 0$:

$$(t \text{ even}) \qquad \theta_{i\to j}^{t+1} = \frac{1}{\sqrt{n_2}} \sum_{\ell \in [n_2]\backslash\{j\}} W_{i\ell} f(\theta_{\ell\to i}^t, t), \quad \forall i \in [n_1], j \in [n_2] \tag{43}$$

$$(t \text{ odd}) \qquad \theta_{j\to i}^{t+1} = \frac{1}{\sqrt{n_1}} \sum_{\ell \in [n_1]\backslash\{i\}} W_{\ell j} f(\theta_{\ell\to j}^t, t), \quad \forall j \in [n_2], i \in [n_1], \tag{44}$$

with the initial condition $\theta_{\ell\to i}^0 = 0$ for $(\ell, i) \in [n_2] \times [n_1]$. Moreover, let the aggregated beliefs be given by

$$(t \text{ even}) \qquad \theta_i^{t+1} = \frac{1}{\sqrt{n_2}} \sum_{\ell \in [n_2]} W_{i\ell} f(\theta_{\ell\to i}^t, t), \quad \forall i \in [n_1] \tag{45}$$

$$(t \text{ odd}) \qquad \theta_j^{t+1} = \frac{1}{\sqrt{n_1}} \sum_{\ell \in [n_1]} W_{\ell j} f(\theta_{\ell\to j}^t, t), \quad \forall j \in [n_2]. \tag{46}$$

Recall $\lambda_i = \frac{K_i^2\mu^2}{n_i}$ for $i = 1, 2$. Suppose as $n \to \infty$, for t even (odd), θ_i^t is approximately $\mathcal{N}(\mu_t, \tau_t)$ for $i \in C_1^*$ ($i \in C_2^*$) and $\mathcal{N}(0, \tau_t)$ for $i \in [n_1]\backslash C_1^*$ ($i \in [n_2]\backslash C_2^*$). Then similar to

the symmetric case, the update equations of message passing and the fact that $\theta^t_{i\to j} \approx \theta^t_i$ for all i, j suggest the following state evolution equations for $t \geq 0$:

$$\mu_{t+1} = \begin{cases} \sqrt{\lambda_2}\mathbb{E}\left[f(\mu_t + \tau_t Z, t)\right] & t \text{ even} \\ \sqrt{\lambda_1}\mathbb{E}\left[f(\mu_t + \tau_t Z, t)\right] & t \text{ odd} \end{cases} \tag{47}$$

$$\tau_{t+1} = \mathbb{E}\left[f(\tau_t Z, t)^2\right]. \tag{48}$$

The optimal choice of f for maximizing the signal-to-noise ratio $\frac{\mu_{t+1}}{\tau_{t+1}}$ is again $f(x,t) = e^{x\mu_t - \mu_t^2}$. With this optimized f, we have $\tau_{t+1} = 1$ and the state evolution equations reduce to

$$\mu^2_{t+1} = \begin{cases} \lambda_2 e^{\mu_t^2} & t \text{ even} \\ \lambda_1 e^{\mu_t^2} & t \text{ odd} \end{cases} \tag{49}$$

with $\mu_0 = 0$.

To justify the state evolution equations, we rely on the method of moments, requiring f to be polynomial. Thus, we choose $f = f_d(\cdot, t)$ as per Lemma 7, which maximizes the signal-to-noise ratio among all polynomials with degree up to d. With $f = f_d$, we have $\tau_{t+1} = 1$ and the state evolution equations reduce to

$$\widehat{\mu}^2_{t+1} = \begin{cases} \lambda_2 G_d(\widehat{\mu}_t^2) & t \text{ even} \\ \lambda_1 G_d(\widehat{\mu}_t^2) & t \text{ odd} \end{cases} \tag{50}$$

where $G_d(\mu) = \sum_{k=0}^d \frac{\mu^k}{k!}$.

Combining message passing with spectral cleanup, we obtain the following algorithm for estimating C_1^* and C_2^*.

Algorithm 4 Message passing for biclustering

1: Input: $n_1, n_2, K_1, K_2 \in \mathbb{N}$, $\mu > 0$, $W \in \mathbb{R}^{n_1 \times n_2}$, $d^* \in \mathbb{N}$, $t^* \in 2\mathbb{N}$, and $s^* > 0$.
2: Initialize: $\theta^0_{\ell\to i} = 0$ for $(\ell, i) \in [n_2] \times [n_1]$. For $t \geq 0$, define the sequence of degree-d^* polynomials $f_{d^*}(\cdot, t)$ as per Lemma 7 and $\widehat{\mu}_t$ according to (50).
3: Run t^* iterations of message passing as in (43) and (44) with $f = f_{d^*}$ and compute $\theta_i^{t^*}$ for all $i \in [n_1]$ as per (45) and $\theta_j^{t^*+1}$ for all $j \in [n_2]$ as per (46).
4: Find the sets $\widetilde{C}_1 = \{i \in [n_1] : \theta_i^{t^*} \geq \widehat{\mu}_{t^*}/2\}$ and $\widetilde{C}_2 = \{j \in [n_2] : \theta_j^{t^*+1} \geq \widehat{\mu}_{t^*+1}/2\}$.
5: (Cleanup via power method) Denote the restricted matrix $W_{\widetilde{C}_1\widetilde{C}_2}$ by $\widetilde{W}$. Sample u^0 uniformly from the unit sphere in $\mathbb{R}^{|\widetilde{C}_1|}$ and compute $u^{t+2} = \widetilde{W}\widetilde{W}^\top u^t / \|\widetilde{W}\widetilde{W}^\top u^t\|$, for t even and $0 \leq t \leq 2\lceil s^* \log(n_1 n_2)\rceil - 2$. Let $\widehat{u} = u^{2\lceil s^* \log(n_1 n_2)\rceil}$. Return $\widehat{C}_1$, the set of K_1 indices i in $\widetilde{C}_1$ with the largest values of $|\widehat{u}_i|$. Compute the power iteration with $\widetilde{W}^\top\widetilde{W}$ for odd values of t and return $\widehat{C}_2$ similarly.

We now turn to the performance of Algorithm 4. Let

$$\mathcal{G} = \{(\lambda_1, \lambda_2) : \mu_t \to \infty\}, \tag{51}$$

$$\mathcal{G}_d = \{(\lambda_1, \lambda_2) : \widehat{\mu}_t \to \infty\}. \tag{52}$$

As $d \to \infty$, $G_d(\mu) \to e^\mu$ uniformly over bounded intervals. It suggests that if $(\lambda_1, \lambda_2) \in \mathcal{G}$, then there exists a $d^*(\lambda_1, \lambda_2)$ such that $(\lambda_1, \lambda_2) \in \mathcal{G}_{d^*}$ and hence $\widehat{\mu}_t \to \infty$ as $t \to \infty$. The following lemma confirms this intuition.

Lemma 16 *For $d \geq 1$, $\mathcal{G}_d \subset \mathcal{G}_{d+1}$ with $\mathcal{G}_1 = \{(\lambda_1, \lambda_2) : \lambda_1\lambda_2 \geq 1\}$, and $\cup_{d=1}^\infty \mathcal{G}_d = \mathcal{G}$.*

Proof By definition, $G_1(x) = 1 + x$ and thus for t even, $\widehat{\mu}^2_{t+2} = \lambda_1(1 + \lambda_2(1 + \widehat{\mu}_t^2))$. As a consequence, $\widehat{\mu}_t \to \infty$ if and only if $\lambda_1\lambda_2 \geq 1$, proving the claim for $\mathcal{G}_1$. Let $\phi_d(x) \triangleq \lambda_1 G_d(\lambda_2 G_d(x))$ so that $\widehat{\mu}^2_{t+2} = \phi_d(\widehat{\mu}_t^2)$ for t even . The fact $\mathcal{G}_d \subset \mathcal{G}_{d+1} \subset \mathcal{G}$ follows from the fact $\phi_d(x)$ is increasing in d and $\phi_d(x) < \phi(x)$, where ϕ is defined in Remark 17. To prove $\cup_{d=1}^\infty \mathcal{G}_d = \mathcal{G}$, fix $(\lambda_1, \lambda_2) \in \mathcal{G}$. It suffices to show that $(\lambda_1, \lambda_2) \in \mathcal{G}_d$ for d sufficiently large. Since $\phi_2(x)/x^2 \to \infty$ as $x \to \infty$, there exists an absolute constant $x_0 > 1$ such that $\phi_d(x) \geq x^2$ whenever $x \geq x_0$ and $d \geq 2$. Let t_0 be an even number such that $\mu^2_{t_0} > x_0$. Since $\phi_d(x)$ converges to $\phi(x)$ uniformly on bounded intervals, it follows that the first $t_0/2$ iterates using ϕ_d converge to the corresponding iterates using ϕ. So, for d large enough, $\widehat{\mu}^2_{t_0} > x_0$, and hence, for such d, $\widehat{\mu}^2_t \to \infty$ as $t \to \infty$, so $(\lambda_1, \lambda_2) \in \mathcal{G}_d$. ■

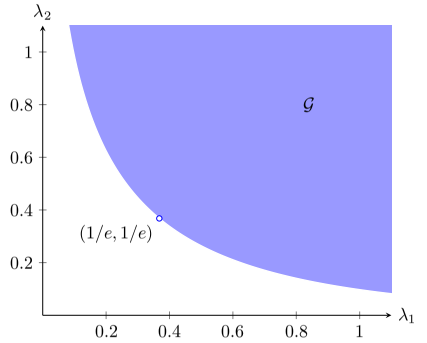

Figure 1: Required signal-to-noise ratios by Algorithm 4 for biclustering.

Remark 17 *Clearly $\mathcal{G}$ is an open subset of $\mathbb{R}^2_+$ and $\mathcal{G}$ is an upper closed set. Let $\partial\mathcal{G}$ denote its boundary and let $\phi(x) \triangleq \lambda_1 e^{\lambda_2 e^x}$, so that $\mu^2_{t+2} = \phi(\mu_t^2)$ for t even. Note that $(\lambda_1, \lambda_2) \in \partial\mathcal{G}$ if and only if the function is such that for some $x > 0$, $\phi(x) = x$ and $\phi'(x) = 1$. Since $\phi'(x) = \phi(x)y$, where $y = \lambda_2 e^x$, it follows that $xy = 1$ where $x = \lambda_1 e^y$. Therefore, it is convenient to express the boundary of $\mathcal{G}$ in the parametric form*

$$\partial\mathcal{G} = \{(xe^{-1/x}, x^{-1}e^{-x}) : x > 0\}.$$

It follows that $(1/e, 1/e) \in \partial G$ and $\{(\lambda_1, \lambda_2) \in \mathbb{R}^2_+ : \lambda_1\lambda_2 \geq e^{-2}\}\backslash\{(1/e, 1/e)\} \subset \mathcal{G}$ (see Fig. 1 for an illustration). Boundaries of $\mathcal{G}_d$ can be determined similar to (25) (see Fig. 2 for plots).

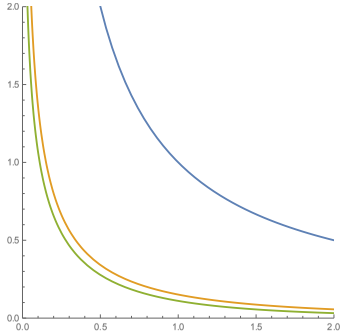

Figure 2: Boundaries of the regions $\mathcal{G}_d$ for $d = 1, 2, 3$; as d increases, $\mathcal{G}_d$ converges to $\mathcal{G}$ in Fig. 1.

The correctness proof for the spectral clean-up procedure in Algorithm 4 is given by Lemma 18 below with s^* defined by (56); it is similar to Lemma 12 used in Theorem 1 but applies to rectangular matrices and uses singular value decomposition.

Lemma 18 *Suppose*

$$\frac{\mu\sqrt{K_1 K_2}}{\sqrt{n_1}+\sqrt{n_2}} \geq \frac{1}{c_0} \tag{53}$$

for some $c_0 > 0$. For $i = 1, 2$, suppose that $\frac{|C_i^*|}{K_i} \to 1$ in probability and $\widetilde{C}_i$ is a set (possibly depending on W) such that

$$\frac{1}{K_i}|\widetilde{C}_i \cap C_i^*| \geq 1 - \epsilon \tag{54}$$

$$K_i(1-\epsilon) \leq |\widetilde{C}_i| \leq n_i\epsilon \tag{55}$$

hold for some $0 < \epsilon < \epsilon_0$, where ϵ_0 depends only on c_0. Let

$$s^* = \left(\log \frac{1-\epsilon-3c_0\sqrt{h(\epsilon)+\epsilon}}{3c_0\sqrt{h(\epsilon)+\epsilon}}\right)^{-1} \tag{56}$$

where $h(\epsilon) \triangleq \epsilon \log \frac{1}{\epsilon} + (1-\epsilon)\log\frac{1}{1-\epsilon}$ is the binary entropy function. Then $\widehat{C}_i$ returned by Algorithm 4 satisfies $|\widehat{C}_i \Delta C_i^*| \leq \eta(\epsilon) K_i$ for $i = 1, 2$, with probability converging to one as $n \to \infty$, where

$$\eta(\epsilon) = 2\epsilon + 650c_0^2\,\frac{h(\epsilon)+\epsilon}{(1-\epsilon)^2}. \tag{57}$$

With Lemma 18, we are ready to show that the bicluster message passing algorithm (Algorithm 4) approximately recovers C_1^* and C_2^*, provided that $(\lambda_1, \lambda_2) \in \mathcal{G}$.

Theorem 19 *Fix $\lambda_1, \lambda_2 > 0$. Suppose $\frac{K_i^2\mu^2}{n_i} \to \lambda_i$, $K_1 \asymp K_2$, and $\Omega(\sqrt{n_i}) \leq K_i \leq o(n_i)$ as $n \to \infty$, for $i = 1, 2$. Consider the model (1) with $|C_i^*|/K_i \to 1$ in probability as $n \to \infty$. Suppose $(\lambda_1, \lambda_2) \in \mathcal{G}$ and define $d^*(\lambda_1, \lambda_2)$ as in (59). For every $\eta \in (0, 1)$, there exist explicit positive constants t^*, s^* depending on $(\lambda_1, \lambda_2, \eta)$ such that Algorithm 4 returns $|\widehat{C}_i \cap C_i^*| \geq (1-\eta)K_i$ for $i = 1, 2$ with probability converging to 1 as $n \to \infty$, and the total running time is bounded by $c(\eta, \lambda_1, \lambda_2) n_1 n_2 \log(n_1 n_2)$, where $c(\eta, \lambda_1, \lambda_2) \to \infty$ as either $\eta \to 0$ or (λ_1, λ_2) approaches $\partial\mathcal{G}$.*

Remark 20 (Exact biclustering via message passing) *If the assumptions of Theorem 19 hold and the voting condition* (39) *(respectively,* (41)*) holds, then C_1^* (respectively, C_2^*) can be exactly recovered by message passing plus a voting procedure as described in Algorithm 3. Similar to the analysis in the symmetric case, whenever information-theoretic sufficient conditions for exact recovery* (39)–(41) *imply the sufficient condition of message passing for weak recovery, i.e., $(\lambda_1, \lambda_2) \in \mathcal{G}$ defined in (52), there is no computational gap for exact recovery.*

To be more precise, consider $K_i = \frac{\rho_i n}{\log n}$ for $i = 1, 2$. Then (39) *and* (41) *are equivalent to $\lambda_i > 8\rho_i$. Thus, whenever K_1 and K_2 are large enough so that $(8\rho_1, 8\rho_2)$ lies in the closure $\boldsymbol{cl}(\mathcal{G})$, or more generally,*

$$\left(\liminf_{n\to\infty} \frac{K_1 \log n_1}{n_1},\ \liminf_{n\to\infty} \frac{K_2 \log n_2}{n_2}\right) \in \frac{1}{8}\boldsymbol{cl}(\mathcal{G}), \tag{58}$$

then Algorithm 4 plus voting achieves the information-theoretic exact recovery threshold with optimal constants. This result can be viewed as a two-dimensional counterpart of (20) obtained for the symmetric case.

Proof [Proof of Theorem 19] The proof follows step-by-step that of Theorem 1; we shall point out the minor differences. Given λ_1 and λ_2, define

$$d^*(\lambda_1, \lambda_2) = \inf\{d \in \mathbb{N} : (\lambda_1, \lambda_2) \in \mathcal{G}_d\}. \tag{59}$$

By the assumptions of Theorem 19, there exists $c_0 > 0$ so that (53) holds. Given any $\eta \in (0, 1)$, choose an arbitrary $\epsilon \in (0, \epsilon_0)$ such that $\eta(\epsilon)$ defined in (57) is at most η. Notice that ϵ_0 is determined by c_0. Let $M = 8\log(1/\epsilon)$ and choose

$$t^*(\lambda_1, \lambda_2, M) = \inf\left\{t : \min\{\widehat{\mu}_t, \widehat{\mu}_{t+1}\} > M\right\}. \tag{60}$$

In view of Lemma 16 and the assumption that $(\lambda_1, \lambda_2) \in \mathcal{G}$, d^* is finite. Since $(\lambda_1, \lambda_2) \in \mathcal{G}_{d^*}$, it follows that $\widehat{\mu}_t \to \infty$ and thus $t^*(\lambda_1, \lambda_2, M)$ is finite.

The assumptions of Theorem 19 imply that $n_1 \asymp n_2$. Lemmas 27 - 29 therefore go through as before, with n in the upper bounds taken to be $\min\{n_1, n_2\}$, so that $\frac{1}{\sqrt{n_i}} \leq \frac{1}{\sqrt{n}}$. This modification then implies that Lemma 6, justifying the state evolution equations, goes through as before. See Section 6.1 for more details.

Finally, the proof is complete by invoking Lemma 18. ∎

6. Justification of state evolution equations

In this section we prove Lemma 6. Let $f(x,t) = \sum_{i=0}^{d} q_i^t x^i$ with $|q_i^t| \le C$ for a constant C. Let $\{A^t, t \ge 1\}$ be i.i.d. matrices distributed as A conditional on C^* and let $A^0 = A$. We now define a sequence of vectors $\{\xi^t, t \ge 1\}$ with $\xi^t \in \mathbb{R}^n$ given by

$$\xi_{i\to j}^{t+1} = \sum_{\ell \in [n]\setminus \{i,j\}} A_{\ell i}^t f(\xi_{\ell\to i}^t, t), \quad \forall j \ne i \in [n] \tag{61}$$

$$\xi_i^{t+1} = \sum_{\ell \in [n]\setminus\{i\}} A_{\ell i}^t f(\xi_{\ell\to i}^t, t)$$

$$\xi_{i\to j}^0 = 0. \tag{62}$$

In the definition of ξ^t, fresh samples, A^t, of A are used at each iteration, and thus the moments of ξ^t in the asymptotic limit are easier to compute than those of θ^t. Use of the fresh samples A^t does not make the messages $(\xi_{i\to\ell}^t : i \in [n]\setminus\ell)$ independent for fixed $\ell \in [n]$ and fixed $t \ge 2$, because at $t = 1$ the messages sent by any one vertex to all other vertices are statistically dependent, so at $t = 2$ the messages sent by all vertices are statistically dependent. However, we can take advantage of the fact that the contribution of each individual message is small in the limit as $n \to \infty$. Hence, we first prove that ξ^t and θ^t have the same moments of all orders as $n \to \infty$, and then prove the lemma using the method of moments.

The first step is to represent $(\theta_{i\to j}^t, \theta_i^t)$ and $(\xi_{i\to j}^t, \xi_i^t)$ as sums over a family of finite rooted labeled trees as shown by (Deshpande and Montanari, 2015, Lemma 3.3). We next introduce this family in detail. We shall consider rooted trees T of the following form. All edges are directed towards the root. The set of vertices and the set of (directed) edges in a tree T are denoted by $V(T)$ and $E(T)$, respectively. Each vertex has at most d children. The set of leaf vertices of T, denoted by $L(T)$, is the set of vertices with no children. Every vertex in the tree has a *label* which includes the *type* of the vertex, where the types are selected from $[n]$. The label of the root vertex consists of the type of the root vertex, and for every non-root vertex the label has two arguments, where the first argument in the label is the type of the vertex (in $[n]$), and the second one is the *mark* (in $\{0,\dots,d\}$). For a vertex v in T, let $\ell(v)$ denote its type, $r(v)$ its mark (if v is not the root), and $|v|$ its distance from the root in T. For clarity, we restate the definition of family of rooted labeled trees introduced in (Deshpande and Montanari, 2015, Definition 3.2).

Definition 21 *Let $\mathcal{T}^t$ denote the family of labeled trees T with exactly t generations satisfying the conditions:*

1. *The root of T has degree 1.*
2. *Any path $(v_1, v_2, \dots, v_k)$ in the tree is non-backtracking, i.e., the types $\ell(v_i), \ell(v_{i+1}), \ell(v_{i+2})$ are distinct for all i, k.*
3. *For a vertex u that is not the root or a leaf, the mark $r(u)$ is set to the number of children of v.*
4. *Note that $t = \max_{v\in L(T)} |v|$. All leaves u with $|u| \le t-1$ have mark 0.*

Let $\mathcal{T}_{i\to j}^t \subset \mathcal{T}^t$ be the subfamily satisfying the following additional conditions:

1. *The type of the root is i.*
2. *The root has a single child with type distinct from i and j.*

Similarly, let $\mathcal{T}_i^t \subset \mathcal{T}^t$ be the subfamily satisfying the following:

1. *The type of the root is i.*
2. *The root has a single child with type distinct from i.*

We point out that under the above definition, a vertex of a tree in $\mathcal{T}^t$ can have siblings of the same type and mark. Also two trees in $\mathcal{T}^t$ are considered to be the same if and only if the labels of all vertices are the same, with the understanding that the order of the children of any given vertex matters. In addition, the mark of a leaf u with $|u| = t$ is not specified and can possibly take any value in $\{0,\dots,d\}$. The following lemma is proved by induction on t and the proof can be found in (Deshpande and Montanari, 2015, Lemma 3.3).

Lemma 22

$$\theta_{i\to j}^t = \sum_{T\in\mathcal{T}_{i\to j}^t} A(T)\Gamma(T,\mathbf{q},t)\theta(T),$$

$$\theta_i^t = \sum_{T\in\mathcal{T}_i^t} A(T)\Gamma(T,\mathbf{q},t)\theta(T),$$

where[9]

$$A(T) \triangleq \prod_{u\to v\in E(T)} A_{\ell(u),\ell(v)},$$

$$\Gamma(T,\mathbf{q},t) \triangleq \prod_{u\to v\in E(T)} q_{r(u)}^{t-|u|},$$

$$\theta(T) \triangleq \prod_{u\to v\in E(T): u\in L(T)} (\theta_{\ell(u)\to\ell(v)}^0)^{r(u)}.$$

Similarly,

$$\xi_{i\to j}^t = \sum_{T\in\mathcal{T}_{i\to j}^t} \bar{A}(T)\Gamma(T,\mathbf{q},t)\theta(T),$$

$$\xi_i^t = \sum_{T\in\mathcal{T}_i^t} \bar{A}(T)\Gamma(T,\mathbf{q},t)\theta(T),$$

where

$$\bar{A}(T) \triangleq \prod_{u\to v\in E(T)} A_{\ell(u),\ell(v)}^{t-|u|}.$$

9. Often the initial messages for message passing are taken, with some abuse of notation, to have the form $\theta_{i\to j}^0 = \theta_i^0$ for all j, and then only the n variables θ_i^0 need to be specified. In that case, the expression for $\theta(T)$ simplifies to $\theta(T) \triangleq \prod_{u\in L(T)} (\theta_{\ell(u)}^0)^{r(u)}$.

Since the initial messages are zero, $f(\theta^0_{i\to j},0)=q^0_0$. *Thus, for notational convenience in what follows, we can assume without loss of generality that $f(x,0)\equiv q^0_0$, i.e., $f(x,0)$ is a degree zero polynomial.* With this assumption, it follows that for a labeled tree $T\in\mathcal{T}^t$, $\Gamma(T,\mathbf{q},t)=0$ unless the mark of every leaf of T is zero. If the mark of every leaf is zero, then $\theta(T)=1$, because in this case $\theta(T)$ is a product of terms of the form 0^0, which are all one, by convention. Therefore, $\Gamma(T,\mathbf{q},t)\theta(T)=\Gamma(T,\mathbf{q},t)$ for all $T\in\mathcal{T}_t$. Consequently, the factor $\theta(T)$ can be dropped from the representations of $\theta^t_{i\to j}$, θ^t_i, $\xi^t_{i\to j}$, and ξ^t_i given in Lemma 22. Applying Lemma 22, we can prove that all finite moments of θ^t_i and ξ^t_i are asymptotically the same. Before that, we need two key auxiliary lemmas.

Let $\phi(T)_{rs}$ denote the number of occurrences of edges $(u\to v)$ in the tree T with types $\ell(u),\ell(v)=\{r,s\}$.

Definition 23 *For $m\geq 1$ and given an m-tuple of trees $T_1,\ldots,T_m$, let G denote the undirected graph obtained by identifying the vertices of the same type in the trees and removing the edge directions. Let $E(G)$ denote the edge set of G. Then an edge (r,s) is in $E(G)$ if and only if $\sum_{\ell=1}^m\phi(T_\ell)_{rs}\geq 1$, i.e., the number of times covered is at least one. Let G_1 denote the restriction of G to the vertices in C^* and G_2 the restriction of G to the vertices in $[n]\backslash C^*$. Let $E(G_1)$ and $E(G_2)$ denote the edge set of G_1 and G_2, respectively. Let E_J denote the set of edges in G with one endpoint in G_1 and the other endpoint in G_2.*

Lemma 24 *Suppose an m-tuple of trees $T_1,\ldots,T_m\in\mathcal{T}^t$ has α edges in total, and there are k different edges (r,s) in $E(G_1)$ which are covered exactly once, i.e., $\sum_{\ell=1}^m\phi(T_\ell)_{rs}=1$. Then*

$$\left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right]\right|\leq c\mu^k n^{-\alpha/2}$$

for a consant c independent of n. The same conclusion also holds when replacing $A(T_\ell)$ by $\bar{A}(T_\ell)$.

Proof By the definition of $A(T)$,

$$\begin{aligned}
\left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right]\right| &= \left|\mathbb{E}\left[\prod_{j<j'}(A_{jj'})^{\sum_{\ell=1}^m\phi(T_\ell)_{jj'}}\right]\right| \leq \prod_{j<j'}\left|\mathbb{E}\left[(A_{jj'})^{\sum_{\ell=1}^m\phi(T_\ell)_{jj'}}\right]\right| \\
&= \left(\frac{\mu}{\sqrt{n}}\right)^k \prod_{j<j':\sum_{\ell=1}^m\phi(T_\ell)_{jj'}\geq 2}\left|\mathbb{E}\left[(A_{jj'})^{\sum_{\ell=1}^m\phi(T_\ell)_{jj'}}\right]\right| \\
&\leq \left(\frac{\mu}{\sqrt{n}}\right)^k \prod_{j<j':\sum_{\ell=1}^m\phi(T_\ell)_{jj'}\geq 2}\mathbb{E}\left[|A_{jj'}|^{\sum_{\ell=1}^m\phi(T_\ell)_{jj'}}\right] \\
&\leq c\left(\frac{\mu}{\sqrt{n}}\right)^k \prod_{j<j':\sum_{\ell=1}^m\phi(T_\ell)_{jj'}\geq 2}\left(\frac{1}{\sqrt{n}}\right)^{\sum_{\ell=1}^m\phi(T_\ell)_{jj'}} \\
&= c\mu^k n^{-\alpha/2},
\end{aligned}$$

where the last inequality follows because Z_{ij} are zero-mean subgaussian random variables with proxy variance γ and consequently for $1\leq p\leq\alpha$, $\mathbb{E}\left[\left|\frac{Z_{ij}}{\sqrt{n}}\right|^p\right]\leq cn^{-p/2}$ and $\mathbb{E}\left[\left|\frac{Z_{ij}+\mu}{\sqrt{n}}\right|^p\right]\leq cn^{-p/2}$ where c is a finite constant depending on γ,α, and $\mu_{\max}$, where $\mu_{\max}$ is an upper bound on μ for all n, which is finite[10] by the assumptions that $K=\Omega(\sqrt{n})$ and $\lambda=\Theta(1)$. ■

We next define an equivalence relation on the family of m-tuples of trees in $\mathcal{T}^t$, which is useful for enumerating such m-tuples. Fix a set $D\subset[n]$ of distinguished types; the notion of equivalence depends on D. In this paper when we focus on the messages formed by one vertex $\{i\}$ we take $D=\{i\}$ and when we focus on the covariance of messages formed by two vertices, i and j, we take $D=\{i,j\}$.

Definition 25 *For $D\subset[n]$, two m-tuples of trees in $\mathcal{T}^t$ are* equivalent *(relative to D) if there is a permutation of the set of types $[n]$ such that i maps to i for each $i\in D$, C^* maps to C^*, so also $[n]\backslash C^*$ maps to $[n]\backslash C^*$, such that the following is true: the second m-tuple of trees is obtained by applying the permutation to the types of the vertices of the first m-tuple of trees.*

To clarify, if two m-tuples of trees are equivalent, in particular, the marks of the two m-tuples must be the same, and the set of vertices with type $i\in D$ is the same. Recall that for trees to be considered equal, the order of children matters. The same is true when considering trees to be equivalent relative to D. Thus, for example, if (T_1,T_2) is equivalent to (T_1',T_2') and if (T_1,T_2) has the following property: the first child of the first child of the root in T_1 has the same type as the third child of the second child of the root in T_2, then (T_1',T_2') must have the same property. Furthermore, if the common type for those two vertices in (T_1,T_2) is some $i\in D$, then those two vertices in (T_1',T_2') must also have type i. If the common type for those two vertices in (T_1,T_2) is some $k\in C^*\backslash D$, then those two vertices in (T_1',T_2') must also have some common type $k'\in C^*\backslash D$.

Lemma 26 *For a given set of distinguished types D, let $\mathcal{S}$ denote the set of equivalence classes on the family of m-tuples of trees in $\mathcal{T}^t$. Then $|\mathcal{S}|\leq c$ for a constant c dependent on only $m,t,d,|D|$ (not on n). Moreover, fix any equivalence class $S\in\mathcal{S}$ and a representative m-tuple of trees $(T_1,\ldots,T_m)$ which has t_1 and t_2 distinct types in $C^*\backslash D$ and $[n]\backslash(C^*\cup D)$, respectively. Then $|S|\leq K^{t_1}n^{t_2}$.*

Proof The total number of vertices of an m-tuple $(T_1,\ldots,T_m)$ is bounded by a function of m,t,d alone and thus independently of n, therefore so are the number of ways to partition these vertices into subsets of vertices with the same type. For each such subset, we need to designate whether the type of the vertices in this subset is one of the distinguished types $i\in D$, or is in $C^*\backslash D$, or is in $[n]\backslash(C^*\cup D)$. The total number of distinct such designations is bounded by a function of $m,t,d,|D|$ independently of n. Finally, we need to assign marks to the vertices of the trees, and the number of distinct assignments is bounded by a function of m,t,d alone. Hence, $|\mathcal{S}|$ is bounded by a function of m,t,d alone.

10. This is where the assumption $K=\Omega(\sqrt{n})$ is used because $\frac{K^2\mu^2}{n}$ is assumed to be a constant λ.

Fix a given equivalence class $S \in \mathcal{S}$ and a representative m-tuple of trees $(T_1, \ldots, T_m)$ in S. Consider all the types from $[n]\backslash D$ that appear at least once for some vertex of some tree in the m-tuple. Then t_1 is the number of such types in $C^*\backslash D$ and t_2 is the number of such types in $[n]\backslash(C^* \cup D)$. The cardinality of S is at most the product of the number of partial permutations of length t_1 of elements chosen from $C^*\backslash D$, times the number of partial permutations of length t_2 of elements chosen from $[n]\backslash(C^* \cup D)$. The conclusion follows. ■

Combining Lemmas 22, 24, and 26, we have the following lemma, showing that all finite moments of θ_i^t and ξ_i^t are asymptotically close.

Lemma 27 *For any $t \geq 1$, there exists a constant c independent of n and dependent on m, t, d, C such that for any $i \in [n]$:*

$$\left|\mathbb{E}\left[(\theta_i^t)^m\right] - \mathbb{E}\left[(\xi_i^t)^m\right]\right| \leq cn^{-1/2}.$$

Proof As explained right after Lemma 22, the assumption that $f(x, 0) \equiv q_0^0$ implies that the factor $\theta(T)$ can be dropped in the representations given in Lemma 22. Therefore, it follows from Lemma 22 that for $t \geq 1$,

$$\mathbb{E}\left[(\theta_i^t)^m\right] = \sum_{T_1,\ldots,T_m \in \mathcal{T}_i^t} \prod_{\ell=1}^m \Gamma(T_\ell, \mathbf{q}, t)\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right],$$
$$\mathbb{E}\left[(\xi_i^t)^m\right] = \sum_{T_1,\ldots,T_m \in \mathcal{T}_i^t} \prod_{\ell=1}^m \Gamma(T_\ell, \mathbf{q}, t)\mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right].$$

Because the coefficients in the polynomial are bounded by C and there are m trees with each tree containing at most $1+d+\cdots+d^{t-1} \leq (d+1)^t$ edges, $|\prod_{\ell=1}^m \Gamma(T_\ell, \mathbf{q}, t)| \leq C^{m(d+1)^t}$. Therefore, it suffices to show

$$\sum_{T_1,\ldots,T_m \in \mathcal{T}_i^t} \left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right] - \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right]\right| \leq cn^{-1/2}.$$

In the following, let c denote a constant only depending on m, t, d and its value may change line by line. Recall (G, G_1, G_2) obtained from a given m-tuple of trees $T_1, \ldots, T_m$ as defined in Definition 23. We partition set $\{(T_1, \ldots, T_m) : T_\ell \in \mathcal{T}_i^t\}$ as a union of four disjoint sets $Q \cup R_1 \cup R_2 \cup R_3$, where

1. Q consists of m-tuples of trees $(T_1, \ldots, T_m)$ such that there exists an edge (r, s) in $E(G_2) \cup E_J$ which is covered exactly once.
2. R_1 consists of m-tuples of trees $(T_1, \ldots, T_m)$ such that all edges in $E(G_2) \cup E_J$ are covered at least twice and at least one of them is covered at least 3 times.
3. R_2 consists of m-tuples of trees $(T_1, \ldots, T_m)$ such that each edge in $E(G_2) \cup E_J$ is covered exactly twice and the graph G contains a cycle.

4. R_3 consists of m-tuples of trees $(T_1, \ldots, T_m)$ such that each edge in $E(G_2) \cup E_J$ is covered exactly twice and the graph G is a tree.

Fix any $(T_1, \ldots, T_m) \in Q$ and let (r, s) be an edge in $E(G_2) \cup E(J)$ which is covered exactly once. Since $\mathbb{E}[A_{rs}] = 0$ and A_{rs} appears in the product $\prod_{\ell=1}^m A(T_\ell)$ once, it follows that $\mathbb{E}[\prod_{\ell=1}^m A(T_\ell)] = 0$. Similarly, $\mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right] = 0$. Therefore, it is sufficient to show that for $j = 1, 2, 3$,

$$\sum_{(T_1,\ldots,T_m) \in R_j} \left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right] - \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right]\right| \leq cn^{-1/2}.$$

First consider R_1. Further, divide R_1 according to the total number of edges in $T_1, \ldots, T_m$ and the number of edges in $E(G_1)$ which are covered exactly once. In particular, for $\alpha = 1, \ldots, m(d+1)^t$ and $k = 0, 1, \ldots, \alpha$, let $R_{1,\alpha,k}$ denote the subset of R_1 consisting of m-tuples of trees $T_1, \ldots, T_m$ such that there are α edges in $T_1, \ldots, T_m$ and there are k edges in $E(G_1)$ which are covered exactly once. It suffices to show that

$$\sum_{(T_1,\ldots,T_m) \in R_{1,\alpha,k}} \left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right] - \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right]\right| \leq cn^{-1/2}. \tag{63}$$

Fix α, k and an m-tuple of trees $(T_1, \ldots, T_m) \in R_{1,\alpha,k}$. It follows from Lemma 24 that

$$\left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right]\right| \leq c\mu^k n^{-\alpha/2}. \tag{64}$$

Throughout the proof of this lemma, let $D = \{i\}$ be the set of distinguished types for defining equivalence classes as specified in Definition 25. We consider breaking $R_{1,\alpha,k}$ down into a large number of smaller sets, where each set is an equivalence class. While large, it follows from Lemma 26 that the number of these smaller sets depends on m, t, d, but not on n. Hence, it suffices to upper bound $|S|$ for any given equivalence class $S \subset R_{1,\alpha,k}$. It follows from Lemma 26 that $|S| \leq K^{n_1} n^{n_2}$, where n_1 is the number of vertices in G_1 with types in $C^*\backslash\{i\}$ and n_2 is the number of vertices in G_2 with types in $[n]\backslash(C^* \cup \{i\})$.

We further upper bound n_1 and n_2. The graph G is connected (because all the trees have a root of type i), so $n_1 + n_2$ (the number of vertices of G minus one) is less than or equal to the number of edges in G. The number of edges in G is at most $k + \frac{\alpha-k-1}{2}$ because there are k edges in G covered once, and the rest are covered at least twice, with one edge covered at least three times. So $n_1 + n_2 \leq k + \frac{\alpha-k-1}{2}$. Also, since k of the edges in G have both endpoints in C^*, and the vertices of G_2 have types in $[n] - C^*$, there are at most $\frac{\alpha-k-1}{2}$ edges in G with at least one endpoint in G_2. Moreover, since G is connected, each connected component in G_2 is connected by at least one edge to a vertex in G_1. Therefore, $n_2 \leq |V(G_2)| \leq \frac{\alpha-k-1}{2}$. The bound $K^{n_1} n^{n_2}$ is maximized subject to $n_1 + n_2 \leq k + \frac{\alpha-k-1}{2}$ and $n_2 \leq \frac{\alpha-k-1}{2}$ by letting equality hold in both constraints, yielding $|S| \leq K^k n^{\frac{\alpha-k-1}{2}}$. Combining with (64) shows that

$$\sum_{(T_1,\ldots,T_m) \in S} \left|\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right]\right| \leq c\mu^k n^{-\alpha/2} K^k n^{\frac{\alpha-k-1}{2}} = c\left(\frac{\mu K}{\sqrt{n}}\right)^k n^{-1/2} \leq cn^{-1/2}, \tag{65}$$

where we've used the fact that $\frac{\mu K}{\sqrt{n}}$ is bounded independently of n. In a similar way, it can be shown that

$$\sum_{(T_1,\ldots,T_m)\in S}\left|\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\right]\right|\le cn^{-1/2}$$

and thus

$$\sum_{(T_1,\ldots,T_m)\in S}\left|\mathbb{E}\left[\prod_{\ell=1}^{m}A(T_\ell)\right]-\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\right]\right|\le cn^{-1/2}. \tag{66}$$

Since the number of equivalence classes S does not depend on n, (63) follows.

Next consider R_2. The previous argument carries over with a minor adjustment on the step of upper bounding n_1 and n_2. In particular, define $R_{2,\alpha,k}$ accordingly as $R_{1,\alpha,k}$ and then consider an equivalence class $S\subset R_{2,\alpha,k}$ corresponding to some representative m-tuple in $R_{2,\alpha,k}$. The number of edges in G is at most $k+\frac{\alpha-k}{2}$ because there are k edges in G covered once, and the rest are covered at least twice. Since G has n_1+n_2+1 vertices, is connected, and has a cycle, n_1+n_2 is less than or equal to the number of edges of G minus one, so $n_1+n_2\le k+\frac{\alpha-k-2}{2}$. Also, since k of the edges in G have both endpoints with types in C^*, and V_2 has types in $[n]-C^*$, there are at most $\frac{\alpha-k}{2}$ edges in G with at least one endpoint in V_2. Moreover, since G is connected, each connected component in G_2 is connected by at least one edge to a vertex in G_1. Therefore, $n_2\le|V(G_2)|\le\frac{\alpha-k}{2}$. The bound $K^{n_1}n^{n_2}$ is maximized subject to these constraints by letting equality hold in both constraints, yielding $|S|\le K^{k-1}n^{\frac{\alpha-k}{2}}$. So $|S|\mu^k n^{-\alpha/2}\le\left(\frac{\mu K}{\sqrt{n}}\right)^k/K\le c/K\le cn^{-1/2}$, and the reminder of the proof for bounding the contribution of R_2 is the same as for R_1 above.

Finally, consider R_3. It suffices to establish the following claim. The claim is that for any m-tuple such that G has no cycles, if two directed edges $(a\to b)$ and $(c\to d)$ map to the same edge in G, then they are at the same level in their respective trees (their trees might be the same). Indeed, if the claim is true, then for any m-tuple $(T_1,\ldots,T_m)$ in R_3 and any pair $\{r,s\}\subset[n]$, A^t_{rs} appears in $\prod_{\ell=1}^m\bar{A}(T_\ell)$ for at most one value of t, so that $\mathbb{E}\left[\prod_{\ell=1}^m A(T_\ell)\right]=\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right]$.

We now prove the claim. Let $\{r,s\}$ denote the edge in G covered by both $(a\to b)$ and $(c\to d)$, i.e. $\{\ell(a),\ell(b)\}=\{\ell(c),\ell(d)\}=\{r,s\}$. First consider the case that $\ell(b)=\ell(d)$. Let $u_1,\ldots,u_k$ denote the directed path in the tree containing b that goes from b to the root of that tree, so $b=u_1$ and u_k is the root of the tree. Since there are no cycles in G, and hence no cycles in the set of edges $\{\{\ell(u_1),\ell(u_2)\},\ldots,\{\ell(u_{k-1}),\ell(u_k)\}\}$, (viewed as a simple set, i.e. with duplications removed) it follows from the non-backtracking property that $\ell(u_1),\ldots,\ell(u_k)$ are distinct vertices in G. That is, $(\ell(u_1),\ldots,\ell(u_k))$ is a simple path in G. Similarly, let $v_1,\ldots,v_{k'}$ denote the path in the tree containing d that goes from d to the root of that tree, so $d=v_1$ and $v_{k'}$ is the root of that tree. As for the first path, $(\ell(v_1),\ldots,\ell(v_{k'}))$ is also a simple path in G. Since the roots of all m trees have the same type, $\ell(u_k)$ and $\ell(v_{k'})$ are the same vertex in G. Therefore, $(\ell(u_1),\ldots,\ell(u_k),\ell(v_{k'-1}),\ldots,\ell(v_1))$ is a closed walk in G that is the concatenation of two simple paths. Since G has no cycles those two paths must be reverses of each other. That is, $k=k'$ and $\ell(u_j)=\ell(v_j)$ for all j, and hence $(a\to b)$ and $(c\to d)$ are at the same level in their trees.

Consider the remaining case, namely, that $\ell(b)=\ell(c)$. Let $u_1,\ldots,u_k$ be defined as before, and let $v_1,\ldots,v_{k'}$ denote the path in the tree containing c that goes from c to the root of that tree, so $c=v_1$, $d=v_2$, and $v_{k'}$ is the root of that tree. Arguing as before yields that $k=k'$ and $\ell(u_j)=\ell(v_j)$ for $1\le j\le k$. Note that $k'\ge 2$ and so $k\ge 2$ and $\ell(u_2)=\ell(v_2)=\ell(d)=\ell(a)$. Thus, the types along the directed path $a\to u_1\to u_2$ within one of the trees violates the non-backtracking property, so the case $\ell(b)=\ell(c)$ cannot occur. The claim is proved. This completes the proof of Lemma 27. ■

The second step is to compute the moments of ξ^t in the asymptotic limit $n\to\infty$. We need the following lemma to ensure that all moments of ξ^t are bounded by a constant independent of n.

Lemma 28 *For any $t\ge 1$, there exists a constant c independent of n and dependent on m,t,d,C,γ such that for any $i,j\in[n]$*

$$|\mathbb{E}\left[(\xi^t_{i\to j})^m\right]|\le c,\quad |\mathbb{E}\left[(\xi^t_i)^m\right]|\le c.$$

Proof We prove the claim for ξ^t_i; the claim for $\xi^t_{i\to j}$ follows by the similar argument. Since $\xi^0_{i\to j}=\theta^0_{i\to j}=0$ for all $i\in[n]$, it follows from Lemma 22 that

$$\mathbb{E}\left[(\xi^t_i)^m\right]=\sum_{T_1,\ldots,T_m\in\mathcal{T}_i^t}\prod_{\ell=1}^m\Gamma(T_\ell,\mathbf{q},t)\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right].$$

Recalling (G,G_1,G_2) defined as Definition 23 and following the same argument as used for proving Lemma 27, we can partition set $\{(T_1,\ldots,T_m):T_\ell\in\mathcal{T}_i^t\}$ as a union of four disjoint sets $Q\cup R_1\cup R_2\cup R_3$, and show that

$$\sum_{T_1,\ldots,T_m\in Q}\prod_{\ell=1}^m\Gamma(T_\ell,\mathbf{q},t)\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right]=0,$$

and

$$\sum_{T_1,\ldots,T_m\in R_1\cup R_2}\left|\prod_{\ell=1}^m\Gamma(T_\ell,\mathbf{q},t)\right|\left|\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right]\right|\le cn^{-1/2}.$$

Hence, we only need to check R_3. Again divide R_3 according to the total number of edges in $T_1,\ldots,T_m$ and the number of edges in $E(G_1)$ which are covered exactly once. In particular, $R_3=\cup_{1\le\alpha\le m(d+1)^t,0\le k\le\alpha}R_{3,\alpha,k}$, where $R_{3,\alpha,k}$ is defined in the similar way as $R_{1,\alpha,k}$. Furthermore, similar to $R_{1,\alpha,k}$, consider dividing $R_{3,\alpha,k}$ into a number of equivalence classes (defined relative to $D=\{i\}$), the number of which depends only on m,t,d, as shown in Lemma 26. To prove the lemma, it suffices to show that for any such equivalence class S,

$$\sum_{(T_1,\ldots,T_m)\in S}\left|\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right]\right|\le c.$$

Invoking Lemma 24, we have that

$$\left| \mathbb{E}\left[\prod_{\ell=1}^{m} \bar{A}(T_\ell)\right] \right| \le c\mu^k n^{-\alpha/2},$$

so

$$\sum_{(T_1,\ldots,T_m)\in S} \left| \mathbb{E}\left[\prod_{\ell=1}^{m} \bar{A}(T_\ell)\right] \right| \le c\mu^k n^{-\alpha/2}|S|.$$

Fix a representative m-tuple $(T_1,\ldots,T_m)$ for S. It follows from Lemma 26 that $|S| \le K^{n_1}n^{n_2}$, where n_1 is the number of vertices in G_1 with types in $C^*\backslash\{i\}$ and n_2 is the number of vertices in G_2 with types in $[n]\backslash(C^*\cup\{i\})$.

We can further bound n_1 and n_2 in the similar way as we did for $|R_{1,\alpha,k}|$, with the only adjustment being we cannot use the assumption that there exists at least one edge which is covered at least three times. There are n_1+n_2+1 vertices in the connected graph G and, since the m-tuple is in $R_{3,\alpha,k}$, there are at most $k+\frac{\alpha-k}{2}$ edges in G, so $n_1+n_2 \le k+\frac{\alpha-k}{2}$. Also, at most $\frac{\alpha-k}{2}$ edges of G have at least one endpoint in V_2 so $n_2 \le \frac{\alpha-k}{2}$. Therefore, $|S| \le K^{n_1}n^{n_2} \le K^k n^{\frac{\alpha-k}{2}}$. It follows that

$$\sum_{(T_1,\ldots,T_m)\in S} \left| \mathbb{E}\left[\prod_{\ell=1}^{m} \bar{A}(T_\ell)\right] \right| \le c\mu^k n^{-\alpha/2} K^k n^{\frac{\alpha-k}{2}} = c\left(\frac{K\mu}{\sqrt{n}}\right)^k \le c,$$

and the proof is complete. ■

We also need the following lemma to show the convergence of $\frac{1}{|C^*|}\sum_{i\in C^*}(\xi_i^t)^m$ in probability using the Chebyshev inequality.

Lemma 29 *For any $t \ge 1$, $m \ge 1$ and $i \in [n]$,*

$$\lim_{n\to\infty} \mathsf{var}\left(\frac{1}{K}\sum_{i\in C^*}(\xi_i^t)^m\right) = 0$$

$$\lim_{n\to\infty} \mathsf{var}\left(\frac{1}{K}\sum_{\ell\in C^*\backslash\{i\}}(\xi_{\ell\to i}^t)^m\right) = 0$$

$$\lim_{n\to\infty} \mathsf{var}\left(\frac{1}{n}\sum_{i\in[n]\backslash C^*}(\xi_i^t)^m\right) = 0$$

$$\lim_{n\to\infty} \mathsf{var}\left(\frac{1}{n}\sum_{\ell\in[n]\backslash(C^*\cup\{i\})}(\xi_{\ell\to i}^t)^m\right) = 0,$$

where the same also holds when replacing ξ^t by θ^t.

Proof We prove the first claim; the other claim follows by a similar argument. Notice that

$$\mathsf{var}\left(\frac{1}{K}\sum_{i\in C^*}(\xi_i^t)^m\right) = \frac{1}{K^2}\sum_{i,j\in C^*}\left(\mathbb{E}\left[(\xi_i^t)^m(\xi_j^t)^m\right] - \mathbb{E}\left[(\xi_i^t)^m\right]\mathbb{E}\left[(\xi_j^t)^m\right]\right).$$

There are K diagonal terms with $i=j$ in the last displayed equation and each diagonal term is bounded by a constant independent of n in view of Lemma 28. Hence, to prove the claim, it suffices to consider the cross terms. Since there are $\binom{K}{2}$ cross terms, we only need to show that for each cross term with $i\neq j$, $\mathbb{E}\left[(\xi_i^t)^m(\xi_j^t)^m\right] - \mathbb{E}\left[(\xi_i^t)^m\right]\mathbb{E}\left[(\xi_j^t)^m\right]$ converges to 0 as $n\to\infty$. Using the tree representation as shown by Lemma 22 yields

$$\begin{aligned}&\left|\mathbb{E}\left[(\xi_i^t)^m(\xi_j^t)^m\right] - \mathbb{E}\left[(\xi_i^t)^m\right]\mathbb{E}\left[(\xi_j^t)^m\right]\right| \\ &\le c\sum_{T_1,\ldots,T_m\in\mathcal{T}_i^t,T_1',\ldots,T_m'\in\mathcal{T}_j^t}\left|\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\bar{A}(T_\ell')\right] - \mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\right]\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell')\right]\right|,\end{aligned}$$

where c is a constant independent of n and dependent of m,t,d,γ.

Let (G,G_1,G_2) denote the undirected simple graphs obtained from $2m$-tuple of trees $(T_1,\ldots,T_m,T_1',\ldots,T_m')$ as defined in Definition 23. Notice that roots of $T_1,\ldots,T_m$ have type i and roots of $T_1',\ldots,T_m'$ have type j, so either G is disconnected with one component containing i and the other component containing j, or G is connected. In the former case, there is no edge $(r,s)\in E(G)$ which is covered by $T_1,\ldots,T_m$ and $T_1',\ldots,T_m'$ simultaneously and thus $\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\bar{A}(T_\ell')\right] = \mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell)\right]\mathbb{E}\left[\prod_{\ell=1}^m\bar{A}(T_\ell')\right]$. In the latter case, i.e., G is connected. We partition set $\{(T_1,\ldots,T_m,T_1',\ldots,T_m') : T_\ell\in\mathcal{T}_i^t, T_\ell'\in\mathcal{T}_j^t\}$ as a union of two disjoint sets $Q\cup R$, where

1. Q consists of $2m$-tuples of trees such that G is connected and there exists an edge (r,s) in $E(G_2)\cup E_J$ which is covered exactly once.
2. R consists of $2m$-tuples of trees such that G is connected and all edges in $E(G_2)\cup E_J$ are covered at least twice.

If $(T_1,\ldots,T_m,T_1',\ldots,T_m')\in Q$, then

$$\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\bar{A}(T_\ell')\right] = 0 \quad \text{and} \quad \mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\right]\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell')\right] = 0.$$

We are left to check R. Following the argument used in Lemma 27, further divide R according to the total number of edges in trees and the number of edges in $E(G_1)$ which is covered exactly once. In particular, define $R_{\alpha,k}$ in the similar manner as $R_{1,\alpha,k}$. Invoking Lemma 24, it can be shown that for any $2m$-tuple in $R_{\alpha,k}$

$$\left|\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\bar{A}(T_\ell')\right]\right| \le c\mu^k n^{-\alpha/2}$$

$$\left|\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell)\right]\mathbb{E}\left[\prod_{\ell=1}^{m}\bar{A}(T_\ell')\right]\right| \le c\mu^k n^{-\alpha/2},$$

Furthermore, let $D = \{i, j\}$ to be the set of distinguished vertices in defining equivalence classes as specificed in Definition 25, so that $R_{\alpha,k}$ is divided into a number of equivalence classes, the number of which depends only on m, t, d, by Lemma 26. For any such equivalence class $S \subset R_{\alpha,k}$, it follows from the last displayed equation that

$$\sum_{T_1,\ldots,T_m,T_1',\ldots,T_m' \in S} \left| \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\bar{A}(T_\ell')\right] \right| + \left| \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right] \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell')\right] \right| \leq c\mu^k n^{-\alpha/2}|S|.$$

There are two distinguished vertices, i and j, in the graph G, corresponding to the type of the root vertices of the first m trees and the second m trees, respectively. It follows from Lemma 26 that $|S| \leq K^{n_1} n^{n_2}$, where n_1 is the number of vertices in G_1 with types in $C^* \backslash \{i, j\}$ and n_2 is the number of vertices in G_2 with types in $[n] \backslash (C^* \cup \{i, j\})$. There are $n_1 + n_2 + 2$ vertices in the connected graph G and at most $k + \frac{\alpha-k}{2}$ edges, so $n_1 + n_2 \leq k - 1 + \frac{\alpha-k}{2}$. At most $\frac{\alpha-k}{2}$ edges have at least one endpoint in V_2 and G is connected, so $n_2 \leq \frac{\alpha-k}{2}$. Thus, $|S| \leq K^{n_1} n^{n_2} \leq K^{k-1} n^{\frac{\alpha-k}{2}}$. Hence,

$$\sum_{(T_1,\ldots,T_m,T_1',\ldots,T_m') \in S} \left| \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\bar{A}(T_\ell')\right] \right| + \left| \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell)\right] \mathbb{E}\left[\prod_{\ell=1}^m \bar{A}(T_\ell')\right] \right| \leq c\mu^k n^{-\alpha/2} K^{k-1} n^{\frac{\alpha-k}{2}} = c\left(\frac{K\mu}{\sqrt{n}}\right)^k / K \leq c/K.$$

In conclusion, $\mathsf{var}\left(\frac{1}{K}\sum_{i \in C^*} (\xi_i^t)^m\right) \leq c/K$ and the first claim follows. ■

With Lemma 28 and Lemma 29 in hand, we are ready to compute the moments of ξ^t in the asymptotic limit $n \to \infty$.

Lemma 30 *For any $t \geq 0$, $m \geq 1$:*

$$\lim_{n\to\infty} \mathbb{E}\left[(\xi_{i\to j}^t)^m\right] = \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right], \quad \forall i \in C^*, j \in [n], j \neq i \tag{67}$$

$$\lim_{n\to\infty} \mathbb{E}\left[(\xi_{i\to j}^t)^m\right] = \mathbb{E}\left[(\tau_t Z_t)^m\right], \quad \forall i \notin C^*, j \in [n], j \neq i. \tag{68}$$

$$\lim_{n\to\infty} \mathbb{E}\left[(\xi_i^t)^m\right] = \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right], \quad \forall i \in C^*$$

$$\lim_{n\to\infty} \mathbb{E}\left[(\xi_i^t)^m\right] = \mathbb{E}\left[(\tau_t Z_t)^m\right], \quad \forall i \notin C^*.$$

Proof Below we shall use the following version of the Berry-Esseen central limit theorem. There is an absolute constant C_0 such that if $X_1, X_2, \ldots, X_n$ are independent mean zero random variables and $S_n = X_1 + \cdots + X_n$ then

$$\sup_{x\in\mathbb{R}} \left| \mathbb{P}\left\{ \frac{S_n}{\sqrt{\mathsf{var}(S_n)}} \leq x \right\} - \Phi(x) \right| \overset{(a)}{\leq} \frac{C_0 \sum_{i\in[n]} \mathbb{E}\left[|X_i|^3\right]}{(\mathsf{var}(S_n))^{3/2}} \overset{(b)}{\leq} \frac{C_0 n^{1/4} \left(\sum_{i\in[n]} \mathbb{E}\left[X_i^4\right]\right)^{3/4}}{(\mathsf{var}(S_n))^{3/2}},$$

where Φ is the standard normal CDF; (a) is the original result of Esseen (Esseen, 1942); (b) follows by Jensen's inequality.

We prove the first two claims, (67) and (68). The other two follow similarly. The proof is by induction, so suppose (67) and (68) hold for some t and all $n \geq 1$. We aim to show they also hold for $t+1$. The above identities hold for the base case $t = 0$, because $\xi_{i\to j}^0 = 0$ for all $i \neq j$ and $\mu_0 = \tau_0 = 0$. By the induction hypothesis, Lemma 29, and Chebyshev's inequality,

$$\lim_{n\to\infty} \frac{1}{K} \sum_{\ell \in C^* \backslash \{i\}} (\xi_{\ell\to i}^t)^m \overset{p}{=} \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right], \quad \forall i \in [n], \tag{69}$$

$$\lim_{n\to\infty} \frac{1}{n} \sum_{\ell \in [n] \backslash (C^* \cup \{i\})} (\xi_{\ell\to i}^t)^m \overset{p}{=} \mathbb{E}\left[(\tau_t Z_t)^m\right], \quad \forall i \in [n], \tag{70}$$

where $Z_t \sim \mathcal{N}(0, 1)$.

Fix an $i \in C^*$. Then

$$\begin{aligned}
\lim_{n\to\infty} \mathbb{E}\left[\xi_{i\to j}^{t+1} | \mathcal{F}_t\right] &= \lim_{n\to\infty} \mathbb{E}\left[\sum_{\ell \in C^* \backslash \{i,j\}} A_{\ell i}^t f(\xi_{\ell\to i}^t) + \sum_{\ell \in [n] \backslash (C^* \cup \{j\})} A_{\ell i}^t f(\xi_{\ell\to i}^t) | \mathcal{F}_t\right] \\
&= \sqrt{\lambda} \lim_{n\to\infty} \frac{1}{K} \sum_{\ell \in C^* \backslash \{i,j\}} f(\xi_{\ell\to i}^t) \\
&\overset{p}{=} \sqrt{\lambda} \lim_{n\to\infty} \frac{1}{K} \sum_{\ell \in C^* \backslash \{i\}} f(\xi_{\ell\to i}^t) \\
&\overset{p}{=} \sqrt{\lambda} \mathbb{E}\left[f(\mu_t + \tau_t Z_t)\right] = \mu_{t+1},
\end{aligned} \tag{71}$$

where the first equality follows from the definition of ξ^{t+1} given by (61); the second equality holds because $\mathbb{E}\left[A_{\ell i}^t\right] = \mu/\sqrt{n}$ if $\ell \in C^*$ and $\mathbb{E}\left[A_{\ell i}^t\right] = 0$ otherwise; the third equality holds in view of Lemma 28, the fourth equality holds due to (69) and the fact f is a finite-degree polynomial; the last equality holds due to the definition of μ_{t+1}.

Similarly,

$$\begin{aligned}
\lim_{n\to\infty} \mathsf{var}\left(\xi_{i\to j}^{t+1} | \mathcal{F}_t\right) &= \lim_{n\to\infty} \sum_{\ell \in [n] \backslash \{i,j\}} \mathsf{var}\left(A_{\ell i}^t f(\xi_{\ell\to i}^t) | \mathcal{F}_t\right) \\
&= \lim_{n\to\infty} \frac{1}{n} \sum_{\ell \in [n] \backslash \{i,j\}} f(\xi_{\ell\to i}^t)^2 \qquad (72) \\
&= \lim_{n\to\infty} \frac{1}{n} \left\{ \sum_{\ell \in [n] \backslash C^* \cup \{j\}} f(\xi_{\ell\to i}^t)^2 + \sum_{\ell \in C^* \backslash \{i,j\}} f(\xi_{\ell\to i}^t)^2 \right\} \qquad (73) \\
&\overset{p}{=} \lim_{n\to\infty} \frac{1}{n} \sum_{\ell \in [n] \backslash C^*} f(\xi_{\ell\to i}^t)^2 \qquad (74) \\
&\overset{p}{=} \mathbb{E}\left[f(\tau_t Z_t)^2\right] = \tau_{t+1}^2, \qquad (75)
\end{aligned}$$

where the first equality follows from the conditional independence of $A_{\ell i}^t f(\xi_{\ell\to i}^t)$ for $\ell \in [n]$; the second equality holds because $\mathsf{var}(A_{\ell i}) = 1/n$ for all ℓ; the third equality is the result of breaking a sum into two parts, the fourth equality holds in view of Lemma 28 and the

assumption that $K = o(n)$; the fifth equality holds in view of (70) and the fact f is a finite-degree polynomial; the last equality holds due to the definition of τ_{t+1}.

Conditional on $\mathcal{F}_t$, $\xi_{i\to j}^{t+1} - \mathbb{E}\left[\xi_{i\to j}^{t+1}\right]$ is a sum of independent random variables. Therefore, by the form of the Berry-Esseen central limit theorem noted above,

$$\begin{aligned}
&\sup_{x\in\mathbb{R}}\left|\mathbb{P}\left\{\frac{\xi_{i\to j}^{t+1} - \mathbb{E}\left[\xi_{i\to j}^{t+1}|\mathcal{F}_t\right]}{\mathsf{var}(\xi_{i\to j}^{t+1}|\mathcal{F}_t)} \le x\middle|\mathcal{F}_t\right\} - \Phi(x)\right| \\
&\le \frac{C_0 n^{1/4}}{\left(\mathsf{var}(\xi_{i\to j}^{t+1}|\mathcal{F}_t)\right)^{3/2}}\left(\sum_{\ell\in[n]\setminus\{j\}} f(\xi_{\ell\to i}^t)^4\mathbb{E}\left[(A_{\ell i}^t - \mathbb{E}\left[A_{\ell i}^t\right])^4\right]\right)^{3/4} \\
&\le \frac{C_0 c^{3/4} n^{-1/2}}{\left(\mathsf{var}(\xi_{i\to j}^{t+1}|\mathcal{F}_t)\right)^{3/2}}\left(\frac{1}{n}\sum_{\ell\in[n]\setminus\{j\}} f(\xi_{\ell\to i}^t)^4\right)^{3/4}, \qquad (76)
\end{aligned}$$

where we used the fact $\mathbb{E}\left[(A_{\ell i}^t - \mathbb{E}\left[A_{\ell i}^t\right])^4\right] \le cn^{-2}$, for a constant c depending only on the constant γ appearing in the subgaussian assumption. Taking the limit $n\to\infty$ and noticing that $\mathsf{var}(\xi_{i\to j}^{t+1}|\mathcal{F}_t) \xrightarrow{p} \tau_{t+1}^2$ and $\frac{1}{n}\sum_{\ell\in[n]\setminus\{j\}} f(\xi_{\ell\to i}^t)^4 \xrightarrow{p} \mathbb{E}\left[f(\tau_t Z_t)^4\right]$ (using the same steps as in (72)-(75)), we find the righthand side of (76) converges to zero in probability. Thus, in view of (71), (75), and (76), for any $x\in\mathbb{R}$,

$$\lim_{n\to\infty}\mathbb{P}\left\{\xi_{i\to j}^{t+1} \le x|\mathcal{F}_t\right\} \stackrel{p}{=} \mathbb{P}\left\{\mu_{t+1} + \tau_{t+1}Z_{t+1} \le x\right\}.$$

It follows by the dominated convergence theorem that

$$\lim_{n\to\infty}\mathbb{P}\left\{\xi_{i\to j}^{t+1} \le x\right\} = \mathbb{P}\left\{\mu_{t+1} + \tau_{t+1}Z_{t+1} \le x\right\}.$$

and, since convergence in distribution is preserved under continuous transformations:

$$\lim_{n\to\infty}\mathbb{P}\left\{\left(\xi_{i\to j}^{t+1}\right)^m \le x\right\} = \mathbb{P}\left\{(\mu_{t+1} + \tau_{t+1}Z_{t+1})^m \le x\right\}.$$

Since $\mathbb{E}\left[\left|\xi_{i\to j}^{t+1}\right|^{m+1}\right] \le c$ for some c independent of n, the family of random variables $(\xi_{i\to j}^{t+1})^m$ is uniformly integrable, so that convergence in distribution implies convergence of means to the mean of the limiting distribution. Therefore (67) holds with t replaced by $t+1$.

To complete the proof by induction it remains to show (68) holds with t replaced by $t+1$, so fix $i\notin C^*$. Following the previous argument, one can easily check that

$$\begin{aligned}
\mathbb{E}\left[\xi_{i\to j}^{t+1}|\mathcal{F}_t\right] &= 0 \\
\lim_{n\to\infty}\mathsf{var}\left(\xi_{i\to j}^{t+1}|\mathcal{F}_t\right) &\stackrel{p}{=} \tau_{t+1}^2,
\end{aligned}$$

and that, by the central limit theorem, uniformly bounded $m+1^{th}$ moments, and uniform integrability, (68) holds with t replaced by $t+1$. ■

Proof [Proof of Lemma 6] We show the first claim; the second one follows analogously. Fix $t\ge 1$. The convergence property to be proved depends only on the sequence of random empirical distributions of $(\theta_i^t : t\in C^*)$ indexed by n. We may therefore assume without loss of generality that all the random variables $(\theta_i^t : t\in C^*)$ for different n are defined on a single underlying probability space; the joint distribution for different values of n can be arbitrary. To show the convergence in probability, it suffices to show that for any subsequence $\{n_k\}$ there exists a sub-subsequence $\{n_{k_\ell}\}$ such that for $j\neq i$,

$$\lim_{\ell\to\infty} d_{\mathrm{KS}}\left(\frac{1}{K_{k_\ell}}\sum_{i\in C^*}\delta_{\theta_i^t}, \mathcal{N}(\mu_t,\tau_t^2)\right) = 0, \text{ a.s.} \qquad (77)$$

Fix a subsequence n_k. In view of Lemmas 27 and 30, for any fixed integer m,

$$\lim_{k\to\infty}\mathbb{E}\left[(\theta_i^t)^m\right] = \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right].$$

Combining Lemma 29 with Chebyshev's inequality,

$$\lim_{k\to\infty}\frac{1}{K_k}\sum_{i\in C^*}\left(\theta_i^t\right)^m \stackrel{p}{=} \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right], \qquad (78)$$

which further implies, by a well-known property of convergence in probability, that there exists a sub-subsequence such that (78) holds almost surely. Using a standard diagonal argument, one can construct a sub-subsequence $\{n_{k_\ell}\}$ such that for all $m\ge 1$,

$$\lim_{\ell\to\infty}\frac{1}{K_{k_\ell}}\sum_{i\in C^*}\left(\theta_i^t\right)^m = \mathbb{E}\left[(\mu_t + \tau_t Z_t)^m\right] \text{ a.s.}$$

Since a Gaussian distribution is determined by its moments, by the method of moments (see, for example, (Chung, 2001, Theorem 4.5.5)), applied for each outcome ω in the underlying probability space (excluding some subset of probability zero), it follows that the sequence of empirical distribution of θ_i^t for $i\in C^*$ weakly converges to $\mathcal{N}(\mu_t,\tau_t^2)$, which, since Gaussian density is bounded, is equivalent to convergence in the KS distance,[11] proving the desired (77). ■

Remark 31 *We discuss the difference between the proof of Lemma 6 and that of (Deshpande and Montanari, 2015, Lemma 2.2). First, a larger K requires modification of bounds from (Deshpande and Montanari, 2015) to calculate the moments of messages in Lemmas 27 - 29. In particular, $(\theta_{i\to j}^t)^m$ can be expanded as a sum of monomials in terms of $A_{k\ell}$ for $k,\ell\in[n]$. A larger K implies that in the expansion, there are more monomials containing $A_{k\ell}$ for $k,\ell\in C^*$. That effect is offset by μ being smaller. Our approach is to balances these two effects by accounting separately the contributions of those $A_{k\ell}$'s which appear only once in a monomial. Such $A_{k\ell}$'s correspond to singly covered edges with both endpoints in C^*. See Lemma 24, as well as $R_{1,\alpha,k}$ in Lemma 27, $R_{3,\alpha,k}$ in Lemma 28, and $R_{\alpha,k}$ in Lemma 29. Finally, Lemma 6 is phrased in terms of KS distance while (Deshpande and Montanari, 2015, Lemma 2.2) is in terms of convergence of expected values of bounded Lipschitz functions.*

11. This follows from the fact that when one of the distributions has bounded density the Lévy distance, which metrizes weak convergence, is equivalent to the KS distance (see, e.g. (Petrov, 1995, 1.8.32)).

6.1 Justification of state evolution equations for biclustering

In this subsection, we briefly describe how to generalize the method of moments from symmetric case to asymmetric biclustering case. Recall $f(x,t)=\sum_{r=0}^{d} q_r^t x^r$ with $|q_r^t|\le C$ for some constant C. Let $\{W^t, t\ge 1\}$ be i.i.d. matrices distributed as W conditional on (C_1^*, C_2^*) and let $W^0=W$. Similar to (61), we define a sequence of vectors $\{\xi^t, t\ge 1\}$ given by

$$(t \text{ even}) \qquad \xi_{i\to j}^{t+1} = \frac{1}{\sqrt{n_2}} \sum_{\ell\in[n_2]\backslash\{j\}} W_{i\ell}^t f(\xi_{\ell\to i}^t, t), \quad \forall i\in[n_1], j\in[n_2] \tag{79}$$

$$(t \text{ odd}) \qquad \xi_{j\to i}^{t+1} = \frac{1}{\sqrt{n_1}} \sum_{\ell\in[n_1]\backslash\{i\}} W_{\ell j}^t f(\xi_{\ell\to j}^t, t), \quad \forall j\in[n_2], i\in[n_1], \tag{80}$$

with the initial condition $\xi_{\ell\to i}^0=0$ for $(\ell,i)\in[n_2]\times[n_1]$. Moreover, let

$$(t \text{ even}) \qquad \xi_i^{t+1} = \frac{1}{\sqrt{n_2}} \sum_{\ell\in[n_2]} W_{i\ell}^t f(\xi_{\ell\to i}^t, t), \quad \forall i\in[n_1] \tag{81}$$

$$(t \text{ odd}) \qquad \xi_j^{t+1} = \frac{1}{\sqrt{n_1}} \sum_{\ell\in[n_1]} W_{\ell j}^t f(\xi_{\ell\to j}^t, t), \quad \forall j\in[n_2]. \tag{82}$$

The first step is to represent $(\theta_{i\to j}^t, \theta_i^t)$ and $(\xi_{i\to j}^t, \xi_i^t)$ as sums over a family of finite rooted labeled trees. Abusing notation slightly, we treat elements from $[n_1]$ and $[n_2]$ as distinct elements. We define $\mathcal{T}^t$ as Definition 21 with an additional constraint: a vertex u must have type from $[n_1]$ if $t-|u|$ is odd and from $[n_2]$ if $t-|u|$ is even. In particular, all leaves u with $|u|=t$ must have type from $[n_2]$, and the root has type from $[n_1]$ if t is odd and from $[n_2]$ if t is even.

The following lemma similar to Lemma 22 can be proved by induction on t similar to (Deshpande and Montanari, 2015, Lemma 3.3).

Lemma 32

$$\theta_{i\to j}^t = \sum_{T\in\mathcal{T}_{i\to j}^t} A(T)\Gamma(T,\mathbf{q},t),$$
$$\theta_i^t = \sum_{T\in\mathcal{T}_i^t} A(T)\Gamma(T,\mathbf{q},t),$$

where

$$A(T) \triangleq \prod_{\substack{u\to v\in E(T)\\ \ell(u)\in[n_1]}} \frac{1}{\sqrt{n_1}} W_{\ell(u),\ell(v)} \prod_{\substack{u\to v\in E(T)\\ \ell(u)\in[n_2]}} \frac{1}{\sqrt{n_2}} W_{\ell(v),\ell(u)}$$

and $\Gamma(T,\mathbf{q},t)$ *is defined as before:*

$$\Gamma(T,\mathbf{q},t) = \prod_{u\to v\in E(T)} q_{r(u)}^{t-|u|}.$$

Similarly,

$$\xi_{i\to j}^t = \sum_{T\in\mathcal{T}_{i\to j}^t} \bar{A}(T)\Gamma(T,\mathbf{q},t),$$
$$\xi_i^t = \sum_{T\in\mathcal{T}_i^t} \bar{A}(T)\Gamma(T,\mathbf{q},t),$$

where

$$\bar{A}(T) \triangleq \prod_{\substack{u\to v\in E(T)\\ \ell(u)\in[n_1]}} \frac{1}{\sqrt{n_1}} W_{\ell(u),\ell(v)}^{t-|u|} \prod_{\substack{u\to v\in E(T)\\ \ell(u)\in[n_2]}} \frac{1}{\sqrt{n_2}} W_{\ell(v),\ell(u)}^{t-|u|}.$$

Similar to Definition 23, let G denote the undirected *bipartite* graph obtained by identifying the vertices of the same type in the tuple of trees $T_1,\dots,T_m$ and removing the edge directions. Note that the vertices of type from $[n_1]$ ($[n_2]$) in trees constitute the left (right) part of G. Let $E(G)$ denote the edge set of G. Let G_1 denote the restriction of G to the vertices in (C_1^*, C_2^*) and G_2 the restriction of G to the vertices in $([n_1]\backslash C_1^*, [n_2]\backslash C_2^*)$. Let $E(G_1)$ and $E(G_2)$ denote the edge set of G_1 and G_2, respectively. Let E_J denote the set of edges in G with one endpoint in G_1 and the other endpoint in G_2. Then Lemma 24 goes through as before, with n in the upper bound taken to be $\min\{n_1,n_2\}$. Note that in the definition of $A(T)$, either W_{ij} is divided by $\sqrt{n_1}$ or W_{ji} is divided by $\sqrt{n_2}$ depending on whether $i\in[n_1]$ or $i\in[n_2]$. However, it always holds that $\frac{1}{\sqrt{n_1}}\le\frac{1}{\sqrt{n}}$ and $\frac{1}{\sqrt{n_2}}\le\frac{1}{\sqrt{n}}$.

For a given set of distinguished types D, we can define the equivalence classes on the family of m-tuples of trees in $\mathcal{T}^t$ similar to Definition 25 except that we only allow either permutations of types in $[n_1]$ or permutations of types in $[n_2]$. Then Lemma 26 goes throught as before, with the upper bound in Lemma 26 changes to

$$|S| \le (\max\{K_1,K_2\})^{t_1} (\max\{n_1,n_2\})^{t_2},$$

where we assume a representative m-tuple of trees $(T_1,\dots,T_m)$ has t_1 and t_2 distinct types in $C_1^*\cup C_2^*\backslash D$ and $[n_1]\cup[n_2]\backslash(C_1^*\cup C_2^*\cup D)$, respectively. By assumptions that $\lambda_1,\lambda_2=\Theta(1)$ and $K_1\asymp K_2$, it follows that $n_1\asymp n_2\asymp n$. Furthermore, let $K=\min\{K_1,K_2\}$. Then $K_1\asymp K_2\asymp K$. Hence, $|S|\le cK^{t_1}n^{t_2}$ for an absolute constant $c>0$.

With Lemma 32, modified Lemma 24, and modified Lemma 26, Lemmas 27 - 29 go through as before. In particular, we still partition set $\{(T_1,\dots,T_m): T_\ell\in\mathcal{T}_i^t\}$ as a union of four disjoint sets $Q\cup R_1\cup R_2\cup R_3$, and introduce $R_{1,\alpha,k}$, $R_{2,\alpha,k}$, $R_{3,\alpha,k}$ and $R_{\alpha,k}$ as before.

A. Row-wise thresholding

We describe a simple thresholding procedure for recovering C^*. For simplicity and information theoretic comparisons, we consider the Gaussian case. Let $R_i = \sum_j W_{i,j}$ for $i \in [n]$. Then $R_i \sim \mathcal{N}(K\mu, n)$ if $i \in C^*$ and $R_i \sim \mathcal{N}(0, n)$ if $i \notin C^*$. Let $\widehat{C} = \left\{ i \in [n] : R_i \geq \frac{K\mu}{2} \right\}$. Then $\mathbb{E}\left[\left| \widehat{C} \triangle C^* \right| \right] = nQ\left(\frac{K\mu}{2\sqrt{n}} \right)$. Recall that $\lambda = \frac{K^2\mu^2}{n}$. Hence, if

$$\lambda = \omega\left(\log \frac{n}{K} \right), \tag{83}$$

then we have $\mathbb{E}[|\widehat{C} \triangle C^*|] = o(K)$ and hence achieved weak recovery. In the regime $K \asymp n \asymp (n-K)$, $\lambda = \omega(\log \frac{n}{K})$ is equivalent to $\lambda \to \infty$, which is also equivalent to $K\mu^2 \to \infty$ and coincides with the necessary and sufficient condition for the information-theoretic possibility of weak recovery in this regime (Hajek et al., 2017, Corollary 2). (If instead $n - K = o(n)$, weak recovery is trivially provided by $\widehat{C} = [n]$.) Thus, row-wise thresholding provides weak recovery in the regime $K \asymp n \asymp (n-K)$ whenever information theoretically possible. Under the information-theoretic condition (15), an algorithm attaining exact recovery can be built using row-wise thresholding for weak recovery followed by voting, as in Algorithm 2 (see (Hajek et al., 2017, Theorem 3) and its proof). In the regime $\frac{n}{K} \log \frac{n}{K} = o(\log n)$, or equivalently $K = \omega(n \log\log n / \log n)$, condition (15) implies that $\lambda = \omega(\log \frac{n}{K})$, and hence in this regime exact recovery can be attained in linear time $O(n^2)$ whenever information theoretically possible.

B. Proof of Lemma 12

Proof We remind the reader that in this paper we let $A = W/\sqrt{n}$ so that $\mathsf{var}(A_{ij}) = 1/n$ for $i, j \in [n]$ and $\mathbb{E}[A_{ij}] = \mu/\sqrt{n}$ for $i, j \in C^*$.

Fix a $\widetilde{C}$ that satisfies (29) – (30), i.e., $|\widetilde{C} \cap C^*| \geq K(1-\epsilon)$ and $K(1-\epsilon) \leq |\widetilde{C}| \leq n\epsilon$. Let $m = |\widetilde{C}|$ and abbreviate the restricted matrix $A_{\widetilde{C}} \in \mathbb{R}^{|\widetilde{C}| \times |\widetilde{C}|}$ by $\widetilde{A}$. Let $\mathbf{1}_{\widetilde{C} \cap C^*} \in \mathbb{R}^{|\widetilde{C}|}$ denote the indicator vector of $\widetilde{C} \cap C^*$. Then the mean of $\widetilde{A}$ is the rank-one matrix $\mathbb{E}[\widetilde{A}] = \frac{\mu}{\sqrt{n}} \mathbf{1}_{\widetilde{C} \cap C^*} \mathbf{1}_{\widetilde{C} \cap C^*}^\top$, whose largest eigenvalue is $\frac{\mu |\widetilde{C} \cap C^*|}{\sqrt{n}}$ with the corresponding eigenvector $v \triangleq \frac{1}{\sqrt{|\widetilde{C} \cap C^*|}} \mathbf{1}_{\widetilde{C} \cap C^*}$. Let $Z = \widetilde{A} - \mathbb{E}[\widetilde{A}]$, and let u denote the principal eigenvector of $\widetilde{A}$ such that $\langle u, v \rangle \geq 0$. Note that $\|u - v\| = \sqrt{2(1 - \langle u, v \rangle)} \leq \sqrt{2(1 - \langle u, v \rangle^2)} = \sqrt{2} \sin\theta$, where θ is the angle between u and v. Combining this observation with the sin theorem of (Davis and Kahan, 1970) yields

$$\begin{aligned} \|u - v\| \leq \sqrt{2} \sin\theta \leq \sqrt{2} \min\left\{ 1, \frac{\|Z\|}{\mu |\widetilde{C} \cap C| / \sqrt{n} - \|Z\|} \right\} \\ \leq \frac{2\sqrt{2}\|Z\|}{\mu |\widetilde{C} \cap C| / \sqrt{n}} \leq \frac{2\sqrt{2}\|Z\|}{\sqrt{\lambda}(1-\epsilon)}, \end{aligned} \tag{84}$$

where the last inequality follows from the assumption (29). Observe that Z is a symmetric matrix such that $\{Z_{ij}\}_{i \leq j}$ are independent subgaussian random variables with zero mean

and proxy variance γ/n. To bound $\|Z\|$, we use the following standard concentration inequality, see e.g.. (Deshpande and Montanari, 2015, Lemma A.3): For any $t > 0$,

$$\mathbb{P}\left\{ \|Z\| \geq t \right\} \leq 2 \exp\left(-m \left(\frac{t^2 n}{16 e \gamma m} - \log \frac{5 t^2 n}{16 \gamma m} \right) \right).$$

Note that if

$$t \geq \sqrt{64 e \gamma h(\epsilon) + 160 e \gamma m / n},$$

then

$$m \left(\frac{t^2 n}{16 e \gamma m} - \log \frac{5 t^2 n}{16 \gamma m} \right) \geq \frac{t^2 n}{32 e \gamma} \geq 2 n h(\epsilon).$$

By assumption we have $K(1-\epsilon) \leq m \leq \epsilon n$. Therefore, by setting $\beta = \sqrt{64 e \gamma h(\epsilon) + 160 e \gamma \epsilon}$, we have for any fixed $\widetilde{C}$,

$$\mathbb{P}\left\{ \|Z\| \geq \beta \right\} \leq 2 e^{-2nh(\epsilon)}. \tag{85}$$

The number of possible choices of $\widetilde{C}$ that fulfills (30) so that $|\widetilde{C}| \leq \epsilon n$ is at most $\sum_{k \leq n\epsilon} \binom{n}{k}$ which is further upper bounded by $e^{nh(\epsilon)}$ (see, e.g., (Ash, 1965, Lemma 4.7.2)). In view of (85), the union bound yields $\|Z\| \leq \beta$ with high probability as $n \to \infty$.

Throughout the reminder of this proof we assume A and $\widetilde{C}$ are fixed with $\|Z\| \leq \beta$. Combining with (84), we have,

$$\|u - v\| \leq \frac{2\sqrt{2}\beta}{\sqrt{\lambda}(1-\epsilon)}. \tag{86}$$

Next, we argue that either $\widehat{u}$ or $-\widehat{u}$ is close to u, and hence, close to v by the triangle inequality. By the choice of the initial vector u^0, we can write $u^0 = z/\|z\|$ for a standard normal vector $z \in \mathbb{R}^m$. By the tail bounds for Chi-squared distributions, it follows that $\|z\| \leq 2\sqrt{m}$ with high probability. For any fixed u, the random variable $\langle u, z \rangle \sim \mathcal{N}(0, 1)$ and thus with high probability, $|\langle u, z \rangle|^2 \geq 1/\log n$, and hence

$$|\langle u, u^0 \rangle| = |\langle u, z \rangle| / \|z\| \geq (2\sqrt{n \log n})^{-1}. \tag{87}$$

Replacing u^0 by $-u^0$ would result in replacing u^t by $-u^t$ for each t, and since $\widehat{C}$ returned by Algorithm 1 only depends on $|u_i^t|$, replacing u by $-u$ would have no effect on the ouput $\widehat{C}$ of the algorithm. Thus, we can assume without loss of generality that $\langle u, u^0 \rangle \geq 0$, and (87) becomes

$$\langle u, u^0 \rangle \geq (2\sqrt{n \log n})^{-1}. \tag{88}$$

By Weyl's inequality, the maximal singular value of $\widetilde{A}$ satisfies $\sigma_1(\widetilde{A}) \geq \frac{\mu K(1-\epsilon)}{\sqrt{n}} - \beta$ and the other singular values are at most β. Let $r = \frac{\sigma_2}{\sigma_1}(\widetilde{A})$. By the assumption that $\epsilon < \epsilon_0$ and $\lambda \geq 1/e$, we have $\sqrt{\lambda}(1-\epsilon) > 2\beta$. As a consequence, $r \leq \frac{2\beta}{\sqrt{\lambda}(1-\epsilon)} < 1$. Since $u^t = \widetilde{A}^t u^0 / \|\widetilde{A}^t u^0\|$, it follows that

$$u^t = \frac{\langle u, u^0 \rangle u + y}{\|\langle u, u^0 \rangle u + y\|}$$

for some $y \in \mathbb{R}^m$, depending on t, such that $\|y\| \le r^t$. Hence,

$$\begin{aligned}\langle u^t, u\rangle &= \frac{\langle u, u^0\rangle + \langle y, u\rangle}{\|\langle u, u^0\rangle u + y\|} \\ &\ge \frac{\langle u, u^0\rangle - r^t}{\langle u, u^0\rangle + r^t} \\ &= 1 - \frac{2r^t}{\langle u, u^0\rangle + r^t},\end{aligned}$$

or, equivalently,

$$\|u^t - u\|^2 = 2(1 - \langle u^t, u\rangle) \le \frac{4r^t}{\langle u, u^0\rangle + r^t}. \tag{89}$$

Recall that $\widehat{u} = u^{\lceil s^* \log n\rceil}$. Thus, choosing $s^* = \frac{2}{\log(\sqrt{\lambda}(1-\epsilon)/(2\beta))}$ as in (33), we obtain $r^{\lceil s^* \log n\rceil} \le n^{-2}$ and consequently in view of (88) and (89),

$$\|\widehat{u} - u\|^2 \le \frac{4n^{-2}}{(2\sqrt{n \log n})^{-1} + n^{-2}} \le \frac{1}{n},$$

for sufficiently large n.

Therefore, by the triangle inequality,

$$\|\widehat{u} - v\| \le \|\widehat{u} - u\| + \|u - v\| \le n^{-1/2} + \frac{2\sqrt{2}\beta}{\sqrt{\lambda}(1-\epsilon)} \overset{(a)}{\le} \frac{3\beta}{\sqrt{\lambda}(1-\epsilon)} \triangleq \beta_o, \tag{90}$$

where (a) holds for sufficiently large n. Let $\widehat{C}_o$ be defined by using a threshold test to estimate C^* based on $\widehat{u}$:

$$\widehat{C}_o = \{i \in \widetilde{C} : |\widehat{u}_i| \ge \tau\},$$

where $\tau = 1 \Big/ \left(2\sqrt{|\widetilde{C} \cap C^*|}\right)$. Note that $v_i = 2\tau \mathbf{1}_{\{i \in \widetilde{C} \cap C^*\}}$. For any $i \in \widehat{C}_o \backslash (\widetilde{C} \cap C^*)$, we have $|\widehat{u}_i| \ge \tau$ and $v_i = 0$; for any $i \in (\widetilde{C} \cap C^*)\backslash \widehat{C}_o$, we have $|\widehat{u}_i| < \tau$ and $v_i = 2\tau$. Therefore $|\widehat{u}_i - v_i| \ge ||\widehat{u}_i| - |v_i|| \ge \tau$ for all $i \in \widehat{C}_o \triangle (\widetilde{C} \cap C^*)$ and thus

$$\|\widehat{u} - v\|^2 \ge |\widehat{C}_o \triangle (\widetilde{C} \cap C^*)|\tau^2.$$

In view of (90), the number of indices in $\widetilde{C}$ incorrectly classified by $\widehat{C}_o$ satisfies

$$|\widehat{C}_o \triangle (\widetilde{C} \cap C^*)| \le 4\beta_o^2 |\widetilde{C} \cap C^*| \le 4\beta_o^2 |C^*|.$$

Since $|C^* \backslash \widetilde{C}| \le \epsilon K$, we conclude that $|C^* \triangle \widehat{C}_o| \le \epsilon K + 4\beta_o^2 |C^*|$. Thus, if the algorithm were to output $\widehat{C}_o$ (instead of $\widehat{C}$) the lemma would be proved.

Rather than using a threshold test in the cleanup step, Algorithm 1 selects the K indices in $\widetilde{C}$ with the largest values of $|\widehat{u}_i|$. Consequently, with probability one, either $\widehat{C}_o \subset \widehat{C}$ or $\widehat{C} \subset \widehat{C}_o$. Therefore, it follows that

$$|C^* \triangle \widehat{C}| \le 2|C^* \triangle \widehat{C}_o| + \big||C^*| - K\big|.$$

By assumption, $|C^*|/K$ converges to one in probability, so that, in probability,

$$\limsup_{n\to\infty} \frac{|C^* \triangle \widehat{C}|}{K} \le 2\epsilon + 8\beta_o^2 \le \eta(\epsilon, \lambda), \tag{91}$$

where η is defined in (34), completing the proof. ■

C. An adaptive variant of Algorithm 1

Recall that the last step of the spectral clean-up of Algorithm 1 involves choosing the K coordinates of the largest magnitude of $\widehat{u}$. In order to be adaptive to the cluster size K, in this section we show that this step can be simply replaced by applying k-means clustering with $k = 2$ to $\{|\widehat{u}_i|\}_{i \in \widetilde{C}}$ so that Theorem 1 continues to hold. Let w denote an optimal solution, i.e., a minimizer of $\|x - |\widehat{u}|_{\widetilde{C}}\|$ over all x in $\mathbb{R}^{|\widetilde{C}|}$ whose coordinates take at most two distinct values. Since $|\widehat{u}_i|$ is a scalar, w can be easily found by sorting $\{|\widehat{u}_i|\}_{i \in \widetilde{C}}$ in descending order, and checking all vectors of the form $(a, \ldots, a, b, \ldots, b)$, where a and b with $a \ge b \ge 0$ are given by the average of the respective set of $|\widehat{u}_i|$'s. Thus w can be found in time $O(n \log n)$.

Define $\widehat{C} = \{i \in \widetilde{C} : w_i = a\}$. To show this $\widehat{C}$ fulfills the same performance guarantee as in Theorem 1, it suffices to modify the proof of Lemma 12 to show that, for any ϵ sufficiently small, if $\widetilde{C} \subset [n]$ satisfies (29) – (30), then $\mathbb{P}\left\{\frac{|C^* \triangle \widehat{C}|}{K} \le \eta\right\} \to 1$ as $n \to \infty$, where η is a function of ϵ and λ such that $\eta \to 0$ as $\epsilon \to 0$ for λ fixed. Without loss of generality we may also assume that

$$|\widetilde{C} \backslash C^*| = \Omega(K). \tag{92}$$

This extra condition is fulfilled by the output of the message-passing algorithm with high probability, because, in view of (32), $|\widetilde{C} \backslash C^*| = \Theta(n)$ with probability tending to one.

Recall that we have shown in (90) that $\min\{\|\widehat{u} - v\|, \|\widehat{u} + v\|\} \le \beta_o$. By the definition of w, since $v \ge 0$ is binary-valued componentwise, we have

$$\||\widehat{u}| - w\| \le \||\widehat{u}| - v\| \le \min\{\|\widehat{u} - v\|, \|\widehat{u} + v\|\} \le \beta_o,$$

and thus

$$\|w - v\| \le \|w - |\widehat{u}|\| + \||\widehat{u}| - v\| \le 2\beta_o.$$

Define

$$S = \{i \in \widetilde{C} : \big|w_i - v_i\big| \ge \tau\}, \qquad \tau \triangleq \frac{1}{2\sqrt{|\widetilde{C} \cap C^*|}}.$$

Then

$$|S|\tau^2 \le \|w - v\|^2 \le 4\beta_0^2,$$

and consequently, $|S| \le 16\beta_0^2 |\widetilde{C} \cap C^*|$. Since β_0 can be made to be sufficiently small by choosing ϵ to be small, we have $|S| < |\widetilde{C} \cap C^*|$. Furthermore, by the assumption that $|C^*|/K \to 1$ in probability and (92), we have $|S| < |\widetilde{C} \backslash C^*|$. Define $T_1 = (\widetilde{C} \cap C^*)\backslash S$ and $T_0 = (\widetilde{C} \backslash C^*)\backslash S$, both of which are non-empty. For each $i \in T_1$ and $j \in T_0$, we have

$$w_i - w_j \ge v_i - v_j - |w_i - v_i| - |w_j - v_j| > 2\tau - \tau - \tau = 0,$$

that is, $w_i = a > b = w_j$. Hence, $\widehat{C}\Delta(\widetilde{C} \cap C^*) \subset S$ and thus

$$|\widehat{C}\Delta(\widetilde{C} \cap C^*)| \leq |S| \leq 16\beta_0^2 |\widetilde{C} \cap C^*| \leq 16\beta_0^2 |C^*|.$$

Since $|C^* \backslash \widetilde{C}| \leq \epsilon K$, we have that $|\widehat{C}\Delta C^*| \leq \epsilon K + 16\beta_0^2 |C^*|$. Therefore,

$$\limsup_{n\to\infty} \frac{|C^*\Delta\widehat{C}|}{K} \leq \epsilon + 16\beta_0^2.$$

Since $\beta_0 \to 0$ as $\epsilon \to 0$, Theorem 1 holds for the adaptive variant of Algorithm 1.

D. Proofs of Theorems 13 and 14

In the proofs below we use the following notation. We write $\mathsf{p}_e(\pi_1, s^2)$ to denote the minimal average error probability for testing $\mathcal{N}(\mu_1, \sigma^2)$ versus $\mathcal{N}(\mu_0, \sigma^2)$ with priors π_1 and $1 - \pi_1$, where $\mu_1 \geq \mu_0$ and $s^2 = \frac{(\mu_0 - \mu_1)^2}{\sigma^2}$. That is,

$$\mathsf{p}_e(\pi_1, s^2) \triangleq \min_x \{\pi_1 Q(s - x) + (1 - \pi_1) Q(x)\}.$$

Proof [Proof of Theorem 13] The proof of sufficiency for weak recovery is closely based on the proof of sufficiency for exact recovery by the MLE given in (Butucea et al., 2015); the reader is referred to (Butucea et al., 2015) for the notation used in this paragraph. The proof in (Butucea et al., 2015) is divided into two sections. In our terminology, (Butucea et al., 2015, Section 3.1) establishes the weak recovery of C_1^* and C_2^* by the MLE under the assumptions (37), (39), and (41). However, the assumption (39) (and similarly, (41)) is used in only one place in the proof, namely for bounding the terms $T_{1,km}$ defined therein. We explain here why (37) alone is sufficient for the proof of weak recovery. Condition (37), in the notation[12] of (Butucea et al., 2015), implies that there exists some sufficiently small $\alpha > 0$ such that

$$\frac{a^2 m}{2\log(N/n)} \geq 1 + \alpha.$$

So (Butucea et al., 2015, (3.4)) can be replaced as: there exist some sufficiently small $\delta_1 > 0$ and $\alpha_1 > 0$ such that

$$\frac{(1-\delta_1)^2}{2} a^2 m \geq (1 + \alpha_1)\log(N/n) \geq (1 + \alpha_1)\log\left(\frac{\delta(N-n)}{n-k}\right),$$

where we use the assumption $0 \leq k < (1 - \delta)n$, or $n - k > \delta n$. Thus, for large enough n,

$$\begin{aligned} T_{1,km} &\leq \exp\left(-\frac{\delta n \alpha_1}{2}\left(\log\left(\frac{N-n}{n-k}\right)\right)\right) \\ &\leq \exp\left(-\frac{\delta n \alpha_1}{2}\log\left(\frac{N-n}{n}\right)\right) = o(1/n), \end{aligned}$$

12. The notation of (Butucea et al., 2015) is mapped to ours as $N \to n_1$, $M \to n_2$, $n \to K_1$, $m \to K_2$, and $a \to \mu$.

from which the desired conclusion, $\sum_{k:(n-k)>\delta n} T_{1,km} = o(1)$, follows. This completes the proof of sufficiency of (37) for weak recovery of both C_1^* and C_2^*, and marks the end of our use of notation from (Butucea et al., 2015).

The rate distortion argument used in the proof of (Hajek et al., 2017, Theorem 1) shows that (38) must hold if C_1^* and C_2^* are both weakly recoverable. ■

Proof [Proof of Theorem 14] We give the proof for exact recovery of C_1^*; the proof for exact recovery of C_2^* is analogous. For the sufficiency part, Recall that in Algorithm 3, the set $[n_1]$ is partitioned into sets, $S_1, \ldots, S_{1/\delta}$ of size $n_1\delta$. There are $1/\delta$ rounds of the algorithm, and indices in S_k are classified in the k^{th} round. For the k^{th} round, by assumption, given $\epsilon > 0$, there exists an estimator $\widehat{C}_{2k}$ based on observation of W with the rows indexed by S_k hidden such that $|\widehat{C}_{2k}\Delta C_2^*| \leq \epsilon K_2$ with high probability. Then the voting procedure estimates whether $i \in C_1^*$ for each $i \in S_k$ by comparing $\sum_{j\in\widehat{C}_{2k}} W_{i,j}$ to a threshold. This sum has approximately the $\mathcal{N}(K_2\mu, K_2)$ distribution if $i \in C_1^*$ and $\mathcal{N}(0, K_2)$ distribution otherwise ; the discrepancy can be made sufficiently small by choosing ϵ to be small (See (Hajek et al., 2017, Theorem 3) for a proof). Thus, the mean number of classification errors is well approximated by $n_1\mathsf{p}_e(K_1/n_1, K_2\mu^2)$, which converges to zero under (39), completing the sufficiency proof for exact recovery of C_1^*. The necessity part is proved in (Butucea et al., 2015, Section 4.2). ■

E. Proof of Lemma 18

Proof (Similar to proof of Lemma 12.) We prove the lemma for $\widehat{C}_1$; the proof for $\widehat{C}_2$ is identical. For the first part of the proof we assume that for $i = 1, 2$, $\widetilde{C}_i$ is fixed, and later use a union bound over all possible choices of $\widetilde{C}_i$. Recall that $W_{\widetilde{C}_1\widetilde{C}_2}$, which we abbreviate henceforth as $\widetilde{W}$, is the matrix W restricted to entries in $\widetilde{C}_1 \times \widetilde{C}_2$. Let $Z = \widetilde{W} - \mathbb{E}[\widetilde{W}]$ and

$$\mathbb{E}[\widetilde{W}] = \mu\sqrt{|\widetilde{C}_1 \cap C_1^*||\widetilde{C}_2 \cap C_2^*|}\, v_1 v_2^\top \tag{93}$$

is a rank-one matrix, where v_i is the unit vector in $\mathbb{R}^{|\widetilde{C}_i|}$ obtained by normalizing the indicator vector of $\widetilde{C}_i \cap C_i^*$. Thus, thanks to (54), the leading singular value of $\mathbb{E}[\widetilde{W}]$ is at least $\mu\sqrt{K_1K_2}(1-\epsilon)$ with left singular vector v_1 and right singular vector v_2.

It is well-known (see, e.g., (Vershynin, 2010, Corollary 5.35)) that if M is an $m_1 \times m_2$ matrix with i.i.d. *standard normal* entries, then $\mathbb{P}\left\{\|M\| \geq \sqrt{m_1} + \sqrt{m_2} + t\right\} \leq 2e^{-t^2/2}$. Applying this result for $m_i = |\widetilde{C}_i|$, which satisfies $m_i \leq \epsilon n_i$ by (55), and $t = 2\sqrt{h(\epsilon)(n_1+n_2)}$, we have for fixed $(\widetilde{C}_1, \widetilde{C}_2)$,

$$\mathbb{P}\left\{\|Z\| \geq (\sqrt{n_1} + \sqrt{n_2})\beta\right\} \leq 2e^{-2(n_1+n_2)h(\epsilon)},$$

where $\beta \triangleq 3\sqrt{\epsilon + h(\epsilon)}$). Similar to the proof of Lemma 12, the number of $(\widetilde{C}_1, \widetilde{C}_2)$ that satisfies (55) is at most $e^{(n_1+n_2)h(\epsilon)}$. By union bound, if we drop the assumption that $\widetilde{C}_i$ is fixed for $i = 1, 2$, we still have that with high probability, $\|Z\| \leq (\sqrt{n_1} + \sqrt{n_2})\beta$.

Denote by u the leading left singular vector of $W_{\widetilde{C}_1\widetilde{C}_2}$ such that $\langle u, v_1\rangle \geq 0$. Then, letting θ denote the angle between u and v_1,

$$\|u - v_1\| \leq \sqrt{2}\sin(\theta) \overset{(a)}{\leq} \sqrt{2}\min\left\{\frac{\|Z\|}{\left(\sigma_1\left(\widetilde{W}\right) - \sigma_2\left(\mathbb{E}\left[\widetilde{W}\right]\right)\right)_+}, 1\right\} \overset{(b)}{\leq} \frac{2\sqrt{2}\|Z\|}{\sigma_1(\mathbb{E}[\widetilde{W}])},$$

where (a) follows from Wedin's sin-θ theorem for SVD (Wedin, 1972), and (b) follows from $\sigma_2\left(\mathbb{E}\left[\widetilde{W}\right]\right) = 0$ and Weyl's inequality $\sigma_1(\widetilde{W}) \geq \sigma_1(\mathbb{E}[\widetilde{W}]) - \|Z\|$. In view of (93), conditioning on the high-probability event that $\|Z\| \leq (\sqrt{n_1} + \sqrt{n_2})\beta$, we have

$$\|u - v_1\| \leq \frac{2\sqrt{2}\beta(\sqrt{n_1} + \sqrt{n_2})}{\mu(1-\epsilon)\sqrt{K_1K_2}} \leq \frac{2\sqrt{2}c_0\beta}{1-\epsilon}, \tag{94}$$

where the last inequality follows from the standing assumption (53).

Next, we argue that $\widehat{u}$ or $-\widehat{u}$ is close to u, and hence, close to v_1 by the triangle inequality. By (88), the initial value $u^0 \in \mathbb{R}^{|\widetilde{C}_1|}$ satisfies $|\langle u, u^0\rangle| \geq (2\sqrt{n_1 \log n_1})^{-1}$ with high probability, and without loss of generality we can assume as in the proof of Lemma 12 that $\langle u, u^0\rangle \geq (2\sqrt{n_1 \log n_1})^{-1}$. By Weyl's inequality, the largest singular value of $\widetilde{W}$ is at least $\mu\sqrt{K_1K_2}(1-\epsilon) - (\sqrt{n_1}+\sqrt{n_2})\beta$, and the other singular values are at most $(\sqrt{n_1}+\sqrt{n_2})\beta$. In view of (53), $\frac{1-\epsilon}{c_0\beta} - 1 > 1$ for all $\epsilon < \epsilon_0$, where $\epsilon_0 > 0$ depends only on c_0. Let λ_1 and λ_2 denote the first and second eigenvalue of $\widetilde{W}\widetilde{W}^\top$ in absolute value, respectively. Let $r = \lambda_2/\lambda_1$. Then $r \leq (\frac{c_0\beta}{1-\epsilon-c_0\beta})^2$. Since for even t, $u^t = (\widetilde{W}\widetilde{W}^\top)^{t/2}u^0/\|(\widetilde{W}\widetilde{W}^\top)^{t/2}u^0\|$, the same analysis of power iteration that leads to (89) yields

$$\|u^t - u\|^2 = 2(1 - \langle u^t, u\rangle) \leq \frac{4r^{t/2}}{\langle u, u^0\rangle + r^{t/2}}.$$

Since $\widehat{u} = u^{2\lceil s^* \log n\rceil}$ and $s^* = (\log\frac{1-\epsilon-c_0\beta}{c_0\beta})^{-1}$, we have $r^{\lceil s^* \log n_1\rceil} \leq n_1^{-2}$ and thus $|\langle\widehat{u}, u\rangle^2| \geq 1 - n_1^{-1}$ and consequently, $\|uu^\top - \widehat{u}(\widehat{u})^\top\|_{\mathrm{F}}^2 = 2 - 2\langle u, \widehat{u}\rangle^2 \leq n_1^{-1}$. Similar to (90), applying (94) and the triangle inequality, we obtain

$$\|\widehat{u} - v\| \leq \|\widehat{u} - u\| + \|u - v\| \leq n^{-1/2} + \frac{2\sqrt{2}c_o\beta}{\sqrt{\lambda}(1-\epsilon)} < \frac{3c_o\beta}{\sqrt{\lambda}(1-\epsilon)} \triangleq \beta_o, \tag{95}$$

By the same argument that proves (91), we have $\limsup_{n\to\infty} |C_1^* \triangle \widehat{C}_1|/K_1 \leq 2\epsilon + 8\beta_0^2 \leq \eta(\epsilon)$ with η defined in (57), completing the proof. ■

Abstract

We introduce a method to train Quantized Neural Networks (QNNs) — neural networks with extremely low precision (e.g., 1-bit) weights and activations, at run-time. At train-time the quantized weights and activations are used for computing the parameter gradients. During the forward pass, QNNs drastically reduce memory size and accesses, and replace most arithmetic operations with bit-wise operations. As a result, power consumption is expected to be drastically reduced. We trained QNNs over the MNIST, CIFAR-10, SVHN and ImageNet datasets. The resulting QNNs achieve prediction accuracy comparable to their 32-bit counterparts. For example, our quantized version of AlexNet with 1-bit weights and 2-bit activations achieves 51% top-1 accuracy. Moreover, we quantize the parameter gradients to 6-bits as well which enables gradients computation using only bit-wise operation. Quantized recurrent neural networks were tested over the Penn Treebank dataset, and achieved comparable accuracy as their 32-bit counterparts using only 4-bits. Last but not least, we programmed a binary matrix multiplication GPU kernel with which it is possible to run our MNIST QNN 7 times faster than with an unoptimized GPU kernel, without suffering any loss in classification accuracy. The QNN code is available online.

Keywords: deep learning, neural networks compression, energy efficient neural networks, computer vision, language models

1. Introduction

Deep Neural Networks (DNNs) have substantially pushed Artificial Intelligence (AI) limits in a wide range of tasks, including but not limited to object recognition from images (Krizhevsky et al., 2012; Szegedy et al., 2015), speech recognition (Hinton et al., 2012; Sainath et al., 2013), statistical machine translation (Devlin et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015), Atari and Go games (Mnih et al., 2015; Silver et al., 2016), and even computer generation of abstract art (Mordvintsev et al., 2015).

Training or even just using neural network (NN) algorithms on conventional general-purpose digital hardware (Von Neumann architecture) has been found highly inefficient due to the massive amount of multiply-accumulate operations (MACs) required to compute the weighted sums of the neurons' inputs. Today, DNNs are almost exclusively trained on one or many very fast and power-hungry Graphic Processing Units (GPUs) (Coates et al., 2013). As a result, it is often a challenge to run DNNs on target low-power devices, and substantial research efforts are invested in speeding up DNNs at run-time on both general-purpose (Vanhoucke et al., 2011; Gong et al., 2014; Romero et al., 2014; Han et al., 2015) and specialized computer hardware (Farabet et al., 2011a,b; Pham et al., 2012; Chen et al., 2014a,b; Esser et al., 2015).

The most common approach is to compress a trained (full precision) network. HashedNets (Chen et al., 2015) reduce model sizes by using a hash function to randomly group connection weights and force them to share a single parameter value. Gong et al. (2014) compressed deep convnets using vector quantization, which resulteds in only a 1% accuracy loss. However, both methods focused only on the fully connected layers. A recent work by Han et al. (2016) successfully pruned several state-of-the-art large scale networks and showed that the number of parameters could be reduced by an order of magnitude.

Recent works have shown that more computationally efficient DNNs can be constructed by quantizing some of the parameters during the training phase. In most cases, DNNs are trained by minimizing some error function using Back-Propagation (BP) or related gradient descent methods. However, such an approach cannot be directly applied if the weights are restricted to binary values. Soudry et al. (2014) used a variational Bayesian approach with Mean-Field and Central Limit approximation to calculate the posterior distribution of the weights (the probability of each weight to be +1 or -1). During the inference stage (test phase), their method samples from this distribution one binary network and used it to predict the targets of the test set (More than one binary network can also be used). Courbariaux et al. (2015) similarly used two sets of weights, real-valued and binary. They, however, updated the real valued version of the weights by using gradients computed by applying forward and backward propagation with the set of binary weights (which was obtained by quantizing the real-value weights to +1 and -1).

This study proposes a more advanced technique, referred to as Quantized Neural Network (QNN), for quantizing the neurons and weights during inference and training. In such networks, all MAC operations can be replaced with $XNOR$ and *population count* (i.e., counting the number of ones in the binary number) operations. This is especially useful in

QNNs with the extremely low precision — for example, when only 1-bit is used per weight and activation, leading to a Binarized Neural Network (BNN). The proposed method is particularly beneficial for implementing large convolutional networks whose neuron-to-weight ratio is very large.

This paper makes the following contributions:

- We introduce a method to train Quantized-Neural-Networks (QNNs), neural networks with low precision weights and activations, at run-time, and when computing the parameter gradients at train-time. In the extreme case QNNs use only 1-bit per weight and activation (*i.e.*, Binarized NN; see Section 2).
- We conduct two sets of experiments, each implemented on a different framework, namely Torch7 and Theano, which show that it is possible to train BNNs on MNIST, CIFAR-10 and SVHN and achieve near state-of-the-art results (see Section 4). Moreover, we report results on the challenging ImageNet dataset using binary weights/activations as well as quantized version of it (more than 1-bit).
- We present preliminary results on quantized gradients and show that it is possible to use only 6-bits with only small accuracy degradation.
- We present results for the Penn Treebank dataset using language models (vanilla RNNs and LSTMs) and show that with 4-bit weights and activations Recurrent QNNs achieve similar accuracies as their 32-bit floating point counterparts.
- We show that during the forward pass (both at run-time and train-time), QNNs drastically reduce memory consumption (size and number of accesses), and replace most arithmetic operations with bit-wise operations. A substantial increase in power efficiency is expected as a result (see Section 5). Moreover, a binarized CNN can lead to binary convolution kernel repetitions; we argue that dedicated hardware could reduce the time complexity by 60% .
- Last but not least, we programmed a binary matrix multiplication GPU kernel with which it is possible to run our MNIST BNN 7 times faster than with an unoptimized GPU kernel, without suffering any loss in classification accuracy (see Section 6).
- The code for training and applying our BNNs is available on-line (both the Theano [1] and the Torch framework [2]).

2. Binarized Neural Networks

In this section, we detail our binarization function, show how we use it to compute the parameter gradients, and how we backpropagate through it.

[1] https://github.com/MatthieuCourbariaux/BinaryNet
[2] https://github.com/itayhubara/BinaryNet

2.1 Deterministic vs Stochastic Binarization

When training a BNN, we constrain both the weights and the activations to either +1 or −1. Those two values are very advantageous from a hardware perspective, as we explain in Section 6. In order to transform the real-valued variables into those two values, we use two different binarization functions, as proposed by Courbariaux et al. (2015). The first binarization function is deterministic:

$$x^b = \text{sign}(x) = \begin{cases} +1 & \text{if } x \geq 0, \\ f-1 & \text{otherwise,} \end{cases} \tag{1}$$

where x^b is the binarized variable (weight or activation) and x the real-valued variable. It is very straightforward to implement and works quite well in practice. The second binarization function is stochastic:

$$x^b = \text{sign}(x-z) = \begin{cases} +1 & \text{with probability } p = \sigma(x), \\ -1 & \text{with probability } 1-p, \end{cases} \tag{2}$$

where $z \sim U[-1,1]$, a uniform random variable, and σ is the *"hard sigmoid"* function:

$$\sigma(x) = \text{clip}(\frac{x+1}{2}, 0, 1) = \max(0, \min(1, \frac{x+1}{2})). \tag{3}$$

This stochastic binarization is more appealing theoretically (see Section 4) than the sign function, but somewhat harder to implement as it requires the hardware to generate random bits when quantizing (Torii et al., 2016). As a result, we mostly use the deterministic binarization function (i.e., the sign function), with the exception of *activations at train-time* in some of our experiments.

2.2 Gradient Computation and Accumulation

Although our BNN training method utilizes binary weights and activations to compute the parameter gradients, the real-valued gradients of the weights are accumulated in real-valued variables, as per Algorithm 1. Real-valued weights are likely required for Stochasic Gradient Descent (SGD) to work at all. SGD explores the space of parameters in small and noisy steps, and that noise is *averaged out* by the stochastic gradient contributions accumulated in each weight. Therefore, it is important to maintain sufficient resolution for these accumulators, which at first glance suggests that high precision is absolutely required.

Moreover, adding noise to weights and activations when *computing* the parameter gradients provide a form of regularization that can help to generalize better, as previously shown with variational weight noise (Graves, 2011), Dropout (Srivastava et al., 2014) and DropConnect (Wan et al., 2013). Our method of training BNNs can be seen as a variant of Dropout, in which instead of randomly setting half of the activations to zero when computing the parameter gradients, we binarize both the activations and the weights.

2.3 Propagating Gradients Through Discretization

The derivative of the sign function is zero almost everywhere, making it apparently incompatible with back-propagation, since the exact gradients of the cost with respect to the

quantities before the discretization (pre-activations or weights) are zero. Note that this limitation remains even if stochastic quantization is used. Bengio (2013) studied the question of estimating or propagating gradients through stochastic discrete neurons. He found that the fastest training was obtained when using the "straight-through estimator," previously introduced in Hinton's lectures (Hinton, 2012). We follow a similar approach but use the version of the straight-through estimator that takes into account the saturation effect, and does use deterministic rather than stochastic sampling of the bit. Consider the sign function quantization over the activations values from a previous layer, r,

$$q = \text{sign}(r),$$

and assume that an estimator g_q of the gradient $\frac{\partial C}{\partial q}$ has been obtained (with the straight-through estimator when needed, where C is the cost function). Then, our straight-through estimator of $\frac{\partial C}{\partial r}$ is simply

$$g_r = g_q 1_{|r|\leq 1}. \tag{4}$$

Note that this preserves the gradient information and cancels the gradient when r is too large. Not cancelling the gradient when r is too large significantly worsens performance.

To better understand why the straight-through estimator works well, we consider the stochastic binarization scheme similar to that in Eq. (2),

$$q = \text{sign}\left(r - z\right),$$

where we recall that $z \sim U\left[-1, 1\right]$. During training, we update each weight $W_{ij,l}$ (connecting neuron j in layer $l-1$ to neuron i in layer l), using the gradient from the previous layer (here $\frac{\partial C}{\partial r_{i,l}}$) and the layer input:

$$\frac{\partial}{\partial W_{ij,l}}\mathbb{E}\left[C\right] = \mathbb{E}\left[\frac{\partial C}{\partial r_{i,l}} q_{j,l-1}\right] = \mathbb{E}_{/z_{i,l}}\left[\mathbb{E}_{z_{i,l}}\left[\frac{\partial C}{\partial r_{i,l}}\right] q_{j,l-1}\right],$$

where $\mathbb{E}$, $\mathbb{E}_{z_{i,l}}$, and $\mathbb{E}_{/z_{i,l}}$ are, respectively, expectations over everything (all the noise sources, (z), and data samples); only $z_{i,l}$ (the noise in neuron i at layer l); or everything except $z_{i,l}$.

Next, we calculate the expectation over $z_{i,l}$ (dropping all indices, for brevity):

$$\begin{aligned}
&\mathbb{E}_z\left[\frac{\partial}{\partial r} C\right] = \frac{\partial}{\partial r}\mathbb{E}_z\left[C\right] \\
&= \frac{\partial}{\partial r}\left[C\left(q=1\right)p\left(r > z|r\right) + C\left(q=-1\right)\left(1 - p\left(r > z|r\right)\right)\right] \\
&= \frac{\partial p\left(r > z|r\right)}{\partial r}\left[C\left(q=1\right) - C\left(q=-1\right)\right] \\
&= 2\left.\frac{\partial C}{\partial q}\right|_{q=0} \mathbf{1}_{|r|\leq 1} + O\left(\left.\frac{\partial^3 C}{\partial q^3}\right|_{q=0}\right),
\end{aligned}$$

where in the last line we used a Taylor expansion. The $O(\cdot)$ contribution to the last equation is usually negligible, since the output of a single neuron ($q = \pm 1$) typically has only a small effect on the cost, and therefore

$$\left.\frac{\partial C}{\partial q}\right|_{q=0} \gg \left.\frac{\partial^2 C}{\partial q^2}\right|_{q=0} \gg \left.\frac{\partial^3 C}{\partial q^3}\right|_{q=0}.$$

Thus, using a Taylor expansion we can approximate

$$\left.\frac{\partial C}{\partial q}\right|_{q=\pm 1} = \left.\frac{\partial C}{\partial q}\right|_{q=0} + O\left(\left.\frac{\partial^2 C}{\partial q^2}\right|_{q=0}\right)$$

Therefore, since $g_r = \partial C/\partial r$ and $g_q = \partial C/\partial q$, we obtain the straight-through estimator defined in Eq. (4), up to a scale constant 2. The use of this straight-through estimator is illustrated in Algorithm 1.

A similar binarization process was applied for weights in which we combine two ingredients:

- Project each real-valued weight to [-1,1], i.e., clip the weights during training, as per Algorithm 1. The real-valued weights would otherwise grow very large without any impact on the binary weights.
- When using a real-valued weight w^r, quantize it using $w^b = \text{Sign}(w^r)$.

Projecting the weights to [-1,1] is consistent with the gradient cancelling when $|w^r| > 1$, according to Eq. (4).

2.4 Shift-based Batch Normalization

Batch Normalization (BN) (Ioffe and Szegedy, 2015) accelerates the training and reduces the overall impact of the weight scale (Courbariaux et al., 2015). The normalization procedure may also help to regularize the model. However, at train-time, BN requires many multiplications (calculating the standard deviation and dividing by it, namely, dividing by the running variance, which is the weighted mean of the training set activation variance). Although the number of scaling calculations is the same as the number of neurons, in the case of ConvNets this number is quite large. For example, in the CIFAR-10 dataset (using our architecture), the first convolution layer, consisting of only $128 \times 3 \times 3 \times 3$ filter masks, converts an image of size $3 \times 32 \times 32$ to size $128 \times 28 \times 28$, which is more than an order of magnitude larger than the number of weights (29 to be exact). To achieve the results that BN would obtain, we use a shift-based batch normalization (SBN) technique, presented in Algorithm 2. SBN approximates BN almost without multiplications. Define AP2(z) as the approximate power-of-2 of z, LogAP2(z) as log(AP2(z)) (i.e., the index of the most significant bit), and $\ll\gg$ as both left and right binary shift. SBN replaces almost all multiplication with power-of-2-approximation and shift operations:

$$x \times y \rightarrow x \ll\gg \text{LogAP2}(y). \tag{5}$$

The only operation which is not a binary shift or an add is the inverse square root (see normalization operation Algorithm 2). From the early work of Lomont (2003) we know that the inverse-square operation could be applied with approximately the same complexity as multiplication. There are also faster methods, which involve lookup table tricks that typically obtain lower accuracy (this may not be an issue, since our procedure already adds a lot of noise). In our experiments we did not use those methods since it requires a dedicated hardware. However, the number of values on which we apply the inverse-square operation

Algorithm 1: Training a BNN. C is the cost function for minibatch, λ, the learning rate decay factor, and L, the number of layers. ($\circ$) stands for element-wise multiplication. The function Binarize($\cdot$) specifies how to (stochastically or deterministically) binarize the activations and weights, and Clip(), how to clip the weights. BatchNorm() specifies how to batch-normalize the activations, using either batch normalization (Ioffe and Szegedy, 2015) or its shift-based variant we describe in Algorithm 2. BackBatchNorm() specifies how to backpropagate through the normalization. Update() specifies how to update the parameters when their gradients are known, using either ADAM (Kingma and Ba, 2015) or the shift-based AdaMax we describe in Algorithm 3.

Require: a minibatch of inputs and targets (a_0, a^*), previous weights W, previous BatchNorm parameters θ, weight initialization coefficients from (Glorot and Bengio, 2010) γ, and previous learning rate η.

Ensure: updated weights W^{next}, updated BatchNorm parameters θ^{next} and updated learning rate η^{next}.

{1. Computing the parameter gradients:}

{1.1. Forward propagation:}

for $k = 1$ to L **do**

$W_k^b \leftarrow \text{Binarize}(W_k)$

$s_k \leftarrow a_{k-1}^b W_k^b$ {$a_0^b = a_0$, i.e., the input is not quantize, see Section 2.6}

$a_k \leftarrow \text{BatchNorm}(s_k, \theta_k)$

if $k < L$ **then**

$a_k^b \leftarrow \text{Binarize}(a_k)$

end if

end for

{1.2. Backward propagation:}

{Note that the gradients are not binary.}

Compute $g_{a_L} = \frac{\partial C}{\partial a_L}$ knowing a_L and a^*

for $k = L$ to 1 **do**

if $k < L$ **then**

$g_{a_k} \leftarrow g_{a_k^b} \circ 1_{|a_k| \leq 1}$

end if

$(g_{s_k}, g_{\theta_k}) \leftarrow \text{BackBatchNorm}(g_{a_k}, s_k, \theta_k)$

$g_{a_{k-1}^b} \leftarrow g_{s_k} W_k^b$

$g_{W_k^b} \leftarrow g_{s_k}^\top a_{k-1}^b$

end for

{2. Accumulating the parameter gradients:}

for $k = 1$ to L **do**

$\theta_k^{\text{next}} \leftarrow \text{Update}(\theta_k, \eta, g_{\theta_k})$

$W_k^{\text{next}} \leftarrow \text{Clip}(\text{Update}(W_k, \gamma_k \eta, g_{W_k^b}), -1, 1)$

$\eta^{\text{next}} \leftarrow \lambda \eta$

end for

Algorithm 2: Shift-based Batch Normalizing Transform, applied to activation x over a mini-batch. $\text{LogAP2}(x) = \text{sign}(x) \times 2^{\text{round}(\log 2|x|)}$ is the approximate power-of-2[(a)], and $\ll\gg$ stands for left or right shifting of x according to the index of the MSB of y.

Require: Values of x over a mini-batch: $B = \{x_{1...m}\}$; Parameters to be learned: γ, β

Ensure: $\{y_i = \text{BN}(x_i, \gamma, \beta)\}$

$\mu_B \leftarrow \frac{1}{m}\sum_{i=1}^m x_i$ {mini-batch mean}

$C(x_i) \leftarrow (x_i - \mu_B)$ {centered input}

$\sigma_B^2 \leftarrow \frac{1}{m}\sum_{i=1}^m (C(x_i) \ll\gg \text{LogAP2}(C(x_i)))$ {approximate variance}

$\hat{x_i} \leftarrow C(x_i) \ll\gg \text{LogAP2}((\sqrt{\sigma_B^2 + \epsilon})^{-1})$ {normalize}

$y_i \leftarrow \text{LogAP2}(\gamma) \ll\gg \hat{x_i}$ {scale and shift}

(a) Hardware implementation of LogAP2 is as simple as extracting the index of the most significant bit from the number's binary representation

Algorithm 3: Shift-based AdaMax learning rule (Kingma and Ba, 2015). g_t^2 indicates the element-wise square $g_t \circ g_t$. Good default settings are $\alpha = 2^{-10}$, $1 - \beta_1 = 2^{-3}$, $1 - \beta_2 = 2^{-10}$. All operations on vectors are element-wise. With β_1^t and β_2^t we denote β_1 and β_2 to the power t.

Require: Previous parameters θ_{t-1}, their gradient g_t, and learning rate α.

Ensure: Updated parameters θ_t

{Biased 1st and 2nd raw moment estimates:}

$m_t \leftarrow \beta_1 \cdot m_{t-1} + (1 - \beta_1) \cdot g_t$

$v_t \leftarrow \max(\beta_2 \cdot v_{t-1}, |g_t|)$

{Updated parameters:}

$\theta_t \leftarrow \theta_{t-1} - (\alpha \ll\gg (1 - \beta_1)) \cdot \hat{m} \ll\gg \text{LogAP2}(v_t^{-1}))$

is rather small, since it is done after calculating the variance, i.e., after averaging (for a more precise calculation, see the BN analysis in Lin et al. (2015)). Furthermore, the size of the standard deviation vectors is relatively small. For example, these values make up only 0.3% of the network size (i.e., the number of learnable parameters) in the Cifar-10 network we used in our experiments.

In our experiment we observed no loss in accuracy when using the shift-based BN algorithm instead of the vanilla BN algorithm.

2.5 Shift-Based AdaMax

The ADAM learning method (Kingma and Ba, 2015) also reduces the impact of the weight scale. Since ADAM requires many multiplications, we suggest using instead the shift-based AdaMax we outlined in Algorithm 3. In the experiment we conducted we observed no loss in accuracy when using the shift-based AdaMax algorithm instead of the vanilla ADAM algorithm.

Algorithm 4: Running a BNN with L layers using only the XnorDotProduct kernel (see Section 5).

Require: 8-bit input vector a_0, binary weights W^b, and BatchNorm parameters θ.
Ensure: the MLP output a_L.
{1. First layer:}
$a_1 \leftarrow 0$
for $n = 1$ to 8 **do**
  $a_1 \leftarrow a_1 + 2^{n-1} \times \text{XnorDotProduct}(\text{a}_0^{\text{n}}, \text{W}_1^{\text{b}})$
end for
$a_1^b \leftarrow \text{Sign}(\text{BatchNorm}(a_1, \theta_1))$
{2. Remaining hidden layers:}
for $k = 2$ to $L - 1$ **do**
  $a_k \leftarrow \text{XnorDotProduct}(a_{k-1}^b, W_k^b)$
  $a_k^b \leftarrow \text{Sign}(\text{BatchNorm}(a_k, \theta_k))$
end for
{3. Output layer:}
$a_L \leftarrow \text{XnorDotProduct}(a_{L-1}^b, W_L^b)$
$a_L \leftarrow \text{BatchNorm}(a_L, \theta_L)$

2.6 First Layer

In a BNN, only the binarized values of the weights and activations are used in all calculations. As the output of one layer is the input of the next, the inputs of all the layers are binary, with the exception of the first layer. However, we do not believe this to be a major issue. First, in computer vision, the input representation typically has far fewer channels (e.g, red, green and blue) than internal representations (e.g., 512). Consequently, the first layer of a ConvNet is often the smallest convolution layer, both in terms of parameters and computations (Szegedy et al., 2015). Second, it is relatively easy to handle continuous-valued inputs as fixed point numbers, with m bits of precision. For example, in the common case of 8-bit fixed point inputs:

$$s = x \cdot w^b, \qquad s = \sum_{n=1}^{8} 2^{n-1}(x^n \cdot w^b), \tag{6}$$

where x is a vector of 8-bit inputs, x_1^8 is the most significant bit of the first input, w^b is a vector of 1-bit weights, and s is the resulting weighted sum. This method is used in Algorithm 4.

3. Quantized Neural network - More Than 1-bit

Observing Eq. (6), we can see that using 2-bit activations simply doubles the number of times we need to run our XnorDotProduct Kernel (i.e., directly proportional to the activation bitwidth). This idea was recently proposed by Zhou et al. (2016) (DoReFa net) and Miyashita et al. (2016) (published on arXive shortly after our preliminary technical report was published there). However, in contrast to to Zhou et al., we did not find it useful to initialize the network with weights obtained by training the network with full precision weights. Moreover, the Zhou et al. network did not quantize the weights of the first convolutional layer and the last fully-connected layer, whereas we binarized both. We followed the quantization schemes suggested by Miyashita et al. (2016), namely, linear quantization:

$$\textbf{LinearQuant}(x, bitwidth) = \text{Clip}\left(\text{round}\left(\frac{x}{2^{\text{bitwidth}}-1}\right) \times 2^{\text{bitwidth}-1}, \text{minV}, \text{maxV}\right) \tag{7}$$

and logarithmic quantization:

$$\textbf{LogQuant}(x, bitwidth)\,(\mathbf{x}) = \text{Clip}\left(\text{LogAP2}(x), -(2^{\text{bitwidth}-1}-1), 2^{\text{bitwidth}-1}\right), \tag{8}$$

where minV and maxV are the minimum and maximum scale range respectively and $\text{LogAP2}(x)$ is the log of the approximate-power-of-2 of x as described in Section 2.4. In our experiments (detailed in Section 4) we applied the above quantization schemes on the weights, activations and gradients and tested them on the more challenging ImageNet dataset.

4. Benchmark Results

We performed two sets of experiments, each based on a different framework, namely Torch7 and Theano. Other than the framework, the two sets of experiments are very similar:

- In both sets of experiments, we obtain near state-of-the-art results with BNNs on MNIST, CIFAR-10 and the SVHN benchmark datasets.
- In our Torch7 experiments, the activations are *stochastically* binarized at train-time, whereas in our Theano experiments they are *deterministically* binarized.
- In our Torch7 experiments, we use the *shift-based BN and AdaMax* variants, which are detailed in Algorithms 2 and 3, whereas in our Theano experiments, we use *vanilla BN and ADAM*.

Results are reported in Table 4.1. Implementation details are reported in Appendix A.

4.1 Results on MNIST,SVHN, and CIFAR-10

In this subsection we will detail the setting used in our MNIST,SVHN and Cifar-10 experiments.

4.1.1 MNIST

MNIST is an image classification benchmark dataset (LeCun et al., 1998). It consists of a training set of 60K and a test set of 10K 28×28 gray-scale images representing digits ranging from 0 to 9. The Multi-Layer-Perceptron (MLP) we train on MNIST consists of 3 hidden layers. In our Theano implementation we used hidden layers of size 4096 whereas

Data set	MNIST	SVHN	CIFAR-10
Binarized activations+weights, during training and test			
BNN (Torch7)	1.40%	2.53%	10.15%
BNN (Theano)	0.96%	2.80%	11.40%
Committee Machines' Array Baldassi et al. (2015)	1.35%	-	-
Binarized weights, during training and test			
BinaryConnect Courbariaux et al. (2015)	1.29± 0.08%	2.30%	9.90%
Binarized activations+weights, during test			
EBP Cheng et al. (2015)	2.2± 0.1%	-	-
Bitwise DNNs Kim and Smaragdis (2016)	1.33%	-	-
Ternary weights, binary activations, during test			
Hwang and Sung (2014)	1.45%	-	-
No binarization (standard results)			
No reg	1.3± 0.2%	2.44%	10.94%
Maxout Networks Goodfellow et al. (2013b)	0.94%	2.47%	11.68%
Gated pooling Lee et al. (2016)	-	1.69%	7.62%

Table 1: Classification test error rates of DNNs trained on MNIST (fully connected architecture), CIFAR-10 and SVHN (convnet). No unsupervised pre-training or data augmentation was used.

in our Torch implementation we used much smaller size 2048. This difference explains the accuracy gap between the two implementations. Both Implementations use the squared

hinge loss. In our theano implementation we tried to understand how low can the validation error decrease if we simply inflate the network. As can be seen from the results adding more units improves accuracy. The use of dropout in this case appears to be important.

4.1.2 CIFAR-10

CIFAR-10 is an image classification benchmark dataset. It consists of a training set of size 50K and a test set of size 10K, where instances are 32×32 color images representing airplanes, automobiles, birds, cats, deer, dogs, frogs, horses, ships and trucks. Both implementations share the same structure as reported in Appendix A. Since the Torch implementation uses stochastic binarization, it achieved slightly better results. As expected the Torch version has better validation performance than the Theano implementation but worse training performance. We believe this is due to the shift-based batch normalization (SBN) and the stochastic units. Both are additional "noise" sources, which make the model harder to train, but can improve generalization.

4.1.3 SVHN

Street View House Numbers (SVHN) is also an image classification benchmark dataset. It consists of a training set of size 604K examples and a test set of size 26K, where instances

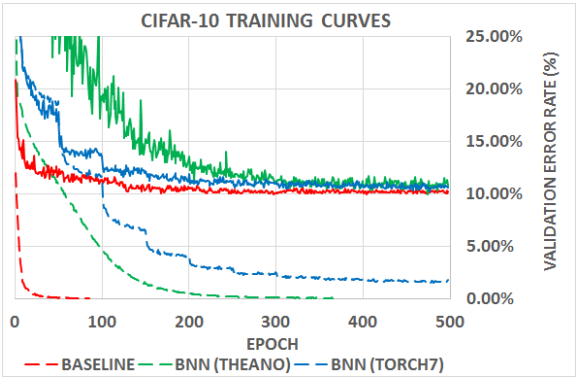

Figure 1: Training curves for different methods on the CIFAR-10 dataset. The dotted lines represent the training costs (square hinge losses) and the continuous lines the corresponding validation error rates. Although BNNs are slower to train, they are nearly as accurate as 32-bit float DNNs.

are 32×32 color images representing digits ranging from 0 to 9. Here again we obtained a small improvement in the performance by using stochastic binarization scheme.

In all our experiments with shift-base AdaMax and BN we did not observe any performance hit. The results tend to stay very close with and without the Shift-base approximation.

4.2 Results on ImageNet

To test the strength of our method, we applied it to the challenging ImageNet classification task, which is probably the most important classification benchmark dataset. It consists of a training set of size 1.2M samples and test set of size 50K. Each instance is labeled with one of 1000 categories including objects, animals, scenes, and even some abstract shapes. On ImageNet, it is customary to report two error rates: top-1 and top-5, where the top-x error rate is the fraction of test images for which the correct label is not among the x labels considered most probable by the model. Considerable research has been concerned with compressing ImageNet architectures while preserving high accuracy. Previous approaches include pruning near zero weights (Gong et al., 2014; Han et al., 2016) using matrix factorization techniques (Zhang et al., 2015), quantizing the weights (Gupta et al., 2015), using shared weights (Chen et al., 2015) and applying Huffman codes (Han et al., 2016) among others.

To the best of our knowledge, before the first revision of this paper was published on arXive, no one had reported on successfully quantizing the network's activations. On the contrary, a recent work (Han et al., 2016) showed that accuracy significantly deteriorates when trying to quantize convolutional layers' weights below 4-bit (FC layers are more ro-

bust to quantization and can operate quite well with only 2 bits). In the present work we attempted to tackle the difficult task of binarizing both weights and activations. Employing the well-known AlexNet and GoogleNet architectures, we applied our techniques and achieved 41.8% top-1 and 67.1% top-5 accuracy using AlexNet and 47.1% top-1 and 69.1% top-5 accuracy using GoogleNet. While these performance results leave room for improvement (relative to full precision nets), they are by far better than all previous attempts to compress ImageNet architectures using less than 4-bit precision for the weights. Moreover, this advantage is achieved while also binarizing neuron activations.

4.3 Relaxing "Hard-Tanh" Boundaries

We discovered that after training the network it is useful to widen the "hard tanh" boundaries and retrain the network. As explained in Section 2.3, the straight-through estimator (which can be written as "hard tanh") cancels gradients coming from neurons with absolute values higher than 1. Hence, towards the last training iterations most of the gradient values are zero and the weight values cease to update. Similarly we can decrease the standard deviation of the output of the batch-normalization layer (i.e., dividing the input by scale $\times \sigma_B$ where scale > 1). By relaxing the "hard tanh" boundaries we allow more gradients to flow in the back-propagation phase and improve top-1 accuracies by 1.5% on AlexNet topology using vanilla BNN.

4.4 2-bit Activations

While training BNNs on the ImageNet dataset we noticed that we could not force the training set error rate to converge to zero. In fact the training error rate stayed fairly close to the validation error rate. This observation led us to investigate a more relaxed activation quantization (more than 1-bit). As can be seen in Table 4.4, the results are quite impressive and illustrate an approximate 5.6% drop in performance (top-1 accuracy) relative to floating point representation, using only 1-bit weights and 2-bit activation. Following Miyashita et al. (2016), we also tried quantizing the gradients and discovered that only logarithmic quantization works. With 6-bit gradients we achieved 5.2% degradation. Those results are presently state-of-the-art, surpassing those obtained by the DoReFa net (Zhou et al., 2016). As opposed to DoReFa, we utilized a deterministic quantization process rather than a stochastic one. We did so because stochastic binarization is harder to optimize as it requires additional memory and computational resources. Moreover, it is important to note that while quantizing the gradients, DoReFa assigns for each instance in a mini-batch its own scaling factor, which increases the number of MAC operations.

While AlexNet can be compressed rather easily, compressing GoogleNet is much harder due to its small number of parameters. When using vanilla BNNs, we observed a large degradation in the top-1 results. However, by using QNNs with 4-bit weights and activation, we were able to achieve 66.5% top-1 accuracy (only a 5.1% drop in performance compared to the 32-bit floating point architecture), which is the current state-of-the-art-compression result over GoogleNet. Moreover, by using QNNs with 6-bit weights, activations and gradients we achieved 66.4% top-1 accuracy. Full implementation details of our experiments are reported in Appendix A.6.

Model	Top-1	Top-5
Binarized activations+weights, during training and test		
BNN	41.8%	67.1%
Xnor-Nets[3] (Rastegari et al., 2016)	44.2%	69.2%

4.5 Language Models

Recurrent neural networks (RNNs) are very demanding in memory and computational power in comparison to feed forward networks. There are a large variety of recurrent models with the Long Short Term Memory networks (LSTMs) introduced by Hochreiter and Schmidhuber (1997) are being the most popular model. LSTMs are a special kind of RNN, capable of learning long-term dependencies using unique gating mechanisms. Recently, Ott et al. (2016) tried to quantize the RNNs weight matrices using similar techniques as described in Section 2. They observed that the weight binarization methods do not work with RNNs. However, by using 2-bits (i.e., $-1, 0, 1$), they have been able to achieve similar and even higher accuracy on several datasets. Here we report on the first attempt to quantize both weights and activations by trying to evaluate the accuracy of quantized recurrent models

trained on the Penn Treebank dataset. The Penn Treebank Corpus (Marcus et al., 1993) contains 10K unique words. We followed the same setting as in (Mikolov and Zweig, 2012) which resulted in 18.55K words for training set, 14.5K and 16K words in the validation and test sets respectively. We experimented with both vanilla RNNs and LSTMs. For our vanilla RNN model we used one hidden layers of size 2048 and ReLU as the activation function. For our LSTM model we use 1 hidden layer of size 300. Our RNN implementation was constructed to predict the next character hence performance was measured using the bits-per-character (BPC) metric. In the LSTM model we tried to predict the next word so performance was measured using the perplexity per word (PPW) metric. Similar to (Ott et al., 2016), our preliminary results indicate that binarization of weight matrices lead to large accuracy degradation. However, as can be seen in Table 4.5, with 4-bits activations and weights we can achieve similar accuracies as their 32-bit floating point counterparts.

Model	Layers	Hidden Units	bits(weights)	bits(activation)	Accuracy
RNN	1	2048	3	3	1.81 BPC
RNN	1	2048	2	4	1.67 BPC
RNN	1	2048	3	4	1.11 BPC
RNN	1	2048	3	4	1.05 BPC
RNN	1	2048	FP	FP	1.05 BPC
LSTM	1	300	2	3	220 PPW
LSTM	1	300	3	4	110 PPW
LSTM	1	300	4	4	100 PPW
LSTM	1	900	4	4	97 PPW
LSTM	1	300	FP	FP	97 PPW

Table 4: Language Models results on Penn Treebank dataset. FP stands for 32-bit floating point

5. High Power Efficiency During The Forward Pass

Computer hardware, be it general-purpose or specialized, is composed of memories, arithmetic operators and control logic. During the forward pass (both at run-time and train-time), BNNs drastically reduce memory size and accesses, and replace most arithmetic operations with bit-wise operations, which might lead to vastly improved power-efficiency. Moreover, a binarized CNN can lead to binary convolution kernel repetitions, and we argue that dedicated hardware could reduce the time complexity by 60% .

5.0.1 Memory Size and Accesses

Improving computing performance has always been and remains a challenge. Over the last decade, power has been the main constraint on performance (Horowitz, 2014). This is why considerable research efforts have been devoted to reducing the energy consumption of

[3] First and last layers were not binarized (i.e., using 32-bit precision weights and activation.)

Table 6: Energy consumption of memory accesses; see Horowitz (2014)

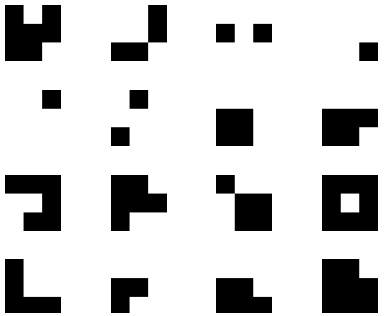

Figure 2: Binary weight filters, sampled from of the first convolution layer. Since we have only 2^{k^2} unique 2D filters (where k is the filter size), filter replication is very common. For instance, on our CIFAR-10 ConvNet, only 42% of the filters are unique.

neural networks. Horowitz (2014) provides rough numbers for the energy consumed by the computation

(the given numbers are for 45nm technology), as summarized in Tables 5 and 6. Importantly, we can see that memory accesses typically consume more energy than arithmetic operations, and *memory access cost increases with memory size*. In comparison with 32-bit DNNs, BNNs require 32 times smaller memory size *and* 32 times fewer memory accesses. This is expected to reduce energy consumption drastically (i.e., by a factor larger than 32).

5.0.2 XNOR-Count

Applying a DNN mainly involves convolutions and matrix multiplications. The key arithmetic operation of deep learning is thus the multiply-accumulate operation. Artificial neurons are basically multiply-accumulators computing weighted sums of their inputs. In BNNs, both the activations and the weights are constrained to either -1 or $+1$. As a result, most of the 32-bit floating point multiply-accumulations are replaced by 1-bit XNOR-count operations. We named this operation the XnorDotProduct kernel. This could have a big impact on dedicated deep learning hardware. For instance, a 32-bit floating point multiplier costs about 200 Xilinx FPGA slices (Govindu et al., 2004; Beauchamp et al., 2006), whereas a 1-bit XNOR gate only costs a single slice.

When using a ConvNet architecture with binary weights, the number of unique filters is bounded by the filter size. For example, in our implementation we use filters of size 3×3, so the maximum number of unique 2D filters is $2^9 = 512$. However, this should not prevent expanding the number of feature maps beyond this number, since the actual filter is a 3D matrix. Assuming we have M_ℓ filters in the ℓ convolutional layer, we have to store a 4D weight matrix of size $M_\ell \times M_{\ell-1} \times k \times k$. Consequently, the number of unique filters is $2^{k^2 M_{\ell-1}}$. When necessary, we apply each filter on the map and perform the required multiply-accumulate (MAC) operations (in our case, using XNOR and popcount operations). Since we now have binary filters, many 2D filters of size $k \times k$ repeat themselves. By using dedicated hardware/software, we can apply only the unique 2D filters on each feature map and sum the results to receive each 3D filter's convolutional result. Note that an inverse filter (i.e., [-1,1,-1] is the inverse of [1,-1,1]) can also be treated as a repetition; it is merely a multiplication of the original filter by -1. For example, in our ConvNet architecture trained on the CIFAR-10 benchmark, there are only 42% unique filters per layer on average. Hence we can reduce the number of the XNOR-popcount operations by 3.

QNNs complexity scale up linearly with the number of bits per weight/activation, since it requires the application of the XNOR kernel several times (see Section 3). As of now, QNNs still supply the best compression to accuracy ratio. Moreover, quantizing the gradients allows us to use the XNOR kernel for the backward pass, leading to fully fixed point layers with low bitwidth. By accelerating the training phase, QNNs can play an important role in future power demanding tasks.

6. Seven Times Faster on GPU at Run-Time

It is possible to speed up GPU implementations of QNNs, by using a method sometimes called SIMD (single instruction, multiple data) within a register (SWAR). The basic idea of SWAR is to *concatenate* groups of 32 binary variables into 32-bit registers, and thus obtain a 32-times speed-up on bitwise operations (e.g., XNOR). Using SWAR, it is possible to evaluate 32 connections with only 3 instructions:

$$a_1 += \text{popcount}(\text{xnor}(a_0^{32b}, w_1^{32b})), \tag{9}$$

where a_1 is the resulting weighted sum, and a_0^{32b} and w_1^{32b} are the concatenated inputs and weights. Those 3 instructions (accumulation, popcount, xnor) take $1+4+1 = 6$ clock cycles on recent Nvidia GPUs (and if they were to become a fused instruction, it would only take

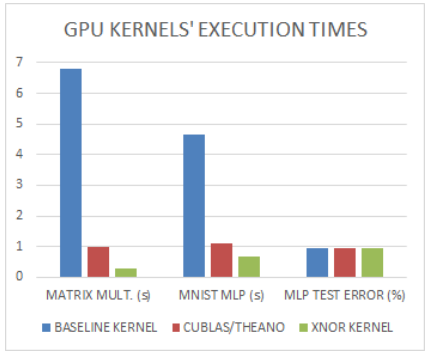
a single clock cycle). Consequently, we obtain a theoretical Nvidia GPU speed-up of factor of $32/6 \approx 5.3$ (a GPU core can preform 32 fused multiply and add (FMA) operations in 32 cycles). In practice, this speed-up is quite easy to obtain as the memory bandwidth to computation ratio is also increased 6 times.

In order to validate those theoretical results, we programmed two GPU kernels [4]:

- An unoptimized matrix multiplication kernel that serves as our baseline.
- The XNOR kernel, which is nearly identical to the baseline, except that it uses the SWAR method, as in Equation (9).

The two GPU kernels return identical outputs when their inputs are constrained to -1 or $+1$ (but not otherwise). The XNOR kernel is about *23 times faster than the baseline kernel* and *3.4 times faster than cuBLAS*, as shown in Figure 3. Our rather unoptimized binary matrix multiplication kernel can benefit from using better optimization techniques such as blocking, hence the XNOR kernel can be even faster. Last but not least, the MLP from Section 4 runs 7 times faster with the XNOR kernel than with the baseline kernel, without suffering any loss in classification accuracy (see Figure 3). As MNIST's images are not binary, the first layer's computations are always performed by the baseline kernel. The last three columns show that the MLP accuracy does not depend on which kernel is used.

Figure 3: The first 3 columns show the time it takes to perform a $8192 \times 8192 \times 8192$ (binary) matrix multiplication on a GTX750 Nvidia GPU, depending on which kernel is used. The next three columns show the time it takes to run the MLP from Section 3 on the full MNIST test set. The last three columns show that the MLP accuracy does not depend on the kernel



[4] Both kernels are block matrix multiplication based on the CUDA C programming guide: `http://docs.nvidia.com/cuda/cuda-c-programming-guide/index.html#shared-memory`

7. Discussion and Related Work

Until recently, the use of extremely low-precision networks (binary in the extreme case) was believed to substantially degrade the network performance (Courbariaux et al., 2014). Soudry et al. (2014) and Cheng et al. (2015) proved the contrary by showing that good performance could be achieved even if all neurons and weights are binarized to ± 1 . This was done using Expectation BackPropagation (EBP), a variational Bayesian approach, which infers networks with binary weights and neurons by updating the posterior distributions over the weights. These distributions are updated by differentiating their parameters (e.g., mean values) via the back propagation (BP) algorithm. Esser et al. (2015) implemented a fully binary network at run time using a very similar approach to EBP, showing significant improvement in energy efficiency. The drawback of EBP is that the binarized parameters are only used during inference.

The probabilistic idea behind EBP was extended in the BinaryConnect algorithm of Courbariaux et al. (2015). In BinaryConnect, the real-valued version of the weights is saved and used as a key reference for the binarization process. The binarization noise is independent between different weights, either by construction (by using stochastic quantization) or by assumption (a common simplification; see Spang and Schultheiss, 1962). The noise would have little effect on the next neuron's input because the input is a summation over many weighted neurons. Thus, the real-valued version could be updated using the back propagated error by simply ignoring the binarization noise in the update. With this method, Courbariaux et al. (2015) were the first to binarize weights in CNNs and achieved near state-of-the-art performance on several datasets. They also argued that noisy weights provide a form of regularization, which could help to improve generalization, as previously shown by Wan et al. (2013). This method binarized weights while still maintaining full precision neurons.

Lin et al. (2015) carried over the work of Courbariaux et al. (2015) to the back-propagation process by quantizing the representations at each layer of the network, to convert some of the remaining multiplications into binary shifts by restricting the neurons' values to be power-of-two integers. Lin et al. (2015)'s work and ours seem to share similar characteristics .However, their approach continues to use full precision weights during the test phase. Moreover, Lin et al. (2015) quantize the neurons only during the back propagation process, and not during forward propagation.

Other research (Baldassi et al., 2015) showed that full binary training and testing is possible in an array of committee machines with randomized input, where only one weight layer is being adjusted. Gong et al. (2014) aimed to compress a fully trained high precision network by using quantization or matrix factorization methods. These methods required training the network with full precision weights and neurons, thus requiring numerous MAC operations (which the proposed QNN algorithm avoids). Hwang and Sung (2014) focused on a fixed-point neural network design and achieved performance almost identical to that of the floating-point architecture. Kim and Smaragdis (2016) *retrained* neural networks with binary weights and activations.

As far as we know, before the first revision of this paper was published on arXive, no work succeeded in binarizing weights *and* neurons, at the inference phase *and* the entire training phase of a deep network. This was achieved in the present work. We relied on the

idea that binarization can be done stochastically, or be approximated as random noise. This was previously done for the weights by Courbariaux et al. (2015), but our BNNs extend this to the activations. Note that the binary activations are especially important for ConvNets, where there are typically many more neurons than free weights. This allows highly efficient operation of the binarized DNN at run time, and at the forward-propagation phase during training. Moreover, our training method has almost no multiplications, and therefore might be implemented efficiently in dedicated hardware. However, we have to save the value of the full precision weights. This is a remaining computational bottleneck during training, since it is an energy-consuming operation.

Shortly after the first version of this paper was posted on arXiv, several papers tried to improve and extend it. Rastegari et al. (2016) made a small modification to our algorithm (namely multiplying the binary weights and input by their L_1 norm) and published promising results on the ImageNet dataset. Note that their method, named Xnor-Net, requires additional multiplication by a different scaling factor for each patch in each sample (Rastegari et al., 2016) Section 3.2 Eq. 10 and figure 2). This in itself, requires many multiplications and prevents efficient implementation of XnorNet on known hardware designs. Moreover, (Rastegari et al., 2016) didn't quantize first and last layers, therefore XNOR-Net are only partially binarized NNs. Miyashita et al. (2016) suggested a more relaxed quantization (more than 1-bit) for both the weights and activation. Their idea was to quantize both and use shift operations as in our Eq. (4). They proposed to quantize the parameters in their non-uniform, base-2 logarithmic representation. This idea was inspired by the fact that the weights and activations in a trained network naturally have non-uniform distributions. They moreover showed that they can quantize the gradients as well to 6-bit without significant losses in performance (on the Cifar-10 dataset). Zhou et al. (2016) applied similar ideas to the ImageNet dataset and showed that by using 1-bit weights, 2-bit activations and 6-bit gradients they can achieve 46.1% top-1 accuracies using the AlexNet architecture. They named this method DoReFa net. Here we outperform DoReFa net and achieve 46.8% using a 1-2-6 bit quantization scheme (weight-activation-gradients) and 51% using a 1-2-32 quantization scheme. These results confirm that we can achieve comparable results even on a large dataset by applying the Xnor kernel several times. Merolla et al. (2016) showed that DNN can be robust to more than just weight binarization. They applied several different distortions to the weights, including additive and multiplicative noise, and a class of non-linear projections.This was shown to improve robustness to other distortions and even boost results. Zheng and Tang (2016) tried to apply our binarization scheme to recurrent neural network for language modeling and achieved comparable results as well. Andri et al. (2016) even created a hardware implementation to speed up BNNs.

8. Conclusion

We have introduced BNNs, which binarize deep neural networks and can lead to dramatic improvements in both power consumption and computation speed. During the forward pass (both at run-time and train-time), BNNs drastically reduce memory size and accesses, and replace most arithmetic operations with bit-wise operations. Our estimates indicate that power efficiency can be improved by more than one order of magnitude (see Section 5). In terms of speed, we programmed a binary matrix multiplication GPU kernel that enabled

running MLP over the MNIST datset 7 times faster (than with an unoptimized GPU kernel) without any loss of accuracy (see Section 6).

We have shown that BNNs can handle MNIST, CIFAR-10 and SVHN while achieving nearly state-of-the-art accuracy. While our results for the challenging ImageNet are not on par with the best results achievable with full precision networks, they significantly improve all previous attempts to compress ImageNet-capable architectures. Moreover, by quantizing the weights and activations to more than 1-bit (i.e., QNNs), we have been able to achieve comparable results to the 32-bit floating point architectures (see Section 4.4 and supplementary material - Appendix B). A major open research avenue would be to further improve our results on ImageNet. Substantial progress in this direction might go a long way towards facilitating DNN usability in low power instruments such as mobile phones.

Acknowledgments

We would like to express our appreciation to Elad Hoffer, for his technical assistance and constructive comments. We thank our fellow MILA lab members who took the time to read the article and give us some feedback. We thank the developers of Torch, (Collobert et al., 2011) a Lua based environment, and Theano (Bergstra et al., 2010; Bastien et al., 2012), a Python library that allowed us to easily develop fast and optimized code for GPU. We also thank the developers of Pylearn2 (Goodfellow et al., 2013a) and Lasagne (Dieleman et al., 2015), two deep learning libraries built on the top of Theano. We thank Yuxin Wu for helping us compare our GPU kernels with cuBLAS. We are also grateful for funding from NSERC, the Canada Research Chairs, Compute Canada, and CIFAR. We are also grateful for funding from CIFAR, NSERC, IBM, Samsung. This research was supported by The Israel Science Foundation (grant No. 1890/14)

Appendix A. Implementation Details

In this section we give full implementation details over our MNIST,SVHN, CIFAR-10 and ImageNet datasets.

A.1 MLP on MNIST (Theano)

MNIST is an image classification benchmark dataset (LeCun et al., 1998). It consists of a training set of 60K and a test set of 10K 28×28 gray-scale images representing digits ranging from 0 to 9. In order for this benchmark to remain a challenge, we did not use any convolution, data-augmentation, preprocessing or unsupervised learning. The Multi-Layer-Perceptron (MLP) we train on MNIST consists of 3 hidden layers of 4096 binary units and a L2-SVM output layer; L2-SVM has been shown to perform better than Softmax on several classification benchmarks (Tang, 2013; Lee et al., 2015). We regularize the model with Dropout (Srivastava et al., 2014). The square hinge loss is minimized with the ADAM adaptive learning rate method (Kingma and Ba, 2015). We use an exponentially decaying global learning rate, as per Algorithm 1, and also scale the learning rates of the weights with their initialization coefficients from (Glorot and Bengio, 2010), as suggested by Courbariaux et al. (2015). We use Batch Normalization with a minibatch of size 100 to speed up the training. As is typical, we use the last 10K samples of the training set as a validation set for early stopping and model selection. We report the test error rate associated with the best validation error rate after 1000 epochs (we do not retrain on the validation set).

A.2 MLP on MNIST (Torch7)

We use a similar architecture as in our Theano experiments, without dropout, and with 2048 binary units per layer instead of 4096. Additionally, we use the shift-base AdaMax and BN (with a minibatch of size 100) instead of the vanilla implementations, to reduce the number of multiplications. Likewise, we decay the learning rate by using a 1-bit right shift every 10 epochs.

A.3 ConvNet on CIFAR-10 (Theano)

CIFAR-10 is an image classification benchmark dataset. It consists of a training set of size 50K and a test set of size 10K, where instances are 32×32 color images representing airplanes, automobiles, birds, cats, deer, dogs, frogs, horses, ships and trucks. We do not use data-augmentation (which can really be a game changer for this dataset; see Graham 2014). The architecture of our ConvNet is identical to that used by Courbariaux et al. (2015) except for the binarization of the activations. The Courbariaux et al. (2015) architecture is itself mainly inspired by VGG (Simonyan and Zisserman, 2015). The square hinge loss is minimized with ADAM. We use an exponentially decaying learning rate, as we did for MNIST. We scale the learning rates of the weights with their initialization coefficients from (Glorot and Bengio, 2010). We use Batch Normalization with a minibatch of size 50 to speed up the training. We use the last 5000 samples of the training set as a validation set. We report the test error rate associated with the best validation error rate after 500 training epochs (we do not retrain on the validation set).

Table 7: Architecture of our CIFAR-10 ConvNet. We only use "same" convolutions as in VGG (Simonyan and Zisserman, 2015).

CIFAR-10 ConvNet architecture
Input: 32×32 - RGB image
3×3 - 128 convolution layer
BatchNorm and Binarization layers
3×3 - 128 convolution and 2×2 max-pooling layers
BatchNorm and Binarization layers
3×3 - 256 convolution layer
BatchNorm and Binarization layers
3×3 - 256 convolution and 2×2 max-pooling layers
BatchNorm and Binarization layers
3×3 - 512 convolution layer
BatchNorm and Binarization layers
3×3 - 512 convolution and 2×2 max-pooling layers
BatchNorm and Binarization layers
1024 fully connected layer
BatchNorm and Binarization layers
1024 fully connected layer
BatchNorm and Binarization layers
10 fully connected layer
BatchNorm layer (no binarization)
Cost: Mean square hinge loss

A.4 ConvNet on CIFAR-10 (Torch7)

We use the same architecture as in our Theano experiments. We apply shift-based AdaMax and BN (with a minibatch of size 200) instead of the vanilla implementations to reduce the number of multiplications. Likewise, we decay the learning rate by using a 1-bit right shift every 50 epochs.

A.5 ConvNet on SVHN

SVHN is also an image classification benchmark dataset. It consists of a training set of size 604K examples and a test set of size 26K, where instances are 32×32 color images representing digits ranging from 0 to 9. In both sets of experiments, we follow the same procedure used for the CIFAR-10 experiments, with a few notable exceptions: we use half the number of units in the convolution layers, and we train for 200 epochs instead of 500 (because SVHN is a much larger dataset than CIFAR-10).

A.6 ConvNet on ImageNet

ImageNet classification task consists of a training set of size 1.2M samples and test set of size 50K. Each instance is labeled with one of 1000 categories including objects, animals, scenes, and even some abstract shapes.

A.6.1 AlexNet

Our AlexNet implementation ("One weird trick" - Krizhevsky, 2014) consists of 5 convolution layers followed by 3 fully connected layers (see Section 8). Additionally, we use Adam as our optimization method and batch-normalization layers (with a minibatch of size 512). Learning rate was set to 0.01 and decrease to 10^{-7} by dividing by 2 every 20 epochs. We did not use Glorot et al. (2011) weight initialization coefficients.

A.6.2 GoogleNet

Our GoogleNet implementation consist of 2 convolution layers followed by 10 inception layers, spatial-average-pooling and a fully connected classifier. We also used the 2 auxilary classifiers. Additionally, we use Adam (Kingma and Ba, 2015) as our optimization method and batch-normalization layers (with a minibatch of size 64). Learning rate was set to 0.1 and decrease to 10^{-7} by dividing by 2 every 10 epochs.

Table 8: Our AlexNet Architecture.

AlexNet ConvNet architecture
Input: 224×224 - RGB image
11×11 - 64 convolution layer and 3×3 max-pooling layers
BatchNorm and Binarization layers
5×5 - 192 convolution layer and 3×3 max-pooling layers
BatchNorm and Binarization layers
3×3 - 384 convolution layer
BatchNorm and Binarization layers
3×3 - 384 convolution layer
BatchNorm and Binarization layers
3×3 - 256 convolution layer
BatchNorm and Binarization layers
4096 fully connected layer
BatchNorm and Binarization layers
4096 fully connected layer
BatchNorm and Binarization layers
1000 fully connected layer
BatchNorm layer (no binarization)
SoftMax layer (no binarization)
Cost: Negative log likelihood
